Previous studies revealed that bone loss in CLD individuals could be explained by a strong link between systemic hyperproduction of inflammatory mediators and increased bone resorption (Figure 3)[21,32,67]. Most commonly, it is understood that tumor necrosis factor-α, interleukin (IL)-1, IL-6, IL-7, IL-11, IL-13, IL-15, and IL-17, produced by immune cells, could directly activate osteoclast precursors or display an indirect effect by osteoblasts[8,10,72]. Namely, increased secretion of receptor activator for nuclear factor kappa B ligand (RANKL), the disturbed ratio between RANKL and osteoprotegerin, matrix metalloproteinases activity, and cathepsin K are described as contributing factors in CLD-induced bone loss *via* increased bone resorption (Figure 3)[10,79-81]. The recent recommendation for therapy targeting RANKL advocates the importance of the RANK-RANKL-osteoprotegerin system in bone loss among CLD patients[20,82]. In addition, increased circulating macrophage colony-stimulating factor 1 in CLD patients could promote bone resorption due to its role in priming a larger number of monocytes to form osteoclasts in these patients[6].

Lastly, low vitamin D levels, unbalanced diet (low calcium and protein intake), malabsorption, disruption in the homeostasis of the intestinal microbiome, coupled with a variety of hormonal and metabolic disruptions (such as increased levels of parathyroid hormone, hypogonadism, and hypercorticism) were identified as factors that contribute to bone loss in CLD individuals[20,72,83]. Based on these data, new nutritional support guidelines were recently introduced by the European Association for the Study of the Liver[20,84]. However, given that bone changes in CLD patients are undoubtedly present, it is vital to further investigate more direct etiopathogenetic mechanisms involved in the relationship between liver and bone disorders.

CONCLUSION

Bone alterations are a common complication in patients with CLD, especially in those with liver cirrhosis. Over the previous period, numerous studies have contributed to understanding bone fragility in CLD patients. However, numerous ambiguities are still present due to the modest reliability of clinical diagnostic methods, which could lead clinicians to doubt whether or when it is necessary to start treating CLD-induced skeletal alterations. Thus, evaluating small-length structural bone properties could improve understanding of the multifactorial nature of bone fragility in CLD patients. All these data could set a base for developing a patient-specific diagnostic algorithm that will reliably predict bone strength based on the information available in a clinical context. Additionally, specific clinical guidelines for preventing, diagnosing, and treating skeletal disorders in patients with CLD need to be established in the near future.

Abstract

During the first wave of the pandemic, coronavirus disease 2019 (COVID-19) infection has been considered mainly as a pulmonary infection. However, different clinical and radiological manifestations were observed over time, including involvement of abdominal organs. Nowadays, the liver is considered one of the main affected abdominal organs. Hepatic involvement may be caused by either a direct damage by the virus or an indirect damage related to COVID-19 induced thrombosis or to the use of different drugs. After clinical assessment, radiology plays a key role in the evaluation of liver involvement. Ultrasonography (US), computed tomography (CT) and magnetic resonance imaging (MRI) may be used to evaluate liver involvement. US is widely available and it is

considered the first-line technique to assess liver involvement in COVID-19 infection, in particular liver steatosis and portal-vein thrombosis. CT and MRI are used as second- and third-line techniques, respectively, considering their higher sensitivity and specificity compared to US for assessment of both parenchyma and vascularization. This review aims to the spectrum of COVID-19 liver involvement and the most common imaging features of COVID-19 liver damage.

Key Words: Liver; Fatty liver; Hepatomegaly; Hepatic infarction; Liver diseases; Liver failure; Biliary tract diseases; COVID-19; SARS-CoV-2; Infection; X-Ray computed tomography; Magnetic resonance imaging; Ultrasonography; Adults; Pediatrics

Core Tip: Coronavirus disease 2019 (COVID-19) infection has an impact not only on lung involvement but also in other systems, in particular the gastrointestinal one, with a special focus on the liver. Hepatocytes express the receptor of angiotensin-converting enzyme which is the main door of the entrance of severe acute respiratory syndrome coronavirus 2. Consequently, different mechanisms can lead to different hepatic scenarios, such as hepatomegaly, steatosis, steatohepatitis, and drug-induced liver injury. As for lung involvement, the infection can lead to hepatic vascular involvement, especially portal vein thrombosis. Finally, it has been demonstrated a possible biliary involvement in COVID-19 patients.

INTRODUCTION

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection, named coronavirus disease 2019 (COVID-19), represents an epoch-making global healthcare crisis, with 603711760 confirmed cases and 6484136 deaths caused to date worldwide[1].

Although the lung represents the most affected organ, COVID-19 may present as a multiorgan disease. Clinical manifestations may vary from flu-like symptoms, such as fever, dry cough, myalgia, and fatigue, often coupled with hypo-/anosmia and ageusia[2-4], to more severe conditions with dyspnea and respiratory impairment requiring admission to the intensive care unit (ICU) and advanced respiratory assistance[5]. A severe course of the disease has been reported in 5%-22 % of COVID-19 patients[3,5].

In this scenario, we focused our attention on hepatic manifestations of COVID-19 infection. Hepatic involvement in patients with COVID-19 infection is not negligible. Liver damage can occur in different ways, ranging from hepatomegaly, acute hepatitis, steatosis and steatohepatitis, portal vein thrombosis (PVT) and liver infarction, biliary and gallbladder involvement, up to drug-induced liver injury (DILI), with chronic liver disease that needs further long-term studies to be understood (Figure 1).

In this review, we aim to describe the spectrum of COVID-19 liver involvement and the most common imaging features of COVID-19 liver damage with a descriptive correlation to the underlying pathogenesis.

IMAGING TECHNIQUES

The standard radiological approach for liver assessment (*i.e.* anatomy, focal liver lesions, or diffuse diseases) has been widely described and does acknowledge the use of ultrasound (US), computed tomography (CT), and magnetic resonance imaging (MRI). Technical advances in liver imaging have also been conducted over the last decades, with lots of research on quantitative and functional assessments in different liver pathologies[6].

US

Brightness-mode (B-mode) transabdominal US generally represents the first-line approach in patients with suspected liver disease[7]. US is widely available, non-invasive, low cost, safe, ionizing radiation-free[6] and can be performed at the bedside, particularly in ICU or isolated patients. Anatomical and

vascular imaging and lesion detection are feasible, although limited by the field of view and are dependent on operator experience[7].

During the last decades, different US developments have been introduced, including elastography, contrast-enhanced US (CEUS), and novel doppler techniques[6-9].

Moreover, an advanced multiparametric US approach for the evaluation of the liver could be an option, particularly for long-term follow-up of COVID-19 patients. The multiparametric US includes elastography, share wave dispersion, and attenuation imaging. The evaluation by the 2D-shear wave elastography technique allows quantification of the increase in liver stiffness related to the evolution toward fibrosis, but it can be altered in the inflammatory early stages (*e.g.*, steatohepatitis)[10]. Shear-wave dispersion is a measure of liver viscosity that is changed during inflammatory processes in the liver. Finally, hepatic attenuation imaging is a useful tool for quantifying steatosis.

Elastography enables the assessment of liver fibrosis[6]. Usually, a quantitative assessment of liver stiffness is obtained by applying an external force by means either of a US-induced focused impulse (point shear wave elastography) or a mechanically induced impulse (transient elastography)[7]. More recent developments of US elastography include a volumetric assessment of liver stiffness and its real-time variations. Clinical use of US elastography is mainly limited by cutoff values for fibrosis staging that vary across US systems from different vendors[6].

CEUS is accepted as a second-line imaging modality for the characterization of focal liver lesions after inconclusive baseline US, and its cost-effectiveness is higher compared to CT or MRI[6,7,11]. CEUS interpretation is similar to CT and MRI, relying on the similar post-contrast phases (arterial, portal-venous, delayed), vascular architecture, and phase-specific enhancement of the lesion compared with the adjacent liver parenchyma[7]. CEUS is useful for lesion detection and characterization in several clinical settings, without the use of ionizing radiations and with higher temporal resolution compared to CT or MRI[6]. It can be useful in non-oncologic, non-cirrhotic patients[6,9], for the assessment of incidental focal lesions, in cirrhotic patients, allowing characterization of contrast enhancement patterns of hepatocellular carcinoma (HCC) with good sensitivity and specificity[6], and in oncologic patients, providing higher sensitivity compared to the standard US for liver metastases detection and indeterminate CT or MRI lesions characterization[12]. CEUS can also be used to guide, in real-time, both focal lesions procedures[7,8] and locoregional ablative therapies, as well as for treatment response assessment[13,14]. According to the latest guidelines[14], US contrast agents can be safely administered in various applications, with minimal risks to patients. The reported rate of anaphylactoid-type reactions is extremely rare (0.014%).

Among novel third-generation doppler developments, US manufacturers have introduced techniques such as superb microvascular imaging (SMI) that has improved the sensitivity and accuracy of Doppler US in the assessment of hepatic vascular anatomy[9] and the detection of liver tumors vascularity with a safe, inexpensive, and readily available modality[6]. SMI is based on an adaptive algorithm that separates low flow signals from overlaying tissue motion artifacts; thereby SMI allows visualization of microscopic vessels (either native or within lesions), with no need for contrast agents injection[9].

CT

CT represents the mainstay technique for liver imaging, with the majority of acquisitions performed with multiphase acquisition protocols, and standardized assessment based on size and density measurements. Due to its wide availability, CT is generally preferred to MRI in daily clinical practice, despite its overall lower sensitivity. Moreover, reproducibility and high temporal and spatial resolutions allow its employment in both standard and emergency settings[6,15-17].

Contrast-enhanced CT allows the characterization of liver lesions deemed indeterminate on US in non-oncologic and non-cirrhotic patients. In cirrhosis, while the US remains the standard technique for follow-up, contrast-enhanced CT and MRI are the currently recommended techniques for the characterization of US-detected nodules, diagnosis and post-treatment follow-up of HCC[6,18]. In oncologic patients, CT is generally used for staging and follow-up. Accurate timing of image acquisition during the various dynamic phases is critical to enable a correct determination of liver lesion characteristics and enhancement features[11]. In these scenarios, CT acquired during the portal-venous phase is the most common performed study in oncologic patients[6], but its main limitation is the detection and characterization of small hypoattenuating lesions and lesion detection in the background of liver steatosis[6,19]. On the other hand, multiphase scans (arterial, portal-venous, and delayed phases) are generally used in cirrhotic patients, for focal liver lesions characterization, and in trauma patients[6,8].

More advanced and emerging techniques include perfusion CT, dual-energy CT (DECT) and photon-counting detector CT (PCD-CT)[6,17].

DECT is based on CT data acquisition by using X-rays generated at two different energy spectra; therefore, allowing for superior materials discrimination and characterization. Images are obtained either with dual-source, ultra-fast kV switching, or sandwich detector[6,16]. Then, DECT data post-processing generates several types of images: monochromatic image reconstructions, useful to improve iodine contrast visualization; attenuation maps of different elements according to their atomic number, including iodine, calcium, and water[6]. Moreover, the possibility of generating virtual unenhanced (VUE) images may help reduce radiation dose exposure. DECT improves the delineation of hypo- and hypervascular liver lesions by increasing the lesion to parenchyma contrast. Given the possibility of

material decomposition, DECT can also allow distinguishing contrast from calcifications, and noninvasively quantifying fat, iron, and other moieties, compensating for the high cost and examination time length of MRI and invasiveness of biopsy[6,16,17]. However, DECT is affected by some shortcomings, including technical limitations (limited field-of-view, reduced spectral separation depending on vendor or scanner) and software challenges (lack of enough research comparing vendors and scanners' variability on VUE and iodine attenuation values)[16].

PCD-CT is the most recent promising technique but nowadays is still mainly limited to preclinical or small *in vivo* studies in volunteers. More clinical and validation research is therefore needed over a longer time[6].

MRI

MRI is fundamental in the workup of patients with liver disease[6,17,20] and has been addressed as the preferred imaging modality for the characterization of equivocal focal lesions detected by other imaging modalities[17]. Along with appropriate clinical information, MRI can also allow a definitive diagnosis, avoiding in most cases invasive procedures such as biopsy[21].

A properly dedicated MRI liver protocol requires it to be short, comprehensive, standardized, and reproducible[6,17,21]. Pre-contrast MRI, given its higher contrast resolution compared to CT, provides information about tissue and lesion composition (*i.e.* solid or liquid; iron, fat, glycogen, blood products) and lesions cellularity, either neoplastic or inflammatory[6,11,17,22]. Diffusion-weighted imaging (DWI) has been reported to improve the detection and characterization of focal liver lesions, also allowing differentiation of cysts from solid masses. Moreover, by combining hyperintensity on high b-value DWI (hypercellular lesions) with dynamic multiphasic studies, improvement in lesions detection and characterization (in particular for tumors < 2 cm) can be achieved[11].

Contrast-enhanced MRI represents a relevant component of any liver MRI protocol. It provides reliable information about focal lesions characterization, vascular and biliary anatomy, and more recently organ function[17,20,21]. Both gadolinium-based extracellular (ECA) and hepatobiliary (HBA) contrast agents can be used for multiphase imaging[6,17,21]. Morphologic and vascular-related information are obtained with ECA and HBA through the dynamic study[21].

Moreover, HBA provides the ability to acquire images in the hepatobiliary phase (HBP), offering information about hepatocytes uptake and excretion in the biliary system[6,11,20,21]. Therefore, HBP may provide functional information[21]. Indeed, lesions, or abnormalities without hepatocytes or with non-functioning hepatocytes, appear as hypointense compared to the surrounding liver parenchyma [20]. Among reported HBA advantages, it is worth mentioning higher lesion conspicuity with increased sensitivity in lesion detection, and improved lesion characterization with increased ability in the differential diagnosis.

One of the most used advanced MRI techniques useful to detect and characterize focal or diffuse liver disease is DWI. Highly cellular tissues or those with cellular swelling exhibit lower diffusion coefficients, and these aspects can be useful for the evaluation of liver diseases[22].

The evaluation of the biliary tree can be easily made using highly weighted T2 sequences in different planes. In this setting, magnetic resonance cholangiopancreatography (MRCP) is nowadays considered the reference standard for noninvasive biliary evaluation. Thanks to the improvement of MRI techniques, it is now possible to acquire 3D images that can be reformatted in every plane of space by post-processing techniques[23].

LIVER DISEASE INVOLVEMENT

COVID-19 liver injury is defined as any liver involvement that occurs during the course of COVID-19, whether there is a known history of liver disease or not[24]. The presence of liver damage from a laboratory point of view is very common: an increase in liver enzymes is described in around 40% of patients[24], it is greater with severe COVID-19 and at the same time a predictor of adverse events[25,26].

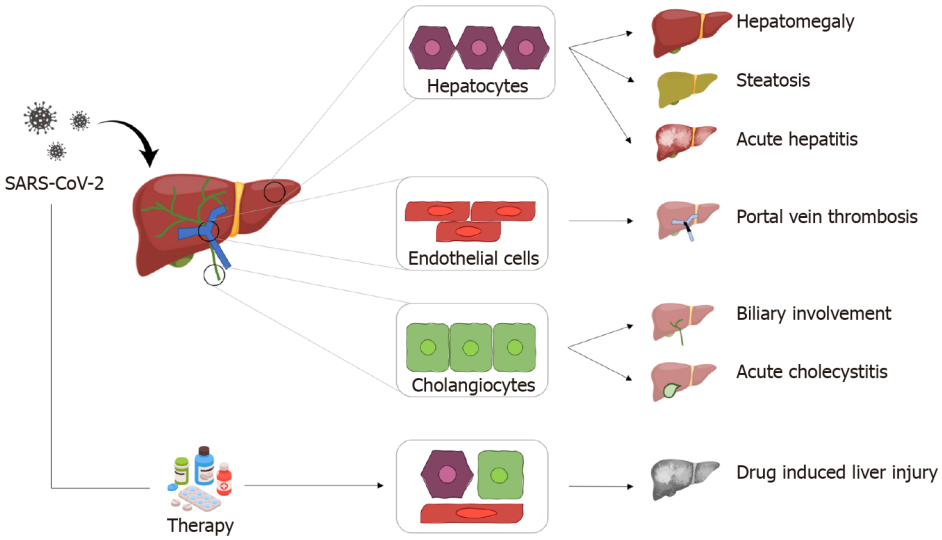
SARS-CoV-2 primarily infects respiratory epithelial cells *via* angiotensin-converting enzyme 2 (ACE2). ACE2 is also expressed at high levels in the endothelium layer of tiny blood arteries, cholangiocytes and in hepatocytes. Furthermore, the SARS-CoV-2 virus may use the gut-liver route *via* the hepatic reticular system to reach the liver[25]. Finally, other organ systems and drugs have a significant influence on the liver. As a result, the causative mechanisms of liver damage in COVID-19 infection are many, including direct cytotoxicity caused by active SARS-CoV-2 replication, immune-mediated liver injury, vascular impairment caused by coagulopathy, endothelium, or cardiac congestion, hypoxic changes caused by respiratory failure, DILI, and exacerbation of the underlying chronic liver disease[25] (Figure 1 and Table 1).

Hepatomegaly and steatosis

COVID-19 causes twice as much liver damage at the cellular level. First, hepatocellular damage occurs, resulting in mild steatosis, lobular and portal inflammation, and areas of apoptosis and necrosis. This

Table 1 Summary of the most common findings in liver involvement due to coronavirus disease 2019 infection

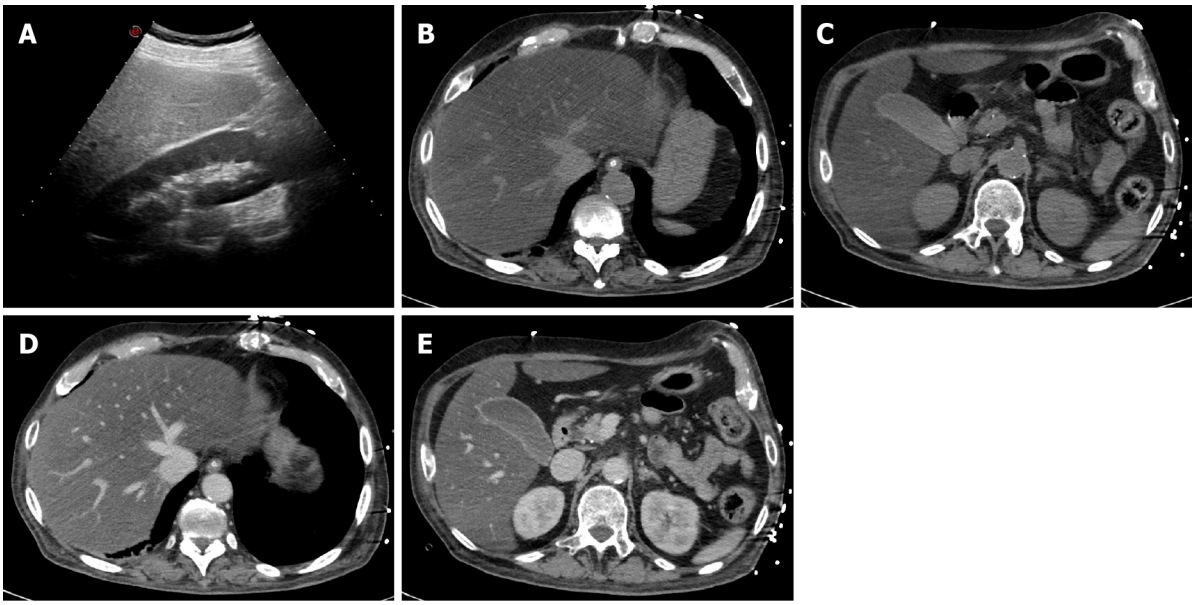
Liver involvement	Ultrasound	Computed tomography	Magnetic resonance
Hepatomegaly	Qualitative criteria: The right lobe extends inferiorly over the lower pole of the right kidney; Rounding of the hepatic inferior border Quantitative criterion: Length of the right liver lobe > 16.5 cm		
Steatosis	Hyperechoic liver in comparison to the spleen or neighboring kidney; Absence of the normal echogenic walls of the portal and hepatic veins; Poor visualization of deep portions of the liver	Unenhanced: Relative hypoattenuation: liver attenuation more than 10 HU less than that of spleen; Absolute low attenuation: liver attenuation lower than 40 HU; C+: Does not add information	IP/OOP imaging: Signal drop out on OOP; T2W: Isointense; T1: Isointense; T1 C+: Does not add significant information
Acute hepatitis	Hepatomegaly; Reduced echogenicity; Steatosis; Peri-portal edema; Reduced Doppler signal in the hepatic artery; Thickening of the gallbladder wall	Hepatomegaly; Homogeneous/heterogeneous hypoattenuation (steatosis); Peri-portal edema; Thickening of the gallbladder wall; Periportal/hepatoduodenal enlarged nodes	IP/OOP imaging: Steatosis can be present; T2W: Diffuse mild increase in signal; Increased signal around the portal system (periportal edema); T1 C+: Periportal enhancement; Thickening of the gallbladder wall; Hilar enlarged nodes
DILI	Nonspecific findings: Hepatomegaly, steatosis, and peri-portal edema can be present		
Portal vein thrombosis	Absent or reduced flow in the portal vein on Color Doppler; Presence of heterogeneous material (focal or diffuse) in the portal vein lumen	Unenhanced: Higher attenuation into the portal vein lumen; Dilation of the portal trunk; C+: Hypoattenuating material into the lumen; Enhancement of vein walls	T2W: Iso- to hyperintense clot according to the phase (acute or subacute); T1: Hyperintense clot; T1 C+: Hypointense material into the lumen; Enhancement of vein walls
Biliary involvement	Focal or diffuse bile duct dilatation (with/without intrahepatic or extrahepatic stones)	Unenhanced: Does not add information; C+: Focal or diffuse bile duct dilatation (with/without intrahepatic or extrahepatic stones); Heterogeneous enhancement of parenchyma; Peri-portal edema	MRCP: Focal or diffuse bile duct dilatation with/without intrahepatic or extrahepatic stones; Stone(s) in the biliary lumen (hypointense); Multifocal biliary strictures alternated with dilated tracts (beaded appearance); T2W: Hypointense stone; Increased T2 signal around the portal system (periportal edema); T1: Hyperintense stone; T1 C+: Heterogeneous enhancement of peri-biliary parenchyma
Acute cholecystitis	Gallbladder wall thickening (> 3 mm); Pericholecystic fluid; Gallbladder distension; Possible sludge	Unenhanced: Gallbladder distension; Possible sludge (hyperattenuating); Pericholecystic fluid; C+: Gallbladder wall thickening (> 3 mm); Inhomogeneous gallbladder wall; Mural or mucosal hyperenhancement	MRCP: May show an impacted stone in the gallbladder neck or cystic duct; T2W: Gallbladder wall thickening (> 3 mm); Inhomogeneous gallbladder wall due to edema; T1: Sludge (hyperattenuating); T1 C+: Inhomogeneous gallbladder wall; Mural or mucosal hyperenhancement



HU: Hounsfield unit; IP: In-phase; OOP: Out-of-phase; C+: Contrast-enhanced; DILI: Drug-induced liver injury; MRCP: Magnetic resonance cholangiopancreatography.

type of damage raises aspartate aminotransferase (AST) and alanine transaminase (ALT) levels. Later on, the damage is direct to cholangiocytes, with bile duct damage and increase in gamma-glutamyl transferase (GGT) and bilirubin[27].

When there is a clinical suspicion of liver involvement in COVID-19, bedside US is the first imaging technique used in the diagnostic workup. A quick and targeted bedside US may be critical in referring selected patients to second-level imaging techniques, to reduce unnecessary exams and diagnostic delays. US can detect morphological or structural changes in the liver: the most encountered findings in COVID-19 patients are hepatomegaly[28,29] and steatosis[29,30].



According to Abdelmohsen *et al*[28], the most common morphological change in the liver in critically ill COVID-19 patients is hepatomegaly (about 55% of patients), which is also consistent with autopsies in COVID-19 patients[29-31]. Spogis *et al*[29] found hepatomegaly associated with gallbladder wall thickening and decreased echogenicity (*i.e.* signs of acute hepatitis) in 33% of COVID-19 patients with elevated liver cytolysis indices (> 10-fold). Hepatomegaly is usually identified subjectively during imaging: the "qualitative criteria" include the inferior extension of the right lobe to the lower pole of the right kidney and the rounding of the hepatic inferior border. Otherwise, the quantitative criteria are based on the length of the right liver lobe, with a cutoff of 16.5 cm[31].

