Abstract

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) can cause pancreatic damage, both directly to the pancreas *via* angiotensin-converting enzyme 2 receptors (the transmembrane proteins required for SARS-CoV-2 entry, which are highly expressed by pancreatic cells) and indirectly through locoregional vasculitis and thrombosis. Despite that, there is no clear evidence that SARS-CoV-2 is an etiological agent of acute pancreatitis. Acute pancreatitis in coronavirus disease 2019 (COVID-19) positive patients often recognizes biliary or alcoholic etiology. The prevalence of acute pancreatitis in COVID-19 positive patients is not exactly known. However, COVID-19 positive patients with acute pancreatitis have a higher mortality and an increased risk of intensive care unit admission and necrosis compared to COVID-19 negative patients. Acute respiratory distress syndrome is the most frequent cause of death in COVID-19 positive patients and concomitant acute pancreatitis. In this article, we reported recent evidence on the correlation between COVID-19 infection and acute pancreatitis.

Key Words: Acute pancreatitis; SARS-CoV-2; Severe acute pancreatitis; Multiparametric scores; Infected necrosis; Step-up approach

Core Tip: The outbreak of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), causing a severe acute respiratory syndrome, has rapidly spread from China all over the world, affecting millions of people. Whereas typical presentations of this infection (such as fever, cough, myalgia, fatigue and pneumonia) are well recognized, several studies report a low incidence of gastrointestinal symptoms. The relationship between SARS-CoV-2 infection and acute pancreatitis is controversial. Acute pancreatitis is not specifically caused by SARS-CoV-2. Furthermore, coronavirus disease 2019 positive patients are more likely to develop severe acute pancreatitis and multiple organ failure.

INTRODUCTION

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) secondary to coronavirus disease 2019 (COVID-19) has spread rapidly from China. The disease has affected millions of people[1]. Whereas typical presentations of this infection (such as fever, cough, myalgia, fatigue and pneumonia) are well recognized, few studies reported the incidence of atypical gastrointestinal symptoms[2-5]. COVID-19 is linked to organ damage including lungs, heart and kidneys and can lead to multiple organ failure. Evidence shows that SARS-CoV-2 has a strong tropism for the gastrointestinal tract[6,7]. Moreover, pancreatic injury in COVID-19 has not been common.

Acute pancreatitis is an inflammatory process that originates from the glandular parenchyma, causing damage and/or destruction to the acinar component first and then extending to the surrounding tissues[8-11]. There are several etiological factors contributing to its onset. However, it is possible to ascribe most of the episodes to two main causes, namely gallbladder lithiasis and alcohol abuse. Pharmacological, iatrogenic and viral causes must also be taken into account[12].

The severity of acute pancreatitis does not always correlate with pancreatic structural changes. It is possible to distinguish interstitial pancreatitis when the organ is locally or wholly increased in volume due to the presence of interstitial edema and necrotizing pancreatitis (10%-20% of all cases)[10,13,14]. It is unclear why COVID-19 starts with exclusively gastrointestinal symptoms, albeit in a low percentage of cases. However, acute pancreatic involvement induced by COVID-19 is severe and can develop rapidly. Close monitoring and admission are necessary to offer proper treatment. The following sections of this editorial discuss some of the recent findings and the approaches for a more effective clinical diagnosis and treatment of acute pancreatitis in patients with SARS-CoV-2 infection.

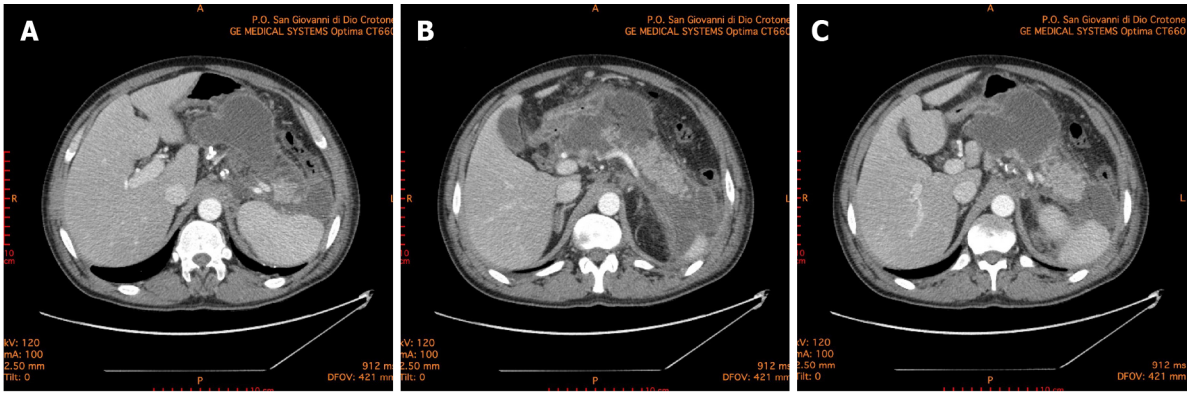
COVID-19 AND THE PANCREAS

Viral RNA has been found in the stools of COVID-19 patients[1,2,15-17]. High replication of the virus has been documented in both the small and large intestines by electron microscopy studies on tissues derived from biopsies and/or autopsy material[7,18,19]. Additionally, fecal-oral transmission has been documented for SARS-CoV-2[20]. Some molecules are receptors for the virus. These determine a specific tropism for different tissues and organs. SARS-CoV-2 uses its surface envelope called the spike glycoprotein. By means of this protein, SARS-CoV-2 interacts and enters host cells. The virus enters the cell *via* the angiotensin-converting enzyme 2 (ACE2) receptor. As such, the spike glycoprotein-ACE2 binding is the determinant for virus entry and propagation and for the transmissibility of COVID-19-related disease. ACE2 is expressed in human pancreatic cells and pancreatic islets and highly represented in pancreas microvasculature pericytes[6,21,22]. As ACE2 is internalized by SARS-CoV-2 binding, an imbalance of the RAS peptides can be established with a rise of angiotensin II and a decrease in angiotensin 1-7. The latter exerts anti-thrombogenic, anti-inflammatory and pro-resolving actions[23]. Laboratory abnormalities, suggesting pancreatic injury, have been noted in 8.0%-17.5% of cases in several studies[24,25], with 7.0% displaying significant pancreatic changes on computed tomography.

The etiopathogenesis of pancreatic injury in SARS-CoV-2 patients is still unclear. Both pancreatic ACE2 expression and drugs taken before the hospitalization might be involved[26]. The inflammation that occurs in the intestine causes the release of cytokines and bacteria. Both cytokines and bacteria can

reach and enter the lung through the bloodstream. At this level, a direct influence on the immune response and inflammation is observed[27-29]. The gut-liver axis is also strongly influenced by damage to the intestinal mucosa and bacterial imbalance[30]. The host and the microbial metabolites present in the intestine are transferred to the liver through the mesenteric-portal circulation; these affect liver function. The liver releases bile acids and bioactive media into the biliary and systemic circulation in order to transport them to the intestine. This could lead to pancreatic function damage in patients and may also explain the abnormality of pancreatic function indicators in COVID-19 patients. It is important not to consider each COVID-19 patient with increased serum amylase level as affected by acute pancreatitis[31]. Elevated levels of pancreatic enzymes may occur during kidney failure or diarrhea in the course of COVID-19[32]. It could be useful to find some criteria that can guide clinical suspicion.

WHAT DO WE KNOW ABOUT ACUTE PANCREATITIS IN COVID-19 POSITIVE PATIENTS?



Available literature is not able to determine whether the tissue damage leading to acute pancreatitis occurs as a result of direct SARS-CoV-2 infection or as a results of systemic multiple organ dysfunction with increased levels of amylase and lipase[33,34]. Only a few COVID-19 positive patients also have acute pancreatitis; the association between the two pathologies is infrequent. Only 10% of COVID-19 positive patients show abdominal symptoms exclusively[35]: Usually, these patients have the most severe forms of COVID-19 infections. Furthermore, it has not been demonstrated that an increased incidence of acute pancreatitis occurred during the COVID-19 pandemic period[36]. SARS-CoV-2 cannot be said to be an etiological agent of acute pancreatitis[33,37]. Acute pancreatitis in COVID-19 positive patients is idiopathic in most cases[37], and there is no sufficient evidence showing that COVID-19 can cause acute pancreatitis or negatively impact its prognosis.

The involvement of the pancreatic gland appears possible, in consideration of the fact that ACE2 receptors are present both on exocrine cells and on pancreatic islets[23]. In addition, the ACE2 receptor is expressed more in the pancreatic tissue than in the lungs. Furthermore, SARS-CoV-2 induces the onset of endotheliitis, which results in ischemic damage and that can also occur in the pancreas[38].

In the COVID PAN study, it was documented that acute pancreatitis is more severe in COVID-19 positive patients than in COVID-19 negative patients. In them, the onset of multiple organ failure can be linked to factors other than acute pancreatitis[39]. A greater severity of acute pancreatitis, an increased risk of necrosis, intensive care unit admission, persistent organ failure and the need for mechanical ventilation were observed in COVID-19 positive patients with acute pancreatitis. In this same study, 30-d overall mortality from acute pancreatitis was statistically higher in COVID-19 positive (14.7%) than in COVID-19 negative patients (2.6%, $P < 0.04$)[39]. Furthermore, necrosectomy was more likely to be performed in SARS-CoV-2 positive patients, occurring in 5% compared with 1.3% in the control group ($P < 0.001$).

The predominant organ dysfunction was respiratory failure in the majority of COVID-19 positive patients. In addition, acute pancreatitis with concomitant SARS-CoV-2 was more likely to have poorer outcomes due to double pulmonary damage[40]. Lung involvement is common in severe acute pancreatitis. This involvement can progress to full blown acute respiratory distress syndrome[40]. At present, it could be difficult to stratify the severity of symptoms and the degree of lung involvement. Acute respiratory distress syndrome due to acute pancreatitis can worsen lung injury related to COVID-19 pneumonia. Moreover, changes in the gastrointestinal flora affect the respiratory tract through the common mucosal immune system, the so-called "gut-lung axis"[27,29]. COVID-19 positive patients with gastrointestinal symptoms are more likely to be complicated with acute respiratory distress and pancreatic damage. In these patients the prognosis is poorer. In COVID-19 positive patients with gastrointestinal symptoms, attention should be paid to the patient's gastrointestinal symptoms in the diagnosis and treatment process. It also appears essential to prevent the transmission of the virus *via* the fecal-oral route. In a retrospective cohort study, Inamdar *et al*[37] concluded that pancreatitis should be included in the list of gastrointestinal manifestations of COVID-19.

There are few studies in the literature that investigate the relationship between COVID-19 infection and acute pancreatitis. In their experience, Inamdar *et al*[37] documented 189 cases of acute pancreatitis in 48012 hospitalized patients (0.39%). Thirty-two (17%) of these 189 patients were COVID-19 positive, with a prevalence of 0.27% of acute pancreatitis among the patients hospitalized for COVID-19. Idiopathic forms were more frequent (69%) in this patient group than in COVID-19 negative patients (21%, $P < 0.0001$). Wang *et al*[41] found that of 52 COVID-19 patients enrolled, 17% had pancreatic injury, defined as an abnormal increase of amylase and lipase serum levels. Stephens *et al*[31] showed that COVID-19 patients had an amylase serum peak not always related with acute pancreatitis. They enrolled 234 patients, 158 of which had a serum amylase level three times greater than the normal upper limit, but only 1.7% of the studied population met the revised criteria of Atlanta for diagnosis of acute pancreatitis[31].

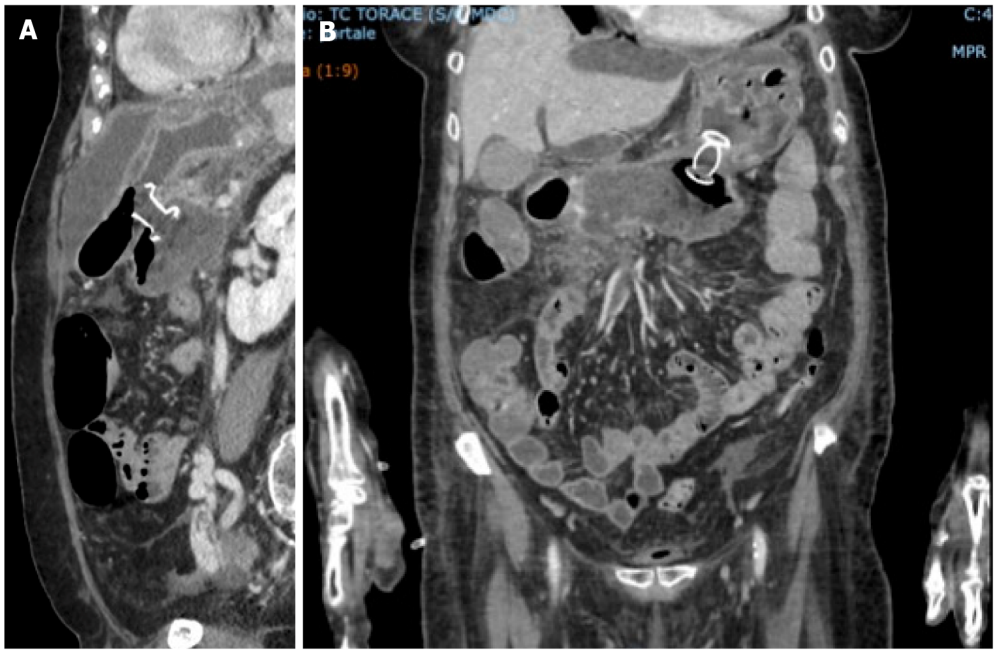
COVID-19 VACCINE AND PANCREATITIS

Vaccines are considered one of the most important public health achievements of the last century. Many vaccines have side effects. One of these adverse events is the onset of pancreatitis. In these cases, it is believed that acute pancreatitis is secondary to an immunologically induced phenomenon as demonstrated by reports in the literature after the administration of vaccines against the hepatitis virus or other viruses[42-44]. The vaccine BNT162b1 developed by Pfizer-BioNTech is a nucleoside-modified mRNA that encodes the receptor binding domain of the SARS-CoV-2 spike protein. The vaccine RNA is formulated in lipid nanoparticles for an efficient delivery into cells after injections[45].

In the literature there are several cases reporting acute pancreatitis after mRNA-based vaccine[46-50]. Although the vaccine has been proven to be effective and safe, vaccine-induced side effects have been observed. There are nausea, diarrhea, decreased appetite, abdominal pain, vomiting, heartburn and constipation among the most frequently reported gastrointestinal side effects. Most of the cases describe mild acute pancreatitis, however Ozaka *et al*[46] and Walter *et al*[47] reported a single case of necrotizing pancreatitis. According to Pfizer's data, 1 case of pancreatitis and 1 case of obstructive pancreatitis as adverse reactions were observed during the phase II/clinical trial of the COVID-19 mRNA vaccine. The trial included about 38000 participants, indicating that such a link between vaccination and pancreatitis is a very rare adverse event[51]. Between December 9, 2020 and July 21, 2021, information obtained from the United Kingdom database showed 275820 adverse reaction reports, which included 18 cases of mild acute pancreatitis and 1 case of necrotizing pancreatitis[52]. In France, out of a total of 42523573 doses, the Agence Nationale de Securité du Medicament et des Produits de Santé reported 57 cases of acute pancreatitis[53]. VigiBase, the World Health Organization global database of individual case safety reports, included 298 cases of acute pancreatitis and 17 cases of necrotizing pancreatitis[54]. The Agenzia Italiana del Farmaco reported 497 gastrointestinal adverse events equal to 14.1% of the total observations in 1 year. The document does not specify the number of cases of acute pancreatitis[55]. Although it is difficult to make conclusions about the likelihood of the vaccine being the etiologic factor of pancreatitis, it is essential to continue monitoring it for possible under-reported side effects until we have extensive long-term data available in post-marketing surveillance for long-term and rare side effects. Surveillance is also necessary because there are currently no conclusive data on the severity of pancreatitis in the population of subjects vaccinated against COVID-19 compared to patients who have not undergone vaccination. Preliminary results would document a reduced incidence of severe forms of acute pancreatitis in subjects vaccinated against SARS-CoV-2.



DO WE NEED TO CHANGE THE DIAGNOSTIC AND THERAPEUTIC APPROACH?

Since pancreatitis in COVID-19 positive patients occurs more frequently in severe forms, treatment must be intensive and prompt. It is crucial to define and stratify the severity of illness in patients with acute pancreatitis because of the extreme range of potential clinical courses due to the wide range of organs and tissues that may become involved. It is also fundamental to identify patients with potentially severe pancreatitis who require a multidisciplinary approach and an earlier and more aggressive treatment[56, 57]. Suspected acute pancreatitis can be confirmed with laboratory and instrumental investigations. Increased pancreatic enzymes levels are associated with a poor prognosis in COVID-19 patients. Recent findings show that the increment of pancreatic enzymes are significant in critical COVID-19 patients, but only a few of them progress to acute pancreatitis[58]. The rapid response of C-reactive protein to

Figure 3 Abdominal computed tomography scan documenting correct placement of lumen-apposing metal stents for the treatment of walled-off necrosis in coronavirus disease 2019 positive patient. A: Sagittal scan; B: Front scan.

changes in the inflammatory process intensity has also suggested its use in the management and monitoring of acute pancreatitis. C-reactive protein is not specific, and although it is correlated with severity, it cannot be used to predict clinical evolution. Serum procalcitonin is also one of the parameters used in predicting the development of severe acute pancreatitis. Its continuous increase correlates with a bacterial superinfection of pancreatic necrosis[59]. In all patients with or without SARS-CoV-2 illness contrast-enhanced computed tomography scan is the gold standard for the diagnosis of acute pancreatitis to evaluate both pancreatic and extrapancreatic alterations (Figure 1).

The revised Atlanta classification provides a good clinical distinction between mild, moderate and severe acute pancreatitis, and it is used in most COVID-19 positive patients with acute pancreatitis[8]. Several scoring systems have been developed to predict the severity of acute pancreatitis; however, none of them represents a gold standard. The scoring systems are without clinical relevance because of their low predictive value[56]. The bedside index for severity in acute pancreatitis failed to identify the severity of acute pancreatitis in COVID-19 positive patients[37].

Early fluid resuscitation is recommended in order to improve tissue perfusion[60], and the maintenance of microcirculation may be associated with resolution of multiple organ failure[61], especially in patients with COVID-19 and acute pancreatitis. Enteral nutrition is safe during acute pancreatitis[62]. Moreover, supplementation of enteral nutrition with probiotics may decrease septic

complications. In patients with COVID-19 requiring mechanical ventilation, early enteral nutrition is associated with earlier liberation from ventilator support, shorter intensive care unit and hospital stay and decreased cost[63,64].

Most patients with sterile necrosis can be managed without invasive treatments. Walled off necrotic collections or pseudocysts may cause mechanical obstruction and a step-up approach is indicated. Percutaneous or transmural endoscopic drainage are both appropriate first-line approaches in managing these patients (Figure 2). However, endoscopic drainage is preferred as it avoids the risk of forming a pancreatocutaneous fistula. In the earlier phase of the pandemic, patients with COVID-19, especially with severe pneumonia and considered highly contagious, did not undergo endoscopic ultrasound or endoscopic treatments. In the later stages, patients with COVID-19 and acute pancreatitis were subjected, with necessary precautions, to percutaneous and endoscopic treatments similar to the COVID-19 negative patients (Figure 3).

The step-up approach might reduce the rates of complications and death by minimizing surgical trauma in already critically ill patients[65,66]. Currently, there is general agreement that surgery in severe acute pancreatitis should be performed as late as possible[67]. In the management of necrotizing acute pancreatitis, open operative debridement (Figure 4) maintains a role in cases not amenable to less invasive endoscopic and/or laparoscopic procedures. Open operative debridement was performed in patients with COVID-19 related lung symptoms and lesions.

CONCLUSION

In pandemic times, clinical conditions could be worsened by COVID-19 infection. SARS-CoV-2 cannot be said to be an etiological agent of acute pancreatitis. Acute pancreatitis in COVID-19 positive patients is idiopathic in most cases, and there is no sufficient evidence showing that SARS-CoV-2 can negatively impact prognosis. On the other hand, acute pancreatitis with concomitant SARS-CoV-2 is more likely to have worse outcomes due to double lung damage and greater pancreatic severity. The multiparametric scores could not recognize and stratify the severity of pancreatic diseases and concomitant COVID-19 infection. In these patients, computed tomography is the gold standard for the diagnosis. Management of COVID-19 positive patients with pancreatitis is complex, and it is optimally provided by a multidisciplinary team. Operative treatments should be modulated, preferably, from the least to the most invasive option. Thus, surgical necrosectomy is relegated to the role of "last resort", remembering that necrotizing pancreatitis is a heterogeneous disease with marked variations in extent and course. This also means that one size treatment does not fit all.

Abstract

Transforming growth factor-beta (TGF-β) is a multifunctional cytokine that performs a dual role as a tumor suppressor and tumor promoter during cancer progression. Among different ligands of the TGF-β family, TGF-β1 modulates most of its biological outcomes. Despite the abundant expression of TGF-β1 in the liver, steatosis to hepatocellular carcinoma (HCC) progression triggers elevated TGF-β1 levels, contributing to poor prognosis and survival. Additionally, elevated TGF-β1 levels in the tumor microenvironment create an immunosuppressive stage *via* various mechanisms. TGF-β1 has a prime role as a diagnostic and prognostic biomarker in HCC. Moreover, TGF-β1 is widely studied as a therapeutic target either as monotherapy or combined with immune checkpoint inhibitors. This review provides clinical relevance and up-to-date information regarding the potential of TGF-β1 in diagnosis, prognosis, and therapy against HCC.

Key Words: Transforming growth factor-beta 1; Inflammation; Immunosuppression; Fibrogenesis; Hepatocellular carcinoma; Biomarker; Immunotherapy

Core Tip: Transforming growth factor-beta 1 (TGF-β1) exhibits a progressive elevation throughout hepatic dysfunction starting from hepatitis to hepatocellular carcinoma (HCC) as an inflammatory cytokine, pro-fibrogenic marker, immunosuppressive agent and pro-carcinogenic growth factor. Aberrant TGF-β1 activation in HCC is associated with poor prognosis and survival. TGF-β1 mediated immunosuppression disturbs the anticancer surveillance and the efficacy of the immunotherapeutic agent. This pleiotropic effect of TGF-β1 in the context of HCC makes it ideal as a diagnostic, prognostic, and therapeutic candidate in HCC.

INTRODUCTION

Hepatocellular carcinoma, an aggressive and refractory cold tumor

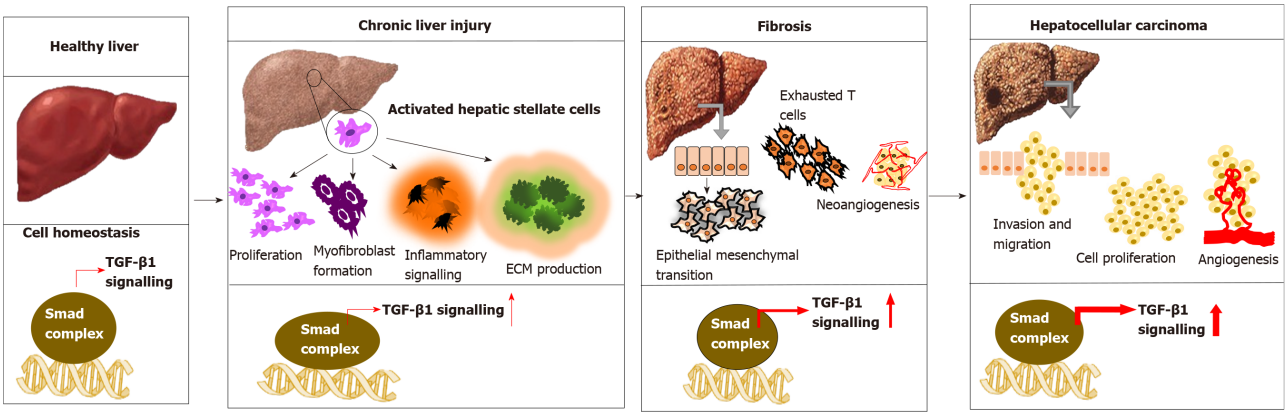
Liver cancer, specifically hepatocellular carcinoma (HCC) is often recognized as an aggressive malignancy, ranking 6th in incidence and 3rd in terms of mortality in 2020, where mortality rates are roughly equivalent to incidence rate[1]. As it develops in the background of chronic inflammation starting from the fatty liver, HCC remains undiagnosed for years until it worsens. The progressive transformation from cirrhosis to HCC also creates longer delays in diagnosis[2]. HCC is commonly diagnosed by liver imaging techniques such as ultrasound, computed tomography and magnetic resonance imaging. Blood biomarkers such as alpha fetoprotein (AFP), protein induced by vitamin K absence or antagonist II levels, and liver biopsy are also used to diagnose HCC[3,4]. Even though the recent guidelines recommend HCC surveillance biannually and antiviral vaccination, the lack of effective surveillance programs significantly contributes to HCC progression to the advanced stage, particularly in high-risk individuals. Once established, HCC cells rapidly proliferate and spread to the extrahepatic site, such as the lungs, portal vein, and lymph nodes. In such cases, in an advanced stage, curative interventions such as liver transplantation, resection, percutaneous ablation, and chemoembolization were not responsive. Systemic drug therapy remains the primary treatment modality[5,6], where immunotherapy and tyrosine kinase inhibitors are the approved treatment options[7]. However, limited response to therapy, the emergence of multidrug resistance, immunosuppressive tumor microenvironment, and lack of validated diagnostic and prognostic biomarkers pose significant obstacles in establishing effective treatment against HCC[8,9].

Transforming growth factor-beta (TGF-β) is a critical homeostasis regulator, which is aberrantly activated during inflammation, fibrosis and carcinogenesis[10]. Among the three isoforms, TGF-β1 is superior in TGF-β signal transduction, especially those related to chronic liver diseases. Since HCC is an inflammation-induced-immunosuppressed malignancy, the role of TGF-β1 signaling in HCC has been extensively evaluated recently[11]. This review presents the potential of the TGF-β superfamily of ligands, specifically TGF-β1, to develop as a therapeutic and prognostic-diagnostic marker candidate against HCC.

TGF-β1 signaling in HCC

TGF-β superfamily of ligands is a dimeric peptide growth factor with more than 30 members in humans, mainly TGF-βs, activins, inhibins, and bone morphogenetic proteins. TGF-βs are categorized into three different isoforms TGF-β1, TGF-β2, and TGF-β3. Of the three isoforms, TGF-β1 is the most evaluated and abundant, found in epithelial, endothelial, hematopoietic, and connective tissue. TGF-β 2 is expressed in epithelial and neuronal cells, while TGF-β3 is found in mesenchymal cells[12]. TGF-βs are implicated in diverse physiological processes, including cell homeostasis and embryonic development[13]. It is a pleiotropic factor that regulates inflammation, fibrogenesis, cell differentiation, proliferation, epithelial-mesenchymal transition (EMT), extracellular matrix (ECM) formation, tumor-suppressive and pro-tumor effect in a cell-context dependent manner[14].

The three isoforms of TGF-β have structural similarity and functional redundancy[15]. However, TGF-β1 is often considered a potent and superior isoform with significant physiological and pathological importance[16]. Importantly, TGF-β1 exerts a cell-context dependent effect in the liver[17,18]. Normal to activated TGF-β1 signature confers a protective effect by inhibiting hepatocyte proliferation and hepatic stellate cells (HSCs) activation, apoptosis induction, preventing fibrosis and improving liver function. While, aberrantly activated TGF-β1 signature manifests as HSC activation and worsening fibrosis to HCC, where tumor cells lose their sensitivity toward the inhibitory effect of TGF-β1[19-21]. Exposure of hepatocytes to various causative factors such as viruses, alcohol, toxicants and



other metabolic disorders leads to the release of TGF-β1. Also, other pro-inflammatory cytokines such as tumor necrosis factor-α and growth factors from non-parenchymal liver cells switch on inflammation, production of ECM, and accumulation of fibrous material that eventually progress to cirrhosis[22,23]. A simultaneous increase in integrins, a vital cell adhesion molecule, is observed as the fibrogenesis continues. These integrins interact with TGF-β1 and other ECM proteins, altering signal transduction pathways[24]. Along with the accumulation of genetic mutations, HSC induces TGF-β and β-catenin-dependent EMT, leading to tumor growth in the liver. TGF-β1 continues to increase, promoting neo-angiogenesis by interacting with other pathways and mediating stromal-tumor cell interaction, conferring aggressive phenotype and metastasis[25] (Figure 1). Wang *et al*[26] demonstrated that both TGF-β1 and TGFβR1 have a crucial role in regulating proliferation, invasion, metastasis and immune response in HCC cells.

TGF-β1 exerts biological and pathological effects *via* Smad and non-Smad pathways. TGF-βs are synthesized in the inactivated form and exist as latent TGF-β complex (LTC) by binding with latency-associated protein. Later, LTC is converted to large latent complex (LLC) by interacting with latent TGF-β binding protein in ECM. Integrin signaling plays a significant role in the activation and subsequent release of TGF-β1 from LLC. It is also mediated by other factors such as pH, protease enzyme *etc.*[27]. In the canonical Smad pathway, activated TGF-β first binds with the extracellular domain of TGF-β receptor type II, which triggers the cross phosphorylation of the kinase domain of TGF-β receptor type I. TGF-β R1 activation leads to the phosphorylation of Smad proteins, Smad 2 and Smad 3. Later Smad-2 and 3 complex bind with the co-Smad, Smad-4 to form a ternary complex. This ternary complex is then translocated into the nucleus, binds to Smad binding elements in DNA, and activates the transcription of TGF-β-dependent genes[28]. Binding of inhibitory Smad, Smad-7 will shut down the activated pathway[29]. In addition to the Canonical Smad pathway, TGF-β can exert biological functions by activating other diverse signalings such as P38, JNK, PI3K/AKT, RAS-ERK, and RHO-ROCK, which constitute the non-Smad pathway of TGF-β signal transduction[30] (Figure 2).

Smad pathway of TGF-β signal transduction also enhances the transcription of FoxP3, predominantly present in T regulatory (Treg) cells[31,32]. A high amount of tumor-infiltrating Treg cells and FoxP3 positive Treg cells in blood is reported in HCC patients, leading to the deterioration of effector T cells such as CD4+ and CD+ cytotoxic T cells lymphocytes, which are pillars of anticancer immunity[33,34]. Together, TGF-β inhibits natural killer (NK) cells, blocks interferon (IFN)-γ secretion, and prevents effector immune cells recruitment to tumor tissue[35,36]. Additionally, TGF-β inhibits IFN-γ secretion by interacting with the activating transcription factor 1[37]. Likewise, TGF-β-RUNX3 transcription factor interaction and co-expression of programmed death ligand 1 (PD-L1) and interleukin-10 promote the transformation of naïve B cells to immunoglobulin A producing B cells, which are crucial in HCC development from non-alcoholic fatty liver[38]. Elevated TGF-β can directly enhance the transcription of PD-1 in HCC. The interaction of PD-1 with PD-L1 causes significant immunosuppression by T cell exhaustion, which manifests as inhibition of T cell activation, proliferation, and cytotoxic action[39,40]. In a recent study, Bao *et al*[41] reported that TGF-β1 trigger the expression of immune checkpoints such as PD-1 and CTLA4 on HCC cells and attenuates T-cell-mediated anti-tumor immune surveillance. Therefore, up-regulated TGF-β mainly isoforms 1 directly affect immune checkpoint inhibition, and it works as an indicator of T cell exhaustion. This evidence suggests the potential of TGF-β1 targeted immunotherapies against HCC. The pivotal role of the TGF-β1 signature in hepatic dysfunction and HCC extends its potential as a biomarker molecule for diagnosis and prognostic prediction and a therapeutic target.

Clinical utility of TGF-β1 as diagnostic marker of HCC

As an inflammatory-fibrogenic cytokine molecule, the involvement of TGF-β1 in all stages of liver injury, starting from fatty liver, steatosis, fibrosis to cirrhosis, and HCC, is evident. Intergromic analysis of TGF-β gene alterations among the 33 cancer types in the TGCA dataset revealed 39% alterations. Gastrointestinal cancers and HCC exhibited prominent mutation compared with other cancer types[42]. Later, in an HCC-specific transcriptomic analysis, 40% of HCC samples were found with mutations in genes of the TGF-β pathway[43]. Higher TGF-β1 levels in HCC correlate with the high rate of extrahepatic metastasis (EHM), poor prognosis, and low survival rate[44]. After acute/chronic liver injury, liver sinusoidal endothelial cells and HSCs secrete TGF-β1 and up-regulate TGF-β receptors[45,46]. Elevated TGF-β1 level was found in viral and alcohol-induced fibrosis[47]. Thus, TGF-β levels can be used to track the response to therapy so that the decrease in TGF-β 1 level followed by IFN treatment in hepatitis B virus (HBV) patients is associated with improved treatment outcomes. Apart from HSC-triggered TGF-β secretion, hepatitis C virus (HCV) infection can also induce TGF-β1 production in hepatocytes[48]. Likewise, proteomic and phospho-proteomic characterization of 110 tumor and non-tumor tissues of early-stage HBV-associated HCC found an increased expression of TGF-β genes compared with the non-tumor tissue[49]. However, the dichromatic role of TGF-β1 on cancer growth *i.e.*, tumor suppressive in early-stage or oncogenic effect in late-stage, is a matter of concern. Another study indicated a comparative functional genomic approach and illustrated the link between TGF-β expression signature and HCC subtypes. The study shows that TGF-β positive HCC clusters can be categorized into two. HCC with early TGF-β signature exhibit physiological responses while HCC associated with late TGF-β signature showed metastasis and poor survival[50]. N-2-fluorenylacetamide-

Figure 1 Involvement of transforming growth factor-beta 1 in various stages of liver dysfunction. Transforming growth factor-beta (TGF-β) regulates cell homeostasis in normal physiological conditions. As an inflammatory-fibrogenic cytokine molecule, the involvement of TGF-β1 in all phases of liver injury, from fatty liver, steatosis, fibrosis to cirrhosis, and hepatocellular carcinoma, is evident. Causative agents like viral infection, alcohol and co-morbidities like diabetes and obesity trigger the release of a pro-inflammatory cytokine such as TGF-β1, which stimulates inflammation, extracellular matrix (ECM) production, and accumulation of fibrous material that eventually progress to cirrhosis. As the fibrosis continues, the interaction of overexpressed TGF-β1 with integrins and other ECM proteins can alter signaling, accumulate gene mutation, and induce epithelial-mesenchymal transition and hepatocarcinogenesis. TGF: Transforming growth factor; ECM: Extracellular matrix; HCC: Hepatocellular carcinoma.

induced rat hepatoma model is used to investigate the association of TGF-β1 expression with different stages of hepatocarcinogenesis and a progressive elevation of hepatic TGF-β1 and TGF-β1 mRNA was found during the transformation of hepatocytes to malignant cells[51]. Another study indicates that elevated plasma TGF-β1 level was found in 89.5% of HCC patients, and interestingly, among these patients, 93.3% had an AFP level less than 400 μg/L[52]. This suggested that TGF-β1 expression can be a more accurate and sensitive biomarker for early diagnosis of HCC for monitoring the disease progression.

The diagnostic importance of TGF-β1 is established significantly earlier itself. In 1997, Tsai *et al*[53] investigated the correlation of urine TGF-β1 level with HCC. They found a significant increase in TGF-β 1 level in HCC patients compared with other healthy control groups, cirrhotic chronic hepatitis patients. They also reported the association of TGF-β 1 levels with poor prognosis and shorter survival[53]. Later, the same team compared the study with another important tumor marker, AFP, and found that disease progression from cirrhosis to HCC is characterized by a typical elevation in both urinary TGF-β1 and serum AFP with a diagnostic accuracy of about 90%[54,55]. These collective data suggest the potential of TGF-β1 be used along with AFP as a complementary tumor marker to differentiate HCC from cirrhosis correctly. Another study investigated the rationale for parallel determination of TGF-β1 and AFP to diagnose HCC. They found that the TGF-β1 level exhibited a stage-dependent increase in all liver diseases where AFP showed HCC-specific elevation[56]. As TGF-β1 estimation tracks the disease progression pattern, TGF-β can be considered a more sensitive diagnostic marker of HCC. Its specificity is higher when it is analyzed along with AFP. To diagnose and select patients for galunisertib (TGF-β inhibitor) therapy, Cao *et al*[57] in 2017 performed next-generation sequencing-based analysis in HCC samples and found that m RNA levels of TGF-β1 along with SKIL and PMEPA1 could be better diagnostic markers as well as to select patients who are more likely to respond with galunisertib.

Another study investigated the association of serum TGF-β1 with disease severity in HCC using 180 subjects in different stages of HCC. Group of cirrhotic patients, as well as healthy control, was also maintained. Consistent with the previous reports, this study also found a significant increase in TGF-β1 level in HCC (1687.47 ± 1462.81 pg/mL) as compared with cirrhotic patients (487.98 ± 344.23 pg/mL) and control (250.16 ± 284.16 pg/mL). Additionally, the serum level of TGF-β1 showed exponential elevation as the disease progressed from early to advanced, *i.e.*, during progression from Barcelona Clinic Liver Cancer stage A to D, TGF-β 1 level increased from 652.83-1668.78 pg/mL[56]. The best cut-off value of TGF-β1 detection was determined as 301.9 pg/mL, comparable with the value (370 pg/mL) reported by Shehata *et al*[58] (Table 1).

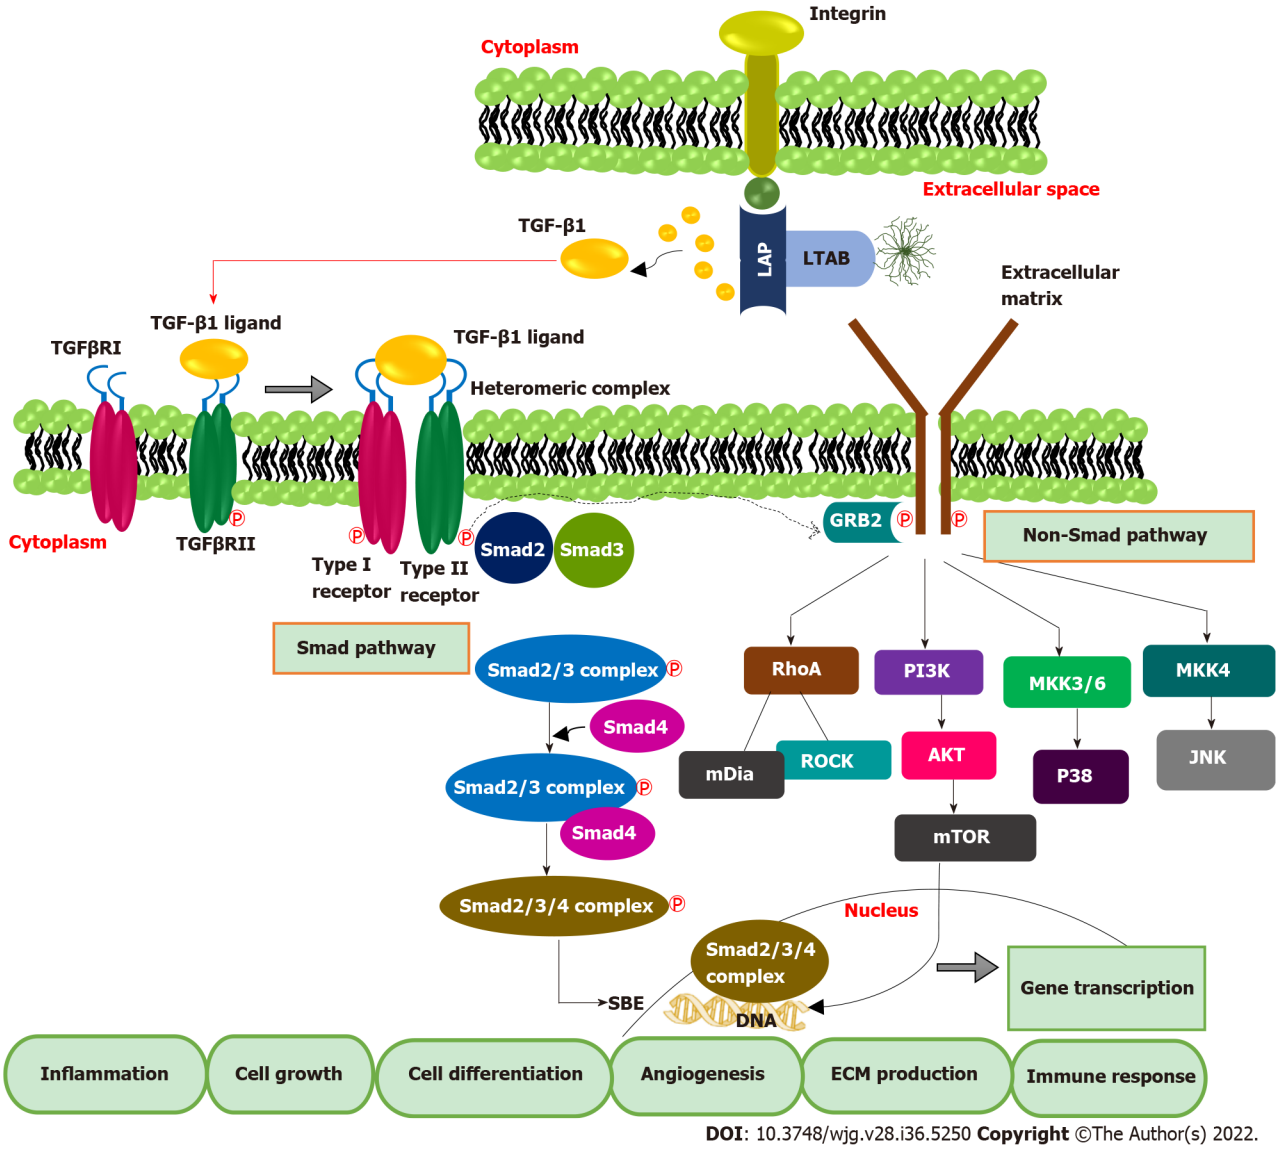
Background inflammation and indolent transformation are the critical factors that create a waiting time paradox in diagnosing HCC, making the tumor more aggressive and refractory. Since TGF-β, specifically TGF-β1 plays an essential function from the initial hepatic injury to hepatocarcinogenesis, it holds immense potential to validate as a diagnostic marker of HCC. Though the dual functioning of TGF-β1 is still debatable, the diagnostic relevance of TGF-β1 is well evident, and thus, it warrants further investigations and clinical validation.

Table 1 Research progress on the clinical utility of transforming growth factor-beta 1 as diagnostic marker against hepatocellular carcinoma

Ref.	Sample size HCC/control	Assay type	TGF-β1 level	Sample type	Outcome of the study
[60, 61]	26/20	ELISA	Control: 1.4 ± 0.8 ng/mL HCC: 19.3 ± 1.95 ng/mL (P < 0.05)	Plasma	TGF-β1 level showed a progressive elevation from cirrhotic to HCC patients to normal subjects. No significant association was found between plasma TGF-β1 and serum AFP levels
[62, 63]	70	ELISA	Control: 2.7 ± 0.7 ng/mL HCC: 7.3 ± 4.3 ng/mL (P < 0.05)	Plasma	Elevated plasma TGF-β1 levels in HCC patients are associated with increased tumor size, overexpression of tissue inhibitor of metalloproteinase-1 and tumor severity
[54, 55]	94/50	^{125}I-Radio Immuno Assay Kit	Control: 1.5-33.6 μg-^{1} creatinine Cirrhotic: 4.3-52.5 μg^{-1} creatinine HCC: 3.5-184 μg^{-1} creatinine (P < 0.0001)	Urine	Urinary TGF-β1 and serum AFP levels were higher in HCC than in cirrhotic patients. The study suggested that both TGF-β and AFP can be used as complementary biomarkers to distinguish between HCC and cirrhosis
[64]	54/30	ELISA	TGF-β1 score Control: 0.6 ± 0.2 HCC: 1.6 ± 0.5	Serum	The study team calculated the serum concentration score based on the cut-off limit of 74 pg/mL and 637 pg/mL for TGF-β1 and sFas, respectively. TGF-β1 levels were higher than the cut off value in 23% HCC patients with negative AFP values, suggesting its diagnostic potential in AFP negative HCC
[65]	38/23	ELISA	Control: 300 pg/mL HCC: 954.9 pg/mL (P < 0.0001)	Plasma	Elevated plasma TGF-β1 level can be a useful diagnostic marker in detecting small HCC, with higher sensitivity than AFP
[66]	70/32	ELISA	Control: 2 ng/mL HCC: 7.5 ng/mL (P < 0.0001)	Plasma	Higher circulating TGF-β1 in HCC patients is associated with suppression of anti-tumor immunity and disease progression
[52]	50/30	ELISA	Control: 0.67 ± 0.1 μg/mL HCC: 2.21 ± 1.1 μg/mL (sensitivity = 89.5%, specificity = 94%)	Serum	Aberrant TGF-β1 expression in HCC is associated with differentiation and worsening of HBV infection
		RT-PCR	Overexpression TGF-β1 mRNA in HCC patients, P < 0.0001		Circulating TGF-β1 level and TGF-β1 mRNA expression can be used as sensitive biomarkers for diagnosing HBV induced HCC
[56]	23/40	ELISA	Control: 14.35 ± 8.76 ng/mL HCC: 64.35 ± 33.68 ng/mL (P < 0.05)	Serum	TGF-β1 is a sensitive diagnostic marker for HCC than AFP. Specificity can be increased with combined evaluation of TGF-β1 and AFP levels
[67]	54/30	ELISA	Control: 39.5 ± 9.8 pg/mL HCC: 1194 ± 331 pg/mL (P < 0.0001)	Serum	The study suggested elevated TGF-β1 and EGFR levels as reliable diagnostic markers for HCC induced, AFP negative HCC
[68]	120/30	ELISA	Control: 250.16 ± 284.61 pg/mL Cirrhotic: 487.98 ± 344.23 pg/mL HCC: 1687.47 ± 1642 pg/mL (P < 0.0001)	Serum	TGF-β1 showed progressive elevation during various stages of liver dysfunction. Higher TGF-β1 level in HCC is associated with tumor grade, pathological stage and invasiveness
[69]	100/36	ELISA	Control: 57.29 ± 11.70 ng/mL HCC: 225.82 ± 48.93 ng/mL (P < 0.0001)	Serum	Serum levels of TGF-β were significantly higher in HCC patients than in normal controls

ELISA: Enzyme-linked immunosorbent assay; RT-PCR: Reverse transcription-polymerase chain reaction; HCC: Hepatocellular carcinoma; TGF-β: Transforming growth factor-beta; AFP: Alpha fetoprotein; HBV: Hepatitis B virus; EGFR: Epidermal growth factor receptor.

The clinical utility of TGF-β1 as a prognostic marker of HCC



Poor prognostic characteristics of HCC contribute to late detection, aggressiveness and failure of therapeutic interventions[70]. Molecular pathways of hepato-carcinogenesis are still confusing because of the involvement of diverse molecular pathways, genetic alterations and evolution of malignant cells. Thus, this ultimately results in the worst prognosis within the early stage itself[71]. The expression of TGF-β1 is remarkably increased at the advanced stages of HCC and is involved in initiating EMT, regulating tumor proliferation, and promoting immunosuppressive tumor microenvironment during HCC progression under the challenges like liver cirrhosis, HBV and HCV infections. This warrants screening TGF-β1 levels from the early stages of HCC as a tool for evaluating the clinical outcomes. Depending upon the expression profile of TGF-β1, it is effortless to estimate the clinical impact of therapeutic strategies[72].

A research study conducted by Giannelli *et al*[73] proposed that TGF-β1 promotes EMT by stimulating homologous proteins like snail and slug. Secretion of TGF-β1 by HCC invasive cell lines, especially cell lines with α3β1-integrin expression, is significantly higher than in non-invasive and cirrhotic cell lines. The patients at the initial and advanced stages of HCC with a higher profile of TGF-β 1 possess a poor prognostic ratio with lower overall survival (OS) and disease-free survival rate (DFS) [73,74]. Likewise, another notable experimental study by Lee *et al*[75] demonstrated that plasma TGF-β1 is positively correlated with critical conditions like EHM, portal vein thrombosis, EHM, and regional lymph node involvement. Statistical studies involving the detailed examination of overall and cumulative survival rates of HCC patients showed that candidates with abundant levels of plasma TGF-β1 manifested remarkably lower survival rates than the candidates with lower expression of TGF-β1. This evidence points to the usefulness of TGF-β1 as a prognostic marker in HCC.

Wang *et al*[76] elucidated the crucial involvement of TGF-β1 in tumor progression. A total of 180 patients with HCC were selected for the study, and out of 180 HCC patients, 105 patients were found with a solid expression of TGF-β1. This study showed a positive correlation between TGF-β1 and Treg cells. The increased secretion of TGF-β1 at the starting stage of HCC indicates that the tumor may be one of the most critical sources of TGF-β1 in HCC patients. Earlier studies also provided evidence that TGF-β1 promotes the regulatory phenotype and modulates the biological functions of Tregs. By Kaplan-Meier evaluation, HCC patients overexpressing TGF-β1 in neoplastic tissues had a considerably shorter OS and a greater recurrence rate than patients with lower expression[76]. A meta-analysis study conducted by Peng *et al*[77] reported that TGF-β1 implements an unfavorable prognosis on OS rates of HCC patients with a hazard ratio of about 1.71 and 2.29 from both univariate and multivariate analysis. Additionally, the study indicates the worst prognosis of TGF-β1 upon DFS, relapse-free survival and progression-free survival of 1422 patients *via* COX univariate analysis with a hazard ratio of about 1.60. In summary, the results from these studies draw out the negative prognostic impact of high TGF-β1 expression on the OS in HCC patients.

TGF-β1 possesses a dual functional role in malignancy; initially, it acts by blocking epidermal growth and promoting tumor suppression, but in later stages, it appears to be involved in the up-gradation of advanced tumors[78]. Embryonic liver fodrin (ELF), a novel form of β-spectrin is involved as a Smad3/4 adaptor in TGF-β mediated tumor suppression signaling pathway. Miscolocalization of Smad3 and Smad4 caused by the dysregulation of ELF resulted in the disruption of TGF- β signaling pathways[79]. A research study conducted by Ji *et al*[80] investigated the predictive value of both TGF-β1 and ELF in HCC patients after hepatic resection. The expression of TGF-β1 is significantly higher in HCC tissues than in normal liver tissues, while the incidence of ELF is higher in normal liver tissue in contrast with HCC samples. The reports of post-operative survival rates of HCC patients with lower expressions of TGF-β1 showed that DFS and OS rates of HCC patients over 1 (79.4%), 3 (73.5%), and 5 (62.0%) years were significantly higher than the patients with higher expression of TGF-β1 (28.0%, 12.0%, and 12.0%). The study also showed a negative correlation between TGF-β1 and ELF levels. The study also indicates that DFS rates of HCC patients with higher expression of ELF and lower TGF-β1 levels are remarkably more elevated than the HCC patients with low expression of ELF and higher TGF-β1 levels for 1, 3, and 5 years (75.0%, 60.0%, and 57.5% *vs* 25.0%, 15.9%, and 10.2%, respectively), with *P*-value less than 0.001. Data from clinicopathological examination exhibited that TGF-β1 positively relates with hepatitis B surface antigen, tumor size, tumor number, TNM, and recurrence, while ELF is negatively correlated with all metastatic characteristics suggesting that ELF is associated with tumor suppressing features. This research study indicates that both TGF-β1and ELF can be included in the category of relevant biomarkers as prognostic agents for evaluating clinical results after hepatic resection[80].

An experimental approach described the correlation and the possibility of Fibroblast growth factor (FGF) receptor 4 (FGFR4) and TGF-β1 as prognostic biomarkers in HCC. FGFR4 is the most predominant isoform of the FGFRs family and is actively involved in various biological activities, including metastasis, differentiation, embryonic development, proliferation, apoptosis and angiogenesis [81]. Multiple studies showed that FGFR4 plays a clear-cut role in the pathogenesis of HCC and the up-regulation of FGFR4 possesses resistance to various targeted therapies[82]. A clinicopathological examination conducted by Chen *et al*[83] showed that elevated expression of both TGF-β1 and FGFR4 enhances tumors' invasiveness and metastatic nature. Clinicopathologic characteristics revealed that HCC patients at advanced stages with high TGF-β1 and FGFR4 expression were more likely to be at a higher TNM stage. Statistical data showed that the OS of patients over five-year survival rate is about

Figure 2 Transforming growth factor-beta 1 signaling pathway. Smad and non-Smad pathways mainly regulate transforming growth factor-beta 1 (TGF-β 1) signal transduction. Integrin signaling triggers the activation and release of TGF-β1 from LCC (large latent complex). Activated TGF-β1 binds TGF-β type II receptor, leading to phosphorylation of TGF-β type I receptor and associated Smad proteins, mainly Smad-2 and Smad-3. Phosphorylated Smad-2 and 3, complex with the co-Smad, Smad-7, form a ternary complex. This ternary complex then translocates into the nucleus, binds to Smad binding elements and regulates the transcription of TGF-β-related genes. TGF: Transforming growth factor; LAP: Latency associated protein; LTAB: Latent transforming growth factor-beta binding protein; SBE: Smad binding elements; ECM: Extracellular matrix; mTOR: Mammalian target of Rapamycin; PI3K: Phosphoinositide 3-kinase; AKT: AKT serine/threonine kinase 1; MKK: Mitogen-activated protein kinase kinase; JNK: C-Jun N-terminal kinase.

8.5%, and the median survival duration is 32.3 mo in case of TGF-β1 positive cases. In contrast, in TGF-β 1 negative expression cases, the OS of the patient is about 45.6% and the median survival rate is 50.4 mo. Candidates with high TGF-β1 expression had a short OS rate in contrast to those with negative TGF-β1 expression profiles. Likewise in cases of high levels of FGFR4, the OS rate of patients is very low, that is five-year survival rate is only about 8.3%, and median survival rate is 29.4 mo while in the condition of impeded FGFR4 expression, the five-year survival rate is about 70.1% and the median survival period is 51.2 mo. This study showed a positive correlation between TGF-β1 and FGFR4 as prognostic markers in HCC. Additionally, the results from univariate and multivariate analyses showed that both TGF-β1 and FGFR4 are independent and reliable prognostic factors in HCCs for evaluating the therapeutic response in HCC patients, especially after post-operative procedures[83]. The strong correlation between TGF-β1 expression and survival rates of HCC patients suggests its potential as a prognostic biomarker for HCC (Table 2). In addition to the role of TGF-β1 as an effective prognostic marker, it can also be used for targeted therapeutic strategies.

The clinical utility of TGF-β1 as therapeutic target in HCC

Tyrosine kinase inhibitor, Sorafenib was the first approved first-line therapy for advanced HCC. Sorafenib was the first-line therapy for ten years until another tyrosine kinase inhibitor, Levatinib was

Table 2 Research progress on the clinical utility of transforming growth factor-beta 1 as a prognostic marker against hepatocellular carcinoma

Ref.	Sample size HCC/control	Sample and assay type	TGF-β1 level	Survival rate (%), (patients with higher TGF-β1 *vs* patients with lower TGF-β1)	Outcome of the study
[75]	571/551	Plasma ELISA	Control: 3.58 ± 0.17 $\log_{10}$ pg/mL Cirrhotic: 3.20 ± 0.37 $\log_{10}$ pg/mL HCC: 3.83 ± 0.31 $\log_{10}$ pg/mL	1 yr survival (47 *vs* 60) 3 yr survival (28 *vs* 36) $P < 0.05$	Plasma TGF-β1 levels showed a positive correlation with tumor size, invasion and extrahepatic metastasis and inversely correlated with survival rates in HCC patients
[83]	126	Tumor tissue Immunohistochemistry	84% samples (106/126) showed high intra-tumoral TGF-β1 expression 64.3% samples (81/126) showed high peri-tumoral TGF-β1 expression	5 yr survival (8.5 *vs* 45.6)	TGF-β1 and FGFR4 were positively correlated in HCC tumor tissues and showed a significant association with shorter survival rates in patients
[80]	84/20	Tumor tissue Immunohistochemistry	TGF-β1 overexpression found in 59.5% samples (50/84) than that of normal liver tissue	1 yr survival (28 *vs* 79.4) 5 yr survival (12 *vs* 62.6)	TGF-β1 expression was dominant, whereas ELF expression was suppressed in HCC tissues Patients with high TGF-β1 and lower ELF expression are associated with poor overall survival and post-operative disease free survival compared with low TGF-β1 and high ELF group
[76]	184/30	Plasma and tumor tissue ELISA and immunohistochemistry	Elevated plasma TGF-β1 level TGF-β1 was strongly stained in tumor tissue	2 yr survival (51 *vs* 77) 3 yr survival (4 *vs* 68), $P < 0.05$	Higher TGF-β1 expression in tumor tissues triggers Treg cells mediated immunosuppression in tumor microenvironment and contribute to poor prognosis in HCC

approved in 2018. Even though tyrosine kinase inhibitors dominated HCC therapy as first-line or second-line options, the efficacy was only modest, with limited treatment outcome, the emergence of drug resistance, and also relapse[85]. Recently treatment strategies adopted a paradigm shift to immunotherapeutic approaches because of the importance of the immune microenvironment in carcinogenesis.

The liver is the most extensive reticuloendothelial system and peripheral immunomodulatory organ in the human body. Immunotherapy is being extensively evaluated in liver cancer[86]. The liver constitutes a vast repository of immune cells including NK cells, kupffer cells, sinusoidal endothelial cells, and innate T cells[87]. Aberrant immune checkpoint activation makes HCC a cold tumor, where anti-tumor immune surveillance is completely abolished[88]. Combination of immune checkpoint inhibitors (ICIs) such as Nivolumab (PD-1 inhibitor) + Ipilimumab (CTLA4 inhibitor) and Atezolizumab (PD-L1 inhibitor) + Bevacizumab [vascular endothelial growth factor (VEGF) inhibitor] got approval as first-line therapy for various cancer such as non-small cell lung cancer (NSCLC), HCC in 2020[89]. Though ICIs exerted a superior effect to tyrosine inhibitors, current immunotherapeutic drugs failed to establish an effective anticancer immunity against HCC. Though the immunotherapeutic approaches modify effector immune cells functions to elicit anti-tumor immune response, the immunosuppressive tumor microenvironment neutralizes the effects of immunotherapy[90].

Analysis of the TGF-β profile of HCC samples in the TGCA data set revealed four categories with typical TGF-β expression[91]. The cluster with a highly activated TGF-β signature, which accounts for 14.5% of samples, exhibited prominent immune exhaustion and poor prognosis. ICIs may not work well in this cluster. Additionally, anti-inflammatory/anti-fibrotic agents targeting TGF-β can improve the

Table 3 Clinical trials of transforming growth factor-beta 1 blockade with Galunisertib in hepatocellular carcinoma and other cancers

Drug	Title of the study	Treatment	Phase	Status	Trial ID
Galunisertib	A study of Galunisertib on the immune system in participants with cancer	Monotherapy	Phase I	Completed	NCT02304419
Galunisertib	Galunisertib (LY2157299) and stereotactic body radiotherapy in advanced hepatocellular carcinoma	Combination with radiotherapy	Phase I	Completed	NCT02906397
Galunisertib	A study of LY2157299 in participants with unresectable hepatocellular cancer	Combination with Nivolumab	Phase II	Completed	NCT02423343
Galunisertib	A study of LY2157299 in participants with unresectable hepatocellular cancer	Combination with Sorafenib	Phase I	Completed	NCT02240433
Galunisertib	A study of LY2157299 in participants with advanced hepatocellular carcinoma	Combination with Sorafenib	Phase II	Completed	NCT02178358
Galunisertib	A study of LY2157299 in participants with hepatocellular carcinoma	Combination with Sorafenib/Ramucirumumab	Phase II	Completed	NCT01246986
Galunisertib	Galunisertib and Capecitabine in advanced resistant TGF-beta activated colorectal cancer (EORTC1615)	Combination with Capecitabine	Phase II	Withdrawn	NCT03470350
Galunisertib	A study of LY2157299 in participants with pancreatic cancer (advanced or has spread to another part of the body)	Combination with Gemcitabine	Phase I	Completed	NCT02154646
Galunisertib	A study of Galunisertib (LY2157299) and Durvalumab (MEDI4736) in participants with metastatic pancreatic cancer	Combination with Durvalumab	Phase I	Completed	NCT02734160

TGF: Transforming growth factor.

immune milieu[92,93]. The majority of HCC samples belong to a cluster of activated TGF-β signature (45%) and showed a low level of an immune response. Hence, combining a TGF-β inhibitor with an immune checkpoint inhibitor can exert a synergistic effect. 30% of HCC samples showed a normal TGF-β signature associated with active immune surveillance; therefore, immunotherapy will be most suitable for this cluster. The fourth cluster is a minor population (9.9%) that exhibits inactivated TGF-β signature with poor immune cell activation and response[94]. With this evidence, it is clear that TGF-β1 signature can be used to decide the suitable therapy or predict the outcome of immunotherapy.

Several specific and non-specific inhibitors of TGF-β, mainly TGF-β1 and 2 inhibitors, are being developed and evaluated against various tumors, including HCC. Regarding non-specific inhibitors, as the primary molecular target is different, its ability to block the TGF-β pathway offers additional benefits as anticancer agents. One such example is Halofuginone, an alkaloid coccidiostat with reported preclinical activity against HCC. In addition to the prominent inhibition of collagen synthesis, Halofuginone also blocks TGF-β1, inhibits ECM formation and fibroblast proliferation, increases IFN-γ and anti-tumor immune response[95,96]. The effect of Halofuginone against advanced progressive solid tumor has been evaluated in phase I clinical trial (NCT00027677), and in 2000, United States Food and Drug Administration gave orphan drug approval status to Halofuginone for treatment of scleroderma [97]. Histone deacetylase exerts epigenetic regulation of TGF-β1 mediated fibrosis and carcinogenesis [98]. Studies indicate that histone deacetylase inhibitors such as Panobinostat have shown effectiveness in HCC animal models and phase I human trials combined with sorafenib (NCT00823290)[99]. Apart from the non-specific inhibitors, recent preclinical interventions combined TGF-β1 targeting antibodies or TGF-βR1 inhibitor with PD-L1 inhibitors and obtained prominent cytotoxic effect and anticancer immune surveillance in various solid tumors[100,101]. Likewise, M7824 is a bifunctional fusion protein with dual targeting of PD-L1 and TGF-β, which has been evaluated in animal models of various cancers either alone or in combination with vaccines[102]. M7824 exerted a significant inhibitory effect on TGF-β 1[103]. Among the different TGF-β inhibitors, LY2109761 is an orally bioavailable TGF-β receptor type I inhibitor, which exhibited an antitumor effect in various HCC animal models[104]. LY2109761 inhibited TGF-β1 induced migration, invasion, and anoikis in HCC cells[105,106]. Another study suggested the anti-angiogenic potential of LY2109761, which was superior to the typical VEGF inhibitor, Bevacizumab, and the effect was mediated by suppression of VEGF through inhibition of Smad dependent TGF-β1 signaling[107,108]. In addition to this, anti-TGF-β agents targeting other isoforms are also developed. AP-12009 is a TGF-β2 specific antisense oligonucleotide in a clinical trial to treat glioma and anaplastic astrocytoma[109,110]. Likewise, TGF-β1 directed mRNA was developed as AP-11011, which is evaluated against NSCLC, colon cancer in preclinical models[111]. Lordelimumab is a TGF-β2 specific monoclonal antibody with an anti-fibrotic effect[112]. Many preclinical studies investigated different TGF-β inhibitors, yet, Galunisertib (LY2157299), a kinase inhibitor of TGF-β1, is only the one in current clinical trials[113]. Several clinical trials of Galunisertib are ongoing or completed either alone or combined with Sorafenib, ICIs, and alkylating agents (Table 3).

CONCLUSION

TGF-β1 exerts a unique regulatory power on inflammation, fibrogenesis, and immune response in HCC. Among other TGF-β isoforms, significant and progressive expression of TGF-β1 during the entire course of HCC pathogenesis, starting from chronic hepatitis to HCC makes it a sensitive and accurate diagnostic marker of HCC. The specificity and sensitivity of TGF-β1 based diagnosis of HCC by parallel estimation of serum AFP. Even after establishing HCC, TGF-β1 continues to elevate as HCC progresses and is associated with poor prognosis and shorter survival. Since TGF-β1 is the master regulator of the immunosuppressive tumor milieu in HCC, TGF-β1 inhibition could sensitize ICI, tyrosine kinase inhibitors, and other systemic or curative interventions. HCC remains the deadliest-refractory tumor predominantly due to its delayed diagnosis. In that context, TGF-β1 is relevant for early diagnosis, prognosis, and therapy. Even though a plethora of supporting evidence is available, still TGF-β1 is not much studied and evaluated compared with other markers such as AFP. Notably, the dichotomic nature of TGF-β signaling in HCC needs to be defined accurately to establish the clinical utility of TGF-β1. Thus, proper and careful determination of the TGF-β1 profile of patients is necessary to choose the suitable patients for TGF-β1 targeted therapy.

Abstract

The intestinal mucosa is a highly compartmentalized structure that forms a direct barrier between the host intestine and the environment, and its dysfunction could result in a serious disease. As T cells, which are important components of the mucosal immune system, interact with gut microbiota and maintain intestinal homeostasis, they may be involved in the process of intestinal barrier dysfunction. P2X7 receptor (P2X7R), a member of the P2X receptors family, mediates the effects of extracellular adenosine triphosphate and is expressed by most innate or adaptive immune cells, including T cells. Current evidence has demonstrated that P2X7R is involved in inflammation and mediates the survival and differentiation of T lymphocytes, indicating its potential role in the regulation of T cell function. In this review, we summarize the available research about the regulatory role and mechanism of P2X7R on the intestinal mucosa-derived T cells in the setting of intestinal barrier dysfunction.

Key Words: Intestinal barrier dysfunction; P2X7 receptor; T lymphocyte

Core Tip: Intestinal barrier dysfunction is usually accompanied by inflammation and the death of epithelial cells, which may lead to an elevated concentration of extracellular adenosine triphosphate and the intestinal immune response. Meanwhile, available studies have demonstrated that P2X7 receptor (P2X7R) can be an important regulatory factor in the activation and differentiation of T cells, suggesting that P2X7R may play a key role in intestinal barrier disruption by regulating T cells. Therefore, in this review, we summarized the recent advances regarding the intestinal barrier, the role of P2X7R and T-cells in the pathophysiology of intestinal barrier disruption, and the role of T cell-derived P2X7R in the pathophysiology of intestinal barrier dysfunction.

INTRODUCTION

The intestinal tract is one of the largest interfaces in the human body that directly contacts the external environment[1]. The intestine, a highly specialized and complex organ, plays an important role in absorbing useful substances and presenting potentially harmful substances[2]. The intestinal barrier also maintains the homeostasis of the inner environment and develops the intestinal immune system[3]. The intestinal barrier is composed of several parts, including the microbiological barrier, the chemical barrier, the physical barrier and the immune barrier[4]. Dysfunction of the intestinal barrier increases intestinal permeability and is related to the pathophysiology of several serious diseases[5]. The intestinal tract is exposed to various commensal bacteria, dietary antigens and pathogens that are related to immune tolerance and defense, showing the importance of the immune system in the intestine [6]. The immune barrier mainly includes the lamina propria lymphocytes, dendritic cells (DCs), mast cells, macrophages and lymphocytes — mainly $CD8^+$ T cells — located among epithelial cells[7]. Considering the involvement of T cells in the oral tolerance and immune defense against pathogens in the intestine, it is not surprising that they have an essential role in the pathology of intestinal barrier dysfunction[8,9].

The purinergic signaling pathway is highly conserved and plays a critical role in immune regulatory response[10]. This signaling pathway is mainly mediated by adenosine triphosphate (ATP) and nicotinamide adenine dinucleotide (NAD^+). Purinergic receptors are a group of transmembrane proteins widely expressed in immune cells[11]. According to their different structural properties, these receptors can be divided into the following three families: P2X receptor, P2Y receptor and P1 receptor[12]. Among them, P2X receptors, a class of ligand-gated, cationic-selective channels, are mainly activated by extracellular ATP (eATP)[13]. P2X7 receptors (P2X7R) have a low affinity for ATP and need to be triggered by high concentrations of ATP[14]. When the concentration of ATP is low, P2X7R can act as ion channels for Na^+, K^+ or Ca^{2+}. However, P2X7R can form nonselective and large-conductance pores in settings with high concentrations of ATP, thereby inducing cell apoptosis[14]. Under normal conditions, the cell membrane is impermeable to ATP and other related substances, and the maintenance of low eATP concentration is achieved by the strong degrading activity of ATPases[15,16]. The leakage of intracellular ATP due to the destruction of cell membrane could result in significant elevation of eATP concentration, thereby inducing the activation of the immune system[17-19]. Indeed, an ultrahigh concentration of eATP can be observed at the inflammatory sites[20]. In the process of acute inflammation, ATP activates P2X7R on the Treg cells, inhibiting their activity and viability[21]. P2X receptor channels on effector T cells are stimulated by eATP, facilitating the activation of nuclear factor of activated T cells and the production of IL-2, which could increase the activation of effector T cells[22,23]. The receptor can also be activated by NAD^+ released from damaged cells or activated T cells[24,25]. This NAD^+-dependent process is associated with ecto-ADP-ribosyltransferase ARTC2.2, which is activated by NAD^+ and induces the ADP-ribosylation of P2X7. In the presence of low micromolar concentrations of extracellular NAD^+, this process finally leads to cell death because of the activated P2X7R, a phenomenon known as NAD^+-induced cell death (NICD)[26,27]. In contrast, NAD^+ may be degraded into hydrolysate in the case of high levels of ATP, which would block the NAD^+-dependent process[28,29] (Figure 1). Intestinal barrier dysfunction is usually accompanied by inflammation and the death of epithelial cells, which may lead to an elevated concentration of eATP and the intestinal immune response[30]. Meanwhile, available studies have demonstrated that P2X7R can be an important regulatory factor in the activation and differentiation of T cells[31], suggesting that P2X7R may play a key role in intestinal barrier disruption by regulating T cells.

Therefore, in this review, we summarized the recent advances regarding the intestinal barrier, the role of P2X7R and T-cells in the pathophysiology of intestinal barrier disruption, and the role of T cell-

Figure 1 The activation of the P2X7 receptor and NLRP3 inflammasome. The P2X7 receptor is activated by extracellular ATP and NAD^+ and serves as an ion channel. It can also form non-selective macropores. The activated P2X7 receptor induces the decreasing of intracellular K^+, which initiates NOD-like receptor family pyrin domain containing 3 (NLRP3) inflammasome activation. The activated process of pro-interleukin (IL)-1β and pro-IL-18 are triggered by the active caspase-1 that results from the formation of NLRP3 inflammasome. Mature inflammatory cytokines are released into extracellular space from cells, which finally results in the cell death. derived P2X7R in the pathophysiology of intestinal barrier dysfunction.

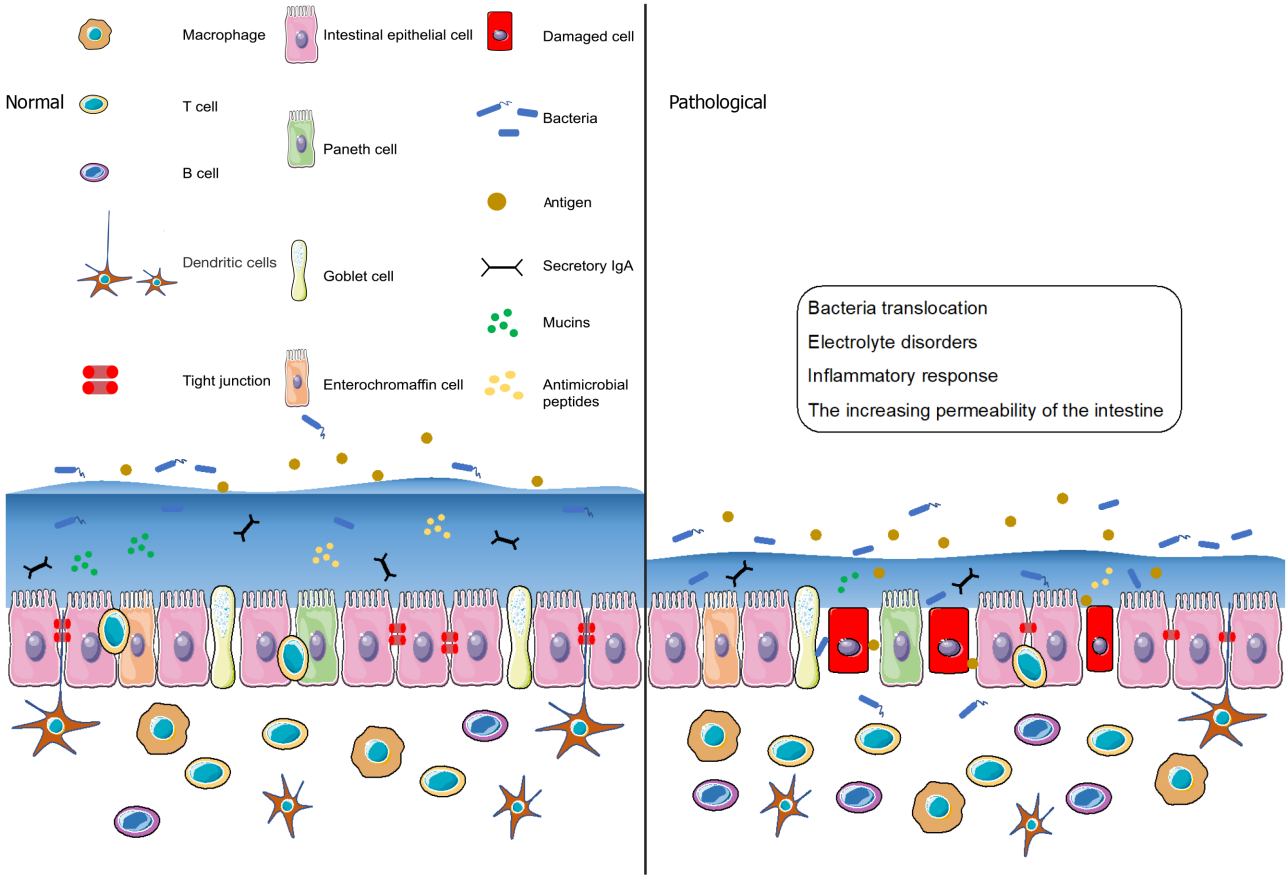
THE OVERVIEW OF THE INTESTINAL BARRIER

The intestinal barrier, one of the most important biological barriers in the body, is composed of various extracellular and cellular components. It works as a semipermeable membrane that allows nutrients to pass through while limiting the transport of pathogens and noxious substances. This dual function is regulated by the interaction among the four components of the intestinal barrier (the microbiological barrier, the chemical barrier, the physical barrier and the immunological barrier)[2].

There are over 10^{14} microorganisms and about 10000 bacterial species in the human intestine[32]. The microbiological barrier is formed by symbiotic microorganisms in the outermost position of the mucus layer, which effectively prevents harmful substances from entering intestinal epithelial cells[31,33,34]. The chemical barrier, also known as the inner mucus layer, is composed of macromolecules, including proteins, enzymes, peptides and immunoglobulins[35,36]. Mucin2 secreted by goblet cells is the main mucus protein and it serves as a protective barrier[37]. In intestinal crypts, pluripotent stem cells can differentiate into five different cell types, including enterocytes, goblet cells, Paneth cells, enteroendocrine cells and microfold cells[38]. The physical barrier beneath the mucus layer is composed of intestinal epithelial cells which are critical to the physical features of the intestinal barrier[30].

Beneath the intestinal epithelium, the immunological barrier consists of various immune cells, including T lymphocytes, B lymphocytes, dendritic cells, macrophages and plasma cells. This barrier is involved in innate and adaptive immune responses *via* antigen presentation and the secretion of inflammatory mediators and antibodies[39,40]. In addition to immune cells, substances secreted from these cells are also important in the construction of the intestinal immunological barrier. Secretory IgA, another constituent of the immunological barrier, is mainly found at the intestinal mucosal surface, and it provides antipathogen protection by interacting with bacteria[41].

There are several interactions among different components of the intestinal barrier. The physical barrier and the inner mucus layer separate the microbiological barrier and the intestinal immunological barrier, preventing unnecessary conflict and maintaining intestinal homeostasis[42]. The intestinal microbiota induces the functional maturation of innate and adaptive immunity, and instructs immune response through microbiota-derived metabolites and components (such as lipopolysaccharides and



peptidoglycans)[43,44]. The metabolites maintain intestinal homeostasis and regulate inflammation through immune responses, while the components of the microbiota direct immune responses by activating the intestinal TLR pathway[45-47]. For example, the expression of IL17, an inflammatory cytokine produced by γδ T cells, can be inhibited by propionate, a metabolite of intestinal bacteria[48]. Conversely, intestinal immune cells precisely regulate the microbial community both directly and indirectly, thus establishing a sustainable balance between the immune cells and intestinal microbiota [49-51].

The intestinal barrier should be considered a highly dynamic and complex structure that responds to internal and external stimuli[52,53]. Dysfunction of the intestinal barrier often occurs when the damage of the intestinal mucosa is severe and the components of the intestinal barrier change[54]. Under pathological conditions such as stress[55] and ischemia or hypoxia[56], the intestinal barrier is destroyed and the permeability of the intestine increases, thereby inducing bacterial translocation, electrolyte disorders and inflammatory response[57] (Figure 2). With the increasing permeability of the intestine, locally produced ATP is released into the intestinal microenvironment, followed by the activation of immune cells *via* ATP receptors, including P2X7 purinoceptor. When the intestinal immune system is activated, the inflammatory effects may not be regulated, which may lead to the irreversible destruction of the intestinal barrier[58]. More recently, it has been reported that increased ATP concentrations promote T-cell responses by enhancing the expression of the CD86 costimulatory molecule on antigen-presenting cells, an effect mediated through P2X7 purinergic receptor. Thus, the immune system may be the key player in barrier dysfunction and T cells may be involved in adaptive immune responses.

THE ROLE OF T CELLS IN THE INTEGRITY OF THE INTESTINAL BARRIER

T lymphocytes, which are adaptive immune cells, respond to specific antigens and remain the bacterial diversity by complex mechanisms in the homeostatic condition[2]. In the intestine, invariant NKT (iNKT) cells could either enhance or inhibit the immune response, and they might directly or indirectly regulate the microbiota in the intestine[59-62]. $CD8^+$ T cells are the main intraepithelial lymphocytes that monitor and respond to pathogens[63]. $CD4^+$ T cells and T-helper (Th) cells are mainly located in the intestinal lamina propria, and Th1 and Th17 cells can be found in the intestine[64]. Activated intestinal effector T cells could mount immune responses and influence the gut microbiota, and the excess of these cells might induce advanced inflammatory responses and acute or chronic inflammatory diseases[65-67]. In the intestinal adaptive immune response, dendritic cells ingest antigens and activate T cells, and Th cells are induced to differentiate into three different types of Th cells[68]. When lymphocytes respond to different stimuli, they can be divided into different groups based on their cytokine profile, such as Th1, Th2, or Treg cells, which are regulated by P2X7 purinergic receptor, mechanistically[69]. Activated T cells can modulate immune responses by secreting inflammatory cytokines or by interacting with other cells. The function of Th1 cells is to activate and proliferate cytotoxic T cells, thereby inducing the damage of infected intestinal epithelial cells[70]. Th2 cells can release inflammatory cytokines (IL-4, IL-5, and IL-13) and activate B cells to attack the infected cells[71-73]. Transforming growth factor β is capable of suppressing immunoglobulins M and G and promoting their switch to immunoglobulin A. This cytokine is secreted by T cells in Peyer's patches, suggesting the role of T cells in oral tolerance[74]. When intestinal permeability is damaged, antigens can pass through the intestinal epithelial cells and be taken up by macrophages or dendritic cells. Then, the antigens are presented to T cells in the lamina propria by these antigen-presenting cells, which stimulates T cells and induces their proliferation[75, 76]. Some antigens may be taken up by intestinal epithelial cells *via* endocytosis and then be presented to T cells after intracellular processing. This process is based on the classical and nonclassical histocompatibility molecules[77,78]. T cells use both their receptor and a costimulatory signal to recognize antigens[79].

Intestinal barrier disruption is usually accompanied by intestinal inflammation and pathogen invasion. T cells, the key components of adaptive immunity, can effectively limit the invading bacteria and regulate the inflammatory response together with the innate immune system and cytokines[80]. For example, the T helper cell type (Th)1 immune response is necessary in antipathogen protection and is involved in intestinal inflammation[81,82]. In humans, Th17 cells mainly reside in the intestine, where their polarization occurs. Because of the plasticity of Th17 cells, polarized cells have antipathogenic functions and maintain the intestinal epithelial integrity under normal physiological conditions, but they may turn into proinflammatory cells when exposed to IL-23[83]. Th17 cells can mediate inflammation by secreting a proinflammatory cytokine, IL-17A[70]. Peripheral Th17 cells are produced and migrate to the intestine in the case of oral inflammation, which may cause intestinal inflammation[84]. In addition to suppressing the proliferation of Th cells, Treg cells can protect against bacteria and dietary antigens and can produce anti-inflammatory cytokines to exert their anti-inflammatory function, thereby maintaining the homeostasis of the intestinal epithelium[85-87]. With the development of intestinal inflammation, the balance between Th17 cells and Treg cells may be broken up, biasing the function of Th17 cells[88]. In a recent study, it has been found that tissue-resident memory T cells are important in the development of intestinal inflammation, but the role of these cells in this process is not

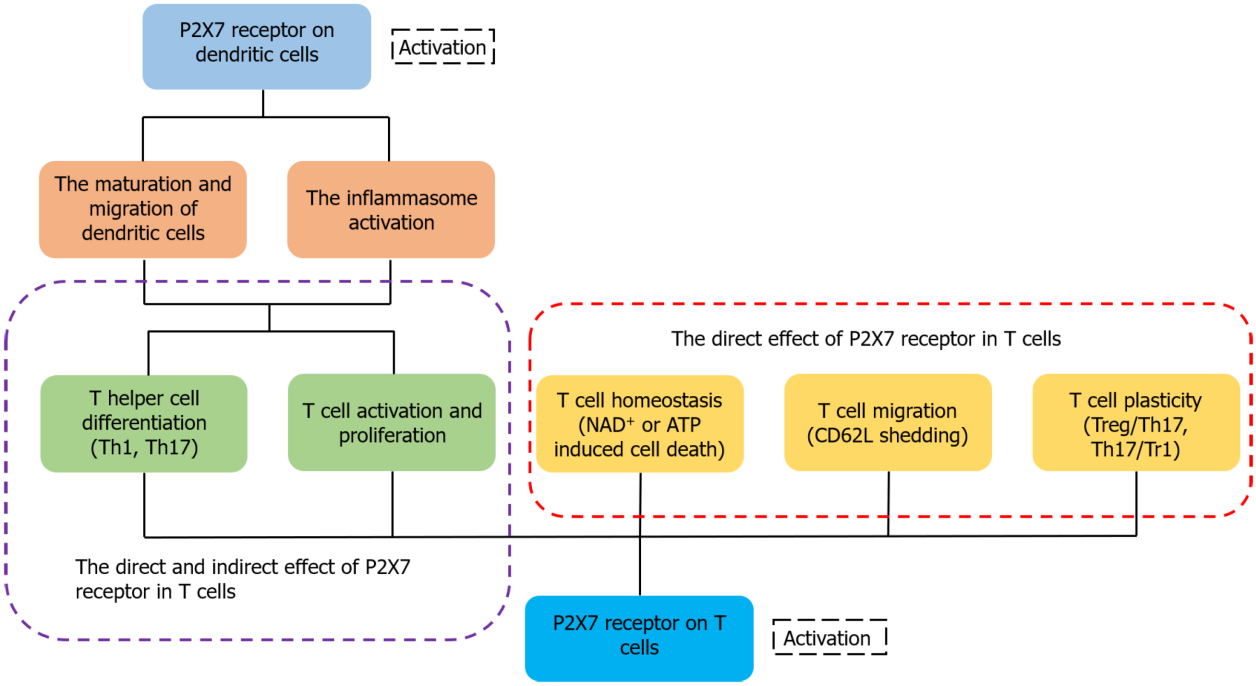
The intestinal barrier dysfunction results in the increasing of the intestinal permeability, which subsequently causes the inflammatory response and bacteria translocation.

clear[89]. In summary, T cells are very likely to become effective regulatory targets in the intestinal barrier, and T cell-associated therapy may be used in clinical settings in the future.

THE ROLE OF P2X7R IN THE INTESTINAL BARRIER DYSFUNCTION

Among the members of P2X receptor family, P2X7R (encoded by p2rx7) is the largest (with 595 amino acids in humans). It has special structural and signaling features because of its long intracellular carboxy-terminal, which helps prevent receptor desensitization[90,91]. The monomeric structure of P2X7R has two intracellular domains (C-terminal and N-terminal) and an extracellular ATP-binding domain that separates two transmembrane domains[92]. There were over 1500 single nucleotide polymorphisms (SNPs) reported in NCBI database, and most of them were missense, intronic or nonsynonymous[93]. In highly polymorphic human P2RX7, SNPs play a critical role in the biological process and function of P2X7R. About 10 loss of function SNPs and 3 gain of function SNPs have been identified[12]. For example, the activity of human P2X7R was reduced when Ala replaced Glu 496[94]. When Asn replaced lle-568, the expression of P2X7R was decreased to approximately 50% of normal, and P2X7R became nonfunctional[95]. The mutation of R307Q located in the ATP-binding pocket impaired the binding of ATP to P2X7R[96]. Genetic variants in P2X7R may be involved in the inflammatory response[97,98]. P2X7R function related SNPs played a regulatory role in inflammatory diseases [32]. Unlike other P2X receptors, the complete activation of P2X7R requires a higher concentration of ATP (range from about 0.1 to 2.5 mmol/L)[99]. When activated by ATP, P2X7R not only mediates the uptake of cations and macromolecules, but also leads to the activation of intracellular signaling pathways[100-102]. It has been demonstrated that the formation of macropores requires pannexin-1 channels, and pannexin-1 antagonists can decrease the formation of these pores[103]. However, recent data have suggested that the formation of macropores may be intrinsic to P2X7R without accessory molecules[104-106]. Moreover, P2X7R is associated with the activation of the signaling pathway and transcription factors, including MAP kinases, the cyclic AMP response element[107,108]. P2X7R is widely expressed in immune cells, which suggests its importance in the regulation of both the innate



and adaptive immunity, especially in the regulation of inflammation[109,110].

ATP is the most important energy molecule and a common extracellular signaling nucleotide that participates in the regulation of cellular proliferation, differentiation and death[111-113]. In a healthy body, eATP is maintained in a low concentration thanks to ATPases in extracellular spaces. ATP can leak from damaged or distressed cells, and can also be released by nonlytic regulated mechanisms, which increase the concentration of eATP16[114-117]. It has been proven that the concentration of eATP is higher in different inflammatory conditions than in normal conditions[118,119].

The intestinal barrier dysfunction induces the inflammatory response and epithelial cell death[120, 121]. In the acute-inflammatory tissue, high amounts of IL-6 are released, thereby inducing the synthesis and release of ATP from Treg cells exposed to IL-6[122]. The concentration of eATP may increase after intestinal barrier dysfunction, which may activate P2X7R. T follicular helper cells enhance germinal center reactions by deleting P2X7, resisting ATP-mediated immune cell death[123]. When the concentration of eATP produced by the intestinal microbiota is high, commensal-specific IgA responses initiated by intestinal lymphoid tissues are inhibited, which influences the composition of intestinal microbiota[124,125]. Moreover, Perruzza *et al*[126] showed that the blockade of P2X7R could decrease proinflammatory cytokines and protect the intestinal barrier function by inhibiting the activation of macrophages. Nucleotide-binding domain, leucine-rich-repeat receptor, pyrin domain-containing NLR family pyrin domain containing 3 (NLRP3) is a multiprotein complex that participates in the occurrence and development of many inflammatory diseases[127]. The inhibition of NLRP3 can reduce intestinal inflammation and enhance the barrier function[128]. Both NLRP3 and P2X7R are expressed in different immune cells, including T cells, B cells and monocytes[99]. Several signaling pathways induced by activated P2X7R may lead to a decrease in intracellular K^+, an increase in Ca^{2+} and the production of reactive oxygen species, which are key steps in NLRP3 activation[129-132] (Figure 1).

THE ROLE OF T CELL-DERIVED P2X7R IN THE INTESTINAL BARRIER DYSFUNCTION

It has been reported that activated P2X7R can affect several of the biological processes of T cells, including activation, differentiation and death[133]. After recognizing antigens, T cells rapidly release ATP through pannexin channels due to the T cell receptor signaling and co-stimulatory molecules[134, 135]. Because of the highly expressed P2X7 in iNKT cells, they were susceptible to P2X7-mediated cell death and regulated by vitamin A, finally influencing the intestinal homeostasis[136]. ATP released from T cells can activate P2X receptor which increases the expression of the *p2rx7* gene[14,135]. Yip *et al* [135] found that the silencing of P2X7R blocked Ca^{2+} influx and inhibited T cell activation in human $CD4^+$ T cells. These findings suggest that activated P2X7R is essential for the activation of T cells. L-selectin (CD62L) is related to the migration of T cells[137,138]. Low expression of L-selectin is necessary for activated or differentiated T cells to egress from the lymph node[139]. P2X7R activated by ATP can trigger CD62L shedding in human naïve T cells[140]. In a lymph node, activated P2X7R also affects the motility of T cells by inducing their calcium waves[141]. When intracellular ATP and NAD^+ nucleotides are released from cells, they can trigger the activation of P2X7R and induce apoptosis or necrosis[142]. In the case of low micromolar concentration of extracellular NAD^+, ADP ribosylation of P2X7R induces cell death because of persistent P2X7R activation[27]. Under the condition of activated P2X7R, there are two independent ways to induce T cell death: one of them depends on the phosphorylation of ERK1/2, and the other is associated with the nonselective pore[143,144]. In addition, CD62L shedding triggered by the activated P2X7R may induce cell death by apoptosis[145,146]. Compared with native T cells, activated T cells are less sensitive to NICD induced by P2X7R[147]. The expression of P2X7R is different in different populations of T cells. For example, Tregs and follicular helper T cells exhibit high expression of the P2X7 receptor, suggesting that they are more susceptible to cell death than other populations of T cells[148,149]. eATP and P2X7R influence the differentiation of T cells and play a significant role in the metabolism, generation, and memory function of $CD8^+$ T cells[150]. It has been shown that the AMP-activated protein kinase signaling pathway may promote constant efflux of intracellular ATP in memory $CD8^+$ T cells, and is involved in the differentiation and maintenance of memory T cells induced by P2X7R[151,152]. In an inflammatory environment, activated P2X7R drives the differentiation from T cells to Th17 cells[153], and the receptor reduces the differentiation of Tr1 cells with a high expression of IL-10 without Foxp3[21,155]. Activated P2X7R can also regulate the plasticity of Th17 cells and induce Th17 cells to differentiate[156]. In addition to acting directly on T cells, P2X7R can regulate the differentiation of T cells by affecting the physiological functions of dendritic cells[157, 158]. Although ATP may not only reduce the DCs-induced Th1 cell differentiation but can also influence the interaction of DCs with T cells, there is little research on the role of P2X7R during this process[159, 160]. Moreover, activated P2X7R regulates the cytokine secretion and polarization of Th17 cells by influencing dendritic cells[161,162] (Figure 3). Myeloid derived suppressor cells were considered as the regulator of immunosuppression *via* affecting the amounts, functions, or phenotypes of T cells, and the ATP/P2X7R signaling axis may be involved in this process[163].

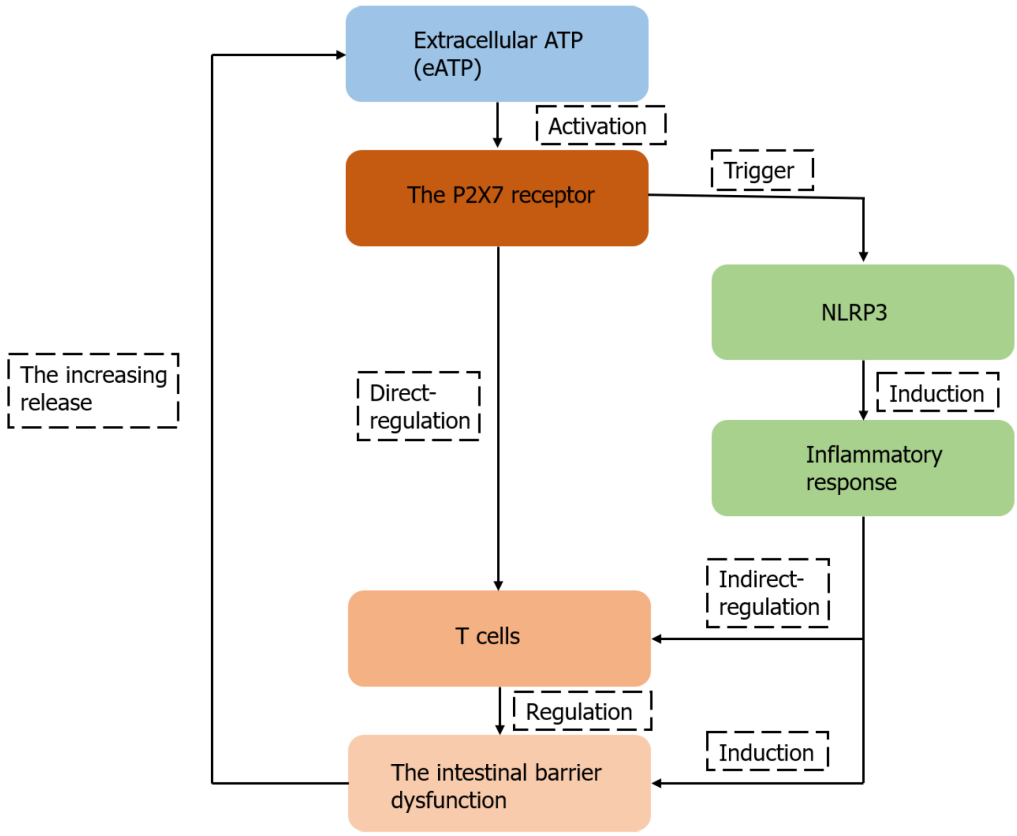
Figure 3 P2X7 receptor on dendritic cells and T cells influences the fate of T cells indirectly or directly, respectively. The activation of P2X7 receptor on dendritic cells induces the maturation and migration of cells and promotes the inflammasome activation, affecting the activation and differentiation of T cells finally. The activation of P2X7 receptor in T cells can directly regulate the activation, differentiation, migration and homeostasis of T cells[33].

DISCUSSION



The intestinal barrier dysfunction is a complex and severe pathological condition, which induces the inflammatory response and bacterial invasion. Sepsis is a serious systemic inflammatory disease with high morbidity and mortality in the intensive care unit because it can cause multiple organ failure in patients[164]. Given that the progression and pathogenesis of sepsis have been attributed to intestinal barrier dysfunction, further research on the immune and inflammatory factors of the intestinal barrier dysfunction is necessary[165,166].

According to the above description, T cells are involved in oral tolerance and immune response to antigens in the intestine, and they are the most common lymphocytes that reside in the intestine[167]. Moreover, infiltration by inflammatory T cells is a significant pathological characteristic of intestinal inflammation[168]. Thus, an appropriate number and population of T cells may mitigate the damage of intestinal barrier dysfunction.

P2X7R is widely expressed in T cells and serves as a regulatory factor of their biological processes. Heiss *et al*[169] found that intestinal $CD8^+$ T cells express a high concentration of P2X7R and are highly sensitive to extracellular nucleotides, indicating that P2X7R can regulate intestinal T cell responses. Inflammatory effector T cells can be depleted and intestinal inflammation can be relieved after treatment with NAD^+[170]. P2X7R has been shown to be the trigger for the activation of NLRP3, indicating that this receptor regulates the release of inflammatory cytokines (IL-18, IL-1β) and the initiation of an inflammatory response[171-174]. Therefore, P2X7R may influence inflammation *via* T cells which is indirect. The selectively P2X7 antagonist was proven to significantly inhibit the innate immune cells and upregulate the immunosuppressive-associated T cells, indicating that this antagonist may be a kind of potential treatment[175]. The effect of P2X7-blockade drug has also been demonstrated in the mouse models with advanced tuberculosis[176]. In addition to the above intracellular signaling pathways (MAPK pathway), previous studies verified that P2X7R also regulated MyD88/NF-κB and PI3K/Akt/mTOR signaling pathways in innate and adaptive immune responses, which suggested that the key proteins in these pathways can be considered as novel therapeutic targets[177].

CONCLUSION

In summary, T cells, the key participant in the intestinal barrier dysfunction, are regulated by P2X7R. The roles and mechanisms of P2X7R are associated with T lymphocytes in the intestinal barrier dysfunction and may be a potential research direction, although there have been few studies on this topic (Figure 4). Furthermore, different specific molecules that inhibit the expression of P2X7R may be

Abstract

Alcohol-associated liver disease (ALD) is a common chronic liver disease and major contributor to liver disease-related deaths worldwide. Despite its prevalence, there are few effective pharmacological options for the severe stages of this disease. While much pre-clinical research attention is paid to drug development in ALD, many of these experimental therapeutics have limitations such as poor pharmacokinetics, poor efficacy, or off-target side effects due to systemic administration. One means of addressing these limitations is through liver-targeted drug delivery, which can be accomplished with different platforms including liposomes, polymeric nanoparticles, exosomes, bacteria, and adeno-associated viruses, among others. These platforms allow drugs to target the liver passively or actively, thereby reducing systemic circulation and increasing the 'effective dose' in the liver. While many studies, some clinical, have applied targeted delivery systems to other liver diseases such as viral hepatitis or hepato-

cellular carcinoma, only few have investigated their efficacy in ALD. This review provides basic information on these liver-targeting drug delivery platforms, including their benefits and limitations, and summarizes the current research efforts to apply them to the treatment of ALD in rodent models. We also discuss gaps in knowledge in the field, which when addressed, may help to increase the efficacy of novel therapies and better translate them to humans.

Key Words: Liver targeted delivery; Nanoparticles; Liposomes; Polymeric nanoparticles; Precision medicine; Alcohol associated liver disease

Core Tip: Alcohol-associated liver disease (ALD) is a common chronic liver disease and global healthcare burden. While a great deal of pre-clinical research attention is paid to ALD, many experimental therapeutics which are administered systemically suffer from poor pharmacokinetics or poor efficacy. Liver-targeted delivery may address these drawbacks while avoiding extra-hepatic side effects. This article reviews literature applying liver-targeted drug delivery platforms such as liposomes, exosomes, polymeric nanoparticles, viruses, and bioengineered bacteria to the treatment of ALD.

INTRODUCTION

Pathogenesis and pharmacological management of alcohol-associated liver disease

Alcohol-associated liver disease (ALD) is a common chronic liver disease and contributes to the global healthcare burden caused by excess alcohol consumption, which is defined as more than 1 or 2 standard drinks of alcohol per day for females and males, respectively. Globally, nearly half of liver cirrhosis deaths are attributed to alcohol abuse[1]. The pathogenesis of ALD follows a well-described pattern of disease stages beginning with simple liver steatosis progressing to steatohepatitis (steatosis with inflammation), cirrhosis (advanced liver fibrosis), and in some severe cases, hepatocellular carcinoma (HCC) [2] (Figure 1A). In individuals who chronically consume alcohol, binge-drinking episodes may cause acute alcohol-associated hepatitis (AH), a life-threatening condition with high short-term mortality due to infection, severe inflammation, and multi-organ failure[3]. The pathophysiology of ALD is multifactorial and involves a variety of effects of alcohol on multiple organs, including the liver and the gut (Figure 1B). For example, alcohol-induced intestinal permeability and subsequent translocation of gut bacteria and bacteria-derived products into the portal circulation may contribute to inflammation, hepatic stellate cell (HSC) activation, and fibrosis in the liver. Further, direct effects of alcohol on the liver may result in dysregulated lipid signaling, hepatocyte cell death, and production of reactive oxygen species leading to steatosis as well as further inflammation, fibrosis, and ultimately liver cancer (these concepts have been reviewed in detail previously[2]). Most patients with early-to-mid-stage ALD (*i.e.*, hepatic steatosis or mild steatohepatitis) are asymptomatic, therefore a diagnosis of ALD is often not made until later stages of the disease. In those individuals where a diagnosis is made, abstinence and nutrition are key, and indeed, some stages of the disease (*e.g.*, steatosis) are reversible upon alcohol cessation. Limited pharmacological options exist for patients with alcohol-related late-stage liver disease (*e.g.*, cirrhosis or AH), including prednisolone (a corticosteroid) and pentoxifylline (a phosphodiesterase inhibitor used in patients for which corticosteroids are contraindicated or not effective), but importantly, these drugs only reduce short-term mortality[4,5]. There is much research attention being given to drug development in ALD using animal models. These therapies target various pathogenic mechanisms in ALD including oxidative stress (*e.g.*, S-adenosylmethionine, betaine, natural antioxidants), inflammation [*e.g.*, anti-tumor necrosis factor (TNF) therapy, interleukin (IL)-22, glucocorticoids, steroids, IL-1R inhibitors, granulocyte-colony stimulating factor], fibrosis (*e.g.*, transforming growth factor-β inhibitors, phosphodiesterase inhibitors, PPAR agonists), gut barrier dysfunction and microbial dysbiosis (*e.g.*, probiotics and antibiotics), and other processes (these drugs and others are thoroughly reviewed in[6]).

Overview of liver-specific drug delivery systems

While much pre-clinical research attention is given to new drug development for liver diseases,

Figure 1 Spectrum and pathophysiology of alcohol-associated liver disease. A: Schematic diagram describing the spectrum of disease stages in alcohol-associated liver disease (ALD). Percentages represent proportion of chronic drinkers who progress to the indicated disease stage; B: Schematic diagram depicting the pathophysiology of ALD. Ethanol affects both the gut and liver to induce changes in lipid metabolism, generation of reactive oxygen species and hepatocyte cell death, gut permeability, and downstream consequences including inflammation, hepatic stellate cell activation, fibrosis, DNA damage, and carcinogenesis. ALD: Alcohol-associated liver disease; ROS: Reactive oxygen species; HSC: Hepatic stellate cell.

including ALD, many experimental therapeutics relying on systemic drug administration suffer from drawbacks including poor pharmacokinetics or a low margin of safety due to off-target effects in other organs. An example of an early attempt to address some of these drawbacks is covalent conjugation of polyethylene glycol (PEG) to drug molecules (termed 'PEGylation'), a strategy that has been used for many years to lengthen half-life, improve water solubility, and decrease immunogenicity[7]. For instance, PEGylated interferon-α has been the first line treatment for chronic hepatitis B since 2005[8]. However, since that time, advances in nanomedicine have produced numerous liver-specific drug delivery platforms based on lipid vesicles, inorganic nanoparticles, and biological systems which allow: (1) Improved pharmacokinetics for drugs with poor solubility, low bioavailability, rapid metabolism, *etc*.; (2) Reduced systemic side effects by delivering drugs to the liver while avoiding other organs; and (3) Improved efficacy of drugs intended to act in the liver by increasing the 'effective dose'.

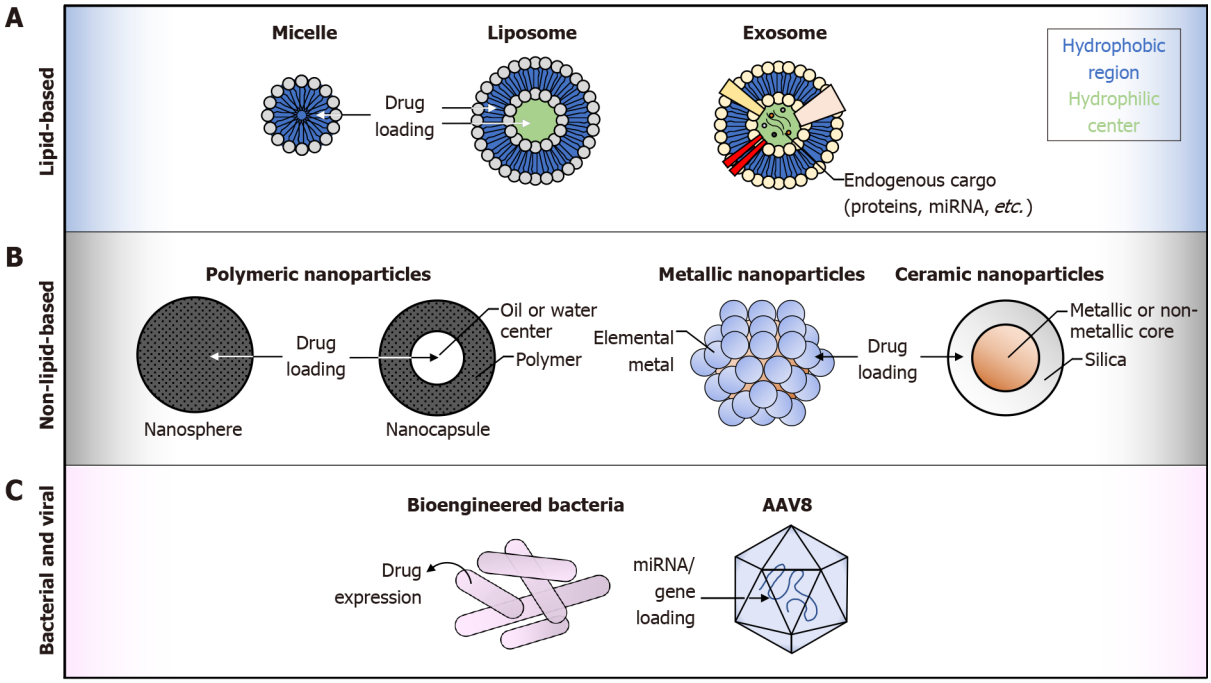
There are several types of liver-targeting drug delivery platforms which can be broadly categorized by their composition, including: lipid-based particles (*e.g*., micelles, liposomes, and exosomes, Figure 2A), non-lipid-based particles [*e.g*., polymeric nanoparticles (PNPs), metallic nanoparticles, and ceramic nanoparticles, Figure 2B], and bacterial and viral platforms (*e.g*., bioengineered bacteria and adeno-associated viruses, Figure 2C). These systems are either synthetic or derived from living systems, and have distinct advantages and disadvantages based on their efficacy, pharmacokinetics, and side effects (summarized in Table 1). Briefly, lipid-based particles are composed of endogenous lipids which keep the risk of immunogenicity and toxicity low. Metallic, ceramic, and some PNPs are non-biodegradable and sometimes cytotoxic, but can be modified to reduce toxicity and have additional uses in medical imaging and diagnostics[9]. Bacterial and viral drug delivery platforms benefit from the natural tropism of certain bacteria or viruses for a particular organ or niche but are also potentially immunogenic. These liver-targeting approaches have been used for the treatment of various liver diseases including HCC (*e.g*., liposomal, PEGylated, or PNP-encapsulated anti-cancer compounds[10-12]), viral hepatitis (*e.g*., metal nanoparticles[13] and PEGylated interferon[8]), and liver fibrosis (*e.g*., liposomal vitamin A[14]) with some reaching full FDA approval (*e.g*., Pegasys, Miriplatin, and others)[15].

Biodistribution of liver-targeted drug delivery platforms

The benefits of the liver specific drug delivery platforms stem from their unique ability to biodistribute to the liver while avoiding accumulation in other organs. To better understand the *in vivo* pharmacokinetics of these platforms, a knowledge of the structural organization of the liver and distribution of liver cell types is necessary. A graphical representation of liver structure and cell types can be found in Figure 3. The well-accepted lobular model of liver architecture describes the organ as being divided into discrete hexagonal anatomical units called lobules (Figure 3A)[16]. Surrounding the perimeter of the lobule at each vertex is a portal triad — a vascular bundle composed of a hepatic artery, portal vein, and bile duct. Portal blood and arterial blood fill fenestrated hepatic sinusoids and drain toward the central vein, providing oxygen and nutrients (as well as drugs and nanoparticles) to liver tissue. With regard to

Table 1 Summary of liver-specific drug delivery platforms, including molecular composition, potential modifications, benefits, and limitations

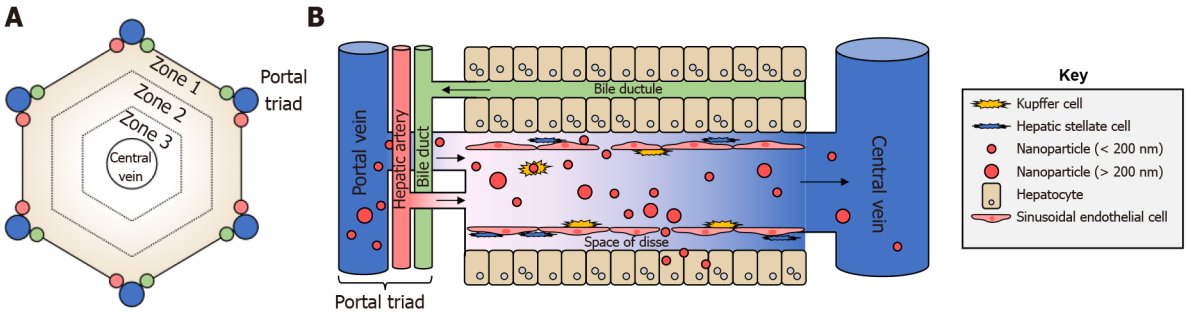
Platform	Composition	Origin	Benefits	Limitations
Lipid-based				
Liposomes	Lipids	Synthetic	Non-immunogenic, non-toxic, modifiable	High clearance by liver/spleen RES
Exosomes	Lipids	Biological	Endogenous cargo (proteins, nucleic acids, *etc.*), but can add additional cargo	Non-standardized isolation methods, potentially immunogenic
Micelles	Lipids	Biological	Non-immunogenic, non-toxic, modifiable	High clearance by liver/spleen RES
Non-lipid-based				
Polymeric nanoparticles	Polymers	Synthetic	Modifiable, capable of controlled drug release	High clearance by liver/spleen RES, potentially immunogenic
Metallic nanoparticles	Gold, silver, aluminum, zinc, iron, gadolinium, copper, rubidium, palladium, titanium	Synthetic	Modifiable, magnetic (iron), anti-microbial (copper, silver, titanium)	Non-biodegradable and potentially cytotoxic, immunogenic, or allergenic
Ceramic nanoparticles	Carbon, silicon with metallic or non-metallic core	Synthetic	Modifiable, resistant to pH change	Potentially cytotoxic or immunogenic, non-biodegradable or lowly biodegradable
Bacterial and viral				
Bacteria	Bacterial cells	Biological	Self-propulsion, chemotaxis, on-site drug production, transfection	Immunogenicity, infection risk
Viral vectors	AAVs, HSVs	Biological	Active liver tropism	Immunogenicity, toxicity, neutralizing antibodies



RES: Reticuloendothelial system; AAV: Adeno-associated virus; HSV: Herpes simplex virus.

cellular composition, the liver is divided into parenchymal and non-parenchymal cell types. The parenchymal cells of the liver are the hepatocytes, constituting a majority of cells by both number and volume (60% and 80%, respectively, Figure 3B)[17]. The remaining non-parenchymal cells include liver sinusoidal endothelial cells (LSECs), tissue resident macrophages (Kupffer cells, KCs), HSCs, and intra-hepatic lymphocytes (T cells, B cells, natural killer cells, *etc.*). LSECs form a fenestrated endothelium lacking a basal lamina separating liver sinusoids from the liver parenchyma.

The biodistribution of liver-specific drug delivery platforms in the body after systemic administration is based on the physical properties of the particle. For example, before reaching target liver cells, many particles may be opsonized by binding plasma proteins (*e.g.*, albumin, apolipoproteins, antibodies, complement component proteins) and cleared by the reticuloendothelial system (RES) of the liver and spleen, including by LSECs, particularly if the particles are greater than 200 nm in diameter or carry a negative charge[18]. Particle modifications such as PEGylation help avoid RES surveillance by preventing plasma protein binding, thereby improving *in vivo* half-life. Stealth liposomes, for example, are PEGylated phospholipid particles commonly used to improve the pharmacokinetics of a drug with a short half-life[19]. Particles which avoid RES clearance and have favorable size and charge can pass through the liver sinusoidal fenestrae, which are approximately 100-150 nm in diameter[20], to access HSCs in the space of Disse and the liver parenchyma. Accordingly, particles must have roughly the same or smaller diameter than these fenestrae and carry a charge which is not excessively positive or negative, as high charge magnitude is associated with increased plasma clearance[21]. Controlling these physical properties to allow accumulation of particles in the liver is called passive liver targeting, whereas active liver targeting relies on conjugation of a "homing" ligand whose receptor is expressed in the target organ, and in particular, the specific target cell type. For example, carbohydrate receptors such as the asialoglycoprotein receptor can be targeted to deliver therapeutics to hepatocytes with ligands including galactose, lactose, pullulan, and others (more information regarding active targeting has been reviewed by Kang *et al*[22]).



LIVER-SPECIFIC DRUG DELIVERY: IMPLICATIONS FOR ALD

The goal of this review is to summarize pre-clinical research efforts which apply liver-specific drug delivery platforms in various rodent models to prevent or treat ALD, as well as to further discuss the

Figure 3 Lobular liver architecture and biodistribution of nanoparticles. A: Top-down view of a liver lobule. Portal triads, consisting of a portal vein, hepatic artery, and bile duct, surround a central vein in a hexagonal shape. Concentric hexagons designate zones 1-3 moving from the outside to the inside. Portal and arterial blood flows from the triads toward the central vein, whereas bile travels the opposite direction; B: Side view. With the portal triad on the left, portal blood brings nanoparticles from the digestive tract to the liver sinusoids where they can interact with Kupffer cells, liver sinusoidal endothelial cells, and others. Nanoparticles of sufficiently small size can pass through the liver fenestrae formed by liver sinusoidal endothelial cells to access the Space of Disse, and subsequently, hepatocytes. Images are not drawn to scale.

drug delivery systems themselves, which include liposomes, exosomes, PNPs, bacteria, and adeno-associated viruses. To this end, we searched the PubMed (https://pubmed.ncbi.nlm.nih.gov), Google Scholar (https://scholar.google.com), and Web of Science (https://www.webofscience.com/wos/woscc/basic-search) databases for studies published up to June 1, 2022 using a combination of text keywords "alcohol liver disease" and the following: "liposome(s)", "liposomal", "nanoparticle(s)", "nanoformulated", "polymersome(s)", "polymeric nanoparticle(s)", "micelle(s)", "exosome(s)", "AAV", "adenovirus", "adeno-associated virus", and "bioengineered bacteria". Our search strategy identified 846 unique results, which were screened individually by title and abstract and were included based on relevance to liver-targeted drug delivery in ALD. Studies were not excluded based on date of publication, model organism, funding source, or drug delivery platform used. Based on these criteria, 16 studies were included, and then categorized by drug delivery platform (n = 7 studies related to liposomes, n = 2 related to exosomes, n = 5 related to PNPs, and n = 2 related to bacterial or viral systems). A graphical summary of the search strategy and study categorization can be found in Figure 4. The 16 key studies are described in detail in Table 2. The reader is encouraged to refer to this table for

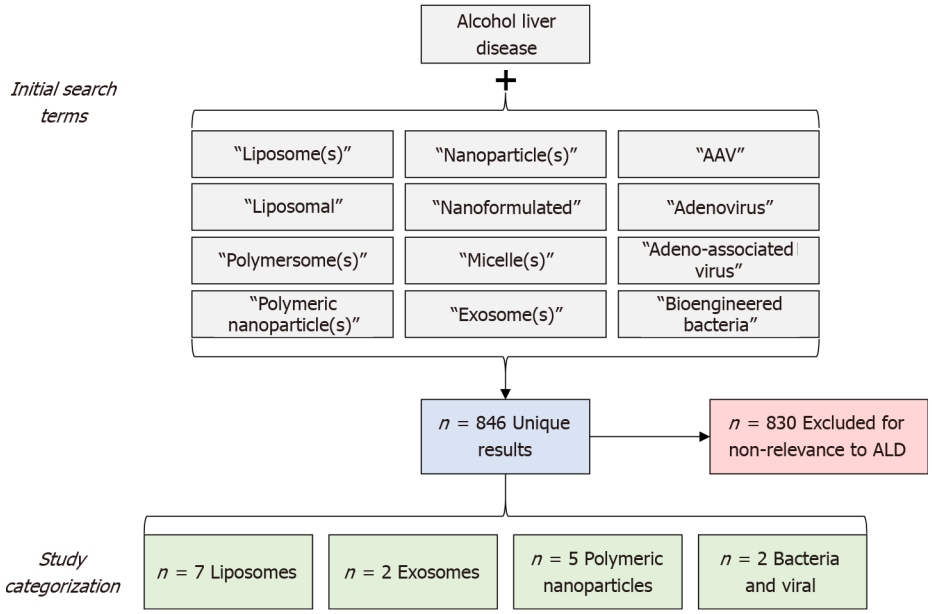
Passive targeting denotes a strategy wherein the physical properties of a particle are modified to target the liver, and active targeting denotes a strategy wherein a particle targets the liver through a ligand/receptor interaction.



Treatment paradigm denotes models wherein the drug is administered after liver injury has been established (*e.g.*, half-way through the model, at the end of the model, *etc.*), whereas prevention paradigm denotes models wherein the drug is administered for the entire duration of the model. Changes in results/mechanisms columns are in liver unless otherwise stated. AAV8: Adeno-associated Virus Serotype 8; ADH1: Alcohol dehydrogenase 1; AhR: Aryl hydrocarbon receptor; AKT: Protein kinase B; ALP: Alkaline phosphatase; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ATF3: Activating transcription factor 3; cAMP: Cyclic adenosine monophosphate; CCl4: Carbon tetrachloride; CCR2: C-C motif chemokine receptor 2; CHOP: C/EBP homologous protein; COX2: Cyclooxygenase 2; DCF: Dichlorodihydrofluorescein; DHE: Dihydroethidium; EE%: Encapsulation efficiency percent; EGF: Epidermal growth factor; EGFR: Epidermal growth factor receptor; ER: Endoplasmic reticulum; GPx: Glutathione peroxidase; GSH: Glutathione; HDL: High density lipoprotein; HSC: Hepatic stellate cell; i.p.: Intraperitoneal injection; i.v.: Intravenous injection; IL: Interleukin ; iNOS: Inducible nitric oxide synthase; LDL: Low density lipoprotein; LGG: Lactobacillus rhamnosus GG; LPS: Lipopolysaccharide; MCP1: Monocyte chemoattractant protein 1; MDA: Malondialdehyde; miR: Micro-RNA; MMPs: Matrix metalloproteinases; MPO: Myeloperoxidase; mTOR: Mechanistic target of rapamycin; N/A: Not applicable; N/P: Not provided; NRF2: Nuclear factor erythroid 2-related factor 2; ORO: Oil red O; P-AMPKα: Phospho-AMP-activated protein kinase alpha; PCX: Polycationic CXCR4 antagonists; PEG: Polyethylene glycol; PG: Propylene glycol; PI3K: Phosphoinositide 3-kinase; RoA: Route of administration; ROS: Reactive oxygen species; SOD: Superoxide dismutase; S-ODN: Antisense phosphorothioate oligodeoxynucleotide; TBARS: Thiobarbituric acid reactive substances; TG: Triglycerides; TGFβ: Transforming growth factor beta; TIMPs: Tissue inhibitors of metalloproteinases; TNFα: Tumor necrosis factor alpha; ZO1: Zonal occludin 1.

information such as the platform employed, the cargo molecule(s), the physical characterization of the particles used (if provided), and the animal model of ALD used, among other information.

Liposome-mediated drug delivery in ALD

Liposomes are one of the most common targeted drug delivery platforms, and indeed, about a third of the studies reviewed here used liposomal drug delivery in some form. Liposomes are vesicles composed of a phospholipid bilayer consisting of one (unilamellar) or more (multilamellar) concentric spherical layers enclosing an aqueous center (Figure 2A, middle panel)[23]. The presence of both aqueous and lipid compartments allows encapsulation or attachment of large quantities of both hydrophilic and lipophilic drugs, respectively (even simultaneously). Liposomes can be modified in many ways to alter their biodistribution *in vivo*, for example by modifying the lipid composition (saturated *vs* unsaturated, positively charged *vs* negatively charged), controlling size, attaching molecules such as PEG to improve stability, or adding proteins, antibodies, peptides, or carbohydrates to facilitate targeting of a specific cell type. The use of naturally occurring phospholipids gives liposomes the advantage of typically being non-immunogenic and non-pharmacologically active when administered alone. A major challenge in using liposomes to deliver drugs to the liver is opsonization and clearance by KCs and LSECs, as well as by RES components in the liver and other organs including the spleen, kidney, lung, bone marrow, and lymph nodes, although the liver is the primary site of liposome retention[23]. Attaching PEG to the liposome surface is an effective way to improve pharmacokinetics and avoid RES clearance, as PEG prevents attachment of opsonizing molecules and subsequent recognition by macrophages[19]. Controlling liposome size and surface charge can also avoid opsonization, as smaller (approximately 200 nm), more neutral liposomes do not as readily bind plasma proteins as larger, more highly charged liposomes.

An early study by Ponnappa *et al*[24] used pH-sensitive liposomes consisting of phosphatidylethanolamine, cholesterol hemisuccinate, and cholesterol to encapsulate an antisense oligonucleotide against *Tnf* mRNA (termed S-ODN) for delivery to the liver in a passive targeting approach. TNF-α is a pro-inflammatory cytokine elevated in ALD which, at high concentrations, sensitizes hepatocytes to cell death signals[25]. Liver macrophages and monocytes are a large source of liver TNF-α production[26]. Given the ability of liposomes to passively target liver macrophages, liposomes were therefore a natural choice of platform for the authors to employ in order to increase delivery of S-ODN to KCs. Intravenous administration of liposomal S-ODNs in a rat chronic ALD model decreased liver *Tnf* mRNA expression

Figure 4 Schematic representation of literature search strategy. Initial search terms included "alcohol liver disease" combined with the boxed terms. Eight hundred and forty-six unique results were generated, screened by title and abstract, and excluded based on relevance to the scope of the review. Sixteen studies were included in the review, broken down into four categories based on drug delivery platform. ALD: Alcohol-associated liver disease; AAV: Adeno-associated virus.

as expected, and subsequently prevented liver injury as demonstrated by plasma ALT[24]. The concentration of S-ODN in KCs was confirmed as being 20-fold higher compared to hepatocytes. In that study, liver-targeted delivery of the therapeutic was necessary to prevent side effects, specifically, to avoid the inhibition of blood coagulation associated with systemic administration (a process already perturbed in liver diseases[27]). A study by Rodriguez *et al*[28] also used a liposomal delivery system to avoid the systemic side effects of the hepato-protective drug rolipram, a phosphodiesterase 4 inhibitor. Previous studies demonstrated the beneficial effects of rolipram for ALD and other liver diseases[29]. However, in humans, rolipram causes significant central nervous system and gastrointestinal side effects (headache, vomiting, *etc*.). To this end, Rodriguez *et al*[28] used fusogenic liposomes composed of 1,2-Dioleoyl-sn-glycerol-3-phosphocholine and 1-palmitoyl-2-oleoyl-sn-glycerol-3-phosphate to passively deliver rolipram to the liver. Fusogenic liposomes differ from conventional liposomes because they avoid endocytosis and lysosomal degradation and instead fuse with the target cell membrane to release the drug cargo into the cytoplasm (for hydrophilic drugs) or membrane (for lipophilic drugs)[30]. Since phosphodiesterase 4 is expressed in the cytoplasm and plasma membrane of HSCs, among other liver cell types[31], the fusogenic liposome platform was an obvious choice for rolipram delivery. Indeed, in an acute-on-chronic mouse model of ALD, rolipram-loaded liposomes reduced liver damage (as determined by plasma ALT/AST activity), steatosis, oxidative stress, and endoplasmic reticulum (ER) stress similar to unencapsulated rolipram. However, encapsulated rolipram prevented liver cell death to a greater degree than un-encapsulated rolipram.

In 2016, Zhao *et al*[32] employed a liposome approach to deliver puerarin to the liver. Unlike the previous two studies, liposomal encapsulation in this study was used to improve pharmacokinetics, because puerarin, a plant-derived isoflavin, is rapidly cleared from the blood by the kidneys (with a half-life of less than one hour[33]). Liposomal encapsulation of this hydrophilic drug was achieved with liposomes composed of phosphatidylcholine, cholesterol, and propylene glycol. The authors demonstrated improved pharmacokinetics when administering puerarin liposomes to mice compared to non-encapsulated puerarin. Specifically, plasma area under the curve and half-life improved by 2.37- and 4.16-fold, respectively, and puerarin was detected most highly in the liver compared to other organs in both preparations. Previous studies supported puerarin as a beneficial molecule in a rat ALD model [34], but liposomal encapsulation improved efficacy further with respect to liver injury (decreased plasma ALT and AST levels) and, to a lesser degree, steatosis. In 2019, Wu *et al*[35] similarly employed a liposomal encapsulation technique to improve the pharmacokinetics of a naturally produced anti-inflammatory carotenoid, astaxanthin. Liposomal astaxanthin was administered to mice either orally or by intraperitoneal injection in an intragastric ethanol feeding model of ALD. Oral and intraperitoneal liposomal astaxanthin ameliorated alcohol-induced liver injury and histological signs of fibrosis. Whereas biodistribution of astaxanthin liposomes was not directly characterized in this study, the physical properties of the drug (low bioavailability, poor water solubility) suggest that liposomal encapsulation was necessary for efficacy. Silymarin is another excellent example of a beneficial

compound with poor pharmacokinetics which can be improved by incorporation into liposomes. Kumar *et al*[36] showed that encapsulation of this hepato-protective flavonolignan in phosphatidylcholine and cholesterol liposomes (either un-modified or PEGylated) improved pharmacokinetics and efficacy. Liposomal encapsulation improved the maximum plasma concentration and plasma area under the curve, while also increasing the solubility of the drug. *In vitro*, silymarin liposomes protected Chang Liver (HeLa) cells against ethanol-induced cell death. *In vivo*, in a rat chronic model of ALD, both un-modified and PEGylated silymarin liposomes ameliorated alcohol-induced liver injury while retaining the anti-inflammatory and antioxidant properties of silymarin. Recently, Yu *et al*[37] encapsulated Saikosaponin D, an anti-inflammatory/anti-oxidant plant-derived compound, in liposomes and demonstrated improved pharmacokinetics and efficacy in a mouse model of ALD compared to the nonencapsulated compound.

Lastly, Jain *et al*[38] employed a liposomal encapsulation approach for a plant-derived molecule, mangiferin. Like silymarin, mangiferin is a natural antioxidant with demonstrated benefits in the treatment of ALD and other diseases[39,40], but is not efficacious when used alone due to low bioavailability and metabolism by gut bacteria, as demonstrated by Jain *et al*[38]. To this end, the authors used a so-called 'herbosome' encapsulation strategy for mangiferin to improve the bioavailability of this compound. Herbosomes are defined as plant-derived compounds encapsulated in phospholipid particles, which in this study consisted of phosphatidylcholine and cholesterol. In a chronic rat model of ALD, unencapsulated mangiferin was able to significantly decrease liver injury, and mangiferin-loaded herbosomes further decreased the liver injury. Mechanistically, the authors attributed this protection to the antioxidant effects of mangiferin, as demonstrated by rescued SOD, catalase, and GSH levels and decreased liver MDA.

These studies support liposomal encapsulation as an effective approach not only for targeting drugs to the liver to avoid systemic side effects, but also for increasing the bioavailability of various compounds. The studies cited herein accomplished these goals by using liposomes composed of various glycerophospholipids including phosphatidylethanolamine, phosphatidyl choline, phosphatidic acid, and lecithin. Selection of certain lipids over others influences membrane fluidity/rigidity, which indirectly alters the permeability of the liposomal bilayer[41]. Certain phospholipids can also be chosen over others to impart fusogenic character, wherein liposomal cargoes can be targeted to the cell cytoplasm by fusing with the plasma membrane while avoiding endocytic degradation[30]. Rodriguez *et al*[28] employed this approach by using liposomes composed of 1,2-dioleoyl-sn-glycero-3-phosphocholine and 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphate to target cytosolic phosphodiesterase. Further, most other groups incorporated cholesterol into their formulation, which can alter the release of the drug cargo and prevent unwanted 'leakage', thereby contributing to the overall stability of the nanoparticle[42].

Exosomes in ALD

Exosomes are another type of lipid-based liver-targeting nanoparticle which have been evaluated pre-clinically as potential therapeutics for ALD as well as potential biomarkers of disease progression in AH [43] (Figure 2A, right panel). Exosomes can be derived from bacteria or food, and are often small (approximately 30-150 nm in diameter) compared to synthetic liposomes (150 nm and larger in the studies cited here)[44]. Because they are products of the host cell membrane which are excreted by exocytosis, they are composed of phospholipids and cholesterol. While originally thought to be used by cells for waste removal, more recent evidence has supported a role in cell signaling, antigen presentation, tissue repair and regeneration, among other processes[44]. Unlike liposomes, exosomes contain numerous surface proteins (*e.g.*, CD63 in eukaryotic exosomes[45]) and internal cargo molecules including lipids, proteins, and nucleic acids. Despite the presence of existing cargo, additional molecules including drugs can be added to exosomes after isolation. The surface proteins present on exosomes mediate their cellular uptake, which has been shown to occur mostly in the liver and spleen, but also to some degree in the kidney, lung, and gastrointestinal tract, although pharmacokinetics depend on the source of the exosomes[46]. Liver macrophages are the cell type thought to be most responsible for exosome uptake through recognition of their charge by scavenging receptors, or recognition of surface signals such as sialic acid or phosphatidyl serine[47,48]. Thus, clearance by macrophages is again a drawback when trying to administer drugs to the liver parenchyma. Another significant consideration is standardization of isolation or purification protocols. Some techniques, for example, fail to completely exclude extraneous types of extracellular vesicles, leading to an impure drug product preparation[49]. Lastly, there are many unanswered questions related to how the choice of cell type from which to isolate exosomes impacts immunogenicity and efficacy.

A study from Gu *et al*[50] aimed to use exosomes derived from the beneficial bacteria *Lactobacillus rhamnosus GG* (LGG) to treat ALD. LGG has previously been demonstrated to be beneficial for ALD as a probiotic supplement which prevents gut permeability, thereby ameliorating liver injury[51,52]. The benefits of LGG probiotic supplementation are mediated, in part, by molecules secreted by LGG, as evidenced by the protective effects of LGG cell culture supernatant[53,54]. These soluble mediators are thought to be released from bacteria in exosomes. Gu *et al*[50] showed that orally administered LGG-derived exosomes (termed LDNPs) ameliorated experimental ALD in an acute-on-chronic mouse model. In contrast to previous studies aiming to deliver drugs to the liver, LDNPs in this study were

designed to ameliorate liver injury *via* the gut-liver axis, by targeting intestinal cells. Fluorescent labeled LDNPs were detectable in the intestine to a much larger extent than in the liver. Mice that received LDNPs were protected from the ethanol-associated reduction in intestinal tight junction protein expression and had boosted expression of intestinal anti-microbial peptides (*e.g.*, *Reg3b*, *Reg3g*) and IL-22. As a result, circulating endotoxin levels were decreased in LDNP-treated mice. Consequently, liver injury, steatosis, and inflammation were attenuated, confirming the critical importance of intestinal barrier defense in preventing ALD pathogenesis. Mechanistically, Gu *et al*[50] showed that the beneficial effects of LDNPs were mediated by the aryl hydrocarbon receptor (AhR), suggesting that the cargo molecules responsible for the benefits of LDNPs are likely AhR ligands.

Foods are another excellent source of exosomes with beneficial endogenous cargo molecules which target the intestinal epithelium or translocate to the bloodstream to target various organs including the liver[55]. Fluorescently labelled milk-derived exosomes, for example, have been shown to localize in the liver after oral administration to mice[56]. Food-derived exosomes from ginger, grapefruit, grape, garlic, ginseng, lemon, and others have been shown to be efficacious in the treatment of numerous diseases by nature of their antioxidant, anti-tumor, or anti-inflammatory cargo[55]. To investigate the efficacy of food-derived exosomes in ALD, Zhuang *et al*[57] used exosomes derived from ginger, a food which has been demonstrated to protect against liver injury of multiple etiologies, including alcohol, *via* antioxidant compounds called gingerols[58]. In an acute-on-chronic mouse model of ALD, daily oral ginger-derived exosome delivery decreased liver injury and steatosis. The antioxidant effects of the exosomes were also demonstrated, with increased expression of antioxidant genes in the liver through activation of NRF2. The authors also analyzed the distribution of the exosomes by fluorescent labeling, showing that the liver was the primary site of accumulation, with no detectable signal in lung, spleen, or other organs. Further, co-localization with albumin-positive cells by immunofluorescence showed that the ginger-derived exosomes primarily associated with hepatocytes, indicating cell-specificity. Collectively, these studies show the utility of exosomes as 'pre-packaged' lipid vesicles which can deliver beneficial cargo molecules from various sources to the liver for the treatment of ALD.

PNP-mediated drug delivery in ALD

PNPs are a class of non-lipid-based nanoparticles composed of natural or synthetic polymers that are gaining popularity in numerous applications, including medicinal and non-medicinal (material science, electronics, ecology, *etc*., Figure 2B, left panel)[59]. PNPs are classified as either nanospheres (composed entirely of polymer matrix) or nanocapsules (a polymer shell with a water or oil center) with an approximate size of 100-250 nm, which can be controlled during synthesis. Poly(lactic-co-glycolic acid) (PLGA) and vinyl monomer-based polymers are commonly used in PNP synthesis (*e.g.*, polystyrene, polyalkyl acrylates), although many other polymers can be used including polyesters, polyurethanes, polysaccharides, polypeptides, and biopolymers (*e.g.*, lignin)[60]. Polymer choice can be adjusted to control stability, particle size, and *in vivo* drug release. As with liposomes, surface modifications can also be made to PNPs to alter their pharmacokinetic profile and biodistribution, such as active targeting moieties or hydrophilic molecules that prevent opsonization (*e.g.*, PEG). Surface modifications can also change the intrinsic negative charge of most PNPs to neutral or positive. PEGylation, for example, shifts the charge to neutral, whereas conjugation of other molecules such as chitosan imparts a positive charge [61,62]. After reaching target cells, PNPs are up taken by pinocytosis or clathrin-mediated endocytosis but can escape lysosomal degradation and enter the cell cytoplasm within 10 min[63]. Other benefits of PNPs include low immunogenicity, low toxicity, and large surface area. As with liposomes, one drawback of PNPs is their susceptibility to opsonization in plasma and rapid clearance by the liver and spleen RES.

Several studies have applied PNPs to the treatment of ALD by attaching various cargo molecules. A study by Nag *et al*[64] used PLGA PNPs to deliver tannic acid and vitamin E to the liver in a chronic mouse model of ALD. These two naturally occurring molecules have previously been established to be beneficial for the treatment of ALD through anti-inflammatory and antioxidant mechanisms[65]. PNP formulation is necessary to ensure extended release of these molecules due to intestinal modification, poor absorption, rapid metabolism, and short half-life[66,67]. Nag *et al*[64] demonstrated that tannic acid/vitamin E PLGA PNPs ameliorated ALD as evaluated by multiple endpoints including reduced liver injury, steatosis, fibrosis, inflammation, oxidative stress, and liver cell apoptosis, as well as increased hepatocyte viability. Importantly, *in vitro* pharmacokinetic analysis showed that the PNPs slowed the movement of tannic acid and vitamin E across a semi-permeable membrane compared to free tannic acid and vitamin E, indicating that this formulation may improve the retention time of these compounds in the liver.

Another study targeting oxidative stress in ALD was conducted by Natarajan *et al*[68], who employed a PNP approach to deliver the enzyme superoxide dismutase (SOD) to the liver. Oxidative stress is a key mechanism in ALD pathogenesis[69]. A previous study in rats demonstrated that increasing hepatic SOD expression (*via* gene therapy) alleviated ALD by scavenging superoxide[70]; however, PNP-mediated SOD delivery is a more favorable translational therapy due to clinical issues surrounding the use of gene therapy (hepatotoxicity and generation of anti-adenovirus antibodies, for example)[71]. Further, previous studies suggest that administration of unencapsulated recombinant SOD does not produce effects that are as long-lasting as those by encapsulated SOD[72]. After establishing successful

delivery of functional SOD *in vitro* in E-47 hepatocytes and protection against ethanol and linoleic acid-induced oxidative stress, the authors administered SOD PNPs to mice by intraperitoneal injection in a chronic model of ALD. Compared to ethanol-treated mice, mice which received ethanol and SOD PNPs had decreased liver steatosis and inflammation as quantified by hematoxylin-eosin staining and decreased liver cytokine expression, respectively. Interestingly, the authors could not detect an increase in SOD in SOD PNP-treated mice, although the authors speculate that the time course of the study may not allow proper detection of elevated SOD levels. In a follow up study by the same research group, Gopal *et al*[73] again assessed the efficacy of intraperitoneal administered SOD PNPs in ALD, although in a modified model where mice are fed a high fat diet prior to the beginning of the ethanol feeding paradigm. Unlike the previous study, here the authors were able to show evidence of increased SOD expression and activity in the livers of mice administered SOD PNPs. Ethanol significantly induced liver injury in control mice, but not in mice administered SOD PNPs, as evidenced by plasma ALT levels. Again, ethanol-induced hepatic steatosis and inflammation were attenuated, corroborating the beneficial effects and mechanisms of protection of liver-specific SOD delivery.

Apart from proteins, another group of novel cargo molecules which can be delivered by PNPs are anti-micro RNAs (anti-MIRs), which are designed to inhibit endogenous MIRs, such as MIR-155, which has been previously shown to play a pathogenic role in ALD[74]. Zhang *et al*[75] aimed to not only block the effects of MIR-155, but also to deliver CXCR4 antagonists (collectively termed polycationic CXCR4 antagonists, or PCX, by the authors), which block alcohol-induced liver fibrosis *via* inhibition of HSC activation. Thus, the group administered synthetic cholesterol-modified polyethyleneimine nanoparticles *via* i.v. injection to mice to target HSCs and KCs in a model of alcohol + CCL_4-induced fibrosis. Indeed, compared to nanoparticles harboring a MIR negative control, the anti-MIR-155/PCX-loaded PNPs significantly reduced liver injury, fibrosis, and inflammation when administered in a treatment paradigm. This study supports the idea that numerous therapeutic cargos are compatible with the PNP platform, even when combined in a dual approach.

In contrast to the synthetic PNPs used in the studies mentioned above, a study by Wang *et al*[76]. used PNPs synthesized from a naturally occurring polysaccharide isolated from *Angelica sinensis* root [*Angelica sinensis* polysaccharide (ASP)]. ASP was combined with cholesterol hemisuccinate to prepare self-assembling ASP-cholesterol hemisuccinate PNPs (termed ACNPs), which were loaded with curcumin, a plant-derived compound with antioxidant effects which has previously shown beneficial effects in ALD[77,78]. The authors used PNPs to improve the delivery of curcumin, which is not readily water-soluble and has low bioavailability due to rapid metabolism[79]. In an intragastric feeding mouse model of ALD, the authors demonstrated that curcumin-loaded ACNPs decreased liver oxidative stress, and consequently, liver injury. Mechanistically, curcumin ACNPs increased NRF2 protein, consistent with other studies implicating NRF2 signaling for the beneficial effects of curcumin[77,80]. These studies show that PNPs, in addition to liposomes, are an effective choice of delivery platform to target drugs to the liver, and importantly, improve the bioavailability of compounds such as tannic acid, vitamin E, and curcumin.

Bacteria and adeno-associated virus-mediated liver-specific delivery in ALD

Certain bacteria have long been considered for their therapeutic potential either as whole organisms (probiotics), colonies of many bacterial species (*i.e.*, fecal transplant), or bacterial products[81]. More recently, genetically engineered bacteria have been developed to facilitate delivery of drugs, proteins, enzymes, and genes for the treatment of numerous pathologies[81] (Figure 2C, left panel). Bacteria as drug delivery systems are beneficial in several ways, including that they can provide their own propulsion and taxis *via* flagella or pili in response to external stimuli (*e.g.*, phototaxis, chemotaxis, thermotaxis, *etc.*), they can be designed to seek a certain molecule (*i.e.*, active targeting), they can produce a desired drug 'on-site' by metabolism, and they can even be designed to transfect host cells. These benefits, and numerous others (described in great detail in[81]), come at the cost of potential host immune response. Use of non-pathogenic bacterial strains, commensal bacteria, or genetic modification can decrease immunogenicity, but there is still considerable risk of septic shock which can result in mortality when targeting sterile body compartments (*e.g.*, blood, abdominal cavity, *etc.*)[82]. Hendrikx *et al*[83], for example, used genetically engineered *Lactobacillus reuteri* (*L. reuteri*), a commensal gut microbe, as a means of increasing intestinal IL-22 for the treatment of ALD in an acute-on-chronic mouse model. This approach aimed to ameliorate alcohol-associated changes in both the intestine and the liver. The gut and liver are connected *via* the so-called gut-liver axis, where alcohol-induced gut permeability allows pro-inflammatory bacteria and bacterial products (*e.g.*, endotoxins) to enter the hepatic portal system and exacerbate liver injury[84]. IL-22 is a cytokine which contributes to gut barrier defense and homeostasis[85], which the authors demonstrated to be decreased in the intestines of ethanol-fed mice. Mice which were enterally provided IL-22-expressing *L. reuteri* throughout the feeding protocol had increased expression of the gut anti-microbial peptide, *Reg3g*, decreased translocation of bacteria to the liver, and consequently, decreased liver injury, steatosis, and inflammation. Increased intestinal IL-22 was confirmed, but there was no increase in plasma IL-22, indicating that a localized increase in gut IL-22 was sufficient to restore gut barrier health and ameliorate liver injury. This engineered bacteria approach may be more clinically useful than simply administering recombinant IL-22 protein systemically, as systemic administration is associated with increased risk of tumor

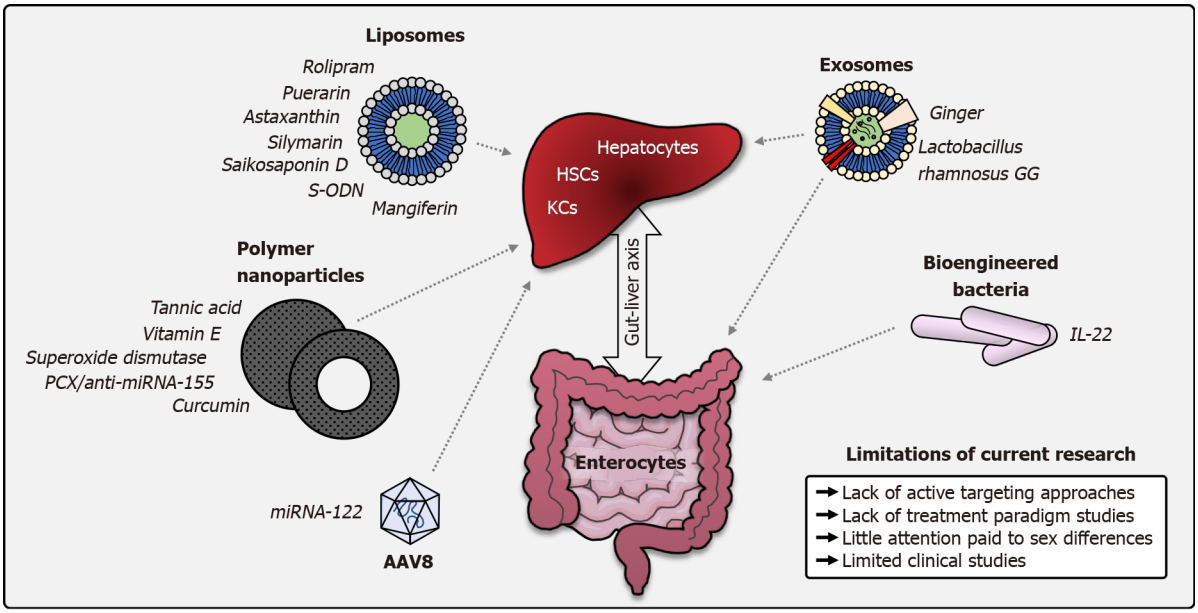
development in chronic liver disease patients[86-88]. Indeed, bacteria serve as a unique drug delivery system with several key advantages, especially given that liver diseases such as ALD can be targeted indirectly *via* the gut-liver axis.

AAVs (adeno-associated virus) vectors are another biological system with the capability to target specific organs (Figure 2C, right). There exist multiple AAV serotypes with differing capsid proteins (13 in total), which confer serotype-specific functional features, including tropism for different organs[89]. AAV serotype 8 (AAV8), for example, exhibits high liver tropism, since the capsid proteins expressed in this serotype interact with the laminin receptor, which is highly expressed in the liver (for this reason, we have defined AAV8 as 'actively' targeting the liver in Table 2)[90]. This natural ability to target the liver comes at the cost of immunogenicity, liver toxicity, and the production of neutralizing antibodies by the host, several key hurdles for clinical AAV8-based therapy[89]. In contrast to the previous nanoparticle- and bacteria-based delivery systems discussed in this review, AAV vectors are used as a gene delivery vehicle, rather than a carrier of natural or synthetic drugs, based on their ability to transfect host cells[91]. This review will discuss one study using AAV8 as a delivery mechanism for a microRNA; for more information regarding gene therapy for the treatment of liver disease the reader is encouraged to read Kattenhorn *et al*[92]. Satishchandran *et al*[93] employed an AAV8 vector to rescue the ethanol-associated loss of microRNA 122 (MIR-122), which was demonstrated in both human ALD patients and mice in a 5-week chronic model of ALD. Previous work showed that loss of liver *Mir122* alone led to hepatic steatosis with spontaneous development of liver fibrosis and even HCC[94], suggesting a beneficial or homeostatic role of this microRNA in the liver. The authors used the AAV8 serotype to transfect hepatocytes with *pri-MiR122* or a scrambled control vector. Compared to controls, mice receiving AAV8-MIR122 had increased mature liver MIR-122 and, importantly, decreased alcohol-induced liver injury, steatosis, inflammation, and fibrosis. The AAV8 vector was shown to specifically target hepatocytes (as liver mononuclear cells had no increase in MIR122), suggesting this platform may be effective in targeting genes, including microRNAs, to not only the liver, but specifically to hepatocytes.

GAPS IN KNOWLEDGE

Research efforts to apply targeted drug delivery systems for the treatment of ALD are growing, but there are still considerable gaps in knowledge and several barriers to address. First is the lack of use of active targeting strategies, where addition of a ligand to a liposome or nanoparticle targets a drug to a particular liver cell type. Targeting a drug to a particular cell type (*e.g.*, targeting an antioxidant to hepatocytes) may increase efficacy, or produce the same beneficial effect with a lower total dose, thereby reducing the possibility of off-target effects. In additional to hepatocytes, other cell types contribute to ALD, including HSCs and both resident (Kupffer cells) and infiltrating macrophages, thus presenting opportunities to target these non-parenchymal liver cells. In this way, such treatments could target various stages of ALD such as hepatic fibrosis, which is largely driven by these cell types in their activated states (*i.e.*, activated HSCs or M1-polarized KCs)[95]. Fifteen of the 16 studies used a passive targeting approach, where the physical properties of the particle (*i.e.*, size and charge) were controlled in such a way that the particles would passively accumulate in the liver. The Satishchandran *et al*[93] study using AAV8 is one example of biological active targeting, where the AAV8 capsid binds to a particular receptor in the liver. Future research should consider ligand conjugation and active targeting of liposomes and PNPs to improve their drug formulations.

Next, with respect to the paradigm in which drug therapies were administered, in the 16 studies reviewed here, only about half used a so-called 'treatment paradigm', where the drug was given after establishment of liver injury (*i.e.*, half-way through the model or later). The remaining half administered their therapeutics in a 'prevention paradigm', where the drug was given at the start (or even prior to the start) of the alcohol feeding model. Studying the efficacy of a drug in a prevention paradigm certainly provides useful insight into whether the drug has any beneficial effect in ALD. However, this paradigm has limited clinical relevance, since most patients with mild to moderate ALD are asymptomatic, and they would not receive a diagnosis nor treatment until after injury has developed. In the case of studies establishing benefits of a liver-targeted drug in ALD in a prevention paradigm, additional studies should be carried out to determine whether administration of that drug formulation later in the feeding model is still effective. Another issue related to the models used in these studies is the lack of knowledge of the efficacy of these therapies in advanced ALD stages such as fibrosis/cirrhosis. Only one study discussed here (Zhang *et al*[75]), employed a model which is known to produce liver fibrosis, in this case by use of a 'second hit' of carbon tetrachloride superimposed on chronic EtOH feeding. While the authors did note reductions in fibrosis as measured by immunohistochemistry, this is only one study. Most of the studies discussed herein employed chronic, acute-on-chronic, or multiple-binge models which typically produce mild ALD characterized by hepatic steatosis, low-level inflammation, and mild liver injury with elevated ALT but no fibrosis[96,97]. Future studies should investigate the efficacy of nanoformulated drugs in experimental models of more advanced ALD which mimic alcohol-associated cirrhosis or severe AH, especially as better models are developed.



Another consideration with significant clinical implications is the route of administration. The studies reviewed here applied oral (gavage) or injection routes of delivery. Clearly, oral delivery is most attractive from a patient compliance perspective due to ease of self-administration and the absence of potential adverse effects from injections (injection site pain, inflammation, and infection). In general, nanoparticle systems tend to improve the pharmacokinetics of a drug to enable oral delivery in cases where this route would be otherwise unfeasible due to enzymatic digestion or poor absorption[98]. Indeed, many of the studies discussed here employed these platforms with this goal in mind, particularly for poorly soluble plant-derived compounds. However, compared to oral delivery, injection allows the highest level of control over the rate of drug delivery and can bypass any issues associated with first-pass metabolism or poor gastrointestinal absorption, resulting in a bioavailability of 100% and a rapid onset of action[99]. Direct injection of the drug solution into circulation does, however, pose a higher risk of adverse reactions and requires a healthcare professional to administer the treatment. This may be most acceptable in cases where drugs are developed for advanced ALD stages such as AH, where patients are already hospitalized. Regardless, authors should justify their chosen route of administration in the context of their future translational goals.

Additionally, in pre-clinical ALD research, it is important to consider sex differences, since men and women consume and metabolize alcohol differently, have different risk factors contributing to ALD, and ultimately, have different susceptibility to developing the disease[100]. Even in mice, there are sex differences in susceptibility to ALD when controlling for alcohol intake, diet, and other factors[101]. Further, evidence suggests biodistribution of nanoparticles may also differ by sex[102], providing an additional rationale for studying nanoparticle systems in ALD in both sexes. Despite these differences, many of the studies reviewed here (14 of 16) used either only male mice or only female mice, and the remaining two which used both sexes did not report the results for each sex separately.

Lastly, keeping in mind the goal of translating effective therapies to humans for the treatment of ALD, there is a lack of knowledge regarding the efficacy of liver-targeted therapies in humans for this disease. Critically, however, nanoparticle platforms have been used for many years for the treatment of other diseases. For example, liposomes have been used in numerous drug formulations for the treatment of various cancers, fungal and viral infection, pain, and other diseases since 1995 with excellent safety and efficacy[103]. Liposomes are also increasing in popularity as an excellent vaccine delivery system with several benefits over conventional vaccines (*e.g.*, liposomes are used in the Moderna and Pfizer/BioNTech COVID-19 mRNA vaccines)[104]. Although less common than liposomes, PNPs have also undergone clinical evaluation for the treatment of head, neck, lung, and breast cancers[105]. Other platforms not discussed in this review, such as N-acetyl-galactosamine (GalNac) conjugate (commonly used to delivery nucleic acids to hepatocytes by binding the asialoglycoprotein receptor[106]), have also been shown to have favorable safety profiles in clinical trials[107]. Clearly, drug delivery platforms with the capability to deliver drugs to the liver have undergone significant clinical evaluation, although not for the treatment of ALD. Future work should build on the growing pre-clinical data supporting the efficacy of particle therapeutics in ALD and the existing clinical data showing the safety of these systems in humans to move these nanomedicines to the clinic.

CONCLUSION

The research efforts reviewed here employed liver-targeted (or intestine-targeted) drug delivery platforms to improve their drug formulations and more effectively develop pharmacological interventions for ALD (summarized in Figure 5). These platforms, including liposomes, PNPs, exosomes, bacteria, and AAV vectors are aimed at improving a drug's pharmacokinetics, efficacy, and safety by reducing off target effects associated with systemic delivery and increasing the concentration of the drug locally in the liver. The authors of these studies used nanomedicine platforms to deliver phosphodiesterase inhibitors, naturally occurring antioxidants, oligonucleotides, miRNAs, enzymes, and anti-inflammatory cytokines in various rodent models of ALD, showing promising results which will move the pace of drug development for this disease forward toward clinical translation. Future studies should continue to apply and characterize targeted delivery platforms, as well as consider active targeting approaches, drug administration paradigms, and sex-specific differences in the pursuit of supporting future clinical trials in this field.

Figure 5 Summary of studies applying nanoparticle platforms in alcohol-associated liver disease. A graphical summary of nanoparticle platforms which to date have been applied for the treatment or prevention of alcohol-associated liver disease in rodent models. Arrows represent organ targets of each platform. Example cargoes used in research articles discussed in this review are listed next to each platform. Current limitations of the field are described on the lower right. AAV8: Adeno-associated virus serotype 8; HSCs: Hepatic stellate cells; IL-22: Interleukin 22; KCs: Kupffer cells; miRNA: Micro-RNA; PCX: Polycationic CXCR4 antagonists; S-ODN: Antisense phosphorothioate oligodeoxynucleotide.

ACKNOWLEDGEMENTS

We apologize to and acknowledge any authors whose studies were not identified by our literature search strategy. We also acknowledge Marion McClain for manuscript editing support.

Abstract

Advances in diagnostics of inflammatory bowel diseases (IBD) and improved treatment strategies allowed the establishment of new therapeutic endpoints. Currently, it is desirable not only to cease clinical symptoms, but mainly to achieve endoscopic remission, a macroscopic normalization of the bowel mucosa. However, up to one-third of IBD patients in remission exhibit persisting microscopic activity of the disease. The evidence suggests a better predictive value of histology for the development of clinical complications such as clinical relapse, surgical intervention, need for therapy escalation, or development of colorectal cancer. The proper assessment of microscopic inflammatory activity thus became an important part of the overall histopathological evaluation of colonic biopsies and many histopathological scoring indices have been established. Nonetheless, a majority of them have not been validated and no scoring index became a part of the routine bioptic practice. This review summarizes a predictive value of microscopic disease activity assessment for the subsequent clinical course of IBD, describes the most commonly used scoring indices for Crohn's disease and ulcerative colitis, and comments on current limitations and unresolved issues.

Key Words: Crohn's disease; Microscopy; Predictor; Score; Ulcerative colitis

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Approximately one third of the patients with inflammatory bowel diseases in endoscopic remission show persisting signs of microscopic disease activity. Histology seems to have a predictive value for development of severe clinical complications. Proper assessment of the microscopic activity of the disease using respective scoring indices is thus necessary. This review summarizes the most widely used histological scoring indices, discusses their advantages and limitations and comments persisting unresolved issues from the perspective of gastrointestinal pathologists.

INTRODUCTION

The first description of inflammatory bowel disease (IBD) dates back to 1932, when Burrill Bernard Crohn published the article "Regional ileitis: A pathologic and clinical entity"[1]. In the following decades, our understanding of IBD has evolved. Currently, we perceive both Crohn's disease (CD) and ulcerative colitis (UC) as systemic inflammatory conditions showing predilection to the gastrointestinal (GI) tract[2-4]. Despite persisting ominous etiology and poorly understood pathogenesis, substantial advances in diagnostics and therapy of IBD have been made, allowing new therapeutic endpoints to be laid out. At present, we strive not only to cease all clinical symptoms, but mainly to reach the endoscopic remission, defined as normalization of endoscopic mucosal appearance[5,6]. However, normal endoscopic finding does not necessarily reflect normal histology. Correlation between endoscopy and histology is poor and up to 1/3 of both CD and UC patients in endoscopic remission show signs of persisting histological activity[7-10]. There is increasing evidence that histological activity of the disease may be a better predictor of important clinical endpoints such as hospitalization rate, risk of clinical relapse, need for systemic corticosteroid use, or development of colorectal cancer when compared to sole endoscopy[11-16]. This is even more important for certain IBD subtypes such as IBD associated with primary sclerosing cholangitis, currently considered a distinct phenotype of IBD entailing a four times higher risk of a colorectal cancer development compared to conventional IBD[17, 18]. The evaluation of the histological disease activity by reliable scoring indices thus represents an important part of the overall microscopic assessment. Nonetheless, a majority of them lack proper validation and none of them have been established in routine clinical practice. Endoscopy remains a gold standard for the assessment of luminal activity of the disease[5].

The aim of this review is to provide a summary of the most commonly used scoring indices for CD and UC, highlight clinical benefits of the microscopic disease activity assessment and comment on current limitations and unresolved issues from the pathologists' perspective.

BASIC PRINCIPLES OF IBD HISTOPATHOLOGY

To better conceive microscopic features included in histopathological scoring indices, it seems convenient to briefly summarize a basic IBD pathology first. UC is characterized by a continuous inflammation affecting a rectum and progressing towards the proximal colon and terminal ileum. The inflammatory infiltrate is usually confined to the mucosa. Submucosa may be affected in case of severe colitis, but transmural inflammation is not a feature of UC. As far as CD is concerned, the inflammation displays a discontinuous pattern on both macroscopic and microscopic levels. Any part of the GI tract from the oral cavity to the anal region may be affected, while the terminal ileum is the most frequent site of the disease. The inflammation is typically transmural, infiltrating deeper layers of the bowel wall. In both IBD subtypes, the infiltrate is mainly mononuclear, with a predominance of lymphocytes and plasmacytes. The presence of neutrophils is a sign of the disease activity. In case of mildly active disease, they are scarce and confined to lamina propria. With an increasing degree of activity, they tend to infiltrate surface epithelium and colonic crypts (defined as cryptitis). Later on, the crypt walls are disrupted and neutrophils exudate into their lumina forming crypt abscesses. The most severe grade of activity is usually characterized by the presence of erosions and ulcerations. Erosions were traditionally defined as defects confined to the mucosa, whilst ulcerations penetrated deeper into the submucosa, but there is no strict adherence to this criterion in pathological practice. Currently, ulcerations are often recognized rather by the presence of granulation tissue and erosions by fibrinopurulent exudate covering the defect[4,19,20]. The inflammatory infiltrate is often accompanied by numerous eosinophils. However, their proper assessment remains challenging due to the lack of a clearly defined cut-off value for their pathological increase[21]. Their numbers also vary among bowel segments being more

prevalent in the right-sided colon[22] and several studies document their substantial seasonal and geographic oscillation[23,24]. Other characteristic features of IBD are basal plasmacytosis and disrupted mucosal architecture. Basal plasmacytosis is defined as an increased number of plasmacytes between the base of the crypts and muscularis mucosae. It is a strong indicator of IBD and also one of the earliest signs of chronicity[25]. Disrupted mucosal architecture refers to any distortion of the physiological appearance of the crypts. Normally, colonic crypts are straight, parallel, and evenly spaced. In IBD, they show changes such as branching, angulation, dilatation, shortening, or dropout[26]. A hallmark of CD diagnosis is the presence of non-caseating epithelioid granulomas. Although a differential diagnosis of granulomatous colitis is broad, the presence of immune granuloma in IBD patients excludes the diagnosis of UC. Their incidence ranges from 15% to 85% according to various studies[26]. They are more closely tied to an ileocolic form of CD or CD with upper GI involvement[27] and seem to be almost twice as frequent in pediatric CD[28].

A PREDICTIVE VALUE OF MICROSCOPIC DISEASE ACTIVITY FOR THE DEVELOPMENT OF CLINICAL COMPLICATIONS

According to a recent meta-analysis by Gupta *et al*[8] performed on 2677 UC patients in endoscopic remission, the presence of persisting microscopic activity is associated with an increased risk of clinical relapse [odds ratio (OR) 2.41; 95% confidence interval (CI): 1.91-3.04]. These findings are supported by another meta-analysis by Yoon *et al*[29], which showed similar results based on the analysis of 757 UC patients in endoscopic remission. In their cohort, an absence of histological activity of the disease was associated with a 63% lower risk of clinical relapse (risk ratio 0.37; 95%CI: 0.24-0.56). In the study by Hefti *et al*[30], the authors evaluated 561 UC patients with a median follow-up of 21.4 years since the onset of the disease. According to both univariate and multivariate analyses, a mean histological inflammatory activity showed to be a significant predictor of colectomy ($P < 0.001$). Azad *et al*[31] showed that the presence of mucosal neutrophils and eosinophils in clinically and endoscopically quiescent UC was associated with an increased risk of clinical relapse over 12 mo ($P < 0.01$). Last but not least, Bryant *et al*[12] performed a study on 91 UC patients assessing a prognostic value of endoscopic and histological remission for the prediction of corticosteroid use, hospitalization and colectomy in a median 6-year follow-up. In their analysis, a histological remission was a predictor of colectomy and development of an acute severe colitis, in contrast to endoscopy (OR 0.42, 95%CI: 0.2-0.9, $P = 0.02$; OR 0.21, 95%CI: 0.1-0.7, $P = 0.02$ respectively). These results suggest that persisting histological activity of the disease seems to be associated with an adverse clinical course in UC patients.

Studies documenting a prognostic value of histology in CD are still limited in number. However, Christensen *et al*[14] demonstrated that the absence of histologic activity in patients with ileal CD is associated with a lower risk of clinical relapse [hazard ratio (HR) 2.05; 95%CI: 1.07-3.94; $P = 0.031$], corticosteroid use (HR 2.44; 95 % CI 1.17 - 5.09; $P = 0.018$) and medical escalation (HR 2.17; 95%CI: 1.2-3.96; $P = 0.011$) in a 21-mo follow-up. In the study by Brennan *et al*[32], the absence of histological activity was associated with a lower percentage of disease flares at both 12 mo (2.4% *vs* 25.5%, $P = 0.03$) and 24 mo (10.5% *vs* 37.8%, $P = 0.05$) of follow-up, in contrast to endoscopy, where no significant difference between an endoscopically active and an inactive disease was found. On the other hand, the aforementioned meta-analysis by Gupta *et al*[8], which analyzed the predictive value of histology in 2677 UC patients, did not confirm the results, which were displayed by the group of 129 CD patients.

A predictive value of histology for the development of colorectal dysplasia and cancer is of no less importance. A meta-analysis by Flores *et al*[33] performed on 1443 UC patients found that even isolated histologic activity in otherwise endoscopically normal mucosa increased the risk of neoplasia (OR 2.6, 95%CI: 1.49-4.46, $P = 0.01$). In the study by Gupta *et al*[16], the severity of histological inflammation correlated with the risk of progression to an advanced neoplasia (high-grade dysplasia, invasive cancer), with HR being 3.0 (95%CI: 1.4-6.3) for the mean inflammatory score, HR 3.4 (95%CI: 1.1-10.4) for the binary inflammatory score and HR 2.2 [inter-quartile range (IQR) 1.2-4.2] for the maximum inflammatory score. A case-control study of Rutter *et al*[34] included 68 patients with a colorectal neoplasia matched with 136 controls without a neoplasia revealed a highly significant correlation between the histological severity of inflammation and the risk of neoplasia development (OR 4.69, 95%CI: 2.10-10.48, $P < 0.001$). Pai *et al*[35] correlated 52 UC patients with colorectal cancer to 122 patients without cancer. Based on the retrospective re-evaluation of biopsies from the last five years, a mean histological disease activity assessed by two independent histological scores appeared to be a predictor of cancer development, in contrast to endoscopy (HR 7.53, 95%CI: 2.56-12.16, $P < 0.001$ and HR 5.89, 95%CI: 2.18-15.92, $P < 0.001$ respectively). In CD, the predictive value of histology for cancer development is still equivocal. However, in the study by Kirchgesner *et al*[36] assessing a cohort of 398 IBD patients including 237 patients with CD, mean histological disease severity was associated with the risk of cancer development (OR 1.69, 95%CI: 1.29-2.21, $P < 0.001$ per one-unit increase).

In summary, a vast majority of evidence suggests that cessation of microscopic inflammatory activity has a positive impact on the future clinical course of the disease, especially for patients suffering from UC. Assessment of the histological activity should therefore be an integral part of bioptic reports in all

patients with IBD. However, the appropriate extent of the microscopic normalization is still not precisely established. In other words, we still lack a proper definition of histological remission. As a result, establishing it as a primary therapeutic endpoint in clinical practice or clinical trials still lacks validity[6,37,38].

HISTOPATHOLOGIC SCORING INDICES FOR UC

The first histopathological scoring index for UC and the first scoring index for IBD, in general, was established in the 1960s by Truelove and Richards[39]. Since then, up to thirty indices have been proposed according to Cochrane Collaboration review[40], although only a few of them have been fully validated. One of the most widely used remains the Geboes score (GS), established in 2000[41]. This score assesses seven histopathological features including architectural mucosal changes, chronic inflammatory infiltrate, neutrophils and eosinophils in lamina propria, intraepithelial neutrophils, crypt destruction, and mucosal defects. Each of the given variables is further subclassified according to its severity (Table 1). The overall microscopic inflammatory severity should be based on the worst score in the bioptic sample, not on the average grade counted from all samples. Although, such a score may appear overly complicated at the first glance (*i.e.*, grading of the cryptitis severity as < 5%, < 50%, and > 50% of the affected crypts in the sample), it showed surprisingly good interpersonal agreement in preliminary phases of the study, especially when evaluating the presence of disease activity and mucosal defects (Cohen's kappa coefficient κ was above 0.9). A weak agreement was reached for the assessment of an inactive chronic inflammation. The original purpose of the score was a classification scheme, intended to define specific thresholds of the inflammatory severity, such as the presence of the disease activity. In subsequent studies, the score was also used as a continuous scale, assessing treatment efficacy in clinical trials[42,43]. The score seems to have a decent predictive value, being a reliable predictor of a clinical relapse in patients in clinical and endoscopic remission[31,44]. However, it has not been completely validated. In 2017, the Geboes Simplified Score was proposed[45]. The score reduced grading of the inflammatory activity and included the presence of basal plasmacytosis (Table 2). The score shows better overall agreement compared to the original GS (κ 0.56 *vs* 0.4). With regards to individual grades, the best agreement was reached for the detection of the inflammatory activity (κ 0.7). However, the score has not yet been widely used.

Robarts histopathology index (RHI)[46] was established in 2017 and was primarily intended to assess microscopic changes induced by the treatment. The construction process of the index was based on the original GS, from which the histopathological variables with reliable interobserver agreement and good correlation with grades of the inflammatory activity according to Visual Analogue Scale were used and served as a foundation for the final index. The definitive index consists of four histopathological features including chronic inflammatory infiltrate, neutrophils in lamina propria, neutrophils in the epithelium and mucosal defects. Each of the features is further subclassified according to its severity (range 0 to 3), giving the final index range from 0 to 33 points (Table 3). In contrast to GS, RHI exclusively assesses the histologic activity of the disease and excludes the features of chronicity. The agreement among the index grades is very good, with an intraclass correlation coefficient above 0.8. A predictive value of the index is still not fully elucidated. However, the aforementioned study by Pai *et al* [35] showed that a mean index score ≥ 8 during 5 years of observation predicted the development of colorectal cancer.

In the same year, a Nancy histological index (NHI) was proposed[47,48]. It uses five-grade scale based on the presence of chronic and active inflammatory infiltrate and mucosal defects (Table 4 and Figure 1). The final grade is determined by the worst histopathologic feature found in a biopsy sample. Despite the subjective nature of some features making the thresholds between several grades prone to possible higher interobserver variability (*i.e.*, mild *vs* moderate intensity of the chronic inflammatory infiltrate defining grades 0 and 1 respectively), the index shows very good overall interobserver agreement (κ above 0.8) and also a good reciprocal correlation with RHI [49]. The score is fully validated and widely used in clinical practice. With regards to its predictive value, in the study of D'Amico *et al* [49] patients with histologic presence of the inflammation (NHI ≥ 1) had a higher risk of surgical intervention (14% *vs* 0%, $P = 0.01$) and hospitalization (36% *vs* 7.1%, $P = 0.001$) compared to patients in histological remission (NHI grade 0) during a 30-mo median follow-up.

HISTOPATHOLOGIC SCORING INDICES FOR CD

Scoring indices for CD are limited in number. The Cochrane collaboration review mentions 14 indices [50], but the only one used on the larger scale is the Global Histology Activity Score (GHAS)[51]. The score was established by D´Haens *et al* in 1998 with the purpose to assess early postoperative recurrence after ileocecal resection. It includes the following variables: the presence of architectural changes, degree of chronic, neutrophilic and eosinophilic inflammatory infiltration in lamina propria, presence of intraepithelial neutrophils, epithelial damage, mucosal defects, presence of granulomas, and a number of

Table 1 Original Geboes score

Original Geboes score	
Grade 0: Architectural changes	0.0 No abnormality; 0.1 Mild abnormality; 0.2 Mild/moderate diffuse or multifocal abnormalities; 0.3 Severe diffuse or multifocal abnormalities
Grade 1: Chronic inflammatory infiltrate	1.0 No increase; 1.1 Mild but unequivocal increase; 1.2 Moderate increase; 1.3 Marked increase
Grade 2A: Eosinophils in lamina propria	2A.0 No increase; 2A.1 Mild but unequivocal increase; 2A.2 Moderate increase; 2A.3 Marked increase
Grade 2B: Neutrophils in lamina propria	2B.0 No increase; 2B.1 Mild but unequivocal increase; 2B.2 Moderate increase; 2B.3 Marked increase
Grade 3: Neutrophils in epithelium	3.0 None; 3.1 < 5% crypts involved; 3.2 < 50% crypts involved; 3.3 > 50% crypts involved
Grade 4: Crypt destruction	4.0 None; 4.1 Probable: local excess of neutrophils in part of the crypts; 4.2 Probable: marked attenuation; 4.3 Unequivocal crypt destruction
Grade 5: Erosions and ulcerations	5.0 No erosion, ulceration or granulation tissue; 5.1 Recovering epithelium + adjacent inflammation; 5.2 Probable erosion: focally stripped; 5.3 Unequivocal erosion; 5.4 Ulcer or granulation tissue

Table 2 Simplified Geboes score

Simplified Geboes score	
Grade 0: No inflammatory activity	0.0 No abnormalities; 0.1 Presence of architectural changes; 0.2 Presence of architectural changes and chronic mononuclear cell infiltrate
Grade 1: Basal plasma cells	1.0 No increase; 1.1 Mild increase; 1.2 Marked increase
Grade 2A: Eosinophils in lamina propria	2A.0 No increase; 2A.1 Mild increase; 2A.2 Marked increase
Grade 2B: Neutrophils in lamina propria	2B.0 No increase; 2B.1 Mild increase; 2B.2 Marked increase
Grade 3: Neutrophils in epithelium	3.0 None; 3.1 < 50% crypts involved; 3.2 > 50% crypts involved
Grade 4: Epithelial injury (in crypt and surface epithelium)	4.0 None; 4.1 Marked attenuation; 4.2 Probable crypt destruction: probable erosions; 4.3 Unequivocal crypt destruction: unequivocal erosion; 4.4 Ulcer or granulation tissue

Table 3 Robarts histopathology index

Histopathological variable	Grade
Chronic inflammatory infiltrate	0 = No increase; 1 = Mild but unequivocal increase; 2 = Moderate increase; 3 = Marked increase
Lamina propria neutrophils	0 = None; 1 = Mild but unequivocal increase; 2 = Moderate increase; 3 = Marked increase
Neutrophils in epithelium	0 = None; 1 = 50% crypts involved
Erosion or ulceration	0 = No erosion, ulceration or granulation tissue; 1 = Recovering epithelium + adjacent inflammation; 2 = Probable erosion-focally stripped; 3 = Unequivocal erosion; 4 = Ulcer or granulation tissue

affected bowel segments (Table 5). Later on, the score became used separately for terminal ileum and large bowel as Ileal and Colonic GHAS[52]. However, the score is not validated and its utility is limited. Instead of being a continuous scale, it rather represents a sum of present variables, putting minute changes such as architectural distortion or increased mononuclear cells in lamina propria on the same level of importance, for instance mucosal defects. According to a recent multidisciplinary consensus panel[53], the score does not represent a reliable index for the assessment of the inflammatory severity in CD. Its eventual predictive value has not been evidenced.

PRACTICAL ISSUES OF THE MICROSCOPIC ACTIVITY ASSESSMENT

The sole fact that we have been regularly confronted with new indices indirectly implies that we are still struggling to find the perfect one that would satisfy all our demands. A lot of unresolved issues persist

Table 4 Nancy histological index

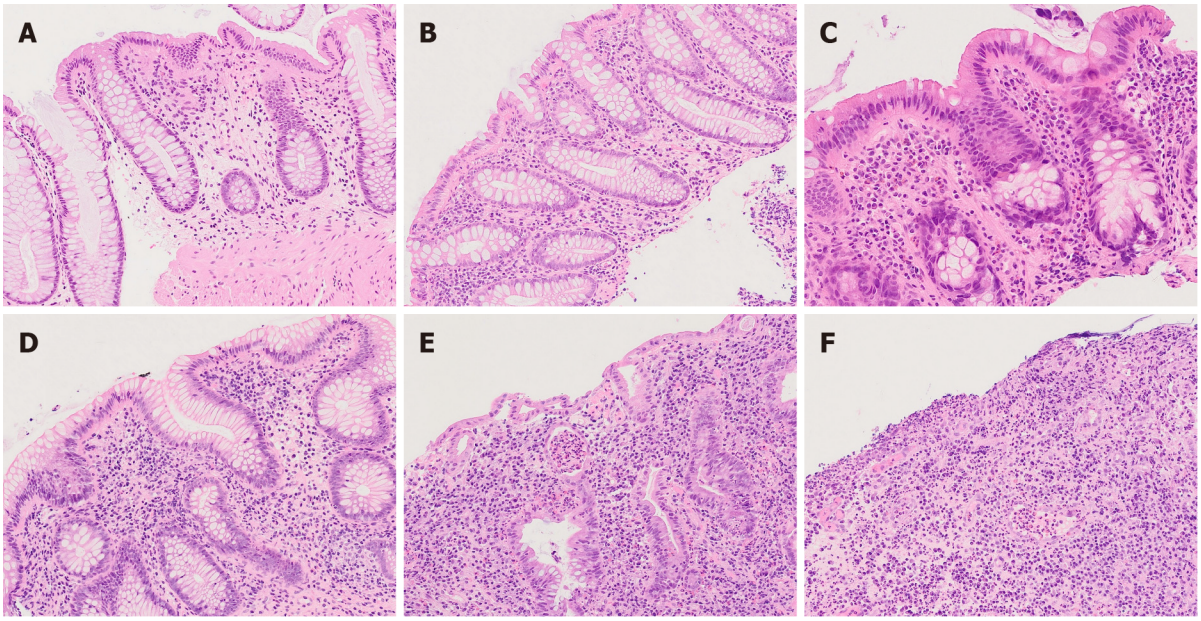
Grade	Criteria
Grade 0 (no histological significant disease)	No or mild increase in chronic inflammatory infiltrate
Grade 1 (chronic inflammatory infiltrate with no acute inflammatory infiltrate)	Moderate or marked increase in chronic inflammatory infiltrate that is easily apparent. No acute inflammatory infiltrate is present
Grade 2 (mildly active disease)	Few or rare neutrophils in lamina propria or in the epithelium that are difficult to see
Grade 3 (moderately active disease)	Presence of multiple clusters of neutrophils in lamina propria and/or in epithelium that are easily apparent
Grade 4 (severely active disease)	Loss of colonic crypts replaced with "immature" granulation tissue (disorganized blood vessels with extravasated neutrophils) or the presence of fibrinopurulent exudate

Table 5 Global Histology Activity Score

Histopathological variable	Grade
Epithelial damage	0 = Normal; 1 = Focal; 2 = Extensive
Architectural changes	0 = Normal; 1 = Moderate; 2 = Severe
Mononuclear cells in lamina propria	0 = Normal; 1 = Moderate increase; 2 = Severe increase
Neutrophils in lamina propria	0 = Normal; 1 = Moderate increase; 2 = Severe increase
Neutrophils in epithelium	1 = Surface epithelium; 2 = Cryptitis; 3 = Crypt abscess
Erosion or ulceration	0 = No; 1 = Yes
Granuloma	0 = No; 1 = Yes
Number of segmental biopsy specimens affected	1 = < 1/3; 2 = 1/3-2/3; 3 = > 2/3

Each variable is scored independently. The total score is the sum of all individual scores.

throughout the whole diagnostic process, reflecting both the proper biology of the disease and the limitations of given diagnostic modalities.



Segmental and transmural character of the inflammation in CD

A correlation between endoscopic and histologic activity in CD is poor due to the segmental nature of the inflammation on both macroscopic and microscopic levels. Indeed, some degree of discrepancy between endoscopy and histology is desirable since the histology should not only confirm the endoscopic findings but represent an additional value by increasing the sensitivity of the inflammatory activity detection. On the other hand, a focal character of the disease may lead to a false underestimation of the histological activity. It is especially true in patients on therapy since treated IBD typically shows a focal and patchy character of the inflammation, even in UC[54].

In CD, a transmural character of the inflammation is one of the defining features, modifying the overall clinical severity of the disease and eventual development of complications. However, both histology and endoscopy provide information exclusively about the luminal activity of the disease. There is thus an increasing effort to establish a reliable scoring index of transmural severity of the disease. The well-known Lemann index[55] represents a clinical score, assessing the cumulative damage of the intestinal wall according to the presence of strictures, penetrating disease (fistulas or abdominal abscesses), previous surgical interventions, and perianal involvement. The majority of histopathological indices of transmural involvement are aimed at the assessment of resection margins of ileocecal resections. Later on, more complex indices were established, evaluating a full spectrum of transmural CD pathology including a degree of inflammatory intensity, fibrosis, smooth muscle changes, or neuronal hypertrophy[56-58]. However, such scores cannot be applied to endoscopic bioptic samples. In some instances, the sample is so superficial, that the basal portion of the mucosa is missing, precluding the assessment of important predictors such as basal plasmacytosis, which is also included in some scoring indices such as Simplified GS.

Upper GI and small intestinal involvement

Both CD and UC are systemic inflammatory conditions capable of affecting any part of the GI tract. This is especially true for pediatric patients, in which the inflammation in the upper GI is more frequent. As defined by the revised Porto criteria for the diagnosis of IBD in children and adolescents[59], pediatric

Figure 1 Microphotographs representing individual grades of Nancy Histopathological Index (hematoxylin and eosin, magnification 100×). A: Grade 0 with no increase in inflammatory cells; B: Grade 0 with mild increase in chronic inflammatory cells; C: Grade 1 with moderate increase in chronic inflammatory cells including more numerous eosinophils, but no neutrophils; D: Grade 2 with scarce neutrophils in lamina propria and epithelium; E: Grade 3 with numerous neutrophils including cryptitis and crypt abscess; F: Grade 4 with completely ulcerated colonic mucosa replaced by granulation tissue.

UC with upper GI involvement is even one of the atypical UC subtypes. However, grading of upper GI inflammatory severity is not a part of any available histological scoring index. In adult patients, a routine esophagogastroduodenoscopy is not even a part of the official recommendations for IBD diagnosis[2,3,59]. A subsequent clinical course may also be aggravated by the persisting inflammatory activity in a small bowel. However, an endoscopy can usually assess only its proximal and distal segments, frequently missing jejunum, and a large portion of the ileum. Key modalities for assessment the small bowel involvement are imaging techniques such as magnetic resonance imaging, computer tomography, ultrasonography or other radiologic procedures[60]. Some of them are also accompanied by respective scoring indices such as Simplified Magnetic Resonance Index of Activity for CD[61]. In recent years, scoring indices for capsule endoscopy were established, with Lewis Score[62] and Capsule Endoscopy Crohn Disease Activity Index[63] being among the most frequently used ones, recommended by both European Crohn's and Colitis Organisation (ECCO) and European Society of Gastrointestinal Endoscopy. Currently, there is no feasible way to sample biopsies during capsule endoscopy.

Number of bioptic samples

According to an official recommendation from the European Society of Pathology and ECCO[4,5], a diagnostic endoscopy should include at least two bioptic samples from at least five or six bowel segments including the terminal ileum and rectum. However, there is still no official recommendation for patients on treatment. Many gastroenterologists still prefer to perform an extensive sampling of severely affected regions and avoid normally appearing segments. This may falsely underestimate an overall histological inflammatory severity and negatively affect some scoring indices such as GHAS, which includes the number of affected regions into a final score.

Assessment of the disease activity in pediatric IBD

A Histopathological scoring index primarily designated for the pediatric population has not been established. Adult indices are used instead, but their feasibility for children is not self-evident. Studies aiming at the predictive value of histology in pediatric IBD are still limited in number. A few years ago, our group performed a retrospective analysis of 63 children with CD[64]. The microscopic severity of the inflammation at the time of diagnosis assessed by GHAS showed moderate correlation with endoscopic activity evaluated by Simple Endoscopic Score for Crohn's Disease (r = 0.48, P = 0.0001), no correlation with clinical activity of the disease, and had no predictive value for the development of defined complications [bowel stricture, intraabdominal or perianal abscess or fistula, initiation of anti-tumor necrosis factor (anti-TNF) therapy] during at least one year of follow-up. On the other hand, endoscopic activity appeared to be a predictor of the complications (HR 3.20, IQR 1.04-4.91, P = 0.037). With regards to pediatric UC, our recently conducted retrospective study[65] including 49 children with

UC showed that microscopic activity of the inflammation assessed by NHI and GS had no predictive value for complications development (acute severe colitis, need of colectomy, initiation of anti-TNF therapy, initiation of systemic 5-aminosalicylic therapy and systemic corticosteroid use). By contrast, levels of fecal calprotectin (FCPT) and clinical activity of the disease assessed by Pediatric Ulcerative Colitis Activity Index (PUCAI) showed to be independent predictors of the systemic 5-aminosalicylic acid induction (FCPT: HR 2.42, IQR 1.042-5.631, P = 0.040; PUCAI: HR 2.98, IQR 1.011-8.787, P = 0.048) and systemic corticosteroid use (FCPT: HR 2.517, IQR 1.115-5.681, P = 0.026; PUCAI: HR 2.98, IQR 1.011-8.787, P = 0.048).

ARE WE ASKING THE RIGHT QUESTION?

Histological activity in IBD is defined by the presence of neutrophils. Hence, strictly speaking, the histological index of the disease activity should be based on the extent of neutrophilic infiltration, their localization (lamina propria, superficial epithelium, cryptitis, crypt abscesses), and the presence of mucosal defects. Grading of the microscopic disease activity thus seems to be apparently straightforward. However, such grading per se is of no use if it does not provide any additional value to other means of disease activity assessment such as endoscopy or non-invasive biomarkers. There is thus a fundamental question about whether histological appearance is predictive of subsequent clinical outcomes. As mentioned before, the bulk of evidence suggests that persisting microscopic activity of the disease harbors an increased risk of development of complications. However, disease activity is not the only microscopic variable associated with an adverse clinical course. Other microscopic features such as basal plasmacytosis or granulomas have proven prognostic value. According to Johnson *et al*[66], the presence of granulomas was associated with increased serum levels of C-reactive protein, higher rates of stricturing and penetrating disease, higher rates of steroid, immunomodulators, biological therapy and narcotic use and higher healthcare utilization. With regards to basal plasmacytosis, the aforementioned meta-analysis by Gupta *et al*[8] demonstrated its predictive value for clinical recurrence in UC patients in endoscopic remission, as well. However, these features represent signs of chronicity rather than activity. Apart from that, there is still unresolved issue regarding the contribution of eosinophils, macrophages and other inflammatory cell types. Therefore, it seems to be more convenient to search for a suitable combination of microscopic features, providing the most accurate prediction for the subsequent clinical course of the disease, with a presence of neutrophils as a sign of the disease activity among the assessed variables. Apropos, the very presence of both chronic lymphoplasmacytic and active neutrophilic inflammatory infiltrate in one scoring index of disease activity may not properly reflect the biology of the process. In a majority of the scoring indices, the presence of isolated chronic inflammatory infiltrate is considered a lower grade of the inflammatory activity, aggravating with the increasing presence of neutrophils and eventually with the appearance of mucosal defects. But the lymphoplasmacytic infiltrate reflects rather chronicity of the process than its activity and these two variables don't necessarily represent a continuum. Such a hypothesis was taken into consideration in the recently established scoring index called Inflammatory Bowel Disease-Distribution, Chronicity, Activity (IBD-DCA) score (Table 6)[67]. The score was proposed at Erlangen International Consensus Conference and consists of three parameters - Distribution (D), Chronicity (C) and, Activity (A), which are assessed in this order. Distribution determines the overall extent of the disease, independently of the presence or absence of the activity. Chronicity is represented by the disrupted mucosal architecture, presence of basal plasmacytosis and increased lymphoplasmacytic infiltration in lamina propria. Activity is marked by the presence of neutrophils. The score thus represents not only a scoring index of the histopathological inflammatory activity, but provides information about the overall microscopic severity of the disease. According to the recent evidence[68], it showed moderate inter-rater reliability for parameter D (median intraclass correlation coefficient 0.645), poor to moderate for parameter C (0.568), and moderate to good for parameter A (0.748) for UC and moderate to good for parameter D and A (0.655 and 0.644 respectively) and poor for parameter C (0.303) for CD. The intra-rater agreement was moderate to excellent for D and C parameters (0.894 and 0.798 respectively) and good to excellent for A (0.909) parameter for UC, whilst CD showed moderate to excellent agreement for parameter D (0.854), poor to excellent for parameter C (0.714) and good to excellent for parameter A (0.888). There is a moderate correlation with NHI and Simplified GS. The unique feature of the score is its versatility, which means that it can be used for both CD and UC, as well as for IBDU, which represents 5%-15% of both adult and pediatric IBD[69-71] and in some cases becomes a definite diagnosis. By this, the score questions the necessity of separate scoring indices for CD and UC. Both diseases share a similar pattern of inflammatory activity and the inferior utility of scoring indices for CD stems rather from the segmental and transmural nature of the disease that from inappropriate assessment of its histological activity. Such a hypothesis is also supported by several studies. In the aforementioned study of Kirchgesner *et al*[36] assessing a predictive value of histology for the development of colorectal cancer, the authors used NHI to evaluate microscopic disease severity for the whole IBD cohort. In both UC and CD, the grade of the NHI correlated with the risk of cancer development. In the study by Löwenberg *et al*[72], the authors evaluated the ability of vedolizumab to induce endoscopic and histological remission in patients with

Table 6 Inflammatory Bowel Disease-Distribution, Chronicity, Activity score

Histopathological variable	Grade
Distribution	0 = Normal; 1 = < 50% of tissue affected per same biopsy site; 2 = > 50% of tissue affected per same biopsy
Chronicity	0 = Normal; 1 = Crypt distortion and/or mild lymphoplasmacytosis; 2 = Marked lymphoplasmacytosis and/or basal plasmacytosis
Activity	0 = Normal; 1 = Two or more neutrophils in lamina propria in one high-power field and/or any presence of intraepithelial neutrophils; 2 = Crypt abscesses, erosions, ulcers

Each variable is scored independently.

CD and the microscopic disease activity in the study was assessed by RHI. Using UC scoring indices for CD patients is suggested also by the recent expert consensus panel[53].

STILL FAR FROM THE HISTOLOGICAL REMISSION

Although achieving deeper mucosal healing is presumably associated with improved clinical course, it is far from synonymous with histological remission. However, establishing its proper definition remains challenging. In previous studies, the definition varied from the absence of active inflammation to the complete normalization of bowel mucosa. A recent position paper from ECCO defines histological remission as a "return to normal". Cessation of the microscopic activity undoubtedly correlates with a lower percentage of future complications. But even a mucosa without a presence of neutrophils may display increased chronic lymphoplasmacytic infiltration or architectonic changes that may aggravate the clinical course of the disease. Returning to the meta-analysis by Gupta *et al*[8] once more, their analysis showed that disrupted mucosal architecture was one of the features independently predicting the disease recurrence (OR 2.22). On the other hand, strict adherence to the histological normalization of the mucosa in each patient in endoscopic and clinical remission could lead to an unreasonable burden of aggressive therapy including all possible side effects. More studies need to be performed until a proper degree of histological normalization with an appropriate cost-benefit ratio will be established. One way or another, a complex histopathological scoring index assessing not only a disease activity but rather an overall microscopical severity seems to be necessary before we finally reach a standardized definition of the histological remission in IBD.

CONCLUSION

A proper assessment of the histological disease activity in IBD represents an essential component of the overall disease severity evaluation and provides important data for the subsequent clinical management of the patients. Many histopathological scoring indices exists, especially for UC, and they seem to be useful tools for the proper objectivization of the microscopic activity. However, their broader validation, subsequent implementation in routine bioptic practice and establishing the universally accepted definition of the histological remission are necessary before we could recognize the absence of the microscopic activity as the primary therapeutic target in IBD.

Abstract

BACKGROUND

Magnetic compression anastomosis (MCA) is a novel suture-free reconstruction of the digestive tract. It has been used in gastrointestinal anastomosis, jejunal anastomosis, cholangioenteric anastomosis and so on. The traditional operative outcomes of congenital esophageal atresia and benign esophageal stricture are poor, and there are too many complications postoperatively.

AIM

To test MCA technology to reconstruct the esophagus in dogs, prior to studying the feasibility and safety of MCA in humans.

METHODS

Thirty-six dogs were randomized into either the study or control group (n = 18 per group). The dogs in the study group were subjected to end-to-end esophageal anastomosis with the magnetic compression device, while those in the control group underwent hand-sewn anastomosis with 4-0 absorbable multifilament Vicryl. We used interrupted single-layer inverting sutures. The anastomosis time, gross appearance, weight and pathology of the anastomosis were evaluated at one month, three months and six months postoperatively.

RESULTS

The anastomosis time of the MCA group was shorter than that of the hand-sewn group (7.5 ± 1.0 min *vs* 12.5 ± 1.8 min, $P < 0.01$). In the MCA group, X-ray examination was performed every day to locate the magnetic device in the esophagus before the magnetic device fell off from the esophagus. In the hand-sewn group, dogs did not undergo X-ray examination. One month after the surgeries, the mean weight of the dogs in the hand-sewn group had decreased more than that of the dogs in the MCA group (11.63 ± 0.71 kg *vs* 12.73 ± 0.80 kg, $P < 0.05$). At 3 mo and 6 mo after the operation, the dogs' weights were similar between the two groups (13.75 ± 0.84 kg *vs* 14.03 ± 0.82 kg, 14.93 ± 0.80 kg *vs* 15.44 ± 0.47 kg). The number of inflammatory cells in MCA group was lower than that in hand-sewn group on 1 mo after operation.

CONCLUSION

MCA is an effective and safe method for esophageal reconstruction. The anastomosis time of the MCA group was less than that of the hand-sewn group. This study shows that MCA technology may be applied to human esophageal reconstruction, provided these favorable results are confirmed by more publications.

INTRODUCTION

Esophageal atresia (EA) is a serious and fatal gastrointestinal developmental malformation in the neonatal period. It has a worldwide prevalence of 2.4 to 3.8 per 10000 newborns[1-4]. Because of the development of surgical and good neonatal intensive care, the survival is about 90% in those born with EA with severe associated anomalies and is even higher in those born with EA alone[5]. However, the postoperative complications of traditional hand-sewn anastomosis are numerous, and the therapeutic effect is not good. The primary complications during the postoperative period are leakage (incidence 15%-20%), stenosis of the anastomosis (30%-40%), gastroesophageal reflux (40%-65%), esophageal dysmotility, fistula recurrence, scoliosis, deformities of the thoracic wall and respiratory disorders[6-8]. After surgery, children suffer from various complications, which seriously affect their development and quality of life.

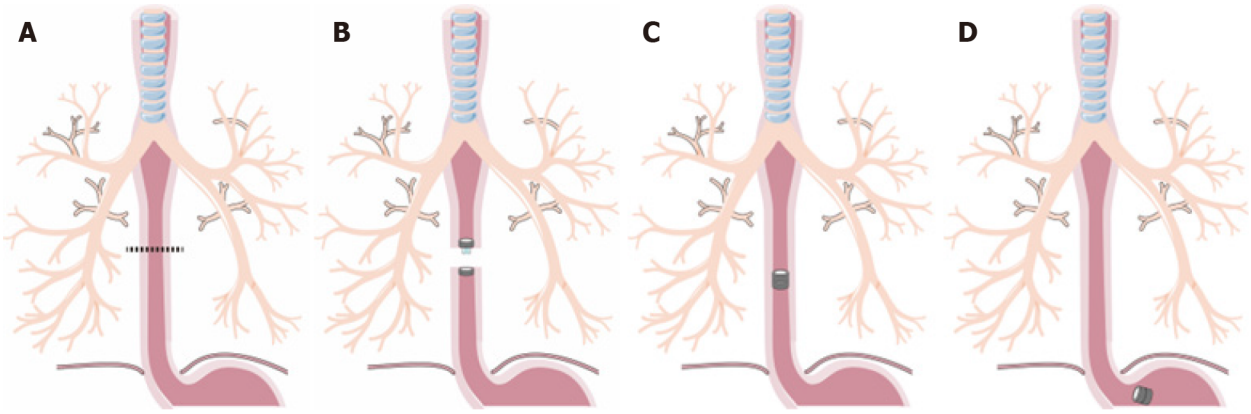
Magnetic compression anastomosis (MCA) is a novel suture-free reconstruction of the digestive tract. Since Kanshin *et al*[9] reported using a magnetic device to anastomose gastroduodenal and cecojejunal in dogs in 1978, there have been many reports of this technique using animal experiments and regarding its clinical applications. At present, clinically, it has been used in gastrointestinal anastomosis[10,11], jejunal anastomosis[12,13], cholangioenteric anastomosis[14-16] and so on. Fourteen patients underwent MCA for gastrointestinal anastomosis, and the technical success of MCA was achieved in 100% of the cases. Two patients underwent anastomotic restenosis, and 1 patient had an anastomotic perforation due to balloon dilatation to prevent restenosis. Fifteen patients underwent MCA for jejunal anastomosis, of which five patients had severe systemic disease and underwent complex open urinary reconstruction procedures. The device was successfully placed and effectively formed a side-to-side, functional end-to-end jejunal anastomosis. Forty-seven patients underwent MCA for cholangioenteric anastomosis. Thirty-eight patients had a malignant primary disease, while nine had benign disease. With a median

follow-up of 547.5 d (range 223-1042 d), no patients had biliary fistula, while two developed anastomotic stricture at 4 mo and 14 mo after surgery. Magnetic materials have noncontact suction characteristics that will greatly simplify the process of gastrointestinal anastomosis, especially in the case of gastrointestinal stenosis or atresia. Recently, Kamada *et al*[10] reported that MCA without general anesthesia is a valuable alternative to surgery for gastrointestinal obstruction. Some patients with biliary obstruction are not eligible for conventional endoscopic procedures or are unsuitable for surgery. The MCA technique is an available method for performing choledochocholedochostomy and choledochoenterostomy interventionally[16]. The mean age of the patients in these two reports was above 60 years. Therefore, MCA technology can be designed as a minimally invasive technique and is tolerated by elderly patients.