On the other side, the most common liver structural change associated with COVID-19 is the presence of hepatic steatosis[28,29] (Figure 2). Coagulation activation can produce hepatic steatosis, and this could be a unique mechanism that leads to both thrombosis and steatosis that are common findings in COVID-19 patients[32]. US B-mode is the most used technique for diagnosing and classifying hepatic steatosis[33], particularly in the moderate or severely affected liver. It has an overall sensitivity and specificity of 85% and 93%, respectively[33]. However, the detection of a moderate degree of steatosis remains poor, with about 60% sensitivity[34]. B-mode US imaging is mostly used to analyze the liver

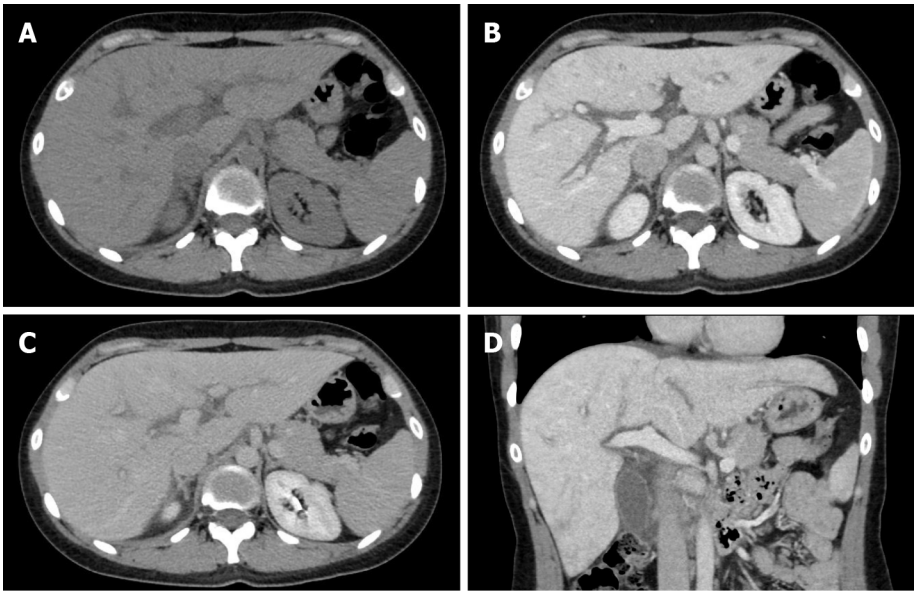
Figure 2 A 45-year-old woman with coronavirus disease 2019 infection underwent abdominal ultrasonography due to elevated liver enzymes. A: As shown on ultrasonography, the liver is hyperechoic in comparison to the renal parenchyma, suggesting marked steatosis; B-E: The patient underwent contrast-enhanced computed tomography; B and C: On unenhanced images, the liver is diffusely hypoattenuating while its main vessels (*i.e.* portal vein and hepatic veins) appear brighter than the parenchyma due to a marked hepatic fatty infiltration; D and E: On post-contrast images, the liver is homogeneous without any focal lesion; C and E: The gallbladder is filled by sludge, with normal wall thickness. Finally, the combination of clinical and radiological findings allowed the final diagnosis of steatohepatitis.

qualitatively, searching for characteristic markers of steatosis (*i.e.* hyperechoic liver in comparison to the spleen or neighboring kidney)[29]. US findings can be confirmed on abdominal CT. According to Lei *et al*[35], the most common CT abnormalities in COVID-19 patients include diffuse hypoattenuation of the liver (26%) – more common in severe patients (59%) – and the CT-quantified liver/spleen attenuation that can predict prognosis in COVID-19 patients[35,36]. Furthermore, because the liver is partially included in every chest CT, liver data from chest CT scans performed in many COVID-19 patients can be easily retrieved.

Using a multiparametric US approach, Radzina *et al*[30] evaluated 90 patients affected with COVID-19 in the previous 3-9 mo demonstrating how liver elasticity, viscosity, and steatosis are altered after COVID-19 and that these alterations well correlate with liver enzyme abnormalities, even better than CT or MRI findings.

Other consequences of chronic liver disease, such as nonalcoholic fatty liver disease (NAFLD), must be considered in addition to COVID-19-induced liver damage[37]. Obesity and other components of metabolic syndrome have been linked to COVID-19 severity. The impact of NAFLD in COVID-19 patients is controversial in the literature[37]. In a meta-analysis of 1851 patients, Singh *et al*[38] found that, while there was an increase in the course severity of COVID-19 with a 2.60 odds ratio (OR), the adjusted OR (aOR) for mortality risk was 1.01; however, these data should be considered with caution due to the significant heterogeneity among the included studies. Interestingly, Ghoneim *et al*[39] analyzed 8885 patients with common comorbidities known to be linked with COVID-19 and found out that the cumulative incidence of disease was higher if metabolic syndrome was the primary diagnosis (OR 7.0). COVID-19 patients who were African Americans (aOR 7.45), hypertensive (aOR 2.53), obese (aOR 2.20), diabetic (aOR 1.41), hyperlipidemic (aOR 1.70) or had non-alcoholic steatohepatitis (NASH) (aOR 4.93) had higher aORs. These findings demonstrated that, among all concomitant metabolic disorders, NASH had the strongest connection with COVID-19. In support of these data, Roca-Ferná ndez *et al*[40] analyzed 41791 people who underwent MRI for assessment of liver fat, liver fibro-inflammatory disease, and liver iron with proton density fat fraction calculation before February 2020 and found that people with fatty liver (> 10%) had a higher likelihood of testing positive (OR 1.35), and people with obesity and fatty liver had a 5.14 times higher risk of hospitalization. Obese people who did not have a fatty liver can have an increased risk (OR 1.75). According to the findings, obese people with fatty liver disease are at a higher risk of COVID-19 infection and hospitalization.

To summarize, COVID-19 patients have a remarkable risk of liver damage, with the main morphologic and structural changes being hepatomegaly and steatosis, which have a significant impact on patients' prognosis and can be easily studied with US (Table 1). Epidemiologically, people with NAFLD/NASH appear to be at a higher risk of severe COVID-19 infection. However, it is unclear how much of this rise is due to hepatic steatosis or the presence of overlapping risk factors and comorbidities.



Acute hepatitis in COVID-19

Liver test abnormalities are frequently encountered in COVID-19 patients at admission, and their increase is associated with the severity of the disease[41,42]. In the majority of cases, COVID-19-induced hepatitis occurs as benign new transient hepatitis with gradual onset, elevated AST and ALT levels, and lack of any radiological changes[29,42,43]. Occasionally, COVID-19-induced hepatitis may occur in otherwise asymptomatic patients as the sole manifestation of COVID-19 infection[44]. Liver damage in COVID-19-induced hepatitis may be the result of viral infection of hepatocytes or cholangiocytes, hypercoagulability with both microangiopathy and local thrombus formation, immune-mediated damage, systemic inflammation, or hypoxic hepatitis due to the respiratory disease[45-49]. Regarding the first mechanism, the virus enters the hepatocytes, and then viral replication results in rupture of cells, generating elevated serum liver enzymes[48,50]. Thrombotic complications in COVID-19 patients are likely to occur due to a pro-coagulant effect or a progressive endothelial thrombo-inflammatory syndrome[49]. Interestingly, in a systematic review of pathology studies, hemodynamic compromise and thromboembolic disease in the liver were demonstrated in 48.3% and 39.4%, respectively, while liver microthrombi were not identified[48].

Radiological hallmarks of acute hepatitis in COVID-19 patients are encountered in approximately 8% of patients with mild-to-moderated liver test abnormalities, and the occurrence increases in patients with severe elevation of liver enzymes. Radiological hallmarks of COVID-19-induced hepatitis – particularly in the most severe cases – include thickening of the gallbladder wall, hepatomegaly, reduced echogenicity of the liver on the US or homogeneous/heterogeneous liver hypoattenuation on CT, and reduced Doppler signal in the hepatic artery[29,35,51]. Liver hypoattenuation is significantly more common in the most severe cases, with the decrease of the liver to spleen CT attenuation ratio being significantly correlated with the severity of pulmonary lesions and the overall COVID-19 severity[35] (Figure 3). A pathology-radiology correlation study demonstrated that the histological features in patients with sonographic changes included macrophage activation, centroacinar necrosis, granulocytic and histiocytic infiltrate, endothelial damage, and severe cholestasis[29,52]. Among these, macrophage activation was particularly interesting as it may represent the histopathologic correlate of a hyperinflammatory syndrome[29]. In a case of COVID-19-induced hepatitis being the sole symptom and without any other cause for liver damage, pathology demonstrated periportal and interstitial inflammation with predominantly lymphocytes, rare plasma cells, and neutrophils, hepatocyte rosette formation, apoptotic bodies, centrilobular congestion, and mildly increased portal and pericellular fibrosis[52] (Table 1).

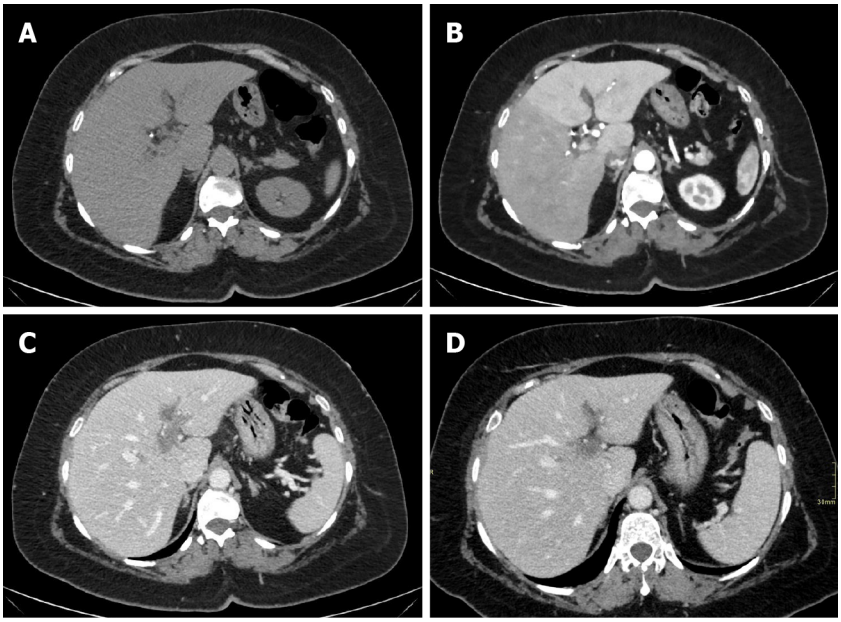
DILI

DILI is a liver dysfunction caused by drugs used as a treatment for COVID-19 disease. Therapeutic choices for COVID-19 have rapidly expanded and changed over time with the increased understanding of the virus and the disease[53]. The various therapeutic treatments used over time included antiviral drugs, antibiotics, antimalarials, immunomodulator agents, antipyretic agents, adjunctive treatments, and several investigational treatments including convalescent plasma administration from COVID-19 recovered patients[54]. Different studies reported that liver injury in patients with COVID-19 infection

DOI: 10.3748/wjg.v29.i5.834 **Copyright** ©The Author(s) 2023.

Figure 3 A 33-year-old woman with coronavirus disease 2019 infection underwent contrast-enhanced computed tomography due to a suspicion of portal vein thrombosis. A: On unenhanced phase liver is enlarged, homogeneous and without any focal lesion; B: On the portal venous phase the liver enhancement is slight inhomogeneous associated with peri-portal edema, a typical finding of acute hepatitis; C and D: These aspects can be clearly observed also on the coronal reconstruction acquired on the portal venous phase (D) and the delayed phase (C).

could be a direct consequence of the administration of different drugs, such as antivirals and monoclonal antibodies, with most patients showing elevation of AST and ALT levels, and some also of bilirubin, lactate dehydrogenase, and C-reactive protein[55-59]. However, in most cases, elevated levels of AST and ALT do not lead to severe liver injury and the outcome is favorable[59].



The mechanisms underlying DILI in COVID-19 patients are not yet fully understood and they seem to vary depending on drug type[59,60]. A hepatocellular injury has been more often reported than cholestatic or mixed injury in COVID-19 patients with DILI[59]. On one hand, the drug-induced injury may lead to microvesicular steatosis as a result of drug interference with β-oxidation of fatty acids, mitochondrial respiration, or both which leads to the accumulation of non-esterified fatty acids which are subsequently converted into triglycerides[61,62]. On the other hand, there could be a downregulation of cytochromes p450 or CYPs family enzymes involved in oxidative biotransformation of many drugs, thus altering the metabolism of several COVID-19 drugs[60,61]. DILI could be enhanced by the production of reactive oxygen species by inflammatory cells, in addition to immune mechanisms shown in a small subset of DILI cases[63,64].

The radiological manifestations of DILI in COVID-19 patients are non-specific. One of the most frequent radiological signs of DILI is hepatic steatosis[65]. Hepatic steatosis is seen in the US as a bright liver echo pattern with the markedly increased liver to kidney contrast, and on CT as a reduction of liver attenuation below 40 UH as an absolute value or liver attenuation reduced of more than 10 HU compared to the spleen[66]. MRI is the gold standard for detection and quantification of liver steatosis: new quantitative techniques are now available, and others are still being investigated in US and CT[6]. DILI may occasionally lead to acute hepatitis and, therefore, radiological signs in these cases include hepatomegaly with decreased parenchymal enhancement, periportal edema, gallbladder wall thickening, and ascites[29]. However, the role of traditional and new quantitative techniques for assessing hepatic steatosis and liver injury occurring as a manifestation of DILI in COVID-19 is poorly investigated, and it seems quite difficult to analyze: COVID-19 patients may have more commonly hepatic steatosis and liver injury not related to DILI and there are not specific signs allowing us to differentiate between steatosis and liver injury caused by drugs or by other causes (*e.g.*, steatohepatitis, viral infection)[30] (Table 1).

PVT

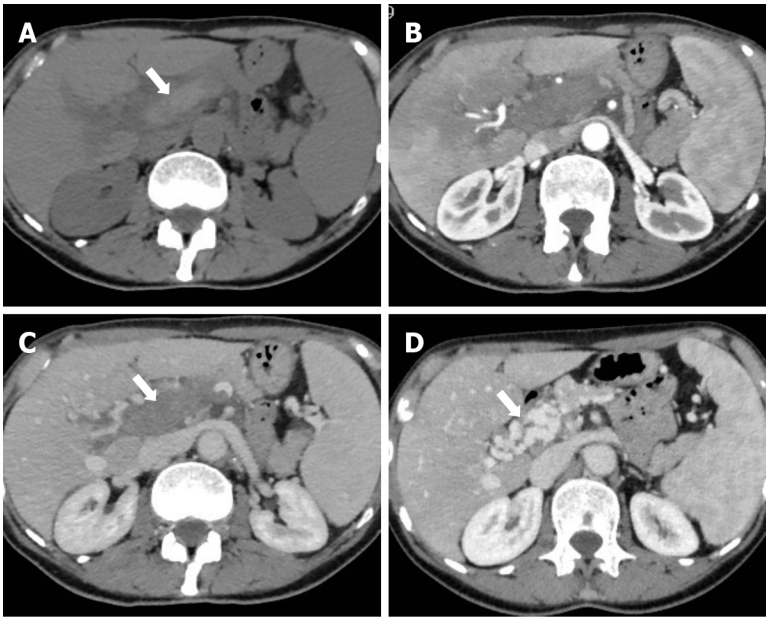
The pandemic taught us the great impact of COVID-19 infection on the development of coagulation disorders, especially disseminated intravascular coagulation-like massive intravascular clot formation [67]. In this setting, it has been partially explained that the cytokines' cascade and endothelial damage can lead to the development of intravascular coagulation in the whole body, as reported by Cui *et al*[68]: critically ill patients showed a significantly higher incidence of thrombosis, up to 25%.

One of the most important visceral districts to consider in a setting of an altered vascular and endothelial environment is the portal vein, considering its importance in blood drainage from the

DOI: 10.3748/wjg.v29.i5.834 **Copyright** ©The Author(s) 2023.

Figure 4 A 40-year-old men with coronavirus disease 2019 infection and marked respiratory symptoms, underwent contrast-enhanced computed tomography due to elevated liver and biliary enzymes. A and B: On unenhanced phase (A) the liver is within normal limits. After the injection of contrast agent, on arterial phase (B) liver parenchyma shows inhomogeneous enhancement, with hypervascularization of the left liver lobe, as in case of transient hepatic attenuation differences; C: On the portal venous phase, the arterial hypervascularization fades to homogeneous enhancement and diffuse thrombosis of the left branch of the portal vein is demonstrated; D: After 6 mo the patient underwent contrast-enhanced computed tomography that demonstrated persistent portal vein thrombosis without venous collaterals.

gastrointestinal tract.



In non-cirrhotic patients, acute PVT may present with pain, even though the majority are found incidentally[69] (Figure 4). Different causes have been demonstrated as key roles in the development of PVT, with infection and inflammation being the most common. Rajani *et al*[70], reported that gastrointestinal inflammation accounts for about 14% of all causes of PVT. As for other viral and bacterial infections, COVID-19 can manifest with different gastrointestinal manifestations, including diarrhea, nausea, vomiting, and abdominal pain, which typically present after the respiratory symptoms (9 d *vs* 7.3 d)[71].

Even if it is well known that the inflammatory environment can lead to the development of micro- and macro-thrombosis, the current literature has not been focused on the impact of PVT in COVID-19 patients. In fact, by searching medical databases, few studies were published regarding this topic, the majority being case reports.

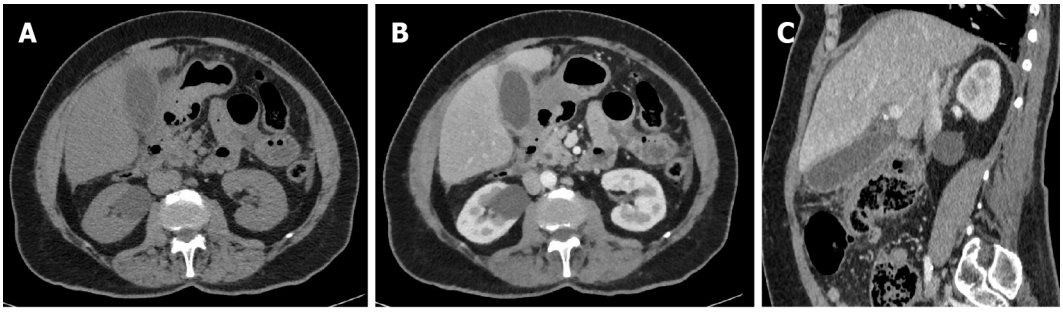
A meta-analysis published in 2020[72] included 18 studies and reported that all COVID-19 patients were over 15-years-old, and the majority were male (62%). The authors found a pooled prevalence of vascular thrombosis of 29.4%, one of the most representative signs in the autoptic series. Similarly, Kheyrandish *et al*[73] (2021) reviewed all cases of PVT published in the literature, confirming the higher incidence in males during infection and in females after vaccination. Thrombocytopenia was the most common laboratory finding, followed by high D-Dimer values, and abnormal coagulation tests.

Radiology plays a key role in the diagnosis of PVT. The first imaging technique useful to determine portal vein patency is US, which can be performed at bedside, especially in critically ill or isolated patients. Acute PVT can manifest as the presence of heterogenous material in the portal vein lumen, which can be partial or complete[74]. Occasionally, the portal vein thrombus can be iso- or hypoechoic on US; in this setting, the use of color doppler can support the final diagnosis, showing the lack of flow in all or some parts of the portal vein lumen[75]. Nowadays, CT is the reference standard imaging technique to evaluate PVT and its extension, both intra-hepatic and into the whole mesenteric venous system. On the unenhanced images, a higher attenuation into the portal vein lumen, due to the fresh clot, can be appreciated. The injection of an intravenous iodinated contrast agent is necessary to evaluate the lack of enhancement in the lumen, more evident in the portal-venous phase. Liver enhancement can be inhomogeneous due to areas of hypervascularization during the arterial phase, then becoming homogenous in the portal-venous and delayed phases[74]. The portal trunk can be dilated, and, sometimes, it is possible to appreciate the enhancement of vein walls due to inflammatory response[76].

Due to the different imaging spectrum of COVID-19 infection, patients may undergo MRI of the upper abdomen. In these settings, acute PVT is represented by an inhomogeneous intraluminal area(s) both on T1- and T2-weighted sequences. On T1-weighted sequences, PVT can manifest as hyperintense to the muscle if it is recent (acute), while isointense if subacute. On T2-weighted sequences PVT can

DOI: 10.3748/wjg.v29.i5.834 **Copyright** ©The Author(s) 2023.

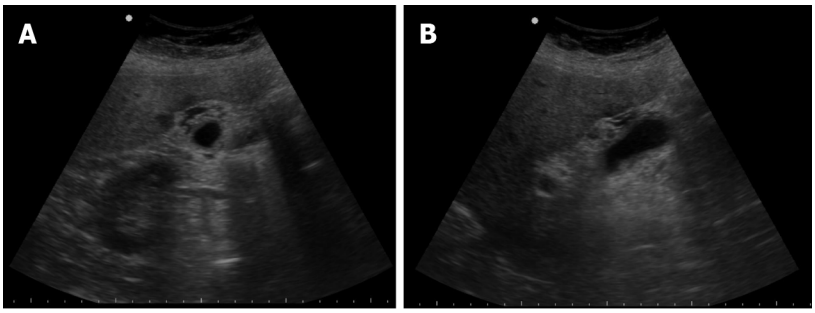
Figure 5 A 62-year-old woman with acute portal vein thrombosis after coronavirus disease 2019 infection. A-C: Computed tomography (CT) images show acute thrombosis with hyperintense thrombus on unenhanced phase (A, arrow), heterogeneous enhancement of the liver parenchyma on hepatic arterial phase (B), and complete portal vein thrombosis on portal venous phase (C, arrow); D: Contrast-enhanced CT at 6-mo follow-up demonstrates chronic findings of portal cavernoma with multiple collateral vessels at the hepatic hilum (arrow).



manifest with different grades of hyperintense signal according to the phase (acute or subacute). If MRI is performed also after intravenous injection of contrast agents, the appearance is superimposable to the above-mentioned CT scan (Table 1).

If the PVT is not treated, cavernous transformation can occur (Figure 5): the main portal venous trunk is not appreciable and the development of periportal venous collaterals can help the drainage of venous flow from the gastrointestinal tract to the liver. Considering that chronic PVT is not reported in any patients with COVID19 infection, its findings are out of the scope of the present review.

Biliary and gallbladder involvement



The development of biliary injury in patients with COVID-19 represents an important complication, associated with poor prognosis and clinical outcome[77]. Biliary involvement in patients with COVID-19 often demonstrates clinical and biochemical features similar to sclerosing cholangitis in critically ill patients (SSC-CIP), manifesting as increased cholestasis indexes (GGT and total bilirubin) in patients with prolonged admission to the ICU and no history of biliary or liver disease nor signs of mechanical obstruction[77,78]. Severe cholestasis has been reported in up to 27% of patients with COVID-19 admitted to the ICU[79]. The mechanism of the cholestatic injury in patients with COVID-19 is not completely understood and it is likely multifactorial, with direct viral damage due to the expression of ACE2 on cholangiocytes, immune or inflammatory damage associated with liver injury, toxic bile injury, and ischemic or hypoxic injury of the biliary epithelium[80]. Cholangiopathy has also been observed after chronic exposure to ketamine, a general anesthetic used for sedation of patients with COVID-19 and acute respiratory distress syndrome[81]. The prognosis of patients with SSC-CIP is poor, with mortality in up to 50% of cases due to the development of biliary complications and worsening of liver function[82]. Particularly, patients with pre-existing chronic liver disease have an increased risk of SSC-CIP and higher mortality during COVID-19 infection[83].

Imaging is important to guide the diagnosis of cholangiopathy in patients with COVID-19 in conjunction with laboratory markers and to exclude other causes of biliary obstruction. US and CT can be performed as first-line imaging examinations and can reveal the presence of bile duct dilatation with intrahepatic stones[84] (Figures 6 and 7). Heterogeneous enhancement of the liver parenchyma with periportal edema can also be observed on contrast-enhanced CT[85]. MRI with MRCP should be performed in patients with persistent cholestasis and elevated liver function tests to assess the extension of biliary damage. MRCP can demonstrate features of secondary sclerosing cholangitis characterized by multifocal biliary strictures alternated with dilated tracts, with a "beaded" appearance[79,85]. Biliary strictures can be complicated by biliary cast, presenting as intraductal filling detects on MRCP and T2-weighted images with corresponding linear hyperintensity on unenhanced T1W images. In a recent study by Ghafoor *et al*[86], MRCP findings associated with COVID-19 cholangiopathy included intrahepatic bile duct strictures associated with upstream dilatation in 58% of patients and the presence of biliary casts in 11.8% of cases (Figure 8). Peribiliary changes characterized by hyperintensity on T2W

Figure 7 A 53-year-old woman with coronavirus disease 2019 infection and markedly elevated biliary enzymes and C reactive protein levels. A and B: Ultrasonography demonstrates diffuse thickening of the gallbladder wall, associated with multiple small anechoic components into the walls, as in case of intramural abscesses. No stone is appreciated. The final diagnosis was acute acalculous cholecystitis.

DOI: 10.3748/wjg.v29.i5.834 **Copyright** ©The Author(s) 2023.

Figure 8 A 44-year-old woman with coronavirus disease 2019 infection underwent magnetic resonance cholangiopancreatography due to elevated biliary enzymes with negative findings on ultrasonography and contrast-enhanced computed tomography. A and B: In-phase (A) and out-of-phase (B) imaging demonstrates hepatic homogeneous parenchyma without areas of fatty infiltration; C: On the T2-weighted image liver inflammation, especially in the right lobe, is characterized by areas of slight hyperenhancement, located nearby the biliary ducts; D: Finally, magnetic resonance cholangiopancreatography allows the evaluation of the biliary tree, showing multiple and diffuse focal biliary stenosis, in particular in the right lobe, with upstream dilation of small biliary ducts. This radiological aspect is typical of sclerosing cholangitis and the final diagnosis was a biliary involvement due to severe acute respiratory syndrome coronavirus 2.

images and DWI restriction were reported in 70.6% of patients, while peribiliary enhancement was observed in 23.1% of cases[86]. Extrahepatic bile duct involvement is rare[86]. Other complications include sepsis with the possible development of hepatic abscesses and progressive liver disease with morphologic features of biliary cirrhosis. Endoscopic retrograde cholangiopancreatography can be performed to confirm the diagnosis of biliary strictures and stones in selected cases and allow treatment of biliary obstruction.

Acalculous cholecystitis has been reported as the most common gallbladder involvement in patients with COVID-19[87,88]. Despite the pathogenesis of acalculous cholecystitis in COVID-19 is still under investigation, the presence of SARS-Cov-2 virus was demonstrated in samples from the gallbladder wall, probably due to the presence of ACE2 receptors in the gallbladder[87]. Other possible causes include mechanical ventilation and prolonged total parenteral nutrition[89]. The US is the first-line imaging modality in patients with suspected acalculous cholecystitis and it may reveal thickened gallbladder wall with peri-cholecystic fluid collection and gallbladder distension, in the absence of gallstones. Contrast-enhanced CT may be performed in case of suspected complications, such as gallbladder perforation, fistula, or necrosis (*i.e.* gangrenous cholecystitis)[90]. CT findings include distended gallbladder with wall thickening, hyperenhancement of the gallbladder wall during postcontrast phases, and pericholecystic fluid[91] (Table 1).

Chronic findings

The current literature is lacking studies evaluating the chronic findings of COVID-19 on liver imaging. The type of hepatic chronic findings should be related to the sequelae of acute liver damage during COVID-19 infection after recovering from the acute disease. Severe liver cholestatic injury can progress into chronic liver disease with the development of cirrhosis, manifesting as abnormal liver morphology with associated imaging features of portal hypertension and ascites. On US, a prospective multiparametric assessment of post-COVID-19 patients observed increased liver stiffness and steatosis at 3-9 mo after COVID-19 compared to normal controls[30]. Complete PVT can progress to portal vein cavernoma if not promptly recanalized and resulting in chronic findings of noncirrhotic portal hypertension and risk of variceal bleeding[49].

Further studies are still needed to assess the evolution of hepatic findings and the possible long-term sequelae of liver damage in patients recovering from COVID-19.

CONCLUSION

Even if COVID-19 is extensively reported as a disease that mainly affects the lungs, the viral infection may cause an involvement of abdominal parenchymal organs and the gastrointestinal tract, increasing the risk of both acute and long-term health problems, especially of liver parenchyma. The liver damage may be caused by different mechanisms, including direct hepatocytes involvement from the viral infection, indirect response to the systemic inflammatory status, or hepatotoxicity due to drugs used to manage the infection. In this setting, the diagnostic imaging workup plays a crucial role for early detection of liver manifestations and assessment of long-term complications.

US should be considered as the main diagnostic option for the first evaluation of liver, biliary tree, and vascular district, in patients with abdominal symptoms, or with altered blood test, while abdominal contrast enhanced CT seems to be the most useful diagnostic tool for the overall abdominal assessment offering useful information regarding not only the liver itself, but also other parenchymal organs and vascular system. Finally, MRI should be considered the tool that better clarifies liver alterations in patients with COVID infection deemed indeterminate on US and CT.

It's important to underline that the main limitation in this field which should still be considered is the difficulty to understand the main COVID-19 pathological mechanisms and their related consequences. Further studies should be more focused on the evaluation of COVID-19 patients, in particular those with liver involvement, to quickly address the diagnosis and the best management possible.

A comprehensive knowledge of COVID-19 hepatic involvement assessed through the different diagnostic imaging modalities can help clinicians in addressing the correct treatment and long-term management of the disease.

Abstract

BACKGROUND

Postoperative recurrence (POR) after ileocecal resection (ICR) affects most Crohn's disease patients within 3-5 years after surgery. Adherent-invasive *Escherichia coli* (AIEC) typified by the LF82 strain are pathobionts that are frequently detected in POR of Crohn's disease and have a potential role in the early stages of the disease pathogenesis. *Saccharomyces cerevisiae* CNCM I-3856 is a probiotic yeast reported to inhibit AIEC adhesion to intestinal epithelial cells and to favor their elimination from the gut.

AIM

To evaluate the efficacy of CNCM I-3856 in preventing POR induced by LF82 in an HLA-B27 transgenic (TgB27) rat model.

METHODS

Sixty-four rats [strain F344, 38 TgB27, 26 control non-Tg (nTg)] underwent an ICR at the 12th wk (W12) of life and were sacrificed at the 18th wk (W18) of life. TgB27 rats were challenged daily with oral administration of LF82 (10^9 colony forming units (CFUs)/day (d), n = 8), PBS (n = 5), CNCM I-3856 (10^9 CFUs/d, n = 7) or a combination of LF82 and CNCM I-3856 (n = 18). nTg rats receiving LF82 (n = 5), PBS (n = 5), CNCM I-3856 (n = 7) or CNCM I-3856 and LF82 (n = 9) under the same conditions were used as controls. POR was analyzed using macroscopic (from 0 to 4) and histologic (from 0 to 6) scores. Luminal LF82 quantifications were performed weekly for each animal. Adherent LF82 and inflammatory/regulatory cytokines were quantified in biopsies at W12 and W18. Data are expressed as the median with the interquartile range.

RESULTS

nTg animals did not develop POR. A total of 7/8 (87%) of the TgB27 rats receiving LF82 alone had POR (macroscopic score ≥ 2), which was significantly prevented by CNCM I-3856 administration [6/18 (33%) TgB27 rats, P = 0.01]. Macroscopic lesions were located 2 cm above the anastomosis in the TgB27 rats receiving LF82 alone and consisted of ulcerations with a score of 3.5 (2 - 4). Seven out of 18 TgB27 rats (39%) receiving CNCM I-3856 and LF82 had no macroscopic lesions. Compared to untreated TgB27 animals receiving LF82 alone, coadministration of CNCM I-3856 and LF82 significantly reduced the macroscopic [3.5 (2 - 4) *vs* 1 (0 - 3), P = 0.002] and histological lesions by more than 50% [4.5 (3.3 - 5.8) *vs* 2 (1.3 - 3), P = 0.003]. The levels of adherent LF82 were correlated with anastomotic macroscopic scores in TgB27 rats (r = 0.49, P = 0.006), with a higher risk of POR in animals having high levels of luminal LF82 (71.4% *vs* 25%, P = 0.02). Administration of CNCM I-3856 significantly reduced the levels of luminal and adherent LF82, increased the production of interleukin (IL)-10 and decreased the production of IL-23 and IL-17 in TgB27 rats.

CONCLUSION

In a reliable model of POR induced by LF82 in TgB27 rats, CNCM I-3856 prevents macroscopic POR by decreasing LF82 infection and gut inflammation.

Key Words: Crohn's disease; Recurrence; *Escherichia coli*; Probiotic; *Saccharomyces cerevisiae*; Colorectal surgery

Core Tip: Gut dysbiosis plays a main role in the postoperative recurrence (POR) of Crohn's disease (CD). CD dysbiosis is characterized by a lower microbiota diversity with an increase in pathogenic species. Among them, adherent-invasive *Escherichia coli* (AIEC) has been linked to POR. *Saccharomyces cerevisiae* (*S. cerevisiae*) CNCM I-3856 is a probiotic yeast that specifically targets AIEC by preventing the bacterial adhesion process and inhibiting its persistence within the bowel. This study confirmed the capacity of *S. cerevisiae* CNCM I-3856 to prevent AIEC-induced POR by decreasing the infection in a transgenic HLA-B27 rat model of POR after ileocecal resection.

INTRODUCTION

Crohn's disease (CD) is a complex chronic inflammatory bowel disease that requires surgical resection of macroscopic lesions in approximately 30%-50% of patients in their lifetime[1]. Unfortunately, surgery is not curative, and endoscopic recurrence at the anastomotic site occurs in up to 70% of patients in the first year after surgery, followed by clinical recurrence a few years later[2]. Postoperative management of these patients is crucial to identify those at highest risk of recurrence to begin rapid prophylactic treatments targeting mainly tumor necrosis factor α (TNFα)[3], interleukins 12/23 and α4β7 integrins on leukocytes[4]. Given the high rate of recurrence after intestinal resection for CD and the cost and potential adverse effects of biologic therapies used in prophylaxis, there is a clear need to identify the mechanisms leading to postoperative recurrence (POR), to develop noninvasive methods predicting

recurrence and to propose new evidence-based therapeutic strategies.

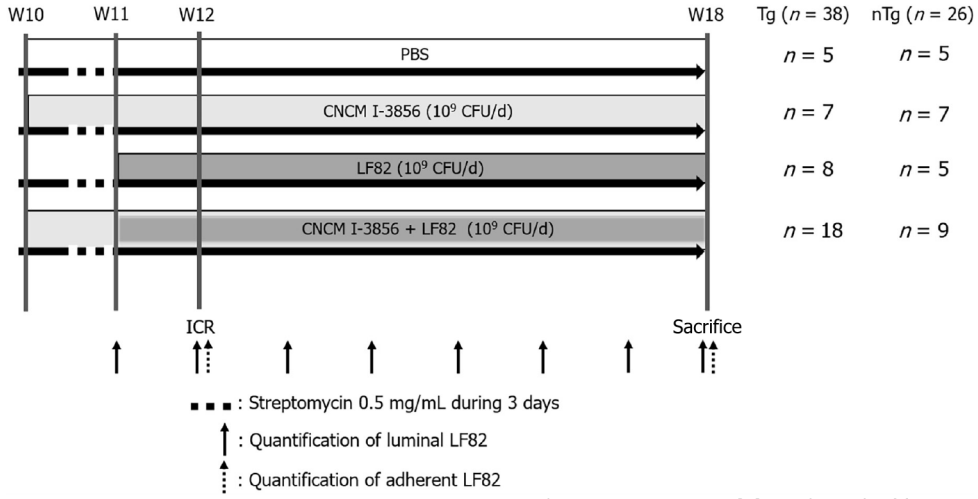
The physiopathology sustaining POR of CD remains partially unknown. Abnormal interactions between the mucosal/mesenteric immune system and the intestinal microbiota favored by surgical techniques and environmental factors are pivotal hallmarks in POR dynamics[5]. Recently, ileal transcriptome analyses of CD patients found a gene signature of POR characterized by an upregulation of the interleukin (IL)-23 and IL-17 pathways together with abnormal JAK/STAT activation[6]. Numerous changes in the microbial composition and a reduction in species diversity have been observed in the intestinal flora of CD patients[7], and a few studies have identified an intestinal microbial signature associated with POR. Recolonization of the neoterminal ileum by *Escherichia coli* (*E. coli*), Bacteroides, and Fusobacteriaceae and the depletion of Streptococcaceae, Actinomycineae and *Faecalibacterium* are associated with endoscopic recurrence of CD[8]. Among these microorganisms, adherent-invasive *E. coli* (AIEC) isolated more than 20 years ago by Darfeuille-Michaud *et al*[9] from the ileal mucosa of a patient with CD[10] remains one of the most prominent and influential strains associated with CD. AIEC are pathobionts found in approximately 30% of CD patients and in 10% of healthy controls[11]. They are not strictly pathogenic bacteria, and their influence on CD physiopathology remains incompletely understood. However, AIEC is associated with the early stages of CD and is predictive of endoscopic POR at 6 mo[12], reinforcing the need for interventional studies targeting these bacteria to better understand their direct impact on mucosal inflammation and to find new opportunities to treat CD patients.

Several therapeutic strategies, including the use of antibiotics[13], pre/probiotics[14] and fecal microbiota transplantation[15], have been proposed to target the intestinal flora in CD. Due to side effects or limited efficacy, their routine utilization cannot be recommended[16,17]. Other strategies to inhibit adhesion or to specifically erase AIEC using FimH blockers[18,19] or specific bacteriophages[20,21] are ongoing and seem more promising in preclinical studies. In this context, *Saccharomyces cerevisiae* (*S. cerevisiae*) CNCM I-3856 is a probiotic yeast with good tolerance and beneficial effects on gastrointestinal symptoms[22,23] that has been shown to agglutinate the LF82 AIEC strain and to prevent its adhesion to intestinal epithelial cells *in vitro*, favoring LF82 elimination from the gut of mice [24]. Among the thousands of strains belonging to the AIEC family and identified from European and USA isolates, LF82 remains the most studied reference strain that can both adhere to and invade epithelial cells and, moreover, survive and replicate within macrophages without inducing cellular death[25,26].

In the present study, we developed a new animal model of POR of CD occurring 6 wk after ileocecal resection (ICR) in HLA-B27 transgenic (Tg) rats[27,28] infected by the LF82 AIEC strain[29] to better evaluate the causal role of LF82 on the early steps of CD lesions and the effectiveness of a rationally selected *S. cerevisiae* CNCM I-3856 probiotic to prevent recurrence of the disease.

MATERIALS AND METHODS

Animals



HLA-B27 transgenic (Tg) and nontransgenic (nTg) control Fisher rats (strain F344) were provided by Professor M. Breban (Cochin Institute, INSERM U1016, Paris, France). Sixty-four rats were maintained in a specific pathogen-free facility at the Institut Pasteur (Lille, France) and were fed a standard diet with free access to water. Animals were maintained at a constant temperature with a 12-hour light/dark cycle. Intragastric gavage administration was carried out with conscious animals using straight gavage needles appropriate for the animal size. Surgery was performed under general anesthesia, and postoperative analgesia by opioid treatment was provided. All animals were euthanized by cervical dislocation under general anesthesia. Experiments were realized according to the European directive 2016/63/UE enforced by the decree n°2013-118 and authorized by the departmental ethics committee (No. CEEA 01292-01).

AIEC LF82 and S. cerevisiae CNCM I-3856 strains

The streptomycin-kanamycin-resistant AIEC strain LF82 isolated from an ileal biopsy of a patient with CD was provided by Professor Nicolas Barnich (Clermont-Auvergne University, France) and used as an AIEC reference strain[30]. Bacteria were routinely grown at 37 °C in Brain-Heart broth or on Drigalski agar plates. The dry *S. cerevisiae* CNCM I-3856 yeast strain was provided by Lesaffre International (Marcq-en-Baroeul, France). The LF82 and *S. cerevisiae* CNCM I-3856 strains were rehydrated at room temperature in PBS (pH = 7.2, 2 × 10^9 colony forming units (CFUs)/mL) before gavage.

Experimental design

ICR with end-to-end anastomosis was performed at 12 wk (W) of life (W12) in 64 rats (38 Tg, 26 nTg) (Figure 1). ICR was performed blindly by two operators (Caroline Dubuquoy and Caroline Valibouze) in Tg and nTg animals. Tg rats were challenged daily by oral gavage in the morning with PBS (n = 5), *S. cerevisiae* CNCM I-3856 alone (10^9 CFUs/day (d)) (n = 7), LF82 alone (10^9 CFUs/d) in the afternoon (n = 8), or the combination of *S. cerevisiae* CNCM I-3856 (10^9 CFUs/d) and LF82 (10^9 CFUs/d) (n = 18) given

DOI: 10.3748/wjg.v29.i5.851 **Copyright** ©The Author(s) 2023.

Figure 1 Study design. HLA-B27 transgenic rats (Tg) and wild-type rats (nTg) were randomized to receive phosphate buffered saline (*n* = 10), *Saccharomyces cerevisiae* (*S. cerevisiae*) CNCM I-3856 (*n* = 14), adherent-invasive *Escherichia coli* strain LF82 (*n* = 13), or *S. cerevisiae* CNCM I-3856 and LF82 (*n* = 27) by oral gavage from week (W) 10 or 11 to W18. Ileocecal resection was performed at W12, and animals were sacrificed at W18. Streptomycin (dotted line) was given on the last 3 d of W10 in all rats. Luminal (arrows) and/or adherent (dotted arrows) LF82 was quantified weekly during the 8-wk study. CFU: Colony-forming unit; PBS: Phosphate buffered saline; ICR: Ileocecal resection; d: Day.

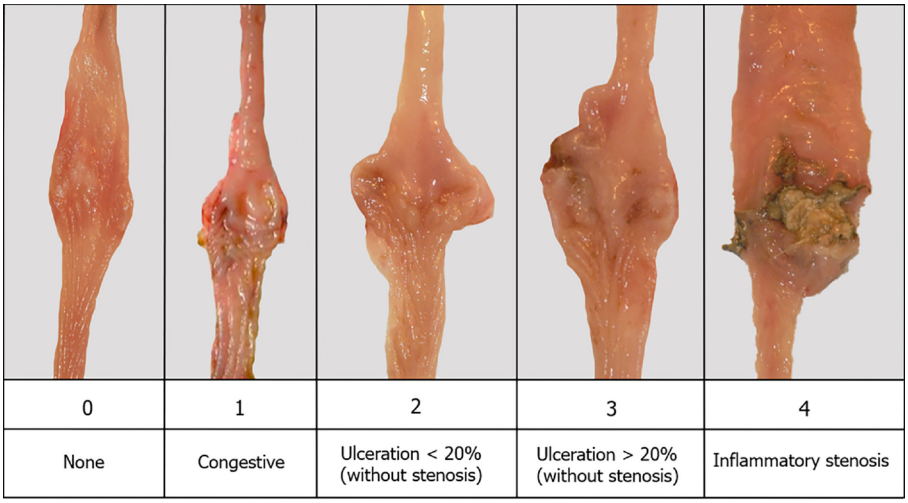
in the morning and in the afternoon, respectively. Age-matched nTg rats receiving PBS (*n* = 5), *S. cerevisiae* CNCMI-3856 alone (*n* = 7), LF82 alone (*n* = 5), or the combination of *S. cerevisiae* CNCM I-3856 and LF82 (*n* = 9) under the same conditions were used as controls. LF82 was administered from W11 to W18, and *S. cerevisiae* CNCM I-3856 was similarly administered from W10 to W18 in Tg and nTg rats. Streptomycin was given in drinking water at 0.5 mg/mL for the last 3 d of W10 in Tg and control animals. The rats were followed during the eight-week procedure for weight changes (% of change compared to initial body weight at W11), diarrhea and the presence of macroscopic bloody stools and were killed at W18.

Macroscopic and histologic lesions

At W18, the whole intestine was excised and photographed. Anastomotic macroscopic lesions (± 2 cm above anastomosis) were assessed blindly using a macroscopic grading scale adapted from the Rutgeerts score ranging from 0 to 4 (Figure 2)[2]. By analogy with endoscopic recurrence after surgery in patients with CD (25), POR was defined by a macroscopic score of ≥ 2 corresponding to the presence of ulcerations ± stenosis. The results were expressed as the median with the interquartile range (IQR).

Transparietal biopsies of anastomotic areas were collected during surgery at W12 and W18. Tissues were fixed in 4% buffered formaldehyde, embedded in paraffin and stained by May-Grunwald Giemsa for scoring (from 0 to 6) using the adapted score of Geboes (Table 1)[31]. Identical areas of each section of the different biopsy specimens were examined at 10× magnification by two blinded observers familiar with the scoring system (Caroline Dubuquoy and Caroline Valibouze). Anastomotic histologic scores were expressed as the median score with IQR when an interobserver coefficient of variation < 15% was obtained.

Luminal and adherent quantification of LF82



Feces (10 - 600 mg) were collected weekly from W11 to W18 for each animal after abdominal massage for the quantification of luminal LF82. Mucosal anastomotic swabs (10 - 100 mg) were performed at W12 during surgery and at sacrifice (W18) in all animals for the quantification of anastomotic adherent LF82. Fresh feces and swabs were collected in 1.5 mL of sterile cysteinated Ringer's solution. After serial dilutions, samples were incubated for 24 - 48 h at 37 °C in Drigalski agar containing 100 μg/mL streptomycin to select and quantify LF82 expressed as log10 CFUs *per* gram of feces. The results are expressed as the median with the IQR.

mRNA quantification in anastomotic biopsies at W12 and W18

Anastomotic biopsies were frozen at -80 °C, and total RNA was extracted using a Nucleospin RNA kit (Macherey Nagel). After RNAse inactivation, genomic DNA was suppressed from the samples by DNAse treatment, and total RNA was extracted in RNAse-free water. The RNA content was measured using a NanoDrop Spectrophotometer (Thermo Fisher Scientific, Waltham, Massachusetts, USA). Retro-transcription of total RNA was achieved using a High-Capacity cDNA Reverse Transcription Kit (Thermo Fisher Scientific). Random primers, RT buffer and reverse transcriptase were added to 1 μg of

Table 1 Anastomotic histologic score (0-6)

Score	Histologic lesions
0	None
1	Inflammatory infiltrate and mucosal erosions < 30% of the section
2	30% < inflammatory infiltrate and mucosal erosions < 70% of the section
3	Inflammatory infiltrate and mucosal erosions > 70% of the section
4	Mucosal ulceration < 30% of the section
5	30% < mucosal ulceration < 70% of the section
6	Mucosal ulceration > 70% of the section

DOI: 10.3748/wjg.v29.i5.851 **Copyright** ©The Author(s) 2023.

Figure 2 Anastomotic macroscopic score (0-4).

total RNA, and the samples were incubated for 10 min at 25 °C, then 2 h at 37 °C and finally 5 min at 85 °C in the Gene AmpPCR System 9700 automaton (Thermos Fisher Scientific, Waltham, Massachusetts, USA). All kits were used according to the manufacturers' protocols. IL-1β, IL-6, TNFα, interferon (IFN)γ, IL-17, IL-23 and IL-10 were quantified by quantitative polymerase chain reaction (PCR) in real time for 40 cycles in the StepOnePlus™ Real Time PCR system (Thermo Fisher Scientific, Waltham, Massachusetts, USA) using SYBR Green PCR Master Mix (Thermo Fisher Scientific). qPCR signal quantification was expressed relative to the expression of β-actin as the reference gene. The results are expressed as the median with IQR.

Statistical analysis

Data are expressed as the median with IQR. Comparisons were performed using the nonparametric Mann-Whitney test for unmatched data and the Wilcoxon signed-rank test for matched data. Pearson's chi-square test was used for contingency analysis. The correlation between macroscopic scores and the number of LF82 was tested using Spearman's test. To classify animals with low or high quantities of LF82, a cutoff value was determined using the receiver operating characteristic (ROC) curve. The risk of recurrence for low and high producers was compared using Pearson's chi-square test. All statistical tests were two-tailed and considered statistically significant if $P < 0.05$. Statistical analyses were conducted using the GraphPad Prism 5.00 (GraphPad Software, San Diego, CA) software package for PCR and Xlstat 2020.1 version for the ROC curve.

RESULTS

Effect of S. cerevisiae CNCM I-3856 on clinical signs

No mortality, diarrhea or bloody stools were observed in any animals receiving PBS, LF82 alone, *S. cerevisiae* CNCM I-3856 alone or *S. cerevisiae* CNCM I-3856 and LF82 during the 8-wk observation study.

A similar pattern of weight evolution was observed in nTg (Figure 3A) and Tg animals (Figure 3B), with significant weight loss occurring one week after surgery followed by a weight recovery phase. More important weight loss was transiently observed at W13 in Tg rats receiving LF82 *vs S. cerevisiae* CNCM I-3856 and LF82 (95.7, IQR: 92 - 97 *vs* 85.4, IQR: 81 - 94, $P = 0.007$). The global weight changes assessed by the relative difference in weight variation between W11 and W18 were similar in the 4 groups of Tg and nTg animals.