Because of the many complications of traditional operations and the ability to obtain minimally invasive surgery by MCA, MCA could be a superior method to treat congenital EA. There have been several clinical reports on esophageal reconstruction using MCA[17-19]. Muensterer *et al*[17] reported that they used esophageal MCA for staged EA repair in 3 patients (Gross type A, B, and C) at high risk for conventional surgical repair. Surgeries were all successful, and there were no perioperative complications. Liu *et al*[18] reported that two patients who had severe stricture after simultaneous EA and duodenal obstruction repair underwent magnetic compression stricturoplasty. Magnetic compression stricturoplasty successfully established the patency of the esophagus in these two patients with refractory EA stricture. These two cases required multiple additional procedures, but durable esophageal patency with absence of dysphagia was achieved at 15 or 10 mo after magnetic compression stricturoplasty. Dorman *et al*[19] reported a case in which EA was repaired with a proximal fistula using endoscopic MCA after staged lengthening. Magnetic coupling occurred at 4 d, and after magnet removal at 13 d, an esophagram demonstrated a 10 French channel without leakage. A series of studies on MCA technology have been carried out in our laboratory. The technology has been used in choledochojejunostomy, rectovaginal fistula repair, laparoscopic pancreatoduodenectomy (LPD) and liver transplantation. Twenty-six mongrel dogs underwent choledochojejunostomy magnamosis with different magnetic pressure magnets. The surgical procedures were all successful[20]. There was a comparative study with 12 pigs for rectovaginal fistula repair. Eight animals were in the MCA group, and four animals were in the hand-sewn group. The rectovaginal fistula site was smooth, and healing was complete. This technology was used in one case clinically and achieved success[21]. Seven patients received MCA technology in LPD. LPD was successfully completed in all seven patients, of which seven underwent laparoscopic magnetic compression choledochojejunostomy and two received laparoscopic magnetic compression pancreatojejunostomy. No leakages were observed after the operation. After a median follow-up period of 11 mo (range 4-18 mo), there was no incidence of anastomotic stricture[22]. We also used MCA to reconstruct vessels in liver transplantation. In pig liver transplantation, we used MCA to reconstruct the suprahepatic vena cava, infrahepatic vena cava and portal vein. They were all successful, and the pig lived for over one month[23]. Currently, we want to use MCA technology to treat EA, but there is a paucity of published research data and animal studies. Therefore, the purpose of this study was to study the difference between MCA and hand-sewn anastomosis of the esophagus in dogs.

MATERIALS AND METHODS

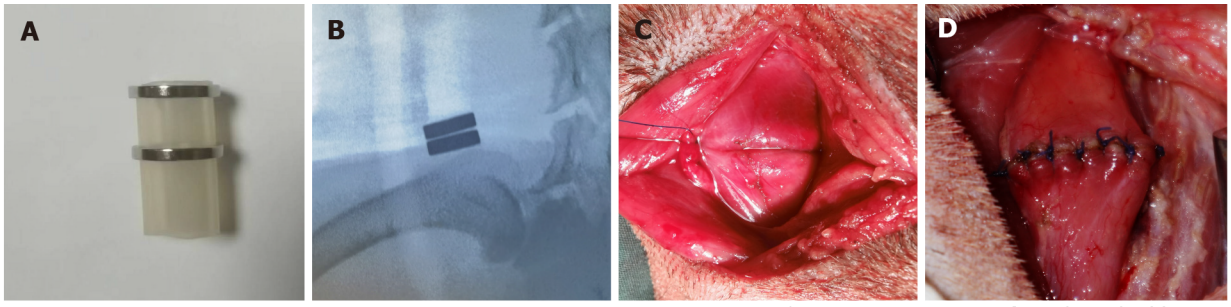
Animals



The protocol of the animal study was reviewed and approved by the committee for Ethics of Animal Experiments of Xi'an Jiaotong University (No. XJTULAC2020-1441). Thirty-six mongrel dogs (male = 18, female = 18) with body weights of 10-15 kg were provided by the Laboratory Animal Center of Xi'an Jiaotong University. Dogs were acclimatized to laboratory conditions (23 °C, ad libitum access to food and water) for 2 wk prior to experimentation. In this study, we selected mongrel dogs because the esophagus in the neck is long enough for reconstruction. This purpose is to avoid performing surgery in the thoracic cavity and to improve the survival rate.

Study design

Thirty-six dogs were randomized into either the MCA group or the hand-sewn group, n = 18 per group, with the same male to female ratio. The dogs in the MCA group were subjected to end-to-end esophageal anastomosis with the magnetic device, while those in the hand-sewn group underwent hand-sewn anastomosis with 4-0 absorbable multifilament Vicryl. We used interrupted single-layer sutures. In both groups, there was no surgical left in place. Postoperative complications and weight were observed. The anastomosis time, gross appearance and pathology of the anastomoses were evaluated at one month, three months and six months after the operation.



Magnetic anastomosis device

The magnetic anastomosis device used in the study possessed a parent magnetic ring (PMR) and daughter magnetic ring (DMR), which were made of rare earth neodymium iron boron (NdFeB, N40) and plated with nickel from Northwest Institute for Nonferrous Metal Research, Xi'an, China. A special

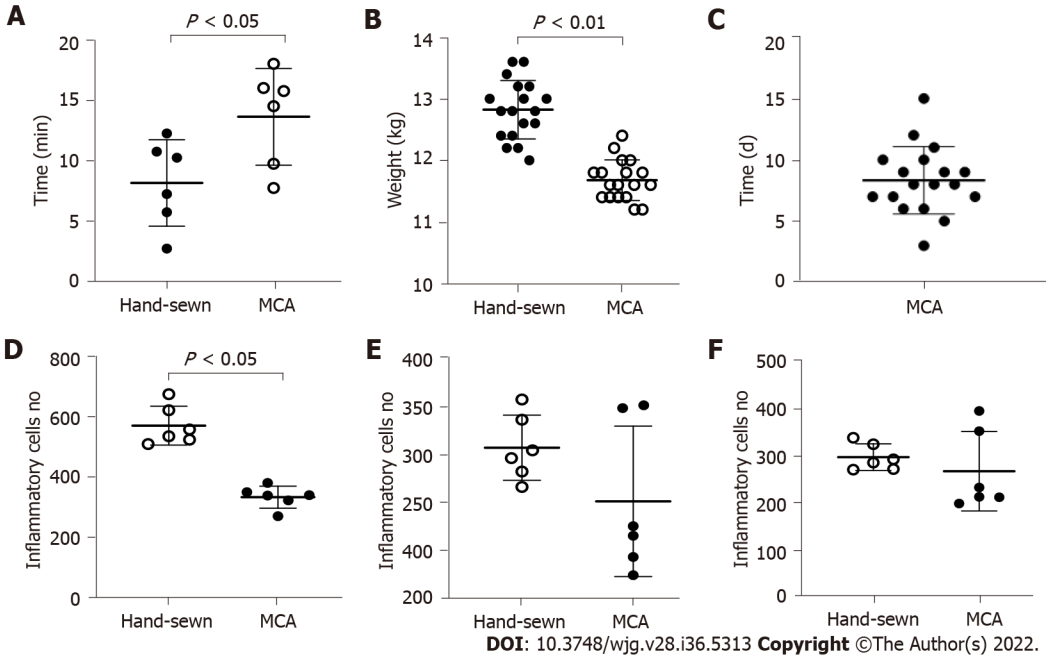
Figure 2 The magnetic device and the appearance on X-ray, the esophageal anastomosis of magnetic compression anastomosis and hand-sewn suture. A: The magnetic device, composed of two magnetic rings and one special catheter; B: The magnetic ring position on X-ray postoperatively, and the anastomosis face is smooth; C: Using the magnetic compression anastomosis technology to finish the esophageal anastomosis; D: The anastomosis by hand-sewn suture.

drainage tube was placed between the PMR and DMR, and both the PMR and DMR had outer diameters of 20 mm, inner diameters of 14 mm, and thicknesses of 2 mm. The magnetic force between the PMR and DMR is 30 Newton at zero distance with a magnetic density of 8000 GS.



Surgical procedures

The dogs were first anesthetized with an intraperitoneal injection of 30 mg/kg pentobarbital sodium solution. The dogs were anesthetized and then placed in the right lateral position on a temperature-controlled operating table with their cervical region shaved and sterilized. The experimental process is shown in Figure 1. A 5 cm incision was made along the anterior edge of the sternocleidomastoid muscle in the neck. Then, the muscle was separated layer by layer, and a 3 cm long portion of the esophagus was found. Next, the esophagus was transected.

In the MCA group, the PMR and DMR were placed in the upper and lower esophagus, respectively, after transecting the esophagus (Figure 1A). The magnetic anastomosis device was shown in Figure 2A. The upper and lower ends of the esophageal anastomosis were sutured with 4-0 silk thread and tightened to the position of the special drainage tube. Under the action of attraction, the magnetic rings at both ends are attracted to each other automatically and press the anastomotic tissue together, and the esophageal anastomosis is then completed (Figure 2C). When the anastomotic tissue is necrotic and falls off, the magnetic device is discharged into the stomach with the digesta and is discharged out of the body. In the control group, the operation was the same as that in the study group, except that end-to-end anastomosis was performed with 4-0 absorbable sutures (Figure 2D).

Postoperative care

An X-ray (Perlove Medical Equipment incorporated company, Nanjing, China) was performed on the dogs in the study group to confirm the target location and precise mating of the magnetic compression rings (Figure 2B). X-ray was performed every day before the magnets fell off the esophagus. Postoper-

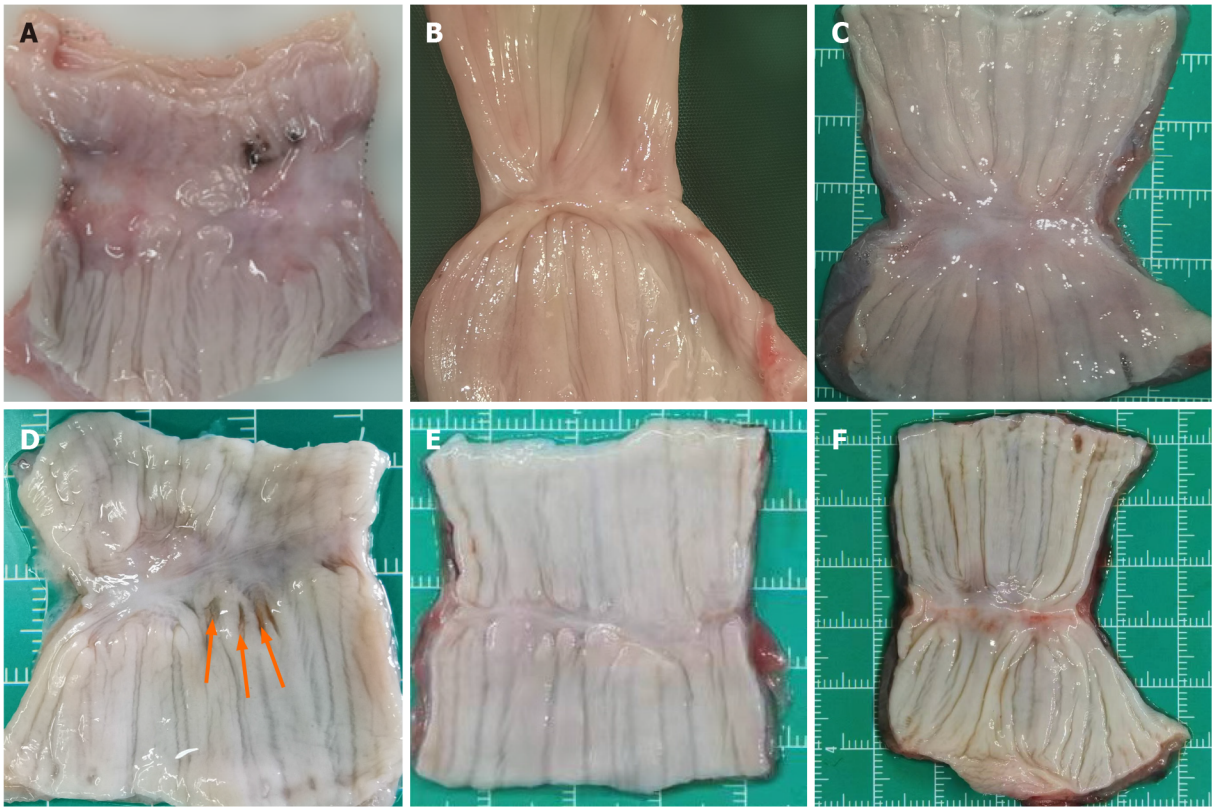
Figure 3 The analysis about anastomosis time, weight changes, the time of the magnetic device fell and the number of inflammatory cells between two groups. A: The anastomosis time of the magnetic compression anastomosis group and hand-sewn group. There were 18 dogs in each group; B: The dogs were weighed at 1 mo, and every group contained 6 dogs. There was a significant difference between the two groups; C: The time when the magnetic device had fallen into the stomach of 18 dogs; D-F: The number of inflammatory cells respectively at 1 mo, 3 mo and 6 mo. MCA: Magnetic compression anastomosis.

atively, every dog was kept in a cage. After the surgery, the dogs in the two groups were fasted for two days and then started on enteral nutrition. However, in the hand-sewn group, dogs generally showed poor appetite and even refused to eat. They started enteral nutrition at 4 d, 5 d, or even longer. During this period, we can only keep them alive with parenteral nutrition. The dogs in the MCA group started enteral nutrition earlier than those in the hand-sewn group. All dogs in both groups were given cefazolin sodium intramuscularly for 3 d postoperatively to prevent infection. Intramuscular injection (0.5 g) was administered twice a day. After a week, dogs were given enteral nutrition, a liquid diet, a semiliquid diet, and a normal diet according to their recovery. Six dogs were randomly selected in each group at 1 mo, 3 mo and 6 mo after the operation. They were weighed and intravenously injected with an overdose of anesthetic.

Specimen collection and histological analysis

All anastomosis segments with a sufficient length were harvested. The anastomotic stoma was found and severed 2 cm above and below the anastomosis. The gross information was observed, and all samples were immersed in 10% buffered formalin overnight. The samples were embedded in paraffin after fixation. Four-micrometer-thick sections were cut at the anastomosis site. Sections were stained with hematoxylin and eosin and Masson's trichrome dye. Then, we observed the changes in the tissue and cells under a light microscope.



Statistical analysis

Data were analyzed using GraphPad Prism v8 software (GraphPad, La Jolla, CA, United States). Quantitative data are expressed as the mean ± SD, and differences between the two groups were analyzed with the independent samples *t* test. The anastomosis time and weight data conformed to a normal distribution and homogeneity of variance. Statistical significance was set at $P < 0.05$.

RESULTS

Procedural parameters

Anastomosis was successfully created in all dogs. The anastomosis time of the MCA group was shorter than that of the hand-sewn group (7.5 ± 1.0 *vs* 12.5 ± 1.8, $P < 0.01$) (Figure 3A). X-ray examinations showed that the esophagi were all unobstructed and that the contrast agent could pass through the anastomosis in the MCA group. All dogs survived. There was one dog in the hand-sewn group and one dog in the MCA group with stenosis after the operation. These were found when we obtained

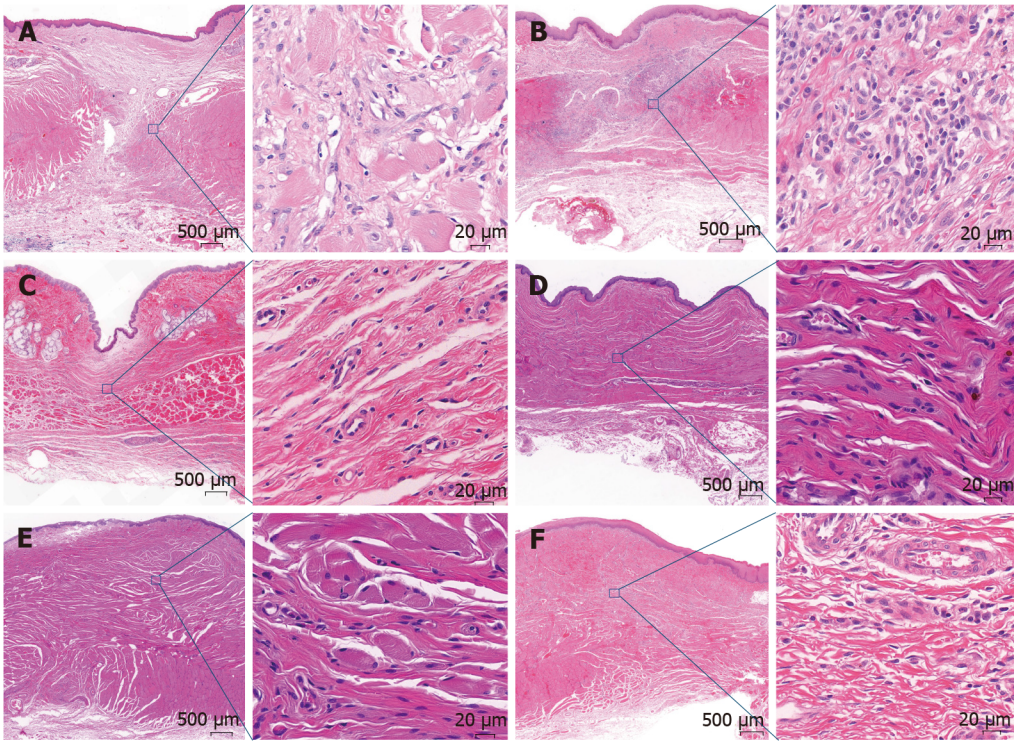
Figure 4 Gross appearance of the anastomosis in magnetic compression anastomosis and hand-sewn group. A: The tissue of magnetic compression anastomosis (MCA) group is thin at 1 mo, but the mucous membrane is intact; B: Anastomotic tissue of the MCA group at 3 mo; C: At 6 mo, the tissue becomes smooth and flat in the MCA group. There is little difference from normal tissue; D: The tissue of the hand-sewn anastomotic stoma is incomplete, and the mucous membrane has a small pinhole at 1 mo, which was caused by the suture needle. Red arrow indicates; E: Anastomotic tissue of the hand-sewn group at 3 mo; F: Anastomotic tissue of the hand-sewn group at 6 mo.

anastomotic stoma tissue. We observed one dog in the hand-sewn group who suddenly refused to eat, and the incision skin was red, swollen and purulent 8 d after the operation. We performed surgical exploration and performed a second esophageal reconstruction.

Expulsion time of the magnetic compression rings and weight changes



We observed how long the magnetic rings took to fall off into the stomach. The mean time was 8.3 ± 2.7 d (range 3-15 d) (Figure 3C). The weights of dogs in the MCA group (13.87 ± 0.63 kg) and the hand-sewn group (13.98 ± 0.80 kg) were similar at the beginning of the experiment. The difference in weight between the two groups was not statistically significant. However, the weights decreased more in the hand-sewn group than in the MCA group 1 mo after the operation. The mean weight of the MCA group was 12.73 ± 0.80 kg, while the mean weight of the hand-sewn group was 11.63 ± 0.71 kg, $P < 0.05$. At 3 mo and 6 mo after the operation, the dog weights were similar between the two groups (13.75 ± 0.84 kg *vs* 14.03 ± 0.82 kg, 14.93 ± 0.80 kg *vs* 15.44 ± 0.47 kg).

Gross appearance of the anastomosis

The esophagi grew well, and there were no ulcerations or fistulas. The mucosa layers were intact. However, the anastomotic stomas were slightly thinner than the peripheral tissue at 1 mo. We could see that the muscle layer tissues were not completely covered. In the hand-sewn anastomosis group, the suture plots were still visible 1 mo after the operation (Figure 4D). With the passage of time, the submucosa and muscle layers were gradually covered, and the anastomoses became increasingly smooth and flat. However, at 1 mo, 3 mo and 6 mo, the anastomoses of the MCA group were smoother than those of the hand-sewn group.

Histological appearance of the anastomosis

Light microscopy showed that the anastomotic mucosa of the MCA group had grown well during the first month after surgery, while the submucosal and muscular layers were still fractured (Figure 5A). Three months after the operation, the submucosal and muscular layers had completely covered the anastomoses, and the anastomotic tissue was similar to the normal esophageal tissue under light microscopy (Figure 5C). In the hand-sewn group, the mucosa was continuous one month after surgery,

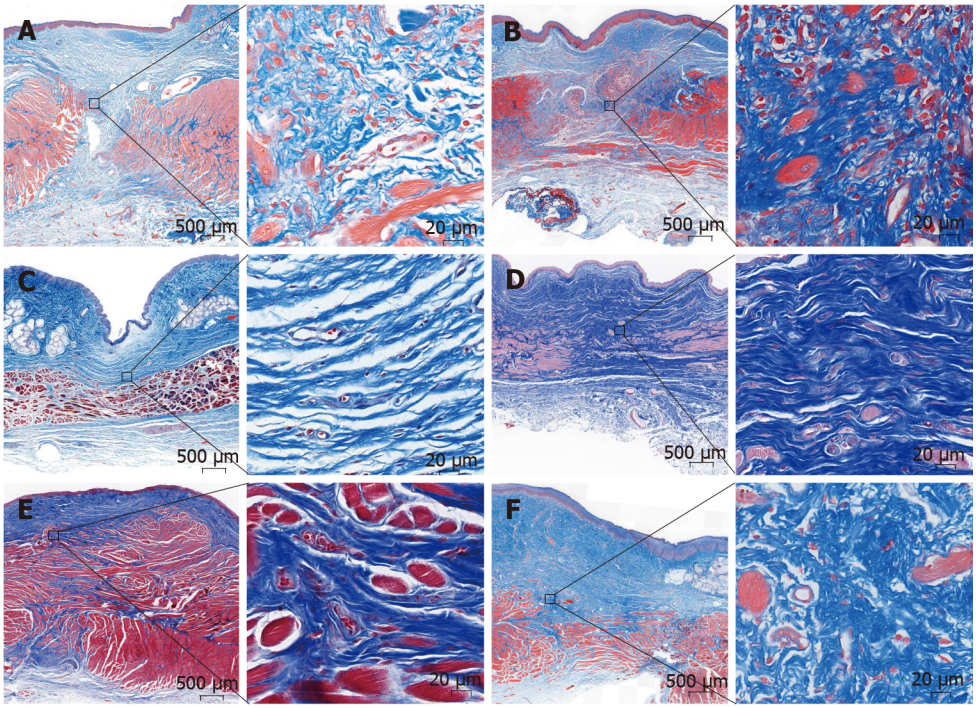
Figure 5 Hematoxylin and eosin dye of the anastomotic tissue in magnetic compression anastomosis and hand-sewn group. Each image consists of two parts, one with a 2 × objective view and the other with a 40 × objective view. A: The anastomotic tissue of the magnetic compression anastomosis (MCA) group at 1 mo. The mucous membrane was intact, but the muscularis was separated; B: The anastomotic tissue of the hand-sewn group at 1 mo. There were more inflammatory cells in the tissue of the hand-sewn group than that of the MCA group; C: The anastomotic tissue of the MCA group at 3 mo. The muscularis became continuous; D: The anastomotic tissue of the hand-sewn group at 3 mo; E: The anastomotic tissue of the MCA group at 6 mo; F: The anastomotic tissue of the hand-sewn group at 6 mo.



but the submucosa and muscle layers were still broken, similar to the findings in the MCA group at one month (Figure 5B). At 3 mo postoperatively, the anastomotic site was covered by the submucosa and muscularis (Figure 5D). The number of inflammatory cells in the hand-sewn group was greater than that in the MCA group at 1 mo (Figures 5A and B). We counted the number of inflammatory cells in one high-power field (40 ×) in both groups (334 ± 37 *vs* 572 ± 65, $P < 0.01$). At 3 mo and 6 mo, the number of inflammatory cells was less than that at 1 mo. Between the two groups, the number of inflammatory cells was equal at 3 mo and 6 mo (Figures 5C-F). Masson staining showed that the number of collagen fibers in the hand-sewn group was greater than that in the MCA group. The blue fibers are collagen fibers (Figures 6A-F).

DISCUSSION

We studied the tissue status of the anastomotic esophagus after esophageal reconstruction by magnetic anastomosis technology and clarified the safety of MCA surgery. A comparative study was conducted between magnetic anastomosis and hand-sewn anastomosis for esophageal reconstruction to determine whether the effects of MCA were superior to those of the hand-sewn method.

By observing gross specimens and tissue sections at different time periods in the MCA and hand-sewn groups, we found that in both the MCA group and the hand-sewn anastomosis group, the anastomotic tissues were not completely healed at 1 mo after surgery. The mucosal surface of the two groups was smooth without ischemia or necrosis, while some submucosa and muscularis were still missing. After 3 mo, the anastomotic sites of the two groups had healed well, and the mucosal layer, submucosal layer and muscular layer were continuous. Liquid food is still the main diet in the early stage to reduce the stimulation of esophageal mucosa and prevent the occurrence of ulcers. Based on the results of the experiment, we suggest that MCA patients should consume a liquid diet or a semiliquid diet for at least one month.

The tissue healing of the MCA group was faster and better than that of the hand-sewn group. Six months after the operation, the specimens of the MCA group were smoother than those in the hand-sewn group, and a slight amount of scar tissue was observed in the hand-sewn group. There are several reasons for this. Magnetic anastomosis technology applies the mutual attraction between magnetic rings

Figure 6 Masson Thrichrome dye staining of the anastomotic tissue in magnetic compression anastomosis and hand-sewn group. Each image consists of two parts, one with a 2 × objective view and the other with a 40 × objective view. A: The anastomotic tissue of the magnetic compression anastomosis (MCA) group at 1 mo. The mucous membrane was intact, but the muscularis was separated at 1 mo, and the appearance was similar to that of hematoxylin and eosin staining; B: The anastomotic tissue of the hand-sewn group at 1 mo. There were more collagenous fibers than that in MCA group; C: The anastomotic tissue of the MCA group at 3 mo. The muscularis became continuous; D: The anastomotic tissue of the hand-sewn group at 3 mo; E: The anastomotic tissue of the MCA group at 6 mo; F: The anastomotic tissue of the hand-sewn group at 6 mo.

to maintain a constant and balanced pressure on the tissues at the anastomosis, resulting in slow ischemic necrosis of the tissues between the magnetic rings and the growth and healing of the surrounding tissues. This is a slow process that allows time for esophageal compensation to grow. Hand-sewn sutures use Vicryl to quickly tighten the tissues at both ends of the esophagus. There is a certain tension at both ends of the esophagus, which may lead to shearing forces placed on the esophageal tissue from Vicryl. Second, Vicryl, as an absorbable thread, will exist in the tissue for a long time as a foreign body, which may cause infection and scar hyperplasia. The suture material could play an important role in the healing of esophageal anastomosis. Vicryl is an absorbable material, but the time of absorption is more than 1 mo. During this period, Vicryl may act as a foreign body, leading to foreign body granuloma or anastomosis edema. Braided sutures are more prone to infection than monofilament sutures. Vicryl is the braided suture and perhaps in this study Vicryl is not the best selection.

At six months postoperatively, the magnetic anastomosis group grew slightly better than the hand-sewn group. Before surgery, the weights of the dogs in both groups were the same. One month after surgery, the body weight of the hand-sewn group was significantly lower than that of the magnetic anastomosis group. Three months after surgery, the weights of the dogs were similar in both groups. This suggests that MCA may contribute to enhanced recovery after esophageal reconstruction. There are two reasons that may contribute to the enhanced recovery with MCA technology: (1) The magnetic device has a gap in the middle, through which the liquid can enter the stomach, while it will not contact the anastomotic tissue. It may relieve pain and reduce the incidence of infection; and (2) The shedding time of the magnetic device is shorter than the time of the suture being discharged or absorbed by the tissues. The absorbable time of Vicryl RapideR is approximately 40 d[24], while the magnetic device discharge time is approximately 8 d. We observed that the dogs in the MCA group could feed earlier than those in the hand-sewn group. The MCA group of dogs recovered faster and better than the dogs in the hand-sewn group.

During 6 mo of observation, there was 1 stenosis in the MCA group and 1 stenosis and 1 Leakage in the hand-sewn group. Because the sample size was small, there was no statistically significant difference between the two groups. The rate of stenosis and leakage of anastomosis using the traditional hand-sewn operation is high. This has seriously affected the postoperative growth of children. We hope that this novel MCA technology can improve EA. The complication rate needs to be verified by more animal experiments and clinical case reports.

One clinical report showed that anastomosis was achieved in an average of 6 d (range 3 to 7 d) in 5 patients (age 6 mo to 5.9 years) with severe recurrent postsurgical esophageal stenosis refractory to dilatation[25]. Another MCA was achieved on day 36[26]. Clinical reports have shown that the anastomosis time ranges from 3 d to 36 d[26-28]. It involves many factors, such as the age of the child, type of EA, size of the magnetic ring and field strength of the magnetic device. This will be our next experimental purpose. Based on a large amount of experimental and clinical data, a model was established to estimate various parameters of magnetic devices preoperatively.

There are also some limitations of the study. First, our surgery location was on the dog's neck, not in the thoracic cavity. This is not consistent with the clinicopathology. The position of EA is generally flush with the bifurcation of the main bronchus and may have a tracheoesophageal fistula. Second, in this study, we did not consider the effect of different structural sutures on the anastomosis. Does monofilament have less effect on anastomotic healing than multifilament? Third, this is a model of esophageal anastomosis, and not of anastomosis in the setting of an atresia, there are several differences.

CONCLUSION

MCA is an effective and safe method for esophageal reconstruction in dogs. The anastomosis with MCA is faster than the hand-sewn anastomosis. Postoperatively, some aspects of the recovery of the MCA group were faster and better than those of the hand-sewn group. We provide some information useful for the future clinical application of the device in selected cases.

ARTICLE HIGHLIGHTS

Research background

Magnetic compression anastomosis (MCA) is a novel suture-free reconstruction of the digestive tract. It has been used in gastrointestinal anastomosis, jejunal anastomosis, cholangioenteric anastomosis and so on. The traditional operative outcomes of congenital esophageal atresia and benign esophageal stricture are poor, and there are too many complications postoperatively.

Research motivation

There are several case reports of using MCA to treat esophageal stenosis. However, systematic animal experimental studies are scarce. This has restricted further clinical application of MCA.

Research objectives

This study was conducted to demonstrate the feasibility and safety of MCA for esophageal reconstruction and studied the difference between MCA and hand-sewn esophageal reconstruction.

Research methods

Thirty-six dogs were randomized into either the study or control group (n = 18 per group). The dogs in the study group were subjected to end-to-end esophageal anastomosis with the magnetic compression device, while those in the control group underwent hand-sewn anastomosis with 4-0 absorbable multifilament Vicryl. We used interrupted single-layer sutures. The anastomosis time, gross appearance, weight and pathology of the anastomosis were evaluated at one month, three months and six months postoperatively.

Research results

The anastomosis time of the MCA group was shorter than that of the hand-sewn group (7.5 ± 1.0 min *vs* 12.5 ± 1.8 min, $P < 0.01$). One month after the surgeries, the mean weight of the dogs in the hand-sewn group had decreased more than that of the dogs in the MCA group (11.63 ± 0.71 kg *vs* 12.73 ± 0.80 kg, $P < 0.05$). At 3 mo and 6 mo after the operation, the dogs' weights were similar between the two groups (13.75 ± 0.84 kg *vs* 14.03 ± 0.82 kg, 14.93 ± 0.80 kg *vs* 15.44 ± 0.47 kg). Under an optical microscope, the number of inflammatory cells in MCA group was lower than that in hand-sewn group on 1 mo after operation.

Research conclusions

MCA is an effective and safe method for esophageal reconstruction. The anastomosis time of the MCA was less than that of the hand-sewn group. This study shows that MCA technology may be applied to human esophageal reconstruction, provided these favorable results are confirmed by more publications.

Research perspectives

MCA for esophageal reconstruction in the thoracic cavity needs to be tested, and further clinical trials

are needed to test its safety and guide its clinical application.

Abstract

BACKGROUND

At the diagnosis of hepatocellular carcinoma (HCC), more than 90% of HCC patients present cirrhosis, a clinical condition often associated to malnutrition. Sarcopenia is an indirect marker of malnutrition assessable on computed tomography (CT).

AIM

To evaluate the prognostic value of sarcopenia in patients with HCC treated by trans-arterial (chemo)-embolization.

METHODS

Patients with HCC treated by a first session of trans-arterial (chemo)embolization and an available CT scan before treatment were included. Sarcopenia was assessed using skeletal muscle index at baseline and at the first radiological assessment. Radiological response was recorded after the first session of treatment using mRECIST.

RESULTS

Of 225 patients treated by trans-arterial bland embolization (n = 71) or trans-arterial chemoembolization (n = 154) for HCC between 2007 and 2013, Barcelona Clinic of Liver Cancer stage was A, B, and C in 27.5%, 55%, and 16.8% of cases, respectively. Sarcopenia was present in 57.7% of the patients. Patients with sarcopenia presented a higher rate of progressive disease (19% *vs* 8%, P = 0.0236), a shorter progression-free survival (8.3 *vs* 13.2 mo, P = 0.0035), and a shorter median overall survival (19.4 mo *vs* 35.5 mo, P = 0.0149) compared with non-sarcopenic patients. Finally, patients whose sarcopenia appeared after first transarterial treatment had the worst prognosis (P = 0.0004).

CONCLUSION

Sarcopenia is associated with tumor progression and poor survival outcomes after trans-arterial (chemo)-embolization for HCC.

Key Words: Hepatocellular carcinoma; Transarterial chemoembolization; Bland embolization; Sarcopenia; Skeletal muscle index

Core Tip: This work evaluated the predictive value of sarcopenia for tumor response and survival outcomes in hepatocellular carcinoma patients treated by transarterial chemoembolization or transarterial embolization. In this study, sarcopenia at imaging was observed in 57.7% of patients. It was associated with a higher rate of progressive disease and a decreased overall survival after adjustment with usual risk factors of death. Sarcopenia is an easy-to-assess radiological biomarker of poor prognosis that should be measured in order to assess prognosis and test a targeted intervention mixing nutritional support and physical activity.

INTRODUCTION

Liver cancer is the second cause of cancer-related deaths worldwide[1], mostly represented by hepatocellular carcinoma (HCC). At the diagnosis, 70% of HCC patients have only access to palliative treatments, and among intermediate HCC, classified as Barcelona Clinic of Liver Cancer (BCLC)-B[2], transarterial chemoembolization (TACE) and transarterial embolization (TAE) are the best therapeutic options to offer[3-5]. Nonetheless, despite a good level of tumor response, around 50%-55% of patients receiving these treatments suffer from a high level of relapse[6]. It is well demonstrated that TACE presents the best results on patients with a good general status and a low level of liver insufficiency[7], but additional reliable predictive markers are needed to better define which patients will take full benefit of this procedure, and which ones present an increased risk of low efficacy and liver deterioration. At the diagnosis, more than 90% of HCC patients present with cirrhosis, a clinical condition

often associated to malnutrition with sarcopenia. Indeed, sarcopenia, defined as the "progressive loss of muscle mass and strength with a risk of adverse outcomes such as disability, poor quality of life, and death"[8], is a consequence of chronic inflammation, hypercatabolism, and anorexia found in cirrhosis and advanced tumor stages. Sarcopenia has already been described as a poor prognostic factor in HCC patients undergoing surgical resection or treated by systemic therapies[9-12]. Further studies are needed to clarify the predictive value of sarcopenia in other HCC treatment settings, such as TAE or TACE. Indeed, several studies with small numbers of patients showed interesting results on the predictive value of sarcopenia regarding survival outcomes of patients treated by TACE but without clear impact on tumor response[13]. This study aimed to evaluate the predictive value of sarcopenia for tumor response and survival outcomes in a bicentric cohort of HCC patients treated by TACE or TAE.

MATERIALS AND METHODS

Patient selection

Patients were retrospectively included from December 1, 2007 to November 1, 2013 in Jean Verdier Hospital and from June 1, 2011 to December 1, 2014 in Grenoble-Alpes University Hospital. The inclusion criteria were as follow: Age > 18 years, HCC diagnosed by histology or non-invasive criteria [7], first treatment using TAE or TACE, and available pre- and post-therapeutic computed tomography (CT) scan. Transarterial procedures performed for acute bleeding of HCC were excluded.

Transarterial procedures

Patients were treated with transarterial therapy following standard local protocol[14]. Each indication of TACE or TAE was validated during multidisciplinary tumor board including a hepatologist, an interventional radiologist, and a liver surgeon. In case of TACE, chemotherapy was either doxorubicin or idarubicin according to institutional standards of care, as previously described[15]. The choice of chemotherapy was left to the investigator's discretion. Every TACE or TAE was performed by an expert interventional radiologist.

As recommended by European guidelines, TACE could be repeated 2 mo after the first treatment in case of partial response on postoperative scan and preserved liver function after rediscussion in multidisciplinary tumor board[7].

Ethical approval

Written consent was obtained for every patient before transarterial procedures and the study protocol respects the ethical guidelines of the 1975 Declaration of Helsinki (6th revision, 2008). Study ethics was also approved by the independent French ethic committee CERIM (*Comité d'éthique de la recherche en imagerie médicale;* No. CRM-2004-084).

Clinical and paraclinical data collection

Clinical and biological data were recorded before the treatment: Demographic data, body mass index, liver function, platelets, presence of cirrhosis, etiology of the underlying liver disease, alpha-fetoprotein (AFP) level, tumor size, number of nodules, tumor portal invasion, and esophageal varices at the last upper endoscopy.

After the first treatment, all patients were prospectively followed until death or the last recorded visit until June 30, 2018.

Anthropometric measurements

Anthropometric measurements were assessed on the pre-therapeutic CT scan and the first follow-up CT scan realized 1-3 mo after the transarterial treatment by two radiologists (OSu and YT) using the software Image J®. Skeletal muscle and psoas muscle area were measured on a cross-sectional CT image at the level of the 3rd lumbar vertebra. Skeletal muscle index (SMI) was calculated using the total muscle area on the L3 CT slice divided by squared height as previously described[16]. Sarcopenia was defined by SMI < 50 cm^2/m^2 in male and < 39 cm^2/m^2 in female patients as defined by the North American expert statement on sarcopenia in liver transplantation[17]. Psoas muscle index (PMI) defined as the psoas muscle area on height ratio was also assessed as previously described[17].

The following data were recorded on imaging: Liver volume, spleen volume, presence of ascites at imaging, presence of para-umbilical vein, presence of esophageal varices, and presence of splenomegaly defined by a spleen's cranio-caudal diameter superior to 12 cm.

Assessment of tumor response and survival outcomes

All imaging examinations were archived in a picture archiving and communication system and blindly read by two radiologists (OSu and YT). Clinical and paraclinical parameters were extracted from the patient's electronic medical records.

Radiological response was assessed by two radiologists (OSu and YT) comparing the baseline imaging and the imaging available 1-3 mo after the first session of trans-arterial treatment as recommended[7]. Radiological response was classified into complete response, partial response, stable disease, and progressive disease as defined by the modified RECIST criteria[7].

Progression-free survival was defined as the time between the date of the first treatment and the date of death, radiological progression, or the last recorded visit. Patients were censured at the date of liver transplantation. Overall survival (OS) was defined as the time between the date of the first treatment and the date of death or the last recorded visit, with censoring at the date of liver transplantation in transplanted patients.

Statistical analysis

Categorical variables were compared using the Fisher exact test for two groups and Chi squared test for three groups and more. Continuous variables were compared using the Mann-Whitney test. Logistic regression was used to compare the association with radiological response and baseline variables.

Survival outcomes as OS and progression free survival (PFS) were computed using the Kaplan-Meier method, and the Log-rank test was used to compare survival rates. The association between baseline variable and OS and PFS was assessed in univariate analysis using the Cox model. Variables with a P value < 0.05 in the univariate analysis were computed in multivariate analysis using the Cox model. Statistical analyses were performed using Graph Pad (PRISM) and R software.

RESULTS

Description of the population

A total of 225 patients were included in the analysis, including 93 from Jean Verdier Hospital and 132 from Grenoble-Alpes University Hospital (Figure 1). Patients were mainly male (88.8%) with a median age of 65 (58-75) years old. The underlying liver diseases were mainly related to chronic alcohol intake (61%), hepatitis C (28%), and non-alcoholic steatohepatitis (29%) with 81.6% of patients classified as Child-Pugh A.

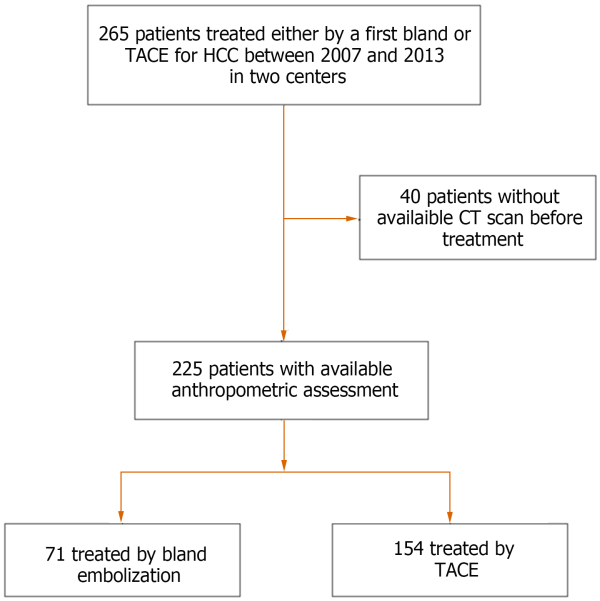
HCCs were classified as BCLC-A in 27.5%, BCLC-B in 55.5%, and BCLC-C due to segmental portal vein thrombosis in 16.8% of patients. One hundred and fifty-four (68.4%) of the patients were treated by TACE (127 with doxorubicin and 27 with idarubicin; including 87 by lipiodol TACE and 40 by TACE using drug eluting beads). Seventy-one (31.5%) patients were treated by TAE using lipiodol with gelatin sponge. Patients' characteristics are detailed in Table 1.

Anthropometric and portal hypertension assessment at imaging

Anthropometric measurements including the value of total muscle area in L3 and psoas area in L3 are detailed in Table 1. Ascites was identified in 23.5% of the cases at imaging as well as splenomegaly in 57% of the cases, umbilical vein repermeabilization in 36.4%, and esophageal varices in 71.1%. About 57.7% (n = 130) of the patients had sarcopenia based on the SMI. The value of psoas area/squared height (cm^2/m^2) was significantly positively associated with body mass index (BMI), liver volume, albumin, alcohol intake, male, and non-alcoholic steatohepatitis (NASH), and negatively associated with age and hepatitis C virus (Figure 2A). Sarcopenia at imaging (defined by SMI < 50 cm^2/m^2 in male and < 39 cm^2/m^2 in female patients) was observed in 130 (57.7%) patients.

Sarcopenic patients were significantly older (67.5 years old *vs* 62.5 years old; P = 0.0338), with a lower BMI (24.3 *vs* 28.7 P < 0.0001) and a higher median serum AFP level (11.5 ng/mL *vs* 7.7 ng/mL; P = 0.0152) compared to non-sarcopenic patients at imaging (Table 1 and Figure 2B). Sarcopenia was also associated with a higher tumor burden (sum of the size of the 2 main tumors) and a lower BMI, ALAT level, and spleen volume, and was less frequent in alcohol-related cirrhosis and in NASH patients (Figure 2B). At the first radiological assessment, 28.7% of the patients with sarcopenia harbored an increase in Child-Pugh Class (A to B/C or B to C) compared to 24.53% of patients without sarcopenia (P = 0.6862, Fisher exact test). Patients' baseline features as well as treatments following TACE or TAE, according to the presence or not of sarcopenia, are detailed in Table 1.

Relationship between sarcopenia and radiological response



At the first radiological evaluation after TACE or TAE, 23% (n = 52) of patients harbored a complete response, 39% a partial response (n = 88), 23% a stable disease (n = 52), and 15% (n = 33) a progressive disease based on mRECIST criteria. Presence of portal hypertension signs on endoscopy or imaging was not encountered as predictive markers of radiological response. Presence of sarcopenia had a significant impact on progression proportions after TACE (P = 0.0084, Chi square test Figure 3A). Whereas objective tumor response (complete and partial radiological response) was not statistically different in sarcopenic (64%) compared to non-sarcopenic patients (67%, P = 0.66, Fisher exact test), a higher rate of progressive disease was observed in patients with sarcopenia compared to patients without (19% *vs* 8%, P = 0.0236, Fisher exact Test, Figure 3B). In univariate analysis, sarcopenia [odds ratio (OR): 2.59; 95%CI:

Figure 1 Flowchart of the study. TACE: Transarterial chemoembolization; CT: Computed tomography; HCC: Hepatocellular carcinoma.

1.16-6.40, P = 0.0274], serum AFP level (OR: 1.00029; 95%CI: 1.00008-1.0006, P = 0.0226), and BCLC-C stage (OR: 2.22; 95%CI: 1.25-4.05; P = 0.00758) were related to progressive disease at imaging. In multivariate analysis, only BCLC-C stage (OR: 1.98; 95%CI: 1.038-3.88, P = 0.0416) remained independently associated with a higher rate of progressive disease.

Relationship between sarcopenia before TACE and survival

The median progression-free survival was 9.4 mo. Patients with sarcopenia had a lower median PFS compared to patients without (8.3 mo *vs* 13.2 mo, P = 0.0035, log rank test, Figure 4A). In univariate analysis, sarcopenia, tumor portal vein thrombosis, size of the largest nodule, serum AFP level, and platelet level were significantly associated with a lower PFS (Table 2). In multivariate analysis, sarcopenia [hazard ratio (HR): 1.62; 95%CI: 1.15-2.28], tumor portal vein thrombosis (HR: 1.77; 95%CI: 1.11-2.83), size of the largest nodule (HR: 1.008; 95%CI: 1.002-1.013), and platelet level (HR: 1.002; 95%CI: 1.002; 95%CI: 1.0001-1.005) remained independently associated with a lower PFS (Table 2).

The median OS was 24.3 mo. OS was shorter in patients with sarcopenia compared to patients without (19.4 mo *vs* 35.5 mo, P = 0.0149, log rank test, Figure 4B). Sarcopenia, ascites at imaging, size of the largest nodule, serum AFP level, Child-Pugh score, and BMI were associated with OS at univariate analysis (Table 3). In multivariate analysis, sarcopenia (HR: 1.68; 95%CI: 1.04-2.72), AFP level (HR: 1.0001; 95%CI: 1.00001-1.002), and size of the largest nodule (HR: 1.007, 95%CI: 1.0015-1.013) were independently associated with a higher risk of death (Table 3).

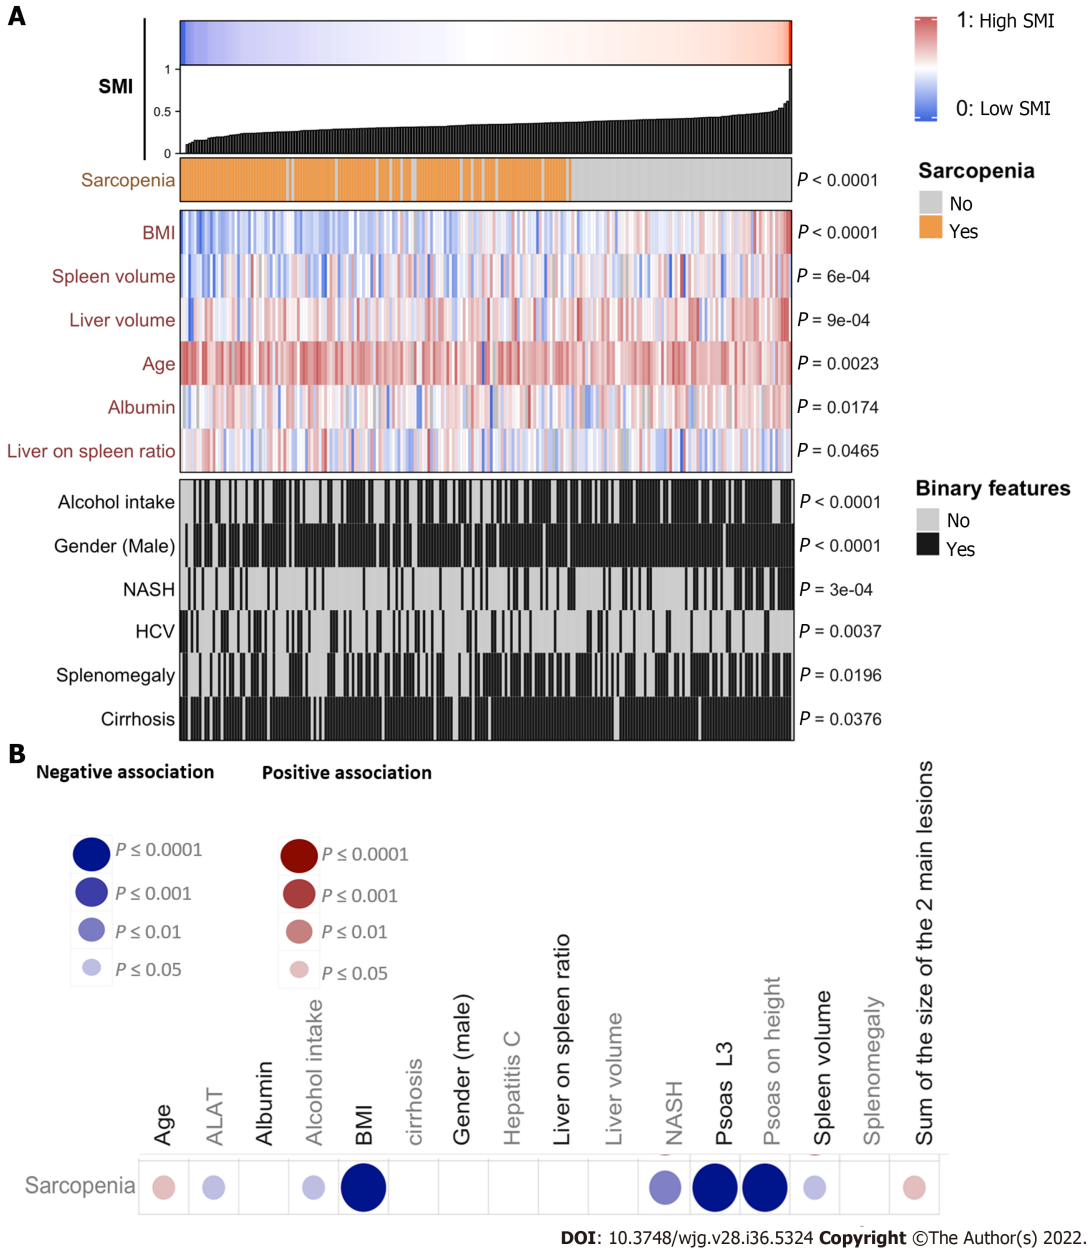
Sarcopenia was analyzed as a categoric factor (yes *vs* no). AFP: Alpha-fetoprotein; BCLC: Barcelona clinic liver cancer; HCV: Hepatitis C virus; HBV: Hepatitis B virus; NASH: Non alcoholic steatohepatitis.

Evolution of sarcopenia after TACE and its impact on OS

Post-TACE SMI was assessed by CT scan at the first radiological assessment in 218 patients in order to assess the evolution of sarcopenia after treatment. Among the patients without sarcopenia at baseline, 71 were still non-sarcopenic, and 22 became sarcopenic. Among the 22 patients who became sarcopenic, 19 had a progressive disease at the first radiological assessment.



Patients with post-TACE sarcopenia presented a shorter median OS (n = 147, 18.15 mo) compared with non-sarcopenic patients (n = 71, 35.7 mo, P = 0.0019) (Figure 4C).

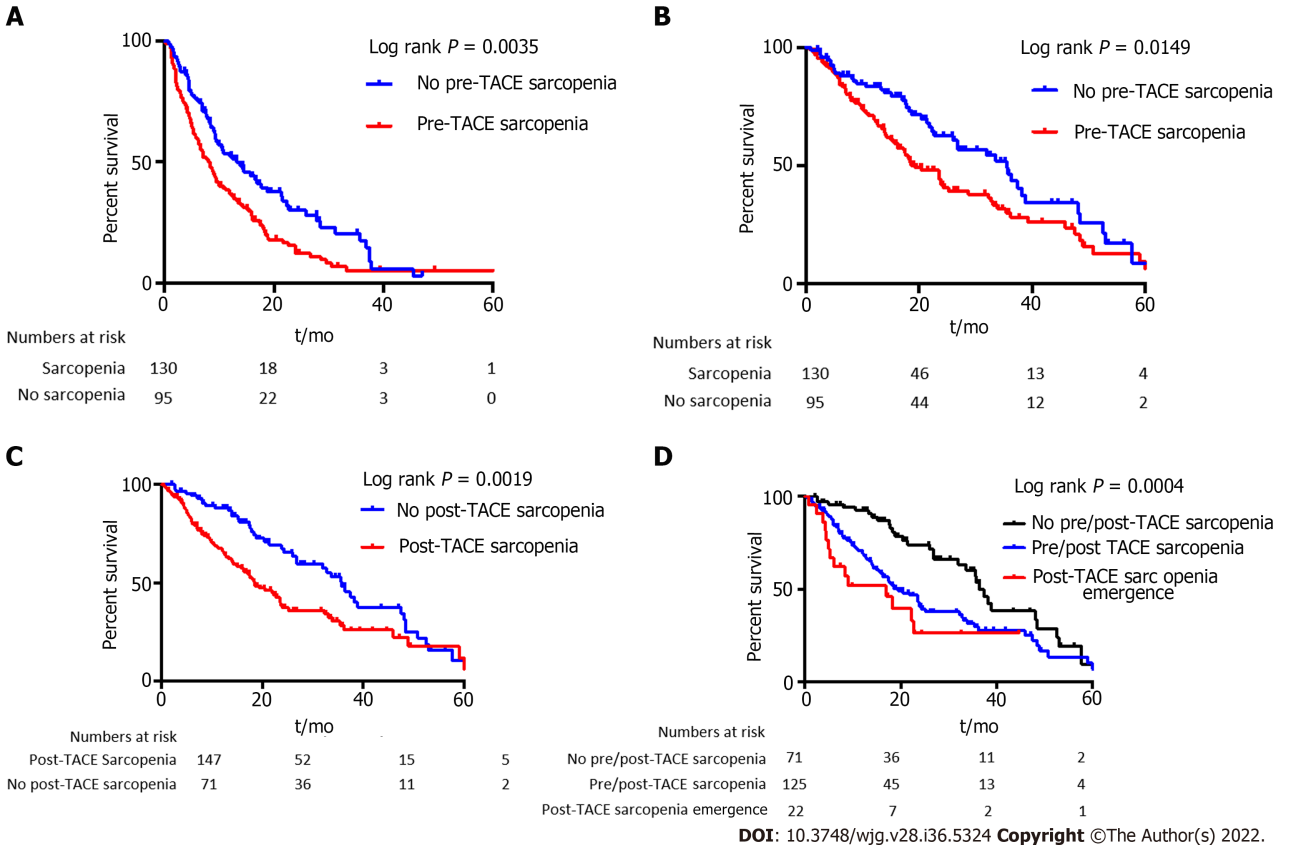
Figure 2 Correlation of biological and clinical features with sarcopenia. A: Association of clinical, biological, and radiological features with skeletal muscle index expressed as a continuous variable; B: Association of clinical, biological, and radiological features with the presence or not of sarcopenia. Comparison of a continuous variable in two or more than two groups was performed using Wilcoxon signed-rank test or Kruskal-Wallis test, respectively. Qualitative data were compared using the Fisher's exact test. Correlation analysis between continuous variables was performed using Spearman's rank-order correlation. All tests were two-tailed and a *P*-value < 0.05 was considered significant. BMI: Body mass index; HCV: Hepatitis C virus; NASH: Non-alcoholic steatohepatitis; SMI: Skeletal muscle index.



DISCUSSION

This study is the largest multicentric cohort study exploring the impact of sarcopenia on tumor response and survival outcomes in patients with HCC treated by TACE or TAE. Sarcopenia represents a major challenge in chronic diseases and especially in the treatment of cancers in which the general status is classically altered, and aggressive treatments with poor tolerance profiles are frequent. Sarcopenia in cirrhosis has already been described as impacting survival, confirming the need of a global approach with a close nutritional support of these patients. Sarcopenia measures were assessed on the open-access software Image J®, which has been proved as equivalently efficient as other commercial programs, meaning that radiological assessment of sarcopenia is accessible to every center[18]. The use of SMI was preferred to methods only based on the measurement of PMI or the transverse psoas muscle thickness. Even though the two latter are simple to assess and showed interesting results in term of survival in HCC patients treated by TACE in previous studies, SMI seems to offer a more robust and complete measurement of the muscle mass in cirrhotic patients. Besides, PMI may identify fewer patients at risk of an increased mortality and presents a higher inter-observer variability. To finish, SMI is easy to use

Figure 4 Survival according to presence of sarcopenia before and after trans-arterial chemoembolization. A and B: Progression free survival (A) and overall survival (OS) (B) according to the presence or not of sarcopenia before trans-arterial chemoembolization (TACE); C: OS according to presence or not of sarcopenia after TACE; D: OS according to the presence or not of sarcopenia before TACE, and appearance of sarcopenia after TACE designated as post-TACE sarcopenia. Results were computed using the Kaplan-Meier method and compared by the log rank test. The patients at risk are represented under the x-axis.

and recommended by the North American Expert Opinion Statement on Sarcopenia in Liver Transplantation[17,19,20]. In this study, measures were performed by only one radiologist *per* center, which limits bias induced by potential interobserver variability. This also constitutes a limit as interobserver variability should be studied to improve result exportability and better evaluate their reproducibility.

In this study, a high prevalence of sarcopenia (57%) in patients with HCC treated by transarterial treatment was observed despite the predominance of Child-Pugh A patients and intermediate stage tumors (BCLC-B). This is consistent with a recent HCC cohort study exploring the impact of sarcopenia on survival in patients treated by hepatectomy where 54% of patients were sarcopenic, as well as published data in liver transplantation[17]. Even if patients with sarcopenia have a lower BMI than patients without, most of patients with sarcopenia harbored a normal BMI (median value of 24). Moreover, with the increase of overweight and obesity which represents 15%-20% of the worldwide population[21], BMI is even less sensitive to detect malnutrition in patients with chronic diseases and especially liver diseases. These elements suggest that sarcopenia measured by performant radiological methods reflect more precisely the nutritional state and the protein catabolism of these patients. Nonetheless, other markers that could impact the outcomes after trans-arterial (chemo)embolization such as patient's daily activities and diet are not collected in this study due to its retrospective character. As well, this study lacked of other frailty parameters such as grip strength or walking speed. It constitutes another limit that cannot be addressed due to the retrospective character of the study.

One of the main strengths of this study is the radiological reviewing of radiological response using mRECIST criteria. This analysis revealed that sarcopenia was associated with a higher risk of progressive disease after trans-arterial treatment but without any difference on objective tumor response. Nevertheless, in multivariate analysis, only BCLC-C (segmental portal thrombosis) was independently associated with progressive disease. Sarcopenia was also associated with a shorter PFS together with tumor size in multivariate analysis. These data suggest that a subgroup of patients with advanced tumor stage and sarcopenia have a more aggressive disease which is more prone to resist to trans-arterial treatments. Indeed, sarcopenia may reflect the consequences of an intense hypercatabolism due to a particularly aggressive disease. In these patients, transarterial treatment may be deleterious in addition to be less effective as it could lead to liver failure and decrease the possibility of using systemic treatments after progression. Besides, the increased rate of radiological response obtained with the recent combination atezolizumab-bevacizumab forces us to better select the optimal treatment for patients between TACE and systemic treatments[22]. However, as sarcopenia has also been associated with poorer survival outcomes in patients under systemic therapies[10], it remains to be studied if sarcopenic patients with a high tumor burden benefit more from systemic treatments than trans-arterial procedures. In any case, sarcopenia needs to be detected as early as possible to initiate a medical intervention using nutritional support and physical activity to reverse sarcopenia and potentially improve survival. Indeed, muscle restoration before starting these treatments showed interesting results in terms of survival[10,23], and this type of intervention should be tested in a randomized controlled trial as up to 60% of patients treated by TACE harbored sarcopenia.

Sarcopenia was also associated with a shorter OS independently of tumor burden, suggesting that undernutrition and loss of muscle are key prognostic factors in patients with HCC treated by TACE or TAE. As sarcopenia is easily assessable using a CT scan in clinical practice, it could be useful to stratify patients in clinical trials. This study showed that sarcopenia assessed at the first radiological evaluation after TACE was also associated with a shorter OS, underlying the robustness of this association. Moreover, a subset of patients rapidly developed sarcopenia at the first radiological assessment which was particularly associated with a poor OS. Almost all these patients presented a progressive disease at the first evaluation, suggesting that they harbored an aggressive tumoral disease potentially responsible for the fast development of sarcopenia.

CONCLUSION

In conclusion, sarcopenia is associated with a higher rate of tumor progression and shorter survival in patients with HCC treated by TACE or TAE. Moreover, sarcopenia is an easy-to-assess radiological biomarker of poor prognosis that should be measured in order to better estimate prognosis and test a targeted intervention mixing nutritional support and physical activity.

ARTICLE HIGHLIGHTS

Research background

At the diagnosis of hepatocellular carcinoma (HCC), more than 90% of HCC patients present a cirrhosis, a clinical condition often associated to malnutrition. Sarcopenia has been associated with a lower tumor response or poorer survival of patients undergoing various treatments such as surgery or systemic therapies. Transarterial chemoembolization is the treatment of choice for intermediate HCC and is largely used worldwide, but the impact of sarcopenia on its results was poorly studied.

Research motivation

Finding easy ways to detect sarcopenia within daily practice should benefit to patients by better charac-

terizing their prognosis and taking their nutritional status into account in therapeutic decisions.

Research objectives

This study aimed to evaluate the prognostic value of sarcopenia in patients with HCC treated by transarterial (chemo)-embolization based on baseline computed tomography (CT) findings and study its impact on objective tumor response and survival outcomes.

Research methods

Sarcopenia is easy to assess on CT by measuring the skeletal muscle index. A skeletal muscle index (SMI) < 50 cm^2/m^2 in male and < 39 cm^2/m^2 in female patients corresponding to sarcopenia was observed in 57.7% of the patients.

Research results

Based on SMI analysis measured on baseline imaging, sarcopenia was observed in 57.7% of the patients. After full review of radiological response using mRECIST criteria, sarcopenia was associated with a higher rate of progressive disease. It was also associated with a decrease overall survival even after adjustment with usual risk factors of death.

Research conclusions

Sarcopenia is an easy-to-assess radiological biomarker of poor prognosis that should be measured in order to better assess prognosis of HCC patients.

Research perspectives

Sarcopenia should be systematically detected at baseline, and induce a targeted intervention mixing nutritional support and physical activity. Further studies are needed to assess the benefit of these strategies in HCC patients.

Abstract

BACKGROUND

The most important consideration in determining treatment strategies for undifferentiated early gastric cancer (UEGC) is the risk of lymph node metastasis (LNM). Therefore, identifying a potential biomarker that predicts LNM is quite useful in determining treatment.

AIM

To develop a machine learning (ML)-based integral procedure to construct the LNM gray-level co-occurrence matrix (GLCM) prediction model.

METHODS

We retrospectively selected 526 cases of UEGC confirmed through pathological examination after radical gastrectomy without endoscopic treatment in four tertiary hospitals between January 2015 to December 2021. We extracted GLCM-based features from grayscale images and applied ML to the classification of candidate predictive variables. The robustness and clinical utility of each model were evaluated based on the following factors: Receiver operating characteristic curve (ROC), decision curve analysis, and clinical impact curve.

RESULTS

GLCM-based feature extraction significantly correlated with LNM. The top 7 GLCM-based factors included inertia value 0° (IV_0), inertia value 45° (IV_45), inverse gap 0° (IG_0), inverse gap 45° (IG_45), inverse gap full angle (IG_all), Haralick 30° (Haralick_30), Haralick full angle (Haralick_all), and Entropy. The areas under the ROC curve (AUCs) of the random forest classifier (RFC) model, support vector machine, eXtreme gradient boosting, artificial neural network, and decision tree ranged from 0.805 [95% confidence interval (CI): 0.258-1.352] to 0.925 (95%CI: 0.378-1.472) in the training set and from 0.794 (95%CI: 0.237-1.351) to 0.912 (95%CI: 0.355-1.469) in the testing set, respectively. The RFC (training set: AUC: 0.925, 95%CI: 0.378-1.472; testing set: AUC: 0.912, 95%CI: 0.355-1.469) model that incorporates Entropy, Haralick_all, Haralick_30, IG_all, IG_45, IG_0, and IV_45 had the highest predictive accuracy.

CONCLUSION

The evaluation results indicate that the method of selecting radiological and textural features becomes more effective in the LNM discrimination against UEGC patients. Additionally, the ML-based prediction model developed using the RFC can be used to derive treatment options and identify LNM, which can hence improve clinical outcomes.

Key Words: Undifferentiated early gastric cancer; Machine learning; Lymph node metastasis; Gray-level co-occurrence matrix; Feature selection; Prediction

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Gray-level co-occurrence matrix-based feature extraction can be a robust and promising tool to improve the efficiency in predicting lymph node metastasis of individual undifferentiated early gastric cancer patients. Additionally, machine learning adopts more optimized algorithms and more clear feature extraction. Models developed using random forest classifier have the highest predictive accuracy in terms of Entropy, Haralick full angle, Haralick 30°, inverse gap full angle, inverse gap 45°, inverse gap 0°, and inertia value 45°. Further research is required to develop these models for clinical practice.

INTRODUCTION

Gastric cancer (GC) is one of the most common and fatal malignancies worldwide and is an important part of the global cancer burden[1,2]. In GC, undifferentiated early GC (UEGC) differs from differentiated-type GC in terms of clinical features and disease state, and their treatment and prognosis vary[3]. Therefore, UEGC should be identified and diagnosed early.

The incidence of lymphatic vessel invasion and risk of lymph node metastasis (LNM) in UEGC are high in surgical specimens of GC[4,5]. Endoscopic resection (ER), including endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD), has been considered a minimally invasive treatment option for early GC with negligible risk of LNM[6,7]. Nevertheless, indication or curability evaluation has not been conducted for ESD of undifferentiated GC (*e.g.*, poorly differentiated adenocarcinoma, signet ring cell carcinoma, or mucinous adenocarcinoma) due to the potential risk of LNM. Although ER can be used as painless treatment, the LNM incidence after non-curative ER can be as low as 5.1% and as high as 12.2%[8-10]. Additionally, ESD is only applicable to intramucosal cancer with a tumor diameter of ≤ 20 mm and without ulcer lesions; thus, treating lesions that meet the ESD indications through surgery is unnecessary[11,12]. That is, when resection beyond the expanded

standard is considered ineffective, the potential risk of LNM cannot be ignored. Hence, additional surgical resection and lymph node dissection should be performed. Unlike differentiated early GC, ER indications of UEGC are limited. Therefore, to address this challenging problem, a precise tool that can predict LNM must be explored.

Previous studies have mainly focused on risk factors for LNM or distant metastasis of differentiated-type early GC[13-15]. However, for UEGC, LNM has different risk factors. Thus, objective and universal evaluation indicators for evaluating its risk are lacking. In this study, we clarified the LNM risk factors of patients with UEGC who underwent surgical resection. Subsequently, we analyzed clinical-pathological factors by introducing gray-level co-occurrence matrix (GLCM) image feature extraction mining to classify LNM risk groups according to the combination of risk factors. This study aims to provide a reference for clinical diagnosis and treatment.

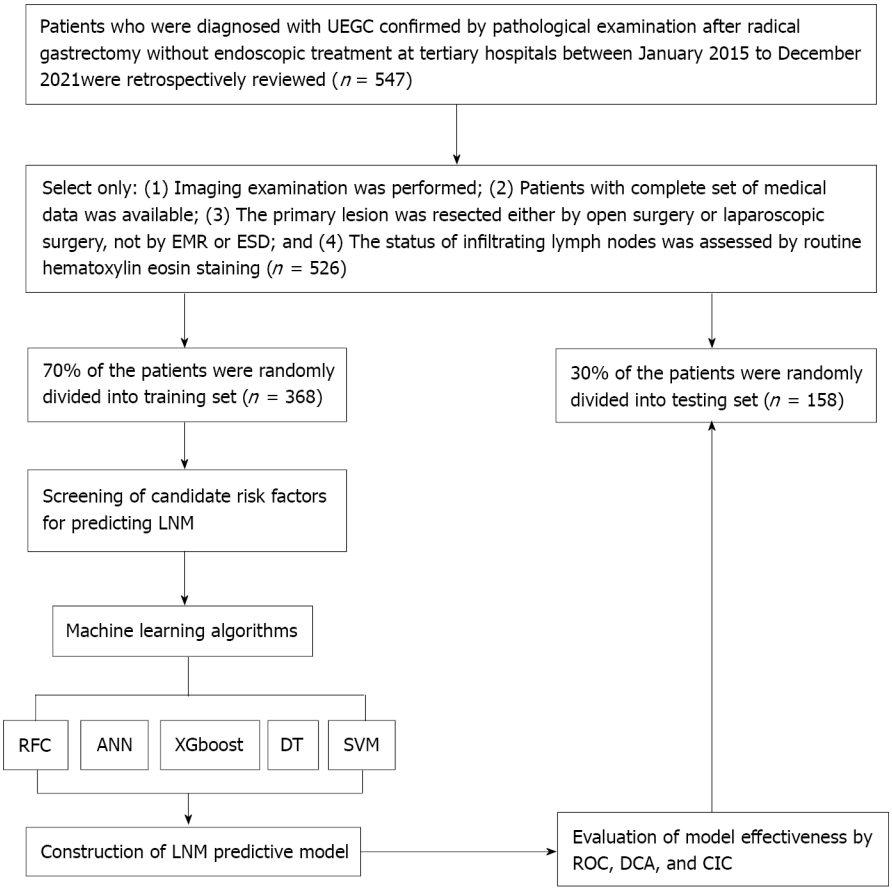
MATERIALS AND METHODS

Patient selection

The clinical records of 526 patients who were diagnosed with UEGC were confirmed through pathological examination after radical gastrectomy without endoscopic treatment at four tertiary hospitals. These hospitals are Shaanxi Provincial People's Hospital, Shaanxi Provincial Tumour Hospital, the First Affiliated Hospital of Xi'an Jiaotong University, and the Second Affiliated Hospital of Xi'an Jiaotong University. The clinical records were between January 2015 to December 2021 and were retrospectively reviewed. The following were the inclusion criteria: (1) Imaging examination was performed; (2) Patients have a complete set of medical data; (3) Primary lesion was resected either *via* open surgery or laparoscopic surgery and not *via* EMR or ESD; and (4) The status of infiltrating lymph nodes was assessed through routine hematoxylin-eosin staining. To minimize the confounding effect of unnecessary variables, the following were the exclusion criteria: (1) Sufficient information cannot be extracted or mismatched clinical data of patients; and (2) Patients without complete magnetic resonance imaging (MRI) plain scan or the MRI image quality being unacceptable. This study complies with the provisions of the Helsinki Declaration (revised in 2013) and was approved by the Institutional Review Committee of Shaanxi Provincial People's Hospital (2021-Y024). Figure 1 presents in detail the patient screening steps and modeling process.

Construction strategy of the GLCM

All texture parameter post-processing was conducted on Omni dynamics software (GE pharmaceuticals, Shanghai). Two radiologists who have vast experience in gastrointestinal diagnosis referred to the MRI images to sketch the lesions on the ADC map. First, they manually sketch the entire area with cancer on each layer of the map, avoiding the gas in the intestine, until the whole tumor volume was cut out. Second, the software automatically generates the texture features. In this study, the following are the selected texture parameters of the GLCM: Total frequency, energy value, entropy, inertia value, correlation coefficient, inverse moment, cluster shadow, and cluster prominence.



Data extraction and quality assessment

For variables with missing values (often this missing value is less than 10%), the variable's mean value should be filled. If ≥ 10% of the given variables are missing, this value is excluded from the variable screening of the final model. Similarly, this study adopted unit feature interpolation for the missing values that meet the interpolation requirements. That is, the missing values can be interpolated using the constant values provided or using the statistical data of each column where these missing values are located (*e.g.*, average value, median value, or the most frequently occurring value)[16,17].

Construction and effectiveness evaluation of the LNM model

Based on the machine learning (ML) algorithm, the commonly used iterative algorithm models are included: Random forest classifier (RFC), decision tree (DT), support vector machine (SVM), eXtreme gradient boosting (XGBoost), and artificial neural network (ANN). The RFC is an integrated method that forms a cumulative effect by integrating multiple relatively simple evaluators. Random forest is an integrated learning tool based on DT. The SVM is a type of a generalized linear classifier that categorizes data binary through supervised learning. The ANN is a nonlinear equation transformation output algorithm comprising input, hidden, and output layers. Finally, XGBoost is an additive model. In each iteration, only the sub-models in the current step are optimized. In this study, we refer to the guide proposed by Luo *et al*[18] for the best use of prediction models in biomedical research, that is, the Delphi method, which is used to generate the list of reported items.

For the screening of candidate variables, we mainly rely on the principle of "bag repeatedly put back and extract", sort according to variables' weight, and finally obtain the final predictor of the prediction model from the top 10 variables[19]. For the effectiveness evaluation of the prediction model, the receiver operating characteristic (ROC) curve is used to evaluate the accuracy of the model. Meanwhile,

the decision curve analysis and clinical impact curve (CIC) were used to evaluate the model's robustness and differentiation, respectively.

Statistical analysis

The measurement and counting data in this study are expressed by interquartile spacing (25%, 75%) and percentage (%), respectively. For the comparison between groups, the continuous variables adopt the *t*-test or Mann-Whitney *U* test of independent samples (provided that it does not conform to the normal distribution). The counting data adopt the chi-square goodness-of-fit test. Values of Bonferroni corrected probability are used to compare the qualitative data[20]. The prediction model visualization and other data analysis are performed using R software (version 4.0.4, http://www.r-project.org/). For the comparison between groups, P value < 0.05 is considered statistically significant and vice versa.

RESULTS

Comparison of baseline data between LNM and non-LNM queues

Table 1 summarizes the baseline characteristics of 526 hospitalized patients with UEGC. For internal validation, the patients were randomly divided into two sets using the caret package: Training set (n = 368, 70%) and validation set (n = 158, 30%). Regarding the LNM rate, the training and validation cohorts were 62 (16.85%) and 29 (18.35%), respectively. In addition to the previously reported clinical-related indicators (*e.g.*, tumor size, infiltration depth, vascular_invasion, and vascular tumor thrombus), significant differences exist between the LNM and non-LNM groups. We found that GLCM-based texture acquisition features also have significant statistical differences between the two groups.

Feature correlation and potential predictors

We conducted a correlation analysis on the variables with significant differences based on the statistical difference analysis of baseline data. As shown in Figure 2A, the correlation matrix (based on Pearson

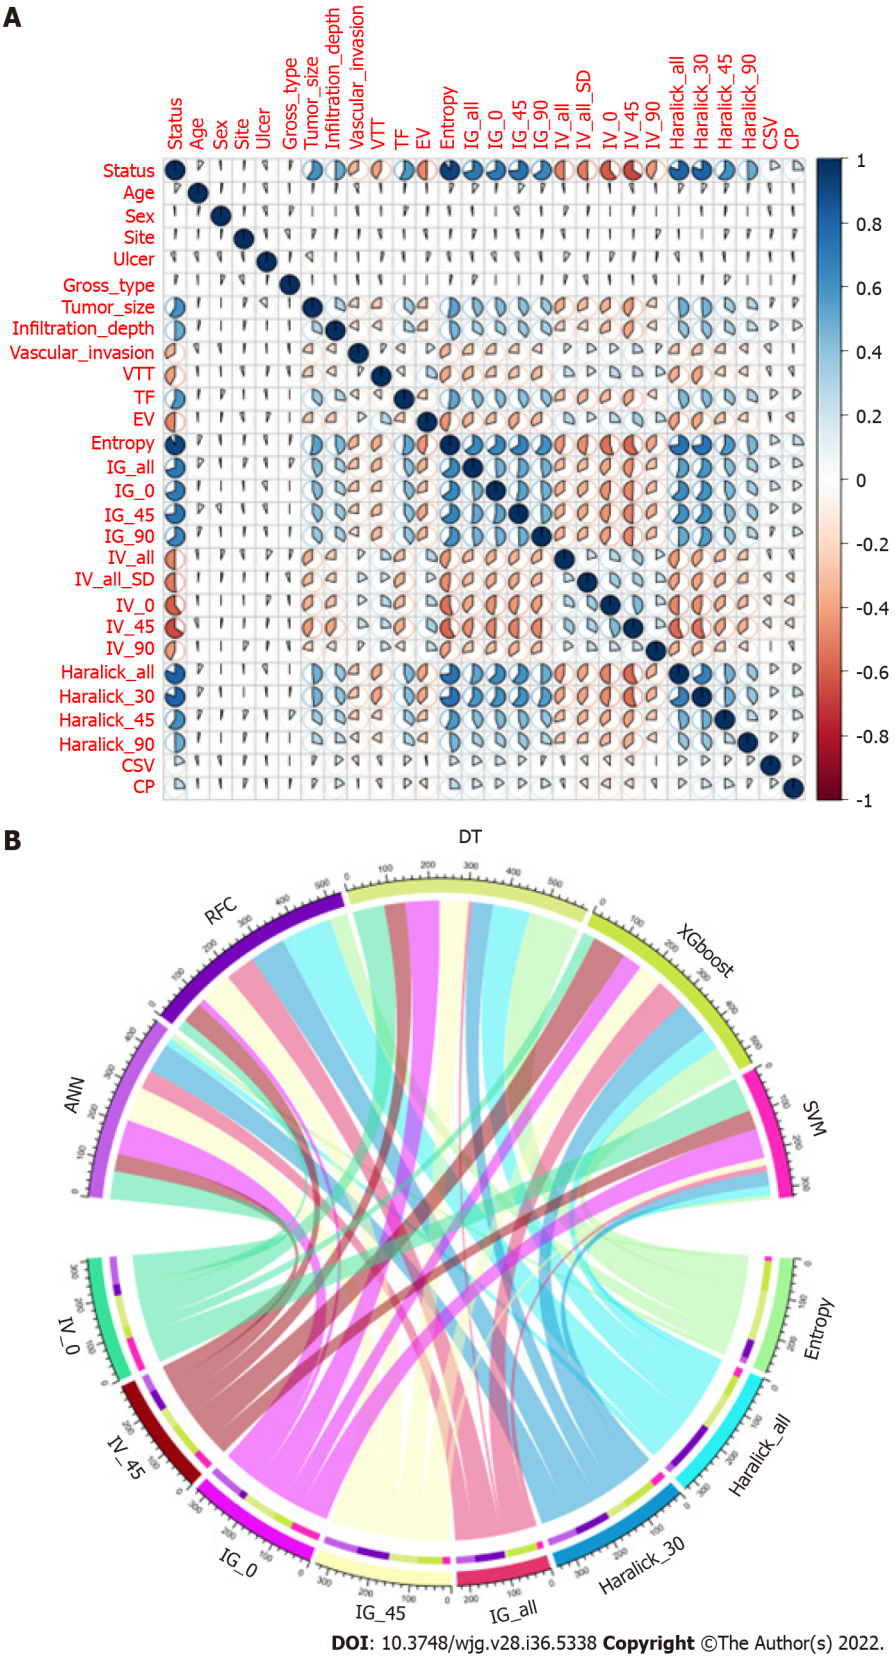
IQR: Interquartile range; TF: Total frequency; EV: Energy value; IV_0: Inertia value 0°; IV_45: Inertia value 45°; IV_90: Inertia value 90°; IG_0: Inverse gap 0°; IG_45: Inverse gap 45°; IG_90: Inverse gap 90°; IG_all: Inverse gap full angle; Haralick_30: Haralick 30°; Haralick_45: Haralick 45°; Haralick_90: Haralick 90°; Haralick_all: Haralick full angle; CSV: Cluster shadow value; CP: Cluster prominence.

correlation analysis) indicates that the characteristic variables in the GLCM and LNM had a strong correlation degree ($r > 0.6$). For example, Entropy, Haralick full angle (Haralick_all), Haralick 30° (Haralick_30), Inverse gap full angle (IG_all), Inverse gap 45° (IG_45), Inverse gap 0° (IG_0), *etc.* were highly correlated with LNM. This suggests that these potential candidate variables can be used as LNM predictors and for the construction of subsequent models. Interestingly, in the subsequent models developed based on ML algorithms, we found that Entropy, Haralick_all, Haralick_30, IG_all, IG_45, IG_0, and Inertia value 45° (IV_45) occupied high weights as the top 7 GLCM-based factors (Figure 2B). Specifically, Entropy has the largest weight among these factors.

Establishment and performance evaluation of the LNM prediction model

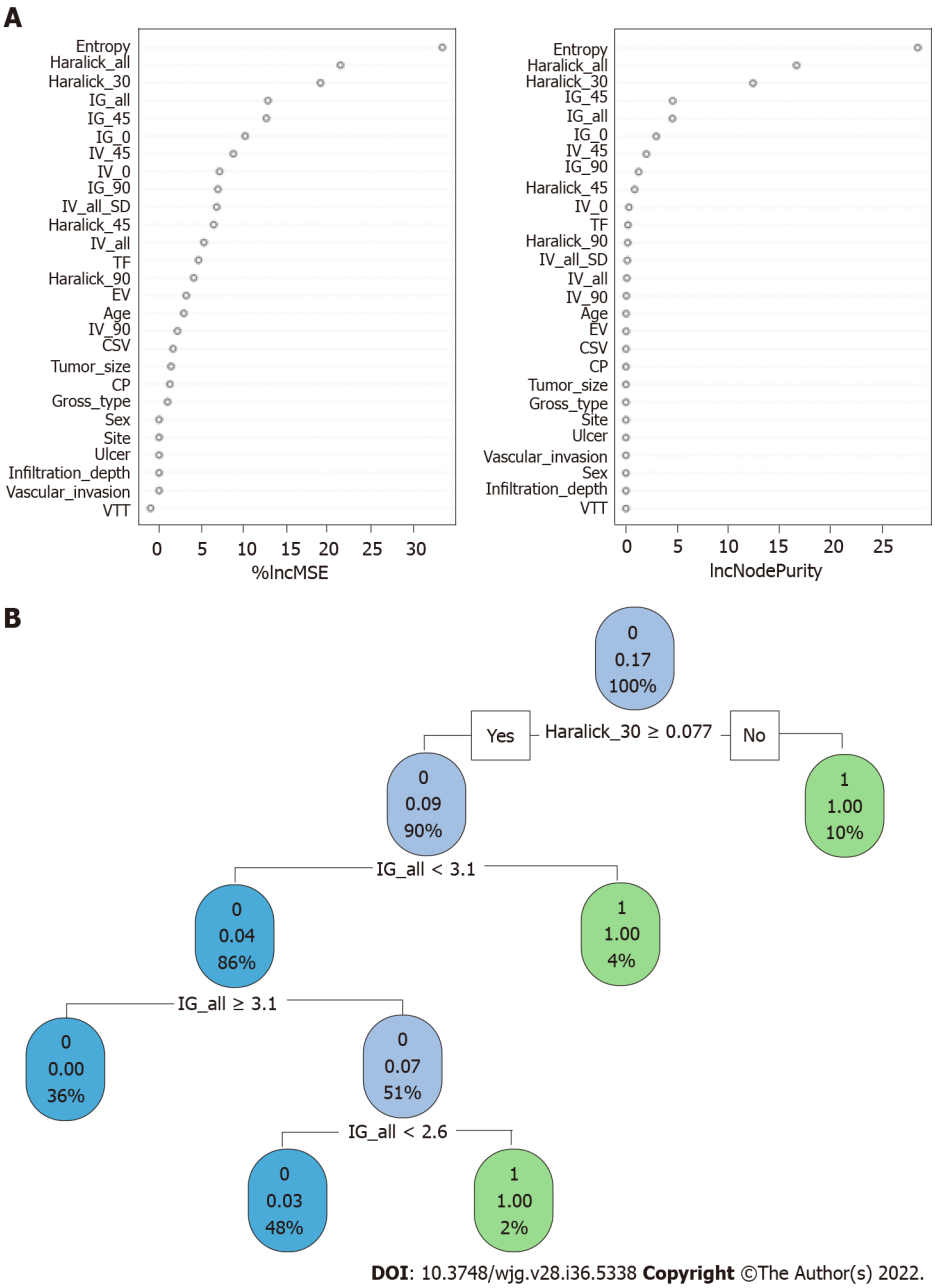


When constructing the RFC model [training set: Areas under the ROC curve (AUC): 0.925, 95% confidence interval (CI): 0.378-1.472; testing set: AUC: 0.912, 95%CI: 0.355-1.469], we repeatedly randomly selected *N* samples from the original training set *N* to generate the new training set DT and then generate *M* DTs to form a random forest according to the above steps. As shown in Figure 3A and Supplementary Table 1, the smallest Gini index after splitting was selected, including that for Entropy, Haralick_all, Haralick_30, IG_all, IG_45, IG_0, and IV_45. Similarly, Haralick_30 and IG_all served as important weight at DT branches (training set: AUC: 0.856, 95%CI: 0.309-1.403; testing set: AUC: 0.813, 95%CI: 0.256-1.370) (Figure 3B). In the ANN model (Figure 4), the accuracy of the prediction model developed using the prediction variables in the GLCM can also reach 0.887 (95%CI: 0.340-1.434) and 0.837 (95%CI: 0.280-1.394) in the training and verification sets, respectively. Although this accuracy is slightly inferior to that of the RFC model, it is better than those of other prediction models (*i.e.*, DT, XGBoost, and SVM). Table 2, Supplementary Table 1, and Figure 5 summarize the predictive performance of ML-based models. In general, the prediction model constructed by using any ML algorithm was better than the logistic regression algorithm in predicting LNM, further confirming the superiority of ML algorithm, especially the robustness of the RFC.

Internal validation of the optimal RFC predictive model

The prediction efficiency of the RFC model was the best in the process of precise stratification of LNM patients. To further evaluate the "stratification effect" of the RFC, results of CIC analysis indicate that high-risk LNM was accurately distinguished using the RFC model, and "cross-linking" did not occur in the stratification process. The results of this model for the validation and training sets were consistent (Supplementary Table 2), implying that the robustness and LNM discrimination of the RFC model were satisfactory.

DISCUSSION



The standard treatment for early GC is surgery. However, recently, ER has become the standard local

treatment for some patients with early GC without LNM[21]. For a long time, it has been used to treat differentiated-type early GC limited to the mucosa, with a diameter of < 2 cm[22,23]. Recent studies have shown that ER indications have been expanded in many studies, even including UEGC and ≤ 2 cm diameter, without ulcer or lymphatic vessel invasion[24]. However, whether UEGC can accept the

Candidate factors associated with fracture risk are named through random forest classifier algorithm, and prediction nodes and weights are assigned by the decision tree algorithm.

standard treatment of ER remains a subject of debate. That is, additional surgery should be performed if curability is considered questionable. Given this situation, the risk factors of LNM or distant metastasis and mortality after non-curative ER of UEGC should be investigated. Previous studies have also shown that patients with two or more risk factors (*e.g.*, ulcer, submucosal invasion, and positive vertical margin) benefit greatly from surgical resection after ER that cannot be cured by UEGC[14,25]. However, due to the heterogeneity of clinical characteristics, risk stratification based on these predictions provides a simple prediction, which is challenging to apply in clinical practice.

The potential application of the GLCM in the prediction of LNM of UEGC has not been systematically explored thus far. In this study, GLCM-based features were extracted from underlying grayscale images collected through MRI. We developed an LNM risk prediction model for patients with UEGC using an ML-based algorithm. The following are the two important findings of our study. First, the accurate risk stratification of UEGC patients who should undergo additional surgery depends on the added value of the GLCM. Second, a new ML-based prediction model was used to identify patients and whether they have LNM. According to previous studies[26], texture analysis can quantify the spatial differences of pixels and the subtle differences reflected in gray values, which is consistent with the conclusion of this study. To some extent, we used GLCM features to gather spatial information and reduced the

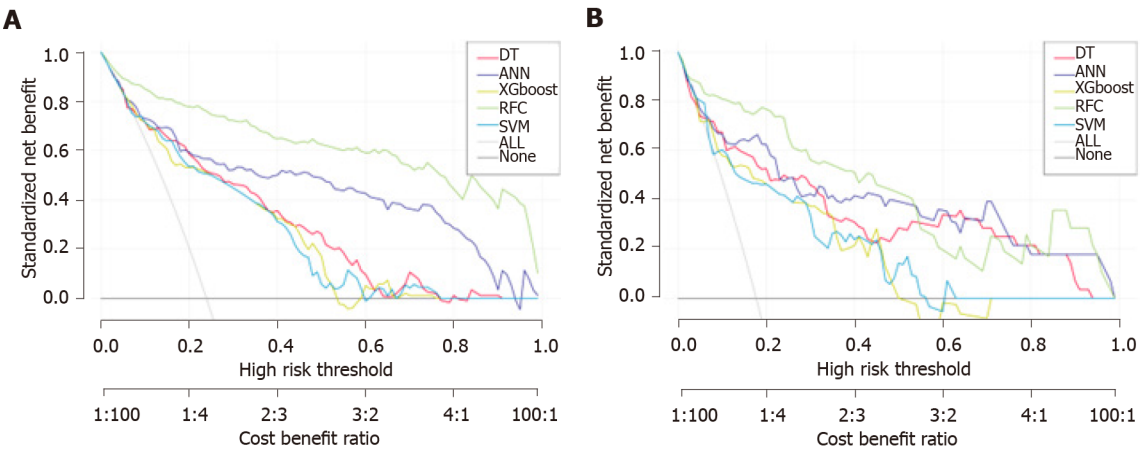
overfitting effect by replacing the softmax layer with the ML-based algorithm.



In this study, we created five types of ML-based models (*i.e.*, RFC, ANN, DT, XGBoost, and SVM), which used GLCM features to predict LNM. Interestingly, there were differences in the prediction efficiency obtained by ML-based models of different algorithms. For example, the RFC model had the highest predictive accuracy, which was achieved by incorporating Entropy, Haralick_all, Haralick_30, IG_all, IG_45, IG_0, and IV_45. Meanwhile, the ANN, DT, XGBoost, and SVM exhibited an inferior performance compared with the RFC. This suggests that the accuracy of the RFC in predicting LNM is superior to that of the ML model. A previous study indicated that a random forest algorithm is more

efficient in processing classification problems, which is consistent with the results of this study[27]. Meanwhile, DT is not as good as the RFC in terms of fitting, and the low prediction ability of the ANN model indicates that an "overfitting" phenomenon may occur. In general, different ML models show consistent accuracy, indicating that the prediction performance of ML can be improved through data processing.

Our results confirm a GLCM-based LNM classification, which has an ideal predictive effect on the diagnosis and treatment of patients with UEGC. However, the following problems were inevitably encountered in this study. First, because this study involved a retrospective analysis, the case inclusion criteria may have a certain bias on the results, which remains to be confirmed by a large sample of prospective studies in the future. Second, there were relatively few selected cases in this study, and only some parameters of the GLCM were extracted. Thus, the results of its prediction model should be verified by external data. Third, when data from multi-center and large sample studies are available in the future, it is crucial to predict the presence or absence of LNM. Additionally, the GLCM is an important imaging sequence of UEGC, and hence we will further perform other image texture analyses

in subsequent research.

CONCLUSION

GLCM-based feature extraction could, in general, serve as a robust and promising tool to improve predictive efficiency for LNM in individual UEGC patients. ML adopts the algorithm of "classification and pruning" and clearer feature extraction, leading to better data fitting than the conventional prediction model. The model constructed using the RFC had the highest predictive accuracy, with the following being the most important predictors: Entropy, Haralick_all, Haralick_30, IG_all, IG_45, IG_0, and IV_45. In the future, we are still required to validate and optimize these prediction models using datasets of various scenarios to better apply them to clinical practice.

ARTICLE HIGHLIGHTS

Research background

Gray-level co-occurrence matrix (GLCM) based feature extraction could serve as a robust and promising tool to improve the predictive efficiency for lymph node metastasis (LNM) of individual undifferentiated early gastric cancer (UEGC) patients. Additionally, machine learning (ML) adopts more optimized algorithms and more clear feature extraction. Models built using random forest classifier (RFC) have the highest predictive accuracy in Entropy, Haralick full angle (Haralick_all), Haralick 30° (Haralick_30), Inverse gap full angle (IG_all), Inverse gap 45° (IG_45), Inverse gap 0° (IG_0), and Inertia value 45° (IV_45). Further research is needed to develop these models for clinical practice.

Research motivation

The evaluation results indicate that the method of selecting radiological and textural features becomes more effective in the discrimination of LNM from UEGC patients. In addition, an ML-based prediction model developed using RFC can be used to derive treatment options and identify LNM that can improve clinical outcomes.

Research objectives

GLCM based feature extraction significantly correlated with LNM. The top 7 GLCM based factors included Inertia value 0°, IV_45, IG_0, IG_45, IG_all, Haralick_30, Haralick_all, and Entropy. The areas under the receiver operating characteristic (ROC) curve (AUCs) of the RFC model, support vector machine (SVM), eXtreme gradient boosting (XGBoost), artificial neural network (ANN), and decision tree (DT) ranged from 0.805 [95% confidence interval (CI): 0.258-1.352] to 0.925 (95%CI: 0.378-1.472) in the training set and from 0.794 (95%CI: 0.237-1.351) to 0.912 (95%CI: 0.355-1.469) in the testing set, respectively. The RFC (training set: AUC: 0.925, 95%CI: 0.378-1.472; testing set: AUC: 0.912, 95%CI: 0.355-1.469) model incorporating Entropy, Haralick_all, Haralick_30, IG_all, IG_45, IG_0, and IV_45 had the highest predictive accuracy.

Research methods

We retrospectively selected 526 cases of UEGC confirmed by pathological examination after radical gastrectomy without endoscopic treatment in four tertiary hospitals between January 2015 to December 2021. GLCM-based features were extracted from grayscale images and ML was applied to the classification of candidate predictive variables. In order to evaluate robustness and clinical utility of each model, the following were made: ROC, decision curve analysis, and clinical impact curve.

Research results

Identifying a potential biomarker that predicts LNM is proven to be very useful in determining treatment.

Research conclusions

To develop a ML-based integral procedure to construct the LNM gray level co-occurrence matrix (GLCM) prediction model.

Research perspectives

The risk of LNM is the most important consideration in determining treatment strategies for UEGC. Therefore, identifying a potential biomarker that predicts LNM is proven to be very useful in determining treatment.

Abstract

BACKGROUND

Surgical resection is one of the most widely used modalities for the treatment of hepatocellular carcinoma (HCC). Early extrahepatic recurrence (EHR) of HCC after surgical resection is considered to be closely associated with poor prognosis. However, data regarding risk factors and survival outcomes of early EHR after surgical resection remain scarce.

AIM

To investigate the clinical features and risk factors of early EHR and elucidate its association with survival outcomes.

METHODS

From January 2004 to December 2019, we enrolled treatment-naïve patients who were ≥ 18 years and underwent surgical resection for HCC in two tertiary academic centers. After excluding patients with tumor types other than HCC and/or ineligible data, this retrospective study finally included 779 patients. Surgical resection of HCC was performed according to the physicians' decisions and the EHR was diagnosed based on contrast-enhanced computed tomography

or magnetic resonance imaging, and pathologic confirmation was performed in selected patients. Multivariate Cox regression analysis was performed to identify the variables associated with EHR.

RESULTS

Early EHR within 2 years after surgery was diagnosed in 9.5% of patients during a median follow-up period of 4.4 years. The recurrence-free survival period was 5.2 mo, and the median time to EHR was 8.8 mo in patients with early EHR. In 52.7% of patients with early EHR, EHR occurred as the first recurrence of HCC after surgical resection. On multivariate analysis, serum albumin < 4.0 g/dL, serum alkaline phosphatase > 100 U/L, surgical margin involvement, venous and/or lymphatic involvement, satellite nodules, tumor necrosis detected by pathology, tumor size ≥ 7 cm, and macrovascular invasion were determined as risk factors associated with early EHR. After sub-categorizing the patients according to the number of risk factors, the rates of both EHR and survival showed a significant correlation with the risk of early EHR. Furthermore, multivariate analysis revealed that early EHR was associated with substantially worse survival outcomes (Hazard ratio, 6.77; 95% confidence interval, 4.81-9.52; $P < 0.001$).

CONCLUSION

Early EHR significantly deteriorates the survival of patients with HCC, and our identified risk factors may predict the clinical outcomes and aid in postoperative strategies for improving survival.

Core Tip: Surgical resection of hepatocellular carcinoma is effective and curative treatment modality. However, early extrahepatic recurrence (EHR) after resection is related to poor prognosis. This study indicates the close correlation between the early EHR and survival outcome (hazard ratio 6.77, 95% confidence interval 4.81-9.52). The time to EHR was 8.8 mo and in 52.7% of early EHR group, EHR occurred as the first recurrence. On multivariate analysis, serum albumin < 4.0 g/dL, serum alkaline phosphatase > 100 U/L, surgical margin involvement, venous and/or lymphatic involvement, satellite nodules, tumor necrosis, tumor size ≥ 7 cm, and macrovascular invasion were associated risk factors with early EHR.

INTRODUCTION

Surgical resection remains one of the best options for treating early hepatocellular carcinoma (HCC), along with liver transplantation and radiofrequency ablation[1-3]. With the development of surgical techniques and medical devices, surgical resection of tumors has been performed for a wide spectrum of patients with HCC. Nonetheless, HCC recurrence after surgery leads to an unfavorable prognosis and is still a major issue, with the 2-year recurrence rate ranging from 30.0% to 43.0%[4,5].

HCC recurrence after surgical resection mostly occurs inside the liver (intrahepatic), but recurrence outside the liver (extrahepatic) can also occur[2,6]. Most cases of extrahepatic recurrence (EHR) of HCC generally have an aggressive phenotype, and this contributes to poor survival outcomes[7]. Taketomi *et al*[6] reported the 3-, 5-, and 10-year cumulative survival rates of EHR as 60.3%, 24.0%, and 6.0%, respectively, which were lower than those in patients with intrahepatic recurrence (IHR) (74.5%, 57.7%, and 23.1%, respectively; $P = 0.004$). Although IHR of HCC can be managed by various loco-regional treatment modalities and systemic therapies, there are only limited methods for the treatment of EHR. However, despite an expected poor prognosis, favorable outcomes in selected patients with limited EHR have been reported with treatment modalities, such as metastasectomy[8]. Therefore, predicting the risk of EHR is essential, and better outcomes can be accomplished by predicting high-risk patients and monitoring these patients with close follow-up surveillance for early detection of EHR and/or timely postoperative adjuvant therapy.

We have reported simple parameters for predicting EHR after hepatectomy[9], and in that study, approximately 49.2% of the patients with EHR (31 of 63 patients) showed early EHR and demonstrated poorer recurrence-free survival (RFS) and overall survival rates. There have been many reports regarding the risk factors and predictive models for early recurrence mostly concerning IHR of HCC after surgery[10-12]; however, there are limited data regarding the risk factors and survival outcomes related to early EHR after surgical resection of HCC. Moreover, the clinical characteristics and survival outcomes of patients with early EHR in comparison with those with a later onset of EHR have not been examined. Hence, we aimed to investigate the characteristics and potential risk factors of early EHR after curative surgical resection for HCC and explore the relationship between early EHR and survival outcomes.

MATERIALS AND METHODS

Patients

This study enrolled 890 patients who underwent surgery for HCC from January 2004 to December 2019 at two tertiary hospitals. Patients with tumor types other than HCC, previous treatment experience, and ineligible data were excluded. Finally, 779 patients were enrolled for this study and were analyzed. Surgical resection of HCC was determined by a physician's decision regarding the tumor stage, liver function, and the patient's physical status. There had been no changes in the keynote of surgical resection during the study period in both centers. To exclude potential bias regarding surgical technique and concentrate on EHR development and survival rate based on tumor findings, patients who developed EHR prior to the completion of the post-surgical duration of 60 d were excluded.

Baseline HCC staging, surgical resection, and follow-up

HCC was diagnosed according to the guidelines of the Korean Liver Cancer Study Group and the National Cancer Center[13]. HCC staging at the time of diagnosis was determined using the modified Union for International Cancer Control (mUICC) staging system[14] and the Barcelona Clinic Liver Cancer (BCLC) classification system[3]. Milan criteria were based on radiologic findings at initial the diagnosis of HCC[15]. Abdominal computed tomography (CT) or magnetic resonance imaging (MRI) and assessment of serological tumor markers were routinely performed 1 mo after surgical resection and at each 3-6-month follow-up visit.

The tumor sizes were measured by radiologic modalities with CT or MRI. The histological differentiation of HCC was graded according to the criteria of Edmondson and Steiner[16]. The presence of macrovascular invasion was defined as vascular invasion of HCC detected on CT imaging or MRI while microvascular invasion was defined as invasion of vascular structures on microscopic analysis of resected tumor specimens. Lymph node metastasis, serosal invasion, bile duct invasion, capsule formation, multicentricity, satellite nodule, intrahepatic metastasis, tumor necrosis, tumor hemorrhage, and fatty changes within tumors were all confirmed from pathological findings of resected specimens. Overall survival was defined as the time interval in days between the date of diagnosis of HCC and the date of death or last follow-up examination. The cause of death of each patient is presented in Supplementary Table 1.

Diagnosis of recurrence and EHR

The diagnosis of EHR was confirmed by contrast-enhanced CT or MRI, and pathological examination was performed only for selected patients as decided by the physician. In addition, chest radiographs, bone scintigraphy, positron emission tomography-CT, and brain MR or CT imaging were used when new signs suggesting tumor metastasis manifested. Early EHR was defined as EHR that developed within 2 years after initial surgical resection. Most cases of EHR were diagnosed during the routine follow-up studies, with a few cases diagnosed during the evaluation of new-onset symptoms or based on significant elevation in alpha-fetoprotein (AFP) or serial AFP elevation without definite intra-hepatic lesions.

Ethics statement

This study was approved by the Institutional Review Board of Chonnam National University Hospital (IRB No. CNUH-2019-203). Because of the retrospective design of our study and the use of de-identified data, the requirement for informed consent was waived under the approval of the Institutional Review Board of Chonnam National University Hospital. The study was performed in compliance with the tenets of the 1975 Helsinki Declaration.

Statistical analysis

The data are presented as means ± SD or as medians and ranges, as appropriate, for the data type and distribution. Univariate analyses were performed using the chi-squared test or Student's *t*-test, as appropriate. Variables with a P value of < 0.05 on univariate analyses were included in a multivariate

logistic regression analysis to identify factors predictive of EHR. A multivariate Cox regression model was built using a stepwise backward selection of variables, and variables with a P value of < 0.05 were retained as predictive factors. The risk levels of EHR were defined based on the number of risk factors present, and Kaplan-Meier survival curves were constructed for each risk level. All statistical analyses were performed using SPSS software version 27.0 (IBM Corp., Armonk, NY, United States). The statistical methods of this study were reviewed by Cho Hee Hwang from the Biomedical research institute of Chonnam National University Hospital.

RESULTS

Baseline characteristics of the enrolled patients

The baseline characteristics of patients with early EHR were assessed (Table 1). These patients were younger, had lower serum albumin levels, and higher initial serum AFP concentration > 400 (IU/mL) than those without early EHR. Additionally, patients with early EHR showed more advanced tumor stage with respect to tumor size, BCLC stage, mUICC stage, and beyond Milan criteria. The patients in the early EHR group presented higher rates of macrovascular invasion and longer duration of hospital stay after liver resection. Furthermore, when we subdivided the patients into those without EHR, those with non-early EHR, and those with early EHR, the following factors exhibited a close relationship to the interval of EHR development: younger age, ALP levels, albumin levels, preoperative serum AFP > 1500 IU/mL, tumor size, tumor numbers, tumor stages, and the presence of macrovascular invasion (Supplementary Table 2).

Comparison of clinicopathological findings and clinical outcomes

We analyzed the surgical findings of tumor specimens categorized by the presence of early EHR (Table 2). Patients with early EHR had more metastatic lymph nodes, microvascular invasion, and satellite nodules (0.1% *vs* 4.1%, 16.3% *vs* 44.6%, and 12.2% *vs* 23.0%, respectively). Furthermore, the tumor specimens in the early EHR group showed a higher probability of tumor necrosis, hemorrhages, and absence of fatty changes (41.5% *vs* 82.4%, 43.0% *vs* 62.2%, and 36.0% *vs* 20.5%, respectively). On subgroup analysis stratifying patients with EHR into the early EHR and non-early EHR groups, microvascular invasion, serosal invasion, presence of satellite nodules, tumor necrosis, hemorrhages, and absence of fatty changes still showed consistent significance (Supplementary Table 3).

When comparing the findings on the first recurrence between the early and non-early EHR groups, the proportion of patients with serum AFP > 400 IU/mL was higher (10.2% *vs* 31.0%, P < 0.001) (Table 2) and the RFS was shorter (32.4 *vs* 5.21 mo, P < 0.001) in the early EHR group. These trends for serum AFP and RFS also showed consistency when we compared all patients with non-early EHR and early EHR (Supplementary Table 1). Furthermore, the mUICC stage at first recurrence was more advanced in the early EHR group (38.7% *vs* 75.7% with mUICC stage ≥ 3, P < 0.001), and 52.7% of patients developed EHR as the first recurrence after surgical resection.

Analysis of factors associated with early EHR

We performed Cox regression analysis to assess multiple factors relevant to EHR after surgical resection of HCC (Table 3). Among various risk factors, eight were proven to be closely associated with EHR, including serum albumin < 4.0 g/dL [Hazard ratio (HR), 2.12; P < 0.001], serum ALP > 100 U/L (HR, 1.586; P = 0.018), surgical margin involvement (HR, 2.53; P = 0.032), venous and/or lymphatic involvement (HR, 1.900; P = 0.002), satellite nodules (HR, 1.73; P = 0.011), tumor necrosis (HR, 1.92; P = 0.001), sum of tumor size ≥ 7 cm (HR, 1.84; P = 0.004), and macrovascular invasion (HR, 2.30; P = 0.008).

Analysis of factors associated with overall survival

We conducted Cox regression analysis to determine the risk factors associated with survival after surgical resection of HCC and to assess the relationship between early EHR and survival. On multivariate analysis, serum albumin < 4.0 g/dL (HR, 2.44; P < 0.001), serum ALP > 100 U/L (HR, 1.61; P = 0.001), major Edmondson-Steiner grade ≥ 3 (HR, 1.45; P = 0.008), pathological mUICC stage III or IVa (HR, 1.63; P = 0.002), satellite nodules (HR, 1.92; P < 0.011), tumor necrosis (HR, 1.35; P = 0.030), and early EHR (HR, 6.77; P < 0.001) were identified as factors related to survival outcome.

Cumulative rates of early EHR and overall survival

Among the 779 patients enrolled, 136 (17.5%) developed EHR during a median follow-up period of 4.41 years, and 74 (54.4%) exhibited early EHR after surgical resection of HCC. Both the cumulative rates of recurrence and the overall survival rates after surgical resection of HCC showed stepwise correlations with the interval to EHR (Figure 1). The 1-, 3-, 5-, and 10-year cumulative rates of recurrence were 15.8%, 35.4%, 46.5%, and 60.1% in the non-EHR group and were 32.3%, 64.5%, 85.5%, and 100.0% in the non-early EHR group. The early EHR group had a 1-year recurrence rate of 83.8% and 100.0% from the 2nd year after surgical resection (Figure 1A). The 1-, 3-, 5-, and 10-year cumulative rates of overall

survival were as follows: 97.8%, 90.2%, 80.9%, and 66.8% for the non-EHR group; 100.0%, 90.3%, 67.2%, and 9.9% for the non-early EHR group; and 74.9%, 23.0%, 15.2%, and 10.8% for the early EHR group (Figure 1B).

Cumulative rates of early EHR and survival categorized by risk factors

Depending on the eight factors proven to be associated with early EHR, we categorized the patients according to the number of risk factors. The cumulative rates of early EHR onset and survival were analyzed in the sub-categorized patients, and both rates showed stepwise correlations according to the number of risk factors (Figure 2A and B). Consequently, we stratified the patients into three categories: a low-risk group with 0-1 risk factor, an intermediate-risk group with 2-3 risk factors, and a high-risk group with ≥ 4 risk factors. The rates of EHR and survival exhibited a significant correlation with the risk stratification model (Figure 2C and D). The 1-, 2-, 3-, 5-, and 10-year cumulative rates of EHR in each group were as follows: 0.5%, 2.0%, 3.4%, 6.2%, and 16.8% in the low-risk group; 10.3%, 16.1%, 18.6%, 23.8%, and 42.8% in the intermediate-risk group; and 31.7%, 44.0%, 50.2%, 66.2%, and 77.5% in the high-risk group. The 1-, 3-, 5-, and 10-year overall survival rates in each group were as follows: 98.9%, 94.7%, 89.5%, and 70.0% in the low-risk group; 93.9%, 75.7%, 59.3%, and 38.1% in the intermediate-risk group; and 78.8%, 47.7%, 31.2%, and 12.5% in the high-risk group.

DISCUSSION

EHR of HCC is a well-known predictive marker of poor survival outcomes, and EHR after surgical resection of HCC is deemed to be a pivotal factor for grave prognosis[7,9,17,18]. In this large-scale 15-year observational study conducted at two academic tertiary hospitals, EHR and early EHR occurred in 17.5% and 9.5% of 779 patients with HCC, respectively. Patients with early EHR had a rapid recurrence of HCC after surgical resection and poor survival outcomes. Furthermore, we elucidated the potential risk factors for early EHR after curative surgical resection of HCC.

Since the proportion of IHR cases is higher than that of EHR cases after surgical resection of HCC, previous studies have analyzed various risk factors associated with IHR alone, previous studies have analyzed various risk factors associated with IHR. Portolani *et al*[19] examined the early and late recurrence of HCC after liver resection and showed that the survival rates in the early recurrence group were significantly lower than those in the late recurrence group (25.7% *vs* 4.5% at 5 years). Moreover, similar results were demonstrated in a large-scale multicenter study conducted in China by Yan *et al*[20] comprising 1426 patients, where patients in the early recurrence group showed poor post-recurrence

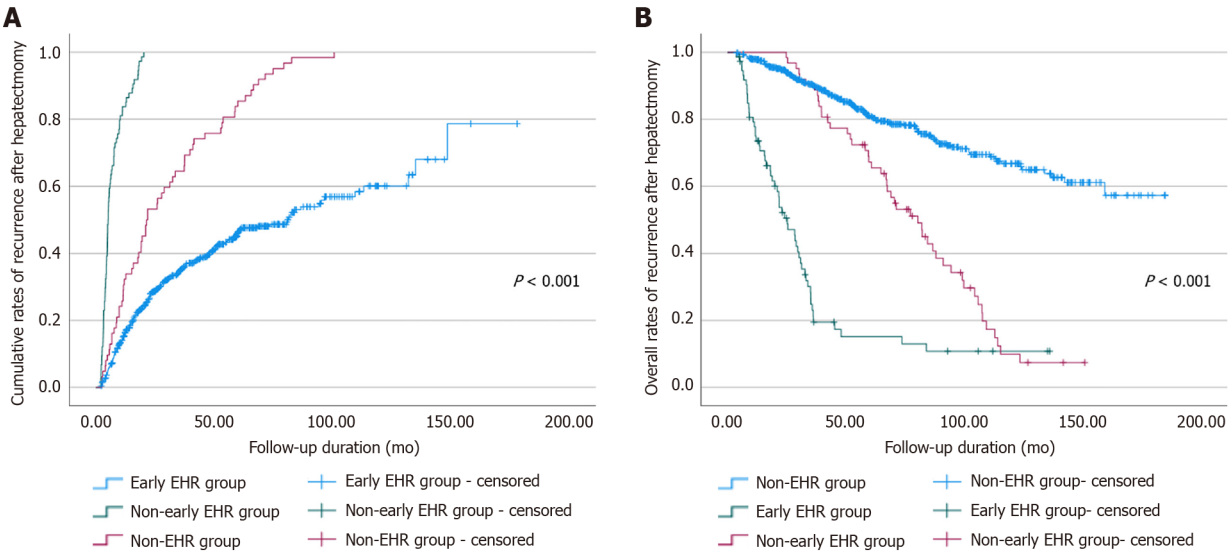

Figure 1 Both the cumulative rates of recurrence and the overall survival rates after surgical resection of hepatocellular carcinoma showed stepwise correlations with the interval to extrahepatic recurrence. A: Cumulative rate of the first recurrence of hepatocellular carcinoma after curative surgical resection; B: Overall survival rates stratified by the characteristics of extrahepatic recurrence. EHR: Extrahepatic recurrence.

survival (13.5 *vs* 36.6 mo, $P < 0.001$). Furthermore, Yang *et al*[21] stated that recurrent HCC cases with multicentric recurrence may have had greater survival than intrahepatic metastasis cases. In contrast, Byeon *et al*[22] compared the outcomes of 111 patients with IHR and 41 patients with EHR who had undergone surgical resection for HCC and found that patients in the EHR group showed significantly lower 5-year survival rates than those in the IHR group (21.5% *vs* 36.3%, $P < 0.001$). Considering the

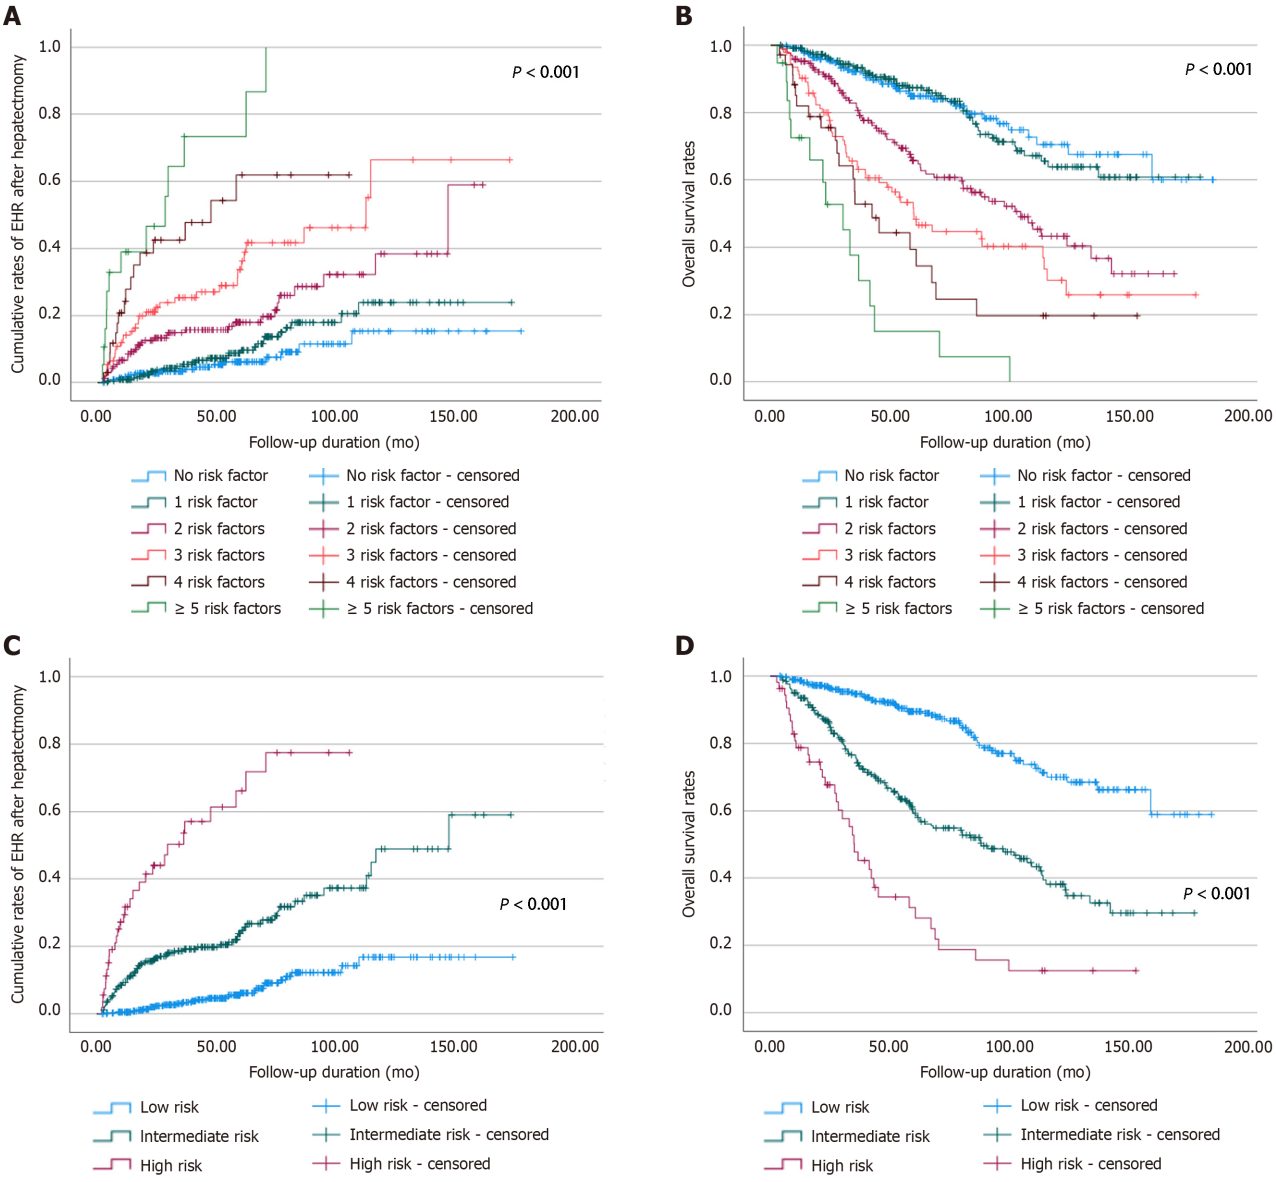

Figure 2 Patients were classified according to the number of eight risk factors related to early extrahepatic recurrence, and the probability of extrahepatic recurrence and overall survival rate was evaluated. A: Cumulative rates of extrahepatic recurrence; B: Cumulative rates of overall survival after surgical resection; C: The cumulative rates of extrahepatic recurrence; D: The cumulative rates of overall survival. EHR: Extrahepatic recurrence.

non-negligible rates of EHR after surgical resection of HCC and the dismal prognosis of patients with EHR, risk stratification and prediction of early EHR may have been of great importance in improving the clinical outcome.

In 52.7% of the patients with early EHR, EHR was the first recurrence of HCC after surgical resection (Supplementary Table 1), and both interval to first recurrence and EHR were significantly shorter in the early EHR group compared with that in the non-early EHR group (5.2 *vs* 21.6 mo, $P < 0.001$; and 8.81 *vs* 58.57 mo, $P < 0.001$). Moreover, a higher proportion of patients with early EHR showed an advanced stage at first recurrence (mUICC stage ≥ 3, 75.7% *vs* 38.7%, $P < 0.001$), and 43.2% of patients had no intrahepatic HCC (mUICC T stage 0) at EHR. This suggests that EHR may occur within a very short interval after surgical resection of HCC with an advanced tumor stage while intrahepatic HCC is not exhibited. Considering the aggressive nature of the tumors in patients with early EHR, adjuvant therapy after surgical resection or meticulous postoperative surveillance may be highly required in a specific group of patients to prompt detection of EHR. In addition, with respect to the high proportion of patients with EHR as their first recurrence (52.7%), pre- and/or peri-operative factors are considered to play critical roles in predicting early EHR.

Among the several factors associated with early EHR, serum albumin < 4.0 g/dL, serum ALP > 100 U/L, surgical margin involvement, venous and/or lymphatic involvement, satellite nodules, tumor necrosis, tumor size ≥ 7 cm, and the presence of macrovascular invasion confirmed on radiologic examination were identified as risk factors related to early EHR, as determined by multivariate Cox regression analysis (Table 3). The concentrations of albumin and/or ALP alone or in combination with

other parameters have been proposed as useful markers for predicting recurrence after surgical removal of HCC in previous studies[23-26]. Li *et al*[27] showed the prognostic value of the albumin-to-ALP ratio in patients with HCC who received liver transplants, whereas Yu *et al*[26] determined ALP concentration as an independent factor influencing disease-free survival and overall survival that aids in the prediction of recurrence in high-risk patients with HCC. Additionally, involvement of the surgical margins was related to poor clinical outcomes, as shown by a previous study[28] and a meta-analysis conducted by Zhong *et al*[29], which is consistent with the findings of our study. Chen *et al*[30] reported a poorer prognosis related to microvascular invasion in solitary small HCC in their meta-analysis, while Hasegawa *et al*[31] reported the association between lymphatic system involvement and patient survival after surgical resection of HCC, which are consistent with our findings. In a large-scale study of 734 patients who underwent surgery for HCC, satellite nodules, tumor size (> 5 cm), and the presence of macrovascular invasion were closely related to late recurrence of HCC in multivariate analysis (HR, 1.59, 1.49, and 4.63, respectively), and these findings are concordant with our study[32]. A recent study by Wei *et al*[33] reported that tumor necrosis was associated with the prognosis of patients undergoing surgery for HCC with regard to overall survival and RFS and advanced tumor characteristics, and Ling *et al*[34] also reported tumor necrosis as a potential parameter of the aggressiveness of HCC. Concordant with these previous study results, our study also demonstrated a significant association between tumor necrosis and early EHR.

In addition, we analyzed multiple factors associated with overall survival after surgical resection of HCC and identified that serum albumin < 4.0 g/dL, serum ALP > 100 U/L, major Edmondson-Steiner grade ≥ 3, pathological mUICC stage III or IVa, satellite nodules, tumor necrosis, and early EHR were related to survival (Table 4). Most risk factors exhibited similar results in the multivariate analysis of factors associated with early EHR (serum albumin < 4.0 g/dL, serum ALP > 100 U/L, satellite nodules, and tumor necrosis). The Edmondson-Steiner grade has been previously reported as a crucial predictor of recurrence and survival by Zhou *et al*[31] and Martins-Filho *et al*[32], and our study also showed poor survival outcomes in patients with major Edmondson-Steiner grade ≥ 3. Finally, early EHR showed a significant association with poor survival and increased the risk of death more than six times (HR, 6.77; 95%CI, 4.81-9.52; $P < 0.001$).

The cumulative rates of first recurrence and overall survival were correlated with the development of EHR and the interval to EHR (Figure 1). In particular, patients with early EHR showed substantially worse survival outcomes (HR, 6.77; 95%CI, 4.81-9.52; $P < 0.001$). Furthermore, considering the heterogeneity of patient characteristics regarding the tumor nature, degree of liver cirrhosis, and diverse disease courses after surgical resection, predictive markers of early EHR within 2 years after surgical resection with preoperative and/or operative factors may well reflect the initial state of the tumor.

We categorized the patients by the number of eight risk factors associated with early EHR and assessed the probability rates of EHR and overall survival. As demonstrated in Figure 2, there was a significant relationship between the number of the risk factors and the cumulative rates of both EHR and overall survival ($P < 0.001$). For a simple and intuitive predictive model of EHR, we subgrouped the patients into three categories: a low-risk group with 0-1 risk factor, an intermediate-risk group with 2-3 risk factors, and a high-risk group with ≥ 4 risk factors. The rates of both EHR and survival showed a substantial correlation with these risk stratifications. Hence, the prediction of early EHR after surgical resection of HCC may be regarded as essential, especially for high-risk patients.

Our study had several limitations. First, this study was retrospective and included patients with heterogenous clinical courses and outcomes. The postoperative surveillance methods, schedule, and treatment methods for recurrence of HCC were not fully standardized. To minimize the potential bias owing to the design of this study, we strived to enroll a large number of patients in multiple tertiary academic hospitals. Furthermore, the fact that more than half of the patients (52.7%) developed EHR as their first recurrence highlighted the importance of preoperative and operative factors. Second, although pathological confirmation of EHR was performed for a few patients, most instances of EHR were solely identified at the physician's discretion using imaging diagnostic modalities. Finally, owing to patient geographic characteristics, the majority of patients had chronic hepatitis B as the etiology of liver cirrhosis and HCC. Further studies are warranted to investigate characteristics and risk factors for early EHR in patients with diverse chronic hepatitis by using a standardized study protocol. Especially, the use of radiomic tumor features for the prediction of recurrence after HCC treatment can be considered as an additional tool for prompt detection of early EHR[35,36]. Using an accurate tool for the prediction of early EHR, the prognosis of patients with a high risk of early EHR may be improved with the utilization of adjunctive post-operative therapy.

CONCLUSION

Patients with early EHR showed rapid recurrence of HCC after surgical resection and significantly worse survival outcomes. . We derived several risk factors associated with early EHR and the numbers of risk factors correlated with not only with cumulative rates of EHR but also with survival rates. In terms of poor prognosis associated with early EHR, patients who undergo surgical resection for HCC

can be stratified by the risk of EHR with our model, and meticulous postoperative surveillance and adjuvant therapies may be required for timely EHR detection and positive clinical outcomes.

ARTICLE HIGHLIGHTS

Research background

Surgical resection is one of the most widely used modalities for the treatment of hepatocellular carcinoma (HCC). Early extrahepatic recurrence (EHR) of HCC after surgical resection is considered to be closely associated with poor prognosis.

Research motivation

Data regarding risk factors and survival outcomes of early EHR after surgical resection remain scarce.

Research objectives

We decided to investigate the clinical features and risk factors of early EHR and elucidate its association with survival outcomes.

Research methods

From January 2004 to December 2019, we enrolled treatment-naïve patients who were ≥ 18 years and underwent surgical resection for HCC in two tertiary academic centers. After excluding patients with tumor types other than HCC and/or ineligible data, this retrospective study finally included 779 patients. Surgical resection of HCC was performed according to the physicians' decisions and the EHR was diagnosed based on contrast-enhanced computed tomography or magnetic resonance imaging, and pathologic confirmation was performed in selected patients. Multivariate Cox regression analysis was performed to identify the variables associated with EHR.

Research results

Early EHR within 2 years after surgery was diagnosed in 9.5% of patients during a median follow-up period of 4.4 years. The recurrence-free survival period was 5.2 mo, and the median time to EHR was 8.8 mo in patients with early EHR. In 52.7% of patients with early EHR, EHR occurred as the first recurrence of HCC after surgical resection. On multivariate analysis, serum albumin < 4.0 g/dL, serum alkaline phosphatase > 100 U/L, surgical margin involvement, venous and/or lymphatic involvement, satellite nodules, tumor necrosis detected by pathology, tumor size ≥ 7 cm, and macrovascular invasion were determined as risk factors associated with early EHR. After sub-categorizing the patients according to the number of risk factors, the rates of both EHR and survival showed a significant correlation with the risk of early EHR. Furthermore, multivariate analysis revealed that early EHR was associated with substantially worse survival outcomes (hazard ratio, 6.77; 95% confidence interval, 4.81-9.52; $P < 0.001$).

Research conclusions

Early EHR significantly deteriorates the survival of patients with HCC, and our identified risk factors may predict the clinical outcomes and aid in postoperative strategies for improving survival.

Research perspectives

Further studies are warranted to investigate characteristics and risk factors for early EHR in patients with diverse chronic hepatitis by using a standardized study protocol. Using an accurate tool for the prediction of early EHR, the prognosis of patients with a high risk of early EHR may be improved with the utilization of adjunctive post-operative therapy.

Abstract

BACKGROUND

Early identification of metabolic-associated fatty liver disease (MAFLD) is urgent. Atherogenic index of plasma (AIP) is a reference predictor of obesity-related diseases, but its predictive value for MAFLD remains unclear. No studies have reported whether its combination with waist circumference (WC) and body mass index (BMI) can improve the predictive performance for MAFLD.

AIM

To systematically explore the relationship between AIP and MAFLD and evaluate its predictive value for MAFLD and to pioneer a novel noninvasive predictive model combining AIP, WC, and BMI while validating its predictive performance for MAFLD.

METHODS

This cross-sectional study consecutively enrolled 864 participants. Multivariate logistic regression analysis and receiver operating characteristic curve were used to evaluate the relationship between AIP and MAFLD and its predictive power for MAFLD. The novel prediction model A-W-B combining AIP, WC, and BMI to

predict MAFLD was established, and internal verification was completed by magnetic resonance imaging diagnosis.

RESULTS

Subjects with higher AIP exhibited a significantly increased risk of MAFLD, with an odds ratio of 12.420 (6.008-25.675) for AIP after adjusting for various confounding factors. The area under receiver operating characteristic curve of the A-W-B model was 0.833 (0.807-0.858), which was significantly higher than that of AIP, WC, and BMI (all $P < 0.05$). Subgroup analysis illustrated that the A-W-B model had significantly higher area under receiver operating characteristic curves in female, young and nonobese subgroups (all $P < 0.05$). The best cutoff values for the A-W-B model to predict MAFLD in males and females were 0.5932 and 0.4105, respectively. Additionally, in the validation set, the area under receiver operating characteristic curve of the A-W-B model to predict MAFLD was 0.862 (0.791-0.916). The A-W-B level was strongly and positively associated with the liver proton density fat fraction ($r = 0.630$, $P < 0.001$) and significantly increased with the severity of MAFLD ($P < 0.05$).

CONCLUSION

AIP was strongly and positively associated with the risk of MAFLD and can be a reference predictor for MAFLD. The novel prediction model A-W-B combining AIP, WC, and BMI can significantly improve the predictive ability of MAFLD and provide better services for clinical prediction and screening of MAFLD.

Core Tip: Metabolic-associated fatty liver disease (MAFLD) is the most common chronic liver disease, and early identification of MAFLD is urgent. This study demonstrated that the atherogenic index of plasma was strongly and positively associated with the risk of MAFLD, and it can be a reference predictor for MAFLD. Then, we pioneered a novel noninvasive prediction model, A-W-B, combining atherogenic index of plasma, waist circumference, and body mass index and validated its excellent predictive performance for MAFLD. Furthermore, we also pointed out the optimal cutoff values of the A-W-B model to predict MAFLD in males and females, which will facilitate early clinical identification of MAFLD in different sex populations. This study is highly innovative, and the noninvasive prediction model, A-W-B, is convenient, affordable, and easy to obtain, which can provide better services for clinical prediction and screening of MAFLD and metabolic-related diseases.

INTRODUCTION

Metabolic-associated fatty liver disease (MAFLD), formerly known as nonalcoholic fatty liver disease, is a common disease closely related to genetic, obesity, and metabolic abnormalities and has become a global public health problem[1,2]. In recent decades, obesity has become increasingly widespread owing to huge changes in dietary structure and living habits[3,4]. The prevalence of MAFLD has risen rapidly, and patients tend to be younger[5]. Notably, MAFLD can not only progress to hepatitis, liver cirrhosis, and liver cancer[6] but also increase the occurrence and development of diabetes[7] and cardiovascular diseases[8,9], which seriously endangers individual health and increases the social and medical economic burden[10]. Therefore, it is necessary to predict and screen MAFLD at an early stage to intervene in a timely manner.

The occurrence and development of MAFLD are closely related to lipid metabolism disorders and dyslipidemia caused by the accumulation of visceral fat[11]. Patients with fatty liver usually have elevated triglycerides (TG) and generally lower high-density lipoprotein cholesterol (HDL-C) than healthy people[12]. Waist circumference (WC) and body mass index (BMI) are commonly used as

indicators to assess obesity, and it has been shown that elevated WC and BMI can significantly increase the risk of fatty liver disease. However, they have certain limitations in accurately reflecting the accumulation of visceral fat[13].

Recently, the atherogenic index of plasma (AIP), calculated from the logarithm of the ratio of TG to HDL-C[14], has been proven to be closely related to abdominal obesity, and it can sensitively reflect the accumulation of visceral fat and effectively predict the risk of atherosclerosis and cardiovascular disease [15,16]. Previous studies indicate that AIP is significantly higher in patients with fatty liver and may be a potential indicator for identifying fatty liver disease[17]. However, few studies have systematically reported the predictive value of AIP for MAFLD and whether AIP combined with WC and BMI can improve the predictive ability for MAFLD is unclear.

Therefore, the two main objectives of this study were: (1) To systematically assess the relationship between AIP and MAFLD and evaluate its predictive value for MAFLD; and (2) To establish a novel noninvasive prediction model combining AIP, WC and BMI and validate its predictive performance for MAFLD.

MATERIALS AND METHODS

Study design and participants

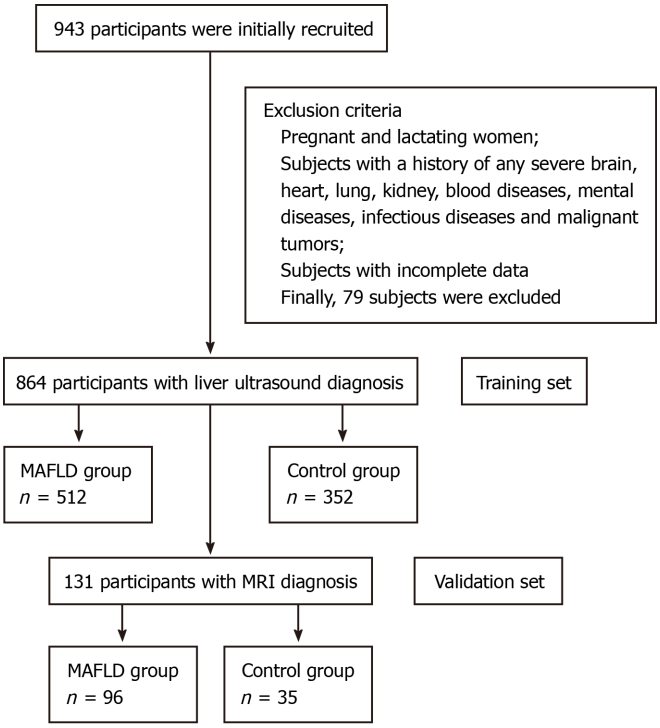
This study was conducted in Beijing, China. Among the adults who underwent a physical examination for health at China-Japan Friendship Hospital in Beijing from September 2018 to October 2021, we consecutively recruited 943 participants who completed the standardized questionnaire, finished anthropometric and laboratory tests, and underwent liver ultrasonography. All subjects agreed to participate in this study voluntarily and submitted informed consent forms.

According to quality control, after excluding pregnant and lactating women, subjects who had a history of any severe brain, heart, lung, kidney, or blood diseases, mental illness, infectious diseases, malignant tumors, *etc* as well as the subjects with incomplete data, a total of 864 subjects were finally included (Figure 1), with 624 males and 240 females, aged from 20-years-old to 78-years-old.

This study was approved by the Clinical Research Ethics Committee of China-Japan Friendship Hospital (2018-110-K79-1).

Data collection and definition

The physical examination was performed in the morning in a fasting state. Anthropometric indicators were measured by professionally trained doctors. Height, weight, and waist circumference were measured while subjects were naturally standing barefoot with lightweight clothes. After 10 min of rest, the blood pressure was measured with an upper arm electronic sphygmomanometer. Peripheral blood was drawn into an EDTA-containing tube and subjected to biochemical experiments within 2 h. The relevant laboratory indicators were obtained through the electronic database of this physical examination center, including alanine aminotransferase (ALT), aspartate aminotransferase (AST), total cholesterol, TG, HDL-C, low-density lipoprotein cholesterol, fasting blood glucose (FBG), serum uric acid (SUA) and so on.



BMI was calculated as the body weight (in kilograms) divided by the square of the height (in meters). WC referred to the waist circumference at the level of the flat navel. AIP was calculated as the logarithmic transformation of the ratio of TG to HDL-C [log (TG/HDL-C)].

Diagnostic criteria and detection methods of MAFLD

The diagnostic criteria of MAFLD refer to the consensus of international experts in 2020 that in addition to the evidence of hepatic steatosis[18], one of the following three criteria, namely, overweight/obesity, type 2 diabetes, or metabolic dysregulation, needs to be met[19,20]. Among them, metabolic dysregulation refer to the existence of at least two of the following metabolic risk criteria: (1) Waist circumference ≥ 102/88 cm in Caucasian males and females, respectively, or ≥ 90/80 cm in Asian males and females; (2) Blood pressure ≥ 130/85 mmHg or specific drug treatment; (3) Plasma TG ≥ 1.70 mmol/L or specific drug treatment; (4) Plasma HDL-C < 1.0 mmol/L for males and < 1.3 mmol/L for females or specific drug treatment; (5) Prediabetes (*i.e.* fasting glucose levels 5.6 to 6.9 mmol/L or 2-h post load glucose levels 7.8 to 11.0 mmol or glycated hemoglobin 5.7% to 6.4%; (6) Homeostasis model assessment-insulin resistance score ≥ 2.5; and (7) Plasma high-sensitivity C-reactive protein level > 2 mg/L.

In the training set, fatty liver (hepatic steatosis) was defined by liver ultrasound examination based on at least two of the following three abnormal findings: (1) Diffusely increased echogenicity of the liver relative to the kidney or spleen; (2) Ultrasound beam attenuation; and (3) Poor visualization of intrahepatic structures.

In the validation set, the proton density fat fraction (PDFF) based on magnetic resonance spectroscopy and magnetic resonance imaging (MRI) was used to diagnose fatty liver and to evaluate the severity of MAFLD[21]. PDFF < 5% was defined as no fatty liver, PDFF 5.0%-14.0% was defined as mild MAFLD, and PDFF > 14.0% was defined as moderate to severe MAFLD.

Figure 1 Flow chart of the study subjects. MAFLD: Metabolic-associated fatty liver disease; MRI: Magnetic resonance imaging.

Statistical analysis

First, the baseline characteristics of the MAFLD and non-MAFLD groups were compared. The independent samples *t* test was used for comparing normally or approximately normally distributed quantitative data between groups, expressed as the mean and standard deviation (SD). The Mann-Whitney *U* test was used for comparing nonnormally distributed quantitative data between groups, represented as medians and quartiles. The χ^2 test was used for comparing categorical data between groups, represented as numbers and percentages.

Then, multivariate logistic regression analysis was conducted to calculate the odds ratios (ORs) and 95% confidence intervals of AIP for MAFLD under different adjustment conditions. The logistic regression prediction model A-W-B combining AIP, WC, and BMI was established. The Hosmer-Lemeshow test and the receiver operating characteristic (ROC) curve were used to evaluate the calibration and discrimination of this model. The DeLong test was used to compare the predictive ability of the AIP, WC, BMI, and A-W-B model for MAFLD. Spearman's correlation analysis was used to explore the correlation between parameters. Finally, the internal verification was completed with MRI as the diagnostic standard.

All statistical tests were two-tailed and were considered significant for *P* less than 0.05 ($P < 0.05$). Statistical analyses were performed using Statistical Package for the Sciences (SPSS, version 25.0) and MedCalc statistical software (version 19.6.4).

RESULTS

Characteristics of participants

The demographics, anthropometrics, and laboratory test characteristics of 864 subjects are presented in Table 1. The prevalence of male and young patients (age < 40-years-old) and the percentage of smoking history, drinking history, overweight, obesity, elevated ALT, and elevated ALT in MAFLD subjects were significantly higher than those in the non-MAFLD subjects (all $P < 0.05$). Participants with MAFLD had dramatically higher WC, BMI, SBP, DBP, ALT, AST, total cholesterol, TG, low-density lipoprotein cholesterol, FBG, and SUA and significantly lower AST/ALT and HDL-C (all $P < 0.05$). In addition, a significant association between AIP and MAFLD was initially demonstrated.

Multivariate logistic regression analysis of AIP on the risk of MAFLD

Multivariate logistic regression analyses were conducted to further explore the relationship between AIP and MAFLD, and the results are shown in Table 2. AIP had a strong association with the risk of MAFLD, and the OR for a 1-SD increase in AIP was 50.286 (26.953-93.819) without adjustment (Model

[1]Comparison of significant differences between the two groups; χ2 value calculated by the χ2 test; *Z* value calculated by the Mann-Whitney *U* test; *t* value calculated by the independent samples *t* test. Data are presented as median and interquartile range, mean and standard deviation or frequency (percentage). MAFLD: Metabolic-associated fatty liver disease; WC: Waist circumference; BMI: Body mass index; SBP: Systolic blood pressure; DBP: Diastolic blood pressure; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; TC: Total cholesterol; TG: Triglyceride; HDL-C: High-density lipoprotein cholesterol; LDL-C: Low-density lipoprotein cholesterol; FBG: Fasting blood glucose; SUA: Serum uric acid; AIP: Atherogenic index of plasma.

1). After adjusting for sex and age, the OR for a 1-SD increase in AIP was 48.874 (26.087-91.569) (Model 2). After further adjusting for smoking history, drinking history, WC, and BMI, the degree of this association changed but was still strong; the OR for a 1-SD increase in AIP was 16.184 (7.961-32.902) (Model 3). Further adjusting for SBP, DBP, ALT, AST, total cholesterol, TG, HDL-C, low-density lipoprotein cholesterol, FBG, and SUA attenuated the association but only slightly; there was still a 12.420-fold (6.008-25.675) higher risk for MAFLD with a 1-SD increase in AIP (Model 4).

After dividing AIP into quartiles, the risk of MAFLD increased robustly with higher AIP quartiles. When comparing the top quartiles with the bottom categories, the risk of MAFLD increased 16.882-fold to 7.160-fold from Model 1 to Model 4. The *P* values for the linear trend were less than 0.01, signifying that linear trends from the lowest to the highest quartiles were eminent.

Predictive ability of AIP for MAFLD in different subgroups

The ROC curve of AIP for predicting MAFLD in different sex, age, and weight subgroups was plotted, and the DeLong test was used to compare the area under the ROC curve (AUC) between the subgroups. As shown in Figure 2, the AUC of AIP for MAFLD in the young was significantly higher than that in middle-age and elderly subjects [0.816 (0.779-0.849) *vs* 0.726 (0.678-0.771), $P < 0.05$]. The AUC of AIP for MAFLD in nonobese subjects was significantly higher than that in obese subjects [0.783 (0.747-0.816) *vs* 0.579 (0.519-0.638), $P < 0.0001$]. However, there was no significant difference between males and females

Model 1: Unadjusted. Model 2: Adjusted for age and sex. Model 3: Adjusted for age, sex, smoking history, drinking history, waist circumference and body mass index. Model 4: Adjusted for age, sex, smoking history, drinking history, waist circumference, body mass index, systolic blood pressure, diastolic blood pressure, alanine aminotransferase, aspartate aminotransferase, total cholesterol, triglyceride, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, fasting blood glucose, and serum uric acid. AIP: Atherogenic index of plasma; SE: Standard error; OR: Odds ratio; CI: Confidence interval; SD: Standard deviation.

(P = 0.0639).

In addition, the best cutoff values for AIP to predict MAFLD in males and females were 0.0821 and -0.1390, respectively. The AUCs of AIP, WC, and BMI for predicting total MAFLD were 0.780 (0.751-0.807), 0.790 (0.761-0.817), and 0.788 (0.759-0.814), respectively, with no significant difference among the three (Table 3).

Establishment of the A-W-B model for better predicting MAFLD

To further improve the predictive ability of MAFLD, we combined AIP, WC, and BMI and put them into the binary logistic regression model to construct a new logistic regression prediction model, A-W-B. The regression equation was logit (A-W-B) = -8.782 + 2.560 × AIP + 0.049 × WC + 0.170 × BMI (Table 4).

The Hosmer-Lemeshow test and ROC curve analysis were used to evaluate the calibration and discrimination of the A-W-B model. Figure 3A illustrated the calibration line graph of the A-W-B model, and the result of the Hosmer-Lemeshow test showed that χ^2 = 8.5901, P = 0.3780 > 0.05, indicating that the A-W-B model had a good calibration ability for MAFLD. Figure 3B illustrated the ROC curve of the A-W-B model, with the AUC of 0.833 (0.807-0.858), indicating that the A-W-B model had a good

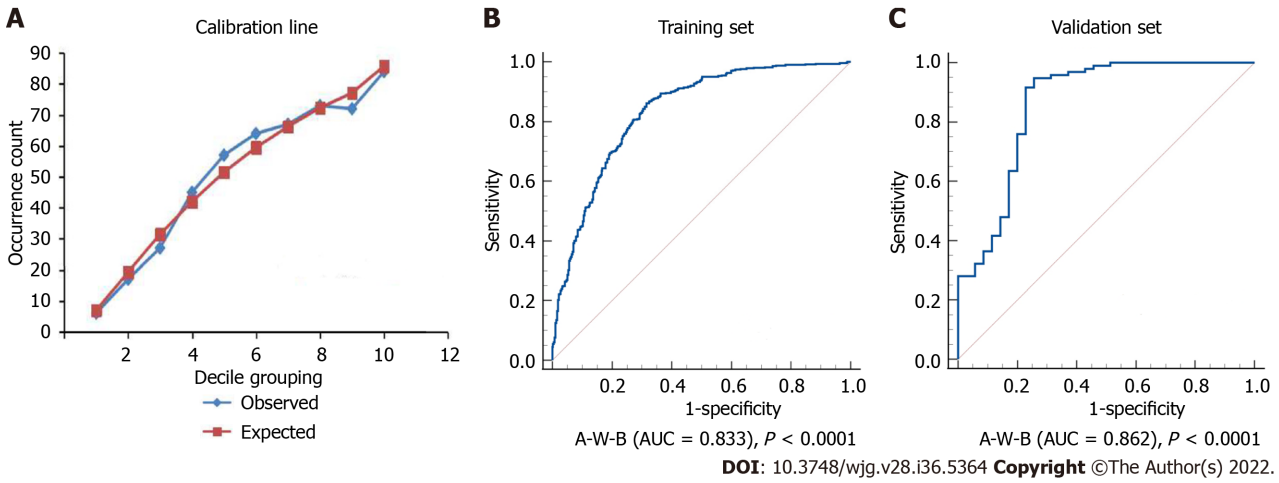
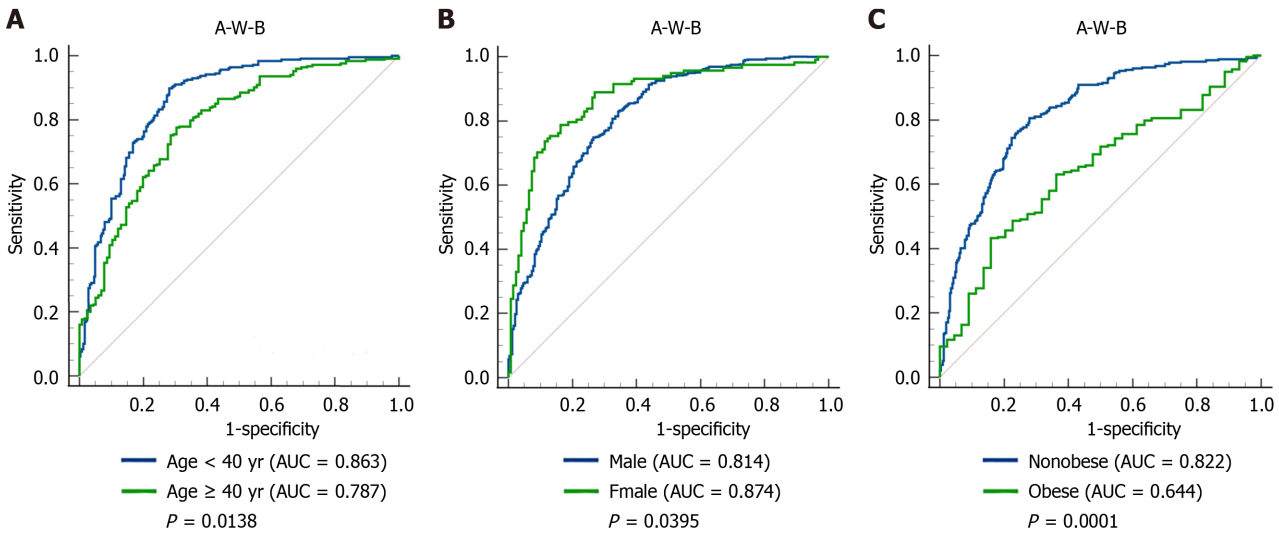
discrimination ability for MAFLD.



Predictive ability of the A-W-B model for MAFLD in different subgroups

To further evaluate the predictive power of the A-W-B model for MAFLD in different populations, we performed a subgroup analysis. As shown in Figure 4, the AUCs of A-W-B for MAFLD in female, young, and nonobese subjects were 0.874 (0.826-0.914), 0.863 (0.830-0.892), and 0.822 (0.789-0.852), respectively, which were significantly higher than those in male [0.814 (0.781-0.843)], middle-aged and elderly [0.787 (0.742-0.828)], and obese subjects [0.644 (0.585-0.700)] (all $P < 0.05$). These results indicated that the A-W-B model had stronger predictive power for MAFLD in female, young, and nonobese subjects. Furthermore, the results in Table 3 showed that the best cutoff values for A-W-B to predict MAFLD in males and females were 0.5932 and 0.4105, respectively.

Comparison of the A-W-B model and AIP, WC, and BMI for predicting MAFLD



The DeLong test was used to compare the predictive ability of the A-W-B model and AIP, WC, and BMI. The AUC of the A-W-B model for MAFLD was 0.833 (0.807-0.858), which was significantly higher than that of AIP, WC, and BMI ($P < 0.05$). The sensitivity, specificity, Youden index, and cutoff value of the A-W-B model were 86.13%, 68.47%, 0.5460, and 0.5019, respectively (Table 3).

As shown in Figure 5A-E, subgroup analysis showed that the AUCs of the A-W-B model were significantly higher than those of AIP, WC, and BMI in male, female, young, middle-aged and elderly, and nonobese subjects (all $P < 0.01$), demonstrating that the A-W-B model has a higher ability to predict MAFLD than AIP, WC, and BMI in different age, sex, and nonobese subjects. However, as shown in Figure 5F, among obese subjects, the predictive ability of the A-W-B model for MAFLD was only better than that of AIP. In addition, the Z values between the AIP, WC, BMI, and the A-W-B model in different subgroups were illustrated in Supplementary Table 1.

Figure 4 Receiver operating characteristic curves of the A-W-B model to predict metabolic-associated fatty liver disease in different subgroups. A: Comparison between young (age < 40 years) and middle-age and elderly (age ≥ 40 years) subjects (P = 0.0138); B: Comparison between male and female subjects (P = 0.0395); C: Comparison between nonobese and obese subjects (P = 0.0001); AUC: Area under the receiver operating characteristic curve; A-W-B: Prediction model combining atherogenic index of plasma, waist circumference, and body mass index.

The concrete ROC curve results of the AIP, WC, BMI, and A-W-B model for predicting MAFLD in different subgroups were illustrated in Table 3. Compared to AIP, WC, and BMI, the A-W-B model had the best sensitivity in male, young and nonobese subjects, which may be more conducive to identifying patients with positive MAFLD to reduce the missed diagnosis rate. Meanwhile, the A-W-B model had the best specificity in female and middle-aged and elderly subjects, which may be more beneficial to identifying people without MAFLD and reducing the misdiagnosis rate.

Moreover, Spearman's correlations between A-W-B, AIP, WC, BMI, and various physical and chemical indicators are illustrated in Table 5. Compared with AIP, WC, and BMI, the A-W-B model had a higher positive association with SBP, DBP, ALT, AST, FBG, and SUA.

Validation of the A-W-B model

To further validate the diagnostic performance of the A-W-B model for MAFLD, we randomly selected approximately 15% of the subjects (131 cases) from the overall subjects as the validation set and used MRI to diagnose MAFLD. Among them, 35 cases were in the control group, 67 cases were mild MAFLD, and 29 cases were moderate to severe MAFLD. The data comparison between the training set and validation set was shown in Table 6. There was no statistically significant difference in age, sex, and

various indicators between the two groups (all $P > 0.05$).

Figure 3C illustrated the ROC curve of the A-W-B model in the validation set, with the AUC of 0.862 (0.791-0.916), indicating that the A-W-B model also exhibited outstanding discrimination for MAFLD in the validation set. In addition, Figure 6 shows that the A-W-B level was strongly and positively associated with the PDFF ($r = 0.630$, $P < 0.001$). With the degree of severity of MAFLD increased, the A-W-B level also increased significantly ($P < 0.05$).

DISCUSSION

In this study, the relationship between AIP and MAFLD was systematically assessed, and it was confirmed that AIP had a strong and positive association with the risk of MAFLD and can be used as a reference predictor for MAFLD. Then, to further improve the predictive power for MAFLD, we combined AIP, WC, and BMI to pioneer a novel noninvasive prediction model, A-W-B, and confirmed that it had a better predictive value for MAFLD than AIP, WC, and BMI. At the same time, we also pointed out the optimal cutoff values of the A-W-B model to predict MAFLD in males and females, which will facilitate early clinical identification of MAFLD in different sex populations. Finally, we internally validated the model with MRI as the diagnostic standard, further affirming its outstanding predictive performance for MAFLD, which provided a new tool for the early prevention and screening of MAFLD.

As a new type of body fat index calculated as the logarithmic transformation of the ratio of TG to HDL-C, AIP is more sensitive to visceral fat accumulation than WC and BMI and has shown predictive potential for fatty liver in previous studies[15]. Xie *et al*[17] found that a higher AIP level was positively associated with fatty liver, which might be a novel and strong predictor associated with fatty liver in the Chinese Han population. In this study, the multivariate logistic regression results showed that the subjects with higher AIP still exhibited a significantly increased risk of MAFLD after adjusting for age, sex, smoking history, drinking history, WC, BMI, and various physical and chemical indicators, indicating that AIP was strongly and positively associated with the risk of MAFLD.

Visceral fat accumulation has been proven to increase the prevalence of a variety of cardiovascular risk factors, including insulin resistance and dyslipidemia, which also play a tremendously crucial role in the pathogenesis of fatty liver disease[16]. It is widely accepted that the increased TG caused by liver lipid accumulation is a prerequisite for MAFLD and that insulin resistance is a key factor during its development. Previous studies demonstrated that increasing levels of TG and decreasing concentrations of HDL-C could reduce sensitivity to insulin, and higher TG/HDL-C usually indicates insulin resistance [22], which may explain the close relationship between AIP and MAFLD. In addition, this study also pointed out the optimal cutoff values of AIP for predicting MAFLD in males and females, which provided a new idea for the early prevention of MAFLD. People with AIP levels above this cutoff point may be at higher risk for MAFLD and require more attention to liver conditions.

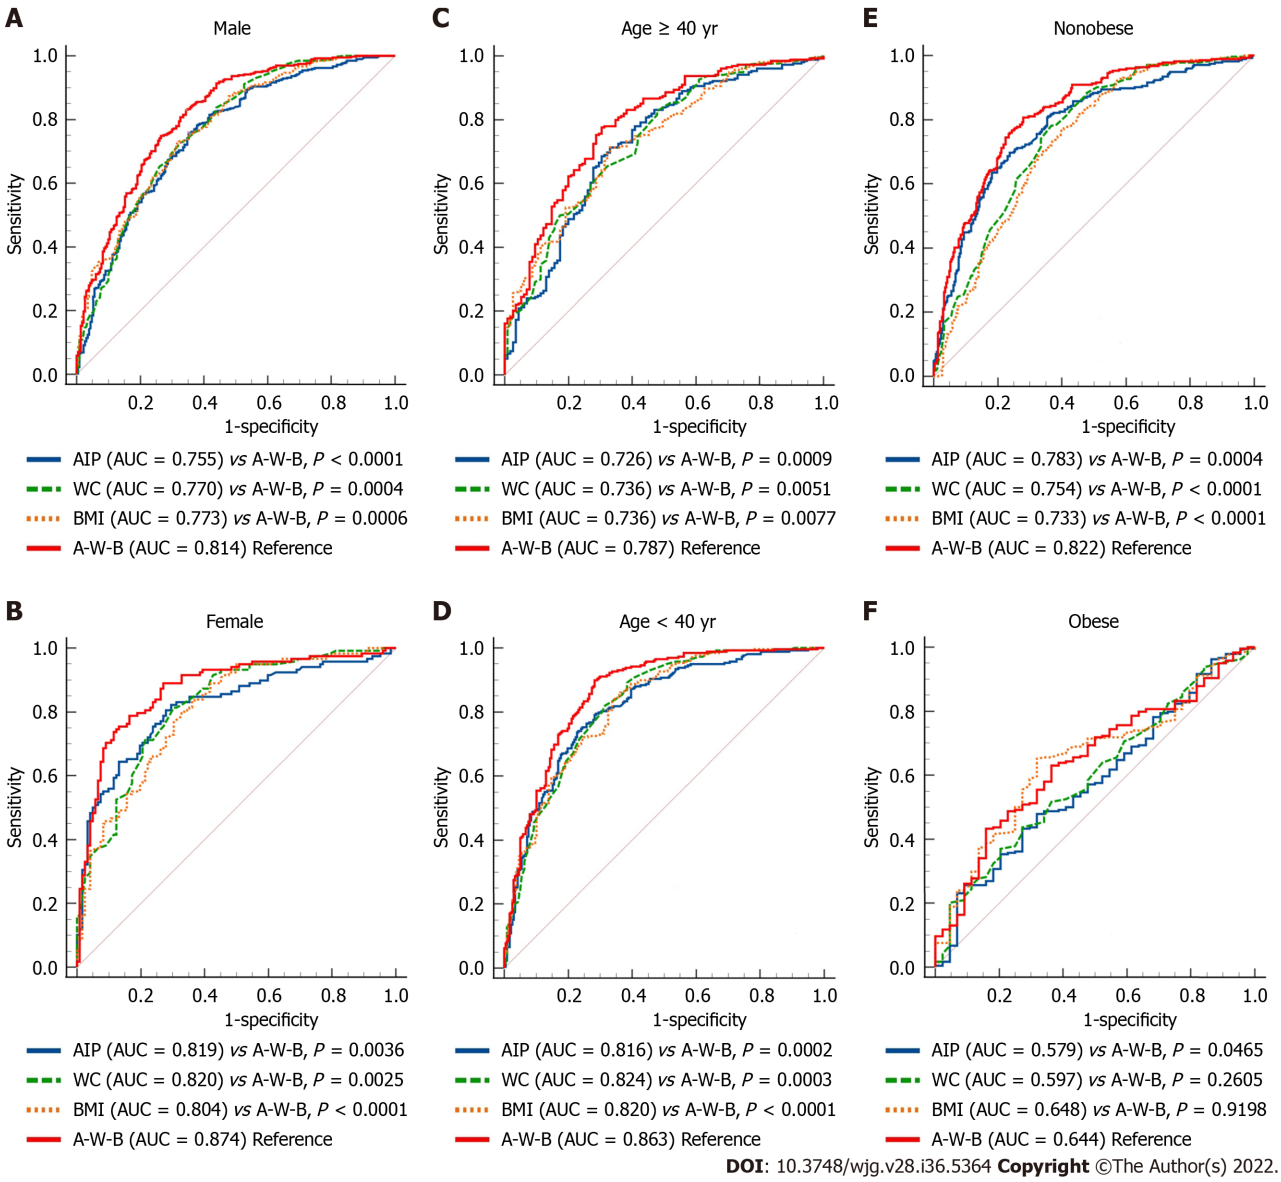

Table 6 Data comparison between training set and validation set

Variable	Training set, *n* = 864	Validation set, *n* = 131	*P* value
Sex, female	240 (27.8)	38 (29.0)	0.770
Age in yr	39.820 ± 10.934	39.660 ± 10.861	0.885

SUA in μmol/L	359.434 ± 88.800	342.901 ± 88.448	0.052
AIP	0.09 (-0.13, 0.30)	0.12 (-0.13, 0.33)	0.306

Data are presented as median and interquartile range, mean ± SD, or *n* (%). WC: Waist circumference; BMI: Body mass index; SBP: Systolic blood pressure; DBP: Diastolic blood pressure; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; TC: Total cholesterol; TG: Triglyceride; HDL-C: High-density lipoprotein cholesterol; LDL-C: Low-density lipoprotein cholesterol; FBG: Fasting blood glucose; SUA: Serum uric acid; AIP: Atherogenic index of plasma.

Xie *et al*[17] indicated that the ORs of AIP on the risk of fatty liver disease in women and young adults increased faster. This study showed that the AIP had a better predictive ability for MAFLD in young subjects, which may be related to the higher excessive fat accumulation of young people caused by dietary irregularities and insufficient exercise. However, there was no significant difference between males and females. Wang *et al*[23] and Dong *et al*[24] studied the predictive value of AIP for nonalcoholic fatty liver disease in obese and nonobese populations separately, with AUCs of 0.718 and 0.803, respectively. It seems that the predictive ability of AIP in the nonobese population might be better, but no studies have directly compared the ability of AIP in identifying MAFLD between different weights. Fortunately, our study filled this gap, and confirmed that the AIP had a remarkably higher predictive ability for MAFLD in nonobese subjects. A cohort study demonstrated that visceral obesity was dose-dependently associated with nonalcoholic fatty liver disease[25]. It is worth noting that lean people with unhealthy metabolism may have a greater accumulation of visceral fat[26], and nonobese MAFLD patients with unhealthy metabolism usually exhibit higher liver damage and cardiovascular risks[27]. AIP, as a sensitive indicator that reflects the accumulation of visceral fat, might have a stronger association with nonobese MAFLD patients and thus might have a better predictive ability for MAFLD in nonobese populations.

WC and BMI are common indicators for obesity evaluation and have been proven to be good predictors of fatty liver[17]. This study confirmed that they also had good predictive ability for MAFLD, with no significant difference compared to AIP. However, no previous study has assessed the predictive power of AIP combined with WC and BMI for MAFLD. Therefore, another focus of this study was to explore whether AIP combined with WC and BMI can improve the ability to identify MAFLD. The results showed that the logistic regression prediction Model A-W-B established by AIP combined with WC and BMI had excellent calibration and discrimination for MAFLD and had a significantly better ability to identify MAFLD. At the same time, it also had an outstanding ability to identify MAFLD in the validation, further affirming its outstanding predictive performance for MAFLD. Interestingly, we also found that the level of A-W-B was positively correlated with the liver fat content and the degree of severity of MAFLD in the validation, which may be objective evidence explaining the positive association and excellent predictive ability of the A-W-B model for MAFLD.

Figure 5 Receiver operating characteristic curves of atherogenic index of plasma, waist circumference, body mass index, and A-W-B model to predict metabolic-associated fatty liver disease in different subgroups. A-E: The area under the receiver operating characteristic curve (AUC) of the prediction model combining atherogenic index of plasma, waist circumference (WC), and body mass index (BMI) (A-W-B) model was significantly higher than that of A-W-B in male, female, young, middle-aged and elderly, and nonobese subjects (all $P < 0.01$); F: The AUC of the A-W-B model was only better than atherogenic index of plasma (AIP) in obese subjects ($P = 0.0465$).

The Spearman's correlation analysis showed that AIP, WC, and BMI were all positively associated with SBP, DBP, ALT, AST, FBG, and SUA. Notably, these physical and chemical indicators were also risk factors for MAFLD, and compared with AIP, WC, and BMI, the A-W-B model had a higher correlation with SBP, DBP, ALT, AST, FBG, and SUA, which may indirectly explain the better correlation and predictive ability of the A-W-B model for MAFLD. Furthermore, this study also pointed out that the optimal cutoff values of the A-W-B model to predict MAFLD in males and females were 0.5932 and 0.4105, respectively, which will facilitate early clinical identification of MAFLD in different sex populations. When the A-W-B level of the subject is above the cutoff point, it can be preliminarily identified as MAFLD.

In summary, compared with other studies, this study has the following advantages. First, this study confirmed that AIP was strongly and positively associated with the risk of MAFLD, and it can be a reference predictor for MAFLD and determined the optimal cutoff values of AIP for predicting MAFLD in males and females, providing a new idea for early prevention of MAFLD. Then, we pioneered a novel noninvasive prediction model A-W-B combining AIP, WC, and BMI that can significantly improve the predictive ability for MAFLD and determined its optimal cutoff values of the A-W-B model to predict MAFLD in males and females. Furthermore, we also validated the model with MRI as the diagnostic standard, further affirming its outstanding predictive performance for MAFLD. This study is highly innovative, and this noninvasive prediction model A-W-B is convenient, affordable, and easy to obtain,

Figure 6 Correlation between A-W-B levels with liver proton density fat fraction and the severity of metabolic-associated fatty liver disease. A: The prediction model combining atherogenic index of plasma, waist circumference, and body mass index (A-W-B) level was strongly and positively associated with liver proton density fat fraction (PDFF) (r = 0.630, P < 0.001); B: Compared with the control group, ^{b}P < 0.001; compared with the mild group, ^{a}P < 0.01. MAFLD: Metabolic-associated fatty liver disease.

which can provide better services for clinical prediction and screening of MAFLD and metabolic-related diseases.

However, there are still some limitations. First, to avoid subject recall bias, this study did not collect confounding factors, such as specific dietary structure and physical activity, and mainly focused on objective laboratory indicators and basic demographic indicators, which may slightly affect the results of multiple logistic regression analysis. Second, the subjects in this study were limited to a single physical examination center, which may cause selection bias. Third, fatty liver in the training set of this study was diagnosed by abdominal ultrasonography, and we did not use ultrasonography to accurately classify the severity of MAFLD. Therefore, the relationship between AIP, A-W-B model, and the severity of fatty liver by ultrasonography was unclear. Notably, we found that the A-W-B levels were positively correlated with MRI-diagnosed MAFLD severity in the validation set. However, due to limited funds, the number of validation sets using MRI as the diagnostic standard was relatively small. Therefore, further multicenter, large-sample prospective cohort studies are needed in the future to verify and explore the predictive value of AIP and A-W-B for MAFLD and differential severity.

CONCLUSION

AIP was strongly and positively associated with MAFLD, and it can be a reference predictor for MAFLD. The novel noninvasive prediction model A-W-B combining AIP, WC, and BMI can significantly improve the predictive ability for MAFLD and provide better services for clinical prediction and screening of MAFLD.

ARTICLE HIGHLIGHTS

Research background

Metabolic-associated fatty liver disease (MAFLD) is the most common chronic liver disease and poses great harm to people's health. Early identification of MAFLD is imminent.

Research motivation

Atherogenic index of plasma (AIP) is a reference predictor of obesity-related diseases, but its predictive value for MAFLD remains unclear. No studies have reported whether its combination with waist circumference (WC) and body mass index (BMI) can improve the predictive performance for MAFLD.

Research objectives

This study had two main objectives: (1) To systematically explore the relationship between AIP and MAFLD and evaluate its predictive value for MAFLD; and (2) To pioneer a novel prediction model combining AIP, WC, and BMI and validate its predictive performance for MAFLD.

Research methods

This cross-sectional study consecutively enrolled 864 participants. Multivariate logistic regression analysis and receiver operating characteristic curve were used to evaluate the relationship between AIP and MAFLD and its predictive power for MAFLD. The novel prediction model A-W-B combining AIP, WC, and BMI to predict MAFLD was established, and internal verification was completed by magnetic resonance imaging diagnosis.

Research results

Subjects with higher AIP exhibited a significantly increased risk of MAFLD, with an odds ratio of 12.420 (6.008-25.675) for AIP after adjusting for various confounding factors. The area under receiver operating characteristic curve of the A-W-B model was 0.833 (0.807-0.858), which was significantly higher than that of AIP, WC, and BMI (all P <0.05). The best cutoff values for the A-W-B model to predict MAFLD in males and females were 0.5932 and 0.4105, respectively. Additionally, in the validation set the area under receiver operating characteristic curve of A-W-B model to predict MAFLD was 0.862 (0.791-0.916). The A-W-B level was strongly and positively associated with the liver proton density fat fraction (r = 0.630, P < 0.001) and significantly increased with the severity of MAFLD (P < 0.05).

Research conclusions

AIP was strongly and positively associated with MAFLD and can be a reference predictor for MAFLD. The novel noninvasive prediction model A-W-B combining AIP, WC, and BMI can significantly improve the predictive ability for MAFLD and provide better services for clinical prediction and screening of MAFLD.

Research perspectives

Studies that may be conducted in the future should further explore the predictive value of AIP and the A-W-B model for different severities of MAFLD and other related metabolic diseases.

Abstract

The burden of non-alcoholic steatohepatitis (NASH) related hepatocellular carcinoma (HCC) is drawing attention due to the emerging epidemic of obesity and metabolic syndrome and is expected to increase in the near future. Antidiabetic medications, air pollutants, and newer genetic mutations are latest concerns as risk factors for HCC development in patients with NASH. Although molecular signatures are very accurate, they are not cost-effective and cannot be applied in larger population due to logistic issues. We need multicentric longitudinal studies including diverse geographical areas to evaluate the complex interplay of different risk factors and genetics in these patients.

Key Words: Non-alcoholic steatohepatitis; Hepatocellular carcinoma; Cirrhosis; Genetic factors; Lifestyle factors; Surveillance

Core Tip: Nonalcoholic steatohepatitis (NASH) is a metabolic liver disease which also involves multiple organs like the heart, lungs, and kidneys. NASH may arise primarily, followed by involvement of other organs, or it may come late in the course of metabolic syndrome. The multidisciplinary approach is needed towards a patient with diabetes, obesity, and metabolic syndrome to address all issues related to the liver, heart, *etc.* Genetic and molecular signatures have provided a ray of hope for estimating risk in these patients; however, it has many practical issues. The impact of environmental pollutants and toxins as a causative factor in NASH, especially lean patient population, should also be considered. We need population based studies from different geographical areas for estimation of metabolic, environmental, and genetic risk factors.

TO THE EDITOR

Chrysavgis *et al*[1] have extensively reviewed the literature on non-alcoholic steatohepatitis (NASH) related hepatocellular carcinoma (HCC) with regard to its risk stratification, screening, and surveillance strategies. Metabolic syndrome is a systemic disease involving the heart, kidneys, lungs, and liver, *etc.* NASH is the liver manifestation of metabolic syndrome. With the emerging epidemic of obesity and metabolic syndrome, NASH is expected to supersede all other etiologies of liver cirrhosis as well as HCC. In various studies as discussed by Chrysavgis *et al*[1], the prevalence of HCC in non-cirrhotic non-alcoholic fatty liver disease (NAFLD) patients ranges from 15%-55%. Factors like age, male sex, concomitant smoking and alcohol intake, obesity, and type 2 diabetes mellitus have been shown to increase the risk of HCC in non-cirrhotic NASH. Recently, use of insulin and sulfonylureas has also been shown to increase the long-term risk of HCC in patients with diabetes. In an Italian study[2], an increased HCC risk with an odds ratio of 3.7 for insulin, 1.3 for sulfonylureas, and 2.1 for repaglinide was found in patients with diabetes. Even the duration of treatment with insulin, though not with other therapies, increased the risk of HCC. The same has also been confirmed in a nationwide nested case-control study[3] in Korea which showed an increased HCC risk with glimepiride instead of other sulfonylureas. And yet we do not have long-term data for GLP-1 agonists and DPP4 inhibitors. Chinese data[4] recently showed an increased association of air pollutants of particulate matter (PM) with an aerodynamic diameter of < 1 (PM_1), < 2.5 ($PM_{2.5}$), and < 10 μm (PM_{10}) with metabolic associated fatty liver disease. The role of intestinal dysbiosis has also been investigated in animal models and found to be associated with an increased risk of NASH and HCC.

In a multicentric trial, Pinyol *et al*[5] collected samples from NASH-HCC and NASH patients, performed expression array and whole exome sequencing, and compared it with HCC from non-NASH etiologies like viral/alcohol. They found *TERT* promoter, *CTNNB1*, *TP53*, and *ACVR2A* most frequently to be present in NASH-HCC patients. The *ACVR2A* (activin type 2 receptor gene) mutation was found in a higher number of patients with NASH-HCC as compared to those with HCC of other etiologies. The molecular signature revealed higher expression of bile acid and fatty acid signaling pathways. The Wnt/TGF-β proliferation subclass was more common in NASH-HCC. The upcoming data suggests that the molecular signature of NASH-HCC is different from that of HCC due to other etiologies. Collectively, the development of NAFLD-HCC results from a complex interplay of multiple factors related to unhealthy life style, environment, and genetics of an individual.

The authors have included abbreviated magnetic resonance imaging (MRI) in their suggested algorithm for HCC surveillance in NAFLD due to a poor window of ultrasound in obese patients. We have concerns regarding this strategy. First, a large number of individuals would need surveillance, so its cost-effectiveness, availability on large scale, and practicality need to be addressed. Second, how frequently MRI would have to be repeated is a practical issue. Third, when during the clinical course of NASH, screening should be performed. Although authors have included HCC risk model as suggested by Ioannou *et al*[6] in their algorithm, we believe that future prospective longitudinal studies are needed to determine the weightage of different risk factors in determining HCC risk in patients with cirrhotic and non-cirrhotic NAFLD, separately. The role of extracellular vesicles (EVs) for molecular characterization of HCC in patients with NASH may further be evaluated for HCC surveillance also. NAFLD is a risk factor not only for HCC but also for colorectal and breast cancers. Instead of screening for each carcinoma separately, we need to have studies on a common platform targeting the molecular signatures in blood for surveillance of different carcinomas in the body which share the pathogenetic mechanisms or pathways. The challenges involved are large population-based studies in different geographical regions, mapping of molecular signatures, and implementation. It has to be cost-effective, easily accessible, and readily available.

In patients with NAFLD, all-cause mortality includes mortality related to issues of the liver, heart, kidneys, lungs, *etc.* It is time to recognise the need for multidisciplinary approach towards a patient with diabetes, obesity, and metabolic syndrome to address all issues related to the liver, heart, kidneys, *etc.* Large prospective, multicentric studies including diverse geographical regions and dietary habits are needed to evaluate for risk stratification in these patients regarding need for HCC surveillance.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Masahiro Iizuka, MD, PhD, Director, Akita Health Care Center, Akita Red Cross Hospital, 3-4-23 Nakadori, Akita-shi, Akita 010-0001, Japan. maiizuka@woody.ocn.ne.jp

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

After three rounds of rigorous evaluation of core journals in gastroenterology and hepatology conducted by the *Reference Citation Analysis* (*RCA*) editorial team of Baishideng Publishing Group (Baishideng), the *RCA* database of Baishideng officially released the 2022 *Journal Article Influence Index* (2022 *JAII*) of 101 core journals in gastroenterology and hepatology, for the first time. The list of 101 core journals can be found at: https://www.referencecitationanalysis.com/Search-Journal. Among them, the highest 2022 *JAII* is 48.014 and the lowest is 3.900. This article highlights the top 20 journals, describes the calculation method for the 2022 *JAII*, the evaluation process, and the inclusion principles for journals in the *RCA*. These steps are the underpinning of the *RCA*'s empirical journal academic evaluation service by which the digital platform addresses the needs of authors to select reliable journals for submission, readers to select high-quality literature for reading, and editors to track their own journal citation performance. As such, the *RCA* core journal list will serve as a useful Find-a-Journal tool. Any interested party is welcome to use this journal list and recommend it to their peers.

Key Words: *Reference Citation Analysis*; *Journal Article Influence Index*; Gastroenterology and hepatology; Journal list; Find a journal; Announcement

INTRODUCTION

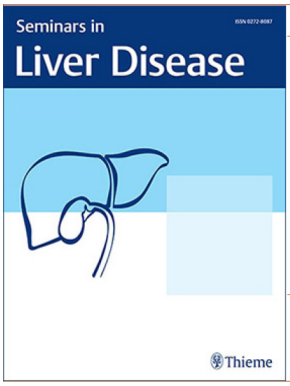
We are very pleased to announce that the *Reference Citation Analysis* (*RCA*) database of Baishideng Publishing Group (Baishideng) has, for the first time, officially released the 2022 *Journal Article Influence Index* (2022 *JAII*) of 101 core journals in the field of gastroenterology and hepatology on August 8, 2022. A total of 101 core journals in gastroenterology and hepatology can be found at: https://www.referencecitationanalysis.com/SearchJournal.

RCA is an artificial intelligence technology-based open multidisciplinary citation analysis database. It was carefully designed to lead the development of wisdom, knowledge innovation, and emerging disciplines[1]. As such, the functions of *RCA* include: Find an Article (54753299), Find a Category (254), Find a Journal (14087), Find a Scholar (631), and Find an Academic Assistant (15). *RCA* updates its list of journals daily, according to relevant data including total number of articles, total citations, and the *JAII*. *RCA* acquires newly released abstracts and references from Crossref and adds them to the *RCA* database weekly. *RCA* also acquires abstracts and references released within the calendar year from Crossref and adds them to the *RCA* database monthly, and then updates the total number of articles, citations, and *JAII* accordingly. Herein, we introduce the top 20 2022 *JAII* from the total 101 core journals in the field of gastroenterology and hepatology included in *RCA*, the calculation method for the 2022 *JAII*, and the evaluation process and the inclusion principles of *RCA* journals.

TOP 20 2022 *JAII* JOURNALS IN THE FIELD OF GASTROENTEROLOGY AND HEPATOLOGY INCLUDED IN THE *RCA*

The *RCA* classifies academic journals with a *JAII* of 20.0 or above as high quality academic journals, which will be highly recommended to authors and readers. There are 101 core journals in the field of gastroenterology and hepatology in the *RCA*, of which 20 were identified to be high quality academic journals, accounting for 19.8%. These 20 journals are listed below.

2022 JAII and rankings of Seminars in Liver Disease



In the *RCA* database, the 2022 *JAII* for *Seminars in Liver Disease* is 48.014, ranking 1st among 101 core journals in the field of gastroenterology and hepatology included in the *RCA*, with a total of 83641 citations (28/101) and a total of 1742 articles (50/101) (Figure 1). For more information on *Seminars in Liver Disease*, please visit: https://www.referencecitationanalysis.com/SearchJournal.

2022 JAII and rankings of Hepatology

In the *RCA* database, the 2022 *JAII* for *Hepatology* is 43.054, ranking 2nd among 101 core journals in the field of gastroenterology and hepatology included in the *RCA*, with a total of 1169100 citations (2/101) and a total of 27154 articles (2/101) (Figure 2). For more information on *Hepatology*, please visit: https://www.referencecitationanalysis.com/SearchJournal.

2022 JAII and rankings of Gastroenterology

In the *RCA* database, the 2022 *JAII* for *Gastroenterology* is 37.170, ranking 3rd among 101 core journals in the field of gastroenterology and hepatology included in the *RCA*, with a total of 1711173 citations (1/101) and a total of 46037 articles (1/101) (Figure 3). For more information on *Gastroenterology*, please

RCA'S MISSION

The mission of *RCA* is to provide a high quality academic article evaluation service platform for various categories. At present, there are many evaluation methods for academic articles, but their calculation methods are complicated. The *RCA* is a new method of evaluating the quality of academic articles,

OPENNESS AND TRANSPARENCY OF RCA EVALUATION

RCA is unique in its objective, impartial, fair, and transparent release of citation analysis data of important academic journals to authors and readers, including evaluation data, evaluation indices, evaluation methods, and evaluation results, in order to ensure the reliability of academic evaluation[2].

CALCULATION METHOD FOR 2022 *JAII*

The 2022 *JAII*, calculated as Total citations/Total articles, is not a 2-year or 5-year average of citations, but is an average of citations for all articles since the journal was assigned its DOI number. Article types are not only limited to original articles and review articles, but for all types of articles. In this way, it is a more objective, fair, and transparent calculation of the academic influence index of an academic journal. Furthermore, the journal list itself is evaluated dynamically, its bibliographic metrics being updated daily, including total number of articles, total citations, and *JAII*[2].

EVALUATION PROCESS OF *RCA* JOURNALS

The journals included in the *RCA* core journal list need to undergo three rounds of strict evaluation. The evaluation process is as follows[2]:

First-round evaluation: Verify the basic information on the journal, including Journal Name, Abbreviated Title, Print ISSN, Online ISSN, Language, Category, Peer-Reviewed Journal, Ownership, Publisher, Journal Website, Editorial Board Members, Submit a Manuscript, and Indexed by.

Second-round evaluation: Verify the activity of the journal, including Total Articles, Total Citations, Cited by in F6Publishing, and the *JAII*.

Third-round evaluation: Based on the reliability of journal information, the activity of publication data, whether the journal is a peer-reviewed journal or not, and *JAII*, the editorial team evaluates every journal, makes the decision to accept or reject the journal, and creates a list of core journals by discipline. The function of the list of core academic journals is to classify journals according to categories and rank them according to various bibliometrics, including Total Views, *JAII*, Total Citations, Cited by in F6Publishing, Total Articles, and Number of Years.

INCLUSION PRINCIPLES OF *RCA* JOURNAL

The *RCA* editorial team of Baishideng conducted three rounds of rigorous evaluation on core journals in gastroenterology and hepatology. The resultant *RCA* core journal list for the field of gastroenterology and hepatology includes a total of 101 journals, among which the highest 2022 *JAII* is 48.014 and the lowest *JAII* is 3.900, the highest total number of citations is 1711173 and the lowest is 698, and the highest total number of articles is 46037 and the lowest is 133. The *RCA* core journal list does not include any journals with a *JAII* lower than 3.0. We implement dynamic evaluation inclusively for the *RCA* core journal list. Evaluation is initiated once an *RCA*-nonincluded journal receives a *JAII* over 3.0. Similarly, if a journal included in the *RCA* core journal list receives a *JAII* lower than 3.0, it will be excluded[2]. The *RCA* core journal list is designed by publishers, scientific editors, and engineers for use by readers, authors, and editorial offices, and is free-of-charge to users.

Upon completion of the three rounds of rigorous evaluation on core journals in gastroenterology and hepatology by the *RCA* editorial team, all data in each journal are organized for public consumption according to category rank, including the 2022 *JAII*, total citations, cited by in F6Publishing, total articles, and the 2021 Journal Impact Factor™. All information in each journal, including Journal Name, Print ISSN, Online ISSN, Language, Free Access, Peer-Reviewed Journal, Ownership, Publisher, Journal Website, Editorial Board Members, Submit a Manuscript, and Indexed by are made available in *RCA*. Moreover, the citations of each journal can be then ranked in *RCA* by the *Impact Index Per Article*, Cited by in Crossref, and Cited by in F6Publishing parameters. Results analysis available for each journal includes Year Published Analysis, Article Type Analysis, Journal Title Analysis, and Category Analysis. The references of each journal are also refined by Year Published and Article Type. Each reference's citation information is displayed, including PMID, DOI, Cited by in Crossref, *Impact Index Per Article*, *RCA*, and Track Full Text[2].

CONCLUSION

The ultimate purpose of *RCA* is to provide an open, objective, fair, and reliable academic evaluation service platform for readers, authors, and journal editors. The *RCA* journal academic evaluation service platform is designed and actively maintained to address the needs of authors to select reliable journals for submission, readers to select high-quality literature for reading, and editors to track their own journal citation performance. The *RCA* core journal list itself will serve as a useful Find-a-Journal tool. Any interested party is welcome to use this journal list and recommend it to their peers.

Abstract

The discovery of hepatitis C has been a landmark in public health as it brought the opportunity to save millions of lives through the diagnosis, prevention and cure of the disease. The combined work of three researchers, Alter H, Houghton M and Rice C, which set the basis for the diagnosis, treatment and prevention of hepatitis C apart from laying the ground work for a new approach to study infections in general and developing new antiviral agents. This is a story of a transfusion-associated infection. A series of clinical studies demonstrated the existence of an infectious agent associated with hepatitis. That was followed by the identification of what was later known to be the hepatitis C virus (HCV) and the development of diagnostic tests. It all preceded the full molecular identification and demonstration of a causal effect. Finally it ended up with the development and discovery of a new class of therapeutic drugs, the direct acting antivirals, which are now used not only to cure the disease but most probably, to eliminate the problem. This work started with Dr Alter H who demonstrated that a new virus was responsible for the majority of post-transfusion hepatitis followed by Houghton M who cloned the virus and developed the blood test to identify those cases that carried the virus. Finally, the work of Rice C demonstrated that a cloned HCV produced after applying molecular biology techniques could cause long-standing infection and cause the same disease as the one observed in humans.

Key Words: Hepatitis C; Nobel prize; Discovery; Diagnosis; Treatment; Elimination; World Health Organization initiative

INTRODUCTION

"*The methodological studies of transfusion-associated hepatitis by Harvey J. Alter demonstrated that an unknown virus was a common cause of chronic hepatitis. Michael Houghton used an untested strategy to isolate the genome of the new virus that was named Hepatitis C virus. Charles M. Rice provided the final evidence showing that Hepatitis C virus alone could cause hepatitis.*" Nobel Prize assembly, 2020[1].

THE DISCOVERY OF HEPATITIS C VIRUS WAS A LANDMARK IN PUBLIC HEALTH

The prolonged campaign to discover and treat the various causes of viral hepatitis is a major medical success story as it brought about the opportunity to save thousands of lives through the diagnosis, prevention and cure of the disease, sparing lives that would be lost to chronic hepatitis C and its complications. It was through the combined work of three researchers starting with Dr Alter H working at National Institutes of Health (NIH) who demonstrated that a new virus was responsible for the majority of post-transfusion hepatitis. That was followed by Houghton M who cloned the virus and developed the blood test to identify those cases that carried the virus. And finally, Rice C demonstrated that a cloned hepatitis C virus (HCV), produced after applying molecular biology techniques (a virion), could cause long-standing infection and cause the same disease as the one observed in humans[2]. These scientific breakthroughs enabled the World Health Organization (WHO) to set the, once unthinkable, goal for HCV elimination by 2030[3]. The implications of this work are not limited to hepatitis C as the new diagnostic techniques and methods of drug development may be applicable to other viral pathogens. Furthermore, the complete new approach to treatment based on the study and new knowledge of the HCV genetics and lifecycle together with the molecular biology approach attacking many targets directly (in the HCV lifecycle) *i.e.*, protease inhibitors, polymerase inhibitors and NS5A inhibitors[4-6], the former being the most successful prodrug developed and currently used in the WHO policy for world elimination of hepatitis C aimed at either[6,7], virion processing, RNA replication and virion assembly in the liver cell[6,8].

For those of us who grew up in the hepatology field when non-A non-B hepatitis (what a strange name!) was a common topic of discussion in the clinic and the laboratory, the award of the Nobel prize for the discovery of HCV in 2020 marked a fitting end to a long saga. This is the second Nobel prize awarded to investigators in viral hepatitis recognizing the major advances in this field of clinical and laboratory research [the first Nobel prize was awarded to Blumberg B in 1976 for the discovery of hepatitis B virus (HBV)][9]. Initially viral hepatitis was regarded as an epidemic disease which was a major problem in congregated settings such as residential schools and military establishments. It became a major issue in time of war when epidemics reduced the effectiveness of armies in the field. Much important early research was funded by the military. Only later did it become apparent that chronic viral hepatitis could lead to cirrhosis and hepatocellular carcinoma (HCC). Many millions of people were infected making it one of the leading causes of morbidity and mortality in some parts of the world. In the early 2000's it was estimated that chronic viral hepatitis was responsible for over one million deaths annually[10]. The development of vaccines for hepatitis B and effective anti-viral therapy for hepatitis B and C have been dramatically effective and offer the prospect of banishing these diseases to the sidelines of human history.

BRIEF HISTORY OF HEPATITIS

The hepatitis problem was perhaps noticed 5000 years ago when epidemics of jaundice were attributed to a devil called "Ahhazu" by the Sumerians[11] and many years later were described by Hippocrates in the 5th century BC in his book "Epidemics". They were particular noted in armies during time of war, hence the term "campaign jaundice". The cause of jaundice was not understood and up till the outbreak of the second world war many clinicians accepted Virchow's theory that a mucous plug at the mouth of the common bile duct caused "catarrhal jaundice"[12]. The large number of hepatitis cases and the impact it had on battle readiness acted as a major stimulus to understanding hepatitis. Most of the subsequent advances in knowledge were described in the British and American literature. Up until D-day in 1944 the British army was mainly engaged in fighting in the Mediterranean theatre. Hepatitis, with malaria and venereal disease were the three most important medical conditions afflicting the troops there[13]. On the other side of the Atlantic ocean, 28585 United States servicemen developed jaundice after receiving the yellow fever vaccine[14]. Clinical, epidemiological and transmission studies established that there were two distinct forms of hepatitis, characterized as infectious or serum hepatitis. Infectious hepatitis was transmitted by the fecal-oral route whereas serum hepatitis was transmitted by injection or blood products[15].

Stokes and Neff of the United States Army Medical Corps had been using concentrated gamma globulin to prevent or attenuate measles infection. Despite several thousand treatments they recorded no cases of hepatitis[16]. They reasoned that there may be neutralizing antibodies in gamma globulin prepared from large pools of adult plasma and suggested that gamma globulin could be useful in the treatment of viral hepatitis. The hypothesis was tested when there was a large epidemic of hepatitis in a summer camp for boys and girls in September 1944. There was sufficient gamma globulin to treat 45 children, who were compared to 246 controls. Hepatitis was subsequently documented in 16% (7/45) treated compared to (70%) 172/246 controls. None of those treated developed clinical jaundice thus demonstrating that gamma globulin could prevent or attenuate infectious hepatitis[17]. Many of the subsequent transmission studies on viral hepatitis of questionable procedures were performed in the Willowbrook State School in New York for children with mental disorders which had a major problem with endemic infectious hepatitis[15]. The investigators clearly demonstrated two types of hepatitis, with different incubation periods and no cross-immunity, subsequently proven to be hepatitis A and hepatitis B. The ethics of that program have since been questioned[18].

The problem of hepatitis continued up until modern times when many cases of un-explained jaundice continued to puzzle clinicians until some 51 years ago when Holland, Schmidt, Purcell, Walsh and Alter began to study what was called "Transfusion-associated hepatitis" in 1969[19]. It would take some 20 years more until the infectious agent, HCV, was discovered[20]. Those of us who grew up in the hepatology field when non-A non-B hepatitis was a common topic for discussion in clinical meetings and on the wards remember the cases of unexplained post-transfusion hepatitis. In addition there were many cases of "nosocomial" hepatitis[21] and cryptogenic hepatitis and a lack of diagnostic tests. The journey to unravel this problem took another 39 years, 14 years from the identification of non-A non-B hepatitis to the discovery of the HCV and 25 years from the discovery of HCV in 1989 to the approval of one of the most prescribed direct acting antiviral agents (DAA) Sofosbuvir in 2013 for the treatment of hepatitis C[22]. In all, those 39 years don't seem too bad now when we look at the progress made from those early clinical and epidemiologic studies by Alter and others up to the incredibly creative and imaginative pharmacological approach to therapy involving the design of DAA that inhibit HCV infection by blocking viral assembly and replication at the present time[22].

Currently, it is estimated, that there are more than 71 million people around the world infected with HCV. Complications of end-stage liver disease due to hepatitis C make it one of the world's most important causes of death with 400000 cases a year[23]. It is well-known that HCV can cause chronic hepatitis C, a silent but progressive condition which may progress to cirrhosis and HCC over decades. Hepatitis C is transmitted by the parenteral route. As blood products for transfusion have become increasingly safe due to effective viral testing, the main route of transmission in most countries is through intravenous drug use. Eradication of hepatitis C requires effective harm reduction strategies for intravenous drug use in addition to antiviral therapy[7,20].

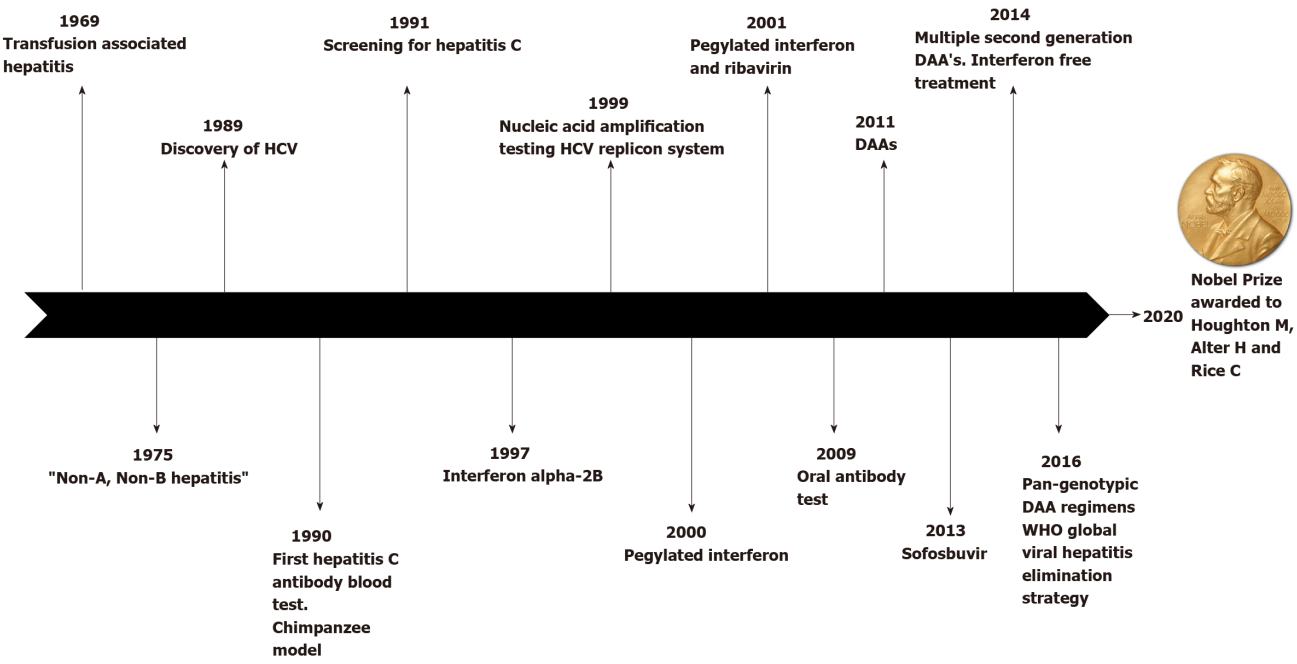
Interest in this problem (now known as hepatitis C) was renewed almost 70 years ago when there was a high incidence of chronic hepatitis after blood transfusions or use of blood products. At that time it was impossible to know who of the donors carried the disease. In 1960, Alter[24] started his search for the "source" of post-transfusion hepatitis having previously worked with Blumberg B with whom he had observed a "precipitin line … that stained intensely red" in a reaction between blood from a patient with hemophilia and blood from an Australian aborigine which they called initially the "Australia antigen". That was later identified as the surface protein of the HBV (HBsAg). Blumberg continued his research on the Australia antigen to establish the link with HBV for which he won the Nobel prize in Medicine in 1976[11]. In his studies, Alter[19] found that even if hepatitis B contaminated blood was excluded from use most post-transfusional hepatitis remained. He tested the blood supplies for the presence of suspected known viruses and followed up patients who developed hepatitis after receiving a blood transfusion and found that an incredible high number of cases could not be explained. Alter[19] and other researchers suspected there was another infectious agent. In 1978, Alter[24] demonstrated that

plasma from those patients with post-transfusion hepatitis could infect chimpanzees who developed clinical and laboratory signs of hepatitis suggesting that the cause of that liver inflammation was infectious. Further studies by Alter[24] showed that the causative agent had characteristics of a virus. The next goal was the search for the virus which took lots of effort and time *i.e.*, years! Nevertheless Alter[19] had learnt from Blumberg to work with tenacity and perseverance to carry on with his work. Robert Purcell and Steve Feinstone at the NIH[19] and Alfred Prince in New York noted that most cases of post-transfusion hepatitis were HBsAg negative and hepatitis A virus negative[11]. At that time they started calling it non-A non-B hepatitis (NANBH)[11]. Another important step was the observation that infectivity titers in chimps studied by Purcell were almost identical to the genomic titers in a patient with severe acute NANBH studied by Alter[19]. Alter[19] worked with the assumption that genetic material would be present in pools of DNA sequences isolated from those animals infected with hepatitis, and on the other hand that serum from humans with this form of hepatitis would have specific antibodies against that virus that would bind to some proteins or viral particles and could then be used to identify those samples with the virus. Together with Purcell he attempted every serological approach known at the time to identify the virus without success.