Effect of S. cerevisiae CNCM I-3856 on macroscopic anastomotic lesions and POR

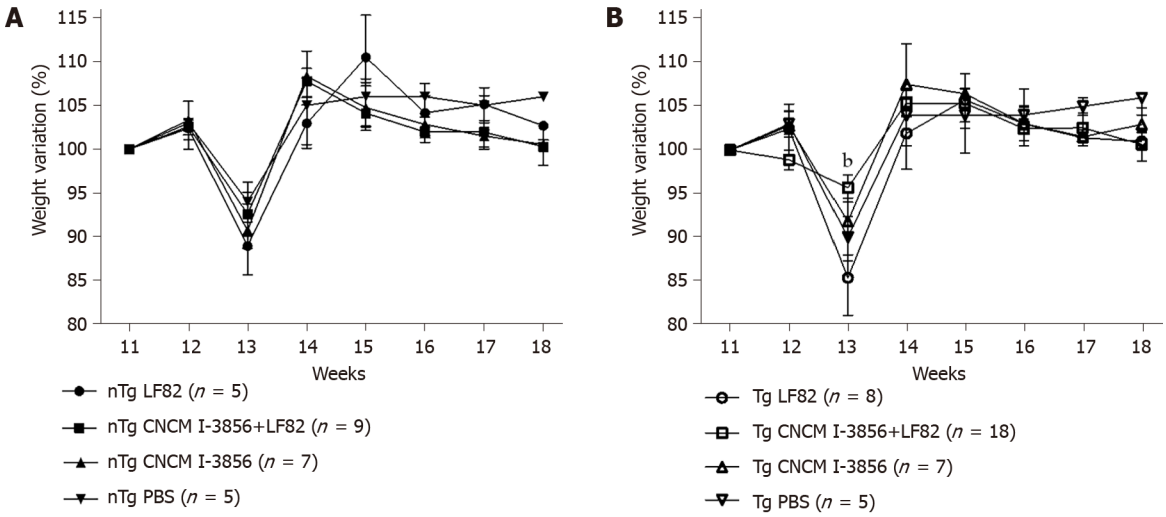
No intestinal lesions were present at W12 in any animal. No macroscopic lesions (or therefore POR) were observed at W18 in control nTg animals receiving PBS, *S. cerevisiae* CNCM I-3856 alone, LF82 alone, or *S. cerevisiae* CNCM I-3856 and LF82 (Figure 4A). In contrast, anastomotic macroscopic lesions corresponding mainly to edema and ulcerations on more than 20% of the anastomotic area without stenosis were observed in Tg rats receiving LF82 (3.5, IQR: 2 - 4), leading to 87.5% POR in this group of animals (Figure 4A and B). Compared to untreated Tg rats receiving LF82 (3.5, IQR: 2 - 4), coadministration of *S. cerevisiae* CNCM I-3856 and LF82 significantly reduced the macroscopic score (1, IQR: 0 - 2, $P = 0.002$) and POR (87.5% *vs* 33.3%, $P = 0.01$) by more than 60% (Figure 4A and B). Anastomotic macroscopic lesions were similar in Tg rats receiving PBS or *S. cerevisiae* CNCM I-3856 alone or *S. cerevisiae* CNCM I-3856 and LF82, without a difference compared to those of control nTg animals (Figure 4A).

Effect of S. cerevisiae CNCM I-3856 on anastomotic histologic lesions

No histologic lesions were present at W12 in any animal (data not shown). At W18, no significant and only mild histologic lesions characterized by neutrophil infiltration not exceeding 30% of lamina propria cells were observed in control nTg animals receiving either PBS, LF82 alone, *S. cerevisiae* CNCM I-3856 alone or *S. cerevisiae* CNCM I-3856 and LF82 (Figure 5). In contrast, erosions and mucosal ulcerations associated with moderate neutrophil infiltration were observed at W18 in Tg rats receiving LF82 (4.5, IQR: 3.3 - 5.8) (Figure 5). Compared to untreated Tg animals receiving LF82, coadministration of *S. cerevisiae* CNCM I-3856 and LF82 significantly reduced the histological lesions by more than 50% (4.5, IQR: 3.3 - 5.8 *vs* 2, IQR: 1.3-3, $P = 0.003$) (Figure 5). No significant lesions were observed in Tg rats receiving PBS or *S. cerevisiae* CNCM I-3856 alone, which was not different from the findings in control nTg animals (Figure 5).

Effect of CNCM I-3856 on luminal and adherent LF82 Levels (W12-W18)

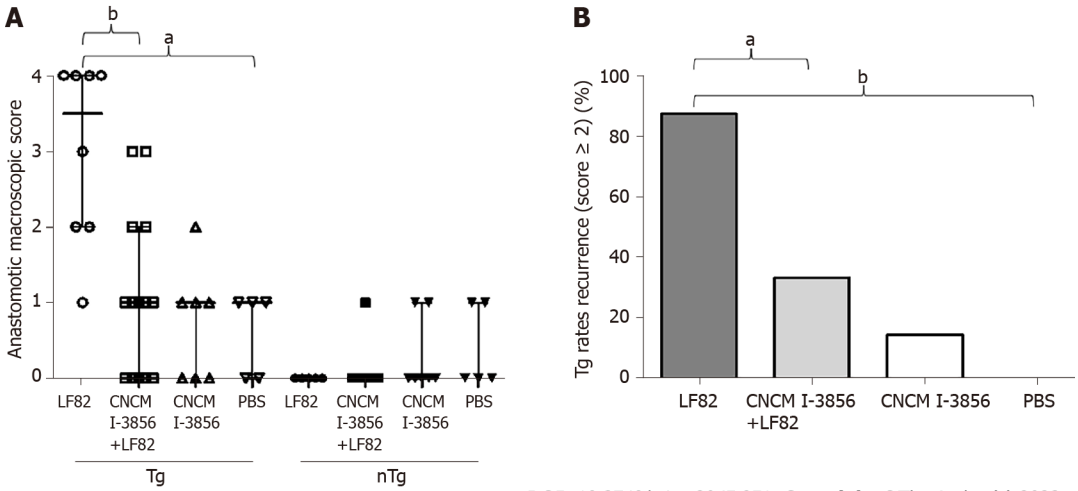
At W12, *i.e.*, one week after the beginning of LF82 administration (10^9 CFUs/d), the quantities of luminal (Figure 6A) and adherent (Figure 7A) LF82 were similar in Tg and nTg rats receiving LF82 alone or *S. cerevisiae* CNCM I-3856 and LF82. The levels of luminal (4.4, IQR: 2.5 - 5.2 *vs* 3.4, IQR: 1.7 - 5.5) and adherent (2.7, IQR: 2.4 - 3 *vs* 3.1, IQR: 2.3 - 5) LF82 remained similar between W12 and W18 in Tg rats receiving LF82 alone (Figures 6 and 7), while a significant decrease in luminal (4.6, IQR: 3.5 - 5.2 *vs* 1.8, IQR: 1.7 - 2.3, $P = 0.0002$) and adherent (3.1, IQR: 2.5 - 3.6 *vs* 2.5, IQR: 2.3 - 2.6, $P = 0.0005$) LF82 was observed between W12 and W18 in paired Tg animals receiving *S. cerevisiae* CNCM I-3856 and LF82 (Figures 6 and 7).



In addition, the global persistence of viable luminal LF82 after surgery and during the last 5 wk of the study was significantly higher in the stools of Tg rats receiving LF82 alone (0.22, IQR: 2.071e-008 - 0.7) compared to Tg rats receiving *S. cerevisiae* CNCM I-3856 and LF82 (-0.6, IQR: -0.7 - 0.3, $P = 0.0004$) (Figure 8).

Correlation between LF82 Levels and macroscopic lesions in Tg rats

A correlation was found between the levels of adherent LF82 and the scores of anastomotic macroscopic lesions observed at W18 in Tg animals receiving LF82 alone or in combination with *S. cerevisiae* CNCM I-3856 ($r = 0.49$, $P = 0.006$) (Figure 9A). These levels of anastomotic adherent LF82 were correlated at W12 ($r = 0.81$, $P = 0.02$) and W18 ($r = 0.79$, $P = 0.03$) with the levels of luminal LF82 in paired Tg animals receiving LF82 alone (Figure 9B and C). Next, we analyzed whether luminal LF82 Levels at W14 may be predictive of POR in the 26 Tg rats receiving LF82 alone ($n = 8$) or in combination with *S. cerevisiae* CNCM I-3856 ($n = 18$). Using a cutoff value of 2.262 Log10 CFUs of luminal LF82 per gram of stool determined by the ROC curve, 14 animals at W14 were classified as highly infected by LF82, and 12 were classified as mildly infected (Figure 10A). POR was significantly more frequent in the highly infected Tg rats than in the mildly infected Tg rats (71.4% *vs* 25%, $P = 0.02$) (Figure 10B). A value of 2.262 Log10 CFUs luminal LF82 *per* gram of stool at W14 had an 80% sensitivity, 69.2% specificity, 71.4% positive predictive value and 75% negative predictive value for POR.



Anastomotic cytokine mRNA quantification

The levels of IL-1β, IL-6, TNFα and IFNγ mRNA were variable and similar in all Tg and nTg animals at W12 and W18, regardless of the presence of POR, LF82 administration or treatment with *S. cerevisiae* CNCM I-3856 (data not shown).

LF82: Adherent-invasive *Escherichia coli* strain LF82; CNCM I-3856: *Saccharomyces cerevisiae* CNCM I-3856; PBS: Phosphate buffered saline.

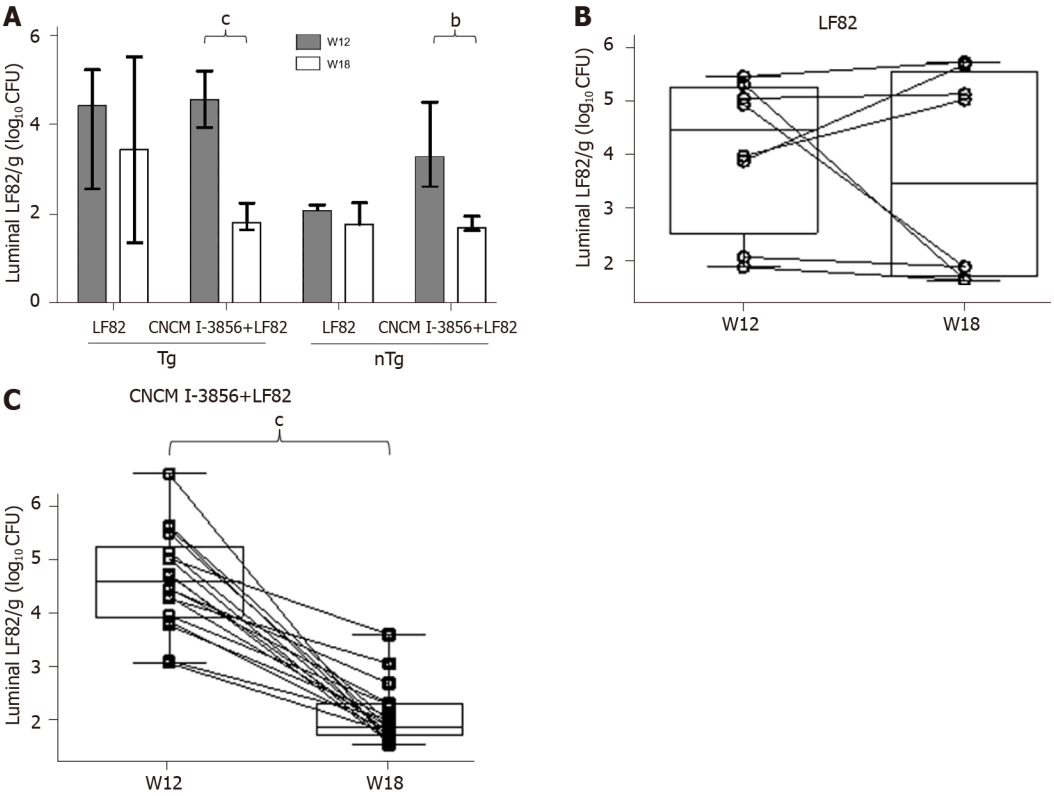
Concerning IL-10 mRNA levels, the only significant difference found by paired analysis in the different groups of animals revealed higher levels of IL-10 mRNA at W18 compared to W12 in animals receiving *S. cerevisiae* CNCM I-3856. In the Tg groups, administration of *S. cerevisiae* CNCM I-3856 with or without the coadministration of LF82 induced a significant increase in IL-10 production between surgery and sacrifice (2.5×10^5, IQR: 1.7×10^5 - 2.6×10^5 *vs* 4.9×10^5, IQR: 3.3×10^5 - 9×10^5, $P = 0.017$ and 2.6×10^5, IQR: 1.5×10^5 - 3.9×10^5 *vs* 7.4×10^5, IQR: 5.3×10^5 - 0.4×10^5, $P = 0.031$, respectively), while similar IL-10 Levels were found in animals receiving LF82 alone (Figure 11A-C).



Concerning IL-23 mRNA levels, a significant increase was observed at W18 in Tg animals receiving LF82 alone in comparison to the groups of rats treated with *S. cerevisiae* CNCM I-3856 with or without administration of LF82 ($P = 0.04$ and $P = 0.006$, respectively) (Figure 12A). Additionally, using a paired t test, a significant increase in inflammatory IL-23 production was observed between surgery and sacrifice in the Tg group receiving LF82 alone (2.2×10^4, IQR: 1.8×10^4 - 8×10^4 *vs* 26.9×10^4, IQR: 6.1×10^4 - 6×10^4, $P = 0.008$), while no significant difference was observed in the Tg groups treated with *S. cerevisiae* CNCM I-3856 with or without administration of LF82 (Figure 12B-D).

Analysis of IL-17 mRNA levels found significantly higher rates at W18 in Tg rats receiving LF82 in comparison with the Tg group receiving *S. cerevisiae* CNCM I-3856 and LF82 (2.7×10^4, IQR: 0.8×10^4 - $9,5 \times 10^4$ *vs* 0.4×10^4, IQR: 0.2×10^4 - 0.6×10^4, $P = 0.015$) (Figure 13).

ileal lesions of CD and particularly in endoscopic POR occurring 6 mo after CD-related ileocolonic resection[12]. In the present study, we show that the probiotic *S. cerevisiae* CNCM I–3856 prevents LF82-induced POR occurring 6 wk after ICR in susceptible HLA-B27 Tg rats. In our model, oral administration of the LF82 AIEC strain induced POR in 85% of HLA-B27 Tg rats raised in a controlled pathogen-free facility. The lesions developed in a concentration-dependent manner to the amount of adherent LF82; moreover, they shared many similarities with CD lesions, including erosions and ulcers that could lead to stenosis, transparietal neutrophil infiltration, and a shift in cytokine profiles toward the IL-23/IL-17 axis. The goal of the postoperative management of CD is to identify patients at highest risk of recurrence to begin prophylactic treatment with biotherapies[8]. In our study, a high fecal concentration

Figure 10 Prognostic value of luminal adherent-invasive *Escherichia coli* LF82 levels in postoperative recurrence. A: Correlation between luminal adherent-invasive *Escherichia coli* strain LF82 Levels at week 14 and the risk of postoperative (POR) recurrence at W18 in transgenic (Tg) animals receiving LF82 alone or *Saccharomyces cerevisiae* (*S. cerevisiae*) CNCM I-3856 and LF82; B: Higher frequency of POR in highly infected (HI) Tg animals receiving LF82 alone or *S. cerevisiae* CNCM I-3856 and LF82 as defined by a cutoff value of 2.262 Log_{10} CFUs (colony-forming units) of luminal LF82 per gram of stool at W14 in comparison with mildly infected (MI) Tg rats (71.4% *vs* 25%, $P = 0.02$). $^{a}P < 0.05$. CFU: Colony-forming unit; log10: Decimal logarithm.

of LF82 had a 70% positive predictive value for POR occurring 4 wk later. The utility of this noninvasive diagnostic biomarker for predicting POR should be considered in future clinical studies evaluating the postoperative management of CD patients.

S. cerevisiae CNCM I-3856[22] is a probiotic yeast that has already been evaluated in large-scale clinical studies showing the safety and efficacy of this strain for abdominal pain management in patients with irritable bowel syndrome[22,32-34]. In the present study, daily oral administration of *S. cerevisiae* CNCM I-3856 at 10^{9} CFU/d was perfectly tolerated and reduced the severity and frequency of POR by more than 60% in HLA-B27 Tg rats. Moreover, an absence of LF82-induced POR without any macroscopic lesions was observed in 40% of transgenic animals treated preventively with *S. cerevisiae* CNCM I-3856. To our knowledge, this is the first time that a probiotic treatment showed such efficacy in preventing POR in a rodent preclinical model of POR of CD.

Different mechanisms of action may be involved in the therapeutic preventive effect of *S. cerevisiae* CNCM I-3856 against POR. Specific fractions of β6-glucan and α4-glucan expressed by *S. cerevisiae* CNCM I-3856 represent the strongest anti-adhesive yeast cell wall components against AIEC adhesion [24,35]. In our study, prevention of LF82-induced POR by *S. cerevisiae* CNCM I-3856 was associated with a significant decrease in adherent LF82 in the intestinal mucosa of animals together with a decrease in the persistence of luminal LF82, demonstrating the ability of *S. cerevisiae* CNCM I-3856 to decolonize AIEC from the gut of rats. Additional preclinical studies will be performed in our model using specific soluble glucan fractions of *S. cerevisiae* CNCM I-3856 to avoid the constraints of a live probiotic and to optimize the therapeutic efficacy. Another possible mechanism by which *S. cerevisiae* CNCM I-3856

prevents POR resides in its immunomodulatory and anti-inflammatory capacities[36]. We observed that the administration of *S. cerevisiae* CNCM I-3856 significantly increased IL-10 production in the intestine of rats and restored the local upregulation of IL-17 and IL-23 associated with LF82-induced POR in transgenic animals. The capacity of *S. cerevisiae* to induce IL-10 production has already been highlighted *in vitro* in bone-marrow dendritic cells and in porcine jejunal epithelial cells[36,37]. In the gut, IL-10 is

Figure 13 Interleukin-17 mRNA expression in the anastomotic mucosa. A: Expression of interleukin (IL)-17 mRNA in the perianastomotic mucosa in all transgenic (Tg) and nontransgenic (nTg) groups at sacrifice; B: IL-17 mRNA expression between surgery [week (W) 12] and sacrifice (W18) in paired Tg rats receiving adherent-invasive *Escherichia coli* strain LF82 alone; C: IL-17 mRNA expression between W12 and W18 in paired Tg rats receiving coadministration of *Saccharomyces cerevisiae* (*S. cerevisiae*) CNCM I-3856 and LF82; D: IL-17 mRNA expression between W12 and W18 in paired Tg rats receiving *S. cerevisiae* CNCM I-3856 alone. $^{a}P < 0.05$. β-act: β-actin; PBS: Phosphate buffered saline.

produced by leukocytes and intestinal epithelial cells and plays important roles in maintaining gut homeostasis and harmonizing the interaction between host immunity and luminal microorganisms[38]. In a previous study of 79 patients with CD undergoing a first ileocolectomy and ileocolonic anastomosis, we reported that a low ileal IL-10 mRNA concentration was predictive of endoscopic recurrence occurring 3 mo later[39]. Thus, the ability of *S. cerevisiae* CNCM I-3856 to induce the intestinal production of IL-10 could be a key factor in preventing POR in our model.

CONCLUSION

In conclusion, our results identified *S. cerevisiae* CNCM I-3856 as a new and original candidate for the prevention of POR in selected AIEC-infected CD patients. In a reliable model of ICR in HLA-B27 Tg rats mimicking POR of CD, *S. cerevisiae* CNCM I-3856 was found to prevent macroscopic and histologic POR through a pathobiont AIEC-targeted mechanism and through its ability to induce intestinal IL-10 production. Given that the majority of patients with CD wish to have safe, natural, nonchemotherapeutic treatment, the *S. cerevisiae* CNCM I-3856 probiotic, which is already an alternative solution for the management of patients with irritable bowel syndrome because of its ability to alleviate abdominal pain and to improve quality of life, should represent a promising therapeutic solution in the management of postoperative CD.

ARTICLE HIGHLIGHTS

Research background

The presence of adherent-invasive *Escherichia coli* (AIEC) in intestinal flora is associated with postoperative recurrence (POR) of crohn's disease (CD). *Saccharomyces cerevisiae* (*S. cerevisiae*) CNCM I-3856 is a safe and effective probiotic yeast that has already been evaluated in randomized placebo-controlled studies in patients with irritable bowel syndrome. Preclinical studies demonstrate the capacity of *S. cerevisiae* CNCM I-3856 to agglutinate invasive *Escherichia coli* strains and to prevent their adhesion to intestinal epithelial cells, favoring AIEC elimination from the gut of mice.

Research motivation

To demonstrate that *S. cerevisiae* CNCM I-3856 should be considered as a postoperative prophylactic medical therapy in CD patients harboring AIEC bacteria.

Research objectives

To evaluate the beneficial effect of *S. cerevisiae* CNCM I-3856 and its mechanisms of action in preventing AIEC-induced POR in an HLA-B27 transgenic (TgB27) rat model of CD.

Research methods

TgB27 and control rats underwent an ileocecal resection at the 12th wk of life and sacrificed 6 wk later to assess POR using macroscopic and histological scores and quantification of mucosal inflammatory/regulatory cytokines. Animals were challenged daily with an oral administration of AIEC and were treated orally with *S. cerevisiae* CNCM I-3856 (10^9 colony forming units/day). Luminal and adherent AIEC were regularly quantified throughout the duration of the study.

Research results

Eighty-seven percent of TgB27 rats developed POR characterized by anastomotic macroscopic ulcerations, transparietal neutrophil infiltration and a shift in the cytokine profile toward the interleukin (IL)-17/IL-23 axis. Oral administration of *S. cerevisiae* CNCM I-3856 reduced this POR by more than 60%, increased AIEC elimination from the gut, induced intestinal IL-10 production and restored the local upregulation of IL-17/IL-23. A high concentration of AIEC quantified in the stool of rats after surgery had a 70% positive predictive value for POR occurring 4 wk later.

Research conclusions

Ileocecal resection in TgB27 rats is a novel, useful, reliable model mimicking POR of CD and aided the discovery of new therapeutic targets. Oral administration of *S. cerevisiae* CNCM I-3856 safely prevented POR of CD through AIEC decolonization and immunomodulatory/anti-inflammatory capacities.

Research perspectives

The probiotic *S. cerevisiae* CNCM I-3856, which is already an alternative solution for the management of patients with irritable bowel syndrome to improve abdominal pain and quality of life, should represent a promising prophylactic natural nonchemotherapeutic solution in the management of postoperative CD. Monitoring AIEC levels in stool after surgery for CD should be considered as a companion test to identify patients at high risk of POR and to monitor treatment response.

ACKNOWLEDGEMENTS

We thank the Foundation DigestScience for its help in the breeding of the HLA-B27 transgenic animals and Lesaffre Company for the provision of *S. cerevisiae* CNCM I-3856.

Abstract

BACKGROUND

Although the associating liver partition and portal vein ligation for staged hepatectomy (ALPPS) induces more rapid liver regeneration than portal vein embolization, the mechanism remains unclear.

AIM

To assess the influence of inflammatory cytokines and endothelial nitric oxide synthase (eNOS) activation on liver regeneration in ALPPS.

METHODS

The future liver remnant/body weight (FLR/BW) ratio, hepatocyte proliferation, inflammatory cytokine expression, and activation of the Akt-eNOS pathway were evaluated in rat ALPPS and portal vein ligation (PVL) models. Hepatocyte proliferation was assessed based on Ki-67 expression, which was confirmed using immunohistochemistry. The serum concentrations of inflammatory cytokines were measured using enzyme linked immune-solvent assays. The Akt-eNOS pathway was assessed using western blotting. To explore the role of inflammatory cytokines and NO, Kupffer cell inhibitor gadolinium chloride ($GdCl_3$), NOS inhibitor N-nitro-arginine methyl ester (L-NAME), and NO enhancer molsidomine were administered intraperitoneally.

RESULTS

The ALPPS group showed significant FLR regeneration (FLR/BW: 1.60% ± 0.08%, $P < 0.05$) compared with that observed in the PVL group (1.33% ± 0.11%) 48 h after surgery. In the ALPPS group, serum interleukin-6 expression was suppre-

ssed using $GdCl_3$ to the same extent as that in the PVL group. However, the FLR/BW ratio and Ki-67 labeling index were significantly higher in the ALPPS group administered $GdCl_3$ (1.72% ± 0.19%, $P < 0.05$; 22.25% ± 1.30%, $P < 0.05$) than in the PVL group (1.33% ± 0.11% and 12.78% ± 1.55%, respectively). Phospho-Akt Ser^{473} and phospho-eNOS Ser^{1177} levels were enhanced in the ALPPS group compared with those in the PVL group. There was no difference between the ALPPS group treated with L-NAME and the PVL group in the FLR/BW ratio and Ki-67 labeling index. In the PVL group treated with molsidomine, the FLR/BW ratio and Ki-67 labeling index increased to the same level as in the ALPPS group.

CONCLUSION

Early induction of inflammatory cytokines may not be pivotal for accelerated FLR regeneration after ALPPS, whereas Akt-eNOS pathway activation may contribute to accelerated regeneration of the FLR.

Key Words: Hepatectomy; Nitric oxide; Liver regeneration; Cytokines; NG-Nitroarginine methyl ester; Molsidomine

Core Tip: In extended hepatectomy for hepatobiliary tumors, adequate future liver remnant (FLR) is essential to prevent postoperative liver failure. Portal vein embolization (PVE) and associated liver partition and portal vein ligation for staged hepatectomy (ALPPS) are performed to increase the FLR. Although ALPPS induces more rapid liver regeneration than PVE, the mechanism remains unclear. In this study, we compared ALPPS with portal vein ligation (PVL) in a rat model and found that activation of the Akt-endothelial nitric oxide synthase pathway promotes liver regeneration. The combination of PVL and nitric oxide-producing agents may induce liver regeneration comparable to ALPPS in a non-invasive manner.

INTRODUCTION

Hepatectomy is the most curative treatment for hepatobiliary carcinoma[1,2]. Extended hepatectomy is occasionally performed to achieve R0 surgical margins. However, postoperative liver failure may occur in these cases because of an inadequate volume of the future liver remnant (FLR)[3,4]. To resolve this issue, portal vein embolization (PVE) is widely performed before major hepatectomy to obtain a sufficient FLR volume[5,6]. Although PVE results in a 10%-45% increase in FLR, it requires a waiting period of 2-8 wk[6-8]. Hepatectomy cannot be performed in some cases because of tumor progression, inadequate volume increase, or both in the FLR, even after PVE. Therefore, the resection rate after PVE has been reported as only 70%[7,8]. Furthermore, it has been reported that hepatocellular carcinoma (HCC) is nourished by abnormal vessels in the hepatic artery (HA). Thus, PVE may reduce blood flow in the portal vein and increase blood flow in the HA of the liver to be resected, which may result in rapid progression of HCC[9]. As described above, PVE has limited indications and therapeutic effects. Therefore, the development of new surgical or therapeutic methods is desired to promote further liver regeneration in the short term.

As an alternative to PVE, associating liver partition and portal vein ligation for staged hepatectomy (ALPPS) was reported in 2012[6]. This method enables the FLR to increase by 70%-80% within 10 d[6]. ALPPS promotes a much faster increase of FLR than PVE[6,9], but the mechanism of this rapid liver regeneration remains unclear. Although increases in inflammatory cytokines, such as interleukin-6 (IL-6), which is an inducer in the early stage of liver regeneration, have been reported as a cause of rapid liver regeneration[10-13], it remains controversial[14]. However, in previous studies on the mechanism of liver regeneration after liver resection and portal vein ligation (PVL), shear stress caused by blood viscosity, blood flow velocity, and endothelial nitric oxide synthase (eNOS) activation, followed by NO induction, has been reported to promote liver regeneration[15,16]. This study aimed to explore the mechanism of promoting liver regeneration in ALPPS and investigate the involvement of inflammatory

cytokines and eNOS activation using PVL and ALPPS rat models.

MATERIALS AND METHODS

Animals

Eight-week-old male Wistar rats (CLEA Japan, Kanagawa, Japan) weighing 230-300 g were used in this study. The animals were housed in wood-chip-bedded cages in an air-conditioned room (24 ± 1 °C) with a 12 h light/dark cycle under specific pathogen free condition. There were no diet restrictions. Based on national and institutional regulations and guidelines, all procedures for animal experiments were reviewed by the Committee for Animal Experiments and approved by the President of Shinshu University (Approval numbers 270018 and 019067).

Surgical procedures and study design

Rats were divided into two groups, PVL and ALPPS, and examined 72 h after surgery. A midline laparotomy was performed under isoflurane-induced anesthesia. In the PVL model, the portal vein branches to the caudate lobe, left lobe, left side of the median lobe, and right lobes were ligated with 7-0 silk (Figure 1A). In the ALPPS model, in addition to PVL, liver parenchymal transection between the right lobe and the left side of the middle lobe was performed based on the gross morphology and demarcation line after PVL. The Glisson flowing into the left side of the median lobe was ligated with 7-0 nylon (Figure 1B). Little bleeding occurred during the liver parenchymal transection because the parenchyma on either side of the dissection line was ligated with 6-0 Prolene before parenchymal transection to control intraoperative bleeding. The abdomen was then closed in layers.

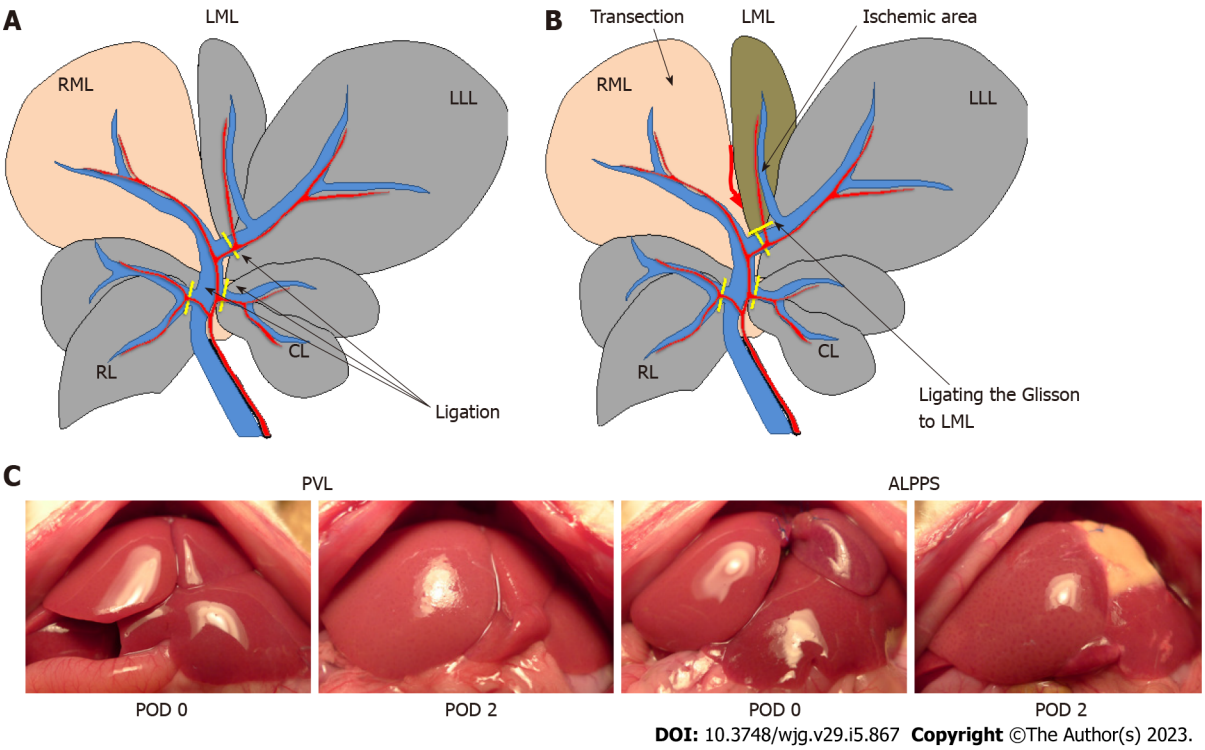
The rats were sacrificed to collect blood samples and liver tissue from the right side of the median lobe (RML) at 1, 4, 6, 24, 48, and 72 h after surgery (n = 5 for each group per time point). Blood samples were collected from the inferior vena cava at the time of liver removal and centrifuged at 2600 × g for 5 min. The serum was stored at -80 °C. Liver tissue samples were frozen in liquid nitrogen and stored at -80 °C. The remaining liver tissue was fixed with 4% paraformaldehyde.

The weight of the FLR, that is, the RML, and body weight (BW) were measured before surgery and at 24, 48, and 72 h after surgery. The BW (FLR/BW) ratio (%) was used as the liver regeneration index. In western blotting analysis and volumetric blood flow analysis, the PVL and ALPPS groups were compared based on the control group, in which only open and closed abdomens were performed.

ELISAs of serum inflammatory cytokines and hepatocyte growth factor

Serum concentrations of IL-6, tumor necrosis factor-α (TNF-α), and hepatocyte growth factor (HGF) were measured at 1, 4, 6, and 24 h after surgery using ELISA kits (R&D Systems, Minneapolis, MN, United States). IL-6 concentration in the RML tissue was also quantified 1 h after surgery.

Immunohistochemistry



The liver tissues were fixed with paraformaldehyde and embedded in paraffin. After deparaffinization, antigen retrieval, and quenching of endogenous peroxidases, the sections were incubated overnight at 4 °C with a mouse monoclonal anti-Ki-67 antibody (1:200 dilution; Dako, Glostrup, Denmark; 1:200 dilution, Abcam, Cambridge, United Kingdom), followed by incubation for 30 min at room temperature with a peroxidase-labeled anti-mouse antibody (Histofine Simplestain Max PO; Nichirei). The sections were immersed in diaminobenzidine solution for visualization and counterstained with hematoxylin. To evaluate hepatocyte proliferation 48 h after surgery, the average percentage of Ki-67-positive cells to total hepatocytes in three random high-power fields was used as the Ki-67 labeling index.

Kupffer cell inhibition in the ALPPS model

To explore the role of inflammatory cytokines in liver regeneration, the Kupffer cell inhibitor gadolinium chloride ($GdCl_3$; Sigma-Aldrich, St. Louis, MO, United States) was used. Another set of animals was used for the Kupffer cell inhibition experiments. We prepared an ALPPS model for $GdCl_3$ administration (n = 3). $GdCl_3$ (10 mg/kg) was administered intraperitoneally 24 h before surgery. In the control group, physiological saline was administered. All rats were sacrificed 48 h after surgery to obtain liver samples.

NOS inhibition in the ALPPS model and NO enhancement in the PVL model

To explore the role of NO in liver regeneration, the NOS inhibitor NG-nitro-arginine methyl ester (L-NAME; Sigma-Aldrich) and the NO enhancer molsidomine (Cayman Chemical, MI, United States) were used. Another set of animals was used for the NOS inhibition and NO enhancement experiments. We prepared the ALPPS model for L-NAME administration, the PVL model for molsidomine administration, and the corresponding control PVL and ALPPS models (n = 5 for each group). L-NAME (100 mg/kg) or molsidomine (10 mg/kg) was administered intraperitoneally 24 h before and during surgery. In each control group, physiological saline was administered. All rats were sacrificed 24, 48, and 72 h

after surgery to obtain liver samples.

Western blot analysis

The RML tissue proteins were collected at 1, 4, and 6 h after surgery using radioimmunoprecipitation assay lysis buffer (Santa Cruz Biotechnology, Inc., CA, United States). The protein concentration was measured using the bicinchoninic acid assay method. Samples of 10 μg proteins from FLRs of PVL and ALPPS models were separated on 4%-12% NuPAGE Gels and transferred onto nitrocellulose membranes. After blocking with 5% dry skim milk for 1 h, the membranes were incubated with primary antibodies overnight at 4 °C, followed by incubation with horseradish peroxidase-conjugated secondary antibodies for 1 h. The blots were developed with ECL Select western blotting Detection Reagent (Amersham, GE Healthcare Life Sciences, Chicago, IL, United States) and photographed using a Molecular Imager ChemiDoc XRS device (Bio-Rad Laboratories, Inc., Hercules, CA, United States). The density of the bands in the immunoblots was analyzed using Image Lab Software (Bio-Rad Laboratories, Inc.). The results are expressed as a percentage of the β-actin internal control. The anti-human antibodies used were rabbit monoclonal antibodies against p-Akt (Ser 473) (cat. no. 4060), p-eNOS (Ser1177) (Cat. no. 9570), p-eNOS (Thr495) (Cat. no. 9574), total eNOS (Cat. no. 32027) (Cell Signaling Technology, Inc., Danvers, MA, United States), and mouse monoclonal antibody against β-actin (Cat. no. A5441; Sigma-Aldrich). Anti-β-actin antibody was used at a 1:3000 dilution, and the other antibodies were used at a 1:1000 dilution.

Volumetric blood flow analysis

Before the estimation of volumetric blood flow in the HA and PV of the FLR, blood velocity and vascular diameter (r) were measured using ultrasonography (Vevo2100, Primetech, Tokyo, Japan). Volumetric blood flow was estimated from the blood velocity and vascular cross-sectional area (πr^2) (volumetric blood flow = blood velocity × πr^2) in mm^3 per second.

Statistical analysis

The collected data were evaluated statistically using the JMP software, version 13.2 (SAS Institute, Cary, NC, United States). Data are expressed as mean ± SD. Statistical analysis was performed using an unpaired student's *t*-test. Statistical significance was defined as $P < 0.05$.

RESULTS

Differences in liver regeneration in PVL and ALPPS models

The FLR/BW ratio increased over time in both groups. At 48 h after surgery, the FLR/BW ratio in the ALPPS group was significantly higher (1.60% ± 0.08%, $P < 0.05$) than that in the PVL group (1.33% ± 0.11%) (Figures 1C and 2A). However, no significant difference was observed between the two groups at 24 and 72 h after surgery. The Ki-67 labeling index of the RML at 48 h after surgery was significantly increased in the ALPPS group (22.1% ± 4.01%, $P < 0.05$) compared with that in the PVL group (12.8% ± 1.73%), which was consistent with the FLR/BW ratio (Figures 2B and 2C).

Association between serum inflammatory cytokines and liver regeneration

The serum concentrations of IL-6, TNF-α, and HGF in RML were measured at 1, 4, 6, and 24 h after surgery. Serum IL-6 and TNF-α levels increased in both groups after surgery compared with the levels before surgery. However, no difference was found in the two groups at 1, 4, and 6 h after surgery. At 24 h after surgery, IL-6 and TNF-α concentrations were significantly higher in the ALPPS group (25.91 ± 6.05 pg/mL, $P < 0.05$ and 1.52 ± 0.68 pg/mL, $P < 0.05$) compared with that in the PVL group (4.11 ± 3.99 pg/mL and 0.54 ± 0.38 pg/mL). Serum HGF concentration at 1 h after surgery was significantly higher in the ALPPS group (68.86 ± 4.89 ng/mL, $P < 0.05$) compared with that in the PVL group (55.34 ± 9.97 ng/mL). However, no significant difference was observed in serum HGF concentration at 4, 6, and 24 h (Figures 3A-C).

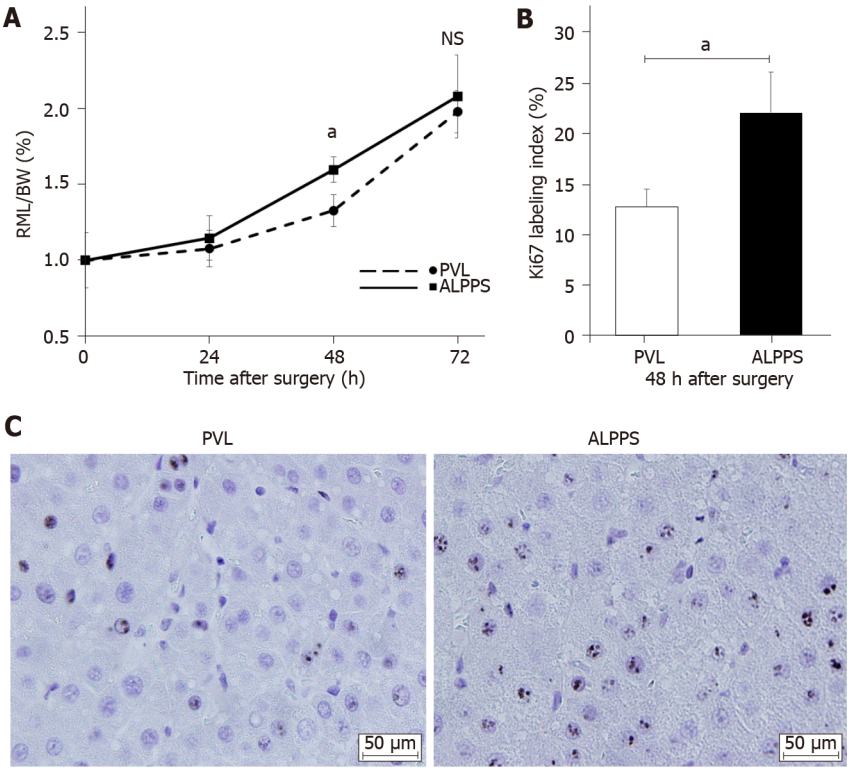
Liver regeneration in the ALPPS model under the suppression of IL-6 using $GdCl_3$

To evaluate the effect of IL-6 on liver regeneration, ALPPS rats were administered $GdCl_3$, which suppressed the activation of Kupffer cells in the liver. In the $GdCl_3$-ALPPS group, the IL-6 concentrations in serum (40.3 ± 11.3 pg/mL, $P < 0.05$) and the RML tissue (3.27 ± 0.54 ng/TP 1 g, $P < 0.05$) 1 h after surgery were significantly decreased compared with the concentrations in the corresponding groups without administration of $GdCl_3$ (Figures 4A and 4B). However, there was no significant difference in the FLR/BW ratio or Ki-67 labeling index at 48 h after surgery in the ALPPS group with or without administration of $GdCl_3$ (Figures 4C and 4D).

Short-term postoperative liver regeneration induced by eNOS

Phosphorylation of Akt and eNOS in RML tissue at 1, 4, and 6 h after surgery was evaluated using western blotting (Figure 5A). Phospho-Akt Ser^{473} and phospho-eNOS Ser^{1177} levels increased in the ALPPS group compared with those in the PVL group. The quantitative measurement revealed that the phosphorylation levels of eNOS Ser^{1177} in the ALPPS group was significantly higher than that in the PVL group at 1 and 4 h after surgery. However, there was no significant difference at 6 h after surgery (Figure 5B).

L-NAME, an NOS inhibitor, was administered to rats to examine whether suppression of eNOS affected liver regeneration. The FLR/BW ratio and Ki-67 labeling index at 48 h after surgery in the L-NAME-ALPPS group were significantly lower than those in the ALPPS group without L-NAME administration and were comparable to those in the PVL group (Figures 6A and 6B).



Additionally, molsidomine, which induces eNOS activation, was administered to the rats to examine whether eNOS activation affects liver regeneration. The FLR/BW ratio and Ki-67 labeling index at 48 h after surgery in the molsidomine-administered PVL (molsidomine-PVL) group were significantly higher than those in the PVL group without molsidomine administration and comparable with those in the ALPPS group (Figures 6C and 6D). However, there was no significant difference in the long-term FLR/BW ratio on a postoperative day 7 between the PVL, ALPPS, and molsidomine-administered PVL groups (data not shown).

Increased HA blood flow in the ALPPS model

PV flow in the PVL and ALPPS groups was significantly faster than that in the control group; however, there was no significant difference in PV flow between the PVL and ALPPS groups (180.1 ± 54.4, 216.6 ± 71.4 mm^3/s) (Figure 7A). HA flow in the PVL group was significantly slower than that in the control group without surgical intervention (1.73 ± 1.14 *vs* 3.66 ± 0.74 mm^3/s, $P < 0.05$), whereas that in the ALPPS group was significantly faster (11.32 ± 2.40 mm^3/s, $P < 0.05$) than that in control and PVL groups (Figure 7B). The total blood flow, that is, the sum of PV and HA, was not significantly different between the PVL and ALPPS groups (Figure 7C).

DISCUSSION

Hepatectomy is the most curative treatment for HCC and intraductal cholangiocarcinoma[1,2]. Additionally, major hepatectomy is the standard operative procedure for perihilar cholangiocarcinoma [17,18]. Extended hepatectomy may be required, depending on the location of the cancer. Postoperative

Values are expressed as the mean ± SD; $n = 5$ for each group; $^{a}P < 0.05$; NS: Not significant; RML/BW: Right side of the median lobe weight/body weight; PVL: Portal vein ligation; ALPPS: Associating liver partition and portal vein ligation for staged hepatectomy.

liver failure that results from insufficient residual liver volume is a fatal complication of hepatectomy. PVE and ALPPS were developed with the aim of pre-operative liver enlargement to avoid postoperative liver failure[5,6,18]. ALPPS leads to the rapid regeneration of FLR compared with PVE, although high mortality (90-d mortality of 9%) and morbidity (grade IIIb of 40% in the Clavien-Dindo classification) are limitations[19]. Elucidation of the mechanism of rapid liver regeneration after ALPPS may contribute to improving surgical outcomes for patients who undergo extended hepatectomy for hepatobiliary malignancies and to the development of novel alternative treatments that provide effective and safe regeneration of the FLR.

In this study, we obtained two crucial findings regarding the mechanism of liver regeneration in ALPPS. First, the induction of inflammatory cytokines, such as IL-6, might not be pivotal for the rapid regeneration of FLR after ALPPS in the early phase. Second, activation of the Akt-eNOS pathway may be an important factor in promoting liver regeneration after ALPPS.

The mechanism of liver regeneration has been studied in animal models of partial hepatectomy. The regeneration process is distinctive, complex, and well-coordinated and depends on the interactions of several signaling pathways, cytokines, and growth factors. Additionally, endocrine hormones, such as norepinephrine, growth hormone, insulin, and thyroid hormones, have been reported to influence these pathways and factors[20-22]. Since Schnitzbauer *et al*[6] reported ALPPS in 2012, there have been several reports to elucidate the major factors in liver regeneration of ALPPS, which promote rapid liver regeneration compared with PVL[10-13,23]. Activation of downstream signals, such as c-Jun N-terminal kinase-Indian hedgehog signaling from stellate cells by inflammatory cytokines[24], activation of the Janus kinase 2/signal transducer and activator of transcription 3 pathway *via* regenerating islet-derived 3α/3β, and hypoxia-induced stabilization of hypoxia-inducible factor-α subunits by hypoxia[14,25,26], have been reported as major factors. However, the mechanism of liver regeneration in ALPPS has not yet been completely elucidated.

Previous studies have reported that the peak of cell proliferation is 48 h after surgery, and inflammatory cytokines and their downstream signal enhancement cause liver regeneration in ALPPS[11,12,23]. Although the peak liver regeneration in this study was consistent with previous studies, the relationship between the early induction of inflammatory cytokines and liver regeneration was not consistent. In this study, serum concentrations of inflammatory cytokines, such as IL-6 and TNF-α, in the short term (1, 4, and 6 h) after surgery did not differ between the ALPPS and PVL groups. However, the ALPPS group showed a greater increase in FLR and a higher Ki-67 labeling index than in the PVL group. Additionally, suppression of inflammatory cytokines using $GdCl_3$ did not suppress liver

regeneration. These results suggest that the induction of inflammatory cytokines in the early phase after ALLPS is not necessarily a major factor in accelerating liver regeneration. The reason why no difference was observed in the expression of inflammatory cytokines may be the site of liver resection, setting of FLR, or differences in animal models. The timing of specimen collection may have influenced the results, as specimens collected 24 h after surgery had higher concentrations in the ALPPS group.