In 1989, Houghton[25] at Chiron Laboratories in California (now part of Novartis) tried a combination of molecular biology and immunology methods. They extracted nucleic acid from plasma and cloned it in an expression vector (GT11) creating a phage expression library. This technique enabled them to identify the first epitope characteristic of the HCV envelope in 1989[11]. They later named it HCV. Houghton rapidly came up with the idea of developing immunoassays to detect antibodies to protein products of those clones establishing a blood test for HCV which he evaluated using Alter's blood samples' collection at NIH[26]. They correctly identified all samples which were thought to be infected with the virus as well as all negative controls. This was a major milestone for medicine and public health. It allowed blood banks to screen all blood supplies resulting in an immediate and dramatic drop in the incidence of post-transfusion hepatitis.

At this point there was another crucial question, that is whether this virus could reproduce infection if inoculated into an experimental model, hence probing that the now called HCV was the causative agent of the formerly known NANBH. Rice C a researcher at the University of Washington who had been working with molecular virology of *Flavivirus*[22] focused on dissecting HCV gene expression using blood from infected chimpanzees to introduce DNA fragments into bacteria to express individual protein fragments. Those products were then screened with the antiviral antibodies until they could isolate one positive clone. The positive clone encoded a sequence that was very similar to sequences of the virus family of flaviviruses. Next, Rice started investigating what was needed for the molecularly cloned HCV to be reproduced *in vitro*. In 1996, he and his group identified the conserved 3'-terminal region of the HCV genomic RNA which was previously unknown[27], and was crucial for recovery of infectious HCV cDNA clones. However, initially they could not produce infection when injected into the liver of animals speculating that there could be some inactivating random mutations in the genome produced during the replication of the virus[28]. That meant that some individual clones may be defective. He sequenced many clones and compared them with each other and found that some of these clones contained potentially inactivating mutations which he thought could be removed with genetic engineering[29]. He later combined that repaired viral genome with the 3'-end of the genomic RNA hoping he would obtain a functional virus. When he injected this genome into the liver of chimpanzees clinical signs of hepatitis ensued and there was virus present in the blood producing now the evidence that the clone of the HCV could produce the disease associated with hepatitis infection[22,30]. That was a very important advance because the development of HCV replicons provided a live HCV system in the laboratory where viral replication, pathogenesis and evolution in culture could be studied in a viable *in vitro* replication system[22]. Later on newer constructs were obtained with higher replicative ability *in vitro*[22]. This was another milestone. Within 1 year of the cloning of HCV the nucleotide sequence of the entire viral genome was determined and the agent was characterized as a single-stranded positive-sense RNA virus of about 9600 nucleotides in length[2,31]. The advent of functional replicons also enabled the assay development for antiviral drug development which made the search for effective anti-viral drugs much easier[22]. Another collaborator of Rice, Ralf Bartenschlager, a molecular biologist who had previously worked with HBV, successfully replicated HCV genomic RNA in a human hepatoma cell line Huh7[32]. Confirmatory reports from various groups worldwide all corroborated that replicons were robust *in vitro* replication (subgenomic HCV replication system) systems that set the basis for production of infectious virus particles in cell cultures[22,32]. That improved the HCV RNA replicon system model was used in collaboration with Michael Sofia to design the new DAA[22]. One of those developed, DAA PSI-7797 (Sofosbuvir), had a very effective antiviral effect with broader genotype coverage and fewer side effects on a shorter duration treatment[11,22]. This prodrug enters the hepatocyte readily where it is metabolized to produce a triphosphate derivative which is a potent viral replication inhibitor[20,22]. It has just recently been announced that it can cure up to 95% of patients infected with HCV[33]. Different prodrugs were tested in genotype-specific cell lines that have been used in preclinical studies to select and validate novel targets for HCV. Those included NS3-4A protease inhibitors, nucleoside analogue viral polymerase inhibitors, non-nucleoside inhibitors of the viral RNA polymerase, NS5A inhibitors, host targeted agents (HTA), cyclophilin inhibitors and a cellular miRNA antagonist[4]. The discovery of over 30 new DAAs and HTAs revolutionized the treatment of chronic

HCV[8]. The swift development of interferon-free protocols using DAA monotherapy or the combined administration of two or three DAAs or HTAs, administered for 8-12 and up to 24 wk, led to sustained virological response (SVR) rates between 90% and 100%[8,33,34].



With the widespread use of DAAs many countries are now reporting a reduction in mortality associated with chronic hepatitis C and it's complications such as liver cirrhosis and HCC[3]. A strategy of "treatment as prevention" has been proposed with the aim of reducing the population prevalence, interrupting the chain of viral transmission and ultimately leading to elimination of HCV infection[11,20], although patients with HCV infection with cirrhosis or decompensated liver disease present special challenges such as post-SVR complications including HCV reinfection, HCC risk, residual HCC which should be addressed by early detection and treatment, combination and multiple DAA therapy avoiding the use of protease inhibitors and risk reduction counseling[7,34]. As epidemiologists, infectious diseases and liver specialists analyze the natural history, epidemiology and public health figures, world experts have proposed a rationale towards hepatitis C elimination based on infection control and disease elimination and eradication[7,20].

ELIMINATION OF HEPATITIS C

Viral hepatitis is a global health burden affecting 325 million people globally of which 71 million have hepatitis C with 1.5 million infections occurring per year and 542316 global HCV related deaths[3,20]. In 2016, the WHO set the Global health sector strategy for viral hepatitis proposing to eliminate viral hepatitis as a public health problem by 2030[3]. That is a 90% reduction in incidence and a 65% reduction in mortality by 2030 and a new guidance was released in June 2021[35]. These targets are achievable with the tools now at our disposal as demonstrated for hepatitis B in Taiwan[36] and hepatitis C in Egypt[37]. The main global strategies are to increase HCV testing, improve clinical education of providers, utilize simple models for HCV care and provide universal access to antiviral treatment at affordable cost. While there have been technical, geographic and policy limitations such as limited funding, lack of transparency and high in-country process, fragmented procurement, HCV diagnostics inefficiencies[3] and most recently the severe acute respiratory syndrome coronavirus 2 pandemic to mention a few there have been many examples around the globe showing that the goals are feasible[35]. In Egypt the cost of hepatitis C antiviral therapy fell from $1650 to $85 United States dollars between 2015 and 2018. A nationwide screening and treatment program identified 1.15 million infected individuals. By September 2019 over 1.05 million had commenced treatment with sustained virological clearance rates of 98.8%[37]. In spite of those challenges mentioned above, the future of mankind looks promising as millions of people will have the chance of a life free of hepatitis virus.

CONCLUSION

We have summarized the contributions of several groups of medical researchers starting with Dr Alter H who demonstrated that a new virus was responsible for the majority of post-transfusion hepatitis followed by Houghton M who cloned the virus and developed the blood test to identify those cases that carried the virus. That was continued with the work of Rice C that demonstrated that a cloned HCV produced after applying molecular biology techniques could produce long-standing infection and cause the same disease in animals as the one observed in humans[2] (Figure 1). That is a milestone not only in the diagnosis, treatment and prevention of hepatitis C, but in the approach to study infections in general apart from contributing to the understanding of the role genetic and environmental factors play in the development of this infection. In all, that set the basis for the production of new antivirals which are central for hepatitis C control and elimination. Of note, the cloning of HCV in 1989 was a remarkable accomplishment that has not only saved a large number of human lives but also demonstrated the power of molecular biology in unearthing new infectious agents. The discovery of HCV, the first virus ever discovered by molecular cloning technology, with its accompanying development of new methodologies such as new generation sequencing and new generation diagnostic automated systems[38], is also a landmark in public health. The discovery of HCV provides the opportunity to save thousands of lives through prevention and now, cure of the disease, which would otherwise be lost to chronic hepatitis C and its complications.

Abstract

Gastrointestinal cancer (GIC) is the most common cancer with a poor prognosis. Currently, surgery is the main treatment for GIC. However, the high rate of postoperative recurrence leads to a low five-year survival rate. In recent years, immunotherapy has received much attention. As the only immunotherapy drugs approved by the Food and Drug Administration (FDA), immune checkpoint blockade (ICB) drugs have great potential in cancer therapy. Nevertheless, the efficacy of ICB treatment is greatly limited by the low immunogenicity and immunosuppressive microenvironment of GIC. Therefore, the targets of immunotherapy have expanded from ICB to increasing tumor immunogenicity, increasing the recruitment and maturation of immune cells and reducing the proportion of inhibitory immune cells, such as M2-like macrophages, regulatory T cells and myeloid-derived suppressor cells. Moreover, with the development of nanotechnology, a variety of nanoparticles have been approved by the FDA for clinical therapy, so novel nanodrug delivery systems have become a research focus for anticancer therapy. In this review, we summarize recent advances in the application of immunotherapy-based nanoparticles in GICs, such as gastric cancer, hepatocellular carcinoma, colorectal cancer and pancreatic cancer, and described the existing challenges and future trends.

Key Words: Gastrointestinal cancer; Gastric cancer; Hepatocellular carcinoma; Colorectal cancer; Pancreatic cancer; Immunotherapy-based novel nanoparticles

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Recently, immunotherapy has received substantial attention. Although there are several Food and Drug Administration-approved immune checkpoint blockade (ICB) drugs, the efficacy remains limited, and the response rate is less than 20%. Because gastrointestinal cancer (GIC) is a group of immunosuppressive cancers, the efficacy of ICB treatment is also limited. Therefore, enhancing the immunogenicity of GIC or reversing the immunosuppressive microenvironment of GIC have become potential approaches for GIC immunotherapy. There are many studies on nanoparticle-based cancer therapy. However, there are only a few studies on immunotherapy-based nanoparticles in GIC. Here, we summarize recent advances in the application of immunotherapy-based nanoparticles in GIC and present our thoughts about this topic.

INTRODUCTION

Gastrointestinal cancer (GIC) has been among the most commonly diagnosed cancers in recent decades [1-3]. In recent reports, the incidence and mortality rates have gradually decreased for gastric cancer (GC), hepatocellular carcinoma (HCC) and esophageal cancer in China; in contrast, the rates for colorectal cancer (CRC) have increased[4]. Regardless of the changes in the incidence and mortality rates of GIC, the disease has greatly affected the quality of life of many individuals.

Similar to other types of cancer, GIC has several therapies available. As the most conventional means of cancer treatment, surgery, chemotherapy and radiotherapy play important roles. Although traditional therapies effectively prolong survival for patients with GIC, there are still many drawbacks that cannot be ignored[5]. Surgery, especially minimally invasive surgery and radiotherapy, can effectively shrink the tumor and even make the local tumor disappear; chemotherapy can be administered systematically to kill cancer cells[6-8]. However, these treatments cannot prevent recurrence. Moreover, for GICs, the side effects of radiotherapy and chemotherapy on the digestive system seriously affect the quality of life of patients and cannot be ignored[9-11]. To improve the therapeutic effect and reduce the occurrence of adverse reactions, clinicians often try a variety of therapeutic combinations to achieve complementary advantages[12,13].

With progress in the concept of cancer treatment and the development of diagnosis and treatment technology, various precision treatment methods, such as targeted therapy, photodynamic therapy (PDT), photothermal therapy (PTT) and immunotherapy, have emerged as new sources of hope for patients[14-19]. Some scholars believe that the characteristics of the GIC immune microenvironment are related to the high mortality of patients with GIC; therefore, treatments that target the GIC immune microenvironment are gradually being recognized[20]. As one of the therapeutic methods that targets the cancer immune microenvironment, immune checkpoint blockade (ICB) treatment has achieved great success in clinical practice, laying a good foundation for the development of cancer immunotherapy[21].

Recently, a variety of nanobased drugs (such as Eligard[22], Marqibo[23], Onivyde[24], Doxil[25], Abraxane[26], Ontak[27] and Nanotherm[28]) have been widely used in clinical practice due to several characteristics, including their low toxicity, long circulation and passive targeting ability[29,30]. However, most of the nanobased drugs mentioned above are liposomes. In addition to liposomes, there are also other types of nanoparticles that possess the same potential for clinical translation. Similar to liposomes, small extracellular vesicles and cell membrane vesicles also have lipid bilayers, and they have better biocompatibility than liposomes due to their origin[31-34]. Furthermore, due to their simple production process and high drug loading efficiency, polymersomes are also considered candidate nanoparticles for clinical translation[35-37]. There are also many kinds of novel nanoparticles, such as gold nanoparticles, manganese dioxide nanoparticles, upconversion nanoparticles (UCNPs), metal organic framework nanoparticles and mesoporous silica nanoparticles (MSNPs), which can also play important roles in different diseases or cancers through their own characteristics[38-42]. Here, among the GICs, we focus on GC, HCC, CRC and pancreatic cancer and summarize the application trends of immunotherapy-based novel nanoparticles in these cancers as well as the challenges and opportunities

in the future.

IMMUNOTHERAPY-BASED NOVEL NANOPARTICLES IN GC

GC remains one of the most common causes of cancer-related death globally. Although a variety of treatments have been developed, the main treatment for GC is still surgery or endoscopic resection. The probability of patients experiencing recurrence after surgery is approximately 60%[43]. Currently, the median overall survival time with fluoropyrimidine-based combination chemotherapy is less than one year. In general, the overall clinical therapeutic effect of GC is not satisfactory[44,45]. In addition, immunotherapy for GC will become an important treatment option in the future, and nanoparticles, as highly efficient drug carriers, have played an important role in clinical practice[46-48]. Whether the combination of immunotherapy and nanoparticles can produce improved therapeutic effects is also worth examining.

Immune checkpoint inhibitors (ICIs), such as anti-programmed death receptor-1 (anti-PD-1) antibody and anti-programmed death receptor-ligand 1 (anti-PD-L1) antibody, can effectively block the PD-1/PD-L1 pathway and enhance the anticancer immune response[49]. Based on ICI treatment, Xu *et al*[50] prepared a novel nanoparticle named docetaxel (DOC)-PEG-PCL-monoclonal antibody (mAb) NP, which contained DOC as the chemotherapeutic drug and conjugated PD-L1 mAb on the surface of the nanoparticle. This nanodrug delivery system (NDDS) can effectively improve drug delivery efficiency and the solubility of hydrophobic drugs such as DOC. In addition, the system can target PD-L1-positive GC cells, exhibiting clinical translation potential. Recently, scientists found that a gradually acquired heritable *de novo* methylation program inhibited T-cell proliferation and clonal diversity during PD-1 blockade therapy[51]. Inspired by this study, Hu *et al*[52] designed copolymers loaded with the epigenetic agent 5-Aza-20-deoxycytidine (DAC), and an anti-PD-1 antibody was conjugated to the surface of the nanoparticles. The nanoparticles increased the stability of DAC and improved the therapeutic effect of ICI treatment *in vivo*.

Due to the characteristics of the cancer immune microenvironment, T-cell infiltration in GC patients is insufficient, which limits the effect of ICB treatment in GC[53]. Guo *et al*[54] constructed an NDDS named HMON@IR820/Pt-NPs, which coencapsulated platinum nanoparticles (chemo-prodrugs) and IR820 (photosensitizer) into hollow mesoporous organosilica nanoparticles. IR820-mediated PDT can lead to the release of oxidative mitochondrial DNA (mitoDNA). In addition, this oxidative process can oxidize Pt(0) to cytotoxic Pt(II), which can lead to the dysfunction of nuclear DNA (nDNA). The dual damage of mitoDNA and nDNA can activate the c-GAS/stimulator of interferon genes (STING) pathway, which can directly stimulate innate immunity and increase the infiltration of $CD8^+$ T cells, thus improving the efficacy of immunotherapy for GC.

Multiple studies have confirmed that tumor-associated macrophages (TAMs) are also involved in the composition of the tumor immune microenvironment. Moreover, M2-like macrophages can inhibit tumor immunity and promote tumor immune escape[55,56]. Zhang *et al*[57]'s group designed a novel human serum albumin (HSA)-Au(III) thiosemicarbazone agent nanoparticle delivery system for chemotherapy and immunotherapy in GC. This NDDS can simultaneously directly kill GC cells and polarize TAMs into M1-like macrophages, providing a new immunotherapy strategy for clinical translation.

The majority of cancer patients are often unable to activate adequate levels of anticancer immunity, whereas therapeutic tumor vaccines can help patients proactively generate adequate anticancer immune responses against tumor-specific antigens (TSAs) and tumor-associated antigens[58]. Among the different types of tumor vaccines, dendritic cell (DC)-based tumor vaccines have been explored in clinical experiments[59,60]. Kohnepoushi *et al*[61] prepared poly(lactic-co-glycolic) acid nanoparticles to protect the human gastric tumor antigen against proteolytic enzymes. In addition, nanoparticles that contain human gastric tumor antigen can facilitate DC maturation and further enhance the efficacy of DC vaccines in clinical practice.

In addition to ICB treatment and other therapies that can improve the cancer immune microenvironment, immunoadjuvants can act as a potential adjunctive therapy to stimulate anticancer immunity [62,63]. Zhang *et al*[64] developed a gold nanoshell-based NDDS that can convert near-infrared (NIR) light into thermal energy, enabling PTT. Moreover, high temperature can also break thiol bonds to release gene therapy agents and oligooxynucleotides that contain cytosine-guanine (CpG) motifs (which are also known as immunoadjuvants). This study designed a novel NDDS combined with hyperthermia, gene therapy and immunotherapy, which exhibited encouraging anticancer efficacy against GC *in vitro* and *in vivo* (Table 1).

IMMUNOTHERAPY-BASED NOVEL NANOPARTICLES IN HCC

Primary liver cancer is among the most commonly diagnosed cancers, most of which are HCC[65,66]. Due to the high infection rate of hepatitis B virus, the incidence of HCC in China remains high[67].

Table 1 Overview of immunotherapy-based novel nanoparticles in the treatment of gastric cancer [PubMed Search (immunotherapy) AND (nanoparticle) AND (gastric cancer)]

Type of nanoparticle	Treatment strategy	Drugs or active substance involved	The main involvement of immune cells	Ref.
Copolymers	ICIs, chemotherapy	DOC, PD-L1 mAb	T cells	Xu *et al*[50]
Copolymers	ICIs, epigenetic treatment	DAC, nivolumab	$PD1^+CD8^+$ TILs	Hu *et al*[52]
Hollow mesoporous organosilica nanoparticles	Dual-damage to nDNA and mitoDNA activates the c-GAS/STING pathway to stimulate innate immunity	Platinum, IR820	$CD8^+$ T cells, DCs	Guo *et al*[54]
HSA nanoparticles	Targeted chemotherapy and immunotherapy	Au(III) thiosemicarbazone agent	TAMs	Zhang *et al*[57]
Polymers	DC vaccine	Human gastric tumor antigens	DCs	Kohnepoushi *et al*[61]
Gold nanoshell	Gene therapy, hyperthermia and immunoadjuvants therapy	HER-2 targeted siRNA, gold, CpG	DCs, T cells	Zhang *et al*[64]

ICIs: Immune checkpoint inhibitors; DOC: Docetaxel; PD-L1: Programmed cell death ligand 1; mAb: Monoclonal antibody; DAC: 5-Aza-20-deoxycytidine; TILs: Tumor-infiltrating T cells; DCs: Dendritic cells; HSA: Human serum albumin; TAMs: Tumor-associated macrophages; HER-2: Human epidermal growth factor receptor-2; CpG: Cytosine–guanine.

Surgical resection of the liver is the main treatment for HCC. However, the prognosis after surgery is still poor. Recently, the development of molecular targeted therapy and immunotherapy for HCC has gained recognition in clinical studies[68]. Moreover, NDDSs can improve the efficiency of drug delivery into the tumor area and reduce side effects[69-71]. At present, a large number of studies using immunotherapy-based NDDSs have shown great potential for clinical translation.

ICB treatment has also emerged as a new option for advanced HCC[72]. However, ICB treatment alone has limited efficacy against HCC. Therefore, how to combine other kinds of therapies to improve the efficiency of ICB treatment has become a new academic topic. For example, Food and Drug Administration (FDA)-approved sorafenib-experienced patients used ipilimumab (anti-CTLA-4) combined with nivolumab (anti-PD-1) in March 2020[73]. In the last two decades, scientists have found that chemotherapeutic drugs, radiotherapy, PDT and some other treatments can induce immunogenic cell death (ICD), which can lead to the release of TSAs and increase tumor antigenicity[74]. Hence, ICD can improve the efficacy of ICB treatment by increasing tumor immunogenicity. According to the therapeutic strategies mentioned above, Xu *et al*[75] designed a cyclic arginine-glycine-aspartic acid peptide-modified self-assembling polymer-based NDDS. Cancer cells were damaged by PDT and chemotherapy, while induced ICD and enhanced tumor immunogenicity provided a suitable immune microenvironment for ICB treatment. Previous studies found that a lack of the p53 tumor suppressor gene leads to tumorigenesis and drug resistance[76-78]. With the development of research on the p53 tumor suppressor gene, an increasing body of evidence indicates that the p53 protein plays an important role in anticancer immunity by regulating the cancer immune microenvironment[79-81]. Furthermore, a recent study suggested that ICD induced by cytotoxic agents, such as chemotherapy drugs, may be involved in the activation of the p53 pathway[82]. Xiao *et al*[83] developed a novel lipid-polymer hybrid nanoplatform for mRNA delivery that can induce the expression of p53, effectively reprogramming the immune microenvironment of HCC. Moreover, combination with anti-PD-1 therapy can reverse the inhibitory immune microenvironment of HCC. To solve the problem of HCC recurrence after surgery, Li *et al*[84] designed a bionic NDDS consisting of MSNPs loaded with anti-PD-L1 and sorafenib and coated with platelet membranes at the surface of the MSNPs. This NDDS can target wounds and generate potent anti-HCC immunity, providing a new therapeutic idea for preventing recurrence in postsurgery HCC patients.

As we mentioned before, chemotherapy-based ICD can cause cancer cells to be more easily recognized by the immune system. However, the effect of single-drug-mediated ICD is very limited. Some studies have attempted to enhance the effect of ICD by combining two different ICD inducers to solve this problem. Yu *et al*[85] evaluated the potential of icaritin as an ICD inducer and utilized NDDS to deliver low doses of icaritin and doxorubicin simultaneously to the tumor area. This NDDS can reprogram the immune microenvironment and induce satisfactory anti-HCC effects. Furthermore, NDDS can lower the dose of chemotherapy to reduce the side effects.

TAMs play a major role in the immunosuppressive microenvironment of HCC[86]. Wang *et al*[87] screened chemokine C-C motif ligand (CCL)2 and CCL5 as two major chemokines responsible for the polarization of M2-like macrophages and designed a CCL2 and CCL5 dual-target lipid nanoparticle system. The combination of TAMs targeting lipid nanoparticles with ICB treatment achieved long-term survival in HCC mice. Similarly, as a common feature of the tumor microenvironment, hypoxia is also

common in HCC. Hypoxia can lead to radioresistance and the formation of an immunosuppressive microenvironment, including the accumulation of TAMs and depletion of effector T cells, which are closely related to the occurrence and development of cancer[88-90]. Dai *et al*[91] synthesized polydopamine-nanoparticle-stabilized oxygen microcapsules that can deliver oxygen to the tumor region and rapidly increase the concentration of oxygen. In this study, oxygen microcapsules increased HCC sensitivity to radiotherapy and polarized M2-like macrophages into M1-like macrophages, consequently activating anti-HCC immunity. In addition to conventional immune cells, liver sinusoidal endothelial cells (LSECs) can also play a significant role in immunosuppressive regulation[92]. Yu *et al*[93] designed a simvastatin-loaded NDDS to target LSECs in HCC patients. This NDDS can reduce the capillarization of LSECs to improve the stromal microenvironment and recruit natural killer T cells to inhibit tumor progression.

Cationic lipid nanoparticles have been suggested to be suitable delivery vectors for RNA, and several messenger RNA vaccines are based on lipid nanotechnology that was approved by the FDA during the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic[94-97]. Zhang *et al*[98] developed a total HCC-derived RNA-loaded lipid nanoparticle vaccine to target DCs and activate anticancer immunity (Figure 1 and Table 2).

IMMUNOTHERAPY-BASED NOVEL NANOPARTICLES IN CRC

CRC is the third leading cause of cancer-related deaths globally[99]. CRC is the only cancer that can be reduced by screening. Most CRC patients can be screened by flexible sigmoidoscopy or guaiac-based fecal occult blood tests[100]. However, approximately 25% of CRC patients are at stage 4, and the 5-year survival rate is only 11%[101,102]. To improve the survival rate of advanced CRC patients, immunotherapy and nanoparticle-based drug delivery systems have become the focus of basic and clinical research for the past few years[103-105].

Similar to GC and HCC, ICB treatment is more widely used in CRC patients, but its curative effect is extremely limited, especially for mismatch repair-proficient/microsatellite stability/microsatellite instability-low CRC patients[106]. As we reported earlier, ICB treatment combined with ICD can achieve a "1 + 1 > 2" effect. A similar treatment strategy has also been applied in CRC research. For example, Yuan *et al*[107] utilized the ability of PDT to induce ICD and developed a photosensitive NDDS combined with ICB treatment that can enhance the response rate of anti-PD-L1 therapy in CRC. Zhu *et al*[108] also designed an oxaliplatin prodrug-conjugated photosensitive NDDS that can be stimulated by the NIR-II window (1000-1700 nm) for PTT, which is a proven to induce ICD. Moreover, oxaliplatin, a chemotherapy drug, is also known as an ICD inducer. This novel NDDS can induce ICD through both PTT and chemotherapy, which may provide a promising immunotherapy strategy for advanced CRC treatment. Shikonin (SK), a major active ingredient isolated from traditional Chinese medicine, has also been proven to induce ICD. Li *et al*[109] designed a versatile nanoparticle that can deliver knockdown siRNA for both the ICD inducer SK and PD-L1, which presents potential for CRC immunotherapy. Recently, ferroptosis was discovered as a nonapoptotic form of regulated cell death [110]. In addition, Duan *et al*[111]'s group proved that dihydroartemisinin (DHA), as a reactive oxygen species (ROS)-producing drug and ferroptosis inducer, can also induce ICD to potentiate anticancer immunity. Therefore, the same research group developed a Zn-pyrophosphate core-shell NDDS codeliver DHA and pyropheophorbide-iron (pyro-Fe). Glutathione and other thiol-based reductants in cancer cells can reduce Pyro-Fe^{III} to Pyro-Fe^{II}, which can catalyze the decomposition of DHA to induce ICD and ferroptosis. This novel NDDS overcame the deficiency of iron in solid tumors, enhanced the ability of DHA to induce ferroptosis and ICD, and increased the infiltration of $CD8^+$ T cells in CRC.

In addition to actively increasing the immunogenicity of CRC, stimulating immune cells can also activate anti-CRC immunity. Immune cells can be activated by stimulating toll-like receptors (TLRs), such as DCs and macrophages. Several TLR agonists have been approved by the FDA. However, none are currently approved for CRC treatment. The major problem for TLR agonists is the small size of the drugs, which allows the drugs to spread rapidly from the administration site and cause severe systemic side effects (Figure 2)[112]. Fortunately, nanoparticle-based delivery systems can solve this problem. Bahmani *et al*[113] prepared a platelet membrane-coated nanoparticle loaded with the TLR7 agonist R848. This biomimetic NDDS enhanced the retention of the drug in the tumor and effectively stimulated the maturation of DCs, resulting in complete tumor eradication in a murine model of CRC.

Notably, long noncoding RNAs (lncRNAs) have recently been reported to be involved in the formation of the immunosuppressive cancer microenvironment and have become a potential immunotherapy target[114-116]. Liu *et al*[117] designed a bioscaffold loaded with a lncRNA-targeting biomimetic NDDS that modulated the cancer immune microenvironment against CRC recurrence after surgery. The biomimetic NDDS coated with a CRC membrane, which provides NDDS with a tumor-homing capacity and carries TSAs into the tumor area, promotes the maturation of DCs. Moreover, a plasmid-encoding short hairpin RNA against Pvt1 was encapsulated inside the NDDS to enhance ICD and ameliorate granulocytic-myeloid-derived suppressor cell (G-MDSC)-mediated immunosuppression. This work provides a new perspective for NDDS-based lncRNA-targeted immunotherapy.

Table 2 Overview of Immunotherapy-based novel nanoparticles in the treatment of hepatocellular carcinoma [PubMed Search (immunotherapy) AND (nanoparticle) AND (hepatocellular carcinoma)]

Type of nanoparticle	Treatment strategy	Drugs or active substance involved	The main involvement of immune cells	Ref.
Nano-micelles	ICD, chemotherapy, PDT	PTX, TPABDTO	CTLs, MDSCs, Tregs, DCs	Xu *et al*[75]
Polymers	p53 gene reprograms the immune microenvironment	p53 mRNA	T cells, NK cells	Xiao *et al*[83]
MSNPs	Anti-angiogenic drugs, ICIs	Sorafenib, PD-L1 antibody	T cells	Li *et al*[84]
Copolymers	ICD, chemotherapy	Icaritin, DOX	T cells, DCs	Yu *et al*[85]

LNPs	Antigen specific vaccine	Tumor-derived RNA	T cells, DCs	Zhang *et al*[98]

ICD: Immunogenic cell death; PDT: Photodynamic therapy; CTLs: Cytotoxic T lymphocytes; PTX: Paclitaxel; MDSCs: Myeloid-derived suppressor cells; DCs: Dendritic cells; CCL2: Chemokine C-C motif ligand 2; CCL5: Chemokine C-C motif ligand 5; DOX: Doxorubicin; PD-L1: Programmed cell death ligand 1; NK cells: Natural killer cells; TAMs: Tumor-associated macrophages; Tregs: Regulatory T lymphocytes; MSNPs: Mesoporous silica nanoparticles; LSEC: Liver sinusoidal endothelial cells; LNPs: Lipid nanoparticles; NKT: Natural killer T.

In recent years, as an important component of the immunosuppressive cancer microenvironment, MDSCs have also been identified as potential targets for cancer immunotherapy. Additionally, recent studies reported that MDSCs could be selectively enlarged because of the enrichment of *Fusobacterium nucleatum* (Fn) in CRC tissue, resulting in a cancer immunosuppressive microenvironment[118-121]. Dong *et al*[122] proposed a phage-based antibacterial system that used the broad-spectrum antibacterial effect of silver nanoparticles (AgNPs) for antibacterial activity and then transported phage M13 into the tumor and utilized the recognition mechanism of phages to selectively kill Fn, thus preventing the recruitment of MDSCs. In addition, phages are highly immunogenic and can directly stimulate the maturation of DCs and promote the activation of M1-like macrophages, significantly enhancing the anti-CRC immune response.

Over the years, CRC vaccines have been a focus of scientific research. Zhang *et al*[123] designed an in situ cancer vaccine. They reported a supramolecular assembled programmable immune activation nanomedicine (PIAN) that can produce strong and durable anticancer immunity in situ. PIAN entered the tumor area through enhanced permeability and retention (EPR) after tail vein injection and was then disassembled by the high ROS within the tumor tissue. The release of poly-[(N-2-hydroxyethyl)-aspartamide]-Pt(IV)/beta-cyclodextrin simultaneously mediated tumor cell death and antigen release. In addition, CpG/polyamidoamine (CpG/PAMAM) captured the released antigen and entered the tumor draining lymph node to stimulate DC maturation, thus activating anti-CRC-specific immunity. This excellent work provides a new idea for designing nanomedicine-based programmable *in situ* cancer vaccines for cancer immunotherapy (Table 3).

IMMUNOTHERAPY-BASED NOVEL NANOPARTICLES IN PANCREATIC CANCER

As one of the most aggressive and fatal cancers, pancreatic cancer has been the leading cause of cancer-related deaths worldwide in the last few decades[124,125]. Most patients experience no obvious symptoms during the development of the disease. Therefore, it is difficult to diagnose the disease in the early stage, and patients often miss the optimal treatment time after they have been diagnosed with pancreatic cancer. Moreover, the majority of patients eventually relapse, even if they receive potentially radical treatment[126]. In contrast to other malignant tumors, stromal hyperplasia is the main feature of the pancreatic cancer microenvironment[127]. As a result, pancreatic cancer does not have a sufficient blood supply, so antiangiogenic drugs are not suitable for pancreatic cancer[128]. In addition, the tumor stroma of pancreatic cancer acts as a natural physical barrier between the tumor tissue and the body's immune system, which also limits the application of immunotherapy[129,130]. Until now, most phase I and II clinical trials of immunotherapy in pancreatic cancer have failed. Interestingly, ICB treatment combined with chemotherapy and/or radiotherapy has shown encouraging clinical efficacy[131]. In recent years, with the continuous development of nanotechnology, scientists have proposed a variety of nanodelivery systems aimed at the unique pathological characteristics of pancreatic cancer. They attempted to utilize NDDSs to achieve synergistic therapy and improve the tumor microenvironment to reverse the current situation of pancreatic cancer[132].

Table 3 Overview of Immunotherapy-based novel nanoparticles in the treatment of colorectal cancer [PubMed Search (immunotherapy) AND (nanoparticle) AND (colorectal cancer)]

Type of nanoparticle	Treatment strategy	Drugs or active substance involved	The main involvement of immune cells	Ref.

ICIs: Immune checkpoint inhibitors; HIF-1α: Hypoxia-inducible factor 1α; PDT: Photodynamic therapy; PTT: Photothermal therapy; ICD: Immunogenic cell death; PD-L1: Programmed cell death ligand 1; PBOXA: Oxaliplatin prodrug; SK: Shikonin, DHA: Dihydroartemisinin; TLR: Toll-like receptor; shPvt1: Short hair-pinned RNA against Pvt1; Fn: *Fusobacterium nucleatum*; PPCD: Poly-[(N-2-hydroxyethyl)-aspartamide]-Pt(IV)/beta-cyclodextrin; PAMAM: Polyamidoamine; MDSCs: Myeloid-derived suppressor cells; DCs: Dendritic cells; CTLs: Cytotoxic T lymphocytes; TAMs: Tumor-associated macrophages; Tregs: Regulatory T lymphocytes; MDSCs: Myeloid-derived suppressor cells.

As we mentioned above, the tumor stroma of pancreatic cancer limits the efficacy of immunotherapy. Wang *et al*[133] reported a pH-responsive clustered nanoparticle (iCluster) loaded with both siPD-L1 and transforming growth factor-β (TGF-β) receptor inhibitors (LY2157299). iCluster can deliver siPD-L1 and LY2157299 to tumor blood vessels and then release small PAMAM at acidic tumor extracellular pH (pH_e). Therefore, siPD-L1 can penetrate into tumor tissue as deeply as possible to activate anticancer immunity, and a TGF-β receptor inhibitor can reduce the barrier function of the tumor stroma to help more drugs penetrate into the tumor tissue, further promoting the activation of anticancer immunity. Similarly, Yu *et al*[134] designed a size-adjustable nanoparticle consisting of IR780 containing the thermosensitive ICB drug (BMS-202) conjugated to HSA-BMS. Under mild hyperthermia therapy, this novel nanoparticle releases the small HSA-BMS into the tumor site and relieves the immunosuppressive environment to normalize immunity. In recent years, some studies have reported that RNA interference (RNAi) has emerged as a better agent for inducing anticancer immunity than antibodies or small molecules *in vivo*[135]. PLGA polymers have been proven to be a potentially excellent siRNA delivery vector exhibiting low toxicity, sustained release and the EPR effect[136,137]. Jung *et al*[138] developed a poly(lactic-co-glycolic) acid (PLGA)-based siRNA nanoparticle named siPD-L1@PLGA. siPD-L1@PLGA increased the infiltration of $CD8^+$ T cells and significantly inhibited tumor growth.

The poor immunogenicity and excessive immunosuppressive cancer microenvironment of pancreatic cancer result in a lack of adequate antigen-presenting cells in the tumor microenvironment. Lorkowski *et al*[139] reported a dual-immunostimulatory nanoparticle that was simultaneously loaded with a STING agonist and TLR4 agonist. These dual-immunostimulatory nanoparticles can be taken up by DCs in the tumor site to significantly increase the number of mature DCs and activate anticancer immunity in pancreatic cancer. Theoretically, cancer immunosuppressive cells mainly include TAMs, MDSCs and regulatory T cells (Tregs). Recent studies have shown that MDSCs are the major inhibitory immune cells in the immunosuppressive microenvironment of pancreatic cancer[140]. A previous study found that low-molecular-weight heparin-D-α-tocopheryl (LMWH) could significantly inhibit G-MDSC recruitment[141]. Therefore, Lu *et al*[142] designed a paclitaxel-loaded 3-aminophenylboronic acid-modified LMWH-based nanoparticle. This novel LMWH-based nanoparticle can inhibit the recruitment of MDSCs and weaken the immunosuppressive state.

Pyroptosis is a mode of programmed cell death[143]. Recent studies have shown that pyrophosis can induce powerful anticancer immunity[144-146]. However, pyrophosis is usually induced by chemotherapeutic drugs, which limits the applications of pyrophosis in drug-resistant tumors[147]. Ding *et al* [148] designed biodegradable K3ZrF7:Yb/Er UCNPs (ZrNPs) as self-therapeutic agents and pyrophosis

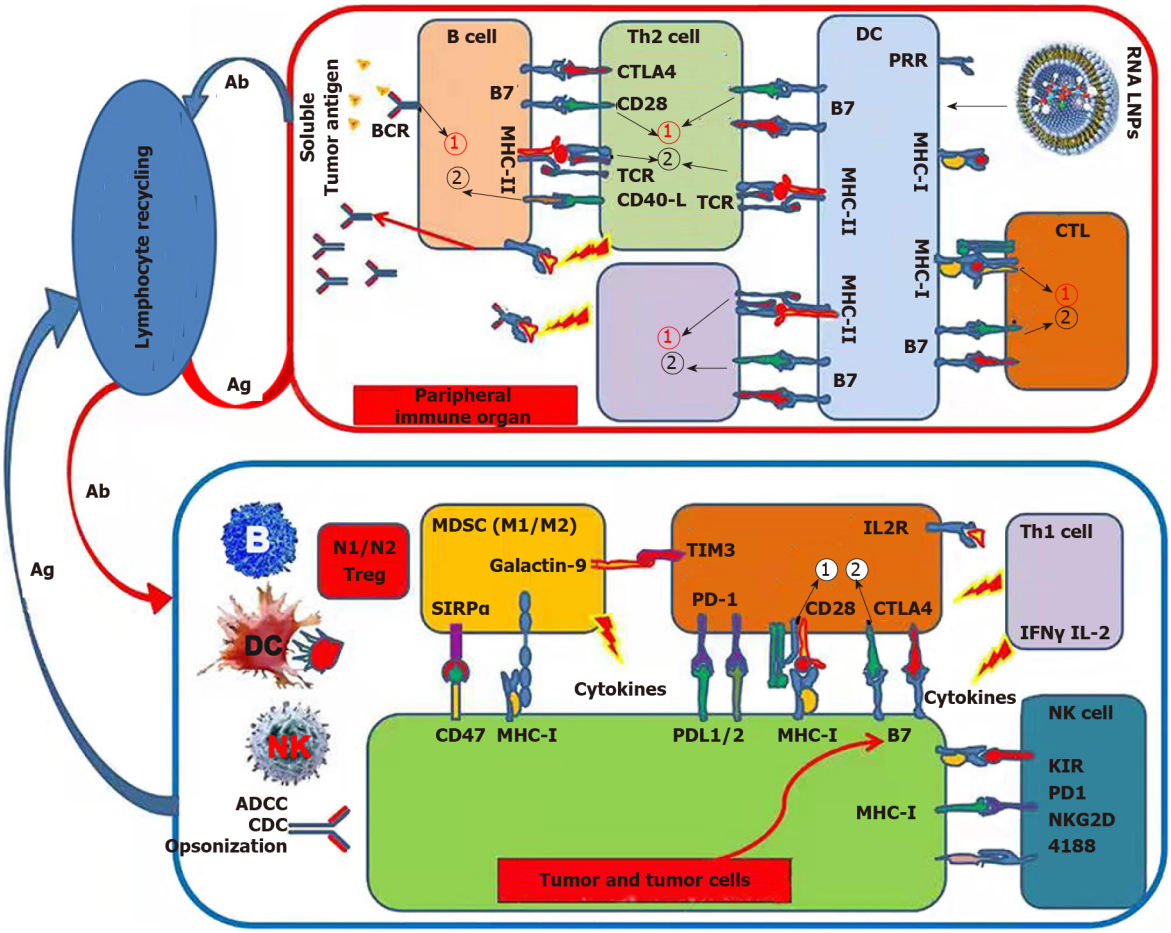

Figure 1 Tumor vaccine and tumor immunotherapy. Total tumor RNA was extracted and mixed with an immune adjuvant to formulate tumor vaccine. inducers for the first time. ZrNP can lead to osmotic pressure disorder and further result in an increase in ROS, the activation of caspase-1 protein, the cleavage of gasdermin, the maturation of interleukin-1β, and ultimately cytolysis. ZrNP-induced pyrophosis can lead to DC maturation and activate effector memory T cells, as well as inhibit tumor growth and metastasis.

Gemcitabine is among the most effective FDA-approved chemotherapy drugs to prolong survival in patients with pancreatic cancer. However, the immunosuppressive cancer microenvironment, especially the presence of TAMs, significantly weakens the efficacy of gemcitabine. It has even been reported that gemcitabine can induce an increase in TAMs and promote the establishment of a tumor-suppressive immune microenvironment, which further increases gemcitabine drug resistance[149]. Furthermore, gemcitabine can even induce an increase in TAMs and promote the establishment of an immunosuppressive tumor microenvironment, which further leads to gemcitabine drug resistance[150]. Thus, Wang *et al*[151] developed a biomimetic nanoparticle named PG@KMCM consisting of gemcitabine-loaded PLGA nanoparticles coated with stable M2-like macrophage targeting peptides (M2pep). Pancreatic cancer cell membranes can deliver PG@KMCM to pancreatic cancer and target M2-like macrophages by M2pep to reprogram TAMs and reverse gemcitabine drug resistance. Cao *et al*[152] also considered TAMs to be a therapeutic target and reported a reduction-responsive RNAi NDDS to regulate the function of TAMs and reprogram tumor lipid metabolism. On the one hand, this novel NDDS can block the activity of monoacylglycerol lipase (MGLL) by MGLL siRNA to reduce the production of free fatty acids and thus cut off the tumor's nutrition supply. On the other hand, MGLL blockade may lead to the accumulation of 2-arachidonoylglycerol, which can be secreted into the cancer microenvironment and activate the endocannabinoid receptor-2 (CB-2), which can transform TAMs into M2-like macrophages.

Therefore, they prepared CB-2 siRNA to block CB-2 expression, preventing the transition of M2-like macrophages. The dual-RNAi NDDS developed in this research shows significant enhancement of the immunological environment in pancreatic cancer.

PTT has achieved satisfactory results in animal experiments, but it is difficult to apply widely in the clinic. The main reason is poor light penetration. It is harder to achieve the desired therapeutic effect for pancreatic cancer due to the depth of pancreatic cancer and the presence of the tumor stroma. To solve this conundrum, Wang *et al*[153] proposed magnetic resonance imaging (MRI)-guided interventional PTT (IPTT). They designed an iron oxide-based nanoparticle loaded with indocyanine green for PTT and imiquimod (IMQ) as an immunostimulant. IPTT can induce *in situ* cancer vaccination, which can be amplified by IMQ. In addition, iron oxide is a widely used MRI contrast agent. A recent study reported that iron oxide can modulate the cancer microenvironment by transforming M2-like macrophages into M1-like macrophages[154]. Overall, these novel iron oxide-based nanoparticles can improve therapeutic effects by directly killing cancer cells and activating the long-lasting immune effect by *in situ* vaccination and regulation of the immune microenvironment (Table 4).

FUTURE DIRECTIONS

In recent years, the increased development of immunotherapy has provided hope to patients with advanced cancer. Several ICB drugs have been approved by the FDA for clinical application in cancer treatment. However, due to the immunosuppressive microenvironment, only approximately 20% of patients can benefit from ICB treatment. In addition to ICB treatment, some conventional therapies, such as chemotherapy and radiotherapy, are also closely related to the immunosuppressive tumor microenvironment. The facts we mentioned above also exist in GIC. Therefore, we believe that in addition to ICB treatment, we should focus on reversing the immunosuppressive microenvironment in the future. Moreover, advances in nanotechnology have made drug delivery more efficient, allowing us to deliver drugs at specific times and locations based on the characteristics of the cancer and the drugs. We wondered whether the combination of nanotechnology and immunotherapy could achieve satisfactory therapeutic efficacy in GIC. Here, we summarize recent advances in immunotherapy-based novel nanoparticles in the treatment of GIC.

Since GC, HCC and CRC share similar tumor immune microenvironments, we will discuss the application of immunotherapy-based nanoparticles in these three kinds of GICs in the following paragraphs. Due to the limited monotherapy effect of ICB treatment, nanoparticles, as drug delivery vehicles, cannot significantly improve the therapeutic effect of ICB treatment. Thus, basically all ICB-based nanoparticles are combined with other therapeutic strategies. ICB treatment can reverse tumor immune escape from T cells. However, the low immunogenicity of the tumor results in insufficient T-cell infiltration in the tumor tissue. Hence, most studies have attempted to promote the therapeutic effect of ICB-based nanoparticles by inducing ICD.

ICD can increase tumor immunogenicity, but similar to ICB treatment, the immune-stimulating effect of ICD is limited. To amplify the ICD effect, some studies utilized the drug-loading capacity of nanoparticles and adopted a combination of multiple ICD inducers to enhance the immune response. Even so, we still do not recommend the combination of multiple ICD inducers to promote anticancer immunity. On the one hand, this strategy does not solve the problem of insufficient T-cell infiltration; on

the other hand, ICD inducers themselves can directly kill tumor cells. It is difficult to determine whether tumor inhibition is due to cytotoxicity or ICD-induced anticancer immunity.

Compared with ICD and ICB treatment, we believe that reprogramming the immunosuppressive tumor microenvironment by targeting inhibitory immune cells (*e.g.*, TAMs, Tregs and MDSCs) will be a revolutionary breakthrough in cancer immunotherapy in the future. Recently, many studies have attempted to successfully reprogram the tumor immune microenvironment by polarizing M2-like macrophages into M1-like macrophages. However, few reports have designed NDDSs to target Tregs and MDSCs in the tumor microenvironment. Therefore, it is of great significance to develop NDDSs for Tregs and MDSCs. In addition, the relationship between the intestinal flora and the immunosuppressive microenvironment of CRC also deserves future attention.

TLR agonists have also emerged as a promising treatment for cancer immunotherapy. However, due to the lack of targeting of TLR agonists, free TLR agonists often lead to serious systemic side effects. Therefore, it is necessary to deliver TLR agonists by nanoparticles. Numerous TLR agonists have been proven to be effective in stimulating anticancer immunity. In addition, combination therapies of TLR agonists with other immunotherapies are also anticipated. However, how to deliver TLR agonists to the tumor site stably and accurately and reduce serious systemic side effects are still problems that need prompt solutions.

With the successful large-scale clinical application of SARS-CoV-2 mRNA vaccines, research on cancer vaccines is also imminent. Due to the high heterogeneity of cancer, RNA vaccines are the best option. However, RNA is highly unstable. Liposomes, as mature NDDSs, can prepare cancer vaccines by encapsulating RNA. In addition, to improve the vaccine effect, NDDSs can be encapsulated with immune adjuvants to promote immune activation. RNA-based cancer vaccines, as a personalized cancer treatment strategy, can effectively improve anticancer immunity.

Next, we will discuss the application of immunotherapy-based nanoparticles in pancreatic cancer. Pancreatic cancer has several characteristics that are not found in other kinds of GICs, including the following: (1) Pancreatic cancer is surrounded by a tumor stroma, resulting in a physical barrier that isolates pancreatic cancer from the surrounding immune microenvironment; (2) Due to the anatomic position of the pancreas, pancreatic cancer is located deep in the abdominal cavity and therefore is not sensitive to PDT and PTT; and (3) Unlike other GICs, pancreatic cancer lacks blood supply and can adapt to nutrient deficiency and in a long-term hypoxic state.

To pass through the physical barrier of pancreatic cancer, size-adjusted NDDSs are the best option. Due to the deep location of pancreatic cancer, PTT has limited efficacy. Inspired by a previous study, we believe that IPTT and interventional PDT can be widely applied in the treatment of pancreatic cancer.

Additionally, interventional light-mediated therapy can be extended to GC, esophageal cancer and CRC, as well as HCC.

Compared with GC, HCC and CRC, pancreatic cancer has a similar immunosuppressive microenvironment, and the immunosuppressive situation is even worse. Most of the treatment strategies mentioned in GC, HCC and CRC can also be applied in pancreatic cancer. In previous reports, immunotherapy-based nanoparticles mainly used liposomes and copolymer nanoparticles, which are chemical synthesis products. Therefore, the nanoparticles can be designed according to demand. To increase biocompatibility and deliver tumor antigens, some literature has used tumor cell membranes to prepare biomimetic NDDSs, which have also achieved good results. In addition to the abovementioned nanoparticles, we particularly recommend small extracellular vesicles (also known as exosomes) as immunotherapy-based nanoparticles. First, exosomes are naturally nanosized. Second, similar to cell membrane vesicles, exosomes derived from tumor cells can carry tumor antigens. Third, exosomes can use surface modification to achieve biological functions, such as targeting. Last, exosomes have a certain drug delivery capacity. Thus, exosomes are potential immunotherapy-based nanoparticles for GIC that have not been reported in previous studies.

CONCLUSION

GIC is a common tumor worldwide. The immune microenvironments of GC, HCC, CRC and pancreatic cancer have similarities and differences. There are still many mechanisms of immune escape in GIC that are not well understood. Therefore, we need an in-depth understanding of the characteristics of each kind of GIC to take advantage of its characteristics and design immunotherapy-based nanoparticles.

Abstract

BACKGROUND

Colorectal cancer (CRC) is one of the most common malignant tumors worldwide. The identification of novel diagnostic and prognostic biomarkers for CRC is a key research imperative. Immunohistochemical analysis has revealed high expression of centromere protein K (CENPK) in CRC. However, the role of CENPK in the progression of CRC is not well characterized.

AIM

To evaluate the effects of knockdown of CENPK and overexpression of Cullin 4A (CUL4A) in RKO and HCT116 cells.

METHODS

Human colon cancer samples were collected and tested using a human gene expression chip. We identified CENPK as a potential oncogene for CRC based on bioinformatics analysis. *In vitro* experiments verified the function of this gene. We investigated the expression of CENPK in RKO and HCT116 cells using quantitative polymerase chain reaction (qPCR), western blot, and flow cytometry. The effect of short hairpin RNA (shRNA) virus-infected RKO cells on tumor growth was evaluated *in vivo* using quantitative analysis of fluorescence imaging. To evaluate the effects of knockdown of CENPK and overexpression of CUL4A in

RKO and HCT116 cells, we performed a series of *in vitro* experiments, using qPCR, western blot, MTT assay, and flow cytometry.

RESULTS

We demonstrated overexpression of CENPK in human colon cancer samples. CENPK was an independent risk factor in patients with CRC. The downstream genes FBX32, CUL4A, and Yes-associated protein isoform 1 were examined to evaluate the regulatory action of CENPK in RKO cells. Significantly delayed xenograft tumor emergence, slower growth rate, and lower final tumor weight and volume were observed in the CENPK short hairpin RNA virus infected group compared with the CENPK negative control group. The CENPK gene interference inhibited the proliferation of RKO cells *in vitro* and *in vivo*. The lentivirus-mediated shRNA interference of CENPK inhibited the proliferation of RKO and HCT116 colon cancer cells, with overexpression of the CUL4A.

CONCLUSION

We indicated a potential role of CENPK in promoting tumor proliferation, and it may be a novel diagnostic and prognostic biomarker for CRC.

Key Words: Colorectal cancer; Centromere protein K; Bioinformatics analysis; Lentivirus-mediated short hairpin RNA interference; Cullin 4A

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer in the Western Hemisphere, and the incidence increases with age. RNA interference has been developed to silence genes of interest. Short hairpin RNA (shRNA) expression vectors are useful in gene silencing[1]. The shRNA-mediated silencing of MASTL expression in colon cancer cells induced cell cycle arrest and apoptosis *in vitro* and xenograft-tumor growth *in vivo*[2]. Emerging studies have suggested that shRNAs play a crucial role in CRC tumorigenesis and progression[3]. Inducible gene knockdown systems based on lentivirus-mediated gene transfer were developed to regulate colon cancer progression[1]. This property of the shRNA system offers unique applications to study gene function in animals that cannot be achieved using knockout technologies[4]. Although lentivirus vectors have been used for several years, the use of Tet-on lentiviral vectors expressing shRNA as a therapeutic tool for CRC has not been clearly explored[5].

The role of centromere protein K (CENPK) in cancer is an emerging research hotspot. CENPK is overexpressed in several tumor types, and it promotes tumor progression. Research on the role of CENPK in the progression of hepatocellular carcinoma (HCC) has shown that CENPK knockdown significantly inhibits proliferation, migration, invasion, and epithelial-mesenchymal transition in HCC cells[6]. The expression of CENPK has been silenced and promoted *via* lentivirus-mediated transfection with shRNA sequences in differentiated thyroid carcinomas, such as two pore channel 1 and FTC-133 cells[7]. CENPK is specifically upregulated in ovarian cancer tissues and cell lines, and its overexpression is associated with a poor prognosis in patients with ovarian cancer[8]. Overexpression of CENPK promotes expression of oncogenic cell cycle regulators[9]. However, there has been little research on the role of CENPK in the progression of CRC.

The ubiquitin ligase Cullin 4A (CUL4A) is highly expressed in CRC. CUL4A promotes proliferation and inhibits apoptosis of CRC cells by regulating the Hippo pathway[10]. CUL4A significantly promotes the migration of CRC cells *in vitro*, which suggests that CUL4A acts as an oncogene in CRC

and may become a potential therapeutic target[11]. Therefore, CUL4A expression positively correlates with the prognosis of CRC[12]. Despite extensive fundamental studies, the role of CUL4A expression and lentivirus-mediated transfection with shRNA for CENPK in CRC is not clear. The present study identified CENPK as a novel proto-oncogene in CRC. Increased CENPK levels were found in CRC specimens and negatively correlated with survival rate. Knockdown of CENPK in RKO and HCT116 CRC cells induced apoptosis and suppressed cell proliferation and xenograft tumor formation. Lentivirus-mediated transfection with shRNA for CENPK and CUL4A overexpression played major regulatory roles in CRC.

MATERIALS AND METHODS

Patient information and immunohistochemistry

Fourteen patients with CRC were enrolled from 2016 to 2019, and five tumor-adjacent normal tissues were taken from an area > 10 cm away from the primary neoplasm. The median age of the patients was 59 years (range: 49-68 years) at the time of surgery, and the median follow-up was 31 mo postoperatively (range: 25-37 mo). The Ethics Committee of The Affiliated Hospital of Inner Mongolia Medical University approved the study. Written informed consent was obtained from all patients.

The expression and localization of CENPK protein in 14 cancerous and five noncancerous tissue samples were detected using immunohistochemistry. An antibody against CENPK (26208-1-AP, 1:100; SIGMA) was used for analysis. Vulcan Fast Red Chromogen kit 2 staining was performed for 15-20 min to stop the reaction until 3,3-diaminobenzidine staining was performed to obtain a yellow color to complete the reaction. The staining intensity and positive rate of cytosolic and membrane staining of the antibody (0/1+/2+/3+) in the cancer and adjacent tissue (epithelium) were interpreted. The intensity of the staining score was 0 (negative), 1 (weak), 2 (middle), and 3 (strong). The positive rate of staining was as follows: 0 (negative), 1 (1%-25%), 2 (26%-50%), 3 (51%-75%), and 4 (76%-100%).

Primeview human gene expression array of PathArray™

Gene expression in a human colon cancer tissue chip (C06161) was detected. The sample was divided into male (age < 57 years) and female (age > 57 years) groups by T stage, N stage, pathological grade, and clinical stage. For the chip assay, total RNA was extracted from tissue using the TRIzol method and measured using a Nanodrop 2000. Qualified samples were used in the chip experiment. The quality checking standard was 1.7 < A260/A280 < 2.2 on Thermo NanoDrop 2000 and RNA integrity number (RIN) ≥ 7.0 and 28S/18S > 0.7 on the Agilent 2100 Bioanalyzer. The quality check results are shown in Table 1. The human gene expression chip type was GeneChip PrimeView Human (100 format, 902487; Affymetrix). Chip hybridization was performed in a GeneChip Hybridization Oven 645 ChIP, washing and dyeing were performed using a GeneChip Fluidics Station 450, and ChIP scanning was performed using a GeneChip Scanner 3000. The reagent used was a GeneChip Hybridization Wash and Stain Kit.

For the chip detection, gradient dilution of poly-A RNA controls was prepared to synthesize the first-chain cDNA and second-chain cDNA, and then cRNA of synthetic markers was synthesized *via* transcription *in vitro*, which was followed by cRNA purification and quantification to obtain cRNA fragment markers. The expression analysis of the CENPK gene in human colon cancer tissue in the chip (C06161) and clinical data are shown in Table 2. A statistical analysis of CRC tissue chips was performed.

Cell culture

The human CRC cell lines RKO and HCT 116 were cultured in RPMI 1640 medium (Invitrogen) supplemented with 10% fetal bovine serum (FBS) (Corning) and 1% penicillin and streptomycin solution (Corning) at 37 °C with 5% CO_2[13].

Quantitative polymerase chain reaction

Total RNA was extracted from RKO cells with TRIzol reagent (Thermo Fisher Scientific). A 1-mg RNA sample was reverse transcribed into first-strand cDNA using the Revert Aid First Strand cDNA Synthesis kit (Thermo Fisher Scientific). Quantitative polymerase chain reaction (qPCR) was performed using the Taq-Man Gene Expression assay (Thermo Fisher Scientific) on an Mx3000P real-time PCR system (Agilent Technologies). The primer pairs were designed and synthesized by Sangon Biotech (GAPDH: Forward, TGACTTCAACAGCGACACCCA and reverse, CACCCTGTTGCTGTAGCCAAA; CENPK: Forward, ATGGTACTGTCCACTAAGGAGTC and reverse, TGTTCATCCAACCACCGTTGT). The mRNA levels were normalized to the internal reference gene GAPDH, with the mRNA relative expression calculated using the $2^{-\Delta\Delta Ct}$ method.

Western blot analysis

After protein extraction from RKO cells, the protein concentrations of different groups were quantified using a commercial BCA kit. Electrophoresis was performed for 2 h at 4 °C and 300 mA, and the protein

was transferred to polyvinylidene fluoride (PVDF) membranes (IPVH00010; Millipore) for immunostaining. The PVDF membranes were incubated in TBST solution containing 5% skimmed milk at room temperature for 1 h. The antibodies were diluted in the blocking solution and then incubated with the PVDF membranes for 2 h at room temperature. The antibodies applied in the present study included those against Yes-associated protein isoform 1 (YAP1) (ab52771; Abcam), CENPK (ab13939; Abcam), CUL4A (ab92554; Abcam), F-box protein 32 (FBX32) (ab168372; Abcam), X chromosome-linked inhibitor of apoptosis (XIAP) (ab28151; Abcam), heat shock protein 90 family class A member 1 (HSP90AA1) (4877; Cell Signaling Technology), class III-tubulin (TUBB3) (#5568; Abcam), and mitogen-activated protein kinase kinase kinase 7 (MAP3K7) (ab109526; Abcam). After primary antibody incubation, the membranes were washed three times with TBST (10 min each) and incubated with the secondary antibodies mouse immunoglobulin G (IgG) (1:2000, sc-2005; Santa Cruz Biotechnology) and rabbit IgG (1:2000, sc-2004; Santa Cruz Biotechnology) at room temperature for 2 h. The Pierce ECL Western Blotting Substrate kit (Thermo) was used for X-ray photography.

Establishment and examination of a tumor model

The Ethics Committee of The Affiliated Hospital of Inner Mongolia Medical University approved the study. RKO cells with sufficient logarithmic growth were digested with trypsin and suspended in culture medium with the final cell density adjusted to 2.0×10^7/mL. To establish the tumor model, 4.0×10^6 cells were subcutaneously injected into mice. The tumor size and animal body weight were measured 5-20 d later. The tumor volume was calculated as $\pi/6 \times L \times W \times W$, where L represents the long diameter, and W and W represent the short diameter. Cancer progression was imaged at 10 d after tumor formation (animals were fasted for 1 d in advance to reduce fluorescence interference) with intraperitoneal injection of 10 μL/g D-luciferin (Bench Mark 15 mg/mL) into mice. After anesthesia by intraperitoneal injection of 10 μL/g pentobarbital solution (BM 7 mg/mL), the mice underwent imaging examination, quantitative analysis, and total fluorescence examination to determine the CENPK function *in vivo*. After imaging, the experimental animals were killed with an overdose of 2% sodium pentobarbital (0.5 mL) and were in a complete coma before removal of the cervical spine to confirm death. Animals were dissected with medical scissors and tweezers to observe the lungs, liver, and other organs and tissues, which were removed for imaging to observe biological changes and measure the fluorescence.

Construction and packaging of lentiviral vectors

293T cells for lentivirus packaging were cultured in Dulbecco's modified Eagle's medium supplemented with 10% FBS. The scramble order for the RNAi negative control was TTCTCCGAACGTGTCACGT. Vector enzyme digestion products were obtained for agarose gel electrophoresis to recover bands of interest. The framework of the viral vector was constructed, and single-strand primers were synthesized. Double-stranded DNA was formed by annealing the primer to the vector. After transformation, the bacterial colonies were assessed by PCR. Identified positive carbendazim transformants were inoculated into Luria-Bertani (LB) liquid medium containing an appropriate amount of antibiotics, and an appropriate amount of bacterial solution was incubated at 37 °C for 12-16 h. The incubated bacterial solution was transferred to 10 mL LB liquid medium containing the corresponding antibiotics for culture at 37 °C overnight. The plasmid was extracted with the small medium-lift kit from Tiangen, and the qualified plasmid was extracted for the following experiments.

Lentiviral infection

The lentivirus-infected HCT116 cells are shown in Table 3. RKO and HCT 116 cells (2×10^5 cell/mL) were cultured in RPMI 1640 medium containing 10% FBS with polybrene in six-well plates. The following experimental groups were used: (1) Cells (RKO or HCT 116 cells) infected with CENPK negative control virus [NC (KD)]; (2) Cells with lentivirus-mediated shRNA interference of CENPK (KD); (3) Cells with overexpression and negative control virus interference [NC (OE)]; (4) Cells virally infected with CUL4A (OE); (5) Cells with shRNA interference of CENPK and overexpression of negative control virus [KD + NC (OE)]; and (6) Cells with lentivirus-mediated shRNA interference of CENPK and CUL4A (KD + OE).

For the lentiviral infection, media for adherent cell inoculation and viral infection were used at a 1:1 ratio in 96-well plates. The culture medium was replaced, and the optimal amount of virus was added for the infection. The most appropriate time point after infection was selected for the replacement of conventional medium and continued culture, 8-12 h after infection. When fluorescently labeled lentiviral infection occurred, the green fluorescent protein reporter signal was observed by fluorescence microscopy 72 h after infection. After infection efficiency reached 80%, 0.5 mL of puromycin was used for cell function experiments. Western blot and qPCR analysis were performed to confirm the knockdown of CENPK.

Detection of cell growth

The proliferation potential of RKO and HCT 116 cells was analyzed by cell growth curve and MTT assay. For the cell growth curve assay, RKO and HCT 116 cells of different groups [shCtrl and shCENPK or NC, NC (KD), NC (OE), OE, KD + NC (OE), and KD + OE] were collected, replated in 24-well plates at 2000 cells/well, and cultured at 37 °C in a 5% CO_2 incubator for 5 d. Beginning on day 2, the optical absorption value of each group was checked once daily and the number of fluorescent cells calculated. A growth curve was drawn to show cell proliferation.

For the MTT assay, RKO and HCT 116 cells were replated in 24-well plates at 2000 cells/well and cultured at 37 °C in a 5% CO_2 incubator for 24 h. Subsequently, 20 μL MTT (5 mg/mL) was added to the wells. After incubation for 4 h, reactions were stopped with 100 μL DMSO. After shaking for 2-5 min, the OD value at 490/570 nm was determined (M2009PR, Tecan Infinite).

Apoptosis detection

Apoptosis was analyzed by flow cytometry (fluorescence-activated cell sorting; FACS) with a commercial Annexin V-APC kit (88-8007, eBioscience). RKO and HCT 116 cells of each group were collected after washing in 1 × binding buffer, and centrifuged at 1300 rpm for 3 min. After centrifugation, the cell suspension was prepared by adding 200 μL of 1 × binding buffer. Subsequently, 10 μL of Annexin V-APC staining solution was added to the suspension. After incubation in the dark at room temperature for 10-15 min, 400 μL of 1 × binding buffer was added to the cell suspension, and FACS was conducted for apoptosis detection.

Caspase 3/7 detection

Caspases 3/7 were detected in RKO and HCT 116 cells using a commercial Caspase-Glo3/7 detection kit (G8091, Promega). For the preparation of Caspase-Glo reaction solution, 10 mL of caspase-Glo3/7 buffer was added and vortexed until the dissolve of substrates. After collection and counting, the RKO and HCT 116 cells at a final density of 10^4 cells/well were replated in 96-well plates, and an empty control group containing culture medium without RKO or HCT 116 cells was established. Next, 100 μL of Caspase-Glo reaction solution was added to each well and shaken for 30 min at 500 rpm at room temperature for 2 h. The signal strength was measured using a microplate reader (M2009PR, Tecan Infinite).

PathScan® array detection

RKO cells were incubated with 1 mL of 1 × cell lysis buffer (Cell Signaling Technology) containing 1 mmol/L PMSF on ice for 2 min. Then, 100 μL of blocking solution was added to RKO cells with the cell

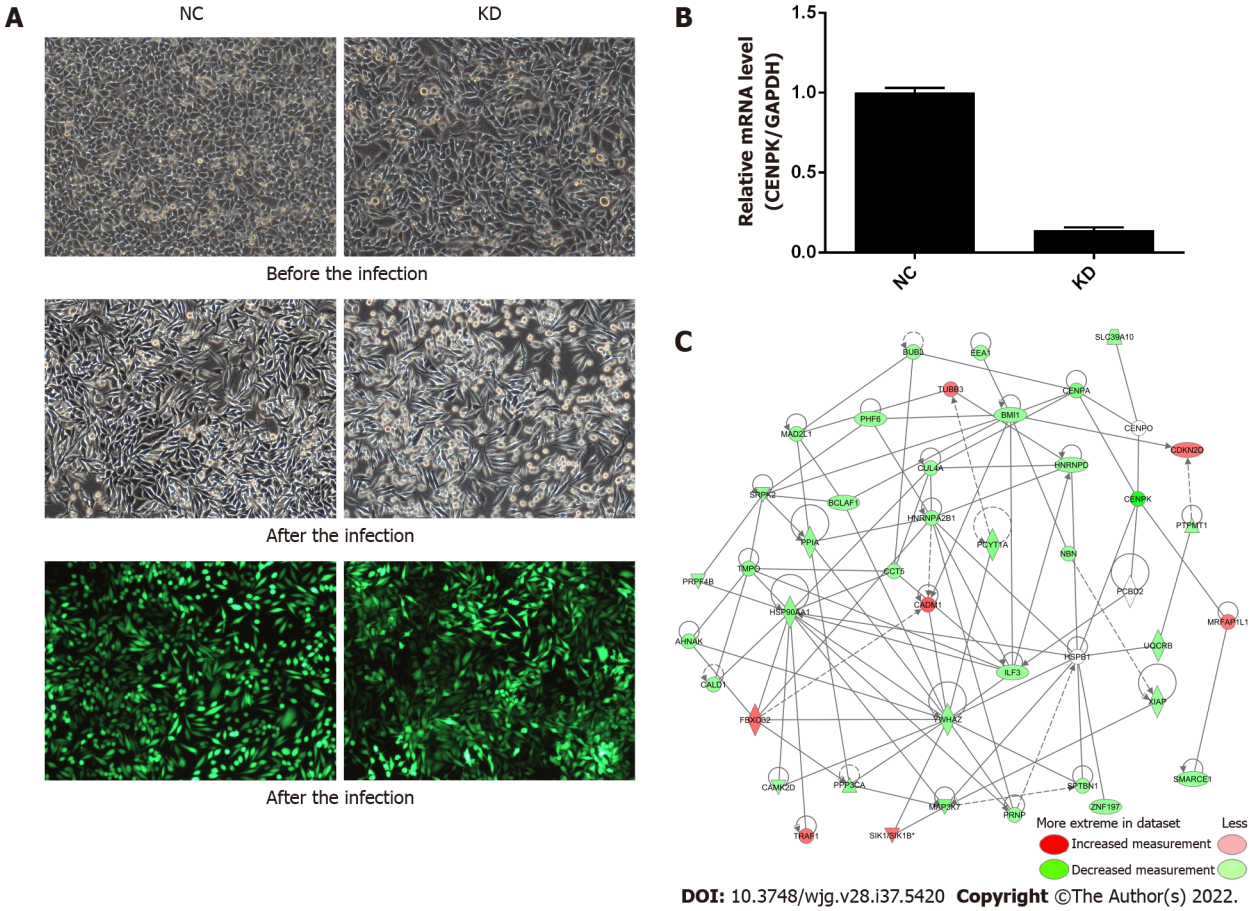
lysate samples shaken at room temperature for 15 min. After incubation at room temperature for 2 h, the cell lysate samples were washed with 1 × cleaning solution on a horizontal shaker for 5 min. After three washes, 75 μL of 1 × antibody was added to the cell lysate samples and incubated on a horizontal shaker for 1 h. Then, 75 μL of 1 × HRP-linked streptavidin solution was added, followed by incubation on a horizontal shaker for 1 h. 1 × array cleaning solution was added to the cell lysate samples, which were then washed on a horizontal shaking bed four times (5 min each). The slides were placed in 1 × cleaning solution and then in exposure liquid (9 mL deionized water + 0.5 mL lumiGlo + 0.5 mL hydrogen peroxide) for 1-2 s, followed by observation with a chemiluminescence imaging system (ChemiScope 5300; Clinx Science Instruments).

Statistical analysis

Statistical analyses were performed using SPSS version 19.0 (IBM Corp.). Data are presented as the mean ± SD. Data comparing two samples were analyzed using student's *t*-test. Comparisons of datasets containing > 3 groups were evaluated by one-way repeated-measures ANOVA followed by the Bonferroni *post hoc* test. Gene expression of cancer and noncancer tissue groups was evaluated by the Mann-Whitney *U* test. $P < 0.05$ was considered to indicate a significant difference.



RESULTS

Lentivirus infection for inducing CENPK knockdown

For lentiviral infection marked with antibiotic resistance genes, the antibiotics (such as puromycin) were used to screen cells after 72 h, and the infection efficiency was approximately 80% for fluorescence labeled lentivirus infection (Figure 1A). CENPK knockdown efficiency in RKO cells in the KD group reached 86.1% compared to the NC group (23.4%) (Figure 1B). This analysis revealed the genes related to tumor cell proliferation and invasion. The genes that inhibited tumor cell proliferation or tumor invasion were selected, together with the target genes of concern, to develop a gene relationship network diagram. This analysis suggested that CENPK affected the proliferation and invasion of cells by acting on YWHAZ and BMI1, which affected the performance of downstream genes. The gene interaction network diagram shows a network of interaction relationships between molecules within a determined functional region. Different shapes represent genes, proteins, and chemicals in the network maps (Figure 1C).

Screening of target genes CENPK by chip detection

The original quality evaluation for the quality control data and the remaining data meeting the filter standards, including significant difference analysis and functional analysis of differential genes, was used to evaluate the tumor occurrence, development, metastasis, and other molecular mechanisms using chip information analysis for target screening and drug design. Figure 2A shows the signal strength distribution of the entire chip probes. Better signal intensity distribution curves of different samples indicated higher reliability of the chip experiment. The average *Z* score of all samples within one signal strength range was < 2, which supported the reliability of all chip results meeting the continuing analysis criteria. Figure 2B shows the distribution of the relative logarithmic signal strength for all chips. Closer distribution of the relative logarithmic signal strength box diagram indicated better repeatability of the data. The median *Z* score for all samples was < 2, which indicated good repeatability of the chip experiments in the project that met the continued analysis criteria. The Pearson correlation coefficient distribution diagram shows the level of correlation of the signal strength between all chips, where each lattice represents the degree of correlation between two samples corresponding to the

ordinate and transverse (Figure 2C). The group sample gene expression patterns were typically similar and demonstrated a high correlation coefficient, as shown in red in the correlation coefficient distribution diagram. The gene expression pattern difference between groups demonstrated a low correlation coefficient, which is shown in blue in the correlation coefficient distribution diagram. The correlation coefficient in the KD and NC groups was > 0.99, which indicated a high similarity of gene expression in the same group. The intergroup correlation coefficient was significantly lower than the group correlation coefficient, which indicated a large difference between groups that met the continuing analysis standard.

From the PCA score chart (Figure 2D), there was an obvious sample aggregation trend in the PC1 and PC2 dimensions in the KD and NC groups and an obvious intergroup separation trend, which indicated similar samples and significant differences between groups that met the standard of the continuing analysis. The cross ordinate of each point in Figure 2E represents the signal strength of a probe group in the NC and KD groups. The parallel green solid line is the reference line difference, and the points in the interval within the reference line represent the probe group without a significant change. The red point outside the interval represents the relatively elevated probe group in the KD group, and the green point represents the relatively elevated probe group in the NC group. A volcano graph was drawn using gene expression differences (fold change) and false discovery rate (FDR) tests between the two samples to show the significant differences between the two samples (Figure 2F). Thermal mapping of KD and NC samples was performed using the differential expression spectrum of genes screened by |fold change| ≥ 1.5 and FDR < 0.05 (Figure 2G). Figure 2H shows the significant enrichment of differentially expressed genes in the classical pathway. The orange notation indicates an activated pathway ($Z > 0$); the blue label indicates inhibition of the pathway ($Z < 0$); shades of orange and blue (or absolute Z values) represent the degree of activation or inhibition ($Z \geq 2$ represents a significant activation and standard, and $Z \leq -2$ denotes significant suppression); and the ratio represents the ratio of the difference of the gene number in this signaling pathway to all genes contained in the pathway. G1/S checkpoint regulation was activated in the cell cycle, and Z was 2.236.

Figure 2 Screening of target genes by chip detection. A: Signal strength distribution curve diagram, with the cross coordinates representing the probe signal strength range and the longitudinal coordinates representing the number of probe sets within the signal strength range; B: Relative line ram of the logarithmic signal strength, with the horizontal coordinate representing the sample name, the vertical coordinate indicating the relative logarithmic signal strength, the red line in the middle representing the average of the relative logarithmic signal strength of all samples, and the upper and lower horizontal lines representing the 90% confidence interval. The upper and lower edges represent the upper and lower quartiles, and the black line in the middle represents the median; C: Distribution diagram of the Pearson correlation coefficient among samples. The correlation coefficient indicates a positive correlation of the expression mode of genes in two subjects, and a negative value indicates an expression mode with a negative correlation. As the absolute value of the correlation coefficient approaches 1.0, the correlation increases; D: Principal component analysis. Red dots represent normal purpose cells with centromere protein K (CENPK) gene short hairpin RNA virus infection (KD) samples, and green dots represent normal purpose cells infected with CENPK negative control virus (NC) samples; E: Scatter diagram. The cross

coordinate represents the NC group, and the vertical coordinate represents the KD group; F: Volcano map, where the cross coordinate is a difference multiple (the logarithmic change in the bottom 2); longitudinal significance false discovery rate (FDR) (of the difference in the bottom 10 Logarithmic change); significantly different genes screened by |fold change| ≥ 1.5 and FDR < 0.05 in red, and other genes with no significant difference in gray; G: Cluster analysis results. Each column represents a sample, and each row represents a differentially expressed gene; H: Statistics for the classical pathway enrichment analysis. The transverse coordinate is the path name and the longitudinal significance level of enrichment (negative logarithmic transformation in the bottom 10).

G1/S checkpoint regulation was significantly activated. Red represents significant upregulation, and green represents the genes. Figure 3A shows the changing trend of gene expression in the pathway, which provided the basis for the study of the molecular mechanisms involved in the changes between sample groups. The upstream regulator network diagram (Figure 3B) shows the interaction between upstream regulators and downstream molecules that were directly associated in the dataset. Let-7 significantly suppressed SOX9 mRNA levels, and consistent trends were observed between let-7 and signal sequence receptor 1. Figure 3C shows the significant enrichment of differentially expressed genes in disease and function. According to the internal algorithms and standards of IPA, $Z \geq 2$ denoted significant activation of the disease or function, and $Z \leq -2$ indicated significant suppression of the disease or function. Significantly activated diseases or functions included morbidity or mortality ($Z = 4.216$) and organismal death ($Z = 4.164$). Significantly suppressed diseases or functions included infection by human immunodeficiency virus 1 ($Z = -3.335$) and viral infection ($Z = -3.2$) (Figure 3D). The network contains all the differentially expressed genes associated with the specified disease or function, and demonstrates possible interactions and changes in expression trends between genes based on the ingenuity knowledge base (Figure 3E). The top ranked regulatory network in this regulatory effect analysis suggested that the dataset was inhibitory due to the regulator miR-8 in the binding of tumor cell lines and the proliferation of stem cells *via* BMI1, COMMD3-BMI1, HMGB1, and YAP1 (Figure 3F). The network of interactions between molecules of a disease or function-related relationship is shown in Figure 3G.

Based on the above biological analysis, we speculated that CENPK was more likely to function in CRC by regulating the expression of the above-mentioned genes. Therefore, these genes were selected for western blot validation. Western blot analyses and qPCR showed that expression of FBX32 was upregulated, and CUL4A and YAP1 were downregulated (Figures 4A-D). Taken together, these results suggested that CENPK played a role in CRC by regulating FBX32, CUL4A, YAP1, and other genes in RKO cells.

High expression of CENPK in CRC

The expression of CENPK in CRC tissue was measured using immunohistochemistry to detect target protein expression and localization in tissue cells. Expression of CENPK was higher in cancerous than in paracancerous tissues (Figure 5A). Positive expression of CENPK in the cancerous and noncancerous tissues exhibited a differential multiple of 2.61, which was a significant difference (Figure 5B). Expression and proportional statistics of the CENPK gene in cancerous and noncancerous tissue are shown in Table 4.

CENPK gene expression in cancerous and noncancerous tissues is shown in Table 5. The differential expression of CENPK gene in cancerous and noncancerous tissues was analyzed using the Mann-Whitney *U* test. The significantly higher expression of CENPK in cancerous than in noncancerous tissues ($P < 0.05$) supports CENPK as an effective diagnostic marker for CRC. The expression and proportion of CENPK genes in cancerous tissues are shown in Table 6. The CENPK gene expression in different types of clinical experiment, including sex, age, T stage, and N metastases, was analyzed to compare its low expression and high expression. Expression of CENPK gene in cancerous tissue differed significantly according to T stage, N stage, and clinical stage, which suggested that CENPK expression was associated with these pathological indicators. The correlation between CENPK expression and clinical data (T stage, N stage, and clinical stage) in cancerous tissues was examined using Spearman's test, and the potential role of these clinical data in the development of CRC was examined (Table 7). Expression of the CENPK gene in cancerous tissues was positively correlated with T stage, N stage, and clinical stage, which suggested that low CENPK expression in the early stage of cancer gradually increased with the disease course.

shRNA lentivirus infects RKO cells and inhibits the growth of tumor cells

RKO cells infected by viruses were subcutaneously injected into nude mice for analysis of tumor growth conditions (Figure 6). RKO cells were infected with lentivirus, and there was no significant cell death, especially in the NC group, which was comparable to the control group. In contrast, the infection efficiency reached approximately 80% in the KD group (Figure 6A). The infection efficiency in the target screening experiment was > 90% in the KD group. Therefore, the good cell conditions and qualified infection efficiency up to 80% were used for downstream testing. Here, RKO cells were injected subcutaneously into the nude mice to analyze the tumor growth conditions and detect the infection efficiency of RKO cells. Based on the PCR results, CENPK gene knockdown efficiency in RKO cells reached 83.2% in the KD group compared to the NC group. The tumor status (the tumor formed and

group (Figure 6H). Tumor weight and volume were significantly decreased in the KD group compared to the NC group ($P < 0.05$) (Figures 6F and 6G). Therefore, lentiviral infection of RKO cells inhibited the growth of tumor cells *in vivo*.

Effect of CENPK on proliferation of RKO cells

Expression of CENPK gene in CRC cells is shown in Figure 7A, and the target gene expression abundance was relatively low. Based on the mRNA level, the CENPK gene reduction efficiency was examined using qPCR. Expression of the CENPK gene in RKO and HCT116 cells in the experimental group was inhibited after 3 d of shRNA lentivirus infection (Figures 7B and 7C). Target reduction of foreign proteins due to CENPK gene expression was detected using western blot, which showed that shCENPK had a significant knockdown effect on the exogenous expression of CENPK gene at the protein level in 293T cells (Figure 7D). Endogenous protein expression of CENPK showed that shCENPK had a significant knockdown effect on endogenous CENPK expression at the protein level in RKO cells (Figure 7D). Endogenous expression of CENPK was knocked down at the protein level in HCT116 cells (Figure 7D).

After 3 d of shRNA lentivirus infection, 1500 cells were seeded in 96-well plates. The effect of CENPK on cell proliferation *via* Celigo detection showed that proliferation of RKO cells was significantly inhibited in the experimental group. Celigo continuous detection for 5 d suggested that the CENPK gene was significantly associated with RKO and HCT116 cell proliferation (Figures 7E-H). To examine the effects of gene reduction on cell proliferation after 3 d of shRNA lentivirus infection, the cells were seeded in 96-well plates. After 5 d, the proliferation rate of RKO and HCT116 cells in the experimental group was significantly inhibited, which suggests a significant correlation between CENPK gene and RKO and HCT116 cell proliferation (Figure 7G). Detection of the effect of CENPK gene reduction on apoptosis using FACS showed that after 5 d of shRNA lentivirus infection, RKO and HCT116 cells in the experimental group increased significantly, which suggested that the CENPK gene was significantly related to apoptosis of RKO and HCT116 cells (Figure 7J, Supplementary Figures 1 and 2). Based on the detection of CENPK for apoptosis, caspase 3/7 activity was increased after 3 d of shRNA lentivirus infection in the experimental group, which suggested that CENPK gene was significantly related to

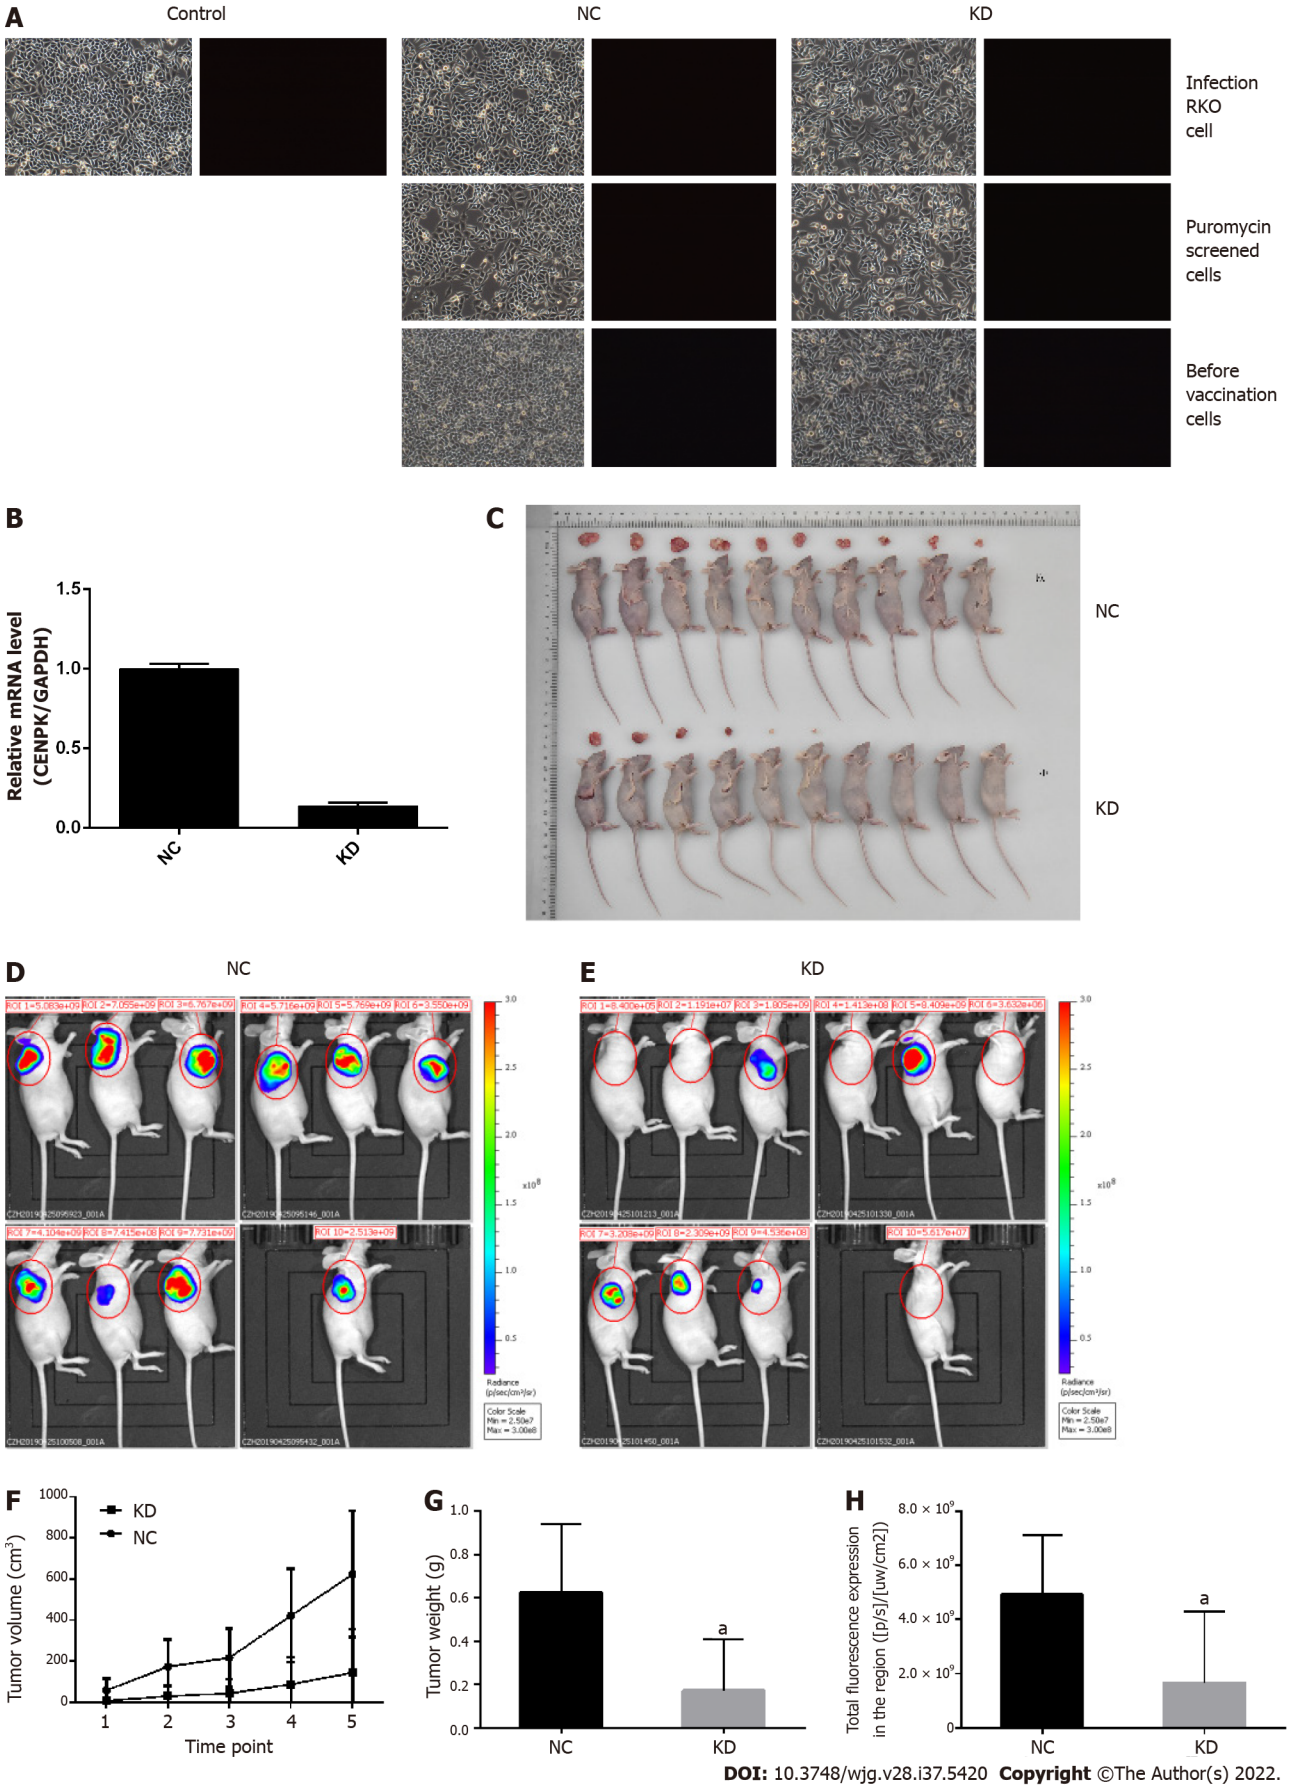
Figure 4 Centromere protein K plays a role by regulating F-box protein 32, Cullin 4A, Yes-associated protein isoform 1, and other genes in RKO cells. A: Downstream gene (Yes-associated protein isoform 1, centromere protein K, Cullin 4A, F-box protein 32, X chromosome-linked inhibitor of apoptosis, heat shock protein 90 alpha family class A member 1, class III-tubulin, and mitogen-activated protein kinase kinase kinase 7) testing using western blot analysis in NC and KD groups; B-D: Relative gene expression detected using quantitative polymerase chain reaction in NC and KD groups. F-box protein 32 was upregulated, while Cullin 4A and Yes-associated protein isoform 1 were downregulated. FBX32: F-box protein 32; YAP1: Yes-associated protein isoform 1; CENPK: Centromere protein K; CUL4A: Cullin 4A; XIAP: X chromosome-linked inhibitor of apoptosis; HSP90AA1: Heat shock protein 90 alpha family class A member 1; TUBB3: Class III-tubulin; MAP3K7: Mitogen-activated protein kinase kinase kinase 7; BUB3: BUB3 mitotic checkpoint protein; EEA1: Early endosomal antigen 1; PCYT1A: Phosphate cytidylyltransferase 1A; TMPO: Thymopoietin; HNRNPD: Heterogeneous nuclear ribonucleoprotein D; PRNP: Prion protein; PPP3CA: Protein phosphatase 3 catalytic subunit alpha; MAD2L1: Mitotic arrest deficient 2 like 1; PHF6: PHD finger protein 6; CENPA: Centromere protein A; TRAF1: TNF receptor associated factor 1; CALD1: Caldesmon 1; PTPMT1: Protein tyrosine phosphatase mitochondrial 1; CCT5: Chaperonin containing TCP1 subunit 5; CAMK2D: Calcium/calmodulin dependent protein kinase II delta; MRFAP1L1: Morf4 family associated protein 1 like 1; ILF3: Interleukin enhancer binding factor 3; CDKN2D: Cyclin dependent kinase inhibitor 2D; SRPK2: SRSF protein kinase 2; PRPF4B: Pre-mRNA processing factor 4B; PPIA: Peptidylprolyl isomerase A; BMI1: BMI1 proto-oncogene; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase. NC: RKO cells infected with CENPK negative control virus; KD: RKO cells with lentivirus-mediated short hairpin RNA interference of CENPK.

apoptosis of RKO and HCT116 cells (Figure 7I). Therefore, CENPK gene inhibited proliferation of RKO cells. After RNAi of the CENPK gene in RKO cells, associated genes in the signaling pathway were detected using PathScan. The protein expression levels in the p-ERK1/2, p-Stat1, p-Stat3, p-Akt (Ser473), p-HSP27, p-p70 S6 kinase, p-PRAS40, and p-p38 signaling pathways were significantly different ($P < 0.05$) (Figure 7K).



Inhibition of RKO and HCT116 cells by abrogation of CENPK and overexpression of CUL4A

Lentivirus-mediated shRNA interference of CENPK in HCT116 cells and RKO cells was observed (Figure 8). The control and target lentivirus-infected cells (HCT116 cells and RKO cells) were observed after 72 h under a microscope, and cell infection efficiency reached > 80%, and the cell state was normal. The effects of CENPK gene reduction and CUL4A gene overexpression on HCT 116 and RKO cell proliferation using Celigo detection are shown in Figures 9A-D. At 3 d after lentiviral infection, the number of HCT 116 cells was 1000, and the number of RKO cells was 2000. After 5 d, the KD group exhibited slower cell proliferation compared to the NC (KD) group. Cell proliferation increased rapidly in the KD + OE and NC (OE) groups compared to the KD + NC (OE) and OE groups in HCT 116 cells (Figures 8A and 8B, Supplementary Figures 3 and 4) and RKO cells (Figures 6C and 6D). HCT 116 and RKO cell proliferation was measured using the MTT assay (Figures 9E-H). Cell proliferation increased slowly in the KD group compared to the NC (KD) group, but it increased rapidly in the OE group compared to the NC (OE) group. However, RKO cell proliferation was not consistently increased in the KD + OE

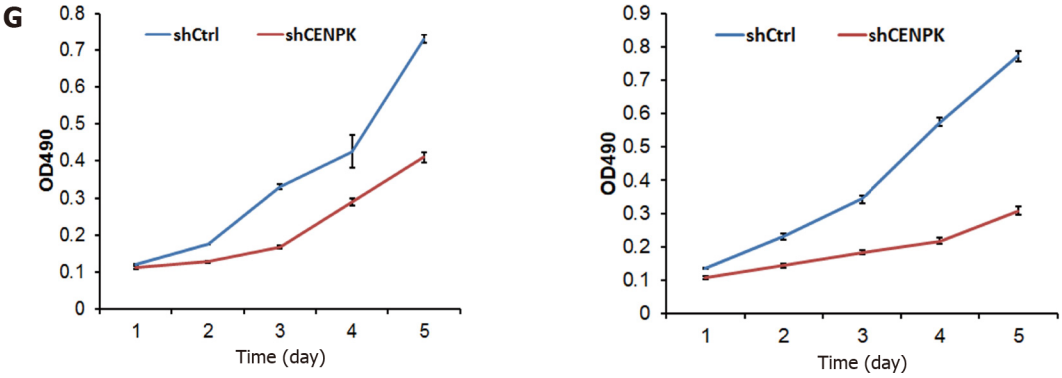
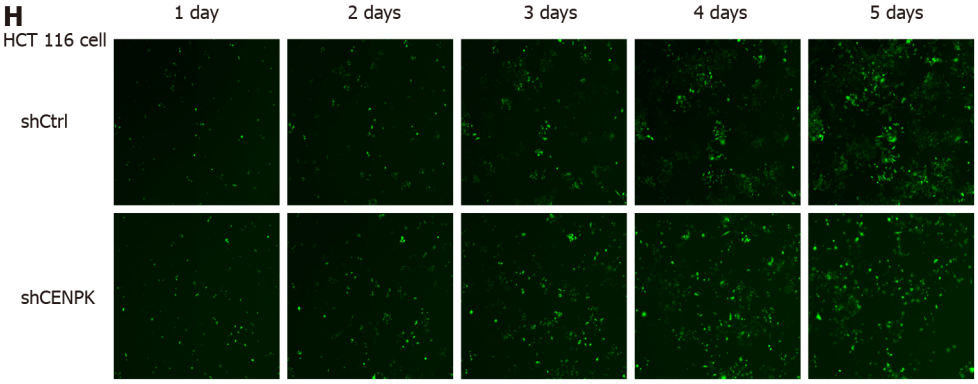
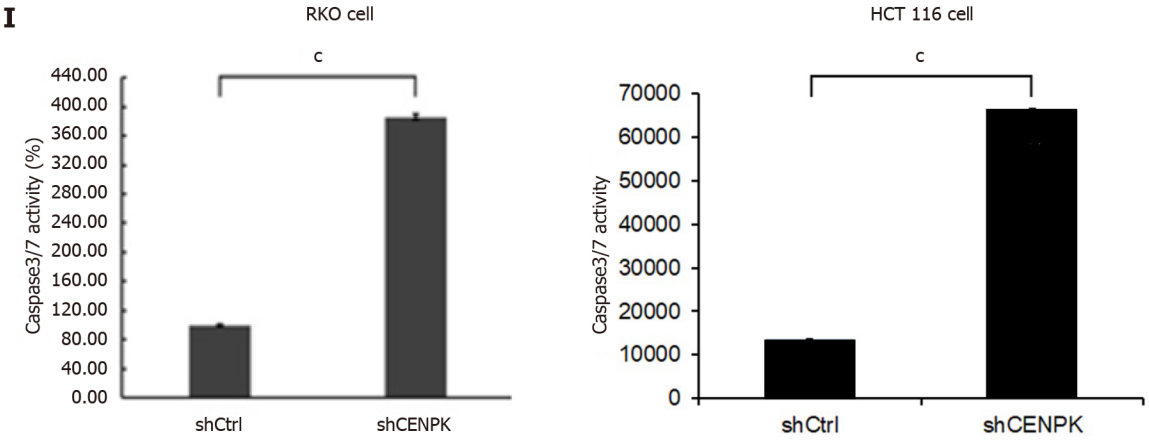
group compared with the KD + NC (OE) group, and HCT 116 cell proliferation was obviously increased in the KD + OE group. HCT 116 and RKO cell apoptosis was induced by CENPK gene reduction and CUL4A gene overexpression; therefore, caspase 3/7 activity and apoptotic cells were measured after lentiviral infection for 5 d. Based on the findings for HCT 116 and RKO cells shown in Figure 9I, caspase 3/7 activity and apoptotic cells were increased in the KD group compared to the NC (KD) group. Caspase 3/7 activity did not change significantly in the OE group, and apoptotic cells did not change significantly compared with the NC (OE) group. Similar to the KD + NC (OE) group, the KD + OE groups exhibited decreased caspase 3/7 activity and apoptosis. HCT 116 and RKO cell apoptosis *via* CENPK gene reduction and CUL4A gene overexpression was detected using FACS (Figure 9K, Supplementary Figures 5 and 6). HCT 116 and RKO cell apoptosis was increased significantly in the KD group ($P < 0.01$) compared to the NC (KD) group. Apoptosis was decreased significantly in the KD + OE group ($P < 0.01$) compared to the KD + NC (OE) group. However, no significant change in apoptosis occurred in the OE group. The FLAG protein level after CUL4A overexpression was detected using western blot (Figure 9J). The proliferation rate in the OE group compared to the NC group after CUL4A overexpression in HCT116 and RKO cells was detected by FLAG. These results suggested that lentivirus-mediated shRNA interference of CENPK inhibited the proliferation of RKO and HCT116 cells, and overexpression of the CUL4A gene reversed this effect in RKO and HCT 116 cells with CENPK gene knockdown.



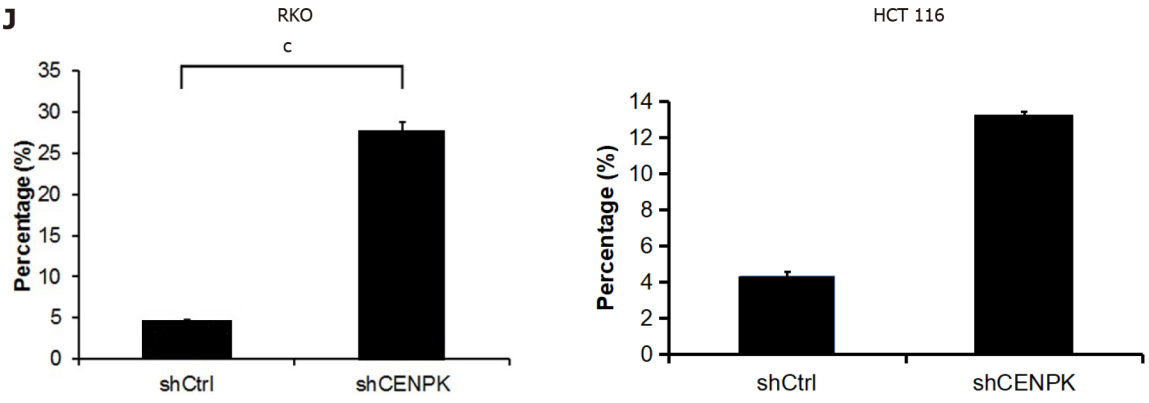
DISCUSSION



CRC is one of the most common malignant tumors. Increasing evidence suggests that CENPK plays a key role in promoting carcinogenesis[14]. To the best of our knowledge, this study is the first to clarify the clinical value of CENPK in human CRC tissues. However, the underlying mechanism is largely unknown. The expression of CENPK in CRC tissues was quantified using western blot and quantitative real-time PCR. CENPK was highly expressed in CRC tissue and positively correlated with large tumor size and advanced tumor stage. CENPK was found to be frequently downregulated in CRC primary tumor samples compared to adjacent normal tissues, using bioinformatics analysis and experiments *in vivo*. Expression of the CENPK gene was significantly different in cancerous and noncancerous tissues, which supports the use of CENPK for diagnosis of CRC and patient selection for therapy. Tissue chip detection showed that CENPK expression was associated with pathological indicators, such as T stage, N stage, and clinical stage. This confirmed the low level of CENPK expression in early cancer and increasing expression during the course of the disease. We used *in vitro* and *in vivo* models to demonstrate that lentivirus-mediated shRNA interference of CENPK regulated the proliferation of CRC cells. The CENPK gene may affect the expression of a series of downstream genes by acting on YWHAZ and BMI1, which affect cell proliferation and invasion. Therefore, CENPK gene functions in the progression of CRC by altering the expression of CUL4A, CENPK, XIAP, FBX32, YAP1, MAP3K7, TUBB3, and HSP90AA1. Western blot analysis showed that FBX32 was upregulated and CUL4A and YAP1 were downregulated.



YAP1 is an effector of the Hippo pathway, which is critical for regulating organ size, cell proliferation, and tumor growth in mammals[15]. Research on YAP1 expression in CRC tissues showed the effect of silencing expression of the YAP1 gene on the proliferation and invasion of SW620 CRC cells [16]. Another study showed that FBX32 and the mRNA levels of several proteasome-related genes were significantly upregulated by methionine limitation[17]. Moreover, CUL4A is highly expressed in colon cancer and promotes the proliferation and inhibits the apoptosis of colon cancer cells by regulating the Hippo pathway[10]. Therefore, the mechanism of the effect of CUL4A expression on cell proliferation and apoptosis in CRC by regulating the CENPK pathway was further investigated.



Lentivirus-mediated shRNA interference of CENPK was successfully and stably induced in RKO cells, which lays a foundation for further study of the role of the CENPK gene in the carcinogenesis and progression of CRC. With regard to therapeutic options for CRC, increased CENPK expression inhibited CRC cell proliferation and induced apoptosis of RKO cells with lentiviral infection, which suggests that CENPK inhibits CRC progression. A xenograft mouse model also confirmed the tumor-suppressive function of CENPK. We used RKO cells with lentiviral infection to control these processes and inhibit tumor growth. Specifically, we found that the CENPK gene regulated tumor growth, and the total

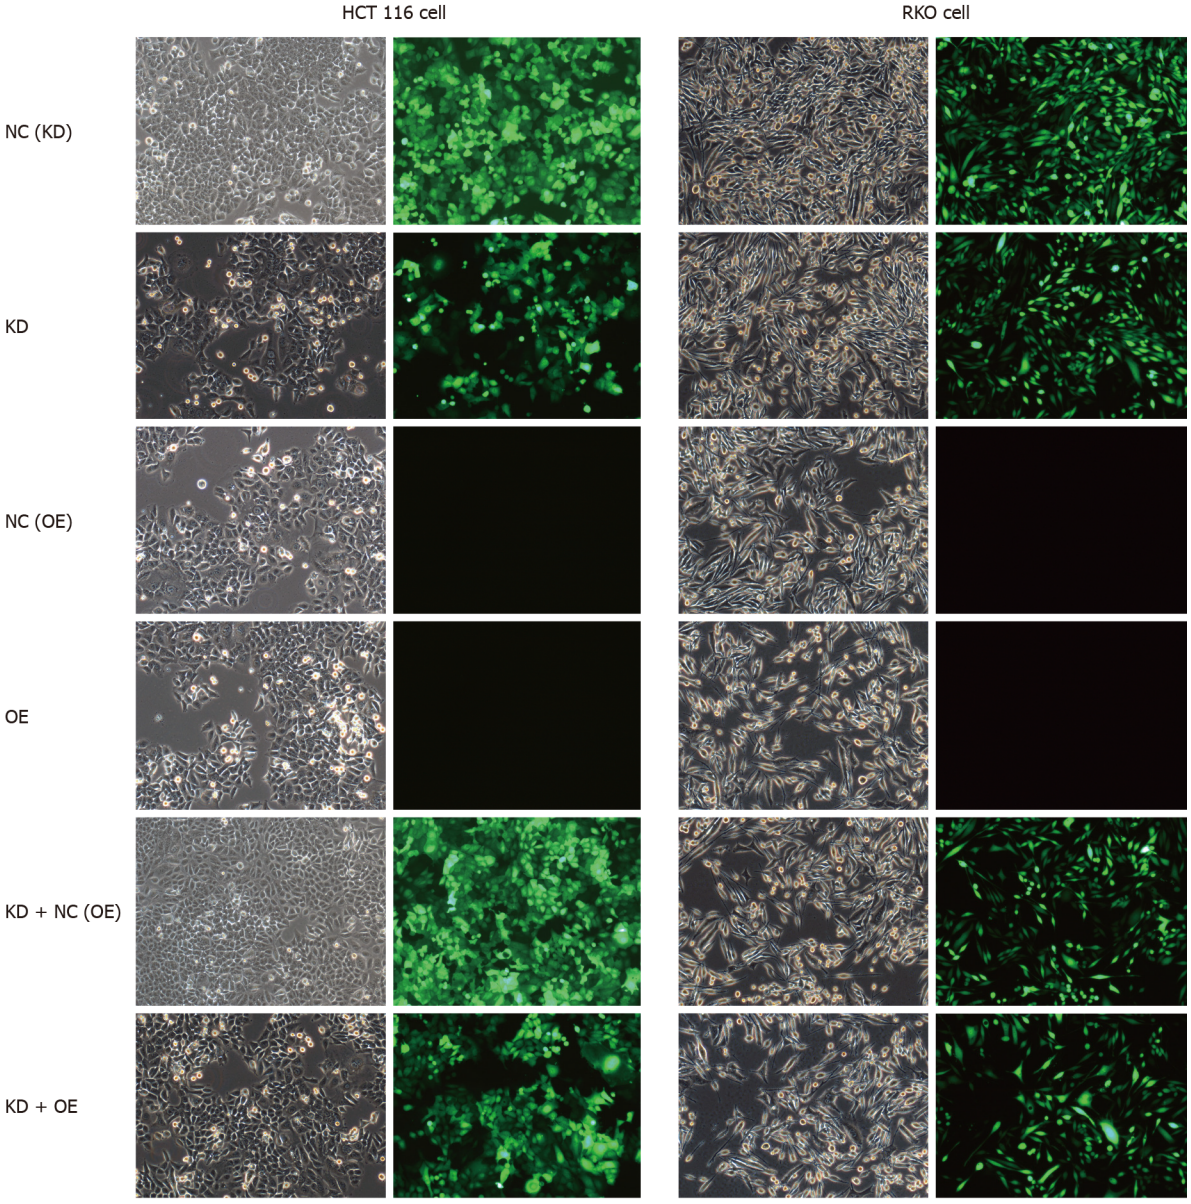
Figure 7 Effects of centromere protein K on proliferation of RKO cells. A: Expression of the centromere protein K (CENPK) gene in colon cancer cells; B and C: CENPK mRNA level reduction in RKO and HCT116 cells; D: Exogenous expression of CENPK protein in RKO cells (a), 293T cells (b), and HCT116 cells (c); E and F: Effects of CENPK gene reduction on RKO cell proliferation by Celigo detection; G: Effects of CENPK gene reduction on RKO and HCT116 cell proliferation detected by MTT assay; H: Effects of CENPK gene reduction on HCT116 cell proliferation by Celigo detection; I: Effects of CENPK gene reduction on RKO and HCT116 cell apoptosis by caspases 3/7 detection; J: Effects of CENPK gene reduction on RKO and HCT116 cell apoptosis by FACS detection; K: Chemiluminescence analysis in the shCtrl and shCENPK groups. $^{a}P < 0.01$, compared with shCtrl; $^{b}P < 0.05$, shCtrl compared to the short hairpin RNA lentivirus treatment group; $^{c}P < 0.01$, shCtrl compared to the short hairpin RNA lentivirus treatment group. CENPK: Centromere protein K.

fluorescence in the tumor was significantly decreased compared to the controls. We analyzed whether lentivirus-mediated shRNA interference of CENPK was involved in cell proliferation and apoptosis. The results indicated that interference with the CENPK gene inhibited RKO cell proliferation. Taken together, these findings support the hypothesis that lentivirus-mediated shRNA suppresses CENPK expression *via* lentivirus epigenetically. Overexpression of CENPK has been observed in various tumor types[8,18,19].

CUL4A plays a critical role in cellular proliferation and tumor invasion[20,21]. *In vitro* experiments were performed to verify the function of the CUL4A gene. To investigate whether CUL4A gene was involved in CENPK-induced CRC cell proliferation, we performed rescue experiments, which indicated that knockdown of CENPK and overexpression of CUL4A partially rescued proliferation in RKO and HCT116 cells. These findings support the hypothesis that interference with the CENPK gene inhibits RKO and HCT116 cell proliferation. Overexpression of CUL4A had a response effect on RKO and HCT 116 cells.



The functional effects of CUL4A proteins on their targets have been well characterized and are involved in the proliferation of cancer cells[22]. CUL4A may be a prognostic marker of precancerous lesions and a potential therapeutic target in cancer[23]. Consistent with these reports, overexpression of CUL4A was observed in 20 pairs of CRC tissues, and knockdown of CUL4A inhibited cell proliferation. A previous study showed that CUL4A was highly expressed in CRC and promoted proliferation and inhibited apoptosis of CRC cells by regulating the Hippo pathway[10]. Our study demonstrated that restoration of CUL4A expression suppressed CRC cell proliferation. These results indicate that CUL4A acts as a tumor suppressor in CRC. It has been found that high CUL4A protein expression is an independent prognostic marker in CRC[12].

CONCLUSION

Our study demonstrated that overexpression of CUL4A led to CRC tumorigenesis, and knockdown of the CENPK gene affected CRC progression and development in target cells. To the best of our knowledge, this study is the first to investigate CUL4A protein expression and its potential interference with CENPK gene interactions in CRC. We demonstrated the critical role of the CUL4A gene in the progression of CRC. However, due to the complexity of shRNA biological function, further analysis is required to achieve a more comprehensive understanding of CRC diagnosis and therapy.

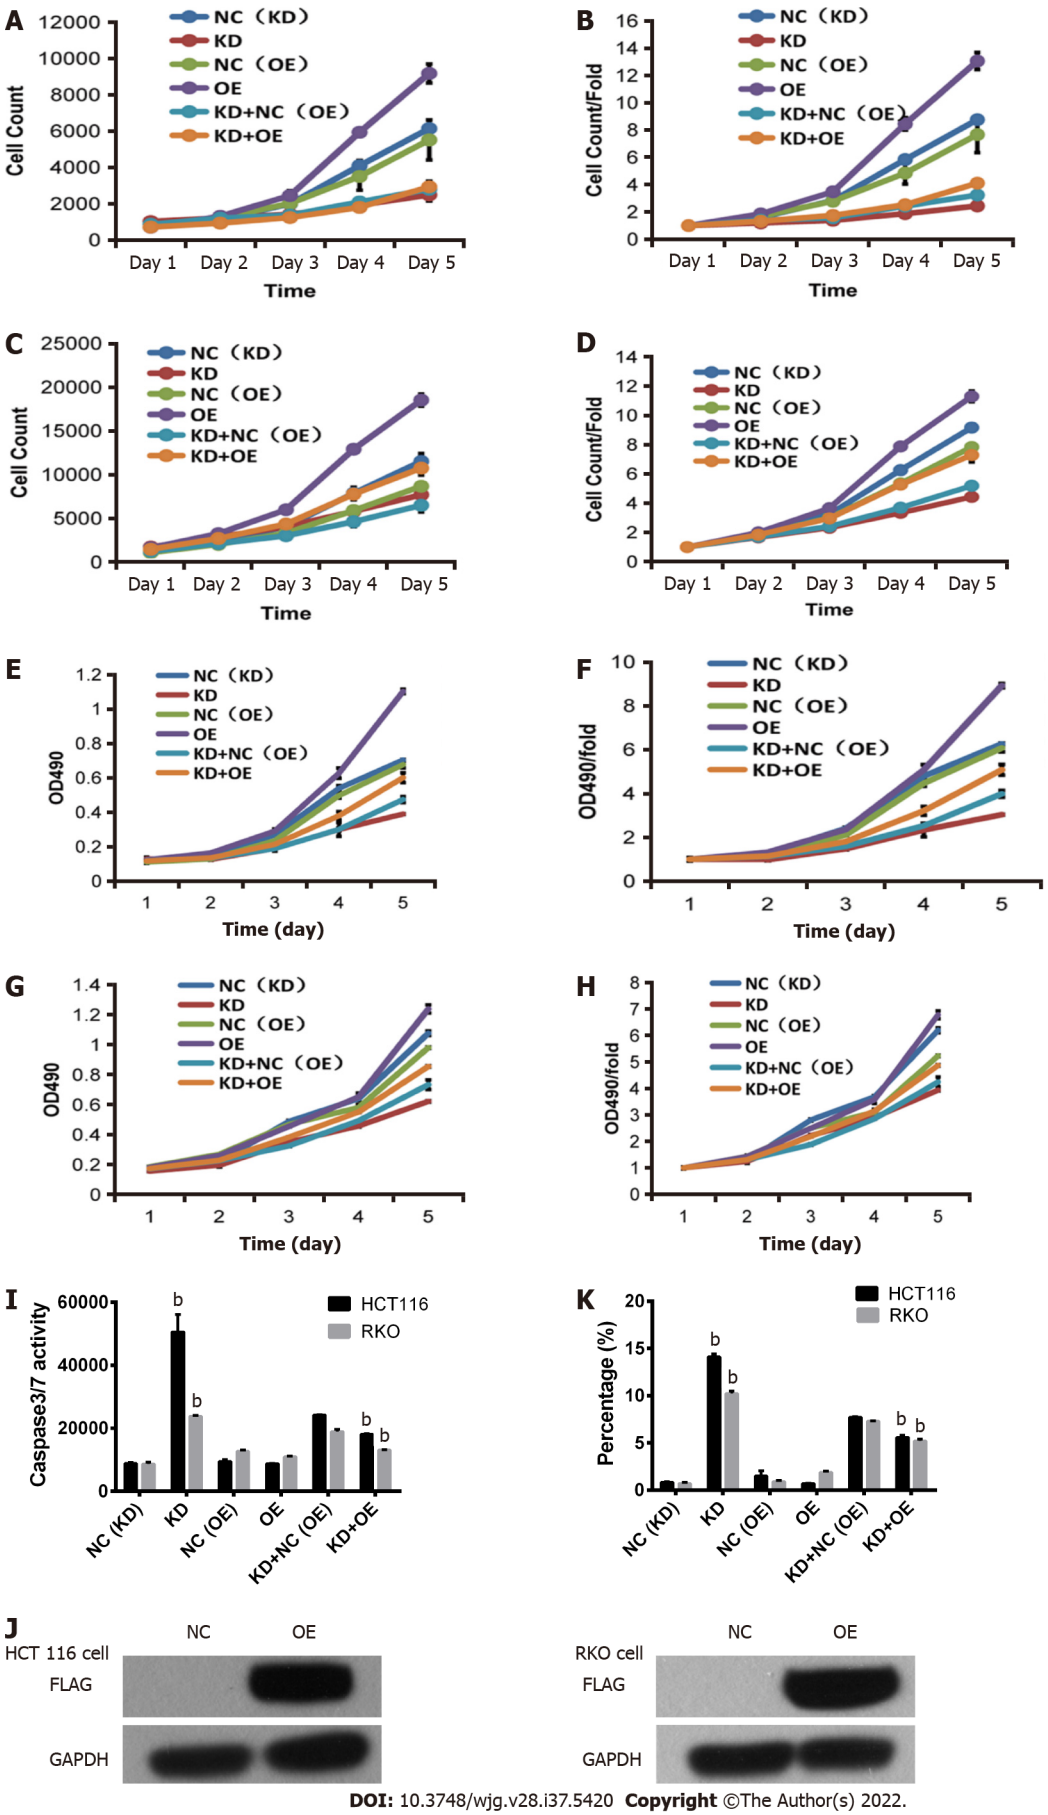


Table 7 Correlation between centromere protein K gene expression and clinical data in cancerous tissues

		Gene expression	T stage	N metastasis	Pathological grade
Gene expression	Correlation coefficient	1.000	0.135	0.143	0.135

ARTICLE HIGHLIGHTS

Research background

Colorectal cancer (CRC) is one of the most common malignant tumors worldwide. Immunohistochemistry has found high expression of centromere protein (CENPK) in CRC. However, the role of CENPK in the progression of CRC is not well characterized.

Research motivation

To explore the role of Cullin (CUL)4A expression and lentivirus-mediated transfection with short hairpin RNA (shRNA) for CENPK in CRC.

Research objectives

We performed a series of *in vitro* experiments, such as quantitative polymerase chain reaction (qPCR), western blot, MTT assay, and flow cytometry, to evaluate the knockdown behavior of CENPK and overexpression of CUL4A in RKO and HCT 116 CRC cells.

Research methods

We identified CENPK as a potential new oncogene for CRC based on bioinformatics analysis. *In vitro* experiments verified the function of this gene. We investigated the expression of CENPK in RKO and HCT 116 cells using virus infection and analyzed datasets from qPCR, western blot, and flow cytometry. The effect of RKO cells infected with virus on tumor growth was evaluated *in vivo* using quantitative analysis of fluorescence imaging.

Research results

The downstream genes FBX32, CUL4A, and YAP1 were examined to evaluate the regulatory action of CENPK in RKO cells. Significantly delayed xenograft emergence, slower growth, and lower final tumor weight and volume were observed in the RKO and HCT 116 with lentivirus-mediated shRNA interference of CENPK. Interference of CENPK inhibited the proliferation rate of RKO cells *in vitro* and *in vivo*. The shRNA interference of CENPK inhibited the proliferation of RKO and HCT 116 cells, and overexpression of CUL4A gene responded to RKO and HCT 116 cells with CENPK silencing.

Research conclusions

Our findings indicate a potential role of CENPK in promoting tumor proliferation, and it may serve as a novel diagnostic and prognostic biomarker in patients with CRC.

Research perspectives

An investigation for lentivirus-mediated transfection with shRNA for CENPK and overexpression of CUL4A demonstrated major regulatory roles in CRC. Further analysis is required to achieve a more comprehensive understanding of CRC diagnosis and therapy.

Abstract

BACKGROUND

Metabolic associated fatty liver disease (MAFLD) is associated with complications and mortality in patients with coronavirus disease 2019 (COVID-19). However, there are no prognostic scores aimed to evaluate the risk of severe disease specifically in patients with MAFLD, despite its high prevalence. Lactate dehydrogenase, aspartate aminotransferase and alanine aminotransferase have been used as markers of liver damage. Therefore, we propose an index based on lactate dehydrogenase, aspartate aminotransferase and alanine aminotransferase for the prediction of complications and mortality in patients with MAFLD and COVID-19.

AIM

To evaluate the prognostic performance of an index based on lactate dehydro-

genase and transaminases (aspartate aminotransferase/alanine aminotransferase) in patients with COVID-19 and MAFLD [liver fibrosis and nutrition (LNF)-COVID-19 index].

METHODS

In this retrospective cohort study, two cohorts from two different tertiary centers were included. The first was the derivation cohort to obtain the score cutoffs, and the second was the validation cohort. We included hospitalized patients with severe COVID-19 and MAFLD. Liver steatosis was evaluated by computed tomography scan. Area under the receiver operating characteristic (ROC) curve analysis and survival analysis were used.

RESULTS

In the derivation cohort, 44.6% had MAFLD; ROC curve analysis yielded a LFN-COVID-19 index > 1.67 as the best cutoff, with a sensitivity of 78%, specificity of 63%, negative predictive value of 91% and an area under the ROC curve of 0.77. In the multivariate analysis, the LFN-COVID-19 index > 1.67 was independently associated with the development of acute kidney injury (odds ratio: 1.8, 95% confidence interval: 1.3-2.5, $P < 0.001$), orotracheal intubation (odds ratio: 1.9, 95% confidence interval: 1.4-2.4, $P < 0.001$), and death (odds ratio: 2.86, 95% confidence interval: 1.6-4.5, $P < 0.001$) in both cohorts.

CONCLUSION

LFN-COVID-19 index has a good performance to predict prognosis in patients with MAFLD and COVID-19, which could be useful for the MAFLD population.

Key Words: COVID-19; Metabolic associated fatty liver disease; Lactate dehydrogenase; Transaminases; Prognosis; Nonalcoholic fatty liver disease

Core Tip: The liver fibrosis and nutrition-coronavirus disease 2019 (LFN-COVID-19) index that includes lactate dehydrogenase and transaminases is a new prognostic index for patients with metabolic associated fatty liver disease and COVID-19; it was developed to specifically predict adverse clinical outcomes, including mortality, in this population with both conditions. The variables included in this index allow an easy, quick and reliable risk assessment in this population with simple markers, allowing for broad implementation.

INTRODUCTION

The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic (coronavirus disease 2019, COVID-19) still affects the entire world. As of June 15, 2022, 536720870 people have been infected, of whom 6312601 have died[1].

Different risk factors associated with the development of complications and mortality in patients with COVID-19 have been identified, including age > 60 years, the presence of cirrhosis, diabetes, immunodeficiencies, obesity, cardiovascular disease, chronic kidney disease and chronic obstructive pulmonary disease, among others[2-4]. Metabolic dysfunction associated fatty liver disease (MAFLD), regarded as the hepatic manifestation of metabolic syndrome, has a controversial role in the prognosis of patients with COVID-19. Some studies have reported a poor prognosis in patients with MAFLD, while others have only showed this finding when fibrosis was present. This could be explained by a more pronounced baseline systemic inflammatory profile and activation of the immune response in patients with liver fibrosis, which contributes to increased inflammation when SARS-CoV-2 infection is added[5, 6].

Acute respiratory distress syndrome is the major complication in patients with severe COVID-19; other complications such as cardiac or cardiovascular, renal and secondary infections may occur[7]. These patients, mainly those admitted to the intensive care unit, may present with laboratory abnormalities, such as leukopenia, lymphopenia (< 800 mm^3 at admission), elevated prothrombin time, elevated serum levels of D-dimer (> 1000 ng/mL), elevated inflammatory markers (ferritin > 300 μg/L), elevated lactate dehydrogenase (LDH), elevated liver enzymes, elevated creatine phosphokinase (twice the upper limit of normal) and elevated troponin I[7-9].

In patients with pneumonia associated with SARS-CoV-2 infection, high LDH levels correlate with lung damage, severe disease and mortality at day 30[10-13]. In the study by Yan *et al*[14], LDH (> 365 U/L), lymphocyte count (< 14.7%) and C-reactive protein (> 41.2 mg/L) were identified as the three laboratory abnormalities that predicted mortality risk with 90% accuracy, which represented a simple way to promptly recognize severe illness.

Likewise, in patients with acute liver injury (non-COVID-19 related), an increase in LDH levels has been reported, secondary to endothelial damage induced by macrophages during acute inflammation, conditioning microcirculation alterations and hypoxia. Thus, it has been suggested that LDH may have a discriminatory role in identifying the etiology of liver damage. As a marker of damage due to liver ischemia, it must be taken into account that LDH has a shorter half-life. Therefore, a faster fall occurs when the damage disappears, and it has been suggested as a parameter to monitor the evolution of patients with acute liver injury. The ubiquitous nature of LHD in the human body makes it a nonspecific but sensitive biomarker, which in the context of organ damage can provide information with diagnostic and prognostic potential. In the same way, increase in alanine aminotransferase (ALT), aspartate aminotransferase (AST) and the AST/ALT ratio has been associated to adverse clinical outcomes including mortality in patients with COVID-19[10-13,15].

Identifying factors associated with poor prognosis that may be related to a pathophysiological mechanism is ideal in patients with COVID-19 since those patients at risk of progressing to a severe illness could be identified promptly. Therefore, measures could be taken to influence the outcomes of those patients. In this sense, having a prognostic index specific for patients with MAFLD who develop COVID-19 may be useful to identify individuals at risk of developing adverse clinical outcomes.

Therefore, the aim of this study was to evaluate the performance of a prognostic index based on LDH, AST and ALT in patients with MAFLD and COVID-19 and its association with the development of adverse clinical outcomes and mortality.

MATERIALS AND METHODS

This was a retrospective cohort study performed at two third-level hospitals in Mexico, (INCMNSZ and ISSEMYM) from March 2020 to July 2020, during the first phase of the COVID-19 pandemic and before steroids became a standard of care for severe COVID-19. The study was carried out according to the Declaration of Helsinki and was approved by the institutional Ethics Committee, ref. No. 3777).

Validation process

This study consisted of two phases. Phase 1, a derivation/training cohort, (its methods are described below) used to create and evaluate the newly proposed prognostic index. This cohort was derived from a tertiary care center hospital in Mexico City (INCMNSZ). Phase 2, the validation cohort aimed to evaluate the diagnostic performance of the proposed index in patients with COVID-19 and liver steatosis at a different center. This cohort was derived from a tertiary care center hospital in Toluca, in the center of Mexico (ISSEMYM).

Patients

All patients admitted during the period of study, > 18 years of age, either sex and with a confirmed diagnosis of SARS-CoV-2 infection by RT-PCR and with severe disease (pneumonia + respiratory rate > 30/respiratory distress/SaO_2 < 90%), were included in the study[19]. Patients without an adequate follow-up were excluded from the analysis (*e.g.*, those requiring referral to another hospital, those with insufficient information in the clinical records, *etc*). Follow-up and evaluation of the clinical outcomes were conducted through revision of electronic clinical records.

Biochemical tests

Upon admission, a blood sample was drawn for determination of the following tests: complete blood count, glucose, creatinine, electrolytes, ferritin, C-reactive protein, LDH, liver chemistry, creatine phosphokinase, arterial blood gases, D-dimer, troponin I and fibrinogen. HIV (human Immunodeficiency virus) and viral hepatitis panel (HCV and HBV) were performed in all participants. All the tests met the quality standards from our central laboratory, accredited by the College of American Pathologists.

Computed tomography scan

In order to evaluate the severity of pulmonary involvement, all patients underwent a pulmonary computed tomography scan, where a portion of the liver was also evaluated for the presence of steatosis. The methodology was previously described from our group[16]. Briefly, an expert radiologist blinded to the patient´s clinical status evaluated computed tomography scans to detect liver steatosis, according to the following criteria: (1) Attenuation coefficient ≤ 40 Hounsfield units in the liver (segments VII and VIII); and (2) Attenuation coefficient ≥ 10 Hounsfield units between the splenic and liver parenchyma.

Estimation of the LFN-COVID-19 index

The liver fibrosis and nutrition (LNF)-COVID-19 index was calculated according to the following formula:

LFN-COVID-19 index = (AST/ALT) × (LDH/LDH_{ULN}).

Where AST/ALT ratio included transaminase levels expressed in U/L and was multiplied by the times above the upper limit of normal value for LDH (U/L). The final value was included in the statistical analysis for characterization of clinical outcomes.

Statistical analysis

Sample size estimation considered a hypothetical area under the receiver operating characteristic curve (AUROC) of 0.8 for LFN-COVID-19 index and 0.7 as null hypothesis. Considering an alpha error of 0.05 and beta 0.20 and a negative/positive ratio of 1/1, estimation yielded 81 negative/positive cases (162 patients in total).

Normality of the data was evaluated with Kolmogorov-Smirnov test. Data was presented as mean ± standard deviation, median (P25-P75) or absolute frequencies. Comparisons between the groups were made through Mann-Whitney *U* or Student's *t* test. ROC curve analysis was performed to obtain the best cutoff from the LFN-COVID-19 index for mortality, through the Youden index as well as sensitivity, specificity, positive and negative predictive values and likelihood ratios.

Clinical outcomes were evaluated by logistic regression and a time-dependent survival analysis, including Kaplan-Meier and Cox regression (Cox proportional-hazards model) for 28-d mortality and general mortality. Statistical analysis was carried out with the statistics software SPSS version 20.0 (IBM, Armonk, NY, United States) and ROC analysis with MedCalc Statistical Software version 19.4.1 (MedCalc Software Ltd, Ostend, Belgium).

RESULTS

In the validation cohort a total of 457 patients were included in the final analysis (Figure 1), after excluding those without an adequate follow-up, those with computed tomography scan issues (artifacts, unable to evaluate liver or spleen tissue, post-surgical changes) or those with known autoimmune liver diseases, HIV, hepatitis C or B chronic infection or cancer.

Participant's characteristics

General characteristics of the study population, with and without MAFLD are presented in Table 1. Mean age in the total population was 50.4 ± 13.3 years, most of the patients were male (65.2%), and the mean body mass index (BMI) was 30.1 ± 5.6 kg/m^2. In general, in the group of patients with MAFLD there was a higher prevalence of overweight and obese patients, they were younger than those without MAFLD, and they had a higher prevalence of diabetes and metabolic syndrome.

Biochemical tests

Biochemical tests related to proinflammatory status, such as LDH, creatine phosphokinase, lymphocytes and neutrophil/lymphocyte ratio, were higher in the MAFLD group, as well as liver chemistry abnormalities, glucose, triglycerides and prognostic scores (SOFA: sequential organ failure assessment;).

Index diagnostic performance

In the group of patients with MAFLD, diagnostic yield of the LFN-COVID-19 index [(AST/ALT) × (LDH/LDH_{ULN})] was investigated through the AUROC analysis to determine the prognostic value of the index as a prognostic marker in patients with COVID-19. Characteristics related to diagnostic yield of the LFN-COVID-19 index are shown in Table 2. According to Youden's index, the best cutoff value of the LFN-COVID-19 index for mortality in patients with MAFLD was > 1.67. This cutoff value showed an AUROC of 0.77 [95% confidence interval (CI): 0.709-0.823, $P < 0.0001$], with a sensitivity of 78.7% and specificity of 63.8% (Figure 2A). In general, the AUROC in this group of patients was better than in patients without MAFLD (AUROC: 0.703, 95%CI: 0.647-0.755, $P < 0.0001$) (Figure 2B).

Table 3 shows the characteristics of patients with MAFLD according to the LFN-COVID-19 index. Similitudes in both groups regarding metabolic syndrome and BMI were observed, while other

variables including age, prognostic scores, and biomarkers related to proinflammatory and prothrombotic status, severe COVID-19 (PaO_2/FiO_2 < 100 mmHg), orotracheal intubation and other clinical outcomes, including mortality, were higher in the > 1.67 group.

Prognostic performance

In order to determine if the LFN-COVID-19 index was independently associated with the presence of acute kidney injury or orotracheal intubation during hospitalization, a logistic regression was performed, observing that a value of > 1.67 was associated to adverse clinical outcomes, independently of metabolic factors, severity scores and demographic variables (Table 4).

A marker of mortality was studied by a 28-d Kaplan-Meier survival analysis (Figure 3), observing that patients with a value > 1.67 have a lower survival than those with a value < 1.67 ($P < 0.001$). The influence of other variables on mortality was evaluated through univariate and multivariate Cox proportional hazard analysis. Table 5 summarized the variables that were significant in the univariate analysis, with the results subjected to the multivariate analysis where the variables that were independently associated with mortality were the LFN-COVID-19 index, the neutrophil/lymphocyte

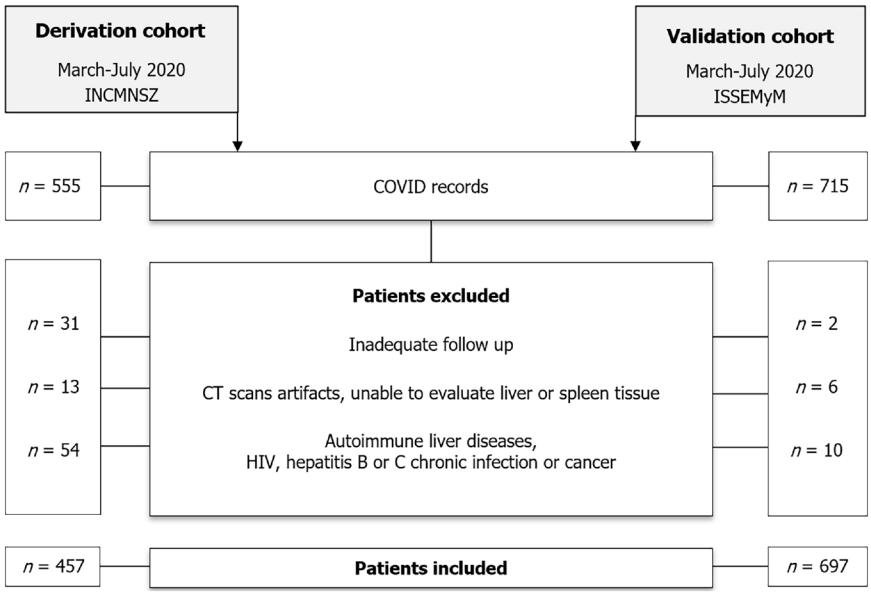
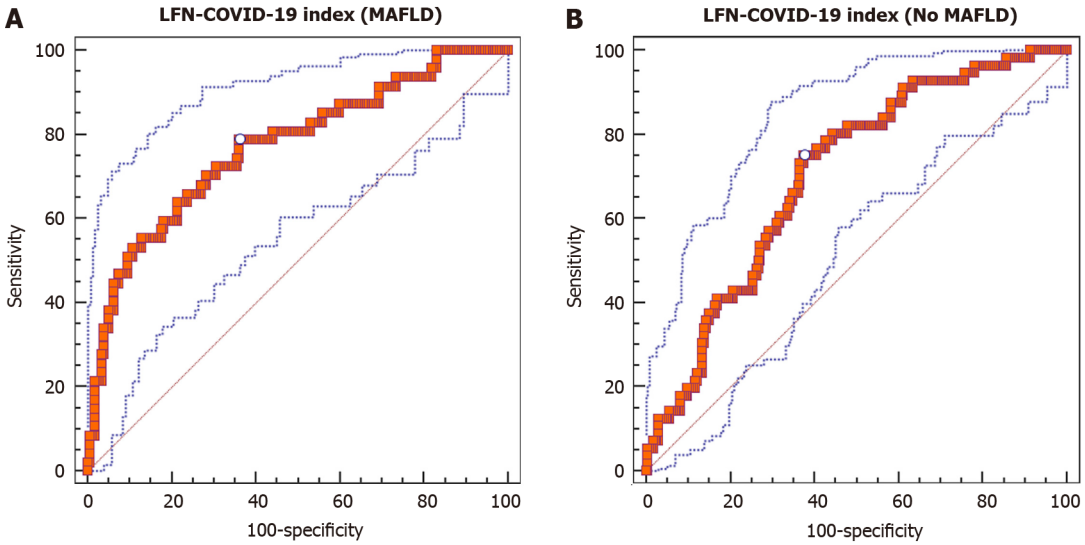
ratio and BMI.



In this analysis, a LFN-COVID-19 index > 1.67 was associated independently to other variables of mortality, including severity markers, prognostic scores and general characteristics (Figure 4).

Validation cohort

From the 697 patients included in the validation cohort, 104 had MAFLD (15.0%). In general, patients with MAFLD were younger and had higher degrees of obesity and mild abnormalities in liver chemistry (Supplementary Table 1). The MAFLD group was further analyzed according to the LFN-COVID-19 index, finding higher levels of C-reactive protein and D-dimer in the group > 1.67, with little changes in the rest of the variables (Supplementary Table 2). Interestingly, mechanical intubation and clinical outcomes including mortality, were more frequent in the > 1.67 group, as was found in the initial cohort (Supplementary Table 3). These same findings in another cohort and in a different hospital highlight the validity of the LFN-COVID-19 index.



DISCUSSION

MAFLD is currently the main etiology of chronic liver disease in the world. The main associated risk factors are obesity, type 2 diabetes, dyslipidemia and metabolic syndrome, all factors with a growing incidence. Both risk factors for MAFLD and MAFLD itself have also been shown to have prognostic value in COVID-19, associating their presence with higher severity and mortality. However, it remains

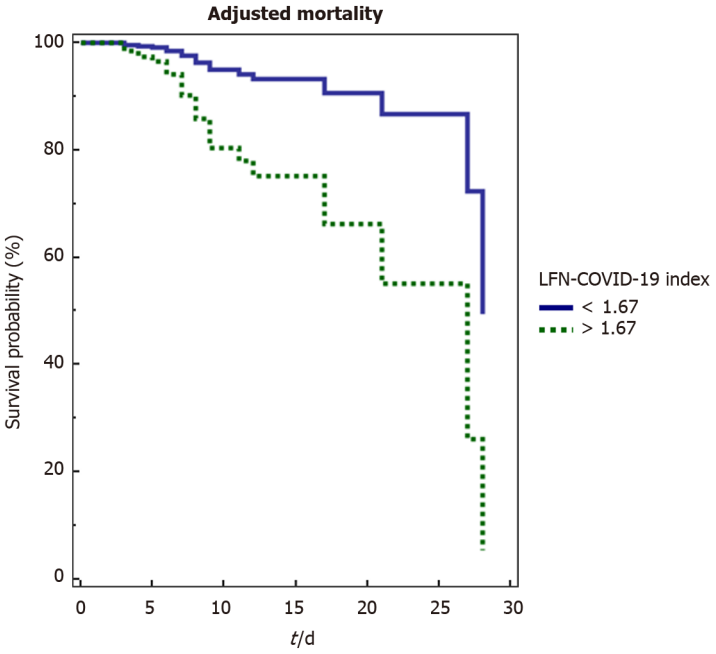
MAFLD: Metabolic associated fatty liver disease; COVID-19: Coronavirus disease 2019; LFN: Liver fibrosis and nutrition.



controversial whether all patients within the spectrum of MAFLD have a worse prognosis or only those who, in addition to steatosis, have fibrosis[16].

Evidence pointing to MAFLD as a prognostic factor emerged from different studies around the world. A retrospective study in patients with COVID-19 found an association of MAFLD with higher intensive care unit admittance (OR: 2.3, 95%CI: 1.27-4.17), mechanical ventilation (2.08, 95%CI: 1.2-3.6) and in patients with cirrhosis with higher mortality (12.5, 95%CI: 2.16-72.5)[6]. In a cohort study in patients with COVID-19 and chronic liver disease (42% MAFLD), the authors observed a relative risk of 2.8 (95%CI: 1.9-4.0) for death in this group of patients, regardless of age, race, BMI, presence of hypertension or diabetes[12]. Another study conducted in Zhejiang, China found that hospitalized COVID-19 patients who had MAFLD with fibrosis (evaluated through FIB-4 and NFS - nonalcoholic fatty liver disease fibrosis score) were at increased risk of severe disease, regardless of other comorbidities[5]. Lastly, a study conducted by Lucifora *et al*[17] showed that patients with COVID-19 and MAFLD had a higher prevalence of alterations in the liver biochemistry test as well as a longer viral clearance time compared with patients without MAFLD.

Figure 4 Adjusted mortality analysis (Cox regression) for 28-d mortality according to LFN-coronavirus disease 2019 index. COVID-19: Coronavirus disease 2019; LFN: Liver fibrosis and nutrition.

Considering the evidence mentioned above, it is possible that the synergism between the baseline proinflammatory state of patients with MAFLD together with the body's inflammatory response to COVID-19 could be the pathophysiological support that explains greater severity and worse prognosis in these patients. Another important component in multiorgan damage in COVID-19, is the state of hypoxemia, cell death and hypoperfusion reflected by biomarkers such as LDH, which correlates positively with worse clinical outcomes (including mortality). Although it is not specific for liver damage, it can be a sensitive and dynamic marker of hypoxic tissue damage due to its short half-life, together with other well-known markers of liver damage, such as AST, ALT and the AST/ALT ratio[10].

Due to the link between MAFLD and COVID-19 and the higher risk of mortality and adverse clinical outcomes, we conceived a prognostic index intended to be used in patients with MAFLD, including variables reflecting the pathophysiology of liver damage, mainly hepatocyte cell death induced by the factors previously mentioned, and associating it with hard clinical outcomes, including mortality[18].

The LFN-COVID-19 index includes the AST/ALT ratio as well as LDH levels normalized by the laboratory's upper limit of normal, facilitating the implementation of the index by non-restricting its usefulness to a specific cutoff value (AST, ALT or LDH). This overcomes the problem of regional variations in laboratory values. The use of this index has potential implications in clinical practice establishing a prognosis of patients. On the other hand, the simplicity of the index allows easy calculation and includes widely available, cheap and reliable laboratory tests.

In the present study, we found a good diagnostic performance of the LFN-COVID-19 index in hospitalized patients with MAFLD and COVID-19. In the ROC curve analysis, a cutoff value of > 1.67 was associated with adverse clinical outcomes including the need for mechanical ventilation, acute kidney injury and higher mortality. This was reproduced in the validation cohort performed at a different center finding this cutoff point as the best for predicting these outcomes[19].

An interesting finding was that there were no differences in the days of stay in the intensive care unit based on this cutoff point. The same length of stay in the intensive care unit could be explained by the severity of the disease, where those with an index below 1.67 were discharged from the critical care area earlier and those with an index above 1.67 present earlier mortality.

Among the weaknesses of this study was the fact that the diagnosis of hepatic steatosis was made with computed tomography. However, given the high risk of transmission of SARS-CoV-2 to healthcare workers, this safer approach was chosen in order to reduce the exposure involved in carrying out a study such as transient hepatic elastography or magnetic resonance imaging requiring more time to perform it. Another aspect to highlight is that patients with COVID-19 usually present with elevated transaminases and LDH from multifactorial causes. Nevertheless, both biomarkers have been widely used as markers of hepatocyte cell death and may reflect liver damage occurring during SARS-CoV-2 infection and exacerbated in patients with MAFLD.

This study has several strengths. The sample size was adequate and sufficient due to the fact that the study was carried out in a center fully converted for the care of COVID-19 patients and included the general population in a country with a highest prevalence of MAFLD and a genetic profile that predisposes the population to the development of metabolic diseases such as type 2 diabetes mellitus, obesity and metabolic syndrome. In addition, we included an external validation cohort, where the results were replicated, enhancing the validity of the LFN-COVID-19 index.

CONCLUSION

Based on the findings of this study, we propose a new prognostic index based on markers of liver damage and severity in patients with MAFLD and COVID-19, which can be used in clinical practice to stratify the risk of adverse outcomes in MAFLD patients. Timely actions to reduce the associated morbidity and mortality in this population could be achieved through the implementation of this index.

ARTICLE HIGHLIGHTS

Research background

This article was conceived considering the high prevalence of metabolic associated fatty liver disease (MAFLD) in the general population amid the coronavirus disease 2019 (COVID-19) pandemic and the risk of these patients in clinical settings with limited resources.

Research motivation

The growing evidence showing worse clinical outcomes in patients with metabolic diseases and COVID-19, including those with fatty liver disease, and the lack of a specific index to specifically stratify patients with both conditions motivated the creation of an index capable of discriminating those patients with an unfavorable outcome.

Research objectives

To evaluate the diagnostic yield of the liver fibrosis and nutrition (LNF)-COVID-19 index (includes lactate dehydrogenase, aspartate aminotransferase and alanine aminotransferase values), to predict adverse clinical outcomes, including mortality, in patients with both COVID-19 and MAFLD.

Research methods

Data from a derivation cohort, including patients admitted with a diagnosis of severe COVID-19 and meeting the MAFLD criteria identified the best LFN-COVID-19 index cutoff value for risk stratification. The results were evaluated using a validation cohort.

Research results

The LFN-COVID-19 index with a cutoff point > 1.67 was associated with higher mortality ($P < 0.001$) with an area under the curve of 0.77 (95% confidence interval: 0.709-0.823), sensitivity of 78.7% and specificity of 63.8%. It was independently associated with worse outcomes such as higher mortality, intubation rate and acute kidney injury in both cohorts.

Research conclusions

The LFN-COVID-19 index with a cutoff point > 1.67 showed good discrimination capability in patients with severe COVID-19 and MAFLD, identifying patients with an unfavorable prognosis associated with the need for mechanical ventilation, acute kidney injury and higher mortality.

Research perspectives

The use of this prognostic index will allow timely identification of patients with MAFLD and COVID-19 at higher risk of adverse clinical outcomes, leading to better therapeutic decision-making and resource allocation.

Abstract

BACKGROUND

Gastrointestinal stromal tumors (GISTs) with a diameter of < 2 cm are called small GISTs. Currently, endoscopic ultrasound (EUS) is widely used as a regular follow-up method for GISTs, which can also provide a preliminary basis for judging the malignancy potential of lesions. However, there are no studies on the accuracy of EUS to assess the malignant potential of small GISTs.

AIM

To evaluate the efficacy of EUS in the diagnosis and risk assessment of small GISTs.

METHODS

We collected data from patients with small GISTs who were admitted to Shengjing Hospital of China Medical University between October 2014 and July 2019. The accurate diagnosis and risk classifications of patients were based on the pathological assessment according to the modified National Institute of Health criteria after endoscopic resection or laparoscopic surgery. Preoperative EUS features (marginal irregularity, cystic changes, homogeneity, ulceration, and strong echogenic foci) were retrospectively analyzed. The assessment results based on EUS features were compared with the pathological features.

RESULTS

A total of 256 patients (69 men and 187 women) were enrolled. Pathological results included 232, 16, 7, and 1 very low-, low-, intermediate-, and high-risk cases, respectively. The most frequent tumor location was the gastric fundus (78.1%), and mitoses were calculated as > 5/50 high power field in 8 (3.1%)

patients. Marginal irregularity, ulceration, strong echo foci, and heterogeneity were detected in 1 (0.4%), 2 (0.8%), 22 (8.6%), and 67 (65.1%) patients, respectively. However, cystic changes were not detected. Tumor size was positively correlated with the mitotic index ($P < 0.001$). Receiver operating curve analysis identified 1.48 cm as the best cut-off value to predict malignant potential (95% confidence interval: 0.824–0.956). EUS heterogeneity with tumor diameters > 1.48 cm was associated with higher risk classification ($P < 0.05$).

CONCLUSION

Small GISTs (diameters > 1.48 cm) with positive EUS features should receive intensive surveillance or undergo endoscopic surgery. EUS and dissection are efficient diagnostic and therapeutic approaches for small GISTs.

Key Words: Gastrointestinal stromal tumors; Endoscopic ultrasound; Diagnosis; Risk classification

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Endoscopic ultrasound (EUS) has been the recommended follow-up method for small gastrointestinal stromal tumors (GISTs); however, it is not clear whether positive EUS features can predict the malignant potential of small GISTs. Besides, undergoing close follow-up is an economic and mental burden on patients with small GISTs. This study illustrates an optimal cut-off value for the tumor size (1.48 cm) of small GISTs and uses heterogeneity to evaluate risk prediction. Overall, small GISTs with diameters > 1.48 cm with positive EUS features should receive more intensive follow-up or undergo endoscopic surgery.

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are the most common mesenchy-derived tumors of the gastrointestinal tract[1,2]. They occur most frequently in the stomach, accounting for approximately 60% of all cases[3,4]. Most GISTs contain mutations that activate the c-kit or platelet-derived growth factor receptor α gene[5,6]. The golden standard for the diagnosis of GISTs relies on pathological features assessed by methods, such as hematoxylin and eosin (H&E) and immunohistochemical staining. Currently, the risk classification of GISTs is mainly based on the National Institute of Health (NIH) 2008 (modified) or Fletcher criteria[7,8], which include tumor size (2, 5, and 10 cm), mitotic index, primary tumor sites, and tumor rupture.

GISTs with a diameter of < 2 cm are called small GISTs[9]. Currently, the management of small GISTs is controversial. There is no consensus on the treatment of GIST with a diameter of < 2 cm in the latest guidelines of the National Comprehensive Cancer Network (NCCN) (United States), European Society for Medical Oncology (ESMO), and Chinese Society of Clinical Oncology (CSCO)[10-12]. Most small GISTs are discovered incidentally during regular endoscopic scanning, and they are now easier to be detected than before using endoscopic ultrasound (EUS). EUS has been the widely recommended surveillance method for small GISTs. In addition, EUS elastography, contrast-enhanced EUS, and EUS-guided fine needle aspiration and biopsy (EUS-FNA/FNB) have further improved their diagnostic accuracy[13-16]. Furthermore, EUS features have been used in some studies to predict the risk degree of GISTs[17-19]. However, the management of small GISTs remains controversial, and endoscopic resection *via* endoscopic submucosal dissection (ESD) or endoscopic full-thickness resection (EFTR) is not recommended as a routine treatment. Conversely, no study has focused on the positive EUS features for determining the degree of risk for small GISTs. Therefore, in this study, we aimed to identify the efficiency of EUS in the risk assessment and safety of endoscopic dissection for small GISTs.

MATERIALS AND METHODS

Patients

Data on consecutive patients with pathologically confirmed GISTs who were admitted to Shengjing Hospital of China Medical University between September 2014 and July 2019 were collected. The study included patients who underwent endoscopic resection and were pathologically or genotypically diagnosed with GISTs with a diameter of ≤ 2 cm. All the patients underwent preoperative EUS examination. Patients with other sarcomatous malignancies and/or with incomplete data were excluded. This study was approved by the Institutional Review Board and the Ethics Committee of China Medical University (No. 2022PS009K), and all the patients provided informed consent to participate in the study.

EUS examination

Linear EUS (EG3870UT; Pentax, Tokyo, Japan) was used for the examination. Two experienced endoscopists, who were blinded to the pathological results of these lesions, retrospectively evaluated the characteristics of the EUS images to determine whether there were positive features, including irregular borders, cystic changes, ulcerations, strong echogenic foci, heterogeneity, and the presence of an exogenous type of development (Figures 1 and 2). According to the NCCN guidelines, one or more positive EUS features indicate the malignant potential of small GISTs.

Endoscopic resection procedure

The equipment and accessories used during the endoscopic procedure included a standard single-channel gastroscope (EG29-i10, Pentax, Tokyo, Japan) and a transparent cap. Triangle- (TT knife, Olympus Corporation, Tokyo, Japan) and insulation- tipped knifes (IT knife, Olympus Corporation, Tokyo, Japan) were used for the dissection and resection of tumors. During the procedure, hot biopsy forceps (FD-410LR, Olympus Corporation, Tokyo, Japan) were used for hemostasis. Metal clips (Boston Resolution™, Boston, United States) and an over-the-scope clips (OTSC) (Ovesco Endoscopy GmbH, Tuebingen, Germany) were used for the closure of defects.

All endoscopic resections were performed by skilled gastroenterologists, following the standard endoscopic treatment regimen. All procedures were performed using propofol sedation under continuous cardiorespiratory monitoring. Ligation-assisted endoscopic resection, ESD, and EFTR were performed to resect gastric GISTs.

Pathological examination

All resected GIST specimens were routinely processed using a standard surgical pathology protocol after overnight fixation in 10% neutral buffered formalin solution. The details of the tumor site, size, shape, surface color, and consistency were documented by a surgical pathologist. Conventional immunochemistry with a panel of antibodies, such as CD117 (c-kit), CD34, Dog-1, S-100, and smooth muscle actin, was used to support the histopathological diagnosis of GIST. Based on the modified NIH criteria, patients with GISTs were divided into very low-, low-, intermediate-, and high-risk groups (Table 1).

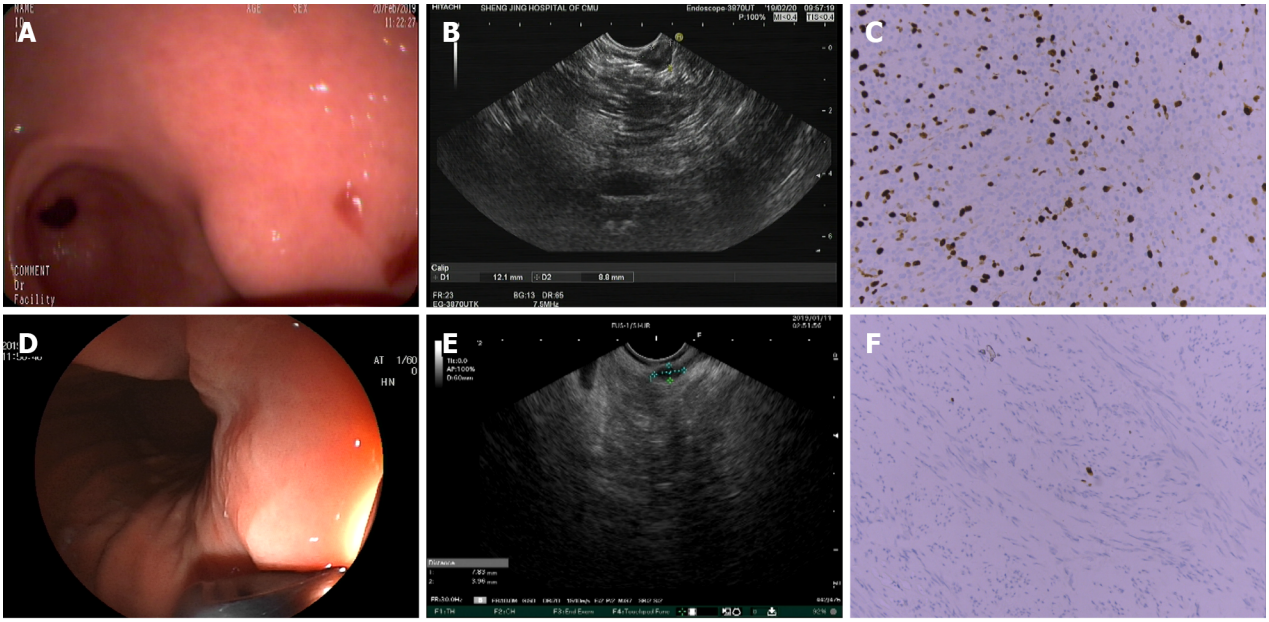
Follow-up strategy

All the patients were routinely followed-up with conventional endoscopic surveillance at 1, 3, 6, and 12 mo after resection. This was followed by annual abdominal computed tomography (CT) for 3 years to rule out recurrence and metastasis. If no residual tumor or tumor recurrence was observed, endoscopic examinations were performed once every 2 years. The follow-up period was up to October 2020. If residual tumor or tumor recurrence was detected, endoscopic resection or surgery could be performed.

Statistical analysis

Data processing was performed using the SPSS statistical software (SPSS 23.0, Chicago, IL, United States). Continuous data are expressed as the mean ± SD, and categorical data are displayed as number (*n*) or percentage (%). The accuracy of the diagnostic test was evaluated by sensitivity, specificity, false negative and positive rates, positive and negative likelihood ratios, and Youden's index. The Chi-square test was applied for intergroup comparisons. A receiver operating characteristic (ROC) curve was performed to determine the optimal tumor diameter for predicting malignant potential. Lesions with positive EUS features or mitoses more than 5/50 high power field (HPF) were defined as true positives. P value < 0.05 was considered statistically significant.

RESULTS



Clinical and pathological features of small gastric GISTs

A total of 256 patients, including 69 men (27%) and 187 women (73%), were enrolled in the study

Table 1 The modified National Institute of Health risk classification of small Gastrointestinal stromal tumors

Risk classification	Tumor diameter (d/cm)	Mitotic count (number/50 HPF)
Very-low	D ≤ 2	Mitotic ≤ 5
Intermediate	D ≤ 2	5 < mitotic ≤ 10
High	D ≤ 2	Mitotic > 10

HPF: High power field.

DOI: 10.3748/wjg.v28.i37.5457 **Copyright** ©The Author(s) 2022.

Figure 1 Endoscopic ultrasound imaging features were consistent with the postoperative pathological results. A: A lesion with a diameter of approximately 1.2 cm was observed in the gastric antrum using an endoscope; B: Heterogeneity was observed as a characteristic of endoscopic ultrasound (EUS) imaging; C: Gastric stromal tumor (intermediate risk). The spindle of the tumor cells is arranged in sheets and bundles with nuclear division of approximately 8-9/50 high power field. Immunohistochemistry: CD117 (+); CD34 (-); Desmin (-); Dog1 (+); Ki-67 (35%+); smooth muscle actin (+); and S-100 (-); D: A lesion with a diameter of approximately 0.6 cm was observed in the gastric fundus using an endoscope; E: EUS images were characterized by a hypoechoic mass in the muscularis propria; F: Gastric stromal tumor (very low risk). The spindle of the tumor cells is arranged in spindle and bundles without obvious nuclear division. Immunohistochemistry: CD117 (+); CD34 (-); Desmin (-); Dog1 (+); Ki-67 (< 1%+); smooth muscle actin (-); and S-100 (-).

(Table 2), with an average age of 57.4 ± 8.6 years. The most frequent locations of the tumors were the gastric fundus (78.1%) and body (17.2%), and the average diameter of all lesions was 1.05 cm (range, 0.30–2.00 cm). These patients were eventually diagnosed with GISTs mainly based on pathological standards, such as H&E and immunohistochemistry staining. According to the modified NIH criterion, mitoses were calculated as > 5/50 HPF and ≤ 5/50 HPF in 8 (3.1%) and 248 (96.9%) patients, respectively. The patients' features in the EUS images are shown in Table 2, illustrating that 67 (65.1%) and 22 (8.6%) cases were identified with heterogenous and hyperechoic foci, respectively. However, a lobular border and ulceration were detected in only 3 cases (1.2%).

ROC curve analysis

To determine a suitable cut-off value for predicting the higher risk potential of small GISTs, aggressive biological behaviors were expanded to mitoses more than 5/50 HPF. Lesions with mitoses more than 5/50 HPF were defined as true positives. A tumor diameter of 1.48 cm was finally identified as the optimal cut-off value, with the area under the curve (AUC) being 0.89 (95% confidence interval: 0.824–0.956; P < 0.001) (Figure 3A), a sensitivity of 0.875, and a specificity of 0.828 (Figure 3B). Subsequently, 208 and 48 patients were classified into groups with tumor size ≤ 1.48 cm and > 1.48 cm, respectively. The comparison of the clinicopathological characteristics between the two groups is presented in Table 3. In the > 1.48 cm group, a higher percentage of patients had more than 5 mitotic indexes/50 HPFs compared to those in the ≤ 1.48 cm group (14.58% *vs* 0.48%, P < 0.001). Moreover, patients with larger tumor diameter tended to display positive EUS features (56.25% *vs* 31.25%, P = 0.002).

Comparison of non-low-risk and low-risk GISTs in terms of EUS features

We compared the consistency of positive EUS features and pathological risk classification of small GISTs, and found that intermediate- and very low-risk cases presented with heterogeneous (Figure 1A-C) and hypoechoic (Figure 1D-F) EUS findings, respectively. This suggests that EUS imaging features were consistent with the postoperative pathological results. However, some cases showed that EUS imaging features were inconsistent with the postoperative pathological results [intermediate-risk case with hypoechoic mass (Figure 2A-C) and very-low-risk case with strong echogenic foci (Figure 2D-F)]. To further identify the efficiency of positive EUS features in the risk assessment of small GISTs, we divided these patients into non-low-risk and low-risk groups (Table 4). Five of eight patients with non-low-risk GISTs (62.5%) and 62 of 248 patients with low-risk GISTs (25%) had heterogeneous features. There was a significant difference (P = 0.031) in the heterogeneous features between low- and high-grade risk GISTs. However, there was no statistical difference in hyperechoic foci and ulceration between low- and high-grade risk GISTs. Hyperechoic foci were found in 0 of 8 (0%) and 22 of 248 (8.87%) non-low- and low-risk groups, respectively. The ulcerative appearance was found in 0 of 8 (0%) and 2 of 248 (0.8%) non-low- and low-risk groups, respectively. Furthermore, other positive EUS

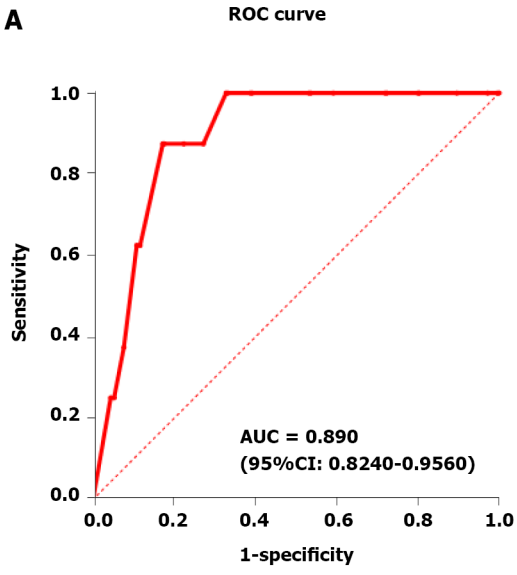
features, such as marginal irregularity and cystic changes, were not detected in small GISTs.



DISCUSSION

The incidence of GIST ranges from 6 to 22 cases *per* 10^6 individuals *per* year[20,21], while that of small GISTs might be higher as more cases of asymptomatic small GISTs have been detected clinically due to the growing popularity of endoscopy in the recent years. Currently, there is no consensus on whether small GISTs (≤ 2 cm) require resection or yearly surveillance in the latest guidelines, including NCCN, ESMO, and CSCO[10-12,22]. However, the ESMO recommends that resection should be the standard

treatment for histologically confirmed small GISTs[21]. Small GISTs are generally considered to have a low malignant potential, and few of them may progress to clinically relevant tumors. However, a population-based study reviewed 378 patients with small GISTs found that approximately 11.4% of small GISTs were accompanied by local progression or even distant metastasis when first diagnosed and claimed that small GISTs might progress and become life-threatening, with a mortality of 12% at 5 years[23]. Additionally, some scholars believe that the conservative observational methods for small GISTs can only evaluate whether the tumor diameter has increased, which will cause psychological

burden and risk to patients as clinicians would only passively wait for the tumor size to increase before performing surgical resection[24]. Therefore, it is critical to choose optimal approaches for accurately evaluating the clinical features and providing risk suggestions for small GISTs before their progression.

EUS has been recommended as an optimal method for the diagnosis and follow-up of small GISTs, while its efficacy in risk assessment of small GISTs is still not clear. The NCCN guidelines recommend that conservative follow-up should be performed in small GISTs lacking high-risk EUS features (marginal irregularity, cystic changes, ulcers, strong echo foci, and heterogeneity)[10]. Moreover, in recent years, many studies have shown that EUS can provide a preliminary basis for assessing the malignant potential of lesions. Palazzo *et al*[25] showed that EUS was reliable in predicting the malignant potential of GISTs, including three most predictive EUS features (one or more of the following: Irregular border, cystic changes, and lymph nodes with a malignant pattern) with a sensitivity of 91% and a specificity of 88%[25]. Jeon *et al*[26] found that the best predictor of high-risk GISTs was the combination of endoscopic and EUS features, including a tumor diameter > 3 cm, irregular border, mucosal ulceration, and a non-oval shape[26]. Concerning small GISTs, Gao *et al*[18] studied 69 patients suspected to have GISTs as indicated by EUS and concluded that the tumor size of > 9.5 mm was significantly correlated with tumor progression, which was of great value in predicting the malignant potential of the GISTs[18]. Wang *et al*[27] examined 648 cases of small GISTs and concluded that GISTs with a diameter of < 1.45 cm had an overall good prognosis; however, those with a diameter > 1.45 cm required intensive monitoring or had to undergo endoscopic surgery[27,28].

Our study enrolled a total of 256 patients who underwent ESD or EFTR during 2014–2019 in Shengjing Hospital including 248 very low- or low-risk cases and 8 intermediate/high-risk cases based on the modified NIH classification. We generated a ROC curve based on the potential malignancy predictor (mitoses more than 5/50 HPF) to determine the optimal cut-off value of tumor size. A tumor diameter of 1.48 cm was identified as the optimal cutoff value, with a sensitivity of 87.5%, a specificity of 82.8%, and an AUC of 0.89. Of all the 256 patients with small gastric GISTs included in our study, EUS features for malignancy prediction were studied retrospectively. Heterogenous, hyperechoic foci, lobular border, and ulceration were detected in 67 (65.1%), 22 (8.6%), 1 (0.4%) and 2 (0.8%) patients, respectively. According to the optimal cut-off value, patients were subsequently divided into two groups: ≤ 1.48 cm and >1.48 cm. We identified that tumors with a diameter > 1.48 cm were more likely to present positive EUS features (P = 0.002). To further identify whether positive EUS features can predict the malignant potential of small GISTs, we compared EUS features between the non-low- and low-risk groups. The results showed that there was a significant difference between the two groups regarding the heterogeneity, which might suggest that patients with GISTs experiencing this EUS feature should be followed-up more frequently while considering endoscopic surgery when regular follow-up is not feasible or EUS-guided tissue acquisition for pathological assessment. However, there was no statistical difference in hyperechoic foci and ulceration features between the two groups. We believed that limited cases with these two EUS features might have resulted in a partial evaluation. Therefore, a larger scale study is needed to further comprehensively evaluate the efficacy of EUS for the risk prediction of small GISTs.

Other studies have shown that contrast-enhanced harmonic EUS and EUS-elastography can distinguish GISTs from other submucosal tumors, but the risk grade of GISTs cannot be evaluated[14,29]. Moreover, another study suggests that EUS-FNA/FNB can be used to obtain tissue for assessing the malignancy risk of tumors[30]. However, for small GISTs, the diagnostic rate of EUS-FNA is low, and due to the small size of the lesion and certain mobility limitations, puncturing the tumor is difficult and the possibility of obtaining sufficient samples is low[31,32]. A study of 53 patients[33] showed that the successful diagnostic rate of an adequate specimen was related to the lesion size: Only 71% of lesions measuring < 20 mm had complications led by repeated needle puncture[34,35]. In contrast, with the advance of endoscopic techniques, complete treatment has become possible *via* endoscopic surgery, such as ESD and EFTR. ESD is currently the most widely used endoscopic treatment for resecting GISTs. Studies have shown that ESD is safe and effective for treating GISTs that originate from the muscularis propria layer, with a diameter ≤3 cm and without extra-gastrointestinal invasion or abdominal metastasis[36-38]. The main adverse events of this technique are bleeding and perforation[39,40]. EFTR is mainly suitable for patients whose lesions are located in the deep muscularis propria layer and are closely connected to the serosal layer, in which metal clips, OTSCs, and other methods are used for rapid closure of defects to prevent pneumoperitoneum and peritonitis. In this study, only one patient treated with endoscopy developed delayed bleeding; however, the patient recovered well after endoscopic hemostasis was performed. Furthermore, all patients who underwent endoscopic resection had no recurrence or metastasis during a mean follow-up period of 40 mo (range, 15–72 mo), suggesting that endoscopic surgery is feasible and safe for small GISTs.

This study had a few limitations. First, the results of this retrospective study may be affected by selection bias. Second, the follow-up period was relatively short, which may result in missing cases of recurrence. Third, limited samples may affect the comprehensive evaluation of positive EUS features for risk classification. Therefore, multicenter randomized controlled trials should be conducted in the future to enhance the robustness of these conclusions.

CONCLUSION

In conclusion, partial EUS features, such as heterogeneity, can be applied to predict higher-risk small GISTs with a diameter > 1.48 cm. These tumors with diameters > 1.48 cm should undergo more intensive surveillance. Endoscopic surgery should be strongly recommended for small GISTs if regular follow-up is infeasible for low recurrence rate and metastatic rate.

ARTICLE HIGHLIGHTS

Research background

Small gastrointestinal stromal tumors (GISTs) have a high incidence, and their prognosis and treatment remain controversial.

Research motivation

Endoscopic ultrasound (EUS) plays a pivotal role in the diagnosis of GISTs, but its ability to assess the prognosis of small GISTs remains to be explored.

Research objectives

To evaluate the efficacy of EUS in the diagnosis and risk assessment of small GISTs.

Research methods

We collected data from patients with small GISTs, the diagnosis and risk classifications of which were based on the pathological assessment according to the modified National Institute of Health criteria after endoscopic resection or laparoscopic surgery. The assessment results based on EUS features (marginal irregularity, cystic changes, homogeneity, ulceration, and strong echogenic foci) were compared with the pathological features.

Research results

A total of 256 patients (69 men and 187 women) were enrolled. Tumor size was positively correlated with the mitotic index ($P < 0.001$). Receiver operating curve analysis identified 1.48 cm as the best cut-off value to predict malignant potential (95% confidence interval: 0.824–0.956). EUS heterogeneity with tumor diameters > 1.48 cm was associated with higher risk classification ($P < 0.05$).

Research conclusions

Small GISTs (diameters, > 1.48 cm) with positive EUS features should receive intensive surveillance or undergo endoscopic surgery. EUS and dissection are efficient diagnostic and therapeutic approaches for small GISTs.

Research perspectives

EUS provides reference evidence for the precise assessment and early risk assessment of small GISTs.

Abstract

BACKGROUND

Efficient and practical methods for predicting the risk of malignancy in patients with pancreatic cystic neoplasms (PCNs) are lacking.

AIM

To establish a nomogram-based online calculator for predicting the risk of malignancy in patients with PCNs.

METHODS

In this study, the clinicopathological data of target patients in three medical centers were analyzed. The independent sample t-test, Mann–Whitney U test or chi-squared test were used as appropriate for statistical analysis. After univariable and multivariable logistic regression analysis, five independent factors were screened and incorporated to develop a calculator for predicting the risk of malignancy. Finally, the concordance index (C-index), calibration, area under the curve, decision curve analysis and clinical impact curves were used to evaluate the performance of the calculator.

RESULTS

Enhanced mural nodules [odds ratio (OR): 4.314; 95% confidence interval (CI): 1.618–11.503, $P = 0.003$], tumor diameter ≥ 40 mm (OR: 3.514; 95%CI: 1.138–10.849, $P = 0.029$), main pancreatic duct dilatation (OR: 3.267; 95%CI: 1.230–8.678, $P =$

0.018), preoperative neutrophil-to-lymphocyte ratio ≥ 2.288 (OR: 2.702; 95%CI: 1.008–7.244, P = 0.048], and preoperative serum CA19-9 concentration ≥ 34 U/mL (OR: 3.267; 95%CI: 1.274–13.007, P = 0.018) were independent risk factors for a high risk of malignancy in patients with PCNs. In the training cohort, the nomogram achieved a C-index of 0.824 for predicting the risk of malignancy. The predictive ability of the model was then validated in an external cohort (C-index: 0.893). Compared with the risk factors identified in the relevant guidelines, the current model showed better predictive performance and clinical utility.

CONCLUSION

The calculator demonstrates optimal predictive performance for identifying the risk of malignancy, potentially yielding a personalized method for patient selection and decision-making in clinical practice.

Key Words: Pancreatic cystic neoplasms; Risk of malignancy; Nomogram; Model; Prediction; Calculator

INTRODUCTION

Pancreatic cystic neoplasms (PCNs) are estimated to be present in 2%–45% of the general population[1-3]. With rapid advancements in medical examination technologies over the past decades, the use of these technologies in the identification of PCNs has dramatically increased. Moreover, PCNs are frequently discovered in asymptomatic patients[4]. Consequently, centers with high volumes of patients undergoing pancreatic surgery are evaluating an increasing number of PCNs cases annually. Nevertheless, how to properly manage patients with PCNs remains a topic of debate.

PCNs are usually divided into serous cystic neoplasms (SCNs), mucinous cystic neoplasms (MCNs), intraductal papillary mucinous neoplasms (IPMNs) and other rare cystic lesions, such as solid pseudopapillary tumors (SPTs) and cystic neuroendocrine tumors (cNET) which show biological behavior ranging from benign to malignant[5,6]. Moreover, the main controversy regarding the treatment of PCNs is related to the inability to precisely determine their histopathological diagnosis without surgical resection[7,8], thereby precluding the accurate identification of different subtypes of PCNs. Consequently, clinicians are challenged to maintain a difficult balance between avoiding excessive surgical treatment and keeping a malignant lesion under surveillance.

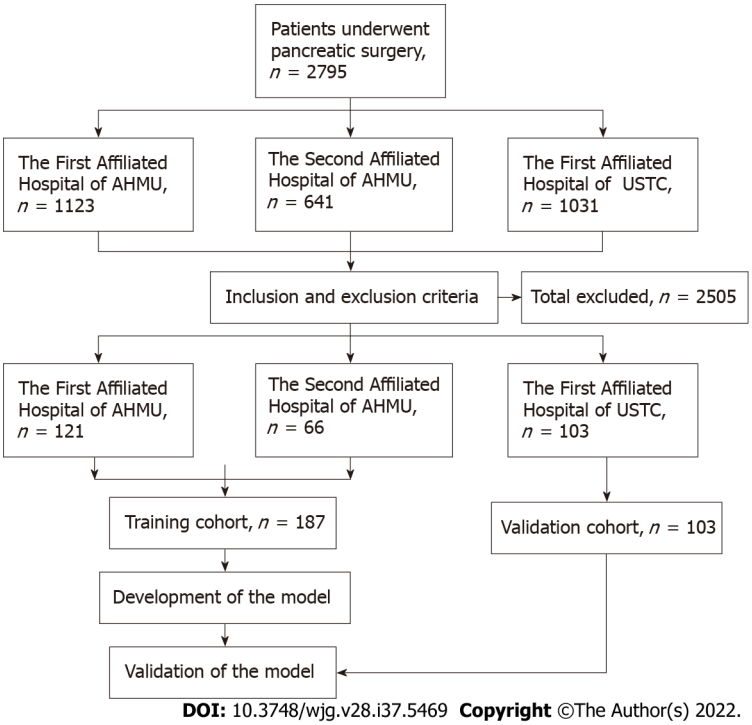
Although previous studies have focused on the identification of different types of PCNs[9-11], only a few of these studies have emphasized the judgment or prediction of malignancy risk in PCNs. Thus, identifying a method that can accurately and preoperatively predict the risk of malignancy in PCNs is of great significance. Nomograms are effective statistical tools that enable the simultaneous consideration of various factors for clinicians to visualize the malignant probability of a neoplasm, allowing the formulation of an optimal therapeutic schedule. Nomogram possess other advantages including ease of comprehension, user-friendliness and personalized evaluation[12]. Therefore, this study aimed to establish a novel clinical online nomogram-based calculator to predict the risk of malignancy in PCNs.

MATERIALS AND METHODS

The clinical and pathological data of patients with PCNs who underwent surgery at the Department of General Surgery in three medical centers between January 2015 and December 2021 were collected and analyzed. Patients from the First Affiliated Hospital of Anhui Medical University and Second Affiliated

Hospital of Anhui Medical University were set as the training cohort, while those from the First Affiliated Hospital of the University of Science and Technology of China were set as the validation cohort. All hospitals were high-volume surgical centers that employed similar therapeutic approaches for PCNs. Pathological diagnosis was confirmed by postoperative specimen examinations by two experienced pathologists. According to the histological classification of PCNs proposed by the World Health Organization (2019) and the Baltimore consensus meeting, PCNs are classified as those with low- or intermediate-grade dysplasia and those with high-grade dysplasia or invasive carcinoma[13,14]. Patients from the three centers who met the following criteria were included: (1) Patients who underwent surgical treatment and were confirmed as showing SCNs, IPMNs or MCNs in postoperative pathological examinations; (2) Patients with complete clinical data, including medical history and laboratory test data; and (3) Patients who underwent preoperative imaging examinations. The following patients were excluded: (1) Patients who were pathologically confirmed as having other rare cystic lesions such as SPTs and cNET; (2) Patients who were pathologically confirmed as having other uncommon and undefined cystic tumors of the pancreas; and (3) Patients with a history of pancreatic surgery, radiotherapy or chemotherapy. All clinical data were screened and collected in a computerized database by a professional research assistant. In this study, patients were categorized as showing low-risk (low- or intermediate-grade dysplasia) or high-risk (high-grade dysplasia or invasive carcinoma) disease based on the pathological diagnosis. The appearance of high-risk disease was characterized as a study endpoint. Figure 1 depicts a flowchart of patient enrollment and the inclusion process. This study was conducted in accordance with the Declaration of Helsinki and was approved by the institutional ethics committee (Quick-PJ2022-06-26). All included patients or their relatives provided written informed consent before their data were analyzed.

Perioperative management



In accordance with the similar preoperative evaluation protocol at all centers, all patients were routinely examined using blood tests, including routine blood counts and analysis of blood biochemistry, hemostatic function, immunological markers and tumor markers. Moreover, all patients underwent at least two preoperative imaging examinations through ultrasound (US), computed tomography (CT), magnetic resonance imaging or 2-^{18}F-fluoro-2-deoxy-d-glucose positron emission tomography-CT, which provided information about the size, number, location and internal condition of the lesions. Definitive planning of the procedure was performed according to the examination results and the patient's age, comorbidities and preferences.

Surgical procedures, including pancreatoduodenectomy, total pancreatectomy, partial pancreatectomy and distal pancreatectomy with or without splenic preservation, were performed depending on the tumor location and characteristics. Experienced pancreatic surgeons performed all surgical procedures. Meanwhile, the balance between the benefits of oncological clearance and the risks of inadequate parenchymal preservation was carefully considered.

Normative and meticulous postoperative care including monitoring of vital signs, maintenance of moderate tissue perfusion and support for nutritional needs was implemented for every patient at the initial stage.

Statistical analysis

All data, including demographic data, preoperative imaging data and clinical and pathological data were recorded in detail using a special recorder. Continuous variables were expressed as mean ± SD for normally distributed variables or median (interquartile range) for non-normally distributed variables and statistical tests were used as appropriate (the independent sample t-test or the Mann–Whitney U test). Categorical variables were expressed as numbers (n) and proportions (%) and compared appropriately *via* Fisher's exact test or the chi-squared test. The cutoff values of continuous parameters were derived from the Youden index[15]. Univariable logistic regression analysis was performed on the training cohort to screen for risk factors associated with malignancy. On the basis of the univariable analysis, multivariable logistic regression analysis was conducted using variables that had statistical significance. A nomogram for the prediction of malignancy in patients with PCNs was developed based on the multivariable logistic regression model. The performance of the nomogram was evaluated using a concordance index (C-index) and calibration plots based on bootstrap validation method (n = 1000) to reduce overfitting bias. The area under the curve (AUC) of the receiver operating characteristic (ROC) curves and the quality indices such as sensitivity, specificity, accuracy, positive predictive value and negative predictive value with the associated 95% confidence intervals (CIs) of the model applied to the training and external validation cohorts were obtained. This allowed assessment of the predictive efficiency of the model in comparison with those of the risk factors identified in the relevant guidelines. The clinical usefulness of the nomogram was examined by determining the net benefit using decision curve analysis (DCA)[16]. DCA can assess the utility of models for decision making by plotting net benefit at a range of clinically reasonable risk thresholds. The predictive accuracy and clinical usefulness of the nomogram were demonstrated by clinical impact curves. Based on the sensitivity, specificity and predictive values, the optimal cutoff value was evaluated for accuracy. An online calculator for public use was created through shinyapps.io by RStudio to facilitate the use of the model in clinical practice. Statistical analyses were performed using R version 4.0.5 (http://www.r-project.org/, R Development

Figure 1 Flowchart of patient recruitment and diagnosis. AHMU: Anhui Medical University; USTC: University of Science and Technology of China.

Core Team) and SPSS version 23.0 (SPSS Inc, Armonk, NY, United States. In this study, the packages rms, nomogramFormula, DynNom and rmda were utilized for statistical analysis and figure drawing. A two-tailed P value < 0.05 was considered significant.

RESULTS

Patient cohorts and clinicopathologic features

The clinicopathologic data of 1764 consecutive patients who underwent pancreatic surgery at the First Affiliated Hospital of Anhui Medical University and the Second Affiliated Hospital of Anhui Medical University between January 2015 and December 2021 were collected. Among them, 246 patients (13.9%) who were pathologically confirmed as having IPMNs, MCNs or SCNs were classified as the initial target population. Of these 246 patients, 59 (24.0%) who did not fulfill the inclusion criteria were excluded, including 19 patients with incomplete clinical or imaging data, nine with a history of pancreatic surgery, 25 with mixed pathological characteristics and 6 with a history of radiotherapy or chemotherapy. Ultimately, 187 patients (76.0%) were included in the training cohort. Based on the same criteria, an independent group consisting of 103 patients from the First Affiliated Hospital of University of Science and Technology of China who were eligible for inclusion in the same period was included in the present study and served as an external validation cohort. The two cohorts showed no significant differences in baseline characteristics (P > 0.05; Tables 1 and 2).

Univariable and multivariable analysis in the training cohort

The results of the univariable and multivariable analyses of variables concerning malignancy in the training cohort were listed in Table 3. The optimal cutoff values of the neutrophil-to-lymphocyte ratio (NLR) was 2.288. Factors that significantly affected the risk of malignancy in the univariable analysis were then included in the multivariable analysis, which demonstrated that the presence of enhanced mural nodules [odds ratio (OR): 4.314; 95%CI: 1.618–11.503, P = 0.003], tumor diameter ≥ 40 mm (OR: 3.514; 95%CI: 1.138–10.849, P = 0.029), main pancreatic duct dilatation (OR: 3.267; 95%CI: 1.230–8.678, P = 0.018), preoperative NLR ≥ 2.288 (OR: 2.702; 95%CI: 1.008–7.244, P = 0.048) and preoperative serum CA19-9 concentration ≥ 34 U/mL (OR: 3.267; 95%CI: 1.274–13.007, P = 0.018) were independent risk factors for a high risk of malignancy in patients with PCNs.

Development and evaluation of the predictive model

The factors that were proven to be related to a high risk of malignancy were utilized to establish a nomogram for evaluating the probability of malignancy (Figure 2). The model obtained using this approach showed good predictive capacity for estimating the risk of malignancy in patients with PCNs

and predicted values (values closer to 0 indicate better predictive ability). A calibration slope of 1.0 was obtained to assess the agreement between observed and predicted values (values closer to 1.0 indicate better performance)[17]. An online calculator for predicting the risk of malignancy was created and was freely available at https://ahmuptt.shinyapps.io/JDYX/.

Comparison of the performance of the nomogram and the risk factors identified in the relevant guidelines

Using ROC analyses, the diagnostic performance of the nomogram established in this study was compared with those of the risk factors identified in the relevant guidelines[6,18], including tumor diameter ≥ 40 mm, enhanced mural nodules and main pancreatic duct dilatation (Figure 4). In the training cohort, the AUC values and 95%CIs of the nomogram and the three factors (tumor diameter ≥ 40 mm, enhanced mural nodules and main pancreatic duct dilatation) were 0.824 (0.735–0.914), 0.619 (0.496–0.742), 0.692 (0.575–0.810) and 0.653 (0.540–0.766), respectively. In the validation cohort, these values were 0.893 (0.823–0.963), 0.718 (0.560–0.876), 0.665 (0.506–0.824) and 0.672 (0.524–0.820), respectively. In both cohorts, significant statistical differences were found between the nomogram and the three factors ($P < 0.05$). The training cohort had an accuracy, sensitivity, specificity, positive predictive value and negative predictive value of 0.829, 0.643, 0.862, 0.451 and 0.932, respectively. In the validation cohort, these values were 0.925, 0.882, 0.826, 0.501 and 0.973, respectively. Thus, the

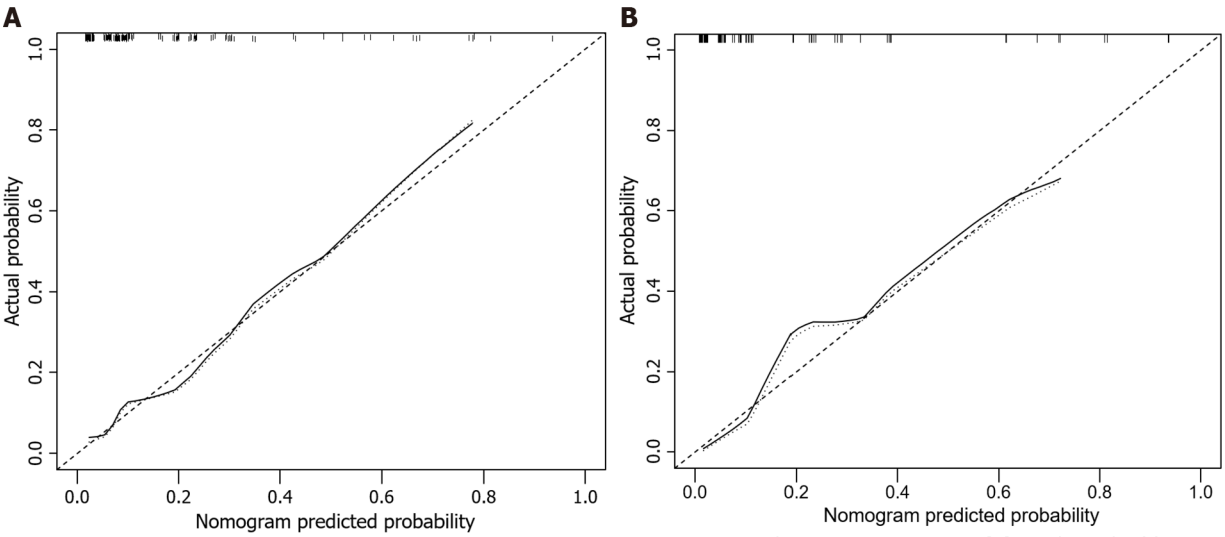
ALP: Alkaline phosphatase; BMI: Body mass index; CA19-9: Carbohydrate antigen 19-9; CEA: Carcinoembryonic antigen; CI: Confidence interval; GGT: γ-glutamyl transpeptidase; NLR: Neutrophil-to-lymphocyte; OR: Odds ratio; TB: Total bilirubin.

nomogram showed high accuracy in predicting the risk of malignancy in patients with PCNs. When considering the maximum Youden index value, the optimal cutoff value of the nomogram was 160.8 in the ROC curve and the sensitivity and specificity for differentiating between high and low risk were 64.3% and 86.2%, respectively. This cut off value is used to categorize patients with total nomogram score of < 160.8 points or ≥ 160.8 points as either low- or high-risk group, respectively. In the training cohort, DCA showed that using the nomogram to predict the risk of malignancy had a greater net benefit than the other three factors when the threshold probability ranged from 0.2 to 1.0. In the validation cohort, DCA showed that the nomogram had a greater net benefit when the threshold probability ranged from 0.0 to 0.4 (Figure 5). Figure 6 depicts the number of high-risk patients (solid red line) and the number of high-risk patients with the outcome (black dotted line) at different threshold probabilities within a given population. In both the training and validation cohorts, the solid red and black dotted lines show a great fit indicating that the model has remarkable predictive ability.



DISCUSSION

The increasing use of high-resolution cross-sectional imaging techniques has resulted in more frequent detection of PCNs in recent years[19]. However, accurate prediction of the risk of malignancy of PCNs as early as possible is of great value in developing more appropriate individualized treatment strategies. In the current study, we developed and validated a preoperative clinical model that strongly predicted the risk of high-grade dysplasia or invasive cancer in patients with PCNs.

Figure 3 Calibration curves for predicting the risk of malignancy. The nomogram had concordance index values of 0.824 and 0.893 in the training and validation cohort, respectively. A: Training cohort; B: Validation cohort.

As shown in Tables 1 and 2, our study analyzed dozens of objective factors, and the findings indicated that for patients with PCNs, lesions with enhanced mural nodules, tumor diameter ≥ 40 mm, main pancreatic duct dilatation, preoperative NLR ≥ 2.288 and preoperative serum CA19-9 levels ≥ 34 U/mL were significant independent predictors. These factors were combined with patients' preoperative imaging and serological data to quantify the risk of malignancy concisely and spontaneously. The sufficient statistical power of the model for predicting the risk of malignancy was verified based on multiple validation methods. The C-index of the model in the validation cohort was 0.893 (0.823–0.963), highlighting the ability of the model to distinguish low-risk disease from high-risk disease in a large group of patients. In addition, we used an independent validation dataset that effectively decreased the risk of overfitting the model to an individual dataset. The similarity between the C-index of the training [0.824 (0.735–0.914)] and validation [0.893 (0.823–0.963)] cohorts suggested that this model was widely applicable. In addition, a mobile-friendly online version of the nomogram was programmed to eliminate the inconvenience of traditional nomograms in clinical use.

The latest guidelines, including the European evidence-based guidelines on PCNs and the International Association of Pancreatology guidelines of 2017, have described the management strategies for different subtypes of PCNs in detail[6,18]. In addition, many published nomogram models for predicting malignancy in patients with a specific subtype of PCNs, such as IPMNs, have been

Figure 4 Receiver operating characteristic curve of the nomogram and other three risk factors identified in guidelines. A: Training cohort; B: Validation cohort. AUC: Area under the curve.

established to facilitate the preoperative prediction of malignant lesions[20-22]. Nevertheless, real-world preoperative diagnosis of the different PCN subtypes remains difficult due to their similarities in both clinical and imaging features. In particular, accurate diagnosis of pathological neoplasms and preoperative assessments of the benign or malignant status of some lesions with atypical manifestations are even more difficult[23]. Previous studies have reported differing probabilities for the accurate preoperative identification of each subtype. Salvia *et al*[24] found that in 476 patients with PCNs, 78% showed postoperative pathological examination results consistent with the preoperative diagnosis[24]. Furthermore, a multicenter study of 2251 patients in China showed that the preoperative diagnosis was not always accurate for a specific subtype with a correct diagnosis rate of only 33%[25]. Meanwhile, the risk factors proposed to be associated with malignant lesions in the guidelines lack universality, efficiency and accuracy in clinical applications to a certain extent. In this study, a model with strong practicability and high predictive efficiency was constructed by analyzing PCNs showing similar clinical and imaging manifestations across subtypes. Therefore, this model can help clinicians predict the risk of lesion malignancy when they are unable to accurately determine the PCN subtype or have difficulties in confirming the nature of the tumor.

NLR was also included as a laboratory indicator in the nomogram. Researches have shown that inflammation contributes to the occurrence and progression of tumors by releasing cytokines and other inflammatory mediators[26,27]. NLR measurement can serve as a simple and convenient way to assess the systemic inflammatory response and many recent studies have confirmed that inflammatory markers play an important role in predicting benign and malignant PCNs[28-30]. In the current study, a significant correlation was found between NLR and high-risk groups by multivariable analysis and the cutoff value of NLR was calculated as 2.43 which was rarely studied and reported in previous studies. We believe that neutrophils can recruit and activate inflammatory cells by producing cytokines and chemokines thus acting on the tumor microenvironment. In addition, reactive oxygen species and proteases produced by neutrophils can regulate tumor cell proliferation, angiogenesis and metastasis [31]. Thus, an increase in NLR may indicate a macroscopic withdrawal of inflammatory and immune responses in the local tumor microenvironment.

The nomogram was chosen to establish the model mainly because of its ability to assign risk probabilities on a continuous scale as an individualized risk score, rather than simply dividing patients into malignant and benign groups. This allows for additional risk stratification and may help patients and doctors tailor treatment decisions based on patients' individual risks. In addition, as shown in Figure 2, the nomogram showed that the model score for cases with serum CA19-9 levels ≥ 34 U/mL (100 points) was significantly higher than that for cases with an NLR of ≥ 2.288 (61 points), suggesting that serum CA19-9 levels ≥ 34 U/mL increase the possibility of a malignant lesion significantly. Moreover, the additive effect of several risk factors is important clinically. In this context, the patient-specific quantitative estimation of risk is valuable. Therefore, in cases where benign and malignant PCNs cannot be easily distinguished, clinicians can calculate the total nomogram scores using this predictive model. We propose that surgical treatment should be considered as the first choice for patients with a total nomogram score ≥ 160.

Figure 5 Decision curve analysis of the nomogram and other three risk factors identified in guidelines. The x-axis represents the threshold probability and the y-axis represents the net benefit. In the training cohort, the nomogram adds more net benefit than the other three factors when the threshold probability ranged from 0.2 to 1.0. In the validation cohort, the nomogram adds more net benefit than the other three factors when the threshold probability ranged from 0.0 to 0.4. A: In the training cohort; B: In the validation cohort.

In recent years, machine learning has rapidly developed as a tool with promising results and improved usability[32]. Machine learning addresses many preexisting and novel medical challenges and is widely discussed by researchers and practitioners alike. Machine learning algorithms have many advantages, such as improved flexibility and scalability when compared with traditional statistical methods. This makes machine learning advantageous for many tasks, including risk stratification, diagnosis, classification and survival predictions. Another advantage of machine learning is the ability to analyze diverse data types (*e.g.*, demographic data, laboratory findings, imaging data and doctors' free-text notes) and to incorporate them into predictions for disease risk, diagnosis, prognosis and appropriate treatment[33]. Despite these advantages, the application of machine learning in healthcare delivery also presents unique challenges, including the need for data pre-processing, model training and refinement of the system with respect to the actual clinical problem. Also crucial are ethical considerations which include medico-legal implications, doctors' understanding of machine learning tools, and data privacy and security[34]. In summary, attempts can be made to refine the model further using advanced machine learning in the future.