Activation of eNOS and NO induction have been reported to be a mechanism of liver regeneration other than inflammatory cytokines[15,16]. In this study, we focused on the effect of eNOS activation on liver regeneration after PVL and ALPPS. Evaluation of eNOS activation in the liver tissue showed that eNOS Ser^{1177} phosphorylation was significantly increased in the ALPPS model at 1 and 4 h after surgery. Thus, the FLR/BW ratio and Ki-67 labeling index in the ALPPS model were increased compared with those in the PVL model. Furthermore, the activation of Akt, which is upstream of eNOS, was observed, suggesting that the Akt-eNOS pathway contributes to the mechanism of liver regeneration in ALPPS. The administration of L-NAME, which suppresses NO, inhibits liver regeneration. The administration of molsidomine, which activates eNOS, promotes liver regeneration. Molsidomine is a nitrate drug used as a coronary vasodilator for the treatment of angina pectoris; its intermediate metabolite, SIN-1 (ionidamine chlorohydrate) produces NO[27]. When endothelial cells are stimulated by shear stress or vascular endothelial growth factor, phosphoinositide 3-kinase (PI3K) is activated and PIP3 is produced, which activates the PI3K-Akt pathway and activates downstream signals such as eNOS[28,29]. An increase in shear stress, which has been reported to cause NO production[30], is due to hemodynamic changes in the residual liver caused by hepatectomy, which is expected to affect liver regeneration in ALPPS. To evaluate the effect of increased shear stress on liver regeneration, we examined the blood flow exchange after PVL and ALPPS. Contrary to our expectations, there was no difference in PV or total blood flow, which might be associated with shear stress, between the PVL and ALPPS groups; however, HA flow in the ALPPS group was significantly higher than that in the PVL and control groups. Therefore, the difference in oxygenation of the FLR, rather than the shear stress between ALPPS and PVL, might be associated with the difference in liver regeneration. However, Schadde *et al*[25] reported that hypoxia due to reduced HA flow in the FLR promotes hepatic regeneration in patients who underwent ALPPS and in the rat ALPPS model. However, in their study, HA flow was evaluated

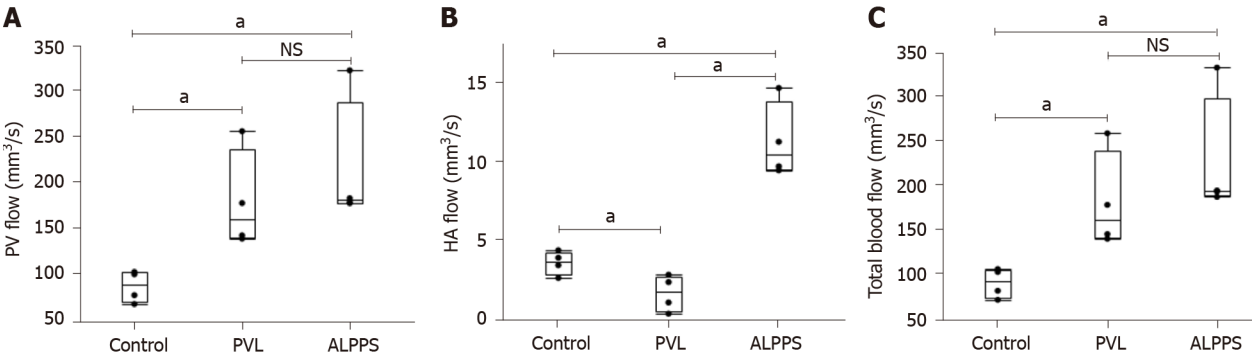

Figure 5 Western blotting of Akt-endothelial nitric oxide synthase pathway-related proteins. A: Western blotting was used to evaluate the expression of phosphorylated Akt and endothelial nitric oxide synthase (eNOS) in right side of the median lobe at 1, 4, and 6 h after surgery in portal vein ligation (PVL) and associating liver partition and portal vein ligation for staged hepatectomy (ALPPS) groups; B: Comparison of the expression of P-Akt Ser^{473} and P-eNOS Ser^{1177} in PVL and ALPPS groups (quantification of western blots, n = 5 for each group). Values are expressed as the mean ± SD; n = 5 for each group; $^{a}P < 0.05$; NS: Not significant; eNOS: Endothelial nitric oxide synthase; PVL: Portal vein ligation; ALPPS: Associating liver partition and portal vein ligation for staged hepatectomy.

only in patients who underwent ALPPS, and this evaluation was not compared with that in patients who underwent PVE. Furthermore, the transition of HA flow before and after ALPPS has not been evaluated in a rat model. In the rat ALPPS model, liver transection between the right and left median lobes with ligation of the Glisson of the left median lobe caused a necrotic change in the left median lobe, which is synonymous with liver resection of the left median lobe considering hemodynamics. These results suggest that both hemodynamic changes and differences in oxygenation of the FLR affect regeneration rates in the ALPPS and PVL models. The increased HA flow to the RML observed in the

ALPPS group may have been due to a hepatic arterial buffer response derived from collateral blood flow blockage by hepatectomy. In contrast, the reason for the observed decrease in HA flow to the RML in the PVL group might be the effect of HA influx from the RML to the left median lobe (LML) *via* collateral circulation after the PV blockade to the LML.

This study had some limitations. First, because we observed short-term changes in rat models, it is unknown whether NO activation promotes clinically meaningful liver regeneration in humans. Second, the mechanism underlying the activation of the Akt-eNOS pathway is unclear and requires further investigation that includes real-time monitoring of oxygenation in the FLR. Despite these shortcomings,

we believe that our results are of interest because few reports have focused on the relationship between eNOS activation and liver regeneration after ALPPS.

CONCLUSION

The activation of the Akt-eNOS pathway in ALPPS may be an important factor in promoting early liver regeneration. If a combination of NO-producing agents and PVL or PVE enables liver regeneration within a short time after surgery, it may be an alternative to ALPPS and is expected to be applied clinically as a less invasive procedure.

ARTICLE HIGHLIGHTS

Research background

Associating liver partition and portal vein ligation for staged hepatectomy (ALPPS) has already been clinically applied in various countries. Although it has been reported that ALPPS offers faster and larger liver regeneration compared to portal vein embolization (PVE), the mechanism of this phenomenon is still unclear.

Research motivation

The aim of this study was to investigate the underlying mechanism of rapid liver regeneration after ALPPS focusing on inflammatory cytokines and endothelial nitric oxide synthase (eNOS) activation.

Research objectives

Activation of eNOS was considered one of key points on mechanism of rapid liver regeneration after ALPPS.

Research methods

Liver regeneration was compared between the rat portal vein ligation (PVL) model and the rat ALPPS model. In addition, impact of administration of gadolinium chloride ($GdCl_3$, Kupffer cell inhibitor), NG-nitro-arginine methyl ester (L-NAME, NOS inhibitor), and molsidomine (NO enhancer) on liver regeneration after PVL and/or ALPPS.

Research results

Administration of $GdCl_3$ before ALPPS provided no significant negative influence of liver regeneration after ALPPS. Administration of L-NAME before ALPPS suppressed liver regeneration after ALPPS, while administration of molsidomine before PVL accerelated liver regeneration after PVL as well as ALPPS.

Research conclusions

ALPPS is an alternative to PVE for reducing posthepatectomy liver failure after major hepatectomy.

Research perspectives

Combination of NO-producing agents and less invasive procedure can be an alternative to ALPPS procedure in the future.

Abstract

BACKGROUND

Small intestinal vascular malformations (angiodysplasias) are common causes of small intestinal bleeding. While capsule endoscopy has become the primary diagnostic method for angiodysplasia, manual reading of the entire gastrointestinal tract is time-consuming and requires a heavy workload, which affects the accuracy of diagnosis.

AIM

To evaluate whether artificial intelligence can assist the diagnosis and increase the detection rate of angiodysplasias in the small intestine, achieve automatic disease detection, and shorten the capsule endoscopy (CE) reading time.

METHODS

A convolutional neural network semantic segmentation model with a feature fusion method, which automatically recognizes the category of vascular dysplasia under CE and draws the lesion contour, thus improving the efficiency and accuracy of identifying small intestinal vascular malformation lesions, was proposed. Resnet-50 was used as the skeleton network to design the fusion mechanism, fuse the shallow and depth features, and classify the images at the pixel level to achieve the segmentation and recognition of vascular dysplasia. The training set and test set were constructed and compared with PSPNet, Deeplab3+, and UperNet.

RESULTS

The test set constructed in the study achieved satisfactory results, where pixel accuracy was 99%, mean intersection over union was 0.69, negative predictive value was 98.74%, and positive predictive value was 94.27%. The model parameter was 46.38 M, the float calculation was 467.2 G, and the time length to segment and recognize a picture was 0.6 s.

CONCLUSION

Constructing a segmentation network based on deep learning to segment and recognize angiodysplasias lesions is an effective and feasible method for diagnosing angiodysplasias lesions.

Key Words: Artificial intelligence; Image segmentation; Capsule endoscopy; Angiodysplasias

Core Tip: Small intestinal vascular malformation (vascular dysplasia) is a common cause of small intestinal bleeding. Herein, we proposed a semantic recognition segmentation network to recognize small intestinal vascular malformation lesions. This method can assist doctors in identifying lesions, improving the detection rate of intestinal vascular dysplasia, realizing automatic disease detection, and shortening the capsule endoscopy reading time.

INTRODUCTION

Small intestinal vascular malformations (angiodysplasias) are common causes of small intestinal bleeding[1,2]. Angiodysplasias are degenerative lesions that manifest as abnormalities of arteries, veins, or capillaries of the original normal blood vessels. Occasionally, the term angiodysplasias include various synonymous disease concepts, such as angioectasia (AE), Dieulafoy's lesion (DL), and arteriovenous malformation. According to the Yano-Yamamoto classification, small bowel vascular lesions are classified into four types under endoscopy[3]. AE includes small erythemas and can be defined as type 1a: punctuate (< 1 mm), or type 1b: patchy (a few mm). They are characterized by thin, dilated, and tortuous veins lacking smooth muscle layers, which explain their weakness and tendency to bleed. Typically, DLs consist of small mucosal defects and can be classified as type 2a: punctuate lesions with pulsatile bleeding or type 2b: pulsatile red protrusions without surrounding venous dilatation[4]. Some arteriovenous malformations and pulsatile red protrusions with dilated peripheral veins are defined as type 3. Congenital intestinal arteriovenous malformations manifest as polypoid or cluster type[5,6] and are classified as type 4. Nevertheless, the Yano-Yamamoto classification cannot fully reflect the histopathological findings.

Capsule endoscopy (CE) is a painless and well-tolerated approach that can achieve complete visualization of the small intestine[7]. It captures images for > 8 h[8]. Previous studies have demonstrated the probability of CE diagnosis of angiodysplasias was 30%-70%, and > 50% of obscure gastrointestinal bleeding patients have angiodysplasias[9-11]. The detection rate of CE was reported to be higher than other diagnostic methods, such as small bowel computed tomography, mesenteric angiography, and enteroscopy. Therefore, using CE as a first-line inspection tool for the diagnosis of angiodysplasias is recommended[12]. Nonetheless, CE has some limitations, and only 69% of angiodysplasias can be diagnosed by gastroenterologists[13]. Less relevant lesions, such as erosions or tiny red spots, are regarded as negative results; however, distinguishing highly relevant lesions from less relevant lesions could be challenging. In addition, the diagnostic efficiency of CE decreases when the presence of bile pigments, food residues, or bubbles affects the observation of the intestinal mucosa. The doctor's manual reading of the entire gastrointestinal tract is time-consuming, and the heavy workload affects the accuracy of the diagnosis. Therefore, making diagnosis of angiodysplasias solely based on CE is challenging.

The detection rate of angiodysplasias in the small intestine can be increased by using artificial intelligence (AI) to assess the effect of automatic diagnosis, which has been successfully applied for the recognition and diagnosis of gastrointestinal endoscopic images[14]. AI assists in the recognition and diagnosis of CE images, eliminates errors in manual reading, reduces the workload of doctors, and

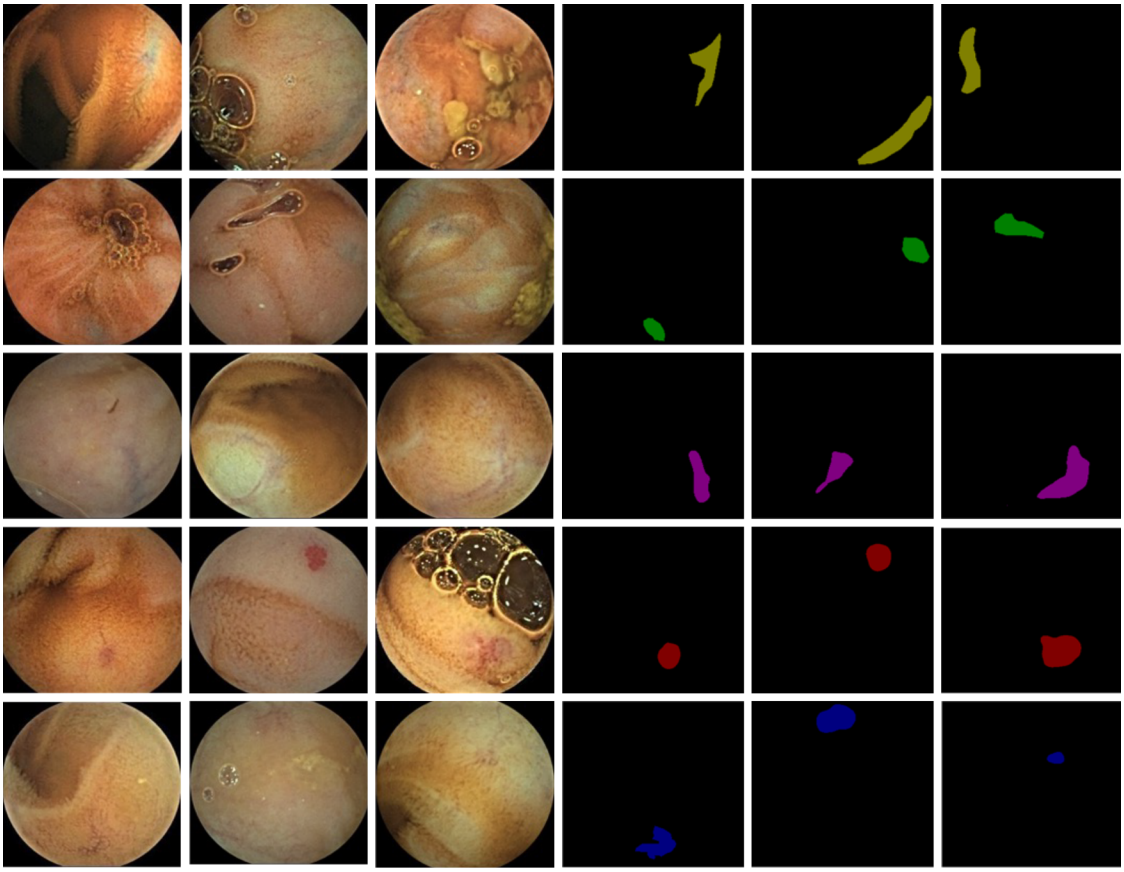
improves diagnosis efficiency. The clinical application of AI-based deep learning technology in wireless CE has been a research focus, which has gained increasing interest in the past two years[15-32]. Several studies[15,23-26] have used deep learning to identify ulcers from CE data. Pogorelov *et al*[27] used the color texture features to detect small intestinal bleeding in CE data. Blanes-Vidal *et al*[28] constructed a classification network to identify intestinal polyp lesions in CE data. Kundu *et al*[29] and Hajabdollahi *et al*[30] identified small bowel bleeding in CE data using a classification neural network. Obscure gastrointestinal bleeding is the main indication for small intestinal CE, and the potential risk of bleeding from vascular malformations is high[14]. Therefore, we focused on AI-assisted recognition technology for angiodysplasias in the present study. Hitherto, there are few semantic segmentation networks based on deep learning to segment and recognize angiodysplasias lesions in CE, which prompted us to introduce a segmentation model in the study. Compared with the classification model and target detection model in deep learning, the segmentation model based on deep learning can more accurately locate the focus of small intestinal vascular malformation, better assist doctors in diagnosing small intestinal vascular malformation, and improve the accuracy and efficiency of doctors' diagnosis.

Currently, significant progress has been made in semantic segmentation in the field of deep learning. To the best of our knowledge, this is the first paper that proposed using a semantic segmentation network to solve the pixel-level small intestinal vascular malformation focus recognition and location. Resnet-50 was used as the skeleton network, and the fusion mechanism based on shallow features and deep features was introduced so that the segmentation model could accurately locate the location and category of lesions. Shallow features can perceive the texture details of lesions, while deep features can perceive the semantic information between lesions. By combining these two features to segment the image, the phenomenon where the lesion area is divided into uncorrelated small areas is reduced, the pixel accuracy (PA) is improved, and the missed detection rate of the lesion is reduced. This paper introduced the proposed network structure in detail and compared three common segmentation models, *i.e.*, PSPNet[31], Deeplabv3+[32], and UperNet[33]. The obtained results confirmed that the model proposed in this paper had high-performance indicators.

MATERIALS AND METHODS

ResNet was introduced in 2015 and won first place in the classification task of the ImageNet competition on account of being "simple and practical". Afterward, many methods, which were based on ResNet50 or ResNet101, have been widely used in detection, segmentation, recognition, and other fields. This method makes a reference (X) for the input of each layer, learning to form residual functions rather than learning some functions without reference (X). This residual function is easier to optimize and can greatly deepen the number of network layers. Moreover, the extracted image features have strong robustness. ResNet50 is faster than ResNet100. Therefore, ResNet50 is selected as the skeleton network of the semantic segmentation network in this paper. Based on the fusion of shallow and deep features, Resnet-50 was used as the skeleton network to construct an improved convolutional neural network (CNN) segmentation network model that automatically recognizes the type of angiodysplasias under CE and draws the outline of the lesion in the study. The present study aimed to assist doctors in diagnosing angiodysplasias lesions with CE.

The model proposed in this study was composed of three sub-units, *i.e.*, down-sampling, up-sampling, and classifier. CE small intestine data were used as input in the module, and the final output was image lesion category information and lesion boundary information.



Research data set

In order to train and evaluate the segmentation model, 378 patients with angiodysplasias who underwent OMOM CE (China Chongqing Kingsoft Technology Co., Ltd) at the Ruijin Hospital between January 2014 and December 2020 were recruited in this study. The sampling frequency of OMOM capsules of 2fps, the working time of > 12 h, and the apex field of view of 150° were used to diagnose the patients. A total of 12403 pictures were identified with an image resolution of 256 × 240. The patient data were anonymized, any personal identification information was omitted, and examination information (such as examination date and patient name) was deleted from the original image. All patients provided written informed consent, and the ethics committee approved the study [the certification number was (2017) provisional ethics review No. 138]. The annotated data were marked by an experienced endoscopy group that included three experts from Ruijin Hospital Affiliated to Shanghai Jiao Tong University. The average age of the experts was 35 years, and their average CE reading experience was 5 years, with an average of 150 CE cases each year. The five types of lesions of vascular malformation were annotated, and 12403 image data and 12403 annotated mask image data were generated. The data sample map is shown in Figure 1.

This project used the image data of 178 cases as the training set and the remaining 200 cases as the test set. The training set was divided into training and verification data at a ratio of 7:3 during the training process. The test set contained 1500 images without lesions and 1500 images with lesions. The training set and test set image data are summarized in Table 1.

Table 1 Details of the training set data and test set data

Lesion type	Lesion morphology	Number of pictures/pieces	
		Training set	Test set
Telangiectasia	Red cluster	838	38
	Red spider nevus	162	4
Venous dilatation	Red branched	752	38
	Blue branched	2583	1088
Vein tumor	Blue cluster	3058	332

Figure 1 Sample image of training data. The left three columns are the original image of the capsule, and the right three columns are the manual annotation results.

Data preprocessing

The training data were preprocessed to meet the requirements of the deep learning model. The preprocessing steps of the model constructed in the study were as follows: (1) Resizing the image to 256 × 240 × 3; (2) using enhancement methods (rotation, flip, and tilt) on the resized image; and (3) normalizing all images. In order to train a deep learning model, the dataset was split. The dataset image was randomly divided into two parts: 70% for training and 30% for verification.

Segmentation network details

The network structure proposed in this study is shown in Figure 2. The construction of the network model was inspired by the UperNet model. ResNet-50 was used as the skeleton network. The fusion mechanism of shallow features and deep features were introduced. Subsequently, the feature with the same size as the original image was obtained through the down-sampling operation. Finally, the classifier was connected to realize the pixel-level segmentation task of the image.

Based on the new semantic segmentation recognition network framework, a single end-to-end network could be trained to capture and analyze the semantic information of the CE small intestine

data. In order to fuse the shallow features and deep feature information, the last feature mapping set output by each stage in ResNet was expressed as C1, C2, C3, and C4, and the two-by-two fusion of features were utilized as down-sampling operation input, where the down-sampling rates were 4, 8, 16, and 32, respectively. The texture features of the lesion were captured at the highest layer, and the pixel-level segmentation of the lesion was completed based on the lowest layer features.

The last down-sampling operation generated a feature map with the same resolution as the original image, with a size of 256 × 240. After the feature was operated by Flatten, a classifier composed of a fully connected layer was connected to complete the segmentation and recognition tasks of the capsule data.

In order to assess the fusion of features of different scales, bilinear interpolation was used to adjust them according to the size, after which a non-evolutionary layer was applied to fuse the features of different levels and reduce the channel size. All non-classifier convolutional layers underwent batch normalization Relu operations after output. The learning rate of the current iteration was equivalent to the initial learning rate multiplied by (1-iter/max-iter_size)^{power}, and the initial learning rate and power were set to 0.02 and 0.9, respectively.

RESULTS

Evaluation index

The performance of the segmentation model of angiodysplasias lesions in CE was evaluated based on the following indicators: Positive predictive value (PPV), negative predictive value (NPV), mean intersection over union (mIOU), and PA. PPV and NPV were calculated using formulae 1 and 2, respectively.

$$PPV = \frac{TP}{TP + FP} \quad (1)$$

$$NPV = \frac{TN}{TN + FN} \quad (2)$$

Where true positive (TP) and true negative (TN) are the true number of positive samples and the true number of negative samples, respectively; FP and FN are false positives and false negatives, respectively. IOU and mIOU calculation formulae are shown as formulae 3 and 4, respectively.

$$OU = \frac{\text{Target area} \cap \text{Prediction area}}{\text{Target area} \cup \text{Prediction area}} \quad (3)$$

$$mIOU = \frac{1}{k+1} \sum_{i=0}^{k} \frac{P_{ii}}{\sum_{j=0}^{k} P_{ij} + \sum_{j=0}^{k} P_{ji} - P_{ii}} \quad (4)$$

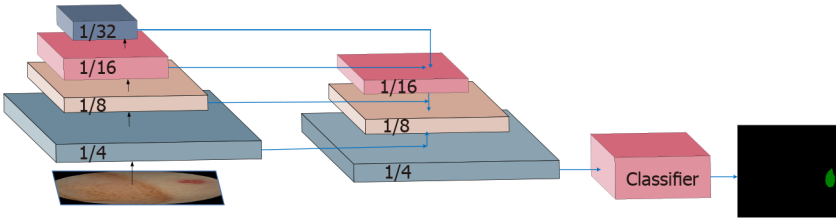
Supposedly, there were K+1 categories (including an empty category or background) in semantic segmentation, which indicated that class i is predicted as i, and class j is predicted as j. The PA is calculated by formula 5.

$$PA = \frac{\sum_{i=0}^{k} P_{ii}}{\sum_{i=0}^{k} \sum_{j=0}^{k} P_{ij}} \quad (5)$$

Experimental design

Python 3 is a good deep-learning programming language that supports multiple deep-learning frameworks. The model was implemented using Python 3 and Torch framework. The training server has a graphics processing unit. All images were first passed to the image data generation class in Pytorch, and the preprocessing operations were performed, including enhancement, resize, and normalization operations. Then, the generated images were sent to the model to start the training. The layers in the backbone network ResNet-50 used pre-trained weights on ImageNet. An optimizer (SGD) was used to train the model, after which a weight decay of 0.0001 and a momentum of 0.9 were applied. Each model ran approximately 25000 Epochs; each Epoch iterated eight times, and the batch size was 8. In the model training process, the loss change, PA index, and mIOU changes were detected (Figure 3).

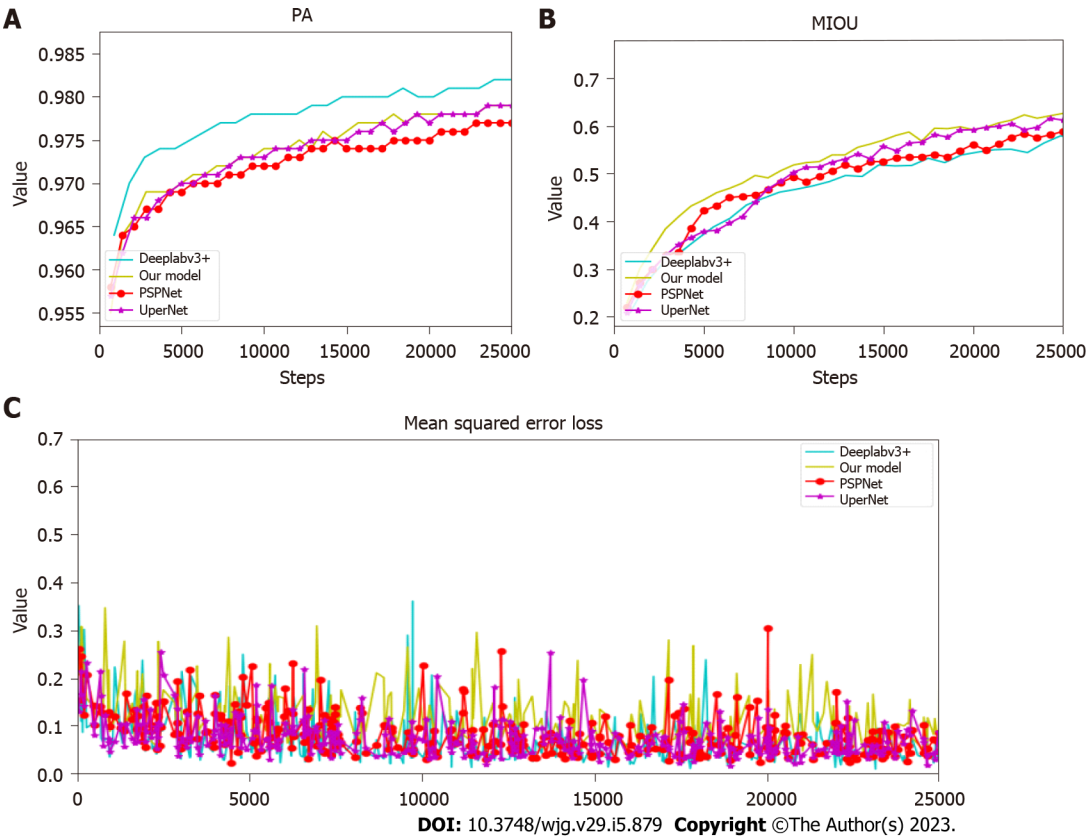
Comparison results of multiple models



On a test set consisting of 3000 image data, the following test indicators were compared on the four models: PPV, NPV, mean IOU, PA, parameter quantity, float calculation quantity, and duration. The results are shown in Table 2.

Based on the method of fusion of shallow and deep features, the CNN segmentation network model was improved and optimized, and the segmentation and recognition of five types of angiodysplasias lesions, *i.e.*, blue branch, blue cluster, red branch, red cluster, and red spider nevus, were realized. This method fully uses the shallow and deep features extracted from the skeleton network to perceive the global information and lesion texture information of the small intestine capsule image data as a whole. Thus, it significantly improves the PPV and NPV of the segmentation model in the angiodysplasias lesion image. In order to obtain the highest PPV, the NPV has to be the highest. The unified perception of the global and local information of the small intestine capsule data was completed through a CNN,

Table 2 Comparison of model accuracy



Network type	PPV (%)	NPV (%)	mIOU	PA (%)	Parameter (M)	Float calculation amount (G)	Time (s)
PSPNet	85.14	98.62	0.64	98	51.43	829.10	0.9
DeeplabV3+	45.07	99.75	0.59	89	59.34	397.00	0.95
UperNet	92.55	95.69	0.69	98	126.08	34.94	0.9
Our model	94.27	98.74	0.69	99	46.38	467.2	0.6

PPV: Positive predictive value; NPV: Negative predictive value; mIOU: Mean intersection over union; PA: Pixel accuracy.

Figure 4 Five rows from top to bottom: blue branch, blue lumpy, red branch, red lumpy and red spider nevus. The first column on the left is the original image, the middle four columns are the results of the current excellent segmentation network, and the last column is the results of the model we proposed.

which reduced the number of network model parameters, the number of float calculations, and the inference time of the deep learning model. Furthermore, a comparative experiment was designed and compared to the current advanced segmentation network models: PSPNet, DeeplabV3+, and UperNet. Our model showed that the NPV reached the highest 98.74% when the PPV was the highest.

The comparison of the segmentation and recognition effects of the four models on the vascular aberration lesions of the CE small intestine data is shown in Figure 4. The model proposed in the study was similar to that of the expert's annotation results.

Compared with relevant literature, Leenhardt *et al*[19] applied technology for segmentation, achieving the highest level of lesion detection, with an NPV value of 96%. However, the algorithm presented in this paper had some advantages in the test set. Also, our NPV value was 98%.

DISCUSSION

The classification network and the target detection network are the mainstream network structure that combines the deep learning model and the CE diagnosis method. In the present study, we introduced the segmentation network in deep learning, segmented and identified the angiodysplasias lesions, and completed the pixel-level segmentation task of the angiodysplasias lesions. The semantic segmentation network model had clinical practicality application as assessed using the training and test sets in comparative experiments.

The segmentation networks have been obviously developed in the field of deep learning. PSPNet uses the prior knowledge of the global feature layer to understand the semantics of various scenes, combined with the deep supervision loss to develop an effective optimization strategy on ResNet and embed difficult-to-analyze scene information features into the functional connectivity networks prediction framework to establish a pyramid. The pooling module aggregates the contextual information in different regions and improves the ability to obtain global information. This system was used for scene analysis and semantic segmentation and was 83% accurate on the COCO data set. The DeepLabV3+ model was based on an encoder-decoder structure, which improved the accuracy and saved the inference time; an accuracy rate of 89% was obtained in the COCO dataset. UperNet used

unified perception analysis to build a network with a hierarchical structure to ensure that multiple levels were resolved at visual concepts, learn the differentiated data in various image datasets, achieve joint reasoning, and explore the rich visual knowledge in the images. Finally, 79.98%-PA was obtained on the ADE20K data set. UperNet used a unified perception analysis module from scenes, objects, parts, materials, and textures to simultaneously analyze the multilevel visual concepts of images, such that many objects could be segmented and recognized, and the rate of missed objects could be reduced. The CE small intestine image data has a simple scene and fewer semantic levels. The use of large segmentation network models would cause over-fitting in training and high computational complexity. This study was inspired by UperNet and optimized basic CNN segmentation network, which led to the creation of a network model suitable for the segmentation and recognition of angiodysplasias with CE.

On the other hand, a case-based dataset encompassing typical vascular malformation images, atypical angiodysplasias images, and normal images was constructed, including pictures with poor intestinal cleanliness. According to the color and morphology of the angiodysplasias lesions in the cases, the five types of angiodysplasias lesions were summarized as blue branched, blue cluster, red branched, red cluster, and red spider nevus. The dataset constructed in this study verified the clinical applicability of the semantic segmentation model. Thus, the dataset was essential in diagnosing CE small bowel vascular malformation based on the deep learning model.

CONCLUSION

The deep learning model constructed in this study showed high PPV and NPV for the segmentation and recognition of angiodysplasias lesions. In the future, it could be used to assist capsule endoscopists in the real-time diagnosis of angiodysplasias lesions. Deep learning does not require prior knowledge, as it can directly learn the most predictive features from image data, as well as segment and recognize the image. The larger the amount of data, the higher the advantages of deep learning and the higher the recognition accuracy. AI facilitates grassroots' CE to obtain the same diagnosis effect as senior experts. However, the current uneven distribution of medical resources and the technical level of grassroots CE are the driving forces for the development of AI. In conclusion, the segmentation model based on deep learning can assist doctors in identifying the lesions of small intestinal vascular malformations.

ARTICLE HIGHLIGHTS

Research background

Small intestinal vascular malformations (angiodysplasias) commonly cause small intestinal bleeding. Therefore, capsule endoscopy has become the primary diagnostic method for angiodysplasias. Nevertheless, manual reading of the entire gastrointestinal tract is a time-consuming heavy workload, which affects the accuracy of diagnosis.

Research motivation

The doctor's manual reading of the entire gastrointestinal tract is time-consuming, and the heavy workload affects the accuracy of the diagnosis. Also, significant progress has been made in semantic segmentation in the field of deep learning.

Research objectives

This study aimed to assist in the diagnosis and increase the detection rate of angiodysplasias in the small intestine, achieve automatic disease detection, and shorten the capsule endoscopy (CE) reading time.

Research methods

A convolutional neural network semantic segmentation model with feature fusion automatically recognizes the category of vascular dysplasia under CE and draws the lesion contour, thus improving the efficiency and accuracy of identifying small intestinal vascular malformation lesions, was proposed.

Research results

The test set constructed in the study achieved satisfactory results: pixel accuracy was 99%, mean intersection over union was 0.69, negative predictive value was 98.74%, and positive predictive value was 94.27%. The model parameter was 46.38 M, the float calculation was 467.2 G, and the time needed to segment and recognize a picture was 0.6 s.

Research conclusions

Constructing a segmentation network based on deep learning to segment and recognize angiodysplasias

lesions is an effective and feasible method for diagnosing angiodysplasias lesions.

Research perspectives

The model detects the small intestinal malformation lesions in the capsule endoscopy image data and draws the lesion area through segmentation.

FOOTNOTES

Author contributions: Chu Y read and reviewed capsule endoscopy imagines, and participated in the design, writing, and revision of the manuscript; Huang F performed AI algorithm research, designed the segmentation recognition protocol, and verified the algorithm; Gao M organized the experimental results, visualized the experiment, and wrote the draft of the paper; Zou DW designed and revised the protocol of the paper; Zhong J reviewed capsule endoscopy images; Wu W and Wang Q participated in the reading of CE and preparation of the material; Shen XN and Gong TT partial writing of the manuscript; Li YY contributed to the coding and debugging of interface between algorithm and software; Wang LF designed and modified the protocol of the paper.

Abstract

BACKGROUND

Conventional transarterial chemoembolization (cTACE) is the current standard treatment for intermediate-stage hepatocellular carcinoma (HCC). Post-embolization syndrome (PES) is complex clinical syndrome that presents as fever, abdominal pain, nausea, and vomiting. Either dexamethasone (DEXA) or N-acetylcysteine (NAC) is used to prevent PES; however, the synergistic effect of their combined therapy for preventing PES and liver decompensation has not been determined.

AIM

To evaluate the efficacy of DEXA and NAC combination in preventing PES and liver decompensation after cTACE.

METHODS

Patients with Barcelona Clinic Liver Cancer stage A or B HCC who were scheduled for TACE were prospectively enrolled. All patients were randomly stratified to receive NAC and DEXA or placebo. The dual therapy (NAC + DEXA) group received intravenous administration of 10 mg DEXA every 12 h, NAC 24 h prior to cTACE (150 mg/kg/h for 1 h followed by 12.5 mg/kg/h for 4 h), and a continuous infusion of 6.25 mg/h NAC plus 4 mg DEXA every 12 h for 48 h after cTACE. The placebo group received an infusion of 5% glucose solution until 48 h after procedure. PES was defined by South West Oncology Group toxicity code grading of more than 2 that was calculated using incidence of fever, nausea, vomiting, and pain.

RESULTS
One-hundred patients were enrolled with 50 patients in each group. Incidence of PES was significantly lower in the NAC + DEXA group compared with in the placebo group (6% *vs* 80%; $P < 0.001$). Multivariate analysis showed that the dual treatment is a protective strategic therapy against PES development [odds ratio (OR) = 0.04; 95% confidence interval (CI): 0.01-0.20; $P < 0.001$). Seven (14%) patients in the placebo group, but none in the NAC + DEXA group, developed post-TACE liver decompensation. A dynamic change in Albumin-Bilirubin score of more than 0.5 point was found to be a risk factor for post-TACE liver decompensation (OR = 42.77; 95%CI: 1.01-1810; $P = 0.049$).

CONCLUSION
Intravenous NAC + DEXA administration ameliorated the occurrence of PES event after cTACE in patients with intermediate-stage HCC.

Key Words: Hepatocellular carcinoma; Post-embolization syndrome; Transarterial chemoembolization; Liver decompensation

INTRODUCTION

Hepatocellular carcinoma (HCC) is a major-public health concern and the fourth common cause of cancer-related deaths worldwide[1]. In Thailand, HCC is the second most common tumor type and the most common cause of cancer-related death. Without treatment, patients with HCC have a one-year overall survival rate of less than 20%. Conventional transarterial chemoembolization (cTACE) has been established as a standard treatment for HCC with Barcelona Clinic Liver Cancer (BCLC) stage B. Systemic reviews and meta-analyses have demonstrated that cTACE therapy improved the survival of patient at this stage. HCC patients who underwent super-selective TACE had a 5-year survival rate of 40%-48%. cTACE involves embolization of vessel supply to tumors, causing ischemia in not only tumor cells but also normal hepatocytes, along with targeted chemotherapy; the systemic effects of chemotherapeutic agents result in the occurrence of post-embolization syndrome (PES)[2-5].

PES is a complex clinical syndrome manifested as fever, abdominal pain, nausea, and vomiting[6,7] with a South West Oncology Group (SWOG) score > 2[7]. PES is self-limited and either resolves within 24 h or exhibits sustained symptoms for up to two weeks based on various factors such as tumor size, tumor numbers, dosage of chemotherapy, and performance status of the patient[6,8,9]. Management of PES mainly includes supportive treatment such as with analgesic, antiemetic, and antipyretic administration[9,10]. Depending on its pathogenesis, PES may be related to systemic inflammation, resulting in toxic and ischemic effects on tumor cells and hepatocytes[9]. Steroids and antioxidants may play an important role in the prevention and treatment of PES. Dexamethasone (DEXA) and prednisolone are recommended by the National Comprehensive Cancer Network as effective medications for preventing chemotherapy-induced nausea/vomiting. Moreover, a few randomized control trials have demonstrated the effect of DEXA in terms of PES prevention[11-14]. N-acetylcysteine (NAC), an established glutathione precursor and a potent antioxidant, was found to ameliorate ischemic liver injury by improving the systemic hemodynamic parameter and tissue oxygen delivery in animal models[14-16]. Further, a pilot study reported that NAC can reduce the incidence of PES after cTACE but cannot reduce that of post-TACE liver decompensation[17]. Currently, there are no standard prevention guidelines for PES. Our study aims to evaluate the dual effect of DEXA and NAC therapy in preventing

PES or liver decompensation after cTACE in patients with HCC.

MATERIALS AND METHODS

Study design

A randomized, double blind, placebo-controlled trial was conducted at the Gastroenterology and Liver Unit, Vajira Hospital, Navamindradhiraj University, Bangkok, Thailand from November 2020 to January 2022.

Study population

Eligible patients were those aged 18-80 years with diagnosed early- or intermediate-stage HCC, according to BCLC classification, and had a good performance status, defined by the Eastern Cooperative Oncology Group. Diagnosis of HCC was based on either histological or radiological typical hallmark criteria according to the American Association for the Study of Liver Disease[18] and European Association for the Study of the Liver[19]. The exclusion criteria were as follows: (1) Decompensated liver cirrhosis (Child-Pugh score ≥ 9) or cirrhosis with main portal vein invasion; (2) Congestive heart failure and/or respiratory failure; (3) Severe comorbid illness, such as end-stage renal disease, persistent poorly-controlled diabetes mellitus or hemoglobin A1C ≥ 8.5, uncontrolled hypertension (systolic blood pressure ≥ 180 mmHg or diastolic blood pressure ≥ 120 mmHg), with a life expectancy of < 6 mo; (4) Severe allergy or anaphylaxis/anaphylactoid to NAC; (5) Pregnancy; and (6) History of non-steroid anti-inflammatory drugs, steroids, or NAC use within 21 d of trial initiation. All enrolled patients agreed on receiving cTACE treatment and provided informed consent before participating in the study.

Sample size calculation

Based on previous results, the incidence of PES among patients with HCC after receiving cTACE was > 60%[12]. Superiority of the DEXA regimen over the control regimen was defined as a 25% decrease in PES. Intravenous DEXA was hypothesized to reduce the incidence of PES by 20%. This study used a two-tailed test that calculated the requirement of at least 44 patients in each group to obtain a P value < 0.05 with alpha and beta errors of 5% and 20%, respectively.

Ethical approval

The study protocol conforms to the ethical guidelines of the 1975 Declaration of Helsinki and was approved by the Institutional Review Board of Faculty of Medicine, Vajira Hospital (COA 051/2564).

Randomized strategy and intervention

All patients were admitted at least 24 h before the prescheduled cTACE procedure and were randomly (1:1) assigned to either NAC–DEXA or placebo group. The randomization sequence was computer-generated in blocks of four and stratified according to Child-Pugh classification (class A or B). All patients were blinded to the treatment assignment. Both groups underwent therapy initiation 24 h prior to the procedure. The specific dosage of the NAC-DEXA protocol was based on a previously reported recommended dosage[11,17]. The NAC-DEXA group received intravenous infusion of 5% dextrose with NAC, with an initial loading dose of 150 mg/kg/h over 1 h followed by 12.5 mg/kg/h for 4 h and 10 mg of intravenous DEXA every 12 h; this was followed by continuous intravenous infusion of 6.25 mg/kg/h NAC and 4 mg of intravenous DEXA every 12 h for the remaining 48 h post-TACE. The placebo group received 5% glucose in normal saline for 48 h at an infusion rate of 60 mL/h post-TACE (as shown in Supplementary Figure 1). If mild-to-moderate allergic symptoms developed (*e.g.*, urticarial rash or bronchospasm), treatment was temporarily stopped for 1 h and intravenous antihistamine was immediately administered; treatment was resumed after the symptoms subsided. If severe allergic or anaphylactoid reaction occurred, treatment was permanently stopped, and the patient was treated according to standard protocol for severe allergic reaction. cTACE was performed by two interventional radiologists (Tanasoontrarat W and Claimon T) who were blinded to the randomization assignment. Pre-procedure single intravenous dose of ceftriaxone (1 g) or amoxicillin-clavulanic acid (1.2 g) along with single intravenous dose of ondansetron (8 mg) was administered to all patients. The femoral artery was catheterized under local anesthesia. A thorough angiographic examination was performed to locate all of the tumor-feeding arteries. An emulsion of lipiodol (2.5-15 mL) and chemotherapeutic agent (mitomycin, 5-20 mg) was infused into the feeders at an optimal dose determined by the interventional radiologist to be sufficient for tumor control. Thereafter, gelatin sponge particles were injected through the tumor-feeding branch. Selective cTACE was defined as occlusion of the segmental or subsegmental arterial feeder.

Post-procedural assessment

After completion of the procedure, all patients were admitted in the hospital for at least 72 h. During

hospitalization period, the following parameters were recorded: Symptoms (nausea, vomiting, fever, abdominal pain, and anorexia), vital signs, and other adverse events. Laboratory parameters, including liver function test, erythrocyte sedimentation rate, and C-reactive protein, were assessed at 24 and 48 h post-procedure. Hemoculture, urinalysis, complete blood count, and chest X-ray were performed if body temperature was > 38 °C.

Outcome measurement

The primary outcome was the development of PES after TACE within 48 h. In the present study, PES was identified using three different definitions: (1) SWOG toxicity coding score characterized by fever, nausea, vomiting, and/or abdominal pain within 48 h post-procedure, defined as calculated sum score more than two point (Supplementary Table 1)[7]; (2) Criteria defined by Ogasawara *et al*[11] in a randomized double-blind control study of DEXA, based on Common Terminology Criteria for Adverse Events (CTCAE) [version 5 (Supplementary Table 2) with symptoms other than those of grade I]; and (3) Criteria defined by Siramolpiwat *et al*[17] in a randomized controlled trial of single NAC dose (temperature ≥ 38.5 °C and 3-fold higher alanine transaminase level from baseline within 48 h post-procedure). The secondary outcome was the development of post-TACE liver decompensation, defined as an increase in Child-Pugh score of more than two points or newly developed decompensating events, such as ascites, hepatic encephalopathy, or serum total bilirubin > 2 mg/dL. Other cumulative adverse events (classified by CTCAE) and length of hospital stay were compared between the two groups. In patients with suspected infection or > 38 °C body temperature, laboratory testing and septic work-up were performed; moreover, these patients were treated with empirical antibiotic therapy until fever subsided or hemoculture was negative. All patients were followed up after 7 d to evaluate other post-procedure events.

Statistical analysis

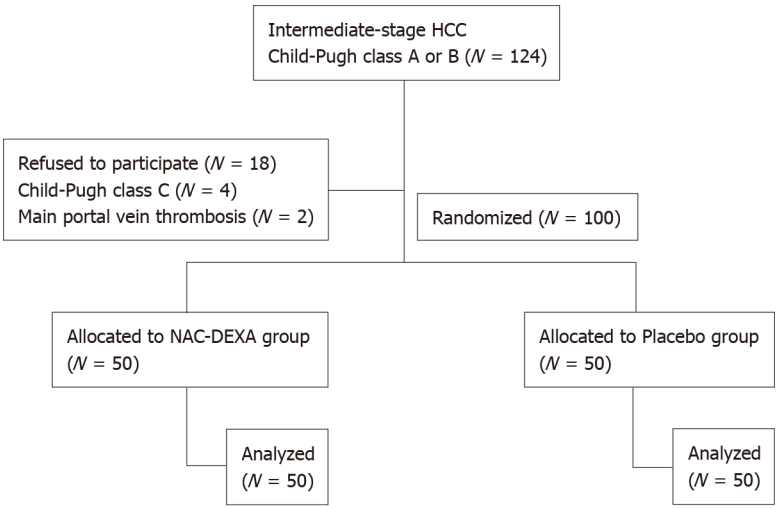
Continuous data are presented as mean with standard deviation (SD) or median with range. Student's *t* test or the Mann-Whitney *U* test was performed to compare between two groups. For categorical data, Chi-square test or Fisher's exact test was applied. Statistical significance was set at $P < 0.05$. For analysis of factors that impact PES development, a logistic regression analysis was performed. Data are reported as odds ratio (OR) with 95% confidence interval (CI). All serious adverse events were reported to the Institutional Review Board of the Faculty of Medicine, Vajira Hospital, Navamindradhiraj University.

RESULTS

Patient characteristics

A total of 124 patients with HCC were screened from November 2020 to January 2022. Eighteen patients who refused to participate in this study, four patients who progressed to Child-Pugh class C, and two patients with main portal vein thrombosis were excluded. The remaining 100 patients who underwent TACE randomly received NAC-DEXA ($n = 50$) or placebo ($n = 50$) treatment. Figure 1 illustrates a flow chart of patients enrolled in this study. The mean age of patients was 60.6 years, with a male predominance (89%). The prevalence of comorbid diabetes was not different between the NAC-DEXA and placebo groups (34% *vs* 32%, $P = 0.83$). All patients exhibited cirrhosis, the majority of which with an etiology of chronic hepatitis B and alcoholic cirrhosis, followed by chronic hepatitis C, and a minority showing non-alcoholic steatohepatitis etiology. Most patients (83%) were classified as Child-Pugh class A, with no difference in mean Child-Pugh scores between the two groups (5.5 ± 0.8 in NAC-DEXA *vs* 5.5 ± 0.9 in placebo). Almost all patients (91%) were in BCLC stage B. Nine patient in BCLC stage A were justified for TACE as it would serve as a bridging therapy before curative treatment. Nearly half of the patients exhibited alpha fetoprotein (AFP) level > 200; however, the distribution of AFP level was not statically significant in both groups. Per tumor characteristics, no difference in the median tumor diameter between the two groups (NAC-DEXA, 5.5 cm; range 1.4-19 cm *vs* placebo, 7.95 cm; range 1.4-17.2 cm; $P = 0.39$) was observed. More than 50% of patients in both groups had multiple nodules (Table 1). Approximately 34% of the patients underwent their first TACE session. The type of chemotherapy and the volume of lipiodol did not differ between the two groups. Level of embolization was selected based on tumor position. In the same TACE episode, more than one-third (36%) of patients in the NAC-DEXA group had embolization of more than two branches.

Primary outcome



According to the various pre-defined criteria mention above, PES was detected in 43% of the patients. Most patients with PES had fever (93.0%) and nausea (72.1%), while only five (11.6%) patients had abdominal pain. The occurrence of PES after TACE was significantly lower in the NAC-DEXA group than in the placebo group in all PES-defining criteria (SWOG score more than 2 point, 6% *vs* 80%; Siramolpiwat *et al*[17] criteria, 2% *vs* 54%; and Ogasawara *et al*[11] criteria, 10 % *vs* 84 %; all $P < 0.001$) as shown in Figure 2A. The NAC-DEXA group had a lower mean SWOG PES score than the placebo group

(0.38 ± 1.1 *vs* 4.04 ± 2.2; $P < 0.001$). Baseline characteristic comparison of patients with or without PES after TACE is shown in Table 2. The PES group had a higher proportion of patients with large tumor size (> 5 cm) (67.4% *vs* 47.4%; $P = 0.045$) and massive tumor burden (up to 12 criteria; 48.8% *vs* 26.3%; $P = 0.02$). Neither volume of embolizing agents nor level of vessels embolization influenced PES occurrence. Nevertheless, most (86%) patients in the PES group underwent TACE with single vessel embolization technique.