The present study had several limitations that merit discussion. First, endoscopic US (EUS) helps identify PCNs with features that may indicate the need for surgical resection[6]. However, in our study, only less than 10% of the patients underwent EUS. This may be attributable to the considerable interobserver variation in EUS-based diagnoses. On the other hand, data on EUS-based differentiation between benign and malignant PCNs are inconsistent[35,36]. Moreover, economic affordability is an important consideration, especially for most patients from rural areas. Second, heterogeneity in pathological diagnosis to determine the grade of dysplasia or malignancy and heterogeneity between different imaging examinations may exist. Third, this was a retrospective study considering only patients who underwent surgery which meant that it had inherent limitations resulting from potential selection biases; prospective validation is therefore required to confirm the value of the findings.

In both training and validation cohort, the solid red line and black dotted line show a great fit. A: In the training cohort; B: In the validation cohort.

CONCLUSION

In conclusion, we developed and validated a novel online calculator using a nomogram based on widely available data to predict the risk of malignancy in patients with PCNs dynamically. The calculator is user-friendly, highly accurate and well validated. Clinicians can use it to alert patients at high risk of malignancy at early stages and to design individual therapy for them.

ARTICLE HIGHLIGHTS

Research background

Efficient and practical methods for predicting the risk of malignancy in patients with pancreatic cystic neoplasms (PCNs) are currently lacking.

Research motivation

Currently, there is no effective clinical prediction model for patients with PCNs and no large study has been conducted to predict malignant risk.

Research objectives

The aim of this study was to identify the risk factors influencing the malignant risk of PCNs and develop a prediction model that is useful for clinical surgeons when making decisions regarding surgical interventions.

Research methods

Data collected in three major medical centers were analyzed to identify independent risk parameters and propose a calculator for patients with PCNs. A number of statistical indices, such as concordance index, calibration curves, area under the curve, decision curve analysis, CIC and others were used to evaluate the performance of the nomogram.

Research results

Five factors, including enhanced mural nodules, tumor diameter ≥ 40 mm, main pancreatic duct dilatation, preoperative neutrophil-to-lymphocyte ratio ≥ 2.288 and preoperative serum CA19-9 concentration ≥ 34 U/mL were found to independently influencing the risk of malignancy. As a result, the model we constructed has a greater predictive value than the factors identified in relevant guidelines.

Research conclusions

For the first time, a model was developed to predict the malignant risk of PCNs and an online calculator was further established to guide decision-making.

Research perspectives

More medical centers included, more data collection and application of "Artificial Intelligence".

ACKNOWLEDGEMENTS

We would like to thank Prof. Faming Pan (Department of Epidemiology and Biostatistics, School of Public Health, Anhui Medical University), who has made valuable support to the data quality and data analysis which ensured the reliability of the study.

Abstract

BACKGROUND

Upper gastrointestinal endoscopy is critical for esophageal squamous cell carcinoma (ESCC) detection; however, endoscopists require long-term training to avoid missing superficial lesions.

AIM

To develop a deep learning computer-assisted diagnosis (CAD) system for endoscopic detection of superficial ESCC and investigate its application value.

METHODS

We configured the CAD system for white-light and narrow-band imaging modes based on the YOLO v5 algorithm. A total of 4447 images from 837 patients and 1695 images from 323 patients were included in the training and testing datasets, respectively. Two experts and two non-expert endoscopists reviewed the testing dataset independently and with computer assistance. The diagnostic performance was evaluated in terms of the area under the receiver operating characteristic curve, accuracy, sensitivity, and specificity.

RESULTS

The area under the receiver operating characteristics curve, accuracy, sensitivity, and specificity of the CAD system were 0.982 [95% confidence interval (CI): 0.969-0.994], 92.9% (95%CI: 89.5%-95.2%), 91.9% (95%CI: 87.4%-94.9%), and 94.7% (95%CI: 89.0%-97.6%), respectively. The accuracy of CAD was significantly higher than that of non-expert endoscopists (78.3%, $P < 0.001$ compared with CAD) and comparable to that of expert endoscopists (91.0%, $P = 0.129$ compared with CAD). After referring to the CAD results, the accuracy of the non-expert endoscopists

significantly improved (88.2% *vs* 78.3%, $P < 0.001$). Lesions with Paris classification type 0-IIb were more likely to be inaccurately identified by the CAD system.

CONCLUSION

The diagnostic performance of the CAD system is promising and may assist in improving detectability, particularly for inexperienced endoscopists.

Key Words: Computer-aided diagnosis; Artificial intelligence; Deep learning; Esophageal squamous cell carcinoma; Early detection of cancer; Upper gastrointestinal endoscopy

Core Tip: Esophageal squamous cell carcinoma (ESCC) poses a heavy burden to high-risk areas, and screening using upper gastrointestinal endoscopy is an established strategy for early detection and prognosis improvement. However, endoscopic detection of superficial-ESCC can be challenging and depends greatly on operator experience. We developed and validated a novel computer-assisted diagnostic system with a deep neural network algorithm to detect superficial ESCC using upper endoscopy with white-light and narrow-band imaging. The system demonstrated high diagnostic accuracy, which is comparable to that of expert endoscopists. The diagnostic performance of non-expert endoscopists was significantly improved under the assistance of this system.

INTRODUCTION

Esophageal cancer is the seventh most common and sixth most fatal malignancy[1], and esophageal squamous cell carcinoma (ESCC) is the most prevalent histological type[2]. Screening high-risk populations using upper gastrointestinal endoscopy may facilitate early detection and treatment[3], and markedly improve the prognosis of ESCC[4]. However, due to its subtlety and flat appearance under white light imaging (WLI) or image-enhanced endoscopy, identification of early stage ESCC may be especially difficult for inexperienced endoscopists[5-7]. A recent multicenter cohort study found that 6.4% of all esophageal cancers were missed during upper gastrointestinal endoscopy, which was associated with poor survival[8].

In recent years, artificial intelligence (AI)-aided endoscopy has garnered attention, and several studies have heralded this technique as a promising tool for improving the detection of early ESCC[9-12]. A systematic review showed that the pooled sensitivity and specificity of AI for ESCC diagnosis were 0.95 and 0.92, respectively, and AI performed better than endoscopists, although the differences were not statistically significant[13]. However, few computer-assisted diagnosis (CAD) systems for ESCC that support WLI and narrow-band imaging (NBI) have been applied in clinical practice. We developed and validated a novel CAD system with a deep neural network algorithm to detect superficial ESCC using upper endoscopy with WLI and NBI. Moreover, we assessed its value for endoscopists with differing experience levels of superficial ESCC detection and investigated the characteristics of lesions that were inaccurately identified by the CAD system.

MATERIALS AND METHODS

Preparation of datasets for training and testing

Static and non-magnified WLI or NBI images used for CAD system training and testing for superficial ESCC were retrospectively retrieved from endoscopic databases of four general hospitals in mainland China between January 2016 and April 2019. For the training dataset, 1503 WLI images and 2100 NBI images from 622 cases of superficial ESCC and high-grade intraepithelial neoplasia (HGIN), and 523 WLI images and 321 NBI images from 215 non-cancerous cases (including normal, esophagitis, submucosal lesion, and leukoplakia) were obtained from the First Affiliated Hospital of Zhengzhou University, Xingtai First Hospital, and Tangyin People's Hospital. For the independent testing dataset,

577 WLI images and 793 NBI images from 209 cases of superficial ESCC and HGIN, and 209 WLI images and 116 NBI images from 114 non-cancerous cases were obtained from Changhai Hospital. All images were captured using an Olympus gastroscope (GIF-H260, GIF-H260Z, GIF-H290, GIF-Q260J, or GIF-HQ290; Olympus, Tokyo, Japan). Poor-quality images, including blurred images, and those with mucus or foam that prevented adequate mucosal inspection were excluded from the study. The personal data of the patients in the images were hidden. This study was approved by the ethics committee of Shanghai Changhai Hospital (No. CHEC2019-002).

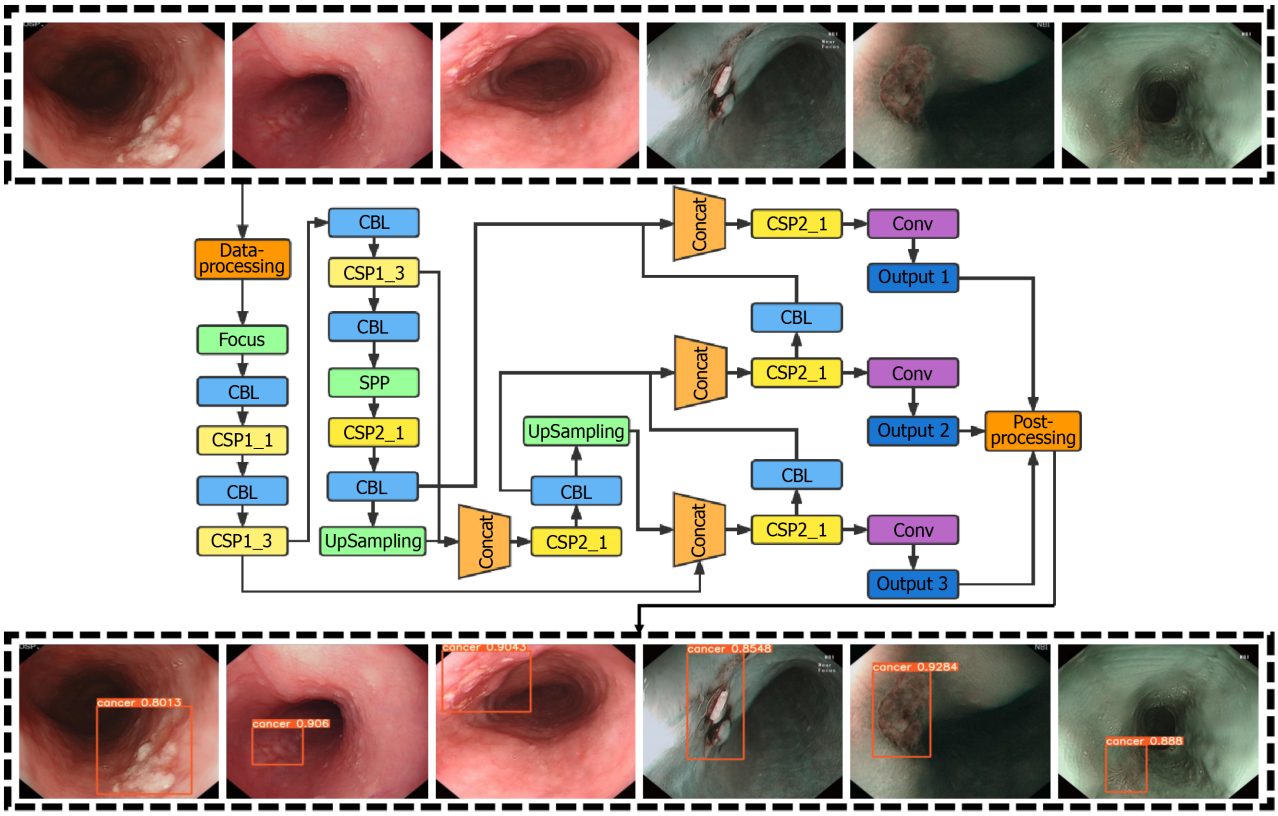
All superficial ESCC and HGIN images were obtained from patients who underwent subsequent endoscopic submucosal dissection. Additionally, histologic results including margin status and invasion depth of endoscopic submucosal dissection specimens were retrieved. Three experienced gastrointestinal (GI) pathologists conducted histological assessments. Histological images were first reviewed by two independent pathologists who determined the final pathological result through diagnostic consensus. In case of disagreement, images were reviewed by a third pathologist, and the final decision was discussed. Non-cancerous images were confirmed by three experienced endoscopists (all with > 15 years of experience), before inclusion in training and testing datasets.

All images were annotated by the three endoscopists mentioned above. The first endoscopist reviewed and marked the WLI and NBI images (margins of the lesion) using specific frames. The second endoscopist reviewed the annotations of the first, and if in agreement, the annotation was completed. Alternately, the images were reviewed by a third endoscopist, and the final decision was made in unison. Paris classification subtypes of lesions were also recorded[14].

Development of the CAD system

CAD system development was based on the YOLO v5 deep-learning algorithm. YOLO v5 employs cross stage partial network as the backbone for feature extraction and path aggregation network to generate a feature pyramid network to perform feature aggregation and pass it to the prediction mode. YOLO v5 demonstrated increased efficiency and efficacy compared to previous versions. To improve network accuracy, we modified the loss function of YOLO V5 and introduced the mapping distance of the aspect ratio. The input of this network was esophageal images, and the output was an indicator frame that captured the rectangular region of interest, together with the predicted quantitative level of confidence for ESCC above the frame (Figure 1).

Testing of the CAD system



The diagnostic accuracy of the CAD system was validated using a previously established independent testing dataset. To compare the performance of the CAD system with that of endoscopists and investigate its added value, four endoscopists from Changhai Hospital were invited to review the images in the testing dataset, independently and with the assistance from the CAD system. Two experts (endoscopy experience ≥ 10 years) and two non-expert endoscopists (endoscopy experience > 1 year but < 5 years) participated. None were involved in the selection and annotation of images. All images in the testing dataset, including 598 WLI and 817 NBI cancerous and 209 WLI and 116 NBI non-cancerous images, were randomly sequenced, and all participating endoscopists independently reviewed the images and made diagnoses within one day. After a washout period of one month, the images were randomly re-sequenced, and endoscopists reviewed the images using the results of the CAD system as a reference. Throughout the study, participating endoscopists were unaware of the correct endoscopic and histologic diagnoses, their own performance, and the diagnostic accuracy of the CAD system.

Outcome measures

Primary outcome measures included the area under the receiver operating characteristic curve (AUROC), accuracy, sensitivity, and specificity of the CAD system. Secondary outcome measures included positive predictive value (PPV) and negative predictive value (NPV) of the CAD system; diagnostic performance of participating endoscopists; and improvement in diagnostic accuracy, sensitivity, and specificity in the expert and non-expert groups, after referring to the CAD system results.

Statistical analysis

AUROC, accuracy, sensitivity, specificity, PPV, and NPV were calculated, and the binominal 95% confidence intervals (CI) were estimated using the CAD-predicted confidence ≥ 0.5, as the prespecified criteria for testing positive. The Delong test was used to compare different AUROCs. A two-sided McNemar test was used to compare differences in accuracy, sensitivity, and specificity. Differences in more than three groups were compared using Cochran's Q test. Additionally, the McNemar test was used for post-hoc comparisons of P values adjusted using Bonferroni's method. Pearson's chi-squared test, t test, and Mann-Whitney U test were used wherever applicable. Superficial ESCC lesions with a CAD-predicted confidence < 0.5 and an intersection over union (IoU) value < 0.45 were defined as inaccurately identified. A P value < 0.05 was considered statistically significant. All statistical analyses were performed using SPSS 26.0 (SPSS Inc., Chicago, IL, United States). The statistical methods of this study were reviewed by XFY from Department of Health Statistics, Naval Medical University.

Figure 1 The architecture of the computer-assisted diagnosis system. The input of this network was the esophageal images, and the output was an indicator frame that captured the interest region, together with the predicted quantitative level of confidence for esophageal squamous cell carcinoma.

RESULTS

Characteristics of subjects and lesions in test dataset

Table 1 summarizes the characteristics of the patients and lesions in the testing dataset. For 209 cases of superficial ESCC, the lesion size was 2.0 (1.2-4.0) cm and most (82.3%) were located in the middle thoracic esophagus. Flat-type (0-IIb) lesions accounted for 53.6%, and most lesions involved < 25% of the esophageal circumference. Regarding histologic depth of invasion, 165 Lesions (78.9%) were limited to the lamina propria (LPM), 38 (18.2%) invaded the muscularis mucosa or superficial submucosa, and 6 (2.9%) extended beyond the superficial submucosa. Of the 114 non-cancerous cases, 23 were diagnosed with gastroesophageal reflux disease, five were diagnosed with esophageal submucosal lesions, and 86 were judged to be normal on upper gastrointestinal endoscopy.

Diagnostic performance of the CAD system

The receiver operating characteristic (ROC) curve of the CAD system is shown in Figure 2. The AUROC of the WLI, NBI, and combined modes were 0.970, 0.988, and 0.982, respectively. The AUROC of WLI, NBI, and the combined mode did not differ significantly. The diagnostic performance measures of the CAD system in the testing dataset are summarized in Table 2. In per-patient analysis, the accuracy, sensitivity, specificity, PPV, and NPV of the CAD system were 92.9%, 91.9%, 94.7%, 97.0%, and 86.4%, respectively. The accuracy ($P < 0.001$), sensitivity ($P < 0.001$), and specificity ($P = 0.015$) of the CAD system were significantly different among the different imaging modes. In post-hoc comparisons, the accuracy of the NBI (adjusted $P < 0.001$) and combined modes (adjusted $P = 0.002$) was significantly higher than that of the WLI mode. Furthermore, the sensitivity of NBI (adjusted $P < 0.001$) and combined modes (adjusted $P = 0.014$) was significantly higher than that of the WLI mode. No statistically significant differences in specificity were found in post-hoc comparisons between the two imaging modes. The results of the per-imaging analysis are presented in Table 2.

Comparison between the CAD system and endoscopists

Figure 3 compares the diagnostic performance of the CAD system under the combined WLI and NBI modes, among endoscopists with different experience levels. The accuracy (91.0% *vs* 78.3%, $P < 0.001$), sensitivity (90.0% *vs* 76.1%, $P < 0.001$), and specificity (93.0% *vs* 82.5%, $P = 0.002$) were significantly higher for expert endoscopists than for non-expert endoscopists. The diagnostic performance of the

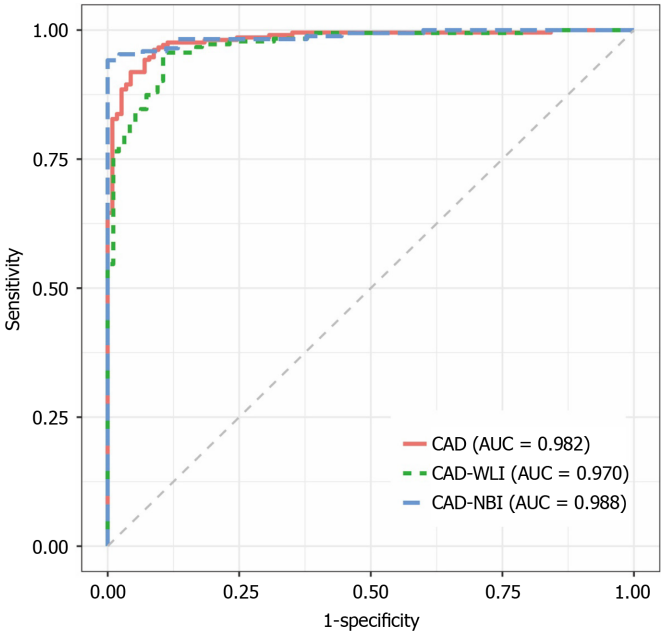
CAD system was significantly higher than that of non-expert endoscopists ($P < 0.001$) and similar to that of expert endoscopists.

Improvement after referring to CAD

Figure 4 depicts improved diagnostic performance of endoscopists for superficial ESCC after referring to the results of the CAD system. The accuracy (88.2% *vs* 78.3%, $P < 0.001$), sensitivity (87.6% *vs* 76.1%, $P < 0.001$), and specificity (89.5% *vs* 82.5%, $P = 0.039$) of the non-expert endoscopists were all significantly improved after using the CAD system, whereas the diagnostic performances of expert endoscopists did not differ significantly between the two stages. After referring to the CAD system, the accuracy (88.2% *vs* 93.2%, $P < 0.001$) and sensitivity (87.6% *vs* 92.3%, $P = 0.013$) of the non-experts were still significantly lower than those of the experts, while the disparities were markedly decreased. The specificity (89.5% *vs* 94.7%, $P = 0.124$) was similar between experts and non-experts after referring to the CAD.



Inaccurately identified lesions

Under the prespecified definition, 23 (11.0%) lesions were inaccurately identified. Table 3 compares the characteristics of lesions with accurate and inaccurate identifications. The proportion of type 0-IIb lesions was significantly higher in inaccurately identified lesions (73.9% *vs* 51.1%, $P = 0.038$), and the proportion of lesions limited to the LPM was higher in the inaccurate identification group, although not significantly so (91.3% *vs* 77.4%, $P = 0.123$).

DISCUSSION

Upper gastrointestinal endoscopy is critical for screening and early diagnosis of ESCC. However, the subtle endoscopic appearance of most superficial ESCC types is challenging for early detection and

Figure 4 The improvements in the diagnostic performance of endoscopists after referring to the results of computer-assisted diagnosis system. A: Accuracy; B: Sensitivity; C: Specificity. CAD: Computer-assisted diagnosis.

relies greatly on the skills and experience of endoscopists. Herein, we developed and validated a novel deep-learning-based CAD system for the detection of superficial ESCC in the WLI and NBI modes of upper gastrointestinal endoscopy. The AUROC, accuracy, sensitivity, and specificity of the CAD system were 0.982, 92.9%, 91.9%, and 94.7%, respectively. The diagnostic performance was significantly superior to that of non-experts and comparable to that of expert endoscopists. After referring to the results of the CAD system, the detectability of non-expert endoscopists significantly improved, and disparities between experts and non-experts markedly decreased. This system may assist in improving the detectability of superficial ESCC, particularly for inexperienced endoscopists and in undeveloped areas with limited resources.

Horie *et al*[9] developed a deep learning-based CAD system for superficial ESCC, with a sensitivity of 98% and low PPV of 40%. Zhao *et al*[15] developed an AI-based model for magnifying NBI images for automated classification of intrapapillary capillary loops, with a mean diagnostic accuracy of 89.6%. In a recent study by Guo *et al*[16], the authors developed a CAD system for real-time automated diagnosis of precancerous lesions and ESCC based on endoscopic video datasets, which achieved a per-lesion sensitivity of 100%. A systematic review by Visaggi *et al*[13] reported that the AUROC, sensitivity, and specificity of AI in diagnosing ESCC were 0.97, 0.95, and 0.92, respectively. However, few existing systems can support WLI and NBI, both of which are indispensable to the diagnosis of superficial ESCC under the same algorithm framework. We developed the current system under the updated YOLO v5 algorithm network supporting WLI and NBI, and achieved an AUROC, accuracy, sensitivity, and specificity of 0.982, 92.9%, 91.9%, and 94.7%, respectively, which was comparable to the best performance reported in previous studies. Esophageal endoscopic imaging is affected by factors such as

esophageal peristalsis, contraction, and imaging quality. Therefore, to supplement data by mimicking the above influencing factors, we added undistorted imaging correction enhancement based on the original data enhancement method of YOLO v5.

Superficial ESCC is difficult to inspect under WLI; however, NBI may significantly improve detectability with similar sensitivity and higher specificity than Lugol chromoendoscopy[6]. This may explain the demonstrated decrease in the accuracy and sensitivity of the CAD system, without NBI. Cai *et al*[10] reported on a deep neural network (DNN)-based system that utilizes WLI with high accuracy and sensitivity, for early ESCC detection. They subsequently developed a CAD-NBI system and found that its accuracy (94.3% *vs* 89.5%, $P = 0.028$) and specificity (96.7% *vs* 83.1%, $P < 0.001$) were significantly better than those of the CAD-WLI system[12]. By using CAD-WLI and CAD-NBI, endoscopists can significantly improve their diagnostic efficacy. Taken together, we recommend the combined implementation of NBI with other image-enhancing techniques for the detection of superficial ESCC, even under the CAD system.

To assess the clinical application value of the CAD system, endoscopists of varying experience reviewed the entire testing dataset independently and after referring to the diagnostic results of the CAD system. During the independent review, non-expert endoscopists showed significantly lower accuracy, sensitivity, and specificity than the experts, which highlighted the difficulty of novices in detecting superficial ESCC and disparities in detectability among endoscopists. The diagnostic performance of the non-experts significantly improved after referring to the CAD system. This suggests that the results of the CAD system provide useful references for non-expert endoscopists and facilitate further inspection and evaluation of potentially malignant lesions. The improved diagnostic performance of non-experts remained unequal to that of the CAD system, suggesting that endoscopists had made independent decisions, rather than relying completely on CAD. Similar results were reported in previous studies[10,12,17]. In the current study, although the performance of non-experts was still inferior to that of the experts after referring to the CAD system, the disparity markedly decreased. This suggests that the CAD system can homogenize the performance of endoscopists by overcoming the differences among endoscopists with different experience levels. In clinical practice, the usefulness of high-definition and imaging-enhanced endoscopy may be jeopardized by the inadequate number of highly trained endoscopists. In contrast, the CAD system does not require additional training and has instead been found to improve the performance of non-expert endoscopists by approximating the level of expertise. Thus, the CAD system may be especially useful in resource-limited areas, to improve the quality of endoscopic services and patient outcomes.

To our knowledge, this is the first study to analyze the characteristics of inaccurately identified lesions. We defined cases of inaccurate identification based on the predicted confidence and accuracy of the location frame. Endoscopists should be aware that flat-type and earlier-stage lesions limited to the LPM may be associated with an increased risk of inaccurate identification. To avoid a missed diagnosis of superficial ESCC, we recommend the use of Lugol's staining or magnifying endoscopy for flat-type lesions that are difficult to distinguish even under CAD.

In clinical practice, the CAD system automatically captures images as endoscopists inspect the esophagus, once integrated into an endoscopy workstation. Additionally, images frozen by endoscopists were input into the CAD system for analysis and detection of potential lesions. The CAD system then address potential malignant lesions with an indicator frame and a predicted quantitative level of confidence. Lesions with a predicted confidence ≥ 0.5 are strongly suggested for further evaluation and endoscopic biopsy. Other lesions may also be further evaluated or biopsied based on endoscopists' discretion. The diagnostic accuracy for ESCC is significantly improved after referring to the CAD system, particularly for non-expert endoscopists. Moreover, an updated CAD system that can process real-time videos or images with suboptimal quality is in development and may further facilitate clinical practice. In future, both endoscopists and patients may benefit from the increasing application of AI in endoscopy.

Our study had several limitations. First, the number of included endoscopists was relatively small, and the representation might be inadequate. Second, only still and non-magnified images were included; thus, the identification of videos and types of intrapapillary capillary loops could not be achieved. Third, the numbers and angles of lesions in NBI and WLI images were not identical in the testing dataset, and biases may exist in the comparison of diagnostic performance among the different modes of the CAD system.

CONCLUSION

We developed and validated a deep-learning CAD system, for the endoscopic detection of superficial ESCC, that achieved a high diagnostic accuracy comparable to that of expert endoscopists and could significantly improve the detecting ability of non-expert endoscopists.

ARTICLE HIGHLIGHTS

Research background

Esophageal squamous cell carcinoma (ESCC) is a leading cause of cancer-related morbidity and mortality worldwide. Upper gastrointestinal endoscopy is critical for ESCC detection; however, endoscopists require long-term training to avoid missing superficial lesions. Artificial intelligence (AI) has been increasingly investigated to assist endoscopic diagnosis.

Research motivation

AI has shown promising results for endoscopic diagnosis of superficial ESCC. However, few AI-based computer-assisted diagnosis (CAD) systems for ESCC that support white-light and narrow-band imaging have been applied in clinical practice.

Research objectives

We aimed to develop a CAD system for endoscopic detection of superficial ESCC and investigate its application value.

Research methods

We configured the CAD system for white-light and narrow-band imaging modes based on the YOLO v5 algorithm. A total of 4447 images from 837 patients and 1695 images from 323 patients were included in the training and testing datasets, respectively. Two experts and two non-expert endoscopists reviewed the testing dataset independently and with computer assistance. The diagnostic performance was evaluated in terms of the area under the receiver operating characteristic curve, accuracy, sensitivity, and specificity.

Research results

The area under the receiver operating characteristics curve, accuracy, sensitivity, and specificity of the CAD system were 0.982 [95% confidence interval (CI): 0.969-0.994], 92.9% (95%CI: 89.5%-95.2%), 91.9% (95%CI: 87.4%-94.9%), and 94.7% (95%CI: 89.0%-97.6%), respectively. The accuracy of CAD was significantly higher than that of non-expert endoscopists (78.3%, $P < 0.001$ compared with CAD) and comparable to that of expert endoscopists (91.0%, $P = 0.129$ compared with CAD). After referring to the CAD results, the accuracy of the non-expert endoscopists significantly improved (88.2% *vs* 78.3%, $P < 0.001$).

Research conclusions

The diagnostic performance of the CAD system is promising and may assist in improving detectability, particularly for inexperienced endoscopists.

Research perspectives

An updated CAD system that can process real-time videos or images with suboptimal quality is in development. Randomized controlled trials are warranted to investigate the clinical pragmaticality.

Abstract

BACKGROUND

Hepatitis E virus (HEV) is an emerging virus of global health concern. The seroprevalence rates differ greatly according to geographic region and population group.

AIM

To analyze the seroprevalence of HEV in exposed (animal-related professions) and nonexposed populations, as well as solid organ and hematopoietic stem cell transplant patients.

METHODS

Forestry workers (n = 93), hunters (n = 74), and veterinarians (n = 151) represented the exposed population. The general population (n = 126) and pregnant women (n = 118) constituted the control group. Transplant patients included liver transplant recipients (LTRs) (n = 83), kidney transplant recipients (KTRs) (n = 43), and hematopoietic stem cell transplant recipients (HSCRs) (n = 39). HEV immunoglobulin G antibodies were detected using the enzyme-linked immunosorbent assay and confirmed by the immunoblot test.

RESULTS

The HEV seroprevalence significantly differed between groups: Veterinarians 15.2%, hunters 14.9%, forestry workers 6.5%, general population 7.1%, and pregnant women 1.7%. In transplant patients, the seropositivity was highest in LTRs (19.3%), while in KTRs and HSCRs, the seroprevalence was similar to the general population (6.9% and 5.1%, respectively). A significant increase in seropositivity with age was observed from 2.9% in individuals less than 30 years to 23.5% in those older than 60 years. Sociodemographic characteristics (sex, educational level, area of residence, and number of household members), eating habits (game meat, offal, and pork products consumption), and environmental and housing conditions (drinking water supply, type of water drainage/sewer, waste disposal, domestic animals) were not associated with HEV seropositivity. However, individuals who reported a pet ownership were more often seropositive compared to those who did not have pet animals (12.5% *vs* 7.0%).

CONCLUSION

The results of this study showed that individuals in professional contact with animals and LTRs are at higher risk for HEV infection. In addition, age is a significant risk factor for HEV seropositivity.

Core Tip: Hepatitis E virus (HEV) is an emerging viral pathogen of public health concern. We analyzed the epidemiological characteristics of HEV infection in different groups in Croatia. The highest seroprevalence was reported in professionally exposed individuals such as veterinarians, hunters, and liver transplant recipients. Seropositivity was similar in the general population, forestry workers, kidney transplant patients, and hematopoietic stem cell transplant patients. The lowest seroprevalence was recorded in pregnant women. A significant increase in seroprevalence with age was observed. Pet ownership was also associated with HEV seropositivity. Sex, environmental and housing conditions, and eating habits were not associated with HEV seroprevalence.

INTRODUCTION

Hepatitis E virus (HEV) is an emerging viral pathogen of global health concern. It is a nonenveloped RNA virus, a member of the *Hepeviridae* family, genus *Orthohepevirus*[1]. Along with hepatitis B and hepatitis C virus (1.5 million new infections per year for each virus)[2,3], HEV is a major cause of viral hepatitis worldwide with approximately 20 million documented infections annually, over three million symptomatic cases, and 60-70000 fatal outcomes[4]. East and South Asia account for more than 60% of all reported cases[5]. There are eight known HEV genotypes. HEV-1 and HEV-2 are confined to humans and mainly cause infections in developing countries of tropical and subtropical regions[4-6]. HEV-3 and HEV-4 have been isolated from humans and different animal species (pigs, wild boars, deer, rabbits, goats, cows), primarily causing sporadic, autochthonous human infections in the developed world[5,7]. HEV-5 and HEV-6 have been restricted to wild boars only, while genotypes 7 and 8 have been isolated in dromedary and Bactrian camels[7,8]. In low-income countries, the main mode of HEV transmission is the fecal-oral route (contaminated drinking water, poor hygiene), whereas in more industrialized countries people are getting infected through zoonotic transmission (uncooked or undercooked animal products, mainly infected meat, and milk)[6,7]. Pigs are the main HEV animal reservoir. Almost 13% of domestic pigs and 9.5% of wild boars are actively infected by HEV with 10% of commercial pork products being HEV-RNA-positive[9]. Several other foods have also been proposed as a potential source of HEV infection in humans, *e.g.*, shellfish, mussels, and oysters[6]. One study found that HEV maintains infectivity for up to 21 d at 37 °C and up to 28 d at usual room temperature[8]. The virus can also be transmitted through blood transfusion, intravenous drug use, solid organ transplantation (SOT), hemodialysis, or maternal-fetal interaction[5,7]. In most cases, HEV presents as a self-limiting acute illness with low mortality rates (1%-2%) in immunocompetent individuals. However, genotypes 3, 4, and 7 may induce chronic infection and subsequent cirrhosis in immunocompromised patients, especially in SOT recipients, and human immunodeficiency virus-positive individuals[4]. Pregnant women are more susceptible to rapid disease progression such as fulminant hepatic and extrahepatic manifestations and obstetric complications leading to high mortality rates (15%-25%) compared to the non-pregnant population[4,5]. Professionally exposed individuals (*e.g.*, forestry workers, veterinarians, hunters, farmers) are also at increased risk of getting infected by HEV. Detected HEV seroprevalence rates in professionally exposed workers differ greatly between countries: Forestry workers (2.2%-31.0%)[10-13], hunters (3.81%-22.2%)[13-15], and veterinarians (10.2%-43.7%)[16,17]. In the transplant population, HEV seroprevalence rates were reportedly between 6.0% and 29.6%[18].

The seroepidemiological studies have shown that HEV is widespread in Croatia with seroprevalence rates ranging from 2.7% in healthcare professionals to 24.4% in liver transplant patients and up to 43.5% in hemodialysis patients[19,20]. However, only preliminary data are available on the HEV seroprevalence in animal-related professions. The aim of this study was to analyze the HEV epidemiology in different professionally exposed (animal-related) and nonexposed population groups in Croatia.

MATERIALS AND METHODS

Study participants

From October 2016 to September 2017, serum samples collected from Croatian residents were tested for the presence of HEV immunoglobulin G (IgG) antibodies. Samples were obtained from different exposed and nonexposed population groups. Forestry workers, hunters, and veterinarians represented the exposed population. The general population and pregnant women constituted the control group. In addition, from January 2021 to December 2021, a total of 165 serum samples were collected from SOT recipients [liver transplant recipients (LTRs) and kidney transplant recipients (KTRs)] and hematopoietic stem cell transplant recipients (HSCRs). None of the participants showed symptoms of acute hepatitis or reported a recent febrile disease. The distribution of study participants according to the population group is presented in Table 1.

Methods

HEV IgG antibodies were detected using a commercial enzyme-linked immunosorbent assay (ELISA) based on recombinant antigens of HEV genotypes 1 and 3 (anti-hepatitis E virus IgG ELISA; Euroimmun, Lübeck, Germany). Reactive samples were tested for the presence of HEV IgM antibodies (anti-hepatitis E virus IgM ELISA; Euroimmun). Additionally, ELISA IgG-positive samples were confirmed by a commercial immunoblot (IB) assay using highly purified recombinant HEV antigens: O2N genotype 1/3, O2C genotype 1/3, O2M genotype 1, O3 genotype 1/3 (HEV Recomline; Mikrogen, Neuried, Germany). IB-positive samples were further retested using a second assay (Euroline anti-hepatitis E virus IgG, Euroimmun, Lübeck, Germany) based on the recombinant HEV genotypes 1-4 antigens (ORF2). For the IB, the manufacturer states a diagnostic sensitivity of 96.6% and specificity of 97.1% (Mikrogen) and 100% (Euroimmun).

Table 1 Exposed and nonexposed population groups included in the study

Population	*n*	Median age, yr	IQR, yr
Exposed group			
Hunters	74	55	41-60
Veterinarians	151	46	36-55.5
Forestry workers	93	43	31-51
Non-exposed group			
General population	126	48	33-62
Pregnant women	118	31.5	29-35
Transplant patients			
Liver transplant recipients	83	60	49-65.5
Kidney transplant recipients	43	52.5	42-62
Hematopoietic stem cell recipients	39	55	51-64

Hematopoietic stem cell recipients	39	2 (5.1)	0.6-7.3	

CI: Confidence interval; HEV: Hepatitis E virus; IgG: Immunoglobulin G.

To identify potential risk factors that may be associated with HEV infection, for animal-related professions (exposed group) and nonexposed group, data on demographic characteristics and potential risk factors (eating habits, environmental and housing conditions, traveling history, and blood transfusion) were collected using a questionnaire. The modified Health-Environment-Life Style questionnaire created by the Andrija Stampar School of Public Health, School of Medicine, University of Zagreb was used in the study.

Statistical analysis

The HEV IgG prevalence is presented as a percentage with 95% confidence intervals (CIs). Differences in categorical variables between HEV seropositive and seronegative participants were tested using the Fisher's exact or Fisher-Freeman-Halton test. Odds ratio (OR) and relative risk (RR) were also calculated. Variables with statistical significance in a bivariate analysis were analyzed in multivariate regression analysis (binary logistic regression). $P < 0.05$ was considered statistically significant. Statistical analysis was performed using MedCalc® Statistical Software version 20.022 (MedCalc Software Ltd., Ostend, Belgium; https://www.medcalc.org; 2021).

RESULTS

HEV IgG antibodies were detected in 72/727 (9.9%; 95%CI: 7.8-12.3) participants: 40/278 (12.6%; 95%CI: 9.3-16.6) in the exposed group, 11/244 (4.3%; 95%CI: 2.3-7.3) in the nonexposed group, and 12/165

Table 3 Hepatitis E virus immunoglobulin G prevalence according to sociodemographic characteristics

Characteristic	Subjects[1], *n*	HEV IgG, *n* (%)	95%CI	*P* value
Sex				0.065
Male	238	29 (10.9)	7.6-15.0	
Female	282	22 (7.2)	4.7-10.6	
Age group in yr				< 0.001
< 30	99	3 (2.9)	0.8-7.6	
30-39	147	11 (7.0)	3.8-11.7	
40-49	94	5 (5.1)	2.0-10.7	
50-59	90	11 (10.9)	5.9-18.1	
60 +	62	19 (23.5)	15.3-33.5	
Area of residence				0.144
Rural	151	16 (9.6)	5.8-14.7	
Suburban	54	11 (16.9)	9.3-27.4	
Urban	255	24 (8.6)	5.7-12.3	
Number of household members				0.301
≤ 3	258	22 (7.9)	5.1-11.4	
> 3	177	21 (10.6)	6.9-15.5	
Educational level				0.467
Primary school	58	5 (7.9)	3.1-16.5	
High school	254	25 (9.0)	6.0-12.7

CI: Confidence interval; HEV: Hepatitis E virus; IgG: Immunoglobulin G.

(12.7%; 95%CI: 8.1-18.8) in transplant patients. None of the participants were HEV IgM-positive. There were significant differences in the IgG seroprevalence rates among population groups (Table 2). In animal-related professions, the seropositivity was higher (14.9% in hunters and 15.2% in veterinarians) than in pregnant women (1.7%) and the general population (7.1%). Seroprevalence in transplant populations was highest in LTR (19.3%), followed by KTR (6.9%) and HSCR (5.1%).

A significant increase in seroprevalence was observed according to age. Participants in the age group 60 + years and 50-59 years showed higher seropositivity rates (23.5% and 10.9%, respectively) compared to younger age groups (2.9%-7.0%). There was no difference in HEV seroprevalence according to sex, area of residence, number of household members, and educational level (Table 3). HEV seropositivity did not differ regarding to the frequency of game meat, offal, and pork products consumption. However, there was a difference in the seroprevalence rates according to the frequency of shellfish consumption (Table 4).

Analyzing the environmental and housing conditions of the study participants and HEV seropositivity (Table 5), no significant difference was found according to drinking water supply, type of water drainage/sewer, and waste disposal. However, participants who reported having pet animals had a higher seroprevalence rate compared to those who did not have pet animals (12.5% *vs* 7.0%). Travel history as well as previous blood transfusion, surgical procedure, and tattoo/piercing were not associated with HEV seroprevalence (Table 6).

Risk analysis showed that animal-related professions and liver transplant patients were more likely to be HEV seropositive than other tested groups: Hunters OR = 3.873, 95%CI: 1.605-9.341; RR = 3.445, 95%CI: 1.556-7.628; veterinarians OR = 3.985, 95%CI: 1.883-8.435; RR = 3.531, 95%CI: 1.771-7.038; LTRs OR = 5.058, 95%CI: 2.240-11.420; RR = 4.276, 95%CI: 2.068-8.839 (Table 7).

DISCUSSION

The zoonotic risk of HEV transmission is well established, while exact transmission routes remain to be determined. The HEV seroprevalence rates vary greatly according to geographical region and study

Table 4 Hepatitis E virus immunoglobulin G prevalence according to eating habits

cohorts. The proposed transmission routes linked to professional exposures include frequent contact with the zoonotic HEV reservoirs, such as pigs and other wildlife species (mainly wild boar)[12]. Forestry workers, hunters, and veterinarians represented risk populations in this study. The HEV seroprevalence was significantly higher in the exposed population (12.6%) compared to the nonexposed population (4.3%). In the exposed group, seroprevalence was similar in the veterinarians (15.2%) and hunters (14.9%), while it was lower in the forestry workers (6.5%).

HEV seropositivity in forestry workers included in this study was similar to the seroprevalence in the Croatian general population (7.1%). Seroepidemiological studies conducted among forestry workers in Europe showed seropositivity of 31% in France (2002-2003)[11] and 18% in Germany (Brandenburg, 2008)[21]. In more recent studies, HEV antibodies were detected in 2.2% of forest rangers from western Poland (Poznan, 2014)[10], 5% of forestry workers from eastern Poland (Lubelskie Voivodship, 2014-2015)[13], and 14% of forestry workers in Italy (Trentino-Alto Adige Region, 2014-2015)[12]. Although forestry workers have been identified as being at risk of HEV infection in several studies, the French study revealed for the first time that woodcutters are at a particularly high risk of infection. Among woodcutters, 37.2% were found to be seropositive compared to game and fishing keepers/rangers and silviculturists (20.0% and 24.8% seropositive, respectively)[11]. Close contact with wild boar stools in the forest environment could be an additional source of HEV infection in this risk population.

HEV seropositivity in the Croatian hunters included (14.9%) was two times higher than that in the general population. Two studies conducted among Polish hunters from 2010 to 2012 showed a HEV seropositivity of 25%[22] and 22.2%, respectively[14]. A similar seroprevalence rate (25%) was detected in Italian hunters from the Latium Region tested during the hunting season[23] and German hunters (21%) from Central Germany tested in 2013[15]. By contrast, only 4.2% of hunters from nine Estonian counties were seropositive to HEV in 2013[24] as well as 3.81% of Polish hunters from the Lubelskie Voivodship (eastern Poland) tested from 2014 to 2015[13].

In 2009, serum samples were collected from participants of the National Veterinary Congress in Helsinki. Finnish veterinarians commonly have HEV antibodies with a seroprevalence of 10.2%. The highest seroprevalence rate of 17.8% was unexpectedly detected in small animal practitioners[17]. A study from Norway in 2013 found IgG seroprevalence of 14%. When stratifying by work experience, HEV seroprevalence in Norwegian veterinarians working with swine was more than two times higher

compared to those who did not work with swine (22% *vs* 9%)[25]. Chinese studies conducted from 2003 to 2017 demonstrated high IgG seropositivity in veterinarians ranging from 26.7%[16] to 43.7%[26]. In addition, a high seroprevalence rate of 23% was notified in swine veterinarians in the United States[27].

By contrast, a Thai study found no association between HEV seroprevalence and frequent direct occupational pig contact[28]. A very low HEV seropositivity (2.6%) was found in Estonian veterinarians. All antibody-positive veterinarians worked in small animal clinics and some of them were cat or dog owners[29]. The majority of veterinarians included in this study are small animal practitioners and showed seropositivity to HEV of 15.2%. In some countries, significant regional differences in the HEV seroprevalence were observed. In Polish hunters, seroprevalence varied from 10% to 42.4%[14].

A recent meta-analysis of 14626 transplant recipients showed that anti-HEV seroprevalence ranges from 6%-29.6%[18]. This wide HEV seroprevalence range reflects the differences in viral circulation within different geographical regions and the impact of assays used in the particular study. In our transplant cohort, LTRs showed the highest seroprevalence rate of 19.3%, and in the risk analysis for HEV IgG seropositivity exhibited the highest OR of 5.058 among tested groups. This supports the hypothesis that HEV in combination with other factors may promote chronic inflammation and even be a cofactor in hepatocellular carcinoma occurrence leading to liver transplant candidacy[30]. Chronicity of HEV infection is of emerging relevance in transplant recipients; however, there are still conflicting viewpoints on the overall anti-HEV seroprevalence and rate of chronic HEV infection in immunocompromised patients[31].

CI: Confidence interval; OR: Odds ratio; RR: Relative risk.

Several studies have found sex variations in HEV seropositivity, with males having higher seropositivity compared to women[14,32]. This study found no significant difference in the seropositivity between men (10.9%) and women (7.2%). Similarly, a German study found no sex differences in the HEV seropositivity[15]. An increase in HEV seroprevalence with age, which is likely to reflect cumulative exposure to HEV over time was observed in many studies[11,12,14,27]. In this study, the highest seropositivity (23.5%) was observed in the age group 60 + years compared to 2.9%-10.9% in other age groups. By contrast, one German study conducted in forestry workers did not find a statistically significant association between seropositivity and age[21]. Similarly, no association of HEV seroprevalence with age was observed in Norwegian veterinarians[25].

Working with a septic tank was identified as a strong risk factor for HEV infection in the Netherlands [33]. Additionally, using a stream or well as a source of water has been identified as a risk factor for HEV infection in some countries[34]. Similar to a previous Croatian study[35], in this study, we found no difference in the HEV seroprevalence regarding the type of drainage/sewer, type of water supply, and waste disposal.

Eating habits were associated with HEV seropositivity in some studies. Eating internal pig organs more than twice a week was linked to a higher seroprevalence of anti-HEV IgG in a rural community in Thailand[28]. In France, the presence of anti-HEV IgG was associated with the consumption of pork meat, pork liver sausages, game meat, offal, and oysters[36]. The association between HEV seroprevalence and consumption of stewed offal was also confirmed among Polish hunters[12]. In Italy, many seropositive individuals reported consumption of raw or undercooked food, particularly shellfish (mussels) and unbottled drinking water[37]. This study found no association between offal consumption

and HEV seropositivity. Although participants who reported eating pork liver every week showed a higher seroprevalence rate (18.2%) compared to those who did not eat or ate pork liver rarely (0%-15.0%), this difference was not significant. In addition, there was no difference in the seropositivity regarding pork meat and game meat consumption. Similar to our results, a German study showed that wild boar meat consumption was not associated with HEV seroprevalence. However, HEV RNA was detected in muscle specimens from wild boar, suggesting this is a possible HEV transmission route[15]. Surprisingly, there was a significant difference in the seroprevalence regarding shellfish consumption in our study, with the highest seroprevalence in participants who reported to never eat shellfish. However, due to a very small number in the tested subgroups regarding the frequency of shellfish consumption, this limitation should be considered when interpreting the results.

In this study, a pet ownership was associated with HEV seroprevalence with a seropositivity rate of 12.5% in individuals who reported having a cat/dog compared to 7.0% in those who did not have pet animals. Animal ownership, including both domestic and pet animals, was not found to be a risk factor for HEV infection in a Jordanian study[38]. The use of a self-reported questionnaire in the study is a limitation that should be addressed. In addition, data on the risk factors in the transplant patients were not available.

CONCLUSION

The results of this study showed that individuals in professional contact with animals are at higher risk for HEV infection. Identification of people at risk for HEV infection is essential to implement preventive measures and educate these groups about modes of HEV transmission and prevention. Since immunocompromised populations such as SOT are at risk of chronic hepatitis E, such individuals should be counseled regarding the risk of HEV before and after transplantation.

ARTICLE HIGHLIGHTS

Research background

Hepatitis E virus (HEV) seroprevalence rates differ greatly according to the geographic region and population group.

Research motivation

Only preliminary data are available on the HEV seroprevalence in some population groups in Croatia.

Research objectives

To determine the HEV seroprevalence in different populations (animal-related professions, transplant patients, general population).

Research methods

HEV immunoglobulin G antibodies were detected using an enzyme-linked immunosorbent assay. Initially, reactive samples were confirmed by immunoblot test.

Research results

Significant differences in HEV seropositivity were observed among the population groups: Veterinarians 15.2%, hunters 14.9%, forestry workers 6.5%, general population 7.1%, pregnant women 1.7%, liver transplant recipients 19.3%, kidney transplant recipients 6.9%, and hematopoietic stem cell recipients 5.1%. Older age was a significant risk factor for HEV seropositivity. In addition, pet ownership was associated with HEV seroprevalence. Sociodemographic characteristics, eating habits, and environmental and housing conditions were not associated with the HEV seropositivity.

Research conclusions

Professional contact with animals and older age are significant risk factors for HEV infection.

Research perspectives

Further studies on a large sample of exposed and nonexposed population are needed to determine the HEV RNA prevalence/seroprevalence and clinical significance of HEV infection in the Croatian population.

Abstract

BACKGROUND

Gastric submucosal arterial collaterals (GSAC) secondary to splenic artery occlusion is an extraordinary rare and potentially life-threatening cause of acute upper gastrointestinal bleeding. Here, we report a case of massive bleeding from GSAC successfully treated by means of a multidisciplinary minimally invasive approach.

CASE SUMMARY

A 60-year-old non-cirrhotic gentleman with a history of arterial hypertension was admitted due to hematemesis. Emergent esophagogastroduodenoscopy revealed pulsating and tortuous varicose shaped submucosal vessels in the gastric fundus along with a small erosion overlying one of the vessels. In order to characterize the fundic lesion, pre-operative emergent computed tomography-angiography was performed showing splenic artery thrombosis (SAT) and tortuous arterial structures arising from the left gastric artery and the left gastroepiploic artery in the gastric fundus. GSAC was successfully treated by means of a minimally invasive step-up approach consisting in endoscopic clipping followed by transcatheter arterial embolization (TAE).

CONCLUSION
This was a previously unreported case of bleeding GSAC secondary to SAT successfully managed by means of a multidisciplinary minimally invasive approach consisting in endoscopic clipping for the luminal bleeding control followed by elective TAE for the definitive treatment.

Key Words: Upper gastrointestinal bleeding; Non variceal upper gastrointestinal bleeding; Acute upper gastrointestinal bleeding; Gastric submucosal arterial collaterals; Splenic artery thrombosis; Case report

Core Tip: Gastric submucosal arterial collaterals (GSAC) secondary to splenic artery occlusion is an extremely rare cause of severe non variceal upper gastrointestinal bleeding. Herein, we describe a previously unreported case of massive bleeding from GSAC secondary to splenic artery thrombosis effectively treated by endoscopic mechanical hemostasis followed by endovascular embolization.

INTRODUCTION

Acute upper gastrointestinal bleeding (UGIB) is a common gastroenterological emergency associated with significant morbidity and mortality. Reported hospitalization rate is 61-78 cases *per* 100.000 adults *per* year[1-3], whereas estimated overall mortality is around 10%[4,5]. Peptic ulcers are the most common cause of acute UGIB, followed by oesophageal varices, Mallory-Weiss syndrome and neoplasms[1,3,4]. Acute UGIB caused by gastric submucosal arterial collaterals (GSAC) secondary to splenic artery occlusion (SAO) is extremely rare, with only few cases reported worldwide up to date. Herein, we describe a previously unreported case of bleeding GSAC secondary to splenic artery thrombosis (SAT) successfully treated by means of endoscopic mechanical hemostasis followed by endovascular embolization.

CASE PRESENTATION

Chief complaints

A 60-year-old non-cirrhotic gentleman was admitted to our dedicated bleed unit for severe anemia (hemoglobin 4.8 g/dL on admission) and recent onset of hematemesis and melena with unstable hemodynamic parameters.

History of present illness

One attack of hematemesis and two episodes of melena occurred two and 24 h prior to the hospital admission, respectively.

History of past illness

The patient had a history of arterial hypertension. He denied any history of, or risk factors for, liver disease, pancreatitis, abdominal trauma and hypercoagulable states.

Personal and family history

The patient denied personal and family history.

Physical examination

At admission, the patient was hemodynamically unstable (pulse of 110 bpm, blood pressure of 100/50 mmHg). He was afebrile, with respiratory rate of 15 rpm and oxygen saturation of 98%. His physical examination was negative for any evidence of portal hypertension or other stigmata of chronic liver disease. Abdominal examination revealed non-distended, non-tender abdomen with normoactive bowel sounds. The digital rectal examination showed black terry feces.

Laboratory examinations

Complete blood count revealed a hemoglobin level of 4.8 g/dL and hematocrit of 14.6%. All other laboratoristic exams, including coagulation, liver and renal function tests, were within normal values.

Imaging examinations

Following high-dose intravenous proton pump inhibitor administration, blood transfusion and hemodynamic stabilization, emergent esophagogastroduodenoscopy (EGD) under monitored anaesthesia care was performed. A moderate amount of fresh blood within the stomach was noted and fully aspirated. The retroflexion maneuver revealed varicose shaped pulsating and tortuous submucosal vessels in the gastric fundus without active bleeding. A small erosion overlying one of the vessels consistent with an area of recent healed rupture was noted (Figure 1). Given the absence of clinical or laboratory signs of portal hypertension, we decided to perform emergent computed tomography-angiography (CTA) in order to further characterize the fundic lesion and to look for signs of portal hypertension. SAT and tortuous arterial structures emerging from the left gastric artery (LGA) and the left gastroepiploic artery (LGEA) in the gastric fundus were showed. No signs of active bleeding were observed (Figure 2).

Further hospital course

Given the high-risk of massive early rebleeding due to the presence of a small erosion overlying one of the GSAC vessels, we decided to attempt therapeutic EGD in order to provide definitive treatment in a more stable non-emergent setting. The patient was informed that in case of luminal bleeding control failure, emergent transcatheter arterial embolization (TAE) would be performed by the pre-alerted interventional radiologist. Immediately after the first endoclip application downstream to the mucosal erosion, spurting bleeding started. Hemostasis was achieved by means of two endoclips placement upstream to the mucosal defect. Finally, two endoclips were further prophylactically positioned (Figure 3 and Video 1).

MULTIDISCIPLINARY EXPERT CONSULTATION

No rebleeding was observed following the endoscopic treatment. However, the patient refused splenectomy for definitive treatment. Therefore, after multidisciplinary evaluation, involving GI endoscopist, surgeon, diagnostic and interventional radiologist, a minimally-invasive approach with elective TAE was planned.

FINAL DIAGNOSIS

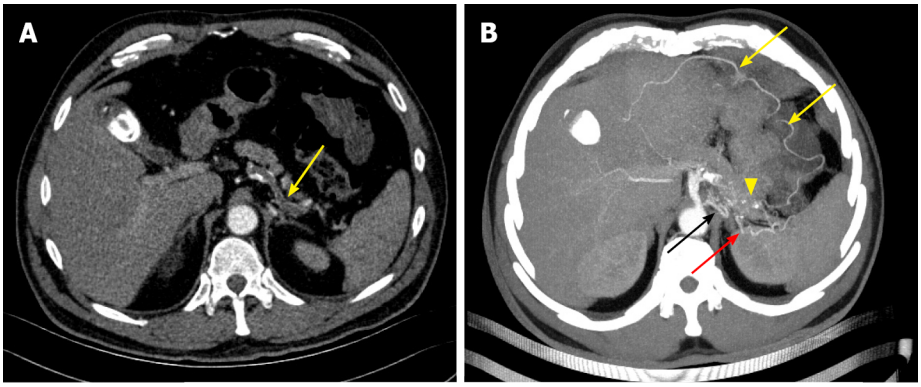
Non variceal acute UGIB from GSAC secondary to SAT.

TREATMENT

Operative angiography showed SAT with multiple collateral arteries arising from the LGA and the LGEA and projecting in the gastric fundus (Figure 4). Selective TAE of the LGA collaterals with trisacryl gelatin microspheres (Embospheres, Guerbet Biomedical, Louvres, France) was effectively realized.

OUTCOME AND FOLLOW-UP

Post-operative stay was complicated by splenic infarction, responsive to conservative treatment (Figure 5). The patient underwent hematology consultation and thrombophilic disorders were excluded. No rebleeding occurred. The patient was discharged with stable haemoglobin value (9.1 g/dL) on post-operative day 18. No rebleeding was observed at 12-mo follow-up.



DISCUSSION

GSAC are an extraordinary rare cause of massive UGIB. They are not related to portal hypertension, resulting from either occlusion or congenital absence of the SA. SAO may be congenital, idiopathic, or secondary to various conditions such as surgery, endovascular procedure, trauma and extrinsic compression. In the case of SAO, in order to provide splenic blood supply, extensive collaterals may

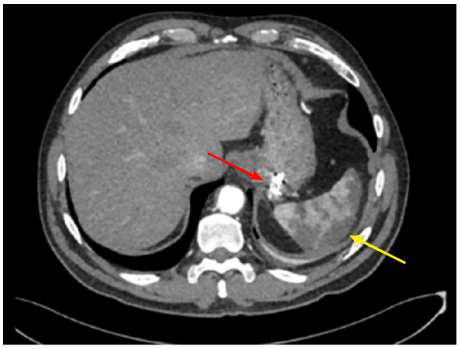
Figure 3 Therapeutic esophagogastroduodenoscopy. A: Spurting active bleeding of the gastric submucosal arterial collaterals after first endoclip application; B: Successful mechanical hemostasis achievement.



arise from adjacent proximal patent arteries, such as the pancreatic, left gastric, gastroepiploic, and short gastric arteries and pass through the gastric wall[6]. Collateral supply may be clinically asymptomatic or may less frequently present with massive UGIB from erosion of GSAC.

The differential diagnosis of GSAC includes mainly isolated gastric varices (IGV). Gastric vascular lesions due to collaterization of an occluded splenic artery may have a very similar endoscopic appearance to IGV and can be easily misinterpreted on EGD. However, they are, as opposed to GSAC, due to cirrhotic portal hypertension or splenic vein obstruction resulting in left-sided portal hypertension[7,8]. Therefore, an accurate differential diagnosis between these two entities is crucial. Indeed, endoscopic cyanoacrylate glue injection (ECGI), currently recommended as the first-line treatment for

Figure 5 Post-operative computed tomography angiography: Axial view showing collateral arteries of the gastric fundus treated by endoscopic clipping plus microspheres embolization (red arrow) and splenic infarction (yellow arrow).

bleeding IGV[9], is associated with a significant risk of systemic embolization and life-threatening adverse events in case of direct arterial injection of cyanoacrylate[10-12]. Finally, fatal arterial embolic complications in hepatolienogastric blood supply have been reported during ECGI to a non-variceal bleeding source[13-16]. A high level of diagnostic certainty is thus required before proceeding with ECGI.

We performed a comprehensive literature search of PubMed/MEDLINE and EMBASE electronic databases up to March 2022, identifying 10 case reports of GSAC secondary to SAO (Table 1).

In 1984, Spriggs[17] first reported a case of severe UGIB due to GSAC secondary to SA congenital absence[17]. The diagnosis was made by arteriography and the treatment consisted in splenectomy followed by partial gastrectomy due to rebleeding. Later on, a similar case was reported, effectively treated by means of splenectomy after ligation of the LGA[18].

In 2000, Baron *et al*[19] reported a case of bleeding GSAC secondary to post-traumatic SAO. It was diagnosed by operative angiography and successfully treated by splenectomy and partial gastric devascularization[19]. Subsequently, Worthley and colleagues described a case of UGIB secondary to SAO due to previous SA aneurysmectomy. As previously reported, it was managed by angiography followed by splenectomy with ligation of the splenic vein and artery together with the left gastric and short gastric arteries[20].

In 2004, Cyrany *et al*[21,22] illustrated the first case of massive UGIB from GSAC secondary to SAT successfully managed endoscopically. Of interest, pre-operative diagnosis was made by endoscopy only, and treatment consisted in ECGI alone. No rebleeding was observed. However, post-procedural stay was complicated by the occurrence of splenic infarction, treated conservatively[21,22].

Later on, the first case of bleeding GSAC successfully treated by endovascular embolization alone was reported by Mnatzakanian *et al*[23] Pre-operative accurate diagnosis was made by CTA followed by

Table 1 Summary of case reports reporting acute upper gastrointestinal bleeding from gastric submucosal arterial collaterals secondary to occlusion or congenital absence of the splenic artery

Case	Ref.	Age/sex	Presentation	SAO etiology	Diagnosis	Treatment	Major AEs	Outcome	Follow-up (months)
1	Spriggs[17], 1984	31/M	Hematemesis	SA congenital absence	Angiography	Splenectomy + partial gastrectomy (due to rebleeding)	Severe respiratory distress	Alive–no rebleeding	-

SAO: Splenic artery occlusion; AEs: Adverse events; SA: Splenic artery; LGA: Left gastric artery; SGA: Short gastric arteries; SAT: Splenic artery thrombosis; CTA: Computed tomography angiography; ECGI: Endoscopic cyanoacrylate glue injection; TAE: Transcatheter arterial embolization; EUS: Endoscopic ultrasound.

angiogram, in order to rule out IGV. No procedure-related major adverse events were observed[23]. Few years later, another case successfully managed in a very similar manner was described[24]. Conversely, Al-Balas *et al*[25] recently reported a case of bleeding GSAC initially managed *via* TEA and subsequently requiring emergency laparotomy with ligation of a bleeding gastric vessel and splenectomy due to severe rebleeding occurrence[25].

In 2011, von Trotha *et al*[26] reported a case of bleeding GSAC secondary to idiopathic SAT. GSAC was endoscopically misdiagnosed as type 1 IGV and ECGI with subsequent clipping was performed in order to control active bleeding. Of note, the authors did not clarify the choice for endoscopic clipping adoption in the setting of supposed IGV. Furthermore, as previously reported by Cyrany and colleagues, ECGI was complicated by splenic infarction. A proper diagnosis was subsequently made by CTA and conventional angiography. Interestingly, endoscopic color doppler ultrasonography was adopted to secure the diagnosis and laparoscopic splenectomy was finally provided for the definitive treatment[26].

Up to date, one case only of fatal UGIB due to GSAC has been reported. In this istance, urgent EGD failed to identify the source of bleeding. CTA examination was then performed showing GSAC due to SAT, in the absence of active bleeding. However, after diagnosis, no treatment was provided and death due to recurrent bleeding occurred[27].

Our case is the first report in which bleeding GSAC was effectively treated with endoscopic mechanical hemostasis alone for the luminal bleeding control and subsequent elective TAE for the definitive treatment. Given the absence of active bleeding and portal hypertension signs or history, emergent CTA was performed prior to endoscopic treatment in order to properly characterize the gastric vascular lesion. Following endoscopic treatment neither adverse events nor rebleeding signs

occurred. The patient refused splenectomy with or without partial gastrectomy for the definitive treatment. Thus, following multidisciplinary evaluation, elective TAE was planned and effectively realized. Post-operative stay was complicated by splenic ischemia, effectively treated by conservative medical treatment. In our case, the presumed etiology of GSAC was idiopathic SAT. Given the formation of an extensive collateral pathway preserving the splenic perfusion, complete SAO likely occurred gradually.

CONCLUSION

Gastroenterologists should be aware of this potentially life-threatening, albeit extraordinary rare, source of massive upper gastrointestinal hemorrhage, in order to allow proper management. In our opinion, endoscopic mechanical hemostasis seems to be a safe and effective method for the luminal bleeding control across referral centers. Conversely, we may not recommend ECGI adoption given the potential occurrence of fatal adverse events due to arterial embolization. CTA appears to be the best modality for a prompt differential diagnosis, and should be performed in all UGIB patients with endoscopic evidence of gastric varicose shaped submucosal vessels and no signs or history of portal hypertension. For the definitive treatment of bleeding GSAC, either a minimally invasive approach with TAE or a standard approach with splenectomy may be provided, taking into account patient preference and status.

ABOUT COVER

Editorial Board of *World Journal of Gastroenterology*, Shunji Fujimori, AGAF, MD, PhD, Director, Department of Gastroenterology, Chiba Hokusoh Hospital, Nippon Medical School, Chiba 270-1694, Japan. s-fujimori@nms.ac.jp

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

Schizophrenia is a severe mental illness which can have a devastating impact on an individual's quality of life. Comorbidities are high amongst patients and life expectancy is approximately 15 years less than the general population. Despite the well-known increased mortality, little is known about the impact of gastrointestinal and liver disease on patients with schizophrenia. We aimed to review the literature and to make recommendations regarding future care. Literature searches were performed on PubMed to identify studies related to gastrointestinal and liver disease in patients with schizophrenia. High rates of chronic liver disease were reported, with Non-Alcoholic Fatty Liver Disease being of particular concern; antipsychotics and metabolic syndrome were contributing factors. Rates of acute liver failure were low but have been associated with antipsychotic use and paracetamol overdose. Coeliac disease has historically been linked to schizophrenia; however, recent research suggests that a causal link is yet to be proven. Evidence is emerging regarding the relationships between schizophrenia and peptic ulcer disease, inflammatory bowel disease and irritable bowel syndrome; clinical vigilance regarding these conditions should be high. Patients with schizophrenia poorly engage with bowel cancer screening programmes, leading to late diagnosis and increased mortality. Clozapine induced constipation is a significant issue for many patients and requires close monitoring. There is a significant burden of gastrointestinal and liver disease amongst patients with schizophrenia. Better levels of support from all members of the medical team are essential to ensure that appropriate, timely care is provided.

Key Words: Schizophrenia; Gastrointestinal disease; Liver disease; Mental health

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: We report significant rates of liver disease, particularly Non-alcoholic Fatty Liver Disease, in patients with schizophrenia, in addition to emerging evidence regarding the prevalence of lower gastrointestinal disease and peptic ulcer disease. We have clearly demonstrated the importance of a multidisciplinary approach to management and propose recommendations to ameliorate future care of this vulnerable group of patients.

INTRODUCTION

Schizophrenia is a complex and frequently devastating illness, worldwide prevalence of which is estimated to be at 0.32%[1]. It is well established that patients with schizophrenia often suffer from a large number of comorbidities, with high rates of alcohol and substance misuse[2]. Life expectancy amongst patients has also been demonstrated to be approximately 15 years shorter than that of the general population[3].

Although the general rate of comorbidities is acknowledged to be high, no comprehensive review currently exists regarding the burden and distribution of gastrointestinal and liver disease amongst this cohort. This is particularly relevant in light of the coronavirus disease 2019 pandemic, as already marginalised patients may have become more isolated from services and only present when seriously unwell. This subject is of importance to gastroenterologists and hepatologists, in addition to general medical physicians, in order to better understand the particular risks associated with these patients and to help ensure that optimal inpatient and outpatient care is provided. It is also relevant to community and inpatient psychiatric teams to highlight when prompt referrals to specialists may be required.

In this review we summarise the available evidence regarding different aspects of gastrointestinal and liver disease in patients with schizophrenia (Figure 1) in a clear and systematic manner, highlighting key findings, and suggesting recommendations (Table 1) regarding the management of each illness to better inform the future care of this vulnerable group of patients. All articles referenced in this review were identified following a PubMed search for literature specifically considering both gastrointestinal and/or liver disease in patients who had a diagnosis of schizophrenia.

CHRONIC LIVER DISEASE

Chronic liver disease (CLD) has consistently been demonstrated to have a higher prevalence amongst those with schizophrenia than amongst the general population. Carney *et al*[2] reported that people with schizophrenia were 4.42 times more likely than healthy controls to have a diagnosis of CLD; amongst a population of veterans, Fuller *et al*[4] reported an eightfold (8.73) increased likelihood of CLD, and Hsu *et al*[5] have also noted a significantly higher prevalence and incidence of CLD than in the general population. Furthermore, mild and severe liver disease were reported in a Danish study[6] (along with dementia) to have the highest incidence rate ratio amongst nineteen somatic chronic diseases in a cohort of 16,079 patients with schizophrenia who were hospitalised between 1995-2007. Only one study[7] has recorded no elevated risk of liver disease, however the results were adjusted for substance use disorders, which undoubtedly will have had a significant effect on results.

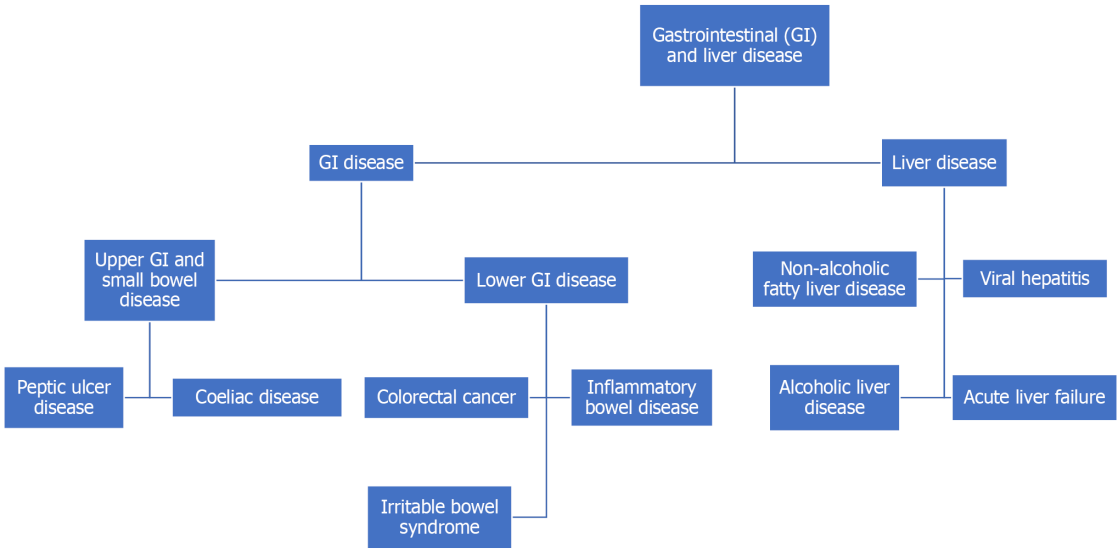
Given such findings, it is essential to reflect on the potential aetiology of the reported results. CLD primarily comprises non-alcoholic fatty liver disease (NAFLD), chronic viral hepatitis and alcohol related liver disease; each will presently be considered and their individual relevance to patients with schizophrenia reviewed.

Non-alcoholic fatty liver disease

Metabolic syndrome: Prior to focusing specifically on NAFLD, the importance of the broader role of metabolic syndrome must be acknowledged. Metabolic syndrome is defined as insulin resistance, impaired glucose tolerance, abdominal obesity, reduced high-density lipoprotein cholesterol levels, elevated triglycerides, and hypertension[8]. A significant association has been widely reported[9,10]

Table 1 Key recommendations

Gastrointestinal/liver disease	Recommendations
NAFLD	Regular monitoring of body mass index and triglycerides
	Encouragement of lifestyle modification
	Liver function tests performed and Fibrosis-4 scores calculated in all psychiatric inpatients and outpatients
Viral hepatitis	Routine screening for viral hepatitis during contact with mental health services
	Integrated approach between mental health, sexual health, substance misuse and specialist hepatology services
ALD	Integrated approach between mental health, substance misuse and hepatology
	Long term studies prospective studies required to fully comprehend burden of ALD
ALF	Clinicians prescribing clozapine should be aware of the potential risk of ALF and have a low threshold for checking liver enzymes and prothrombin time
	Psychiatric review of all patients presenting with POD
	For patients presenting with POD who have a pre-existing psychiatric diagnosis prompt communication must be made with community mental health teams, and appropriate follow-up arranged for those with a new diagnosis
	Decisions regarding liver transplant in patients with schizophrenia must involve the multidisciplinary team and be made on a patient-by-patient basis
PUD	Encouragement of lifestyle modification, particular smoking cessation and alcohol reduction
	Physicians to have a high suspicion for *Helicobacter pylori* infection
Coeliac disease	Large-scale studies amongst diverse population required
	Diagnosis to be considered in patients with schizophrenia presenting with malabsorption
Colorectal cancer	Supporting patients to participate in screening programmes and to attend follow-up appointments is key
IBD	Increased vigilance amongst clinicians regarding a potential diagnosis of IBD is central in enabling prompt diagnosis and maintenance of remission
IBS	Patients should be directly questioned concerning IBS symptoms when undergoing physical health review as many cases may go unrecognised
Clozapine induced constipation	Lifestyle advice to reduce risk
	Regular screening and escalation to GP/secondary care as appropriate
	Physicians to be aware of clozapine as potential cause of constipation and to discuss with psychiatry if considering dose adjustment/cessation



NAFLD: Non-alcoholic fatty liver disease; ALD: Alcohol related liver disease; ALF: Acute liver failure; POD: Paracetamol overdose; PUD: Peptic ulcer disease; IBD: Inflammatory bowel disease; IBS: Irritable bowel syndrome; GP: General practitioner.

between major psychiatric disorders and metabolic syndrome; a prevalence of 32.5% was recorded in a 2013 meta-analysis[11] of patients with schizophrenia and related disorders. An unhealthy lifestyle[12] and use of antipsychotics[13] have been cited as contributing factors to its development in this group.

Definition: The development of NAFLD is associated with obesity, insulin resistance, and type 2 diabetes mellitus and it therefore may be viewed as the hepatic manifestation of metabolic syndrome. NAFLD is characterised by excessive hepatic fat accumulation, which is defined as the presence of steatosis in > 5% of hepatocytes[9]. For a diagnosis of NAFLD to be made, steatosis secondary to factors including hepatitis C, alcohol use, genetics, medications and toxins must first be excluded. NAFLD is reported to have a prevalence amongst the general population of 20% to 30%[14].

Role of antipsychotic medications: The metabolic side effects of antipsychotic medications are well-established, with clozapine and olanzapine in particular being related to weight gain, hyperglycaemia and dyslipidaemia[15]. Understandably, therefore, much of the research into NAFLD and schizophrenia has focused on the potential role of these medications in its development.

A 2016 prospective Spanish study[16] involving 191 patients with a first episode of schizophrenia (94.2% of which were antipsychotic naïve), reported that 25.1% (48/191) of patients demonstrated a fatty liver index (FLI) result suggestive of the presence of steatosis after three years of antipsychotic treatment; none of the included patients had steatosis at index abdominal ultrasound scan (AUSS). The patients in the study were randomised to aripiprazole, risperidone, quetiapine and ziprasidone; the

Figure 1 Summary of gastrointestinal and liver disease in patients with schizophrenia. GI: Gastrointestinal.

dose and type of antipsychotic changed throughout the follow-up period and results were not stratified according to medications. There was no control group. This study is unique in that it prospectively demonstrated the development of NAFLD following the initiation of antipsychotics; the other studies considered hereafter have focused on NAFLD in patients already established on treatment regimes.

In a cohort of 253 patients with schizophrenia, Koreki *et al*[17] reported that 42.7% (108/253) were found to have steatosis on AUSS. All patients included in this study were on at least one antipsychotic treatment (duration was not specified); on univariate analysis total antipsychotic dose (all daily doses were calculated based on chlorpromazine equivalents) was noted to be significantly associated with the presence of steatosis (P = 0.009). On regression analysis, doses of antipsychotic medications recognised as carrying an increased risk of metabolic syndrome and hyperprolactinaemia were significantly associated with NAFLD (P = 0.049 and P = 0.041 respectively). A comparably high prevalence of NAFLD was also reported in a 2017 Chinese study[18] which compared 202 male patients aged 18-35 with schizophrenia and on antipsychotics for at least one month to 149 controls. 49.5% (100/202) of the schizophrenia group had steatosis on AUSS, compared with 20.1% (30/149) of the control group. Although NAFLD prevalence amongst inpatients with schizophrenia was not as high (22.44%) as in the aforementioned studies, in another 2021 Chinese study[19] comprising 66,273 patients with "mental disorders", it was still higher than amongst those with bipolar affective disorder (17.89%), depressive disorder (12.62%) and other mental disorders (12.99%) and was demonstrated to be associated with antipsychotic treatment.

The highest reported prevalence of NAFLD was recorded in a 2021 Taiwanese study[20] which considered 182 patients with schizophrenia who had been hospitalised for at least two years and been on antipsychotic treatment for at least one year. 70.8% (129/182) were diagnosed with steatosis on AUSS; results were stratified according to antipsychotic generation and cumulative dose (using chlorpromazine equivalents), however no significant association between these and NAFLD were demonstrated. Given the reported increased association of NAFLD with second generation antipsychotics[15], the authors attribute the disparity in their results to population demographics and sample size. Interestingly, antipsychotic treatment duration, potentially the biggest contributor to the reported results in this cohort, was not reported in the results.

Rates of NAFLD have also been reported in studies not specifically considering antipsychotic therapies. In a population of veterans in the United States[4], those with a diagnosis of schizophrenia were significantly more likely to be diagnosed with NAFLD ($P \leq 0.001$) and in a cross-sectional Danish study[21] 21.4% (31/145) were diagnosed with moderate-severe steatosis on non-enhanced CT. In these studies, significant associations were however demonstrated with metabolic syndrome, suggesting (although not confirming due to lack of data) that antipsychotics may also be potentially playing a role in these reported results.

Lifestyle and negative symptoms: While research has predominantly focused on the close links between antipsychotics and NAFLD, it is also important to briefly consider potential alternative aetiologies that have been proposed.

Patients with schizophrenia are acknowledged as being at higher risk of an unhealthy lifestyle compared to the general population[17]. They may have an unbalanced diet, poor self-care, avoid certain foods due to paranoid delusions or hallucinations, and withdraw from physical and social

activities, leading to a lack of exercise[22]. Yan *et al*[18] in their 2017 study emphasised the role of negative symptoms in young men with schizophrenia and NAFLD; a negative factor score in the Positive and Negative Syndrome Scale (PANSS) was significantly associated with a NAFLD diagnosis ($P = 0.025$). It is not challenging to understand how the negative symptoms of anhedonia, poor attention, low motivation, apathy and social withdrawal may lead to obesity and the associated sequelae of metabolic syndrome.

Recommendations: It is evident that a diagnosis of schizophrenia carries with it a significant risk of developing NAFLD, both due to treatment with antipsychotics and also due to the intrinsic nature of the illness itself. In order to prevent progression to cirrhosis and its associated complications it is necessary to increase awareness of this risk and consider how it may be ameliorated. At the very least, body mass index (BMI) and triglycerides should be monitored regularly in all patients with schizophrenia and psychiatrists and general medical physicians should make every effort to support patients in modifying their lifestyles. Furthermore, all patients admitted to psychiatric hospitals and attending outpatient psychiatry appointments ought to have liver function tests performed and Fibrosis-4 (Fib-4) scores calculated to determine if a referral to hepatology is necessary.

Chronic viral hepatitis-hepatitis B and hepatitis C

People with serious mental illness (including schizophrenia) have been shown to be at increased risk of blood borne viruses (BBVs)[23]. A significant minority of patients with schizophrenia engage in risky behaviour (unprotected sex with multiple partners, sex work, and intravenous drug use) putting them at risk of infection; they are also more likely to live in shared accommodation and may share personal equipment such as razors and toothbrushes, carrying a potential increased risk of hepatitis B and C transmission[23]. Patients with hepatitis B and C have an increased risk of developing hepatocellular carcinoma[24], therefore adequate treatment and monitoring of the conditions is vital.

In 2017 a Swedish study[25] considered the prevalence and risk factors for BBVs amongst people with severe mental illness; when compared with healthy controls, those with schizophrenia were significantly more likely to have either a diagnosis of hepatitis B ($P \leq 0.001$) or hepatitis C ($P \leq 0.001$). A history of substance misuse was noted as having contributed the most to the risk of developing a BBV ($P \leq 0.001$). Increased prevalence of hepatitis C was also shown in a study of veterans[4] diagnosed with schizophrenia when compared to controls ($P \leq 0.001$). Substance use disorder and alcohol use disorder were identified as significant risk factors for development of schizophrenia ($P \leq 0.001$ and $P \leq 0.001$ respectively). A small study performed in Boston[26] identified eight patients with hepatitis C out of a total cohort of 98 patients (8.2%) treated with clozapine; one was a confirmed intravenous drug user, three had a history of polysubstance misuse and in the remaining four patients no risk factors were identified. A further small Canadian study[27] reported a hepatitis C rate of 2.7% (3/110) of clozapine-treated patients. Two of the three patients diagnosed with hepatitis C had a history of intravenous drug use.

Outcomes in patients with schizophrenia diagnosed with hepatitis C and hepatitis B were considered in a 2021 Chinese study[24]. From a total cohort of 15,914 patients with newly diagnosed schizophrenia between 2007 and 2013, 614 patients were identified with viral hepatitis and were matched with 1228 controls. The primary outcome measure was the incidence and risk of "severe hepatic outcomes" (SHOs), including liver cancer, failure and decompensation. The viral hepatitis group were significantly more likely to develop SHOs ($P \leq 0.001$) than the control group; a total of 26 patients with viral hepatitis developed SHOs (20/26 Liver decompensation, 3/26 Liver failure, and 3/26 Liver cancer).

Recommendations: While the risk of viral hepatitis amongst people with schizophrenia cannot be disputed, optimal management of it is challenging. Routine screening for viral hepatitis during contact with mental health services would allow an opportunity for discussion about safe sex and drug use, it may also prompt consent to other tests (such as HIV), leading to the discovery of potentially treatable illnesses, and, crucially, a positive result may allow prevention of further liver damage[26]. If diagnosed, encouragement of treatment adherence in this population may be difficult, therefore an integrated approach between mental health, sexual health, substance misuse[25] and specialist hepatology services would be required to aid optimal patient outcomes.

Alcohol related liver disease

A high prevalence of alcohol use disorder (AUD) has been demonstrated in patients with schizophrenia, with a recent meta-analysis reporting a lifetime prevalence of AUD of 24.3%[28]. A number of hypotheses have been put forward to explain this association, including genetic polymorphisms, poor cognitive development, poor social functioning, the effects of poverty, poor social environments and "self-medication" to gain relief from distressing symptoms[29].

Despite such a high prevalence of AUD in patients with schizophrenia, research into alcohol related liver disease (ALD) in this cohort is relatively limited with variable results. The most common manifestations of ALD are alcoholic fatty liver, acute alcoholic hepatitis and alcohol related cirrhosis of the liver. In 2014 Hsu *et al*[5] reported an increased risk of alcohol related fatty liver in patients with schizophrenia when compared with the general population ($P = 0.007$); risk of alcoholic hepatitis and cirrhosis

did not vary significantly between the two cohorts. In a 2022 Scottish study[30] of patients with schizophrenia admitted to a general hospital under the care of gastroenterology, 42.5% (17/40) of patients had a background of cirrhosis (88.2% of which had a background of alcohol excess) and 60.0% (24/40) of all patients had a history of alcohol excess. Interestingly, Fuller *et al*[4], in their 2011 study, reported schizophrenia being a protective factor (odds ratio = 0.53) in the diagnosis of alcohol related cirrhosis when a group of veterans with schizophrenia were compared to those without.

Recommendations: In common with viral hepatitis, an integrated approach between mental health, substance misuse services and specialist hepatology services is key in supporting patients with schizophrenia and alcohol use disorder. Further research, including long term prospective studies, is also required to better comprehend the burden of ALD amongst patients with schizophrenia.

ACUTE LIVER FAILURE

Acute liver failure (ALF) is a rare clinical syndrome in which the onset of liver injury, with coagulopathy and hepatic encephalopathy, occurs in a patient with no underlying CLD and previously normal liver function. The associations between ALF and schizophrenia can be considered under the following categories: ALF arising as a result of pharmacological treatment for schizophrenia, ALF arising as a consequence of mental state alteration in patients with schizophrenia and finally the implications of a diagnosis of schizophrenia on decision making around emergency liver transplantation for ALF.

Pharmacological treatments

In patients with treatment resistant schizophrenia (*i.e.*, following the failure of at least two antipsychotics, including a second-generation antipsychotic) prompt initiation of clozapine, the only remaining evidence-based treatment, is required to reduce symptoms and risk of relapse[31,32]. Clozapine acts as a dopamine and serotonin receptor antagonist. The most recognised and feared side effect of clozapine is agranulocytosis, however there are now case reports of clozapine induced ALF[33,34]. The mechanism of liver injury in this scenario is unclear, but it is idiosyncratic. A modest elevation in liver enzymes occurs in up to two thirds of patients treated with clozapine, and often resolves spontaneously[35]. Clinically apparent liver injury (with jaundice) occurs in approximately 1 in 2000 patients treated with clozapine[35] and progression to ALF (and death, or the need for emergency liver transplant) is now reported. ALF secondary to clozapine is extremely rare however, with less than five reported cases in the literature[33,34,36]. ALF has also been reported as a rare side effect of quetiapine therapy[37]; no cases of ALF have been reported with olanzapine or risperidone. Most treatment guidelines do not give clear recommendations on monitoring liver function tests in patients on clozapine and other antipsychotics, in part due to the fact that the vast majority of liver enzyme abnormalities secondary to these drugs do resolve spontaneously. Clinicians prescribing clozapine should be aware of the risk of ALF and could consider checking liver enzymes and prothrombin time when performing blood work monitoring for agranulocytosis.

Paracetamol overdose

Schizophrenia is associated with suicidal ideation[38]. In the United Kingdom, intentional paracetamol overdose is the most frequent cause of ALF. There is no clear evidence that schizophrenia is associated with an increased risk of paracetamol overdose resulting in ALF compared with the general population or patients with other psychiatric diagnoses. Scottish data have shown that of 472 patients with paracetamol overdose requiring admission to the Scottish Liver Transplant Unit who underwent formal inpatient assessment by psychiatry, schizophrenia was diagnosed or recorded in 2.8% of patients [Personal communication: Dr Roger Smyth, Consultant Liaison Psychiatrist, Royal Infirmary of Edinburgh]. In comparison, affective disorders were recorded in 16.1% and personality disorders in 6.9% of patients. One Danish study assessed the association between paracetamol (and other weak analgesic) poisoning and the subsequent diagnosis of a psychiatric disorder[39]. The risk of an admission with schizophrenia increased 3.9-fold after paracetamol poisoning and 2-fold after non-paracetamol poisoning compared with matched population controls. Patients with a previous psychiatric admission were excluded, but it is possible that patients with schizophrenia who had not required prior hospitalisation (*i.e.*, but who already had an established diagnosis) were included in the study. Furthermore, the admission with poisoning is likely to have prompted a psychiatric review and subsequent diagnosis. These data suggest that poisoning is a risk marker for a psychiatric disorder, rather than there being a causative association. Clinicians assessing patients presenting with paracetamol overdose should be aware of the risk of underlying psychiatric disorder and ensure appropriate assessments are arranged.

Interestingly, in addition to its role in treatment of paracetamol overdose, there is ongoing research into the reduction of negative symptoms and anti-suicidal properties of N-acetyl cysteine (NAC) in the treatment of schizophrenia. Chen *et al*[40] identified two placebo-controlled, double-blind, randomised

clinical trials of NAC in schizophrenia and reported that NAC may be efficacious in reducing the negative and general symptoms of schizophrenia. A meta-analysis by Zheng *et al*[41], which included three randomized control trials with 307 (N-acetylcysteine: 153, placebo: 154) participants, showed that NAC significantly improved total symptom scores in schizophrenia. Other related systematic reviews, including a Cochrane review on antioxidant treatment for schizophrenia, have also found NAC to be a promising add-on treatment for schizophrenia[42].

Emergency liver transplantation

Emergency liver transplantation may be required in patients with ALF if spontaneous recovery of sufficient liver function is deemed unlikely. Psychiatric disorders can be relative or absolute contraindications to liver transplantation, particularly if the disorder is deemed "untreatable" and may be graft threatening. A diagnosis of a psychiatric condition such as schizophrenia is relevant if it affects the prospect of survival post-transplant or affects compliance with medication and clinic follow-up. In a Scottish cohort of patients with ALF secondary to paracetamol overdose, 56.6% of patients who were rejected for listing for liver transplantation were rejected on the basis of psychiatric contraindications [43]. As described above, schizophrenia is associated with an increased risk of suicide, and this must be taken into account when considering the role of transplantation in an illness potentially arising from self-harm or parasuicide such as paracetamol overdose; the consequences of further suicidal intent must be reviewed. Specific to severe psychiatric disorders such as schizophrenia, absolute contraindications to liver transplantation include chronic, severe illness with a poor prognosis, especially if refractory to appropriate treatment. The potential impact of a diagnosis of schizophrenia on substance misuse, compliance with immunosuppression and clinic follow-up must be considered. Therefore, patients with schizophrenia being considered for emergency liver transplantation for ALF should be assessed by the wider multi-disciplinary team and decisions made on a highly individualised basis.

Recommendations: While cases of ALF are rare in patients treated with clozapine, prescribing clinicians should be aware of the potential risk and have a low threshold for checking liver enzymes and prothrombin time, particularly in patients presenting with possible symptoms of liver dysfunction such as nausea, vomiting and/or anorexia[44].

Regarding paracetamol overdose, it is essential that treating physicians are aware of the risk of a diagnosis of a psychiatric disorder and ensure patients are reviewed by psychiatric teams during their admission. For patients who have a pre-existing diagnosis prompt communication must be made with community mental health teams (CMHT), and appropriate follow-up arranged for those with a new diagnosis. The use of NAC in the treatment of schizophrenia is an emerging area of research and further evidence is required regarded its potential.

The assessment of patients with schizophrenia for liver transplant is complex. Decisions must involve the multidisciplinary team (MDT) and be made on a patient-by-patient basis.

UPPER GASTROINTESTINAL AND SMALL BOWEL DISEASE

Peptic ulcer disease and upper gastrointestinal bleeding

Upper gastrointestinal bleeding (UGIB) is the consequence of often readily treatable digestive conditions such as gastroduodenal ulcers and reflux oesophagitis progressing to a potentially fatal event; in patients with schizophrenia the risk may be heightened due to high rates of alcohol misuse, smoking and non-steroidal anti-inflammatory drug use, in addition to reluctance to present to medical services. There are relatively limited studies which have considered incidence of peptic ulcer disease (PUD) and UGI bleeds in this cohort, with evidence being inconclusive, and, at times, contradictory.

Helicobacter pylori (*H. pylori*) infection is recognised[45] as a major contributor to PUD and consequently UGIBs. Following a 1997 study by De Hert *et al*[46] and a 2005 study by Yilmaz *et al*[47] (both of which reported high rates of *H. pylori* infection in patients with schizophrenia), a Turkish group [47] discussed the role of *H. pylori* as a possible environmental contributor to the pathogenesis of schizophrenia in genetically predisposed individuals. The authors identified four mechanisms to support this theory: (1) Dopaminergic dysfunction; (2) inflammation; (3) polyunsaturated fatty acids; and (4) hyperhomocysteinaemia. With regard to dopaminergic dysfunction specifically, the authors propose that dopamine antagonists (such as commonly used antipsychotics) promote ulcer formation favouring the growth of *H. pylori*; this is a theory which is supported by Ozdemir[48] in their 2007 paper in which they propose that the lesser prevalence of PUD in their cohort of patients with schizophrenia was due to the over expression (and subsequent protective effect) of dopamine.

The reduced prevalence of PUD in patients with schizophrenia reported by Ozdemir *et al*[48] is in contrast to results reported in other studies. In 1968 Hussar[49] proposed that the incidence of PUD was at least as high amongst long term institutionalised patients with schizophrenia compared with the general population and, more recently, in 2014, Liao *et al*[50] reported an incidence of PUD that was 1.27 times higher in patients with schizophrenia than in the general population. An American study in 2014 [51] of 224,361 patients with schizophrenia, reported an incidence of bleeding ulcers amongst this cohort

as being 1.4 per 1000 person years, compared to 1.2 per 1000 person years in those without schizophrenia. Similarly increased risk of UGIB was also noted in a 2018 Danish study[52] of 39,998 patients with schizophrenia; the authors acknowledge the role that increased rates of *H. pylori* infectivity amongst patients with schizophrenia may have played in the observed results.

Recommendations: It is challenging to draw definitive conclusions regarding biological links between the aetiology of PUD and schizophrenia and more research is required before such links are established. However, it important to acknowledge the increased risk of PUD those patients with schizophrenia has due to lifestyle factors, and, as a result, ensures that help is given to aid modification. Suspicion regarding the presence of *H. pylori* should also be high, particularly as it may have the potential to contribute to mortality through a catastrophic UGIB or the development of gastric cancer[53].

Coeliac disease

Coeliac disease is an autoimmune disease which is triggered by gluten peptides in wheat, rye, barley and other grains. Histologically it is characterised by villous atrophy, hypertrophy of intestinal crypts and increased lymphocytes in the epithelium and lamina propria[54]. This results in malabsorption and the associated bloating, pain and diarrhoea in sufferers. Current prevalence of coeliac disease is estimated at 1% of the general population[54].

Historical perspective: A potential association between coeliac disease (or gluten intolerance) and schizophrenia is one which has long since interested researchers[55], with Bender[56] first reporting in 1953 that children with schizophrenia were more likely to have coeliac disease. This was then followed by the publication of a case series on five patients with schizophrenia with coeliac disease who were admitted to a psychiatric hospital during the same year[57]. Dohan was particularly prolific in the publication of papers regarding coeliac disease and schizophrenia, with results variably showing reduced prevalence of schizophrenia in areas of low grain consumption and an improvement in the symptoms of schizophrenia following the initiation of a gluten free diet[58-62].

Current status: More recent research has focused on the risk of patients with coeliac disease developing schizophrenia as opposed to prevalence of coeliac disease amongst those with schizophrenia; nevertheless, the strength of an association between the two conditions may be extrapolated from the available evidence. A 2018 meta-analysis[63] of the four most recent epidemiological studies[64-67] reported a significantly higher risk (two-fold) of schizophrenia in those with coeliac disease when compared with controls. Of the four studies, three[64,66,67] reported a significant association and one [65] did not (in common with an earlier British study[68]). The authors of the meta-analysis acknowledge that the mechanism underlying this association is unclear, however propose the following potential explanations: (1) There is high prevalence of folate deficiency in individuals with coeliac disease, given the important role of folate in DNA methylation, aberrant methylation may contribute to the development of schizophrenia; (2) schizophrenia may share a genetic diathesis with coeliac disease; and (3) diagnoses of schizophrenia in patients with coeliac disease may be resulting from surveillance bias as those with coeliac will present more often to physicians due to their chronic illness requiring regular follow-up. Since the publication of the meta-analysis, a small study[69] of 16 patients with IgG antigliadin antibodies (raised in coeliac disease) has also demonstrated an improvement in psychiatric patients with schizophrenia or schizoaffective disorder with a gluten free diet; a larger scale clinical trial is planned.

Recommendations: While research into a possible link between coeliac disease and schizophrenia has previously relied on relatively small case reports and series, more recently trial evidence has emerged to strengthen the association. Proof of a causal relationship between the two remains unclear and further large-scale studies, amongst more diverse populations, are required. Nevertheless, current evidence does serve to increase awareness of the likelihood of a diagnosis of coeliac disease amongst patients with schizophrenia presenting with symptoms of malabsorption.

LOWER GASTROINTESTINAL DISEASE

Colorectal cancer

Evidence regarding rates of cancer mortality in patients with schizophrenia has historically been contradictory, with some studies reporting lower or similar risk of cancer mortality compared to the general population[70-72], while others have reported higher rates[73-75]. Regarding colorectal cancer, however, a recent systematic review and meta-analysis[76] found that patients with schizophrenia had a significantly higher risk of mortality, with male patients having a relative risk of 1.90 and female patients 2.42. Increased risk of colorectal cancer[77] was also reported in a 2007 study. As in the general population, screening is vital in promoting earlier diagnosis and reducing mortality; a 2018 Japanese study[78] reported a rate of participation in colorectal cancer screening of 13.4% in patients with schizophrenia (in contrast to 47.8% of men and 40.9% of women in the general population[79]). The benefit of

case management interventions, in the form of three counselling sessions to support adherence to screening, was demonstrated in a 2021 Japanese study[79], which showed a 35.3% increase in participation amongst the case management group.

Recommendations: As reported in the 2021 study[79], participation in screening programmes is key to reducing mortality from colorectal cancer amongst patients with schizophrenia to be in line with the general population. Supporting patients to participate in screening and attend potential follow-up procedures is essential to address the disparity between colorectal cancer mortality in this cohort when compared to the general population.

Inflammatory bowel disease

Crohn's disease (CD) and ulcerative colitis (UC) are the two main types of inflammatory bowel disease (IBD) and are characterised by chronic inflammation - in the case of UC it is limited to the mucosa of colon and rectum, and, in CD, it is transmural and extends potentially to the whole GI tract. Symptoms of both conditions include diarrhoea, abdominal pain and extreme fatigue. Prevalence of IBD is increasing and is projected to reach 1% by 2028[80].

The relationship between IBD and schizophrenia has been explored in a small number of studies, with variable results. Bernstein *et al*[81] reported an increased incidence of schizophrenia amongst patients with CD but not with UC, whereas no increased risk in either form of IBD was demonstrated by West *et al*[68]; a Swedish study actually noted a diminished risk of schizophrenia in those with IBD[82].

In contrast to earlier studies which focused on risk of schizophrenia in IBD patients, a recent study from Taiwan[83] considered risk of a new IBD diagnosis amongst patients with a diagnosis of schizophrenia. It included 116,164 patients with schizophrenia and 464,656 matched controls and concluded that overall incidence of IBD was significantly higher amongst the schizophrenia cohort (1.14% *vs* 0.25%); risk was also higher amongst those with more severe schizophrenia. These findings are potentially supportive of research suggestive of shared genetic susceptibility between the two conditions[84,85], although the role of diet and microbiota remain important confounding factors.

Recommendations: CD and UC are challenging conditions to manage, this risk is heightened in vulnerable patients with schizophrenia as engagement with health services is essential for positive outcomes. As recommended by the authors of the recent Taiwanese study[83], increased vigilance amongst clinicians and other members of the MDT regarding potential cases of IBD may prove vital in enabling prompt diagnoses and maintenance of remission.

Irritable bowel syndrome

Irritable bowel syndrome (IBS) is a functional gastrointestinal disorder characterised by abdominal pain, bloating and a change in bowel habit [either constipation (IBS-C), or, more commonly, diarrhoea (IBS-D)]; diagnosis is made based on the Rome IV criteria. Current prevalence of IBS in the United Kingdom is estimated to be at 14%[86].

The first study to consider IBS in patients with schizophrenia was published in 1997[87]. The authors reported that 19% of the patients with schizophrenia met the diagnostic criteria for IBS, compared with 2.5% of those in the control group. It must however be acknowledged that the study only included 87 patients in total. Interestingly, it was noted that the patients with schizophrenia did not complain of symptoms of IBS, unlike when the authors considered a group of patients with anxiety and depressive disorder; the authors attributed this to a preoccupation with delusions and hallucinations or being due to apathy resulting from negative symptoms.

A further study[88] comprising 134 patients with schizophrenia reported IBS in 48.8%; the study also reported higher rates of IBS-D in patients presenting with positive symptoms of schizophrenia, IBS-C and alternating IBS-D/C were more common in those with negative symptoms. The group was not compared to a control, which makes conclusions limited.

Recommendations: Research suggests that there may be an under-reporting of IBS symptoms amongst patients with schizophrenia. Consideration should therefore be given to IBS symptomatology in patients with schizophrenia undergoing physical health review as many cases may go unrecognized unless patients are directly questioned. Addressing diet and lifestyle factors are also important in improving the quality of life in patients with schizophrenia and IBS symptoms.

Clozapine induced constipation

Whilst recognising it as a side effect of clozapine treatment as opposed to a disease in itself, it is necessary to acknowledge the risk of clozapine induced constipation in patients with schizophrenia. Risk of constipation is greatest in the first four months following treatment initiation, however may occur at any time[89]. A 2016 systematic review and meta-analysis[90] of 11 studies reported a prevalence of clozapine induced constipation of 31.2%. The authors attribute increased risk of constipation to the anti-muscarinic and anti-histaminergic effects of the drug, as well as to a sedentary lifestyle, dehydration, obesity and a diet which is low in fibre. Complications of constipation such as bowel obstruction, ileus (a Danish study[91] reported a 0.8% incidence of ileus in clozapine treated

patients) and toxic megacolon may be life threatening; in severe constipation the case fatality rate has been documented at approximately 20%-30%[89]. Following the aforementioned systematic review and meta-analysis[90], subsequent studies and case reports[92-96] have also reported similarly high incidence of clozapine induced constipation and gastrointestinal hypomotility, highlighting the ongoing significance of this issue.

Recommendations: Given the high prevalence of clozapine-induced constipation, all patients on clozapine should be given lifestyle advice to help prevent the development of constipation. It is crucial to screen for its presence during CMHT review (regular attendance at clozapine blood monitoring may help to facilitate this) and it is particularly important to ask directly about it as incidence may be underreported by patients. Patients may be referred to their general practitioner (GP) for prescription of laxatives and ongoing monitoring if constipation is present, in addition to plasma clozapine levels being reviewed by the CMHT; if there are features concerning for obstruction prompt referral to secondary care is required.

Caution should be exercised in the prescription of anti-cholinergics for hypersalivation (a known side effect of clozapine) due to their potential to contribute to constipation; other regular medications with constipating side effects should also be kept under close review. For secondary care physicians it is important to be aware of clozapine as a potential cause of constipation and essential to seek advice from colleagues in psychiatry if dose adjustment or treatment cessation is being considered.

GUT MICROBIOME AND SCHIZOPHRENIA

In consideration of gastrointestinal disease in schizophrenia it is important lastly to acknowledge an emerging area of active research - the gut microbiome. The gut microbiome in humans comprises a diverse population of microbes, the most numerous of which are reported to be Bacteroidetes and Firmicutes[97]. Factors such as diet, smoking and social circumstances have been suggested to influence the composition of an individual's developing microbiome. While each microbiome is unique, when the microbial composition differs significantly from controls, it is referred to as dysbiosis. Alterations in gut microbiota have been demonstrated to be implicated in several psychiatric illnesses, including depression, addiction and eating disorders. Evidence is now emerging regarding the potential role of gut dysbiosis in the aetiology of schizophrenia and the use of pre and probiotics in treatment pathways is also being explored.

In 2020 Szeligowski *et al*[98] performed a narrative review of research considering the differences in microbiome between healthy controls and patients with schizophrenia; six studies were identified. The authors reported only one consistent finding between the studies-that patients with schizophrenia had significantly elevated Lactobacilli, which also correlated with symptom severity. As Lactobacilli are typically thought to be beneficial for gut health, this finding was attributed to the existence of different subtypes. The authors conclude that different exclusion criteria, stage of illness and treatments make definitive conclusions regarding the role of dysbiosis in schizophrenia challenging and further larger scale prospective studies are required.

Pre and probiotics are also being investigated for their ability to reduce the effect of antipsychotic medications on the microbiome which can lead to potentially life- threatening constipation and significant weight gain. Results of small studies which have been reported in reviews of the literature [98-101] are encouraging, for example co-administration of prebiotics to olanzapine treated rats led to attenuation of weight gain[102]. As with the role of dysbiosis in the aetiology of schizophrenia, more detailed studies in human subjects are of course needed but early results do suggest this may be a promising area for future treatment.

CONCLUSION

Gastrointestinal and liver disease have been shown to have a profound impact on patients with schizophrenia. The scale of liver disease, and metabolic syndrome in particular, in this population, is perhaps the most significant finding upon review of the literature. Optimal management of these conditions deserves close consideration from psychiatrists, hepatologists and all members of the MDT involved in the care of patients with schizophrenia. A recurring theme from consideration of all gastrointestinal and liver diseases is that patients with schizophrenia need appropriate additional levels of support from care providers to ensure that their physical health receives the attention it requires and which they, as individuals, deserve.

FOOTNOTES

Author contributions: Grant RK and Brindle WM conceived the study; Grant RK performed the literature review and drafted all sections of the manuscript except for the section on acute liver failure; Donnelly MC performed the literature review and drafted the section on acute liver failure; Brindle WM, Donnelly MC, McConville PM, Stroud TG, and Bandieri L critically revised the manuscript; Plevris JN was senior author and critically revised the manuscript for important intellectual content.

Conflict-of-interest statement: There are no conflicts of interest to report.

Abstract

Artificial intelligence (AI), especially deep learning, is gaining extensive attention for its excellent performance in medical image analysis. It can automatically make a quantitative assessment of complex medical images and help doctors to make more accurate diagnoses. In recent years, AI based on ultrasound has been shown to be very helpful in diffuse liver diseases and focal liver lesions, such as analyzing the severity of nonalcoholic fatty liver and the stage of liver fibrosis, identifying benign and malignant liver lesions, predicting the microvascular invasion of hepatocellular carcinoma, curative transarterial chemoembolization effect, and prognoses after thermal ablation. Moreover, AI based on endoscopic ultrasonography has been applied in some gastrointestinal diseases, such as distinguishing gastric mesenchymal tumors, detection of pancreatic cancer and intraductal papillary mucinous neoplasms, and predicting the preoperative tumor deposits in rectal cancer. This review focused on the basic technical knowledge about AI and the clinical application of AI in ultrasound of liver and gastroenterology diseases. Lastly, we discuss the challenges and future perspectives of AI.

Key Words: Artificial intelligence; Ultrasound; Liver; Gastroenterology; Deep learning

Core Tip: Artificial intelligence (AI) based on ultrasound has been confirmed to be helpful in diagnosing diffuse liver diseases and focal liver lesions, such as analyzing the severity of nonalcoholic fatty liver and the stage of liver fibrosis, identifying benign and malignant liver lesions, predicting microvascular invasion of hepatocellular carcinoma, curative transarterial chemoembolization effect, and prognoses after thermal ablation. AI based on endoscopic ultrasonography has been applied in some gastrointestinal diseases. We focused on basic technical knowledge about AI and the aforementioned clinical application in the ultrasound of liver and gastroenterology. Additionally, we discuss the challenges and future perspectives of AI.

INTRODUCTION

Liver disease causes two million deaths per year in the world among which cirrhosis is the 11th leading cause of death in the world and liver cancer is the 16th leading cause of death[1]. The prevalence of nonalcoholic fatty liver disease (NAFLD) is 25.0% and is estimated to be 33.5% by 2030[2]. Gastrointestinal diseases affect an estimated 60 to 70 million American citizens annually. It is reported that pancreatic cancer (PC) is one of the top five causes of death from cancer, and colorectal cancer accounts for 8.5% of cancer-related deaths[3-5]. Therefore, it is of great importance to pay attention to these diseases.

In clinical practice, many imaging techniques such as X-ray, computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound have played a vital role in the detection and treatment of diseases[6]. Ultrasound, a noninvasive and real-time diagnostic technique, is the most commonly used method for detecting and diagnosing human digestive diseases[7]. However, the interpretation and analysis of ultrasound images depend deeply on the subjective judgment and experience of human experts. Radiologists may make mistakes due to exhaustion when dealing with a large number of images[8].

Artificial intelligence (AI) is defined as computer algorithms created by humans and improved with analogs of the thoughts, judgments, and reactions that take place in the human brain. In recent years, radiologists have increasingly embraced the aid of AI-powered diagnoses. AI can make a quantitative analysis by recognizing the information of images automatically and is widely applied in the medical images of ultrasound in diffuse liver diseases, focal liver lesions, PC, and colorectal cancer. In this review, we described the development of AI-based ultrasound in the aforementioned applications. In addition, we also discussed the future opportunities and challenges of AI-based ultrasound.

AI

Currently, the algorithms of AI used in medical images mainly include traditional machine learning algorithms and deep learning.

Machine learning

Machine learning is described as a kind of data science that offers computers with the capacity to study without being programmed with specific rules[9]. It focuses on computer algorithms that are studied from the training model and give predictions on another model[10]. Machine learning depends primarily on the predefined characteristics that display the regular patterns inherent in models acquired from regions of interest with explicit parameters on the basis of expert experience. Then, other medical image features, such as various mass shape, size, and echo, can be quantified.

Radiomics, which belongs to traditional machine learning, is a popular field of study related to the acquisition and assessment of patterns within medical images, including CT, MRI, and ultrasound. These patterns include complicated patterns that are difficult to recognize or analyze by the human eye [11].

Deep learning

Deep learning is at the leading edge of AI and is developing rapidly. Deep learning is described as a group of artificial neural network (ANN) algorithms, which include many hidden layers. Namely, deep learning depends on a subset of algorithms that try to model high-level abstractions[12].

Recently, convolutional neural networks (CNNs) are the preferred type of deep learning architecture in the assessment of medical images[13]. CNNs consist of an input layer, multiple hidden layers, and an output layer (Figure 1). The hidden layers include convolutional layers, pooling layers, connected layers, and normalization layers. Convolutional layers and pooling layers can complete feature extraction and aggregation[9].

APPLICATION OF ULTRASOUND-BASED AI IN HEPATOLOGY

Diffuse liver diseases

Diffuse liver diseases display a failure in the metabolic and synthesis processes of the liver[14]. Liver biopsy is the gold standard for the diagnosis of fibrosis and NAFLD. However, liver biopsy is an invasive process that has many complications such as hemorrhage, biliary peritonitis, and pneumothorax[15]. In addition, liver biopsy is not feasible for the long-term management of patients with chronic liver diseases. Noninvasive liver imaging methods such as CT, MRI, and ultrasound have been extensively studied. Ultrasound is one of most common methods to diagnose liver diseases due to its noninvasiveness, inexpensive price, and real-time ability. Machine learning algorithms based on ultrasound have been applied for analysis of steatosis and the staging of liver fibrosis. Table 1 shows the application of ultrasound-based AI in diffuse liver disease.

Fatty liver diseases: An excess amount of fat in the liver cells is found in fatty liver diseases (FLD). The main causes of FLD include obesity, alcoholism, diabetes, nonalcoholic steatohepatitis, drugs, and toxins [16,17]. FLD is related to the growing risk of cirrhosis and liver cancer. The most common cause of FLD is NAFLD, which ranges in prevalence from 25% to 45%[18]. Several noninvasive imaging methods such as CT, MRI, and ultrasound can diagnose NAFLD[19]. Ultrasound is the cheapest diagnostic method with 93% sensitivity, while hepatic steatosis is greater than 33%[18].

Conventional ultrasound is commonly used for NAFLD evaluation, but its qualitative nature, doctor dependency, and unsatisfactory accuracy limits the application. Moreover, the ultrasound images of fatty liver and early cirrhosis have many common features, making it hard to distinguish the two diseases by the human eye[20].

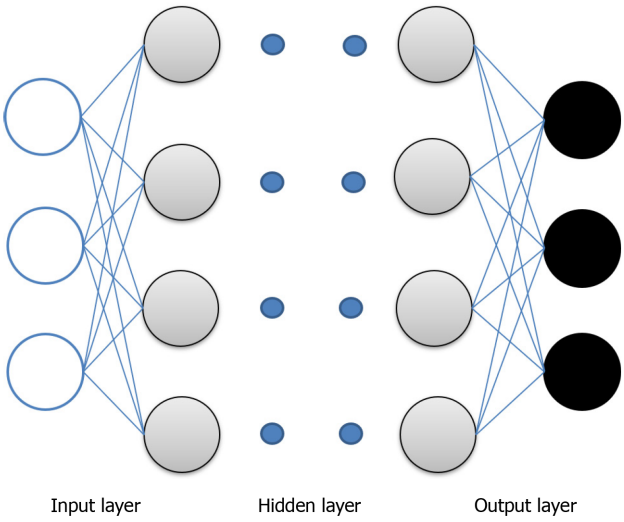
In recent years, ultrasound-based AI has demonstrated high accuracy for detection of steatosis and represents excellent reproducibility and reliability.

Byra *et al*[21] created a CNN model to acquire features from B-mode ultrasound image. It was reported that they could assess the amount of steatosis present in the liver with the area under the receiver operating characteristic curve (AUC) of 0.98, and their approach may assist the doctors in automatically assessing the amount of fat in the liver clinically[21].

Biswas *et al*[22] revealed that a deep learning-based algorithm reached a superior performance for FLD identification and risk stratification with 100% accuracy and AUC of 1.0 when compared with a conventional machine learning system support vector machine (SVM) (accuracy: 82%, AUC: 0.79) and extreme learning machine (accuracy: 92%, AUC: 0.92).

Deep learning has also been applied to quantitatively evaluate NAFLD. The radiofrequency data of ultrasound displays much more information of hepatic microstructure than that of gray-scale B-mode images[23]. Han *et al*[24] developed a deep learning algorithm that used radiofrequency data for NAFLD assessment. The results revealed that the sensitivity, specificity, and positive predictive value (PPV) for NAFLD diagnosis were 97%, 94%, and 97%, respectively. They confirmed that the quantitative analysis of raw radiofrequency ultrasound signals showed the potential of identifying NAFLD and quantifying hepatic fat fraction[24].

Liver fibrosis and cirrhosis: Patients with chronic liver disease may have no clinical symptoms for an extended period, or it may develop to fibrosis and cirrhosis[25]. The activation of the resting hepatic stellate cell into an activated myofibroblast plays an important role in the progression of liver fibrosis. The activated myofibroblast expresses abundant a-smooth muscle actin and collagen[26].



Cirrhosis, which consists of various nodules and is harder than the normal liver, is the advanced period of fibrosis[27]. Liver fibrosis and early cirrhosis are confirmed to be partly reversible. Therefore, the precise diagnosis of liver fibrosis is vital for the treatment and management of chronic liver disease patients.

In clinical practice, liver biopsy is the gold standard for the diagnosis of liver fibrosis. Various noninvasive modalities such as ultrasound and elastography have been used as alternatives to liver biopsy. Some studies suggest that AI models based on ultrasound and elastography have great potential for the classification of liver fibrosis.

Table 1 Application of ultrasound-based artificial intelligence in diffuse liver diseases

Ref.	Diseases: number of cases	Type of ultrasound	Algorithm of AI	Performance
Byra *et al*[21]	Severely obese patients: 55	B-mode	CNN	Sensitivity: 100%
				Specificity: 88%
				Accuracy: 96%
	Fatty liver disease: 38			AUC: 0.98
Biswas *et al*[22]	Normal patients: 27	B-mode	Deep learning	Accuracy: 100%
	Fatty liver disease: 36			AUC: 1.0
Han *et al*[24]	NAFLD: 140	B-mode	CNN	Sensitivity: 97%
				Specificity: 94%
	Control: 64			Accuracy: 96%
				AUC: 0.98
Yeh *et al*[28]	Postsurgical human liver samples: 20	B-mode	SVM	F2 accuracy: 91%
				F3 accuracy: 85%
				F4 accuracy: 81%
				F6 accuracy: 72%
Zhang *et al*[29]	Liver fibrosis or cirrhosis: 239	Duplex	ANN	Sensitivity: 95%
	Training group: 179			Specificity: 85%
	Validation group: 60			Accuracy: 88%
Gao *et al*[30]	S0: 4	B-mode	ANN	S0 accuracy: 100%
	S1: 16			S1 accuracy: 90%
				S2 accuracy: 70%
				S3 accuracy: 90%
	S2: 8			S4 accuracy: 100%
	S3: 5			
	S4: 4			
Lee *et al*[31]	Patients: 3446	B-mode	CNN	AUC: 0.86
	Internal validation set: 263			
	Internal test set: 266			
	External test set: 572			
Gatos *et al*[34,35]	Chronic liver disease: 70	Shear-wave elastography	SVM	Sensitivity: 94%
	Healthy: 56			Specificity: 81%
				Accuracy: 87%
Wang *et al*[36]	Liver fibrosis: 398	Shear-wave elastography	Deep learning radiomic	F4 AUC: 0.97
	Training group: 266			
	Validation group: 132			F3 AUC: 0.98
				F2 AUC: 0.85
Xue *et al*[38]	Liver fibrosis: 401	Elastography	CNN by TL radiomics	S2 AUC: 0.95
	Patient without fibrosis: 65			S3 AUC: 0.93
				S4 AUC: 0.93

Figure 1 Framework of convolutional neural networks. Blue dots represent multiple hidden layers.

AI based on conventional ultrasound: AI based on conventional ultrasound has been applied to improve their performance for the diagnosis and grading of liver fibrosis.

Yeh *et al*[28] built an SVM model to analyze liver fibrosis. B-mode images of 20 fresh postsurgical human livers were used to assess ultrasound capacity in evaluating the stage of fibrosis. The study indicated the best classification accuracy of two, three, four, and six classes were 91%, 85%, 81%, and 72%, respectively[28]. The results confirmed that the SVM model may be suggested to assess diverse liver fibrosis stage.

Other than the B-mode ultrasound, duplex ultrasound has also been applied to diagnose liver fibrosis. Using an ANN model based on duplex ultrasound, Zhang *et al*[29] demonstrated that their model reached the accuracy, sensitivity, and specificity were 88.3%, 95.0%, and 85.0%, respectively. The ANN model included five ultrasonographic parameters: thickness of spleen, liver vein waveform, the hepatic parenchyma, liver artery pulsatile index, and hepatic damping index. The study suggested that their ANN model has the potential to diagnose liver fibrosis noninvasively[29].

Studies confirmed that radiomics show great performance in the grading of liver fibrosis. By the use of texture analysis to analyze ultrasound liver images, the study found the accuracies of S0-S4 were 100%, 90%, 70%, 90%, and 100%, respectively[30].

It was reported that deep learning has great potential for liver fibrosis evaluation. Lee *et al*[31] built a deep CNN and trained a four-class model (F0 *vs* F1 *vs* F23 *vs* F4) to predict METAVIR scores. They used 13608 ultrasound images of 3446 patients who accepted surgery, liver biopsy, or transient elastography to train the deep CNN model. The model achieved a higher AUC of 0.857 for the classification of cirrhosis compared with five radiologists (AUC range, 0.656-0.816; $P < 0.05$) using the external test set [31].

AI based on ultrasound elastography: ultrasound elastography has been performed to acquire quantitative assessment of liver tissue stiffness, which is related to the grades of fibrosis. These technologies include strain elastography and shear wave elastography (SWE)[32]. Recently, some studies confirmed that the AI based on SWE has great value to identify and stage liver fibrosis.

Compared to conventional radiomics, a multiparametric ultrasonic model using machine learning algorithms demonstrated better manifestation in fibrosis assessment[33]. By quantifying color information from SWE images, Gatos *et al*[34,35] created an SVM model that could differentiate patients with liver diseases from controls with accuracy, sensitivity, and specificity of 87.3%, 93.5% and 81.2%, respectively.

Deep learning has also been applied in the assessment of liver fibrosis. A multicenter study used deep learning radiomics on 2D-SWE ultrasound images for the classification of liver fibrosis[36]. 2D-SWE ultrasound images had higher AUCs of 0.97 for F4, 0.98 for ≥ F3, and 0.85 for ≥ F2 fibrosis when compared with standard 2D-SWE.

It is necessary to contain a large training dataset for deep learning. However, it is difficult and expensive to get abundant medical images in clinics. One method to solve this problem is the employment of transfer learning (TL), which can enhance the performance by TL from other areas to the ultrasound area[37]. A study developed a CNN model by TL radiomics to assess ultrasound images of gray-scale modality and elastogram modality for the grade of accurate liver fibrosis. TL in gray-scale modality and elastogram modality revealed much higher diagnostic accuracy of AUCs compared with non-TL. Multimodal gray-scale modality + elastogram modality was confirmed to be the most precise diagnostic model with AUCs of 0.930, 0.932, and 0.950 for classifying ≥ S2, ≥ S3, and S4, respectively. It

was suggested that this TL model had excellent performance in liver fibrosis staging in clinical applications[38].

Focal liver lesion

Focal liver lesions (FLLs) are described as an abnormal part of the liver mainly coming from hepatocytes, biliary epithelium, and mesenchymal tissue[39]. Due to its cheap price, noninvasiveness, and real-time imaging, ultrasound is the preferred method for the diagnosis of FLLs. Based on this trend, the AI models using ultrasound images have more advantages over CT and MRI in routine clinical applications[40]. Table 2 shows the application of ultrasound-based AI in FLLs.

The application of AI in the diagnosis of benign and malignant FLLs: Hepatocellular carcinoma (HCC) is the fifth most common malignancy worldwide and accounts for the second leading cause of cancer-related deaths[41]. It is vital to identify benign and malignant FLLs for patients in the early stage.

AI based on conventional ultrasound: deep learning based on B-mode ultrasound has been demonstrated to be helpful in the diagnosis of benign and malignant FLLs. A CNN model was used to distinguish benign and malignant FLLs and achieved a higher accuracy than two experts[42]. Yang *et al*[43] developed a multicenter study to improve the B-mode ultrasound diagnostic performance for FLLs. The CNN of ultrasound performed high sensitivity and specificity in detecting FLLs, and it may be helpful for less-experienced doctors to enhance their judgment in liver cancer diagnosis.

AI based on B-mode ultrasound images has also been applied for the diagnosis of primary or secondary malignant liver tumors. A study proposed machine learning for discriminating HCC and metastatic liver tumors using SVM. The results revealed a classification accuracy of 91.6% with a sensitivity of 90.0% for HCCs and 93.3% for metastatic liver tumors[44].

AI based on contrast-enhanced ultrasound (CEUS): Recently, CEUS has become a commonly used ultrasound modality for the detection of FLLs[45]. Many studies have indicated that CEUS images had better sensitivity and specificity for the differentiation of malignant and benign tumors compared with B-mode images. One of the advantages of CEUS is that the images can be analyzed quantitatively. Time intensity curve (TIC) is a common quantitative analysis tool for CEUS[46]. Recently, AI based on CEUS images was reported to have great performance for the discrimination of FLLs.

Gatos *et al*[47] created a pretrained SVM algorithm to distinguish benign and malignant FLLs. In this model, a complex segmentation method based on TIC was used to detect lesions and process contours of 52 CEUS images. The accuracy, sensitivity, and specificity were 90.3%, 93.1%, and 86.9%, respectively [47]. Another study using SVM revealed that the sensitivity, specificity, and accuracy of benign and malignant grading were 94.0%, 87.1%, and 91.8%, respectively, while the classification accuracy of HCC, metastatic liver tumor, and benign were 85.7%, 87.7%, and 84.4%, respectively[46].

In addition to TIC, extracting features except TICs from a region of interest on CEUS images and videos was also applied in AI. A two-stage multiview learning framework, which was the integration of deep canonical correlation analysis and multiple kernel learning for CEUS-based computer-aided diagnosis, was proposed to identify liver tumors. The deep canonical correlation analysis-multiple kernel learning framework achieved performance for discriminating benign from malignant liver tumors with the accuracy, sensitivity, and specificity of 90.4%, 93.6%, and 86.8%, respectively[48].

The application of AI for the differential diagnosis of FLLs: With the development of AI, AI based on B-mode ultrasound images has great performance on the diagnosis of different FLLs. Hwang *et al*[49] extracted hybrid textural features from ultrasound images and used an ANN to diagnose FLLs. They indicated that the model revealed enormous potential with the diagnosis accuracy of over 96% among all FLLs groups (hemangioma *vs* malignant, cyst *vs* hemangioma, and cyst *vs* malignant)[49].

Deep learning was also applied in the distinction of different FLLs. Schmauch *et al*[50] created an algorithm that simultaneously detected and characterized FLLs. Although the amount of training data was relatively small, the average AUC of FLL detection and characterization was 0.935 and 0.916, respectively.

A CNN model was developed and validated for tumor detection and 6-class discrimination (HCC, focal fatty sparing, focal fatty infiltration, hemangiomas, and cysts)[51]. This model reached 87.0% detection rate, 83.9% sensitivity, and 97.1% specificity in the internal evaluation. In external validation groups, the model achieved 75.0% detection rate, 84.9% sensitivity, and 97.1% specificity.

CEUS also had excellent potential for AI to distinguish different FLLs. An ANN was applied to study the role of TIC analysis parameters of 4-class discrimination of liver tumors. The neural network had 94.45% training accuracy and 87.12% testing accuracy. The automatic classification process registered 93.2% sensitivity and 89.7% specificity[52].

Căleanu *et al*[53] reported the 5-class classification of liver tumors using deep neural networks with an accuracy of 88%. In this study, deep neural network algorithms were compared with state-of-the-art architectures, and a novel leave-one-patient-out evaluation procedure was presented.

All these studies indicated that AI based on conventional ultrasound and CEUS played a vital role in the detection and distinction of FLLs.

The application of AI in the management of HCC patients: Because of the development of new treatments, the management of HCC patients has become much more complicated. Radiomics can offer

Table 2 Application of ultrasound-based artificial intelligence in focal liver lesions

accurate assessment of great numbers of image features from medical images. These features that are difficult to detect by the human eye can be detected by machine learning or deep learning. AI models based on radiomics has also been reported to be applicable for the management of HCC, such as the prediction of microvascular invasion (MVI), curative transarterial chemoembolization (TACE) effect, recurrence after thermal ablation, and prognosis.

Predicting MVI: MVI is described as the invasion of tumor cells within a vascular space lined by endothelium. It has been proven that MVI is a predictor of early recurrence of HCC and poor survival outcomes[54]. The only way to confirm MVI is *via* histopathology after surgery. Patients with HCC can receive a great benefit when MVI is identified noninvasively and accurately before surgery[55]. The application of AI based on gray-scale ultrasound images and CEUS indicated good performance in predicting preoperative MVI.

A study indicated that the radiological features of gray-scale ultrasound images of gross tumoral area predicted preoperative MVI of HCC with an AUC of 0.81[56]. A CEUS-based radiomics score was built for preoperative prediction of MVI in HCC[57]. The radiomics nomogram revealed great potential in the detection of MVI with an AUC of 0.731 compared with the clinical nomogram with an AUC of 0.634. It

was indicated that the radiomics data based on ultrasound was a single predictor of MVI in HCC. Our group created a radiomics model based on CEUS to evaluate MVI of HCC patients before surgery. The model revealed a better detection in the primary group with an AUC of 0.849 *vs* 0.690 as well as the validation group with an AUC of 0.788 *vs* 0.661 when compared with the clinical model. We confirmed that the portal venous phase, delay phase, tumor size, rad-score, and alpha-fetoprotein level were single predictors related to MVI[58].

Predicting curative TACE effect: Pathways participating in important cancer-related progression, such as cell proliferation and angiogenesis, are major goals for the treatment of HCC patients. Additionally, transcription factors and cell cycle regulators are also considered to be interesting for anti-HCC drugs[59].

TACE is a widely used first-line therapy for HCC patients diagnosed at the intermediate stage. The tumor response to the first TACE treatment is highly different and obviously related to the subsequent therapies as well as the patients' survival[60]. Hence, the exact prediction of HCC responses after the first TACE treatment is vital for patients.

The prediction of tumor responses to TACE heavily depends on MRI and serological biomarkers[61,62]. But these methods achieved unsatisfactory accuracy of prediction. The application of AI based on both B-mode ultrasound and CEUS demonstrated better prediction efficacy.

An AI-based radiomics was established and validated to predict the personalized responses of HCC to the first TACE session. The deep learning radiomics-based CEUS model showed better performance compared with the machine learning radiomics-based B-mode model and machine learning radiomics-based time intensity curve of CEUS model with AUCs of 0.93, 0.80, and 0.81, respectively[63]. They suggested that the deep learning-based radiomics could benefit TACE candidates in clinical work.

Predicting recurrence after thermal ablation: Thermal ablation has been confirmed to be an available therapy for early-stage HCC patients who are unsuitable for operation or recurrence after surgery[64]. In addition, the recent 2-year recurrence rates of HCC patients who underwent thermal ablation were reported as 2%-18%[65]. The accurate preoperative prediction of thermal ablation outcomes is of great importance for HCC patients. Compared with other imaging modalities, CEUS is radiation-free and has better temporal resolution when revealing the blood supply of the tumor. The application of AI based on CEUS could be performed for the preoperative prediction of thermal ablation outcomes.

A radiomics model was created to predict the early and late recurrence of HCC patients who accepted thermal ablation[66]. The combined model including CEUS, ultrasound radiomics, and clinical factors showed better performance for early recurrence with an AUC of 0.89 and for late recurrence prediction with a C-index of 0.77.

Predicting the prognoses: Surgical resection (SR) and radiofrequency ablation (RFA) are common curative strategies for HCC patients diagnosed at the early stage[64]. Some studies have compared the long-term survival of RFA and SR for early-stage HCC patients[67,68]. However, the conclusions were sharply different. Hence, it is necessary to find useful predictive means to select the optimal patients who are suitable for RFA or SR before surgery. AI models based on CEUS had great performance for the prediction of progression-free survival (PFS).

A deep learning-based radiomics from CEUS images was built to predict the PFS of SR and RFA for HCC patients. Both SR and RFA models achieved high prediction accuracy of 2-year PFS. They also identified that a higher average probability of 2-year PFS may be acquired while some RFA and SR patients exchange their choices[69]. By utilizing conventional ultrasound images and CEUS, these AI prediction models can be applied in the individualized management of HCC patients.

APPLICATION OF ULTRASOUND-BASED AI IN UPPER GASTROINTESTINAL DISEASE

Gastric mesenchymal tumors

The majority of gastric mesenchymal tumors are occasionally found during routine esophagogastroduodenoscopy examinations. The incidence of gastric mesenchymal tumors is uncertain, but the prevalence of subepithelial tumors identified under endoscopy in Korea was reported as 1.7%[70]. Most gastric mesenchymal tumors are gastrointestinal stromal tumors (GISTs), which may metastasize to the liver and peritoneum after surgery[71,72]. Hence, distinguishing GISTs from benign mesenchymal tumors such as leiomyomas or schwannomas is of great importance in clinic practice. Endoscopic ultrasonography (EUS) is a common method to assess gastric mesenchymal tumors. It helps doctors evaluate the detailed size, shape, origin, and border of the lesions[73-75]. But the interpretation of EUS images by endoscopists is subjective and has poor interobserver agreement. Recently, EUS image interpretation using AI has developed rapidly and is applied to distinguish GISTs from benign mesenchymal tumors.

A convolutional neural network computer-aided diagnosis (CNN-CAD) model based on EUS images was developed to assess gastric mesenchymal tumors. They reported the model distinguished GISTs from non-GIST tumors with 83.0% sensitivity, 75.5% specificity, and 79.2% accuracy[76]. The CNN-CAD model had the potential to provide diagnostic assistance to endoscopists in the future.

Pancreatic diseases

EUS is currently a common tool to diagnose pancreatic diseases in clinical practice. However, the specificity for the diagnosis of pancreatic diseases using EUS images is low and deeply depends on the subjective judgment of endoscopists. Studies have confirmed that AI based on EUS improves their performance for the diagnosis of pancreatic diseases. Recently, AI using EUS images has been applied in the differential diagnosis of PC, distinguishing intraductal papillary mucinous neoplasms (IPMNs) and detecting pancreatic segmentation.

Pancreatic cancer: PC is relatively uncommon, with an incidence of 8-12 per 100000 per year. PC is attributed to hereditary germline or somatic acquired mutations in some genes such as tumor suppressor genes and cell cycle genes. These mutations are also associated with the progression and metastasis of PC. Moreover, shortened telomerase, cell turnover, and genomic instability have an important role in the development of PC[77].

The early diagnosis and surgery of PC, especially for lesions less than 1 cm, can achieve long-term prognoses with a 5-year survival rate of 80.4%[78]. However, PC is most frequently detected at an advanced stage, and the 5-year survival rate remains as low as 3%-15%[79]. Hence, early detection is vital for the treatment of PC patients. Studies have reported that AI based on EUS has great performance for the diagnosis of PC.

AI based on B-mode EUS: AI models based on B-mode EUS have been applied to improve their performance for the diagnosis of PC. Norton *et al*[80] first reported the use of CAD utilizing EUS images in pancreatic diseases in 2001. The study included 14 patients with focal chronic pancreatitis and 21 patients with PC. They showed the diagnostic sensitivity of the two diseases was 89%, and the overall accuracy was 80%[80]. However, this study cannot be referred to as AI-CAD in current applications as the number of patients was limited and the resolution of images were very low.

With the development of AI, ANN and SVM presented good performance in the diagnosis of PC[81-83]. Das *et al*[81] developed an ANN model to distinguish chronic pancreatitis from PC. The results achieved 93% sensitivity, 92% specificity, 87% PPV, 96% negative predictive value (NPV), and 0.93 AUC [81]. By using a multilayered neural network, the study confirmed the first machine learning results for the EUS images of the pancreas. But the sample size was small and lacked pathological evidence in the chronic pancreatitis and normal pancreas groups.

By selecting better texture features that included multifractal dimensional features, a quantitative measure of fractality (self-similarity), and complexity from EUS images, a SVM prediction model was created to identify PC and non-PC patients[83]. The model reached 97.98% accuracy, 94.32% sensitivity, 99.45% specificity, 98.65% PPV, and 97.77% NPV. The study demonstrated that SVM using EUS images is a useful tool for diagnosing PC and pancreatic diseases.

It was reported that AI was also applied for the age-dependent pancreatic changes on EUS images of PC cases. Ozkan *et al*[84] suggested a high-performance CAD model applying ANN to discriminate PC and noncancer patients in three age groups. In the under 40-year-old group, the accuracy, sensitivity and specificity were 92.0%, 87.5%, and 94.1%, respectively. In the 40-year-old to 60-year-old group, the accuracy, sensitivity, and specificity were 88.5%, 85.7%, and 91.7%, respectively. In the > 60-year-old group, the accuracy, sensitivity, and specificity were 91.7%, 93.3%, and 88.9%, respectively. The total performance of this model showed the accuracy, sensitivity, and specificity were 87.5%, 83.3%, and 93.3%, respectively.

Besides machine learning, deep learning has been applied to B-mode EUS images for analysis of PC. A CNN model using EUS images was developed for the detection of PC[85]. The sensitivity, specificity, PPV, and NPV were 90.2%, 74.9%, 80.1%, and 88.7%, respectively. The CNN model included six normalization layers, seven convolution layers, four max-pooling layers, and six activation layers. The EUS-CNN application was first reported to have the potential to detect PC from EUS images.

AI based on EUS elastography: Real-time EUS elastography can provide more information about the features of pancreatic masses by the use of strain assessment. It was reported that EUS elastography has been applied in the differential diagnosis of pancreatic lesions. However, the accuracy and reproducibility were unstable[86,87].

The application of AI improves their performance in the diagnosis of PC. A prospective, blinded, multicentric study using EUS elastography by ANN was performed in focal pancreatic lesions[88]. They demonstrated the sensitivity, specificity, PPV, and NPV values for the diagnosis of PC were 87.59%, 82.94%, 96.25%, and 57.22%, respectively. The study suggested that the ANN model may provide fast and accurate diagnoses in the clinical.

AI based on contrast-enhanced EUS: Contrast-enhanced EUS has been used to enhance the detection of pancreatic lesions[89]. AI based on contrast-enhanced EUS has great performance for the diagnosis of PC. An ANN model based on the TIC analysis from contrast-enhanced EUS images was designed to diagnose PC and chronic pancreatitis. The study reached 94.64% sensitivity, 94.44% specificity, 97.24% PPV, and 89.47% NPV[90]. The study suggested that the model could provide additional diagnostic value to CEUS interpretation and EUS fine needle aspiration results.

IPMNs: IPMNs are considered to be precursor lesions of pancreatic adenocarcinoma. Early surgical resection of IPMNs can provide a survival benefit for patients[91]. EUS is often used to assess the

malignancy of IPMNs in clinics. Several predictive techniques were used to diagnose the malignancy of IPMNs with no satisfactory results (70%-80%)[92,93].

Compared with human diagnosis and conventional EUS features, AI *via* deep learning algorithms was confirmed to be a more exact and objective way for the differential diagnosis of malignant IPMNs. Kuwahara *et al*[94] performed a predictive CNN model using EUS images to detect malignant IPMNs. The model reached 95.7% sensitivity, 94.0% accuracy, and 92.6% specificity. The accuracy was higher compared with the diagnosis of a radiologist (56.0%). The author suggested that the application of AI can evaluate malignant IPMNs before surgery.

Pancreatic segmentation: AI using EUS images has also been applied in pancreatic segmentation. A deep learning-based classification system was created to utilize the "station approach" in EUS of pancreas[95]. The system obtained 90.0% accuracy in classification and 0.770 and 0.813 in blood vessel and pancreas segmentation, respectively. The results were similar to that of EUS experts. Thus, this study revealed that AI has the feasibility to detect the station and segmentation of the pancreas.

APPLICATION OF ULTRASOUND-BASED AI IN LOWER GASTROINTESTINAL DISEASE

Colorectal tumors

Colorectal cancer is the third most common cancer worldwide and accounts for the second leading cause of cancer-related deaths. Moreover, a growing number of patients diagnosed with rectal cancer are under 50-years-old[96]. Colorectal cancer is attributed to gene mutations of epithelial cells, such as oncogenes, tumor suppressor genes, and DNA repair genes. The specific molecular mechanisms implicated in this type of cancer may include the instability of chromosomes and microsatellites[97].

Recently, some researchers studied tumor deposits (TDs) of rectal cancer. TDs are described as focal aggregates of adenocarcinoma located in the surrounding fat of the colon or rectum. They are discontinuous with the primary tumor and unrelated to a lymph node[98,99].

It was reported that a patient who is TD-positive has more malignant tumors, with decreased disease-free survival and overall survival[100]. However, TDs are often diagnosed by pathology only after surgery. Hence, the noninvasive preoperative prediction of TDs is important for rectal cancer patients. EUS is currently a common tool to detect rectal masses. Recently, ultrasound-based radiomics have been applied to predict the status of TDs.

Chen *et al*[101] developed an ANN system using ultrasound radiomics and clinical factors to predict TDs. Endorectal ultrasound and SWE examinations were conducted for 127 patients with rectal cancer. The accuracy was 75.0% in the validation group. The model reached 72.7% sensitivity, 75.9% specificity, and 0.743 AUC. The study suggested that ultrasound-based radiomics has the potential for the prediction of TDs before treatment. Table 3 shows the application of ultrasound-based AI in gastrointestinal disease.

CONCLUSION

In recent years, AI models using ultrasound images have developed rapidly. They can offer a more precise and efficient diagnosis and ease the burden of doctors. AI based on ultrasound has been confirmed to be helpful in diffuse liver diseases and FLLs, such as assessing the severity of NAFLD and the grade of liver fibrosis, distinguishing benign and malignant liver lesions, predicting the MVI of HCC, curative TACE effect, and prognoses after thermal ablation. In addition, AI based on EUS has great performance in gastrointestinal diseases, such as distinguishing gastric mesenchymal tumors, differential diagnosis of PC, distinguishing IPMNs, and predicting the status of TDs in rectal cancer.

However, the application of AI based on ultrasound in clinical practice has some limitations. The main reason may be due to the high variability between radiologists in ultrasound image acquisition and interpretation[102]. Hence, it is necessary to unify the ultrasonic image acquisition process as well as the standard of ultrasonic data measurement during the ultrasound examination.

In addition, some studies of AI-powered ultrasound were retrospective and trained on limited data offered by a single hospital with potential data selection bias, and the amount of data in the training set was not enough. Abundant multicenter prospective studies should assure the efficiency and stability of these AI models. Additionally, deep learning needs a large number of images, so it is necessary to establish an abundant database with common collaborative efforts.

In addition, the application of AI based on EUS has some limitations. The number of EUS examinations is overwhelmingly low compared to other examinations such as endoscopy and CT, especially in gastrointestinal diseases.

In the future, AI based on ultrasound may be used to develop highly accurate and more efficient models for more digestive diseases such as peptic ulcers, stomach neoplasms, inflammatory bowel disease, and so on. These models may heavily reduce the workload for doctors by automatic identi-

AI: Artificial intelligence; ANN: Artificial neural network; CNN: Convolutional neural network; GISTs: Gastrointestinal stromal tumors; IPMN: Intraductal papillary mucinous neoplasm; EUS: Endoscopic ultrasonography; SVM: Support vector machine.

fication of disease on radiologic and histopathologic images. Moreover, the application of AI can enable building individual management for patients as well as predicting disease progression and complications in clinics. Additionally, AI may improve distance teaching by remote monitoring and enhance medical services in undeveloped areas.

FOOTNOTES

Author contributions: Cui XW and Dietrich CF established the design and conception of the paper; Liu JQ, Ren JY, Xu XL, Xiong LY, Peng YX, Pan XF, Cui XW, and Dietrich CF explored the literature data; Liu JQ provided the first draft of the manuscript, which was discussed and revised critically for intellectual content by Ren JY, Xu XL, Xiong LY, Peng YX, Pan XF, Cui XW, and Dietrich CF; All authors discussed the statement and conclusions and approved the final version to be published.

Supported by the National Natural Science Foundation of China, No. 82071953; and Medical Youth Top-notch Talent Project of Hubei Province.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.

Abstract

The incidence of frailty gradually increases with age. This condition places a heavy burden on modern society, of which the aging population is increasing. Frailty is one of the most complicated clinical syndromes; thus, it is difficult to uncover its underlying mechanisms. Oxidative stress (OS) is involved in frailty in multiple ways. The association between the gut microbiota (GM) and frailty was recently reported. Herein, we propose that OS is involved in the association between the GM and the occurrence of frailty syndrome. An imbalance between oxidation and antioxidants can eventually lead to frailty, and the GM probably participates in this process through the production of reactive oxygen species. On the other hand, OS can disturb the GM. Such dysbiosis consequently induces or exacerbates tissue damage, leading to the occurrence of frailty syndrome. Finally, we discuss the possibility of improving frailty by intervening in the vicious cycle between the imbalance of OS and dysbiosis.

Key Words: Oxidative stress; Gut microbiota; Frail syndrome; Traditional Chinese medicine

Core Tip: Frailty is defined as a decrease in the reserve and restoring capacity of the body. It is recognized that oxidative stress (OS) is involved in frailty in multiple ways; however, the underlying mechanisms are still unknown. The association between the gut microbiota (GM) and frailty was recently reported. Herein, we propose that OS is involved in the association between the GM and the occurrence of frailty syndrome. The role of the imbalance between OS and dysbiosis is discussed in this review.

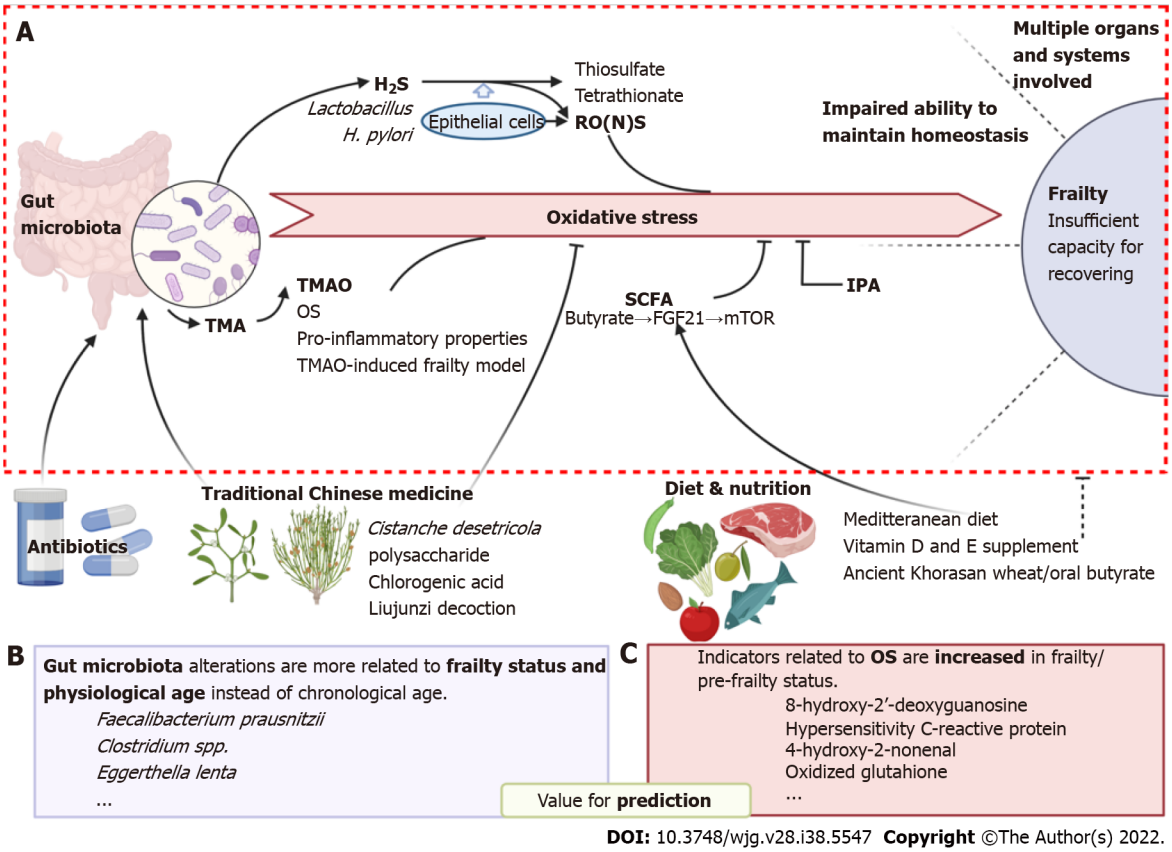
INTRODUCTION

Frailty is one of the most complicated clinical syndromes and is defined as a decrease in the reserve and restoring capacity of the body[1]. For frail people, a slight irritant can result in strong responses, which require a longer period to recover. Thus, frailty can also be regarded as a decline in the ability to maintain homeostasis. Multiple organs and systems, such as the skeletal muscle, immune, endocrine, hematopoiesis, and cardiovascular systems, are involved in the process of frailty[2]. Patients with frailty have a high risk of developing age-related diseases, including neurodegenerative diseases (such as dementia), type II diabetes, atherosclerosis, and chronic heart failure[3]. Frailty places a heavy burden on modern society, which has an extensive elderly population.



Although there are a few hypotheses at present, the mechanisms involved in frailty remain unknown. Researchers have different opinions about the origin of frailty. It is generally accepted that frailty is related to aging. According to Jayanama *et al*'s survey[4], among 9030 volunteers over the age of 20, the average age with a frailty index score of less than 0.1 was 39.7 years old. Moreover, those who had an average age of 65.3 years had a frailty index score of more than 0.3. Miller *et al*[5] reported that 75.4% of 18- to 64-year-old people have an simplified, 5-item frailty index (sFI) = 0, which means they are considered nonfrail. In contrast, 20.1% of the 80 to 89-year-old age group had an sFI ≥ 3, and thus, this age group can be referred to as a frail population. There were 9252 patients included in this analysis.

The incidence of frailty increases with age. However, frailty is not necessarily related to aging. According to an investigation by Xing and Guo[6], 43.2% of 683 older people (≥ 60 years old) from Beijing did not have frailty, while the incidence of prefrailty was 45.7%, and 11.1% of the cohort was frail. These data suggest that healthy aging could be achieved by preventing and improving frailty status.

With the increasing focus on frailty, emerging evidence has increased our understanding of this syndrome. Findings from centenarians suggest that specific gut microbiota (GM) constituents may contribute to healthy aging. For example, *Escherichia*, *Ruminococcus*[7], and *Clostridioides leptum* are increased, whereas *Faecalibacterium prausnitzii* and other species are decreased in centenarians[8]. Biagi *et al*[8] also showed that the proportion of *Clostridioides* cluster XIVa was significantly lower in centenarians than in elderly and younger adults. Furthermore, the diversity and abundance of the GM vary between elderly adults and centenarians. However, the bridge between the GM and the occurrence of frailty remains unclear. In this review, we proposed the possible mechanisms involved in frailty from the perspective of the GM and oxidative stress (OS). The correlations and potential causality among these factors are discussed. The idea of using GM biomarkers to predict frailty is then proposed prospectively. Notably, frailty is not an irreversible status[9]. Timely interventions have the potential to revert the prefrailty or frailty state to a nonfrailty state. According to existing research, dietary interventions are the most commonly used treatment for frailty[10]. Moreover, traditional Chinese medicine (TCM) is a unique application for the treatment of frailty (Figure 1). Achieving healthy aging is becoming a core goal of future research.

THE GM AND FRAILTY

The abundance and diversity of the GM changes with aging. Alterations in the GM partially lead to individual differences in the health status of elderly people by interacting with the host immune system [11]. Evidence has shown that the elderly population has higher abundances of *Clostridioides* cluster XIVa, *Faecalibacterium prauanitzii, Actinomycetes* (mainly *Bifidobacterium*) and *Proteobacteria* than those of young adults[12]. Biagi *et al*[8] showed that the abundance of *Clostridioides* cluster XIVa was significantly higher in the elderly population (49%) than in the centenarians (34%) and the young population (44%). There was no significant difference in the abundance of *Clostridioides* cluster IV among these three age groups, but the subgroups had a different tendency to change. The abundance of *Faecalibacterium*

Figure 1 Oxidative stress is involved in the association between the gut microbiota and frailty syndrome. A: Involving molecular and pathways of how oxidative stress bridges gut microbiota and frailty; B and C: Potential bacterial species and oxidative markers which are valuable for prediction of frailty are listed in B and C, respectively. In addition, possible intervene strategies including traditional Chinese medicine and diet & nutrition are shown at the bottom of the figure. Created with BioRender.com. OS: Oxidative stress; TMA: Trimethylamine; SCFA: Short-chain fatty acid; FGF21: Fibroblast growth factor 21; IPA: Indole-3-propionic acid; RONS: Reactive oxygen and nitrogen species; 8-OdG: 8-hydroxy-2'-deoxyguanosine; 4-HNE: 4-hydroxy-2-nonenal; GSSG: Glutathione.

prausnitzii et rel. decreased in centenarians, and the abundance of *Clostridioides leptum et rel.* was increased. Centenarians had the highest abundance of *Bacilli* (12%) and *Proteobacteria* (2.6%), and the young population and the old population had similar proportions of *Bacilli* (5%) and *Proteobacteria* (1.2%). Jackson *et al*[13] studied the relationship between frailty and the composition of the GM. They found that frailty was negatively correlated with the abundance of *Clostridioides* (in which it accounted for the largest proportion of the GM). Moreover, frailty was positively correlated with the abundance of *Eggerthella lenta*. Centenarians, who are regarded as the "healthy aging" population, have a different GM composition than the aged population. This finding indicates that the GM is not entirely chronological age-correlated but that it is more closely related to the frailty status of the body.

In addition to chronological age, physiological age may better reflect the correlation between frailty and the GM (Figure 1B). In the study by Maffei *et al*[14], 85 volunteers aged 43-79 years were divided into low, medium and upper groups according to either physiological age or chronological age. The chronological age is the number of years from birth to the present. Physiological age was assessed by 34 items of the frailty index (frailty index 34, FI_{34}). According to the FI_{34} value, there were significant differences in the abundance and diversity of the GM among the three age groups. Excluding the effect of sex, body mass index, antibiotic usage, and other confounders, *Eggerthella, Rumen coccus* and *Coprobacillus* were the three main species with the greatest influence. According to the Rockwood FI value, *Faecalibacterium prausnitzii* was negatively correlated with age, while *Eubacterium dolichum* and *Eggerthella lenta* were positively correlated with age[15]. However, there was no significant difference in the GM among the three groups according to chronological age. Although there are contradictory changes in certain strains in the gut, it can be concluded that the change in *Clostridioides* abundance with age is the most remarkable. All the experiments mentioned above suggest that the GM changes with frailty status and that there is a potential link between the GM and frailty syndrome.

In frailty, the most significant change in the GM is a decrease in diversity. In the frail aged population, the microbiota shifts toward a predomination by *Bacteroidetes*, especially in the genus *Prevotella* and its subspecies. Changes in microbiota diversity affect the influence of the metabolites and pathways related to the microbiota. For instance, the GM regulates estrogen levels by secreting β-glucuronidase. β-glucuronidase is an enzyme that can deconjugate estrogen into the active form. Low levels of estrogen downregulate physiological functions that affect neural development, cardiovascular

health, bone density and neoplastic diseases[16]. Scientific evidence suggests that estrogen supplementation could improve physiological functions that prevent or reverse frailty[17]. Said *et al*[18] found that diarylpropionitrile, an estrogen receptor β agonist, had longevity-promoting properties and could reverse frailty.

THE ROLE OF OS IN FRAILTY

OS was regarded as one of the main causes of frailty as early as the 1950s. Harman[19] first proposed the free radical theory of aging; according to this theory, oxygen free radicals damage cell components and intercellular substances, causing the deterioration of body functions and age-related diseases. In the 1980s, OS was discovered. The advent of OS indicates that the balance between oxidation and antioxidation is inclined toward oxidation. This leads to neutrophil inflammatory infiltration, an increase in protease secretion, and the generation of a large number of oxidative intermediates. The study by Viña *et al*[20] suggested that OS was an important negative factor that led to aging and diseases, such as cardiovascular disease, neurodegenerative disease, chronic obstructive pulmonary disease or cancer and other illnesses in aged individuals. Some researchers have thought that oxidative damage may be due to the imbalance between antioxidation defenses and reactive oxygen and nitrogen species (RONS), thus inducing cell apoptosis. This imbalance would lead to alterations in the expression of a number of transcription factors and then cause chemical modifications in macromolecular substances, such as lipids, proteins and DNA[21,22].

Since the free radical theory of aging was proposed, increasing concern has been given to the influence of OS on frailty (Figure 1C). Wu *et al*[23] screened 90 volunteers who were older than 65 years old, dividing them into a frailty group, a prefrailty group and a nonfrailty group according to Fried's phenotype. The serum levels of OS biomarkers such as 8-hydroxy-2′-deoxyguanosine (8-OdG), metabolic markers such as albumin, and inflammatory markers such as hypersensitivity C-reactive protein (hs-CRP) were measured by competitive enzyme-linked immunosorbent assay. The results demonstrated that the serum albumin and hs-CRP levels in the frail group were higher than those in the other two groups. Furthermore, the levels of 8-OdG and hs-CRP increased with the progression of frailty. Serviddio *et al*[24] compared the levels of oxidized glutathione (GSSG), tumor necrosis factor-α, malondialdehyde (MDA), 4-hydroxy-2-nonenal (4-HNE), and other OS-related indicators in patients with frailty syndrome with those in nonfrail individuals. The data suggested that these indicators of OS were all significantly increased in frail individuals.

In addition to the direct evaluation of the frailty index, OS was also found to be related to sarcopenia. Severe sarcopenia in the elderly was defined as the prophase of frailty by the European Working Group on Sarcopenia. Bernabeu-Wittel *et al*[25] found that in 444 polypathological patients, 97 patients had sarcopenia. The number of patients with a combination of sarcopenia and frailty was 80. The authors also reported that OS markers were significantly increased in patients with sarcopenia, frailty or both. OS was evaluated by the levels of catalase, GSSG reductase, total antioxidant capacity to reactive oxygen species (ROS), and superoxide dismutase (SOD). Coto Montes *et al*[26] found that sarcopenia was closely related to lipid peroxidation. Significant increases in biomarkers such as MDA and 4-HNE were observed in 200 independent 80-year-old persons who had been diagnosed with sarcopenia. Liu *et al*[27] also discovered that the incidence of frailty increased with a rise in the levels of interleukin-6 (IL-6), isoprostaglandin and lipoprotein phosphorylation A2. These studies suggested a correlation between frailty and OS. OS-related biomarkers in serum may be potential biomarkers for predicting frailty. This possibility needs further study.

THE UNDERLYING MECHANISM OF THE INFLUENCE OF THE GM ON FRAILTY SYNDROME WAS ANALYZED BY OS

OS is affected by many factors *in vivo* and *in vitro*. The GM plays a role as "environmental factors" which regulates ROS levels in plasma and maintaining the functions of the digestive, endocrine, immune, skeletal, cardiovascular, and nervous systems. The stability of the GM is fragile and easily affected by external factors, including diet, heavy use of drugs, geographic position, individual lifestyle, and the genetic background of the host[28]. Once the GM is disturbed ("dysbiosis"), it may cause a series of related illnesses, such as inflammatory bowel diseases, obesity, and type II diabetes. These diseases can also affect the oxidative balance, thus forming a vicious cycle.

For example, a variety of colon bacteria, such as *Fusobacterium*, *Clostridioides*, *Escherichia*, *Salmonella*, *Klebsiella*, *Streptococcus*, *Desulfovibrio* and *Enterobacter*, can convert sulfide to hydrogen sulfide (H_2S)[29]. Intestinal epithelial cells protect themselves by converting H_2S into thiosulfate ($S_2O_3^{2-}$). Thiosulfate can be oxidized to tetrathionate ions ($S_4O_6^{2-}$) in the case of intestinal inflammation (Figure 1A). This process is accompanied by the formation of RONS. In both anaerobic and microaerobic environments, tetrathionate can specifically promote the proliferation of *Salmonella enterica Typhimurium* model strains

[30]. It has also been reported that certain GM can cause a sharp increase in ROS. *Lactobacillus* is a strong inducer of ROS. It can stimulate the production of ROS by enhancing the ability to pass through the mucous membrane or increasing the secretion of mucus. Additionally, it can interact with certain cellular receptors, such as formylated peptide receptors or Toll-like receptors[31,32]. In addition, *Lactobacilli* promotes the oxidation of soluble redox proteins, such as GSSG and thioredoxin, and it facilitates the transcription of redox regulatory factors by activating the nuclear factor erythroid 2-related factor 2 pathway[32]. The pathogenic mechanisms of action of *Helicobacter pylori* (*H. pylori*) may also be related to its promotion of ROS production. *H. pylori* can induce severe white blood cell tissue infiltration and release virulence factors that stimulate epithelial cells to produce ROS and secrete myeloperoxidase, chemokines, and proinflammatory cytokines. Consequently, *H. pylori* results in gastrointestinal microbiome dysbiosis and induces nonalcoholic fatty liver disease (NAFLD)[33]. The antioxidant enzyme SOD can be used to treat NAFLD. SOD can convert superoxide anion into hydrogen peroxide and molecular oxygen, thus preventing the accumulation of ROS[34]. In addition to *H. pylori*, the GM has been proposed to be strongly associated with the development and progression of metabolic diseases, including NAFLD[33]. NAFLD patients showed lower fecal microbial diversity than that of healthy controls in one study[35]. At the taxonomic and functional levels, another recent study showed that *Lactobacilli* inhibited the incidence and development of NAFLD by improving hepatic mitochondria and lipid metabolism by promoting the production of the antioxidant GSSG[36].

These studies indicate that the activation of OS by the GM is a possible mechanism of frailty. For example, gut microbes metabolize choline, L-carnitine and betaine in the daily diet to trimethylamine (TMA). These substances are mainly found in red meat, meat products, eggs, and shellfish[37,38]. Nine GM strains can convert choline to TMA: *Anaerococcus hydrogenalis*, *Clostridioides asparagiforme*, *Clostridioides hathewayi*, *Clostridioides sporogenes*, *Escherichia fergusonii*, *Proteus penneri*, *Providencia rettgeri*, *Edwardsiella tarda* and *Providencia rustiganii*. These species belong to *Firmicutes* and *Proteobacteria*[39]. Liver enzymes further convert TMA to TMAO through the flavin-containing monooxygenase (FMO) family members FMO1 and FMO3[37]. Researchers have found that the level of TMAO was increased in the aged population and that TMAO was independently associated with frailty. Nam *et al*[40] reported that the average levels of TMAO were 3.21 μM and 4.04 μM in nonfrail and frail participants, respectively. Moreover, participants who had the highest plasma TMAO levels showed a significant 3.7-fold increase in the incidence of frailty syndrome. A high level of plasma TMAO can increase the risk of stroke, atrial fibrillation, diabetes, congestive heart failure, chronic kidney disease, coronary artery disease, peripheral artery disease and other cardiovascular diseases, which are associated with frailty [40]. Moreover, TMAO significantly increases OS, inflammatory conditions and endothelial dysfunction. TMAO stimulates the TXNIP-NLRP3 inflammasome and activates the release of the inflammatory cytokines IL-1β and IL-18. However, it inhibits the production of endothelial nitric oxide (NO) synthase and NO[41]. It has also been reported that TMAO can promote inflammatory hepatocellular carcinoma by inducing ROS and activating ILK/AKT/mammalian target of rapamycin (mTOR) signaling *via* POSTN[42]. Our previous studies showed that administration of TMAO produced a novel model of frailty in mice[43]. In this TMAO-induced frailty model, the abundance of *Firmicutes* was decreased slightly, while the abundance of *Bacteroidetes* was significantly increased in the gut. The ratio of *Firmicutes* to *Bacteroidetes* (F/B) was significantly decreased. Relevantly, the F/B ratio is reported to be a potential marker of obesity and GM disorder[44], both of which are potential factors of frailty[45,46]. According to an investigation, obese females have higher FI values than those of nonobese females. In addition to TMAO, short-chain fatty acids (SCFAs) are also common metabolites of the GM that are converted from undigested carbohydrates, such as starch and pectin (Figure 1A). Butyrate is a SCFA product. Studies have shown that there is a significant association between SCFAs/butyrate and gut/celiac diseases[47,48]. It is transcriptionally activated by peroxisome proliferator-activated receptor α by replacing histone deacetylase 3 on the fibroblast growth factor 21 (FGF21) promoter. This reaction actives FGF21 and induces the expression and secretion of FGF21[46]. FGF21 regulates the adenosine monophosphate-activated protein kinase-Sirtuin1-mTOR pathway, which is associated with longevity. FGF21 can also alleviate various diseases related to aging[49,50]. In addition, the GM can affect the levels of inflammation by regulating the immune system and can affect insulin resistance by regulating the metabolomic system[51].

In addition to these metabolites, indole-3-propionic acid (IPA), another microbiota-derived metabolite of tryptophan, has been proven to have a positive impact at the cellular level by preventing OS injury and lipoperoxidation and inhibiting the synthesis of proinflammatory cytokines[52], suggesting that IPA may be a promising new target for improving frailty.

The GM and metabolites changes with frailty. Scientific evidence also shows that some antibiotics can reverse frailty. This action may be due to the effect of antibiotics changing the composition of the GM. For example, rapamycin is a broad-spectrum antibiotic. It also acts as an immunosuppressor. Rapamycin regulates protein synthesis and redox reactions. Animal studies have shown that rapamycin prolongs lifespan and improves frailty[50]. These results indicate that the GM plays an important role in the process of frailty *via* OS.

POTENTIAL INTERVENTIONS FOR FRAILTY

By understanding the role of the GM and OS in frailty, several interventions have been proposed to improve this syndrome and to achieve the goal of healthy aging.

Effect of diet on frailty

One possible intervention is to regulate the GM *via* the daily diet. Data from short-lived organisms, such as yeast, worms and fruit flies, showed that diet had an anti-senescence effect and prolonged the lives of these organisms by enhancing stress resistance, reliance on lipid fuel use, and the activation of proteostatic mechanisms[53]. Such effects of diet and nutrition on aging can also be reproduced in humans [54]. For example, the Mediterranean diet can improve frailty. The Mediterranean diet is characterized by an increase in the consumption of vegetables, legumes, fruits, nuts, olive oil and fish[55]. At the same time, the consumption of meat and unsaturated fatty acids is reduced. The Mediterranean diet provides a higher intake of micronutrients, such as antioxidant nutrients, polyphenols and plant bioactive compounds[56]. Ghosh *et al*[57] found that one year of Mediterranean diet intervention can change the composition of the GM and alleviate frailty. Some of the GM that belong to the "diet positive" taxa increased, including *Faecalibacterium prausnitzii*, *Roseburia*, *Eubacterium* (*E. rectale, E. eligens,* and *E. xylanophilum*), *Bacteroides thetaiotaomicron*, *Prevotella copri* and *Anaerostipes hadrus*. An increase in these microbiotas facilitates the production of SCFAs and the enhancement of the anti-inflammatory capacity. On the other hand, the microbiota deemed to be "diet negative" taxa, such as *Ruminococcus torques*, *Collinsella aerofaciens*, *Coprococcus comes*, *Dorea formicigenerans*, *Clostridioides ramosum*, *Veillonella dispar*, *Flavonifractor plautii* and *Actinomyces lingnae*, were reduced. These "diet negative" taxa are associated with type II diabetes, colorectal cancer, atherosclerosis, cirrhosis and inflammatory bowel disease. With the progressive aggravation of frailty symptoms, the "diet-positive" taxa decreased, and the "diet-negative" taxa increased. Proper nutritional supplements can improve frailty. Bo conducted a double-blind experiment and found that mixed supplementation with whey protein, vitamin D and vitamin E can significantly improve muscle mass and strength (handgrip strength)[58]. It was also used to treat elderly individuals with sarcopenia, and the supplementation improved frailty and quality of life. Moreover, the Mediterranean diet was found to tend to increase the plasma concentration of IPA[52]. IPA could reduce the level of OS in the body and help to improve frailty.

In addition to the Mediterranean diet, some other diet regimens can also improve GM and OS. For example, the replacement diet based on ancient Khorasan wheat results in beneficial GM compositional and functional modifications that positively correlate with an improvement in fibromyalgia symptomatology[59]. A habitual diet supplemented with oral butyrate could reduce the production of ROS in leukocytes[60]. Whether these diet regimens could improve frailty remains to be further investigated.

Effect of TCM on frailty

With an increasing number of studies on TCM, many effective monomers and prescription preparations of TCM have been found to improve frailty by regulating the GM and OS. For example, *Cistanche deserticola* and *Eucommia ulmoides* are common TCM with a tonifying effect on the kidneys, which are important organs for aging[61-63]. Modern pharmacological investigations have demonstrated that both TCMs can regulate the GM and OS. *Cistanche deserticola* polysaccharide is one of the main active components of *Cistanche deserticola*. It can produce antiaging effects by scavenging free radicals, reducing telomerase activity, improving mitochondrial antioxidant capacity and improving mitochondrial energy metabolism[64]. Moreover, *Cistanche deserticola* polysaccharide can inhibit the growth of a variety of gut pathogenic bacteria and can promote the growth of probiotics. These effects help to maintain the health of the GM[65]. Chlorogenic acid is one of the main effective components of *Eucommia ulmoides*, and it has strong anti-inflammatory and antioxidant effects. It can reduce OS and improve mitochondrial dysfunction[66]. Furthermore, chlorogenic acid and its hydrolytic form, which is called caffeic acid, have been demonstrated to alleviate inflammation and OS by improving the GM[67]. This effect is manifested by an increase in the content of *Ackermann* bacteria and the restoration of the abundance of GM[68]. It can increase the expression of tight junction proteins in intestinal epithelial cells to repair the intestinal barrier and reduce permeability[69]. These actions may contribute to the antiaging effect of chlorogenic acid[69] and further prolong the lifespan in experiments with *Caenorhabditis elegans*[70]. Liujunzi decoction, a TCM prescription consisting of Dangshen, Tuckahoe, Atracylodes macrocephala, Licorice, Pinellia ternata and Orange peel, was found to significantly improve the frailty state of elderly patients with stable chronic obstructive pulmonary disease. This effect was significantly better than that of tiotropium bromide[71]. In addition, administration of Liujunzi decoction for eight weeks increased the muscle weight and exercise endurance of the frail patients. Supplementation with Chinese medicinal plant extracts from *Lonicera hypoglauca* and *Scutellaria baicalensis*, as well as *Dihydroquercetin* supplementation, could mitigate colonic inflammation by regulating OS and the GM[72,73].

Since TCM is popular in China, Japan and other East Asian regions, most of the available literature to date is limited to the data obtained from Asian populations. However, considering that most modern pharmacological studies are performed with standard experimental animals, the anti-frailty effect of

these TCMs may potentially be extended to Western populations based on these basic research data. However, these medicines still need to be more widely investigated in studies involving a larger population.

CONCLUSION

In summary, the abundance and diversity of the GM were found to change with age. Specific GMs and their metabolites stimulate the production of ROS and affect OS in the body, leading to damage to multiple biological macromolecules. The occurrence of OS may be the intermediate process of the GM that leads to frailty, producing a direct action on the body. This may be one of the precipitating factors of frailty syndrome. Thus, the GM and its metabolites can be used as biomarkers of frailty syndrome. Regulating the GM and OS by diet or TCM could help to improve frailty. Additionally, there is increasing evidence indicating that circadian rhythms may also play important roles in mediating the impact of the GM on chronic diseases[74]. Clarifying the mechanisms involved in frailty from the perspective of the GM may be important to achieving the goal of healthy aging.

Abstract

BACKGROUND

The thyroid-gut axis has a great influence on the maintenance of human health; however, we know very little about the effects of low-dose ionizing radiation (LDR) on thyroid hormone levels and gut microbiota composition.

AIM

To investigate the potential effects of low-dose X-ray radiation to male C57BL/6J mice.

METHODS

Peripheral blood was collected for enzyme-linked immunosorbent assay (ELISA), and stool samples were taken for 16S ribosomal RNA (rRNA) gene sequencing after irradiation.

RESULTS

We found that LDR caused changes in thyroid stimulating hormone (TSH) levels in the irradiated mice, suggesting a dose-dependent response in thyroid function to ionizing radiation. No changes in the diversity and richness of the gut microbiota were observed in the LDR-exposed group in comparison to the controls. The abundance of *Moraxellaceae* and *Enterobacteriaceae* decreased in the LDR-exposed groups compared with the controls, and the *Lachnospiraceae* abundance increased in a dose-dependent manner in the radiated groups. And the abundances of *uncultured_bacterium_g_Acinetobacter*, *uncultured_bacterium_o_Mollicutes_RF39*, *uncultured_bacterium_g_Citrobacter*, and *uncultured_bacterium_g_Lactococcus* decreased in the radiated groups at the genus level, which showed a correlation with radiation exposure and diagnostic efficacy. Analysis of

functional metabolic pathways revealed that biological metabolism was predicted to have an effect on functional activities, such as nucleotide metabolism, carbohydrate metabolism, and glycan biosynthesis and metabolism. Furthermore, Kyoto Encyclopedia of Genes and Genomes pathway annotation also suggested that changes in the gut microbiota were related to processing functions, including translation, replication and repair.

CONCLUSION

LDR can change thyroid function and the gut microbiota, and changes in the abundances of bacteria are correlated with the radiation dose.

Key Words: Low-dose ionizing radiation; Thyroid; Gut microbiota; Thyroid-gut axis

INTRODUCTION

According to microecological theory, the ecological balance of the nervous system, endocrine system, metabolic system, microbial system and immune system is the essence of life[1]. The thyroid is an important endocrine gland that regulates multiple metabolic pathways by producing thyroid hormones and has a great impact on the regulation of the internal environment[2]. Several investigations have indicated that the gut microbiota may indirectly participate in disease development and might become a promising biomarker for immune-related adverse events[3]. Studies have found that intestinal flora are related to various thyroid diseases, and the "thyroid-gut axis" theory has been proposed accordingly[4, 5]. The mechanism by which the thyroid-gut axis maintains homeostasis under external stimulation deserves further study.

As one of the environmental stressors affecting people worldwide, low-dose ionizing radiation (LDR) exposure is usually from medical radiotherapy, radiation-contaminated areas and human space exploration[6,7]. The studies previously reported have indicated that the biological responses of LDR exposure on epidemiology, animals, and cells are paradoxical due to discrepancies in the dose rate[8]. The role of LDR in inducing apoptosis, stimulating antioxidant capacity and repairing DNA damage has been well established[9]. Conversely, LDR exposure from radiotherapy for the treatment of autoimmune diseases or carcinoma is associated with an increasing risk of cardiovascular disease or secondary carcinoma[10]. For the thyroid, the levels of thyroid stimulating hormone (TSH), free triiodothyronine (fT3) and free thyroxine (fT4) have been reported to be affected by LDR exposure[11]. In addition, changes between external irradiation and the gut microbiota have been preliminarily confirmed[12]. Thus, we want to know how the thyroid-gut axis responds to radiation exposure and what roles the thyroid and gut microbiota play in an individual's response to radiation injury.

The objective of our research was to investigate changes in thyroid hormone levels and gut microbiota composition in LDR-exposed mice by enzyme-linked immunosorbent assay (ELISA) and 16S rRNA gene sequencing, respectively. Our research revealed the abundances of microbial species in the gut ecosystem following dose-modulated LDR exposure. These investigations predicted possible LDR-induced gut microbiota disorders based on variations in microbial species abundance. Our research aims to explore the influence of LDR on homeostasis from the "thyroid-gut axis" perspective for the first time and may provide a concrete conceptual and analytical basis for the additional study into the long-term impact of LDR on human health.

MATERIALS AND METHODS

Mice and samples

Thirty 6-wk-old female wild-type C57BL/6J mice were divided equally into five groups after one week of adaptive feeding at the Science and Innovation Center of Shanghai Tenth People's Hospital (ID Number: SHDSYY-2022-4381). The low-dose irradiation conditions were as follows: Dose rate, 0.05 Gy/min; 1 min/time; and once every other day. Irradiation was completed by the Irradiation Center of the Institute of Radiation Medicine, Tongji University (160 keV, 1 mA). The two groups were the test group and control group. And the test group was further divided into four groups according to the radiation dose, namely, the 0.05 Gy group, 0.10 Gy group, 0.15 Gy group, and 0.20 Gy group. The general condition of the mice was observed during the experiment.

Assays of thyroid function and acquisition of thyroid tissue

Peripheral blood was collected from the mouse tail vein to measure thyroid hormone levels when the mice completed the planned dose of radiation exposure within 24 h. Serum levels of TSH, fT4, and fT3 were assayed by an ELISA kit (Rayto RT-6100). Histological sections of mouse thyroid tissue were prepared by paraffin embedding and stained with hematoxylin and eosin (HE).

DNA extraction and 16S rRNA gene sequencing

Stool samples were stored in a sterile container and snap-frozen with liquid nitrogen following collection at -80 °C (Sarstedt, 80.734.311, Germany). Using the E.Z.N.A. Soil Kit for DNA extraction (Omega, Bio-Tek, Norcross, GA, United States) and using a Nanodrop 2000 to measure the concentration of bacterial DNA (Thermo Scientific, Wilmington, United States). All the fecal samples were stored at -20 °C until ready for sequencing. Then, the V3-V4 region of the bacterial 16S rRNA was amplified by polymerase chain reaction with barcode index primers using TransStart FastPfu DNA Polymerase (TransGen BioTech, AP221-02, Beijing, China) on an ABI GeneAmp 9700 polymerase chain reaction system (United States). Amplicons were then purified by gel extraction (AxyPrep DNA Gel Extraction Kit, Axygen Biosciences, United States) and quantified using QuantiFluor-ST (Promega, United States). The adapter sequences were added to the purified amplicons using a TruSeq™ DNA Sample Prep Kit (Illumina, San Diego, United States), and paired-end sequencing was performed using an Illumina MiSeq instrument (Illumina, San Diego, United States) (Figure 1).

Microbial analysis

The paired-end readings obtained by MiSeq were first merged by overlapping sequences. Filtering and quality control allow the sequences to be optimized. Operational taxonomic units (OTUs) were clustered using a 97% similarity cutoff with UPARSE (version 10.0). Cohort was randomly generated for a cross-sectional study that included 24 mice exposed to radiation and 6 controls. The alpha diversity was analyzed in terms of the species richness, including CHAO, ACE, SHANNON, and SIMPSON indices. Beta diversity was used to calculate structural variation by principal coordinates analysis (PCoA) and nonmetric multidimensional scaling (NMDS) and was mapped from principal coordinate analysis. Functional pathway analysis was conducted in accordance with the Kyoto Encyclopedia of Genes and Genomes (KEGG) database based on our microbial information.

Statistical analysis

Data that fit the normal distribution are expressed as the mean ± SD, and nonnormally distributed data are expressed as the median (interquartile). The t test or rank-sum test was used for comparing the thyroid hormone levels between the control group (n = 6) and test group (n = 24). Significant differences in the diversity index and microbial abundance between groups was determined by the Mann-Whitney U test. The microbial taxa with differences between the two groups were identified by linear discriminant analysis (LDA) effect size (LEfSe), with an LDA threshold value of > 2.0. The correlation between microbiota abundance and thyroid function was analyzed by Spearman correlation coefficient. The area under the curve (AUC) reflected the diagnostic accuracy of the bacterial indicators based on the receiver operating characteristic (ROC) curve. Unless otherwise stated, all analyses were performed using SPSS Statistics (Version 20.0). Statistical significance was set at $P < 0.05$ for analyses.

RESULTS

LDR caused changes in TSH levels in the mice

To understand changes in thyroid function in the irradiated mice, the levels of thyroid hormones in peripheral blood were determined by ELISA, including TSH, fT3, and fT4. As shown in Figure 2A, the TSH level of mice in the test mice (1.487 ± 0.347 mU/L) was obviously lower than the control mice (1.799 ± 0.289 mU/L), t = 2.188, P = 0.037). The level of TSH was the lowest in the 0.05 Gy group (1.262 ± 0.254 mU/L), which was the lowest among the four test subgroups, and in the 0.20 Gy group, it was the

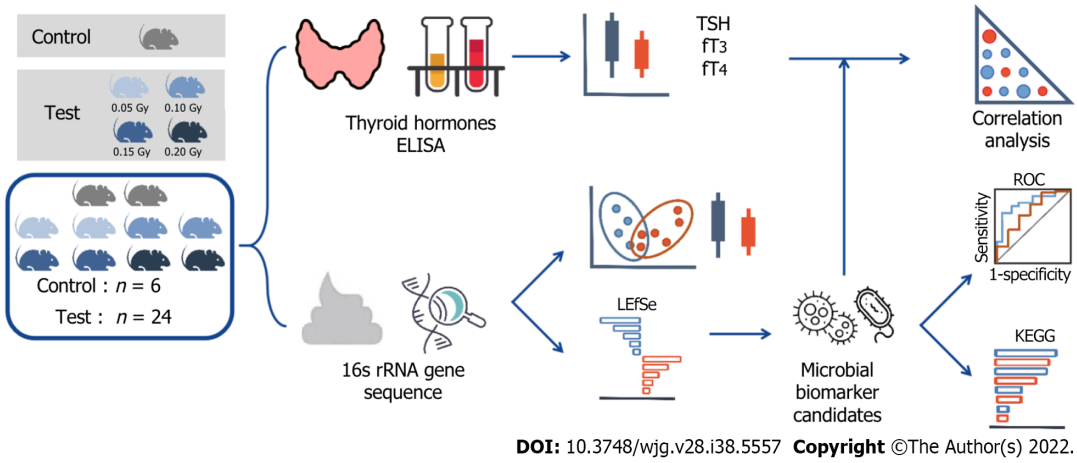

Figure 1 Graphical abstract. Schematic showing sample workflow from sequencing to analysis. TSH: Thyroid stimulating hormone; ELISA: Enzyme-linked immunosorbent assay; ROC: Receiver operating characteristic; KEGG: Kyoto Encyclopedia of Genes and Genomes; LEfSe: Linear discriminant analysis effect size.

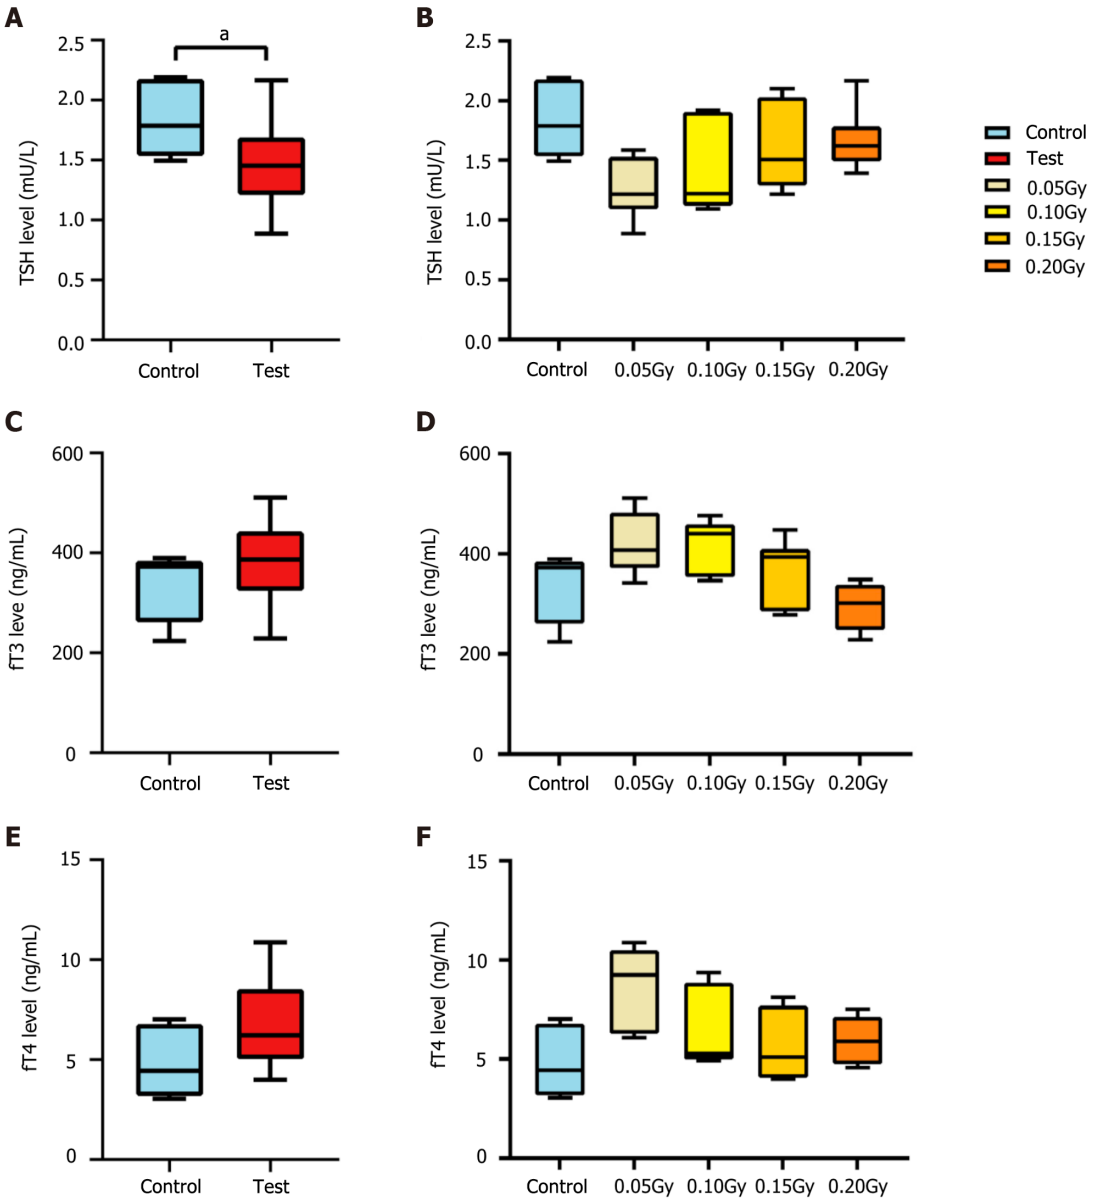
highest (1.664 ± 0.264 mU/L) (Figure 2A and B). The change in thyroid hormone levels increased with increasing radiation dose and was consistent with TSH regulation in the test mice. The average levels of fT3 and fT4 in the test mice [386.560 (323.973, 442.594) ng/mL and 6.211 (5.018, 8.536) ng/mL, respectively] were higher than those in the control groups [372.664 (260.701, 384.492) ng/mL and 4.428 (3.175, 6.781) ng/mL, respectively]; nevertheless, the difference was not statistically confirmed between the two groups (Figure 2C and E). Moreover, the changes in fT3 and fT4 Levels from the different dose groups were consistent with the regulation of TSH (Figure 2D and F). Figure 3 shows thyroid tissue from the different groups of mice, and there were no obvious structural abnormalities.

Overview of the 16S rRNA gene sequencing data

An overview of the thyroid hormone levels and taxonomic data of all mice is visualized in Figure 4. High-throughput sequencing results of the 16S rRNA V3-V4 hypervariable regions obtained from stool samples revealed that the tested taxa were abundant, including 11 phyla, 50 families, 110 genera, and 424 OTUs. Rank-abundance curves according to OTU levels indicated that the species were distributed evenly and richly (Figure 5A). Figure 5B indicates that the curves flattened as increasing the sample size, demonstrating that the sequencing data were adequate and appropriately capturing microbial diversity.



LDR does not cause gut microbiota diversity changes in irradiated mice

According to the outcome of alpha diversity analysis, the results showed that the test group had no differences in the diversity and abundances of certain microbes compared with the control group. The Chao and Ace indices, reflecting richness, indicated no considerable difference was found between the two groups ($P > 0.05$) (Figure 5C and D). Moreover, the Shannon and Simpson indices, which represent alpha diversity, indicated no meaningful difference between the two groups ($P > 0.05$, Figure 5E and F). Figure 5G-J shows the Chao, Ace, Shannon and Simpson indices among the different subgroups from the test group.

PCoA and NMDS analyses of the unweighted UniFrac distance were conducted on evaluation the overall microbiota diversity. PCoA indicated that there were no statistically significant variation in diversity of the microbiota between the test and control mice (R = -0.065, $P = 0.715$, Figure 5K). The NMDS results demonstrated no differences between the two groups (R = -0.065, $P = 0.695$, Figure 5L). Figure 5M and N show the results of the PCoA and NMDS analyses in the four test subgroups. These findings suggest that LDR in this study does not lead to altered microbiota diversity.

Changes in the composition of the gut microbiota in irradiated mice

The taxon compositions were further determined in the two groups. Eleven phyla, 50 families, and 110 genera were present in the samples from both groups. Figure 6A shows that *Firmicutes*, *Bacteroidetes*, *Patescibacteria*, and *Deferribacteres* were the four dominant phyla, with total abundances accounting for 97.83% ± 1.23% and 97.68% ± 0.75% of the microbiota of the test and control groups, respectively. The two dominant phyla were Firmicutes and *Bacteroidetes* in both the test and control group. At the phylum level, no meaningful variation in the relative abundances of the microorganisms was observed between the two groups (Figure 6B). We found that the *Firmicutes*-to-*Bacteroidetes* (F/B) ratio in the test group (median = 1.623 ± 0.679) was higher than controls (median = 1.266 ± 0.345), the differences were not confirmed by statistics. In addition, the microbiota was further analyzed according to the distribution at the family and genus levels.

Figure 2 The level of thyroid hormone in mice exposed to radiation. A: Box and whisker plots of the levels of thyroid stimulating hormone (TSH) in the control (n = 6) and test (n = 24) groups. The TSH level of the mice in the test group was lower than that in the control mice (t = 2.188, P = 0.037); B: Histogram of the levels of TSH from the control and test groups. Statistically significant differences were not confirmed between the two groups; C: Box and whisker plots of the level of fT3 in the control (n = 6) and test groups (n = 24); D: Histogram of the level of fT3 in the control and test subgroups; E: Box and whisker plots of the level of fT4 in the control (n = 6) and test groups (n = 24); F: Histogram of the level of fT4 in the control and test subgroups. TSH: Thyroid stimulating hormone. $^{a}P < 0.05$.

LEfSe analysis results indicated that the control group had relatively high abundance in two families and four genera (LDA > 2, $P < 0.05$, Figure 7A). *Muribaculaceae*, *Lachnospiraceae*, *Ruminococcaceae*, *Lactobacillaceae* and *Bacteroidaceae* were the five dominant families, with total abundances accounting for 83.04% ± 4.59% and 80.68% ± 6.93% of the microbiomes of the test group and control group, respectively (Figure 7A). At the family level, the test group had significantly lower levels of *Moraxellaceae* and *Enterobacteriaceae* (all $P < 0.05$, Figure 7B). We also found that the abundance of *Lachnospiraceae* in the test group (20.05% ± 10.79%) was significantly higher than that in the controls (15.08% ± 10.02%), which increased in a dose-dependent manner following LDR exposure (Figure 7B and C).

Uncultured_bacterium_f_Muribaculaceae, *Lactobacillus*, *uncultured_bacterium_f_Lachnospiraceae*, *Bacteroides*, and *uncultured_bacterium_g_Ruminococcaceae_UCG-014* were the five dominant genera, with total abundances accounting for 59.87% ± 11.92% and 67.05% ± 10.38% of the microbiomes of the test group and control group, respectively (Figure 6C and D). At the genus level, the test group had significantly lower levels of *uncultured_bacterium_g_Acinetobacter*, *uncultured_bacterium_o_Mollicutes_RF39*, *uncultured_bacterium_g_Citrobacter*, and *uncultured_bacterium_g_Lactococcus* (all $P < 0.05$, Figure 7D).

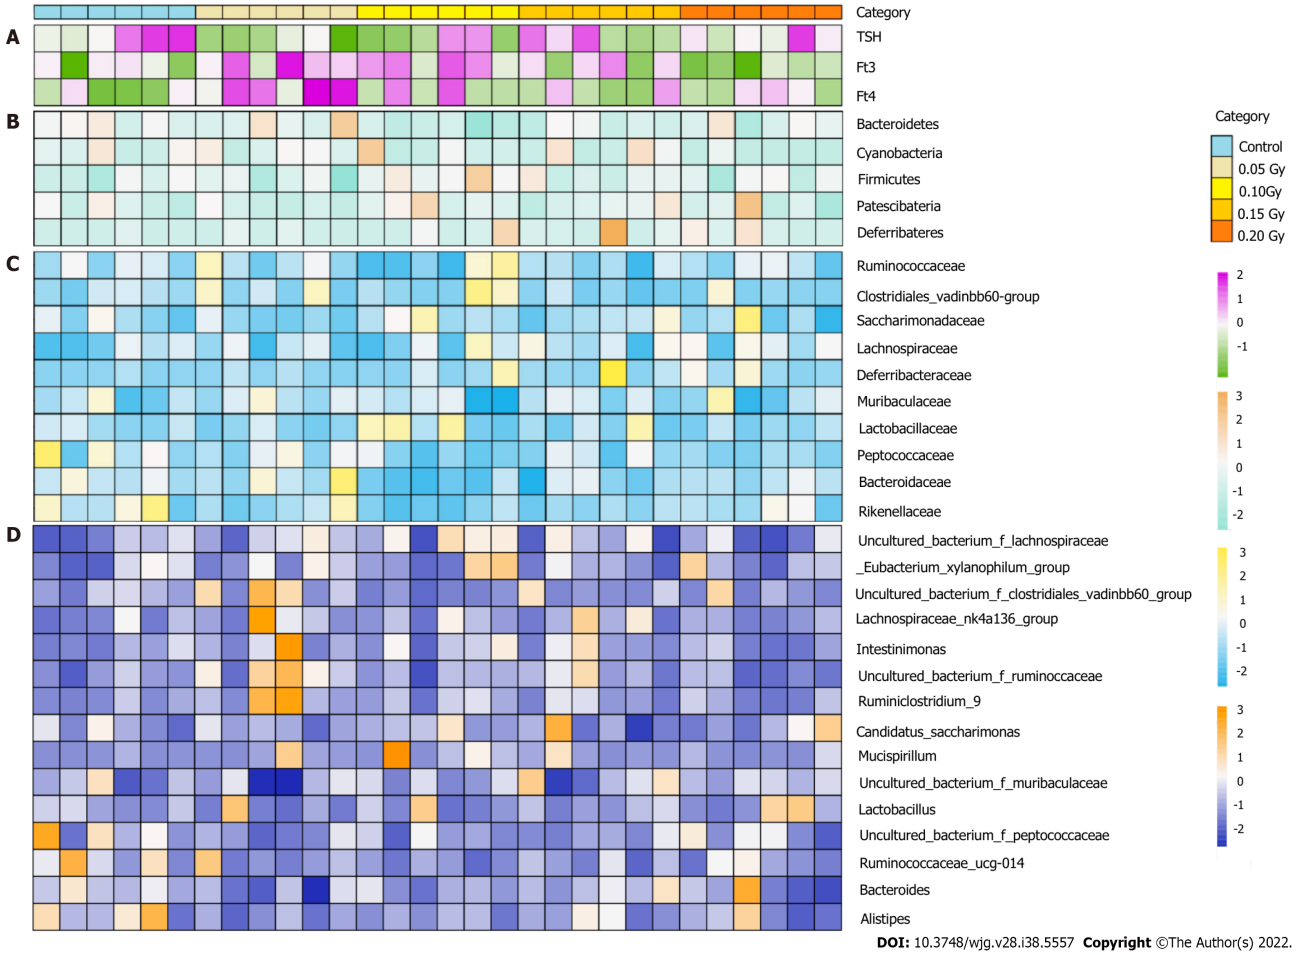
Figure 3 Thyroid tissue from the mice exposed to radiation (HE, × 400). A-D: Thyroid tissue of radiation-exposed mice from the 0.05 Gy group, 0.10 Gy group, 0.15 Gy group, and 0.20 Gy group. TSH: Thyroid stimulating hormone.



ROC curve analysis reveals the diagnostic value of specific intestinal microbiota

Based on the altered gut microbiota composition between the test and control groups, we found that six kinds of bacteria might serve as diagnostic biomarkers. At the family level, *Moraxellaceae* and *Enterobacteriaceae* are the two different bacteria between the two groups, and we selected them to serve as diagnostic biomarkers. ROC curves were generated to evaluate the diagnostic accuracy of these two families [AUC value of 0.819 (95% confidence interval: 0.640-0.999)] (Figure 8A).

At the genus level, we found four different bacteria and selected them to serve as diagnostic biomarkers, including *uncultured_bacterium_g_Acinetobacter*, *uncultured_bacterium_o_Mollicutes_RF39*, *uncultured_bacterium_g_Citrobacter*, and *uncultured_bacterium_g_Lactococcus*. ROC curves were generated to evaluate the diagnostic accuracy of these four genera [AUC value of 0.882 (confidence interval: 0.728-1.000)]. At the same time, the accuracy of the prognostic variables of two families and four genera was also analyzed by ROC curves [AUC value of 0.854 (confidence interval: 0.673-1.000)] (Figure 8).

The test groups included the 0.05 Gy group, 0.10 Gy group, 0.15 Gy group, and 0.20 Gy group according to the total radiation dose the mice received. On the basis of these results, we investigated the following relationships among thyroid function tests, absorbed dose, and levels of the gut microorganisms: *f_Moraxellaceae*, *f_Enterobacteriaceae*, *uncultured_bacterium_g_Acinetobacter*, *uncultured_bacterium_o_Mollicutes_RF39*, *uncultured_bacterium_g_Citrobacter*, and *uncultured_bacterium_g_Lactococcus*. We made an attempt to demarcate the functional influence of these flora according to the KEGG database to determine which biological pathways they may participate. Spearman correlation coefficient testing showed that *Moraxellaceae* (r = -0.789, P = 7.75E-7), *Enterobacteriaceae* (r=-0.662, P = 2.92E-4), *uncultured_bacterium_g_Acinetobacter* (r = -0.789, P = 7.75E-7), *uncultured_bacterium_o_Mollicutes_RF39* (r = -0.365, P = 0.0106), and *uncultured_bacterium_g_Lactococcus* (r = -0.667, P = 4.77E-3) levels were significantly negatively correlated with the absorbed dose (Figure 9).

The OTU abundance table was standardized to acquire information about the prediction of metabolic function in the KEGG pathway (Figure 10). According to the effect size, the top five pathways included carbohydrate metabolism, nucleotide metabolism, glycan biosynthesis and metabolism, xenobiotics biodegradation and metabolism, and metabolism of other amino acids. The effect size of the genetic information processing function is second only to metabolic function, which includes translation, replication and repair, folding, sorting and degradation, and transcription.

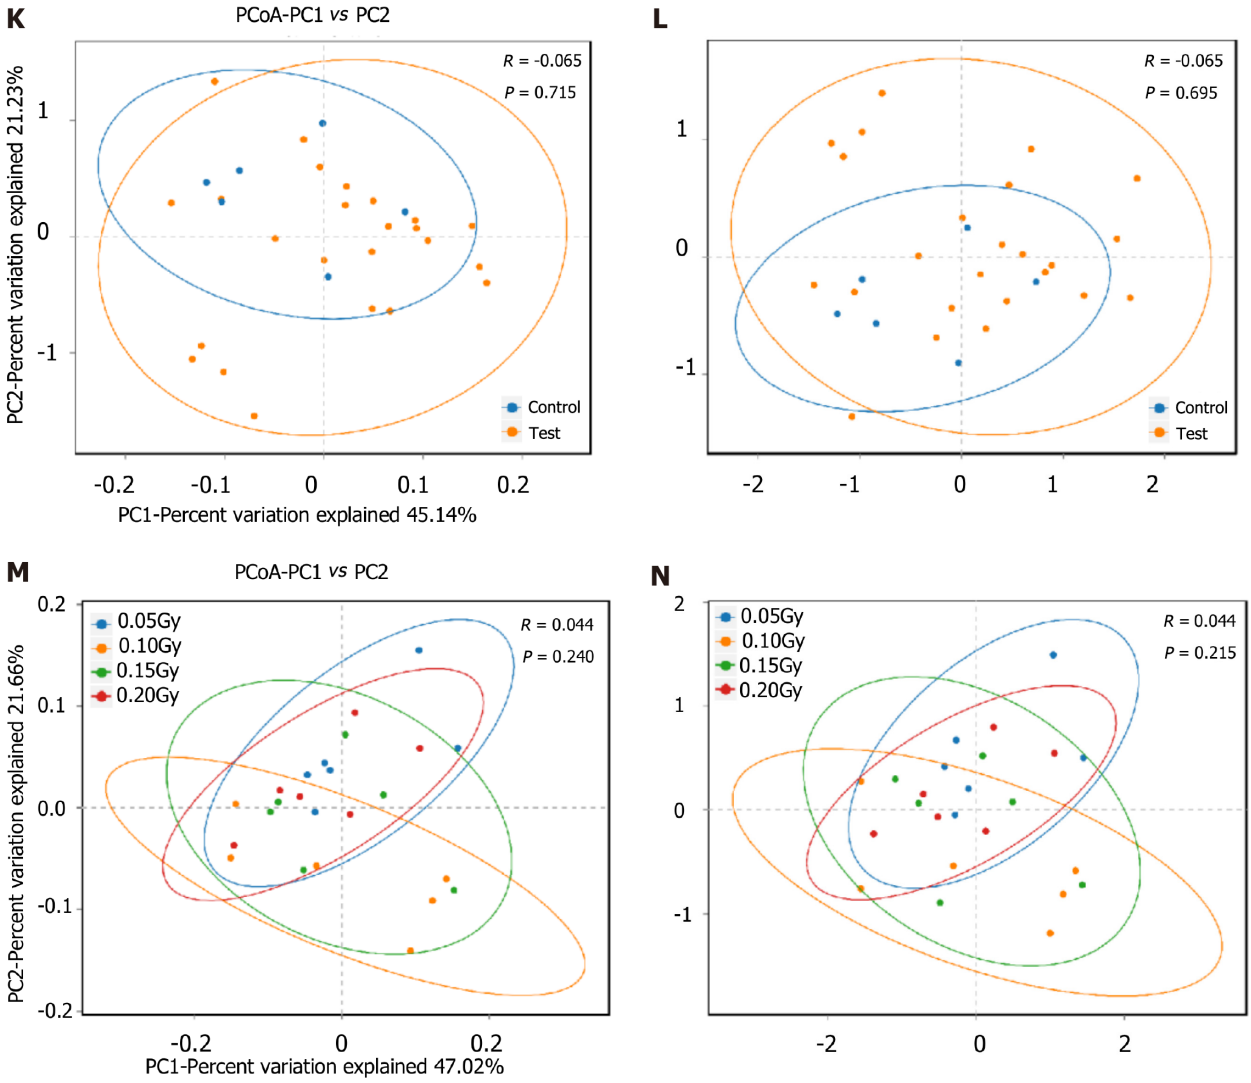

Figure 4 Taxonomic features of the thyroid hormone level and gut microbiota in the control mice (*n* = 6) and radiation-exposed group (*n* = 24). A-D: The thyroid hormone level for all subjects (A), with an overview of the 5 most abundant phyla (B), 10 most abundant families (C) and 15 most abundant genera (D) in fecal samples identified by 16S rRNA gene sequencing. The taxa levels were determined by summing the operational taxonomic units and are presented by relative abundance.

DISCUSSION

As an important organ of the endocrine system, the thyroid participates in homeostatic regulation. Recent studies demonstrated that the gut microbiota, a sophisticated and metabolically active community, is closely related to homeostasis in the host[13]. Although LDR exposure has been demonstrated to induce contradictory effects previously, *i.e.*, beneficial or harmful, the impacts of LDR exposure on the "thyroid-gut axis" have yet to be clarified. Therefore, we analyzed the association among LDR exposure, thyroid function and the gut microbiota in mice in this research. Our group indicated that as the LDR radiation dose increased, subclinical thyroid hyperthyroidism appeared in mice, and the observed species and OTU abundances showed no obvious changes in the radiated groups compared with the controls. It was thought that the low doses of radiation applied in this paper have an influence on the thyroid function of mice but are unable to alter the richness of the intestinal flora.

The thyroid is a radiation-sensitive organ, and internal radionuclide contamination external radiation and exposure (such as therapeutic radiation) may lead to thyroid dysfunction[14,15]. Our research found that the TSH level in the test mice was lower than the controls. Double-strand breaks can lead to cytotoxic, mutagenic and carcinogenic effects if unrepaired or misrepaired, although they only constitute a minority of DNA lesions induced by LDR, which will affect cell function[16,17]. Ishizaki *et al*[18] demonstrated a very small increase in γH2AX-positive foci in a human diploid cell line after exposure to LDR, which indicates the presence of DNA double-strand breaks. Some studies have also suggested that radiation-induced thyroid dysfunction is induced by damage to small thyroid vessels and to the gland capsule, the mechanisms of which include direct thyroid cell injury from radiation damage[19]. Because of the low thyroid dose in patients treated with total body irradiation, the incidence of Graves' disease accompanying this management was also reported in a total body irradiation series[20]. Strikingly, our results indicate pronounced modulation of the TSH level in mice exposed to 0.05 Gy and 0.10 Gy, while those exposed to a much higher dose (0.20 Gy) consistently

Figure 5 Bioinformatic analysis of 16S rRNA gene sequencing data in the exploratory cohort at the operational taxonomic units level. A and B: Rank-abundance curves and rarefaction curves (SOB index) of the gut microbiota; C-F: Box and whisker plots of the alpha diversity indices for richness (Chao index and Ace index) and diversity (Shannon index and Simpson index) of the bacterial communities in control mice (n = 6) and the test mice (n = 24); G-J: Box and whisker plots of the alpha diversity indices for richness (Chao index and Ace index) and diversity (Shannon index and Simpson index) of the bacterial communities among the test subgroups (0.05 Gy, 0.10 Gy, 0.15 Gy, and 0.20 Gy; n = 6 in each group); K and L: Principal coordinates analysis (PCoA) and nonmetric multidimensional scaling (NMDS) analyses indicated that the microbial diversity differed nonsignificantly between the control and test groups based on the unweighted UniFrac distance (PCoA, R = -0.065, P = -0.715; NMDS, R = -0.065, P = 0.695); M and N: PCoA and NMDS analyses indicated that the microbial diversity differed nonsignificantly among the test subgroups based on the unweighted UniFrac distance (PCoA, R = 0.004, P = 0.24; NMDS, R = 0.215, P = 0.695).

clustered with controls in terms of thyroid hormone levels. We speculate that there is an intricate dose-dependent response in thyroid function to ionizing radiation, with enhanced sensitivity for the lowest doses employed here. Therefore, thyroid function and microbial communities might be directly affected by LDR exposure.

Firmicutes and *Bacteroidetes* were the two dominant microbiota in these two groups. We found that the *Firmicutes* proportion in the irradiated group was higher than in the controls, while the *Bacteroidetes* proportion was lower in the irradiated group. One study about environmental radionuclides on the gut microbiota from Lavrinienko came to similar conclusions that the F/B ratio was increased almost 2-fold compared with an unirradiated group[21]. Previous investigation have also revealed that patients with metabolic diseases such as obesity, diabetes, and nonalcoholic fatty liver disease have a reduced F/B ratio compared to healthy individuals[22-24]. Recently, our group demonstrated that thyroid diseases, including Graves' disease and thyroid carcinoma, can cause changes in the F/B ratio[25,26]. Therefore, we speculate that the composition and function of microbial communities might be affected by LDR exposure directly or indirectly through changes in thyroid function.

Compared with the controls, the abundances of *Moraxellaceae* and *Enterobacteriaceae* were decreased in the test group at the family level. Obvious differences in the levels of four species were observed between the two groups at the genus level, and *uncultured_bacterium_g_Acinetobacter*, *uncultured_*

bacterium_o_Mollicutes_RF39, *uncultured_bacterium_g_Citrobacter* and *uncultured_bacterium_g_Lactococcus* were reduced in the test group. On the one hand, the decreased abundance of the bacterium might be directly caused by radiation damage. On the other hand, changes in microbial abundance inhibit the development of gastrointestinal mucositis and promote intestinal repair mechanisms[27]. We hypothesize that metabolites from bacteria impair intestinal barrier function. By regulating bacterial abundance and reducing the release of proinflammatory factors, the intestinal barrier could repair the damage from LDR exposure. Another significant finding in this research was that the abundance of *Lachnospiraceae* increased in a dose-dependent manner following LDR exposure, which was in accordance with the performance outcome of the group of mice that have recovered from high-dose radiation to live a normal life span[28].

The synthesis of short-chain fatty acids (SCFAs) by fermenting polysaccharides in food has made members of the *Lachnospira* family well known[29]. SCFAs are essential substrates for the maintenance of the intestinal epithelium, regulation of the immune system and inflammatory response[30,31]. Broad inhibition of systemic inflammation, through reduction the levels of proinflammatory cytokines or through induction of anti-inflammatory cytokine interleukin-10, mediated by SCFAs may also potentially provide radioprotection. Elevated abundances of *Lachnospiraceae* have been shown to be connected with the repair of gastrointestinal after exposure to radiation[32].

Additionally, we employed KEGG pathway analysis to characterize changes in the gut microbiota associated with the stress from LDR exposure. KEGG pathway analysis based on OTU abundance indicated that biological metabolism was predicted to influence functional activities, including carbohydrate metabolism, glycan biosynthesis and metabolism, and nucleotide metabolism. The gut microbiota composition and metabolic pathways were influenced by LDR exposure. Moreover, processing functions were second only to metabolic functions according to the effect size, including translation, replication and repair. As the most significant influence of radiation, base modifications are a common type of DNA lesion[33]. KEGG pathway analysis may suggest a relationship between radiation damage and functional repair. Nevertheless, our observations provide circumstantial the proof of host-microbiome interactions; more investigations are required to uncover the crosstalk within LDR-responsive alterations and host-derived targets or signals.

Our research did not consider the following issues, and these limitations will also become the focus of follow-up research. First, the effects of exposure dose and recovery time on the thyroid and gut microbiota in the mice were not considered. Second, this was a descriptive study in nature and lacked

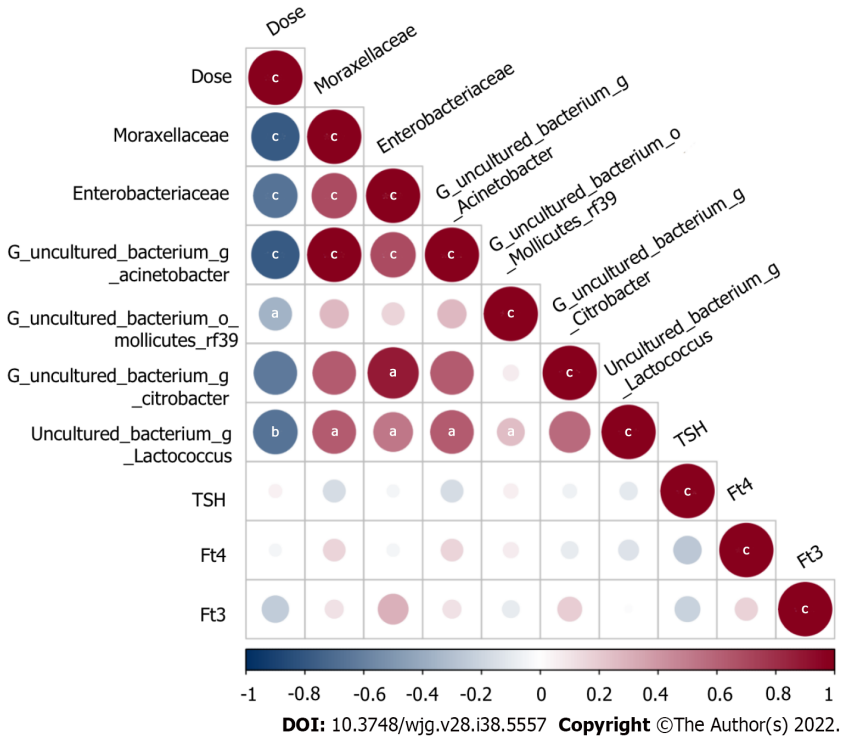
Figure 7 Altered gut microbiota composition in the radiation-exposed group compared with the control group. A: Identification of the significantly different species in the radiation-exposed group and controls at the family and genus levels as determined by linear discriminant analysis (LDA) effect size (LEfSe). Only taxa meeting a significant linear discriminant analysis threshold value of > 2.0 and $P < 0.05$ are shown; B: Comparison of *Moraxellaceae*, *Enterobacteriaceae, and Lachnospiraceae* abundances between the test group and control group at the family level; C: Histogram of the abundance of *Lachnospiraceae* in the control and test subgroups; D: Comparison of the differential bacterial abundances between the test group and controls at the genus level, including *uncultured_bacterium_g_Acinetobacter*, *uncultured_bacterium_o_Mollicutes_RF39*, *uncultured_bacterium_g_Citrobacter*, and *uncultured_bacterium_g_Lactococcus*. $^{a}P < 0.05$.

evidence regarding the underlying mechanisms of the responses to LDR exposure, which could be used to determine the alterations in metabolites from the gut microbiota. Finally, our experiment was a single-center study that lacked external validation. Despite these limitations, our research is one of the few to indicate the effects of LDR on homeostasis from the "thyroid-gut axis" perspective. In summary, our study constitutes a baseline analysis that can not only be used to further study the effects of LDR on human health but also provide potential targets for preventing or predicting radiation damage.



CONCLUSION

LDR can change the thyroid function and gut microbiota of mice, and changes in the abundances of bacteria are correlated with the radiation dose.

ARTICLE HIGHLIGHTS

Research background

The thyroid-gut axis has a great influence on the maintenance of human health.

Research motivation

We know very little about the effects of low-dose ionizing radiation (LDR) on thyroid hormone levels and gut microbiota composition.

Research objectives

To investigate the potential effects by administering low-dose X-ray radiation to male C57BL/6J mice.

Research methods

Peripheral blood was collected for enzyme-linked immunosorbent assay (ELISA), and stool samples were taken for 16S ribosomal RNA (rRNA) gene sequencing after irradiation.

Research results

We found that LDR caused changes in thyroid stimulating hormone (TSH) levels in the irradiated mice, suggesting a dose-dependent response in thyroid function to ionizing radiation. No changes in the diversity and richness of the gut microbiota were observed in the LDR-exposed group in comparison to the controls. The abundance of *Moraxellaceae* and *Enterobacteriaceae* decreased in the LDR-exposed groups compared with the controls, and the *Lachnospiraceae* abundance increased in a dose-dependent manner in the radiated groups. And the abundances of *uncultured_bacterium_g_Acinetobacter*, *uncultured_bacterium_o_Mollicutes_RF39*, *uncultured_bacterium_g_Citrobacter*, and *uncul-tured_*

bacterium_g_Lactococcus decreased in the radiated groups at the genus level, which showed a correlation with radiation exposure and diagnostic efficacy. Analysis of functional metabolic pathways revealed that biological metabolism was predicted to have an effect on functional activities, such as nucleotide metabolism, carbohydrate metabolism, and glycan biosynthesis and metabolism. Furthermore, KEGG pathway annotation also suggested that changes in the gut microbiota were related to processing functions, including translation, replication and repair.

Research conclusions

LDR can change thyroid function and the gut microbiota, and changes in the abundances of bacteria are correlated with the radiation dose.

Research perspectives

We administered low-dose X-ray radiation to male C57BL/6J mice to investigate the potential effects. Peripheral blood was collected for ELISA, and stool samples were taken for 16S rRNA gene sequencing after irradiation.

Abstract

BACKGROUND

Ischemia-reperfusion injury (IRI) is a major risk associated with liver surgery and transplantation, and its pathological mechanism is complex. Interleukin-1 receptor antagonist (IL-1ra) can protect the liver from IRI. However, the regulatory mechanism of IL-1ra expression is still unclear.

AIM

To identify the mechanism that could protect the liver in the early stage of IRI.

METHODS

To screen the key genes in hepatic IRI, we performed RNA sequencing and gene enrichment analysis on liver tissue from mice with hepatic IRI. Subsequently, we verified the expression and effect of IL-1ra in hepatic IRI. We also used promoter mutagenesis and chromatin immunoprecipitation assay to search for the trans-

criptional regulatory sites of hypoxia-inducible factor (HIF)-1α. Finally, to explore the protective mechanism of ischemic preconditioning (IP), we examined the expression of HIF-1α and IL-1ra after IP.

RESULTS

We identified IL-1ra as a key regulator in hepatic IRI. The expression of IL-1ra was significantly upregulated after hepatic IRI both *in vivo* and *in vitro*. Furthermore, we found that HIF-1α regulated *Il-1ra* transcription in response to hypoxia. Increased HIF-1α accumulation promoted IL-1ra expression, whereas inhibition of HIF-1α exhibited the opposite effect. We also confirmed a predominant role for hypoxia response element in the regulation of *Il1ra* transcription by HIF-1α activation. Of note, we demonstrated that IP protects against hepatic IRI by inducing IL-1ra expression, which is mediated through HIF-1α.

CONCLUSION

We demonstrated that ischemia or hypoxia leads to increased expression of IL-1ra through HIF-1α. Importantly, IP protects the liver from IRI *via* the HIF-1α–IL-1ra pathway.

Key Words: Hepatic ischemia-reperfusion injury; Interleukin-1 receptor antagonist; Hypoxia inducible factor 1α; Ischemic preconditioning

INTRODUCTION

Hepatic ischemia (IS)-reperfusion injury (IRI) is a common complication in liver surgery and transplantation[1]. IRI usually results from restoration of the blood supply after brief IS[2]. The sterile inflammatory response induced by hypoxic stress leads to hepatic IRI[3]. The pathogenesis of hepatic IRI is complex and affected by various factors[4,5], which involve the damage-associated molecular patterns, innate immune response, and inflammation. Among them, the inflammation caused by interleukin (IL)-1β plays an important role[6,7]. During hepatic IRI, injured cells activate the inflammasome pathway, allowing the IL-1β precursor to be cleaved into its mature form by caspase-1 and subsequently released. Mature IL-1β is a broad-acting proinflammatory cytokine that increases the recruitment of endothelial adhesion molecules to innate immune cells and promotes the development of inflammatory phenotypes[8]. However, blocking the action of IL-1 can reduce hepatic damage[9,10]. As a natural anti-inflammatory factor, IL-1 receptor antagonist (IL-1ra) is highly expressed in a variety of inflammatory diseases and is closely related to the occurrence and progression of inflammation[11-14]. Several studies have shown a potential protective effect of IL-1ra in inflammation. For example, IL-1ra competes with IL-1β to bind to IL-1 receptor I, thus playing an anti-inflammatory role[15]. However, the transcriptional regulatory mechanism of IL-1ra during IRI remains unclear.

As a transcription factor, hypoxia-inducible factor (HIF)-1α is an important molecule for cell regulation in the hypoxic environment[16,17]. There have been a few reports confirming that HIF-1α plays an irreplaceable role in hepatic IRI[18]. HIF-1α can regulate the expression of multiple genes in cells after hypoxia[19], and consequently reduce organ IRI by regulating metabolism[20]. Furthermore, the mechanism of HIF-1α protection against hepatic IRI deserves further study.

Ischemic preconditioning (IP) was first reported by Murry *et al*[21] in 1986, who demonstrated that multiple IP reduces cell death after coronary artery occlusion. Although the protective effect of IP on hepatic IRI has been subsequently reported[22], its mechanism of action remains unclear. Therefore, it is

necessary to confirm the mechanism underlying this protective effect, which would be of great clinical significance. In the present study, we found that IL-1ra was expressed in hepatic tissue during IRI and was regulated by IS-induced HIF-1α. We also confirmed that the protective effect of IP was exerted precisely *via* the HIF-1α–IL-1ra pathway, leading to inhibition of IL-1β signaling and subsequent reduction in hepatic IRI.

MATERIALS AND METHODS

Reagents and antibodies

2-MeOE2 (S1233) and DMOG (S7483) were purchased from Selleck (China). Percoll (17089101) was purchased from GE Healthcare (United States). Collagenase IV (C8160) was purchased from Solarbio (China). Mouse monoclonal antibody for β-actin (sc-47778) was purchased from Santa Cruz Biotechnology (Santa Cruz, CA, United States). A rabbit monoclonal antibody for IL-1ra (ab124962) was purchased from Abcam (Cambridge, MA, United States). Rabbit antibodies for HIF-1α (36169), BAX (14796), Bcl-2 (3498), and cleaved caspase-3 (9664) were purchased from Cell Signaling Technology (Danvers, MA, United States). ELISA kits for detecting mouse alanine transaminase (ALT) (JL12668), aspartate transaminase (AST) (JL13793), and IL-1ra (JL20255) were purchased from Jonln (China). Recombinant IL-1ra (200-01RA) was purchased from PeproTech (United States).

Animals

Wild-type male C57BL/6 mice, aged 6-8 wk, were purchased from Beijing HFK Bioscience (Beijing, China). The mice were raised in standard conditions[23] and received humanitarian care. The mice were acclimated to the rearing environment for 3-4 d before experimentation.

Animal experiments

Mice were randomly grouped and marked. The mice were weighed and anesthetized with 1% pentobarbital (50 mg/kg). For the hepatic IR experiments, mice were divided into six groups (n = 5 each): Sham group: The portal vein was exposed, and no blood vessels were clamped; ischemia reperfusion (IS) 1.5 h group: We only clamped the left and middle lobe vessels for 1.5 h; IR 3-24 h group: Reperfusion was performed for the corresponding time after the vessels had been clamped for 1.5 h; IP group: We briefly clamped the vessel for 10 min and released it for 10 min before IS; this was named an IP cycle; sh*Il1ra* group: Adenovirus carrying *Il1ra* shRNA was injected *via* the tail vein 48 h before IR. At the end of the experiment, the ischemic hepatic lobes were isolated for subsequent processing or stored at -80 °C. The animal study protocol was approved by the Animal Ethical and Welfare Committee (protocol code: IRM-DWLL-2020173 and date of approval: September 15, 2020).

Nonparenchymal cell and hepatocyte isolation

Nonparenchymal cells (NPCs) and hepatocytes were isolated from mice by collagenase digestion and differential centrifugation using Percoll, as previously described[24].

Histological examination of liver tissue

The left lobe samples of mouse livers were fixed in formaldehyde solution, dehydrated, paraffin-embedded, and cut into 4-μm-thick sections. The IL-1ra levels were determined by immunohistochemistry. The histological analysis was performed using the histochemistry score. A section was selected from the left lobe in every liver, and five views (200 ×) were captured for calculation in each section.

Cell culture

Mouse liver parenchymal cells, AML12 (SCSP-550; American Type Culture Collection, Manassas, VA, United States), were cultured in Dulbecco's modified Eagle's medium (DMEM)/F12 (11965092; Gibco) supplemented with 10% fetal bovine serum (FBS) (10099133; Gibco) and 1% penicillin/streptomycin at 37 °C in an atmosphere containing 5% CO_2. HEK293T cells were cultured in DMEM (11320033; Gibco) supplemented with 10% FBS, 1% sodium pyruvate, 1% non-essential amino acids, and 2% glutamine.

Cell experiment

AML12 cells were subjected to hypoxia and reoxygenation to simulate the ischemic and reperfusion environment *in vivo*. During hypoxia, cells were cultured in a 37 °C incubator with 95% N_2 and 5% CO_2. After a specific time period, cells were removed and placed back into the 37 °C incubator with 5% CO_2. To interfere with HIF-1α, cells were treated with DMOG or 2-MeOE2 at a concentration of 100 μM for 6 h before subsequent experiments were performed.

Plasmid construction

The mouse *Il1ra* promoter (-2113/+143) sequences were obtained by polymerase chain reaction (PCR) from mouse genomic DNA and cloned into the pGL3-basic vector (Promega, Madison, WI, United States). Mutagenesis of HRE-I and HRE-II in the mouse *Il1ra* promoter was performed using a QuickChange® Lightning Site-Directed Mutagenesis Kit (Stratagene, La Jolla, CA, United States). The primer sequences are listed in Table 1. The mouse *Il1ra* shRNA plasmid was purchased from Hanbio Biotechnology (Shanghai, China), and packaged into adenoviral particles.

RNA extraction and quantitative qPCR

Total RNA from liver tissue and AML12 cells was extracted using Trizol (Life Technologies, Carlsbad, CA, United States). cDNA was synthesized using reverse transcriptase (Takara, Japan). The specific product of *Il1ra* was amplified by qPCR using the TransStart Green Q-PCR SuperMix Kit (TransGen, China). β-Actin was used as a normalization control. The primer sequences are listed in Table 1.

Immunoblotting assay

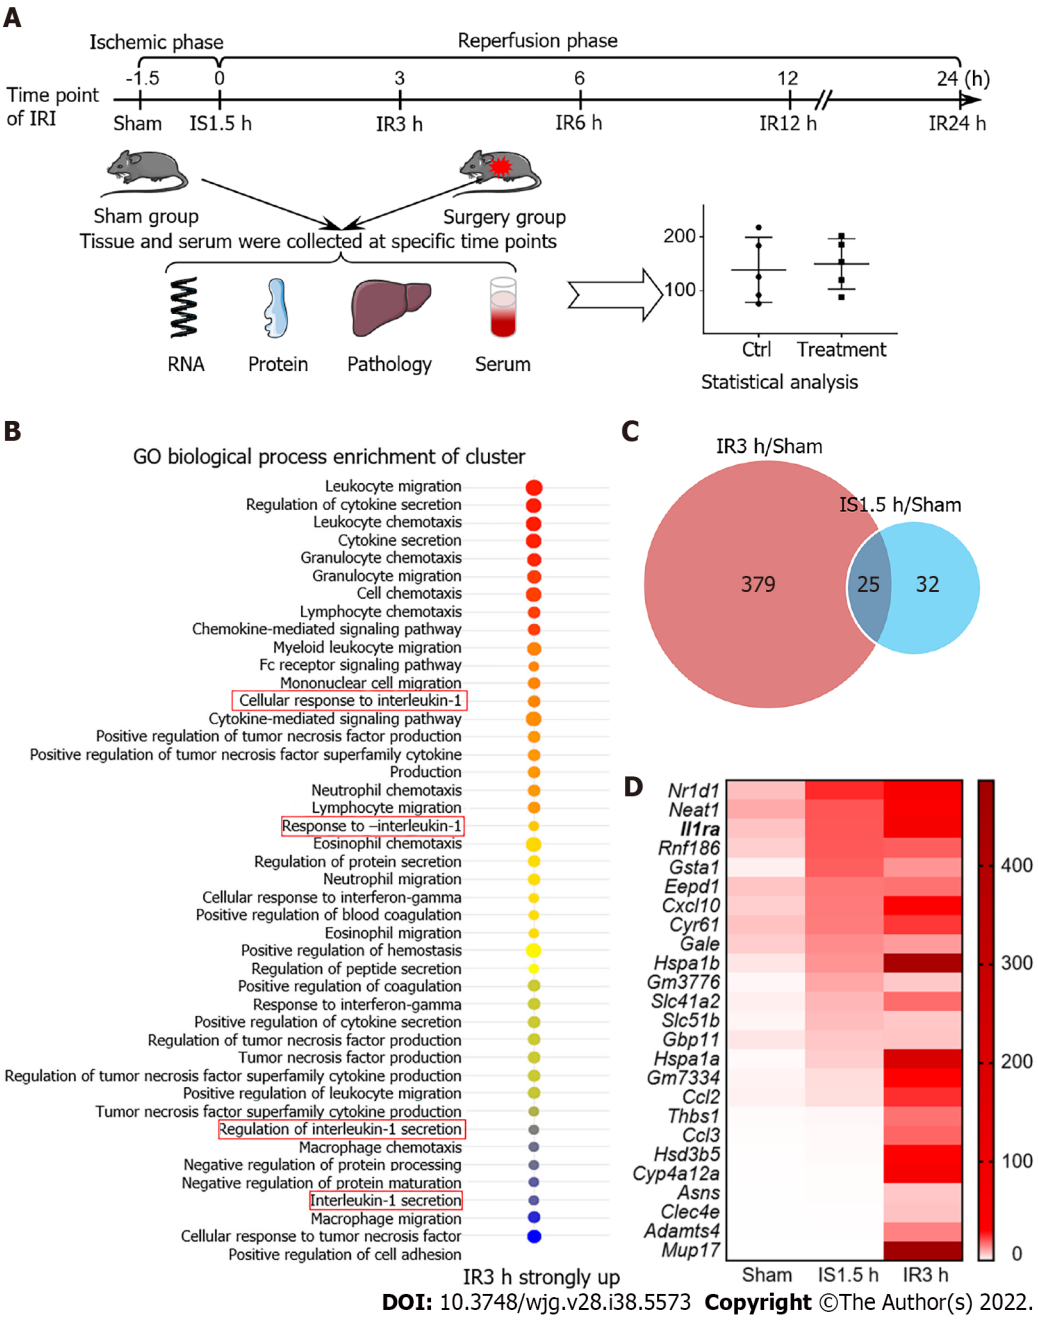
Tissues and cell lysates were prepared in RIPA buffer with protease and phosphatase inhibitors. The immunoblotting procedures can be found in the literature[25].

Luciferase assay

Cells were transfected with wild-type or mutant mouse *Il1ra* promoters, followed by treatment with DMOG or 2-MeOE2 under hypoxia in 24-well plates. Lysates were prepared 48 h after transfection, and the luciferase activity was measured using the Dual-Luciferase Reporter Assay System (Promega). The luciferase activity was normalized to the values for Renilla luciferase.

Chromatin immunoprecipitation

Chromatin immunoprecipitation (ChIP) assays were performed using an EZ-ChIP kit (Millipore, Billerica, MA, United States). The primers and antibodies used in these experiments are shown in Table 1.



Statistical analysis

Statistical analyses were performed using GraphPad Prism 7.0 (San Diego, CA, United States). All the data are presented as the mean ± SEM and represent three or five independent experiments. One-way analysis of variance was used to compare means among treatment groups. Student's *t*-test for unpaired observations was applied. $P < 0.05$ was considered significant.

RESULTS

Screening of protective genes during hepatic IRI

To screen key genes that potentially play protective roles in the liver in IRI, we constructed a mouse model of hepatic IRI and performed transcriptome sequencing using mRNAs of the liver from the Sham, IS 1.5 h, and IR 3 h groups (Figure 1A). Gene enrichment analysis showed that, after IR 3h, a group of genes enriched in the IL-1 pathway were upregulated (Figure 1B). Expression of 25 genes was significantly increased (> 2-fold) in both IS and IR periods (Figure 1C). These genes were then ranked in descending order of ischemic expression abundance, and *Il1ra*, as a key antagonist of the IL-1 signaling, was shown to be one of the highly differentially expressed genes (Figure 1D). Thus, we chose *Il1ra* for further investigation on its regulatory mechanism in the hepatic IRI.

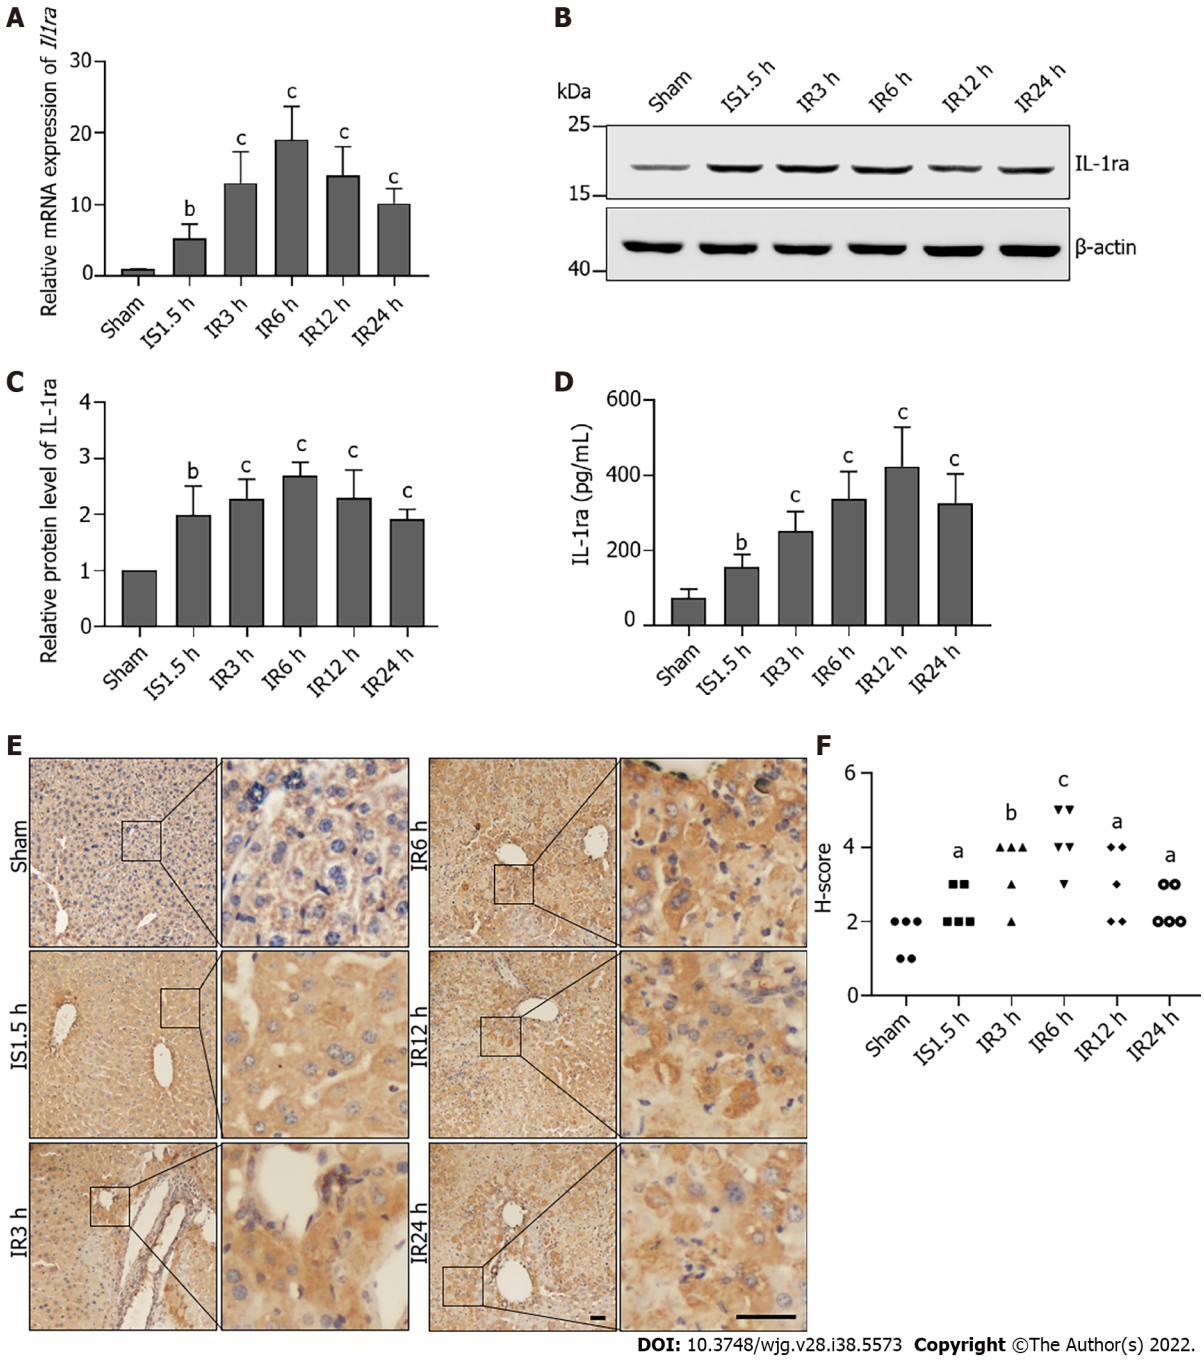

Figure 1 Construction of a mouse model of hepatic ischemia-reperfusion injury and gene enrichment analysis. A: Model of ischemia-reperfusion injury (IRI) in mice; B: GO enrichment analysis upon IR for 3 h; C: Venn diagram shows that the expression of genes for IR 3 h and ischemia (IS) 1.5 h was more than 2-fold than that in the Sham group; D: Twenty-five genes were elevated in both IR 3 h and IS 1.5 h groups according to IS 1.5 h expression level. IS: Ischemia; IR: Ischemia-reperfusion; IRI: Ischemia-reperfusion injury.

IL-1ra expression is elevated during hepatic IRI

We detected IL-1ra expression in mice with IRI. This confirmed that mRNA expression of *Il1ra* was increased in mice that experienced hepatic IRI as compared with the Sham group (Figure 2A). Upregulation of IL-1ra in liver tissue was confirmed at the protein level by immunoblotting (Figures 2B and C), ELISA (Figure 2D), and immunohistochemistry (Figures 2E and F), demonstrating that expression of IL-1ra is significantly elevated in response to hepatic IRI in mice.

Hepatocytes and hepatic NPCs both express high levels of IL-1ra after IRI

The liver is composed of several different embryonic-derived cell types, including hepatocytes, bile duct epithelial cells, stellate cells, Kupffer cells, and sinusoidal endothelial cells[26]. The liver consists of 80% hepatocytes, and 20% of the other cells are collectively called NPCs. Hepatocytes are the major epithelial cell population of the liver and perform various physiological functions. Therefore, we aimed to identify whether there is a difference in the expression of IL-1ra in hepatocytes and NPCs after IRI. To do so, gradient centrifugation was used to separate hepatocytes and NPCs from mouse liver tissue, and

Representative images of immunohistochemical staining for IL-1ra in the liver upon IRI. Scale bars, 100 μm; F: Statistical analysis of immunohistochemical scores. Indicated *P* values were calculated using a two-tailed unpaired Student's *t*-test. Data are presented as the mean ± SEM. Data are representative of five independent experiments. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$. IS: Ischemia; IR: Ischemia-reperfusion; IL-1ra: Interleukin-1 receptor antagonist.

expression of IL-1ra was detected. There was no significant difference in the expression of IL-1ra at both the mRNA (Figure 3A) and protein (Figures 3B and C) levels between hepatocytes and NPCs after IR treatment.

To confirm these results *in vitro*, we performed the hypoxia–reoxygenation experiments in the mouse hepatic cell line AML12 to simulate IRI. We found that the mRNA (Figure 3D) and protein (Figures 3E and F) expression of IL-1ra was increased in AML12 cells upon hypoxia and reoxygenation. Similarly, the content of IL-1ra in the culture medium of the hypoxia-reoxygenation group was significantly higher than that in the control group (Figure 3G). Together, these data suggested that IL-1ra is highly expressed in both hepatocytes and NPCs after IRI.

IL-1ra expression is upregulated upon IS and hypoxia

To verify the regulation of IL-1ra expression in the early stage of hepatic IRI, we constructed hypoxic models at different time points *in vivo* and *in vitro*. Compared with the Sham group, ischemic treatment in mice increased IL-1ra expression in a time-dependent manner at both the mRNA (Figure 4A) and protein (Figures 4B-D) levels. Similar results were also revealed in AML12 cells (Figures 4E-H), demonstrating that IS and hypoxia could promote the expression of IL-1ra.

HIF-1α promotes IL-1ra expression under hypoxic conditions

HIF-1α, as a transcriptional regulator, plays an important role under hypoxic conditions. Therefore, we

speculated that HIF-1α would regulate the expression of IL-1ra. Thus, we moved to evaluate the relationship between HIF-1α and IL-1ra expression in hepatic IRI. Increased expression of HIF-1α was observed upon ischemic treatment in mice in a time-dependent manner (Figures 5A and B). Similar results were confirmed in AML12 cells (Figures 5C and D). Immunofluorescence analysis indicated that HIF-1α was localized in the nuclei of AML12 cells after 1.5 h of hypoxia (Figure 5E).

We treated AML12 cells with 2-MeOE2 (a specific HIF-1α inhibitor) or DMOG (a specific HIF-1α agonist). 2-MeOE2 reduced the expression of *Il-1ra* mRNA during hypoxia, while DMOG increased *Il-1ra* expression under normoxia (Figure 5F). Immunoblotting (Figures 5G-I) and ELISA (Figure 5J) confirmed that 2-MeOE2 reduced the protein levels of HIF-1α and IL-1ra in AML12 cells; however, DMOG had the opposite effect. These results indicated that HIF-1α independently promotes the expression of IL-1ra.

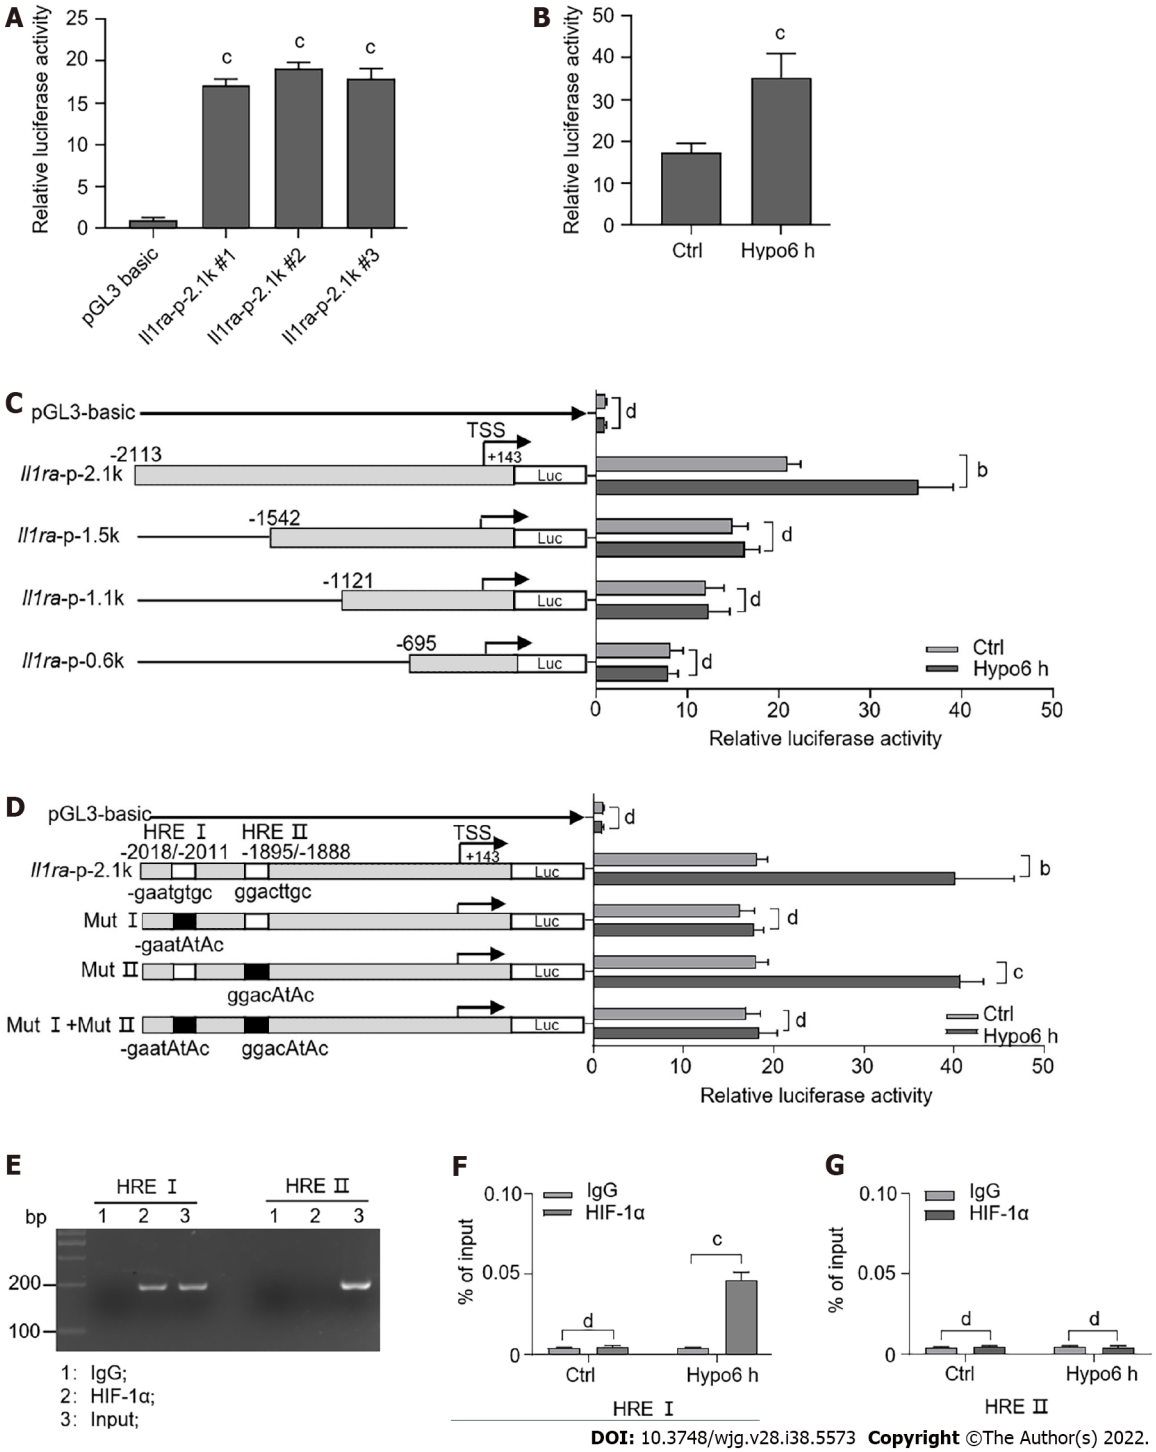
HIF-1α transcriptionally upregulates IL-1ra expression

To investigate the regulatory mechanism of IL-1ra by HIF-1α, we transfected a mouse *Il1ra* promoter-reporter construct into AML12 cells (Figure 6A). Upon treatment with hypoxia, we found that *Il1ra* promoter activity was significantly increased (Figure 6B). To explore the transcriptional regulatory elements of the *Il1ra* promoter in response to hypoxia, we generated a series of truncated *Il1ra* promoter–reporter constructs. *Il1ra*-p-2.1k promoter activity was significantly increased upon hypoxic treatment, while the truncated promoter activity of *Il1ra*-p-1.5k, *Il1ra*-p-1.1k, and *Il1ra*-p-0.6k was not altered by hypoxia (Figure 6C).

We used the JASPAR database to predict the binding site of HIF-1α on the *Il1ra*-p-2.1k promoter and found two possible binding elements, HRE I (-2018/-2011) and HRE II (-1895/-1888) (Figure 6D). Site-directed mutagenesis showed that mutation of HRE II did not affect hypoxia-induced activation of the *Il1ra* promoter, while mutation of either HRE I or HRE I + II eliminated this effect (Figure 6D). Importantly, we used the ChIP assay to verify that HIF-1α was able to be recruited to the HRE I element in the *Il1ra* promoter (Figures 6E and F).

IP protects the liver from IRI via the HIF-1α-IL-1ra pathway

It has been reported that IP can alleviate hepatic IRI[27]. However, the protective mechanism of IP is not yet clear. Here, we speculated that IL-1ra might play a potential role in the regulation of IP. Thus, the mice were subjected to IP with the indicated cycles. Compared with the control group, the IP group had significantly lower ALT and AST levels in their serum, which were further reduced by increased IP cycles (Figures 7A and B). Similar results of IL-1ra upregulation were observed by immunoblotting (Figures 7C and D) and ELISA (Figure 7E).

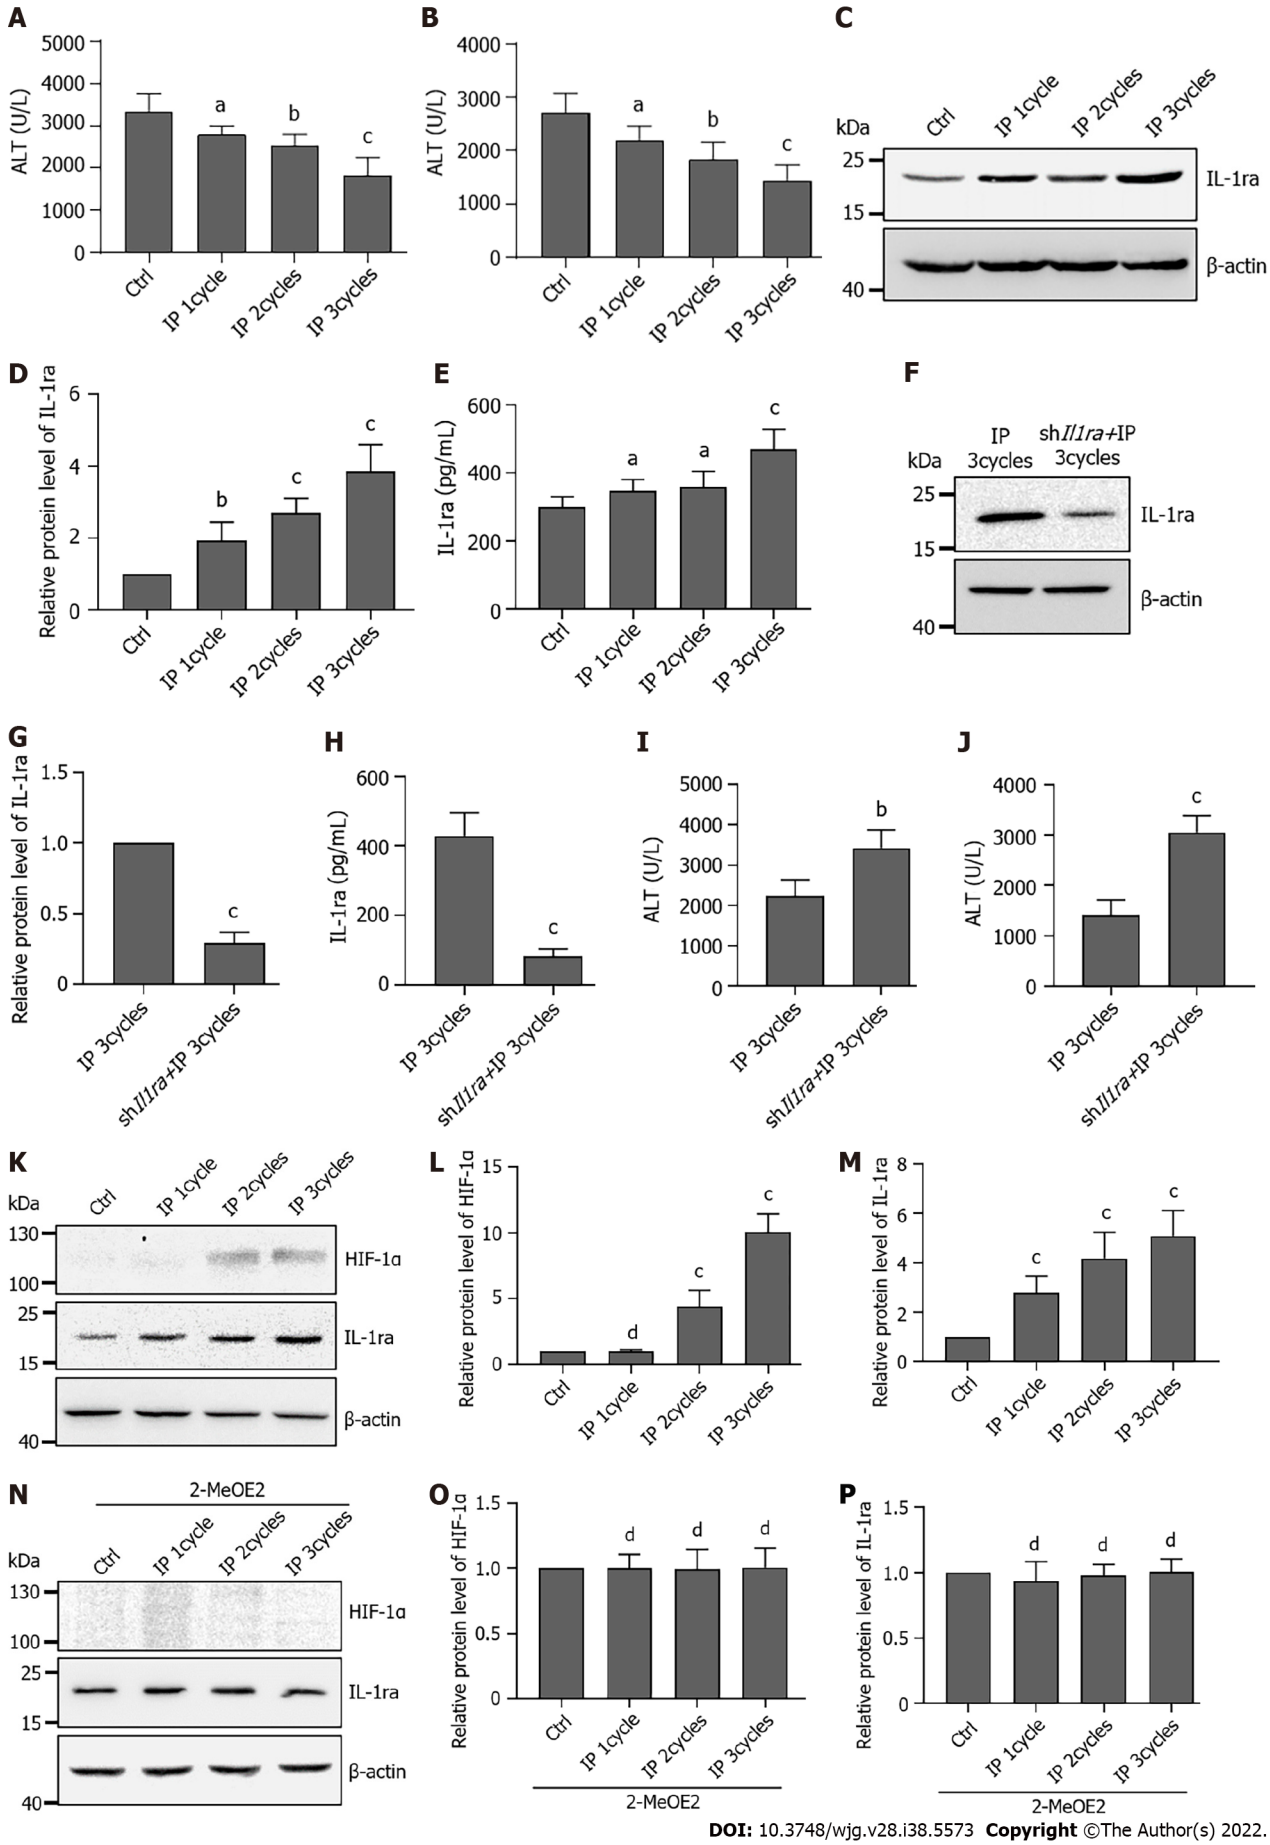


To verify whether IL-1ra plays a protective role in IP, we injected adenovirus carrying *Il1ra* shRNA *via* the tail vein to knock down the expression of IL-1ra in mice. Expression of IL-1ra in the liver and serum of mice injected with adenovirus was significantly decreased (Figures 7F-H). The ALT and AST levels were increased by knockdown of IL-1ra in the liver (Figures 7I and J).

It has been reported that HIF-1α plays an important role in IP[28], and we thus speculated that the expression of IL-1ra in IP is regulated by HIF-1α. We found that IP induced accumulation of HIF-1α in the liver (Figures 7K-M); however, 2-MeOE2 significantly attenuated this effect (Figures 7M-P). These results collectively suggested that IP might exert a protective effect on the liver from IRI through regulating the HIF-1α–IL-1ra signaling.

DISCUSSION

Hepatic IRI is a common complication of liver surgery. Previous studies have demonstrated that the IL-1 signaling pathway plays a pivotal role in the regulation of hepatic IRI. Here, we extended the study, showing that the expression of IL-1ra, an inhibitor of the IL-1 signaling pathway, is increased in response to hepatic IRI, especially in the ischemic stage. Mechanistically, hypoxia induces the transcriptional expression of IL-1ra through HIF-1α accumulation. Of note, we proved that IP could protect the liver from IRI by promoting IL-1ra expression in a HIF-1α-dependent manner. Thus, our study has provided additional evidence for the regulatory mechanism of IL-1ra during IS, indicating a practical strategy for alleviating hepatic IRI.



Previous studies have shown that hepatic IRI not only causes damage to the liver itself, but also leads to the abnormal functioning of various organs, and induces systemic inflammatory response syndrome [29]. Therefore, the question of how to reduce or even eliminate hepatic IRI has received constant attention among clinicians and researchers. Hepatic IRI is a complex pathophysiological process with numerous and relational influencing factors. Among them, the early inflammatory response plays a crucial role in the occurrence and development of hepatic IRI[30], because it is located in the upstream region of the injury response chain. Upon activation, downstream factors often promote each other and thus aggravate the injury[31]. If the activation of early inflammation can be reduced or even blocked, it may be possible to prevent the occurrence and development of hepatic IRI at source.

Current studies have shown that many proinflammatory cytokines are released in the early stage of hepatic IRI[4]. For example, blocking the activation of proinflammatory IL-1 signaling significantly prevents IRI[32]. IL-1 is a major inflammatory response mediator[33]. Experimental results have shown that large amounts of IL-1β and tumor necrosis factor-α are produced in the tissue after hepatic IS and reperfusion[34]. At the same time, this can also stimulate the secretion of inflammatory cells, leading to the inflammatory destruction of local tissues. IL-1β and the nucleotide-binding and leucine-rich repeat protein 3 (NLRP3) inflammasome play a role through high mobility group box 1 protein[35], nuclear

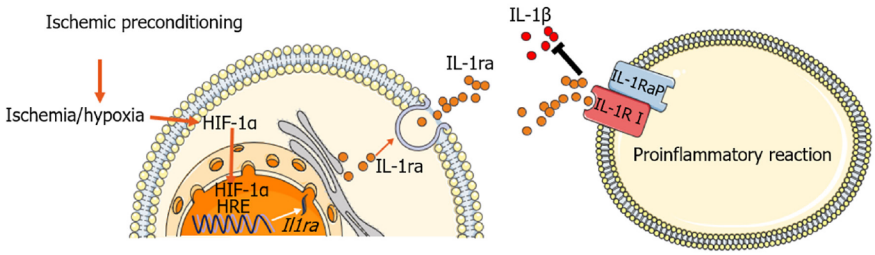
factor-κB and Toll-like receptor 4 in lesions caused by warm IRI[7]. Of note, NLRP3 may be involved in IRI independently of the inflammasome pathway by recruiting neutrophils. Macrophages secrete pro-IL-1β, which is subsequently cleaved and activated by neutrophil-derived proteases in a mouse model. Mature IL-1β is required to induce inflammation during hepatic IR, and the interaction between macrophages and neutrophils is essential in this process[6]. Therefore, the antagonism of proinflammatory IL-1 cytokines has important therapeutic potential for reducing IRI.



IL-1ra is a naturally occurring polypeptide. Recent research has focused on the role of IL-1ra in various pathophysiological states or the effects of recombinant IL-1ra administration in animals and humans[36]. It has been reported that the delivery of the *Il-1ra* gene to the rat liver *via* the adenovirus vector or lipofection can significantly reduce IR-induced proinflammatory cytokine production and hepatocyte injury[15]. This is consistent with our results showing that the knockdown of IL-1ra significantly increased the damage during hepatic IRI, suggesting a potential inhibitory effect of IL-1ra on inflammation in response to hepatic IR.

In the process of IRI, IS is a prerequisite. It is precisely regulated because the depletion of oxygen and energy in the ischemic period cause a series of injuries in the subsequent reperfusion period. In the state of hepatic IS, the metabolic mode switches from aerobic to anaerobic, the redox process in hepatocytes is blocked, the ATP-dependent cellular metabolic activity gradually stops, and the intracellular ATP is rapidly depleted. At the same time, the absence of oxygen causes HIF-1α to gradually accumulate. The increased transport of HIF-1α into the nucleus triggers the expression of genes involved in oxygen transport, oxygen utilization, glycolytic metabolism, cell death, cell survival, and other processes that affect cell survival during IS. Recent studies have demonstrated that HIF-1α can alleviate IRI by regulating the expression of inducible NO synthase[37]. HIF-1α may also enhance tissue anti-inflammatory effects by increasing heme oxygenase-1 expression, thereby reducing damage[38]. In this study, we further showed that HIF-1α, as an important protective factor in IRI, could protect the liver from injury by promoting the expression of IL-1ra and subsequently inhibiting activation of the IL-1 signaling pathway. In terms of the mechanism, we found that HIF-1α recognizes and binds to the basic helix-loop-helix protein sequence in the *Il1ra* promoter region, resulting in the increased transcription of *Il1ra*.

Recent studies have shown that IP has broad protective effects against IRI[39]. However, due to the complexity of IRI, the underlying cellular and molecular mechanisms of IP remain largely unknown. In the present study, we provided evidence that IP promotes the expression and release of IL-1ra into the hepatic microenvironment, thus blocking the downstream activation of IL-1β and protecting the liver from the cascading effects of inflammatory factors. We demonstrated that IP can induce the accumulation of HIF-1α, which increases with the number of IP cycles. These results would explain the protective effect of IP at a mechanistic level and lay a theoretical foundation for the better application of IP.

CONCLUSION

Our study demonstrated a protective effect of IL-1ra on hepatic IRI through the transcriptional regulation of IL-1ra by HIF-1α. Importantly, we found that IP can regulate the expression of IL-1ra through HIF-1α at early stage of hepatic IRI, thereby blocking the inflammatory IL-1 signaling pathway to protect the liver from IRI (Figure 8).

Figure 8 Model of ischemic preconditioning-induced hypoxia-inducible factor-1α-interleukin-1 receptor antagonist signaling to alleviate hepatic ischemia-reperfusion injury. Ischemic preconditioning promotes the accumulation of hypoxia-inducible factor (HIF)-1α, which subsequently increases HIF-1α entry into the nucleus and promotes the transcriptional expression of interleukin-1 receptor antagonist (IL-1ra). In turn, this inhibits the pro-inflammatory effects of IL-1β and eventually protects against hepatic ischemia-reperfusion injury. HIF: Hypoxia-inducible factor; IL-1ra: Interleukin-1 receptor antagonist.

ARTICLE HIGHLIGHTS

Research background

Ischemia-reperfusion injury (IRI) is associated with transplant failures, graft dysfunction, and a relatively poor prognosis. Interleukin-1 receptor antagonists (IL-1ra) play an important role in protecting the liver from IRI. However, the mechanism of its regulatory expression remains unclear.

Research motivation

Inhibition of hepatic inflammation by promoting the expression of IL-1ra is one of the key targets for the treatment of hepatic IRI.

Research objectives

To investigate the regulatory mechanism of hepatocyte-derived IL-1ra expression in the process of hepatic IRI to provide a therapeutic target for hepatic IRI.

Research methods

A 70% hepatic IRI model was established in mice, and AML12 cells were subjected to hypoxia/reoxygenation for the simulation of IRI *in vitro*. The *Il-1ra* promoter-reporter system was constructed to detect the regulatory effect of hypoxia. The ischemic preconditioning (IP) model was established to investigate its regulatory effect on IL-1ra.

Research results

IL-1ra is a key regulator of hepatic IRI. Il-1ra expression was significantly up-regulated after hepatic IRI *in vivo* and *in vitro*. Hypoxia inducible factor (HIF)-1α regulates *Il-1ra* transcription during hypoxia. IP prevents hepatic IRI by inducing the expression of IL-1ra, which is mediated by HIF-1α.

Research conclusions

Ischemia or hypoxia leads to increased IL-1ra expression through HIF-1α. In addition, IP protects the hepatic tissue from IRI through the HIF-1α-IL-1ra pathway.

Research perspectives

HIF-1α-IL-1ra pathway is a potential mechanism of hepatic protection during hepatic IRI, and also a key target for the treatment of hepatic IRI.

Abstract

BACKGROUND

The prognosis of gastric cancer in an advanced stage remains poor. The exact efficacy of the use of intraoperative sustained-release chemotherapy with 5-fluorouracil (5-FU) in advanced-stage gastric cancer is still unelucidated.

AIM

To explore the long-term survival benefit of using sustained-release 5-FU implants

in stage II and stage III gastric cancer patients.

METHODS

Patients with gastric cancer in a locally advanced stage and who underwent an R0 radical resection between Jan 2014, to Dec 2016, in this single institution were included. Patients with pathological diagnoses other than adenocarcinoma were excluded. All included patients were grouped according to whether intraoperative sustained-release (SR) chemotherapy with 5-FU was used or not (NSR). The primary end-point was 5-year overall survival. Kaplan–Meier method with log-rank test was used to analyze the overall survival of patients and Cox analysis was used to analyze prognosis factors of these patients.

RESULTS

In total, there were 563 patients with gastric cancer with locally advanced stage, who underwent an R0 radical resection. 309 patients were included in the final analysis. 219 (70.9%) were men, with an average age of 58.25 years. Furthermore, 56 (18.1%) received neoadjuvant chemotherapy, and 191 (61.8%) were in TNM stage III. In addition, 158 patients received intraoperative sustained-release chemotherapy with 5-FU and were included in the SR group, while the other 161 patients were included in the NSR group. The overall complication rate was 12.94% in the whole group and 10.81%, 16.46% in SR and NSR groups, respectively. There were no significant differences between the two groups in overall survival and complication rate ($P > 0.05$). The multivariate cox analysis indicated that only N Stage and neoadjuvant therapy were independent influencing factors of survival.

CONCLUSION

Intraoperative sustained-release chemotherapy usage with 5-FU, did not improve the survival of patients who underwent an R0 radical resection in locally advanced stage of gastric cancer.

Key Words: Sustained-release 5-fluorouracil implants; Gastric cancer; 5-year survival rate; Safety; Prognostic factor; R0 radical resection

Core Tip: Intraoperative drug administration shows promise in preventing the recurrence of gastric cancer. Sustained-release 5-fluorouracil (5-FU) implant is a new convenient and continuous drug release method that ensures locally high drug concentration for approximately 1 mo. 5-FU implants are widely used to treat various gastric tumors. However, presently, only retrospective research and a small-scale clinical study conducted in China have reported on its use in patients with gastric cancer. In our real-world study, we collected complete datasets, making this the largest study in China. Unfortunately, 5-FU implants did not improve the long-term survival of gastric cancer patients.

INTRODUCTION

Gastric cancer is the fifth most common newly diagnosed cancer and the third most common cause of cancer mortality worldwide[1-3]. In China, there are approximately 400000 new patients with gastric cancer, and nearly 300000 people die of gastric cancer every year[4]. At present, locally advanced gastric cancer with the American Joint Committee on Cancer TNM stages II and III accounts for the majority of these cases[5]. For locally-advanced gastric cancer patients, the current standard treatment is D2 gastrectomy, followed by adjuvant chemotherapy[6]. However, even in those who received standard treatment, 30–60% of them may relapse either locally or distantly[7].

Patients with stages II and III gastric cancer have been found to have a tendency to relapse after treatment[8]. According to the findings of a study by Yago *et al*[9], the 5-year recurrence-free survival rate was 88.3% for stage IIA, 73.8% for stage IIB, 67.4% for stage IIIA, 55.7% for stage IIIB, and 29.9% for stage IIIC. Of the three major recurrence patterns namely hematogenous, peritoneal, and lymph nodal

recurrences after curative gastrectomy, the latter two account for the majority of the cases[10-13]. In order to decrease local recurrence after resection, methods, such as extended peritoneal lavage[14], hyperthermic intraperitoneal perfusion chemotherapy[15], peritoneal lavage with 5-FU, and continuous intraperitoneal chemotherapy using a retained tube or pump, have been developed[16]. Furthermore, it has been reported that intraoperative intraperitoneal chemotherapy can reduce the mortality risk[17]. In addition, increasing the temperature of chemotherapeutic drugs has a synergistic effect with the increase of intraperitoneal chemotherapy. The CYTO-CHIP study group reported that compared with the routine method of cytoreductive surgery combined with hyperthermic intraperitoneal chemotherapy, it can improve median overall survival time and increase the 3-and 5-year overall survival rates [18]. In another study, the use of catheter-based intraperitoneal chemotherapy showed similar results of increased the 5-year overall survival rate and reduced the peritoneal recurrence rate[19]. The use of sustained-release 5-FU implants intraoperatively is a relatively newly developed method and has been used widely in almost all types of digestive tract cancer in China[20]. When this drug was placed intraoperatively into the tumor bed, it was released continuously, and it maintained a locally high drug concentration for approximately 1 mo[21]. The potential remnant tumor tends to grow quickly in the first year after resection owing to the decreased immunity and absence of adjuvant chemotherapy[9]. This is the theoretical basis for the use of sustained-release 5-FU implants.

Moreover, optimistic results concerning the use of sustained-release 5-FU implants in the treatment of gastric cancer have been shown. Recently, a multi-center, randomized, open-label, controlled clinical study showed that for cTNM stage III gastric cancer patients, the use of intraoperative 5-FU implants, combined with postoperative adjuvant chemotherapy, may reduce the risk of peritoneal recurrence and prolong progression-free survival significantly[22]. Another retrospective study with 5-FU implants in advanced gastric cancer patients showed that the use of 5-FU implants may improve 5-years overall survival (OS) and progression-free survival rates after surgery in gastric cancer patients[21]. However, these studies had limitations. The sample size of these studies was limited, the follow-up times were insufficient, and the rate of loss of follow-up was extremely high. In order to explore the long-term survival benefit of the use of sustained-release 5-FU implants, we conducted a real-world study using our own clinical data from a single institution.

MATERIALS AND METHODS

Data Collection and Primary Outcomes

In total, we treated 563 stages II and III gastric cancer patients between January 2014 and December 2016. The inclusion criteria were the presence of clinical TNM stage II and stage III, pathologically diagnosed adenocarcinoma of the stomach, a complete record of history, and age between 18–80 years. The exclusion criteria were the presence of gastric remnant cancer, distant metastases, positive peritoneal cytology, palliative resection, and any unsuitable condition for 5-FU chemotherapy. The primary clinical outcome was 5-year OS. Information on the patients' age, sex, body mass index, tumor (TNM Stage, Borrmann classification, Lauren classification, pathological classification, differentiation, number of resected lymph nodes, number of positive lymph nodes, as well as the extent of nerve invasion, and presence of a vascular tumor thrombus), treatment (resections, neoadjuvant therapy, and use of 5-FU implants), postoperative complications (pulmonary infections, anastomotic fistulas, bleeding, abdominal infections, intestinal obstructions, and admissions to the intensive care unit), and their follow-up results were extracted from our hospital's electronic records.

Treatment methods

All our patients underwent a standard D2 gastric resection with or without neoadjuvant therapy. In addition, all the patients received 6–8 cycles of adjuvant chemotherapy with an S-1 + oxaliplatin regimen. In the sustained-release (SR) group, sustained-release 5-FU implants in a fixed dosage of 1000 mg were placed intraoperatively near the tumor bed after resection. Other patients were divided into non-sustained-release (NSR) group. The placement of 5-FU implants near vessels and anastomotic stoma should be avoided.

Statistical analyses

The continuous variables were presented as central tendencies (means or medians) and dispersions (standard deviations or interquartile ranges). For the group comparisons of the numeric variables, the Student's *t*-test was used when the data were normally distributed, and the Mann–Whitney test for the variables in which distribution was not normal. When the categorical predictors were compared between the groups, we used Pearson's χ^2 test or Fisher's exact test. The survival analysis included the use of the Kaplan–Meier estimator for OS. A Cox regression analysis was performed to obtain the crude and adjusted hazard ratios for OS. Significance level for all tests was reached when the two-tailed P value was < 0.05. Statistical analyzes were performed using the IBM SPSS Statistics (version 26.0, IBM Inc., Armonk, NY, United States), and Prism software (version 9, GraphPad Software Inc., San Diego, CA, United States).

RESULTS

Clinicopathological characteristics

In total, 241 patients with incomplete data and 13 patients with a pathological diagnosis of gastric neuroendocrine tumor were excluded. Finally, 309 patients were included in this study, and they were divided into two groups according to whether sustained-release 5-FU was used or not. Therefore, there were 158 patients in the SR group and 164 patients in the NSR group (Figure 1).

The average age of the whole group was 58.25 ± 11.2 years, with male patients being the majority (70.9%). All the patients were diagnosed pathologically as having a stomach adenocarcinoma of TNM stages II and III. Furthermore, 32.4% of patients had signet ring cell carcinoma. All of the patients underwent an R0 resection surgery. As shown in Table 1, we compared the differences in the clinicopathological characteristics between the two patient cohorts. There were no significant differences between the two groups with respect to age, sex, body mass index, and TNM stage. Similarly, there were no differences between the two groups with respect to their pathological characteristics such as the Borrmann classification, Lauren classification, and differentiation. Although the number of resected lymph nodes in the SR group was higher than that in the NSR (P = 0.0145), the number of positive lymph nodes number was similar (P = 0.2319). Lymph node dissection was satisfactory in both groups, even though there was a gap between the two groups (Table 1).

Postoperative complications in patients

Table 2 shows the major postoperative complications, such as pulmonary inflections, anastomotic fistulas, postoperative bleeding, abdominal infections, and intestinal obstructions. There were no significant differences between the two groups with respect to the incidence of postoperative complications (P > 0.05).

Prognostic factors in gastric cancer patients

Figure 2 shows the results of the univariate and multivariate Cox analyses. From the univariate analysis, N stage (P < 0.001), T stage (P = 0.001), TNM stage (P < 0.001) neoadjuvant therapy (P < 0.001), Borrmann classification (P = 0.001), and resection type (P = 0.002) were found to be influencing prognostic factors in this group of patients. As per the multivariate Cox analysis, only N stage (P = 0.030) and neoadjuvant therapy were found to be independent influencing prognostic factors (Figure 2 and Table 3). The use of sustained-release 5-FU implants was not an independent influencing prognostic factor in this group (P = 0.786).

Survival outcomes

The 5-years OS rate of the SR and NSR groups were 68.2% and 67.9%, respectively (P = 0.9850). The median survival time for both groups was not obtained, as patient mortality numbers were too low to calculate. Furthermore, we performed subgroup comparisons according to the patient's age, sex, and TNM stage. There were no significant differences in any of the subgroups (P > 0.05) (Figures 3 and 4, Table 3).

DISCUSSION

Gastric cancer remains one of the most lethal cancers in China[23,24]. Almost 70% of the relapses occur within 2 years and more than 90% within 5 years[7,25]. In clinical practice, the recurrence patterns are classified as locoregional, peritoneal, and hematogenous. As reported by Wu, approximately all of the recurrences (99.5%) occurred within 7 years after the surgery, with 53.5% having had peritoneal dissemination, 43.3% hematogenous metastases, and 28.6% distant lymphatic spread[26]. The locoregional and peritoneal recurrences, which usually occur in gastric cancer patients, were found to be a critical problem. Peritoneal recurrence has been reported as the most common recurrence pattern in locally advanced gastric cancer patients, which accounts for 50% of the cases and occurs within 2 years after surgery[27]. In another study, almost 60% of the gastric cancer patients experienced a recurrence, which included 32.4% locoregional recurrences, 13.7% peritoneal metastases, and 44.3% distant metastases[28].

To reduce locoregional recurrences, intraperitoneal chemotherapy has been used widely worldwide. Different from other methods, the use of intraoperative sustained-release 5-FU is promising because of the convenient usage and a long effective time of approximately 1 mo. The use of sustained-release 5-FU implants has shown survival benefits in different types of digestive system tumors such as colon cancer and primary hepatic cellular cancer[29,30]. Furthermore, a few studies on the treatment of gastric cancer, which showed similar results, were also reported by Chinese researchers[21,22]. However, P values of survival benefits obtained in previous studies on gastric cancer were lower, but close to 0.05. Therefore, we conducted this real-world study to confirm the findings.

In the present study, the use of sustained-release 5-FU implants did not improve the long-term survival of gastric cancer patients with either TNM stage II or III. The estimated 5-year survival of patients with gastric cancer with TNM stage III in SR and NSR group was 50% and 49%, respectively (P

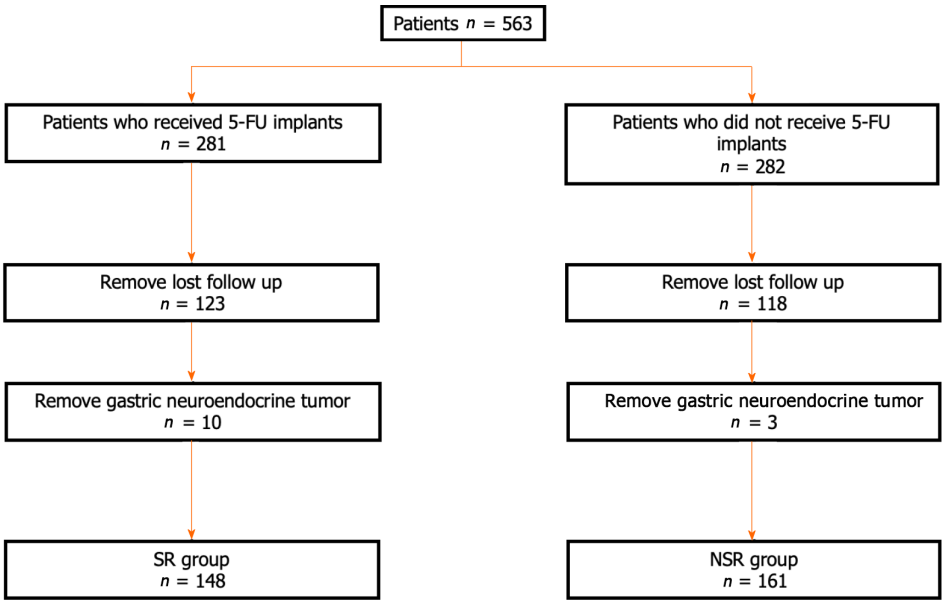
Intestinal obstruction	3 (2.0)	1 (0.6)	0.556

SR: Sustained-release; NSR: Not sustained-release.

= 0.775), slightly higher than that of previous studies[31,32]. This may have been due to the R0 radical resection decreasing the risk of local-regional recurrence and compromising the effects of the sustained-release drug. Therefore, we may hypothesize that in cases of incomplete resections, such as an R1 resection, or if the lymph node dissection did not reach the D2 resection standard, the use of a sustained-release drug may improve survival. Previous results of drug use in the treatment of unresectable tumors, such as pancreatic cancer and colorectal cancer, provided evidence for this hypothesis[33].



Similar to the findings of previous studies, the use of the sustained-release 5-FU implants did not increase postoperative complications, and systemic toxicity was rare in the present study. The use of 5-FU implants is usually recommended in gastric cancer patients, particularly at TNM stage T4 or N1–3

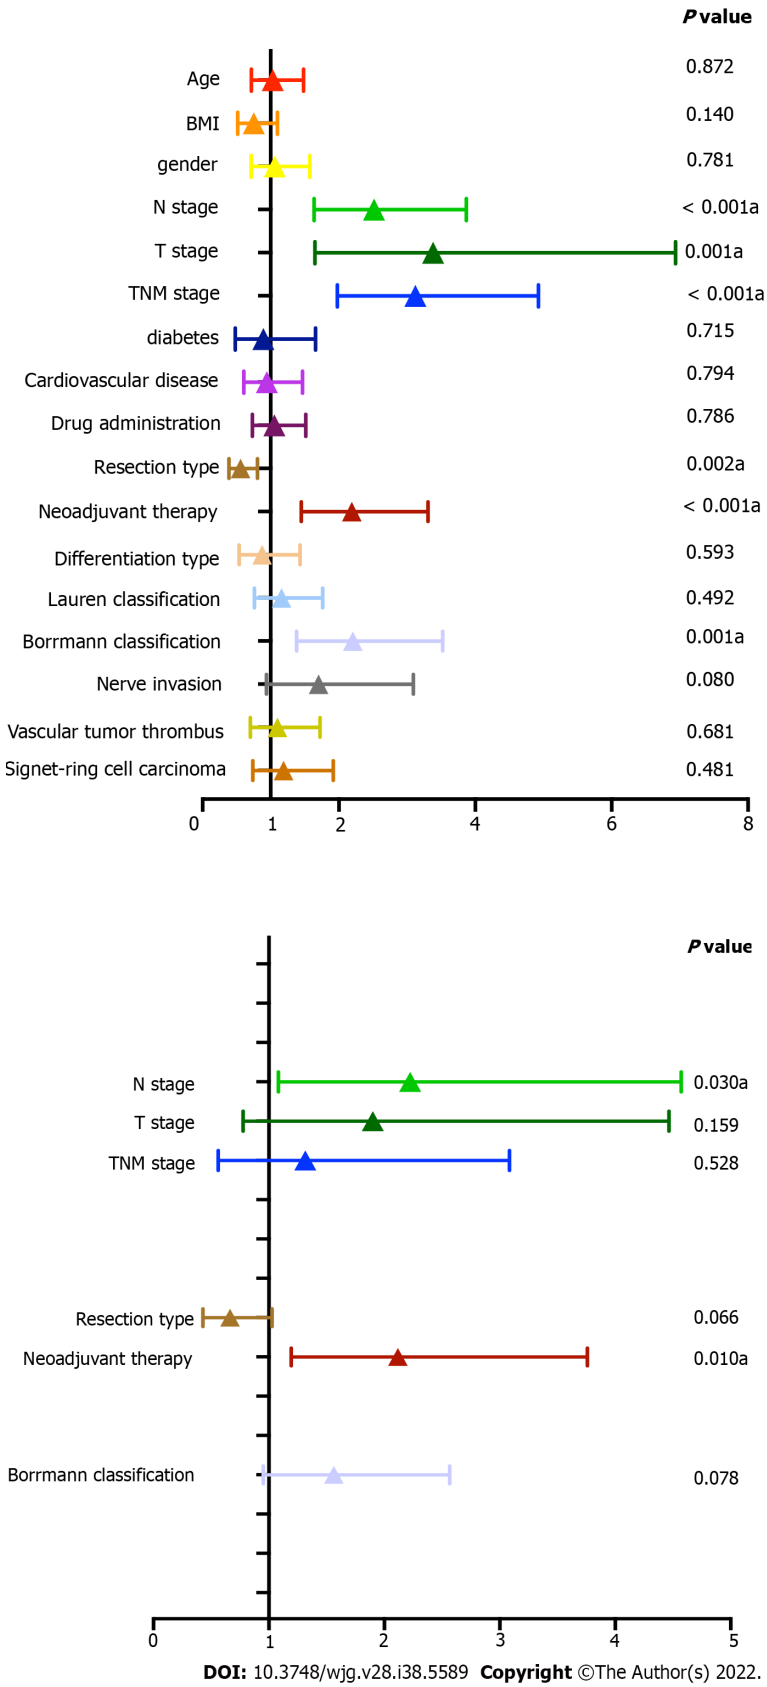

Figure 1 Flowchart of the selection of gastric cancer patients. 5-FU: 5-fluorouracil; NSR: Non-sustained-release.

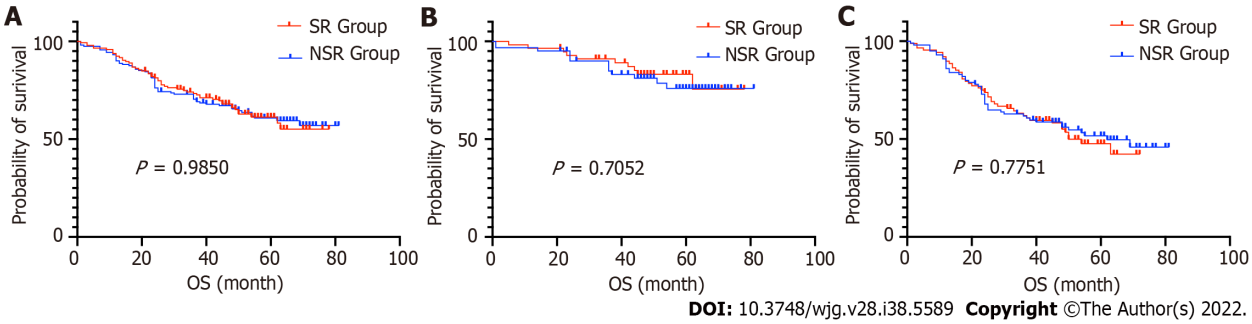
[34]. In our study, the selection criteria were based on preoperative image examinations. Patients treated with 5-FU implants were in stage II and III, which is in accordance with the recommendations from the Chinese expert consensus[34].

Our study had some limitations. First, the sample size was insufficient. However, to date it remains the largest group studied. Second, selection biases existed. Many patients had incomplete history records, which may have contributed to a contrary result. Finally, the exact relapse time and the first site of recurrence were recorded incompletely. Owing to a lack of analysis of the relapses, the results were compromised. In order to understand the survival benefit of the sustained-release 5-FU plants on gastric cancer, a randomized controlled large-scale study is needed.



CONCLUSION

While the use of intraoperative sustained-release chemotherapy with 5-FU did not improve the survival of patients in an advanced stage of gastric cancer who underwent an R0 radical resection, it was a safe method, and it did not increase the complication rate.

NSR: Non-sustained-release.

ARTICLE HIGHLIGHTS

Research background

The prognosis of gastric cancer in an advanced stage remains poor. The exact efficacy of the use of intraoperative sustained-release chemotherapy with 5-fluorouracil (5-FU) in advanced-stage gastric cancer is still unelucidated.

Research motivation

To explore the long-term survival benefit of using sustained-release 5-FU implants in stage II and stage III gastric cancer patients.

Research objectives

To explore the long-term survival benefit of using sustained-release 5-FU implants in stage II and stage III gastric cancer patients.

Research methods

All included patients were grouped according to whether intraoperative sustained-release (SR) chemotherapy with 5-FU was used or not (NSR). The primary end-point was 5-year overall survival. Kaplan–Meier method with log-rank test was used to analyze the overall survival of patients and Cox analysis was used to analyze prognosis factors of these patients.

Research results

309 patients were included in the final analysis. In addition, 158 patients received intraoperative sustained-release chemotherapy with 5-FU and were included in the SR group, while the other 161 patients were included in the NSR group. The overall complication rate was 12.94% in the whole group and 10.81%, 16.46% in SR and NSR groups, respectively. There were no significant differences between the two groups in overall survival and complication rate ($P > 0.05$).

Research conclusions

Intraoperative sustained-release chemotherapy usage with 5-FU, did not improve the survival of patients who underwent an R0 radical resection in locally advanced stage of gastric cancer.

Research perspectives

5-FU implants did not improve survival.

Abstract

BACKGROUND

The optimal timing of endoscopic retrograde cholangiopancreatography (ERCP) in acute cholangitis (AC) is uncertain, especially in patients with AC of varying severity.

AIM

To report whether the timing of ERCP is associated with outcomes in AC patients with different severities.

METHODS

According to the 2018 Tokyo guidelines, 683 patients who met the definite diagnostic criteria for AC were retrospectively identified. The results were first compared between patients receiving ERCP ≤ 24 h and > 24 h and then between patients receiving ERCP ≤ 48 h and > 48 h. Subgroup analyses were performed in patients with grade I, II or III AC. The primary outcome was 30-d mortality. Secondary outcomes were intensive care unit (ICU) admission rate, length of hospital stay (LOHS) and 30-d readmission rate.

RESULTS

Taking 24 h as the critical value, compared with ERCP > 24 h, malignant biliary obstruction as a cause of AC was significantly less common in the ERCP ≤ 24 h group (5.2% *vs* 11.5%). The proportion of cardiovascular dysfunction (11.2% *vs* 2.6%), respiratory dysfunction (14.2% *vs* 5.3%), and ICU admission (11.2% *vs* 4%) in the ERCP ≤ 24 h group was significantly higher, while the LOHS was significantly shorter (median, 6 d *vs* 7 d). Stratified by the severity of AC, higher ICU

admission was only observed in grade III AC and shorter LOHS was only observed in grade I and II AC. There were no significant differences in 30-d mortality between groups, either in the overall population or in patients with grade I, II or III AC. With 48 h as the critical value, compared with ERCP > 48 h, the proportion of choledocholithiasis as the cause of AC was significantly higher in the ERCP ≤ 48 h group (81.5% *vs* 68.3%). The ERCP ≤ 48 h group had significantly lower 30-d mortality (0 *vs* 1.9%) and shorter LOHS (6 d *vs* 8 d). Stratified by AC severity, lower 30-d mortality (0 *vs* 6.1%) and higher ICU admission rates (22.2% *vs* 10.2%) were only observed in grade III AC, and shorter LOHS was only observed in grade I and II AC. In the multivariate analysis, cardiovascular dysfunction and time to ERCP were two independent factors associated with 30-d mortality.

CONCLUSION

ERCP ≤ 48 h conferred a survival benefit in patients with grade III AC. Early ERCP shortened the LOHS in patients with grade I and II AC.

Key Words: Acute cholangitis; Endoscopic retrograde cholangiopancreatography; severity; Timing; Thirty-day mortality; Length of hospital stay

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Compared with endoscopic retrograde cholangiopancreatography (ERCP) > 24 h, ERCP ≤ 24 h group had a significantly higher intensive care unit (ICU) admission rate and shorter length of hospital stay (LOHS). Subgroup analysis showed higher ICU admission rate was only in grade III acute cholangitis (AC); shorter LOHS was only in grade II and I AC. Compared with ERCP > 48 h, ERCP ≤ 48 h group had significantly lower 30-d mortality and shorter LOHS. Subgroup analysis revealed lower 30-d mortality was only in grade III AC; shorter LOHS was only in grade II and I AC. We concluded that ERCP ≤ 48 h conferred a survival benefit in grade III AC; early ERCP shortened LOHS in grade II and I AC.

INTRODUCTION

Without treatment, patients with acute cholangitis (AC) may progress to septicemia and organ failure resulting in mortality[1,2]. Over the past two decades, endoscopic retrograde cholangiopancreatography (ERCP) has been generally accepted as a first-line treatment for AC[3,4]. Although delayed biliary drainage may not affect the risk of complications in patients who respond well to antibiotics, some patients with AC require early ERCP to avoid (persistent) organ failure or mortality[2,5,6]. Despite consensus on the need for biliary drainage, the optimal timing for early ERCP remains unclear due to mixed results in the literature[7]. Different definitions of early ERCP have been used in the literature, ranging from 12 h to 72 h[2,5,8-11]. The varied definitions among studies have led to inconsistent conclusions. In addition, the definitions of AC are not uniform across studies. More importantly, most studies did not define the timing of ERCP by stratifying the severity of AC[7]. In this context, the recently published Tokyo Guidelines 2018 (TG18) provide not only a diagnosis of AC but also a severity grading, which is important for predicting prognosis and determining treatment strategies[3]. However, although TG18 recommends early or urgent biliary drainage for moderate or severe cholangitis, there is no specific timing for early or urgent ERCP. Therefore, this study aims to investigate whether the timing of ERCP is associated with improved outcomes in AC patients with different severities.

MATERIALS AND METHODS

This was a retrospective study conducted at Chang Gung Memorial Hospital Linkou Center. At our center, ERCP has been the first-line of treatment for patients with AC for the past two decades. This study was reviewed and approved by the Ethics Committee of the Chang Gung Memorial Hospital (IRB No. 202200881B0). Since this was a retrospective study using routine clinical treatment or diagnostic

medical records, the Chang Gung Medical Foundation Institutional Review Board approved the waiver of the participant's consent. All methods were carried out under relevant guidelines and regulations.

Definition of acute cholangitis

The diagnostic criteria for AC were based on the 2018 Tokyo Guidelines, including systemic inflammation, cholestasis and imaging findings[3]. Systemic inflammation included fever (body temperature > 38 °C) or evidence of an inflammatory response [white blood cell (WBC) count < 4000 or > 10000/μL or C-reactive protein ≥ 1 mg/dL]. Cholestasis included jaundice (serum total bilirubin ≥ 2 mg/dL) or abnormal liver function tests (serum alkaline phosphatase, r-glutamyl transferase, aspartate aminotransferase, or alanine aminotransferase > 1.5 times the upper limit of the normal value). Imaging findings included bile duct dilatation or imaging evidence of etiology such as strictures, stones or stents. A definite diagnosis of AC was defined as one item in systemic inflammation, one item in cholestasis and one item in imaging findings.

Definition of the severity of acute cholangitis

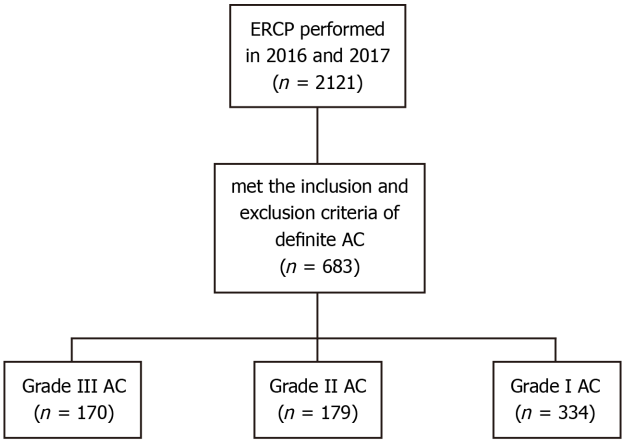
AC severity was divided into three grades based on the 2018 Tokyo Guidelines[3]. Grade III (severe) AC was AC associated with the onset of dysfunction in at least one of the following organs/systems: cardiovascular dysfunction (defined as hypotension requiring dopamine ≥ 5 μg/kg per min, or any dose of norepinephrine), neurological dysfunction (presence of conscious disturbance), respiratory dysfunction (defined as PaO_2/FiO_2 ratio < 300), renal dysfunction (oliguria, serum creatinine > 2.0 mg/dL), hepatic dysfunction [defined as prothrombin time-international normalized ratio (PT-INR) > 1.5] or hematological dysfunction (defined as platelet count < 100 × 10^3/μL). Grade II (moderate) AC was AC associated with any two of the following conditions: abnormal WBC count (> 12000/μL or < 4000/μL), high fever (≥ 39 °C), old age (≥ 75 years), hyperbilirubinemia (serum total bilirubin ≥ 5 mg/dL), or hypoalbuminemia (< lower limit of normal value × 0.7). Grade I (mild) AC was AC that did not meet the criteria of "Grade III" or "Grade II" AC at initial diagnosis.

Definition of time to ERCP

Time to ERCP was defined as the time from the emergency department visit to the commencement of ERCP.

Patient selection and clinical variables

The study flow chart is shown in Figure 1. Between 2016 and 2017, 2121 patients who underwent ERCP in our center were retrospectively collected from the computer database of the Therapeutic Endoscopy Center. The inclusion criteria were patients who met the TG18/TG13 criteria for a definite diagnosis of AC. The exclusion criteria were: (1) Patients who did not meet the criteria for a definite diagnosis of AC; (2) inpatients who developed AC after hospitalization; and (3) patients who received ERCP 7 or more days after an emergency department visit. For patients readmitted for AC during the study period, we included only the first admission and the ERCP procedure.



Medical records were reviewed, and the following data were obtained: sex; age; clinical manifestations, including body temperature, systolic blood pressure, heart rate, saturation, respiratory rate and urine output; laboratory values including WBC count, platelet count, PT-INR, C-reactive protein, creatinine, bilirubin, alkaline phosphatase, r-glutamyl transferase, aspartate aminotransferase, alanine aminotransferase and albumin; diagnosis and treatment of ERCP, including causes of obstruction (such as stones, malignant strictures or stent dysfunction); and the timing of ERCP.

Outcome assessments

The primary outcome was 30-d mortality. Secondary outcomes were ICU admission rate, length of hospital stay (LOHS) and 30-d readmission rate. The results were first compared for patients receiving ERCP ≤ 24 h *vs* > 24 h and then for patients receiving ERCP ≤ 48 h *vs* > 48 h. Subgroup analyses were also performed in patients with grade I, II, and III AC.

Statistical analysis

Continuous variable data are represented by the median and interquartile range (IQR); categorical variables are presented as a number (%). For comparisons, the Kruskal-Wallis test was used for continuous variable data and the chi-square test or Fisher's exact test was used for suitable categorical variables. Logistic regression analysis was performed to identify factors associated with 30-d mortality. Only variables with a P value < 0.05 in the univariate analysis were included in the multivariate analysis. Two-tailed P values < 0.05 were considered statistically significant and P values = 0.05 were considered marginally significant. Statistical analysis was performed using SPSS software (version 22.0; SPSS, Inc., Chicago, IL, United States).

Figure 1 Study flow chart. AC: Acute cholangitis; ERCP: Endoscopic retrograde cholangiopancreatography.

RESULTS

A total of 683 patients who met the eligibility criteria were included in the study. Among them, there were 170 (24.9%) grade III AC patients, 179 grade II AC patients (26.4%) and 334 grade I AC patients (48.9%).

Patient characteristics

The baseline characteristics of the patients are presented in Table 1. The median (IQR) age of the patients was 66 (53-78) years; 57.2% were male. The median body temperature was 37.5 (36.8-38.4) °C and 58.4% of patients had abnormal WBC counts. The median platelet count was 198 × 10^3 (148 × 10^3-251 × 10^3)/μL. The median serum levels of aspartate aminotransferase, alanine aminotransferase and alkaline phosphatase were 150 U/L, 166 U/L and 265 U/L, respectively. Serum amylase and lipase data were available for 307 (44.9%) and 487 (71.3%) patients with median levels of 65 U/L and 37 U/L, respectively. The median serum bilirubin level was 3.7 (2.3-6.3) mg/dL and the median creatine level was 0.93 (0.73-1.24) mg/dL. The median PT/INR was 1.1 (1.1-1.2). Only 133 (19.5%) patients had data on serum albumin and the median level was 3.56 (3.05-3.98) g/dL. Twenty-nine (4.2%) patients had cardiovascular dysfunction, 35 (5.1%) patients had neurological dysfunction and 48 (7%) patients had respiratory dysfunction.

Comparisons between ERCP ≤ 24 h and ERCP > 24 h: Compared with ERCP > 24 h, patients with ERCP ≤ 24 h had significantly lower body temperature (median, 37.2 °C *vs* 37.5 °C. P = 0.003), significantly higher serum alanine aminotransferase (median, 194 U/L *vs* 156 U/L, P = 0.02) and serum creatinine levels (median, 0.96 *vs* 0.93, P = 0.004), and significantly higher proportions of abnormal WBC counts (70.9% *vs* 55.4%, P = 0.001), cardiovascular dysfunction (11.2% *vs* 2.6%, P < 0.001) and respiratory dysfunction (14.2% *vs* 5.3%, P < 0.001).

Comparisons between ERCP ≤ 48 h and ERCP > 48 h: Compared with ERCP > 48 h, patients with ERCP ≤ 48 h had significantly lower body temperature (median, 37.4 °C *vs* 37.6 °C, P = 0.009), significantly higher serum alanine aminotransferase levels (median, 188 U/L *vs* 142 U/L, P = 0.004) and significantly lower PT/INR (median, 1.1 *vs* 1.2, P = 0.001).

ERCP characteristics and causes of AC

The characteristics of ERCP are listed in Table 2. Causes of AC included common bile duct stones (CBDS, 74.4%), malignant biliary obstruction (MBO, 10.2%), biliary stent dysfunction (8.9%), benign biliary stricture (4.5%) and others (1.9%). ERCP failed in 1% of patients. For patients with successful ERCP, endoscopic treatments during ERCP included endoscopic sphincterotomy (81.7%), endoscopic papillary balloon dilatation (0.7%), bile duct stone retrieval (73.5%), stone-free bile duct clearance (5.4%), removal of old biliary stents (8.8%), insertion of new biliary stents (27.4%), dilation of biliary strictures (1%) and others (0.4%).

Comparisons between ERCP ≤ 24 h and ERCP > 24 h: The median time to ERCP was 17.7 (9.0-20.4) h in the ERCP ≤ 24 h group and 67.6 (43.6-98.9) h in the ERCP > 24 h group. Only malignant biliary obstruction as a cause of AC was significantly less common in the ERCP ≤ 24 h group (5.2% *vs* 11.5%, P = 0.032). In therapeutic ERCP, bile duct stone retrieval was higher in the ERCP ≤ 24 h group (80.6% *vs* 71.8%, P = 0.038) whereas the old biliary stent removal rate was lower (4.5% *vs* 9.8%, P = 0.049).

Table 1 Characteristics of the patients

Patient characteristics	Total, *n* = 683	Time to ERCP divided by 24 h			Time to ERCP divided by 48 h		
		ERCP ≤ 24 h, *n* = 134	ERCP > 24 h, *n* = 549	*P* value	ERCP ≤ 48 h, *n* = 314	ERCP > 48 h, *n* = 369	*P* value

[1]Expressed as median (interquartile range).
[2]Abnormal WBC count is defined as WBC < 4000/μL or > 12000/μL.
ALK-P: Alkaline phosphatase; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; BT: Body temperature; ERCP: Endoscopic retrograde cholangiopancreatography; PT/INR: Prothrombin time/international normalized ratio; WBC: White blood cell count.

Comparisons between ERCP ≤ 48 h and ERCP > 48 h: The median time to ERCP was 26.0 (18.8-40.1) h in the ERCP ≤ 48 h group and 88.5 (67.2-114.6) h in the ERCP > 48 h group. Regarding indications for ERCP, CBDS was more common in the ERCP ≤ 48 h group (81.5% *vs* 68.3%, $P < 0.001$) whereas malignant biliary obstruction (6.1% *vs* 13.8%, $P < 0.001$) and stent dysfunction were less common (5.4% *vs* 11.9%, $P = 0.003$). In therapeutic ERCP, endoscopic sphincterotomy (85.7% *vs* 78.3%, $P = 0.013$) and bile duct stone retrieval (79.6% *vs* 68.3%, $P = 0.001$) were more frequent in the ERCP ≤ 48 h group whereas the removal of old biliary stents (5.4% *vs* 11.7%, $P = 0.004$) and the insertion of new biliary stents (22.3% *vs* 31.7%, $P = 0.006$) were less frequent.

Primary and secondary outcomes

The primary and secondary outcomes are summarized in Table 3.

Overall patients: Overall, the 30-d mortality rate was 1.02% (or 7/683). The ICU admission rate was 5.4%; the median LOHS was 7 (5-10) d; and the 30-d readmission rate was 12.7%.

(1) Comparisons between ERCP ≤ 24 h and ERCP > 24 h: The overall 30-d mortality rate was 0 in the ERCP ≤ 24 h group and 1.3% in the ERCP > 24 h group. However, the difference did not reach statistical significance ($P = 0.356$). Regarding secondary outcomes, the ERCP ≤ 24 h group had significantly higher ICU admission rates (11.2% *vs* 4.0%, $P = 0.001$) and shorter LOHS (median, 6 d *vs* 7 d, $P = 0.018$).

(2) Comparisons between ERCP ≤ 48 h and ERCP > 48 h: Overall, the 30-d mortality rate was significantly lower in the ERCP ≤ 48 h group than in the ERCP > 48 h group (0 *vs* 1.9%, $P = 0.017$). For secondary outcomes, the ERCP ≤ 48 h group had a significantly shorter LOHS (median, 6 d *vs* 8 d, $P <$

0.001).

Patients with Grade III AC: The 30-d mortality rate was 3.5% (or 6/170) for patients with grade III AC. The ICU admission rate was 15.3%; the median LOHS was 7 (7-14) d; and the 30-d readmission rate was 13.5% in this patient group.

(1) Comparisons between ERCP ≤ 24 h and ERCP > 24 h: The 30-d mortality rate for grade III AC patients was 0 in the ERCP ≤ 24 h group and 4.6% in the ERCP > 24 h group. However, the difference did not reach statistical significance ($P = 0.338$). Regarding secondary outcomes, the ERCP ≤ 24 h group had significantly higher ICU admission rates (9.0% *vs* 2.6%, $P = 0.002$).

(2) Comparisons between ERCP ≤ 48 h and ERCP > 48 h: Among grade III AC patients, the 30-d mortality rate was significantly lower in the ERCP ≤ 48 h group than in the ERCP > 48 h group (0 *vs* 6.1%, $P = 0.039$). Regarding secondary outcomes, the ERCP ≤ 48 h group had significantly higher ICU admission rates (22.2% *vs* 10.2%, $P = 0.031$).

Patients with Grade II AC: The 30-d mortality rate was 0 for patients with grade II AC. The ICU admission rate was 2.8%; the median LOHS was 7 (5-10) d; and the 30-d readmission rate was 13.4% in this patient group.

(1) Comparisons between ERCP ≤ 24 h and ERCP > 24 h: The only significant finding in grade II AC patients was that the LOHS was shorter (median, 6 d *vs* 7 d, $P = 0.047$) in the ERCP ≤ 24 h group.

(2) Comparisons between ERCP ≤ 48 h and ERCP > 48 h: Among grade II AC patients, the only significant finding was that the LOHS was shorter (median, 6 d *vs* 8 d, $P = 0.001$) in the ERCP ≤ 48 h group.

Patients with Grade I AC: The 30-d mortality rate was 0.3% (or 1/334) for patients with grade I AC. The ICU admission rate was 1.8%; the median LOHS was 6 (5-9) d; and the 30-d readmission rate was 12% in this patient group.

(1) Comparisons between ERCP ≤ 24 h and ERCP > 24 h: The only significant finding in grade I AC patients was that the LOHS was shorter (median, 6 d *vs* 7 d, $P = 0.005$) in the ERCP ≤ 24 h group.

Table 3 Primary and secondary outcomes

Outcomes	Total	Time to ERCP divided by 24 h			Time to ERCP divided by 48 h

LOHS in d[1]	6 (5-9)	6 (4-8.3)	7 (5-9.8)	0.005	6 (4-7)	7 (6-11)	< 0.001
30-d readmission, *n* (%)	40 (12)	8 (14.3)	32 (11.5)	0.56	22 (14.3)	18	0.229

[1]Expressed as median (interquartile range). AC: Acute cholangitis; ERCP: Endoscopic retrograde cholangiopancreatography; ICU: Intensive care unit; LOHS: Length of hospital stay.

(2) Comparisons between ERCP ≤ 48 h and ERCP > 48 h: Among grade I AC patients, the only significant finding was that the LOHS was shorter (median, 6 d *vs* 7 d, $P < 0.001$) in the ERCP ≤ 48 h group.

Factors associated with 30-d mortality

The results of the univariate and multivariate analyses are listed in Table 4. The univariate analysis revealed that malignant biliary obstruction (OR: 6.817, 95%CI: 1.494-31.109, $P = 0.013$), hepatic dysfunction (OR: 8.896, 95%CI: 1.645-48.119, $P = 0.011$), respiratory dysfunction (OR: 10.517, 95%CI: 2.284-48.431, $P = 0.003$), neurological dysfunction (OR: 15.094, 95%CI: 3.241-70.298, $P = 0.001$), cardiovascular dysfunction (OR: 18.750, 95%CI: 3.990-88.112, $P < 0.001$), severity of AC (severe *vs* moderate + mild, OR: 18.732, 95%CI: 2.239-156.728, $P = 0.007$), ICU admission (OR: 7.326, 95%CI: 1.373-39.101, $P = 0.02$), and time to ERCP (every 1-d delay, OR: 1.950, 95%CI: 1.252-3.038, $P = 0.003$) were associated with 30-d mortality. The multivariate analysis revealed that time to ERCP (every 1-d delay, OR: 2.081, 95%CI: 1.154-3.753, $P = 0.015$) was the only independent factor associated with 30-d mortality. However, cardiovascular dysfunction (OR: 17.756, 95%CI: 0.994-317.241, $P = 0.050$) was of marginal significance.

DISCUSSION

Kiriyama *et al*[3] reported that early or urgent ERCP significantly reduced 30-d mortality only in patients with grade II AC compared with patients who did not receive early or urgent ERCP. This result may be due to the lack of well-defined timing for early or urgent ERCP. In a meta-analysis published in 2020, Du *et al*[7] reported that early ERCP reduced in-hospital mortality regardless of whether it was defined as < 24 h, < 48 h or < 72 h. In the present study, we found that ERCP ≤ 48 h but not ERCP ≤ 24 h

Table 4 Univariate and multivariate analyses of the factors associated with 30-d mortality

Variables		Univariate analysis		Multivariate analysis	
		OR (95%CI)	*P* value	OR (95%CI)	*P* value
Age	≥ 75 yr	1.772 (0.393-7.991)	0.456		
	< 75 yr	Reference			
Common bile duct stones	Yes	0.254 (0.056-1.146)	0.075		
	No	Reference			
Malignant biliary obstruction	Yes	6.817 (1.494-31.109)	0.013	7.718 (0.664-89.660)	0.102

	No	Reference			
Time to ERCP	Every 1-d delay	1.950 (1.252-3.038)	0.003	2.081 (1.154-3.753)	0.015

[1]Defined as hypotension requiring dopamine ≥ 5 μg/kg per min, or any dose of norepinephrine. AC: Acute cholangitis; BT: Body temperature; ERCP: Endoscopic retrograde cholangiopancreatography; ICU: Intensive care unit; PT/INR: Prothrombin time/international normalized ratio; WBC: White blood cell count.

significantly reduced 30-d mortality. Our results were consistent with the 2021 American Society for Gastrointestinal Endoscopy guidelines recommending ERCP ≤ 48 h in AC patients[12]. In that study, however, the data were insufficient to stratify by disease severity. In a subgroup analysis, we found that the same survival benefit was observed only in patients with grade III AC but not in patients with grade II or I AC. These results were because patients with grade III AC had significantly higher 30-d mortality than those with grade II or I AC (3.5% *vs* 0 *vs* 0.3%, $P = 0.001$). Hakuta *et al*[10] reported that time to ERCP was not associated with clinical outcomes (including in-hospital mortality) in patients with non-grade III AC. Therefore, we recommend emergent ERCP (≤ 48 h) for patients with grade III AC in terms of survival benefit.

However, 30-d mortality in AC has been reported to range from 1% to 16% between studies, which may be one of the reasons leading to inconsistent conclusions about the optimal timing of ERCP[11,13-

15]. Differences in mortality may be due to different patient populations in different studies, *e.g.*, patients with AC due to CBDS and MBO may have different clinical courses and prognoses. Kiriyama *et al*[14] reported that patients with AC associated with MBO had a higher 30-d mortality rate than those with AC associated with CBDS. In our univariate analysis, MBO was a factor associated with 30-d mortality. Therefore, one of the reasons for the low 30-d mortality in our study was the low proportion of patients with MBO (10.2%). In contrast, Tan *et al*[11] included 43% of MBO patients in their study and reported a 30-d mortality rate of 16%. However, Park *et al*[15] included only patients with AC associated with distal MBO and reported an overall 30-d mortality rate of 4.8%. Therefore, there may be some other factors associated with 30-d mortality between studies.

Of the five organ failure criteria used to diagnose grade III AC, cardiovascular dysfunction was the only independent factor associated with 30-d mortality in the current study. Therefore, among grade III AC patients, those with cardiovascular dysfunction may need to be treated differently[16,17]. Karvellas *et al*[17] reported an overall mortality rate of 37% in 260 patients with AC-related septic shock. They found that delayed biliary decompression > 12 h from the onset of shock was one of three independent factors associated with mortality. The 2019 European Society of Gastrointestinal Endoscopy guidelines recommend biliary drainage (preferably endoscopic) within 12 h of shock onset for AC patients with CBDS-related septic shock[16]. Therefore, cardiovascular dysfunction should be weighed when developing new guidelines in the future.

Some studies found no survival benefit but did find early ERCP to reduce the LOHS[18-21]. Hou *et al*[20] reported that in a multivariate analysis, the LOHS increased by 1.44 d for every 1-d delay in ERCP ($P < 0.001$). Similar results were seen in the study by Zhu *et al*[18]: LOHS increased by 1.49 d for every 1-d delay in biliary drainage ($P < 0.0001$). However, these findings were not stratified by disease severity. Although we did not perform a multivariate analysis of the LOHS, our results suggested that the LOHS could be significantly reduced regardless of ERCP ≤ 24 h or ≤ 48 h. In subgroup analyses stratified by disease severity, this benefit was only observed in patients with grade I or II AC. The benefit of early ERCP in shortening the LOHS might be offset by higher ICU admission rates in grade III AC patients. Similar findings were found by Jang *et al*[19], who recommended urgent ERCP (≤ 24 h) for patients with grade I or II AC because it can shorten the LOHS.

This study has several limitations. First, this retrospective, single-center study might have inherent selection bias. Patients with cardiovascular dysfunction and respiratory dysfunction tended to receive ERCP ≤ 24 h. Therefore, caution is required when interpreting the results of this subgroup analysis. Second, we identified patients from the endoscopy database. AC patients who died before receiving ERCP might not have been included in this study, resulting in an underestimation of 30-d mortality. Third, data on albumin, one of the criteria for class II AC, were available in only 19.5% of patients. Therefore, some patients with grade II AC may be misclassified as grade I AC and vice versa.

CONCLUSION

ERCP ≤ 48 h but not ≤ 24 h has a survival benefit in AC patients; this benefit is only observed in patients with grade III AC. Early ERCP is also recommended for patients with grade I or II AC because it shortens the LOHS.

ARTICLE HIGHLIGHTS

Research background

The optimal timing of endoscopic retrograde cholangiopancreatography (ERCP) for acute cholangitis has been inconsistently reported and there are few studies on the timing of ERCP in acute cholangitis of varying severity.

Research motivation

On the one hand, unnecessary emergent ERCP increases medical costs and the burden on physicians and technicians; on the other hand, delayed ERCP may increase morbidity and mortality in patients with acute cholangitis. The findings of this study may guide the avoidance of unnecessary urgent and delayed ERCP for acute cholangitis.

Research objectives

This study aims to answer the optimal timing of ERCP for acute cholangitis of different severity according to 30-d mortality after ERCP. Answering this question can serve as important evidence for future guideline development.

Research methods

The retrospective cohort study included 683 patients who met the diagnostic criteria for acute cholangitis defined by the 2018 Tokyo Guidelines. Among them, there were 170 (24.9%) grade III acute cholangitis patients, 179 grade II acute cholangitis patients (26.4%) and 334 grade I acute cholangitis patients (48.9%). Results are first compared between patients receiving ERCP ≤ 24 h and > 24 h, and then between patients receiving ERCP ≤ 48 h and > 48 h. Subgroup analyses are performed on patients with grade III, II or I acute cholangitis.

Research results

When 24 h was considered a critical value for ERCP timing, we found that patients with malignant biliary obstruction received ERCP ≤ 24 h less frequently when compared with ERCP > 24 h (5.2% *vs* 11.5%). Patients with organ dysfunction such as cardiovascular dysfunction (11.2% *vs* 2.6%) and respiratory dysfunction (14.2% *vs* 5.3%) or those admitted to the ICU (11.2% *vs* 4%) tended to receive ERCP ≤ 24 h. Patients with ERCP ≤ 24 h had significantly shorter hospital stays (median, 6 d *vs* 7 d). Stratified by the severity of acute cholangitis, higher ICU admission was only observed in grade III acute cholangitis and a shorter length of hospital stay was only observed in grade I and II acute cholangitis. Regarding 30-d mortality, the results of ERCP ≤ 24 h and > 24 h were not significantly different, either in the overall population or in patients with grade I, II or III acute cholangitis. When 48 h was considered a critical value for ERCP timing, patients with choledocholithiasis received ERCP ≤ 48 h more frequently (81.5% *vs* 68.3%). Patients who received ERCP ≤ 48 h had significantly lower 30-d mortality (0 *vs* 1.9%) and shorter hospital stays (6 d *vs* 8 d). Stratified by the severity of acute cholangitis, lower 30-d mortality (0 *vs* 6.1%) and higher ICU admission rates (22.2% *vs* 10.2%) were only observed in grade III acute cholangitis and a shorter length of hospital stay was only observed in grade I and II acute cholangitis. In the multivariate analysis, cardiovascular dysfunction and time to ERCP were two independent factors associated with 30-d mortality.

Research conclusions

ERCP ≤ 48 h but not ≤ 24 h has a survival benefit in acute cholangitis patients; this benefit is only observed in patients with grade III acute cholangitis. Early ERCP is also recommended for patients with grade I and II acute cholangitis because it shortens the length of hospital stay.

Research perspectives

Of the five organ failure criteria used to diagnose grade III AC, cardiovascular dysfunction was the only independent factor associated with 30-d mortality in the current study. Therefore, cardiovascular dysfunction should be weighed more heavily in the development of new guidelines in the future.

Abstract

BACKGROUND

Estimation of the functional reserve of the remnant liver is important to reduce morbidity and mortality.

AIM

To estimate the functional reserve of the remnant liver in patients with hepatocellular carcinoma (HCC).

METHODS

We reviewed the medical records of 199 patients who underwent resection of HCC. Hepatic clearance of the remnant liver was calculated using fusion images of ^{99m}Tc-labelled galactosyl-human serum albumin liver scintigraphy and computed tomography. Posthepatectomy liver failure (PHLF) was classified according to the International Study Group of Liver Surgery. Complications was classified according to Clavien–Dindo classification. We analyzed by the risk factors for PHLF, morbidity and mortality with multivariate analysis.

RESULTS

Twenty-seven (30%) patients had major complications and 23 (12%) developed PHLF. The incidence of major complications increased with increasing albumin–bilirubin (ALBI) grade. The area under the curve values for hepatic clearance of the remnant liver, liver to heart-plus-liver radioactivity at 15 min (LHL15), and ALBI score predicting PHLF were 0.868, 0.629, and 0.655, respectively. The area under the curve for hepatic clearance of the remnant liver, LHL15, and ALBI score predicting major complications were 0.758, 0.594, and

0.647, respectively. The risk factors for PHLF and major complications were hepatic clearance of the remnant liver and intraoperative bleeding.

CONCLUSION
The measurement of hepatic clearance may predict PHLF and major complications for patients undergoing resection of HCC.

Key Words: Liver function; Hepatectomy; Cirrhosis; Fusion image; Complication; Mortality

Core tip: Little is known about the association of remnant hepatic clearance with morbidity and mortality. The aim of present study was to evaluate the effectiveness of measuring hepatic clearance of the remnant liver and to determine its association with morbidity and mortality in patients undergoing hepatectomy for hepatocellular carcinoma. Risk factors significantly associated with morbidity and mortality were remnant liver clearance and intraoperative blood loss. Hepatic clearance was associated with posthepatectomy liver failure and the development of major complications. The estimation of hepatic clearance of the remnant liver may provide guidance for determining the extent of resection in a patient-specific manner.

INTRODUCTION

Advances in surgical technique and postoperative care have improved the outcomes of patients undergoing hepatectomy. However, posthepatectomy liver failure (PHLF) can lead to increased rates of morbidity and mortality in patients with hepatocellular carcinoma (HCC) especially in patients with chronic liver damage[1]. Major hepatectomy must be performed to preserve the maximal remnant liver function. However, adequate hepatectomy must be performed to ensure adequate surgical margins around the tumor[2]. Therefore, preoperative assessment of remnant liver function reserve is important to determine the appropriate surgical procedure.

An algorithm including the presence of ascites, serum bilirubin, serum albumin concentration, prothrombin time and encephalopathy is commonly used to determine the indications for resection of HCC. The indocyanine green (ICG) test is the most commonly used test and is considered relatively reliable for assessment of liver functional reserve[3]. However, the Child–Pugh score and ICG test do not accurately predict the development of PHLF[4]. A simple method using conventional data has been reported. The albumin–bilirubin (ALBI) score is an effective predictor of PHLF in patients with HCC compared to that of ICG test[5].

Computed tomography (CT) volumetry can accurately determine the regional liver volume, and has been used to estimate remnant liver function[6]. However, CT volumetry can never reflect the function of the remnant liver. The liver function of each lobe varies with progression of chronic liver disease or steatosis, which indicate that liver function is not distributed homogeneously[7]. Liver function is unevenly modified, resulting from impaired blood circulation[8], biliary stenosis, or induction by the tumor[9]. Changes in portal hemodynamics and a regional reduction in liver function must be considered to determine the optimal surgical procedure[7,10]. A novel method is needed to preoperatively plan for hepatic resection.

Taniguchi *et al*[11] described that ^{99m}Tc-labelled galactosyl-human serum albumin (GSA) hepatic clearance strongly correlates with the degree of liver fibrosis and conventional liver function tests. GSA scintigraphy is widely used to evaluate liver function[10,12-16]. Asialoglycoprotein receptors exist predominantly in the liver on the surface of hepatocytes and are responsible for the metabolism of serum glycoproteins[17]. The receptor density in the liver is closely related to serum asialoglycoprotein level and hepatocyte function[18]. However, little is known about the clinical utility of hepatic clearance for the prediction of PHLF, morbidity and mortality. The aim of present study was to evaluate the effectiveness of measuring hepatic clearance of the remnant liver and to verify risk factors based on the standardized PHLF criteria and complications in patients undergoing hepatectomy.

MATERIALS AND METHODS

Patients

We included patients who underwent hepatectomy between July 2011 and March 2021 at Jichi Medical University (Shimotsuke, Tochigi, Japan). The protocol for this research project was approved by a suitably constituted Ethics Committee of the institution and it conformed to the provision of the Declaration of Helsinki (Committees of Jichi Medical University, Approval No. A21-029). Blood samples obtained preoperatively were analyzed for conventional liver tests.

The procedures for hepatectomy were categorized according to the Brisbane Nomenclature from the International Hepato-Pancreato-Biliary Association[19]. The anatomical resection was defined as resection of the tumor together with the related portal vein branches and the corresponding hepatic territory. The procedure was classified as a hemihepatectomy, an extended hemihepatectomy (hepatectomy plus removal of additional contiguous segments), a sectionectomy (resection of two Couinaud subsegments), or segmentectomy (resection of one Couinaud subsegment). All other nonanatomical procedures were classified as limited resections.

Contrast-enhanced CT

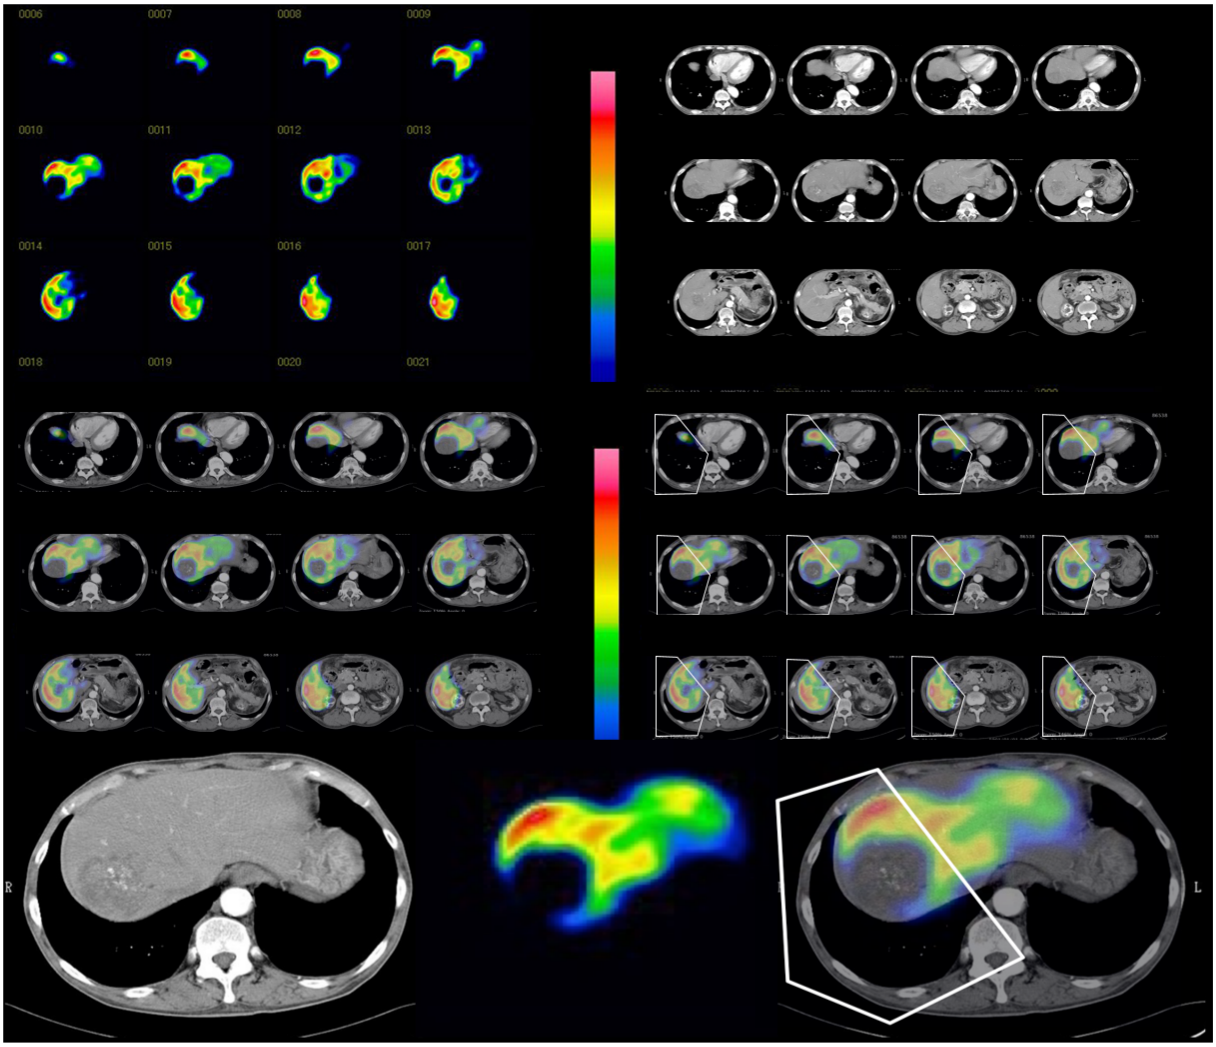
A three-phase enhanced helical CT scan of the liver was used to confirm tumor location and margins before surgery. A 16-row multi-detector CT scan was performed at 3 mm intervals with 100 mL iohexol (Omnipaque 300; Daiichi Sankyo, Tokyo, Japan) (3 mL/s) injected intravenously.

GSA single photon emission CT image

Patients underwent preoperative GSA scintigraphy using a dual-head rotating gamma camera system and a dedicated data processing unit (Prism Axis; Picker Prism International, Cleveland, OH, USA). A single bolus of 3 mg GSA (185 MBq; Nihon Medi-Physics, Tokyo, Japan) was injected intravenously. After confirmation that the detector covered the area in the liver and heart, acquisition of planar images was begun with an acquisition time of 15 s each for 16 min immediately after injection. After acquisition of planar images, dynamic single photon emission CT (SPECT) acquisition was started with an acquisition time of 20 s every 5 min. To generate a set of images equivalent to static SPECT images, projection data from dynamic SPECT were merged. Total liver function was calculated as the total liver GSA clearance, expressed as mL/min by the Patlak plot method.

Region of interest (ROI) was also generated over the entire liver on the tomographic images using isocount methods (25% cutoff of minimal count) to estimate the liver functional volume (mL). Functional liver volume does not include function parameters.

Estimation of function of the remnant liver



Hepatic clearance and functional volume of the remnant liver were estimated from the fusion with CT scan images (Figure 1). Images from the CT scan were aligned with the slice of the liver SPECT image with reference to the hepatic vein on every 3-mm liver cross-slice as a landmark on contrast-enhanced helical CT (Figure 1). After the transection line was set on the SPECT images based on the surgical procedure, the remnant liver with the resection line was determined manually. Remnant liver function was calculated from the proportional allocation of voxel count in static SPECT by the Patlak plot method and expressed by GSA clearance (mL/min). Regional functional liver volume (mL) was also calculated from the SPECT data by the outline extraction method[7].

Definition of major complication and PHLF

Postoperative complications were defined according to the Clavien–Dindo classification[20]. A major complication was defined as grade IIIa or higher. Postoperative mortality was defined as death within 30 d after surgery. PHLF was defined following the definition of the International Study Group of Liver Surgery[21]. Patients with increased prothrombin time–international normalized ratio (PT-INR) and hyperbilirubinemia (according to the normal cut-off levels defined by the local laboratory) on or after postoperative day 5 were considered to have PHLF. PHLF Grade A resulted in abnormal laboratory parameters and required no change in clinical management. Grade B was a deviation from the regular, postoperative clinical pathway, but patients could be managed without invasive treatment. Grade C resulted in deviation from the regular clinical management and required invasive treatment.

Statistical analysis

Continuous variables were expressed as mean ± standard deviation. All categorical data were analyzed by Pearson's χ^2 test. Normally distributed values were analyzed by Student's t test. Non-normally distributed values were analyzed using the Mann–Whitney U test. We analyzed the power for the prediction of PHLF, morbidity and mortality with the parameters of GSA scintigraphy with the area under the receiver-operating characteristic (ROC) curves, and the area under the ROC curve was calculated. In multivariate analysis, risk factors for PHLF were determined by logistic regression multivariate analysis with JMP statistical software (version 13; SAS, Inc. Cary, NC, USA). The level of statistical significance was set at $P < 0.05$.

Figure 1 Schematic model for analysis of regional hepatic clearance with computed tomography fusion images. The images of ^{99m}Tc-galactosyl serum albumin scintigraphy single photon emission computed tomography and computed tomography scans were merged using software. The cutting line was set based on tumor location and size on each fusion image. The liver function was calculated automatically as ^{99m}Tc-galactosyl serum albumin scintigraphy parameters. CT: Computed tomography; SPECT: Single photon emission computed tomography.

RESULTS

Clinicopathological characteristics

A total of consecutive 199 patients with HCC were included, including 156 men and 43 women, with a median age of 70 (range, 24–87 years) (Table 1). Among the 199 patients, 94 (47%) had hepatitis C virus infection and 22 (11%) had hepatitis B virus infection. Most patients were Child–Pugh class A (197/199, 99%) and the remaining patients were class B (2/199, 1%). According to ALBI grade, 68% (135/199) of patients were stratified into Grade 1, 32% (64/199) Grade 2, and 1% (2/199) Grade 3. There were 6% of ALBI Grade 1 patients who developed major complications and 18% ALBI Grade 2 patients had major complications (P = 0.04).

Postoperative morbidity, PHLF and mortality

Among the 199 patients, 41 (21%) developed postoperative complications (Table 2). The most common complication was PHLF (12%, 23/199), followed by wound infection (5.0%, 10/199). Thirty-three (17%) patients developed minor complications, including Grade I complications in 25 (13%) patients and Grade II complications in eight (4.0%) patients. Major complications occurred in 27 (14%) patients, including Grade IIIa (11%, 21/199), Grade IIIb (1.5%, 3/199), Grade IVa (0.5%, 1/199) and Grade V (1%, 2/199). Eleven patients (5%) had PHLF Grade A, eight (4%) had PHLF Grade B, and four (2%) had PHLF Grade C. Two patients died of PHLF within 30 d after surgery, for a postoperative mortality rate of 1% (Table 2).

Figure 2 Analysis of hepatic clearance for post hepatectomy liver failure. A: Receiver-operating characteristic curve analysis of hepatic clearance of the remnant liver, LHL15, and albumin–bilirubin (ALBI) score in predicting PHLF. The area under the receiver-operating characteristic curve values for analysis of hepatic clearance of the remnant liver, LHL15, and ALBI score in predicting PHLF were 0.868, 0.629, and 0.655, respectively; B: Hepatic clearance of the remnant liver for each PHLF. The median hepatic clearances of the remnant liver were 239, 153, 150.5, and 119.5 mL/min for normal, Grades A, B, and C, respectively. LHL15: liver to heart-plus-liver radioactivity at 15 min; ALBI score: Albumin–bilirubin score; PHLF: Post hepatectomy liver failure.

the development of PHLF were 0.868, 0.629, and 0.655, respectively. Hepatic clearance of the remnant liver had the highest area under the curve for predicting the development of PHLF. The cutoff values for predicting PHLF with highest sensitivity and specificity were 192 mL/min (sensitivity, 87.0%; specificity, 76.1%) for hepatic clearance of the remnant liver, 0.91 (sensitivity, 47.8%; specificity, 73.3%) for LHL15, 2.96 (sensitivity, 34.9%; specificity, 95.7%) for ALBI score. The relationship between hepatic clearance of the remnant liver and PHLF grade was evaluated (Figure 2B). The median hepatic clearances of the remnant liver were 239, 153, 150.5 and 119.5 mL/min for no PHLF, Grades A, B and C, respectively. The differences were significant for no PHLF and Grade A (P = 0.002), no PHLF and Grade B (P = 0.003), and no PHLF and Grade C (P = 0.02).

Correlation between hepatic clearance of remnant liver and morbidity and mortality

ROC curve analysis of hepatic clearance of the remnant liver, LHL15, and ALBI score were used to predict the risk of developing major complications (Figure 3A). The area under ROC curves for hepatic clearance of the remnant liver, LHL15, and ALBI score for predicting major complications were 0.758, 0.594, and 0.647, respectively. Hepatic clearance of the remnant liver had the highest area under the curve for predicting the development of major complications. The cutoff values for predicting PHLF with highest sensitivity and specificity were 237 mL/min (sensitivity, 100%; specificity, 51.9%) for

Figure 3 Analysis of hepatic clearance for morbidity and mortality. A: Receiver operating characteristic curve analysis of hepatic clearance of the remnant liver, LHL15, and albumin–bilirubin (ALBI) score in predicting major morbidity. The area under the receiver operating characteristic curve analysis of hepatic clearance of the remnant liver, LHL15, and ALBI score in predicting major morbidity were 0.758, 0.594, and 0.647, respectively; B: Hepatic clearance of the remnant liver for Clavien–Dindo classification. The median hepatic clearances of the remnant liver were 238 and 179 mL/min for Clavien–Dindo < III and Clavien–Dindo ≥ III. LHL15: liver to heart-plus-liver radioactivity at 15 min; ALBI score: Albumin–bilirubin score.

hepatic clearance of the remnant liver, 0.94 (sensitivity, 84.2%; specificity, 36.2%) for LHL15, 2.63 (sensitivity, 69.3%; specificity, 63.2%) for ALBI score. The relationship between hepatic clearance of the remnant liver and Clavien–Dindo classification was evaluated (Figure 3B). The median hepatic clearances of the remnant liver were 238 and 179 mL/min for Clavien–Dindo < IIIa and Clavien–Dindo ≥ IIIa. The differences were significant for Clavien–Dindo < IIIa and Clavien–Dindo ≥ IIIa (P = 0.0004).

Multivariate analysis for PHLF Grade B or C

Multivariate regression analysis was performed between variables, with statistically significant differences following the univariate analysis regarding PHLF Grade B or C (Table 3). Hepatic clearance of the remnant liver [P = 0.001, odds ratio (OR): 0.973, 95% confidence interval (CI): 0.952–0.995] and intraoperative blood loss (P = 0.006, OR: 1.001, 95%CI: 1.0002–1.002) were independent risk factors for PHLF Grade B or C.

Multivariate analysis for major complication and mortality

Multivariate regression analysis was performed between variables, with significant differences following the univariate analysis regarding major complications (Table 4). Hepatic clearance of the remnant liver (P = 0.004, OR: 0.988, 95%CI: 0.979–0.999) and intraoperative blood loss (P = 0.005, OR: 1.0005, 95%CI: 1.0002–1.0014) were independent risk factors for developing major complications.

DISCUSSION

Hepatic clearance was associated with PHLF and major complications. The independent risk factors for developing PHLF and major complications were the hepatic clearance of the remnant liver, and intraoperative blood loss. The results of this study show that the measurement of hepatic clearance of the remnant liver is reliable for predicting the development of PHLF and major complications.

The results of this study support the use of hepatic clearance of the remnant liver, LHL15, and ALBI score for predicting the development of PHLF and postoperative major complications in patient with HCC. LHL15 and HH15, which are hepatic uptake and blood clearance ratios in GSA scintigraphy, are the most popular and widely used in many institutions. However, they may be insufficient for accurately estimating the degree of liver function because these indices are calculated from planar scintigraphic images, which do not correctly reflect hepatocyte volume[11]. In contrast, hepatic clearance measured by SPECT analysis contains volumetric information and may correctly estimate the hepatocyte volume[11]. LHL15 reflects the function of the whole liver, but the hepatic clearance of remnant liver shows the liver function of remnant liver, therefore, hepatic clearance may reflect functional reserve and short term outcome.

Many studies have investigated the relationship between GSA scintigraphy and PHLF. However, this is the first report comparing residual liver function and major complications using GSA scintigraphy. Patients with lower remnant liver function are at higher risk for PHLF, morbidity and mortality. The

quality and volume of the postoperative remnant liver have been shown to be associated with postoperative outcomes[22]. Surgeons should emphasize the remnant liver functional reserve rather than the resected liver volume[12,23]. Elevation of serum bilirubin and PT-INR are associated with morbidity and mortality, regardless of the extent of resection[24]. Liver failure after limited resection can develop. Patients with reduced reserve of the remnant liver are at higher risk for the development of PHLF and major complications[22,25,26]. The extent of surgery should be considered to preserve as much liver function as possible. Moreover PHLF grade C is most severe types of liver failure that may lead to in-hospital death[24]. In ROC curve analysis, the cutoff line of PHLF grade C was 151 mL/min (sensitivity 87.5%, specificity 100%). Patients below the cutoff line should be given special consideration by surgeons before surgery and may not be ideal candidates for hepatic resection. Hepatic clearance of the remnant liver below 100 mL/min is associated with a high mortality rate. Therefore, PTPE should be performed when hepatic clearance of the remnant liver is below 100 mL/min, and surgery should be considered when the clearance is above 100 mL/min. In addition, if hepatic clearance of the remnant liver is greater than 100 mL/min preoperatively, unnecessary PTPE can be avoided.

The risk for developing PHLF and major complications is determined by patient and surgical factors. Intraoperative blood loss is a well-known risk factor for morbidity and mortality after hepatic resection [25,27-30]. Hemorrhage can lead to the development of metabolic acidosis as a consequence of intracellular derangements in oxygen and substrate utilization[29]. Reduced levels of cytokines and humoral factors, such as interleukin-6, hepatocyte growth factors, and growth hormone after extensive blood loss may result in decreased liver regeneration because of loss of growth factors needed for regeneration[28].

The present study had some limitations, including a retrospective design, and being a single center study. Preoperative GSA scintigraphy was routinely performed to estimate total liver function in this hospital. Total liver function, remnant liver function, laboratory data, and liver failure were objectively assessed in advance, which limited the risk of observation bias. Prospective multicenter trials are needed to validate the results of this study.

CONCLUSION

Lower functional reserve of the remnant liver results in a higher risk of developing PHLF and major complications in patients undergoing resection of HCC. The estimation of hepatic clearance of the remnant liver may provide guidance for determining the extent of resection in a patient-specific manner.

ARTICLE HIGHLIGHTS

Research background

Preoperative assessment of liver function is important to reduce the rate of complications.

Research motivation

Few studies evaluate the relationship of residual liver function to complications and prognosis using hepatic clearance.

Research objectives

To measure hepatic clearance of the remnant liver using ^{99m}Tc-galactosyl serum albumin (GSA) scintigraphy, single photon emission computed tomography, to elucidate the association between residual liver function and morbidity and mortality, and to identify risk factors for those factors.

Research methods

We collected data from 199 patients who underwent resection of hepatocellular carcinoma. Hepatic clearance of the remnant liver was measured using fusion images of ^{99m}Tc-labelled GSA liver scintigraphy and computed tomography scans. Risk factors were determined using logistic regression multivariate analysis.

Research results

Risk factors for posthepatectomy liver failure, morbidity, and mortality were low hepatic clearance of the remnant liver and intra-operative bleeding.

Research conclusions

Lower residual liver function is associated with a poor short-term prognosis.

Research perspectives

Preoperative estimation of remnant liver function is useful to determine the surgical approach.

ACKNOWLEDGEMENTS

I especially thank Michio Ashizaki for helping patient data acquisition.

Author contributions: Miki A, Sakuma Y, Shimizu A and Yasuda Y designated the overall concept and outline the manuscript; Ohzawa H, Saito A, Meguro Y, Watanabe J, Morishima K, Endo K, Sasanuma H, and Sata N contributed to the discussion and design of the manuscript; Miki A and Lefor AK contributed to the writing, editing the manuscript, illustrations, and review of literature.

Institutional review board statement: The study was reviewed and approved by the Institutional Review Board of Jichi Medical University, Approval No. A21-029.

Informed consent statement: Written informed consent from any patient for data collection in a prospectively collected data base is available. However, the need for written informed consent for this study was waived by the Institutional Review Board of Jichi Medical University in view of the retrospective design of the study, based on national and local guidelines such as the fact that all clinical/ laboratory measurements and procedures were part of routine care.

Conflict-of-interest statement: The authors declare no conflicts of interest for this study.

Data sharing statement: The database contains highly confidential data which may provide insight in clinical and personnel information about patients and lead to their identification. Therefore, according to organizational restrictions and regulations these data cannot be made publicly available. However, the datasets used and/or analyzed during the current study are available from the corresponding author on reasonable request.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. Abstract

BACKGROUND

At present, there is insufficient medical evidence to determine whether adjuvant chemotherapy is necessary for T2N0M0 gastric cancer.

AIM

To obtain a risk score to assess the need for adjuvant chemotherapy in patients with T2N0M0 gastric cancer.

METHODS

We identified 325 patients with pathological T2N0M0 stage primary gastric cancer at the National Cancer Center between 2011 and 2018. Univariate and multivariate Cox regression analyses were performed to predict factors affecting prognosis. Vascular invasion, tumor site, and body mass index were assessed, and a scoring system was established. We compared the survival outcomes and benefits of adjuvant chemotherapy between the different subgroups.

RESULTS

Five-year survival rates of the score 0, 1, 2, and 3 groups were 92%, 95%, 80%, and 50%, respectively ($P < 0.001$). In the score 2-3 group, five-year survival rates for patients in the adjuvant chemotherapy group and postoperative observation group were 95% and 61%, respectively ($P = 0.021$).

CONCLUSION

For patients with T2N0M0 stage gastric cancer and two or more risk factors, adjuvant chemotherapy after D2 gastrectomy may have a survival benefit.

Key Words: Gastric cancer; Risk score; T2N0M0; Adjuvant chemotherapy; D2

gastrectomy; Survival

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: It is controversial whether adjuvant chemotherapy is necessary for stage T2N0M0 gastric cancer. In our study, we assessed the risk score of patients with pathologic T2N0M0 gastric cancer after D2 gastrectomy, based on clinicopathological factors, and identified a high-risk subgroup that could benefit from adjuvant chemotherapy. For patients with T2N0M0 stage gastric cancer with two or more risk factors, adjuvant chemotherapy after D2 gastrectomy may have a survival benefit.

INTRODUCTION

Gastric cancer is one of the most common malignancies worldwide[1-3]. D2 gastrectomy combined with postoperative adjuvant chemotherapy is the main treatment modality for advanced gastric cancer[4-8]. According to the 8th edition of the American Joint Committee on Cancer (AJCC) guidelines for gastric cancer, T2 was defined as tumor invasion of the muscularis propria[9]. It is controversial whether adjuvant chemotherapy is necessary for stage T2N0M0 gastric cancer[10-16]. Previous studies have suggested that patients with stage I gastric cancer cannot benefit from adjuvant chemotherapy[17]. However, there are some risk factors for recurrence of T2N0M0 gastric cancer, such as lymphatic and/or blood vessel invasion, tumor diameter, perineural invasion, proximal tumor location, and poor differentiation[14,18]. Postoperative adjuvant chemotherapy may inhibit the recurrence in these patients. To further clarify the indications for the use of postoperative adjuvant chemotherapy in T2N0M0 gastric cancer, we reviewed 325 patients with T2N0M0 gastric cancer admitted to the National Cancer Center between 2011 and 2018. In this study, we assessed the risk score of patients with pathologic T2N0M0 gastric cancer after D2 gastrectomy based on clinicopathological factors and identified a high-risk subgroup that could benefit from postoperative adjuvant chemotherapy.

MATERIALS AND METHODS

Patient selection

We identified 402 patients with pathological T2N0M0 stage primary gastric carcinoma and gastroesophageal junction carcinoma (as defined by the AJCC guidelines, 8th edition) who were admitted to the Department of Pancreatic and Gastric Surgery, National Cancer Center, from 2011 to 2018. Three hundred and twenty-five patients were included in our study, all of whom underwent D2 gastrectomy. A total of 63 patients received post-operative adjuvant chemotherapy. The major chemotherapy regimens included platinum + 5-FU; paclitaxel + platinum + 5-FU; and others. Adjuvant chemotherapy is usually performed for 4-6 cycles. Exclusion criteria included loss to follow-up, lack of adenocarcinoma, neoadjuvant chemotherapy, adjuvant radiotherapy, Siewert I type/Siewert II type gastroesophageal junction carcinoma invading the dentate line, and postoperative survival time < 1 mo. Patients were followed-up by telephone. The follow-up was completed on April 30, 2020. The median follow-up time was 65.4 mo.

Statistical analyses

Univariate and multivariate Cox regression analyses were performed to screen for prognostic variables. Variables with a P value < 0.05 and < 0.25 in the univariate and multivariable Cox regression analyses were included in the study. Three variables were included in total: Vascular invasion, tumor site, and body mass index (BMI). The tumor site was classified as cardiac or non-cardiac. Cardiac cancer refers to Siewert type II gastroesophageal junction carcinoma that does not invade the dentate line and Siewert type III gastroesophageal junction carcinoma. BMI of < 18.5 or > 23.9, positive result of vascular invasion, and cardiac cancer were defined as risk factors. Each risk factor was assigned one point, and a total of four groups were obtained, which were defined as scores 0, 1, 2, and 3, respectively. We found that patients with a score ≥ 2 had a poor prognosis, and chemotherapy significantly improved

Table 1 Clinicopathologic variables of 325 T2N0M0 gastric cancer patients

Variable	Overall	Adjuvant chemotherapy group	Postoperative observation group	*P* value
	325	63	262	
Age (yr) *n* (%)				0.609
< 40	20 (6.2)	3 (4.8)	17 (6.5)

BMI: Body mass index.

prognosis. According to the study results, scores of 2-3 were defined as the high-risk group. The Kaplan-Meier method was used to calculate the 5-year survival rate and compare the overall survival (OS) between the different score groups.

Statistical analysis was performed using the R software 4.0.5 (R Foundation for Statistical Computing, Vienna, Austria) and the SPSS 22.0 software (SPSS Inc., Chicago, IL, United States). Each test was bilateral, and statistical significance was set at $P < 0.05$.

RESULTS

Clinicopathological characteristics, univariate and multivariable cox regression analyses

A total of 325 patients were recruited for this study. Table 1 summarizes the clinicopathological characteristics of the patients enrolled in this study. Univariate Cox regression analysis demonstrated that the tumor site ($P = 0.022$, Table 2), vascular invasion ($P < 0.001$, Table 2), and BMI ($P = 0.036$, Table 2) were

significant risk factors for OS. Multivariate Cox regression analysis demonstrated that vascular invasion was an independent risk factor for OS ($P < 0.001$, Table 3).

Vascular invasion, tumor site, and BMI were assessed in the study, and a scoring system was established.

Survival results of different groups

Figure 1A summarizes the survival curves of patients with scores of 0, 1, 2, and 3. There were significant differences among all groups except for the score 0 and 1 groups (score 0 group *vs* score 1 group, $P = 0.537$; score 0 group *vs* score 2 group, $P = 0.049$; score 0 group *vs* score 3 group, $P < 0.001$; score 1 group *vs* score 2 group, $P = 0.003$; score 1 group *vs* score 3 group, $P < 0.001$; score 2 group *vs* score 3 group, $P = 0.008$). For all patients, 5-year survival rates of the adjuvant chemotherapy and postoperative observation groups were 96% and 90%, respectively ($P = 0.676$, Table 4). Five-year survival rates of the score 0, 1, 2, and 3 groups were 92%, 95%, 80%, and 50%, respectively ($P < 0.001$, Table 4). In the score 0 and score 1 groups, there were no differences in the 5-year survival rates between the postoperative observation and adjuvant chemotherapy groups. In the score 2-3 group, 5-year survival rates for patients in the adjuvant chemotherapy group and postoperative observation group were 95% and 61%, respectively ($P = 0.021$, Table 4).

Figure 1B-D summarizes the survival curves of patients with scores of 0, 1, and score 2-3 T2N0M0 gastric cancer in the adjuvant chemotherapy and postoperative observation groups. Table 5 summarizes the distribution of the different risk factors in each risk score group.

DISCUSSION

Our study found that adjuvant chemotherapy is necessary for the treatment of T2N0M0 gastric cancer patients with two or more risk factors. The risk factors included vascular invasion, BMI, and tumor site. Based on these results, we obtained a simple risk score to assess the need for adjuvant chemotherapy in patients with T2N0M0 gastric cancer. Patients with a score 2-3 were assigned to the high-risk group.Previous studies have shown that adjuvant chemotherapy can prolong OS in advanced gastric cancer and reduce recurrence[19]. However, evidence of the survival benefits of adjuvant chemotherapy for early gastric cancer is lacking. Although there is no lymph node metastasis in T2N0M0 gastric cancer, some patients still experience recurrence[10-16]. Therefore, it is important to identify patients with stage T2N0M0 gastric cancer who are at high risk of recurrence and may require adjuvant chemotherapy. Univariate Cox regression analysis demonstrated that tumor site (P = 0.022, Table 2), vascular invasion (P < 0.001, Table 2), and BMI (P = 0.036, Table 2) were significant risk factors for OS in patients with T2N0M0 disease. Multivariate Cox regression analysis showed that vascular invasion was an independent prognostic indicator in patients with T2N0M0 disease[14]. Tumor site has been reported to be a prognostic risk factor for stage IB gastric cancer[11]. The 5-year OS rate of patients with stage IB gastric cancer whose tumors are located in the upper third of the stomach is only 81.8%, which is lower than that of patients with stage II disease receiving S-1 adjuvant chemotherapy[5]. Another study that followed 532 patients reported poorer long-term survival in patients with proximal gastric cancer than in those with distal gastric cancer[20]. Proximal gastric cancer has a higher proportion of undifferentiated tumors, and tumors located in this region can metastasize to almost all lymph nodes, except in the

Table 4 Five-year survival rates of different groups

	Group	*n*	5-year survival rate	Log rank test
All patients				$P = 0.676$
	Adjuvant chemotherapy	63	96%	
	Postoperative observation	262	90%	
Risk score				$P < 0.001$
	Score 0 group	98	92%	
	Score 1 group	152	95%	
	Score 2 group	69	80%	
	Score 3 group	6	50%	
Score 0 group				$P = 0.825$
	Adjuvant chemotherapy	13	92%	
	Postoperative observation	85	92%	
Score 1 group				$P = 0.308$
	Adjuvant chemotherapy	22	92%	
	Postoperative observation	130	96%	
Score 2-3 group				$P = 0.021$
	Adjuvant chemotherapy	28	95%	
	Postoperative observation	47	61%	

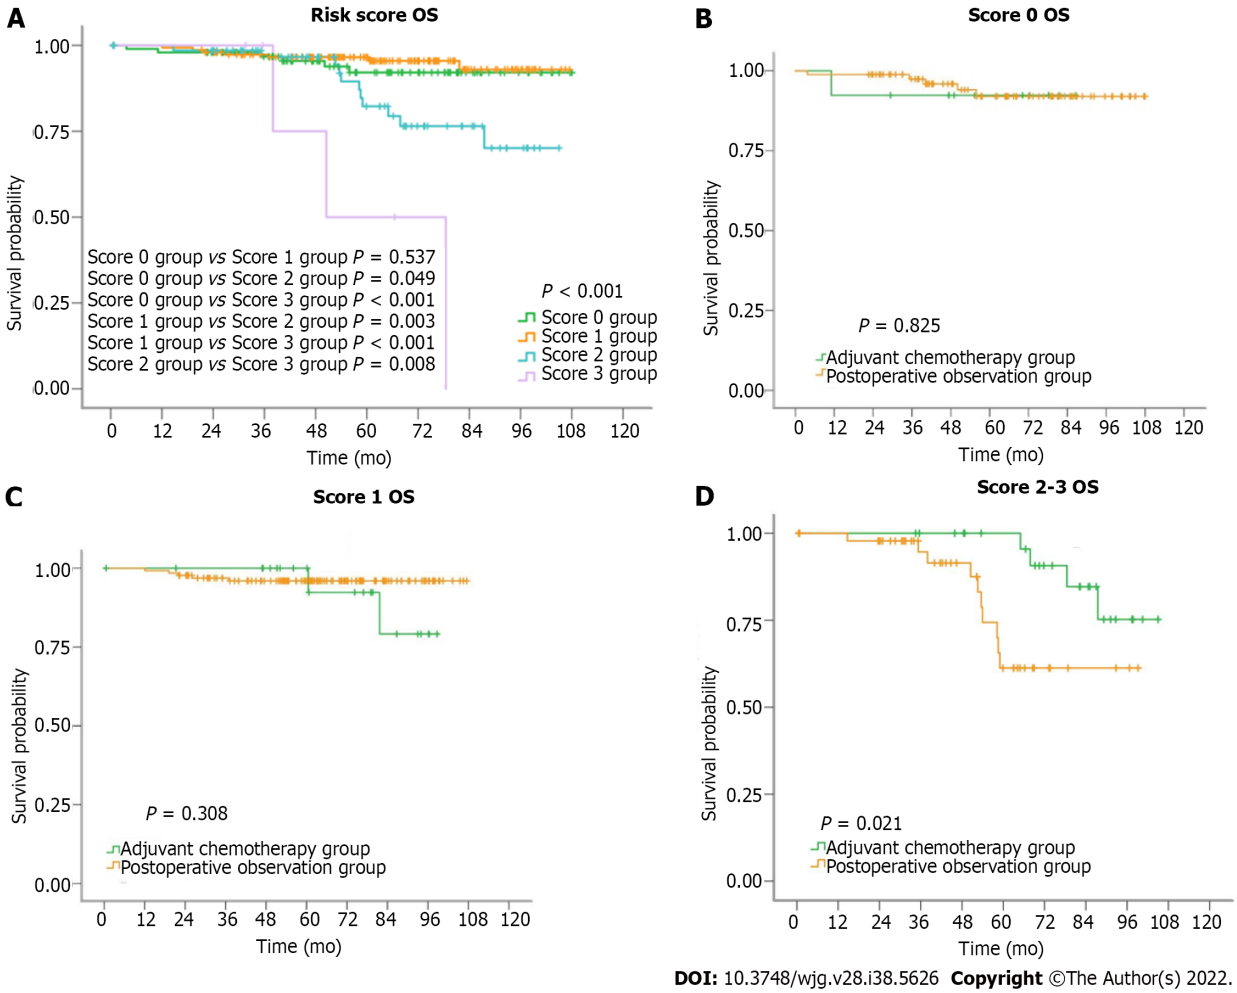

Table 5 Distribution of three different risk factors in each score group

	BMI < 18.5 or > 23.9	Vascular invasion	Cardia cancer
All	149	54	105
Score 0 group	0	0	0
Score 1 group	92	15	45
Score 2 group	51	33	54
Score 3 group	6	6	6

BMI: Body mass index.

five groups[11]. These factors may account for the lower survival rates of patients with proximal gastric cancer. Several studies have shown that BMI affects the prognosis of patients with gastric cancer[21-26]. Low BMI was associated with malnutrition, whereas high BMI was associated with a higher risk of surgery and a higher rate of postoperative complications. A high BMI also increases the risk of stomach cancer[27]. The degree of tumor differentiation was not included in the study, possibly because poorly differentiated tumors do not show significant aggressiveness in the early stages of tumor development.

Based on these findings, we developed a scoring system to assess the need for the use of adjuvant chemotherapy in patients with T2N0M0 gastric cancer. Patients with no or only one risk factor had good prognosis after D2 gastrectomy and did not require adjuvant chemotherapy. Patients in the score 2-3 group had a significantly worse prognosis and could benefit from adjuvant chemotherapy. Our study may help to provide targeted treatment for patients with stage T2N0M0 gastric cancer.This study had some limitations. This was a single-center retrospective study with a lower level of evidence than that of a prospective study. We did not classify the patients into subgroups based on the number of lymph nodes removed. The number of lymph node dissections has a significant effect on OS. For patients with stage T1-2 node-negative gastric cancer, the 5-year survival rate increased by 7.6% for every 10 Lymph nodes examined[28]. No recurrence-free survival or recurrence pattern was observed. We did not discuss the genetic characteristics of patients with gastric cancer included in the study. Genetic characteristics of patients with gastric cancer may influence the efficacy of adjuvant chemotherapy.

OS: Overall survival.

CONCLUSION

For patients with T2N0M0 stage gastric cancer and two or more risk factors, adjuvant chemotherapy after D2 gastrectomy may have a survival benefit. Individualized treatment should be adopted according to examination and pathological results in patients with T2N0M0 gastric cancer.

ARTICLE HIGHLIGHTS

Research background

It is controversial whether adjuvant chemotherapy is necessary for stage T2N0M0 gastric cancer.

Research motivation

To further clarify the indications for the use of postoperative adjuvant chemotherapy in patients with T2N0M0 gastric cancer.

Research objectives

To obtain a risk score to assess the need for adjuvant chemotherapy in patients with T2N0M0 gastric cancer.

Research methods

Univariate and multivariate Cox regression analyses were performed to predict factors affecting prognosis. Vascular invasion, tumor site, and BMI were assessed, and a scoring system was established.

We compared the survival outcomes and benefits of adjuvant chemotherapy between the different subgroups.

Research results

Five-year survival rates of the score 0, 1, 2, and 3 groups were 92%, 95%, 80%, and 50%, respectively ($P < 0.001$). In the score 2-3 group, five-year survival rates for patients in the adjuvant chemotherapy group and postoperative observation group were 95% and 61%, respectively ($P = 0.021$).

Research conclusions

For patients with T2N0M0 stage gastric cancer and two or more risk factors, adjuvant chemotherapy after D2 gastrectomy may have a survival benefit.

Research perspectives

Individualized treatment should be adopted according to examination and pathological results in patients with T2N0M0 gastric cancer.

Abstract

BACKGROUND

Looking for undiscovered blood markers of liver fibrosis and steatosis still remains an issue worth exploring. There are still plenty of unresolved issues related to the actual role of hematological indices as potential markers of liver function.

AIM

To study red blood cell distribution width (RDW), RDW-to-platelet ratio (RPR) and RDW-to-lymphocyte ratio (RLR) in alcohol-related liver cirrhosis (ALC) and metabolic-associated fatty liver disease (MAFLD).

METHODS

The study group was composed of 302 people: 142 patients with ALC and 92 with MAFLD; 68 persons were included as controls. RDW, RPR and RLR were measured in each person. Indirect and direct parameters of liver fibrosis were also assessed [aspartate transaminase to alkaline transaminase ratio, aspartate transaminase to platelet ratio index (APRI), fibrosis-4 (FIB-4), gamma-glutamyl transpeptidase to platelet ratio (GPR), procollagen I carboxyterminal propeptide, procollagen III aminoterminal propeptide, transforming growth factor-α, platelet-derived growth factor AB, laminin]. MELD score in ALC patients and non-alcoholic fatty liver disease (NAFLD) fibrosis score together with BARD score were obtained in the MAFLD group. The achieved results were compared to controls. Then a correlation between assessed markers was done. Diagnostic value of each investigated parameter and its suggested cut-off in the research group

were evaluated with area under the curve (AUC).

RESULTS

RDW, RPR and RLR values turned out to be significantly higher in ALC and MAFLD groups compared to controls (ALC: $P < 0.0001$; NAFLD: $P < 0.05$, $P < 0.0001$ and $P < 0.0001$, respectively). RPR correlated positively with MELD score ($P < 0.01$) and indirect indices of liver fibrosis (FIB-4 and GPR; $P < 0.0001$) in ALC patients; negative correlations were found between PDGF-AB and both: RDW and RPR ($P < 0.01$ and $P < 0.0001$, respectively). RPR correlated positively with NAFLD fibrosis score and APRI ($P < 0.0001$) in the MAFLD group; a positive relationship was observed between RDW and FIB-4, too ($P < 0.05$). AUC values and suggested cut-offs for RDW, RPR and RLR in ALC patients were: 0.912 (> 14.2%), 0.965 (> 0.075) and 0.914 (> 8.684), respectively. AUC values and suggested cut-offs for RDW, RPR and RLR in MAFLD patients were: 0.606 (> 12.8%), 0.724 (> 0.047) and 0.691 (> 6.25), respectively.

CONCLUSION

RDW with its derivatives appear to be valuable diagnostic markers in patients with ALC. They can also be associated with a deterioration of liver function in this group.

Key Words: Hematological indices; Alcohol-related liver cirrhosis; Metabolic-associated liver disease; Red blood cell distribution width; Red blood cell distribution width-to-platelet ratio; Red blood cell distribution width-to-lymphocyte ratio

Core Tip: Red blood cell distribution width (RDW), RDW-to-platelet ratio (RPR) and RDW-to-lymphocyte ratio (RLR) remain uninvestigated in Polish patients suffering from alcohol-related liver cirrhosis (ALC) and metabolic-associated liver disease. Based on the available literature, association between RDW, RPR, RLR and serological (indirect and direct) indices of liver fibrosis have never been explored in a single study to date. We consider RPR as a potential reliable diagnostic tool in the assessment of ALC patients, corresponding with MELD score and serous markers of liver cirrhosis. Hematological parameters could be perceived as possible indices in the noninvasive evaluation of people with liver disorders.

INTRODUCTION

Alcohol-related liver cirrhosis (ALC) and metabolic-associated fatty liver disease (MAFLD) belong to pathologies with an undeniable global impact. Their monitoring and prediction of a possible outcome are of crucial importance. Due to the progress in hepatology and increased access to new imaging techniques, the evaluation of advanced liver fibrosis (even without a biopsy) turned out to be available. Nevertheless, liver elastography in an ultrasound or magnetic resonance mode are not commonly accessible tools in all medical centers. Direct and indirect markers of liver fibrosis obtained from the blood still remain quite trustworthy indices, but they are not perfect, either. Thus, looking for potentially novel parameters of liver disease progression is a key goal in the field of hepatology[1-4]. The most meaningful and valuable future diagnostic tools are new noninvasive blood markers of liver fibrosis; red blood cell distribution width (RDW) together with RDW-to-platelet ratio (RPR) were suggested to be such probable indices. Nevertheless, their probable role in the course of liver steatosis has been poorly explored. RDW reflects the diversity of red blood cells in volume and size. It is obtained from automated hematology analyzers in everyday clinical practice. In the past, RDW was clinically applied only to diagnose anemia or related maladies. Nowadays the spectrum of its possible clinical performance has been significantly broadened. RDW and RPR have already been proven to achieve higher levels in the course of the neoplastic process, being connected with an overall poor survival (*e.g.*, in the course of cervical, colorectal and prostate cancers), as well[5-7]. Cardiovascular disorders and stroke constitute other pathologies that were explored in the context of RDW. Its high level was even

Figure 1 Flow chart demonstrating the selection of study participants. ALC: Alcohol-related liver cirrhosis; MAFLD: Metabolic-associated fatty liver disease; US: Ultrasound.

proved to be associated with a 3-mo poor functional outcome in the course of thrombolytic therapy due to acute ischemic stroke. RDW was additionally described as a marker of acutely decompensated chronic heart failure and an indicator of increased mortality among critically ill patients with myocardial infarction[8-11]. Of note, except for RDW derivatives, hematocrit was found to be inseparably connected with the development of atherosclerosis (evaluated as internal carotid intima-media thickness) in MAFLD patients, suggesting a common potential role of hematological markers - not only in MAFLD, but also due to MAFLD-followed cardiovascular disorders[12]. Thus, RDW derivatives can be perceived as systemic markers of various pathologies. Moreover, according to previously conducted studies, RDW and RPR can even correlate with MELD score and are suggested to behave as markers of poor survival in patients with chronic liver pathologies. RDW-to-lymphocyte ratio (RLR) appears to be a relatively uninvestigated parameter in patients with liver disorders[13-16]. We suspect that no survey to date has explored the diagnostic role of RDW derivatives and their relationships with serological indices of liver fibrosis in the course of ALC and MAFLD. Furthermore, our investigation appears to be the first one performed on Polish patients to evaluate existing dependences between hematological indices and serological markers of liver fibrosis.

MATERIALS AND METHODS

The survey was accepted by the local ethics committee of the Medical University of Lublin (No. KE-0254/86/2016) and all participants signed an informed written consent on the basis of the Helsinki Declaration for the procedures they followed.

Materials

The investigation was conducted retrospectively on 302 persons. The study group was formed by 142 patients with ALC and 92 with MAFLD. The control group was represented by 68 healthy volunteers. Figure 1 displays the selection of the participants included in the survey. Table 1 shows clinical features of the study population. The diagnosis of liver cirrhosis (LC) was established in accordance with commonly used criteria. The doppler mode abdominal ultrasound examination was applied to confirm the presence of portal hypertension (diameter of portal vein ≥ 13 mm). Different underlying factors leading to portal hypertension were ruled out. Panendoscopy was performed in each of the 142 persons belonging to the ALC group - in 126 of them varices in the esophagus or stomach of the different stages were visualized. Ascites was found in 92 of the ALC patients, leading consequently to the paracentesis in 84 of them. None from the study group suffered from hepatic encephalopathy or spontaneous bacterial peritonitis. All persons enrolled to the survey were given 0/9 points on the CHESS scale. Alcohol-related etiology of LC was figured out due to the proven daily intake of pure ethanol more than 30 g. A detailed history of alcohol addiction was obtained directly from the patients or their trustworthy family members. In addition, all included in the study of ALC patients got positive results on the

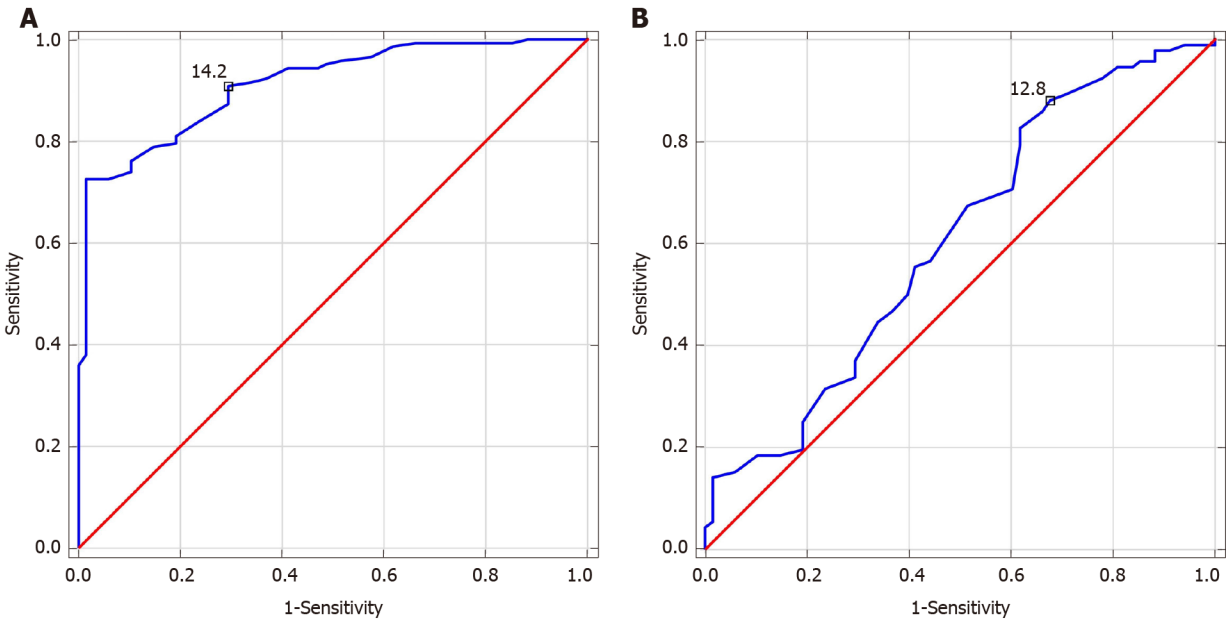
conducted CAGE test. On the other hand, MAFLD was diagnosed according to the previous history, physical examination, laboratory findings and ultrasound imaging. A daily alcohol consumption amount was not greater than 20 g in men and 10 g in women. Disorders potentially responsible for the development of liver steatosis (celiac disease, Wilson's disease, hepatobiliary infections and alpha-1-antitrypsin deficiency) had been ruled out. Diabetes mellitus type 2 was identified among 22 persons. The presence of diabetes mellitus type 1 caused the exclusion from the survey. None of the MAFLD patients was diagnosed with impaired fasting glucose. Forty six of them were found to suffer from arterial hypertension; 84 persons presented features of metabolic syndrome. Viral/autoimmune liver diseases, clinically relevant inflammatory process and anemia constituted other excluding criteria. None of the survey participants was on steroid therapy.

Procedures

Venous blood samples obtained from peripheral blood were collected from all study participants. EDTA was applied to evaluate hematological indices and citrate to evaluate clotting. Biochemical indices were obtained from the blood samples without an anticoagulant. We collected the blood after at least 12 h of fasting. Hematological and biochemical procedures were performed 4 h after blood sample collection. All of the measurements were conducted in the laboratory of Clinical Hospital Number 4, Lublin, Poland. The remaining part of the blood samples, without an anticoagulant, were centrifuged at the speed of 2000 *g* for 10 min within 15 min after blood collection. The obtained serum was then stored in 1 mL Eppendorf test tubes at the temperature of -80 °C until the evaluation of direct markers of liver fibrosis with ELISA. Among morphotic parameters of the blood, the RDW, RPR and RLR were obtained. The evaluation of indirect indices of liver cirrhosis concerned: Aspartate transaminase to alkaline transaminase ratio (AAR), aspartate transaminase to platelet ratio index (APRI), FIB-4 (fibrosis-4) and gamma-glutamyl transpeptidase to platelet ratio (GPR) (GGT to PLT Ratio). MELD score was assessed in the ALC patients and non-alcoholic fatty liver disease (NAFLD) fibrosis score and BARD score were applied to the MAFLD group. Procollagen I carboxyterminal propeptide (PICP), procollagen III aminoterminal propeptide (PIIINP), platelet-derived growth factor AB (PDGF-AB), transforming growth factor-α (TGF-α) and laminin belonged to direct indices of liver fibrosis that were measured. Laboratory procedures were performed in the Department of Biochemistry and Molecular Biology, Medical University of Lublin according to the recommended indications. The assessment of PICP and PIIINP was conducted with quantitative ELISA tests. PDGF-AB and TGF-α were evaluated with the use of R&D Systems Quantikine ELISA Kits. Finally, the measurement of the concentration of laminin was possible because of the Takara Laminin EIA Kit without Sulphuric Acid.



Statistical analysis

Statistical analysis of the results was carried out with Statistica 13.0 (StatSoft Polska Sp. z o.o., Kraków, Poland) for Windows system. The demographic characteristics of study participants and findings of laboratory investigations were shown as the mean ± SD and Student's *t* test was applied to compare these data. Deviation from normality was assessed with the use of Kolmogorov-Smirnov test. Data collected in the study were shown as the median and range (minimum–maximum). The Mann-Whitney *U* test was applied for between-group comparisons due to non-normal distribution. The correlations were verified with Spearman correlation analyses. All probability values were two-tailed, and a value of *P* less than 0.05 was perceived as statistically significant. Receiver operating characteristic (ROC) curves and area under the curve (AUC) values were used to evaluate the sensitivity and specificity of investigated indices and to verify suggested cut-offs of tested markers in ALC and MAFLD patients.

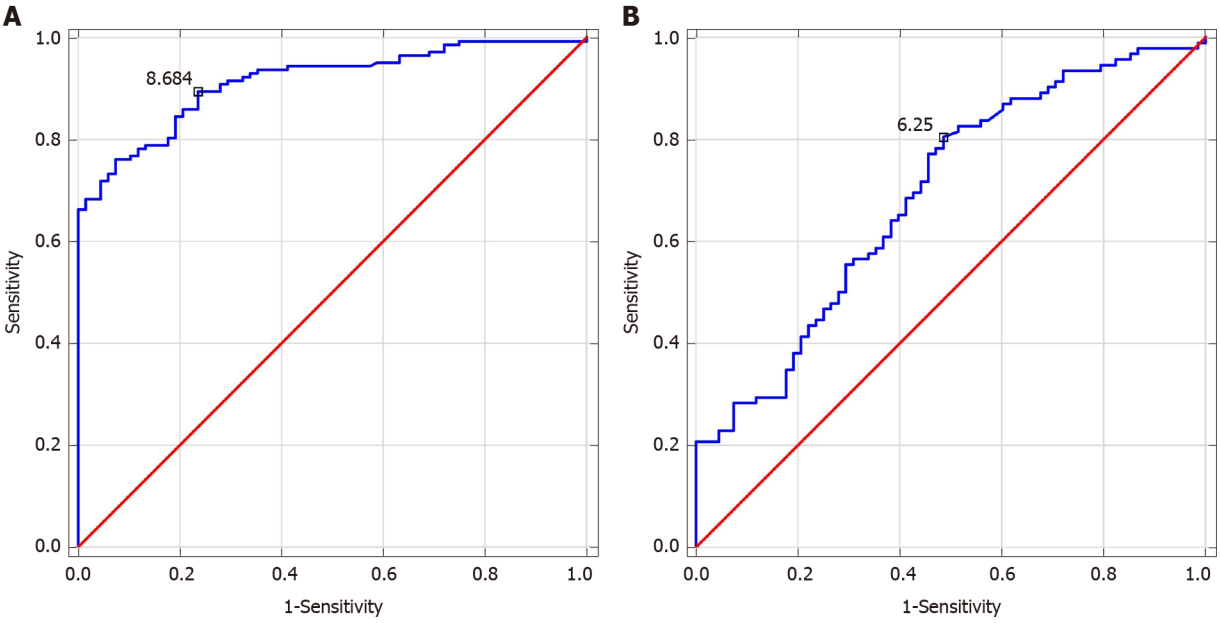
Figure 2 Receiver operating characteristics for red blood cell distribution width. A: Alcohol-related liver cirrhosis (ALC), area under the curve (AUC) = 0.912 (cut-off > 14.2%); B: Metabolic-associated fatty liver disease (MAFLD), AUC = 0.606 (cut-off > 12.8%). Youden index cut-off for red blood cell distribution width in ALC and MAFLD groups = 15.1% and 13%, respectively.



RESULTS

Table 2 presents results of applied scores in the research group. Results of hematological parameters are presented in Table 3. The RDW level was above the reference range in both the ALC and MAFLD groups; its level was significantly higher in comparison to the controls ($P < 0.0001$ and $P < 0.05$, respectively). RPR and RLR values turned out to be significantly higher among ALC and MAFLD patients compared to the control group ($P < 0.0001$). Table 3 presents results of indirect and direct indices of liver fibrosis, as well. The medians of AAR, APRI, FIB-4 and GPR were shown to be significantly higher within the ALC group in comparison to the controls ($P < 0.0001$). Excluding AAR, patients with MAFLD were observed to present notably higher values of all the enumerated above indirect markers of liver fibrosis compared to the control group ($P < 0.0001$). According to the direct parameters of liver fibrosis, laminin value in the course of ALC was importantly higher than in the control group ($P < 0.05$). Except for PICP, medians of PIIINP, PDGF-AB and TGF-α had notably lower levels ($P < 0.01$, $P < 0.001$, $P < 0.0001$, respectively). Concentrations of TGF-α and laminin in MAFLD patients in comparison to controls were found to be remarkably lower ($P < 0.0001$). PICP, PIIINP and PDGF-AB medians did not differ in a significant pattern. Table 4 presents noted correlations between evaluated indices in ALC and MAFLD groups. We observed meaningful positive dependences between RPR and indirect parameters of liver cirrhosis - FIB-4 and GPR ($P < 0.0001$) in the ALC patients. RDW and RPR correlated in a negative pattern with PDGF-AB ($P < 0.01$ and $P < 0.0001$, respectively). A positive correlation was found between RPR and MELD scores ($P < 0.01$). Other positive dependences were observed between: RDW and FIB-4 ($P < 0.05$), and between RPR and APRI ($P < 0.0001$), in the MAFLD group. RPR correlated positively with the NAFLD fibrosis scores ($P < 0.0001$), as well. Table 5 shows diagnostic accuracy of evaluated hematological markers. ROCs describing investigated parameters in the ALC and MAFLD groups are shown below in Figures 2-4. AUC values with

Figure 4 Receiver operating characteristics for red blood cell distribution width-to-lymphocyte ratio. A: Alcohol-related liver cirrhosis (ALC), area under the curve (AUC) = 0.914 (cut-off > 8.684); B: Metabolic-associated fatty liver disease (MAFLD), AUC = 0.691 (cut-off > 6.25). Youden index cut-off for red blood cell distribution width-to-lymphocyte ratio in ALC and MAFLD groups = 11.16 and 6.25, respectively.

suggested cut-offs for RDW, RPR and RLR in ALC patients were: 0.912 (> 14.2%), 0.965 (> 0.075) and 0.914 (> 8.684), respectively. AUC values and proposed cut-offs for RDW, RPR and RLR in the MAFLD groups were: 0.606 (> 12.8%), 0.724 (> 0.047) and 0.691 (> 6.25), respectively.

DISCUSSION

New reliable blood markers required in the evaluation of liver fibrosis and clinical prognosis of cirrhosis are permanently in the interest of scientists. Several years ago, basic hematological indices, used in

Table 3 Results of indirect and direct markers of liver fibrosis together with hematological markers in examined patients

Parameter (reference range)	ALC				MAFLD				Controls

ALC: Alcoholic liver cirrhosis; MAFLD: Metabolic associated fatty liver disease; Min: Minimum; Max: Maximum; AAR: Aspartate transaminase to alkaline transaminase ratio; APRI: Aspartate transaminase to platelet ratio index; FIB-4: Fibrosis-4; GPR: Gamma-glutamyl transpeptidase to platelet ratio; PICP: Procollagen I carboxyterminal propeptide; PIIINP: Procollagen III aminoterminal propeptide; PDGF-AB: Platelet-derived growth factor AB; TGF-α: Transforming growth factor-α; RDW: Red blood cell distribution width; RPR: Red blood cell distribution width-to-platelet ratio; RLR: Red blood cell distribution width-to-lymphocyte ratio.

everyday life, were proposed as potential candidates in this area, *e.g.*, mean platelet volume, platelet crit and RDW. It is assumed that their linkage with liver disorders is due to the inflammation and the release of interleukin-6, interfering hemolytic anemia, hypersplenism and bone marrow activation. The greatest number of surveys in this area of hepatology seems to concern hepatitis B virus- and hepatitis C virus-related cirrhosis; the ALC and MAFLD patients were not explored as much[17-20]. Moreover, a quick diagnosis and further staging of liver steatosis is also a crucial goal nowadays, due to the global prevalence of MAFLD together with its possible severe consequences. RDW derivatives require further investigations in the context of liver disorders. Being the marker of red blood cells heterogeneity, RDW was commonly used as an indicator of anemia. However, it turned out that its potential role can be even more complex. Former surveys proved that the progression of liver cirrhosis is accompanied by an increase in RDW and its elevation might even be a marker of poor prognosis. Similar observations were made with reference to its derivative - RPR. Recent meta-analyses by Cai *et al*[21] and Milas *et al*[22] confirmed these data. RDW and RPR were even found to be markers of increased mortality in ALC

ALC: Alcoholic liver cirrhosis; MAFLD: Metabolic-associated fatty liver disease; RDW: Red blood cell distribution width; RPR: Red blood cell distribution width-to-platelet ratio; MELD: Model of end stage liver disease; APRI: Aspartate transaminase to platelet ratio index; FIB-4: Fibrosis-4; GPR: Gamma-glutamyl transpeptidase to platelet ratio; PDGF-AB: Platelet-derived growth factor AB; NFS: NAFLD fibrosis score.

patients - independently of MELD score. Lately, RDW elevation was found to accompany severe inflammation and liver fibrosis in three independent studies on autoimmune hepatitis patients[23-25]. RDW was even proposed as a prognostic marker in the course of hepatocellular carcinoma[26,27]. What is more, recently a higher level of RLR has been explored as a potential marker of its recurrence[28]. In our ALC group, RPR correlated positively with MELD score and the diagnostic accuracy of both: RDW and RPR turned out to be high (AUC = 0.912 and AUC = 0.965, respectively). A close relationship between RDW derivatives and indirect indices of liver fibrosis in the course of cirrhosis was already established and our results support this association. However, it seems that previous surveys did not explore relationships between RDW derivatives and indirect parameters of liver fibrosis. According to the available literature, we are the first to note a negative correlation between PDGF-AB concentration and both: RDW and RPR levels in the course of ALC. RLR appears to be explored so far, among liver pathologies, only in the course of primary biliary cholangitis (PBC) and in people affected with acute hepatitis E virus (HEV) infection. Its diagnostic accuracy in the assessment of liver fibrosis in PBC patients and in the diagnosis of HEV infection in symptomatic patients was better compared to APRI, FIB-4 and RPR[29-31]. Our study appears to be the first one concentrating on the role of RLR in ALC and MAFLD. Interestingly, its diagnostic accuracy in the ALC patients turned out to be very high (AUC = 0.914). The data on RDW derivatives in MAFLD patients are very limited. However, previous research observed that elevation in RDW can be assumed as a sign of the progression of simple steatosis to steatohepatitis and the progression of liver fibrosis in the course of MAFLD[32-36]. In our examined MAFLD patients, RPR correlated positively with indirect parameters of liver fibrosis and NAFLD fibrosis score, however, its diagnostic accuracy was quite disappointing (AUC = 0.606). In our survey, we did not aim to perform the comparison of selected hematological markers between the ALC and MAFLD patients. The purpose of our study was to find out whether deviations in certain hematological parameters might accompany an isolated liver steatosis. Our investigation focused on the population of people with MAFLD without the evaluation of possible features of hepatitis in liver biopsy. In the future, we would like to differentiate patients with a simple steatosis and already developed steatohepatitis confirmed by liver biopsy in the context of potential deviations among hematological markers.

CONCLUSION

In conclusion, our study gives a new insight into the tight relationship between serological indices of liver fibrosis and RDW derivatives in patients with liver pathologies. Especially, RLR seems to be a valuable unexplored parameter in the course of ALC. Its high diagnostic accuracy in our ALC patients is a promising message for subsequent studies. Undoubtedly, this direction of research should be continued to define a potential role of commonly accessible RDW derivatives as indicators of liver disorders in everyday clinical life.

RLR	**0.914**	89	77	89	78	3,87	0,14	$P < 0.0001$	**0.691**	80	52	69	66	1.67	0.38	$P < 0.0001$

ALC: Alcoholic liver cirrhosis; MAFLD: Metabolic-associated fatty liver disease; AUC: Area under the curve; PPV: Positive predictive value; NPV: Negative predictive value; PLR: Positive likelihood; NLR: Negative likelihood ratio.

ARTICLE HIGHLIGHTS

Research background

The most meaningful and valuable future diagnostic tools are new noninvasive blood markers of liver fibrosis, and red blood cell distribution width (RDW) together with RDW-to-platelet-(PLT)-ratio (RPR) were suggested to be such probable indices. Their potential role in the course of liver disorders still requires further elucidation.

Research motivation

In light of the above, we decided to study the diagnostic role of RDW derivatives and their relationships with direct and indirect indices of liver fibrosis in patients with alcohol-related liver cirrhosis (ALC) and metabolic-associated fatty liver disease (MAFLD). It seems to be the first investigation performed among Polish patients to evaluate the potential dependences between hematological parameters and serological markers of liver fibrosis.

Research objectives

The aim of the study was the evaluation of RDW, RPR and RDW-to-lymphocyte ratio (RLR) in ALC and MAFLD patients.

Research methods

The study group was comprised of 302 persons: 142 patients with ALC, 92 with MAFLD and 68 volunteers as controls. RDW, RPR and RLR were assessed in each participant. Indirect and direct indices of liver fibrosis were also measured [aspartate transaminase to alkaline transaminase ratio, aspartate transaminase to platelet ratio index (APRI), fibrosis-4 (FIB-4), gamma-glutamyl transpeptidase to platelet ratio (GPR), procollagen I carboxyterminal propeptide, procollagen III aminoterminal propeptide, transforming growth factor-α, platelet-derived growth factor AB, laminin]. MELD score in the ALC patients and NAFLD fibrosis score together with BARD score were obtained in the MAFLD

group. The achieved results were compared to controls. Then a correlation between investigated parameters was done. Diagnostic value of each evaluated marker together with suggested cut-off in the research group were assessed with area under the curve (AUC).

Research results

RDW, RPR and RLR values were significantly higher in ALC and MAFLD patients in comparison to controls. RPR correlated positively with MELD score and indirect parameters of liver fibrosis in the ALC group. RPR correlated positively with the NAFLD fibrosis score and APRI in the MAFLD patients; a positive dependency was noted between the RDW and FIB-4. The AUC values and suggested cut-offs for RDW, RPR and RLR in ALC patients were: 0.912 (> 14.2%), 0.965 (> 0.075) and 0.914 (> 8.684), respectively. AUC values and proposed cut-offs for RDW, RPR and RLR in MAFLD patients were: 0.606 (> 12.8%), 0.724 (> 0.047) and 0.691 (> 6.25), respectively.

Research conclusions

Our study gives a new insight into the tight relationship between serological indices of liver fibrosis and RDW derivatives in ALC and MAFLD patients. RLR seems to be a valuable unexplored parameter in the course of ALC patients. Its high diagnostic accuracy in ALC is a promising message for subsequent studies. Undoubtedly, this direction of research should be continued to define a potential role of commonly accessible RDW derivatives as indicators of liver disorders in everyday clinical life.

Research perspectives

It seems that our results have important clinical implications and could be applied in everyday diagnostics of patients with liver disorders.

FOOTNOTES

Author contributions: Michalak A, Lach T and Cichoż-Lach H prepared data; Michalak A and Cichoż-Lach H invented and conducted the study; Guz M, Kozicka J and Jeleniewicz W applied the experiments, gained and interpreted data; Cybulski M statistically analyzed the data; Michalak A and Cichoż-Lach H wrote the article; All authors accepted the current version of the manuscript.

Institutional review board statement: The survey was accepted by the local ethics committee of the Medical University of Lublin (No. KE-0254/86/2016).

Informed consent statement: All study participants, or their legal guardian, provided informed written consent prior to study enrollment.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.

Abstract

BACKGROUND

Accurate assessment of the quality of academic journals is of great significance. While Journal Impact Factor (JIF), calculated by Clarivate and based upon the Web of Science literature database, and CiteScore (CS), developed by Elseiver and based upon the Scopus database, have enjoyed high uptake worldwide, efforts continue towards creation of other scientometric indexes that will provide ever-greater qualitative insights into journal impact. Such efforts have yielded the newly-launched *Journal Article Influence Index* (*JAII*), which is based on the *Reference Citation Analysis* (*RCA*) database, an open multidisciplinary citation analysis database based on artificial intelligence technology.

AIM

To evaluate and summarize the similarities and differences between *JAII* and JIF/CS as journal evaluation indicators, and provide an intuitive method for visual representation of the related data.

METHODS

We searched the Journal Citation Reports to obtain the 2021 JIF list, downloaded the CS list updated in July on the Scopus website, and collected the comprehensive list of 2022 *JAII*s from the *RCA* database (www.referencecitationanalysis.com).

RESULTS

Our research results revealed that by breaking through the time limit of mainstream journal evaluation methods, the *JAII* is able to perform well in data reliability, establishing its benefit as a complementary scientometric index to JIF and CS.

CONCLUSION

JAII provides comprehensive assessment of the quality and performance of journals.

Key Words: *Journal Article Influence Index*; Journal Impact Factor; CiteScore; Gastroenterology and Hepatology; Scientometric index

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Compared with Journal Impact Factor (JIF) and CiteScore (CS), the newly-launched *Journal Article Influence Index* (*JAII*) breaks through the time limit feature of the former indexes. A key benefit of the *JAII* is that it does not require the temporal path (wait-time) of JIF and CS to accurately evaluate a journal's impact. As such, *JAII* is immediately useful for assessing the performance of journals and the drawbacks of time randomness are overcome. Here, we describe the features of *JAII* as a comprehensive assessment of the quality and performance of journals, in its functionality based upon the *Reference Citation Analysis* (*RCA*) database that covers some more specific journals than other literature databases.

INTRODUCTION

The quality assessment of peer-reviewed published research is important for the reputation, substance and growth of various professional associations, individual scientists, and academic institutions, as well as the funding organizations that evaluate and support them[1]. The quality of scientific contributions is primarily assessed on a temporal basis, with quantitative evaluation of the long-term impact in a field or discipline. The impact of an individual scientific article can be inferred from the citations that it receives. A similar principle is applied to evaluation of the journals that publish these scientific articles[2]. These long-standing efforts have led to researchers proposing various methods that improve the assessment of the quality of scientific journals[3,4]. What most of these methods have in common, though, is the use of complex mathematical algorithms to analyze networks of scientific papers to estimate citation quality.

First proposed by Eugene Garfield in 1955, the Scientific Citation Index, Journal Citation Reports [(JCR); published by the Institute for Scientific Information (ISI)] aims to rank, evaluate, classify, and compare journals[5]. The involved metrics are calculated based on the number of articles published by a journal and the number of times that a journal is cited. Moreover, they have been widely adopted as tools to evaluate researchers and research work in a wide range of scientific settings. One of the most prominent among such indicators is the Journal Impact Factor (JIF).

In addition to the JIF, other metrics provided by the ISI include total citation frequency, immediacy index, number of source entries published in the current year, frequency of citations in the previous 2 years, cited half-life, and the ratio of different citations for each article. The ISI introduced a simplified system in 1974, along with a list of topic categories and an accompanying catalog of the total 176 JCR journals. In recent decades, the different journal categories have been subjected to many holistic analyses. The resultant definitions of the common characteristics that underpin particular types of journals and relate to the JIF have served as a useful tool for researchers, both in the scientometric field and in general as contributing authors, to better evaluate journal impact[6,7]. To this day, journals are ranked by JIF within their assigned category. The journals listed in the JCR are further subgrouped by the ranking of JIF-related indicators (*i.e.* JIF variation coefficient, *etc*); this greater detailed categorization has allowed scholars to perlustrate the impact factor values more intuitively from a holistic and comprehensive perspective.

JIF has been the most widely used indicator of quality of scientific journals over the past decades[8]. However, in accordance with the 1999 announcement by the ISI/JCR that the accuracy of JIF is not fully guaranteed[9], it is important to note that the methodological considerations in the JIF calculation still include a lack of assessment of the quality of citations, the inclusion of self-citations, poor comparability between different scientific fields, and an analysis of publications mainly in English[10]. This is in addition to the fact that JIFs of journals representing different disciplines are not comparable to each

other.

On December 8, 2016, Scopus launched the CiteScore (CS) quality metric, in direct competition of JIF but which was developed specifically for journals indexed by Scopus. Over the past few years, the number of journals assigned a CS has increased dramatically, especially for journals that are not included in the JIF annual assignments. Scientometric studies evaluating the relationship between CS and JIF have revealed that although there is a strong correlation between the two metrics, there are also obvious complex differences[11,12]. While CS may be more balanced and most certainly is more transparent[13], it also shares some key limitations with the JIF[14,15].

Reference Citation Analysis (*RCA*) is a very recently launched open multidisciplinary citation analysis database based on artificial intelligence technology. This database covers a wide array of seemingly disparate disciplines such as business, economics and management, chemistry and materials science, engineering and computer science, health and medical sciences, humanities, literature and arts, life sciences and earth sciences, physics and mathematics, and social sciences. Users can search the collective literature based on fields such as author, category, DOI, ISSN, keyword, ORCID number, publication name, PubMed ID, and title to track original innovative research results and cutting-edge progress; they can also sort results by an article impact index metric. Importantly, the results analysis functionality culminates in a comprehensive and customizable report of the retrieved results.

Based on the *RCA* database, the *Journal Article Influence Index* (*JAII*) metric is officially available as a new indicator of journal quality that is calculated *via* the normal approach of quantifiable citations. Systematically comparing this new metric to traditional journal evaluation metrics will help ensure the accuracy of *JAII*. With acknowledgement of the continuous deepening of research in the field of Gastroenterology and Hepatology of recent years[16], we performed such a comparative analysis to determine the similarities and differences between *JAII* and JIF/CS as journal evaluation indicators, with the ultimate aim of providing an intuitive method for visual representation of the related data.

MATERIALS AND METHODS

Data sources

The raw data for this study was obtained in July 2022 from the official websites of the institutions that released each metric under consideration. We searched the JCR to obtain the 2021 JIF list, downloaded the CS list updated in July from the Scopus website, and collected the 2022 *JAII* list from the *RCA* database (www.referencecitationanalysis.com). In addition, we also searched for information related to the characteristics of these scientific journal quality indexes for reference.

Besides, based on the results of *RCA* search by the Gastroenterology and Hepatology category, we compared *JAII* to JIF and CS respectively. The resultant data from the *RCA* database were used as the matching benchmark, and the matching method was based on ISSN, EISSN, and journal name.

RESULTS

Statistical analysis and visualization

The Gastroenterology and Hepatology-categorized journals identified in each database are presented in Table 1 (grouped by the evaluation indicator and in descending order according to the respective quality metric value). In total, 102 journals carried a *JAII*, 81 carried a JIF, and 76 carried a CS (all assigned in 2021).

Next, in order to make an intuitive comparison between the three evaluation indicators, we drew a scatter distribution plot for JIF-*JAII* (Figure 1A) and CS-*JAII* (Figure 1B), and plotted a single-timepoint uniform curve using the least squares method[17]. In this case, we took an intersection, considering that some journals with *JAII* have no JIF or CS. It can be seen from the figure that in the evaluation of lower-quality journals, the linearity of *JAII* and JIF/CS has greater overlap, but in the evaluation of higher-quality journals, the randomness of the data is greater. Journals with a large deviation between JIF and *JAII* include *Nature Reviews Gastroenterology & Hepatology*, *Lancet Gastroenterology & Hepatology*, *Seminars in Liver Disease*, and so on. Journals with a large deviation between CS and *JAII* include *Gut*, *Journal of Hepatology*, *Gastroenterology*, and so on.

The results of the combined analysis of the three journal evaluation indicators are visualized in Figure 2A-C[18]. Figure 2A gives a comparison of the values between the three evaluation indicators of the same journal (73 in total, taking the intersection). Figure 2B gives the JIF-*JAII* ratio and CS-*JAII* ratio for each journal. Figure 2C gives the values of JIF and CS in descending *JAII* order.

Finally, we combined the three journal evaluation indicators together, and through a histogram (Figure 2D), we can more clearly see the impact of the joint evaluation of the three on the ranking of journals without weight. This can also be used as a reference evaluation method.

DISCUSSION

Comparison of databases and calculation principles

JIF: JIFs are obtained through the Web of Knowledge database using the Science Edition of JCR which collects citation data from more than 7300 science and technology journals worldwide. The IF of a T-year journal is defined as the number of times that the journal has been cited in years T-1 and T-2 divided by the number of documents that can be cited in the journal in years T-1 and T-2[19].

CS: CSs are calculated using data from the Scopus database. CS has a publication window of 3 years before the 1-year reference window and counts the references from one document type to another[20]. In other words, CS calculates the average number of citations of papers published in a journal for 3

Figure 2 Visualization of the three journal evaluation indicators. A: Comparison of the values obtained upon application of the three evaluation indicators; B: Journal Impact Factor (JIF)-*Journal Article Influence Index* (*JAII*) and CiteScore (CS)-*JAII* ratios for each journal; C: Values of JIF and CS in descending *JAII* order; D: Histogram combining the three journal evaluation indicators together. JIF: Journal Impact Factor; CS: CiteScore; *JAII*: *Journal Article Influence Index*.

consecutive years in the 4th year. In a given year, CS is calculated as the amount of times that documents published in the previous 3 years were cited in that year divided by the number of documents published in those 3 years that were included in the Scopus database.

JAII: *JAII*s, calculated as total citations divided by total articles, are based on journals and their citations included in the *RCA* database.

Advantages and disadvantages of JAII

It is undeniable that the *JAII* metric has its merits as a journal evaluation indicator. (1) Compared with JIF and CS, *JAII* is able to break through the time limit disadvantage of the first two. Journals do not need to meet the waiting-time thresholds of JIF and CS to be accurately evaluated. As such, *JAII* is able to evaluate more journals accurately in a near-real time manner, which explains why there are more journals with a *JAII* than those with a JIF/CS. (2) Compared with JIF and CS, *JAII* is useful for assessing the performance of journals immediately upon its creation. Moreover, since a small number of articles in journals will result in a high JIF and CS at a given time, *JAII* relieves the chance of biased evaluation of journals. *JAII* is also more conducive to a comprehensive assessment of the quality and performance of journals. And (3), compared with JIF and CS, *JAII* is more conducive to high-quality journal evaluation. In addition to these advantages, *JAII* has a high degree of compliance with JIF and CS in the evaluation of journals with a lower impact.

Another important feature related to the *JAII* is that the *RCA* database, upon which it is based, can enable queries to journals by category, such as focused query of Gastroenterology and Hepatology, representing a ready convenience to researchers.

There exist disadvantages in the *JAII*. These include the lack of statistical timeliness, a feature by which *JAII* is slightly inferior to JIF and CS, and the lack of consideration to different developments of the same journal in different periods. *JAII* also shares some of the drawbacks of both JIF and CS, such as the lack of evaluation of citation quality and the inclusion of self-citations.

Non-linearity interpretation

As we have shown in Figure 1 and described textually in the "Results" section above, the linearity of *JAII*-JIF-CS was clear for lower-quality journals but failed to match each other perfectly for higher-quality journals.

Our explanation is that JIF and CS are subject to changes in citation frequency and number of published articles in different years, and their correlation with time exacerbates the influence of human manipulability[21]. *JAII* reduces this time randomness. In addition, the JIF and CS of high-quality journals may be more susceptible to this effect, and their fluctuations can be effectively explained.

Threats to validity

In addition to the lack of evaluation of citation quality and self-citation, other factors may threaten the effectiveness of the evaluation parameters in use. Research on JIF, CS and other statistical standards for journal quality has shown that there are still many statistical violations at play, including those related to and arising from reliability, incomplete reporting of validity, insignificant results, insignificant effect sizes, and hypothesis checking, as well as uncorrected inferences and multiple comparisons from descriptive statistics[22]. *JAII* is also inevitably affected by the same, to at least some extent, and this limitation cannot be ignored.

CONCLUSION

The main differences between *JAII* and JIF/CS come from the differences in the scientific databases used as the cited sources, as well as the differences in the evaluation methods underpinning each of these indicators. Due to the JIF/CS time factor limitation, the *JAII* method based on the *RCA* database is able to evaluate more journals. Besides, *JAII* provides more focused quantitative insight by considering categories of journal papers. In terms of practicality, the novelty introduced by the *JAII* indicator is its open-accessibility to users (as opposed to a subscription service to select users). To summarize, *JAII* is a reliable index to evaluate the quality of journals in near-real time.

In the future, scientometric researchers can focus on the differences of the different journal evaluation indexes to aid in their studies on the origin of nonlinear characteristics in order to put forward a more perfect journal evaluation standard. Meanwhile, researchers in general can exploit the distinct advantages of each as they currently stand to better understand journal quality and promote the impact of their own scientific communications.

ARTICLE HIGHLIGHTS

Research background

The evaluation of journal quality is very important for researchers. Journal Impact Factor (JIF) and CiteScore (CS) are two of the most popular and authoritative journal evaluation indicators. With the ongoing scientometric research into their advantages and disadvantages, there is a consequent emergence of new journal evaluation indicators. The logical next-step is comparative judgement of the reliability and innovative novelty of such new journal evaluation indexes.

Research motivation

The recently-launched *Reference Citation Analysis* database of Baishideng Publishing Group is an open multidisciplinary citation analysis database founded in artificial intelligence technology. Based on this database, *Journal Article Influence Index* (*JAII*) has been proposed as a new journal evaluation indicator.

Research objectives

To compare the advantages and disadvantages of *JAII* with those of JIF and CS.

Research methods

For comparisons between *JAII* and 2021 JIF/2021 CS, we conducted statistical analyses and provided an intuitive method for visual representation of the related data.

Research results

For lower-quality journals, *JAII*, 2021 JIF, and 2021 CS had a good linear correlation. However, their results of assessments of higher-quality journals varied widely. These three evaluation indexes have their own advantages and disadvantages, including the avoidance of time randomness and ability for near-real time evaluation of the *JAII*.

Research conclusions

JAII is a comprehensive assessment tool to assess the quality and performance of journals.

Research perspectives

In the future, we hope to better explain the current existent nonlinear relationship among the three evaluation indexes, and combine a variety of journal evaluation indicators to allow for more comprehensive evaluation of journal quality by scientometric-focused and general researchers.

ABOUT COVER

Editorial Board of *World Journal of Gastroenterology*, Raquel Rocha, PhD, MD, Professor, Department of Sciences of Nutrition, School of Nutrition, Federal University of Bahia, Salvador 40.110-907, BA, Brazil. raquelrocha@ufba.br

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. Abstract

The frequency of primary small intestinal adenocarcinoma is increasing but is still low. Its frequency is approximately 3% of that of colorectal adenocarcinoma. Considering that the small intestine occupies 90% of the surface area of the gastrointestinal tract, small intestinal adenocarcinoma is very rare. The main site of small intestinal adenocarcinoma is the proximal small intestine. Based on this characteristic, dietary animal proteins/lipids and bile concentrations are implicated and reported to be involved in carcinogenesis. Since most nutrients are absorbed in the proximal small intestine, the effect of absorbable intestinal content is a suitable explanation for why small intestinal adenocarcinoma is more common in the proximal small intestine. The proportion of aerobic bacteria is high in the proximal small intestine, but the absolute number of bacteria is low. In addition, the length and density of villi are greater in the proximal small intestine. However, the involvement of villi is considered to be low because the number of small intestinal adenocarcinomas is much smaller than that of colorectal adenocarcinomas. On the other hand, the reason for the low incidence of small intestinal adenocarcinoma in the distal small intestine may be that immune organs reside there. Genetic and disease factors increase the likelihood of small intestinal adenocarcinoma. In carcinogenesis experiments in which the positions of the small and large intestines were exchanged, tumors still occurred in the large intestinal mucosa more often. In other words, the influence of the intestinal contents is small, and there is a large difference in epithelial properties between the small intestine and the large intestine. In conclusion, small intestinal adenocar-

cinoma is rare compared to large intestinal adenocarcinoma due to the nature of the epithelium. It is reasonable to assume that diet is a trigger for small intestinal adenocarcinoma.

Key Words: Small intestine; Large intestine; Adenocarcinoma; Risk factor; Carcinogenesis

Core Tip: When investigating the risk factors for small intestinal adenocarcinoma, an important point to note is that small intestinal adenocarcinoma is often found in the proximal small intestine. Intestinal contents remain in the ileum longer than in the jejunum, so poorly absorbed food is unlikely to be a carcinogenic factor. Animal proteins and lipids, bile concentrations, and aerobic bacteria, which are thought to be concentrated in the proximal small intestine, may be carcinogens in the small intestine. Since small intestinal adenocarcinoma is much rarer than colorectal adenocarcinoma, it is unlikely that small intestinal villi are involved in carcinogenesis.

INTRODUCTION

Although the small intestine occupies 75% of the gastrointestinal tract length and 90% of the mucosal surface area, primary small intestinal cancer accounts for less than 5% of gastrointestinal cancers[1]. During the last century, enteroscopy was a difficult procedure to perform, and thus, the elucidation of small intestinal cancer was delayed compared to that of other gastrointestinal cancers. However, in this century, capsule endoscopy and balloon-assisted endoscopy have made it easier than ever to examine the small intestine. The frequency of small intestinal cancer has been increasing since 2000 or earlier and continues to rise with the addition of improved diagnostic power *via* new endoscopes[2]. Especially in patients with anemia of unknown cause, cases of small intestinal cancer diagnosed as a bleeding source are increasing[3]. In addition, many cases are diagnosed by positron emission tomography or computed tomography. The frequency of small intestinal adenocarcinoma is still on the rise, partly due to the widespread performance of small intestinal examinations[4].

According to a 2006 French report, the incidence of primary small intestinal malignancies in both men and women was approximately four times that 30 years ago (1.2 males and 0.8 females per 100000 in 2006)[5]. Primary small intestinal malignancies include neuroendocrine tumors, sarcomas, and lymphomas in addition to adenocarcinomas. A report of 10946 primary malignancies of the small intestine, mainly in Europe, showed that adenocarcinomas accounted for 37% of cases, carcinoid tumors accounted for 37% of cases, sarcomas accounted for 12% of cases, and malignant lymphomas accounted for 4% of cases[6]. In the United States, 40% of primary malignancies of the small intestine are reported to be adenocarcinomas, and 36% are carcinoid tumors[7].

According to the cancer statistics published yearly by the American Cancer Society, 5420 small intestinal malignancies and 145290 colorectal malignancies were predicted to develop in the United States in 2005[8]. The frequency of small intestinal malignancies was only 3.7% of that of colorectal malignancies. In 2019, the predicted number of colorectal malignancies was almost 145600 cases. However, the number of small bowel malignancies was 10590, which is 7.3% of the number of colorectal malignancies. Additionally, this percentage is twofold higher than that reported in 2005[9]. In the United States, colorectal adenocarcinomas account for 98% of colorectal malignancies, but small intestinal adenocarcinomas account for only approximately 30%-40% of small intestinal malignancies [10]. Therefore, regarding adenocarcinoma at present, the number of cases of small intestinal adenocarcinoma is approximately 3% of that of large intestinal adenocarcinoma cases. Considering that the small intestinal villi and circular folds have even been reported to occupy 98% of the intestinal surface area [11], the frequency of small intestinal adenocarcinoma per surface area is extremely low compared to that of colorectal adenocarcinoma.

In the 1970s, an experiment was performed in which azoxymethane, a carcinogen, was intravascularly administered to rats. The results showed that adenocarcinomas appeared in the proximal small intestine, which corresponds to the duodenum, and the large intestine. However, no adenocarcinoma appeared in the jejunum/ileum[12]. It is worth noting that in this experiment, in rats in which a part of the small intestine or large intestine had been replaced, tumors still appeared in the large intestine and

not the small intestine, regardless of the position in the digestive tract. In other words, the content of the intestinal tract did not significantly influence the development of tumors in the intestinal tract, and this experiment showed that the properties of the intestinal tract are involved in the development of tumors. This azoxymethane administration experiment was conducted again recently, and the results did not show carcinogenicity in the small intestine[13]. In the 1980s, an experiment was conducted in which dimethylhydrazine was administered to rats to examine the reproducibility of the above experiment, and the results were similar[14]. Based on this fact, many tumors can develop in the proximal small intestine (probably in the papilla of Vater) and in the large intestine, regardless of the position in the digestive tract. However, tumor development is less common in the jejunum and ileum. In other words, there is a decisive difference between the small and large intestines.

Differences between the small and large intestines are mainly the presence or absence of villi, intestinal contents, intestinal content retention time, intestinal flora, intestinal epithelial turnover, mucosal properties, and genetic factors. There are very few adenocarcinomas in the small intestine compared to the large intestine, but small intestinal adenocarcinomas are more common in the jejunum than in the ileum, as shown below. Here, we would like to consider the risk factors for small intestinal adenocarcinoma.

RISK FACTORS FOR SMALL INTESTINAL ADENOCARCINOMA IN THE PROXIMAL SMALL INTESTINE

Table 1 summarizes the reports of small intestinal adenocarcinoma according to site, namely, the duodenum, jejunum, and ileum. The majority of reports show that adenocarcinoma is the most common malignancy in the duodenum. The oral side of the duodenum can usually be explored endoscopically, which is why many malignancies are diagnosed in this area. However, these reports may include cancer of the papilla of Vater. The only Chinese report on this topic does not show a high cancer incidence rate in the duodenum. In this report, 160 cases of cancer of the papilla of Vater were excluded from 202 cases of all small intestinal adenocarcinomas, and adenocarcinomas were more common in the jejunum than in other parts of the small intestine[15]. When we examined the adenocarcinomas of the small intestine that were diagnosed at our institution only in patients in whom a normal papilla of Vater was observed, the jejunum was the most common site. This finding is in agreement with that reported in China. Because the duodenum is short, this result may be appropriate in assessments of the small intestine alone. In recent years, the papilla of Vater has been suggested to have characteristics different from those of the duodenum[16,17]. A mixture of bile and pancreatic juice passes through the papilla of Vater, and the bile and pancreatic ducts themselves have different carcinogenic properties. It is natural to think that the carcinogenic origin in the papilla of Vater is different from that in the small intestinal mucosa. We did not examine cancer of the papilla of Vater here.

When comparing the jejunum and the ileum and excluding the duodenum, adenocarcinoma was more common in the jejunum than in the ileum in all reports. Based on these results, it seems clear that there are more small intestinal adenocarcinomas in the proximal small intestine than in the distal small intestine. According to a report summarizing small intestinal gastrointestinal stromal tumors (GISTs), the jejunum has more GISTs than the ileum[18]. In addition, reports of small intestinal neuroendocrine tumors are often reported in the jejunum within 1 m from the ileocecal valve[19]. Differences in the site of occurrence are observed depending on the type of tumor. Here, since small intestinal adenocarcinoma is more common in the proximal small intestine, we would like to determine the risk factors for adenocarcinoma of the small intestine by considering the difference between the proximal side of the small intestine and the distal side.

Food

Most absorbable dietary components are absorbed in the duodenum and jejunum[20]. In other words, undegraded proteins and unabsorbed lipids flow in the proximal part of the small intestine. Diets containing high volumes of animal fat and protein have been reported to have a high risk of small intestinal adenocarcinoma, with correlation coefficients of 0.61 and 0.75, respectively[21]. Lipids and even small amounts of large peptides penetrate the cell membrane, which may be involved in carcinogenesis. Most proteins and lipids are absorbed in the proximal intestine and rarely reach the ileum, so there is no contradiction in this respect. Therefore, they may be involved in the carcinogenesis of the small intestine.

Bile and pancreatic juice

The proximal part of the small intestine has higher levels of bile and pancreatic juice than the distal part. A review of the literature on the effects of bile and pancreatic juice reveals that bile may be converted to carcinogenic deoxycholic acid by bacteria and that cholecystectomy reduces the incidence of small intestinal cancer[22,23]. In other words, bile may be involved in small intestinal carcinogenesis. However, it is difficult to judge the validity of the results because there are few reports on the effects of

Table 1 Regions where small intestinal adenocarcinoma was reported

Country	Year	Number[1]	Duodenum		Jejunum		Ileum		Ref.

bile on the small intestine.

Intestinal chemicals

The contents of the intestinal tract include chemicals contained in the diet and various chemical substances produced by bacteria. As mentioned above, chemical carcinogenesis occurs when the large intestine comes into contact with chemical substances. However, since the transit time of the intestinal contents into the small intestine is approximately 4 h, which is considerably shorter than that of the large intestine, the effect of chemical substances in the intestine is thought to be smaller than that of the large intestine. In addition, if carcinogenesis due to dietary or bacterial chemical substances is the main cause of adenocarcinoma, more adenocarcinomas would be likely to develop in the ileum, where the intestinal contents stagnate longer than in the jejunum. However, if the carcinogen is absorbed in the oral side of the small intestine, this is not inconceivable.

Intestinal flora

Intestinal bacteria influence the intestinal tract through various means. Among the various chemicals produced by intestinal bacteria, those that not only cause inflammation but also have a direct carcinogenic effect and those that delay or prevent cell division of the intestinal epithelium have been reported[24]. Delaying epithelial turnover may be beneficial for bacteria directly involved in the epithelium. This delay in turnover is considered to be a factor that increases the possibility of cancer cell engraftment. There is a high possibility that intestinal bacteria are involved in carcinogenesis in the large intestine. However, it is difficult to explain why the number of jejunal adenocarcinomas is larger than that of ilial adenocarcinomas if intestinal bacteria are strongly associated with carcinogenesis in the small intestine. This is because it is difficult to explain why there are few bacteria in the proximal small intestine but many small intestinal adenocarcinomas in that area. However, the proximal small intestine is characterized by a relatively large number of aerobic bacteria, although the absolute number of bacteria is small. Therefore, given that small intestinal adenocarcinoma predominantly occurs in the proximal small intestine and aerobic bacteria are abundant in the proximal small intestine, the role of aerobic bacteria in small intestinal adenocarcinoma must be considered.

Immunity

To absorb and excrete various substances, the cell membrane of the small intestine needs to have direct contact with the outside environment of the body. Therefore, the intestinal lumen needs to protect itself against bacteria, viruses, and many substances that invade the body using various types of immune mechanisms. The small intestine has the highest levels of immunity in the body. Additionally, the lymphatic system within the small intestine is stronger in the distal small intestine, where cancer may be strongly eliminated by immune mechanisms. Benzopyrene, for example, has been reported to suppress mouse immunity and thus, in the presence of carcinogens, lead to adenocarcinoma development in the proximal small intestine[25]. However, it remains unclear whether immunity can explain why cancer is overwhelmingly less common in the small intestine than in the large intestine because there are few reports on this topic.

Table 2 Risk factors for small intestinal adenocarcinoma

Factor	Disease	Risks of small intestinal adenocarcinoma	Ref.
Animal fat		Correlation coefficient of 0.61	[21]
Animal protein		Correlation coefficient of 0.75	[21]
		2–3-fold higher risk	[36]
Bile salts		Bile salts may transform into carcinogenic deoxycholic acid	[22]
Hereditary polyposis	FAP	APC mutation; 5% is small bowel adenocarcinoma and half is duodenal adenocarcinoma	[27]
		The incidence is 330 times higher than that in the general population	[28]
	HNPCC	MMR gene mutation; lifetime risk is at approximately 1% in a French registry	[29]
	PJS	STK11 mutation; incidence is 520 times higher than that in the general population	[30]
Disease	Crohn's disease	The incidence is 17.4 times higher than that in the general population	[37]
		The incidence is almost 3 times higher than that in the average American	[38]
	Celiac disease	It is implicated in 8%-13% of small bowel adenocarcinoma cases	[39,40]

FAP: Familial adenomatous polyposis; APC: Adenoma polyposis coli; HNPCC: Hereditary nonpolyposis colorectal cancer; MMR: Mismatch repair: PJS: Peutz-Jeghers syndrome; STK 11: Serine/threonine kinase 1.

Villus length

The small intestine has villi and crypts, and the large intestine has only crypts and no villi. The lifespan of cells that have migrated to the villi is short, and the small intestinal epithelium is thought to be renewed every 3-5 d[26]. The proximal small intestine has longer and denser villi than the distal part. Therefore, the rate of epithelial turnover in the proximal small intestine may be longer than that in the distal part. This may be the reason why small intestinal adenocarcinoma is more common in the proximal small intestine. However, considering that many cancers develop in the large intestine, which has only crypts, it is unlikely that villi are significantly involved in cancer development.

SUMMARY OF SMALL INTESTINAL ADENOCARCINOMA RISK FACTORS

Based on the above rationale and considering that the number of small intestinal adenocarcinomas in the proximal small intestine is larger than that in the distal small intestine, the possible causes of carcinogenesis are the effects of diet, bile concentration, aerobic bacteria, and intestinal immunity, in the order described. However, none of the above causes is definitive. Table 2 briefly summarizes the reported risk factors for small intestinal adenocarcinoma. In addition to the above causes, genetic factors and inflammatory diseases have been added to the table. Papillary carcinoma is increased in patients with familial adenomatous polyposis due to a mutation in adenoma polyposis coli, but it is less associated with the jejunum and ileum[27,28]. Small intestinal adenocarcinoma also occurs in hereditary nonpolyposis colorectal cancer patients due to mismatch repair mutations, but it is much less frequent than colorectal adenocarcinoma[29]. Small intestinal adenocarcinoma occurs 520-fold more often in patients with Peutz-Jeghers syndrome than in healthy individuals, but the population with small intestinal adenocarcinoma was originally small[30]. An increase in small intestinal adenocarcinoma is also observed in patients with Crohn's disease and celiac disease, which are thought to be related to inflammatory carcinogenesis. Therefore, it is understandable that genetic factors and disease factors are involved in small intestinal adenocarcinoma.

CONCLUSION

Small intestinal adenocarcinoma is characterized by its predominance in the proximal small intestine. Animal proteins and lipids, bile concentrations, aerobic bacteria, and intestinal immunity were discussed as factors playing a role in small intestinal adenocarcinoma. Of these, it is highly possible that the dietary content absorbed in the proximal part of the small intestine is a risk factor for small intestinal adenocarcinoma. However, since the number of small intestinal adenocarcinomas is small, there are few reports, and none of the results are definitive. Moreover, in small intestine/large intestine replacement

experiments, at least in rats, the results show that the contents of the intestine are rarely involved in carcinogenesis. It seems that the nature of the organs is strongly related to susceptibility to carcinogenesis. Future studies are expected.

Abstract

Coronavirus disease 2019 (COVID-19) is a highly infectious disease which emerged into a global pandemic. Although it primarily causes respiratory symptoms for affected patients, COVID-19 was shown to have multi-organ manifestations. Elevated liver enzymes appear to be commonly observed during the course of COVID-19, and there have been numerous reports of liver injury secondary to COVID-19 infection. It has been established that patients with pre-existing chronic liver disease (CLD) are more likely to have poorer outcomes following COVID-19 infection compared to those without CLD. Co-morbidities such as diabetes, hypertension, obesity, cardiovascular and chronic kidney disease frequently co-exist in individuals living with CLD, and a substantial population may also live with some degree of frailty. The mechanisms of how COVID-19 induces liver injury have been postulated. Hepatorenal syndrome (HRS) is the occurrence of kidney dysfunction in patients with severe CLD/fulminant liver failure in the absence of another identifiable cause, and is usually a marker of severe decompensated liver disease. Select reports of HRS following acute COVID-19 infection have been presented, although the risk factors and pathophysiological mechanisms leading to HRS in COVID-19 infection or following COVID-19 treatment remain largely unestablished due to the relative lack and novelty of published data. Evidence discussing the management of HRS in high-dependency care and intensive care contexts is only emerging. In this article, we provide an overview on the speculative pathophysiological me-chanisms of COVID-19 induced HRS and propose strategies for clinical diagnosis and management to optimize outcomes in this scenario.

Core Tip: There have been numerous reviews evaluating the causative relationship between coronavirus disease 2019 (COVID-19) and liver pathology, given an emerging number of cases reporting COVID-19 induced liver injury. There are few reports noting the onset of hepatorenal syndrome (HRS) in the face of COVID-19 infection. Occurrence of HRS in any circumstance is typically an indicator of severe and perhaps life-threatening disease, potentially requiring liver transplantation. With a paucity in literature compilation on the associations between COVID-19 and HRS, we provide a review which discusses the purported pathophysiological mechanisms of COVID-19 induced HRS, and propose clinical assessment and management approaches in this scenario.

INTRODUCTION

The impact of coronavirus disease 2019 (COVID-19) has been tremendous since the initial case was reported in December 2019, and COVID-19 subsequently spiraled into a global pandemic which is affecting populations and societies significantly up to this day[1-3]. The severity of COVID-19 could be wide ranging from mild to severe disease[4]. This depends on various intrinsic and environmental factors for each individual[4,5]. The manifestations of COVID-19 are thought to be primarily respiratory, with severe COVID-19 infection leading to acute respiratory distress syndrome potentially progressing towards life-threatening septic shock and multi-organ failure[6,7]. There is emerging evidence on the multi-systemic effects of COVID-19 outside of the respiratory system. It is suggested that COVID-19 has direct associations with acute disease processes across the neurological, cardiovascular, renal and gastroenterological systems amongst other organ systems, but the pathophysiology of how COVID-19 affects these organs has not been fully established in most instances[8-12].

Liver injury secondary to COVID-19 has been investigated, with its incidence ranging between 15% and 53%[13]. In most patients, the effect of COVID-19 on the liver is a transient reaction with elevation of transaminases which resolves and most patients achieve recovery back to their normal baseline[14]. However, individuals with underlying cirrhosis and chronic liver disease (CLD) were found to have significantly greater 30-day mortality and lengthier hospitalization, and poorer prognosis following acute recovery from COVID-19 induced liver injury[15]. Histological damage to hepatocytes and bile duct cells was found in patients testing positive for COVID-19[16].

Hepatorenal syndrome (HRS) is a state of kidney function deterioration (usually profound oliguria and sodium retention) in patients with advanced cirrhosis or acute liver failure[17,18]. The decline in kidney function could be rapid (Type I) or gradual (Type II), dependent on the etiology of HRS[18]. In cirrhosis, Type 1 and Type 2 HRS has been replaced with newer terminology and HRS is now defined as either acute (HRS-AKI), sub-acute (HRS-AKD) or chronic (HRS-CKD)[19]. HRS is a diagnosis of exclusion in which other causes of kidney dysfunction are not identified, and where the kidneys were not found to be structurally damaged[17,18]. The dominant theory to explain for the pathophysiology of HRS is significant constriction of blood vessels which perfuse the kidneys, most likely mediated by splanchnic vasodilation (leading to central hypovolemia) and hepatorenal reflex mechanisms as a result of portal hypertension[17,18]. HRS is most likely seen in the context of advanced stage cirrhosis. The most common etiologies of cirrhosis include alcohol, non-alcoholic steatohepatitis and chronic viral hepatitis[20]. Multiple triggers of HRS have been recognized and spontaneous bacterial peritonitis (SBP) in patients with ascites from decompensated cirrhosis is a leading cause[21]. HRS is a marker of poor prognosis in hepatology, and the risk of death is very high unless prompt liver transplantation or acute dialysis can be provided[22].

There were select case reports of liver injury following COVID-19 infection where acute kidney dysfunction was found, suggesting the potential manifestation of COVID-19 induced HRS[23,24]. Evidence of the pathophysiology, optimal strategies for clinical assessment and management of COVID-19 induced HRS is seldom discussed at present due to a relative lack of cases. In this review, we will explore the speculative pathophysiological mechanisms of HRS following COVID-19 infection based on early evidence, and propose potential clinical assessment and management strategies to optimize HRS outcomes in this scenario.

POTENTIAL PATHOPHYSIOLOGICAL MECHANISMS OF COVID-19 INDUCED HRS

Current perspectives on the potential pathophysiological mechanisms of COVID-19 induced HRS are that of a multifactorial process (Figure 1). COVID-19 induced liver injury can be the result of direct viral cytopathic hepatocyte injury, systemic inflammatory cytokine storms causing hepatocyte cell death, endothelitis and dysfunction of the liver vasculature leading to widespread cell damage and ischemia, and drug-associated exacerbations in COVID-19 induced liver injury[25,26]. Subsequently, these multiple pathways of liver injury may result in circulatory dysfunction, progressing to HRS with vasoconstriction and hypoperfusion of the kidneys amongst other mechanisms[17-19].

Direct COVID-19 infection of hepatocytes

Direct viral cytopathic injury to the liver, similar to how various organs are affected by COVID-19 infection, should be considered as the major pathophysiological mechanism. Ultrastructural histological examination identified severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) particles in the cytoplasm of hepatocytes[27]. Features of cellular viral invasion such as conspicuous mitochondrial swelling, decreased glycogen granules, and endoplasmic reticulum dilatation were observed in SARS-CoV-2-infected hepatocytes[27]. The presence of binuclear hepatocytes, central lobular necrosis and hepatocyte apoptosis were observed features of liver damage following COVID-19 infection[27]. Induction of hepatocyte apoptosis from COVID-19 infection could be the result of p7a overexpression [26,28]. p7a is a protein which can be expressed in cells infected by SARS-CoV-2, and induces apoptosis in cell lines derived from organs including the lungs, liver and kidneys *via* a caspase-dependent pathway[29]. This mechanism confirms the pathway of how SARS-CoV-2 can directly attack liver tissues and cause damage.

The extent of viral tropism is typically dependent on the availability of viral receptors at the surface of host cells in specific tissues[30]. The spike (S) protein of SARS-CoV-2 mediates cellular entry of SARS-CoV-2. S protein is cleaved by transmembrane serine protease 2/transmembrane serine protease 4 and interacts with the angiotensin converting enzyme 2 (ACE2) protein in host cells specifically[30]. In normal circumstances, ACE2 would only be expressed in bile duct epithelial cells, central hepatic vein and portal vein endothelial cells within the hepatobiliary system, being almost absent in hepatocytes [31]. The level of ACE2 expression in bile duct epithelial cells is comparable to that of alveolar epithelial cells in the lungs (commonly recognized to have the greatest expression of ACE2 in the body)[31]. The compensatory differentiation and proliferation of liver parenchymal cells derived from bile duct cells during diseased states may explain the underlying pathophysiological mechanisms of how SARS-CoV-2 induces liver injury[32]. The degree of ACE2 expression in hepatocytes is regulated by multiple factors. Histological studies in mice and humans identified greater ACE2 expression in subjects with cirrhosis [33]. The degree of hypoxia is also shown to correlate with ACE2 expression in hepatocytes, and notably the affinity of S protein towards the ACE2 receptor is increased with hypoxia due to trypsin activation, trypsin being a protein commonly expressed in liver epithelial cells[34,35]. These findings may explain why the effects of COVID-19 infection would tend to be more severe in patients living with underlying CLD and other hypoxic conditions.

Systemic inflammatory cytokine storms in COVID-19 induced liver injury

Another purported pathway of COVID-19 induced liver injury is an excessive immune response triggered by the virus causing a systemic inflammatory cytokine storm[36]. During a systemic inflammatory cytokine storm stimulated by COVID-19 induced liver injury, complement and interleukin-23 (IL-23) are released into the bloodstream, activating kupffer cells and inducing their production of tumor necrosis factor α (TNF-α)[37,38]. As an inflammatory cytokine, TNF-α aggravates the responses of inflammation by upregulating the expression of endothelial cell adhesion molecules and inducing hepatocytes to secrete chemokines[39]. Under the induction of chemokines, $CD4^+$ T cells and neutrophils are rapidly recruited to the liver, in which $CD4^+$ T cells assist mucosal molecules to promote neutrophil entry into the liver parenchyma[40,41]. Neutrophils directly damage hepatocytes by releasing oxidants and proteases, resulting in cell necrosis[41]. In patients who are severely affected or critically ill following COVID-19 infection, much higher plasma levels of inflammatory cytokines and lower lymphocyte counts were observed[42]. Previous studies note that an increase in IL-6 and IL-10 and a decrease in $CD4^+$ T cells were independent risk factors related to severe liver damage, and lymphopenia and C-reactive protein levels were found to be independently associated with the degree of liver injury [43].

The inflammatory storm response from COVID-19 infection is usually mild in the early stages of COVID-19 infection, but patients may clinically deteriorate rapidly if appropriate management of COVID-19 is not administered in a timely manner, with the inflammatory storm response occurring more strongly during the post-viral inflammatory phase[6]. For patients living with decompensated CLD complications, notably ascites, their threshold to develop systemic inflammatory storm responses following COVID-19 infection would even be lower than those without CLD due to underlying pro-inflammatory risks with SBP[44,45].

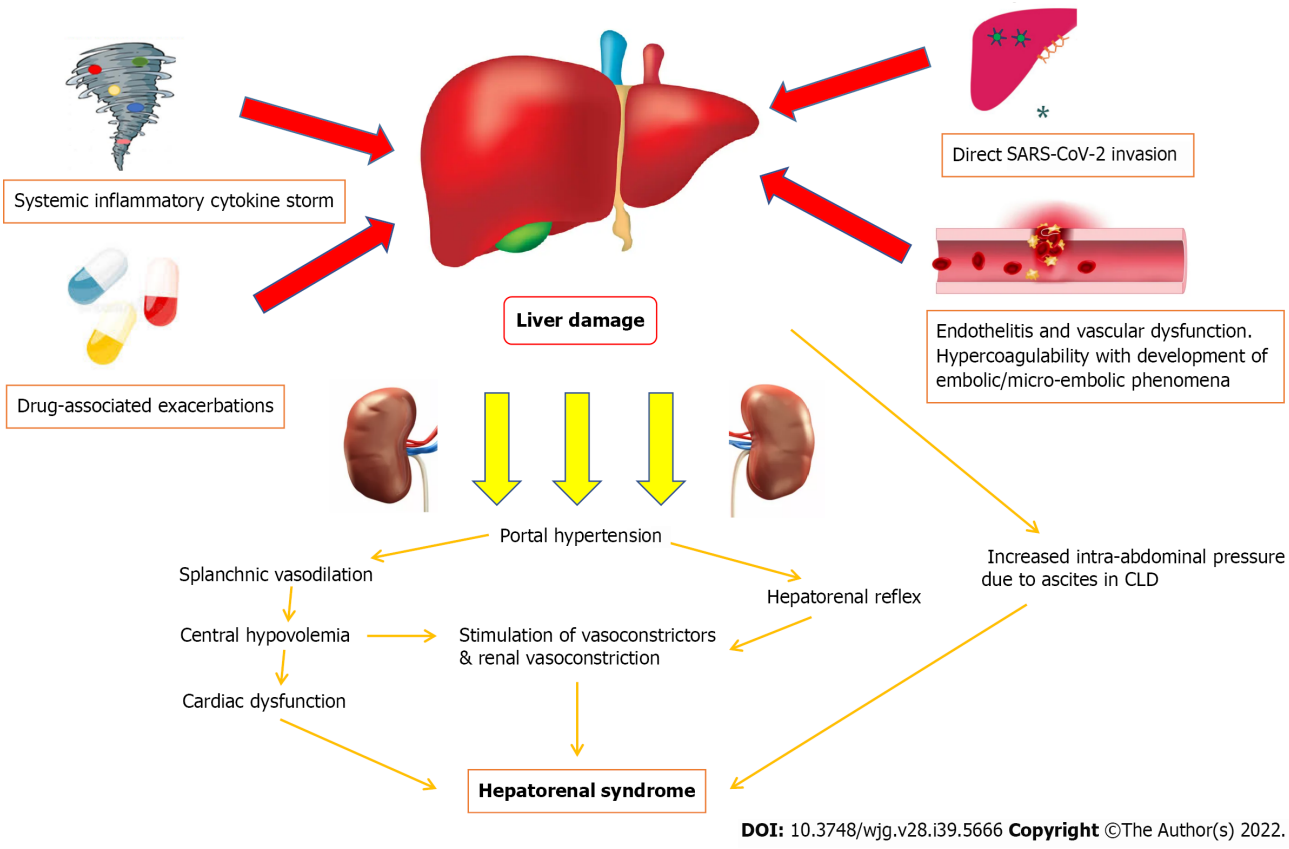

Figure 1 Potential pathophysiological mechanisms of COVID-19 induced hepatorenal syndrome. SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2.

Endothelitis and vascular dysfunction in COVID-19 induced liver injury

The impact of COVID-19 towards thrombo-inflammation in endothelial tissues is significant. The ACE2 protein, which is present in many organs across the body, facilitates SARS-CoV-2 entry into endothelial cells *via* endocytosis with its binding to the ACE2 protein[46]. Viral infection and immune-mediated inflammatory responses occur within endothelial cells, leading to vascular dysfunction, especially in capillaries[47-49]. Subsequently, vascular dysfunction progresses to a hypercoagulable state and the development of embolic/micro-embolic phenomena, tissue edema, and organ ischemia[47-49]. In the liver, ischemia reperfusion injury which occurs typically after rapid recovery of blood circulation following events of vascular dysfunction leading to ischemia, has been touted as an underlying pathophysiological mechanism of COVID-19 induced liver injury[48,49]. Reperfusion following ischemia activates neutrophils, kupffer cells, and platelets within the cellular surroundings, leading to a series of destructive cellular reactions such as reactive oxygen species and calcium overload, which manifests towards widespread inflammatory response and cell damage[48,49]. Eventually, increased anaerobic glycolysis leads to reduced adenosine triphosphate production, which ultimately results in hepatocyte cell death from inhibition of hepatocyte signal transduction[42,48,49].

Drug-associated exacerbations in COVID-19 induced liver injury

In addition to the direct viral and systemic inflammatory mechanisms of liver injury following COVID-19 infection, the impact of various drugs received during acute hospitalization in patients with COVID-19 associated liver injury has been discussed. There has been debate whether these drugs (drugs trialed/used for COVID-19 treatment-antivirals such as Lopinavir/Ritonavir, Remdesivir, Favipiravir, Arbidol, Oseltamivir and others; antibiotics such as Doxycycline and Azithromycin; chloroquines; steroids; non-steroidal anti-inflammatory drugs) play a greater pathophysiological role in causing liver injury compared to COVID-19 infection itself[50].

Several studies have evaluated antivirals targeting COVID-19 infection in the midst of liver injury. For example, Lopinavir is a protease inhibitor conventionally used to treat human immunodeficiency virus infection in combination with a low dose of Ritonavir, another protease inhibitor, which enhances its biological half-life[51]. If high doses of Ritonavir (> 1 g daily) are taken, severe hepatotoxicity may ensue[52]. Recent studies show that Lopinavir/Ritonavir, when prescribed with or without ribavirin, interferon beta, and/or corticosteroids, was independently associated with increased levels of serum alanine transaminase (ALT) and aspartate transaminase (AST) in patients with positive COVID-19

status[53]. It was demonstrated from a retrospective observational study by Jiang and colleagues that Lopinavir/Ritonavir use in COVID-19 patients is associated with liver injury and abnormal liver function, particularly for patients in a non-critical state[54]. Ultimately, considering the fact that there is yet to be a completely effective antiviral therapy for COVID-19 and that antiviral drugs may cause abnormal liver function, there should be careful consideration of whether to prescribe antivirals, in particular for patients with CLD and/or metabolic diseases[52].

Antibiotics, particularly those of tetracycline-class and Azithromycin, have been shown to exacerbate liver damage in the context of COVID-19 induced liver injury[55]. For example, Doxycycline chelates zinc, which is required by the matrix metalloproteinases involved in COVID-19 infection, and inhibits SARS-CoV-2 RNA polymerase activity and direct viral entry[56,57]. Whilst generally safe to use with its anti-inflammatory effects, Doxycycline use may contribute towards hepatotoxicity and has been linked to occasional bile duct injuries[55]. There should be caution when prescribing Doxycycline alongside other potential hepatotoxic drugs, given reports of fulminant liver failure and hepatocellular necrosis occurring following the prescription of Doxycycline in these scenarios[55].

At a molecular level, there has been focused discussion on cytochrome P450 (CYP450) in the context of drug-associated exacerbations in COVID-19 induced liver injury. CYP450 is a superfamily of monooxygenase enzymes that mediate drug interactions during various pathological conditions[58]. It is presumed the metabolic activity of CYP450 would be altered by the effects of acute COVID-19 infection[57]. Liver injury in the context of COVID-19 infection complicates our understanding of how and to what extent CYP450 would be affected, and further work is needed in this area. Nevertheless, it is suggested that there would be clearance-associated pharmacokinetic interactions with antivirals and other drugs that are administered in this situation[57-61]. Common drugs affected by alterations in the CYP450 pathway could include Remdesivir, which is extensively metabolized by CYP450s, particularly CYP3A4, as well as Chloroquine and Colchicine which are both included in clinical trials researching COVID-19 treatment regimes[57-61].

Pathogenesis of HRS in COVID-19 induced liver injury

The multifactorial components of COVID-19 induced liver injury leads to the development of splanchnic vasodilation, with or without portal hypertension[62]. Splanchnic vasodilation is recognized as one of the major causative factors of HRS and occurs as the result of a plethora of vasodilatory responses[63]. With increased severities of hepatic damage, there is increased production of nitrous oxide in the splanchnic bed with reduced production in liver sinusoidal cells, which lead to increased portal gradient pressures[64]. Greater levels of other vasodilating peptides such as calcitonin gene-related peptide and adrenomedullin are also observed, as a result of increased production and reduced hepatic clearance[65].

Splanchnic vasodilation creates a state of hypovolemia in the central circulation, as splanchnic vasodilation combined with restricted portal blood flow causes blood to pool in the splanchnic circulation[66,67]. The body's physiological response to central hypovolemia will eventually lead to dysregulation of blood pressure, due to abnormalities in the baroreflex and cardiovascular responses to angiotensin II, norepinephrine, and vasopressin[68]. Central circulatory dysfunction can cause cardiomyopathy affecting both systolic and diastolic heart function. There will be electrophysiological alterations, which includes QT interval prolongation and electromechanical dyssynchrony[63,64]. The ability of the heart to respond to inotropic and chronotropic stimuli is reduced. Because of decreased systemic vascular resistance, cardiac output (in absolute terms) would be maintained at a high level initially[63,64]. However, the impaired cardiac function due to the aforementioned cardiac physiological changes will become clinically apparent with normalization of systemic vascular resistance and when there are further stress stimuluses[62-64].

Ultimately, renal perfusion pressure and blood flow to the kidneys will be reduced as a result of the various mechanisms which cause central circulatory dysfunction[68,69]. Overactivation of the sympathetic system as a homeostatic response could initially increase the kidney's reliance on blood pressure levels to maintain its perfusion[68]. Reduced blood flow to the kidneys would lead to more active stimulation of both β-adrenergic and subsequently α-adrenergic receptors, which results in afferent and efferent arteriole constriction[69]. The pathophysiological process of kidney damage is exacerbated by an inability of the liver in HRS to degrade renin, which will lead to persistent stimulation of the renin-angiotensin-aldosterone axis[70].

There are other theories of how HRS may manifest following severe liver injury from COVID-19 infection. One relates to the impact of reduced hepatic blood flow to kidneys *via* the hepatorenal reflex and exacerbated further by cytokine-induced vasoconstriction, which alters kidney hemodynamics[62,71]. Animal studies have highlighted that an acute increase in portal vein pressure results in increased renal nerve activity, although this phenomenon does not occur when the liver is denervated[71]. In studies assessing empirical treatment of HRS, a lumbar sympathetic block has been shown to improve kidney function [sodium excretion, blood flow and estimated glomerular filtration rate (eGFR) were shown to be improved][72]. This may explain why medical procedures such as transjugular intrahepatic portosystemic shunt (TIPS) improve HRS in many patients *via* reduction of portal pressure gradients. Another theory explaining the development of HRS in this context may relate to the direct effects of intra-abdominal ascitic pressure, in patients with underlying decompensated CLD where the ascites

may be exacerbated following COVID-19 infection[73]. Increased intra-abdominal ascitic pressure can lead to venous congestion and stimulation of the renin-angiotensin-aldosterone system, resulting in further kidney function decline and histopathological changes[73].

CLINICAL ASSESSMENT AND MANAGEMENT STRATEGIES IN COVID-19 INDUCED HRS

Key components of clinical assessment and management in COVID-19 induced HRS are summarized in Table 1. Clinical assessment of patients presenting with COVID-19 induced HRS should encompass a holistic understanding of an individual's medical history. This should be followed by physical examination to elicit specific signs, before urine, serum and imaging investigations are conducted, with these investigations forming the crux of the diagnostic criteria. Management strategies in this scenario should focus on achieving spontaneous recovery of liver function and resolution of HRS *via* medical management and only if this fails, then to consider the potential for liver transplantation.

Clinical assessment of COVID-19 induced HRS

Our current understanding of the typical signs and symptoms which appear with COVID-19 induced liver injury and HRS remains premature, and there are likely non-specific presentations in most instances. It is reasonable to suggest patients who develop acute liver injury following a positive COVID-19 diagnosis would likely have a COVID-19 infection severe enough to present as such[74]. From a thoroughly taken medical history, clinicians should aim to determine the likely course of COVID-19 infection and rule out other differentials more likely to explain the development of acute liver injury/fulminant liver failure[57]. There should be close observation for systemic (*i.e.*, septic symptoms, monitor hemodynamic stability as likely to have low mean arterial pressure) as well as respiratory-specific signs and symptoms[57]. It has been reported from prospective studies conducted in China that risks of severe liver injury is greater in patients who develop gastrointestinal symptoms such as diarrhea, nausea and vomiting, anorexia and abdominal pain (OR 2.71, 95%CI 1.52-4.83, $P < 0.05$) following acute COVID-19 infection[75]. Given patients with underlying CLD such as cirrhosis are more likely to develop HRS regardless of COVID-19 status, classical features of CLD/decompensated liver disease including jaundice, altered mental status, malnutrition, and ascites (ascites resistant to the use of diuretic medications is characteristic of type 2 HRS) should be meticulously monitored[76]. Whilst there is relative clarity regarding hepatic signs and symptoms in HRS, the same cannot be said for renal-specific signs and symptoms. Both oliguria and normal levels of urine output have been observed for patients diagnosed with HRS[62]. Due to inability in establishing definitive renal symptoms in HRS, there is wide opinion that HRS should be diagnosed mainly on the basis of laboratory results rather than symptomatic presentation.

The utilization of diagnostic tests should initially confirm COVID-19 status *via* a real-time reverse-transcriptase-polymerase chain reaction (rRT-PCR) test and determine the severity of disease through chest imaging (*i.e.*, chest X-ray or computed tomography)[77]. Serum tests evaluating the systemic inflammatory state (*i.e.*, full blood cell count, C-reactive protein, interleukin-6 Levels) should follow alongside tests to identify the presence of liver pathology, typically indicated by the rise in serum ALT, AST, total bilirubin, gamma-glutamyl transferase (GGT), alkaline phosphatase (ALP) levels and reduction in serum albumin[78]. Recent observational data reported the pooled prevalence of the elevated liver enzymes ALT, AST, and total bilirubin in COVID-19 positive patients to be 18% (95%CI 13%-25%), 21% (95%CI 14%-29%), and 6%(95%CI 3%-11%), respectively[79]. These serum tests may prove to be a strong marker of poor prognosis, as a fatal outcome with COVID-19 induced liver disease is estimated to be between 58% and 78%[80]. The presence of hypoalbuminemia also signifies a more severe disease process with poorer prognosis[81,82]. Liver ultrasound could also be a useful front-line diagnostic imaging tool to detect the presence of any acutely developed liver lesions.

Investigations to ascertain kidney function in confirming a HRS diagnosis should encompass urinalysis, a serum urea & electrolytes screen and other renal panel testing to rule out differential diagnoses[83-86]. Important results to look out for in urinalysis is concentrated urine with low urine sodium (< 10 mmol/L) where there is usually no proteinuria or hematuria[85,86]. There would be absence or few granular (hyaline or muddy-brown) casts identified in urine microscopy, in contrast to acute tubular necrosis (ATN) which is a known renal complication of cirrhosis[84]. ATN in the context of liver injury most likely occurs as a result of exposure to toxic medications or the development of decreased blood pressure, and proximal tubular cells are unable to reabsorb sodium from urine[62,84,85]. Because of this, urinary sodium levels in ATN would be expected to be higher than that of HRS[84]. It is expected that there is marked reduction in eGFR with HRS, with no improvements in kidney function despite treatment with intravenous fluids (kidney function improvements are observed in most other causes of pre-renal kidney failure following intravenous fluid administration with reduction in serum creatinine and increased sodium excretion) due to the intra-renal vasoconstricted state[87]. Serum sodium concentration would be low due to retention of fluid together with sodium leading to dilutional hyponaetremia[88]. Plasma renin activity would be elevated considering the metabolic changes in HRS [89]. Kidney ultrasound would rule out obstruction of the kidney outflow tract.

Table 1 Key components of clinical assessment and management in COVID-19 induced hepatorenal syndrome

Clinical Assessment of HRS	Management of HRS
Medical history: (1) Identify likely course of disease progression; and (2) rule out other causes of acute liver injury/fulminant liver failure	Minimize potential drug-induced hepato- and nephron-toxicities: (1) Monitor response to immunosuppressive treatments; (2) monitor response to antivirals and other COVID-19 treatment regimes; and (3) aim to prescribe these medications through a dose-dependent approach
Clinical examination: (1) Identify signs of systemic and/or respiratory decompensation; (2) identify evidence of cirrhosis/decompensated liver disease; and (3) monitor for oliguria	Medical management strategies in COVID-19 induced HRS: (1) Extracorporeal membrane support therapy & dialysis; (2) potential utilization of MARS or other liver support devices; (3) TIPSS to reduce portal vein pressure (if renal function allows and known CLD); (4) adding intravenous albumin to other procedural/medical therapies to expand plasma volume; and (5) combined use of Midodrine (α-agonist) and Octreotide (somatostatin analogue) to regulate blood vessel tone in the gastrointestinal tract and act as systemic vasoconstrictors to inhibit splanchnic vasodilation. Terlipressin may be used as an alternative
Laboratory and imaging tests: (1) Confirm positive COVID-19 status; (2) assess systemic hemodynamic stability through basic observations; (3) chest imaging to assess degree of COVID-19 severity for the respiratory system; (4) serum tests to evaluate the degree of inflammation; (5) liver pathology could be evaluated *via* serum markers (*e.g.*, increased ALT, AST, total bilirubin, GGT and ALP, reduction in albumin) and liver ultrasound; (6) urinalysis to identify low urine sodium *i.e.*, < 10 mmol/L, proteinuria, hematuria and urinary casts seen in ATN; (7) serum eGFR reductions, low serum sodium (dilutional hyponatremia) and elevated plasma renin would be classically observed in HRS; and (8) kidney ultrasound should be performed to rule out obstruction of the kidney outflow tract	Consider liver transplantation if kidney function and hepatic recovery is unlikely with medical management

AKI: Acute kidney injury; ALP: Alkaline phosphatase; ALT: Alanine transaminase; AST: Aspartate transaminase; ATN: Acute tubular necrosis; COVID-19: Coronavirus disease 2019; eGFR: Estimated glomerular filtration rate; GGT: Gamma-glutamyl transferase; HRS: Hepatorenal syndrome; MARS: Molecular adsorbents recirculation systems; TIPS: Transjugular intrahepatic portosystemic shunt.

Management strategies in COVID-19 induced HRS

The mainstay of treatment in HRS from either acute liver failure or cirrhosis, whether the cause is COVID-19 related or not, is usually medical management to aim for gradual liver recovery and resolution of HRS, with supportive dialysis or haemofiltration if required. Liver transplantation would not be indicated if recovery of liver function and resolution of HRS is achieved solely through medical management, with this usually resulting in the best outcome for patients. A key priority is to limit drug-induced hepato- and nephrotoxicity through a dose-dependent adjustment approach of managing immunosuppressive medications, antivirals and other COVID-19 treatment regimes if and when COVID-19 treatment is indicated[57].

The combination of extracorporeal membrane support and dialysis in HRS demonstrated significant effects in removing toxins from the circulation, including systemic inflammatory molecules generated from COVID-19 infection[83,90-92]. There has been greater use of molecular adsorbents recirculation systems in HRS as both a supportive treatment option or as a bridging therapy to liver transplantation if indicated, though wider work is needed to improve accessibility with this technology still being relatively novel[93]. Close haemodynamic monitoring during hemodialysis is recommended, given concerns that this may further deteriorate blood pressure stability in HRS, increasing the risk of mortality[94]. TIPS involves decompressing the high pressures in the portal circulation by placing a small stent between a portal and hepatic vein, *via* placement of a radiologically-guided catheter passed into the hepatic vein either through the internal jugular vein or the femoral vein[95]. This will theoretically reduce portal vein pressure, which as discussed in the previous section is a key factor in the hemodynamic process leading up to HRS[17,18,62,95]. Previous studies in patients with cirrhosis largely noted improvements in kidney function when TIPS is performed, particularly as a bridging treatment if liver transplantation might be indicated[96].

Intravenous albumin can expand plasma volume, and provide other benefits in the form of its immunological, antioxidant, endothelial protective functions. Combining intravenous albumin with other medical and/or procedural treatments displayed better outcomes compared to administering intravenous albumin alone[97]. Other pharmacological options which have demonstrated efficacy across all forms of HRS may include the combined use of Midodrine, an α agonist with somatostatin analogues such as Octreotide[98,99]. In Europe, Terlispressin and albumin are recommended in the best practice guidelines[100]. These drugs regulate blood vessel tone in the gastrointestinal tract, and also systemic vasoconstrictors which inhibit splanchnic vasodilation[97]. Interestingly, these drugs were only found to be effective when used in combination and not when independently prescribed[100]. There is preliminary data that other vasopressin analogues (*e.g.*, Ornipressin), Pentoxifylline, Acetylcysteine and Misoprostol amongst other treatments are potentially useful treatments in HRS, but this will require

further study[101-103].

Liver transplantation would be the ideal treatment in HRS, if renal function cannot be corrected with medical management and hepatic recovery is unlikely with conservative management alone. These situations mostly occur in patients with CLD, where the medical management options aforementioned serve as bridging therapies towards transplantation[17,18,20,62]. The optimal strategy would usually observe effects from treatment of the underlying cause of HRS first before planning for liver transplantation. During the COVID-19 pandemic, most hepatology societies advised the deferral of liver transplantation in stabilized patients[104]. There has been continuous debate throughout the pandemic on how to optimize the procedures of liver transplantation for patients with COVID-19 positive status, such as those with active COVID-19 infection inducing HRS[105]. Currently, there is only one reported case of liver transplantation in HRS with COVID-19 infection, performed 28 d after hospital admission [23]. Individuals with HRS who receive liver transplantation almost universally achieve recovery in kidney function[91]. Previous studies have demonstrated that survival rates at 3-year follow-up for liver transplant recipients in HRS are comparable to liver transplant recipients for other causes of liver disease[106]. Although differences in long-term outcomes are significant between patients who receive liver transplantation and those who do not, acute mortality rates after liver transplantation were found to be up to 25% in the first month[107]. Patients who present with further decline in liver and kidney function following liver transplantation are at higher risk[17]. Kidney function decline following liver transplantation in HRS is usually transient and most likely attributed to drug-induced nephrotoxicity, specifically the introduction of immunosuppressants such as Tacrolimus and Cyclosporine which are known to affect kidney function[17,105].

CONCLUSION

There is increased attention towards the extra-respiratory manifestations of COVID-19 as the pandemic continues to affect billions of lives. Hepatic consequences of COVID-19 infection are now recognized as an important complication of COVID-19. The development of HRS following COVID-19 induced liver injury suggests severe and perhaps life-threatening disease, particularly for individuals with multi-morbidities including pre-existing CLD. The prognosis of HRS is largely dependent on whether liver transplantation would be viable and accessible for the patient. Confounding effects of drug-induced hepato- and nephrotoxicity in exacerbating the systemic damage from COVID-19 induced HRS should always be considered and avoided if possible. A greater understanding of the multi-faceted pathophysiological mechanisms which result in HRS following acute COVID-19 infection is important to guide clinical decisions in a timely manner for the optimization of patient outcomes.

Abstract

Compelling evidence derived from clinical and experimental research has demonstrated the crucial contribution of chronic inflammation in the development of neoplasms, including gallbladder cancer. In this regard, data derived from clinical and experimental studies have demonstrated that the receptor of advanced glycation end-products (RAGE)/AGEs axis plays an important role in the onset of a crucial and long-lasting inflammatory milieu, thus supporting tumor growth and development. AGEs are formed in biological systems or foods, and food-derived AGEs, also known as dietary AGEs are known to contribute to the systemic pool of AGEs. Once they bind to RAGE, the activation of multiple and crucial signaling pathways are triggered, thus favoring the secretion of several proinflammatory cytokines also involved in the promotion of gallbladder cancer invasion and migration. In the present review, we aimed to highlight the relevance of the association between high dietary AGEs intakes and high risk for gallbladder cancer, and emerging data supporting that dietary intervention to reduce gallbladder cancer risk is a very attractive approach that deserves much more research efforts.

Key Words: Gallbladder cancer; Advanced glycation end-products; Receptor of advanced glycation end-products; Chronic inflammation; Nutrition

Core tip: A growing body of data has demonstrated a positive association between the risk of gallbladder cancer and high dietary intake of advanced glycation end-products (AGEs). These noxious compounds are important contributors to the onset of a chronic inflammatory response, through the activation of the receptor of AGEs (RAGE). We herein discuss how RAGE activation is crucial in the development of gallbladder cancer and the relevance of new incoming data supporting the role of dietary interventions to reduce the risk of gallbladder cancer.

INTRODUCTION

Gallbladder cancer development is linked to both genetic and environmental factors, and where the onset of chronic inflammation is a crucial contributor to gallbladder carcinogenesis. This chronic inflammatory condition can be triggered by several factors including not only chronic infection by *Salmonella* spp., or *Helicobacter pylori*[1-4] but also some dietary habits or metabolic conditions[5-9], which are associated with an overactivation of the receptor of advanced glycation end-products (RAGE).

At present, the onset of many of both age- and diet-related noncommunicable diseases, including different cancer types, is widely associated with the chronicity of low-grade inflammation[10,11]. At this point, the diet is widely recognized as an important modulator of this chronic and systemic inflammation[12,13], particularly the western-type dietary patterns[14].

One common and important element in this unhealthy diet is the advanced glycation end-products (AGEs), which are a large and heterogeneous group of compounds that were initially recognized in the Maillard reaction, but they can also form by other reactions, including the oxidation of sugars, lipids, and amino acids[15,16].

Food-derived AGEs, also known as dietary AGEs, substantially contribute to the systemic pool of AGEs. Their intake has been linked in humans and mice to an increased level of oxidative stress and inflammation, thus playing an important role in the onset and development of several health disorders [17,18].

The pathogenic mechanisms of dietary AGEs are the same as those endogenously produced, either by activation of the RAGE or by covalent crosslinking of proteins, thus altering protein structure and function. The receptor-dependent and receptor-independent mechanisms are recognized as important contributors to tumor growth and development[19,20].

In the present review, we aim to highlight the burden of RAGE axis activation on gallbladder cancer, its therapeutic potential, as well as the significance of lowering dietary consumption of AGEs in subjects at risk.

THE RAGE/AGEs AXIS AND GALLBLADDER CANCER: NEW INCOMING PIECES OF EVIDENCE

There is growing evidence supporting the key role of dietary AGEs as major contributors to the systemic pool of AGEs[21], which notably increase oxidative stress and chronic/acute inflammation, contributing to the pathophysiology of many human inflammatory and malignant diseases[18,22,23].

Since the multicenter prospective European Prospective Investigation into Cancer and Nutrition (EPIC) cohort study, which investigated the relationship of dietary and environmental factors with the incidence of cancer and other chronic diseases[24-27], a growing body of evidence has revealed strong findings to support that a proinflammatory diet with high levels of dietary AGEs intake increases the risk of several types of cancer[28], such as breast, skin and those originating from the digestive tract[29-31].

Recently, Mayén *et al*[32] conducted a multinational cohort study using the EPIC database to characterize the daily dietary intake (mg/d) of three AGEs including Nε-[carboxymethyl] lysine (CML), Nε-[1-carboxyethyl] lysine (CEL), and Nδ-[5-hydro-5-methyl-4-imidazolon-2-yl]-ornithine (MG-H1) for each study participant, to assess AGE consumption with hepatobiliary cancer risk. In this study, the authors found a positive association between the risk of gallbladder cancer and high dietary intake of CML [hazard ratio (HR) = 1.30, 95% confidence interval (CI): 1.07–1.57] and MG-H1 (HR = 1.26, 95%CI: 1.06–1.50), and thus suggesting that higher intakes of dietary AGEs may increase the risk of gallbladder

cancer.

Although the study of Mayen *et al*[32] has some limitations, particularly in estimating dietary AGEs exposure, other epidemiological studies have revealed an increased tumor progression and mortality of gallbladder cancer patients, with inflammatory comorbidities related to overactivation of the RAGE axis, such as high-fat diet consumption[33], metabolic syndrome[34], and diabetes mellitus [35-38], due to the increased endogenous formation of AGEs reported in these entities.

Some studies have shown increased expression of RAGE in gallbladder cancer cells, which were directly in concordance with the invasive ability of the neoplastic cell lines[39]. Additionally, compelling evidence has been reported of a strong increase in AGEs formation under hyperglycemic conditions[40, 41]. Noteworthy, the gallbladder accumulation of AGEs is significantly higher in the gallbladder of diabetic mice when compared to control animals. These findings support the role of the RAGE/AGEs axis activation in gallbladder carcinogenesis[42].

Furthermore, other *in vivo* analyses of adenocarcinoma cells treated under a hyperglycemic milieu, a condition favoring the increased accumulation of AGEs, have been revealed to promote tumor cell proliferation and migration[43].

Emerging *in vitro* and *in vivo* analyses have revealed overexpression of several RAGE ligands such as high mobility group B1 (HMGB1) and members of the S100P protein family in malignant gallbladder epithelial cells compared to benign tissue[44,45].

This increased expression of those RAGE ligands in gallbladder cancer cells has been closely correlated with malignant progression and therefore may then be considered an independent risk factor for poor prognosis and proliferation in gallbladder cancer[45-47].

A key consequence of RAGE binding with its ligands is the activation of multiple and crucial signaling pathways[48], that are involved in gallbladder carcinogenesis, such as reactive oxygen species (ROS)[49], Erk1/2 (p44/42) mitogen-activated protein kinases (MAPKs)[50], C-Jun n-terminal kinase and p38 MAPK[51], and phosphatidylinositol 3-kinase pathways[52].

These signals trigger important downstream inflammatory and procarcinogenic consequences such as activation of signal transducer and activator of transcription 3[53,54], activator protein-1[55], and nuclear factor (NF)-κB pathways[49,54,56-58], favoring the secretion of several proinflammatory cytokines also involved in the promotion of gallbladder cancer invasion and migration such as tumor necrosis factor-α[59,60]. Hence, this proinflammatory milieu continuously fuels chronic inflammation in gallbladder carcinogenesis in a RAGE-dependent manner[19,61].

THERAPEUTIC POTENTIAL OF THE RAGE/AGEs AXIS IN TUMOR BIOLOGY

RAGE is recognized as a pattern recognition receptor, and its activation plays a pivotal role in the propagation of immune responses and inflammatory reactions[62]. It is expressed at low levels in most differentiated adult cells in a regulated manner. However, upregulation of RAGE expression is associated with many inflammation-related pathological entities, including cancer[63].

RAGE engagement subsequently converts transient cellular stimulation into a sustained cellular dysfunctional state driven by long-term activation of NF-κB[64]. There is compelling evidence that RAGE activation promotes many crucial steps during tumorigenesis, from DNA damage and genetic instability to supporting many phenotypic changes in tumor cells favoring their growth and dissemination[65].

Since the work by Taguchi *et al*[66], which experimentally reported that *in vivo* blockade of the RAGE–amphotericin axis suppresses tumor growth and dissemination, intense research efforts have been focused towards the development of new therapeutic approaches to modulate both deleterious proinflammatory and procarcinogenesis effects of RAGE axis activation[67,68].

The use of novel RAGE-targeting antibodies and blocking peptides derived from RAGE ligands such as S100P and HMGB1 has demonstrated to block the ability of ligands to stimulate RAGE activation in cancer cells both *in vitro* and *in vivo* models, thus inhibiting tumor growth, metastasis, and inflammation [69], as well as significant reductions in tumor growth with acceptable toxicity levels in several *in vivo* mouse adenocarcinoma models[70,71]. Furthermore, the treatment of cancer cell lines with anti-RAGE antibodies demonstrates that RAGE blocking may even enhance the chemotherapeutic effects of antineoplastic drugs[72,73].

Recent evidence has also revealed that the antibody targeting of RAGE ligands such as HMGB1 and AGEs may effectively decrease tumor progression in solid malignancies[74]. This approach can even enhance the antitumoral response of cancer immunotherapies by remobilizing the antitumor immune response[75].

Another emerging therapeutic approach is based on the high binding affinity to RAGE of some members of the family of glycosaminoglycans such as chondroitin sulfate, heparan sulfate (HS), and low molecular weight and semisynthetic glycosaminoglycan[76]. These molecules have been reported to be involved in effectively inhibiting RAGE signaling pathways in *both in vitro* and *in vivo* models[71,77].

Strikingly, new evidence has revealed that HS acts as a crucial element for RAGE signaling, leading to the formation of stable RAGE–HS complexes, which drive the RAGE oligomerization and subsequent

downstream functional signaling[78,79].

These observations have revealed a new strategy for treating RAGE-associated diseases by hindering RAGE oligomerization.

The use of synthetic compounds with both anticarcinogenic and anti-inflammatory activities based on their capacities to interfere with the HMGB1–RAGE axis seems to be a promising strategy for several cancer types, including gallbladder cancer[80,81].

A novel molecule, recently discovered by Tanuma *et al*[82], 7-methoxy-3-hydroxy-styrylchromone (c6), is not only an effective suppressor of cell cycle/proliferation but also an initiator of apoptosis in cancer cells, and a promising potentiator of the anticancer effects of DNA-damaging antineoplastic agents.

RAGE gene silencing has been demonstrated to significantly downregulate AGE-induced inflammation and RAGE-dependent release of proinflammatory cytokines in normal human cells[83], while in malignant cells, *RAGE* gene silencing can decrease the colony-forming ability, proliferation, migration, and the invasive potential of cancer cells, through inhibiting RAGE-dependent mechanisms that sustain cancer cell progression and invasion[84].

The requirement of the cytoplasmic tail of RAGE to interact with its molecular effector DIAPH1 to mediate downstream signal transduction has been highlighted as a promising approach to inhibit RAGE signaling[85-87].

This novel screening strategy of searching for molecules able to block protein–protein interactions has been demonstrated to be successful to inhibit the RAGE-mediated expression of inflammatory genes in diabetes complications[88,89] and atherosclerosis[90].

A growing body of experimental data using the DNA-aptamer technology against RAGE has demonstrated that this novel approach can inhibit the inflammatory reactions triggered by activation of the RAGE axis in different *in vivo* models[91-93].

Experimental research has reported interesting results in different cancer types, as revealed in tumor-bearing mice treated with RAGE-aptamers, where marked inhibition of tumor growth was achieved [94]. The use of this technology on tumor-bearing mice is also able to inhibit macrophage infiltration and neoangiogenesis through the inhibition of RAGE/NF-κB/VEGF-A-dependent signaling pathways [94-96] (Figure 1).

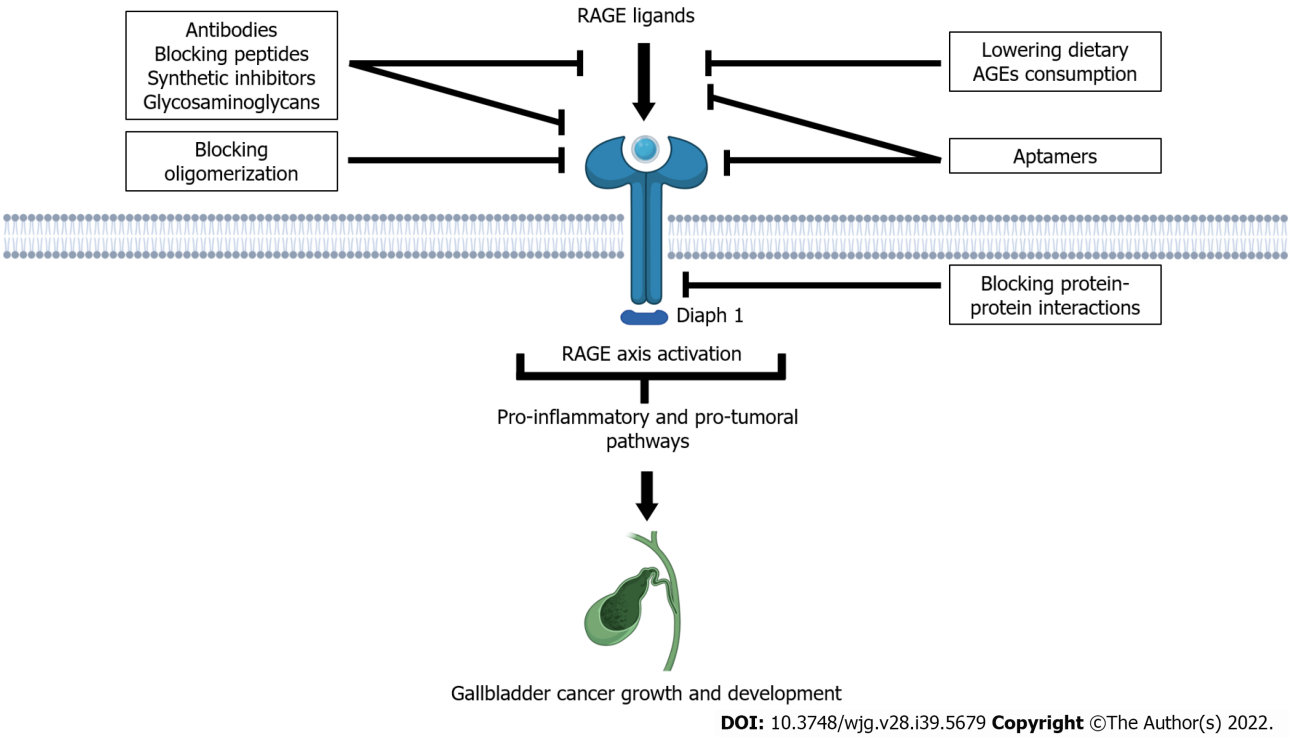
In many clinical entities where the activation of the RAGE/AGEs axis is crucial in the underlying pathogenic mechanisms, restriction of dietary AGEs has been extensively studied in clinical trials[97-101]. Under the same rationale, and based on the active role of RAGE-mediated mechanisms in tumor biology, different interventional clinical studies already published[102-107] (Table 1), or in progress, have supported the use of restriction of AGEs intake in human cancers, as documented on the website ClinicalTrials.gov (ClinicalTrials.gov identifier: NCT03712371, NCT04716764, NCT02946996, NCT03092635, NCT01820299, NCT01363141, NCT03147339). However, it must be emphasized that therapeutic interventions, including dietary interventional actions on the RAGE axis, have been focused on achieving clinical improvements in disease course, including dietary interventional actions, and therefore the potential of modulating RAGE activation in terms of cancer prevention is still controversial.

REDUCING DIETARY AGEs INTAKE IN SUBJECTS AT RISK OF GALLBLADDER CANCER. A HOPEFUL APPROACH?

International consensus estimates that almost 40% of cancer cases are preventable through a healthy lifestyle[108]. Compelling evidence derived from epidemiological studies of different cancer types suggests that lifestyle changes, including dietary habits, may play a crucial role in determining the risk of various cancers[109-113].

Currently, the western diet is considered a major driver of chronic, low-grade, metabolic inflammation, which is a crosswise element in the pathogenesis of many human diseases, including cancer [114]. Data derived from preclinical investigations, and observational and interventional studies, has provided conclusive evidence that the western diet is associated with an increased incidence of many malignancies, such as colorectal, pancreatic, prostate and breast cancers[115-118].

In modern society, dietary AGE consumption – as a component of modern westernized diets – is markedly increased. Therefore, dietary AGE restriction is now recognized as a useful intervention, as demonstrated in several pathologies[119-123].



Western diet generally contains large amounts of fructose, thus promoting AGE formation[124]. This diet is also an important source of AGE precursors, such as methylglyoxal and glyoxal[125]. In light of these findings, dietary AGEs have gained particular importance due to their capacity to support the onset of many human diseases, including cancer, mainly due to their proinflammatory and pro-oxidant properties[17,18].

The role of RAGE/AGEs axis activation has emerged as a crucial element in the tumor microenvironment to promote cancer cell migration, invasion, survival, and even resistance to chemotherapy[19]. Additionally, the accumulation of AGEs in tissues can promote protein structural damage and

modification of the mechanical and physiological functions of the extracellular matrix, thus contributing to carcinogenesis and inflammation[20].

Therefore, the report recently published by Mayén *et al*[32] showed a positive association between dietary AGEs and the risk of gallbladder cancer in the EPIC cohort, which deserves special attention. We believe that actions such as dietary recommendations for the reduction of dietary AGEs intake to individuals at risk of gallbladder cancer will be beneficial. In this regard, it is important to highlight that some pre-existing clinical conditions such as diabetes mellitus and metabolic syndrome are risk factors for the development of gallbladder cancer[34,35-38]. Additionally, the demonstrated links between genetic ancestry and gallbladder cancer development may represent another risk factor for some populations[126,127]. Other recommendations that focus on reducing the RAGE/AGEs axis activation are attractive, particularly the consumption of polyphenol-rich foods due to the inhibitory activities of polyphenols on the RAGE/AGEs axis at different levels, such as by inhibition of ROS formation during glycation reactions, chelation of transition metal ions, trapping dicarbonyls, and activation of AGE detoxification pathways[128].

CONCLUSION

Gallbladder cancer is an aggressive and rare neoplasm with an unusual geographic distribution. Most patients are diagnosed in the advanced stages of the disease, and therefore the life expectancy is low. Compelling evidence supports the role of several risk factors, which are linked to the onset, and chronicity of an inflammatory reaction. The report of Taguchi *et al*[66] represented a critical point in understanding the role of the RAGE axis in tumor biology, and highlighting the potential of therapeutic interventions on a hyperactive cellular signaling pathway that causes disease, as the RAGE axis is[129].

The role of RAGE axis activation in gallbladder cancer is supported by its active contribution to the pathogenic framework of the main risk factors associated with this neoplasm, such as infectious agents [130,131], some metabolic conditions[132,133], and dietary habits[32].

Although much research is needed, lowering dietary AGEs intake as well as increasing the consumption of foods rich in polyphenols in subjects at risk of gallbladder cancer, either by pre-existing metabolic conditions or genetic ancestry, seems to be a plausible recommendation, to avoid the hyperactivation of the RAGE/AGEs axis.

Abstract

The recently proposed nomenclature change from non-alcoholic fatty liver disease to metabolic dysfunction-associated fatty liver disease (MAFLD) has resulted in the reappraisal of epidemiological trends and associations with other chronic diseases. In this context, MAFLD appears to be tightly linked to incident chronic kidney disease (CKD). This association may be attributed to multiple shared risk factors including type 2 diabetes mellitus, arterial hypertension, obesity, dyslipidemia, and insulin resistance. Moreover, similarities in their molecular pathophysiologic mechanisms can be detected, since inflammation, oxidative stress, fibrosis, and gut dysbiosis are highly prevalent in these pathologic states. At the same time, lines of evidence suggest a genetic predisposition to MAFLD due to gene polymorphisms, such as the *PNPLA3* rs738409 G allele polymorphism, which may also propagate renal dysfunction. Concerning their management, available treatment considerations for obesity (bariatric surgery) and novel antidiabetic agents (glucagon-like peptide 1 receptor agonists, sodium-glucose co-transporter 2 inhibitors) appear beneficial in preclinical and clinical studies of MAFLD and CKD modeling. Moreover, alternative approaches such as melatonin supplementation, farnesoid X receptor agonists, and gut microbiota modulation may represent attractive options in the future. With a look to the future, additional adequately sized studies are required, focusing on preventing renal complications in patients with MAFLD and the appropriate management of individuals with concomitant MAFLD and CKD.

Key Words: Metabolic dysfunction-associated fatty liver disease; Chronic kidney disease; Hepatic steatosis; inflammation; Type 2 diabetes mellitus; Obesity

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Metabolic dysfunction-associated fatty liver disease (MAFLD) is a recently defined pathological state aiming to identify individuals at increased risk of adverse prognosis. Numerous epidemiological studies propose that chronic kidney disease may be among its complications. Their shared risk factors, molecular mechanisms, and genetic predisposition represent the basis for this relationship. Accordingly, treatment approaches with combined efficacy in MAFLD and chronic renal impairment are expected to positively impact the natural history of this deleterious interaction, which remains to be confirmed in future studies.

INTRODUCTION

Metabolic abnormalities, namely obesity and type 2 diabetes mellitus (T2DM) constitute contemporary pandemics with a high prevalence and rising incidence[1,2]. Although cardiovascular diseases remain the most prominent complication of metabolic derangement, hepatic insult is frequent, as documented in recently reported epidemiologic trends of non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH)[3,4]. However, the existing NAFLD definition required the exclusion of other forms of liver disease instead of providing positive criteria for the diagnosis of metabolic dysfunction-associated fatty liver disease (MAFLD). A recent expert consensus tried to resolve this gap in evidence by providing a simple and comprehensive MAFLD definition and diagnostic criteria[5]. These included the presence of steatosis along with a main metabolic abnormality (overweight/obesity or T2DM) or at least two metabolic risk factors.

The establishment of MAFLD as an entity may promote the need for intense research in this field to define its epidemiology better, identify predisposing and prognostic factors, and evaluate effective therapeutic approaches. Moreover, investigating the association between MAFLD and other pathological states, primarily cardiac and renal diseases, will improve our understanding of this complex entity. Even though the link between MAFLD and cardiovascular disease has been the most extensively studied[6], ample evidence suggests the relationship between MAFLD and chronic kidney disease (CKD).

In this narrative review, we elaborate on this interaction by assessing its epidemiological features, the involved pathophysiologic pathways, and the potential therapeutic interventions.

MAFLD AND CKD; EPIDEMIOLOGICAL TRENDS

Due to the recent change in terminology and diagnostic criteria, we are now beginning to reevaluate the epidemiological characteristics of MAFLD. In a recently reported study that followed a meta-analytic approach, the prevalence of MAFLD in overweight or obese subjects was 50.7%[7]. The authors pointed to potential geographic variations in MAFLD prevalence, with South American populations exhibiting the highest prevalence rates (approximately 71%). Moreover, they detected a significantly higher prevalence in male subjects and in obese compared to overweight. No differences according to age or income were reported. Finally, T2DM and metabolic syndrome prevalence was 19.7% and 57.5%, respectively. A similar prevalence (47%) was detected in a cross-sectional study of the Mexican population, with male sex, older age, and increasing body mass index (BMI) being predictive factors[8]. Other than high prevalence rates, there is an association between MAFLD and all-cause mortality, which extends to cancer- and cardiovascular disease-related mortality[9]. Moreover, a higher risk of atherosclerotic disease, heart failure, obstructive sleep apnea, and malignancy has been reported[9].

According to the available evidence, MAFLD is tied to a higher incidence of CKD. To begin with, in an analysis of approximately 270000 individuals that underwent National Health Insurance Service health examinations, MAFLD was associated with an increased risk of incident CKD compared to non-metabolic NAFLD (adjusted hazard ratio 1.18, 95% confidence interval [CI]: 1.01-1.39; P = 0.04)[10]. In the study by Tanaka *et al*[11] in a sizeable Japanese population followed up for 10 years, MAFLD was a determinant of incident CKD irrespective of age, sex, smoking, coronary artery disease, estimated glomerular filtration rate (eGFR), and metabolic risk factors (diabetes mellitus [DM], hypertension, hyperlipidemia, obesity). Notably, such observations were not made for the presence of NAFLD or only fatty liver[11]. In a Chinese cohort of 6873 participants with a 4.6-year follow-up, the investigators noted a higher risk of CKD in MAFLD subjects (risk ratio 1.64, 95%CI: 1.39-1.94)[12]. Last but not least, the

authors of a recently published systematic review and meta-analysis found a potent association between a MAFLD diagnosis and new onset of CKD (hazard ratio 1.53, 95%CI: 1.38-1.68)[9]. Contradictory to the findings mentioned above, in an analysis of the National Health and Nutrition Examination Surveys of the United States 2017-2018, the relationship between MAFLD and CKD was not statistically significant after the propensity score matching[13]. Scientific interest is intense in this field due to the recently proposed change in the nomenclature of NAFLD into MAFLD. Future studies are eagerly awaited to assess the association between MAFLD and CKD and the prognosis of individuals with concomitant CKD and MAFLD.

Concerning the interplay between MAFLD and CKD, the use of transient elastography is of great importance. Ciardullo *et al*[14], in their meta-analysis of seven cross-sectional studies, detected an association of non-invasively assessed liver fibrosis with increased urinary albumin-to-creatinine ratio (UACR) (odds ratio [OR] 1.98, 95%CI: 1.29-3.05; $P = 0.002$) and incident CKD (OR 2.49, 95%CI: 1.89-3.29; $P < 0.001$). The study by Freitas *et al*[15] further stressed the role of transient elastography. Liver fibrosis, assessed by the liver stiffness measurements (LSM), was associated with early kidney dysfunction, characterized by the development of microalbuminuria (UACR 30-300 mg/g) or a drop in eGFR to < 60 mL/min/1.73 m^2 in MAFLD individuals[15]. LSM values of over 6.1 kPa were predictive of the endpoint, with a sensitivity and specificity of 85.7% and 67.6%, respectively[15]. It appears that Fibroscan-derived controlled attenuated parameter (CAP) may be a more crucial predictor of prevalent CKD in subjects with MAFLD than LSM. Specifically, CAP values of 353 dB/m were associated with CKD, even after multivariable adjustment (OR 1.07, 95%CI: 1.00-1.20; $P = 0.01$)[16].

PATHOPHYSIOLOGIC PATHWAYS LINKING MAFLD WITH CKD

According to those recently published reports, it is evident that MAFLD is a growing pandemic due to the constantly rising prevalence of its underlying risk factors. Moreover, the association between MAFLD and incident CKD is remarkable but unsurprising, due to the common pathophysiologic mechanisms surrounding those entities (Figure 1). To begin with, the main risk factors for CKD development, T2DM and arterial hypertension[17-19], are among the established diagnostic criteria for MAFLD. The same could be argued for obesity, prediabetes, dyslipidemia, and insulin resistance since studies have proposed an independent association between the risk factors mentioned above and incident CKD[17,19-21].

Inflammatory hypothesis in MAFLD and CKD

Regarding the involved molecular mechanisms, we should stress the role of inflammation. We know that inflammation is among the cardinal features of MAFLD, with elevations of high-sensitivity C reactive protein (hsCRP) being among the criteria of metabolic dysregulation. hsCRP elevation was correlated with the extent of liver steatosis and fibrosis in 393 obese individuals with MAFLD, even after adjustment for confounding factors[22]. Chronic, low-grade inflammation may propagate oxidative stress and endothelial dysfunction in MAFLD[23,24]. Ultimately, liver fibrosis ensues due to extracellular matrix formation and collagen deposition[25], potentially progressing to cirrhosis and hepatocellular carcinoma. Intriguingly, this pro-inflammatory state could facilitate the development of CKD, with nuclear factor kappa B (NF-κB) mediating the activation of endothelial cells, mesangial cells, podocytes, and tubular epithelial cells, resulting in increased permeability, the release of inflammatory mediators, and proteinuria[26]. In this deleterious setting, the additional extracellular matrix remodeling, epithelial-to-mesenchymal transition, and interstitial fibrosis contribute to the progression of CKD[27]. We should also stress that the contribution of MAFLD and CKD to the systemic inflammatory milieu could have deleterious cardiovascular implications[28-32].

Obesity and adipokines

Obesity, another shared risk factor for MAFLD and CKD, is also pivotal in their development. Adipose tissue is a known endocrine organ with critical regulatory functions on satiety, insulin sensitivity, inflammation, and the renin-angiotensin system through the secretion of adipokines[33,34]. The most well-characterized hazardous adipokine in FLD, leptin, by interacting with its primary receptor Ob-Rb, results in Janus kinase 2 phosphorylation, in turn leading to the upregulation of the Akt/mammalian target of rapamycin (mTOR), signal transducer and activator of transcription 5, and mitogen-activated protein kinase (MAPK) pathways[35]. This may aid in the development and progression of hepatic steatosis, steatohepatitis, and liver fibrosis. By contrast, low levels of the protective adipokine adiponectin are significantly associated with advanced fibrosis[36]. Moreover, an increased leptin-to-adiponectin ratio is positively correlated with the increasing severity of steatosis[37]. The imbalance in leptin and adiponectin may influence the development of CKD, as leptin could induce sympathetic nervous system activation and blood pressure increases[38], as well as transforming growth factor-β synthesis[39]. A recently reported longitudinal study of 2646 Koreans without CKD showed that higher plasma leptin was predictive of incident CKD after a 2.8-year mean follow-up[40]. On the other hand, adiponectin could have renoprotective effects by ameliorating renal inflammation, oxidative stress, and

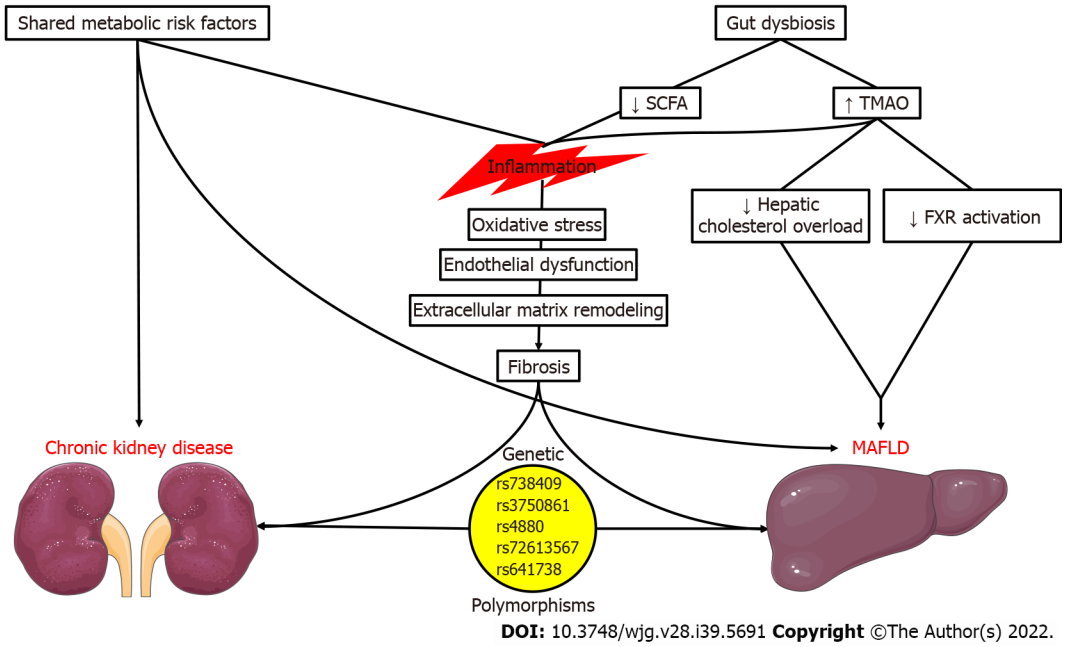

Figure 1 Common pathophysiologic mechanisms in metabolic dysfunction-associated fatty liver disease and chronic kidney disease.
FXR: Farnesoid X receptor; MAFLD: Metabolic dysfunction-associated fatty liver disease; SCFA: Short-chain fatty acid; TMAO: Trimethylamine N-oxide.

fibrosis[41]. However, multiple studies have shown that high adiponectin levels are inversely associated with eGFR in individuals with CKD[42] and were predictive of renal function deterioration in subjects without CKD[43].

Gut dysbiosis

The role of the gut microbiome in human health and disease is a highly relevant field of scientific interest. Therefore, potential associations of gut dysbiosis with MAFLD and CKD have been suggested in the past years, strengthening the importance of the gut-liver-kidney axis. In altered gut microbiome synthesis, hazardous metabolites such as trimethylamine N-oxide (TMAO), p-cresyl sulfate, and indoxyl sulfate may be formed.

TMAO is the most extensively studied metabolite regarding its health implications[44]. According to preclinical studies, it may aggravate hepatic steatosis and steatohepatitis by modulating bile acid metabolism, inhibiting farnesoid X receptor activation, and reducing hepatic cholesterol overload[45,46]. NAFLD presence and severity were correlated with circulating TMAO in a study of Chinese individuals[47]. The levels of TMAO were higher in individuals with obesity and NASH, only in the presence of T2DM[48]. TMAO was also associated with all-cause mortality only in NAFLD patients in the Prevention of Renal and Vascular End-stage Disease cohort study, even after adjustment for confounders[49]. Regarding the kidney, TMAO may exert deleterious effects, such as promoting inflammation and fibrosis[50-52]. In a meta-analysis of kidney function indices involving 32 clinical studies with 42062 participants, TMAO concentration was associated with advanced CKD, inversely correlated with eGFR, and positively correlated with UACR, serum creatinine, and serum cystatin C[53]. Circulating TMAO was predictive of all-cause and cardiovascular mortality in a recently reported systematic review and meta-analysis, with this finding being irrespective of kidney function and common risk factors (DM, hypertension, dyslipidemia, inflammation)[54].

Depletion of bacteria responsible for the production of beneficial short-chain fatty acids (SCFAs), such as acetate, propionate, and butyrate, in the setting of a disrupted gut microbiome may lead to deleterious effects in the liver and kidney. These SCFAs could promote anti-inflammatory and anti-oxidative actions by limiting neutrophil recruitment, macrophage secretion of pro-inflammatory mediators, and histone deacetylase-induced NF-κB activation while promoting anti-inflammatory interleukin-10 formation by T regulatory cells[55]. Increased availability of SCFA-producing bacteria or SCFA treatment in clinical studies of patients on hemodialysis patients has resulted in lowering inflammatory markers and ameliorating renal function[56,57]. SCFAs are also helpful in the prevention of MAFLD due to the effects mentioned above, together with hepatic AMP-activated protein kinase (AMPK) activation and glucagon-like peptide 1 receptor (GLP1-R) activation, promotion of satiety, and abrogation of insulin resistance[58].

Gene polymorphisms

Polymorphisms in a few NAFLD-associated genes may also be associated with CKD. *PNPLA3* rs738409

G allele polymorphism is the most well-studied and correlated with NAFLD risk and severity[59]. Its potential association with renal outcomes has been investigated with conflicting evidence, as it may propagate podocyte activation and lipid nephrotoxicity. Initially, Sun *et al*[60] found a significant link between the G/G *PNPLA3* genotype with glomerular and tubular injury. In a United Kingdom Biobank analysis, the rs738409 single nucleotide polymorphism was associated with decreased eGFR, independently of metabolic risk factors[61]. Patients homozygous for the *PNPLA3* rs738409 had a higher prevalence of CKD and lower eGFR irrespective of liver stiffness and other risk factors in the study of Mantovani *et al*[62]. This study also found similar expression of *PNPLA3* in podocytes, hepatocytes, and hepatic stellate cells[62]. The same study group had previously proven the independent association of the G/G *PNPLA3* rs738409 polymorphism phenotype with eGFR and CKD in post-menopausal women with T2DM[63]. However, no associations between *PNPLA3* rs738409 gene polymorphism and kidney function were detected in other studies[64-67].

Other polymorphisms have also been investigated, albeit to a lesser degree. Risk alleles for *KLF6* rs3750861 and *SOD2* rs4880 polymorphisms correlate with kidney function in MAFLD[65]. Moreover, in a population of biopsy-proven NAFLD, the *HSD17B13* rs72613567 A alleles were protective against albuminuria but not eGFR decline[68]. Lastly, an association between the *MBOAT7-TMC4* rs641738 T/T genotype and lower eGFR was detected in a cohort of Asian individuals with biopsy-proven NAFLD [67]. While the genetic predisposition of kidney dysfunction in FLD represents an exciting hypothesis, further studies are required to improve our understanding of this link.

THERAPEUTIC APPROACHES

Treating patients with MAFLD and CKD requires therapeutic interventions to ameliorate their prognosis by targeting their shared risk factors and pathophysiology. Although studies have not explicitly assessed this subgroup of patients, we may assume that interventions with documented efficacy in MAFLD[69-81] and CKD[82-90] could lead to positive outcomes in this combination of diseases (Table 1). Moreover, due to the recent change in the nomenclature with the introduction of MAFLD, we should stress that most of the available clinical evidence discussed below is derived from studies of NAFLD patients. Therefore, future appropriately designed studies considering the novel MAFLD diagnostic criteria will shed additional light on managing this entity.

Bariatric surgery

Since obesity is among the main risk factors for the development of MAFLD, the role of bariatric surgery may be crucial in carefully selected eligible individuals. Initially, we should state that the prevalence of MAFLD may be exceptionally high in those morbidly obese patients that are eligible for bariatric surgery. Ciardullo *et al*[91] have demonstrated this association in a study of 434 potential candidates for bariatric surgery, with the prevalence of steatosis and fibrosis being 76.7% and 23.1%, respectively. In the only study assessing bariatric surgery in MAFLD patients, Meneses *et al*[69] prospectively enrolled 52 subjects whose MAFLD status was evaluated *via* liver biopsy. Those with a histological diagnosis of steatohepatitis were followed up with an additional biopsy 12 mo after the index procedure. Most subjects with steatohepatitis did not experience any disease progression, while a significant proportion (56.5%) exhibited complete resolution. Additionally, fibrosis and fibrotic scores were improved, highlighting a non-negligible benefit of bariatric surgery in this small-scale study.

Bearing in mind the increased prevalence (~80%) of steatosis in morbidly obese patients (BMI > 40 kg/m^2)[92], several clinical implications can be made regarding kidney outcomes. To begin with, compared with individuals who have undergone a bariatric surgery procedure, severely obese subjects had greater odds of having stage III CKD (OR 3.10, 95%CI: 3.05-3.14, $P < 0.001$) and end-stage renal disease (OR 1.13, 95%CI: 1.09-1.18, $P < 0.001$). This finding was consistent even after adjustment for CKD risk factors[93]. The performance of sleeve gastrectomy could have renoprotective effects, as shown in a retrospective analysis of 1330 individuals undergoing this procedure. The investigators noted a greater improvement of eGFR in subjects with impaired kidney function 12 mo after the procedure[82]. A rise in eGFR, together with albuminuria reduction, was observed by Wee *et al*[83] in their retrospective study of 557 Asian patients after metabolic bariatric surgery. Importantly, the CKD stage improved in 12.9% of the study participants, while the prevalence of albuminuria (UACR > 3.5 mg/mmol) decreased from 24.8% to 1.9% at the 1-year follow-up[83]. Fathy *et al*[84] also noted an astonishing albuminuria remission rate (83%) in 137 non-diabetic, non-hypertensive, severely obese subjects with albuminuria who underwent bariatric surgery. Moreover, in another study, subjects undergoing bariatric surgery had a lesser incidence of kidney disease than the control group (hazard ratio 0.46, 95%CI: 0.22-0.92)[85]. A systematic review and meta-analysis of 19 studies revealed that bariatric surgery led to ameliorated eGFR and lesser odds of incident albuminuria[94]. The observed benefits may be attributed to enhanced glomerular hyperfiltration, reduction in detrimental adipocyte-derived mediators such as leptin, and alterations in pro-inflammatory and pro-fibrotic molecule expression[95].

Table 1 Selected human studies assessing various treatment approaches in metabolic dysfunction-associated fatty liver disease and chronic kidney disease

Study	Treatment	Finding
MAFLD		
Meneses *et al*[69]	Bariatric surgery	Stabilization of fibrosis or complete resolution; ↓ NAFLD fibrosis score
Li *et al*[70]	GLP1-RA	↓ Liver fat
Morieri *et al*[71]	GLP1-RA	↓ MAFLD prevalence
Jianping *et al*[72]	GLP1-RA	Improvement in histological MAFLD features
Akuta *et al*[73]	Canagliflozin	↓ Histological steatosis, lobular inflammation, and fibrosis stage
Takahashi *et al*[74]	Ipragliflozin	↓ Hepatic fibrosis; Steatohepatitis resolution
Pakravan *et al*[75]	Melatonin	↓ Inflammation; Improvement of ultrasonographic fatty liver grade
Akhavan *et al*[76]	Melatonin	↓ Hepatic enzyme levels
Rinella *et al*[77]	Obeticholic acid	↓ Hepatic enzyme levels↓ Liver fibrosis
Neuschwander-Tetri *et al*[78]	Obeticholic acid	Improvement in histological features
Mohamad Nor *et al*[79]	Probiotics	↔ Elastography-derived hepatic steatosis and fibrosis
Derosa *et al*[80]	Probiotics	↓ Hepatic steatosis index; ↓ Ultrasonographic steatosis
Musazadeh *et al*[81]	Probiotics	↓ Hepatic enzyme levels
CKD		
Funes *et al*[82]	Bariatric surgery	↑ eGFR
Wee *et al*[83]	Bariatric surgery	↑ eGFR↓ Albuminuria
Fathy *et al*[84]	Bariatric surgery	↓ Albuminuria
Dash *et al*[85]	Bariatric surgery	↓ Kidney disease incidence
Shaman *et al*[86]	GLP1-RAs	↓ Albuminuria; Halted eGFR decline
Perkovic *et al*[87]	Canagliflozin	Reduction in the renal outcome (ESKD, doubling of serum creatinine, or renal death) by 34%
Heerspink *et al*[88]	Dapagliflozin	Reduction in the renal outcome (decline in eGFR of ≥ 50%, ESKD, or renal death) by 44%
Bhatt *et al*[89]	Sotagliflozin	Reduction in the renal outcome (decline in eGFR of ≥ 50%, ESKD, renal transplantation) by 29%
Wang *et al*[90]	Probiotic	Halted eGFR decline; ↓ Inflammation

↑: Increase; ↓: Decrease; ↔: No change. CKD: Chronic kidney disease; eGFR: Estimated glomerular filtration rate; ESKD: End-stage kidney disease; GLP1-RA: Glucagon-like peptide 1 receptor agonist; MAFLD: Metabolic dysfunction-associated fatty liver disease; NAFLD: Non-alcoholic fatty liver disease.

GLP1-R agonists

GLP1-R agonists (GLP1-RAs) are novel potent antidiabetic agents with proven efficacy in reducing major adverse cardiovascular events. Besides their glucose-lowering action, their beneficial hepatic effects may be related to the influence on the AMPK/mTOR pathway, as shown by Reis-Barbosa *et al*[96] in obese C57BL/6 mice treated with subcutaneous semaglutide. Other inflammatory and oxidative pathways in the liver could be inhibited by GLP1-RAs, such as the receptor for advanced glycation end products/nicotinamide-adenine dinucleotide phosphate oxidase 2, limiting liver injury and fibrosis in mice on a high-fat diet[97]. Concerning human studies, patients with MAFLD treated with GLP1-RAs have exhibited a significant reduction in liver fat, which may be positively correlated to fibroblast growth factor 21[70]. The use of GLP1-RAs also resulted in a significant reduction of MAFLD prevalence (defined based on hepatic steatosis index > 36) during a 24-mo follow-up[71]. Interestingly, the effect was evident only in subjects on human-based GLP1-RAs[71]. Moreover, in a meta-analysis of 4 randomized clinical trials, semaglutide was associated with significant decreases in body weight, alanine aminotransferase, liver steatosis, and stiffness[98]. GLP1-RAs may also improve histologic features on MAFLD, such as liver fat deposition, steatohepatitis, and fibrosis, as shown by the systematic review and meta-analysis of Jianping *et al*[72].

GLP1-RAs have shown benefits in preventing the development or halting the progression of CKD. As demonstrated above, their effect in ameliorating steatosis and promoting anti-oxidative and anti-inflammatory actions may be among the determining factors in this renoprotective effect, together with weight loss, blood pressure, and glucose-lowering[99]. Other speculated mechanisms include glomerular hyperfiltration, the regulation of the renin-angiotensin system, sodium-hydrogen exchanger-3, and renal endothelial vasodilation[100]. Regarding clinical evidence, and as recently shown in a pooled analysis of the SUSTAIN 6 and LEADER trials of patients with T2DM, semaglutide and liraglutide diminished albuminuria and eGFR decline, especially in subjects with CKD (eGFR < 60 mL/min/1.73 m^2)[86]. Moreover, efpeglenatide, an exendin-4-based GLP1-RA, also led to favorable renal outcomes compared to placebo in the AMPLITUDE-O trial of individuals with T2DM, irrespective of eGFR and concurrent sodium-glucose co-transporter-2 (SGLT2) inhibitor use[101,102]. As far as head-to-head comparisons, the renoprotective effects of GLP1-RAs were of greater magnitude compared with dipeptidyl peptidase-4 inhibitors[103], whereas SGLT2 inhibitors may promote increased renal benefits[104,105].

Dual GLP1 and glucose-dependent insulinotropic peptide receptor agonists have recently emerged into the spotlight owing to the results of the SURMOUNT-1 clinical trial of tirzepatide for the treatment of obesity[106]. Regarding FLD, the administration of a hybrid agonist by the name of 19W in C57BL/6J on a high-fat diet decreased the area of liver fibrosis[107]. Moreover, dual GLP1/2 receptor agonists may also ameliorate NASH prognosis, as shown in C57BL/6J mice on a high-fat diet/high fructose and sucrose solution through an improvement in liver fibrosis[108]. However, these concepts need further validation in preclinical settings. Concerning clinical evidence, tirzepatide dose-dependently ameliorated biomarkers of NASH such as alanine transaminase, aspartate aminotransferase, keratin-18, and procollagen III compared to placebo. At the same time, it was associated with an increase in adiponectin[109]. Lastly, in a recently published substudy of the SURPASS-3 MRI clinical trial, administration of tirzepatide in patients with T2DM decreased the liver fat content along with the volume of visceral and abdominal subcutaneous adipose tissue, compared to insulin degludec[110].

SGLT2 inhibitors

SGLT2 inhibitors have been at the forefront of scientific research owing to the remarkable reduction in the rate of heart failure hospitalization and their ability to impact cardiac remodeling[111,112]. Their pleiotropic mechanisms of action have been a topic of continuous investigation[111,113], and their therapeutic indications are constantly expanding. In the field of MAFLD, specifically in obese, diabetic mice with FLD treated with empagliflozin, Kurtz *et al*[114] documented a reduction in hepatic steatosis, which was correlated with the whitening of the adipose tissue. Empagliflozin may also attenuate hepatocyte lipotoxicity through the calcium/calmodulin dependent protein kinase beta/AMPKα pathway[115]. Another SGLT2 inhibitor, ipragliflozin, ameliorated the progression of MAFLD in STAM mice with β cell depletion, evidenced by decreased histologic steatosis, hepatocyte ballooning, inflammation, and fibrosis[116]. This effect was accompanied by antioxidant and mitochondrial transport-related gene upregulation, and overexpression of miR-19b-3p[116]. Additionally, dapagliflozin reduced liver fat accumulation in male NIH mice on a high-fat diet by acting on the AMPK/mTOR pathway [117]. Moving to clinical evidence, empagliflozin may lessen liver fibrosis, insulin resistance, and hepatic enzyme concentrations, as shown by the systematic review and meta-analysis of Zhang *et al* [118]. An interesting study on the importance of SGLT2 inhibition in MAFLD was performed by Akuta *et al*[73], who retrospectively reviewed patients with T2DM and FLD initiated on canagliflozin with consequent biopsy results over a period of 5 years. Compared to pre-treatment biopsy, the investigators noted a histologic improvement in 50% of the participants and a decrease in steatosis, lobular inflammation, and fibrosis stage in 67%, 33%, and 33%, respectively, at the 5th year. In line with this study, ipragliflozin use in patients with T2DM and FLD led to significant improvements in hepatic fibrosis and greater rates of steatohepatitis resolution compared to the control group[74]. According to the available evidence, we can assume that SGLT2 inhibitors will become an essential tool in the prevention and treatment of MAFLD.

While the use of SGLT2 inhibitors in MAFLD is gaining ground, this drug class is an established treatment option for CKD. Among the putative nephroprotective mechanisms are the regulation of autophagy and the resulting inflammation, oxidative stress, endothelial dysfunction, fibrosis, and apoptosis, the reduction of intraglomerular and blood pressure, and the improvement of podocytopathy. Large-scale randomized clinical trials on CKD patients such as CREDENCE[87], DAPA-CKD [88], and SCORED[89] demonstrated the unequivocal benefit of SGLT2 inhibition in reducing the rate of adverse renal outcomes and eGFR decline. The upcoming EMPA-KIDNEY trial was stopped early due to clear efficacy detected in the interim analysis, and the detailed results are eagerly awaited. Subanalyses of the abovementioned trials stressed the effect of SGLT2 inhibitors on kidney outcomes independently of T2DM status, baseline hemoglobin A1c, CKD etiology, and stage[119-122]. The upcoming revision of existing CKD guidelines should incorporate this option in CKD treatment algorithms.

Melatonin

Melatonin, a crucial hormone produced in response to darkness, could be an additional approach to managing MAFLD and CKD due to its pleiotropic effects, as we have previously reviewed[123]. Starting

with its impact on MAFLD, fine particulate matter-induced hepatic steatosis was ameliorated with the administration of melatonin in apolipoprotein E knockout (ApoE$^{-/-}$) mice through anti-oxidative mechanisms involving protein tyrosine phosphatase 1B and nuclear factor erythroid 2-related factor 2 signaling pathways[124]. Furthermore, melatonin promoted anti-inflammatory actions by modulating NACHT, LRR, and PYD domain-containing protein 3 inflammasome activation and downregulating the toll-like receptor 4/NF-κB pathway in C57BL/6 mice models of high-fat diet-induced steatohepatitis [125]. This resulted in histopathological improvement of steatosis, ballooning, inflammation, fibrosis, and overall disease score[125]. In clinical studies, the administration of oral melatonin thrice daily for 3 mo ameliorated metabolic and inflammatory indices, as well as ultrasonography fatty liver grade, in patients with histologically proven NAFLD[75]. In a meta-analysis of studies with NAFLD patients, alanine transaminase, alkaline phosphatase, gamma-glutamyl transferase, triglycerides, and total cholesterol were significantly reduced after melatonin supplementation[76]. However, more clinical trials are needed to improve our understanding of the importance of melatonin treatment in MAFLD development, progression, and prognosis.

Melatonin supplementation has also been attempted in CKD, both preclinically and clinically. Based on experimental studies, several mechanisms of nephroprotection have been suggested, including anti-oxidative, anti-inflammatory, anti-fibrotic, and anti-apoptotic[123]. Although there is no reliable clinical evidence concerning CKD prognosis after melatonin therapy, human trials have proven an anti-oxidative and anti-inflammatory effect, paired with improved glycemia[126,127]. Moreover, ameliorating mitochondrial damage and promoting autophagy could represent other putative effects of melatonin treatment[123].

Farnesoid X receptor agonists

Farnesoid X receptor agonists have demonstrated efficacy both in fatty liver disease regression and kidney disease. The most commonly used agent of this drug class, obeticholic acid, at a dose of 25 mg, led to significant improvement in liver function tests, elastography-derived and histologically proven liver fibrosis in patients with steatohepatitis and liver fibrosis (F2-F3)[77]. Based on the results of the FLINT trial of patients with non-cirrhotic, non-alcoholic steatohepatitis, obeticholic acid 25 mg administration led to an improvement in liver histology in 45% of the participants compared to in the control group (relative risk 1.9, 95%CI: 1.3-2.8)[78]. Although the dosage of 25 mg may be more efficacious than 10 mg, it may be met with a more significant burden of side effects and possibly higher discontinuation rates[128]. Preclinical evidence has suggested the potential of farnesoid X receptor agonists in experimental kidney disease by abrogating inflammation, oxidative stress, fibrosis, and apoptosis[129-132]. Due to the lack of clinical data, the efficacy of farnesoid X receptor agonists in CKD remains speculative to date.

Gut microbiome modulation

Targeting the gut microbiome may represent an appealing approach to the holistic management of MAFLD and CKD. Probiotics such as *Bifidobacterium animalis, B. bifidum, B. adolescentis, Lactobacillus paracasei, L. plantarum, L. reuteri,* and *Weissella cibaria* have been assessed in preclinical FLD models and may alter gut permeability, ultimately affecting the processes of inflammation and oxidative stress among others[133-138]. Unfortunately, a probiotic supplement containing six different Lactobacillus and Bifidobacterium species for 6 mo did not improve hepatic steatosis and fibrosis evaluated by elastography in ultrasonography-diagnosed NAFLD subjects[79]. By contrast, a high-concentration probiotic combination of *Streptococcus thermophilus*, multiple *Bifidobacteria* and *Lactobacilli* led to a reduction of hepatic steatosis index as well as ultrasonographic steatosis in a double-blind, placebo-controlled, randomized clinical trial of NAFLD patients[80]. A recently reported umbrella systematic review and meta-analysis also suggested liver biochemical improvement through the administration of probiotics in NAFLD patients[81]. Although probiotics appear helpful in experimental FLD settings, more clinical trials are required to improve our understanding of their importance in human MAFLD.

Moving to CKD, *L. rhamnosus* administration for 14 wk in 5/6 nephrectomized mice diminished gut-derived uremic toxins and systemic inflammatory markers by restoring intestinal integrity and protecting against renal fibrosis[139]. Anti-inflammatory, anti-apoptotic, and anti-fibrotic effects with *L. rhamnosus* were demonstrated in cisplatin-induced CKD rat models by acting on the MAPK/NF-κB/cyclooxygenase-2, the p53/B-cell lymphoma 2-associated X protein/caspase-3, and the signal transducer and activator of 3 pathway[140]. Moreover, a lactobacillus mixture consisting of *L. paracasei* and *L. plantarum* led to attenuated kidney injury, inflammation, and fibrosis in adenine-induced CKD mouse models, while also restoring gut microbial composition[141]. Translating these findings in a clinical setting of patients with advanced CKD, 6 mo of treatment with a probiotic formulation containing *L. acidophilus*, *B. longum*, and *B. bifidum* significantly halted the eGFR decline, together with lowering of inflammatory markers[90].

Although still experimental, TMAO inhibitors may represent a possible approach to modulating gut microbiota. Using 3,3-dimethyl-1-butanol, a trimethylamine formation inhibitor, decreased plasma TMAO levels and attenuated renal inflammation, oxidative stress, and fibrosis in C57BL/6 mice on a high-fat diet[142]. Importantly, no changes in blood pressure and weight adiposity parameters were noted[142]. Iodomethylcholine (IMC), a selective gut microbial choline TMA-lyase inhibitor, was also

able to diminish TMAO production and revert the renal function decline and tubulointerstitial fibrosis in isoproterenol-induced CKD mouse models on a choline diet[143]. Similar observations were made in ApoE$^{-/-}$ mouse models with adenine-induced CKD treated with IMC, together with ameliorated microalbuminuria, cardiac hypertrophy, and vascular inflammation indices[144]. These molecules have not been assessed yet in FLD, and upcoming studies evaluating their efficacy are awaited.

CONCLUSION

In conclusion, it has become evident that the newly defined MAFLD is associated with high prevalence and mortality rates and is an independent predictor of CKD. The degree of hepatic steatosis and fibrosis in this group of patients correlates with kidney function indices such as urinary albumin-to-creatinine ratio and estimated glomerular filtration rate. This interaction is unsurprising, as these entities have shared risk factors and deleterious molecular mechanisms such as inflammation, oxidative stress, and gut dysbiosis. At the same time, gene polymorphisms associated with fatty liver disease predisposition may also propagate renal dysfunction. In the field of treatment, pharmacologic interventions have demonstrated considerable preclinical and clinical efficacy in ameliorating surrogate disease markers and clinical outcomes in these pathological states. Future studies should aim at the subpopulation of MAFLD patients with renal impairment to appropriately determine their prognosis and the impact of treatment approaches.

FOOTNOTES

Author contributions: Theofilis P contributed to conceiving the study; Theofilis P and Vordoni A contributed to the investigation; Theofilis P contributed to the visualization; Kalaitzidis RG contributed to the supervision; Theofilis P and Vordoni A wrote the original draft; Kalaitzidis RG edited the original draft; All authors have read and agreed to the published version of the manuscript.

Conflict-of-interest statement: The authors have no conflicts of interest to declare.

Abstract

Biliodigestive anastomosis between the extrahepatic bile duct and the intestine for bile duct disease is a gastrointestinal reconstruction that abolishes duodenal papilla function and frequently causes retrograde cholangitis. This chronic inflammation can cause liver dysfunction, liver abscess, and even bile duct cancer. Although research has been conducted for over 100 years to directly repair bile duct defects with alternatives, no bile duct substitute (BDS) has been developed. This narrative review confirms our understanding of why bile duct alternatives have not been developed and explains the clinical applicability of BDSs in the near future. We searched the PubMed electronic database to identify studies conducted to develop BDSs until December 2021 and identified studies in English. Two independent reviewers reviewed studies on large animals with 8 or more cases. Four types of BDSs prevail: Autologous tissue, non-bioabsorbable material, bioabsorbable material, and others (decellularized tissue, 3D-printed structures, *etc.*). In most studies, BDSs failed due to obstruction of the lumen or stenosis of the anastomosis with the native bile duct. BDS has not been developed primarily because control of bile duct wound healing and regeneration has not been elucidated. A BDS expected to be clinically applied in the near future incorporates a bioabsorbable material that allows for regeneration of the bile duct outside the BDS.

Key Words: Bile duct alternative; Bile duct substitute; Biliary regeneration; Bile duct reconstruction; Peribiliary gland; Bioabsorbable polymer

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The bile duct-intestinal anastomosis eliminating the function of the papilla of Vater causes chronic inflammation due to the reflux of bile and is not an ideal reconstruction method. Bile duct alternatives for bile duct defects have not been developed for over 100 years. In the present situation where the wound healing of the bile duct defect cannot be controlled, only the use of a bioabsorbable material, such as a scaffold, and the regeneration of the bile duct outside the scaffold can be expected as a bile duct substitute.

INTRODUCTION

The treatment of gastrointestinal diseases in the 21st century involves robotic and endoscopic surgeries, which aim to minimize potential risks and side effects[1-3]. Minimally invasive endoscopic treatments have been developed to facilitate functional preservation[4,5]. For diseases of the biliary system, the use of laparoscopic cholecystectomy as a treatment for cholelithiasis has become widespread, and minimally invasive approaches have been pursued[6]. In contrast, the incidence of severe iatrogenic extrahepatic bile duct injury due to laparoscopic cholecystectomy has increased significantly worldwide compared to that due to laparotomy surgery[7]. With regard to bile duct injuries, there is currently no bile duct substitute (BDS) for partially defective or damaged parts of the bile duct. Reconstruction by anastomosis of the hepatic bile duct and intestine is typically performed[8].

Bile duct-intestinal anastomosis is a biliary tract reconstruction procedure that was first performed by von Winiwater in 1880[9]. However, liver abscess, cirrhosis, and liver dysfunction were often observed in patients who underwent this anastomosis. In the early 20th century, retrograde cholangitis tended to cause chronic inflammation if duodenal papilla function was not preserved[10,11]. The suboptimal nature of this approach resulted in attempts to preserve papilla function and to develop alternatives for addressing bile duct defects and injury. Chronic inflammation caused by abnormal pancreatic-bile duct junctions, intrahepatic stones[12,13], and exposure to organic solvents from the printing industry is considered a high-risk factor for cholangiocarcinoma[14]. Therefore, the development of BDS has emerged as a critical, unmet need. To date, various alternatives, including autologous tissue[10,15-18], non-bioabsorbable[19-23], bioabsorbable materials[24-28], and decellularized tissue[29,30], have been investigated. Nevertheless, BDSs with widespread clinical applications have not yet been developed. In this review, we discuss potential factors underpinning the failure to develop clinically usable products despite efforts to develop BDSs for more than a century. Furthermore, we highlight the types of BDSs that may be clinically applied in the near future.

MATERIALS AND METHODS

We searched the PubMed electronic database to identify studies conducted to develop bile duct alternatives until December 2021 and identified studies in English. The following search items for the data relevant to "why has a product that can replace bile ducts not been developed?" were included: "bile duct alternative", "bile duct substitute", "bile duct regeneration", "biliary alternative", "extrahepatic bile duct", "biliary regeneration", and "bile duct reconstruction". Studies using large animals such as dogs, pigs, and goats were included, whereas studies using small animals such as rats and mice were excluded. To evaluate the efficacy of the BDS, the "type of substitute", "shape and length of substitute", "method of reconstruction of the bile duct by substitute", and "observation period" were included as search terms. The items to be examined were "presence or absence of regeneration process", "localization of regenerated bile duct to substitute", "number of large animals that could be sacrificed and killed intentionally", and "cause of narrowing of substitute". We also cited high-quality articles in *Reference Citation Analysis* (https://www.referencecitationanalysis.com).

For studies in which the items could be determined from the abstract or text, the number of experimental large animals used was eight or more. The full text was reviewed by two researchers (Miyazawa M, Takashima J). In each of these studies, the cases in which BDS transplantation was successful were as follows: These cases were sacrificed as planned before BDS transplantation, no stenosis was observed at the anastomotic site between the BDS transplantation site and the natural bile duct, and there was no

liver dysfunction after BDS transplantation.

Animal type

In small animals, such as rats, jaundice is unlikely to occur even if the extrahepatic bile duct is narrowed, and liver dysfunction may be difficult to evaluate. As such, BDS transplantation may be difficult[31]. Accordingly, only large-animal studies were considered.

Size of BDS

If the length of the BDS implantation segment was less than 1 cm, tissues such as the omentum may migrate around it after inserting the T-tube into the defective bile duct segment[32]. Therefore, BDSs ≤ 1 cm and > 1 cm in length were considered separately. For the same reason, patch-like or circular implantation of the BDS was examined separately. Regarding the implantation method, the site of BDS implantation (between the common bile duct or between the common bile duct and intestine) was examined separately because it affects the patency of the BDS lumen.

Observation period after BDS implantation

Early after BDS transplantation, stenosis of the BDS may not occur in the event of retrograde cholangitis or severe inflammation at the alternative transplant site. After chronic inflammation, the bile duct becomes narrowed due to the gradual hyperplasia of connective tissue around the substitute[33]. After stent insertion into the BDS, bile may flow through the stent and a bile plug may not be formed in the BDS in the early stage of BDS transplantation[34]. As anastomotic stenosis was considered less likely to occur when a stent was inserted, the observation period after BDS transplantation was included in the examination items.

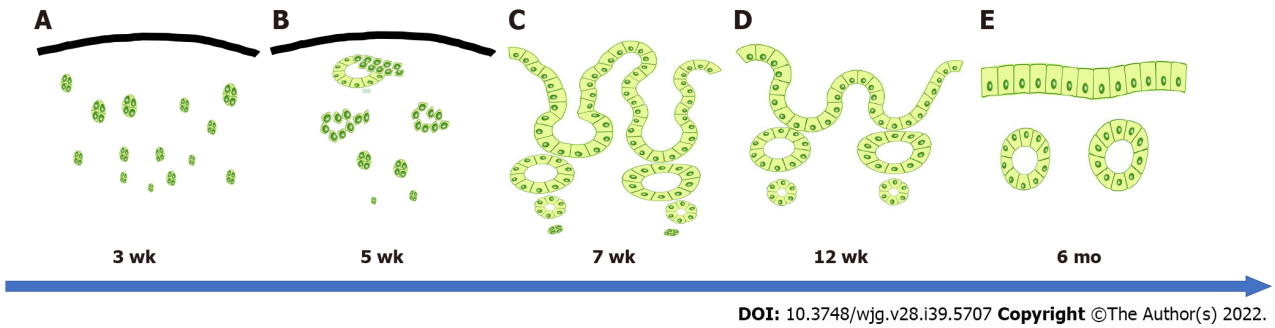
Bile duct regeneration

After the formation of connective tissue in the shape of the bile duct, the BDS lumen does not become completely stenotic early after BDS transplantation, even if bile duct regeneration does not occur and bile remains in the lumen. However, stenosis tends to occur after a prolonged period[35]. Tissue regeneration in the defective bile duct area occurs due to wound healing[35]. The mature bile duct takes time (3 mo or more) to regenerate from bile duct stem cells[25,36,37] (Figure 1). Therefore, to examine the effectiveness of BDS for inducing bile duct regeneration, histological images of bile duct regeneration at the BDS transplantation site were included in the examination. If the study did not report neo-bile duct regeneration and the histology was similar to that of the native bile duct, the tissue was excluded from evaluation. The histology of the anastomotic site between the BDS and native bile duct was examined because the bile duct epithelium is continuous at the anastomotic site if stenosis of the anastomotic site does not occur[38].

Localization of bile duct regeneration with respect to BDS implants

We did not identify any reports of bile duct regeneration on the inner surface of the T-tube when it was placed in the injured part of the bile duct. This suggests that the bile duct does not regenerate on the inner surface of non-bioabsorbable BDSs. However, it is important from the viewpoint of wound healing whether the localization of the regenerated bile duct is the outer surface of the BDS, the part of the BDS itself, or the inner surface of the BDS (only the bile passage surface). For these reasons, the site where the regenerated bile duct regenerates was included in the examination items for the BDS transplantation site. When the localization of bile duct regeneration was not specified, it was judged from the BDS implantation site and bile passage position in the paper.

Causes of stenosis



Narrowing of the anastomotic site between the BDS and the native bile duct or the BDS lumen was evaluated as a separate cause of wound healing. We also examined the stenotic tissue type. For BDS lumen and anastomotic site stenosis, scar contraction was considered to occur over a prolonged period if granulation or connective tissue growth was reported[35,39,40].

BDS REPORTED TO DATE

The literature search enabled the classification of BDSs into four categories: Autologous tissues[10,15-18], non-bioabsorbable materials[19-23], bioabsorbable materials[24-28], and others (decellularized tissues[29,30], structures made with 3D printers[41,42], *etc.*).

BDS using autologous tissue

Tissues with a similar morphology to that of the extrahepatic bile duct and lumen have been investigated as BDSs. In practice, arteries[43], veins[15,17-19,44], ureters[45], skin[46], and jejunum[16] have been used as grafts. Due to the thickness of the extrahepatic bile duct and wall, the femoral vein was

DOI: 10.3748/wjg.v28.i39.5707 **Copyright** ©The Author(s) 2022.

Figure 1 Ideal bile duct regeneration process. A: Bile duct regeneration at approximately 3 wk. Numerous cell masses appear in the stroma that are thought to form peribiliary glands; B: Bile duct regeneration at approximately 5 wk. A ring-shaped peribiliary gland-like structure is observed, in which cell masses that are thought to form peribiliary glands are fused; C: Bile duct regeneration at approximately 7 wk. Numerous bile duct-attached glandular structures are observed on the bile passage surface, and the epithelial surface exhibits a high papillary morphology; D: Bile duct regeneration at approximately 12 wk. The number of peribiliary glands on the bile passage surface is decreased, the peribiliary glands become fused, and the epithelial surface becomes more even; E: Approximately 6 mo after bile duct regeneration. Similar to the native bile duct, the epithelial surface becomes a single layer of cubic columnar epithelium.

often used. In BDSs using these autologous tissues, necrosis of the substitute in the early stage of transplantation and obstruction due to attachment of the bile plug to the substitute in the middle stage of transplantation were common[10,17,18,44,47]. In the long term, scar contraction occurs due to the growth of connective tissue around the substitute and at the anastomotic site[10,17-19,44]. To address these issues, attempts have been made to wrap the omentum around the substitute to supply blood flow or to use stents and cuffs to prevent obstruction of the BDS lumen and anastomotic site[17,48,49]. As the BDS did not regenerate to the extent of the native bile duct, few BDSs were successful, and no clinically usable product was developed[48,49]. The localization of neo-bile ducts to the BDS, which attempted to promote bile duct regeneration, formed a part of the autologous tissue itself.

The most commonly used species in these studies was dog. Pearce *et al*[10] investigated autologous alternative veins as a BDS and concluded that 1 in 32 successful cases over 3 mo was insufficient for the use of autologous tissue as a BDS. A study by Dunphy and Stephens[19] using large animals (44 sheep and 8 pigs) evaluated autologous arteries, veins, and homozygous arteries. Only sheep that received autologous arteries as a BDS survived for 6 mo or more, but bile duct dilation on the liver side was observed. Myers *et al*[18] conducted a circular transplantation experiment using autologous bile ducts, arteries, veins, and genomic grafts to treat bile duct defects in 28 dogs. All homografts were rejected, and the dogs that received transplants died within 13 d.

Even in transplantations using autologous tissue, histological assessment revealed that the bile duct epithelium did not regenerate on the epithelial surface, fibrous connective tissue was increased on the epithelial surface, and the BDS transplantation site became stenotic. The authors concluded that self-organization is not possible in BDS. In 2009, Palmes *et al*[48] reported a high success rate of transplantation of the external jugular vein and a bioabsorbable stent as a BDS in pigs. However, histological changes in the bile ducts of autologous veins have not been reported (Table 1).

Due to the lack of blood supply in autologous tissue BDSs, the tissue becomes necrotic, and the anastomotic site is scar-contracted. A BDS capable of allowing bile to flow freely into the duodenum over a prolonged period has not yet been developed. It is unlikely that autologous tissue will resemble the native bile duct in the context of wound healing[40,50,51]. Stenting through the anastomotic site was effective in preventing narrowing[17,48,49]. High success rates have been reported when bioabsorbable stents are placed in the venous lumen; however, it is unclear how autologous venous tissue is induced for good bile duct regeneration. These findings suggested that autologous tissue cannot be used as a BDS.

BDS using non-bioabsorbable material

Since the 1930s, polyvinyl sponge[20], polytetrafluorethylene[22,23], Teflon[19,52], Dacron[53], and polyethylene[54,55] have been used as non-bioabsorbable BDS materials. These alternatives were used experimentally as patches or rings, but most studies reported high rejection rates early in transplantation and varying degrees of cholangitis, narrowing of the alternative lumen, and stenosis of the anastomotic site with the native bile duct[19,27,28]. Although partial success has been reported, the bile duct epithelium failed to regenerate on either the medial side (bile passage surface) or lateral side of these alternatives[29,30]. As a result, the perimeter of these BDSs was covered with fibrous connective tissue, and the luminal surface was clogged with bile plugs[19-22]. This resulted in stenosis of the anastomosis with the native bile duct, which prevented bile passage. As such, research on cyclic BDS made solely from non-bioabsorbable materials has ceased.

Sherman *et al*[21] transplanted a BDS made from acrylamide into dogs. In the stented group, 7 of the 33 cases were successful over 3 mo. However, bile duct regeneration has not been reported. Bergan *et al*

Table 1 Bile duct substitute using autologous tissue

Ref.	Journal	Substitute (*n*)	Stent (*n*)	Animal type (*n*)	Size of BDS (cm)	Method of reconstruction of bile duct by BDS (*n*)	Observation period after implantation	Localization of regenerated bile duct	Causes of stenosis	Note (planned sacrificial death and epithelialization)
Shea and Hubay[15], 1948	*Ann Surg*	Femoral vein (21)	Vitallium tube	Dog (21)	Ring (1.5)	CBC (21)	Maximum 208 d	BDS itself	Necrosis of BDS itself, narrowing of the BDS lumen, and narrowing of the anastomosis with the native bile duct	Although 14 out of 21 dogs were intentionally killed, the tissue of the regenerated bile duct was shown only as a result, and the process of bile duct regeneration was not demonstrated
Kirby and Fitts[16], 1950	*Arch Surg* (1920)	Jejunum (9)	T-tube	Dog (9)	Jejunum (2.5)	GBC (5); CBC (4)	Maximum 13 mo	BDS itself	BDS stenosis was not observed when the T-tube was inserted	Seven out of nine dogs were intentionally killed; however, no epithelial regeneration was observed at the anastomotic site. The procedure was too complicated
Pearce *et al* [10], 1951	*Ann Surg*	Femoral vein (32)	Lord and blakemore tube	Dog (32)	Ring (1.0)	CBC (10); CBJ (20); GBC (2)	Maximum 6 mo	BDS itself	Necrosis of autologous tissue, narrowing of the lumen of autologous tissue, narrowing of the anastomosis with the native bile duct, necrosis of BDS itself, narrowing of the BDS lumen, and narrowing of the anastomosis with the native bile duct	Only 1 of the 32 dogs survived for more than 6 mo. It was investigated in 32 dogs; however, in the end, fibrosis of the vein and stenosis of the anastomotic site with the native site occurred, and bile duct epithelial regeneration was not observed. It was concluded that the vein was not suitable for BDS
Ulin *et al* [17], 1955	*Ann Surg*	Vascularised jugular vein (10)	Polyethylene tube	Dog (10)	Ring (2.0-5.0)	CBC (10)	Maximum 10 mo	BDS itself	Necrosis of autologous tissue, narrowing of the lumen of autologous tissue, narrowing of the anastomosis with the native bile duct, necrosis of BDS itself, narrowing of the lumen of BDS, and narrowing of the anastomosis with the native bile duct	The omentum was used to maintain blood flow to the BDS, but in some cases, it functioned as a BDS only during the period when the stent was in place (6 out of 10 dogs). Bile duct regeneration process was not studied. No regeneration of the bile duct epithelium was observed
Myers *et al* [18], 1960	*Ann Surg*	Femoral vein and artery, bile duct (17), and homologous bile duct (6)	Polyethylene tube	Dog (28)	Ring (unknown)	CBC (23)	Maximum 449 d	BDS itself	Necrosis of autologous tissue, narrowing of the lumen of autologous tissue, narrowing of the anastomosis with the native bile duct, necrosis of BDS itself, narrowing of the BDS lumen, and narrowing of the anastomosis with the native bile duct	BDS using autologous veins, arteries, or allogeneic arteries also narrowed shortly after transplantation. No bile duct epithelial regeneration was observed
Dunphy and Stephens [19], 1962	*Ann Surg*	Autologous vein and artery (20), and homologous artery (32)	T-tube	Goat (44), dog (8)	Ring (1.0)	CBC (52)	Maximum 9 mo	BDS itself	Necrosis of autologous tissue, narrowing of the lumen of autologous tissue, narrowing of the anastomosis with the native bile duct, necrosis of BDS itself, narrowing of the BDS lumen, and narrowing of the anastomosis	In an experiment using autologous veins and T-tube as BDS, 2 dogs survived for more than 6 mo; however, both dogs demonstrated dilation of the bile duct on the liver side. No bile duct epithelial regeneration was observed

									with the native bile duct	
Belzer *et al* [44], 1965	*Ann Surg*	Femoral vein (20)	T-tube	Goat (20)	Patch (3.0-4.0)	Patch (20)	Maximum 11 mo	BDS itself	Necrosis of autologous tissue, narrowing of the lumen of autologous tissue, narrowing of the anastomosis with the native bile duct, necrosis of BDS itself, narrowing of the BDS lumen, and narrowing of the anastomosis with the native bile duct	Only 3 out of 20 dogs were intentionally killed, but no good bile duct epithelial regeneration was observed
Lindenauer and Child [47], 1966	*Ann Surg*	Vascularized jugular vein (14)	(-)	Dog (14)	Ring (unknown)	CBC (14)	Maximum 18 mo	BDS itself	The omentum increased blood flow to the BDS; however, it resulted in scar contraction. Necrosis of BDS itself, narrowing of the BDS lumen, and narrowing of the anastomosis with the native bile duct	No dog survived for more than 3.5 mo, although the omentum was used to maintain BDS blood flow
Palmes *et al* [48], 2009	*J Invest Surg*	External jugular vein (18)	PLA stent (12)	Pig (18)	Ring (2.0)	CBC (18)	Maximum 6 mo	BDS itself	When the stent was not inserted, the BDS was necrotic. When the stent was inserted, the BDS lumen was preserved, but eventually, it became necrotic and narrowed	Of the 18 dogs, all 12 stented dogs were deliberately killed. However, the process of regeneration of veins into the bile duct was not reported
Liang *et al* [49], 2012	*World J Gastroenterol*	Omentum (8)	Bioabsorbable stent	Pig (8)	Ring (0.5-1.0)	CBC (8)	Maximum 4 mo	BDS itself	The BDS lumen was preserved when the stent was inserted	The bile duct defect was repaired with an omentum, which was similar to inserting a T-tube into the defect. Bile duct regeneration was also poorly demonstrated

[20] attached blood vessels to a BDS composed of polyvinyl sponge in dogs. Of the 12 dogs examined, 4 survived for more than 60 d, but the transplant was ultimately unsuccessful due to the formation of bile plugs inside the substitute. Dunphy and Stephens[19] examined Teflon as a BDS in four dogs and four sheep, but all failed because of severe rejection early in the transplantation. Recently, Gómez *et al*[23] investigated Gore-Tex as a BDS in 12 dogs and reported that 11 cases were successful. However, BDS was surrounded by strong fibrotic tissue and exhibited narrowing, indicating that it was not clinically usable in the long term (Table 2).

Currently, cyclic non-absorbable materials, such as polytetrafluoroethylene, are used clinically as artificial blood vessels. Anticoagulants are used to prevent blood from coagulating in artificial blood vessels when the blood vessel diameter is small[56]. Compared to blood, bile is more viscous and has a slower flow velocity. The bile duct diameter is similar to that of small blood vessels[57]. As such, this material may be unsuitable because the BDS lumen may be blocked by a bile plug[21,22]. In addition, the epithelium does not regenerate continuously at the anastomotic site between the BDS and native bile duct, scar contraction occurs in the long term after transplantation[38]. A bile plug may form if a tubular stent is inserted to secure bile passage, even when using non-bioabsorbable materials. This phenomenon

is similar to current endoscopic stenting for bile duct stenosis[58,59].

BDS using bioabsorbable material

Due to the failure to develop clinically applicable BDSs made from autologous tissue or non-bioabsorbable materials, increasing focus has been placed on bioabsorbable materials as BDSs. This concept is based on the technique of tissue engineering proposed by Langer and Vacanti[60] in 1993 for bile duct regeneration. The complex formed by the bioabsorbable material and cells attached to the material is absorbed in the body while the bioabsorbable material acts as a scaffold to maintain the environment and shape of the organ[60,61]. Concurrently, the cells attached to the scaffold regenerate the target organ. Natural polymers (particularly collagen)[24,27,28] and engineered synthetic polymers [25,26,62-64] have been investigated as BDSs based on bioabsorbable materials.

BDS using natural polymers

Alternative natural polymers to collagen have been investigated, such as the small intestinal submucosa (SIS) using porcine submucosa. Using this SIS, Rosen *et al*[24] reported that 9 cases of patch-like transplantation and 6 cases of circular transplantation were performed as BDS, and 13 of them were successful. However, bile duct regeneration was not observed as a pathological finding. On the other hand, in another study using SIS as a BDS, scar contraction was high[65]. As such, this material has not been clinically applied as a BDS (Table 3).

Nakashima *et al*[66] reported the successful use of collagen as a BDS in consideration of cell adhesion. However, collagen was attached to a non-bioabsorbable material (polypropylene) to maintain the hardness of this BDS; therefore, it may not be a strictly bioabsorbable BDS. The BDS scaffold was sutured to the native bile duct. As bile passes through the lumen, the scaffold must maintain an annular shape and therefore a degree of hardness. Collagen tends to lose its shape when immersed in water[66, 67]. Collagen-based BDSs require hardness in other substances to maintain the scaffold hardness, resulting in an absorption period longer than several months. For this reason, SIS uses collagen and submucosal tissue to maintain hardness[24].

To promote bile duct regeneration within the bioabsorbable material itself, the period of *in vivo* absorption of the bioabsorbable material is important for suppressing scar contraction. In the case of artificial skin using collagen for skin regeneration, it has been reported that the half-life of the bioabsorbable material, which most strongly suppresses scar contraction, is approximately 14 d[67]. If a BDS made of a bioabsorbable material has a half-life of 3-4 wk or more, scar contraction may be high. When bioabsorbable materials other than the skin are used as alternatives for bile duct regeneration, the absorption period of such materials must also be considered, but this is not the case for SIS[24].

In collagen-based BDSs, the density of the material ligand is important for cell adhesion to promote bile duct regeneration[68]. However, there is a paucity of research in this area. If attempts are made for bile duct regeneration within the bioabsorbable material itself, scar contraction of the BDS part cannot be suppressed after transplantation unless these points are taken into consideration.

BDS using synthetic polymers

BDSs based on synthetic polymers are predominantly composed of polyglycolic acid (PGA)[26] and polycaprolactone[24,62], BDSs produced using PGA fibers may fail to maintain their radial shape. In many studies, the major axis of the bile duct has been replaced by approximately 1 cm. The absorption period of PGA is approximately 3 mo; as such, chronic inflammation occurs, and bile duct regeneration occurs at the implanted site. As such, attempts to regenerate the bile duct epithelium on the inner surface (bile passage surface) of this BDS eventually cause scar contraction similar to that of non-bioabsorbable BDS, and previous efforts have been unsuccessful[24,61].

Studies employing polycaprolactone-based BDSs have reported good bile duct regeneration outside the BDS implant. The material in these studies comprised a 50:50 copolymer of lactic acid and caprolactone, which was reinforced with latticed PGA fibers to facilitate suturing[25]. Generally, the absorption period is 6-8 wk, and the material becomes vulnerable *in vivo* for approximately 3 wk. After the BDS becomes fragile and sheds into the duodenum, a bile duct thicker than the outer circumference of the BDS regenerates outside the BDS. Cells migrating to the BDS as a foreign body reaction may promote bile duct regeneration[25]. Previous studies have reported good results, including BDS experiments in infectious reservoirs[69]. The occurrence of bile duct regeneration on the outside of the BDS resembles bile duct regeneration after insertion of a T-tube into a defective bile duct followed by T-tube removal (Table 3).

As BDSs using synthetic polymers can be engineered, the period of absorption in the body can be adjusted[70]. However, if the BDS is hard to maintain the shape of the bile duct, the absorption period may be prolonged. As BDS results in longer chronic inflammation due to a foreign body reaction, the results are likely to be similar to those of non-bioabsorbable materials. In contrast, if the absorption period is too short, the BDS transplantation site becomes fragile and is destroyed after transplantation. Bile may flow out of the BDS transplantation site, making this material unsuitable for BDS. With regard to cell adhesion, the scaffold itself (for example, PGA only) has lower cell adhesion compared to collagen-based scaffolds owing to the lack of receptors for cell adhesion[38]. Therefore, to regenerate the scaffold itself within the bile duct, materials in which receptors are added to the scaffold have been investigated[38]. Failure of the bile duct to regenerate in the scaffold part while being absorbed prevents clinical application as a BDS; hence, these materials remain in the development stage.

BDS made of other materials

In recent years, attempts have been made to utilize decellularized tissues as BDSs because of the lack of an immune reaction when transplanted into a living organism[29,30]. The use of decellularized tissues as scaffolds for liver regeneration has been investigated. The bile was reported to drain into the duodenum as a tube for a prolonged period and functioned while the stent was inserted. However, reports of long-term bile duct regeneration and function after stent removal are lacking.

Scaffolds of the same shape as that of the extrahepatic bile duct have been produced using 3D printing[41,42]. The extrahepatic bile duct has been reported to regenerate in a ring shape, but no

studies to date have examined bile duct regeneration using these BDSs. Furthermore, there have been efforts to develop an actual bile duct as an organoid *in vitro* for transplantation[70]. However, it has not been possible to produce organoids of a certain length in the longitudinal direction for clinical use and with a length that can be sutured.

FACTORS TO CONSIDER FOR BDS DEVELOPMENT

Below, we discuss the factors that should be considered in the development of clinically applicable BDSs.

Bile duct wound healing

Bile duct regeneration must occur concurrently with wound healing[40,50,51]. Notably, the natural course of wound healing involves scar contraction. Therefore, if the BDS does not reduce scar contraction, the migrating cell mass results in scar contraction and lumen narrowing after removal of the BDS or decomposition and absorption[35,51]. For the BDS to promote bile duct regeneration, the BDS implant must be guided into the regeneration process while maintaining the shape of the bile duct rather than increasing scarring of the cell mass[40]. As such, which allows the cell mass that regenerates the bile duct to maintain the shape of the bile duct when the BDS is absorbed or removed.

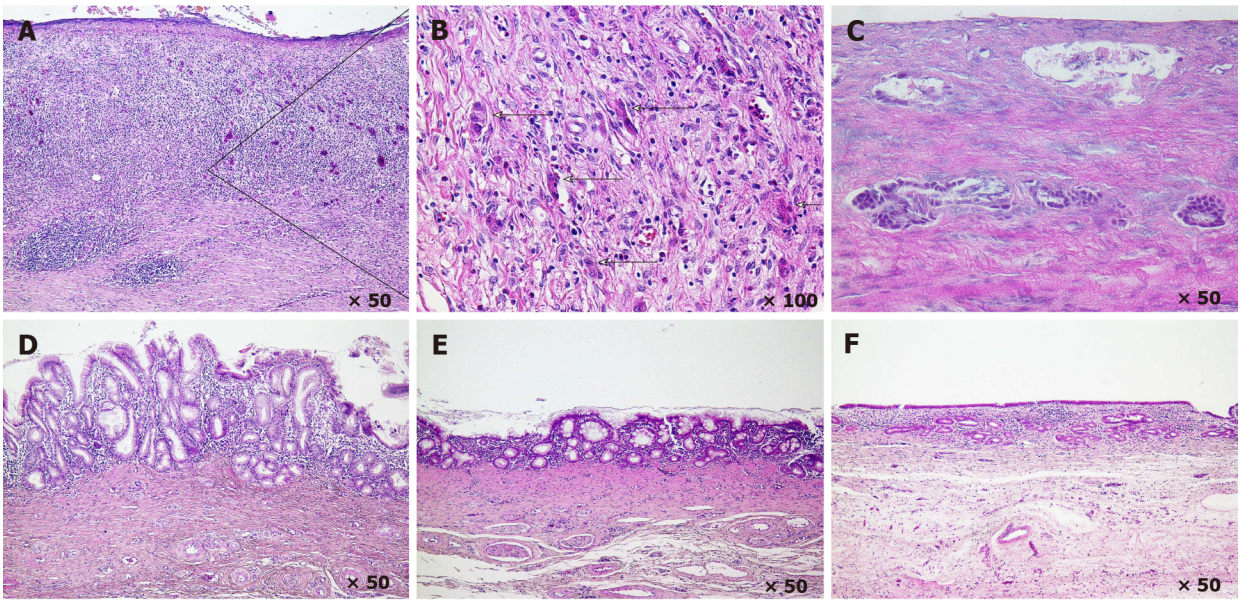
A BDS made of a non-bioabsorbable material that has been present in the body for a prolonged period retains its shape until the BDS is removed, but the lumen is prone to clogging by bile plugs[20-22]. Further, the anastomotic site with the native bile duct will be narrowed due to connective tissue growth[50,51]. Current bile duct regeneration methods using BDSs suggest that after the cell mass gathers around the foreign body and the BDS forms the shape of the bile duct, the cell mass regenerates as a bile duct after BDS removal[25]. If the BDS cannot maintain the shape of the bile duct, a stent may be used instead.

Studies have demonstrated that bone marrow-derived and adipose-derived cells are effective in suppressing scar contraction[72,73]. In addition, it has been reported that fibrosis is suppressed by controlling the function of macrophages that have migrated to the injured region during the remodeling period of wound healing[40,51]. However, methods for reliably suppressing scar contraction have yet to be developed[72,73]. For bile duct regeneration and retention of normal tissue structure, it is necessary for the dynamics and function of multiple types of cells that have migrated around the BDS to be tightly regulated and to reduce scar contraction.

Bile properties

Compared to blood, bile is more viscous and has a slower velocity[57]. If a BDS is not absorbed in the body, a bile plug may adhere to the BDS at the anastomosis site with the lumen or native bile duct. This results in impaired bile flow and narrowing of the lumen. In studies using Teflon (a non-bioabsorbable material) as a BDS, anticoagulants are often used even for blood. Therefore, further measures are required to prevent bile plug formation. This resembles the insertion of metal or tube stents for the treatment of bile duct stenosis, which often clogs the stent with a bile plug[58,59].

Bile duct regeneration



The extrahepatic bile duct is a component of the digestive tract, and the mature bile duct is regenerated *via* a regeneration process similar to that of the stomach and intestine[36,74,75]. In pigs, it takes approximately 6 mo for bile duct stem/progenitor cells to undergo regeneration to form a mature bile duct similar to the native bile duct. Furthermore, the bile duct epithelium is covered with a layer of cubic columnar epithelial cells[25] (Figures 1 and 2). Therefore, it is controversial in studies that do not show the process of bile duct regeneration, even if BDS transplantation is reported to be successful. For example, in the subsequent regeneration of the T-tube insertion site, the portion of the hole with the T-tube inserted reproduced well without any narrowing. This suggests that small partial bile duct regeneration often occurs without stenosis even if a patch of omentum or blood vessel is applied externally[76]. However, if bile duct defects are extensive and the BDS is placed between the native bile ducts, the cell mass must undergo substantial regeneration from the early stage of bile duct regeneration to regenerate the bile duct without stenosis. Studies have demonstrated that cells attached to the bioabsorbable material regenerate the bile ducts, but the mechanisms by which these cells undergo bile duct regeneration in the presence of the bioabsorbable material remain unclear[24].

Immature cells attached to the scaffold migrate using the scaffold of the BDS as a foreign substance [40,50]. These cell masses first form an assembly of the peribiliary gland[25,74,75]. When good bile duct regeneration is achieved approximately 2 mo after the initial stage of regeneration, a tall papillary shape is formed on the inner surface through which bile passes. In pigs, after approximately 3 mo of bile duct regeneration, these peribiliary glands fuse and the epithelial cells become shorter; within approximately 6 mo, these structures mature into bile ducts that are similar to native bile ducts (Figures 1 and 2)[25].

With regard to the mechanisms of bile duct regeneration in the injured part of the bile duct, activated bile duct cells mobilize immune cells, vascular cells, and mesenchymal cells to the inflamed region as a ductular reaction during bile duct ligation and inflammation[77]. This process is involved in regeneration of the inflamed area. Inflammation-activated bile duct cells secrete chemokines, cytokines, and angiogenic factors, which are involved in wound healing[35,50,51]. Furthermore, reactive ductal cells generated *via* complex mechanisms depend on the nature and intensity of bile duct injury[35,50,51]. However, further investigations of bile duct regeneration mechanisms in various bile duct injuries, such as circular transplantation of BDS, are required to develop effective BDSs.

Regeneration of anastomotic site

When the anastomosis between a BDS and the native bile duct is narrowed, the flow of bile into the duodenum is obstructed, which limits the clinical application of the BDS. In a normal gastrointestinal anastomosis, a large anastomotic hole and fixed shape that does not experience deformation are

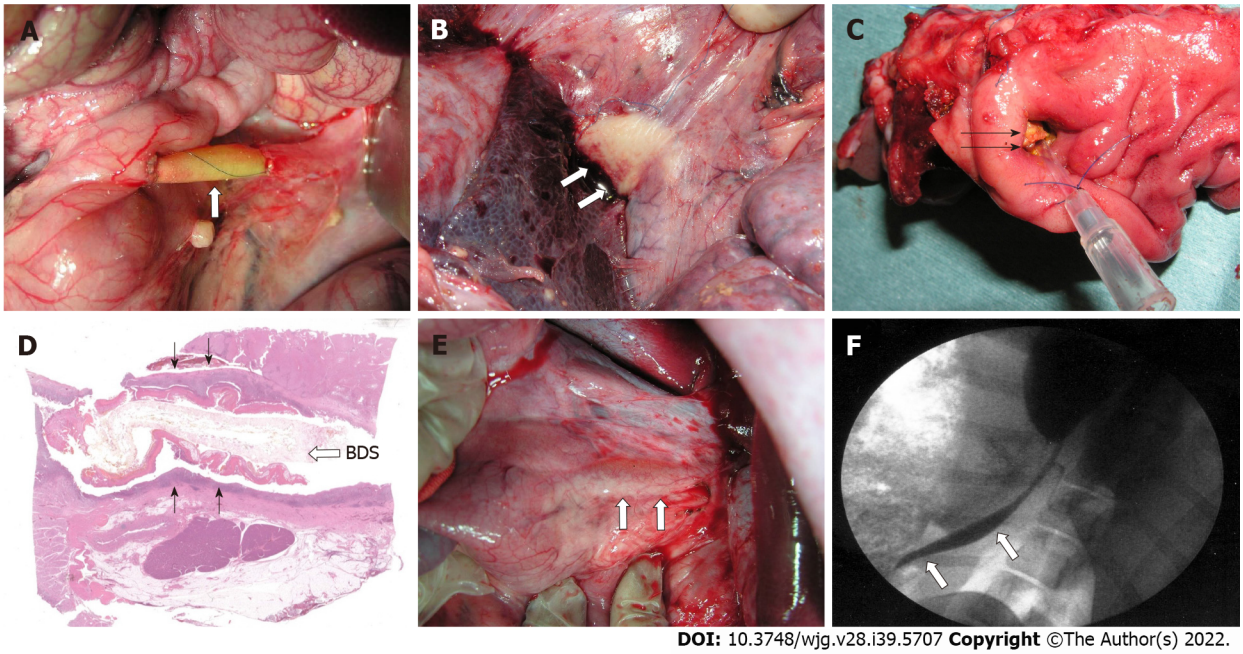
Figure 2 Histology of bile duct regeneration on the outside of the short-term absorption type bile duct substitute. A and B: At 3 wk after bile duct substitute (BDS) implantation, a cell population in the stroma that may comprise the origin of the peribiliary gland is observed; C: At 5 wk after BDS implantation, a ring-shaped biliary gland-like structure is observed in which cell masses that are thought to form peribiliary glands are fused; D: At 7 wk after BDS implantation, many bile duct appendages are observed on the bile passage surface, and the epithelial surface exhibits a high papillary morphology; E: At 12 wk after BDS implantation, the number of peribiliary gland on the bile passage surface is decreased, the appendages begin to fuse, and the epithelial surface becomes more even; F: At 6 mo after BDS implantation, the epithelial surface becomes a single layer of cubic columnar epithelium, similar to the native bile duct.

prerequisites to prevent narrowing of the anastomosis[78]. Therefore, in surgical practice, a stent is inserted when the anastomotic hole is small[78]. For BDSs made from non-bioabsorbable materials, the extrahepatic bile duct is thin; hence, the anastomotic site with the native bile duct is likely to be narrowed by connective tissue in the absence of stent insertion. To prevent anastomotic stenosis between the BDS and the native bile duct, it may be necessary to insert a stent through the anastomotic site to maintain its shape. Even for BDSs made from bioabsorbable materials, it may be difficult to maintain the shape of the anastomotic site and stent insertion is recommended to prevent stenosis.

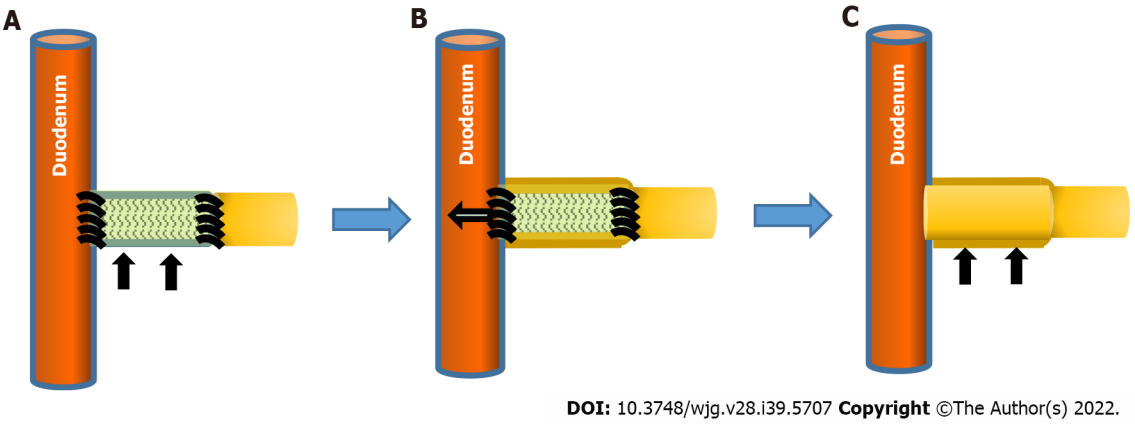
Localization of bile duct regeneration to BDS



Three regenerative localizations of the neo-bile duct with respect to the BDS have been identified: Outside the BDS, within part of the BDS itself, and inside the BDS (bile passage surface). If the BDS is present for a prolonged period, chronic inflammation will persist[50,51]. As such, it is unlikely that the cell mass that has migrated due to detection of the BDS as a foreign substance will regenerate into a structure similar to the native bile duct at the site of the BDS in the context of wound healing[20-22,51].

If the BDS is present for a prolonged period, the bile duct does not regenerate outside the BDS or as part of the BDS itself. Bile duct stem cells do not appear to adhere to the luminal surface of non-living non-absorbable materials, such as T-tubes. Given that the bile duct does not tend to narrow after T-tube removal, a cell mass that has migrated outside the BDS is formed. In the absence of BDS, the cell mass is exposed to fresh bile and regenerates as a bile duct, which may promote good bile duct regeneration at the BDS transplant site[25] (Figures 3 and 4).

The use of decellularized tissue as a BDS is thought to promote bile duct regeneration by cell adhesion to the luminal surface or inside the scaffold[29,30]. For BDSs made of bioabsorbable materials with a short absorption period, cell clusters contributing to bile duct regeneration migrate to the outside of the BDS and regenerate the bile duct. This bioabsorbable material may become fragile in approximately 3 wk and shed to the duodenal side, after which the cells surrounding the BDS regenerate the bile duct[25] (Figures 3 and 4). Although further research is needed, the extant literature suggests that the cell mass forms a ring-shaped structure more rapidly than during chronic inflammation and subsequently disappears from the site. Collectively, these findings suggest that bioabsorbable materials that induce good bile duct regeneration may be harnessed as effective BDSs.



RESEARCH LIMITATIONS

One study reported that when a stent was placed in the BDS, bile flowed through the stent for a certain period, resulting in a successful BDS. However, the study did not demonstrate bile duct regeneration.

Figure 4 Regeneration of the neo-bile duct outside the short-term absorption type bile duct substitute. A: Bile duct substitute (BDS) (black arrows) is anastomosed to the native extrahepatic bile duct; B: Immature cells attach around the BDS, forming a cylindrical cell mass outside the BDS. The bioabsorbable polymer that comprise BDS becomes fragile in the living body from approximately 3 wk and sheds to the duodenal side; C: After BDS is no longer present at the transplant site, immature cell clusters mature as bile duct cells and the bile ducts are regenerated as tissue (black arrows).

This process is similar to that of stent insertion during the treatment of benign bile duct stenosis. Nevertheless, the alternative portion eventually becomes stenotic and clinically unusable over a prolonged period. Our analysis was unable to identify these issues accurately. Although numerous studies using various BDSs have been conducted, the lack of success highlights the limitations of the field. Moreover, we did not analyze successful cases in small animals or studies using a small number of large animals.

FUTURE PERSPECTIVES

Extant research has provided novel insights into the mechanisms of repair after tissue damage[75]. If the injured area does not undergo normal repair, a high degree of fibrosis will occur in the injured area, resulting in scar formation at the site. For bile duct injuries, the injured area or the BDS implant may

become stenotic. For the regeneration of a bile duct similar to the native bile duct at the injury site, cells that have migrated to the bile duct injury site must suppress scar contraction, similar to the regeneration of other organs. In this regard, it is necessary to create a niche for bile duct regeneration similar to that of the native bile duct[73,75]. In addition, chronic inflammation is associated with prolonged and severe fibrosis, resulting in scar formation. Therefore, a BDS should not remain at the transplantation site for a prolonged period.

Based on these caveats, two methods can be considered for regenerating a bile duct similar to the native bile duct at the BDS transplantation site. The first involves the use of a short-term absorption type of bioabsorbable BDS, in which cells that have migrated to repair bile duct injury (BDS transplantation site) form the shape of the bile duct *via* a foreign body reaction. Ultimately, the BDS will no longer be present at that site and chronic inflammation does not occur (*i.e.*, the bile duct regenerates outside the BDS)[25] (Figure 4). The second method involves bile duct stem/progenitor cells adhering to part of the BDS itself, and wound healing is regulated such that bile duct regeneration progresses well while the BDS is being absorbed. Therefore, it is necessary to develop a method to control wound healing so that the scaffold portion of the decellularized tissue and adhering cells do not cause scar contraction. In summary, bioabsorbable BDSs for bile duct regeneration outside the bile duct constitute a promising development that will be clinically useful in the future.

CONCLUSION

To date, successful BDSs have not been developed. This is predominantly due to poor mechanistic understanding and lack of methods for regulating bile duct wound healing and bile duct regeneration. As an alternative to the extrahepatic bile duct, bioabsorbable materials can be used to form the shape of the bile duct, and the cell mass forming the shape of the bile duct can migrate to the external surface of this structure. Once the cell mass was able to maintain the shape of the bile duct, the BDS acting as a scaffold was removed. The development of BDSs that enable this process will permit the treatment of a wide range of bile duct defects.

ACKNOWLEDGEMENTS

The authors would like to thank Dr. Naoe Akimoto for her excellent technical assistance.

FOOTNOTES

Author contributions: Miyazawa M designed and carried out the data analyses, prepared the figures, and wrote the manuscript; Aikawa M, Takashima J, and Ohnishi S performed data analysis; Ikada Y contributed to the design of the polymer and supervised the project.

Supported by the Japan Society for the Promotion of Science, No. 21K08786.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. Abstract

The novel coronavirus disease 2019 is an infection caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and was declared a global pandemic with more than 500 million reported cases and more than 6 million deaths worldwide to date. Although it has transitioned into the endemic phase in many countries, the mortality rate and overall prognosis of the disease are still abysmal and need further improvement. There has been evidence that shows the significance of SARS-CoV-2-related liver injury. Here, we review the literature on the various spectrum of SARS-CoV-2 infection-induced liver injury and the possible mechanisms of damage to the hepatobiliary system. This review aimed to illustrate the latest understanding regarding SARS-CoV-2-induced liver injury including the high-risk populations, the characteristic clinical manifestations, the possible pathogenic mechanism, the pathological changes, the current suggestions for clinical treatment for various spectrum of populations, and the prognosis of the condition. In conclusion, SARS-CoV-2 patients with a liver injury warrant close monitoring as it is associated with the more severe and poorer outcome of the infection.

Key Words: COVID-19; SARS-CoV-2; Pandemic; Liver injury; Pandemics; Prognosis

Core Tip: There are several reviews in the literature that discuss the pathophysiology, management, and outcomes of liver injury in coronavirus disease 2019 (COVID-19). Here, we reviewed the current understanding on various aspects of COVID-19-related liver injury, including the high-risk populations, the characteristic clinical manifestations, the possible pathogenic mechanism, the pathological changes, the current suggestions for clinical treatment for the spectrum of populations, and the prognosis of the condition.

INTRODUCTION

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is the name given to the newly emerged zoonotic virus that causes coronavirus disease 2019 (COVID-19)[1]. It was first reported in Wuhan, China on December 29, 2019 and was declared a global pandemic on March 11, 2020[2]. SARS-CoV-2 is an enveloped, single-stranded positive-sense RNA genome virus that harbors the largest genome among currently known RNA viruses, with a genome length of around 26 to 32 kb. It has an oval shape and an average size of 100 nm in diameter. Electron microscopy revealed large club-shaped spikes of glycoprotein membrane on the viral surface making the viral particles appear like a typical crown-like shape[3].

COVID-19 is a syndrome with various systemic and respiratory symptoms such as fever, fatigue, dry cough, and breathing difficulties. It can be critical, causing severe pneumonia and cardiorespiratory failure that requires specialized management in intensive care units[4]. SARS-CoV-2 can also affect other systems, namely the nervous system causing headache, anosmia, paresthesia, and altered consciousness[5]. Abnormal liver function parameters are commonly found in patients with SARS-CoV-2 infection, indicating that SARS-COV-2 infection is associated with liver injury and even failure. Apart from that, several studies suggested that liver injury has a significant role in determining the severity and mortality rate of the disease. Considering the ongoing global threat of SARS-CoV-2 infection and the necessity to improve the prognosis of the disease, the treating physicians need to be aware of the association and significance of SARS-CoV-2 infection-related liver injury not only for the severity of the disease but also for the mortality rate and prognosis as a whole. Therefore, this review aimed to elucidate the importance of hepatobiliary involvement in SARS-CoV-2 infections and provide helpful information for managing the condition and improving the overall prognosis of the disease.

HIGH RISK POPULATIONS OF SARS-COV-2-INDUCED LIVER INJURY

Since the beginning of the pandemic, it was reported that patients with severe SARS-CoV-2 infection tended to develop liver injury compared to mild infection. Cai *et al*[6] reported that male patients of older age and higher body mass index have a higher tendency to develop liver injury during the course of the disease. A similar finding was seen in a study on 79 non-hospitalized SARS-CoV-2 patients by Xie *et al*[7], who reported that liver injury was more common among male patients. The authors also said that patients with an underlying severe chronic lung disease have a higher rate of liver injury, which was also reported by Zhang *et al*[8]. Cai *et al*[6] and Singh and Khan[9] both found that liver injury was more common among patients with underlying liver disease. According to Da *et al*[10], the common etiology of chronic liver disease that is prone to developing worsening liver injury during the infection is alcohol-related liver disease. Patients with nonalcoholic fatty liver disease and nonalcoholic steatohepatitis are usually associated with additional metabolic risk factors, such as obesity, that can increase the susceptibility to the infection and is commonly associated with a more severe presentation[11].

There has been significant concern about the increased susceptibility to SARS-CoV-2 infection among solid organ transplant recipients. In a systematic review by Piedade and Pereira[12], patients with liver transplant were not associated with an increased risk of SARS-CoV-2 infection. The risk is highly dependent on the sex, age, body mass index, history of hepatocellular carcinoma, and the immunosuppression drug dose of the patient. However, the prevalence of severe infection was higher among liver transplanted patients. A study by Becchetti *et al*[13] found that alterations in liver enzymes among liver transplanted patients with SARS-CoV-2 occurs more commonly among hospitalized patients. In addition, Ali Malekhosseini *et al*[14] showed that the admission rate of liver transplanted patients to the intensive care unit was as high as 33.3%.

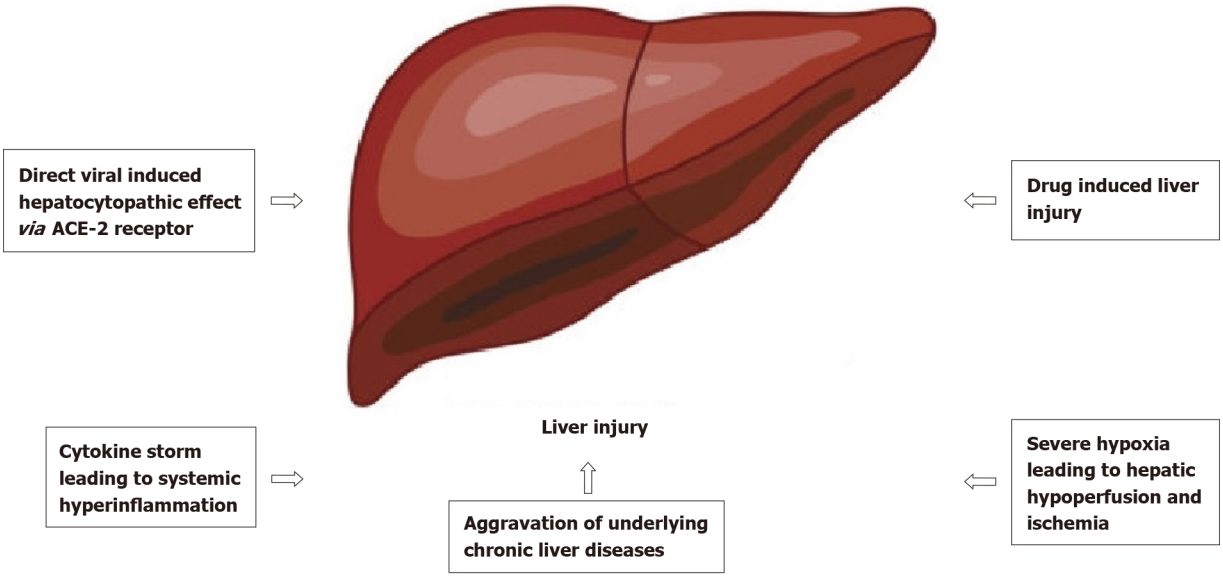
No evidence shows that pregnancy increases susceptibility to SARS-CoV-2-induced liver injury. Nevertheless, a retrospective cohort study involving 122 pregnant patients with confirmed SARS-CoV-2 infection by Can *et al*[15] found that 13.9% developed an abnormal liver function that was generally mild, where most of them were critically ill and had a longer stay in the hospital compared to the normal liver function group.

THE CHARACTERISTIC MANIFESTATIONS OF SARS-COV-2-INDUCED LIVER INJURY

The most common manifestations of SARS-CoV-2 induced liver injury was the elevation of liver enzymes, such as alanine transaminase (ALT), aspartate aminotransferase (AST), gamma-glutamyl transferase, and alkaline phosphatase. In a meta-analysis completed in the first few months of the pandemic by Cai *et al*[6], about 25% of SARS-CoV-2 patients had increased liver enzyme levels, which showed a direct association with the disease activity. The prevalence of increased AST was higher than ALT levels and was positively correlated with the severity of cases, where the level was higher in patients with severe cases[7,8,15]. Lei *et al*[16] reported a significant association between inpatient mortality in SARS-CoV-2 infected patients and liver injury based on liver enzymes, specifically AST elevation.

In a study on 417 SARS-CoV-2 infected patients by Cai *et al*[6], 41.0% of patients had abnormal liver tests, and 5.0% had liver injury upon presentation to the hospital. Throughout hospitalization, 76.3% developed some form of abnormal liver function, and it was high enough to be considered liver injury in 21.5% of patients. A similar finding was reported by Fan *et al*[17], who conducted a retrospective single center study on 148 patients with SARS-CoV-2 infection, where 37.2% had an abnormal liver function at hospital admission. Patients with the abnormal liver function were also found to have an extended hospital stays. A retrospective study of 79 patients with SARS-CoV-2 by Xie *et al*[7] found that patients with an abnormal liver test had an extended stay in the hospital.

Phipps *et al*[18] reported that 21.0% of 2273 patients with SARS-CoV-2 infection had a moderate liver injury, which was defined as elevated liver enzymes two to five times above the upper limit of normal, and 6.4% had severe liver injury, which was defined as liver enzymes more than five times the upper limit of normal. In this study, 69% of the patients with liver injury required intensive care unit care. The reports also mentioned that severe liver injury was associated with elevated inflammation markers, including ferritin and interleukin 6 (IL-6).



PROPOSED PATHOPHYSIOLOGICAL MECHANISM OF SARS-COV-2-INDUCED LIVER INJURY

The exact pathophysiological mechanism of SARS-CoV-2-induced liver injury is still poorly understood, but evidence has shown it to be multifactorial (as shown in Figure 1). One of the factors is direct invasion of SARS-CoV-2, which has been suggested in several studies. The primary receptor for SARS-CoV-2 cellular entry is the angiotensin-converting enzyme 2 (ACE2) receptors, which are found not only in the lung parenchyma but also in other parts of the body[19], such as the brain[5], gastrointestinal tract, biliary tree, and liver epithelia[20]. Zhou *et al*[21] stated that SARS-CoV-2 patients with gastrointestinal symptoms had higher AST and ALT levels, which reflected that ACE2 receptor was expressed within the gastrointestinal tract and the biliary tree. However, even though the ACE2 receptor is expressed more within the biliary tree than the liver parenchyma, most studies showed a predominant pattern of parenchymal liver injury based on the elevated levels of AST and ALT rather than the damage to the bile ducts, which was reflected by increased gamma-glutamyl transferase and alkaline phosphatase[22].

Wu *et al*[23] found that almost 50% of SARS-CoV-2 infected patients who recovered from the disease had persistent virus shedding in their fecal specimens for more than 10 d after viral detection in respiratory tract samples became negative. This may further support the possibility of viral replication in the hepatobiliary system. Similarly, the previous SARS-CoV strains that caused an outbreak from 2002 to 2004 have also been shown to directly injure the liver parenchyma causing lobular inflammation and apoptosis of hepatocytes[24].

Apart from the direct viral-induced hepatocytopathic hypothesis, autoinflammatory mediated injury to the liver is another plausible explanation. Immune dysregulation can occur in severe SARS-CoV-2 infection, which the overactivation of the immune system will lead to systemic hyperinflammation in extreme conditions. This condition is called 'cytokine storm syndrome', which is a phenomenon that will not only cause pulmonary inflammation but also multiorgan involvement, including the nervous system causing encephalitis[25] and peripheral neuritis[26] and the liver causing acute hepatitis and even failure[27,28].

Drug-induced liver injury is also common in SARS-CoV-2 patients, as the medications used to treat the infection can be hepatotoxic. These include lopinavir/ritonavir, remdesivir, tocilizumab, and others

ACE 2: Angiotensin-converting enzyme 2.

[29]. A study of 148 cases of SARS-CoV-2 infected patients in Shanghai by Li *et al*[30] found that the utilization rate of lopinavir/ritonavir among patients with abnormal liver function was higher than the patients with normal liver function. There was no significant difference in the pre-hospital medication between the two groups of patients. The exact mechanism of how lopinavir/ritonavir induces liver injury is still uncertain, but there is evidence that it activates the endoplasmic reticulum stress pathway in the liver and induces hepatocytes apoptosis[31].

Ritonavir is also widely metabolized by the liver through the cytochrome P450 system, where the production of toxic intermediates of any drugs that are metabolized by the system will have the potential of causing liver injury[32]. Tocilizumab, which is an IL-6 inhibitor that is used to reduce overactive inflammation, has been reported to cause drug-induced liver injury and liver failure, which in some cases requires a liver transplant[33]. The exact mechanism is still unknown but may be due to its inhibitory effect on the IL-6 pathway, which is essential for liver regeneration.

SARS-CoV-2 patients with underlying chronic liver diseases are more likely to suffer from liver injury. This may suggest that SARS-CoV-2 infection can aggravate underlying liver diseases. In addition, there is a possibility that the liver damage may be caused by the viral reactivation of existing liver diseases in SARS-CoV-2 infection. Some biological medications such as tocilizumab and baricitinib may cause reactivation of viral hepatitis B, which causes deterioration of liver function[34].

Another simpler hypothesis is that prolonged hypoxia and tissue ischemia in critically ill SARS-CoV-2 patients who suffer from severe pneumonia and acute respiratory distress syndrome can also be one of the mechanisms of liver injury and even failure[35]. This occurs due to prolonged tissue hypoperfusion leading to ischemia, including in the liver. The anaerobic metabolism and lactic acidosis will further depress the cardiorespiratory effort, which will cause the continuation of the vicious circle[36].

PATHOLOGICAL CHANGES IN SARS-COV-2-INDUCED LIVER INJURY

The first post-mortem autopsy on a patient who succumbed to SARS-CoV-2 infection was reported by Xu *et al*[37]. The liver histology showed a moderate degree of microvesicular steatosis with mild lobular and portal vein activity in the study. Ji *et al*[38] reported overactivation of T cells, suggesting viral-induced cytotoxic T cell liver damage. Liu *et al*[39] described various hepatic lesions, including focal lobular necrosis, lobular lymphocytic and monocytic infiltration, ballooning degeneration of liver cells, and sinusoidal congestion with microthrombosis. A study on 48 liver autopsies by Sonzogni *et al*[40] reported focal portal and lobular lymphocytic infiltrates with multiple vascular changes, which are suggestive of hepatic vascular involvement.

Tian *et al*[41] also reported a similar autopsy finding of mild lobular lymphocytic infiltration, with sinusoidal expansion of the central lobule and patchy necrosis in the periportal and centrilobular areas. There was no significant inflammatory cell infiltration around the portal tracts, which is consistent with the mode of acute liver injury. Autopsy reports on 7 SARS-CoV-2 infected patients who died noted multiple platelet-fibrin microthrombi in the hepatic sinusoids[42]. Wang *et al*[43] and Wang *et al*[44]

reported massive hepatic apoptosis, microvesicular steatosis, and inflammatory cell infiltration over the portal systems. In addition, there was a large amount of viral SARS-CoV-2 RNA titers detected in the liver *via* reverse transcriptase-polymerase chain reaction[41,45].

CURRENT MANAGEMENT OF SARS-COV-2-INDUCED LIVER INJURY IN VARIOUS POPULATIONS

Liver injury is a severe complication of SARS-CoV-2 infection and can significantly affect the outcome of the patient. Multiple studies have suggested regular monitoring of liver function parameters in SARS-CoV-2-infected patients. Based on the consensus statement of the American Association for the Study of Liver Diseases[46], it is recommended to consider etiologies outside SARS-CoV-2, such as other viral hepatitis. This has been proven in a case reported by Hambali *et al*[47], where a patient with SARS-CoV-2 infection presented with abnormal liver function and high IL-6, which was due to hepatocellular carcinoma. It is also essential to consider other indirect causes of liver injury such as myositis, cardiac injury, ischemia, and cytokine release syndrome. Patients with liver enzymes more than five times the upper limit of normal may be excluded but not contraindicated from using medications such as remdesivir, tocilizumab, and hydroxychloroquine. Every patient receiving the medications, especially remdesivir and tocilizumab should be regularly monitored for liver biochemical indicators regardless of baseline values. It should not be assumed that patients with autoimmune hepatitis and liver transplantation have a sudden onset of disease or acute cellular rejection without biopsy confirmation. Patients who are immunocompromised or are treated with immunosuppressive drugs should be considered at increased risk for SARS-CoV-2 infection and should be prioritized for testing[46].

SARS-CoV-2-infected patients with ongoing antiviral treatment for hepatitis B or C should be continued, but the initiation of antiviral treatment for hepatitis C may need to be delayed. Patients with an underlying liver disease requiring immunosuppressants should be continued in cases of mild infection, but in moderate to severe infection, the treatment dosage of calcineurin inhibitors should be reduced. The position statement from the European Association for the Study of the Liver-European Society of Clinical Microbiology and Infectious Diseases recommended that the dose of immunosuppressant drugs can be adjusted according to antiviral treatment regimens because the drugs in both regimens will likely interact with each other[48].

THE OUTCOME OF SARS-COV-2-INDUCED LIVER INJURY AND PREDICTORS OF INFECTION SEVERITY

The biomarkers of liver injury were significantly higher in severe cases of SARS-CoV-2 infection. In a meta-analysis by Henry *et al*[49], the severity and mortality rate of SARS-CoV-2 infection was related to the biomarkers of liver functions, which suggests that liver injury has a strong correlation with the severity of SARS-CoV-2 infection. A retrospective study that compared the clinical spectrum between patients with and without liver injury by Xie *et al*[7] found the hospitalization time was significantly longer in patients with liver injury. Lei *et al*[16] reported that abnormal AST in SARS-CoV-2 infection was associated with a higher risk of death during hospitalization than other indicators of liver injury.

Kulkarni *et al*[50] stated that the severity of elevated liver enzyme markers determined the outcome of SARS-CoV-2 infection, with the incidence of liver injury as high as 58%-78% among the death cases. A multicenter study involving 2780 SARS-CoV-2 infected patients by Singh and Khan[9] found that patients with underlying liver disease had higher mortality and hospitalization. In addition to the abnormal liver biochemistry, hypoalbuminemia during the illness is an important indicator of the severity of the SARS-CoV-2 infection. Both studies by Gong *et al*[51] and Huang *et al*[52] showed that hypoalbuminemia was associated with severe infection and an independent risk factor for death.

CONCLUSION

In conclusion, this review illuminated the significance of liver injury in SARS-CoV-2 infection based on the descriptions from the scientific literature. Although it is common and mild in the majority of cases, it is a strong predictor of the severity and a significant risk factor for the mortality rate of the disease, especially if it is associated with male sex, older age, the presence of other comorbidities or underlying chronic liver disease, and in severe respiratory symptoms. Therefore, it is prudent to monitor SARS-CoV-2-infected patients with liver injury and to individualize treatment for patients with an underlying disease who developed liver injury to improve the prognosis by delivering the appropriate management.

Abstract

Letters to the editor can provide useful scientific information and evaluation of published work as well as acting as an additional level of peer review. Furthermore, letters are good reading material, especially if they involve a debate between authors. Finally, letters are relatively short. Therefore, inexperienced career researchers can use such an opportunity to practice putting together a cogent argument. However, it is far from an ideal situation if letters are the only (or main) type of article on which to base an academic career.

Key Words: Correspondence; Journals; Letters to the editor; Medical writing; Peer review; Debate

INTRODUCTION

In this brief overview, three editors express their opinions regarding the scientific value and structure of correspondence sections in journals. Interpretations and suggestions are based on experience and the literature.

THE NEED FOR A CORRESPONDENCE SECTION

We propose that a correspondence section is an essential part of all journals. The reasons are summarised as follows[1-3]: Letters provide an additional level in the peer review process. Essentially, anyone worldwide can comment on a publication. Letters often promote good reading, especially when they involve a debate between authors. This is especially true for journals that have letters openly available. Given that letters are short, they are relatively easy to write. Therefore, they provide a training opportunity for inexperienced authors. Letters do not count as items when the Clarivate journal impact factor is calculated but if they are cited, these citations count. Thus, any citations of a letter may prove helpful for journals. However, we also need to consider that most letters are probably not highly cited.

TIPS ON WRITING A LETTER

A general rule would be a short text (the shorter, the better); brevity is important[1,2]. Therefore, letters need to focus on a restricted number of topics. Most journals impose limits on the word count and number of references. Some journals allow inclusion of a figure or table in a letter[1,2]. However, some editors provide substantial flexibility. Most letters are usually related to publications in the same journal [1-3]. Indeed, some editors do not consider letters unless they relate to material published in their journal. There are broadly two types of letters[1].

Correspondence

This is the commonest type. Such letters aim at one of the following goals[1-3]: (1) To contradict a published finding, for example by citing omitted studies or presenting unpublished results. Letter authors may also wish to highlight methodological or statistical flaws in a published study; (2) To reinterpret a published finding; for example based on additional findings; and (3) To support a published finding; for example on the basis of additional findings, possibly unpublished. This may include indirect evidence (*e.g.*, involving a different gender, ethnicity, species, methodology or related disease).

Early unpublished findings or a case report/series

More rarely, letters present early (unpublished) findings or a case report/series[1,2]. Such letters are miniatures of full studies or case reports. Their main advantages for the authors include rapid publication and the ability to present data on smaller patient series[1,2]. Full papers take longer to be published and processed. This may even take several months and it is possible that during that time more recent and relevant findings become available. For the journals, a potential advantage of full papers (and reviews) is that they are likely to have a higher citation rate than letters.

One final tip for academics and clinicians: avoid exclusively writing letters to the editor without also authoring original or review articles[4]. Indeed, it has already been noted that some authors try to build their career solely on letters published in high-ranking journals[4]. This will be noticed by others and will not be to the authors' benefit.

SUGGESTIONS FOR JOURNAL EDITORS REGARDING MANAGING A CORRESPONDENCE SECTION

We suggest that all journals could benefit from a correspondence section as a peer review "safety net". One of us has resigned as Associate Editor from two journals, because they would not introduce a correspondence section on the grounds that it would require too much editorial work.

A dedicated editor for the correspondence section would be ideal. However, this may be impractical for some journals. One of us has recently experienced a 5-mo delay regarding a decision on a 300-word letter. In our opinion, this represents completely unacceptable standards by the editorial staff of this journal. However, this is probably and hopefully, a rare event.

Letters provide an opportunity for a rapid response by journal editors[1,2]. Based on our experience both as editors and authors, this may be, at least ideally, a matter of a few days. When letters refer to a specific publication, the authors of the latter usually provide a response, pointing out every possible

error.

What to do if authors decline to respond to a letter commenting on their work? There is no simple answer. Possibly, if a letter is highly critical of a study, it may be published together with an editorial message, stating that the authors of the original work declined to respond. It would be unfortunate if some authors avoid criticism just by refusing to respond to valid points raised in a letter. Again, this has happened to us, although the definition of valid comments is based on our knowledge/views. Nevertheless, in our opinion they were obvious. That is why, in similar circumstances, we prefer to underline that the letter containing criticisms will be published, whether the authors of the original work respond or not. Editors must not suppress valid criticism of a publication thinking that it may suggest an oversight of errors by the peer reviewers and editors involved. This is an example of how correspondence provides another valuable level of peer review. One of us is currently involved in resolving such a problem. Obviously, any improvements in peer reviewing are welcome, and are still being sought[5-7].

In defence of authors who refuse to respond to comments in a letter, we need to consider that responding may require considerable additional work, which they do not wish to carry out or would like to reserve for their next publication. In such circumstances, honesty is the best policy. The authors can just state why they cannot provide a detailed response at this time, but they will do so in their forthcoming work. However, the comments will remain in the literature. If they are not covered by future work, this deficiency may be pointed out. Citing an older letter to show that the queries raised were answered is not only professional behaviour, but will also suit the journal where the letter was published by delivering a citation.

Other editorial issues include whether to allow more than one round of exchanges regarding the same publication. The time allowed between publication of an item and the submission of related letters needs to be clearly stated in the instructions for authors.

Finally, in the event of an interesting but too long letter, an option may be to convert it to a commentary or brief communication.

CONCLUSION

Letters to the editor are useful for authors, readers and journals. They provide training for younger researchers and are another valuable level of peer review. For all these reasons, in our opinion as editors, a correspondence section is likely to be a useful part of all scientific journals.

FOOTNOTES

Author contributions: Papanas N, Mikhailidis DP, and Mukherjee D contributed to: (1) Substantial contributions to conception and design, or acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published.

Conflict-of-interest statement: The authors declare that they have no conflict of interest.

Abstract

BACKGROUND

The coronavirus disease 2019 (COVID-19) was perhaps the most severe global health crisis in living memory. Alongside respiratory symptoms, elevated liver enzymes, abnormal liver function, and even acute liver failure were reported in patients suffering from severe acute respiratory disease coronavirus 2 pneumonia. However, the precise triggers of these forms of liver damage and how they affect the course and outcomes of COVID-19 itself remain unclear.

AIM

To analyze the impact of liver enzyme abnormalities on the severity and outcomes of COVID-19 in hospitalized patients.

METHODS

In this study, 684 depersonalized medical records from patients hospitalized with COVID-19 during the 2020-2021 period were analyzed. COVID-19 was diagnosed according to the guidelines of the National Institutes of Health (2021). Patients were assigned to two groups: those with elevated liver enzymes (Group 1: 603 patients), where at least one out of four liver enzymes were elevated (following the norm of hospital laboratory tests: alanine aminotransferase (ALT) ≥ 40, aspartate aminotransferase (AST) ≥ 40, gamma-glutamyl transferase ≥ 36, or alkaline phosphatase ≥ 150) at any point of hospitalization, from admission to discharge; and the control group (Group 2: 81 patients), with normal liver enzymes during hospitalization. COVID-19 severity was assessed according to the interim World Health Organization guidance (2022). Data on viral pneumonia complications, laboratory tests, and underlying diseases were also collected and analyzed.

RESULTS

In total, 603 (88.2%) patients produced abnormal liver test results. ALT and AST levels were elevated by a factor of less than 3 in 54.9% and 74.8% of cases with increased enzyme levels, respectively. Patients in Group 1 had almost double the chance of bacterial viral pneumonia complications [odds ratio (OR) = 1.73, P = 0.0217], required oxygen supply more often, and displayed higher biochemical inflammation indices than those in Group 2. No differences in other COVID-19 complications or underlying diseases were observed between groups. Preexisting hepatitis of a different etiology was rarely documented (in only 3.5% of patients), and had no impact on the severity of COVID-19. Only 5 (0.73%) patients experienced acute liver failure, 4 of whom died. Overall, the majority of the deceased patients (17 out of 20) had elevated liver enzymes, and most were male. All deceased patients had at least one underlying disease or combination thereof, and the deceased suffered significantly more often from heart diseases, hypertension, and urinary tract infections than those who made recoveries. Alongside male gender (OR = 1.72, P = 0.0161) and older age (OR = 1.02, P = 0.0234), diabetes (OR = 3.22, P = 0.0016) and hyperlipidemia (OR = 2.67, P = 0.0238), but not obesity, were confirmed as independent factors associated with more a severe COVID-19 infection in our cohort.

CONCLUSION

In our study, the presence of liver impairment allows us to predict a more severe inflammation with a higher risk of bacterial complication and worse outcomes of COVID-19. Therefore, patients with severe disease forms should have their liver tests monitored regularly and their results should be considered when selecting treatment to avoid further liver damage or even insufficiency.

Core Tip: In our study, elevated liver enzymes were detected in 88.2% of patients hospitalized with coronavirus disease 2019 (COVID-19). Alanine aminotransferase and aspartate aminotransferase were elevated by a factor of less than 3 in 54.9% and 74.8% of cases, respectively. Regardless of underlying diseases, including hepatitis, these patients had higher biochemical indices of inflammation, required an O_2 supply, and exhibited bacterial pneumonia complications more often than those with normal liver tests. Male gender, older age, diabetes, and hyperlipidemia were confirmed as independent factors associated with a more severe course of COVID-19. All deceased patients (2.9%) had underlying diseases - most often heart disease, hypertension, and urinary tract infections.

INTRODUCTION

In addition to the most common symptoms of coronavirus disease 2019 (COVID-19) - such as fever, dyspnea, sore throat, dry cough, headache, fatigue, restlessness, myalgia, anosmia, dysgeusia, and chest pain with ground-glass opacities seen on radiological investigations[1] - approximately half of patients

suffer from gastrointestinal symptoms such as a lack of appetite, nausea, and vomiting[2]. In some cases, gastrointestinal symptoms may precede respiratory symptoms or even occur as the sole symptom of COVID-19[3]. A wealth of evidence suggesting that elevated liver enzymes are also a common finding in COVID-19 pneumonia has already been published[4]. Depending on the population studied, elevated levels of liver enzymes– alanine aminotransferase (ALT) and aspartate aminotransferase (AST) - in the blood have been detected in the range of 14%-76%[5,6]. In patients with severe COVID-19, gamma-glutamyl transferase (GGT) and hypoalbuminemia have also been documented[7]. Although liver injury is often transient and is usually normalized without special treatment in mild cases of disease[8], in severe and critical cases it can be the first sign of life-threatening upcoming events such as acute liver failure[9].

However, the exact triggers of liver damage, how it affects patients, and whether it could predict the course and outcomes of COVID-19 itself remain unclear. To address this issue, this study examines liver enzyme abnormalities in patients hospitalized with COVID-19.

MATERIALS AND METHODS

Study design and participants

This is a retrospective cohort study of patients hospitalized at Vilnius University Hospital's Santaros Clinics during the 2020-2021 severe acute respiratory disease coronavirus 2 (SARS-CoV-2) viral pneumonia pandemic. The inclusion criteria for patients were as follows: documented SARS-CoV-2 infection, diagnosed according to NIH guidelines[10] based on manifestations of clinical pneumonia; positive real-time reverse transcription SARS-CoV-2 polymerase chain reaction (RT-PCR) test from nasopharynx swab specimens (MagMAX™ Viral/Pathogen II Nucleic Acid Isolation Kit and TaqPath COVID-19 CE-IVD kit, Applied Biosystems); radiologically confirmed viral pneumonia; and age over 18 years.

Thus, exclusion criteria were: Age ≤ 18 years; patients with incomplete medical records, and negative SARS-CoV-2 test from nasopharyngeal swab specimen.

The depersonalized data of 684 patients were analyzed. Patients were assigned to two groups according to the results of liver tests: those with elevated liver enzymes (603 patients), where at least one of four liver enzymes were elevated (ALT ≥ 40, AST ≥ 40, GGT ≥ 36, or alkaline phosphatase (ALP) ≥ 150; following the norm of hospital laboratory tests) at any point of hospitalization from admission to discharge; or the control group (81 patients), with all four liver enzymes within normal range during hospitalization (Table 1). Depending on the severity of SARS-CoV-2 pneumonia - which was evaluated by radiological observation of lung damage (lung infiltration, pleura infiltration, ground glass opacities), level of respiratory failure (SpO_2, respiratory rate), and the overall clinical picture of the case – patients were assigned to the groups of moderate, severe, or critical COVID-19 pneumonia following the NIH COVID-19 disease guide (2022)[11].

Data collection

Depersonalized electronic medical records - including symptoms and clinical characteristics of COVID-19, laboratory and instrumental tests, therapeutic interventions, and outcome data - were collected for each patient. Demographic data included only age and gender. Underlying diseases were also recorded for all patients.

To confirm the diagnosis and evaluate the severity of COVID-19, the following tests were performed for all patients upon admission, and were repeated during treatment as required: throat roentgenogram; SARS-CoV-2 RT-PCR of nasopharyngeal swab; routine hematologic (full blood cell formula) and biochemical blood tests (troponin I, glucose, creatinine, blood urea nitrogen test, ferritin, procalcitonin, lactate, eGFR (CKD-EPI), ALT, AST, ALP, GGT, lactate dehydrogenase (LDH), bilirubin, C-reactive protein (CRP), interleukine-6 (IL-6), blood electrolyte tests (K, Na, Mg, Ca, Cl), coagulation tests (ADTL, Stago prothrombin assay, international normalized ratio, fibrinogen, D-dimers); and urea tests. In particular cases, an arterial blood analysis (pH, pCO_2, pO_2, HCO_3, SBC, ABE, SBE) was also performed, as well as additional instrumental, biochemical, and microbiological tests of blood and urea.

Hepatitis B and C markers, together with human immunodeficiency virus, cytomegalovirus, and Epstein-Barr virus markers as required, were also performed on admitted patients.

Statistical analysis

Quantitative data were presented as mean ± SD and range. Qualitative data were presented as numbers and percentages. The characteristics of the data distribution were evaluated using the Shapiro-Wilk test. Depending on data distribution normality, the difference in continuous variables between the groups of patients with elevated and normal liver enzymes was assessed using the Welch two independent sample *t*-test or the nonparametric Mann-Witney-Wilcoxon test. Pearson's chi-squared test was used to compare categorical variables between groups.

Table 1 Characteristics of the studied patients

Variables	Group 1 (with elevated liver enzymes)		Group 2 (with normal liver enzymes)		*P* value
		Number of tested		Number of tested	
n/%	603/88.2	603	81/11.8	81	
Male, *n*/%	356/59.0	356	28/34.6	28	< 0.0001

SPA, %, range	96.1 ± 19.5, 5-176	500	98.6 ± 21.9, 39-154	64	0.3868
INR, range	1.04 ± 0.18, 0.83-3.87	506	1.03 ± 0.11, 0.86-1.6	68	0.4728

ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; GGT: Gamma-glutamyl transferase; ALP: Alkaline phosphatase; INR: International normalized ratio; SPA: Stago prothrombin assay.

Univariate and multivariate logistic regression analysis was performed to assess the likelihood of the cohesion of the variables.

Data were considered statistically significant when the *P* value was < 0.05 for the confidence interval set at 95%. All statistical analysis was performed with the R software, version 4.1.2 (The R Project for Statistical Computing, r-project.org).

RESULTS

Elevated liver enzymes, especially ALT, were detected in the majority of patients hospitalized with SARS-CoV-2 pneumonia (603 out of 684). ALT and AST were elevated by a factor of less than 3 in 54.9% and 74.8% of cases with increased enzyme levels, respectively. Only 9.3% of the cases of elevated ALT, 2.7% of AST, and 11.2% of GGT were in concentrations higher than 300 U/L (Table 1).

In most patients (432, 71.6%), elevated ALT in the range of 41-728 U/L was detected on the first day of hospitalization. In almost half (209) of these patients, ALT increased to 80 U/L; in 91 patients, up to 120 U/L; and in only 17 patients did the level of ALT increase to more than 300 U/L (Table 1). ALT tended to rise during hospitalization and pneumonia treatment, and in some cases its level did not recede to the normal range even after SARS-CoV-2 infection recovery and discharge.

AST levels were elevated in 449 (72.1%) patients overall: for 241 (53.7%) of these patients, AST was found to be elevated in the range of 41-351 U/L on the first day of hospitalization; 159 patients had an up to two-fold elevation of AST; 50 patients up to 120 U/L; and only two patients had AST levels over 300 U/L (Table 1). Similarly to ALT, AST levels were prone to increase during the treatment of SARS-CoV-2 pneumonia, but for most patients, these levels returned to their normal range by the time of discharge.

GGT levels in the range of 40-820 U/L were detected in 438 (70.4%) of the patients tested, and in 353 (80.6%) patients, elevated GGT was detected on the first day of hospitalization. Up to two-fold elevated GGT was detected in 198 patients; 71 patients displayed CGT levels up to 120 U/L; and 25 patients displayed CGT levels over 300 U/L (Table 1). Like ALT, GGT tends to increase during hospitalization and slowly normalizes after patients recover from viral pneumonia.

ALP level was tested for only 103 patients, and most cases 89 (86.4%) were in the normal range (Table 1). Only 7 (6.8%) patients had up to three-fold elevated ALP, and in one patient with a critical course of COVID-19 ALP increased dramatically to 1183 U/L, along with ALT 162 U/L and AST 223 U/L. This patient suffered from acute liver and kidney failure, electrolyte and alkaline-acid imbalance, and sepsis aggravated by resistance to beta-lactam antibiotics, from which they did not recover.

Only 24 patients (3.5%) of the studied cohort had preexisting hepatitis of different etiologies (including two patients with chronic hepatitis C and two patients with chronic hepatitis B), and only two of these patients (8.3%), with hepatitis B in long-term remission, had normal levels of liver enzymes

at admission and during hospitalization. The other 22 (91.7%) patients had elevated liver enzymes, including two patients (8.3%) with chronic hepatitis C. Most patients with preexisting liver diseases had a moderate course of COVID-19 pneumonia (20, 83.3%), three (12.5%) had severe cases, and one patient (4.7%) had a critical course of COVID-19. Only one female patient in this group died of COVID-19. No differences in other comorbidities or COVID-19 complications were observed in the remainder of the patients with preexisting liver disease.

Comparison of patient groups with elevated liver enzymes versus normal liver enzymes

When comparing patients who showed signs of liver impairment with those who did not, the main difference was the severity of inflammation. Patients with elevated liver enzymes (Group 1) more often demanded oxygen, and all biochemical inflammation indices were higher than in those with normal enzymes (Group 2). Of the 684 patients studied, 209 (30.5%) required O_2 supply due to respiratory failure, mostly belonging to Group 1 (Table 2). In addition, these patients required a longer duration of supportive O_2 due to low blood O_2 saturation because of severe lung infiltration.

For most patients, Il-6 blood concentration was in the range of 2-626 ng/L. Only one 62-year-old male with a critical course of pneumonia and elevated liver enzymes had an Il-6 as high as 2499 ng/L. This patient died after the manifestation of a cytokine storm (Table 2).

The level of LDH in the blood was in the range of 134 U/L–979 U/L for most patients. Only one patient (a 72-year-old male), who had normal liver enzyme levels during all stages of the disease, had LDH 1304 U/L and died of critical COVID-19.

Patients with elevated liver enzymes had almost double the chance of bacterial complications of viral pneumonia (univariate logistic regression: odds ratio (OR) = 1.73 (1.087–2.789), P = 0.0217). The incidences of other complications were largely similar in both groups (Table 3).

Underlying diseases - including hypertension, the most common - did not substantially prevail in patients with elevated liver enzymes (Table 4).

Analysis of the association of variables with the seriousness of SARS-CoV-2 pneumonia

A moderate course of SARS-CoV-2 pneumonia was diagnosed in 500 (73.1%) patients; a severe course in 148 (21.6%); and a critical course of SARS-CoV-2 pneumonia was diagnosed in 36 (5.3%) patients. There were no significant differences in the distribution of severity between the two groups of patients studied (Table 2).

To clarify which factors predispose a patient toward a more severe course of COVID-19, univariate (Tables 5 and 6) and multivariate (Table 7) analyses were performed.

The age of patients had almost no influence on the course of the disease, while male patients had forms of COVID-19 that were almost 1.5 times more severe and critical (Table 5). Multivariate logistic regression analysis also confirmed that the male gender was independently associated with more severe COVID-19 (Table 7). Acute kidney failure, but not acute liver failure, was also found to be associated with a more severe course of the disease (Table 5).

Neither the underlying disease that was most frequently presented - primary hypertension - nor less frequent lung diseases, cancers, or obesity were confirmed to be associated with a more severe course of COVID-19. Only heart disease of various etiologies, type 2 diabetes, and hyperlipidemia were prone to aggravate COVID-19 (Table 6). Diabetes and hyperlipidemia, but not heart disease, were also independently confirmed to be associated with more severe COVID-19 (Table 7).

Multivariate logistic regression analysis included age, gender, underlying diseases, and complications of pneumonia. Among the pneumonia complications analyzed, only sepsis, increased respiratory rate, and respiratory failure were independently associated with the severity of COVID-19 (Table 7).

Analysis of patients with liver failure

In our study, five patients, all of whom were male, experienced acute liver failure (0.73%) (Table 8). Septic shock developed in four patients, who did not recover despite all efforts to stabilize their condition. Two patients experienced rapid progression of the disease, and died after three days (a 50-year-old male with angioblastic T lymphoma) and eight days (an 84-year-old male with intracranial abscess, epilepsy, and chronic heart disease) of hospitalization.

Disease outcome analysis

Twenty patients died from COVID-19, 85% of whom (17 patients) had elevated liver enzymes. When comparing between patients with elevated and normal liver enzymes, no significant differences were found in mortality rate - 2.8% for those with abnormal liver test results, and 3.7% for those with normal liver test results.

Most of the deceased patients were older males who experienced much more severe SARS-CoV-2 pneumonia, with more life-threatening complications than recovered patients (Table 9). All deceased patients had at least one underlying disease or a combination thereof, and suffered significantly more often from heart disease, hypertension, and urinary tract infections than patients who made recoveries (Table 9). It should be noted that despite the fact that deceased patients were characterized by developing resistance to antibiotics more often than recovered patients, bacterial complications of viral

pneumonia were less frequently documented in this group. Only two deceased patients were obese (2, or 10%, *vs* 15, or 2.26%, of recovered patients).

DISCUSSION

In our cohort, 88.2% of hospitalized COVID-19 patients had elevated liver enzymes - most often ALT (88.2%) followed by AST (71.6%) and GGT (70.4%). Similar results were found in the Cai *et al*[7], where 76.3% of hospitalized patients displayed abnormal liver test results. On the contrary, the Hao study reported that 79.2% of hospitalized patients displayed normal liver tests[5].

An increase in LDH level was observed in patients with severe forms of COVID-19, and was associated with a poor prognosis. In the acute liver failure group, four patients had elevated LDH in the

range of 448-900 U/L. One patient with normal liver enzymes had an LDH of 1304 U/L. These patients died during treatment. Our findings are consistent with data from an Indonesian meta-analysis in which an association between increased LDH levels and mortality was observed (OR = 4.22, $P < 0.001$)[12].

It should be noted that the proportion of patients with abnormal liver test results varies between published COVID-19 studies for several reasons. As in our case, some studies are restricted only to hospitalized patients[5,7,13,14], whereas other studies include all positive cases of COVID-19[9]. Moreover, the liver test norms that apply in particular hospitals vary, making it somewhat difficult to compare data. In our study, ALT and AST below 40 U/L, GGT below 36 U/L, and ALP below 150 U/L were considered normal for both male and female patients, as in the Cai *et al*[7], while in other studies the normal limits of liver tests were set lower. In the Hao study, the ALT norm for males was 35 U/L, while for females it was 25 U/L[5]; in the Wishniewska study, ALT and AST norms for males were 41 U/L, and for females they were 32 U/L[15].

In general, some reviews provide elevated liver enzymes for COVID-19 patients in the range of 14.8%-53%[16], while others consider 50%-78% to be elevated[6].

Despite the aforementioned discrepancies, abnormalities in liver tests deserve the attention of clinicians due to the wealth of evidence suggesting that patients with elevated liver enzymes, especially ALT and AST, generally have more severe SARS-CoV-2 pneumonia[6,7,17-20]. In different studies, elevated transaminases are associated with a 2–9-fold increased probability of poor outcomes of COVID-19[19,21].

COVID: Coronavirus disease.

In our study, moderate pneumonia was more frequent in patients with normal liver enzymes, while critical pneumonia prevailed in patients with elevated liver test results. Furthermore, the majority of the deceased patients had elevated liver enzymes. Despite this, it should be noted that we have not proved that abnormal liver test results are directly related with the likelihood of more severe COVID-19.

The broader field of research has no consensus on the pathological mechanism by which SARS-CoV-2 infection damages the liver because the histological view of liver injury rarely presents. In the Cai *et al* [7], postmortem histological liver analysis showed neither lesions of the lobular architecture nor portal tract infiltration - only slight vesicular steatosis, watery degeneration of hepatocytes with minimal plasma cells, and neutrophil infiltration of hepatic sinuses[7]. Such alterations prompted the formulation of a hypothesis of ischemic/hypoxic hepatitis due to altered O_2 blood saturation, and cardiac failure in critically affected cases[22].

However, the pattern of increase in transaminase in patients with COVID-19 was different from hypoxic hepatitis, suggesting that this was not the case. ALT and AST were elevated by a factor of less than 3 in 54.9% and 74.8%, respectively, of cases of abnormal liver test results in this study. Only 9.3% of the cases of elevated ALT, 2.7% of AST, and 11.2% of GGT were in concentrations greater than 300 U/L. Other studies also emphasize that transaminases rarely increase by a factor of more than 2-3 in COVID-19 patients[19,23].

It should also be borne in mind that elevated transaminases do not always originate exclusively from the liver; therefore, other causes such as myositis, ischemia, and cytokine release syndrome must be excluded to draw a definitive conclusion regarding liver injury in COVID-19 patients[24]. ACE-2, responsible for the virus entry receptor, is expressed not only in respiratory tract epithelium cells but also in vascular endothelium, cardiovascular tissue, renal tissue, and intestinal epithelia, which is why the possibility for the entry and replication of SARS-CoV-2 theoretically exists in practically all vasculated tissues of the human body[25]. Histopathological analysis of autopsies confirmed inflammatory infiltration of the lamina propria; epithelium of the digestive tract, skin, and kidney blood vessels; features of viral myocarditis; and hypoxic brain injury[26]. Furthermore, other research has established that SARS-CoV-2 can persist in the intestines of infected subjects even longer than in the

respiratory tract[27-29].

Abnormal liver test results are more likely to reflect the severity of COVID-19 in general than a particular liver injury[21]. A comprehensive meta-analysis of 35 studies with more than 10000 total participants concluded that COVID-19, despite its severity, has a minor impact on the liver[4]. We agree with this conclusion.

Patients with elevated liver enzymes also displayed increased indices of inflammation, such as CRP and IL-6 levels. Elevated serum levels of CRP, IL-1, IL-6, and the tumor necrosis factor were reported in several other studies, and this was associated with a non-favorable course of liver injury[30]. Additionally, the bacterial complication of SARS-CoV-2 pneumonia, which contributes to the systemic inflammatory response, was diagnosed more frequently in patients with increased liver enzymes (OR = 1.73, P = 0.0217).

In our study, resistance to antibiotics, most often beta-lactams, was found to be associated with more severe COVID-19 (OR = 3.89, P = 0.004) and was documented more frequently in deceased patients. This issue is rarely discussed in COVID-19-related studies and needs more careful evaluation, as only very few studies with a small number of patients have been published[31,32]. Although concerns that the pandemic has led to an increase in antibiotic resistance due to self-medication of this viral infection have already been raised[33,34], it is necessary to elucidate how resistance to antibiotics modulates COVID-19 itself as very little comprehensive analysis has been published so far.

It also appeared that male patients in our cohort were more likely to have elevated liver enzymes than female patients. Furthermore, the male gender was confirmed as an independent factor associated with more severe COVID-19. This finding is consistent with previous data which highlights the male gender as one of the indicators of liver affliction[7,35]. With some disagreements, the protective effect of estrogen is often mentioned in relation to liver diseases[36], but the specific reasons that males suffer from more severe COVID-19 should be elucidated in more studies involving not only clinical but also detailed epidemiological data.

Weber and co-authors reported that only rare cases of acute liver failure were diagnosed in infected patients[37]. Our findings are in line with this: only five (0.72%) patients experienced acute liver failure, all of whom were male. In four of those patients, sepsis developed, leading to death. Males also prevailed among the total number of deceased patients (20, or 2.9%), most of whom (17, or 85%) displayed abnormal liver test results. Other similar results have been posted elsewhere which suggest that the majority (58%-78%) of deceased COVID-19 patients had liver injuries[38,39]. However, a comprehensive meta-analysis of 158 studies involving 78798 patients drew the conclusion that elevated liver enzymes, despite being a common finding in COVID-19 patients, had no effect on mortality or the critical course of the disease[20].

It should be emphasized that none of the patients in our study who experienced liver failure during the course of COVID-19 had an underlying liver disease. Furthermore, there was no association of elevated liver enzymes with preexisting liver disease.

Overall, 3.5% of patients had underlying liver disease, the majority of whom (91.7%) exhibited abnormal liver test results during the course of COVID-19. Only 12.5% of these patients had severe COVID-19, and one female died of critical COVID-19.

Although chronic comorbid liver diseases are reported in 2.6%-11% of patients[19], it seems that in most cases this does not influence COVID-19-associated liver injury, severe COVID-19 infection, or poor patient outcomes. This was confirmed in our study, was also shown in a nationwide matched cohort study[40], and has been approved in several reviews[19,41]. However, in one publication with 99 patients, preexisting hepatitis B infection was reported as a condition for more severe COVID-19 infection compared to patients without hepatitis B[42]. It is assumed that the immunosuppressive effect of the SARS-CoV-2 virus may lead to the reactivation of the hepatitis B virus[43]. We could neither confirm nor deny this, as our cohort included only two patients with chronic hepatitis B in remission and two patients with chronic hepatitis C.

There is an opinion that the SARS-CoV-2 virus itself could be responsible for liver injury during COVID-19, but the histopathological mechanism remains uncertain[41]. In the liver, the majority of abandonment of ACE-2 expression is determined in cholangiocytes, but in patients with COVID-19, the cytopathic, not cholestatic, profile of elevated enzymes prevails. On the other hand, the level of expression of ACE-2 receptors in hepatocytes is believed to be regulated by the virus. There may also be additional ACE receptors or co-receptors[44]. Thus, we agree with the conclusion that COVID-19-associated liver injury usually occurs as a result of the progression of COVID-19 itself[45].

We did not find any differences between the groups of patients with and without elevated liver enzymes concerning the prevalence of underlying diseases. Therefore, we cannot predict nor draw any conclusions regarding how underlying diseases contribute to liver damage during COVID-19. However, patients with diabetes, heart diseases of various etiologies, and hyperlipidemia, but not obesity, have an increased likelihood of suffering from more severe SARS-CoV-2 pneumonia. Furthermore, diabetes and hyperlipidemia were independently confirmed to be associated with more severe COVID-19 (OR = 3.2, P = 0.0016, and OR = 2.7, P = 0.0238, respectively). Thus, concomitant pathology appeared to be more likely to affect the severity of COVID-19 than the probability of liver damage in our study. Many studies also mention cardiovascular and renal diseases, diabetes, obesity, and hypertension as factors that worsen the course of COVID-19[20].

In summary, elevated liver enzymes are often found in patients with COVID-19. This may be due to a variety of factors, including the effects of medications used to treat the disease, concomitant liver pathology, and the influence of the virus itself. In the cases that we examined, there were significantly more patients with hepatic impairment than with normal liver function, and hepatic-impaired patients had both a higher risk of bacterial complications and a more severe course of viral pneumonia, with increased oxygen demand. This is most likely due to the effects of the SARS-CoV-2 virus, which causes more damage not only to the respiratory system but also to other organs, including the liver, due to more pathogenicity and increased cytopathic aggression which causes a greater storm of cytokines.

Because we only examined inpatients with moderate to severe and critical COVID-19, we cannot compare the frequency of hepatic impairment in mild cases of COVID-19.

Limitations of the study

We must consider several limitations of our study. Because we studied only patients with COVID-19 who needed hospitalization, and outpatients were omitted, the groups of patients differed in size by a factor of almost 8: the group with elevated liver enzymes consisted of 603 patients, and the group with normal liver enzymes consisted of 81 patients. This circumstance perhaps prevented us from statistically proving an association between liver impairment and severity of COVID-19 course - although direct damage of the liver tissue by the SARS-CoV-2 virus itself should be proved histologically, since elevated transaminases do not entirely arise from damage to the liver tissue.

Our study featured no groups with asymptomatic or mild COVID-19; their liver enzymes would likely have been in the normal range. Thus, the group with normal enzymes could be larger. This circumstance is also necessary to consider when evaluating data on the impact of preexisting diseases on COVID-19 severity. We also have not followed up with patients after discharge, which is why we do not know how quickly signs of liver impairment are resolved after the recovery of patients from COVID-19 pneumonia.

CONCLUSION

Despite a wealth of published data analyzing liver tests in COVID-19 patients, it is still difficult to draw inferences not only about the cause of such an effect of the SARS-CoV-2 virus infection on the liver, but also about the prevalence of elevated liver enzymes in such patients.

In summarizing our results, we can conclude that liver impairment allows a more severe inflammation to be predicted, with a higher risk of bacterial complications and worse outcomes in patients with SARS-CoV-2 pneumonia. Because several drugs with potentially hepatotoxic effects are used in severe cases, patients with more aggressive forms of COVID-19 should have their liver enzymes monitored regularly; their results should be considered when selecting a treatment to avoid further hepatic impairment or even insufficiency.

ARTICLE HIGHLIGHTS

Research background

Alongside respiratory symptoms, elevated liver enzymes, abnormal liver function, and even acute liver failure were reported in patients suffering from severe acute respiratory disease coronavirus 2 (SARS-CoV-2) pneumonia. However, the exact triggers of liver damage, how it affects patients, and whether it could predict the course and outcomes of coronavirus disease 2019 (COVID-19) itself remain unclear.

Research motivation

Although liver injury in patients with COVID-19 is often transient and is usually normalized without special treatment in mild cases of the disease, it can be the first sign of life-threatening events such as acute liver failure in severe and critical cases. Therefore, it is essential for everyday clinical practice to have a more precise view of how the liver impairment affects the course and outcomes of SARS-CoV-2 infection itself. Our study contributes to this goal.

Research objectives

This study aims to analyze the impact of liver enzyme abnormalities on the severity and outcomes of COVID-19 in hospitalized patients to have a clearer view of how to evaluate the risk of severe liver impairment from elevated enzyme tests.

Research methods

In this study, 684 depersonalized medical records from patients hospitalized with COVID-19 during the 2020-2021 period were analyzed. Patients were assigned to two groups: those with elevated liver

enzymes, where at least one out of four liver enzymes were elevated at any point of hospitalization, from admission to discharge; and the control group, with normal liver enzymes during hospitalization. COVID-19 severity was assessed according to the interim World Health Organization guidance (2022). Data on viral pneumonia complications, laboratory tests, and underlying diseases were also collected and analyzed.

Research results

In total, 88.2% of patients with SARS-CoV-2 infection produced abnormal liver test results. Alanine aminotransferase and aspartate aminotransferase levels were elevated by a factor of less than 3 in 54.9% and 74.8% of cases with increased enzyme levels, respectively. Patients in Group 1 had almost double the chance of bacterial viral pneumonia complications, required oxygen supply more often, and displayed higher biochemical inflammation indices than those in Group 2. Like in other research, our patients rarely experienced acute liver failure. The majority of the deceased patients had at least one underlying disease or a combination thereof, and most were male. Alongside male gender and older age, diabetes and hyperlipidemia, but not obesity, were confirmed as independent factors associated with more a severe COVID-19 infection in our cohort.

Research conclusions

In our study, the presence of liver impairment allows us to predict a more severe inflammation with a higher risk of bacterial complication and worse outcomes of COVID-19. Therefore, monitoring liver enzyme levels should be a part of the qualitative care of patients with SARS-CoV-2 pneumonia.

Research perspectives

To find out more precisely the sources of increased liver enzymes in patients with COVID-19, it would be beneficial to elucidate whether the SARS-CoV-2 virus can enter and replicate in hepatocytes. For this purpose, an experimental study on the cell line of the liver origin or virus detection in hepatocytes during a histological analysis of autopsies could be promising.

ACKNOWLEDGEMENTS

We are grateful to the collaborators of the Centre for Informatics and the Development of Vilnius University Hospital's Santaros Clinics for their valuable assistance in the data collection process. Our special thanks go to Ulbinas P, whose patience and competence allowed us to perform impersonalized data extraction in the most efficient and relevant manner.

Abstract

BACKGROUND

Immune checkpoint inhibitor-mediated colitis (IMC) is a common adverse event following immune checkpoint inhibitor (ICI) therapy for cancer. IMC has been associated with improved overall survival (OS) and progression-free survival (PFS), but data are limited to a single site and predominantly for melanoma patients.

AIM

To determine the association of IMC with OS and PFS and identify clinical predictors of IMC.

METHODS

We performed a retrospective case-control study including 64 ICI users who developed IMC matched according to age, sex, ICI class, and malignancy to a cohort of ICI users without IMC, from May 2011 to May 2020. Using univariate and multivariate logistic regression, we determined association of presence of IMC on OS, PFS, and clinical predictors of IMC. Kaplan-Meier curves were gen-erated to compare OS and PFS between ICI users with and without IMC.

RESULTS

IMC was significantly associated with a higher OS (mean 24.3 mo *vs* 17.7 mo, P = 0.05) but not PFS (mean 13.7 mo *vs* 11.9 mo, P = 0.524). IMC was significantly associated with OS greater than 12 mo [Odds ratio (OR) 2.81, 95% confidence interval (CI) 1.17-6.77]. Vitamin D supplementation was significantly associated with increased risk of IMC (OR 2.48, 95%CI 1.01-6.07).

CONCLUSION

IMC was significantly associated with OS greater than 12 mo. In contrast to prior work, we found that vitamin D use may be a risk factor for IMC.

Key Words: Immune checkpoint inhibitors; Immune checkpoint inhibitor-mediated colitis; Immune-related adverse events

INTRODUCTION

Immune checkpoint inhibitors (ICI) have dramatically changed the landscape of cancer therapy. Early studies showed significantly prolonged survival in patients with metastatic melanoma compared to standard chemotherapy[1], and evidence now exists for improved outcomes in a variety of tumors ranging from lung cancers to urothelial carcinoma to breast cancer[2-5]. Although these are powerful treatments in our armamentarium against malignancy, ICI can cause immune-related adverse events (irAE) characterized by autoimmune-like inflammation in a variety of non-tumor organs, leading to increased morbidity for patients[6].

One of the most common irAE is immune checkpoint inhibitor-mediated colitis (IMC). IMC may occur in up to 40% of patients treated with ipilimumab, an antibody targeting CTLA-4, 11%-17% of patients treated with antibodies against anti-PD-1 or anti-PD-L1, such as nivolumab, pembrolizumab, or atezolizumab, and around 32% of patients treated with a combination of anti-CTLA-4 and anti-PD-1[7]. Prior retrospective analyses of patients with IMC have attempted to identify characteristics associated with development of IMC, including type of malignancy, ICI class, dose of ICI, cancer stage, and vitamin D use[8-11]. Intriguingly, two prior studies have suggested that development of IMC may positively correlate with improved progression-free survival (PFS) and overall survival (OS)[9,10]. One of these studies controlled for confounding effects of ICI class *via* frequency matching, but was limited to patients with melanoma, hindering wider applicability of their findings[10]. These findings also conflict with data suggesting that use of steroids and the anti-TNF antibody infliximab in patients treated with ICI are associated with worse cancer outcomes[12,13]. These discrepancies represent a significant knowledge gap that impedes our ability to evaluate and manage IMC and ICI use.

Here we present data from a retrospective study of patients treated with ICI at our institution who developed IMC across malignancy types. We compare this cohort to a matched control cohort to determine whether IMC was associated with improved progression-free survival and overall survival. We also evaluate which clinical characteristics increase the risk of developing IMC, including severe IMC.

MATERIALS AND METHODS

Study design and population

We conducted a retrospective case-control single-center study after obtaining approval from the Institutional Review Board at Stanford University (IRB 57125, approved 6/30/2020). Our primary aim was to determine the association of presence and severity of IMC on OS and PFS in ICI users. Our secondary aim was to identify clinical variables which predicted development of IMC in ICI users. We evaluated all patients over the age of 18 who had been treated with immune checkpoint inhibitors (ICI) for

malignancy at Stanford Health Care from May 2011 to May 2020, including anti-CTLA-4 (ipilimumab), anti-PD-1 (nivolumab, pembrolizumab), and anti-PD-L1 (atezolizumab, avelumab, durvalumab), with follow up through October 2020. Using the Stanford Research Repository tool, we screened patients treated with ICI who were assigned International Classification of Diseases (ICD) 9 and ICD 10 codes associated with non-infectious colitis and diarrhea (Supplementary Table 1). Each chart which passed the initial screen was further screened by review of clinic notes to confirm diagnosis of immune checkpoint inhibitor-related colitis by oncology providers. Any patient found to have other explanations for their clinical presentation was excluded from the study.

Control patients were matched one to one with each IMC patient for sex, age, malignancy, type of ICI used, prior ICI exposure, and duration of ICI exposure (matched to number of doses from initiation of ICI to development of colitis in study cohort). Control patients were initially screened by those lacking the above ICD codes and were confirmed *via* direct evaluation of each chart to lack diarrhea and/or colitis ascribable to ICI per their treating oncologist.

We extracted clinical data on IMC and control patient charts including demographics (age at time of ICI initiation, sex, body mass index, race per patient report), medical history (presence of prior non-liver and non-upper gastrointestinal disease, personal history of autoimmune disease, family history of autoimmune disease), and cancer history (type of malignancy, tumor stage at ICI initiation, prior chemotherapy, prior radiation therapy, type of ICI used, duration of ICI use, OS and PFS) (Supplementary Table 2). OS was determined as time from initiation of ICI to death, while PFS was determined as time from initiation of ICI to death or progression of disease as determined by oncology providers, based on radiographic evidence of progression. IMC severity was graded using commonly accepted determinants of IMC and irAE grading[14]. We specifically noted prior use of therapies designed to increase immune responses [interleukin (IL)-2, interferon (IFN)-γ, toll-like receptor (TLR)-9 agonist, tebentafusp, or anti-CD47 antibody]. Vitamin D and non-steroidal anti-inflammatory (NSAID) use were defined as vitamin D supplement or NSAID medication, respectively, noted in the history of present illness or on the patient's medication list at the clinic visit closest to their date of ICI initiation.

We collected data on IMC diagnosis including number of patients who received endoscopy (flexible sigmoidoscopy or colonoscopy), findings on endoscopy, and fecal calprotectin (Supplementary Table 3). Data on management of IMC included treatment with anti-diarrheal medications, mesalamine, steroids (prednisone, budesonide, dexamethasone), infliximab, and vedolizumab.

Statistical analysis

The rate of the primary outcomes (OS > 12 mo and PFS > 6 mo among all ICI users, OS > 12 mo and PFS > 6 mo in patients with IMC) and secondary outcomes (risks of IMC among patients with malignancy using ICI, IMC severity), predictive value of clinical variables on primary and secondary outcomes, odds ratio (OR) with its 95% confidence interval (CI), and *P* values were calculated using Statistics/Data Analysis (Stata/IC 15.1 for Windows, College Station, TX, United States). Dichotomous variables were analyzed for outcomes using the chi-squared test or the Fisher's exact test where appropriate, and continuous variables were analyzed using Student's *t*-tests if normally distributed, or the Wilcoxon signed-rank test for non-normal data. For our multivariate analyses, model building was based on forward stepwise logistic regression, with a *P* value of 0.05 required for entry, and known predictors were also included. We constructed Kaplan Meier curves for the outcomes of OS and PFS between patients with and without IMC and patients with mild *vs* severe IMC using GraphPad Prism (version 8.3; GraphPad Software, Inc., La Jolla, CA, United States). All authors had access to the study data and reviewed and approved the final manuscript.

RESULTS

Clinical characteristics associated with IMC

We identified a total of 314 patients treated with ICI at Stanford Health Care from May 2011 to May 2020 who had ICD codes matching our query (Supplementary Table 1). Of these, 64 had a diagnosis of IMC per review of Oncology providers' notes, after excluding patients with alternative diagnoses for their symptoms. 24 (37.5%) of these IMC patients underwent an endoscopy (colonoscopy or flexible sigmoidoscopy) during workup, of which seven (29.2%) had a normal endoscopic appearance, consistent with prior reports demonstrating that approximately one third of patients with IMC related to anti-PD-1 therapy have microscopic colitis[15] (Supplementary Table 3). An additional 14 patients (21.9%) had imaging findings suggestive of IMC while 3 patients (4.69%) without imaging or endoscopy had an elevated calprotectin or fecal lactoferrin.

These 64 patients were manually matched 1:1 with control patients based on age, sex, malignancy, type of ICI, whether or not the patient had prior ICI exposure, and duration of ICI use. We compared clinical characteristics of patients from the IMC cohort and the control cohort (Table 1). None of the matched characteristics were significantly different between the two cohorts. The mean age across the combined cohorts was 66.6 years, with an average age of 67.4 in the cohort with IMC compared with 65.8 in the control cohort ($P = 0.42$). 57.81% of patients in each group were male ($P = 1.00$). Patients were

Table 1 Baseline characteristics of patients with immune checkpoint inhibitor use

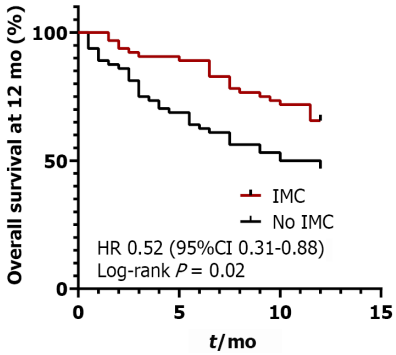
[1]Variable matched between cases and controls.
[a]Number of infusions of immune checkpoint inhibitor prior to immune checkpoint inhibitor-mediated colitis diagnosis (cases) or total (controls).
[b]See Supplementary Table 2.
IMC: Immune checkpoint inhibitor-mediated colitis; ICI: Immune checkpoint inhibitor; SD: Standard deviation; RCC: Renal cell carcinoma; NSCLC: Non-small cell lung cancer; SCC: Squamous cell carcinoma; PFS: Progression-Free Survival; irAE: Immune related adverse event; OS: Overall survival.

predominantly white in both groups, with 52 (81.25%) white individuals in the IMC cohort compared to 50 (78.13%) in the control group (P = 0.66). The most common malignancy in each group was melanoma [33 (51.56%) in both cohorts], followed by renal cell carcinoma [8 (12.5%) in the IMC cohort and 7 (10.94%) in the control cohort] and non-small cell lung cancer [6 (9.38%) in both cohorts]. Both groups had similar numbers of patients with stage IV malignancy [56 (87.5%) in the IMC cohort and 58 (90.63%) in the control cohort, P = 0.778]. Combination ipilimumab and nivolumab was the most commonly used checkpoint therapy [24 (37.5%) of patients in each cohort], followed by nivolumab monotherapy [19 (29.69%) of each cohort] and ipilimumab monotherapy [11 (17.19%) of each cohort].

Among the remainder of the clinical characteristics evaluated, personal history of autoimmune disease (including prior irAE) and family history of autoimmune disease were significantly more common in patients with IMC (P = 0.037 and 0.048, respectively). Intriguingly, prior use of a therapy designed to increase immune responses was more common in the control cohort without IMC (P = 0.027). In contrast to prior data[11], use of vitamin D supplementation at the time of first dose of ICI was significantly more prevalent in patients with IMC (P = 0.020). Neither smoking status, NSAID use at time of ICI initiation, steroid use at the time of ICI initiation, nor recent vaccination were significantly more common in IMC patients compared to controls.

IMC significantly increases overall survival

As IMC has previously been associated with increased OS and PFS in cancer patients[9,10], we evaluated whether this association was seen in our study. We found that OS was significantly longer in patients who developed IMC compared to those who did not, with a mean OS of 24.3 mo in patients with IMC and 17.7 mo in control (P = 0.05, Table 1). OS at 12 mo following ICI initiation was significantly higher in patients who developed IMC compared to those who did not (P = 0.02, Figure 1). However, in contrast to prior findings, our study did not find a significant difference in PFS between IMC patients and controls, with a mean PFS 13.7 mo in IMC patients and 11.9 mo in controls (P = 0.524) (Table 1). PFS also did not differ between patients who developed mild *vs* severe IMC (P = 0.690, Supplementary Table 5).



Across both cohorts, we identified clinical characteristics significantly associated with OS greater than 12 mo and PFS greater than 6 mo, which are correlated with cancer outcomes in patients treated with ICI[16] (Tables 2 and 3) (Supplementary Tables 4 and 5). IMC was significantly and independently associated with OS > 12 mo in the multivariate model (OR 2.81, 95%CI 1.17-6.77, P = 0.021) (Table 2). Number of ICI infusions was also positively associated with OS > 12 mo (OR 1.23, 95%CI 1.09-1.40), while sarcoma as underlying malignancy was significantly associated with OS < 12 mo (OR 0.17, 95%CI 0.029-0.947). Within the IMC cohort, nivolumab use was associated with OS < 12 mo in the univariate analysis (OR 0.09, 95%CI 0.01-0.83), while only age was associated with OS < 12 mo in multivariate analysis (OR 0.93, 95%CI 0.88-0.99) (Table 3). No individual malignancy was significantly associated

Significant risk factors for developing IMC and severe IMC

As certain clinical characteristics were significantly more common in patients with IMC compared to controls, we evaluated whether any of these clinical characteristics were associated with risk of developing IMC (Table 4). In univariate analysis, history of autoimmune disease and vitamin D use were both significantly associated with increased risk of IMC (OR 2.45, 95%CI 1.04-5.78, P = 0.040 for autoimmune disease; OR 2.51, 95%CI 1.14-5.54, P = 0.022 for vitamin D use). Interestingly, the use of vitamin D supplementation has previously been associated with a decreased risk of IMC, in contrast to our findings here[11]. Prior use of an immune-enhancing therapy (Supplementary Table 2) was associated with a significantly decreased risk of IMC (OR 0.20, 95%CI 0.04-0.95, P = 0.043). In the multivariate model which incorporated these characteristics, only the use of immune-enhancing therapy remained significantly associated with decreased risk of IMC, with an OR of 0.20 (95%CI 0.04-1.00, P = 0.050).

We next determined if any variables were associated with an increased risk of severe IMC. Consistent with prior studies of irAE in ICI[17-19], we defined grade 1-2 IMC as mild and grade 3 or higher IMC as severe. In our study, 38 of the 64 patients (59.4%) had severe IMC (Supplementary Table 3). In the univariate model, ipilimumab and vitamin D supplementation were significantly associated with development of severe IMC (OR 8.93, 95%CI 1.07-74.8, P = 0.043 for ipilimumab; OR 3.33, 95%CI 1.10-10.14, P = 0.034 for vitamin D) (Supplementary Table 6). Combination therapy (ipilimumab plus nivolumab) trended towards an increased risk of severe IMC but did not reach significance (P = 0.053). In contrast, pembrolizumab was significantly associated with a decreased risk of severe IMC (OR 0.26, 95%CI 0.09-0.81, P = 0.020). In the multivariate model no characteristic reached significance for association with severe IMC, although both combination therapy and ipilimumab monotherapy approached significance for increased risk of severe IMC (P = 0.058 and 0.060, respectively).

DISCUSSION

In our study, development of IMC following ICI use was associated with improved overall survival, although not improved progression-free survival, compared to ICI users without IMC. This is similar to findings at another center demonstrating both improved OS and PFS in patients with IMC[9,10]. We also found that vitamin D supplementation at the start of ICI treatment is a risk factor for developing IMC, in contrast to other research suggesting vitamin D use is associated with lower risk of IMC[11]. Our results, therefore, provide critical additional information on these previous associations and present a need for prospective studies.

Both publications showing improved survival in patients with IMC were retrospective analyses performed at the same center[9,10]. One study noted that ICI class was significantly associated with development of IMC[9], a finding that has been demonstrated several times in retrospective work[8,17,18,20-23]. However, unlike our work, this study did not match control patients to account for this likely confounder, as ICI class has been associated with differences in PFS in some malignancies[24,25]. The second study at this center examined survival in melanoma patients with IMC, compared to our work across multiple malignancies, although frequency matching was performed to account for use of different ICI classes[10]. Since our study is the first to examine survival in patients with IMC at a different center, our work here reinforces that IMC may be associated with increased overall survival and prompts a need for prospective studies.

The only other independent factor in our study positively associated with OS > 12 mo was number of ICI doses. This finding may be due to trivial length-time bias, as patients who survive longer are more likely to receive more doses of ICI. It is also possible that patients who required cessation of ICI due to IMC had worse outcomes, although prior work has suggested that patients still derive equivalent long-term benefit from ICI even if stopped due to irAE[26]. Type of underlying malignancy (sarcoma) was independently associated with OS < 12 mo in our study. These findings are not unexpected, as most advanced soft tissue sarcomas have a median OS of less than one year[27].

In contrast to prior work, we found a positive association between vitamin D supplementation and development of IMC[11]. It is unclear if this is related to low serum vitamin D levels or negative impact of the supplementation itself, as vitamin D levels near the time of ICI initiation were not recorded in most patients. Additionally, the prior report on vitamin D in IMC was in melanoma patients only, which may partially account for discrepancies with our study. As this association did not remain significant in our multivariate analysis, it is possible that another confounding factor may explain the association between vitamin D supplementation and IMC in our study.

In addition to challenging existing findings, we report here on additional novel risk factors for IMC. We are the first to report that prior use of immune-enhancing medications prior to ICI, such as IL-2 or interferon-γ, is significantly and independently associated with decreased risk of IMC. Much more work should be done to evaluate the relationship between these medications and future risk of IMC.

Finally, our study is the first to examine risk factors for severe IMC. In addition to increasing risk for IMC overall, we find that vitamin D supplementation may also be a risk factor for severe IMC. Similarly, our results suggest that the use of ipilimumab may be associated with increased risk of severe IMC, while pembrolizumab may be associated with decreased risk of severe IMC in patients who develop this syndrome. As ipilimumab has previously been associated with increased risk of IMC overall, while anti-PD-1, including pembrolizumab, are associated with lower risk of IMC overall[8,9], these findings emphasize that ICI class may affect severity of IMC.

Our findings may significantly impact clinical practice by identifying novel risks for IMC and severe IMC that clinicians, including oncologists and gastroenterologists, should be aware of, while also potentially providing reassurance to physicians and patients that development of IMC may be a positive

prognosticator for cancer survival. Neither prior work nor ours found that treatment of IMC, including steroids or infliximab, negatively impacts OS[9,10], and therefore appropriate treatment of IMC should be pursued early on to minimize morbidity and mortality. Both steroid and infliximab use have been suggested to worsen survival in ICI users[12,13], but all current evidence suggests that use of these medications for IMC specifically does not impair cancer outcomes. Our work also cautions against supplementation with vitamin D in ICI users, as this may increase risk of IMC and severe IMC, although carefully designed studies with vitamin D measurements should be performed.

Our work has several strengths. We performed robust cohort matching to minimize confounding effects of ICI class and malignancy. This is also the first study to explore risk factors associated with severe IMC. However, there are limitations to our work. As a retrospective, observational study, it is subject to recall bias and cannot evaluate causation, and may also be subject to immortal time bias (ITB). Patients may have longer exposure to checkpoint inhibitors before developing IMC, compared to patients who do not manifest this irAE, leading to a period where they must survive for long enough to develop IMC and are therefore "immortal"[28]. We found that OS > 12 mo was significantly associated with greater numbers of ICI infusions (Table 2), which is likely due to ITB. However, greater numbers of infusions were not associated with IMC (Table 4). This suggests that the association between OS > 12 mo and IMC is likely independent of the number of ICI infusions, limiting this as a source of ITB in our study.

Other weaknesses of our work include selection of patients based on clinical criteria for IMC, including those who did not undergo endoscopy or other objective testing for intestinal inflammation, and therefore may not have had a true colitis. Like prior work, this is also a single-center study, and our results may not be widely generalizable, particularly since we identified fewer patients compared to prior work and our patient population is highly variable, including individuals with several different underlying malignancies. We did not exclude patients with prior non-GI irAEs in either group, although the presence of these was not independently associated with increased OS in our study. We also have not accounted for other factors which may be potential predictors of ICI response, including tumor PD-L1 expression burden, tumor mutational burden, gut microbial composition, proton pump inhibitor use, and combination treatment with tyrosine kinase inhibitors[29-34].

CONCLUSION

In conclusion, our findings suggest presence of IMC is associated with improved OS in cancer patients when cases were matched closely to controls. We also found that vitamin D supplementation was significantly associated with development of both IMC and severe IMC, while immune-enhancing medications were significantly associated with decreased risk of IMC. Future work should focus on broader populations to resolve the discrepancies raised in our work, and to confirm the association between IMC and increased cancer survival. Closely involving gastroenterologists with the workup and management of IMC will be crucial to ensuring the best care possible for these patients.

ARTICLE HIGHLIGHTS

Research background

Immune checkpoint inhibitor-mediated colitis (IMC) is a common immune-related side effect (irAE) of checkpoint inhibitor treatment for cancer. Prior work has suggested that IMC may be associated with increased survival from cancer.

Research motivation

We sought to determine if IMC was associated with increased overall survival (OS) in a cohort of patients at our institution. These findings could expand existing data on IMC and cancer outcomes and might suggest a common immunological underpinning between the efficacy of checkpoint inhibitors and certain irAEs.

Research objectives
We performed a retrospective case-control study of individuals treated with immune checkpoint inhibitors at our institution who developed IMC, closely matched to a cohort of patients treated with checkpoint inhibitors without IMC. Using univariate and multivariate logistic regression, we determined significant clinical predictors of IMC and the association of presence of IMC on OS.

Research methods
We found that IMC was significantly associated with a higher OS as well as OS greater than 12 mo. In contrast to previous findings, vitamin D supplementation was significantly associated with development of both IMC and severe IMC. However, prior treatment with immune-enhancing medications was significantly associated with decreased risk of IMC.

Research results
In multivariate logistic regression analysis, IMC was significantly associated with a higher OS but not PFS. IMC was significantly associated with OS greater than 12 mo. Vitamin D supplementation was associated with increased risk of IMC.

Research conclusions
Our findings lend strength to the idea that IMC is associated with improved cancer outcomes with checkpoint inhibitor treatment. This may suggest common immunologic underpinnings between IMC and the anti-tumor effects of checkpoint inhibitors. These results also emphasize the importance of involving gastroenterologists with the management of IMC.

Research perspectives
Future research in this area should seek to expand current knowledge of the relationship between IMC and cancer survival. In particular, future work should focus on broadening the type and number of patients treated with immune checkpoint inhibitors and on tracking patients prior to initiating checkpoint inhibitors to determine if this relationship remains significant prospectively.

Abstract

BACKGROUND

Primary biliary cholangitis (PBC) and autoimmune hepatitis (AIH) are two unexplained immune diseases. The golden standard for diagnosis of these diseases requires a liver biopsy. Liver biopsy is not widely accepted by patients because of its invasive nature, and atypical liver histology can confuse diagnosis. In view of the lack of effective diagnostic markers for PBC and AIH, combined with the increasingly mature metabolomics technologies, including full-contour metabolomics and target.

AIM

To determine non-invasive, reliable, and sensitive biochemical markers for the differential diagnosis of PBC and AIH.

METHODS

Serum samples from 54 patients with PBC, 26 patients with AIH and 30 healthy controls were analyzed by Ultra-high performance liquid chromatography-tandem mass spectrometry serum metabolomics. The metabolites and metabolic pathways were identified, and the metabolic changes, metabolic pathways and inter-group differences between PBC and AIH were analyzed. Fifteen kinds of target metabolites of bile acids (BAs) were quantitatively analyzed by SRM, and the differential metabolites related to the diagnosis of PBC were screened by receiver operating characteristic curve analysis.

RESULTS

We found the changes in the levels of amino acids, BAs, organic acids, phospholipids, choline, sugar, and sugar alcohols in patients with PBC and AIH. Furthermore, the SRM assay of BAs revealed the increased levels of chenodeoxycholic acid, lithocholic acid (LCA), taurolithocholic acid (TLCA), and LCA + TLCA in the PBC group compared with those in the AIH group. The levels of BAs may be used as biomarkers to differentiate PBC from AIH diseases. The levels of glycochenodeoxycholic acid, glycochenodeoxycholic sulfate, and taurodeoxycholic acid were gradually elevated with the increase of Child-Pugh class, which was correlated with the severity of disease.

CONCLUSION

The results demonstrated that the levels of BAs could serve as potential biomarkers for the early diagnosis and assessment of the severity of PBC and AIH.

INTRODUCTION

Primary biliary cholangitis (PBC) and autoimmune hepatitis (AIH) are two unexplained immune diseases[1]. Although advanced methods have been presented for diagnosing PBC and AIH, 5%-10% of PBC patients have anti-mitochondrial antibody-negative, and missed diagnosis or misdiagnosis mainly occurs in clinical practice[2]. For some patients with anti-mitochondrial antibody-positive, rather than significant changes in hepatic histology and function, long-term follow-up revealed that these patients eventually developed to PBC. Thus, early diagnosis of these patients is a clinical challenge. Clinical manifestations of AIH may have similarities to other autoimmune liver diseases, such as drug-induced hepatitis, alcoholic liver disease, inherited metabolic disorders, and hepatitis C virus infection, such as regardless of the cause of liver disease, patients may present with fatigue, abdominal distention, skin and sclera yellow staining, laboratory test show liver dysfunction. Because of the complexity and difficulty of diagnosing, leading to the delayed diagnosis of several AIH patients. Liver biopsy remains the golden standard for the diagnosis of autoimmune liver diseases, while it is an invasive, painful, and costly method that is associated with the possibility of sampling error and variability in interpretation. Therefore, identification of novel and accurate noninvasive biomarkers for the diagnosis and assessment of severity is of great importance.

As one of the emerging 'omics' platforms, metabolomics enables the qualitative and quantitative analyses of metabolites in complex biological samples[3]. As products of cellular adjustment processes, metabolites are regarded as the ultimate readouts that reflect genetic or environmental changes in biological systems[4,5] High-throughput metabolic profiling has been successfully used for the identification of novel diagnostic molecules and disease-related pathways, as well as development of new therapeutic targets for some diseases (*e.g.*, cancer, non-alcoholic fatty liver disease, non-alcoholic steatohepatitis, and PBC)[6-10]. Thus, it is essential to identify specific metabolomic markers, and to establish a diagnostic model for AIH or PBC.

In the present study, we aimed to identify serum biomarkers for the differential diagnosis of PBC and AIH using ultra-performance liquid chromatography-quadrupole time-of-flight mass spectrometry (UPLC-QTOF-MS). UPLC-QTOF-MS is a newly developed technique that provides rapid and efficient access to detailed information pertaining to the nature of specific components within complex multicomponent mixtures. Compared with traditional high-performance liquid chromatography (HPLC), UPLC possesses the advantages of ultra-high resolution, high-speed scanning, and high sensitivity. Furthermore, bile acids (BAs) are crucial for the diagnosis, follow-up, and prognosis of liver and intestinal disorders, as well as diseases affecting BA metabolism. We applied a targeted metabolomic approach to quantify and compare 15 BA metabolites in PBC/AIH patients with those in healthy controls (HCs). The findings of the present study may reveal potentially novel biomarkers for the diagnosis of PBC and AIH. This study also aimed to compare metabolic profiles between PBC/AIH patients and HCs.

MATERIALS AND METHODS

Patients and study design

A total of 54 PBC and 26 AIH patients who were admitted to the First Hospital of Jilin University (Changchun, China) between May 2009 and November 2013 were respectively recruited in the present study. The study protocol was carefully reviewed and approved by the Institutional Review Board of The First Hospital of Jilin University. All the eligible patients and HCs signed the written informed consent form prior to enrollment. Patients with AIH were diagnosed according to the revised criteria presented by the International Autoimmune Hepatitis Group in 1999[11]. Patients with PBC were diagnosed according to the criteria released by the American Association for the Study of Liver Diseases [12]. Patients taking medication or supplements, or those with gallstones or other factors that might cause cholestatic liver diseases were excluded. In both groups, patients with primary sclerosing cholangitis (PSC), overlap syndromes (*e.g.*, PBC and AIH or AIH and PSC), hepatitis virus infection, human immunodeficiency virus co-infection, hepatocellular carcinoma, or diabetes were excluded. In total, 30 HCs who were admitted to our hospital for physical check-ups were enrolled. These HCs exhibited normal liver functions and had no evidence of disease. No statistically significant differences were found in age and gender among the PBC, AIH, and control groups (Table 1, $P > 0.05$).

Blood samples at the fasting state were collected from the eligible PBC patients, AIH patients, and HCs, in which 1 mL of serum was collected and stored at -80 °C for subsequent metabolic profiling. Participants' baseline characteristics are summarized in Table 1.

Reagents

HPLC-grade acetonitrile was purchase from Merck Inc. (Kenilworth, NJ, United States). HPLC-grade formic acid was obtained from Sigma-Aldrich (St. Louis, MO, United States). These two reagents were used for the preparation of mobile phases in HPLC. Milli-Q water was used, and obtained by filtering distilled water through a Milli-Q system (Millipore, Bedford, MA, United States). The chemical standards for the validation of molecular structure were obtained from Sigma-Aldrich.

Sample preparation and serum metabolic profiling

In the present study, 100 μL of each serum sample was mixed with 400 μL of cold acetonitrile for protein precipitation, followed by centrifugation at 14000 g for 10 min at 4 °C. Then, 400 μL of the supernatant was subsequently collected and lyophilized, and the residue was resolved in 100 μL of 20% acetonitrile. Equal aliquot of each serum sample was pooled together and mixed thoroughly by vortex for 1 min, which was used as the quality control (QC) sample. A QC sample was prepared after preparation of 10 real samples, and QC samples served to assess the repeatability of sample pretreatment and to monitor the stability of the UPLC-QTOF-MS system at the sequence analysis.

The UPLC-QTOF-MS approach was employed to perform serum metabolic profiling of samples obtained from PBC patients, AIH patients, and HCs, as previously described[13]. In brief, 5 μL of the reconstituted solution was carefully injected into the ACQUITY-UPLC system (Waters Corp., Milford, MA, United States) for separation using chromatography. Then, MS signals were acquired *via* the QTOF-MS system (Micromass, Manchester, United Kingdom), which was equipped with an electrospray source operating in both positive and negative ion modes. During the acquisition of MS signals, the m/z scan was set to a range of 100-1000[14]. Then, the AC18 column (2.1 mm × 100 mm, 1.7 μm), which was purchased from Waters Corp., was used for the separation of small molecular compounds at an elution speed of 0.35 mL/min. The gradient was set to 95% formic acid (0.1%, V/V), and maintained for 1 min. Subsequently, elution strength linearly increased to 100% acetonitrile for 22 min, and was kept for 3 min. The total duration was 30 min, which included equilibration for 1 min.

Analysis of BAs

All samples prepared with GCA-d5 as the internal standard and blood samples were resolved in 100 μL

PBC: Primary biliary cirrhosis; AIH: Autoimmune hepatitis; AST: Aspartatetransaminase; ALT: Alanine aminotransferase; ALP: Alkaline phosphatase; γ-GT: γ-glutamyl transpeptidase; TBiL: Totalbilirubin; DBiL: Direct bilirubin; TBA: Total bile acid; AMA: Anti-mitochondrial antibody; ANA: Anti-nuclear antibody. All data are presented as median and range. Statistically significant differences between controls and patients were determined by the rank sums Mann-Whitney.

of 25% ACN aqueous solution. The LC-MS parameters were as follows: 20 μL of the reconstituted solution was carefully injected into an ACQUITY UPLC C8 column with a particle size of 1.7 μm (Waters Corp.), and the SRM signals were obtained using an Agilent 6460 Triple Quadruple MS system (Agilent Technologies, Inc., Chicago, IL, United States), which was equipped with an electrospray source operating in the negative ion mode. The column was eluted with 10 mmol/L NH_4HCO_3 (solution A) and acetonitrile (solution B) in a linear gradient, in which the initial gradient was set to 75% solution A. Subsequently, after 9.0 min of elution, the strength was linearly elevated to 90% solution B, which lasted for 4 min. Then, this was returned to the initial gradient after 13.5 min of elution. Along with an equilibration of 1.5 min, the total running time was approximately 15 min. The following MS parameters were set in this study: Gas flow rate, 8 L/min; gas temperature, 350 °C; sheath gas temperature, 400 °C; nebulizer gas pressure, 40 psi; capillary voltage, 3500 V; sheath gas flow rate, 8 L/min; nozzle voltage, 400 V. The precursor and product ion pairs were acquired as follows: Cholic acid (CA) (407.5→407.5), glycocholic acid (GCA) (464.2→74.1), taurocholic acid (TCA) (514.2→80.1), ursodeoxycholic acid (UDCA) (391.4→391.4), glycoursodeoxycholic acid (GUDCA) (448.3→74.1), tauroursodeoxycholic acid (TUDCA) (498.3→80.1), chenodeoxycholic acid (CDCA) (391.4→391.4), glycochenodeoxycholic acid (GCDCA) (448.3→74.1), tauroursodeoxycholic acid (TCDCA) (498.2→80.1), glycochenodeoxycholic sulfate (GCDCS) (528.3→448.3), deoxycholic acid (DCA) (391.2→391.2), glycodeoxycholic acid (GDCA) (448.2→74.1), taurodeoxycholic acid (TDCA) (498.3→80.2), lithocholic acid (LCA) (375.3→375.3), taurolithocholic acid (TLCA) (482.1→80.1), and GCA-d5 (469.2→74.1).

Bioinformatics and statistical analyses

The raw data were imported into Databridge (MassHunter Quantitative Analysis software; Agilent Technologies, Inc.), followed by the peak extraction and alignment on the obtained NetCDF files using XCMS 18.0 software. The alignment parameters were set as follows: The retention time window was 7, the full width at half maximum was 14, and the remaining parameters were set as default. Subsequently, the peaks with the paired m/z, as well as their corresponding peak intensities and retention time were exported into the Excel software. Prior to univariate and multivariate logistic regression analyses, each peak area was initially normalized to the total peak area. In the multivariate logistic regression analysis, the principal component analysis (PCA) in combination with the partial least squares-discriminant analysis (PLS-DA) was conducted by SIMCA-P 11.0 software (Umetrics AB, Umea, Sweden) using the prepared data. After scaling for PCA to unit variance, the data provided an overview of the repeatability of the QC samples. Additionally, the data were Pareto scaled for PLS-DA to assess

the performance of the classification models, and to identify variables for the corresponding model.

In the univariate analysis, data were statistically analyzed by SPSS 18.0 software (IBM, Armonk, NY, United States). The biochemical data and the concentrations of BAs were log-transformed to approximately normalize their distributions. $P < 0.05$ was considered statistically significant. Nonparametric statistical analysis was conducted using GraphPad Prism 5.0 software (GraphPad Software Inc., San Diego, CA, United States) for making comparison between two groups.

RESULTS

Patients' baseline clinical characteristics

Patients' baseline clinical characteristics are summarized in Table 1. Previous epidemiological studies have demonstrated that women were more frequently affected by PBC and AIH than men. Consistently, the incidence rates of PBC and AIH were higher in women than in men in our study. Furthermore, to avoid the influences of drugs on the metabolomics analysis, no patient had received any treatment, including traditional Chinese medicine. The mean age of patients with PBC and AIH, and HCs was 56 (range, 38-73), 54.6 (range, 17-75), and 54.9 (range, 30-76) years old, respectively. There were no significant differences in age, parity, and gender among patients with PBC and AIH, and HCs ($P > 0.05$). Besides, 10 cases from the PBC group and 14 cases from the AIH group were newly diagnosed by biopsy. Other cases from the PBC group were diagnosed by M2-positive, and other cases from the AIH group were diagnosed by pathological scores (> 12).

There were 26 cases of Child-Pugh class A, 19 cases of Child-Pugh class B, and 9 cases of Child-Pugh class C in PBC patients. There were 17 Child-Pugh grade A and 9 Child-Pugh grade B patients with AIH. The levels of globulin, transaminases, and specific autoantibodies in the sera are presented in Table 2.

Serum metabolic profiling

A total of 110 serum samples obtained from 54 patients with PBC, 26 patients with AIH, and 30 HCs were analyzed using UPLC-QTOF-MS in both positive and negative ion modes. As shown in Supplementary Figures 1 and 2, a typical base peak chromatogram was detected by MS in positive and negative ion modes, respectively. After the peaks were aligned, 1133 peaks of positive ions and 963 peaks of negative ions were identified using MassLynx and the same acquisition method. The data were transformed into SIMCA-P11 software for PCA. Plots of the PCA scores in positive and negative ion modes are illustrated in Figure 1A, Figure 2A, Figure 3A, Figure 4A, Figure 5A and Figure 6A. Distinct clustering was observed between PBC patients and HCs, and between AIH patients and HCs. No distinct clustering was found between PBC patients and AIH patients. The QC samples were tightly clustered (Figure 1A, Figure 2A, Figure 3A, Figure 4A, Figure 5A and Figure 6A), ensuring the repeatability of the information[13].

Identification of serum metabolites specific to PBC and AIH

To find out the differentially expressed metabolites, *P*-values ($P < 0.05$) in the t-test were combined with variable importance in the projection (VIP) values in the PLS-DA model. The PLS-DA score charts are shown in Figure 1B, Figure 2B, Figure 3B, Figure 4B, Figure 5B and Figure 6B. We also conduct sorting verification on the model to check whether the model is "over-fitting". The results are shown in Figure 1C, Figure 2C, Figure 3C, Figure 4C, Figure 5C and Figure 6C. As can be seen from the sorting test figure, Figure 1C, Figure 2C, Figure 5C and Figure 6C, there is no "over-fitting" in these models. Figure 3C and Figure 4C show that the two models are "overfitted". We only established the discriminant analysis model of multivariate analysis between PBC/Control and AIH/Control, but failed to establish the discriminant analysis model of PBC/AIH. The PBC and AIH samples of the two groups overlaps on the PCA score plot (as shown in Figure 3A and Figure 6A), and the supervised PLS-DA (as shown in Figure 3B and Figure 6B) still failed to distinguish them significantly, indicating that there was little difference in metabolic profile between the two groups of different autoimmune liver diseases.

The METLIN metabolomics database (http://metlin.scripps.edu/) was used to facilitate metabolite annotation through MS analysis. The data of differentially expressed are presented in Tables 3 and 4. Fold-change (FC) was used to indicate changes in potential PBC- and AIH-specific biomarkers, and the chosen FC values were > 2 and < 0.5.

Identification of serum metabolites specific to PBC

As presented in Table 3 the levels of 17 of 26 potential biomarkers identified were elevated in the serum samples of patients with PBC, while the levels of 9 of these 26 potential biomarkers were reduced in the serum samples of patients with PBC compared with those in HCs. Among these biomarkers, the levels of TDCA, GUDCA, tetracosahexaenoic acid, bilirubin, sphinganine, phytosphingosine, L-phenylalanine, L-proline, TCA, LysoPC [18:3 (6Z, 9Z, 12Z)], TUDCA, GCA, LysoPE [0:0/18:4 (6Z, 9Z, 12Z, 15Z)], LysoPE [20:3 (11Z, 14Z, 17Z)/0:0], L-urobilinogen, L-urobilin, and DCA significantly increased in patients with PBC compared with those in HCs ($P < 0.5$). The levels of 12-ketodeoxycholic acid, α-

Figure 1 Multivariate statistical analysis on serum profiling data in positive ions between primary biliary cholangitis and control. A: Plots of principal component analysis (PCA) in positive ion mode. (1) Primary biliary cholangitis (PBC); (2) Control; and (3) Quality control (QC); B: Scatter plots of partial least squares-discriminant analysis (PLS-DA) with a positive model of serum from patients with PBC, autoimmune hepatitis and healthy controls. (1) PBC; (2) Control; and (3) QC; C: Validation plot of the original PLS-DA with a positive model, strongly indicating that the original model is valid and shows signs of overfitting. The permutation test was repeated 200 times in the cross-validation plot.

ketoisovaleric acid, pyroglutamic acid, lactic acid, hypoxanthine, LysoPE [0:0/20:2 (11Z, 14Z)], ketoleucine, LysoPE [0:0/22:4 (7Z, 10Z, 13Z, 16Z)], and MG [0:0/18:4 (6Z, 9Z, 12Z, 15Z)/0:0] in patients with PBC were significantly reduced compared with those in HCs.

Identification of serum metabolites specific to AIH

As shown in Table 4. The levels of 17 of 25 potential biomarkers identified were elevated in the serum samples of the patients with AIH, while the levels of 8 of these 25 potential biomarkers were reduced in the serum samples of patients with AIH compared with those in HCs. Among these biomarkers, the levels of TDCA, GUDCA, L-Urobilin, sphinganine, phytosphingosine, I-Urobilin, bilirubin, stearamide, kynurenine, L-threonine, L-phenylalanine, urea, TCA, LysoPC [18:3 (6Z, 9Z, 12Z)], TDCA, GCA, and LysoPE [20:3 (11Z, 14Z, 17Z)/0:0] significantly increased in patients with AIH compared with those in HCs. The levels of 12-ketodeoxycholic acid, uric acid, pyroglutamic acid, LysoPE [0:0/20:2 (11Z, 14Z)],

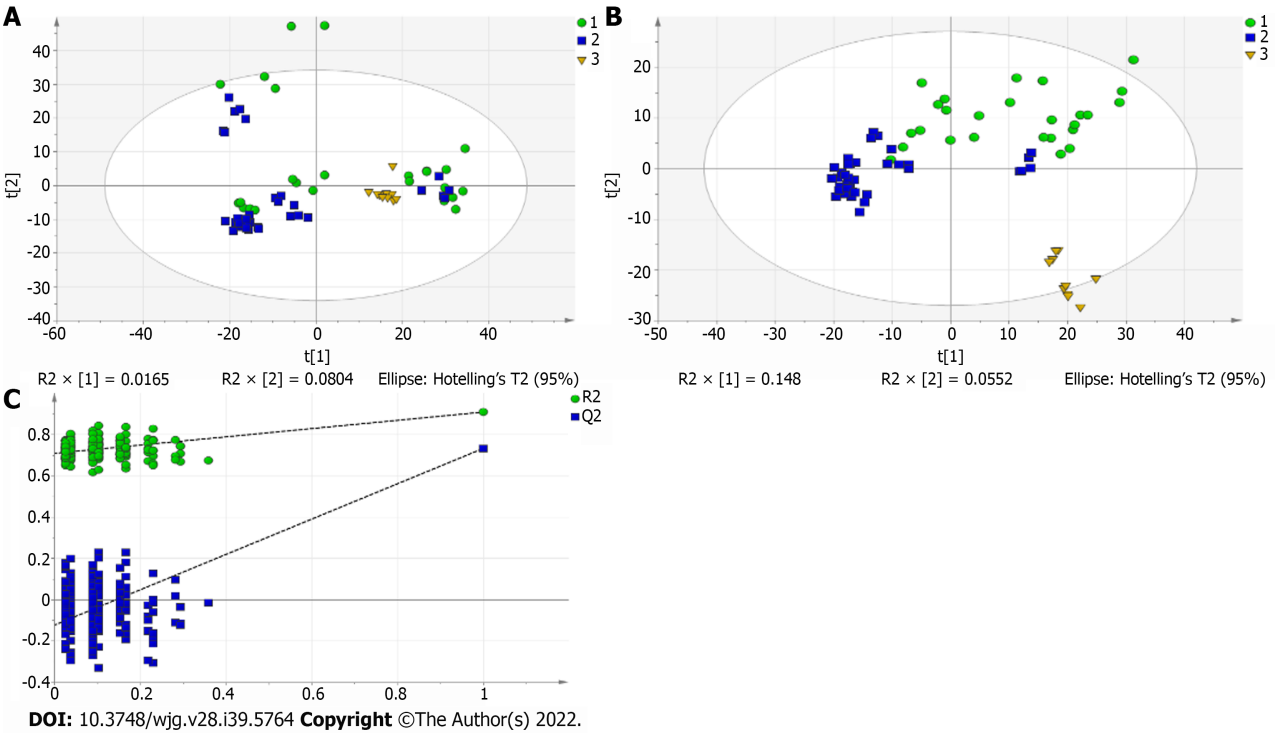
Bile acid (BA) levels are expressed in log10 concentrations. Statistically significant differences in BA concentrations between controls and patients were determined by the rank sums Mann-Whitney test. CA: Cholic acid; CDCA: Chenodeoxycholic acid; DCA: Deoxycholic acid; GCA: Glycocholic acid; GCDCA: Glycochenodeoxycholic acid; GCDCS: Glycochenodeoxycholic sulfate; GDCA: Glycodeoxycholic acid; GUDCA: Glycoursodeoxycholic acid; LCA: Lithocholic acid; TCA: Taurocholic acid; TCDCA: Taurochenodeoxycholic acid; TDCA: Taurodeoxycholic acid; TLCA: Taurolithocholic acid; TUDCA: Tauroursodeoxycholic acid; UDCA: Ursodeoxycholic acid; PBA: Primary bile acid; PBC: Primary biliary cirrhosis; AIH: Autoimmune hepatitis.

lactic acid, pyroglutamic acid, hypoxanthine, CPA (16:0/0:0), and MG [0:0/18:4 (6Z, 9Z, 12Z, 15Z)/0:0] significantly decreased in patients with AIH compared with those in HCs.

Quantification of targeted BAs specific to PBC and AIH

Recently, BAs have been shown to be potentially more effective biomarkers for PBC and AIH. Regarding the most abundant BAs in humans, the following 15 BAs were selected: CA, GCA, TCA, UDCA, GUDCA, TUDCA, CDCA, GCDCA, TCDCA, GCDCS, DCA, GDCA, TDCA, LCA, and TLCA. The levels of these 15 BAs were measured using the UPLC-QTOF-MS. The levels of all BAs in the disease group were higher than those in the control group, and the levels of glycine-bound cholic acid and tauro-bound cholic acid were elevated, shown in Supplementary Table 1.



Furthermore, the levels of BAs in patients with PBC and AIH were compared with the corresponding levels in HCs, show in Table 5. It was revealed that the levels of BAs were elevated in patients with PBC and AIH. The levels of CDCA, LCA, TLCA, and LCA + TLCA in PBC patients were higher than those in AIH patients, in which a significant difference was found in the levels of CDCA and LCA ($P < 0.05$; for TLCA, $P = 0.0767$).The differences in the levels of CDCA, LCA, and LCA + TLCA among the three groups were statistically show in Figure 7. The levels of CDCA, LCA, and LCA + TLCA significantly increased in PBC patients compared with those in AIH patients ($P < 0.05$). Moreover, the CDCA-to-CA ratio decreased in PBC and AIH patients compared with that in HCs.

The receiver operating characteristic curve analysis of BAs with differences between the PBC and AIH groups showed that the area under the curve values of CDCA, LCA, and TLCA were greater than 0.7, and sensitivity was higher than 70%, indicating a high sensitivity, while a low specificity was noted in identification of patients with PBC and AIH (Figure 8 and Table 6). Compared with sensitivity and specificity of the traditional biochemical indicators, such as alanine transaminase, aspartate transaminase, gamma glutamyl transpeptidase, alkaline phosphatase, total bilirubin, direct bilirubin, and total bile acid, sensitivity and specificity of CDCA, LCA and TLCA were higher than the traditional markers of liver injury, which are of great significance for clinical diagnosis and can be further verified by enlarging the sample size. Thus, BAs can be potentially considered as markers for the diagnosis of PBC and AIH.

Table 6 Area under the curve, sensitivity and specificity of difference bile acids, conventional biochemical indicators in primary biliary cirrhosis, autoimmune hepatitis and control group

	AUC	Sensitivity	Specificity
LCA	0.68	0.82	0.50
LCA + TLCA	0.73	0.74	0.46
CDCA	0.74	0.74	0.54

The permutation test was repeated 200 times in the cross-validation plot.

DISCUSSION

In the present study, we established a diagnostic model for PBC and AIH using the UPLC-QTOF-MS. Besides, VIP values from PLS-DA were calculated to describe a quantitative estimation of the discriminatory power of each individual feature. We found changes in the levels of amino acids, BAs, organic acids, phospholipids, sugar, and sugar alcohols in patients with PBC and AIH, and in HCs. These substances are mainly involved in lipid metabolism, BA metabolism, and bilirubin metabolism, which

are related to metabolic functions of the liver and inflammatory reactions. These compound classes are also associated with key hepatic metabolic pathways. Importantly, our findings are consistent with those reported previously; for instance, BAs have been identified as a significant factor contributing to PBC[14-16]. When liver injury occurs, intrahepatic clearance rate of BAs decreases and serum BA level increases. BAs have long been used as markers of liver dysfunction. In recent studies, elevated serum levels of BAs have been found to be closely associated with liver diseases[17-21].

The levels of lysophosphatidylcholine (LPC) and lysophosphatidylethanolamine (LPE) significantly changed in patients with PBC and AIH. To date, no study has used lysophospholipids in the diagnosis of PBC and AIH. Lysophospholipids are biologically active lipids that are involved in a variety of important processes, including cell proliferation, cell migration, angiogenesis, and inflammation[22]. Our results also provided important clues to further explore the pathogenesis of PBC and AIH.

A discriminatory diagnostic model of PBC/AIH could not be established using the UPLC/MS/MS, suggesting that the changes of terminal metabolites in serum samples of patients with PBC and AIH were no special differences. Failure in the establishment of a discriminatory diagnostic model of PBC/AIH could be related to the sample size. Therefore, BAs were quantitatively analyzed according to the differences found between PBC/control and AIH/control groups.

BA is the general term used for a class of bisexual molecules produced by the metabolism of cholesterol. The liver has an effective clearance effect on BAs, and BAs are kept at low levels, confirming the low levels of BAs in the human peripheral blood plasma. In the human liver, cholesterol is metabolized into primary BAs, including CA and CDCA, and then into the intestine, followed by into the corresponding secondary show in Figure 9.

The results of our targeted metabolomic study of BAs showed that the levels of BAs increased in patients with PBC and AIH compared with those in HCs, and the levels of CDCA, LCA, and LCA + TLCA in PBC patients were significantly higher than those in AIH patients. It is noteworthy that CA and CDCA, the two major human BAs, are synthesized from cholesterol in a series of reactions catalyzed by enzymes located in the endoplasmic reticulum, mitochondria, cytosol, and peroxisomes, suggesting that there were significant differences in the levels of BAs in PBC patients, providing clues for the future study on the pathogenesis of PBC. In autoimmune liver diseases, the dysfunction of BA metabolism occurs after liver injury, which may be related to bile stasis after liver injury, especially in

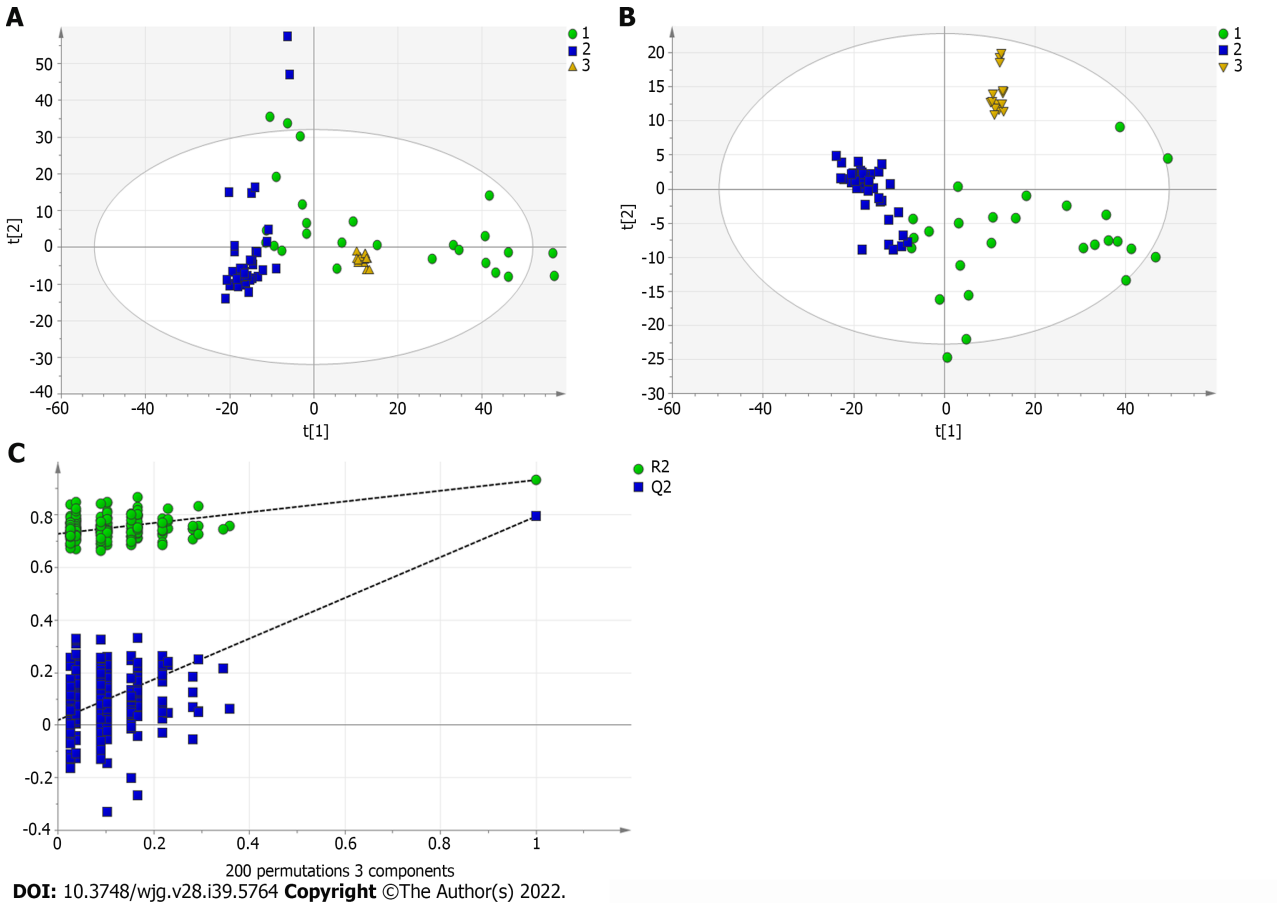
Figure 4 Multivariate statistical analysis on serum profiling data in negative ions between primary biliary cholangitis and control. A: Plots of principal component analysis in negative ion mode. (1) Primary biliary cholangitis (PBC); (2) Control; and (3) Quality control (QC); B: Scatter plots of partial least squares-discriminant analysis (PLS-DA) with a negative model of serum from patients with PBC, autoimmune hepatitis and healthy controls. (1) PBC; (2) Control; and (3) QC; C: Validation plot of the original PLS-DA with a negative model, strongly indicating that the original model is valid and shows signs of overfitting. The permutation test was repeated 200 times in the cross-validation plot.

PBC, which is more drastic, and is related to the pathogenesis of PBC. After bile duct obstruction and sclerosis, BAs cannot be transported and metabolized normally. Patients may present with jaundice and itchy skin.

Therefore, determination of the levels of BAs in plasma can reflect the synthesis, ingestion, and secretion of hepatocytes. Abnormalities in the levels of BAs not only reflect the extent of liver damage, but also indirectly indicate the conditions of blood-bile barrier in the liver.



To our knowledge, this is the first study that used serum metabolic profiling for diagnosing patients with PBC and AIH.

LCA is an endogenous compound associated with hepatic toxicity during cholestasis. A previous study[23] revealed that LCA induced disruption of phospholipid/ sphingolipid homeostasis through the transforming growth factor-β signaling pathway and serum LPC could be a biomarker for biliary injury.

The hepatic level of LCA was reported to elevate in patients with cholestatic liver disease[24,25]. This result is consistent with our finding, in which the levels of CDCA, LCA, TLCA, and LCA + TLCA were higher in PBC patients than those in AIH patients.

Previous studies[26,27] indicated that the activation of cytochrome P450 is correlated with Farnesoid X receptor (FXR). Mammalian FXR, which is a transcription regulatory factor in bile salt synthesis, is activated by BAs, such as CDCA or LCA[28,29]. The derangements of lipid metabolism are weakened in FXR-null mice compared with those in wild-type mice after LCA exposure[30,31]. As a cholestatic liver disease, the high levels of BAs may induce FXR gene transcription in PBC patients. Therefore, we hypothesized that these pathways may lead to LCA poisoning in PBC patients, and LCA metabolic pathway plays an important role in the incidence of PBC. Lian *et al*[14] used the untargeted metabolomic method of UPLC-MS, and clarified the relationship between LCA level and PBC incidence, as well as the relationship between LCA level and the incidence of lipid metabolism disorders. Our study also revealed the abnormal levels of LPC and LPE in PBC patients.

However, the retention of hydrophobic BAs in pathophysiological conditions, such as cholestatic diseases, plays an important role in liver injury by inducing apoptosis or necrosis of hepatocytes[32]. The retention and accumulation of hydrophobic Bas (*e.g.*, CDCA and DCA)inside hepatocytes during cholestasis have long been implicated as a major cause of liver dysfunction[32].

Figure 5 Multivariate statistical analysis on serum profiling data in negative ions between autoimmune hepatitis and control. A: Plots of principal component analysis in negative ion mode. (1) Autoimmune hepatitis (AIH); (2) Control; and (3) Quality control (QC); B: Scatter plots of partial least squares-discriminant analysis (PLS-DA) with a negative model of serum from patients with Primary biliary cholangitis, AIH and healthy controls. (1) Autoimmune hepatitis (AIH); (2) Control; and (3) QC; C: Validation plot of the original PLS-DA with a negative model, strongly indicating that the original model is valid and shows signs of overfitting. The permutation test was repeated 200 times in the cross-validation plot.

The hydrophobicity of BAs is an important determinant of the toxicity and protection of BAs. Under normal conditions, the levels of BAs undergoing further biotransformations to dianionic glucuronidated or sulfated derivatives are negligible, although they may become important in cholestasis[33].

Several mechanisms may be involved in the cytotoxicity associated with the most hydrophobic BAs in cholestatic liver diseases[32]. BAs could disrupt cell membranes through their detergent action on lipid components[34] and promote the generation of reactive oxygen species that, in turn, oxidatively modify lipids, proteins, and nucleic acids, and eventually cause hepatocyte apoptosis[35].

As shown in Figure 9 CDCA/LCA/TLCA are all related to the decomposition and hydrolysis of bacteria in the intestine. CDCA is decomposed into LCA through bacteria in the intestine, and then, synthesizes TLCA through the intestinal bacteria. Intestinal bacteria may play a key role in this process. Therefore, we can hypothesize that dysfunction of intestinal bacteria may increase the incidence of autoimmune liver diseases, including PBC. Lv *et al*[36] and Zheng *et al*[37] found that the interaction of intestinal microflora with metabolism and immunity is crucial for the occurrence or development of PBC.

The Child-Pugh scoring system was used to classify PBC and AIH patients according to their Child-Pugh scores, show in Supplementary Table 2 and the levels of BAs in these patients with Child-Pugh scores were statistically show in Table 7. It was found that the levels of GCA, TCA, GCDCA, GCDCS, TDCA, and tauro-conjugated BAs were gradually elevated with the increase of Child-Pugh scores. The levels of BAs in PBC patients with Child-Pugh class C were significantly different from those in PBC patients with Child-Pugh class A ($P < 0.05$). The levels of BAs in AIH patients with Child-Pugh class B were significantly different from those in PBC patients with Child-Pugh class A ($P < 0.05$). The levels of GCA, GCDCS, and TDCA significantly differed in PBC and AIH patients with Child-Pugh class B (Figure 10). These BAs are all conjugated BAs, suggesting that the levels of conjugated BAs are elevated in patients with severe liver injury. The determination of BA level can not only reflect liver damage, but also indicate the degree of liver damage, which is similar to the results of our previous study on drug-induced liver injury (DILI)[38]. The increase in the levels of GCA, TCA, TUDCA, GCDCA, GCDCS, and TDCA was corresponded to a higher degree of DILI. Tang *et al*[15] used UPLC/Q-TOF-MS to analyze

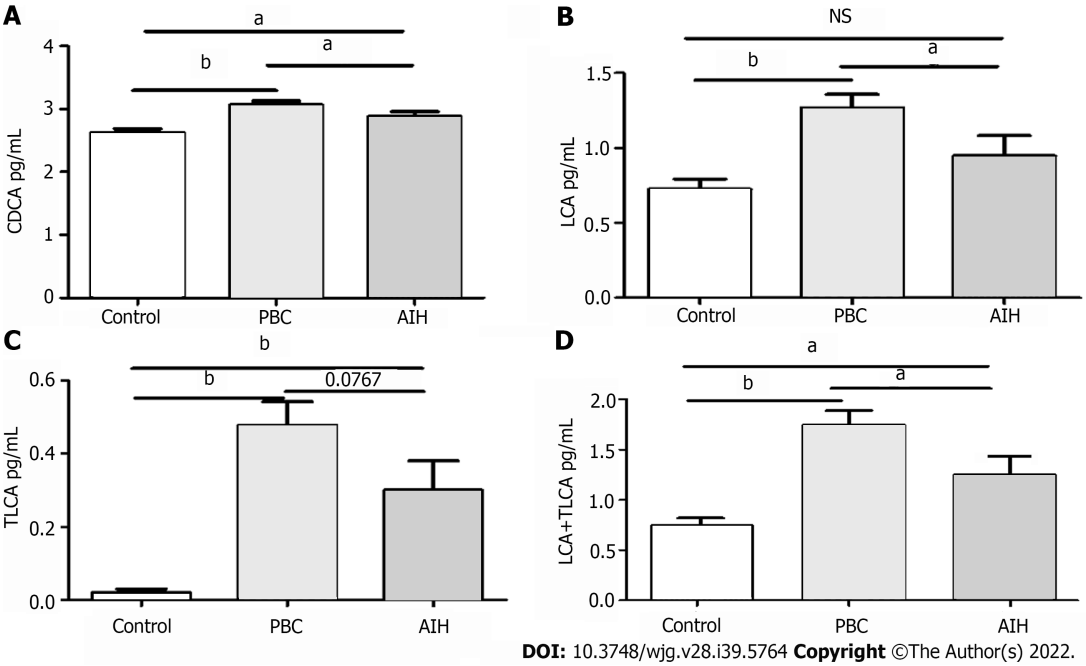
Bile acid (BA) levels are expressed in log10 concentrations. Statistically significant differences in BA concentrations between controls and patients were determined by the rank sums Mann-Whitney test. CA: Cholic acid; CDCA: Chenodeoxycholic acid; DCA: Deoxycholic acid; GCA: Glycocholic acid; GCDCA: Glycochenodeoxycholic acid; GCDCS: Glycochenodeoxycholic sulfate; GDCA: Glycodeoxycholic acid; GUDCA: Glycoursodeoxycholic acid; LCA: Lithocholic acid; TCA: Taurocholic acid; TCDCA: Taurochenodeoxycholic acid; TDCA: Taurodeoxycholic acid; TLCA: Taurolithocholic acid; TUDCA: Tauroursodeoxycholic acid; UDCA: Ursodeoxycholic acid; PBA: Primary bile acid; PBC: Primary biliary cirrhosis; AIH: Autoimmune hepatitis.

the metabolic groups of blood and urine in 32 pairs of PBC patients and HCs. It was found that the BA level increased with the PBC progression, while the higher accuracy of our findings was confirmed. Elevated levels of BAs are correlated with severity of a variety of diseases. BAs can be used as a factor to judge the severity of the disease and as a basis for the diagnosis of the disease. It is necessary to further expand the sample size for research.



CONCLUSION

A discriminatory diagnostic model for PBC and AIH using UPLC-QTOF-MS was established. Besides, differential metabolomics analysis was conducted using the PLS-DA model to screen the differentially expressed substances in the different groups. The changes in the levels of BAs, LPC, LPE, bilirubin, and

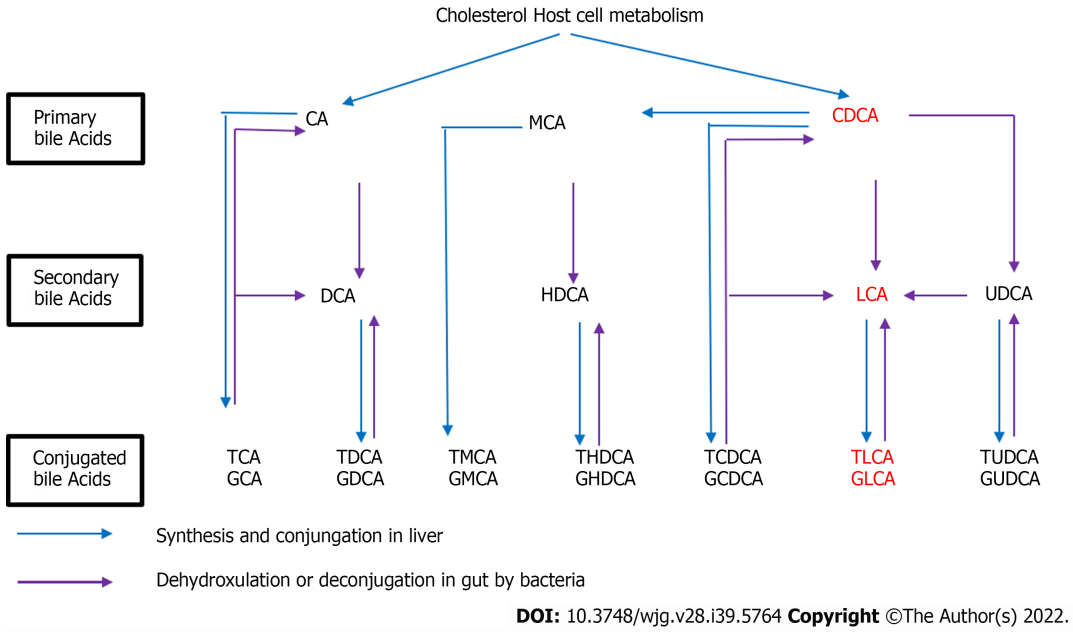
Figure 7 Comparative analysis of alterations in serum bile acid levels in patients in the mild and severe injury groups, and in healthy controls. A: Chenodeoxycholic acid; B: Lithocholic acid (LCA); C: Taurolithocholic acid (TLCA); D: LCA + TLCA; $^{a}P < 0.05$; $^{b}P < 0.0001$; NS: Not significant.



phytosphingosine in PBC and AIH patients and HCs were compared.

The levels of CDCA, LCA, TLCA, and LCA + TLCA significantly increased in the PBC group compared with those in the AIH group. These results suggested that the levels of BAs can be used as a marker to differentiate PBC from AIH, and the results may be advantageous to study the pathogenesis

of PBC/AIH in the future.

In conclusion, this study revealed that in patients with PBC and AIH, there were significant differences in serum levels of BAs. However, due to the existence of some limitations (*i.e.*, the small sample size, the lack of staging methods for PBC and AIH, and phenotypic information), further study with a larger sample size is required to eliminate the above-mentioned limitations and to confirm the findings.

ARTICLE HIGHLIGHTS

Research background

Primary biliary cholangitis (PBC) and autoimmune hepatitis (AIH) are two unexplained immune diseases. It is difficult to identify and Liver biopsy should be done.

Research motivation

Avoid liver perforation and relieve the pain of patient, to improve the diagnostic rate of PBC and AIH.

Research objectives

To determine non-invasive, reliable, and sensitive biochemical markers for the differential diagnosis of PBC and AIH.

Research methods

Metabolomics technologies, including full-contour metabolomics and target.

Research results

We revealed the increased levels of chenodeoxycholic acid, lithocholic acid (LCA), taurolithocholic acid (TLCA), and LCA + TLCA in the PBC group compared with those in the AIH group. The levels of glycochenodeoxycholic acid, glycochenodeoxycholic sulfate, and taurodeoxycholic acid were gradually elevated with the increase of Child-Pugh class, which was correlated with the severity of disease.

Research conclusions

The levels of bile acids could serve as potential biomarkers for the early diagnosis and assessment of the severity of PBC and AIH.

Research perspectives

It is necessary to further expand the sample size for research and search for the mechanism for the changes.

ABOUT COVER

Editorial Board of *World Journal of Gastroenterology*, Julio Mayol, MD, PhD, Professor, Surgeon, Department of Surgery, Universidad Complutense de Madrid Medical School, Hospital Clinico San Carlos, Madrid 28040, Spain. jmayol@ucm.es

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

Hepatitis B virus (HBV) infection is a global public health issue. Interferon-α (IFN-α) treatment has been used to treat hepatitis B for over 20 years, but fewer than 5% of Asians receiving IFN-α treatment achieve functional cure. Thus, IFN-α retreatment has been introduced to enhance antiviral function. In recent years, immune-related studies have found that the complex interactions between immune cells and cytokines could modulate immune response networks, including both innate and adaptive immunity, triggering immune responses that control HBV replication. However, heterogeneity of the immune system to control HBV infection, particularly HBV-specific $CD8^+$ T cell heterogeneity, has consequential effects on T cell-based immunotherapy for treating HBV infection. Altogether, the host's genetic variants, negative-feedback regulators and HBV components affecting the immune system's ability to control HBV. In this study, we reviewed the literature on potential immune mechanisms affecting the immune control of HBV and the clinical effects of IFN-α treatment and retreatment.

Key Words: Hepatitis B virus; Chronic; Functional cure; Heterogeneity; Immunity; Immune control; Interferon-α; Retreatment

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Hepatitis B virus (HBV)-specific immune control is characterized by distinct phenotypical and functional profiles. Owing to the negative feedback associated with all immune responses in an infected host, immunomodulators regulating a single immune pathway are unlikely to fully restore antiviral immunity. Interferon-α (IFN-α) treatment was shown to simultaneously affect multiple immune pathways and various immune cell populations in the host and integrate signals toward improving HBV-specific immune control. In addition, IFN-α retreatment was shown to improved functional cure rates, indicating that could gradually enhance the overall immune control.

INTRODUCTION

Hepatitis B virus (HBV) infection is a major global health problem. It is estimated that over 257 million people are suffering from chronic hepatitis B (CHB) infection[1]. After being infected by HBV, the virus transfers its genome into the nucleus of hepatocytes, where it is converted into covalently closed circular DNA (cccDNA), which has two major roles: Acting as a template for virus replication and acting as a reservoir for long-term virus preservation. Some studies have found that cccDNA persists in the hepatocytes of patients even decades after HBV infection has been resolved[2]. Further, it was shown that part of the viral genome remained integrated into the genomic DNA of the host's hepatocytes. Therefore, targeted eradication of cccDNA and viral genome in hepatocytes is regarded as the holy grail for curing HBV[3-5], which has not yet been achieved with current therapies.

HBV infection induces various immune responses that lead to heterogeneous immune control associated with the HBV infection[5,6]. Acute HBV infection can be terminated by the host's adaptive immune responses, characterized by multi-specific and vigorous HBV-specific $CD8^+$ T cell responses. In contrast, during CHB infection, the adaptive immune responses are severely depressed due to exhausted or reduced HBV-specific $CD8^+$ T-cells[6,7] and dysfunctions in HBV-specific B cells[7-9]. Researchers have noticed different outcomes from HBV infection in different populations and races.

Most CHB cases in the Asian population occur during infancy or childhood. However, asymptomatic infection during childhood makes it very challenging for authorities to determine when the infection actually occurred. Further, due to the uncertain timing of hepatitis flares and disease phases, there is little research on this topic in past literature, and little is known about hepatitis flares and intrahepatic immunity. Recently, studies on the partial immune mechanism in CHB have been performed, and important discoveries were made[2-6].

Currently, CHB is treated with nucleoside/nucleotide analogs (NAs) or interferon-α (IFN-α). NAs can target HBV polymerase/reverse transcriptase, inhibit HBV replication and are better tolerated by patients, but they cannot target cccDNA and unavoidably often results in NAs resistance and associated mutations. Since NAs do not directly influence immune response, functional cure with NAs is rarely achieved. In contrast, IFN-α treatment enhances HBV-specific immune control and can result in a partial or functional cure. However, due to poor efficacy with single course IFN-α treatment, since 1996, researchers have begun using IFN-α retreatment to improve the antiviral efficacy in CHB patients[10-15] or sufferers from NAs multi-drugs resistance[15-18].

In this present article, we reviewed the complex interactions between immune cells and cytokines of the immune response network against HBV, the correlation between host genetic variations and hepatitis B, the interplay between HBV components and HBV-specific immune control, and the heterogeneity of HBV-specifical immune control. Based on this foundation, we also discussed the underlying mechanism of IFN-α treatment and retreatment for improved HBV-specific immune control.

HETEROGENEOUS IMMUNITIES DURING HBV INFECTION

The innate and adaptive immunity work together to control immune responses against HBV. Innate immunity is not HBV antigen-specific but still produces T-cell polarizing and inflammatory cytokines that alter the intrahepatic microenvironment for presenting HBV antigens to naïve T cells to establish HBV-specific immunity. In recent years, researchers have recognized adaptive immunity as a crucial player for persistent and efficient immune control of HBV infection, which comprises a complex web of effector cell types. HBV-specific T cells help clearing HBV-infected hepatocytes and reduce the levels of circulating virus, while B cells neutralize viral particles and prevent reinfection[3,19-22]. Thus, their

levels ultimately determine the outcome of the disease.

The liver is an immunologically tolerant organ in which most immune cells are suppressed to limit hypersensitivity of immune responses against organ damage and local antigens. Thus, in a healthy state, the proportion of immune cells within the liver is much lower than in the peripheral blood. The difference in immune statuses between the liver and peripheral blood is defined as "immune compartmentalization". Investigations into the effects of costimulation have shown that Toll-like receptors (TLRs) and Treg cells participate in the intrahepatic immunopathogenesis in patients with HBV infection[3,23-25].

Recognition of HBV components by the innate immunity

Non-specific recognition of HBV components occurs at the molecular/subcellular level by innate immunosensors, namely pathogen-recognition receptors (PRRs) that recognize pathogen-associated molecular patterns (PAMP). The main PRRs that sense viral infection consists of retinoic acid-inducible gene I (RIG-I)-like receptors, nucleotide-binding oligomerization domain-containing protein-like receptors, TLRs, DNA-sensing receptors and C-type Lectin. These PRRs are expressed in epithelial cells, endothelial cells and immune cells. When PRRs interact with their cognate PAMP, downstream signaling pathways cascade, including adaptor/co-adaptor molecules, kinases and transcription factors are activated. This leads to the expression of interferon-stimulated genes (ISGs) and NFκB-inducible or pro-inflammatory genes, and various inflammatory cytokines are secreted. Primary cytokines include various classes of IFNs, pro-inflammatory cytokines and chemokines. These cytokines recruit various immune cells to the HBV-infected site, causing direct or indirect antiviral actions. These immune responses induce T cell proliferation and increase the efficiency of HBV-specific CD8+ T cells[21,26,27]. In particular, TLRs in hepatocytes and hepatic non-parenchymal cells (NPCs) have been shown to play vital roles in antiviral immunity. Currently, the use of TLR agonists as therapeutic agents to treat CHB is being validated[7].

In addition to cytokines, innate effector cells also participate in the control of HBV infection. Innate effector cells, including natural killer (NK) cells, γδT cells and mucosal-associated invariant T cells, can restrain the virus but are not specific for controlling HBV. Activated NK cells can induce inflammation in the liver, while activated T cells can be killed by NK cells, thereby reducing HBV-specific T cells. Although NK cells can suppress HBV replication, their activity was shown to be inhibited by transforming growth factor β (TGF-β) and IL-10 in CHB patients[3]. In addition, hepatic PCs, such as KCs and liver sinusoidal endothelial cells, can stimulate innate and adaptive immunity against HBV infection[28,29].

In short, the activation of innate immunity can lead to the production of cytokines, enhance antigen presentation, alter the intrahepatic microenvironment and trigger adaptive immunity (Figure 1).

HBV infection and adaptive immunity

HBV-specific T cells play a vital role in controlling HBV infection, and their immune responses can lead to the resolution of HBV replication. In acute hepatitis B patients, spontaneous viral clearance can occur *via* multi-specific $CD8^+$ T cell responses against HBV components[3,30]. In contrast, in CHB, the patients suffer from the exhaustion of HBV-specific $CD8^+$ T-cell responses throughout the HBV infection. Thus, most research on immune dysfunction focus on the activity of T cells, including $CD8^+$ and $CD4^+$ T-cells.

CHB is associated with the exhaustion of HBV-specific $CD8^+$ T-cells, marked by compromising functionality, such as reduced production of antiviral cytokines and immunodulatory cytokines and impaired proliferative capacities, defined as T-cell exhaustion[31,32]. HBV-specific $CD8^+$ T-cell exhaustion can be induced by: (1) Gradual aggravation of $CD8^+$ T-cells dysfunction and decreasing inflammatory cytokines production; (2) Increase in checkpoint inhibitors and immunosuppressive cytokines; (3) Epigenetic alterations leading to unrecoverable $CD8^+$ T-cell functions; (4) Alterations in $CD8^+$ T-cell phenotype; (5) Mitochondrial dysfunction and glycolysis downregulation, (6) Decrease in cell detection rate; and (7) Terminal exhaustion and physical deletion of HBV-specific $CD8^+$ T-cells.

In acute hepatitis B, $CD4^+$ T-cells have an important but indirect role in cleaning the virus. Th1-polarized $CD4^+$ T-cells regulate and maintain $CD8^+$ T-cell responses, contributing to HBV clearance. In contrast, during chronic HBV infection, the activation and upregulation of $CD4^+CD25^+$ Treg-cells suppress effective antiviral immune responses by inhibiting IFN-γ secretion, which inhibits the proliferation and cytokine secretion of $CD4^+$ and $CD8^+$ T-cells[7,30]. Figure 1 illustrates the complex interactions between immune cells and cytokine within the immune response network. The immune cells and their related cytokines are presented in Table 1.

HBV components inhibit innate and acquired immunity

HBV is believed to have existed in the human population for thousands of years and evolved with humans. During this evolution process, HBV has developed a particular lifecycle based on its unique replication mode through cccDNA and viral components that can adapt and suppress its host's immunity. Although the innate immunity can differentiate between different HBV components, HBV virion, antigens and peptides are still able to attack the TLR signaling pathway, resulting in negligible ISGs or IFNs secretions[4,7].

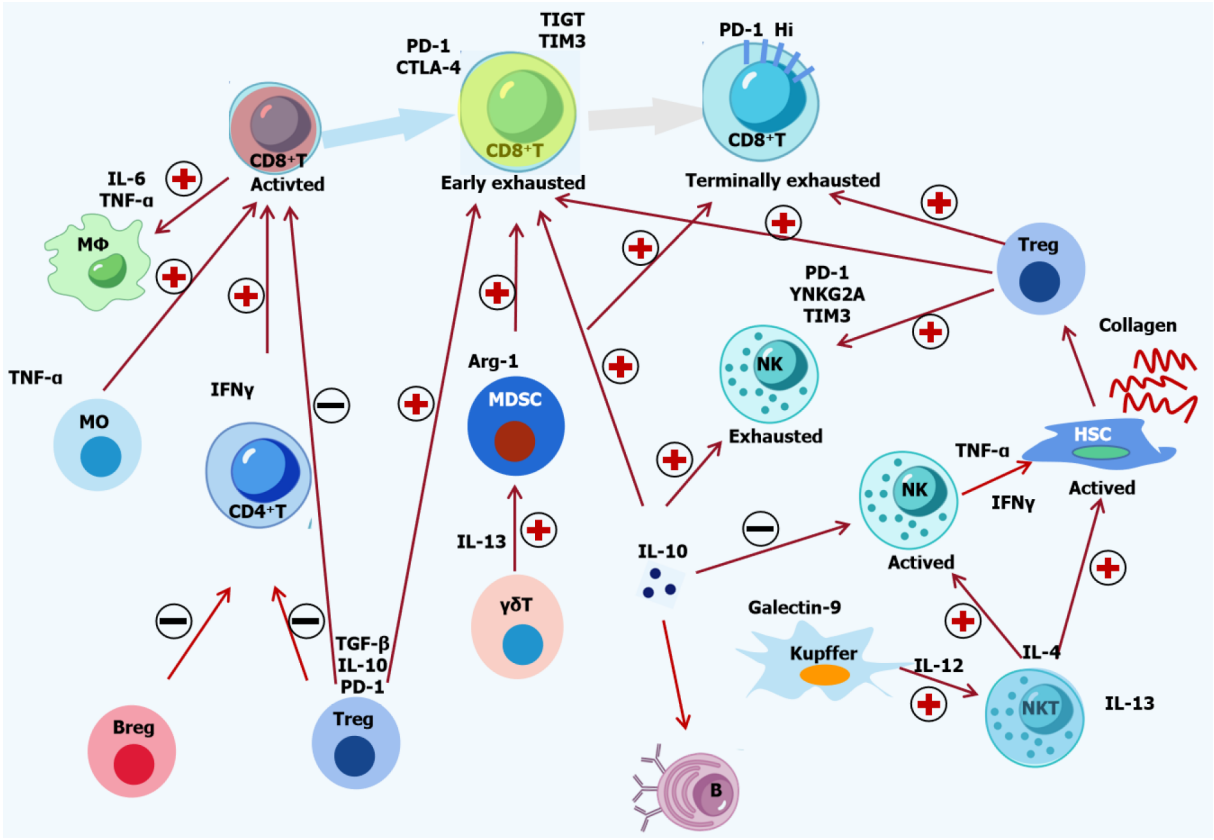
Table 1 Immune cells and their corresponding cytokines released

Immune cells	Released cytokines
NK cells	IFN-γ, TNF-α, IL-10
NKT cells	IFN-γ, IL-4, IL-13
Monocytes	IFN-γ, TNF-α, IL-10
Macrophages	IFN-γ, IL-6, MCP-1, IL-1β, TNF-α, CXCL10
γδT cells	IL-17, TNF-α
HSCs	IL-1β, IL-6, TGF-β
Kupffer cells	IL-10, TGF-β, IL-12, IL-6, TNF-α
$CD8^+$ T cells	IFN-γ, TNF-α, IL-2, IL-10, IL-17, IL-21
CD4+ T cells	IFN-γ, IL-21,IL-17
Regulatory T cells	IL-10, TGF-β, IL-35
Regulatory B cells	IL-10

HSCs: Hepatic stellate cells; IL: Interleukin; TGF-β: Transforming growth factor β; TNF-α: Tumor necrosis factor-α; IFN-γ: Interferon-γ; NK: Natural killer.

Among the ISGs is the apolipoprotein B editing complex (APOBEC) gene. APOBEC3A/B has been shown to cause cccDNA degradation, while APOBEC3G can inhibit HBV replication. However, APOBEC3G expression is often reduced by HBsAg[32].

A viral protein known for influencing HBV replication is HBx. It can interact with the cellular proteins in hepatocytes to increase viral replication by impairing IFN signaling and enhancing HBV gene expression[33-35]. Further, it was shown that HBV antigens could inhibit $CD8^+$ T-cell efficiency. Antagonist functions may provide a means for HBV to escape immune detection. Considering that certain $CD8^+$ T-cell epitopes in hepatitis B core antigen (HBcAg) or HBsAg can act as T-cell receptor (TCR) antagonists, their binding to TCR can lead to the suppression of $CD8^+$ T-cell response, thus decreasing their efficiency (Figure 2). In addition, the chronicity of HBV infection was shown to be promoted by HBeAg *via* the induction of $CD8^+$ T-cell tolerance[36].



Mechanisms of immune escape in antigen-presenting cells/HBV specific-$CD8^+$ T-cells

When the HBV protein is swallowed by antigen-presenting cells (APCs), this protein is digested into tiny pieces, which are transferred onto human leukocyte antigen (HLA) antigens. The HLA antigen complex on APCs is then displayed to T cells, which produce effector molecules to eliminate HBV. However, when HBV enters a hepatocyte, it enhances intracellular survival at the expense of higher levels of HBV replication. Thus, HBV-infected hepatocytes produce a large number of HBV antigens that can, in turn, inhibit HBV antigen processing and presentation in APCs. Further, amino acids flanking the viral epitopes in APCs play a critical role in antigen processing. Mutations at these regions in HBV infection harm the proteasomal processing of epitopes and lead to $CD8^+$ T-cell escape[30].

HLA genes are critical for the immune system as they control pathogens and clear infections. Host HLA polymorphisms have been demonstrated to influence disease progression in HBV infection[37]. Studies found that changes in the surface expression of HLA class I complexes on APCs were associated with HBV replication and persistence. Lower HLA class I expression led to early HBeAg seroconversion, while down-regulation of HLA class II molecules led to pre-core mutants of HBcAg[38]. Lumley *et al*[30] focused on the interplay between the immune escape of HBV and the selective mutation of HLA-binding residues. They reported that this selective mutation of HLA-binding residues in $CD8^+$ epitopes could induce the immune escape of HBV, which is one of the most commonly identified mechanisms for HBV-specific $CD8^+$ immune escape[30].

N-linked glycosylation (NLG) is a post-translational modification that can impact the infectivity and antigenicity of HBV. It can mask immune epitopes, leading to immune escape and interfering with the antibody recognition of hepatitis B surface antigen. NLG can also affect the ability through which the envelope protein of HBV interacts with the surface of capsids to drive HBV virion secretion[30].

The connection between TCR on T-cell and HLA class I/peptide complexes induces the activation of $CD8^+$ T-cells, but alterations in TCR recognition, *i.e.*, epitope mutations in TCR contact residues, can lead to the immune escape of $CD8^+$ T-cells. Immunodominance of HBV epitopes is ensured by the amino acid sequence of the peptide and its concentration and binding affinity with T cell clones. In different $CD8^+$ T-cell clones, the same viral peptide can induce different signaling cascades[22]. Figure 2 illustrates the immune escape of HBV, which can occur through multiple pathways. This has a vital role in HBV infection that can last for decades, with some T cell defects being irreversible.

DOI: 10.3748/wjg.v28.i40.5784 **Copyright** ©The Author(s) 2022.

Figure 1 Crosstalk among immune cells and cytokines in hepatitis B virus infection. The complex interactions among immune cells and cytokines in chronic hepatitis B are shown. Hepatitis B virus (HBV)-specific CD8$^+$ T-cells are activated by monocytes and CD4$^+$ T-cells, followed by recruitment and activation of macrophages by active CD8$^+$ T-cells. The activation of natural killer (NK) T-cells is induced by Kupffer cells, which activate NK cells and hepatic stellate cells (HSCs). Suppressive Tregs, Bregs and Kupffer cells induce the functional impairment of CD8$^+$ T cells, CD4$^+$ T-cells and NK cells. Moreover, Treg cells, Kupffer cells and myeloid-derived suppressor cells can lead to the exhaustion of CD8$^+$ T-cells and NK cells. Inflammatory and inhibitory cytokines, including Monocyte chemoattractant protein-1, tumor necrosis factor-α, interferon-γ, interleukin (IL)-4, IL-6, IL-12, IL-13, IL-17, IL-10, and transforming growth factor-β, are involved in the crosstalk among immune cells. The activation of HSCs in sinusoids is induced by a complement protein such as C5a. Finally, decreasing epigenetic modification and function of HBV-specific CD8$^+$ T-cells inhibits the immune control of HBV. PD-1: Programmed death 1; CTLA-4: Cytotoxic T-lymphocyte antigen-4; IL: Interleukin; TNF-α: Tumor necrosis factor-α; TGF-β: Transforming growth factor β; IFN-γ: Interferon-γ; HSC: Hepatic stellate cell; MDSC: Myeloid-derived suppressor cells; NK: Natural killer.

Negative feedback regulation in immune response pathways

Negative feedback regulations commonly occur in immune response pathways. These regulations include negative regulation of immune signal pathways (*i.e.*, negative feedback regulation in TLRs pathway), activation of immune checkpoints, expression of inhibitory cytokines, and activation of inhibitory immune cells. An active innate immunity can induce the secretion of cytokines with antiviral activity, enhance the efficiency of APCs and alter the microenvironment of the liver. However, inflammatory cytokines such as IFNs and tumor necrosis factor-α (TNF-α) can induce immune tolerance[39-41]. Many immune cells and signaling pathways in the liver contribute to immune responses against HBV infection. These immune responses are contact-dependent and can be affected by environmental factors. Inhibitory molecules are produced by hepatic stellate cells, Kupffer cells, T-regulatory cells and myeloid-derived suppressor cells. Through a contact-dependent manner, NK cells can kill HBV-specific CD8$^+$ T-cells. Moreover, HBV-specific CD8$^+$ T-cells can be suppressed by inhibitory ligands such as programmed death-ligand 1 (Figure 1)[6,42]. However, considering HBV has adaptive and active strategies to evade innate immune responses and negative feedback exists in all immune responses, immune regulator therapy targeting only a single pathway is unlikely to be effective in treating HBV infection.

Host genetic variations associated with HBV infection

Researchers have made great efforts to confirm the associations between HBV infection and host immunogenetics. Host genetic variants, including mutations in TLRs, HLAs, vitamin D-related genes, cytokine and chemokine genes, microRNAs, and HBV receptor sodium taurocholate co-transporting polypeptide, have been observed to impact the outcomes of HBV infection (Table 2)[43-46]. The HLA genes are divided into two classes: HLA-class I (HLA-A, B, C, E, F and G) and HLA-class II (HLA-DP, DQ, DR, DM and DO). Polymorphisms in HLA genes were shown to be significantly associated with the

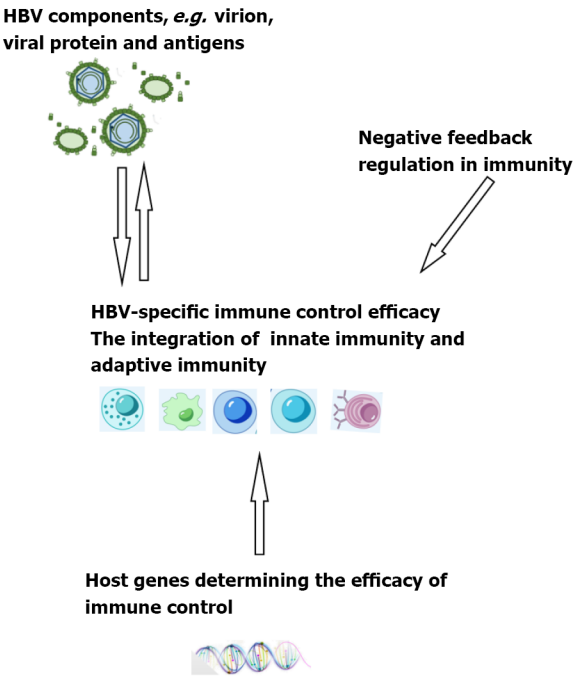
Figure 2 Mechanism of immune escape in antigen-presenting cell/hepatitis B virus special T-cell. Hepatitis B virus (HBV)-infected hepatocytes produce various HBV antigens that are swallowed and digested by antigen-presenting cells (APCs), producing HBV peptide/human leukocyte antigen (HLA) complexes. Antigen processing escape mutants, down-regulating HLA expression and mutation of HLA binding residues may appear in APCs. The HBV peptide/HLA complexes are transferred to the surface of APC and make contact with T-cell receptor (TCR) on the surface of $CD8^+$ T-cells. Masking HLA/TCT binding residues with N-linked glycosylation and mutation of TCR binding residues influences TCR affinity/avidity, leading to $CD8^+$ T-cell stimulation or inhibition. The square icon displays: (1) Increase in viral antigen; (2) Antigen processing escape mutants; (3) Down-regulation of HLA expression; (4) Mutation of HLA binding residues; (5) Masking of HLA/TCT binging residues with N-linked glycosylation; (6) Mutation of TCR binding residues; (7) Stimulation induced by cytokine production and cytolytic activity; and (8) Inhibition caused by exhaustion, anergy and tolerance. HBV: Hepatitis B virus; TCR: T-cell receptor; HLA: Human leukocyte antigen.



pathogenesis of HBV infection[47,48]. Studies have also reported that the genes encoding cytokines such as interleukins, TNF-α, IFNs and TGF-β, can influence the immune state of CHB patients[49-53]. In a study by Nitschke *et al*[54], the authors confirmed that specific HLA class I alleles restricted the efficacy of HBV-specific $CD8^+$ T-cells[54], indicating that the host's immune-related genes can affect the outcome of hepatitis B infection.

Researchers have observed significant differences in HBV infection rates between Western and East/Southeast Asian populations. Prior to HBV vaccination programs, the prevalence of HBsAg was less than 1% in the Caucasian population but higher than 10% in the Chinese population[43]. This difference was investigated in several studies, which showed that HLA molecules in European, Caucasian, Middle East, African-American and Asian populations affected the rate of HBV infection[43,55,56]. In addition, discordances in HBV-specific $CD8^+$ T-cell repertoires observed in different races, i.e., between Chinese and Caucasian populations, could be related to race-dependent HLA gene variants, leading to the different T-cell responses observed between different populations and ethnicities[57].

Thus, these findings underline the complexity of HBV-specific immune control efficacy, which is influenced by HBV components, negative feedback regulation in immunity and host genetic variants (Figure 3).

Heterogeneity of immune control in HBV infection

Heim *et al*[6] reviewed the heterogeneity of HBV-specific $CD8^+$ T-cells and described the functional

DOI: 10.3748/wjg.v28.i40.5784 **Copyright** ©The Author(s) 2022.

Figure 3 Interplay between hepatitis B virus-specific immune control, hepatitis B virus components, and negative feedback regulation in immunity and host genes. HBV: Hepatitis B virus.

deficiencies and distinct phenotypical characteristics associated with HBV-specific $CD8^+$ T-cells exhaustion. T-cell impairment demonstrates hierarchical and progressive loss in antiviral functions, from functional suppression to physical deletion in T-cells, which depend on the quantity of HBV antigens and the duration of T cell exposure to these antigens[31,58]. Moreover, exhausted $CD8^+$ T-cells do not represent a homogeneous T-cell population but are rather heterogeneous in function and phenotype. Kuipery *et al*[5] proposed concepts related to the heterogeneity of immune responses in CHB patients[5]. Based on reports from literature, we summarized the following concepts to improve our understanding on the heterogeneity of immune control.

Figure 1 illustrates the activation and inhibition of immune signaling pathways that overlap in HBV infection, multiple immune cell populations and integrated signals pathways that simultaneously respond to the stimulation of HBV components, and the ability of HBV-specific immune control depends on the overall immune responses of an individual rather than the capability of single immune cells or a single immune pathway.

Based on the immune escape mechanisms of APCs/$CD8^+$T-cells presented in Figure 2, the heterogeneous immune responses of T-cells are related to very fine mechanisms of immune regulation that influence the immune control of HBV-specific T-cells, or T-cells sensitivity/inhibition.

Figure 3 outlines the reasons for heterogeneous immune control. The overall immune control against HBV in an individual is influenced by HBV, negative feedback regulation in the immune signaling network and host genetic variants. Therefore, any changes in these three countenances could lead to fluctuations affecting the effectiveness of immune control. Thus, CHB infection is divided into four clinical phases: Immune tolerant with HBeAg-positive, HBeAg-positive immune-activation, inactive carrier with HBeAg-negative, and HBeAg-negative immune-activation. Further, heterogeneous immune controls can lead to different clinic phases and disease outcomes such as acute hepatitis, chronic hepatitis, cirrhosis, hepatocellular carcinoma and hepatic failure[43].

Reports have shown that host genetic polymorphisms are crucial determinants influencing HBV infectious rate and disease outcomes in Caucasian, Saudi Arabian, African-American, European, and Asian populations[56,59,60]. In addition, the host genetic variants of individuals from the same race can influence disease outcomes and the efficacies of antiviral therapy.

Researcher and immunologists who often overlook immune compartmentalization should be cautious when interpreting findings from the peripheral blood of patients.

IFN-α TREATMENT FOR CHB

Definition of partial cure and functional cure

A complete cure from HBV infection is currently hypothesized to be possible if the cccDNA and integrated HBV DNA are eliminated from hepatocytes. However, this is challenging as cccDNA can still persist in patients despite spontaneous recovery from an acute HBV infection. Since 2017, some advances in CHB therapeutics have been achieved[61], and researchers have proposed new definitions of cure. For instance, a partial cure has been defined as persistently undetectable HBV DNA and HBeAg in patients' serum after the completion of a limited course of antiviral therapy. Functional cure has been defined as sustained and undetectable HBV DNA and HBsAg in patients' serum, with or without seroconversion to hepatitis B surface antibody (anti-HBs), after a limited course of therapy. Complete sterilizing cure has been defined by the absence of HBsAg and eradication of HBV DNA, including HBV virion, integrated HBV DNA and cccDNA in the liver and serum of patients. However, because current treatments cannot deliver complete sterilizing cure, functional cure is the selected goal of therapy.

NAs and immunotherapy

Therapeutic strategies for CHB can be classified into two categories: NAs targeting HBV replication and immune modulators targeting immune control. NAs can cause rapid decay of HBV DNA in the peripheral blood but cannot completely eradicate HBsAg from patients' serum and cccDNA in hepatocytes[62,63]. Even though the virus might be undetectable in the serum after long-term treatment with NAs, low-level viral replication still persists due to the conservation of cccDNA in the nucleus of hepatocytes. Thus, prolonged NAs treatments are rarely associated with CHB cure and inevitably result in either NAs resistance or viral relapse[62-66].

In contrast, immunotherapy can target the innate and adaptive immunity to reinvigorate the host immune response to long-term inhibition of viral replication. Therapeutic strategies involving innate immunity include activating pattern recognition receptors (*i.e.*, TLRs and RIG-I), enhancing cytokine secretion, and improving the efficacy of NK cells. For adaptive immunity, therapies are directed at restoring the effects of HBV-specific T-cells and B-cells. Clinically, although immunotherapy can lead to sustained HBsAg loss, it cannot eradicate cccDNA from hepatocytes. Thus, being the more promising treatment compared to NAs, the ultimate goal of immunotherapy is currently targeted at achieving functional cure, enabling spontaneous control of HBV replication and maintaining disease remission without antiviral therapy[3]. Hoogeveen and Boonstra[32] reported that immunomodulators regulating a single immune pathway might not restore antiviral immunity as multiple immune pathways in the host enhance specific HBV immune responses[32].

Mechanism and clinical application of IFN-α therapy

IFNs are produced and released by immune cells in response to HBV components[67,68]. Of the known IFNs, IFN-α has broad-spectrum effects on viruses and tumors, and contributes to immune regulation by suppressing viral replication and cell growth. The antiviral function of IFN-α is cascaded by binding to IFN receptors on immune cells, activating signal transcription pathways, and inducing ISGs expression and related product secretion. Various ISGs products were found to inhibit different stages of the viral life cycle[69]. Further, epigenetics was shown to play a critical role in regulating cccDNA transcription[70-73]. IFN-α can regulate the epigenetic repression of cccDNA transcription by inducing cccDNA-bound histone hypo-acetylation and increasing the recruitment of transcription co-repressor on cccDNA[63,65,73]. In addition, IFN-α can upregulate HLAs expression to activate innate and adaptive immune responses. Many researchers have investigated the host genes associated with IFN-α treatment outcomes and observed its genetic polymorphisms[43,44,74-78] (Table 3).

As described earlier, due to negative feedback mechanisms, immune modulators targeting a single signal pathway might not improve the overall and long-term immune responses[61]. In this regard, the advantages of IFN-α treatment are that IFN-α can simultaneously affect multiple immune pathways and various immune cell populations in the host and integrate signals to improve the efficacy of immune control[10,11,15,36]. Currently, only IFN-α treatment was found to improve the efficacy of immune control[64,65].

IFN-α has been approved for the treatment of hepatitis B for over 20 years[36,61,65]. Compared with NAs, IFN-α has shown better efficacy in HBeAg seroconversion and HBsAg loss, with no risk of drug resistance[79]. For groups of patients with good prognoses, such as Caucasians, young age, low viral load, and females, IFN-α treatment has been more effective[80,81]. One study reported functional cure in 10%–20% of Caucasians who underwent IFN-α treatment, while it was < 5% in Asian patients[82]. However, most of the underlying mechanisms of IFN-α therapy are still unclear. More research is needed to investigate these significant differences in IFN-α efficacy between different groups of patients.

IMPROVEMENT OF HBV-SPECIFIC IMMUNE CONTROL BY IFN-α RETREATMENT

IFN-α retreatment

In 1996, although IFN-α was already being used to treat CHB patients, only 20%-30% of the patients achieved viral suppression or partial cure with single IFN-α treatment. Then, it was found that IFN-α retreatment in these remaining patients could enhance treatment outcomes. Thus, multiple courses of IFN-α were implemented to treat these patients and researchers observed that three courses of IFN-α treatment were effective in treating HBeAg positive or negative patients. With multiple frequencies of IFN-α treatment, partial or functional cure rates gradually increased to approximately 25%-40% but were mostly observed in patients of white race[10-14] (Table 4).

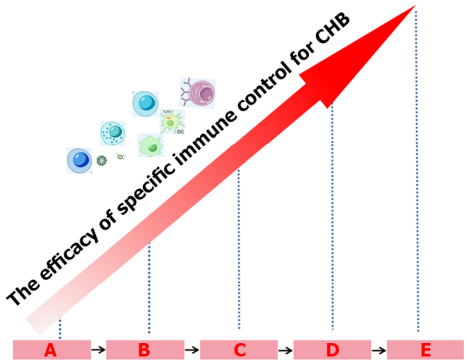
By 2008, failures from combination therapy with nucleoside and nucleotide were reported, and multi-drug resistance with NAs treatment started to increase in China. Comparatively, IFN-α retreatment was associated with safe stopping of NAs administration and induced better-sustained responses to IFN-α [15]. Thus, when researchers started to investigate the effects of increasing the frequency and extending the total course of IFN-α treatment and found that these could significantly improve the rate of functional cure in Asian and Caucasian patients[73-75,80-83]. IFN-α retreatment was recommended by the Asian-Pacific clinical practice guidelines[16-18] and by Yin *et al*[64] (Table 4). Based on these promising findings and recommendations, we estimate that more CHB patients in Asia would receive IFN-α retreatment and experience better antiviral efficacy.

Interplay between IFN-α retreatment and the HBV-specific immune control

Recently, more and more HBV-specific immune mechanisms have been discovered, inspiring clinicians and immunologists to collaborate to study the interplay between immune mechanisms and clinical events in hepatitis B. Chang *et al*[84] summarized the relationship between hepatitis flare and immune responses in CHB patients to explore the underlying immune mechanism of hepatitis flares[84]. The observations made from the strategy of Chang's *et al*[84] were used below to discuss the immune control involved in IFN-α retreatment.

Table 4 Summary and timeline of interferon-α retreatment for chronic hepatitis B virus infection

Ref.	Year	The regimens of INF-α retreatment
van Zonneveld *et al*[10]	2004	One hundred and sixty-five patients received their first IFN-α treatment. Of them, 48 non-responders received 2-3 courses of IFN-α
Manesis and Hadziyannis[11]	2001	Two hundred and sixteen patients received IFN-α therapy, of whom 51 received a second IFN-α treatment and 9 were treated with three courses of IFN-α
Niederau *et al* [12]	1996	One hundred and three cases were treated IFN-α. Of them, 29 received a second course of therapy, and 17 received a third course of IFN-α
Carreño *et al*[13]	1999	Fifty-seven patients underwent a course of IFN-α therapy. Of them, 27 received a second course of IFN-α; and 30 others who did not receive IFN-α retreatment served as controls. IFN-α retreatment was found to enhance the antiviral effects against HBV
Ballauff *et al*[14]	1998	After all the children received the first course of IFN-α treatment, 15 were given the second course of IFN-α (study group), while the other 19 did not receive the second course of IFN-α, serving as the control group. HBV DNA clearance and anti-HBe seroconversion occurred in 5 of 15 children (33%) in the study group and 5 of 19 children (26%) in the control group
Yin and Zhong [15]	2016	Inappropriate therapies induced HBV resistance, multi-drug resistance and failure of combination therapy with nucleoside plus nucleotide in China. An IFN-α regimen, *i.e.* (1) Switch from nucleoside plus nucleotide to IFN-α therapy; and (2) subsequent IFN-α retreatment, was used to treat these patients. IFN-α switching therapy leaded to safe cessation of nucleoside plus nucleotide combination therapy, and IFN-α retreatment induced sustained response of IFN-α
Sarin *et al*[16]	2016	Asian-Pacific clinical practice guidelines 2015 recommended IFN-α retreatment to treat chronic HBV infection
Liaw *et al*[17]	2012	Asian-Pacific clinical practice guidelines 2012 recommended IFN-α retreatment to treat chronic HBV infection
Liaw *et al*[18]	2008	Asian-Pacific clinical practice guidelines 2008 recommended IFN-α retreatment to treat chronic HBV infection
Yin *et al*[64]	2021	IFN-α retreatment was recommended for patients on entecavir or tenofovir monotherapy with persistent low-level viremia



IFN-α: Interferon-α; HBV: Hepatitis B virus.

Asymptomatic persistence of cccDNA in the liver of patients who had acute hepatitis B or self-limiting HBV infection, despite the resolution of HBV infection[3], indicates that the host's immune system can fully inhibit HBV replication and that the specific HBV immune control in these individuals had an overwhelming advantage over HBV replication. In addition, investigations on the heterogeneous immune control of HBV infection have shown that the heterogeneity depends on the interplay between the host, virus and therapy, including host genes and immunity state, HBV load, duration of HBV infection, and IFN-α treatment and course of treatment[5,6,31,58]. However, the exact mechanism *via* which IFN-α retreatment exerts its benefits is yet to be fully elucidated.

Apart from HBV load, HBsAg and HBeAg, markers associated with the immune control of IFN-α treatment are lacking. In a study by Konerman and Lok[79], the authors proposed a scoring system that could help assess the efficacy of immune control[79]. The type of immune control could be estimated from a patient's HBV DNA, HBeAg seroconversion, HBsAg loss and times of IFN-α treatment, based on the following criteria: (1) Patients with acute hepatitis B or self-limiting HBV infection could achieve automatic cure without IFN-α treatment; (2) Patients with acute hepatitis B could achieve functional cure with one time IFN-α treatment; (3) CHB patients with one time IFN-α treatment could achieve functional cure; (4) CHB patients with one time IFN-α treatment could achieve partial cure; (5) CHB patients with multiple times of IFN-α treatment could achieve functional cure; and (6) CHB patients with multiple times of IFN-α treatment could achieve partial cure. These criteria suggest a step-like decline in immune control with increasing infection severity.

Clinical studies have confirmed that IFN-α retreatment could gradually increase the rate of partial and functional cure (Table 4)[10,11,13,15,36] and that CHB patients often have diverse HBV-specific immune control. Since 2016, researchers in China have reported numerous findings from clinical trials in which patients with inactive HBsAg carriers or low-level viremia were selectively enrolled and treated with IFN-α to evaluate their functional cure rate[85-88]. However, it should be noted that these were performed under trial settings because clinical guidelines do not recommend IFN-α therapy for the treatment of CHB in these patients[16,89,90]. A high rate of functional cure, 44.7%-84.2% of HBsAg loss and 20.2%-68.2% of HBsAg seroconversion were reported, in which a distinctive pattern of immune control whereby a close correlation between lower HBsAg at baseline and higher rates of HBsAg loss or HBsAg seroconversion was observed[85-88]. This pattern also appeared in the final course of IFN-α retreatment in previous studies[10,11,13,15,36], indicating that reducing HBsAg could be a prerequisite for achieving functional cure during IFN-α retreatment.

Taken together, current literature indicates that IFN-α retreatment could gradually enhance the overall immune control and improve the antiviral efficacy of IFN-α in CHB patients (Figure 4).

DOI: 10.3748/wjg.v28.i40.5784 **Copyright** ©The Author(s) 2022.

Figure 4 Interferon-α retreatment improves the efficacy of hepatitis B virus-specific immune control. Interferon-α (IFN-α) retreatment can lead to various treatment outcomes, namely no response, hepatitis B virus (HBV) decline, partial cure and functional cure. Multiple frequencies of IFN-α treatment can potentially restore specific immune control to HBV infection and simultaneously increase the rate of partial cure and functional cure. A: Exhausted immune control to HBV before IFN-α therapy (Baseline); B: Without HBV decline following IFN-α therapy; C: HBV decline; D: Partial cure; E: Functional cure. CHB: Chronic hepatitis B.

CONCLUSION

The interactions between immune cells and cytokines form a complex immune response network that exerts immune control over HBV infection. The efficacy of HBV-specific immune control is affected by HBV components, negative feedback regulation in the immune system, host genetic variants, and heterogeneity in the function and phenotype of immune control to HBV. Treatment with IFN-α can simultaneously affect multiple immune pathways and various immune cell populations in the host and integrate signals to improve the efficacy of immune control. Clinically, increasing the frequency and extending the total course of IFN-α retreatment have improved functional cure rates, indicating that IFN-α retreatment could gradually enhance the overall immune control. Further research on IFN-α retreatment could help promote this strategy in CHB patients with.

Altogether, this article outlined immune control without detailed discussions on immunity-related markers during immune transformation. In future studies, the discovery of detailed markers associated with immune transformation could provide important clues in understanding the underlying mechanism of immune control to improve the treatment of HBV infection.

ACKNOWLEDGEMENTS

We are very grateful to Prof. Gao-Jun Teng in Zhong-Da Hospital, Southeast University and Prof. Bei Zhong in the sixth Affiliated Hospital of Guangzhou medical University/Qingyuan People's Hospital for the comprehensive evaluation of the manuscript and valuable advices. Authors acknowledge Dr. Cun Shan in the Department of infectious disease, Nanjing Zhong-Da Hospital for data collection.

FOOTNOTES

Author contributions: All authors contributed to the study conception and design; The first draft of the manuscript was written by Yin GQ; All authors commented on previous versions of the manuscript, they all read and approved the final manuscript.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.

Abstract

The whole world has been continuously afflicted by the coronavirus disease 2019 (COVID-19) pandemic for the past 3 years. Many countries have tried many methods to control this virus infection with varying successes and failures. The gut microbiota is a biosystem spanning the entire length of the digestive tract and playing important roles in health and disease. It is much affected by COVID-19. In return it also substantially impacts infection. In particular, the gut microbiota has established a bidirectional interaction with the COVID-19 vaccines, enhancing or reducing vaccine efficacy by virtue of its varying components. Conversely, COVID-19 vaccines also make a substantial impact on the gut microbiota, reducing its overall population and biodiversity. It is hoped that by exploring and harnessing this bidirectional interaction we may break new ground and develop new methods to prevent and treat this formidable virus infection.

Key Words: Gut microbiota; COVID-19 vaccines; Vaccine interactions; Gut microbiota alterations

INTRODUCTION

The gut microbiota is a highly important and intriguing biosystem extending throughout the alimentary tract, covering an area of 400 square meters and with a biodiversity spanning over 2000 species, including protozoa, fungi, bacteria and viruses[1]. These organisms could be intraluminal or attached to the linings of the gut. Some even occupy an intracellular or subepithelial intercellular residence, while others enter the tissue fluid, the lymphatics and even the blood stream[1].

With such a background, the gut microbiota is constantly engaged in interactions with the various systems of the host and plays an important part both in health and in disease. In health, it is an integral part of digestion, absorption and nutrition. The contribution of gut microbiota in the production of vitamins of the B family and vitamin K has become common knowledge. More recently, it has been shown that gut microbiota, with their rich endowment of enzymes, could digest far more varieties of carbohydrates than their host could do alone[2]. Gut microbiota could also synthesize essential amino acids from inorganic nitrogen so that the host could survive even on a protein-free diet.

In fat metabolism, some bacteria are able to synthesize long chain fatty acids, contributing to the host energy supply as well as obesity, while many others, typically the strict anaerobes, ferment carbohydrates into short chain fatty acids (SCFAs). SCFAs inhibit histone deacetylase and activate G-protein coupled receptors with benefits in antioxidant, anti-inflammatory, antitumorigenic and antide-generative functions[3]. Indeed, research has shown the potential of fecal SCFA content as a marker of intestinal health, being at a lower level in colon cancer *vs* healthy controls[4]. Further studies of serum free fatty acid profiles especially the SCFA profiles show distinct patterns for healthy colon, colonic adenomatous polyps, colon cancer and coeliac disease reflecting the differences of gut microbiota among these conditions[5].

It is beyond the scope of this review to cover all aspects of the gut microbiota in health and disease but rather to focus on the intriguing interaction between the gut microbiota and coronavirus disease 2019 (COVID-19). The COVID-19 pandemic has been continuously ravaging the whole world for the past 2.5 years. Up to August 22, 2022, the World Health Organization's statistics showed the cumulative number of infected cases exceeded 211 million and was still increasing at 4.5 million *per* week, while the cumulative number of deaths had exceeded 4.4 million and was still increasing at around 68000 *per* week[6]. Various well-established methods of infection control have been tried, mostly with only partial success, and complete control remained elusive. Meanwhile, the phenomenon of "pandemic fatigue" has set in, and people become less inclined to adhere to control measures instead of tightening infection control measures[7]. In this review, aspects of gut microbiota that are relevant to the pandemic and its potential contribution to pandemic control was the focus.

GUT MANIFESTATION IN COVID-19 AND MICROBIOTA ALTERATIONS

The earliest report of COVID-19 in The Lancet on January 24, 2020 on the first 41 cases in Wuhan stated that diarrhea was the presenting symptom in only 1 case[8]. Three months later, when a New York center reported its first 393 cases of COVID-19[9], diarrhea was the presenting symptom in 23.7%. The incidence of diarrhea in the two districts remained almost unchanged over the next year with China at 3.80% diarrhea among 1141 cases[10] and New York at 20.14% diarrhea among 278 cases[11]. The difference is obvious and significant. Conceivably the diet in the Wuhan population is quite different from that in New York. It is probable that the gut microbiota in these two localities would also have a considerable difference, offering a plausible explanation of the increased diarrhea among the New York patients. In addition a Western diet, rich in processed meat but deficient in microbiota accessible carbohydrates, would have lower biodiversity[12] and less favorable to health. Unfortunately for the research investigator, most of these early studies did not report details of gut microbiota status, and the opportunity to study the influence of the gut microbiota on the early phase of the pandemic was lost.

GUT MICROBIOTA ALTERATIONS AND COVID-19 SEVERITY

By 2021, it became obvious that gut involvement and diarrhea were associated with greater severity of COVID-19[13]. An investigation in Hong Kong further demonstrated that certain components of the gut microbiota with immune-modulatory potential were depleted in severe and long-lasting COVID-19, notably *Faecalibacterium prausnitzii*, *Eubacterium rectale* and bifidobacterial species[14]. The investigators proposed that depletion of these bacteria could be taken as biomarkers predictive of severe and prolonged COVID-19. It is tempting to suggest that further studies might even explore the therapeutic value of replenishing these organisms to mitigate the disease.

GUT MICROBIOTA AND THE IMMUNE SYSTEM AND IMMUNE THERAPY

The interaction between the gut microbiota and the immune system goes far beyond the three groups of bacteria mentioned in the last section. In fact, beginning with the first colonization of the gut at birth or even before birth, the gut microbiota continuously evolve and influence the development of the host immune system, fostering reactivity against pathogenic invaders and tolerance towards harmless colonizers or beneficial symbionts[15]. Such actions are mediated by both regulatory cytokines (like interleukin-10 and interferon-beta) and T regulatory cells. This not only promotes diversity and increases beneficial microbes but actually helps to reduce host autoimmune disorders.

On the other hand, antibiotics have been shown to reduce the gut microbiota in both quantity and diversity, with reduced efficacy of immune checkpoint inhibitors in immunotherapy of cancer, and fecal transplantation has been shown to successfully restore the immune therapeutic response in such patients[16].

GUT MICROBIOTA'S IMPACT ON COVID-19 VACCINES: EFFICACY AND SIDE EFFECTS

With the foregoing background we now come to the important consideration of controlling the ongoing COVID-19 pandemic. It is common knowledge that pandemic control rests on five pathways: (1) Isolation of patients at the infectious stage by quarantines and social distancing; (2) Blocking the routes of infection by masking, air filtering/exchanging and sanitation; (3) Building up resistance among the population with vaccination; (4) Development of effective medicines to cure the infected patients and eliminate the carrier status; and (5) Letting the pandemic run its natural course, eliminating all susceptible components of the population and leaving those with inborn or naturally acquired immunity to survive.

The first four measures at present run into many obstacles, including social, economic, political, even personal egocentric considerations and biased sentiments. What is left is the fifth choice, otherwise called "herd immunity," a rather primitive, counter-intuitive and inhuman approach. Fortunately, amidst these dark looming clouds appears a silver lining. The gut microbiota might not only modify the COVID-19 disease but actually improve the efficacy and reduce the side effects of its vaccines, winning more skeptics to accept this highly important preventive measure.

This seminal work, a combined effort of the two universities in Hong Kong, was reported by Ng *et al*[17] and published on February 9, 2022[17]. It showed that for vaccine recipients of the inactivated virus, CoronaVac, the relatively low induction of neutralizing antibodies could be increased with a higher level of *Bifidobacterium adolescentis* (*B. adolescentis*) in the gut microbiota, while *Bacteroides vulgaris*, *Bacteroides thetaiotaomicron* and *Ruminococcus gnavus* were enriched in low responders. Another vaccine, the viral spike protein-encoded messenger RNA, BNT-162b, under the brand name Comirnaty, although capable of eliciting high antibody levels, could be further improved by the abundance of flagellate and fimbriate bacteria like *Roseburia faecis*. In addition, for both vaccines, enrichment of *Prevotella copri* and two *Megamonas* species led to fewer side effects, likely due to the anti-inflammatory influence of these organisms.

Interestingly, the role of *B. adolescentis* in CoronaVac seems very specific. So far, according to these researchers, any other species of the same *Bifidobacterium* genus tested would not work. As the species *B. adolescentis* is not present in commonly available health food or probiotic preparations, there seems no way to simply make an off-the-counter purchase of "health foods" to obtain such benefit. By contrast, the requirements of BNT-162b for *Roseburia faecis* seem less fastidious, and various bacteria with flagella and fimbriae might also impart benefit. Even *Bacteroides thetaiotaomicron*, known to be associated with low antibody production in CoronaVac, joins the company of antibody-enhancers for BNT-162b. This list may also include a minimal existence of *B. adolescentis* because the only BNT-162b recipient who failed to develop adequate antibody level was entirely devoid of *B. adolescentis*.

IMPACT OF COVID-19 VACCINES ON GUT MICROBIOTA: A BIDIRECTIONAL INTERACTION

Ng *et al*[17] not only showed the impact of gut microbiota on vaccine efficacy but also showed the impact of vaccination on gut microbiota 1 mo after delivering two doses[17]. For CoronaVac, only *Bacteroides caccae* was increased. For BNT-162b2, both *B. caccae* and *Alistipes shahii* increased. Common to both vaccines, a large number of species were diminished including *Adlercreutzia equolifaciens*, *Asaccharobacter celatus*, *Blautia obeum*, *Blautia wexlerae*, *Dorea formicigenerans*, *Dorea longicatena*, *Coprococcus comes*, *Streptococcus vestibularis*, *Collinsella aerofaciens* and *Ruminococcus obeum*[17]. There seemed to be a substantial loss of biodiversity, but no further elaboration on the clinical and pathological significance was mentioned. With such substantial changes in the gut microbiota one would expect some alterations in bowel habits after vaccination. On a theoretical basis, vaccine-induced loss of diversity would

Table 1 Diarrhea in persons aged 19-55 years after Pfizer-BioNTech coronavirus disease 2019 vaccination based on The Centers for Disease Control online published table[23] under the title "Vaccines and Immunizations"

Subjects	First injection number		Second injection number	
	Vaccine 2291	Placebo 2298	Vaccine 2098	Placebo 2103
Symptoms				
Any diarrhea	255 (11.10%)	270 (11.70%)	219 (10.40%)	177 (8.40%)
Severe diarrhea	3 (0.13%)	1 (0.04%)	4 (0.19%)	1 (0.05%)

increase the opportunity of pathogens to thrive in the intestine. There would be less competition for nutrition and for the niche of bacteria habitat, with less antagonistic factors produced by healthy bacteria such as bacteriocin and SCFAs to discourage the growth of pathogenic organisms[18]. With the proliferation of pathogenic organisms, the chance of diarrhea would be increased. Minor changes in bowel habits, however, tend to be under-reported, and severe diarrhea would tend to be so uncommon that it is often underpowered to establish a statistically significant conclusion. Table 1 was constructed from data published online by the Centers for Disease Control and Prevention (United States).

While there is no significant difference in mild diarrhea between recipients of vaccine and placebo, a signal of increased severe diarrhea among vaccine recipients seems to show up in the bottom row for both first and second injections, possibly reflecting the increase in severe diarrhea by 3.2 times (for first injection) to 3.8 times (for second injection) as a result of diminished diversity of gut microbiota. This table has two limitations. First, the actual number of severe diarrhea cases are too small for statistically significant computation. Second, no information is given for the composition of the microbiota of these patients, and it is not possible to relate the diarrhea to any particular organism or to the vaccine itself.

BIDIRECTIONAL INTERACTION BETWEEN GUT MICROBIOTA AND IMMUNE ACTIVITIES BEYOND COVID-19

Therapeutic agents, including vaccines, may have therapeutic value well beyond their originally intended effects. One of the best-known examples is the anti-tuberculosis BCG vaccine, whose role in protection against leprosy is well studied and documented[19]. For over 40 years it has also played a role in the treatment of non-muscle-invasive bladder cancer[20]. Indeed, many vaccines have been actively studied as a platform for anticancer treatment[21]. In certain areas, like hepatocellular carcinoma and carcinoma of the cervix, anti-viral vaccines have successfully prevented the cancer by preventing infection of the respective oncogenic virus. In other cancers, the mRNA technology has played a pivotal role in stimulating the patient's immune system to recognize and react against tumor-associated neo-antigens[22].

For three decades scientists have been struggling to iron out technical obstacles and the overall reluctance of recruiting the body's immune cells to produce an antigen and provoke an immune reaction, which is like retracing the steps of autoimmune disorders (the same sentiment still prevails among COVID-19 vaccine doubters today). Consequently, the predominant form of cancer immunotherapy at present is immune checkpoint inhibition, which involves abolishing major mechanisms of evasion of cancer from the host immunity *via* immune checkpoints. Even in this context, certain components of the gut microbiota, notably *Bifididobacterium longum* and *Akkermansia muciniphila* are found to be associated with good response to checkpoint inhibitors in melanoma and lung cancer, respectively, while lowered diversity and population of the gut microbiota under antibiotic treatment would have the opposite effect[16]. When the COVID-19 pandemic broke out, the mRNA-based vaccines, backed by years of research in previous anticancer immunotherapy, had a chance to be tested extensively and speedily with resounding success.

CONCLUSION

As mentioned earlier in the study of Ng *et al*[17], certain gut microbes could enhance vaccine efficacy in antibody stimulation while other microbes have the opposite effect[17]. Conversely, COVID-19 vaccines could impact the gut microbiota, enhancing the growth of some microbes but suppressing the growth of many others[17]. This bidirectional interaction between gut microbiota and COVID-19 vaccine is highly reminiscent of that between gut microbiota and anticancer immunotherapy. Conceivably, modifying the gut microbiota might enhance the vaccine-induced therapeutic value for both infection and cancer. It will take further study to understand and possibly harness such interactions and convert their potential therapeutic value into reality.

Abstract

Liver transplantation (LT) is currently the only curative treatment option for selected patients with end stage liver disease or hepatocellular carcinoma. Improving waiting list-mortality, post-transplant morbidity and mortality and refining the selection of the patients remain our current central objectives. In this field, different concepts dealing with nutrition and the muscle such as sarcopenia, malnutrition, frailty or myosteatosis have emerged as possible game changers. For more than a decade, many prospective studies have demonstrated that sarcopenia and frailty are major predictive factors of mortality in the waiting list but also after LT. Malnutrition is also a well-known risk factor for morbidity and mortality. Muscle composition is a newer concept giving insight on muscle quality which has also been shown to be linked to poorer outcomes. Each of these terms has a precise definition as well as pathophysiological mechanisms. The bi-directional liver-muscle axis makes sense in this situation. Defining the best, easy to use in clinical practice tools to assess muscle quality, quantity, and function in this specific population and developing quality prospective studies to identify interventional strategies that could improve these parameters as well as evaluate the effect on mortality are among the important challenges of today.

Key Words: Muscle; Liver; Transplantation; Sarcopenia; Myosteatosis; Frailty

Core Tip: Patients suffering from end stage liver disease currently have liver transplantation as the only curative treatment. In order to improve the pre and post transplantation management of patients, muscle related concepts such as sarcopenia, myosteatosis, frailty and malnutrition could be important potential game changers. Considering a bidirectional axis between the muscle and the liver, it is therefore justified to characterize the condition of the muscles adequately and to identify interventional strategies that could improve both muscle parameters and patient survival.

INTRODUCTION

To date, despite medical developments in knowledge and drug treatments, liver transplantation (LT) remains the only curative treatment option for selected patients with acute liver failure, end-stage liver disease (ESLD), liver cancer and acquired or genetic metabolic liver disease[1]. ESLD is the most frequent indication for LT with alcohol-related liver disease as the main etiology[2]. Other common etiologies are metabolic dysfunction-associated fatty liver disease (MAFLD) and viral hepatitis[3,4]. Autoimmune related liver diseases and cholestatic diseases are rarer indications in Western countries. The epidemiology of LT has changed over the last 20 years since the selection of patients suffering from hepatocellular carcinoma (HCC) with the Milan criteria and the progressive eradication of hepatitis C virus since the universal use of direct-acting antivirals[5]. MAFLD is probably becoming one of the main indications for LT in parallel with the epidemic of obesity in Western countries. This disease can coexist with other causes and act as an important co-factor. This specific population represents a series of challenges in the pre-, peri- and post-transplant settings due to the presence of medical comorbidities that include obesity, type 2 diabetes and cardiovascular risk factors[6,7].

For years, graft allocation has been based on the model for end-stage liver disease (MELD) score that has been used to predict 3-mo mortality on the waiting list. The use of the MELD score has led to a better selection of patients requiring LT but also to a reduction in waiting time and a reduction in mortality on the waiting list[8]. However, the score suffers from several limitations: Patients with cholestatic liver diseases, severe portal hypertension as well as those with hepatic encephalopathy are disadvantaged due to a preserved synthesis function which does not reflect the severity of the disease and the related morbimortality. Another major limitation is the absence of assessment of malnutrition and more specifically of sarcopenia[8-10]. Abnormalities of body composition are frequently found in patients with chronic diseases such as cirrhosis. Interestingly, there is a close relationship between the skeletal muscle compartment and liver function (Figure 1)[11].

In the field of chronic liver disease (CLD) and particularly ESLD and LT, different concepts have emerged and are commonly used, such as sarcopenia, malnutrition, frailty or myosteatosis[12]. They affect between 40%-70% of cirrhotic patients with important clinical outcomes. They have been evaluated independently in different studies and it is confirmed that they are robust predictors of poor outcomes[13]. This fragile population is at increased risk of hepatic decompensation, reduced quality of life, increased risk of infection, and prolonged hospitalization. It leads to a higher morbidity and mortality[14,15]. Adding the concept of frailty on the waiting list prioritization, specifically helps a population that is listed with low priority based on a low MELD score (< 15). While adding muscle surface to the MELD score had limited added value for organ allocation in a global cirrhotic population, this measurement is highly correlated with waiting list mortality in patients with low MELD score (< 15) [16]. It is therefore important to define the best tools to evaluate these functional concepts in the field of liver diseases and LT[13].

Understanding these different concepts and their implications in our clinical practice is of major interest to improve the management of our patients. There is clearly a certain overlap in these definitions, but it is important to understand them separately to develop tailored behavioral interventions and targeted pharmacotherapies for these conditions[17]. It is necessary to clearly define the gold standard of sarcopenia management with standardized cut-offs for this specific cirrhotic population. These clear definitions will allow us to evaluate the impact of interventions on patients' outcome[13]. We then review the pathophysiology of cirrhosis-related sarcopenia and myosteatosis, provide a narrative review of the major studies on the subject and discuss the tools available for muscle assessment and treatment.

DEFINITIONS OF COMMONLY USED YET DISTINCT CONCEPTS

As explained above, various terms are now frequently used in the field of CLD, sometimes incorrectly or inappropriately. However, they each have a precise definition.

Malnutrition

Malnutrition can be defined as a state resulting from an insufficient intake of nutrients or an imbalance in essential nutrients and/or in their utilization. This imbalance will have a deleterious impact on the body composition and body cell mass that could lead to diminished physical and mental function, as well as impaired clinical outcomes from disease. Malnutrition has multiple causes combined or take alone, which are starvation and diseases such as CLD and aging[18]. It is also important to note that malnutrition can affect the entire body mass index (BMI) spectrum from obese to anorexic[17]. Different clinical scores exist to estimate the presence of malnutrition such as the nutritional risk score or the Global Leadership Initiative on Malnutrition criteria. Malnutrition is associated with increased mortality in cirrhotic patients[19].

Sarcopenia

The term sarcopenia comes from Greek origin and literally means the "loss of flesh". Sarcopenia is characterized by 3 components: Decreased muscle mass, decreased muscle strength as well as decreased physical performance[20]. Initially, sarcopenia was described as associated with aging. The term is now also used in association with chronic diseases such as cirrhosis[12]. Nevertheless, even today, the criteria to be included as well as the cut-off values are still discussed. The diagnosis of sarcopenia is still complicated today as the criteria can be so variable, especially in obese people[21]. Cutoffs for muscle mass depletion exist but are still currently under debate. Nevertheless, the use of muscle area measurement at the level of the third lumbar vertebra on a computed tomography (CT) slice is recognized as acceptable by relating the muscle area to the patient's height squared [skeletal muscle index (SMI)]. By extension, the term sarcopenia is often used based on the sole criterion of low muscle area. Sarcopenia is then defined when SMI is < 41 cm^2/m^2 for a woman and < 53 cm^2/m^2 for a man in the field of obesity[22] or < 39 cm^2/m^2 for a woman and < 50 cm^2/m^2 for a man in the field of ESLD[23]. In the field of liver diseases, this measure is particularly interesting because it is minimally affected by hydro-sodium retention. Measurement of the brachial circumference (BC) or mid-arm muscle circumference and arm strength using the hand dynamometer are other frequently used techniques.

Myosteatosis

Myosteatosis can be defined as the ectopic accumulation of fat in the muscle. This increased accumulation around and within the myocyte can lead to an impairment of normal physiological function. We will therefore speak of intra and extra cellular fat. It can be estimated on the basis of the decrease in muscle density on an ultrasound image or a CT scan section for example[24,25]. A skeletal muscle radiation attenuation below 41 Hounsfield units (HU) in normal weight patients (BMI up to 24.9 kg/m^2)

and 33 HU in overweight patients (BMI ≥ 25 kg/m²) could be used[24]. Muscle density can also be related to the muscle surface to give an idea of the absolute amount of intramuscular fat[26]. This leads to the following parameters: The skeletal muscle density index (SMDI)[27] and the skeletal muscle fat index (SMFI) described in patients with MAFLD without ESLD[26,28]. Different groups of patients are compared in clinical studies, but pathological cut-offs for SMDI or SMFI are not yet defined[26-28]. Finally, imaging allows us to assess the homogeneous or heterogeneous distribution of fat in the muscle. This parameter can be associated with certain pathological conditions[29].

Frailty

Defined in the field of geriatrics, frailty is considered a metabolic syndrome associated with a decrease in physiological reserves and an increase in vulnerability to stress factors. In the case of cirrhosis, the stressors are variable, ranging from a dysfunction in protein synthesis to muscle toxicity. A reproducible and objective assessment of patients with liver disease is offered by several simple, non-invasive tests. For example, based on the results of handgrip, sit to stand and balance tests, the liver frailty index (LFI) can be calculated. A patient is considered frail if the score is between 4.5 and 6[15].

Physical exercise

Physical exercise is defined as activity requiring physical effort, performed specifically to maintain or improve health and fitness. The term is therefore relevant to physical activity interventions offered to patients with CLD to improve their condition. The data available so far concerns patients with compensated liver disease with no separate results for patients with ESLD[30]. An increase in functional capacity, strength and muscle mass is noted in the patients with compensated cirrhosis who are subjected to physical exercise for 12 wk and then compared to a group of patients with relaxation activity[31]. In patients awaiting LT, specific protocols are being evaluated (NCT04604860, NCT05061576, NCT05237583, *etc*). The type (endurance and/or resistance), duration and frequency should be determined, bearing in mind that these programs must be adapted to the patients' situation (safety, absence of contraindications).

PATHOPHYSIOLOGICAL BASIS OF SARCOPENIA AND MYOSTEATOSIS IN END STAGE LIVER DISEASE

Several mechanisms exist that link sarcopenia to CLD and ESLD. Nevertheless, these exact mechanisms are particularly not well known. Sarcopenia is often a feature of malnutrition. The reasons for this malnutrition, in the case of cirrhosis, are multiple and often result from the combination of several factors (Figure 1)[32]. The first factor in the context of CLD and cirrhosis is the presence of a hypermetabolic status resulting from chronic inflammation and altered gut barrier function[33]. Low liver glycogen content induces muscle protein catabolism for blood glucose maintenance[34]. In addition, ascites present in cirrhotic patients may be responsible for an increase of energy expenditure and therefore increase the catabolism of protein[35]. Partly due to the pro-inflammatory environment, patients with cirrhosis and HCC showed accelerated sarcopenia[36]. Second, the hyperammonemia level is also increased due to its poor elimination because of a pathological architecture of the liver. The consequence of this increase will be the activation of myostatin and consequently the inactivation of protein synthesis which will lead to sarcopenia. Third, inadequate intake of micro and macronutrients can be due in cirrhotic patients to loss of appetite (dysgeusia, cytokines), prolonged gastric emptying or a restrictive diet (sodium and protein) for example. The sedentary lifestyle is probably the most obvious factor in sarcopenia. Indeed, a study showed that one of the causes of sarcopenia in the elderly was partly due to lack of physical exercise[20]. It is therefore easy to think that decompensated cirrhotic patients with high frailty and malnutrition may also suffer from a lack of physical activity aggravating their sarcopenia even more. Fourth, cirrhosis is associated with some degree of cholestasis. An increase in bile acids related to deregulation of the enterohepatic cycle (also due to the dysbiosis associated with cirrhosis) is observed. These have a potentially toxic effect, particularly on the muscle that expresses some bile acid receptors, inducing muscle atrophy[37]. Malabsorption in the context of cirrhosis also plays an important role. A decrease in bile excretion will result in a decrease in the reabsorption of lipids and certain lipo-soluble vitamins. Altered intestinal motility as well as changes in the composition of the gut microbiota will also affect nutrient absorption and utilization[33]. Finally, in cirrhotic patients, a decrease of testosterone levels has been associated with a decrease of muscle mass that could favor sarcopenia[34].

The mechanism through which myosteatosis occurs is still not well understood. Myosteatosis is a well-known characteristic of patients with CLD due to MAFLD[27]. Cirrhotic patients are also characterized by muscle insulin resistance, regardless of the cause of the cirrhosis[34]. This insulin resistance status may also be responsible for myosteatosis[34]. Other proposed mechanisms include hyperammonemia (inducing impaired mitochondrial oxidative phosphorylation and decreased lipid oxidation in muscle), decreased lipid storage capacity within the subcutaneous adipose tissue and age-related differ-

entiation of muscle stem cells into adipocytes[38].

WHY IS IT IMPORTANT TO CONSIDER THE MUSCLE IN A LIVER TRANSPLANT SETTING?

Screening and preventing sarcopenia and frailty is of major interest to patients with CLD. The challenge is big because muscle composition and muscle function have a direct impact on the prognosis of the cirrhotic patient. Sarcopenia and frailty will condition the prognosis of the cirrhotic patients awaiting LT, independently of the severity of the liver disease (MELD score)[39]. Table 1 summarizes the main studies investigating the deleterious role of sarcopenia, frailty and myosteatosis in the context of LT.

For more than a decade, many prospective studies have demonstrated that low muscle mass is a major predictive factor of mortality in the waiting list but also after LT. In a study involving more than 200 patients on the waiting list, both low muscle quantity and quality were independent risk factors for mortality in patients with ESLD[40]. Low muscle mass is more frequent in patients with hepatic encephalopathy and associates with poor survival[41]. Two meta-analyses confirm these results, the first one includes more than 19 studies with 3800 patients awaiting LT. Sarcopenia was assessed by a wide range of CT-assessed skeletal muscle mass cut-points. Despite these limitations, the study described an independent association between low muscle mass and the post-LT and the waiting list mortality[42]. The second meta-analysis, although it has multiple biases, shows an association between sarcopenia in the pre-LT period and greater post-operative mortality, higher infection risk and post-operative complications, longer intensive care unit stay and ventilator dependency[43].

In patients with cirrhosis (decompensated or not), frailty, easily measured by the LFI, is an independent predictor of death, cirrhosis progression and unplanned hospitalizations (mainly due to infections)[44]. Frail cirrhotic patients also have an increased risk of acute kidney injury[45] and hepatorenal syndrome[46]. In cirrhotic patients awaiting LT, frailty is associated with a 2-fold increased risk of mortality, regardless of the presence of ascites or hepatic encephalopathy[15]. Frail cirrhotic LT recipients have increased postoperative morbidity with prolonged hospital stays[47] and an increased risk of acute rejection[48].

While the link between sarcopenia and mortality is well established, the long-term prognostic value of skeletal muscle quality is less clear. However, several studies tend to demonstrate that pre-transplant myosteatosis is an important prognostic marker for LT recipients in the post-operative period. The prognosis value of myosteatosis seems to be particularly important in the early post-operative phase with higher rates of deaths due to respiratory and septic complications[48]. Unfortunately, most studies are retrospective and the clinical impact of myosteatosis on the transplant waiting list still needs to be demonstrated with prospective studies.

In view of these results, the American Association for the Study of Liver Diseases guidance document suggests that all cirrhotic patients should be assessed for sarcopenia and frailty with standardized tools both at baseline and longitudinally[17]. These recommendations are consistent with the implementation of specific protocols such as "enhanced recovery after surgery" protocols to improve recovery after surgery, especially for LT candidates[49].

HOW TO EVALUATE THE MUSCLE IN ROUTINE PRACTICE?

To assess physical activity, muscle function, composition and mass, several tools exist. It is important to note that many tests, questionnaires and radiological methods are possible. A non-exhaustive list of these tools is presented in Table 2 with their advantages and disadvantages. Some of them have been included in a recent review manuscript[50]. It is interesting to note that patients' baseline physical activity can be assessed by questionnaire or objective measurement (Table 2). Easy tests are possible in consultation or at the patient's bedside, such as measuring BC or handgrip strength. Tests that are more complex to implement in routine practice are also available, such as the 6 min walk test, which correlates well with survival in patients awaiting LT[51], or isokinetic testing, the detailed results of which have given interesting information in other diseases such as type 2 diabetes[29]. Finally, among imaging techniques, the same dilemma exists between easier and less expensive techniques (such as ultrasound)[52,53] and time-consuming but probably more objective and reproducible techniques (such as CT or magnetic resonance imaging)[54] (Table 2).

HOW TO IMPROVE THE MUSCLE IN CLINICAL PRACTICE?

It is well defined that malnutrition plays a major role in the prognosis of the cirrhotic patient and that the resulting loss of muscle mass is a real complication of cirrhotic disease with a significant impact on the morbidity and mortality of these patients. All patients with CLD should be evaluated for nutrition

Table 1 Main studies investigating the deleterious role of frailty, low muscle mass, sarcopenia and myosteatosis in patients undergoing pre-transplant assessment

Ref.	Patient selection	Patients, *n*	Sarcopenia, myosteatosis	Frailty parameters	Outcome	Results

and sarcopenia at the time of diagnosis and then regularly at least annually for compensated cirrhosis and every 8-12 wk for decompensated cirrhosis[17]. The ultimate goal of the medical practitioner is the prevention of the occurrence of complications that may result from sarcopenia and undernutrition. Nevertheless, although there is no clear evidence for an appropriate guideline for patients at present, the current management in transplant centers is that patients with cirrhosis who are placed on the list benefit from efforts by the multidisciplinary team to try to preserve muscle mass and function, through the interventions of dieticians (screening for undernutrition, implementation of standard nutritional measures, early oral intake) and physical therapists (mobilization)[54]. However, it is not yet proven that we are able to slow down the progression of complications or reverse advanced situations *via* muscle targeted interventions[13]. There are two main options, non-exclusive: Dietary interventions and physical activity. Additional specific pharmacological measures are under investigation.

The current nutrition guidelines for patients with CLD recommend a weight-based daily caloric intake of at least 35 kcal/kg/d with a protein intake of 1.2-1.5 g/kg/d[18]. These recommendations are derived from data assessing energy expenditure (indirect calorimetry). They are difficult to achieve in routine practice. Protein intake is easily found in staple foods such as meat and vegetables. Several studies have analyzed the benefit of branched-chain amino acid (BCAA) supplementation but the results of these data are contradictory. While some authors suggest that BCAA improve hepatic encephalopathy and muscle mass[55], a meta-analysis shows that there is no effect on mortality and nutritional parameters[56]. Because of these contradictions and the limitations of clinical studies, BCAA supplementation is not currently recommended. Prolonged periods of fasting should be avoided in cirrhosis and it is important to favor split meals associated with a late evening snack or an early morning breakfast[17]. Oral nutritional supplements given before bedtime showed a muscle benefit in Child A patients but not Child B or C[57]. If not achieved *via* oral route, energy intake *via* enteral nutritional supplementation may be considered to achieve targets.

Besides these nutritional recommendations, physical activity improvement is also important. The latest recommendations propose to assess frailty and/or sarcopenia with standardized tools in order to define a personalized approach for the sarcopenic patient. This personalized activity prescription is

Table 2 Set of techniques to evaluate the physical activity as well as the quantity and quality of muscle

Technique	Goal	Advantages	Disadvantages
Physical activity assessment			
IPAQ	Reflects physical activity over the last 7 d	Easier to implement. Understandable for the patient. Representative over 7 d	Subjective. Poor estimation by the patient
Pedometer	Measures walking activity	Inexpensive and easy to set up. Represents the physical activity of walking	Reliability decreases with walking speed. Could induce changes in patient's habits. Does not measure other physical activities
Accelerometer	Measures walking activity	Takes slope and weight carried in consideration	Long to wear for good representation. Not sensitive to the inclination of the walk or the load worn during the walk. Could induce changes in patient's habits
Anthropometric measurement			
BC	Gives information on arm circumference and stage of muscle mass depletion	Very easy to perform (requires only a tape measure)	User dependent
MAMC (BC-TSF)	Gives information on arm muscle volume	Well described and easy to perform. Assesses muscle volume better than BC alone	User dependent. Requires a caliper
BIA	Allows to assess the body composition	Simple. Non-invasive. Reproductible	Requires specific equipment. Varies with fluid retention (common in cirrhosis)
Function tests			
Handgrip	Allows to measure the strength of the forearm and wrist muscles	Low cost. Easy to perform. Gold standard	Not representative of total body strength
6MWT	Measures distance walked for 6 min	Easy to perform. Reflects endurance and general fitness	Caution in patients with cardiac and respiratory problems
LFI	Measures frailty of patients calculated with a score	Easy to perform. Little training	Not assessable in severe encephalopathy
Isokinetic	Measures the function and strength of a of group muscles	Gold standard. Reproducible	Cost. Requires training and collaboration. Caution in patients with cardiac and respiratory problems
Leg press	Measures the strength of the lower limbs	Simple device	Requires collaboration. Rougher assessment. Not well evaluated/used
Imaging techniques			
US	Allows to measure the echogenicity of the muscle	Non-invasive. Not expensive	User dependent. Variability with fat thickness, position of the probe. Requires training
CT-scan	Allows to measure the surface of the muscle (easily) as well as its density	Clear image. Reproduceable	Radiation exposition
MRI	Can be used to evaluate the muscle surface. Measures the amount of fat within the muscle (PDFF)	Clear image. Reproduceable	Cost. Time consuming. Contra-indications (claustrophobia, pacemaker, *etc*)
DXA	Allows to measure the body composition (muscle, fat, water, *etc*)	Clear image. Reproduceable	Radiation exposition. Varies with fluid retention (common in cirrhosis)

IPAQ: International physical activity questionnaire; BMI: Body mass index; BC: Brachial circumference; TSF: Tricipital skin fold; MAMC: Mid-arm muscle circumference; BIA: Bio-impedance analysis; 6MWT: 6 min walk test; LFI: Liver frailty index; US: Ultrasound; CT-Scan: Computed tomography scan; MRI: Magnetic resonance imaging; PDFF: Proton density fat fraction; DXA: Dual x-ray absorptiometry.

guided by the principles of frequency-intensity-time-type: A combination of aerobic exercise that improves cardiorespiratory endurance and resistance exercise that improves strength and skeletal muscle mass[17]. Personalized physical activity allows patients to improve their cardiopulmonary capacity and quality of life. Unfortunately, current randomized controlled data are limited by small samples of well-compensated cirrhosis patients (mean MELD = 10)[31,58]. Despite these promising results, there are no randomized controlled studies with patients with ESLD or a waiting list for LT. It is therefore not currently possible to conclude whether a personalized physical activity program would improve the outcomes in the waiting list and post-LT surgery.

Several randomized controlled trials evaluating the benefit of nutritional and/or physical exercise on muscle mass (SMI) and frailty (LFI) pre- and post-LT would help to answer these uncertainties. Finally, pharmacological treatments are being studied to treat sarcopenia (hormone replacement therapy such as testosterone or growth hormone, ammonia reduction and myostatin inhibition)[59].

CONCLUSION

Malnutrition, sarcopenia and frailty are very common in patients with cirrhosis, especially in cases of disease requiring organ transplantation. Bi-directional pathophysiological links exist between muscle and liver that underlie this association. This highlights the interest of prospective studies comparing the different tools at our disposal to evaluate the cirrhotic patient as well as translational studies to understand these mechanisms and find a possible therapeutic or diagnostic target. Through a better understanding of mechanistic links, the muscle can become a game changer. A better understanding of the situation will also allow us to prioritize fragile patients who need a faster LT or to identify negative factors in certain recipients in whom the situation would be irreversible post-LT and deleterious to the graft. Interventional strategies (nutritional, physical exercise and pharmacological treatments) are also being evaluated. The rationale for their efficacy is clear, even if at this ESLD, evidence of their impact on reducing pre-LT and post-LT mortality is lacking, as well as a precise characterization of the protocols to be implemented. Again, quality prospective studies will be able to answer this question.

Abstract

There is increasing incidence and prevalence of acute and chronic liver diseases (CLDs) all over the world which influence the quality of life and can give rise to life threatening complications. The burden of advanced liver disease due to hepatitis B has been controlled by antivirals but its eradication is difficult soon. Highly effective directly acting antiviral therapy has reduced the burden of hepatitis C but is partially offset by increasing IV drug abuse. Non-alcoholic fatty liver disease pandemic is on and there is recent alarming increase in alcohol related liver disease, both of which have no drug cure apart from control of the risk factors. Genetic factors have been identified in progression of all forms of CLD. Due to better management of complications of CLD, the life span of patients have increased spiking the number of hepatocellular carcinoma (HCC) and patients needing liver transplantation (LT). The present severe acute respiratory syndrome coronavirus pandemic has affected the outcome CLD including LT in addition to causing acute hepatitis. Better diagnostics and therapeutics are available for liver fibrosis, portal hypertension, HCC and post LT management and many drugs are under trial. The present review summarises the current scenario of the epidemiology and the advances in diagnosis and treatment of liver diseases including their complications like portal hypertension, HCC and LT.

Key Words: Chronic liver disease; Genes; Biomarkers; Therapy; Hepatocellular carcinoma; Liver transplantation; Recent advances

Core Tip: The incidence and prevalence of liver disease is rising all over the world. Hepatitis B is difficult to eradicate and the benefit of directly acting antiviral therapy for hepatitis C is partially offset by increasing IV drug abuse. Non-alcoholic fatty liver disease pandemic is on and alcohol related liver disease is rising alarmingly, both having no drug cure. Due to better management of complications, patients of chronic liver disease are living longer spiking the number of hepatocellular carcinoma (HCC) and patients needing liver transplantation (LT). Better diagnostics and therapeutics are available for fibrosis, portal hypertension, HCC and post LT management which are discussed.

INTRODUCTION

Chronic liver disease (CLD) and cirrhosis pose substantial health burden worldwide. In the period 2007-2017, the age standardised prevalence increased 10.4% with 1.5 billion cases in 2017[1]. Of the four chief etiology, hepatitis B virus (HBV) and hepatitis C virus (HCV) burden still remains high [though decreased due to availability of vaccination for HBV and directly acting antiviral therapy (DAA) for HCV] although with the non-alcoholic fatty liver disease (NAFLD) pandemic and increasing global alcohol consumption, they are fast catching up. NAFLD is the leading cause in developed nations, it is also gradually becoming important in newly developed nations like India, China[2,3]. The age standardised prevalence of HBV/HCV related CLD rose by 9%/10.2% in the last decade whereas for NAFLD it was 23.5%[1]. The high HBV and HCV burden is mostly due to poor diagnostic coverage and linkage to treatment and care of the susceptible population.

HBV

The HBV pool is chiefly contributed to by the Western Pacific and Subsaharan Africa region (mostly tribals) and some southeast Asian countries (China, Vietnam, Thailand, Laos) where the load remains high despite the success of HBV vaccination programme at birth. It is the leading cause of hepatocellular carcinoma (HCC) in these countries[4]. Among some developed and newly developing nations where prevalence is intermediate to low, its burden is contributed by the indigenous tribal population like India, Australia[5,6] maintained through intracaste marriages, close living, tribal customs, illiteracy and poor access to health care resources. With the present attrition rate (present burden of 296 million from 350 million 3 decades back and present annual mortality of 8 lakh and addition of 1.5 million cases in 2019[7]), it is still a long way for natural elimination of the pool. In future some redistribution is also likely due to population migration from high to low endemicity regions. World Health Organization (WHO)'s ambitious programme for eradication of HBV by 2030 therefore incorporate the best preventive measures *i.e.*, increase vaccination at birth, prevent vertical and horizontal transmission among toddlers by treating at risk mothers, and scale up screening, care and treatment services. Curative treatment is difficult and < 20% who receive the currently approved drugs [interferon, nucleos(t)ide analog (NA) or combination as sequential/add on/switch therapy] achieve loss of HBsAg (functional cure). Combination strategies are less cost effective than first line NA monotherapy although this may lead to more HBsAg loss in some subgroup of HBV patients[8]. Even with long term NA monotherapy (Tenofovir disoproxil for 5 years) half fail to achieve fibrosis regression[9] and there is high relapse rate in e negative patients (RETRACT B study showing relapse rate of 47.8% at 6 mo, 68.9% at 12 mo, 83.4% at 48 mo)[10]. The other problem is the risk of relapse in previously exposed person or inactive HBsAg carriers (who constitute a sizable majority of the present pool not requiring drug therapy) needing immunosuppression (IS) or cancer chemotherapy. Fortunately, highly active antivirals are capable of controlling the virus and reducing the burden of advanced liver disease from HBV. The chief impediments to HBV functional cure are intrahepatic viral reservoir cccDNA with integrated sequencing, high HBsAg levels, and defective host innate and adaptive immune responses. Newer strategies target these *e.g.*, targeting HBV life cycle without damaging hepatocyte by inhibiting ccc DNA replenishment pathways or degrading them by entry inhibitors like Bulevirtide [used for HBV/HDV coinfection including post liver transplantation (LT)], nucleic acid polymer assembly inhibitors (Lonafarnib), CRISPR/Cas9 protein base editors (DNA endonucleases), siRNAs, core protein modulators (Morphothiadin,Vebicorvir, Bersacapavir) and antisense oligonucleotide (Bepirovirsen)[2], immunomodulation to safely eliminate infected cells. Potential targets in innate immune response pathway include pathogen recognition receptors [Toll-like receptors 7/8, retinoic acid-inducible gene

(RIG)-1-like receptors and nucleotide-binding oligomerization domain (NOD)-like receptors], natural killer cells and antigen presenting cells (dendritic cells and Kupffer cells) whereas in adaptive immune response pathway, it includes modulation of HBV-specific CD4+ and CD8+ T cell (especially the relative functional and numerical deficiency of CD8+ T-cells by PD-1 checkpoint inhibitors), regulatory T cell, HBV-specific T and B cell (autologous, engineered or by vaccine).

HCV

Gratifying results have been obtained with the introduction of affordable short term (3-6 mo) DAA therapy for HCV (with sustained viral response rates of > 95%, decreased fibrosis and HCC) with increasing treatment coverage in newly developed and developing nations which have decreased the HCV burden to 58 million as of 2019[7]. HCV still remains the leading cause of HCC in the developed world (Western countries, Japan) though alcohol related liver disease (ALD)/NAFLD are fast taking the lead due to treatment with DAA. But challenges still remain like limited drug availability, interaction with other drugs used to treat comorbidities (HIV, coronary artery disease and hyperlipidemia), inability to afford even the low drug cost by patients who pay from their own pocket and increasingly recognized metabolic dysfunctions associated with hepatitis C. Even in Denmark, 50% HCV patients are yet to attend specialist care especially IV drug users[11]. HIV coinfection is also a deterrent for good treatment outcome for both HBV and HCV. In future the HCV pool is likely to be maintained by intravenous drug users and the increasing population with drug/alcohol abuse and other psychiatric disorders, those needing repeated blood transfusion (for haematological disorders, hemodialysis) and reinfection in those who continue to have risk factors even after cure by DAA. WHO recommends increased access to treatment by onsite diagnosis by dried blood spot and initiating treatment at point of care and by trained non specialist doctors and nurses at harm reduction centres.

NAFLD

NAFLD is the most common liver disease worldwide affecting about a quarter population with regional differences[12]. It is fast becoming the leading cause of cirrhosis in developed nations. Genetic inheritance (25%-34%), ancestry (HispanicAmerican/Asian/Indian > European > African American), advancing age and male sex are non modifiable whereas obesity (especially central), diabetes mellitus, hyperlipidemia and insulin resistance are modifiable risk factors. There is currently no approved pharmacological therapy for NAFLD apart from those treating the risk factors. Weight loss through dietary alteration, physical exercises and bariatric surgery leads to improved liver histology but only small percentage of patients can achieve and maintain the degree of weight loss needed for sustaining the benefit and 50% fail to improve histology[13]. Ursodeoxycholic acid (UDCA)/obeticholic acid (OCA), Vitamin E have no proven benefit. Therefore it is the hottest area of newer drug research which modulate key metabolic, inflammatory, and fibrogenic pathway. Pan PPAR agonists (Lanifibranor), GLP 1 agonists (Semaglutide), CCR 5 inhibitors (Leronlimab), thyroid hormone receptor agonist (Resmetirom) and hepatic SCD1 inhibitor (Aramchol) are in phase 2 and 3 clinical trial (Table 1). Other antifibrotic and disease modifying agents as well as genetic factors are discussed below. But considering the multiple risk factors and complex pathophysiology, it is unlikely that a panacea will be discovered soon.

ALCOHOL

Approximately 2 billion people worldwide consume alcohol of whom 283 million suffer from AUD[14]. ALD is most prevalent in the western world and in some affluent Asian countries (South Korea, Japan) though there is increasing global trend especially in newly industrialised southeast Asian nations (China, India, Vietnam, Thailand) where it was low due to traditional"dry" culture. ALD has become the leading cause of CLD/cirrhosis in India[5]. The recent coronavirus disease 2019 (COVID-19) pandemic has significantly increased the incidence of ALD in young adults. DALYs per 1000 people due to ALD was highest in India (2356.4), followed by the United States (467.9), China (466.3), Nigeria (424.5) and Indonesia (365.1). For alcohol related liver cancer, DALYs were highest for China followed by Vietnam, Russia, Thailand, India[15]. Consumption depends on age, sex, religion, culture, health status and national income distribution. Globally it is a tussle between national income from alcohol retail *vs* health expenditure for AUD, the latter being dismal even in developed nations. Being a fully preventable disease, WHO's "best buys" are the most cost effective ways for prevention, *i.e.*, increasing taxation on alcoholic beverages, enforcing bans or comprehensive restrictions on exposure to alcohol advertising and restricting physical availability of retailed alcohol. A recent global study shows no safe dose for alcohol[16]. Abstinence can reverse fatty liver and halt the progression of CLD. It is responsible

Table 1 Interrim results of selective drug trials for non-alcoholic fatty liver disease and liver fibrosis

Agent	Mechanism	Phase	ClinicalTrials.gov number	Results
Simtuzumab	Lysyl oxidase-like 2 monoclonal antibody	IIb	NCT01672879	Ineffective in decreasing hepatic venous pressure gradient
Selonsertib	Selective inhibitor of apoptosis signal-regulating kinase 1	III	NCT03053063	Ineffective in improving fibrosis without worsening NASH
Emricasan	Pan-caspase inhibitor	II	NCT03205345	No reduction in composite outcome of mortality and decompensation
Pegbelfermin	PEGylated fibroblast growth factor 21 analogue	IIa	NCT03486912	Ineffective in improving fibrosis without worsening NASH
Lanifibranor	Pan peroxisome proliferator-activated receptor agonists	III	NCT04849728	Decrease of ≥ 2 points in the Steatosis Activity Fibrosis score without worsening of fibrosis in phase 2b trial
Resmetirom	Thyroid hormone receptor agonist	III	NCT03900429	Significant reductions in liver fat content and serum atherogenic lipids in phase 2 trial
Aramchol	Hepatic stearoyl-CoA desaturase1 inhibitor	IIb	NCT02279524	Insignificant decrease in liver triglycerides but significant improvement in liver inflammation and improvement of fibrosis ≥ 1 stage and serum ALT level
Leronlimab	Chemokine receptor 5 monoclonal antibody	II	NCT04521114	Significant drops in liver fat, inflammation and fibrosis values as also in liver enzymes and multiple inflammation markers at week 14 compared to placebo

NASH: Non-alcoholic steatohepatitis; ALT: Alanine transaminase.

for 50% of deaths due to CLD because no specific drug therapy is available apart from some short term benefit of steroids in pure acute hepatitis. Tumour necrosis factor alpha, growth hormone, pentoxyfylline and antioxidants at best show mixed results from highly variable to weak, efficacy depending on the stage of disease. The unclear molecular mechanism of disease deter identifying treatment target and disincetivize drug development. Naltrexone, disulfiram and acamprosate helps to decrease addiction. Obesity and cigarette smoking are known risk factors so weight control and quitting smoking are routinely encouraged. A poor overall nutritional status (protein calorie malnutrition, micronutrient deficiencies) often accompanies ALD and correlates positively with the development of serious complications hence a well-conceived nutrition support by oral, enteral, and parenteral routes is an essential part of standard care. Recent evidence also strongly implicates intestinal dysbiosis in ALD progression. These targets are being addressed by trials of probiotics, fecal microbiota transplantation, growth factors (granulocyte colony stimulating factor, bovine colostrum), antioxidants (ω5 and synthetic fatty acids, S-adenosyl methionine + choline, N-Acetyl cysteine, vitamin C), in addition to liver regenerative biologics and device assisted behavioural alteration[17]. The other hindrances are disease stratification for early identification when it is most reversible, monitoring abstinence (as recidivism is high) and identifying risky drinking behaviour like binges. Various biomarkers under study for this purpose include circulating small noncoding RNAs, long noncoding RNAs, selective cytokines profiles, phosphatidyl ethanol and urine ethyl glucuronide and ethyl sulphate[18-21].

AUTOIMMUNE LIVER DISEASE

Autoimmune hepatitis appears to be increasing in incidence as a part of the general increase in immune mediated and allergic diseases resulting from decreasing infectious disease with mounting antibiotics use globally. Some antibiotics like nitrofuranotin, minocycline and coamoxyclav can induce autoimmune hepatitis by themselves and some antibiotic associated drug induced liver disease (DILI) may resemble autoimmune hepatitis. The standard treatment of autoimmune hepatitis is with steroids with/without azathioprine. Mycophenolate mofetil is a second line drug. Substantial advances in treatment of autoimmune cholangiopathies has been achieved with PPAR α agonist bezafibrate, FXR agonist OCA and recombinant FGF 19 (which alter bile acid synthesis along with antifibrogenic effect [22], see below) and drugs inhibiting intestinal apical sodium-dependent bile acid transporter (linerixibat, maralixibat, odevixibat)[23]. in addition to bile acid resins and UDCA. Combinations of such enterohepatic with cholehepatic and/or anti-fibrotic drugs could result in synergistic/additive effects in decreasing the fibrosis along with the pruritus.

ADVANCES IN DIAGNOSIS

Non invasive biomarkers of CLD (patented ones like fibrotest, fibrometer, Hepascore, ELF model and non patented ones like FIB 4 index, APRI, BARD, NFS) and elastography (fibroscan, MRE, point SWE, 2D-SWE, 3D Velacur™) or their combination (MEFIB, MAST, FAST) have been investigated across the whole spectrum of NAFLD to delineate the stage as well as correlating genes with liver fat, enzymes and fibrosis[24]. Novel ones like computerised tomography (CT) scan with objective measures of liver nodularity and shunts, multiparametric magnetic resonance imaging (MRI) (iron corrected T1, cT1), extracellular vesicles, microbiome (stool microbial profiles), biomarker for extracellular matrix remodelling (TGF-β, MMP, TIMP)[25-27] are being investigated. Graph convolution networks (a deep learning technique) is being tested for quantitative assessment of fibrosis[28].

GENETIC FACTORS IN CLD

Genetic factors are important in progression of all forms of CLD (ALD, NAFLD, metabolic associated fatty liver disease, chronic hepatitis) including HCC with interplay of genes involved in glucose, lipid and iron metabolism, insulin signalling, oxidative stress, inflammatory pathways and fibrogenesis. Most reliable fatty liver genes include PNPLA3, TM6SF2, HSD17B13, GCKR and MBOAT7 (associated with increased liver fat, NASH, cirrhosis, HCC). The evidence for others like MARC1, GPAM, APOE, ALDH1B, PCKS7, SERPINA1, HNF1A etc are less robust. Rare variants like APOB and MTTP are associated with an increased risk of fat accumulation leading to HCC while protecting at the same time against dyslipidemia and cardiovascular risk[24]. Polygenetic risk score [with/without clinical risk markers] are being investigated to stratify disease risk *e.g.*, PNPLA3 and TM6SF2 can become a reason for HCC surveillance whilst giving protection from cardiovascular complications[29] It can also help in proper drug selection. Genetic therapies in CLD include gene silencing approaches (PNPLA3, HSD17B13), CRISPR/Cas9-based approaches[30] (which alter responsible genes) and modulating genes involved in liver regeneration.

ACUTE HEPATITIS

The etiology of acute liver failure (in those with normal liver) varies in different countries at different times. Most commonly these include viruses (hepatitis A, B and E), DILI (CAM, anti tuberculous drugs, paracetamol, anticonvulsants, antibiotics), toxins (herbs, alcohol) and autoimmune flares; else these may precipitate acute liver failure in those with CLD (acute-on-chronic liver failure, ACLF). Hepatitis E virus may be associated with fulminant course in pregnancy. In tropical areas, malaria, dengue, enteric fever, leptospirosis and scrub typhus may also cause acute hepatitis. Traditionally Wilson disease and autoimmune hepatitis has been considered to cause acute liver failure but in adults majority of such acute flares occur on background CLD. Most acute hepatitis of viral etiology recover by themselves and of drug/toxin on their discontinuation, some DILI may need corticosteroid (especially those resembling autoimmune hepatitis). Bacterial infections respond to antibiotics. But the course of ACLF depends on the stage of the background CLD and the precipitating cause, alcohol having the worst outcome[31,32]. Undefined number of acute hepatitis are occurring recently due to COVID-19 infection, recreational drugs and alcohol.

PORTAL HYPERTENSION AND LIVER FIBROSIS

With the increasing prevalence of CLD, portal hypertension and its complications are also increasing. Refractory ascites/hepatorenal syndrome/hydrothorax are now being better managed with terlipressin, noradrenaline, midodrine, octreotide and long-term albumin supplementation (with its newly discovered wider pleiotropic non-oncotic properties positively impacting decompensated CLD). Sodium-dependent glucose cotransporter 2 inhibitors and Alfa pump are under trial. Endohepatology (the application of endoscopic ultrasound in liver disease treatment)[33] has brought about dramatic improvement in the treatment of variceal bleed by better delineation of collaterals and guided treatment (coiling, balloon retrograde transvenous occlusion of collaterals, glue injection in gastric varix), directed liver biopsy, portal pressure gradient measurement and deployment of dedicated esophageal stents. Pre emptive transjugular intrahepatic portasystemic shunt has been used for uncontrollable ascites or variceal bleed.

Fibrosis in the liver is caused by activated HSC whose biology connects damage, regeneration and cancer. Severe hepatic fibrosis represses regeneration and accumulation of senescent HSCs creates a pro-inflammatory, pro-fibrotic environment. Fibrogenesis inhibitor drugs resolve inflammation, cause loss of activated myofibroblasts, and ECM degradation Those under investigation (Table 1) include [FXR

agonist OCA/cilofexor, acetyl-coenzyme A carboxylase inhibitor Firsocostat, ASK-1 inhibitor Selonsertib, CCR 2/5 inhibitor Cenicriviroc, FGF 19 analog Aldafermin/21 analogue Pegbelfermin, PPAR α/δ agonist Elafibranor, PPARγ agonist pioglitazone, PPAR α/γ agonist Saroglitazar, galectin 3 inhibitor Belapectin, CB1 antagonist Rimonabant, ECM production inhibitors like TIMP and MMP, lysyl oxidase 2 inhibitor Simtuzumab, HSP 47 inhibitor Pirfenidone, pan caspase inhibitor Emricasan and anti inflammatory lipids derivatives of PUFA (lipoxins, resolvins, protectins, and maresins)][34-36]. Statins have been found to have beneficial effect in halting the progress of CLD[37].

HCC

The chief cause of HCC in the West is hepatitis C followed by NAFLD and alcohol whereas it is hepatitis B in Asia and Africa. Eighty percent occur in low and middle resource countries. Screening programme for HCC in cirrhotics is cost effective and better cancer surveillance can be achieved by the recently developed GALAD (incorporating AFP, AFP-L3, PIVKA, age and sex) screening tool[38] along with radiologic strategies (contrast enhanced ultrasonogram using Li-RADS, multiphasic CT/aMRI scan) every 6 mo in high risk patients. Ninety percent HCC occur on background CLD which pose additional health risk to HCC itself. Liver biopsy carries risk hence liquid biopsy using detection of circulating tumor cells specific to HCC, mutation or methylation of circulating tumor DNA, and transcriptomic profiling of extracellular vesicles are promising. The widely followed BCLC staging system have been upgraded (to be more inclusive for surgery with/without downgrading of tumor) and provide better platform for optimal use of different treatment modalities like ablation, resection, LT, stereotactic body radiation, locoregional and systemic therapy. LT has been extended outside Milan criteria to include more patients by various expanded selection criteria with reduced but excellent long term results[39]. Cancer in non cirrhotic liver is treated by LT with better understanding of transplant oncology. Newer drugs like multikinase inhibitors (Lenvatinib, Regorafinib, Cabozantinib, Ramucirumab), checkpoint inhibitors (atezolizumab, bevacizumab, durvalumab, pembrolizumab, nivolumab, ipilimumab and tremelimumab) are now available over sorafenib for systemic therapy with better outcome[40]. Limitations are their unclear safety profile in Child Pugh stage B, best response not more than 50%, unclear treatment sequence and use in early stage of tumor.

LT

ALD is now the predominant cause for LT followed by HCV and NAFLD in the West[41] whereas it is still HBV/HCV in the East with ALD at its heels[42]. With good patient selection, the present 1 year survival is 90% and 5 year of 70%. Good outcome has been substantially influenced by betterment of surgical techniques, perioperative management, organ preservation (normothermic machine perfusion), recipient selection (through organ sharing network), post transplant immunosuppressive management and of viral etiology (DAA for HCV. Bulevirtide/NA for HBV/HDV). The challenge of limited organ availability has been addressed by accepting marginal and extended criteria donors (donors of cardiac death, 30%-60% steatotic liver explant without inflammation, HBsAg and HCV positive donors), split liver grafts and live donor transplant especially in Asia[41]. Liver regeneration based approaches like stem cell therapy and organ bioengineering can also help. Most post transplant morbidity arise from prolonged use of immunosuppressive with resultant infections, hypertension, dyslipidemia, cardiovascular events, renal failure, malignancy and chronic organ rejection. Long term outcome can be improved by minimising/late introduction of standard IS or withdrawing it completely (20% become operationally tolerant) and using less toxic IS drugs (mToR inhibitors, interleukin 2 receptor blockers). With increased understanding of transplant immunology, research is on whether IS can be completely withdrawn after finite treatment by modulating recipient immunity (by CD4 Treg cells, regulatory dendritic cells or hematopoietic stem cell transplantation)[43]. The problem of HCV relapse leading to cirrhosis in 30% has been addressed by DAA. Present challenges for liver transplant are: (1) High alcohol recidivism; (2) ACLF grade 3 and severe acute alcohol related hepatitis; (3) NAFLD/non-alcoholic steatohepatitis with high comorbities; (4) Frailty in advance CLD; (5) Recipient and caregiver challenges; (6) Genetic variants; and (7) COVID-19. Severe acute respiratory syndrome coronavirus vaccine fails to decrease mortality as the patient's immunity is already weakened.

Artificial intelligence and digital transformation of various diagnostic modalities, decision making tool and management will further advance the treatment of liver diseases.

CONCLUSION

The current scenario of the epidemiology and the advances in diagnosis and treatment of liver diseases including their complications are summarised in this review.

Abstract

Acinar cell carcinoma (ACC) is a rare pancreatic malignancy with distinctive clinical, molecular, and morphological features. The long-term survival of ACC patients is substantially superior to that of pancreatic adenocarcinoma patients. As there are no significant patient series about ACCs, our understanding of this illness is mainly based on case reports and limited patient series. Surgical resection is the treatment of choice for patients with the disease restricted to one organ; however, with recent breakthroughs in precision medicine, medicines targeting the one-of-a-kind molecular profile of ACC are on the horizon. There are no standard treatment protocols available for people in which a total surgical resection to cure the condition is not possible. As a result of shared genetic alterations, ACCs are chemosensitive to agents with activity against pancreatic adenocarcinomas and colorectal carcinomas. The role of neoadjuvant or adjuvant chemoradiotherapy has not been established. This article aims to do a comprehensive literature study and present the most recent information on acinar cell cancer.

Key Words: Acinar cell carcinoma; Pancreas; Imaging; Immunohistochemical stains; Molecular features; Surgery; Chemotherapy

Core Tip: Acinar cell carcinoma (ACC) of the pancreas is a rare, malignant neoplasm that accounts for a small percentage of all pancreatic neoplasms. Our understanding of this disease remains unclear as there are no large series of patients with ACC. This review article aims to conduct a comprehensive literature review and present current knowledge about ACC.

INTRODUCTION

The rising prevalence of abdominal imaging has resulted in an uptick in historically rare pancreatic cancer cases. The exocrine pancreas primarily comprises acinar and ductal cells[1]. Although acinar tissue accounts for most of the pancreatic organ, pancreatic neoplasms that mainly exhibit acinar differentiation are rare. The expression of various pancreatic enzymes, such as chymotrypsin, trypsin, and lipase, leads to acinar differentiation in the exocrine pancreas[1]. Most acinar neoplasms are solid, malignant, and not well-recognized[2]. Acinar cell cystadenoma is the sole benign acinar neoplasm documented; uncommon benign cystic, malignant cystic, and mixed carcinomas also exist.

Acinar cell carcinoma (ACC) of the pancreas is a rare, malignant tumor composed of cells with morphological resemblance to acinar cells and with evidence of exocrine enzyme synthesis by the neoplastic cells, accounting for 1%-2% of all pancreatic neoplasms[2-4]. ACC of the pancreas is a high-grade malignancy with no apparent site preference; it can occur in any section of the pancreas, but the head is the most common location.

Currently, there is no definitive course of treatment for ACC; however, vigorous surgical resection with negative margins has been linked to improved long-term survival[5]. Particularly with the use of computerized tomography (CT) and magnetic resonance imaging (MRI), as well as with the confirmation of fine needle aspiration (FNA) biopsies, early recognition and diagnosis are of particular relevance. Knowledge of these lesions' morphologic and immunohistochemical characteristics is also essential for a precise clinical diagnosis. In addition, extensive molecular analyses of acinar neoplasms have identified genomic alterations that may be amenable to specific therapies, thereby increasing the likelihood of widespread clinical molecular testing of these tumors.

This article aims to do a comprehensive literature study and present the most recent information on acinar cell cancer.

EPIDEMIOLOGY

ACC of the pancreas accounts for 1%-2% of all adult exocrine pancreatic neoplasms and 15% of pediatric neoplasms. ACC occurs most frequently in white males and is usually bimodal in age, with peaks in childhood at 8-15 years of age and adulthood with a peak incidence at 60 and is rare between the ages of 20 and 40. ACC has a 3.6 male-to-female ratio. No known racial relationships exist[1,6,7].

CLINICAL FEATURES

Most ACC s exhibit vague symptoms, which include weight loss (45%), abdominal pain (60%), back pain (50%), nausea and vomiting (20%), melena (12%), weakness, anorexia, and diarrhea (8%) are typical non-specific symptoms of ACC[8,9]. In distinction to ductal adenocarcinoma, ACC infrequently obstructs the bile duct and causes jaundice only in 12% of patients. ACC causes a mass effect and displaces those organs but does not infiltrate[10].

Some patients experience paraneoplastic disease known as "Schmid's Triad" or lipase hypersecretion syndrome due to increased lipase levels reaching over 10000 U/dL[11,12]. Elevated lipase may be the first sign of ACC. Patients may present with multiple nodular foci of subcutaneous fat necrosis, polyarthralgia may occur due to fat necrosis in the cancellous bone, and may have peripheral blood eosinophilia[13,14]. On imaging, fat necrosis within the bone can appear as a focal area of sclerosis.

Paraneoplastic syndrome may occur following tumor recurrence. Most patients have hepatic metastases at presentation; however, some may present with only a bulky pancreatic mass. The serum lipase levels may normalize after surgical resection of the tumor, and patients may have symptomatic relief. Lipase may be used as a tumor marker in these patients. Alpha-fetoprotein (AFP) blood levels can be elevated in young patients[15].

MACROSCOPY (GROSS FEATURES)

On FNA, an abundance of cells with fluctuating degrees of acinar differentiation but no endocrine or ductal cells are seen. The aspirates consist primarily of cohesive fragments creating acini, cellular cords, or solid nests of neoplastic epithelium, composed of clusters of uniform cells with smoothly contoured, eccentric nuclei containing one or two prominent nuclei nucleoli[16,17].

ACCs can occur in any region of the pancreas and, on average, are 10 to 11 cm in size at the time of diagnosis[18-20]. The tumors are well circumscribed and have a soft, fleshy, tan to red appearance[2]. They occasionally exhibit lobulated appearances, necrosis, and cystic degeneration[20]. On occasion, the neoplasm is found attached to the surface of the pancreas. Involvement of the duct system by ACCs can sometimes be observed grossly as polypoid or fingerlike projections extending from the primary tumor mass toward the duct[21].

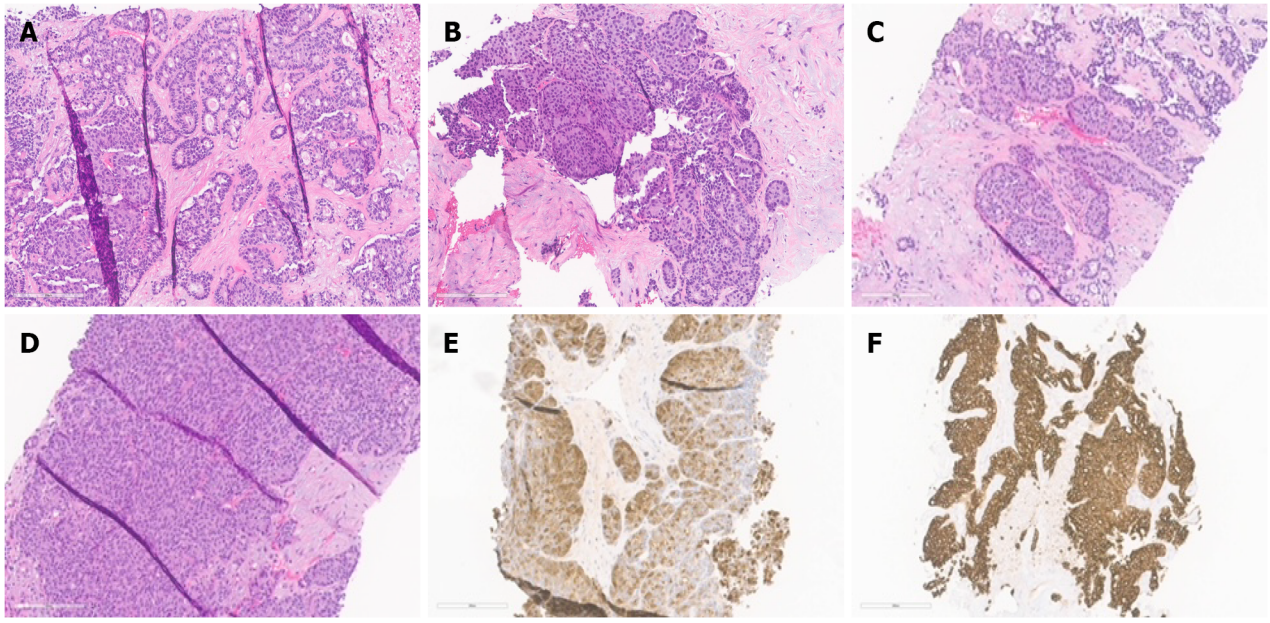
PATHOLOGY

ACCs are cellular neoplasms with minimal stroma on microscopic examination. Multiple architectural patterns, including acinar (Figure 1A), solid (Figure 1B), glandular (Figure 1C), and trabecular (Figure 1D), can be observed. Solid and acinar patterns are the most prevalent. The acinar pattern is characterized by structures resembling normal acini, with small lumina and cells arranged in a monolayer with basally located nuclei. Large sheets of cells depict the solid pattern without lumina. Acinar structures with the dilated lumen characterize the less common granular pattern. The trabecular pattern, which resembles the architecture of well-differentiated neuroendocrine tumors, consists of more pronounced palisading with thinner, interlacing ribbons of cells. Multiple architectural patterns are visible within a single tumor.

IMMUNOHISTOCHEMISTRY

The immunohistochemical labeling of enzyme production from pancreatic cells aids in confirming the diagnosis of ACC (Table 1). There are commercially available antibodies for chymotrypsin, trypsin, lipase, and amylase, with the first three being the most frequently used in clinical settings (Figure 1E). These enzymes exhibit varying degrees of specificity and sensitivity. In approximately 95% of cases, trypsin and chymotrypsin reactivity can be demonstrated, and this combination is reportedly the most sensitive for diagnosing ACC[10,22].

ACC is also positive for CK8 and CK18, and as a result, they will label for AE1/AE3 and CAM5.2. CK7 (Figure 1F) and CK19, which are usually expressed in ductal adenocarcinomas, are generally missing in ACC but may be expressed in a subgroup of ACCs[15,23]. Focal labeling for chromogranin and synaptophysin is observed in a substantial proportion of ACCs, displaying the need to assess with further clear-cut acinar markers, especially in small samples, to avoid misidentifying an ACC as a neuroendocrine tumor or mixed acinar-neuroendocrine differentiation[10,24,25]. Recent research on histological and cytological samples has proven that the monoclonal antibody directed against the COOH-terminal region of the BCL10 protein, which identifies the COOH-terminal portion of CEL, is a highly specific and sensitive approach for detecting ACCs[26,27].



MOLECULAR FEATURES

The genetic alterations driving ACC have been thoroughly characterized and sequenced. The outcomes of these studies have emphasized the diversity of modified genes and pathways among various tumors, as well as the marked genomic instability in a subset of instances, including at the base pairs and chromosomes level. Several studies analyzed ACC for mutations in gene changed in pancreatic ductal adenocarcinoma (PDAC), the most prevalent subtype of pancreatic cancer, before the wide availability of whole genome and exome. Several of these studies reported uncommon mutations in *TP53*, *KRAS*, and *SMAD4*, in addition to the unusual loss of SMAD4 expression in acinar neoplasms, while others reported no modifications in these genes[28-33]. In these studies, the most prevalent ACC mutations

Figure 1 Histopathological patterns. A: Acinar cell carcinoma with the predominant acinar pattern. The acinar pattern is characterized by structures resembling normal acini, with small lumina and cells arranged in a monolayer with basally located nuclei; B: Acinar cell carcinoma with the predominant glandular pattern. Acinar structures with dilated lumina characterize the glandular pattern; C: Acinar cell carcinoma with the predominant trabecular pattern. The trabecular pattern is characterized by ribbons of cells resembling those of pancreatic neuroendocrine tumors; D: Acinar cell carcinoma with a predominant solid pattern. Large sheets of cells characterize the solid pattern without lumina; E: Acinar cell carcinoma, immunohistochemical staining for trypsin; F: Acinar cell carcinoma, immunohistochemical staining for cytokeratin 7.

affected WNT signalings, such as mutations in APC that rendered inactive and mutations in CTNNB1 that rendered it active; these alterations were found in roughly 20% of ACCs[30]. Recent sequencing studies of the entire exome have highlighted the diversity of mutated genes in the ACC[34,35]. Several other studies have shown substantial chromosomal gains and losses in ACCs and altered regions in various carcinomas; nevertheless, the target genes (if any) in these regions have not been detected[29,30,36,37].

Multiple potentially targetable genetic alterations in pancreatic ACC have been identified. A subset of cases exhibits genomic instability due to mutations in genes involved in DNA repairs, such as *ATM*, *BRCA1*, *BRCA2*, *PALB2*, and *MSH2*[34,35]. According to various studies, microsatellite instability has been documented in fluctuating proportions of ACC, ranging from 7% to 14%[30,35,38]. Also, platinum agents and PARP inhibitors treat tumors with mutations in BRCA pathway genes[39,40]. Even though it has not yet been proven in major clinical trials, preliminary findings indicate that tumors with BRAF fusions react to MEK inhibitors, providing ACC with targeted therapy[41-43]. In a subgroup of ACCs,

Table 2 Summary of pertinent differential diagnostic features

Differential diagnoses	Age/sex	Imaging/gross findings	Histology	Prognosis
ACC	Predominant in males; mean age of 62 yr	Solid, well-circumscribed, bulky tumors; hemorrhage and necrosis are also frequent	Predominant acinar or solid architecture; uniform cells; basally located nuclei; eosinophilic granular cytoplasm; prominent single nucleoli. minimal stroma	Overall aggressive, with high rates of recurrence and metastasis
PDAC	Slightly higher in males; 6th-8th decade of life	Solid, poorly defined mass	Large, medium, or small malignant ducts with a tubular pattern; desmoplastic stroma. Processes of mitosis and necrosis	Poor survival rates
PanNET	Even distribution between the genders; more prevalent in adults; mean age of 40	Solid, well-circumscribed. 5% are cystic	Variable architectural patterns; uniform cells; oval or spherical nuclei; granular cytoplasm; undetected nucleoli; minimal stroma	Relatively languid, but with variable results
SPN	Almost exclusively female; average age of 28	Well-defined and encased with cystic degeneration	Pseudopapillae; cells with hyaline/myxoid stroma surrounding vessels; large cytoplasmic hyaline globules; nuclear groove	Overall low malignant potential: The majority are successfully treated surgically
PBL	First decade of life, mean age of 4; adults can be affected	Partially encapsulated, frequently lobulated, and substantial	Solid and acinar structure; cellular stroma; keratinization of squamoid nests; heterologous mesenchymal elements	Aggressive; better outcomes for children

ACC: Acinar cell carcinoma; PanNET: Pancreatic neuroendocrine tumors; PBL: Pancreatoblastoma; SPN: Solid pseudopapillary neoplasm; PDAC: Pancreatic ductal carcinoma

MYC abnormalities, including chromosome 8 polysomy and gene amplification, have been identified recently[44].

DIAGNOSIS

Laboratory analysis

Besides an increase in serum lipase levels associated with the syndrome of lipase hypersecretion, serum tumor markers are not consistently elevated in ACC. Even in the absence of lipase hypersecretion syndrome, lipase might be high. There have been numerous AFP increases, especially in younger patients[2]. Typically, Serum tumor markers such as carbohydrate antigen 19-9, alpha-fetoprotein, and carcinoembryonic antigen are expressed.

Radiological features (imaging)

In recent years, the incidence of uncommon pancreatic cancers has grown, likely due to the increased use of cross-sectional imaging[45]. In most instances, pancreatic cancers are incidentally found by CT. MRI is often used as a secondary test for further characterization. ACC of the pancreas is a well-defined, primarily oval or round exophytic mass in cross-sectional imaging[46,47]. Rarely have cystic variations been described. Typically, it manifests as a dense, largely solid tumor devoid of noticeable cystic alterations[46,48]. One-third of patients may exhibit calcifications, and the majority of the tumor increases constantly, but less so than the adjacent pancreatic parenchyma[49]. The tumor displays heterogeneous enhancement after intravenous infusion of contrast material[46]. Other studies also concluded that when confronted with a large mass with an ovoid shape, exophytic, well-circumscribed arising from the pancreas, with slight and persistent enhancement after contrast administration, and without appreciable biliary or pancreatic dilation, the diagnosis of ACC should be considered[18,47,50]. Another study stated that MRI is better than CT for identifying tumor margination, intratumoral bleeding, tissue invasion, and ductal dilation[51]. On the other hand, CT is more sensitive to detecting central calcification and is commonly utilized due to its accessibility and quickness[50,51]. CT and MRI accurately depict most ACC imaging characteristics, and the two modalities correlate well[51].

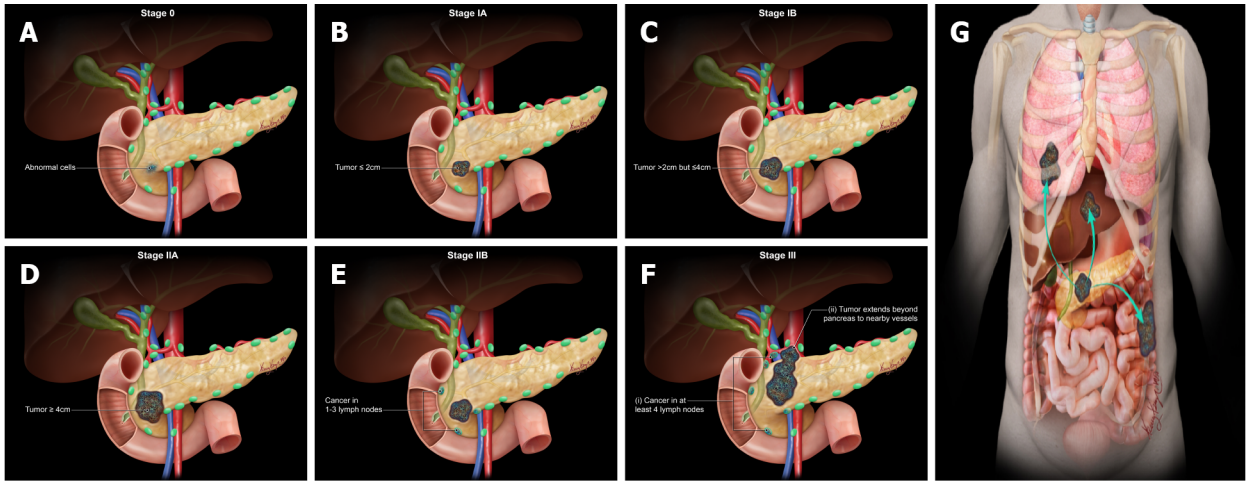
Differential diagnosis

Pancreatic endocrine neoplasms that are well-differentiated, solid pseudopapillary neoplasms (SPNs), mixed acinar neoplasms, pancreatoblastoma (PBL), and PDACs should be included in the differential diagnosis (Table 2). Well-differentiated endocrine neoplasm, also commonly known as pancreatic neuroendocrine tumors (PanNET), is the entity most widely confused and misdiagnosed[2]. Both neoplasms typically contain a high number of cells and little amount of stroma, are capable of forming cell sheets and can consist of medium-sized, spherical, monomorphic cells with a microglandular or

solid pattern of growth[2]. In addition, the red cytoplasmic zymogen and neurosecretory granules from ACC and PanNETs, respectively, are similar with appropriate differentiation. PanNETs are associated with a more favorable prognosis, making differentiation crucial. ACCs are distinguished from PanNETs by their primary acinar development, cytoplasmic granulation, basally oriented nuclei, and individual conspicuous nucleoli. However, hyalinized stroma, plasmacytoid cell appearance, and a "salt and pepper" chromatin pattern are indicative of PanNET[6]. Immunohistochemistry is advantageous, but it must be utilized with care. Using general neuroendocrine markers such as synaptophysin and chromogranin A alone may be unsafe because several ACCs contain neuroendocrine cells, which are particularly abundant in 30% of cases, as stated before[10,24]. Therefore, the demonstration of acinar cell products is mandatory if an ACC is suspected.

SPNs present as massive, dense pancreatic masses that are clinically identical to ACC; however, SPNs virtually entirely affect women of young age[52]. Cytological smears are characterized by delicately branched vasculature with lightly adherent cells generating pseudopapillary structures, a homogenous population of microscopic cells with cuboidal formation, and a unique hyaline myxoid matrix[52]. Additionally, cytoplasmic hyaline globules are occasionally visible. Moreover, the SPNs nuclei are often normochromic, with numerous indentations, and lack the conspicuous nucleoli found in acinar cells [53]. Typically, SPNs exhibit nuclear immunoreactivity for β-catenin and high expression of CD10, which are also detectable in roughly 10% and 60% of ACCs, respectively. As a result, these two markers must be utilized in conjunction with markers specific to acinar cells, such as trypsin and BCL10[53-55].

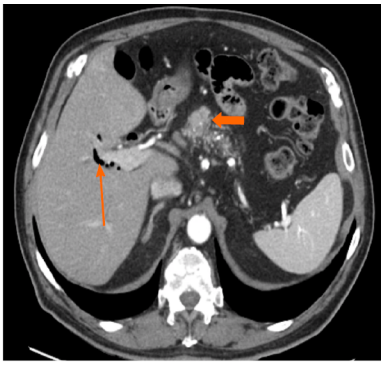
PBL is another entity with stroma-poor acinar differentiation that must be evaluated in the differential diagnosis. Similar to ACCs, upon the appearance, PBLs are typically large, with an average size of 10 cm ranging from 1.5 to 20 cm[56]. This uncommon tumor shares nearly all of the cytologic and clinical characteristics of ACC, notably in the population of younger age, where it is frequently observed [2,57]. Cytologically, the neoplasms may be indistinguishable because they both display a predominant acinar-cell differentiation[2]. Heterologous components and squamous nests, such as osseous and cartilage development, characterize PBL[2]. In addition to immunochemistry and clinicopathologic data, the heterogeneous cytologic elements of the types of the tumor-cell present, including a combination of squamoid, mesenchymal, and glandular cells, are a general clue to diagnosing PBL[58]. Histologically, the presence of squamoid nests in PBL is the distinguishing characteristic of the two entities.



ACCs typically lack the characteristic cytomorphologic features of PDACs, allowing these two tumors to be distinguished easily. PDACs typically exhibit "drunk honeycomb" and "tombstone cells" arrangements alongside nuclear heterogeneity and nuclear silhouette abnormalities[59]. This is in contrast to the relatively homogeneous polygonal cells of ACCs, which are arranged in three-dimensional arrays and tissue fragments[1]. ACCs lack the large desmoplastic stroma that describes PDACs and display an overall solid and acinar architecture, whereas PDACs feature a prominent desmoplastic stroma[10,59,60].

STAGING FOR ACINAR PANCREATIC CARCINOMA

The staging system for acinar pancreatic cancer is undergoing continuous development. Clinical staging is determined by resectability, which is heavily impacted by surgical expertise. The agreed guidelines for the resectability of surgical procedures continue to be refined (*e.g.*, National Comprehensive Cancer Network, MD Anderson Cancer Center, American Hepato-Pancreato-Biliary Association, and International Hepato-Pancreato-Biliary Association). Traditionally, they are categorized as resectable, borderline resectable, locally progressed, and metastatic. To begin with, resectable tumors lack vascular involvement. Next, the borderline resectable tumors involve vascular, local structures, or other signs indicating a high risk of R1 resection. Local invasions (particularly vascular involvement) prevent surgical intervention for locally progressed malignancies. Lastly, metastatic cancer has spread to other organs beyond the main pancreatic tumor. The American Joint Committee on Cancer (AJCC) has classified staging by TNM (tumor, node, metastasis) classification using the consensus guidelines for resectability (Table 3 and Figure 2)[61]. Imaging cases with different AJCC TNM staging were added in chronological order (Figures 3 - 7) to appreciate the differences in changes.



PROGNOSIS, FACTORS OF PREDICTION, SPREAD, AND METASTASES

ACCs are exceptionally malignant neoplasms; relatively 50% of patients have metastasis during diagnosis[62]. Initial studies indicate that the prognosis for ACCs is better than that for ductal carcinomas but worse than that for PanNETs[5,63,64]. Previous research using population-based cancer databases and epidemiological methods indicated that individuals diagnosed with ACCs have a median overall survival time of roughly 47 mo for patients with localized disease and 14 mo for patients with metastatic disease, with a 5-year survival rate ranging from 36.2% to 72.8% for resected cancers[5,64,65]. A recent study shows that ACC has a better prognosis than adenocarcinoma. They found that the prognosis was deteriorating with a decrease of 25% in a 5-year survival rate to previously reported rates

Figure 3 Stage IA (T1, N0, M0). A 77-year-old male patient with acinar cell carcinoma. Axial post-contrast portal-venous phase computed tomography image shows a solid mass (short arrows) measuring 1.8 cm × 1.6 cm and involving the region of the pancreatic head/body. Incidental findings are calcifications seen throughout the pancreas (likely related to changes in chronic pancreatitis) and mild dilatation of the biliary tree with pneumobilia (long arrow).

[66]. However, data from a few studies published and anecdotal reports hint that some patients with ACCs have a greater survival rate than expected; unfortunately, no parameters are available to identify this group of patients[67,68].

Rarely do patients with ACC are diagnose with lung, cervical lymph nodes, and ovary metastases. Metastatic illness is typically detected in regional lymph nodes and the liver[69]. Patients presenting as their first disease symptom with distant metastases are infrequent. It has been proposed that ACCs in patients younger than 20 may be less aggressive than in adults[10]. The most significant prognostic indicator is the tumor stage, with patients without lymph nodes or distant metastases having a better prognosis[5,70]. In addition, a poor prognosis is also associated with being male, being over 60, and having a tumor larger than 10 cm[5].

TREATMENT

Current, surgical, radiotherapeutic, and chemotherapeutic treatments used for PDAC are typically used to treat ACC (Table 4). Surgery is regarded as the optimal treatment modality for ACCs that are

Table 3 American Joint Committee on Cancer 8th Edition cancer staging for exocrine pancreatic tumor such as pancreatic acinar cell carcinoma

Stage	TNM	Description
0	Tis	Carcinoma in situ[1]
	N0	No regional lymph node metastases
	M0	No distant metastasis
IA	T1	T1 = Tumor is ≤ 2 cm in any direction
		T1a = Tumor is ≤ 0.5 cm in any direction
		T1b = Tumor is > 0.5 cm and < 1 cm in any direction
		T1c = Tumor is 1–2 cm in any direction
	N0	No regional lymph node metastases
	M0	No distant metastasis

		T2 = Tumor is > 2 cm and ≤ 4 cm in any direction
		T3 = Tumor is > 4 cm in any direction
		T4 = Regardless of tumor size, the cancer has grown outside the pancreas, into the nearby large blood vessels[2]
	Any N	NX = Regional lymph nodes cannot be assessed
		N0 = No regional lymph node metastases
		N1 = Metastasis in one to three regional lymph nodes
		N2 = Metastasis in four or more regional lymph nodes
	M1	Distant metastasis

[1]Included in this category are high-grade pancreatic intraepithelial neoplasia, intraductal papillary mucinous neoplasm with high-grade dysplasia, intraductal tubulopapillary neoplasm with high-grade dysplasia, and mucinous cystic neoplasm with high-grade dysplasia.
[2]Celiac axis, superior mesenteric artery, and/or common hepatic artery are involved.
T: Primary tumor; N: Regional lymph node; M: Distant metastasis.

Table 4 Acinar cell carcinoma treatment options

Clinical stage	Treatment options
Resectable or borderline resectable	Neoadjuvant therapy[1]
	Surgery
	Postoperative chemotherapy
	Postoperative chemoradiation therapy
Locally advance	Chemotherapy[2]
	Chemoradiation therapy
	Surgery
	Palliative surgery
Recurrent or metastatic	Chemotherapy[2]

[1]Chemotherapy with or without chemoradiation therapy given before surgery.
[2]With or without target therapy.

regionally circumscribed and resectable. Holen *et al*[8] found that median survival for surgically resected cases was 36 mo, compared to 14 mo for those without surgical resection[8]. Another systematic research by Glazer *et al*[71] indicated that the total median survival rate for patients with ACC who had resection was approximately 47 mo[71]. More aggressive therapeutic regimens must be

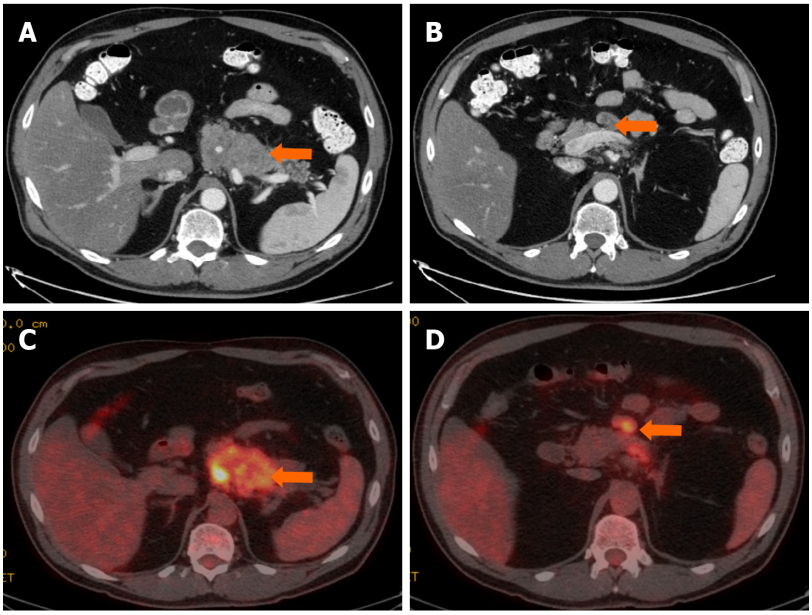
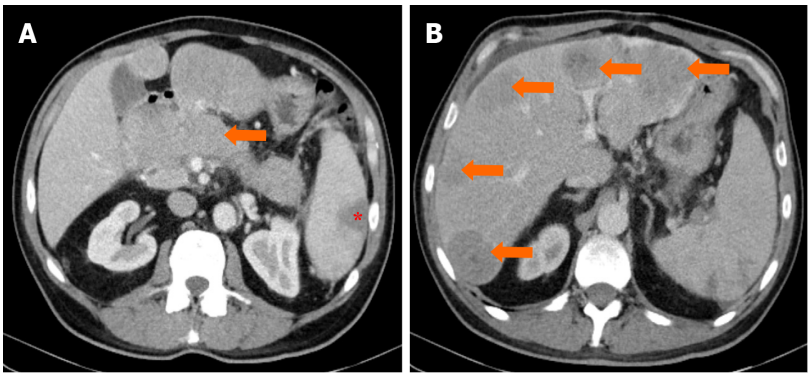
Figure 4 Stage IB (T2, N0, M0). An 89-year-old male patient with acinar cell carcinoma. Axial post-contrast computed tomography arterial phase image shows a large mass in the body of the pancreas (arrow) measuring 3.3 cm × 3 cm. No regional adenopathy is identified.



DOI: 10.3748/wjg.v28.i40.5827 **Copyright** ©The Author(s) 2022.

Figure 5 Stage IIA (T3, N0, M0). A 66-year-old patient with acinar cell carcinoma. Axial post-contrast computed tomography image in the arterial phase shows a solid lobulated mass measuring 6.5 cm × 5.4 cm arising from the tail of the pancreas (arrow). The mass is heterogeneous in density with areas of low-density and solid-enhancing areas. No regional or distant lymphadenopathy was detected.

sought when surgery is unavailable for locally advanced and metastatic diseases.



Due to the rareness of ACC and the absence of sufficient randomized trials comparing different treatment approaches, the role of adjuvant therapy remains debatable. Table 5 enlists characteristics of studies on various regimes used for treating ACC. In a study at Memorial Sloan-Kettering Cancer Center, systemic chemotherapy for ACC was determined to be ineffective[8]. Following surgical resection, there are no clear treatment guidelines, and most adjuvant therapies are individualized with variable response rates. Lack of prospective data to create therapy guidelines and genetic variation in the *APC* gene/β-catenin pathway observed in pancreatic acinar cells, ACC patients are frequently treated with chemotherapeutic agents known to be active against PDAC or colorectal cancer[72]. Most study participants received combination chemotherapy protocols based on gemcitabine or fluoropyrimidine[11,73]. If the ACC cannot be resected, the patient should undergo neoadjuvant or palliative 5-FU chemotherapy[70,74]. Combination fluoropyrimidine-based chemotherapies have increased disease control rates[8,11,73,75-77]. Glazer *et al*[71] systematic review showed that patients with a high-performance status typically receive folinic acid/fluorouracil/oxaliplatin or folinic acid/fluorouracil/irinotecan. In contrast, patients with a lower performance status typically receive gemcitabine/protein-bound paclitaxel[71].

Conventional fractionation and hypofractionated stereotactic body radiotherapy are used to "down-stage" or convert a borderline resectable tumor to one that is resectable[73]. Patients who could potentially benefit from resection can be identified through the absence of ACC development following neoadjuvant radiotherapy. Several studies reported a "major response" rate from 25% to 35% of these individuals[8,11].

Figure 7 Stage IV. A 64-year-old patient with acinar cell carcinoma. A: Axial post-contrast image port venous phase shows a pancreatic head mass measuring about 3.2 cm × 2.8 cm (arrow); B: Axial post-contrast image port venous phase shows multiple bilobar variable-sized hepatic metastatic lesions (arrows). An incidental finding is an area of splenic infarction (asterisk in image A).

CONCLUSION

Pancreatic acinar neoplasms are a molecularly and morphologically heterogeneous group of diseases far less prevalent than ductal neoplasms. Due to its low surgical resectability, high rate of recurrence, and high frequency of metastases at diagnosis, pancreatic ACC has been regarded as cancer with a poor prognosis. At least a subset of the neoplastic cells exhibits acinar differentiation, as defined morphologically (granular cytoplasm, single prominent nucleoli) or immunohistochemically. The molecular system underlying the advancement of ACCs has been elucidated, revealing potentially targetable mutations that offer optimism for developing additional curative options. ACC usually appears as a bulky mass that does not obstruct the pancreatic or bile duct and does not cause jaundice. Elevated lipase levels, subcutaneous nodules, and the presence of bone infarct should help clinch a diagnosis of ACC. Also, these tumors have large lymph nodes at presentation. In the future, molecular diagnostics to detect lesions susceptible to targeted therapy will likely play an important role in patient care.

Table 5 Characteristics of studies on various acinar cell carcinoma treatment regimes

Ref.	Year of publication	ACC sample size	Type of treatment	No. of patients	Conclusion
Holen *et al* [8]	2002	39	Resection	9	A high recurrence rate following complete surgical resection suggests that micrometastases are present even in localized disease, and that adjuvant therapies may be indicated. Chemotherapy and radiation are ineffective, however, and novel treatments are required
			RT alone	22	
			Fluoropyrimidine-based chemotherapy and RT	1	
			Fluoropyrimidine-based chemotherapy	7	
Kitagami *et al*[65]	2007	115	Resection	88	To improve prognosis, surgical resection should be pursued if possible. If ACC cannot be resected or recurs, chemotherapy is likely to be beneficial. A multidisciplinary treatment centered on the role of surgery must be developed
			Palliative operation	12	
			Exploratory laparotomy	4	
			Other treatment[1]	11	
Seth *et al* [11]	2008	14	Resection	10	When feasible, surgical resection is the optimal first-line treatment for resectable ACC due to its superior survival, which can be further improved by the addition of a planned neoadjuvant and/or adjuvant chemoradiation regimen
			Resection, mixed chemotherapy[2] and RT	4	
Wisnoski *et al*[64]	2008	672	Resection	266	ACC surgical resection appears to improve survival, and the findings support an aggressive strategy for resectable disease. In order to define the role of chemoradiation in the palliative, adjuvant, and neoadjuvant settings, additional research is required
			Other treatment[1]	406	
Schmidt *et al*[5]	2008	865	Resection	190	In these favorable pancreatic cancers, aggressive surgical resection with negative margins is associated with long-term survival. Second, cancer registries lack certain information, such as the specific type of chemotherapy administered and radiation therapy details. Consequently, institutional and multi-institutional reports of ACC continue to be essential for performing a more comprehensive analysis of the presentation, pathology, natural history, and treatment-related outcomes of ACC
			Resection and chemotherapy	33	
			Resection and RT	10	
			Resection and chemoradiation	100	
			Other treatment[1]	532	
Matos *et al* [75]	2009	17	Resection	12	ACC requires aggressive surgical resection. Importantly, some patients with locally advanced ACC have responded to a neoadjuvant approach allowing resection of a downstaged tumor; therefore, a combined modality approach should be considered for these patients
			Mixed chemotherapy[2]	3	
			Mixed chemotherapy[2] and RT	2	
Seki *et al* [76]	2009	4	Gemcitabine-based chemotherapy	1	A partial response suggested that fluoropyrimidine-based chemotherapy may have some activity against this tumor. To confirm the efficacy of fluoropyrimidine in treating pancreatic ACC, prospective clinical trials are required
			Fluoropyrimidine-/gemcitabine-based chemotherapy	3	
Lee *et al* [78]	2010	29	Resection	12	In Korea, the clinical characteristics of ACC include a young age, a large size, a location in the tail, and nonspecific tumour markers. ACC should always be actively treated with surgery, regardless of its size
			Resection, mixed chemotherapy[2] and RT	10	
			Mixed chemotherapy[2] and RT	1	
			Other treatment[1]	6	
Butturini *et al*[73]	2011	9	Resection	2	Using multiple chemotherapy regimens and regional treatments sequentially for recurrent disease allowed for 45-, 85-, and 52-mo post-primary survival. Long-term survival and clinical benefit may be possible with repeated surgery, neoadjuvant and adjuvant chemoradiation therapies, and locoregional therapy
			Resection and gemcitabine-based chemotherapy	7	
Hartwig *et al*[79]	2011	17	Resection	13	ACC of the pancreas is a relatively uncommon tumor entity for which resection may lead to long-term survival, even in the presence of limited metastatic disease. Optimized adjuvant treatment protocols are required to improve the long-term survival of ACC patients
			Resection and gemcitabine-based chemotherapy	4	

Lowery *et al*[77]	2011	20	Gemcitabine-based chemotherapy	20	Observed efficacy of combination chemotherapy in metastatic patients. ACC supports the use of combination therapies based on gemcitabine or 5-fluorouracil and incorporating irinotecan, a platinum analog, or docetaxel in patients with advanced disease. A potential association between germline mutations in DNA mismatch repair genes and ACC warrants further evaluation
Zheng *et al*[80]	2015	15	Resection	12	Clinicians generally regard pancreatic acinar cell carcinoma as a low-grade malignancy due to its unique clinical features. Positive sentiments towards ACC should be held
			Resection and gemcitabine-based chemotherapy	3	
Kruger *et al*[81]	2016	15	Resection	3	In contrast to PDAC, gemcitabine alone does not appear to have significant activity in ACC. Based on the findings, advanced ACC should be treated with chemotherapy regimens containing 5-FU and/or a platinum compound (such as oxaliplatin). Undetermined is whether this observation also applies to adjuvant chemotherapy administered after surgical resection of ACC
			Resection and gemcitabine-based chemotherapy	8	
			Chemoradiation	1	
			Mixed chemotherapy[2]	3	
Seo *et al* [82]	2017	20	Resection	9	Compared to PDAC, patients with resectable pancreatic ACC had a favorable prognosis after curative resection. Although adjuvant chemotherapy was not associated with improved survival in this study, it is unknown whether this was due to a selection bias or the ineffectiveness of 5-FU monotherapy in pancreatic ACC. On the basis of molecular analysis utilizing innovative genetic analytic tools, additional research on effective adjuvant chemotherapy is required
			Resection and 5-fluorouracil-based chemotherapy	9	
			Resection and gemcitabine-based chemotherapy	1	
			Resection and etoposide plus cisplatin-based chemotherapy	1	
Pishvaian *et al*[83]	2020	12	Mixed chemotherapy[2]	12	Molecularly guided treatments targeting oncogenic drivers and the DNA damage response and repair pathway require further prospective evaluation, based on these real-world findings
Zong *et al* [84]	2020	11	Resection	4	For pancreatic acinar cell carcinoma, surgery is a potentially curative treatment contributing to long-term survival. It has been confirmed that adjuvant systemic therapy, including chemotherapy and chemoradio-therapy, significantly improves survival compared to surgery alone for resectable ACC. To investigate the role and protocol of perioperative and palliative treatments, additional research with a large sample size is required
			Resection and gemcitabine-based chemotherapy	4	
			Resection and capecitabine	1	
			Resection and mixed chemotherapy[2]	2	
Xu *et al* [85]	2022	22	Resection	6	Although the value of adjuvant chemotherapy remains obscure, fluoropyrimidine-based chemotherapy merits consideration. Fluorouracil-based chemotherapy, such as FOLFIRINOX, may be the preferred treatment for patients with metastasis, but additional research is required due to the small sample size in this study
			Resection and S1-based chemotherapy	3	
			Resection and SOX-based chemotherapy	2	
			Resection and fluoropyrimidine-based chemotherapy	3	
			Resection and AG-based chemotherapy	1	
			Resection and gemcitabine-based chemotherapy	7	
Chen *et al* [86]	2022	26	Resection	11	After radical resection, patients with ACC had a longer overall survival than those with PDAC. ACC is also an aggressive tumor with a similar recurrence-free survival trend to PDAC, necessitating multidisciplinary treatment for resectable ACC disease
			Resection and adjuvant chemotherapy	15	

[1]Not specified in manuscript.

[2]Treatment using more than one anticancer drug including FOLFIRNOX (5-FU + oxaliplatin + leucovorin + irinotecan), CAPOX (oxaliplatin + capecitabine), and S1 (tegafur/gimeracil/potassium).

ACC: Acinar cell carcinoma; PDAC: Pancreatic ductal adenocarcinoma; RT: Radiotherapy; 5-FU: 5-fluorouracil; SOX: S1 + Oxaliplatin; AG: Albumin-bound paclitaxel + gemcitabine; FOLFIRNOX: 5-FU + oxaliplatin + leucovorin + irinotecan.

ACKNOWLEDGEMENTS

We thank Kelly Kage for the beautiful illustrations.

Abstract

BACKGROUND

Inflammatory bowel disease (IBD) constitutes a substantial risk factor for colorectal cancer. Connexin 43 (Cx43) is a protein that forms gap junction (GJ) complexes involved in intercellular communication, and its expression is altered under pathological conditions, such as IBD and cancer. Recent studies have implicated epigenetic processes modulating DNA methylation in the pathogenesis of diverse inflammatory and malignant diseases. The ten-eleven translocation-2 (TET-2) enzyme catalyzes the demethylation, hence, regulating the activity of various cancer-promoting and tumor-suppressor genes.

AIM
To investigate Cx43 and TET-2 expression levels and presence of 5-hydroxymethylcytosine (5-hmC) marks under inflammatory conditions both *in vitro* and *in vivo*.

METHODS
TET-2 expression was evaluated in parental HT-29 cells and in HT-29 cells expressing low or high levels of Cx43, a putative tumor-suppressor gene whose expression varies in IBD and colorectal cancer, and which has been implicated in the inflammatory process and in tumor onset. The dextran sulfate sodium-induced colitis model was reproduced in BALB/c mice to evaluate the expression of TET-2 and Cx43 under inflammatory conditions *in vivo*. In addition, archived colon tissue sections from normal, IBD (ulcerative colitis), and sporadic colon adenocarcinoma patients were obtained and evaluated for the expression of TET-2 and Cx43. Expression levels were reported at the transcriptional level by quantitative real-time polymerase chain reaction, and at the translational level by Western blotting and immunofluorescence.

RESULTS
Under inflammatory conditions, Cx43 and TET-2 expression levels increased compared to non-inflammatory conditions. TET-2 upregulation was more pronounced in Cx43-deficient cells. Moreover, colon tissue sections from normal, ulcerative colitis, and sporadic colon adenocarcinoma patients corroborated that Cx43 expression increased in IBD and decreased in adenocarcinoma, compared to tissues from non-IBD subjects. However, TET-2 expression and 5-hmC mark levels decreased in samples from patients with ulcerative colitis or cancer. Cx43 and TET-2 expression levels were also investigated in an experimental colitis mouse model. Interestingly, mice exposed to carbenoxolone (CBX), a GJ inhibitor, had upregulated TET-2 levels. Collectively, these results show that TET-2 levels and activity increased under inflammatory conditions, in cells downregulating gap junctional protein Cx43, and in colon tissues from mice exposed to CBX.

CONCLUSION
These results suggest that TET-2 expression levels, as well as Cx43 expression levels, are modulated in models of intestinal inflammation. We hypothesize that TET-2 may demethylate genes involved in inflammation and tumorigenesis, such as Cx43, potentially contributing to intestinal inflammation and associated carcinogenesis.

Key Words: Demethylation; Inflammation-induced carcinogenesis; Ulcerative colitis; Colorectal cancer; Connexins

Core Tip: Chronic inflammation of the colon is a risk factor for colorectal cancer. Intestinal inflammation has been associated with reduced gap junction-mediated intercellular communication and downregulation connexins [mainly connexin 43 (Cx43)]. The involvement of the demethylating enzyme ten-eleven translocation-2 (TET-2) (methylcytosine dioxygenase) in the inflammatory process has motivated the investigation of Cx43 and TET-2 expression in colitis and colorectal carcinoma. *In vitro* and *in vivo* data report on the upregulation of Cx43 in inflammatory states and a downregulation of TET-2. In human samples of colon adenocarcinoma, both TET-2 and Cx43 were downregulated, potentially implicating them in the malignant transformation of inflamed intestinal tissues.

INTRODUCTION

The gastrointestinal tract is constantly exposed to environmental insults that may potentially lead to pathologies. Inflammatory bowel disease (IBD) is a relapsing and remitting inflammatory disorder affecting distinct parts of the gastrointestinal tract. It comprises two primarily encountered disorders: Crohn's disease and ulcerative colitis, which can be distinguished by their localization in the different

parts of the gut and the endoscopic appearance of the inflamed segment[1-3]. IBD increases the risk of developing colon adenocarcinoma[4], and colitis-associated colon adenocarcinoma remains a fundamental consequence of sustained IBD, possibly because both IBD and colon adenocarcinoma share etiological factors implicated in their development[5].

Gap junctions (GJs), components of junctional complexes, have a potential role in regulating epithelial integrity and function. GJs are formed by the docking of two hemichannels (connexin hexamers) contributed from two adjacent cells, allowing the direct exchange of ions and small signaling molecules (< 2 kDa)[6]. Connexins play a pivotal role in cellular proliferation, differentiation, and function and are recognized as putative tumor-suppressor genes[7-9]. The library of connexin-related diseases has been emerging for many years, and includes various types of syndromes and disorders, such as inflammatory diseases and cancer. Several studies have revealed that the inflammatory response relies in part on connexins and GJ-mediated intercellular communication (GJIC)[10]. More specifically, alteration in the expression of connexin 43 (Cx43) in the gastrointestinal tract is associated with IBD, gastrointestinal infections, and impaired motility[11,12]. We have previously shown an alteration of Cx43 expression and localization, as well as a direct heterocellular communication between intestinal epithelial cells (IECs) and macrophages, which may contribute to IBD pathogenesis[12].

In complex diseases, such as IBD and colon adenocarcinoma, in addition to the heritable component, environmental and epigenetic (DNA methylation and demethylation, histone marks, higher order chromatin structure, *etc.*) factors are likely to influence onset[13]. DNA methylation state is controlled by the interplay between DNA methyltransferases and demethylating enzymes, such as ten-eleven translocation (TET) proteins. Methylation occurs at normally demethylated CpG-rich regions named "CpG islands", of which 70% overlap with human gene promoters, and results in gene silencing[14]. DNA methylation profiles from IBD patients are considerably altered compared to healthy counterparts[15]. Moreover, in IBD-associated colon adenocarcinoma, DNA methylation status was distinct from sporadic colon adenocarcinoma, with different gene expression profiles[16]. DNA methylation is counteracted by demethylation mechanisms, catalyzed by TET enzymes (TET-1, TET-2, TET-3), thus activating gene transcription[17]. Following a series of oxidation reactions by TET enzymes, previously methylated 5-methylcytosine is converted to 5-hydroxymethylcytosine (5-hmC) and further oxidized products that will be recognized and excised by thymine-DNA glycosylase/base enzyme repair pathway to result in an unmethylated cytosine residue[18]. TET genes are mutated in a variety of diseases and cancers. In inflammatory diseases, TET-2 is crucial for the repression of the pro-inflammatory cytokine, interleukin (IL)-6[19], while in several cancers, TET-2 expression is downregulated[20]. In particular, tumors of the digestive tract express different levels of TET enzymes, which are explored as potential factors informing prognosis[21]. Downregulation of TET-1, TET-2, and TET-3 have been reported in gastric cancers with concomitant loss of 5-hmC marks[22] and in colorectal carcinoma[23], with TET-2 transcriptional levels potentially serving as indicators for treatment outcome and disease recurrence [23]. In addition, a recent study reported that the human gene coding for TET-2 contains three promoter elements which are differently regulated in different tissues and developmental stages[24] and may play a role in cancer development.

While many studies have reported the Cx43 promoter to be hypermethylated during the transition from inflammation to cancer[25-27], the expression statuses of Cx43 and TET-2 in IBD and colorectal cancer have not been simultaneously described. This study investigated the effect of inflammation and Cx43 expression levels on the intestinal cell membrane integrity and described TET-2 expression and 5-hmC marks under inflammatory states *in vitro, in vivo*, and in human samples of ulcerative colitis and sporadic colon carcinoma.

MATERIALS AND METHODS

Cell lines and culture conditions

The HT-29 and Caco-2 cell lines derived from colorectal adenocarcinoma tissues were used as models for human IECs. When grown in monolayer, these cells become more differentiated and IEC-like[12,28,29] and are widely used as a model of intestinal transport and pathology, including inflammation. Human embryonic kidney cells (packaging HEK 293T cells) were used for production of viral supernatant for transduction purposes.

In addition, the human monocytic cell line (THP-1) was used as an *in vitro* model for activated macrophages[12,30,31] for the production of conditioned inflammatory medium. After exposure to phorbol myristate acetate (PMA) and lipopolysaccharide (LPS), THP-1 cells become activated; they adhere to the cell culture vessel and show increased transcriptional levels of connexins, Toll-Like Receptor (TLR)-2, TLR-4, NF-κB p65, COX-2, inflammatory cytokines tumor necrosis factor-α (TNF-α), and IL-1β[12]. In this study, suspension THP-1 cells were activated with 50 ng/mL PMA (Sigma-Aldrich, St Louis, MO, United States) for 24 h, followed with 1 μg/mL of LPS (Sigma-Aldrich) for 4 additional hours. When activated THP-1 cells adhered to the cell culture plate, they were washed with PMA- and LPS-free media and left to grow for 72 h. Conditioned media was then collected, filtered, and applied *in vitro* onto colon cell lines to create an inflammatory milieu.

Cells were maintained in complete RPMI-1640 (Sigma-Aldrich) for HT-29 and THP-1 cells or Dulbecco's Modified Eagle's medium (DMEM AQ; Sigma-Aldrich) for HEK 293T cells supplemented with 10% FBS (Sigma-Aldrich), 100 U/mL penicillin G, and 100 µg/mL streptomycin (Sigma-Aldrich). Cells were grown at 37 °C in a humidified incubator with 5% CO_2 atmosphere.

Generation of HT-29 cells upregulating Cx43 gene

The Cx43-pDendra2N construct (Evrogen, Moscow, Russia) was previously cloned into pCSCW lentiviral vectors[12]. The plasmid was then used to transform DH5α competent *Escherichia coli* bacteria, which were then left to proliferate. Plasmid was then isolated and purified using the EndoFree Maxi plasmid purification kit (Qiagen, Hilden, Germany) to be used for transfection along with other plasmids (gag/pol/env) into HEK 293T cells for production of viral supernatant, which carries the Cx43-pDendra2 chimeric proteins. The viral supernatant was used to transduce HT-29 cells. Following the transduction, HT-29 cells were cultured, expanded, and highly positive cells (referred to as HT-29 Cx43D cells thereafter) were sorted using the BD FACSAria™ III sorter (BD Biosciences, Franklin Lakes, NJ, United States). Viral supernatants were obtained from HEK 293T cells and used to transduce HT-29 cells. These cells, named HT-29 Cx43D, were then isolated using a BD Fluorescence-Activated Cell Sorting Aria SORP cell sorter in the single-cell mode. Green fluorescence in HT-29 Cx43D cells attests to the successful upregulation of exogenous Cx43 in these cells.

Generation of HT-29 cells downregulating Cx43 gene using CRISPR/Cas9 system

HT-29 cells knocking down Cx43, referred to as HT-29 Cx43$^-$ cells, were generated using the CRISPR/Cas9 gene-editing system. After cloning the Cx43 target sequence (20 bp) into the guide RNA scaffold of the pX330-CRISPR plasmid, the bacterial transformation was performed as above and 10-15 colonies were picked to check for the correct insertion of the guide RNA by sequencing. Transfection of HT-29 cells with positive clones was performed, and cells were selected with puromycin (1 µg/mL) until isolated colonies were obtained. Several positive clones were validated for Cx43 knockdown at the RNA and protein levels. One specific clone resulted in more than 90% down-regulation of Cx43 mRNA, generating the experimental HT-29 Cx43$^-$ cells. This downregulation was confirmed by western blot and immunofluorescence assays.

Cell growth assay

Parental HT-29, HT-29 Cx43D, and HT-29 Cx43$^-$ cells were seeded in 24-well plates at a density of 25000 cells/cm^2. At 24 h, 48 h, and 72 h, cells were washed with PBS and trypsinized. Viable cells were counted using the trypan blue exclusion dye.

Evaluation of barrier integrity

Trans-epithelial electrical resistance: This method evaluates barrier integrity of epithelial cells grown in monolayer; by describing the impedance of barrier-forming cell cultures. Briefly, electrodes are placed on both sides of the cellular barrier and an electric current is applied. The resulting current established in the circuit is measured and trans-epithelial electrical resistance (TEER) is calculated. The higher the TEER, the better the membrane integrity[32]. In this study, HT-29, HT-29 Cx43D, and HT-29 Cx43$^-$ cells were cultured on Transwell® inserts with 0.4 µm-pore size filters (Corning, Corning, NY, United States). TEER was measured on confluent cells in the presence or absence of 2% dextran sulfate sodium (DSS) using an EVOM voltmeter with an ENDOHM-12 (World Precision Instruments, Sarasota, FL, United States). Electrical resistance was expressed as Ω × cm^2. DSS was applied onto the cells to reproduce *in vitro* the membrane breach it is known to induce *in vivo* and characterize the loss of membrane integrity. TEER was calculated by subtracting the resistance of blank filters from that of filters covered with a monolayer of parental HT-29, HT-29 Cx43D, or HT-29 Cx43$^-$ cells.

Evans blue assay

Epithelial cells form tight junctions that prevent paracellular transit. Evans blue is a dye that strongly binds to serum albumin *in vivo* and *in vitro*, becoming a protein tracer[33]. When Evans Blue is added on the apical aspect of cells in culture, it is retained in this compartment due to the established epithelial barrier. Any perturbation of barrier integrity will result in seeping of Evans Blue to the basolateral aspect of the cells. HT-29, HT-29 Cx43D, and HT-29 Cx43$^-$ cells were grown on transparent PET membrane cell culture inserts with 0.4 µm-pore size (Corning) until confluent (monolayer). Evans Blue solution (Sigma-Aldrich) was prepared in a 1% bovine serum albumin (cell culture grade; GIBCO®, Paisley, Scotland) at a concentration of 170 µg/mL and then filtered through 0.22 µm-filters (Corning®, Wiesbaden, Germany). At confluence, cells were exposed to 2% DSS for 24 h. Cells were then washed twice with PBS and 400 µL of Evans Blue solution were added on top of the cells (seeded in inserts). Plate wells were rinsed and 1 mL of PBS was added into each well. Cells were then incubated at 37 °C. Every 30 min, 200 µL of solution from the well were collected and replaced with fresh 200 µL PBS, for a total of 2 h. The optic density of collected solution was recorded at 630 nm and concentrations of Evans Blue were calculated.

DSS-induced colitis mouse model

This study was approved by the Institutional Animal Care and Utilization Committee of the American University of Beirut (IACUCC# 18-03-476). The acute DSS-induced colitis mouse model was performed as previously reported[34]. The DSS colitis model in mice is a well-established model for IBD. Using this mouse model, studies have shown disruption of the epithelial barrier function with the infiltration of immune cells, as well as an uncommon production of cytokines[35,36]. In addition, DSS has been previously used *in vitro* to induce a cell membrane breach in a monolayer of colon cells, mimicking the intestinal mucosal barrier. DSS exposure resulted in impairment of protein trafficking and alterations in membrane composition in the intestinal Caco-2 cell line[37,38], resembling the intestinal mucosa integrity breach that occurs in IBD.

In this study, carbenoxolone (CBX) was used as a non-specific GJ inhibitor, injected intraperitoneally at the dose of 30 mg/kg every other day. Briefly, adult BALB/c male mice were distributed into the following experimental groups, each comprised of five mice: (1) Control group that received normal drinking water with no CBX injections; (2) CBX group that received normal drinking water with CBX injections starting on day 11; (3) DSS group where mice were exposed to 2.5% DSS in their drinking water for 10 d, followed by normal drinking water as of day 11; and (4) DSS + CBX group that received DSS-containing drinking water for 10 d followed by CBX injections. All four groups were given normal drinking water from day 11 to day 21 (end of experimental duration) and body weights were measured daily. All mice were given standard chow *ad libitum* and were housed in a temperature-controlled environment on a 12-h automated light/dark cycle. On day 21, mice were anesthetized with isoflurane and then euthanized by cervical dislocation. Colon lengths were measured using a ruler and colon tissues were collected for histological and molecular examinations to assess tissue integrity and expression of inflammatory markers, Cx43, and TET-2.

RNA isolation

Cells in culture: Cells were washed with PBS and total RNA was extracted using the RNeasy® Plus mini kit (Qiagen) as *per* manufacturers' instructions.

Cryopreserved tissues: Colon tissues from experimental mice were collected and snap-frozen in liquid nitrogen. RNA was then isolated using TRI reagent (Sigma), as *per* manufacturers' protocol. Since DSS treatment inhibits mRNA amplification from tissues by quantitative polymerase chain reaction (qPCR) by inhibiting the activities of both polymerase and reverse transcriptase, RNA purification for all samples in all conditions was done by the lithium chloride method according to Viennois *et al*[38].

qPCR

One μg of total RNA was reverse-transcribed to cDNA using the iScriptTM cDNA synthesis kit (Bio-Rad, Hercules, CA, United States). qPCR was conducted using a homemade SYBR green mix in a CFX96 system (Bio-Rad). Products were amplified using primers that recognize Cx43, TET-2, IL-1β, TNF-α, and glyceraldehyde 3-phosphate dehydrogenase (GAPDH) (Table 1). PCR settings were as follows: A pre-cycle at 95 °C for 5 min followed by 40 cycles consisting of 95 °C for 10 s, 52-62 °C for 30 s, and 72 °C for 30 s with a final extra-elongation at 72 °C for 5 min. The fluorescence threshold cycle value (Ct) was obtained for each gene and normalized to the corresponding GAPDH Ct value. All experiments were carried out in technical duplicates and independently performed at least three times.

Protein extraction and Western blot

Cells in culture: Cells were washed with ice-cold PBS, and scraped on ice in lysis buffer (0.5 M Tris-HCl buffer, pH 6.8; 2% SDS, and 20% glycerol) containing protease and phosphatase inhibitors (Roche, Basel, Switzerland).

Cryopreserved tissues: Snap-frozen mouse colon tissues were homogenized on ice in ice-cold RIPA buffer containing 10% of a 0.5 M Tris-HCl buffer, pH 7.5, 3% of 5 M NaCl, 1% NP-40, 10% sodium deoxycholate, and 1% SDS as well as phosphatase and protease inhibitors.

The lysate was then sonicated. Proteins were quantified, loaded onto 10% SDS-polyacrylamide gels, and subjected to electrophoresis. Migrated proteins were transferred to polyvinylidene fluoride membranes (Bio-Rad) and membranes were blocked with 5% fat-free milk in PBS. Membranes were then incubated with either human or mouse primary antibodies for 3 h at room temperature or overnight at 4 °C. Primary antibodies were hybridized with horseradish peroxidase-conjugated secondary antibodies (anti-rabbit: SC-2357 and anti-mouse SC-2005; Santa Cruz Biotechnology, Dallas, TX, United States) and blots were visualized using an enhanced chemiluminescence detection kit. GAPDH (MAB5476; Abnova, Taipei, Taiwan) and β-actin (A2228; Sigma-Aldrich) were used as loading controls. The quantification of bands was performed using the ImageJ software (United States National Institutes of Health, Bethesda, MD, United States). Immunoreactivity of proteins under study was reported as a ratio of protein-of-interest expression to the housekeeping gene used as loading control.

Specimens from human patients

Archived formaldehyde-fixed paraffin-embedded (FFPE) colon blocks (ulcerative colitis, sporadic colon adenocarcinoma and normal) were obtained from the American University of Beirut Medical Center. All patients' identifiers were kept confidential from the study team.

Histological evaluation

Sections obtained from animals and human samples were stained with hematoxylin and eosin (H&E) for observation under the light microscope (CX41; Olympus, Tokyo, Japan).

Immunofluorescence microscopy

Cells in culture: Cells were grown on coverslips and then fixed either with 4% paraformaldehyde and permeabilized with 0.05% Triton X-100 for 20 min for Cx43 probing (SAB4501175; Sigma-Aldrich) or with ice-cold methanol at -20 °C for TET-2 (ab94580; Abcam, Cambridge, United Kingdom) and 5-hmC (ab214728; Abcam) probing before blocking of non-specific binding.

FFPE tissues: Human and murine 5-μm-thick tissue sections were immune-stained using antibodies against Cx43, TET-2, 5-hmC, and CD68 (ab201340, Abcam, United States). Briefly, paraffin blocks were sectioned using a microtome and sections were mounted onto glass slides. Specimens were deparaffinized in xylene and rehydrated using a gradient series of alcohol to water. Antigen retrieval was performed by incubating sections in sodium citrate buffer (pH 6.0) in a steamer for 30 min. Sections were allowed to cool, then washed twice with deionized water before blocking of non-specific binding.

Non-specific binding was blocked with 5% normal goat serum (Chemicon, Burlington, MA, United States) in PBS for 1 h in a humidified chamber and incubated with the primary antibody against Cx43, TET-2, and 5-hmC overnight at 4 °C. Cells were then washed and incubated with IgG-conjugated secondary antibody: Either Texas Red (T862; Life Technologies, Carlsbad, CA, United States) or Alexa Fluor 488 (A11070; Life Technologies) at 1 μg/mL for 1 h at room temperature. Nuclei were counter-stained with 4',6-diamidino-2-phenylindole at 1 μg/mL for 10 min. Coverslips were then mounted onto

the glass slides using Prolong Anti-fade kit (Life Technologies).

Slides were examined under a fluorescence microscope and images were acquired using a 63×/1.46 Oil Plan-Apochromatic objective (on the laser scanning confocal microscope LSM 710, operated by the Zeiss LSM 710 software; Carl Zeiss, Oberkochen, Germany).

Statistical analyses

Numerical values were expressed as mean ± SEM or mean ± SD. The *P* value was determined and considered significant for $P < 0.05$. Differences between experimental groups were assessed using Student *t*-test, one-way analysis of variance (ANOVA) or by two-way ANOVA followed by Tukey's multiple comparisons test.

RESULTS

Characterization of the HT-29 cell model used in this study

In an attempt to investigate TET-2 modulation in the context of different Cx43 expression levels in HT-29 cells, Cx43 was upregulated (HT-29 Cx43D cells) or downregulated (HT-29 Cx43$^-$ cells). Increases and decreases in Cx43 levels were reflected at the translational level: Western blot analysis (Figure 1A) shows upregulation of exogenous Cx43 protein levels in HT-29 Cx43D and loss of endogenous Cx43 protein expression in HT-29 Cx43$^-$ cells compared to parental HT-29 cells ($P < 0.001$). Figure 1B also shows increased expression of Cx43 in HT-29 Cx43D cells and their localization at the cell periphery, where they form GJ plaques, and a decrease in Cx43 levels in HT-29 Cx43$^-$ cells.

Cells manipulated for *Cx43* gene showed differential proliferation rates 48 h and 72 h post-seeding. As depicted in Figure 1C, Cx43 upregulation (HT-29 Cx43D cells) significantly decreased the number of viable cells compared to parental HT-29 cells ($P < 0.05$ at 48 h and $P < 0.001$ at 72 h). However, cells devoid of Cx43 (HT-29 Cx43$^-$ cells) demonstrated a significantly greater proliferation rate compared to parental HT-29 cells at 48 h and 72 h post-seeding ($P < 0.001$). The increased proliferation rate of HT-29 Cx43$^-$ cells was also accompanied by increased migratory potential, as suggested by the wound healing and the invasion assays (Supplementary Figure 1). Compared to parental cells, HT-29 Cx43$^-$ cells seemed more efficient at closing the artificially created gap ($P < 0.05$).

These observations are in accordance with the tumor suppressor role of Cx43, greatly inhibiting the proliferation of HT-29 cells.

Modulation of TET expression in HT-29 cellular subsets

Transcriptional levels of TET-1, TET-2, and TET-3 were evaluated in HT29 cells, manipulated for Cx43 expression. TET-2 specifically demonstrated the highest transcriptional levels between all three TET genes (Figure 1D). TET-2 protein expression was verified by immunofluorescence in parental HT-29 cells (Figure 1D). While TET-1 and TET-3 levels were not significantly different in HT-29 cells expressing lower or higher levels of Cx43, TET-2 levels significantly increased in HT-29 Cx43$^-$ cells compared to parental HT-29 ($P < 0.05$) and to HT-29 Cx43D ($P < 0.001$) cells.

For the remainder of this study, TET-2 expression levels and 5-hmC mark were evaluated given the greater expression of TET-2 in HT-29 cells and the prevalence of loss-of-function mutations of TET-2 in cancer[21,39-41].

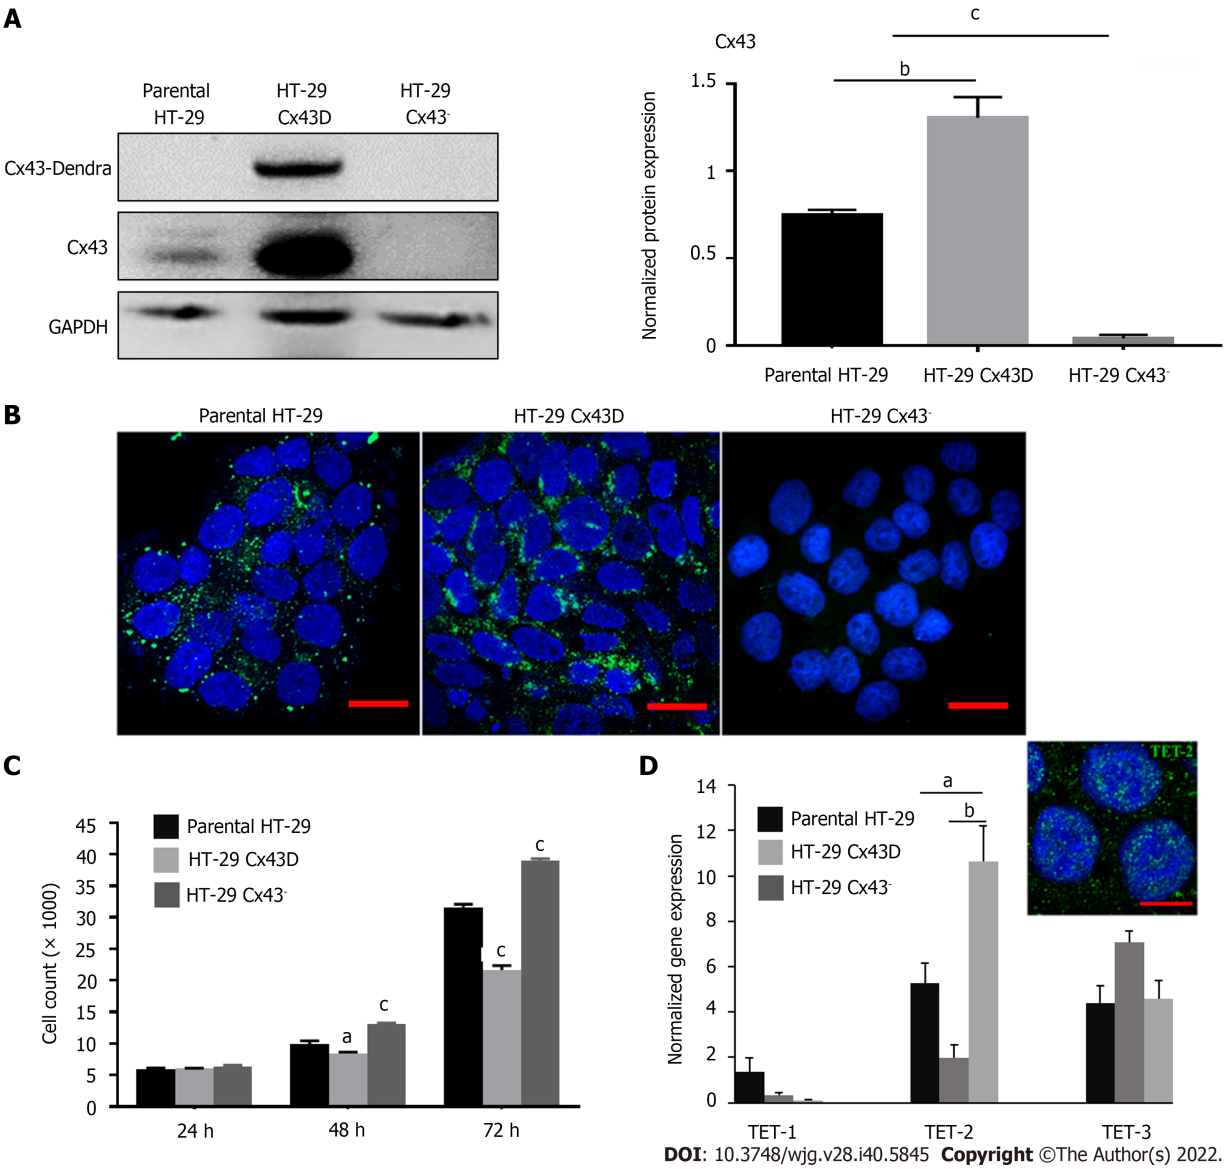
Inflammation induces increase in Cx43 and TET-2 expression levels in HT-29 cells

In order to explore a potential pattern of expression for TET-2 and Cx43 in inflammation, parental HT-29, HT-29 Cx43D, and HT-29 Cx43$^-$ cells were screened for TET-2 mRNA and protein expressions, as well as 5-hmC marks by immunofluorescence using an antibody against 5-hmC, a product of the reaction catalyzed by TET-2. In Cx43-expressing cells, the addition of inflammatory media (supernatant from activated THP-1 cells) resulted in upregulation of Cx43 (Figure 2A). Similarly, under inflammatory conditions, all three cellular subsets upregulated their TET-2 expression ($P < 0.05$) at the transcriptional and translational levels (Figure 2B). Interestingly, HT-29 cells down-regulating Cx43 showed higher expression of TET-2 compared to parental cells or cells overexpressing Cx43 (Figure 2B). The 5-hmC marks also increased with increased TET-2 levels in HT-29 Cx43$^-$ cells. Levels of TET-2 and 5-hmC both increased in cells exposed to inflammation, as shown by quantified immunofluorescence micrographs (Figure 2C). Changes in TET-2 expression were less pronounced in HT-29 Cx43D cells than in HT-29 Cx43$^-$ cells. This trend was also evident with the 5-hmC marks (Figure 2C) where increased expression of TET-2 correlated with increased amounts of 5-hmC.

In order to strengthen these findings, experiments were performed on Caco-2 cells. Levels of Cx43 and TET-2 were also upregulated in Caco-2 cells exposed to inflammatory medium (Figure 2D), with a five-fold increase in Cx43 levels ($P < 0.001$) and two-fold increase in TET-2 levels ($P < 0.01$).

Downregulating Cx43 contributes to the disruption of epithelial membrane integrity

Parental HT-29, HT-29 Cx43D, and HT-29 Cx43$^-$ cells were grown as monolayers and exposed to 2% DSS



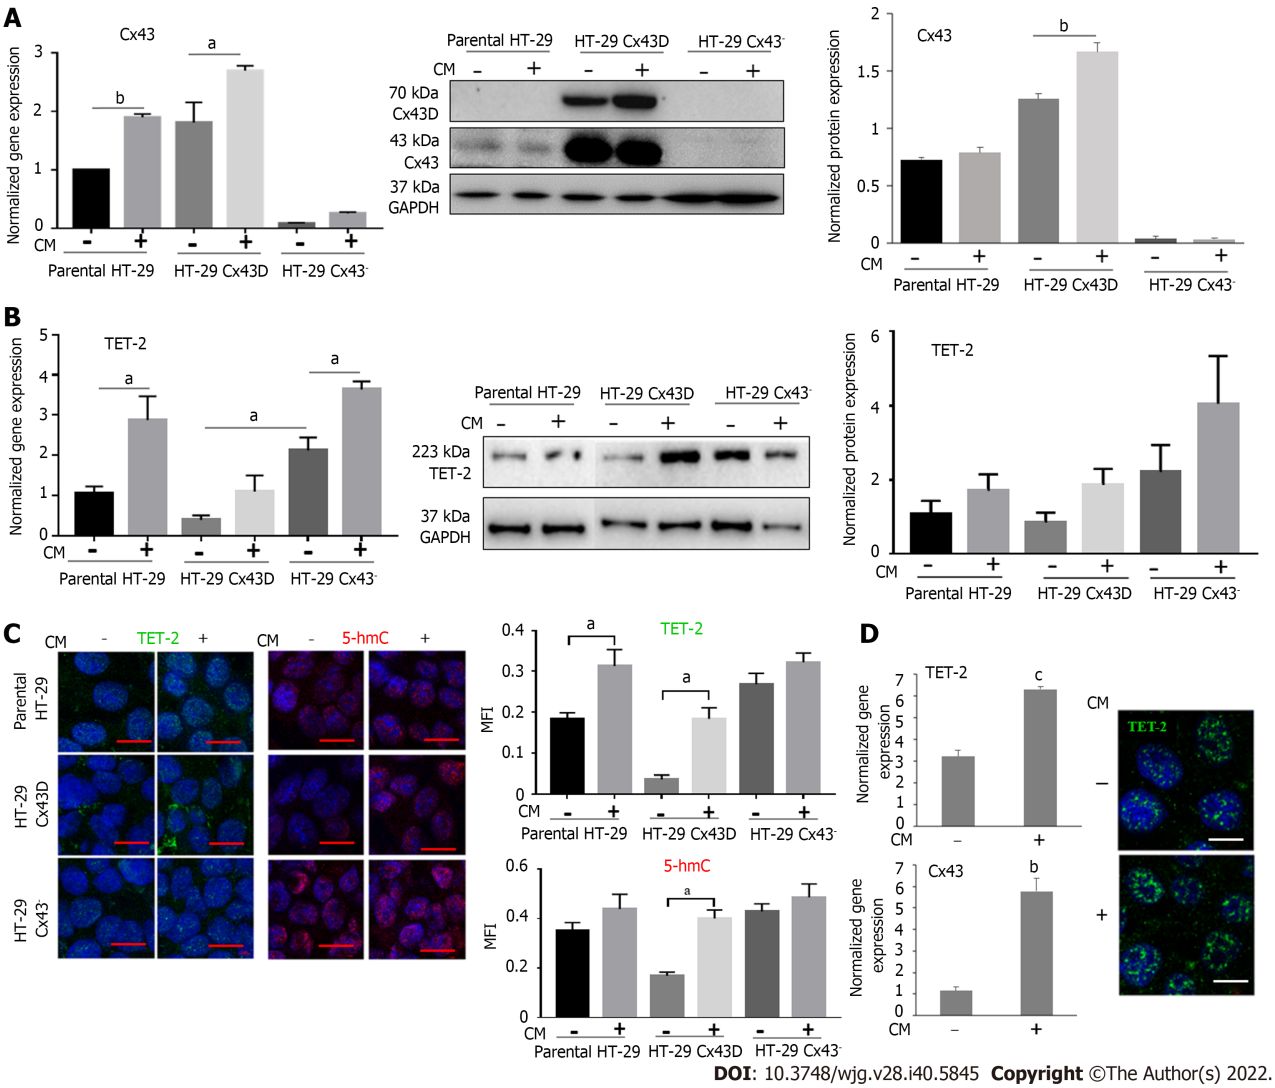


Figure 1 Characterization of the *in vitro* HT-29 cell model. A: Western blot of connexin 43 (Cx43) protein expression in parental HT-29, HT-29 Cx43-Dendra (Cx43D), and in HT-29 Cx43- cells. Bar graphs display mean densitometric analysis (of three independent experiments) after normalizing protein expression to glyceraldehyde 3-phosphate dehydrogenase (GAPDH); B: Immunofluorescence micrographs of parental HT-29 and HT-29 Cx43- cells, as well as a fluorescent micrograph of HT-29 cells transduced with the GFP-Cx43 construct. Highly GFP positive cells were sorted using BD-Fluorescence-Activated Cell Sorting cell sorter, generating the HT-29 Cx43D. Scale bar 10 μm; C: Cells were counted at three different time points (24, 48 and 72 h), using the trypan blue dye exclusion assay. Compared to parental HT-29 cells, HT-29 Cx43D cells had a slower proliferation rate and HT-29 Cx43- cells a faster proliferation rate at 48 and 72 h; D: Histograms show normalized gene expression of ten-eleven translocation (TETs) in parental HT-29, HT-29 Cx43D and HT-29 Cx43- cells, as detected by quantitative polymerase chain reaction (qPCR). TET-2 was the highest expressed TET in HT-29 cells, and cells with differential Cx43 expression also had significantly different TET-2 expression levels. The inset is an immunomicrograph of TET-2 in HT-29 C43D cells. Scale bar 5 μm. Results are presented as means ± SEM of three independent qPCR runs in duplicates. One-way ANOVA, [a]$P < 0.05$; [b]$P < 0.001$; [c]$P < 0.0005$. Cx43: Connexin 43; GAPDH: Glyceraldehyde 3-phosphate dehydrogenase.

for 24 h to evaluate if differential Cx43 levels would have any bearing on DSS-induced membrane integrity breach. DSS was previously shown to impair IEC membrane integrity *in vitro*[42] and it was used in our study to induce membrane injury similar to that observed upon chronic inflammation. Figure 3A shows that DSS resulted in decreased cell contacts and increased spaces between cells (red arrows), indicating loss of membrane integrity. The TEER assay was performed to assess how Cx43 modulation affects membrane integrity in the presence of DSS. Figure 3B shows that, in the absence of DSS, differentially expressed Cx43 had no major impact on epithelial barrier integrity, with an average TEER of 20 Ω × cm^2 in parental and in HT-29 Cx43- cells and 23 Ω × cm^2 in HT-29 Cx43D cells. However, the addition of DSS resulted in a significant decrease in TEER values by approximately 37% in parental cells and 50% in HT-29 Cx43- cells ($P < 0001$). Therefore, overexpression of Cx43 in HT-29 Cx43D cells seemed to be protective against DSS-induced loss of membrane integrity (Figure 3B).

The Evans Blue permeability assay was then performed to evaluate the monolayer integrity under DSS exposure and in cells with different Cx43 expression status. The level of cell permeability or "leakage" was correlated to the concentration of Evans Blue measured at the bottom of the well. As

Figure 2 Connexin 43 and ten-eleven translocation-2 expression increases in cells exposed to inflammation. Parental HT-29, HT-29 connexin 43-Dendra (Cx43D), and HT-29 Cx43$^-$ cells were exposed to inflammatory conditioned media (CM) obtained from activated THP-1 cells for 24 h. A: Histograms show the normalized gene expression of Cx43, as detected by quantitative polymerase chain reaction. Cx43 mRNA levels increase in parental HT-29 and HT-29 Cx43D, in the presence of inflammatory media. Western blot of endogenous Cx43 and exogenous Cx43D protein expression in parental HT-29, HT-29 Cx43D, and in HT-29 Cx43$^-$ cells. Densitometric analysis (ratio of protein-of-interest to loading control band intensity) shows a slight increase in Cx43 levels upon exposure to inflammation; B: Bar graphs show ten-eleven translocation-2 (TET-2) transcriptional levels increase in all three HT-29 cellular subsets when exposed to CM. Western blots of TET-2 and densitometric analysis shows increased protein levels of TET-2 in CM-treated cells; C: Immunofluorescence images showing TET-2 expression and 5-hmC marks in parental HT-29, HT-29 Cx43D, and HT-29 Cx43$^-$ cells. Bar graphs in the right panel reflect mean fluorescence intensity of at least five different fields acquired from three different experiments. Levels and activity of TET-2 increase in all CM-exposed cells. Scale bar 5 μm; D: Bar graphs display levels of Cx43 and TET-2 in Caco-2 cells exposed to CM. Fluorescent micrographs show increased levels of TET-2 in the nucleus upon exposure to CM. Scale bar 5 μm. Experiments were repeated at least three different times. One-way ANOVA, $^aP < 0.05$; $^bP < 0.001$; $^cP < 0.0005$. TET-2: Translocation-2; Cx43: Connexin 43; GAPDH: Glyceraldehyde 3-phosphate dehydrogenase; MFI: Mean fluorescence intensity.

shown in Figure 3C, after 60 min of incubation with Evans Blue, the concentration of the dye significantly and rapidly increased in DSS-treated parental HT-29 ($P < 0.05$) and HT-29 Cx43$^-$ cells ($P < 0.0001$). However, within the two-hour timeframe, cells overexpressing Cx43 (HT-29 Cx43D cells) had not leaked substantial levels of Evans Blue dye.

DSS was subsequently used to reproduce the murine colitis model to evaluate modulation of Cx43 and TET-2 levels in the inflamed colons of mice. Figure 3D shows that upon exposure of HT-29 cells to DSS *in vitro*, levels of Cx43 and TET-2 vary. Specifically, in Cx43-expressing cells, DSS exposure results in upregulation of Cx43 ($P < 0.001$). Levels of TET-2 also significantly increase in all HT-29 cellular subsets ($P < 0.01$).

In summary, *in vitro* results suggest that inflammation leads to upregulation of Cx43 and of TET-2 in HT-29 cells. TET-2 upregulation was more pronounced in HT-29 cells devoid of Cx43. Moreover, Cx43 knockdown rendered HT-29 cells more sensitive to DSS-induced membrane integrity breach, in favor of a role of Cx43 protein in the maintenance of epithelial barrier integrity. Modulation of Cx43 and TET-2 *in vitro* displayed similar trends whether cells were exposed to conditioned inflammatory media

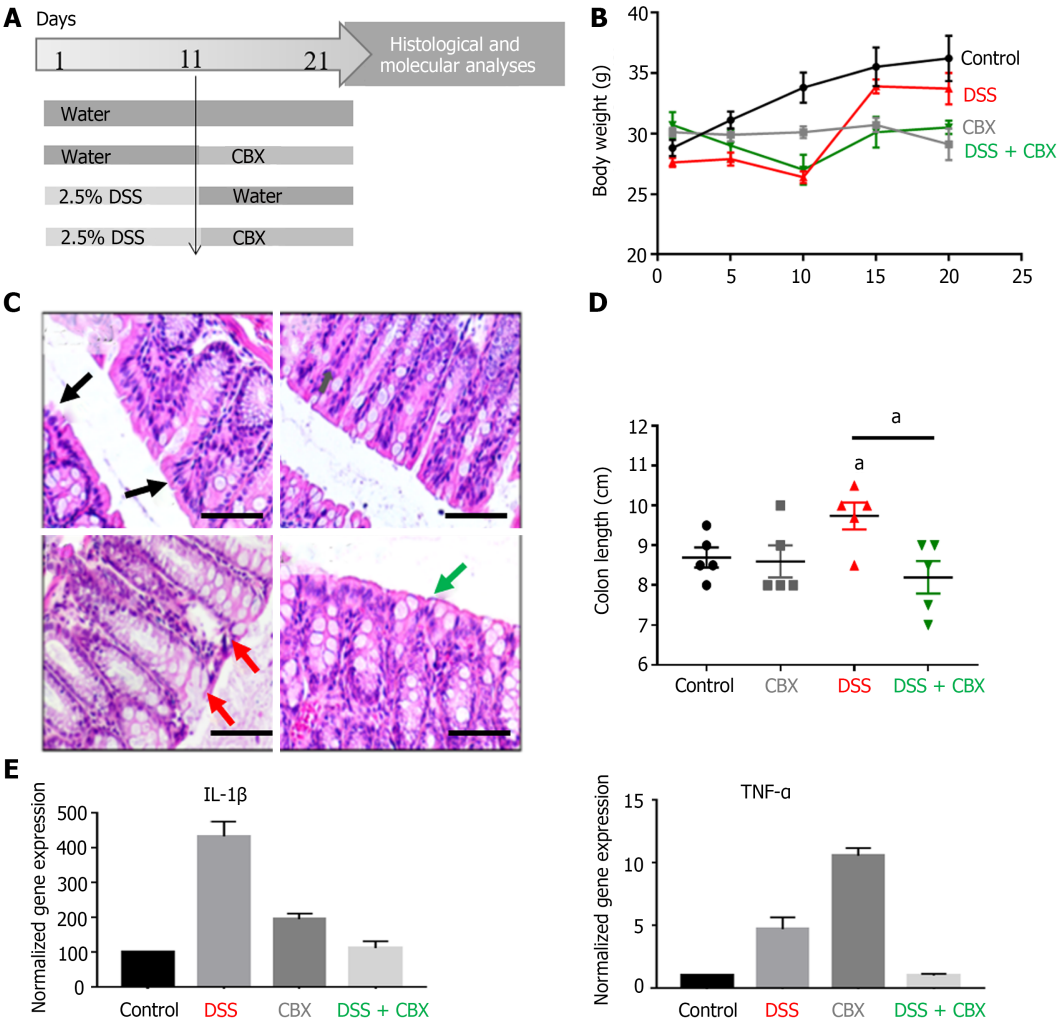
Figure 3 Dextran sulfate sodium treatment disrupts the integrity and permeability of intestinal epithelial barrier, notably in HT-29 connexin 43- cells. A: Light microscopy images of HT-29 cells in the presence or absence of 2% dextran sulfate sodium (DSS). Scale bar 50 μm; B: The membrane integrity of parental HT-29, HT-29 connexin 43-Dendra (Cx43D), and HT-29 Cx43- cells in the presence or absence of 2% DSS was measured by trans-epithelial electrical resistance (TEER). Bar graphs indicate average TEER measurements; C: Membrane permeability was evaluated by Evans Blue permeability assay in all three cell subsets. Levels of Evans Blue that crossed are measured by spectrophotometry and are plotted as means over time; D: Quantitative polymerase chain reaction data show that transcriptional levels of Cx43 and ten-eleven translocation-2 (TET-2) significantly increase in DSS-treated cells. All experiments have been repeated at least three times. Two-way ANOVA, $^{a}P < 0.05$; $^{b}P < 0.001$; $^{c}P < 0.0005$. Cx43: Connexin 43; DSS: Dextran sulfate sodium; TEER: Trans-epithelial electrical resistance.



(obtained from activated THP-1 cells) or to DSS (subsequently used in the colitis mouse model).

An established and widely used DSS-induced colitis mouse model was reproduced[34] to evaluate Cx43 and TET-2 expression. A subset of mice was also administered CBX, a GJ inhibitor, to examine TET-2 expression modulation in varying functional states of GJs.

DSS-induced colitis in mice is attenuated by CBX-induced GJ blockade

The experimental design was as described in Figure 4A, where each group comprised five mice. Body weight was recorded daily, throughout the 21-d experimental duration. Figure 4B reflects weight changes; while mice in the control group (Group 1) consistently gained weight over the 21-d experiment, mice exposed to CBX alone (Group 2) maintained their baseline weight throughout the experiment. On the other hand, DSS-exposed mice lost a moderate amount of weight until day 10, after which they were switched to normal drinking water (Group 3) and their average weight picked up to almost control group levels. Mice in the DSS group who were injected with CBX starting day 11 recovered some of the weight lost until day 10, but did not reach the normal weight recorded in the control group.

At the end of the experimental duration, mice were euthanized and their colons examined and collected for measurement purposes and a biopsy was used for histological and molecular analyses.

DOI: 10.3748/wjg.v28.i40.5845 **Copyright** ©The Author(s) 2022.

Figure 4 Dextran sulfate sodium induces inflammation in mice and carbenoxolone restores the normal phenotype. A: A flowchart schematizing the *in vivo* experimental design. BALB/c male mice were distributed into four experimental groups, each comprised of five mice: (1) Control group that received normal drinking water with no carbenoxolone (CBX) injections; (2) CBX group that received normal drinking water with CBX injections starting day 11; (3) Dextran sulfate sodium (DSS) group where mice were administered with 2.5% DSS in their drinking water for 10 d but not subjected to any CBX injections; and (4) DSS + CBX group that received DSS-containing drinking water as well as CBX injections. Mice were given 30 mg/kg CBX *via* intraperitoneal injections from day 11 every other day to the end of the experiment; B: Variation of animal body weight over 21 d. DSS-exposed mice lost weight. Significance in body weight change was detected between days 4 and 12 in DSS-treated mice, and days 11 and 21 in CBX-injected mice only; C: Hematoxylin and eosin images showing the architecture of mice colon tissues from all experimental groups. Arrows indicate representative sites in each experimental condition. Scale bar 50 μm; D: Colon length was measured at the end of the experiment. DSS-treated mice showed significantly longer colons compared to the control group; E: Bar graphs showing the normalized gene expression of interleukin-1β and tumor necrosis factor-α in mouse colon tissues, as detected by quantitative polymerase chain reaction. Experiments were repeated five times and results are displayed as means ± SEM. One-way ANOVA, $^{a}P < 0.05$. IL: Interleukin; CBX: Carbenoxolone; DSS: Dextran sulfate sodium; TNF-α: Tumor necrosis factor-α.

Histological examination of H&E stained sections of colons showed a disruption of epithelial barrier as well as an increase in infiltrating cells in crypts of colons from DSS-treated mice compared to control. CBX-treated animals seem to have retained (albeit not fully) some normalcy (Figure 4C). DSS-treated mice showed significantly longer colons compared to the control group ($P < 0.05$). CBX significantly reduced the length of DSS-treated colons to approximately normal levels ($P < 0.05$) (Figure 4D).

Levels of inflammatory cytokines, IL-1β and TNF-α, previously shown to be modulated in IBD models[12,38,43], were evaluated by qPCR. In accordance with weight changes and colon length indicative of intestinal damage, DSS-treated mice of Group 3 had increased expression of both IL-1β and TNF-α, compared to control Group 1 ($P < 0.05$) (Figure 4E).

These data propose that CBX alleviates DSS-induced inflammation in mice, as demonstrated by normalized colon length and histology, as well as decreased levels of inflammatory mediator transcripts in colon tissues.

DSS-induced inflammation increases Cx43 and TET-2 expression in vivo

Colon tissues obtained from mice on day 21 (end of experimental duration) were processed for total

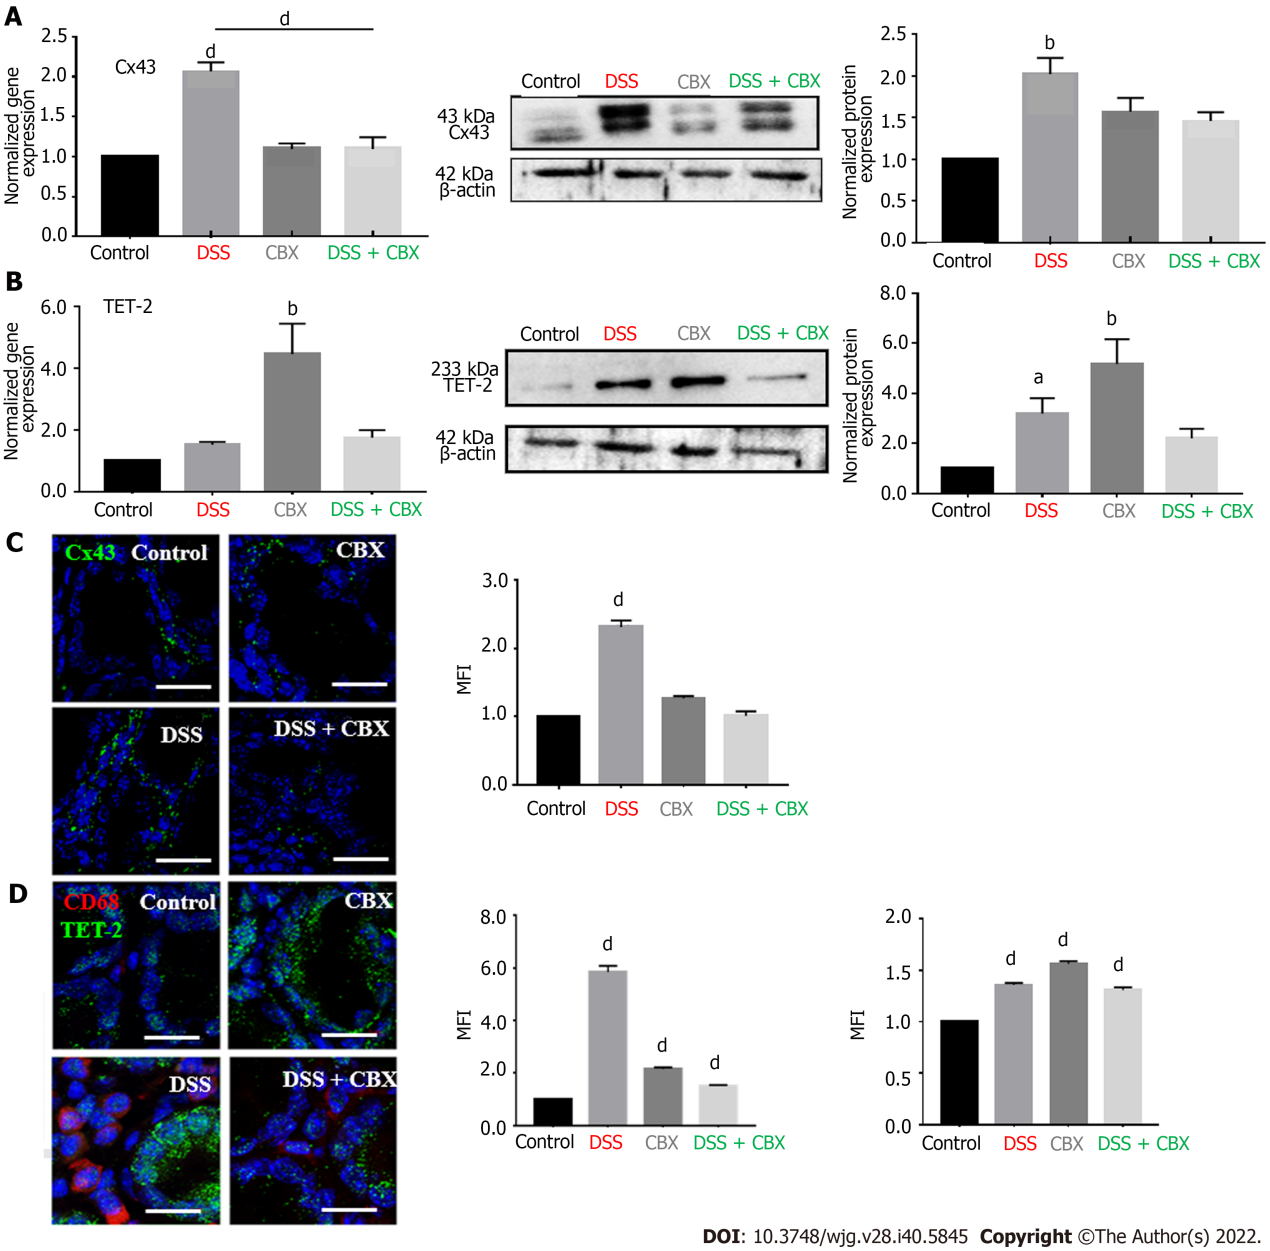
RNA and protein extraction. Cx43 expression was significantly higher in tissues from mice exposed to DSS both at the transcriptional (Figure 5A, $P < 0.0001$) and translational levels (Figure 5A, middle and right panels). However, CBX injections restored Cx43 mRNA and protein levels back to control levels. Not only did GJ inhibition attenuate the inflammatory state in the colon, it also led to downregulated Cx43 expression.

Levels of TET-2 were also evaluated in the colon tissues obtained from mice in all four experimental groups. Gene expression analysis pointed to an increase of TET-2 mRNA levels in the CBX-treated group (Group 2, Figure 5B, $P < 0.001$). In the tissues of mice from Group 4 (DSS + CBX), TET-2 levels were similar to those in the DSS group (slightly, but not significantly, higher than control levels). The same pattern was observed at the protein level (Figure 5B, middle and right panels). Changes in TET-2 levels were accompanied by changes in Cx43 levels, which increased in DSS-treated (inflamed) colons and decreased upon addition of CBX (Figure 5C). Inflammation was further underscored by immunostaining using CD68 antibody. As shown in Figure 5D, levels of infiltrated $CD68^+$ cells (macrophages) increased significantly by six-fold in colons of DSS-treated mice as opposed to those of control or CBX-treated mice alone ($P < 0.0001$). In accordance with CBX effects on inflammatory mediators and histological aspects, CBX injections following DSS exposure resulted in a decreased amount of macrophages. Sections from colons of mice in the DSS group also showed considerable levels of TET-2 protein in epithelial cells with neighboring macrophages, both indicative of an active inflammatory process. TET-2 levels increased further in colons of CBX-treated mice. In addition, and consistent with transcriptional and translational data, CBX-treated mice had upregulated TET-2 protein levels in their colons (Figure 5D). Immunofluorescent micrographs reflect TET-2 level increase in mucosal cells, though not to the same extent as qPCR data; due to the contribution of TET-2 mRNA from $CD68^+$ macrophages in the vicinity of IECs.

These data indicate that inhibiting GJs in inflamed tissues mitigates DSS-induced inflammation. In addition, the increase in Cx43 expression upon exposure to DSS is accompanied by an increase in TET-2 protein expression levels, and disabling GJs by CBX is paralleled by a significant increase in TET-2 levels. Data therefore suggest that, under inflammatory conditions (DSS), GJ inhibition by CBX restores Cx43 levels down to control. In accordance with *in vitro* data where HT-29 $Cx43^-$ cells had upregulated TET-2 levels, chemical inhibition of Cx43 *in vivo* also was accompanied by increased TET-2 levels.

Collectively, *in vitro* and *in vivo* data indicate that under inflammatory conditions, levels of both TET-2 and Cx43 increase.

Cx43 levels increase and TET-2 levels decrease in colons of patients with ulcerative colitis

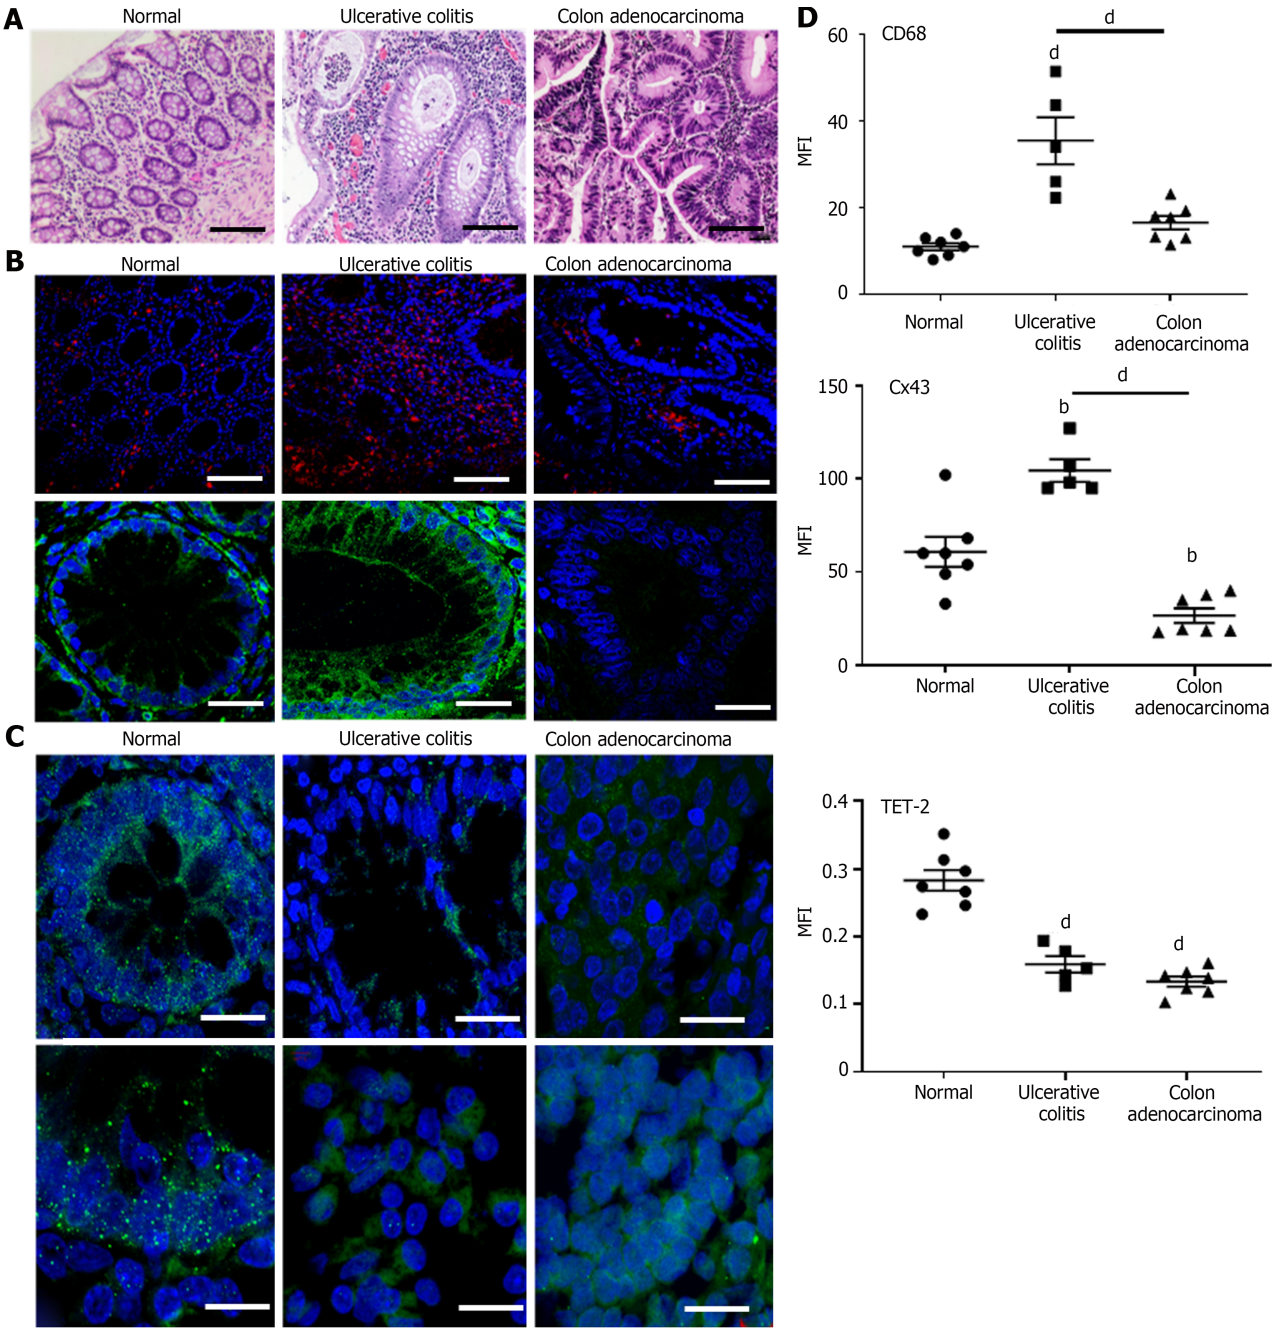


In an attempt to correlate *in vitro* and *in vivo* findings with clinical data, FFPE colon biopsies from normal non-dysplastic non-inflamed colons ($n = 7$), ulcerative colitis ($n = 5$), and colon adenocarcinoma ($n = 7$) patients were obtained anonymously. Sections were stained with H&E for light microscopy, as well as with antibodies against CD68 (macrophage marker), Cx43, and TET-2 for immunofluorescence analyses.

Histological staining exposed a clearly disorganized intestinal mucosal layer in ulcerative colitis and sporadic colon adenocarcinoma tissues as compared to normal tissues (Figure 6A). The disrupted architecture was due to extensive immune activity in the tissues underlying the mucosa. Figure 6B shows $CD68^+$ macrophages infiltrating tissues from ulcerative colitis patients ($P < 0.0001$), underscoring the inflammatory profile. Tissues obtained from patients with sporadic adenocarcinoma of the colon also displayed macrophage foci, but to a much lesser extent than ulcerative colitis tissues ($P < 0.001$). Although comparable to control in terms of fluorescence intensity, $CD68^+$ cells in the adenocarcinoma specimen were not uniformly distributed in the tissue.

Moreover, Cx43 and TET-2 expression and localization were evaluated by immunofluorescence (Figure 6C and D). Consistent with data obtained *in vitro* (Figures 2 and 3) and *in vivo* (Figure 5), Cx43 protein levels were significantly increased in ulcerative colitis (*i.e.* inflamed) tissues ($P < 0.005$) and sharply decreased in adenocarcinoma. Unlike *in vitro* and *in vivo* data that reflect parallel patterns of Cx43 and TET-2 expression in inflammatory conditions, Cx43 level increase in ulcerative colitis was accompanied by a decrease in TET-2 expression ($P < 0.001$). This observation, however, resembles the *in vitro* scenario illustrated in Figure 2. In fact, while TET-2 expression had increased upon exposure of cells to an inflammatory milieu, Cx43 upregulation in HT-29 Cx43D cells was associated with lower overall TET-2 expression compared to parental cells, and Cx43 knockdown resulted in elevated TET-2 levels.

DISCUSSION



In various pathologies, including inflammation and cancer, the alteration of the expression, regulation, and association of junctional complexes with other proteins have been reported. Epigenetic methylation and demethylation processes are also major players in a cell's malignant transformation. Specifically, GJ-forming Cx43 and demethylating enzyme TET-2 have both been documented to be impaired in inflammation and cancer[10-12,19,20].

Figure 5 Dextran sulfate sodium increases connexin 43 and ten-eleven translocation-2 expressions *in vivo*. A: Left panel: Histograms show the normalized gene expression of connexin 43 (Cx43) in mice colon tissues, as detected by quantitative polymerase chain reaction (qPCR). Middle panel: Western blot of Cx43 protein in mouse colon tissues. Right panel: Densitometric analysis of protein expression after normalization to β-actin. Dextran sulfate sodium (DSS)-treated mice had the highest expression of Cx43 in their colons; B: Left panel: Histograms display the normalized gene expression of ten-eleven translocation-2 (TET-2) in mouse colon tissues, as detected by qPCR. Middle panel: Western blot of TET-2 protein expression in mouse colon tissues. Right panel: Densitometric analysis of protein expression after normalization to β-actin. DSS exposure resulted in enhanced TET-2 transcription and carbenoxolone inhibition of gap junctions significantly increased TET-2 expression; C: Immunofluorescence images of colon tissues stained for Cx43 with the mean fluorescence intensity (MFI) analysis. Scale bar 20 μm; D: Immunofluorescence images of mouse colon tissues stained for CD68 and TET-2. Histograms reflect the MFI analysis. High levels of CD68$^+$ cells correlated with greater expression of Cx43 and TET-2 in DSS-exposed mice. Scale bar 10 μm. Experiments were repeated five times. One-way ANOVA, $^aP < 0.05$; $^bP < 0.005$; $^dP < 0.0001$. MFI: Mean fluorescence intensity; CBX: Carbenoxolone; DSS: Dextran sulfate sodium.

Studies have shown that the inflammatory response relies in part on intercellular communication mediated by channel-forming connexins. The role of GJ-mediated signaling in the initiation of inflammation is mainly through the transfer of ATP between neighboring cells. ATP molecules are then released in the extracellular environment where they act as signaling molecules that activate purinergic receptors, amplifying the inflammatory response[10]. Wong *et al*[11] partly elucidated the role of Cx43 in intestinal epithelial barrier injury. TLR activation in the disrupted intestinal epithelium translates intracellularly into Cx43 transcription, translation, post-translational modification, and assembly into connexons. GJIC regulates intestinal epithelial function during both acute and chronic inflammation [11]. Furthermore, Al-Ghadban *et al*[12] demonstrated a role of GJs in the pathogenesis of IBD by a direct communication between IECs and macrophages enhanced by basement membrane degradation [12]. Long-term IBD associates with amplified risk of colon carcinogenesis, and the deregulation of

Figure 6 Modulation of connexin 43 and ten-eleven translocation-2 expression in human colon tissues under pathological conditions. A: Hematoxylin and eosin images of human colon tissues. Compared to normal (histopathologically unchanged) samples, tissues from inflamed (ulcerative colitis) and sporadic malignant colons show disorganization of colon crypts and infiltration of immune cells within the lamina propria. Scale bar 50 μm; B: Immunofluorescence images of $CD68^+$ cells (macrophages) and connexin 43 (Cx43) show that Cx43 expression increases in inflamed tissues. Scale bar 10 μm; C: Immunofluorescence images of ten-eleven translocation-2 (TET-2) in human colon tissues (upper panel: Low magnification; lower panel: Higher magnification). TET-2 protein was minimally detected in ulcerative colitis and colon adenocarcinoma tissues. Scale bar 10 μm; D: Mean fluorescence intensity (MFI) analyses reflecting the expression of CD68, Cx43, and TET-2. One-way ANOVA, $^bP < 0.005$; $^dP < 0.0001$. MFI: Mean fluorescence intensity; TET: Ten-eleven translocation.

connexin expression is regarded as one of the hallmarks of different cancers. Shilova *et al*[44] reviewed *in vitro* and *in vivo* studies that point at a correlation between the loss of connexin expression and cancer onset. In fact, downregulation of Cx26, Cx32, and Cx43 accompanies the development of human bladder cancer, hepatocarcinoma, and breast cancer, respectively[44]. A recent study on breast cancer proposed that Cx43 upregulation in a triple negative breast cancer cell line led to a reversal of its mesenchymal phenotype *in vitro* and to a decreased metastatic potential *in vivo*[7]. While connexin downregulation is observed in many cancers, elevated Cx43 levels have also been associated with increased malignancy. In a hepatocellular carcinoma cell line, Cx43 was shown to enhance malignancy by inhibiting Cx32-mediated GJIC[45], and, in prostate cancer, Cx43 promoted invasion and metastasis[46]. Variability of data on connexin involvement in cancer onset and progression warrants more research to identify the

underlying factors that dictate a tumor-suppressing or tumor-enhancing activity of connexins. Epigenetic regulation of various genes could explain the differential expression of tumor-suppressor and tumor-enhancer genes in inflammation and cancer onset and progression.

The role of demethylating enzyme TET-2 in IBD and colorectal adenocarcinoma has not been fully described. In fact, TET proteins have mostly been studied in hematological malignancies. TET-1 was characterized as a partner gene to the *Mixed-Lineage Leukemia* gene in acute myeloid leukemia (AML), and the *TET-2* gene was described in a study on the myelodysplastic syndrome[47]. Recent investigations report that frequent point mutations in the *TET-2* gene can lead to the truncation of the resulting protein and loss of enzymatic activity, reflected by reduced global levels of the 5-hmC marks in AML patients[41,48]. However, although mutations in the *TET-1* and *TET-3* genes are rare in hematological malignancies compared to *TET-2*, both still exhibit a tumor-suppressor role: TET-1 in B-cell lymphomas [41] and TET-3, together with TET-2, in murine aggressive myeloid cancer[49]. Mutations and reduced expression of TET proteins were also observed in solid tumors, and decreased translational levels of TETs seem like an important hallmark of different cancers, including cancers of the digestive system[50-52].

In addition to carcinogenesis, a study by Zhang *et al*[19] shows an anti-inflammatory role for TET-2, which, under inflammatory conditions, repressed IL-6 transcription in dendritic cells and macrophages [19]. Moreover, TET-2-deficient bone marrow-derived dendritic cells and macrophages had high transcriptional levels of IL-6 upon LPS challenge. Another study also reported an increase of TET-2 transcriptional levels in colon tissues from patients with IBD[53].The present study examined the expression of Cx43 and TET-2 in an *in vitro* model of colon epithelium, where HT-29 cells were used in their parental state or with upregulated or knocked-out Cx43 in the presence or absence of inflammation (induced by DSS or by the addition of an inflammatory medium). A DSS-induced colitis murine model was used to describe how inflammation modulates the expression of Cx43 and TET-2. Data were then compared to Cx43 and TET-2 expression levels in tissues obtained from patients with ulcerative colitis or sporadic colorectal cancer.

Results from this study indicate that knockout of Cx43 in the HT-29 intestinal cell line leads to disruption of membrane integrity exacerbated by the DSS chemical insult. In Cx43-deficient cells and in mice that were subjected to chemical inhibition of GJs by CBX, loss of GJs was paralleled with increased TET-2 expression, further intensified in the presence of inflammation. In fact, inflammation triggered an upregulation of Cx43 and TET-2 expression in all cell subsets, which is in accordance with the literature [19,47]. An exploratory analysis of human colon samples obtained from ulcerative colitis patients revealed an increase in Cx43 and a decrease in TET-2 protein levels accompanied by the disruption of colon architecture. Though these findings are not aligned with the overall trend implicating TET-2 in intestinal inflammatory conditions, little is known about characteristics of patients whose colon biopsies were examined, including potential pharmacological agents that could lead to TET-2 degradation *via* one of the four pathways reviewed by Cong *et al*[54] in October 2020: A caspase-dependent pathway, calpain1-promoted degradation of TET-2, proteasome-dependent degradation, and p53-facilitated autophagy of TET-2 proteins[54]. Moreover, TET-2 seems to be implicated in both initiation of the inflammatory process by activating innate pro-inflammatory signaling pathways and its resolution by inducing the repression of pro-inflammatory mediators[55]. Therefore, the exact status of TET-2 in the colon of IBD patients remains to be elucidated, in light of multiple factors governing post-transcriptional and post-translational TET-2 regulation. In specimens from sporadic colon adenocarcinoma, both TET-2 and Cx43 proteins were considerably downregulated, underscoring the tumor-suppressor role of Cx43.

In the context of IBD (specifically ulcerative colitis) and colon cancer, we propose that Cx43 upregulation in inflamed colons could attenuate or slow down the onset of malignancy. Therefore, loss of Cx43 in tissues from colon cancer could be attributed to a malignant switch, turning off tumor-suppressor genes and activating tumor-promoting genes. The presence of $CD68^+$ cells (macrophages) was concomitant with loss of TET-2 expression in the colon adenocarcinoma samples. This could be explained by an immune-active phenotype in tumors, with tumor-associated macrophages having little to no TET-2 expression[55]. A 2018 study reported increased levels of TET-2 in T lymphocytes from colorectal tumor tissues, leading to demethylation and activation of FOXP3 and regulation of regulatory T cell (Treg) function[56], further implicating TET-2 in immune-related processes. In particular, TET-2 has been reported to regulate the innate immune response[57,58]. While it serves to activate the inflammatory response, TET-2 has also been implicated in inflammation resolution, where in response to IL-1/RMyD88 signaling, TET-2 downregulates the expression of inflammatory cytokines, such as IL-6 in innate myeloid cells and IL-1β in macrophages by recruiting HDACs for histone deacetylation[19,57]. This property might explain low levels of TET-2 in human ulcerative colitis samples where unresolved inflammation can be attributed to persistent inflammatory cytokines.

TET-2 status and role in digestive cancers remain unclear and variable, depending on the cancer site and grade, but also on possible mutations that could lead to cancer progression and resistance to chemotherapy, as recently reviewed[21].

CONCLUSION

Data presented in this manuscript show that exposure of intestinal cells to inflammation is associated with Cx43 and TET-2 upregulation *in vitro* and *in vivo*. We propose that, as part of its potential anti-inflammatory role and through its demethylating activity, TET-2 might be responsible for promoting the expression of anti-inflammatory genes and for indirectly repressing the expression of pro-inflammatory genes under inflammatory conditions. Similarly, we hypothesize that the demethylating TET-2 enzyme might promote the expression of tumor-suppressor genes (among others, Cx43) in the inflamed colon. Extrapolating from observations made on human colon samples, a malignant switch could happen in chronically inflamed colons. This malignant switch could be associated with downregulation of TET-2 (and potentially other TET enzymes[20,23]) in ulcerative colitis, possibly resulting in the hypermethylation of genes that are relevant in the context of carcinogenesis, such as Cx43. Although we present evidence on the modulation of TET-2 expression and we reiterate the role of Cx43 in intestinal inflammation, further investigation is under way to more solidly explore the mechanism of action behind a potential interplay between Cx43 and TET-2 that might, at least partly and indirectly, bridge chronic inflammation (such as in IBD) and IBD-induced carcinogenesis in the colon.

ARTICLE HIGHLIGHTS

Research background

Patients with inflammatory bowel disease (IBD) have a higher propensity to acquire colorectal cancer. The link between inflammation and cancer has long been established; however, the molecular players in the switch to cancer are still poorly defined.

Research motivation

In previous work, we have demonstrated a potential role for connexin 43 (Cx43) in inflamed intestinal cells. Recognizing the tumor-suppressor role of Cx43 in several cancers, we set out to explore whether the loss of Cx43 is associated with the switch to carcinogenesis. One potential mechanism for downregulating Cx43 expression is through methylation. We hypothesized that ten-eleven translocation-2 (TET-2), a demethylating enzyme, previously described to have a role in inflammation, may be involved in this process.

Research objectives

Using cell culture, a colitis animal model, and archived human tissues, we assessed the expression of both Cx43 and TET-2 in intestinal inflammation. Specific objectives include: (1) Assessment of the expression levels of Cx43 and TET-2 under inflammatory conditions; (2) Assessment of the expression and activity of TET-2 in HT-29 cell lines with up- or down-regulated for Cx43 expression; (3) Reproduction of a colitis mouse model and assessment of Cx43 and TET-2 levels in colons of mice; and (4) Explore Cx43 and TET-2 expression levels in archived biopsies obtained from patients with ulcerative colitis and colon adenocarcinoma.

Research methods

This study employed several modalities to verify the hypothesis, which include intestinal epithelial cell (IEC) line modified for Cx43 expression grown under inflammatory conditions. A dextran sulfate sodium-induced colitis mouse model was reproduced and tissues from different experimental conditions were analyzed. Gene expression profile, protein expression levels, morphology and cellular localization were described. In addition, archived formalin-fixed paraffin-embedded tissues were sectioned and evaluated for Cx43 and TET-2 expression.

Research results

In vitro, TET-2 expression was elevated under inflammatory conditions and even more so in HT-29 cells devoid of Cx43. The barrier function of IECs was breached when Cx43 levels were down-regulated. These results were corroborated in the murine colitis model. In archived biopsies from ulcerative colitis patients, Cx43 expression was upregulated compared to non-inflamed counterparts. In sporadic colon adenocarcinoma sections, both TET-2 and Cx43 expression levels were decreased.

Research conclusions

Under inflammatory conditions, levels of Cx43 and of the demethylating enzyme TET-2 are upregulated. Through demethylation, TET-2 would turn on the expression of several factors involved in inflammation (presumably Cx43 included). When TET-2 levels were diminished in sporadic colon adenocarcinoma, we also observed that Cx43 was downregulated, which may indicate a role of TET-2 in shutting down Cx43 and its tumor-suppressing potential.

Research perspectives

In vitro, manipulation of TET-2 levels in intestinal cells may yield further insight into the mechanism of action. Methylation studies will also be undertaken. The animal model will be expanded to allow for the development of colon carcinoma, and timed evaluation of molecular players will be performed. More stringent criteria will be implemented for prospective tissue collection from non-inflamed subjects, patients with IBD, and with IBD-associated colorectal cancer.

FOOTNOTES

Author contributions: El-Harakeh M, Saliba J, Haidar M, and Sharaf Aldeen K equally contributed to the study; El-Sabban M conceived and designed the study; Hashash JG, Awad MK, Shirinian M, and El-Sabban M provided the material and resources for the experiments; El-Harakeh M, Haidar M, Sharaf Aldeen K, and El Hajjar L performed the experiments; Saliba J and El-Harakeh M analyzed the data and wrote the manuscript; Shirinian M and Hashash JG critically reviewed the manuscript; Saliba J and El-Sabban M revised the manuscript; All authors read and approved the final version of the manuscript.

Institutional review board statement: Archived formaldehyde-fixed paraffin-embedded (FFPE) colon blocks (ulcerative colitis, sporadic colon adenocarcinoma and normal) were obtained from the American University of Beirut Medical Center (AUBMC). All patients' identifiers were kept confidential and all samples were anonymous, hence exempted from ethics committee approval.

Institutional animal care and use committee statement: All procedures involving animals were reviewed and approved by the Institutional Animal Care and Use Committee of the American University of Beirut, No. 18-03-476.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.

Data sharing statement: Raw data are available upon reasonable request.

ARRIVE guidelines statement: The authors have read the ARRIVE guidelines, and the manuscript was prepared and revised according to the ARRIVE guidelines.

Abstract

BACKGROUND

Immune dysfunction is the crucial cause in the pathogenesis of inflammatory bowel disease (IBD), which is mainly related to lymphocytes (T or B cells, including memory B cells), mast cells, activated neutrophils, and macrophages. As the precursor of B cells, the activation of memory B cells can trigger and differentiate B cells to produce a giant variety of inducible B cells and tolerant B cells, whose dysfunction can easily lead to autoimmune diseases, including IBD.

AIM

To investigate whether or not curcumin (Cur) can alleviate experimental colitis by regulating memory B cells and Bcl-6-Syk-BLNK signaling.

METHODS

Colitis was induced in mice with a dextran sulphate sodium (DSS) solution in drinking water. Colitis mice were given Cur (100 mg/kg/d) orally for 14 consecutive days. The colonic weight, colonic length, intestinal weight index, occult blood scores, and histological scores of mice were examined to evaluate the curative effect. The levels of memory B cells in peripheral blood of mice were measured by flow cytometry, and IL-1β, IL-6, IL-10, IL-7A, and TNF-α expression

in colonic tissue homogenates were analyzed by enzyme-linked immunosorbent assay. Western blot was used to measure the expression of Bcl-6, BLNK, Syk, and other signaling pathway related proteins.

RESULTS

After Cur treatment for 14 d, the body weight, colonic weight, colonic length, colonic weight index, and colonic pathological injury of mice with colitis were ameliorated. The secretion of IL-1β, IL-6, TNF-α, and IL-7A was statistically decreased, while the IL-35 and IL-10 levels were considerably increased. Activation of memory B cell subsets in colitis mice was confirmed by a remarkable reduction in the expression of IgM, IgG, IgA, FCRL5, CD103, FasL, PD-1, CD38, and CXCR3 on the surface of $CD19^+CD27^+$ B cells, while the number of $CD19^+CD27^+$ IL-10^+ and $CD19^+CD27^+$ Tim-3^+ B cells increased significantly. In addition, Cur significantly inhibited the protein levels of Syk, p-Syk, Bcl-6, and CIN85, and increased BLNK and p-BLNK expression in colitis mice.

CONCLUSION

Cur could effectively alleviate DSS-induced colitis in mice by regulating memory B cells and the Bcl-6-Syk-BLNK signaling pathway.

Key Words: Curcumin; Experimental colitis; Memory B cell; Bcl-6; BLNK

Core Tip: As the precursor of B cells, the activation of memory B cells can trigger the activation of B cells, thus producing numerous inducible B cells and tolerant B cells, whose dysfunction can easily result in inflammatory bowel disease (IBD). Also, the disorder of humoral immune function mediated by memory B cells has a critical position in the pathogenesis of IBD. As an immune suppressant, curcumin (Cur) has a therapeutic role in treating many immune diseases, such as IBD and rheumatoid arthritis. Meanwhile, it has proven efficacy in experimental colitis mice and patients with ulcerative colitis (UC), while the disturbances in memory B cells have been observed in IBD. However, few studies have explored whether Cur treatment of colitis is closely related to memory B cells. In the present research, our results indicated that Cur effectively alleviated DSS-induced UC in mice *via* a potential mechanism involving memory B cells and the Bcl-6-Syk-BLNK signaling pathway.

INTRODUCTION

Curcuma longa L, also named turmeric, is a perennial herb pertaining to the genus Curcuma in the *Zingiberaceae* of the *Scitamineae,* native to China, Indonesia, and India. According to the existing literature, *Curcuma longa L* can promote Qi, break blood stasis, facilitate menstruation, and relieve pain [1]. The bioactive natural polyphenols extracted from the rhizome of *Zingiberaceae* are called curcumin (Cur) [1,7-bis(4-hydroxy-3-methoxyphenyl)- 1,6-heptadiene-3,5-dione]. They are also known as diferuloylmethane, and their molecular formula $C_{21}H_{20}O_6$ accounts for 75% to 80% of curcumin compounds[2] (a structure is shown in Figure 1A)[3]. According to recent carefully designed clinical studies, with an excellent safety profile, Cur has the potential effect of prevention and/or management of various diseases including inflammatory bowel disease, dysentery, chronic enteritis, gastrointestinal syndrome, and so on, due to its anti-oxidant, anti-apoptotic, and anti-inflammatory properties[4]. In addition, many preclinical studies have indicated that Cur has perfect anti-cancer properties to inhibit carcinogenesis and the proliferation of various cancer cells[5], including prostate, oral epithelial leukemia, hepatic, breast, and colon cancers in human and animals, and the probable mechanisms are closely related to modulating the activation of a variety of cellular signals as apoptosis and angiogenesis [6].

As a chronic nonspecific inflammatory disorder, inflammatory bowel disease (IBD), classified into ulcerative colitis (UC) and Crohn's disease (CD), is characterized by recurrent abdominal pain, diarrhea, anemia, bleeding, and weight loss. However, the pathogenesis of IBD is still unclear, and is closely

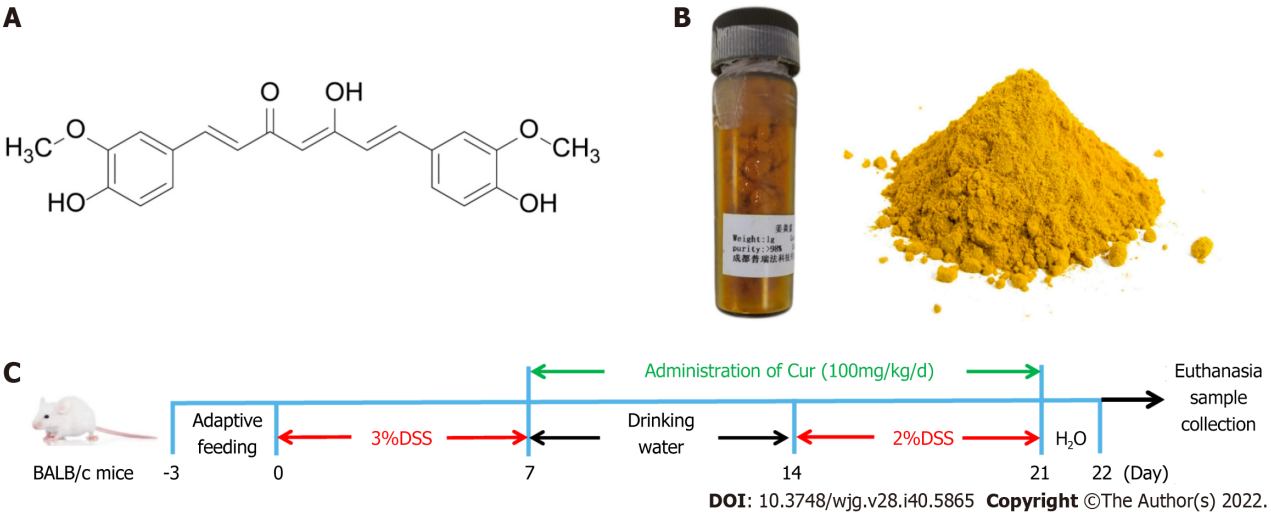

Figure 1 Drugs and protocols used in the study. A: Molecular structural formula of curcumin (Cur); B: Cur used in the experiment; C: Colitis induction and Cur administration. The experiment lasted for 22 d, including 3 d of adaptive feeding, 0-7 d of treatment with 3% DSS treatment with drinking water, and 7 d of free drinking water. Animals were divided into four groups: Control (n = 10), DSS (n = 10), DSS + Cur (100 mg/kg/d, n = 10), and Ctrl + Cur (100 mg/kg/d, n = 10) groups.

associated with heredity, environment, infection, immunity, and so on[7]. Among these, immune system dysfunction has been regard as the main cause of IBD, which is mainly involving abnormal lymphocytes (including T and B cells, including memory B cells), macrophages, mast cells, and activated neutrophils[8]. As a precursor to B cells, the activation of memory B cells can trigger the activation of B cells, thus producing numerous inducible B cells and tolerant B cells, whose dysfunction predisposes to autoimmune diseases, including IBD[9]. Pararasa *et al*[10] reported a decrease in $CD27^+IgD^-$ memory B cells in the blood of patients with IBD, but a concomitant increase in $CD27^-IgD^-$ memory B cells in gut-associated lymphoid tissue, which suggests that the disorder of humoral immune function mediated by memory B cells has a very important role in the pathogenesis of IBD.

Many previous studies have demonstrated that Cur can be used to effectively treat UC patients and animals. An endoscopic study revealed that NCB-02 enema (containing 140 mg Cur) used once per day for 8 wk could ameliorate the disease symptoms in patients with UC[11]. In an animal study, Cur administration effectively alleviated the colonic mucosal inflammation, restored colonic length, and reduced colonic weight and colonic damage[10]. Potential mechanisms of Cur for treating UC are diverse, including regulating immune function (such as regulating the function and level of T cells, regulatory T cells, memory T cells, macrophages, and dendritic cells), inhibiting the secretion of IL-2, IL-6, IL-12, IL-17, and TNF-α[12], downregulating the expression of costimulatory molecules[13], inhibiting the chemotaxis of chemokines and neutrophils, and inducing antioxidant effect[14]. Cur may induce apoptosis in colorectal cancer as it induces reactive oxygen species production, suppressing NF-κB signaling activation and cyclooxygenase-2 expression, activating caspase 3 and c-Jun N-terminal kinases (JNK), and inducing the release of cytochrome C. It is known that Cur can promote the activation of caspase 3, caspase 8, caspase 9, Bax, and poly (ADP-ribose) polymerase (PARP) to induce apoptosis in HCT-116 colon cancer cells[15]. Furthermore, it also exerts its effect on other autoimmune diseases by effectively regulating memory B cells. Elham and colleagues[16] found that Cur achieved effective results for autoimmune diseases such as RA and systemic lupus erythematosus (SLE) by targeting B lymphocyte stimulating factor (BLYS), which is an important cytokine for memory B cell proliferation. However, it is unclear whether Cur exerts a therapeutic effect on IBD by regulating the subsets or function of memory B cells. Therefore, in this study, DSS-induced colitis model, a classic animal model replicating human UC, was used to evaluate and explore the mechanism and therapeutic effect of Cur on IBD. Flow cytometry and other experiments were performed to explore the possible mechanisms and the changes in memory B cell subsets after Cur treatment.

MATERIALS AND METHODS

Mice

BALB/c male mice, aged 8-9 wk and weighing 20-22 g, were purchased from the Hunan Silaike Jingda Experimental Animal Co. Ltd. (Changsha, China; Animal Certificate No. SCXK 2016-0002). Mice were provided with standard food and water *ad libitum*, and lived under specific pathogen-free (SPF) conditions at the temperature of 23 °C ± 2 °C and relative humidity of 55% ± 10% with alternating light/darkness for 12 h. They were acclimatized for 3 d prior to the start of the experiment. All animal

experiments were conducted and performed in line with the regulations and guidelines of the Jiangxi University of Chinese Medicine Animal Care and Use Committee and the AAALAC and the IACUC (Permit No. JZLLSC2021-196).

All experimental mice were randomly divided into the following four groups: Control group, in which mice were fed normal food without DSS or drug treatment; Control + Cur group, in which normal mice were given Cur treatment; DSS group, in which mice with DSS-induced colitis were administrated with Cur; DSS + Cur group, in which mice with DSS-induced colitis were treated with Cur.

DSS-induced experimental colitis

As previously described, mice with colitis were freely given a 3% (w/v) solution of DSS (Batch No. 160110) in drinking water for 7 d (Figure 1C), then with sterile drinking water for 7 d, and finally with 2% (w/v) DSS for 7 d. Meanwhile, mice in the control group were given tap water. Cur was provided by Chengdu Purifa Technology Development Co., LTD (Chengdu, China; Batch No. PRF10052344, purity > 98%), as shown in Figure 1B. In order to better dissolve the drug, Cur was dissolved in 1.5% sodium carboxymethylcellulose. According to our previous study[17], mice in the DSS + Cur group and Control + Cur group were administrated with Cur (100 mg/kg/d) by gavage for 14 consecutive days, while mice in the Control and DSS groups were administrated with an equal volume of saline starting from day 8. The mice were weighed daily to evaluate body weight changes, and their fecal character, stool bleeding, and live state were monitored[18].

Histological evaluation

After the last administration, the mice were fasted for 12 h. All mice were weighed before anesthesia with sodium pentobarbital (20 mg/kg *i.p.*). After euthanasia, the whole colons were rapidly separated on the ice box, and their length and weight were measured to calculate the colon weight index (CWI) as [colon weight/body weight] × 100%, and the colon length index (CLI) as (colon weight/colon length) × 100%. The distal colon tissue was fixed in 4% paraformaldehyde for 72 h. After embedding in paraffin to cut 4 μm thick sections, the sections were dehydrated in an ethanol gradient series and stained with hematoxylin-eosin for histopathological analysis. Finally, the slices were sealed with neutral gum. And then the colonic pathological changes were observed and double-blindly scored by two pathologists under a microscope (Leica, Wetzlar, Germany, Product model: DM2500). According to the previous standards, a composite score was computed and totalized with inflammatory cell infiltration (scores 0-3), mucosal damage (scores 0-3), crypt damage (scores 0-4), and regeneration (scores 0-4)[19].

Flow cytometry

In order to isolate peripheral lymphocytes, 500 μL of peripheral blood from each mouse was collected and treated with 1 mL of lysing buffer (BD Biosciences, Franklin Lakes, NJ, United States) and incubated for 15 min in the darkness to remove red blood cells. The cell suspension was combined with an Fcγ receptor-blocking mAb (CD16/32; BioLegend, San Diego, CA, United States) for 15 min at 4 °C. Later on, the cells were detected for surface antigens by labelling with BV510 rat anti-mouse CD19 (Lot No. BD562956), AF488 rat anti-mouse CD27 (Lot No. BD124222), PE-A rat anti-mouse IgM (Lot No. BD553409), BV421 rat anti-mouse IgG (Lot No. BD742475), APC rat anti-mouse IL-10 (Lot No. BD505010), BV421 rat anti-mouse IgA (Lot No. BD743293), APC rat anti-mouse FCRL5 (Lot No. BD340305), PE-A rat anti-mouse CD103 (Lot No. BD562772), BV421 rat anti-mouse FasL (Lot No. BD740054), APC rat anti-mouse PD-1 (Lot No. BD562671), BV421 rat anti-mouse CXCR3 (Lot No. BD126529), and PE-A rat anti-mouse Tim-3 (Lot No. BD119704), which were purchased from BD Bioscience (San Jose, CA, United States). Finally, the single-cell suspensions were analyzed with a FACS Canto II flow cytometer (BD Biosciences, Franklin Lakes, NJ, United States). Gates were set for the quadrant markers based on negative populations and isotype controls. FlowJo VX software (TreeStar, San Carlos, CA, United States) was used to analyze all data to differentiate the memory B cell subgroups.

Enzyme-linked immunosorbent assay (ELISA)

One hundred micrograms of mouse colon tissue was homogenized by adding 1000 μL of RIPA lysis buffer (Cell Signaling Technology, Danvers, MA, United States). The samples were incubated at 4 °C for 1 h, ultrasonically homogenized, and centrifuged at 13000 rpm for 10 min, and the supernatant was taken to obtain colonic tissue homogenate. The total protein in colonic tissue homogenate was quantified with a total protein detection kit (Aidlab Biotechnologies Co., Ltd., Beijing, China; Lot No. PP0102). According to the manufacturer's instructions, commercial ELISA kits (Thermo Fisher Scientific, Waltham, MA, United States) were used to detect the secretion of IL-1β (Lot No. BMS6002TEN), IL-6 (Lot No. BMS603-2), IL-10 (Lot No. 88-7105-88), IL-35 (Lot No. BMS616), IL-17A (Lot No. BMS6001), and TNF-α (Lot No. BMS607-3).

Western blot analysis

Colon tissue homogenate was prepared and protein concentration determination was performed

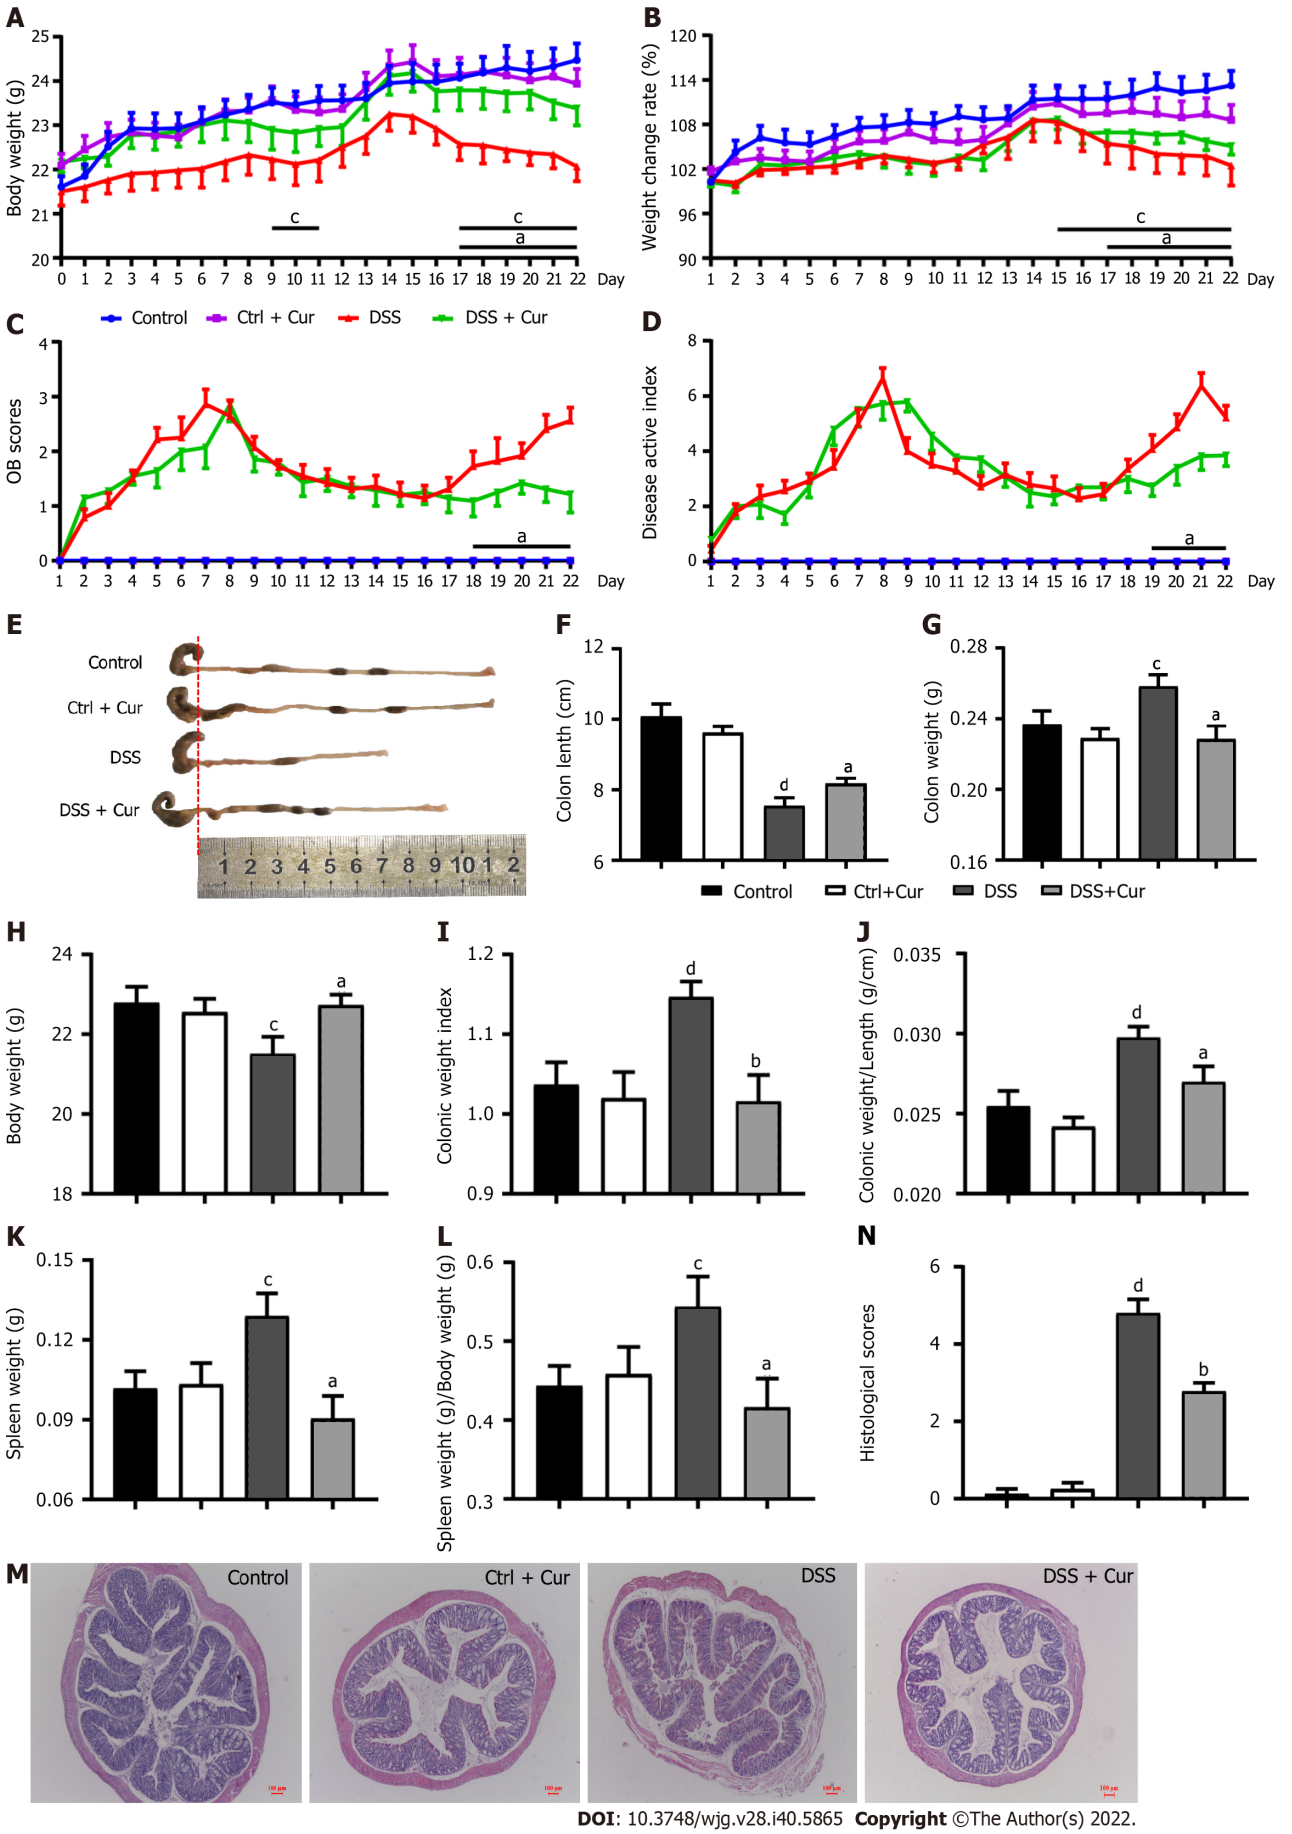
according to the above methods. First, equal amounts of colonic mucosa protein were resolved by polyacrylamid gel electrophoresis and transferred onto PVDF membranes, which were then blocked with 3% bovine serum albumin (BSA) solution for 1 h at room temperature and then incubated with the following primary antibodies overnight at 4 °C: BLNK (Abcam, ab32418, 1:500), p-BLNK (Abcam, ab174837, 1:1000), Syk (Abcam, ab40781, 1:1000), p-Syk (Abcam, ab300410, 1:1000), CIN85 (1:1000), Bcl-6 (Abcam, ab19011, 1:1000), and anti-GAPDH (Abcam, ab181602, 1:1000) antibodies. Next, the corresponding HRP-coupled secondary antibody (Abcam, ab205718, 1:5000) was added and incubated for 2 h at room temperature, and the ECL hypersensitive solution (Thermo, Rockford, IL, United States) was used to visualize the protein blotting. Photographs were taken by using the Highly Sensitive Chemiluminescence Imaging system (UVP ChemStudio 515; Analytik Jena, Jena, Germany). Image-Pro Plus 6.0 software (Media Cybernetic, Bethesda, MD, United States) was used to quantify the images, and the gray value of the band and the ratio to that of the internal reference GAPDH was used for statistical analysis.

Statistical analysis

GraphPad Prism 7.0 software (San Diego, CA, United States) was used to analyze the difference between groups by performing independent samples *t*-test, one-way analysis of variance, least-significant difference test, and Turkey test for multiple comparisons. All data are presented as the mean ± SE. $P < 0.05$ was considered statistically significant.

RESULTS

Cur alleviates DSS-induced colitis

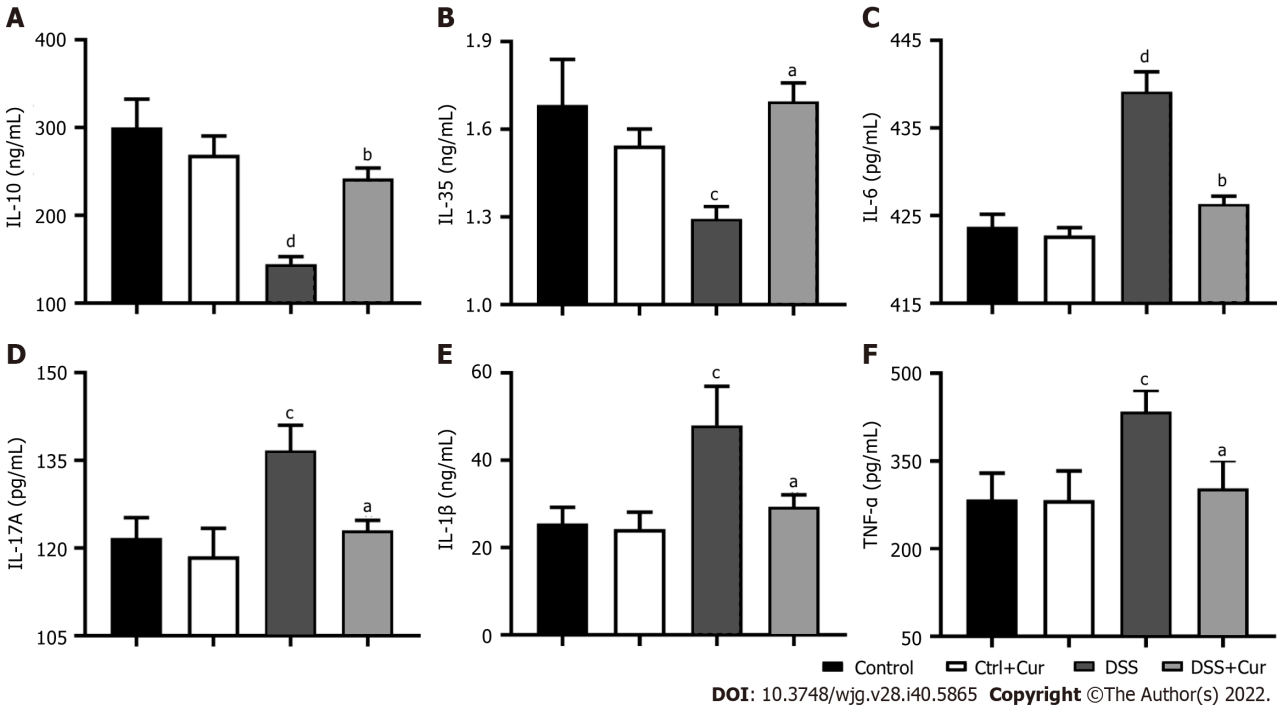


Many studies have shown that mice with DSS-induced colitis may present diarrhea, abdominal pain, bloody stool, weight loss, shortened colon length, increased colon weight, and other symptoms[20]. Under the microscope, altered colonic gland structure, a decrease in the number of goblet cells, massive infiltration of inflammatory cells in the mucosa and submucosa, and obvious erosive ulcer in DSS-induced colitis can be observed[21]. In our pilot study, DSS-induced colitis mice exhibited significant weight loss from day 4 to day 21 of the experiment (Figure 2A), and the changes in body weight (Figure 2B) were significantly lower in contrast with those of the Control group. From days 1 to 22, the occult blood (OB) test score (Figure 2C) gradually started to be different from that of the Control group, while disease activity index (DAI) scores (Figure 2D), which were significantly higher than those of the Control group, exhibited a similar trend to OB scores. In addition, the colonic weight (Figure 2G), index of colon length (Figure 2I), index of colonic weight (Figure 2J), spleen weight (Figure 2K), and the spleen weight index (Figure 2L) of mice in the DSS group statistically increased, whereas the body weight in the last day (Figure 2H) and colonic length (Figure 2E and F) decreased significantly. Meanwhile, the histopathological analysis (Figure 2M) showed that the colonic mucosa of mice was intact in the control group, with no obvious ulceration or inflammatory cell infiltration, neat arrangement of cup-shaped cells, and no congestion or edema, while the colitis mice showed exudation of the colonic mucosal epithelium, changes in crypt structure, disordered arrangement, local ulcer formation, hyperemia and edema in the colon mucosa, and infiltration of inflammatory cells in the lamina propria and submucosa, and the pathological injury scores were significantly increased (Figure 2N), which was consistent with our previous study. The above findings indicated that the chronic colitis model has been successfully constructed.

After Cur gavage administration, significant changes in body weight (Figure 2A), weight change rate (Figure 2B), OB scores (Figure 2C), and DAI scores (Figure 2D) were effectively reversed in colitis mice. Also, colon weight (Figure 2G), colon mass per unit length (Figure 2J), index of colonic weight (Figure 2I), spleen weight (Figure 2K), and spleen weight index (Figure 2L) were significantly decreased when compared with those in the DSS group, while the body weight in the last day (Figure 2H) and colonic length (Figure 2E and F) were obviously higher in the DSS + Cur group than in the DSS group. Meanwhile, ulceration and inflammatory infiltration in the colitis mice treated with Cur were distinctly improved (Figure 2M), and the pathological injury scores (Figure 2N) were observably decreased compared to those of colitis mice without treatment. Moreover, the above data were not evidently different between the Control and Control + Cur groups. Therefore, these data suggest that Cur can effectively alleviate DSS-induced colonic injury.

Cur regulates inflammatory cytokine expression

UC is a form of IBD characterized by rising levels of pro-inflammatory factors and declining levels of anti-inflammatory factors[22]. Disruption of the balance between pro-inflammatory and anti-inflammatory factors is one of the important characteristics of IBD[23].



In our experiment, we found that the levels of IL-6 (Figure 3C), IL-17A (Figure 3D), IL-1β (Figure 3E), and TNF-α (Figure 3F) were remarkably increased in the DSS group compared to the Control group, while the IL-10 (Figure 3A) and IL-35 levels (Figure 3B) in the DSS group were dramatically decreased, suggesting that the imbalance of pro-inflammatory and anti-inflammatory factors was one of the

important characters in DSS-induced colitis. More importantly, the IL-6 (Figure 3C), IL-17A (Figure 3D), IL-1β (Figure 3E), and TNF-α (Figure 3F) expression was significantly downregulated, while IL-10 (Figure 3A) and IL-35 (Figure 3B) expression was observably upregulated in colitis mice after Cur treatment. Altogether, Cur could effectively decrease IL-1β, IL-6, IL-17A and TNF-α production and increase IL-10 level, thus reestablishing the equilibrium between anti-inflammatory and pro-inflammatory factors in colitis.

Cur regulates memory B cell subsets

In the humoral immune response, there are two layers of memory cells, namely, long-lived B memory cells and B effector cells (plasma cells). The production of long-lived cells depends on the antigenic activation of B cells in the presence of T helper cells to induce germinal centers[24]. When the body comes in second contact with an antigen, memory B cells are quickly activated, differentiate into new tolerant or inducible plasma cells, secrete high-quality antibodies, and produce more efficient, faster, and more specific humoral immunity[9]. The tolerant type generally expresses factors such as IL-10 and TIM-3, while the induced type usually expresses molecules such as IgG, IgM, IgA, PD-1, CD38, CXCR3, FCRL5, CD103, and FasL, thus having opposite roles in the process of disease development[25]. Their balance determines the development, genesis, and development of memory B cells, while their dysfunction is one of the pathogenesis of IBD.

Recent studies have revealed that CD27 is expressed at higher levels in memory B cells than in plasma blasts and can be used as a biological biomarker of memory B cells. The CD19-positive cells were selected as the gate of B cells. Memory B cells ($CD19^+CD27^+$) could be marked and separated according to the expression of CD27 and CD19, which could then be divided into many subgroups in accordance with the expression of different cytokines on the surface of memory B cells[26,27].

In this study, compared with mice in the Control group, the level of $CD19^+CD27^+$ memory B cells in peripheral blood of colitis mice was significantly decreased (Figure 4A-D), the percentages of $CD19^+CD27^+IgM^+$ (Figure 5A and B), $CD19^+CD27^+IgG^+$ (Figure 5C and D), and CD19 + $CD27^+IgA^+$ (Figure 5E and F) cells were obviously increased, and the percentages of $CD19^+CD27^+FCRL5^+$ (Figure 6A and B),

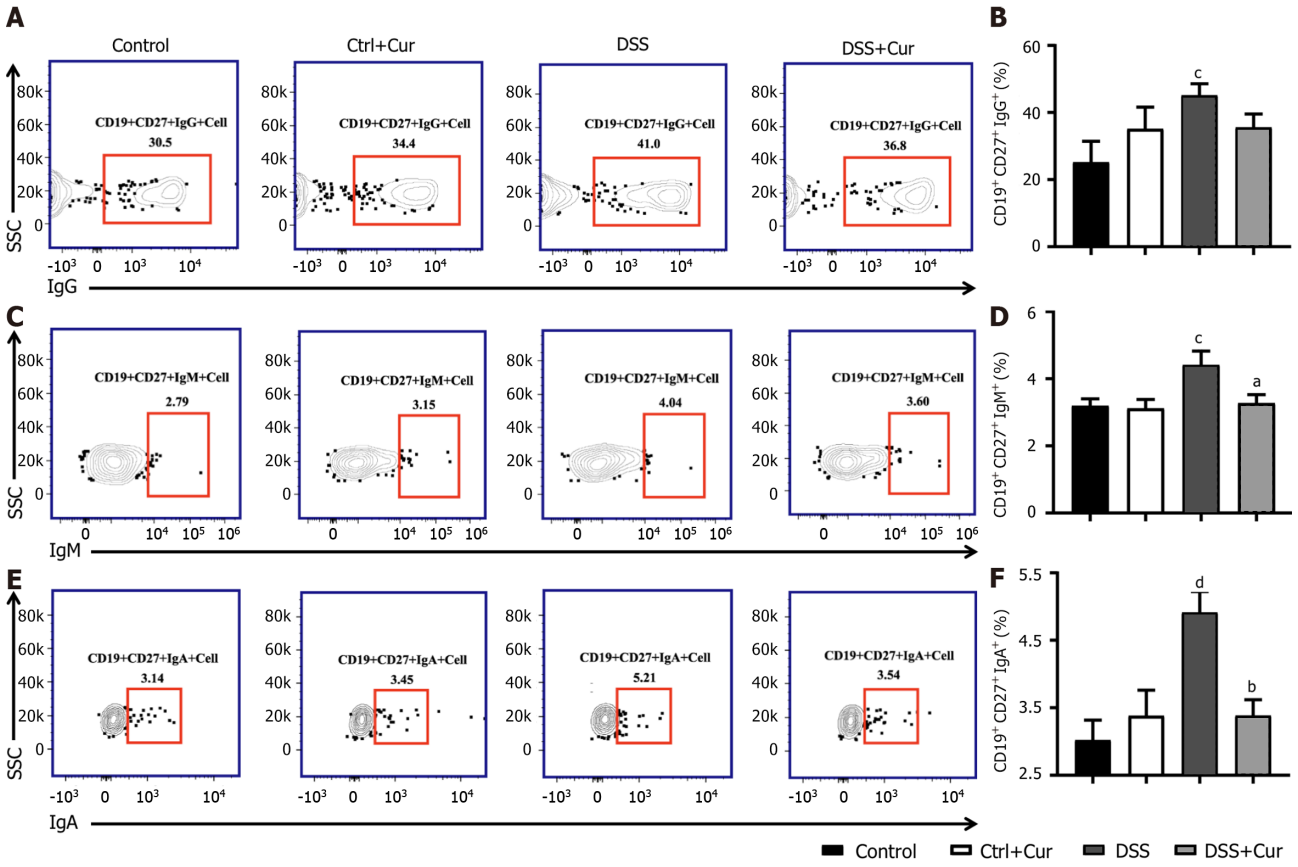
CD19$^+$ CD27$^+$ CD103$^+$ (Figure 6C and D), CD19$^+$ CD27$^+$ FasL$^+$ (Figure 6G and H), CD19$^+$ CD27$^+$ PD-1$^+$ (Figure 7A and B), CD19$^+$ CD27$^+$ CD38$^+$ (Figure 7C and D), and CD19$^+$ CD27$^+$ CXCR3$^+$ (Figure 7E and F) cells were significantly increased. These percentages were significantly decreased after DSS-induced colitis mice were treated with Cur for 14 d. Meanwhile, the percentages of CD19$^+$ CD27$^+$ IL-10$^+$ (Figure 6E and F) and CD19$^+$ CD27$^+$ Tim-3$^+$ (Figure 7G and H) cells were remarkably decreased in mice of the DSS group, whereas the percentages of CD19$^+$ CD27$^+$ Tim-3$^+$ and CD19$^+$ CD27$^+$ IL-10$^+$ cells were markedly increased after experimental colitis mice were treated with Cur. These results suggested that Cur could effectively regulate memory B cell subsets in mice with colitis.



Cur regulates the activation of the Bcl-6-Syk-BLNK signaling pathway

Next, we used Western blot analysis to explore the effect of Cur on the regulation of memory B-cell-related signaling pathways in mice with colitis. The Bcl-6-Syk-BLNK signaling pathway is a crucial signaling pathway involved in the activation, differentiation, proliferation, and functional display of immune cells, including B cells and memory B cells. In our experiments, the expression levels of Bcl-6 (Figure 8A and B), CIN85 (Figure 8A and E), Syk (Figure 8A and F), and p-Syk (Figure 8A and G) were higher in the DSS group than in the Control group. After 14 d of Cur treatment, Bcl-6, CIN85, Syk, and p-Syk expression in the colonic tissues of colitis mice was significantly inhibited. In addition, the expression levels of BLNK (Figure 8A and C) and p-BLNK (Figure 8A and D) were obviously lower in the DSS group than in the Control group, and the expression levels of BLNK and p-BLNK in the treatment group were evidently increased compared with the DSS group. Thus, these results suggested that Cur effectively regulates the activation of the Bcl-6-Syk-BLNK signaling pathway in colitic mice.

DISCUSSION

The incidence of UC has been gradually increasing worldwide, especially in adults between 30 and 40 years old. Patients with UC have mucosal inflammation, which starts in the rectum but continues into the proximal colon, usually presenting with bloody stool. Its pathogenesis is multifactorial, involving destroyed epithelial barrier, dysregulated immune responses, genetic predisposition, and imbalance of the gut microbiota. The dysfunction of immune cells and the destruction of immune homeostasis are deemed as the direct causes of UC[28,29].

B cells have an important role in adaptive immunity, and can differentiate into plasma cells and participate in inflammatory responses by producing a large number of antibodies and suppressing immune responses by releasing anti-inflammatory cytokines[30]. Previous studies on the role of B cells in immune diseases have indicated that the disruption of B cell subsets was a common characteristic in various autoimmune diseases. The variations in B cell frequency, abnormal molecular expression, key

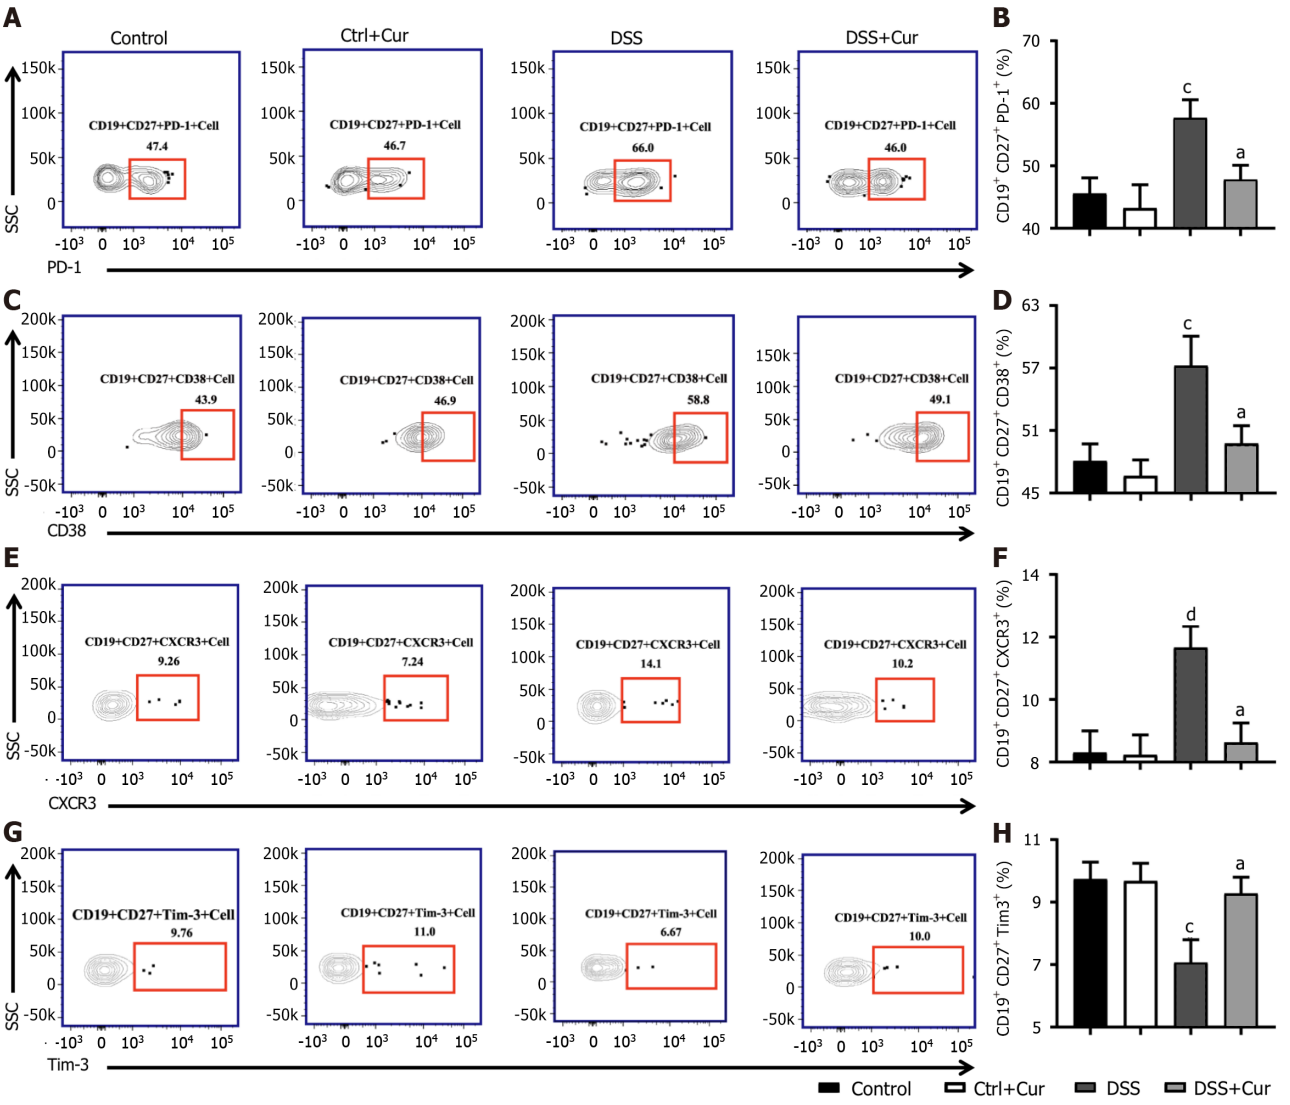
pathways, and the imbalance in subgroup distribution are closely related to the immunological pathogenesis of many diseases. Different B cell subsets can promote and inhibit inflammation. Overactivation of B cell responses, abnormal expression of signaling factors and cytokines, and imbalance in subpopulations, including memory B cells, are involved in the pathogenesis of many immune diseases. Meanwhile, memory B cells were considered as the source of several pro-inflammatory cytokines, which are involved in the pathogenesis of many autoimmune diseases[31]. In recent years, domestic and foreign scholars have extensively focused on this special class of B cells and their relationship with autoimmune diseases, such as myasthenia grais, Gillan barre syndrome, and other immune system diseases[32]. Dysregulation of memory B cells was found in several autoimmune diseases. Previous studies[17] have found that the B cell immune response, namely, the antibody response, is abnormally activated, and the memory B cells are significantly reduced in UC patients.

It is known that the body's immune system generates memory during the body's first antigen-antagonism and antibody response to specific antigens. The initial B cells can transform into memory B cells to complete the rapid category conversion in the next immunization[33]. These plasma cells migrate to bone marrow and lymphoid tissue, secrete specific antibodies such as immunoglobulins, inflammatory cytokines, and chemokines, mediate rapid and effective secondary immune response, and have an important role in humoral immunity[34].



When memory B cells are stimulated again by the same antigen, they are rapidly activated to produce IgG, IgM, IgA, FCRL5, CD103, IL-10, FasL, PD-1, CD38, CXCR3, Tim3, and so on. It is known that the destruction of the intestinal mucosal barrier during the onset of IBD causes abnormal expression of immunoglobulins, which are a major participant in humoral immunity, including IgG, IgA, IgM, *etc* [35]. IgG has the function of opsonizing phagocytes and neutralizing toxins, IgA has an antibacterial and antiviral function, while IgM has the function of lysing pathogens and binding antigens. Previous studies have shown that the increased number of endoplasmic cells in the intestinal mucosa of IBD patients leads to an increase in the secretion of IgG, IgA, IgM, and other immunoglobulins, which further participate in the formation of local immune complexes in the intestinal mucosa and trigger intestinal inflammation[36]. "FCR-like" (FCRL) is an evolutionarily conserved gene family associated with IgG and IgE Fc receptors (FCRS). FCRL5 is preferentially expressed in B cells and encodes

transmembrane proteins with tyrosine-based immunoregulatory motifs[37]. CD103 (human mucosal lymphocyte antigen-1) is highly expressed at mucosal sites, and CD103-positive lymphocytes have a remarkable ability to move directly toward the intestinal epithelial cell model and immobilize mucosal lymphocytes with E-cadherin at the basolateral side of the intestinal epithelium[38]. IL-10 has anti-inflammatory effects by inhibiting inflammation and cellular immune response, improving B cell survival rate, B cell proliferation, MHC II antigen expression, and immunoglobulin secretion, and inhibiting the production of NK cytokines, monocytes, and macrophage pro-inflammatory factors[39]. In the gastrointestinal tract, IL-10 is secreted by T cells, B cells, macrophages, neutrophils, and natural killer cells, and maintains mucosal homeostasis and immune tolerance during inflammation[40]. FasL is a membrane receptor protein that belongs to the superfamily of nerve growth factor receptors. It has a signal transduction role in cell apoptosis, and can induce colon epithelial cells and protect Th2 cells from apoptosis or even directly kill Th2 cells. In colonic epithelial cells, FasL can mediate the apoptosis of colonic epithelial cells through caspase-mediated apoptosis, which ultimately leads to the destruction of the colonic mucosal barrier and the formation of ulcers[41]. Indeed, expressed of Fas L in B cells is upregulated by IL-10 in some autoimmune diseases and GVHD models. CD5 is expressed in both $FasL^+$ B cells and IL-10-producing B10 cells, suggesting the possibility of a feedforward cycle in which B cells can express IL-10 to enhance their other immunomodulatory mechanisms[42]. Programmed death receptor 1 (PD-1) is a coinhibitory receptor expressed on T cells, B cells, natural killer cells, and monocytes. It has been confirmed that PD-1 is highly expressed in intestinal mucosal cells. Its ligand

binding can participate in the occurrence of intestinal mucositis by activating initial T lymphocytes, inhibiting activated effector T lymphocytes, and regulating the secretion of cytokines[43]. Studies have shown that in patients with UC, the expression level of PD-1 in inflammatory sites is significantly increased, while intestinal mucositis is alleviated when the PD-1 pathway is blocked[44]. CD38 is expressed on intestinal inflammatory cells, which has been reported to promote intestinal inflammation. Therefore, CD38 indirectly promotes intestinal inflammation[45]. CXCR3 is a chemokine receptor of the CXC family, expressed in epithelial and endothelial cells, as well as various lymphocytes such as NK cells, B cells, memory T cells, monocytes, and neutrophils. In IBD patients, CXCR3 and its corresponding ligands are strongly expressed in the intestinal mucosa. They can also recruit pro-inflammatory cells into the colon during colitis, leading to IBD[46]. As an important immune checkpoint molecule, Tim-3 regulates immune response. According to previous studies, Tim-3 is also expressed on the surface of B cells, while B cell activation affects the expression of Tim-3. After knocking out Tim-3, its protective effect disappeared, and the protective effect of B cells depended on Tim-3. Wang *et al*[47] found that during the development of acute enteritis, the expression of Tim-3 on the surface of infiltrated immune cells, especially B cells in the lamina propria of the colon, significantly decreased. After knocking out Tim-3, enteritis was significantly aggravated, and the protective effect of B cells on enteritis potentially depended on Tim-3. When the humoral immune balance related to memory B cells is disrupted, the expression of proinflammatory factors is induced, and the expression of anti-inflammatory factors is inhibited, leading to a variety of autoimmune diseases, including IBD[48].

Figure 8 Curcumin regulates expression of memory B cell-related proteins in DSS-induced ulcerative colitis mice. A: Expression of Bcl-6, BLNK, p-BLNK, CIN85, Syk, and p-Syk in colon tissues as revealed by Western blot analysis. GAPDH served as the internal reference; B-G: Quantitative evaluation of (B) Bcl-6, (C) BLNK, (D) p-BLNK, (E) CIN85, (F) Syk, and (G) p-Syk. Data are presented as the mean ± SE (n = 8-10). $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* Control group; $^{c}P < 0.05$, $^{d}P < 0.01$ *vs* DSS group.

Our experimental results revealed that the level of memory B cells in the peripheral blood of DSS-induced colitis mice was obviously abnormal, which was consistent with other literature reports. In our experiment, induced memory B cells (IgG^+, IgM^+, IgA^+, $FCRL5^+$, $CD103^+$, $FasL^+$, $PD\text{-}1^+$, $CD38^+$, and $CXCR3^+$ memory B cells) were over-expressed and tolerant memory B cells ($IL\text{-}10^+$ and $Tim\text{-}3^+$ memory B cell) were under-expressed. After Cur administration, the levels of induced memory B cells with pro-inflammatory factor expression were significantly inhibited, while the levels of tolerant memory B cells and anti-inflammatory factors were increased. These phenomena were accompanied by Cur's effective inhibition of pathological damage in colitis mice, which indicated that Cur could effectively regulate the balance of memory B cells in colitis mice, so as to restore the balance of pro-inflammatory factors and anti-inflammatory factors and alleviate the symptoms of DSS-induced colitis. These findings suggest that the therapeutic effect of Cur on UC in mice might be closely related to the balance regulation of memory B cells.

In order to explore the mechanisms by which Cur regulates the balance of memory B cells, we examined the activation of the Bcl-6-Syk-BLNK signaling pathway in colon tissue. Bcl-6 protein is highly expressed in germinal B cells, and the germinal response is the maturation of antigen-specific B cells

into memory B cells, which constitute the cellular components of immune memory of the B cell lines [49]. Previous studies have suggested that Bcl-6 expression is necessary to enable germinal center B cells to differentiate into memory B cells. Bcl-6 expression was also found to enhance B cell survival and thereby regulate self-renewal of memory B cell. High expression of Bcl-6 sustains a germinal center B cell phenotype and inhibits the differentiation of memory B cells *in vitro*. Furthermore, it has been established that Syk/p-Syk is a key signal pathway, which is required to couple the BCR to all downstream signaling pathways in mature B cells. Also, the B cells with Syk deficiency could not differentiate into the germinal center or plasma cells, suggesting that Syk is required for the survival of memory B cells[50,51]. When BLNK/p-BLNK is deficient, the transformation of primordial B cells into memory B cells is disrupted, and the level of memory B cells is significantly reduced[52]. CIN85 is widely involved in various physiological activities in the body, especially vesicle transport, membrane transport, and invasion and migration of various cancer cells. It also participates in cell differentiation, cell cycle, and apoptosis[53,54]. According to the above analysis, the Bcl-6-Syk-BLNK signaling pathway plays a crucial role in the development, activation, and differentiation of B cells and memory B cells.

In our experiment, after Cur administration, the levels of other proteins were increased, but BLNK and p-BLNK protein expression was decreased. This result indicated that Cur could significantly inhibit the activation of the Bcl-6-Syk-BLNK signaling pathway, which is consistent with its regulatory effect on memory B-cell balance.

As a new member of regulatory immunity, the biological characteristics and functions of memory B cells have been studied extensively, providing a new perspective for studying immune regulation mode and a new method for treating IBD. It has been proven that Cur is effective against DSS-induced micron colitis. In this experiment, we found that Cur could effectively improve the mucosal damage of DSS-induced colitis mice and significantly regulate the balance of induced type and tolerance memory B cells in colitis mice. As a result, the Bcl-6-Syk-BLNK signaling pathway was significantly inhibited. The effectiveness of Cur for murine UC was closely related to the regulation of memory B cell balance. Cur regulated the balance of memory B cell subgroups in mice with colitis, which was realized by activating the Bcl-6-Syk-BLNK signaling pathway. These results suggest that through the activation of the Bcl-6-Syk-BLNK signaling pathway, Cur harmonizes the differentiation and activation of inducible and inhibitory memory B cells, promotes the balance between them, reduces the expression of chemokines related to the inhibition of inducible memory B cells, and prevents excessive accumulation of inflammatory cells. It can also prevent overproduction of pro-inflammatory factors, increase the expression of tolerant memory B cells and anti-inflammatory factors to alleviate the immune damage by correcting memory B cell disorder, and maintain the humoral immune homeostasis mediated by memory B cells.

CONCLUSION

Cur could effectively alleviate DSS-induced colitis in mice by regulating memory B cells and the Bcl-6-Syk-BLNK signaling pathway.

ARTICLE HIGHLIGHTS

Research background

Curcumin (Cur) has shown promising efficacy in experimental colitis mice and ulcerative colitis patients. Disturbance in memory B cells has been observed in various autoimmune diseases, including inflammatory bowel disease. However, few studies have explored whether Cur treatment of colitis is associated with memory B cells.

Research motivation

To the best of our knowledge, this is the first study to explore the mechanisms by which Cur regulates memory B cells in the treatment of experimental colitis.

Research objectives

To investigate whether Cur can alleviate experimental colitis induced by DSS through regulating memory B cells and Bcl-6-Syk-BLNK signaling.

Research methods

Cur (100 mg/kg/d) was intragastrically administered in mice with colitis induced by DSS for 14 consecutive days. The effect of Cur was evaluated by macroscopic and histological observation. The levels of memory B cell subgroups in mouse peripheral blood were detected by flow cytometry, and the levels of cytokines in colonic tissue homogenates were measured by using ELISA. The expression of Bcl-6, BLNK, and Syk was measured by Western blot analysis.

Research results

After mice were treated with Cur for 14 d, the body weight, colonic weight and length, colonic weight index, and histopathological injury were ameliorated. In colitis mice, the concentrations of IL-1β, IL-6, TNF-α, and IL-7A were significantly decreased, while the concentrations of anti-inflammatory cytokines IL-35 and IL-10 were obviously increased. Activation of memory B cell subsets in colitis mice was confirmed by a remarkable reduction in the expression of IgM^+, IgG^+, IgA^+, $FCRL5^+$, $CD103^+$, $FasL^+$, $PD\text{-}1^+$, $CD38^+$, and $CXCR3^+$ on the surface of $CD19^+CD27^+$B cells, while the number of $CD19^+$ $CD27^+$ $IL\text{-}10^+$ and $CD19^+CD27^+$ $Tim\text{-}3^+$ B cells increased significantly. In addition, Cur observably decreased the protein levels of Syk, p-Syk, Bcl-6, and CIN85, and increased BLNK and p-BLNK expression in colitis mice.

Research conclusions

Cur could effectively alleviate DSS-induced colitis in mice, which is realized *via* a potential mechanism involving memory B cells and the Bcl-6-Syk-BLNK signaling pathway.

Research perspectives

In the present study, Cur effectively ameliorated the pathological colonic injury induced by DSS, which was achieved through a potential mechanism involving regulating the balance of memory B cells and activating the Bcl-6-Syk-BLNK signaling pathway.

Abstract

BACKGROUND

Liver transplantation for the most critically ill remains controversial; however, it is currently the only curative treatment option.

AIM

To assess immediate posttransplant outcomes and compare the short (1 year) and long-term (6 years) posttransplant survival among cirrhotic patients stratified by disease severity.

METHODS

We included cirrhotic patients undergoing liver transplantation between 2015 and 2019 and categorized them into compensated cirrhosis (CC), decompensated cirrhosis (DC), and acute-on-chronic liver failure (ACLF). ACLF was further divided into severity grades. Our primary outcomes of interest were total days of intensive care unit (ICU) and hospital stay, development of complications and posttransplant survival at 1 and 6 years.

RESULTS

235 patients underwent liver transplantation (CC = 11, DC = 129 and ACLF = 95). Patients with ACLF had a significantly longer hospital stay [8.0 (6.0-13.0) *vs* CC, 6.0 (3.0-7.0), and DC 7.0 (4.5-10.0); $P = 0.01$] and developed more infection-related complications [47 (49.5%), *vs* CC, 1 (9.1%) and DC, 38 (29.5%); $P < 0.01$]. Posttransplant survival at 1- and 6-years was similar among groups ($P = 0.60$ and $P = 0.90$, respectively). ACLF patients stratified according to ACLF grade [ACLF-1 $n = 40$ (42.1%), ACLF-2 $n = 33$ (34.7%) and ACLF-3 $n = 22$ (23.2%)], had similar ICU and hospital stay length ($P = 0.68$, $P = 0.54$), as well as comparable frequencies of overall and infectious post-transplant complications ($P = 0.58$, $P = 0.80$). There was no survival difference between ACLF grades at 1 year and 6 years ($P = 0.40$ and $P = 0.15$).

CONCLUSION

Patients may benefit from liver transplantation regardless of the cirrhosis stage. ACLF patients have a longer hospital stay and frequency of infectious complications; however, excellent, and comparable 1 and 6-year survival rates support their enlisting and transplantation including those with ACLF-3.

Key Words: Liver transplantation; Acute-on-chronic liver failure; Prognosis; Survival analysis; Critical care

©The Author(s) 2022. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Cirrhotic patients classified into compensated or decompensated cirrhosis and acute-on-chronic liver failure (ACLF) underwent liver transplantation. Patients with ACLF have a longer hospital stay and a higher frequency of infectious complications, but despite that, have similar posttransplant survival at one year and up to 6 years of follow-up.

INTRODUCTION

Cirrhosis is the consequence of chronic liver disease originated by a variety of etiological factors, characterized by the disruption of the normal hepatic architecture due to fibrosis with consequent hemodynamic repercussions. Unless the hepatic insult is removed, patients with this condition will suffer progression and transition from a stage of compensated cirrhosis (CC) to a stage of decompensated cirrhosis (DC) with the occurrence of portal hypertension-related symptoms[1]. An entity of recent definition known as acute-on-chronic liver failure (ACLF) is now recognized[2,3], which imposes the highest mortality risk given by a state of profound cirrhosis-associated immune dysfunction and the development of organ failures additional to that of the liver[4,5].

Currently, liver transplantation (LT) is the only definitive therapeutic measure for any of these patients, albeit with the implied risks including posttransplant complications and the long-term use of immunosuppressive drugs. However, patients benefit in general from excellent posttransplant survival.

There is controversial literature, and uncertainty prevails concerning the possible futility of assigning a liver to a patient with advanced cirrhosis and systemic alterations such as in those with ACLF. Some studies have demonstrated the presence of ACLF at the time of LT as a risk factor for mortality and graft loss, and that these patients may have lower short and long-term survival after transplant[6-8]. However, others have shown non-significant survival differences between ACLF and non-ACLF patients including a marked improvement in the prognosis of those with the highest severity (ACLF-3) [9-12]. The development of early allograft dysfunction and renal dysfunction is also comparable between these groups, as well as long-term liver and kidney function[12,13]. However, unfavorable outcomes can be expected and a higher frequency of perioperative and postoperative complications has been reported[8,9]. Differences may be found when ACLF patients are subdivided by ACLF grade, however, survival disparities are still controversial[7,9].

We here report our transplant center's experience in an effort to further contribute to the evidence on the benefit of LT in ACLF. The aim was to assess immediate posttransplant outcomes and to compare the short (1 year) and long-term (6 years) posttransplant survival among cirrhotic patients stratified by

disease severity. Unlike other studies so far, this study specifically compares survival and outcomes between compensated, decompensated cirrhosis and ACLF, thus distinctly contrasting the extremes of disease severity. Additional analyses were performed to determine possible differences between ACLF grades. These results should encourage further transplantation in those with this severe form of cirrhosis and even in patients with ACLF grade 3.

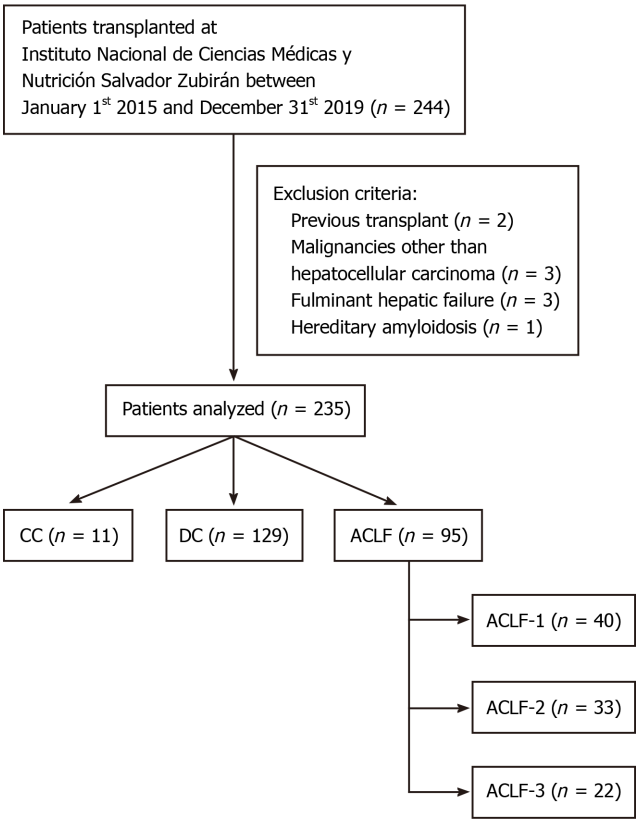
MATERIALS AND METHODS

Patients and operational definitions

This study included all patients undergoing LT between January 1st 2015 and December 31st 2019. Patients with a previous transplant, malignancies other than hepatocellular carcinoma, fulminant hepatic failure, and amyloidosis were excluded. Patients were classified into compensated cirrhosis (CC), decompensated cirrhosis (DC), and ACLF, and the latter were further subdivided into ACLF grades 1, 2 and 3 (Figure 1). Diagnoses of CC and DC were based on the absence or presence of symptoms related to portal hypertension, including ascites, encephalopathy, or variceal bleeding, respectively, as previously described[14]. All CC patients received liver transplant because of hepatocarcinoma mainly due to hepatitis C virus (HCV) infection.

ACLF was diagnosed in a patient that fulfilled ACLF criteria any time during their clinical course while waiting to receive a LT according to the EASL-CLIF consortium criteria[2] which state the following organ failure (OF) definitions: liver (total bilirubin ≥ 12 mg/dL); kidney (creatinine ≥ 2 mg/dL); brain (encephalopathy grade 3 or 4 according to West-Haven criteria); coagulation (INR ≥ 2.5); circulation (vasopressor use due to circulatory failure); and lung ($PaO_2/FiO_2 \leq 200$ or $SpO_2/FiO_2 \leq 214$ or mechanical ventilation due to lung failure). ACLF grading was performed as follows: ACLF-1, patients with single kidney OF or non-renal OF plus kidney dysfunction (creatinine between 1.5-1.9 mg/dL) and/or brain dysfunction (encephalopathy grade 1 or 2 according to West-Haven criteria); ACLF-2, patients with two OFs; and ACLF-3, patients with three or more OFs.

Patients at our center are considered for LT based on cirrhosis disease severity according to an unrestricted evaluation of the Model for End-Stage Liver Disease (MELD), MELD-Na and CLIF-C scores and are ultimately listed according to an interdisciplinary consensus reached by the gastroenterology, cardiology, pneumology, infectology, otorhinolaryngology, psychiatry, surgery, anesthesiology, and stomatology specialties. Liver transplants were carried out in their majority with classic technique. Briefly, recipient hepatectomy involved a bilateral subcostal incision with or without midline extension. Then dissection and clamping of the portal vein, hepatic artery, bile duct, and superior and inferior vena cava were done. Implantation of the donor's liver was attained by anastomosing first the superior vena cava from the donor with that of the recipient, followed by the inferior vena cava, and portal vein, after which reperfusion of the donor liver was begun. Total reperfusion was then obtained by anastomosing the hepatic artery of the graft with the junction of the gastroduodenal artery and the common hepatic artery of the recipient. The procedure was completed after performing cholecystectomy and duct to-duct anastomosis.



The immunosuppressive regimen in all patients following the procedure consisted of all or a combination of the following drugs: a calcineurin inhibitor (tacrolimus or cyclosporine), corticosteroids, mycophenolate mofetil and the interleukin-2 (IL-2) receptor antagonist basiliximab. In the event of renal disease in the post-orthotopic liver transplant period, modifications to the immunosuppression regimen including CNI dose reduction with the addition of MMF, were performed.

No donor organs were obtained from executed prisoners or other institutionalized people.

This study was approved by the ethics committee of our institution (GAS-2368-17-20) and conforms to the provisions of the Declaration of Helsinki. Requirement of informed consent was waived due to its observational nature.

Data collection and primary outcomes

Medical records of all patients were examined to extract the following demographic and clinical variables [gender, age, cirrhosis etiology, presence of ascites and encephalopathy, vasopressor use, PaO_2/FiO_2 or SpO_2/FiO_2 relation, requirement of mechanical ventilation and precipitant event (bacterial infection, gastrointestinal hemorrhage, active alcoholism, other or unknown)]. Laboratory data measured at the time of LT necessary to determine disease severity and for the computation of the MELD-Na score was further registered: total bilirrubin (mg/dL), creatinine (mg/dL), INR, and leukocyte count ($\times 10^9$/L). Our primary outcomes of interest were: the development of immediate posttransplant infectious complications, defined as any type of nosocomial-acquired, donor-derived or surgery-related infection presented during the immediate hospital stay following LT until the patients' discharge; the development of any type of immediate postoperative complication according to Clavien-Dindo classification[15]; and post-LT survival at 1 year and 6 years. Similarities in donor liver graft quality were assessed by evaluation of the donor risk index (DRI[16]) which considers the donor's age, height, race and cause of death, donation after cardiac death, split/partial graft, organ allocation and cold ischemia time.

Statistical analyses

Results of categorical variables are presented as frequencies and percentages, and as means and standard deviations or medians with interquartile range (IQR) for normally or not normally distributed continuous variables, respectively. Univariate statistical comparisons between categorical variables were performed with Pearson's Chi-squared test or Fisher's exact test and between continuous variables with the analysis of variance test or the Kruskal-Wallis test according to the normal distribution. Paired *t*-tests were carried out between disease severity scores among ACLF groups. Posttransplant survival was analyzed with the Kaplan-Meier method and survival curves were compared with the log-rank test. Statistical analyses were done with SPSS version 28.0 for Windows, IBM Corp., Armonk, NY, United States and survival curves were plotted using R version 4.1.0 (R Foundation for Statistical Computing, Vienna, Austria; www.r-project.org) with the survminer package. Statistical significance was considered at a P value less than 0.05.

RESULTS

Non-ACLF and ACLF patient characteristics

A total of 235 patients that underwent LT from 2015 to 2019 were included in this study, of which 95 (38.9%) fulfilled ACLF criteria, 129 (52.9%) were classified as DC, and 11 (4.5%) as CC (Table 1). When compared to the CANONIC study, we identified an overall younger population with ACLF patients being even younger than those with DC and CC [50.0 years (IQR 37.0-59.0) *vs* 52.0 years (IQR 43.0-61.0) and 57.0 years (IQR 53.0-59.0), respectively; $P = 0.02$]. Autoimmune etiologies (autoimmune hepatitis, primary biliary cholangitis, primary sclerosing cholangitis and overlapping syndromes) were the most frequent in ACLF patients (44.2% *vs* 27.9% DC, and 9.1% CC; $P < 0.01$), whereas the leading cause in DC and CC patients was HCV infection (72.7% CC, 32.6% DC, and 13.7% ACLF; $P < 0.0001$). With regard to comorbidities, no statistical differences were observed between cirrhosis groups for frequencies of either type 2 diabetes mellitus or primary hypertension ($P = 0.44$ and $P = 0.06$, respectively). ACLF patients had the highest MELD-Na score (25 ± 6 *vs* 19 ± 4 and 11 ± 3, DC and CC respectively), and accordingly the highest bilirubin and creatinine values. The presence of clinical ascites and encephalopathy (including West-Haven grade 3-4 encephalopathy) was also significantly higher in ACLF patients (Table 1).

ACLF: Acute-on-chronic liver failure; CC: Compensated cirrhosis; DC: Decompensated cirrhosis; HCV: Hepatitis C virus; INR: International normalized ratio; MELD Na: Model for End-Stage Liver Disease-Sodium; NASH: Non-alcoholic steatohepatitis.

When assessing the last ACLF event of these patients before undergoing LT, the majority were classified as ACLF grade 1 [*n* = 40 (42.1%)] followed by ACLF-2 [*n* = 33 (34.7%)] and ACLF-3 [*n* = 22 (23.2%)] (Table 2). Overall median time to LT since their ACLF event was 31 d (IQR 11.0-88.0). However, those with ACLF-1 had a significantly longer time to LT compared to ACLF-2 and ACLF-3 [54.0 (IQR 21.3-122.8) *vs* 31.0 (IQR 7.0-59.5) and 22.0 (IQR 9.5-46.8), respectively; *P* = 0.03]. Demographic data and etiologies were similar within these three groups, with autoimmune etiologies being the most frequent among all ACLF grades (*P* = 0.30). The most common ACLF precipitant overall were bacterial infections and the absence of an identifiable factor (unknown). Other precipitants including pharmacological and procedure-related complications, were more frequent in ACLF-1 patients (*P* = 0.01). Kidney OF was the only one that did not differ significantly between ACLF groups [18 (45.0%) ACLF-1, 11 (33.3%) ACLF-2, and 14 (63.6%) ACLF-3; *P* = 0.09], whereas liver, brain, coagulation, circulation and lung failure were significantly higher in patients with ACLF-3 (Table 2).

Parameters reflecting disease severity including MELD-Na, CLIF-C OF and CLIF-C ACLF scores, total bilirubin, INR and leukocyte count were higher in ACLF-3 and lower in ACLF-1. We observed a generalized improvement of clinical parameters in ACLF patients at the time of LT, with a concomitant reduction of the disease severity scores evaluated. For instance, MELD-Na decreased significantly among all three ACLF grades (*P* < 0.01), and an improvement in the CLIF-C OF score was also observed. Interestingly, the CLIF-C ACLF score became similar within ACLF-1, 2 and 3 patients with no significant difference among them (*P* = 0.18), as well as INR and leukocyte count (*P* = 0.05 and *P* = 0.92,

respectively) (Table 2).

ACLF patients have a more complicated posttransplant stay, but comparable short and long-term survival

Although severity of cirrhosis clearly differed between CC, DC and ACLF patients, posttransplant outcomes were mostly similar. While total days at the intensive care unit (ICU) were comparable and non-significant among these groups, patients with ACLF had a significantly longer hospital stay [8.0 d (IQR 6.0-13.0) *vs* 6.0 d (IQR 3.0-7.0) and 7.0 d (IQR 4.5-10.0), CC and DC, respectively; $P = 0.01$]. The frequency of patients who developed any type of complication (Clavien-Dindo I-V complications[15]) during their immediate hospital stay following LT was also similar, however those with ACLF more commonly presented an infectious complication ($P < 0.01$) (Table 3). When comparing days of hospital stay and posttransplant outcomes between ACLF-grades no significant differences were observed, thus the clinical course after LT of ACLF-3 patients was similar to that of those with ACLF-1 and 2 (Table 4).

Assessment of posttransplant mortality revealed that ACLF, DC and CC patients have a comparable survival at 1 and 6 years after LT [87 (91.6%), 114 (88.4%), 11 (100%) at 1 year, respectively; $P = 0.60$. 80 (84.2%), 112 (86.8%), and 10 (90.9%) at 6 years, respectively; $P = 0.90$]. Early transplant mortality at the critical periods of 30 d and 3 mo was also non-significant ($P = 0.38$ and $P = 0.30$, respectively).

All groups received the same quality grafts as there were no significant differences between groups in the DRI ($P = 0.13$) (Table 5). Survival as assessed by Kaplan-Meier analysis showed no significant differences among groups ($P = 0.79$; Figure 2A). These analyses were additionally performed in the ACLF population by subdividing them into their severity grades and no significant differences were observed at 30-d and 3-mo mortality ($P = 0.17$ and $P = 0.65$, respectively), 1-year and overall survival ($P = 0.40$ and $P = 0.15$, respectively). Likewise, no differences were observed in the DRI index ($P = 0.08$) (Table 5). This was reflected in a non-significant Kaplan-Meier analysis ($P = 0.17$; Figure 2B), which confirms similar posttransplant outcomes even among ACLF-3 patients.

DISCUSSION

Despite controversies, LT has been increasingly encouraged in patients with ACLF, including those with the highest severity grade. Hemodynamic derangements and systemic inflammation may restrain clinicians from considering an ACLF patient as a candidate for this procedure; however, the decision is so urgent that mortality on the waiting list may be even higher than that of status-1a patients[17]. In support of LT benefit for critically ill patients, this study demonstrates that according to our single-center experience, posttransplant outcomes in ACLF are favorable and in fact comparable with those of CC and DC patients. Moreover, even when comparing between ACLF grades a worse prognosis was not observed in those with ACLF-3.

In contrast to the CANONIC study[2], our patient population was in general younger, and interestingly ACLF patients were also the youngest even though no differences were found by ACLF grade. However, the main etiology in this group was of autoimmune nature. Although autoimmune diseases in cirrhosis follow a progressive and complicated clinical course, autoimmune ACLF patients in our center showed non-significant posttransplant survival differences in comparison with non-ACLF patients regardless of ACLF grade, which goes accordingly to the reported excellent survival observed in ACLF patients with autoimmune etiology[18]. A clear clinical difference between ACLF, CC and DC patients was evident by a significantly higher MELD-Na score and leukocyte count at the time of the ACLF event. These two parameters along with the CLIF-C and CLIF C-ACLF decrease at the time of LT, indicating improvement of the ACLF syndrome and hence a more favorable profile that allowed eventual transplantation. Indeed, Kim *et al*[19] has previously reported that both lower MELD scores and no ACLF progression are considered independent factors associated with a high survival rate after LT. Moreover, we also observed that the CLIF-C ACLF score at the time of LT was now similar between ACLF grades, which may further explain improvement and thus equally excellent posttransplant outcomes within these subgroups.

Compared to other studies[9,20-22], ACLF-3 patients in our center benefited from an even greater 1-year survival rate (90.9%) which remained higher even after our 6 year follow-up (77.3%). There are several risk factors associated with worse 1-year posttransplant mortality in ACLF-3 patients, such as

older age (≥ 53 years), high pretransplant arterial lactate levels, mechanical ventilation and high leukocyte count (≤ 10 g/L)[23]. Contributing to the favorable outcome observed in our ACLF population, including those with ACLF-3, several of the above mentioned reported risk factors for worse posttransplant mortality were not present in our patients. First, a younger age characterized our ACLF population and clinical parameters were mostly stable across all severity grades at the time of LT. Leukocyte counts were higher than in DC and CC patients, but generally always lower than 10×10^9/L either during the ACLF event or at LT. While bacterial infections were the main ACLF precipitant followed by unknown factors, important differences regarding other cohorts can be found with the frequency of certain OFs. Respiratory failure which is a risk factor for lower posttransplant survival[11,20,23] was uncommon as lung OF seldom occurred. Instead, liver OF prevailed in those with severe ACLF although closely followed by extrahepatic OFs including kidney OF, which was the most frequent in those with ACLF-1.

Inevitably, ACLF patients will have a longer and more complicated hospital stay after LT as has been reported thus far[9,22]. This was true in our center, where the latter required more days of ICU and hospital stay. Posttransplant complications by the Clavien-Dindo classification[15], were not different between ACLF and non-ACLF patients (CC and DC) in accordance with a systematic review[22]. Despite this encouraging finding, infectious complications were specifically more common in the

Figure 2 Kaplan-Meier analyses for survival after liver transplant between compensated cirrhosis, decompensated cirrhosis, and acute-on-chronic liver failure (A), and between acute-on-chronic liver failure grades (B). LT: Liver transplant; CC: Compensated cirrhosis; DC: Decompensated cirrhosis; ACLF: Acute-on-chronic liver failure.

former, occurring in over half of them, which is also in agreement with the study of Artru *et al*[9]. This may warrant a more directed antibiotic regimen in ACLF patients and physicians should be aware of this frequent outcome to promote a longer posttransplant survival. Interestingly, infections were equally prevalent in ACLF-3 patients according to our experience, which may be due to the similar pretransplant profile identified among severity grades including non-significant CLIF-C ACLF score differences. A good donor liver graft quality which was comparable between CC, DC and ACLF patients is another factor that may have contributed to an overall excellent outcome; however, optimal graft quality must not impede the decision for LT given its lesser impact compared to early transplantation, as has been recently reported[24]. Overall, our results encourage further transplantation in those with ACLF, considering that this procedure is the only effective treatment option and that survival was not significantly different compared to patients with less advanced cirrhosis, despite a more complicated posttransplant clinical course.

This study is limited by its retrospective nature and its single-center design; hence, findings must be compared to those of other authors. We report here the experience of one of the largest transplant centers in Mexico; however, demographics in this center will certainly vary with those seen in the rest of the country. This may explain the high proportion of autoimmune patients compared to HCV or alcoholic hepatitis. Regardless, during the five-year study period we have found a comparable proportion of ACLF patients who undergo LT, whose disease severity is markedly different from CC and DC patients. In spite of these differences, we observed a clear LT benefit as has been supported by

previous studies.

CONCLUSION

In conclusion, out of 235 liver transplantation procedures that were carried out between 2015 and 2019 in our center, 38.9% corresponded to ACLF patients. Although important clinical differences were found with non-ACLF patients (CC and DC) and among each other when divided by severity grade, posttransplant survival was uniformly excellent. A longer hospital stay and frequency of infectious complications is to be expected, however, this should not restrain the decision to transplant those with ACLF. Furthermore, our observations support benefit even in the most critically ill patients (ACLF-3), given comparable 1-year and 6-year survival rates.

ARTICLE HIGHLIGHTS

Research background

Currently, liver transplantation (LT) is the only definitive therapeutic measure for patients with cirrhosis, albeit with the implied risks including posttransplant complications and the long-term use of immunosuppressive drugs. However, these patients benefit in general from excellent posttransplant survival. The benefit and survival of this procedure for patients with more advanced cirrhosis such as those with acute-on-chronic liver failure (ACLF), still remains controversial, with some reports showing a clear benefit, while others reporting lower short and long-term survival after transplant.

Research motivation

In order to contribute to the current literature regarding the benefit of LT even in those with more severe diseases, we evaluate the immediate posttransplant outcomes and compared the posttransplant survival in patients stratified by disease severity.

Research objectives

To assess immediate posttransplant outcomes and compare the short (1 year) and long-term (6 years) posttransplant survival among cirrhotic patients stratified by disease severity.

Research methods

We included cirrhotic patients undergoing liver transplantation between 2015 and 2019 and categorized them into compensated cirrhosis (CC), decompensated cirrhosis (DC), and ACLF. ACLF was further divided into severity grades. Medical records of all patients were examined to extract demographic and clinical variables as well as laboratory data measured at the time of LT and in the posttransplant period. Our primary outcomes of interest were: the development of immediate posttransplant infectious complications, defined as any type of nosocomial-acquired, donor-derived or surgery-related infection presented during the immediate hospital stay following LT until the patients' discharge; the development of any type of immediate postoperative complication according to Clavien-Dindo classification; and post-LT survival at 1 year and 6 years. Posttransplant survival was analyzed with the Kaplan-Meier method and survival curves were compared with the log-rank test.

Research results

A total of 235 patients underwent liver transplantation (CC = 11, DC = 129 and ACLF = 95). Patients with ACLF had a significantly longer hospital stay and developed more infection-related complications. Posttransplant survival at 1- and 6-years was similar among groups. When ACLF patients were stratified according to ACLF grade, similar intensive care unit and hospital stay lengths were found, as well as comparable frequencies of overall and infectious posttransplant complications. Despite that, there was no survival difference between ACLF grades at 1 year and 6 years.

Research conclusions

Patients may benefit from liver transplantation regardless of the cirrhosis stage. Despite having a longer hospital stay and a higher frequency of infectious complications, ACLF patients have excellent and comparable 1 and 6-year survival rates.

Research perspectives

A multicenter study would be required to determine the value of LT in advanced disease patients such as those with ACLF according to disease etiology.