Secondary outcomes

Interestingly, post-TACE liver decompensation occurred only in the placebo group (14% *vs* 0%; $P < 0.006$). All cases were accompanied by PES. A higher proportion of patients with baseline Child-Pugh class B was observed in the post-TACE liver decompensation group, but no statistical significance was found (28.6% *vs* 16.1%, $P = 0.39$). A higher proportion of patients with abnormal liver function test, except albumin levels, was observed in the liver decompensation group. Neither tumor burden nor number of cTACE episodes influenced the occurrence of post-TACE liver decompensation. Multiple vessel embolization was performed for more patients in the post-TACE liver decompensation group compared with the group without liver decompensation (57.1% *vs* 28%, $P = 0.02$). A shorter median duration of hospital stay was observed in the NAC-DEXA group (4 *vs* 6 d; $P < 0.001$) as seen in Figure 2B. Most patients with PES were febrile, requiring empirical antibiotics therapy that was provided until negative hemoculture was obtained; this was the main reason for increased duration of hospitalization. Acute kidney injury was observed in three patients with baseline chronic kidney disease. All of them showed improved creatinine level and glomerular infiltration rate and received standard intravenous fluids at a rate of 60 mL/h from 24 h pre-TACE till 48 h post-TACE.

AFP: Alpha fetoprotein; ALBI: Albumin-bilirubin; ALP: Alkaline phosphatase; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; BCLC: Barcelona Clinic Liver Cancer; cTACE: Conventional transarterial chemoembolization; Hct: Hematocrit; IQR: Interquartile range; MELD: Model of end-stage liver disease; PES: Post-embolization syndrome; PTT: Prothrombin time; SD: Standard deviation; WBC: White blood cell.

Predictors of PES

In univariate analysis of tumor volume, calculated increase in Albumin-Bilirubin (ALBI) score of more than 0.5 and a dynamic change in liver function (more than 20-fold and 1.5-fold increase from baseline in transaminase and bilirubin levels, respectively) within 48 h post-TACE were associated with the development of PES. Multivariate analysis showed that only intravenous NAC-DEXA pre-procedure could reduce the incidence of PES (OR = 0.04; 95%CI: 0.01-0.2; P < 0.001) (Table 3).

Predictors of liver decompensation

In univariate analysis, an occurrence of PES after TACE with an SWOG score > 4, more than 0.5 point increase in ALBI score, and a 1.5-fold increase from baseline in bilirubin level were associated with the development of liver decompensation (Table 3). In multivariate analysis, only a dynamic change in ALBI score > 0.5 point was considered an important risk for occurrence of liver decompensation with an OR of 42.77 (95%CI: 1.01-1810; P = 0.049).

Safety

Only two patients in the NAC-DEXA group developed a minor allergic skin reaction; in which, we disrupted treatment immediately. Six hours after drug discontinuation and administration of anti-allergic medication, the symptoms resolved. Subsequently, both patients completed the NAC-DEXA protocol with a lower infusion rate. No serious adverse event was reported in the NAC-DEXA group (Figure 2C). One patient in the placebo group died within 90 d post-procedure due to severe sepsis with liver decompensation. Although most patients were febrile post-TACE procedure, none contracted intrahospital secondary bacterial infection. The incidence of hyperglycemia did not differ between the NAC-DEXA and placebo groups (34% *vs* 32%, P = 0.83). Only three patients experienced grade 3 CTCAE hyperglycemia that was managed with antidiabetic therapy. According to changes in the liver function test at 48 h post-TACE, the 3-fold increase in total bilirubin level from baseline, but not transaminase, was more pronounced in the placebo group compared with that in the NAC-DEXA group (58 % *vs* 18 %, P = 0.006; Supplementary Table 3).

DISCUSSION

Pathogenesis of PES is conceivably related to multiple factors, such as direct toxic effects of chemotherapeutic agents and release of inflammatory cytokines related to tumor cell necrosis or ischemic hypoxic injury of normal hepatocytes[13,17,20]. The incidence of PES after TACE, per previous reports, ranges

ALBI: Albumin-bilirubin; aOR: Adjusted odds ratio; AST: Aspartate aminotransferase; CI: Confidence interval; DEXA: Dexamethasone; NAC: N-acetylcysteine; OR: Odds ratio; PES: Post-embolization syndrome; TACE: Transarterial chemoembolization.

widely (45%-83%). Studies that did not provide a strategic prophylaxis for PES reported an incidence of up to 80%. The incidence of PES in the present study was 43%. PES was verified by the occurrence of symptoms such as fever, nausea, vomiting, and abdominal pain, using SWOG toxicity code score of more than two point[7]. Fever is the most common symptom exhibiting a heterogeneity of prevalence (11.6%-74%), followed by nausea (11.6%-80.6%) and vomiting (16.2%-58.9%)[6,9,12,13,21]; in this study, the reported prevalence is 90%, 66%, and 54% for fever, nausea, and vomiting, respectively. Amelioration of nausea and vomiting by ondansetron premedication (8 mg) and selection of the less adverse chemotherapeutic events-causing agent, mitomycin C, may explain the lower incidence of nausea/vomiting in the present study than that in previous studies. Despite the application of super-selective single vessel embolization technique by radio-intervention at our center, a large tumor burden and a trend of higher mitomycin dose (> 10 mg) was observed and may have affected both tumor and normal liver cell necrosis, resulting in a higher PES occurrence.

NAC not only lowers free-radical levels, attributed to its antioxidant properties, but also acts as an indirect antioxidant by increasing the glutathione level and anti-inflammatory effect[22]. Therefore, many gastrointestinal guidelines recommend NAC for the treatment of alcoholic hepatitis[23], acetaminophen overdose[24], and non-acetaminophen acute liver failure[25]. Other favorable effects could be linked to its hepatoprotective activity. Interestingly, Siramolpiwat *et al*[17] demonstrated this protective effect; intravenous NAC minimized PES compared with the placebo group even though criteria for PES diagnosis was defined as only occurrence of fever and elevated serum alanine transaminase, without reference to clinical symptoms.

The beneficial effects of DEXA were presumably attributed to its antiemetic and inflammation dampening properties. Kogut *et al*[26] demonstrated that patients receiving prophylactic DEXA tended to require lower doses of antiemetic agents than those who do not. Ogasawara *et al*[11] reported that intravenous administration of a combination of DEXA and antiemetics (total 36 mg) for 3 d ameliorated PES by 52.5%. Recently, a randomized controlled trial by Sainamthip *et al*[12] demonstrated that a single

NAC: N-acetylcysteine; DEXA: Dexamethasone.

dose of intravenous DEXA (8 mg) can prevent PES, achieving a negative PES rate of 63.3%.

We decided to maximize the protective effect of DEXA and NAC in prevention of PES by combining the two, with intravenous administration of DEXA (cumulative dose of 36 mg) and NAC 24 h before and continuous infusion until 48 h after cTACE. Interestingly, our study found that pre-TACE therapy with NAC-DEXA regimen led to a lower PES occurrence of less than 10%, which is the lowest incidence compared with those reported in previous publications (24.6% in a NAC study[17] and 37%-47% in DEXA studies[11,12]. The synergistic effect of NAC and DEXA can diminish systemic inflammatory response and ischemic hepatitis[27-29]. Hence, this study emphasizes the advantage of NAC-DEXA combination due to its synergistic PES-reducing effect.

Post-TACE liver decompensation is one of the most important complications and is associated with significant morbidity and mortality[21,30]. It is characterized by an increase in Child-Pugh score of more than 2 points, ≥ 2 mg/dL rise in serum total bilirubin level, newly developed ascites, or hepatic encephalopathy within two weeks post-procedure. In the present study, seven patients developed post-TACE

liver decompensation. Previous studies reported that portal vein thrombosis, poor baseline liver status, high serum AFP, and PES were associated with this complication[17,27,28]. Correspondingly, all patients with liver decompensation in our study had concurrent PES. In patients who underwent post-TACE without any prophylaxis treatment, we observed a lower incidence (14%) of liver decompensation compared with those in previous reports (13.4%-17.3%)[28,29]; the lower incidence in our study is attributed to the fact that a majority of patients had good liver reserve with Child-Pugh class A. Because all eligible cTACE patients in the present study fulfilled BCLC staging criteria, neither Child-Pugh nor Model for End-Stage Liver Disease score influenced the outcome. Further, more than half of our decompensated patients received cTACE intervention with multiple vessel embolization technique, which may have compromised the vessels; however, owing to the small sample size in this group, further studies are warranted.

ALBI score is the only objective parameter to stratify patients into different grades and is used to predict the prognosis of all HCC stages. This new model outperforms the Child-Pugh score for evaluation of liver function reserve. In a previous study, evaluation of baseline ALBI score in HCC patients who underwent cTACE not only predicted survival but also estimated liver decompensation and liver failure[31]. In our study, the mean pre-treatment ALBI score was not significantly different between the NAC-DEXA and placebo groups. Our findings indicate that the proportion of preserved liver, defined by ALBI grade 1, was comparable between the two groups. Moreover, all patients who developed post-TACE liver decompensation had a baseline ALBI grade 1 or 2 with a mean pre-treatment ALBI score of -2.57. The increase in ALBI score was hypothesized to be a novel non-invasive tool for earlier prediction of post-TACE liver decompensation than Child-Pugh score. Our study demonstrated that a dynamic increase in ALBI score of more than 0.5 point had a marked impact on liver decompensation. Thus, the application of dynamic increase in ALBI score, but not albumin level, for a prediction of early post-TACE liver decompensation requires further research.

Limitation

Our study had some limitations. First, we did not perform dose optimization for DEXA and NAC in order to minimize PES. Second, this dual treatment was not compared with single DEXA. The dynamic changes in cytokine levels due to this dual treatment is an interesting topic for further study.

CONCLUSION

A combination of DEXA and NAC can not only maximize the reduction in PES incidence but also shorten hospitalization period in HCC patients undergoing cTACE procedure. Dynamic alterations in ALBI score, but not CPS, may predict liver decompensation.

ARTICLE HIGHLIGHTS

Research background

Transarterial chemoembolization (TACE) is the current standard treatment for intermediate-stage hepatocellular carcinoma (HCC). Post-embolization syndrome (PES) is a complex clinical syndrome which may occur after conventional TACE (cTACE). Either N-acetylcysteine (NAC) or dexamethasone (DEXA) is used to prevent PES.

Research motivation

The synergistic effect of the combined therapy for preventing PES and liver decompensation has not been determined.

Research objectives

The aim of this study was to evaluate the efficacy of NAC and DEXA combination in preventing PES and liver decompensation after cTACE.

Research methods

A single-center randomized controlled clinical trial.

Research results

Our study provides clinical evidence that intravenous NAC plus DEXA administration ameliorates the occurrence of post-TACE PES in patients with intermediate-stage HCC. Interestingly, we found that a dynamic change in Albumin-Bilirubin (ALBI) score was a risk factor for post-TACE liver decompensation.

Research conclusions

A combination of NAC and DEXA ameliorated the occurrence of PES after cTACE in patients with intermediate-stage HCC.

Research perspectives

The application of dynamic increase in ALBI score for a prediction of early post-TACE liver decompensation requires further research.

Abstract

Severe acute cholangitis (AC) exacerbates the risk of death because of the rapid progression of the disease. The optimal timing of biliary decompression (BD) as a necessary intervention in patients with severe AC is controversial. A recently report titled "Timing of endoscopic retrograde cholangiopancreatography in the treatment of acute cholangitis of different severity" in the *World Journal of Gastroenterology* that the optimal time of endoscopic retrograde cholangiopancreatography for treating patients with severe AC is ≤ 48 but not ≤ 24 h, providing clinical evidence for selecting the optimal time for implementation of BD. Here, we discuss the controversy over the optimal timing of BD for AC based on guidelines and clinical evidence, and consider that more high-level clinical researches are urgent needed to benefit the management of patients with different severity of AC.

Key Words: Acute cholangitis; Biliary decompression; Endoscopic retrograde cholangiopancreatography; Severity; Optimal time; Clinical evidence

Core Tip: Severe acute cholangitis (AC) exacerbates the risk of death because of the rapid progression of the disease. The optimal timing of biliary decompression (BD) as an intervention for severe AC is controversial. The purpose of this letter is to highlight the controversy surrounding the existing clinical evidence regarding BD for the treatment of AC of varying severity and to suggest that clinical studies providing higher levels of evidence will improve the therapeutic benefits.

TO THE EDITOR

Acute cholangitis (AC) originates as an infection of the extrahepatic biliary system and is usually characterized by rapid progression leading to systemic sepsis. The morality rate of severe AC may reach 30% [1]. In most cases, biliary decompression (BD) is necessary to treat patients with severe AC, regardless of the treatment modality chosen [endoscopic retrograde cholangiopancreatography (ERCP), percutaneous transhepatic biliary drainage, or stone removal][2]. However, the optimal time at which to implement BD to obtain the maximum therapeutic benefit for patients with AC remains uncertain.

We recently became extremely interested in a retrospective study by Huang *et al*[3] published in the October 2022 issue of the *World Journal of Gastroenterology*. This was a high-quality observational study with a Newcastle-Ottawa Quality Assessment Scale score of 7 (3, 2, 2)[4]. It was independently assessed by two of our authors, and disagreements were resolved by a third author. Based on a retrospective analysis of 683 patients with AC, the conclusions drawn by the authors properly summarize the data in the study. The authors' data indicated that 30-d mortality in patients with AC was not significantly different between ERCP performed at > 24 and ≤ 24 h. However, patients with AC had lower 30-d mortality and a shorter length of stay when ERCP was performed at ≤ 48 h. Additionally, patients with grade III AC had lower 30-d mortality rates than patients with grade I and II AC, although they had higher intensive care unit admission rates and longer lengths of stay[3]. Huang *et al*[3] suggested that a ≤ 48-h duration from the patient's presentation to initiation of ERCP therapy, rather than a ≤ 24-h duration, provided the best survival benefit for patients with AC, especially for patients with grade III AC. This unique insight breaks with the traditional treatment concept that earlier performance of BD is associated with better outcomes in patients with severe AC. We thank Huang *et al*[3] for their study, which provides clinical evidence for the optimal timing of BD in patients with grade III AC.

The 2018 revised Tokyo guideline (TG18) currently serves as the most influential guideline for assessing AC severity. It delineates three grades of assessment of AC severity and indicates that the impact of the BD implementation time on the therapeutic benefit is significantly correlated with AC severity[5]. Therefore, we consider that the AC severity characterizes the urgency of the BD implementation time.

Reference Citation Analysis (RCA) (https://www.referencecitationanalysis.com/) is an artificial intelligence technology-based open multidisciplinary citation analysis database. We searched the RCA database for articles in cutting-edge fields in the last 3 years using the search terms "endoscopic retrograde cholangiopancreatography", "biliary decompression", and "acute cholangitis". Recent guidelines and clinical evidence suggest that the optimal timing of BD implementation remains controversial. First, controversy regarding the timing of BD implementation in the guideline exists primarily for patients with grade II and III AC. The American Society for Gastrointestinal Endoscopy (ASGE) 2021 guideline states that important outcome indicators for evaluating the survival benefit in patients with AC are 30-d mortality, inpatient mortality, length of stay, and organ failure[2]. The guideline also suggests that performance of ERCP at ≤ 48 h may be associated with lower 30-d mortality and a shorter length of stay[2]. However, the ASGE 2021 guideline does not report the correlation between the time to BD implementation and AC severity because the available clinical evidence is insufficient[2]. TG18 states that BD in patients with grade II AC should be performed within 24 h, and although clinical data do not indicate the optimal time for BD in patients with grade III AC, urgent decompression (within 24 h) may improve the prognosis of patients with grade III AC[5]. The European Society of Gastrointestinal Endoscopy 2019 guideline states that for patients with severe AC (grade III), implementation of BD is recommended within 12 h; for patients with moderate AC (grade II), it should be performed within 48 to 72 h[6]. Second, recent clinical studies have produced controversial results in terms of early implementation of BD for patients with grade III AC. In addition to the study by Huang *et al*[3] discussed herein (BD at ≤ 48 but not ≤ 24 h), another retrospective study by Lu *et al*[7] showed that BD is recommended at 24 h of admission for patients with grade III AC and within 12 h for those with AC accompanied by neurological or cardiovascular dysfunction. However, a study by Becq *et al*[8] using a propensity score matching approach indicated that the use of BD within 6h or 12 h of AC onset was not associated with better clinical outcomes, but possibly reduced readmission rates. Finally, the results of three recent systematic reviews and meta-analyses suggest that the controversy over the optimal timing of BD is mainly focused within 24 h and 48 h based on data analysis of superior outcomes within their respective time zones[9-11]. However, the three studies did not report that the optimal timing of BD affects survival outcomes in populations with different severities of AC (*i.e.*, grades I, II, and III)[9-11].

Based on the above-mentioned current controversies, we present the following future outlook. First, because of the controversy in the current guidelines and among recent clinical studies regarding the optimal timing of BD for patients with grade II and III AC, a multicenter prospective cohort study or randomized controlled trial should be conducted. Second, the medical community is called upon to pay attention to the clinical studies that have been reported and to perform systematic reviews and meta-analyses on the optimal time to implement BD for the treatment of patients with grade II and III AC.

In conclusion, a higher level of clinical evidence regarding the optimal time to implement BD in patients with different severities of AC is needed to improve the therapeutic benefit.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Neil Donald Merrett, MBBS, FRACS, Professor, Division of Surgery, Western Sydney University, Locked Bag 1797, Penrith NSW 2571, Australia. n.merrett@westernsydney.edu.au

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

Coronavirus disease 2019 is an infectious disease caused by the severe acute respiratory syndrome coronavirus 2 that manifests as a variety of clinical manifestations, including liver damage commonly detected by a hepatocellular pattern from liver function tests. Liver injury is associated with a worse prognosis overall. Conditions associated with the severity of the disease include obesity and

cardiometabolic comorbidities, which are also associated with nonalcoholic fatty liver disease (NAFLD). The presence of NAFLD, similarly to obesity, is associated with an unfavourable impact on the coronavirus disease 2019 outcome. Individuals with these conditions could present with liver damage and elevated liver function tests due to direct viral cytotoxicity, systemic inflammation, ischemic or hypoxic liver damage or drug side effects. However, liver damage in the setting of NAFLD could also be attributed to a pre-existing chronic low-grade inflammation associated with surplus and dysfunctional adipose tissue in these individuals. Here we investigate the hypothesis that a pre-existing inflammatory status is exacerbated after severe acute respiratory syndrome coronavirus 2 infection, which embodies a second hit to the underestimated liver damage.

Key Words: COVID-19; SARS-CoV-2; Non-alcoholic fatty liver disease; Obesity; Inflammation; Liver; Adipose tissue

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The severe acute respiratory syndrome coronavirus 2 that causes coronavirus disease 2019 has a variety of clinical manifestations, including liver damage. Obesity and other dysmetabolic diseases linked to nonalcoholic fatty liver disease are a few of the factors that contribute to the severity of the illness. Due to direct viral cytotoxicity, people with these illnesses may have liver damage and increased liver function tests. However, liver injury might also be related to pre-existing inflammation and the detrimental effects of excessive and dysfunctional adipose tissue in these people.

INTRODUCTION

Coronavirus disease 2019 (COVID-19) is an infectious disease caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)[1,2], which was first identified in December 2019 in Wuhan, China, and has since spread globally, resulting in an ongoing pandemic[2]. COVID-19 represents a systemic disease that can cause a variety of clinical manifestations, which range from asymptomatic individuals to mild respiratory symptoms and severe critical illness[3-7]. A plethora of underlying pathways drive the pathophysiology, including activation or dysregulation of localized (*e.g.*, vascular) and generalized inflammation, which leads to multiorgan failure and eventually death[8-12].

Among the clinical manifestations, liver involvement, indicated by abnormal liver function tests (LFT) in patients, was noted early in the pandemic's development[13]. However, major liver damage is not common[14-18]. The liver may be affected by SARS-CoV-2 directly (*i.e.* translocation of the virus from the intestines to the liver) or *via* indirect ways (*i.e.* systemic inflammatory response, ischemic and hypoxic liver damage, drug-related liver injury and impacts on pre-existing liver diseases)[14,16,17]. Coexisting liver disease, including metabolic/obesity related nonalcoholic fatty liver disease (NAFLD), may also negatively impact the course of COVID-19[14,15].

Early observations of COVID-19 have highlighted obesity as one of the most common underlying conditions in patients hospitalized with COVID-19[19-21]. Obesity was further associated with hospital admission and as an independent predictor of severity, intensive medical intervention and mortality of COVID-19[15,19]. Obesity, determined by increased total fat mass (body mass index > 30 kg/m^2), is a chronic multifactorial disease that predisposes patients to numerous comorbidities, including metabolic diseases (insulin resistance states, type 2 diabetes mellitus, NAFLD), cardiovascular diseases[15,22-24] and various types of cancer[25-28].

Patients with poorer clinical outcomes for COVID-19 are characteristically older (more than 60 years) and have several metabolic syndrome manifestations, obesity and type 2 diabetes mellitus, a profile similar to those at increased risk of NAFLD[13,29,30]. Coexisting hepatic diseases like NAFLD and metabolic dysregulations could theoretically impact the manifestations and progression of COVID-19, and the liver injury in that population could represent a combination of the underlying condition exacerbated by the virus and inflammatory responses.

Here, we presented the current evidence for hepatic involvement in COVID-19 in obese individuals and the impact of fatty liver disease. Then, we tested the idea that liver damage in people with obesity and/or NAFLD could be caused by a "second hit" from the virus on top of hepatic dysfunction that was already there. This is likely caused by metabolic dysregulation and a chronic inflammatory state that is linked to obesity.

CURRENT EVIDENCE OF HEPATIC INVOLVEMENT IN COVID-19

Patients with COVID-19 have experienced varying degrees of liver damage, ranging from self-limited hepatitis to significant liver injury and liver failure[31,32]. Impaired LFT without other hepatic manifestations was shown to be present in almost 50% of patients with COVID-19 in various studies[31-33]. The spectrum of pathological LFT includes elevated liver enzyme concentrations of transaminases [aspartate transaminase (AST), alanine transaminase (ALT)], cholestatic enzymes including alkaline phosphatase (ALP) and gamma-glutamyl transferase (GGT), lactate dehydrogenase and bilirubin and impaired synthetic activity as seen with prothrombin time (PT) prolongation and decreased albumin concentrations[31,34]. Based on the pattern of the affected LFT, liver damage is categorized as parenchymal (AST, ALT), cholestatic (ALP, GGT) or mixed. The most common type of liver damage, in up to 75% of cases, is parenchymal, indicating hepatocellular damage as a major part of physiopathology[31,34,35].

Several studies have shown elevated AST or ALT during acute COVID-19 illness[36-39]. A higher proportion of patients with severe cases (46.2% *vs* 12.7% in mild cases) had elevated AST and ALT[36,40-42]. AST appeared to be elevated first, followed by ALT in patients with severe disease[33,34]. Accordingly, AST was found to be correlated with mortality and liver dysfunction[5], showing an increased odds ratio in severe cases in other studies[42,43]. Elevated LFT was also recorded in subclinical cases (AST in 8.7% and ALT in 8.9%)[39].

The cholestatic pattern of elevated LFT was typically accompanied by elevated parenchymal enzymes [31]. In both mild and severe cases, ALP and bilirubin levels were found to be moderately elevated[37]. In a systematic review and meta-analysis of 64 studies, it was shown that the prevalence of elevated total bilirubin (9.7%), GGT (15.0%) and ALP (4.0%) were lower compared to elevated levels of aminotransferases (AST 23.2% and ALT 21.1%)[44]. Interestingly, in a retrospective study where ALP and GGT concentration levels were usually within normal values, pathological levels of GGT were found in 37.6% of patients with NAFLD[45].

In addition, a meta-analysis of 24 studies showed that a significantly longer PT in patients with severe COVID-19 was associated with higher morbidity rates. Elshazli *et al*[46] also concluded in their systematic review that prolonged PT was associated with a higher risk of disease progression to severe COVID-19 and admission to an intensive care unit. Impaired synthetic liver function, as assessed by hypoalbuminemia, was present and associated with an increased risk in patients with COVID-19[47]. Similarly, hypoalbuminemia was correlated with the severity of the disease and morbidity[31].

Overall, irrespectively of which LFT was affected, once hepatic damage was involved, patients had an increased risk of mortality and severe disease, which was shown in a systematic review of 107 studies and 20874 patients[48]. Acute liver injury is an important predictor for disease development[49]. In patients with chronic liver disease, including NAFLD, liver damage may occur more often. Chronic liver disease from any cause was discovered to be a risk factor for extended hospitalization and the fatal course of COVID-19[31].

FATTY LIVER DISEASE AND COVID-19

The occurrence of NAFLD in patients with SARS-CoV-2 infection is substantial[4,31,50]. This is the case as specific cardiometabolic chronic conditions intrinsically linked to NAFLD (hypertension, diabetes, obesity, coronary artery disease, and cerebrovascular disease) have been noted as important risk factors associated with an increased risk of severe COVID-19[4,45,51]. In a recent meta-analysis and systematic review of 16 studies, Hayat *et al*[29] examined NAFLD prevalence, COVID-19 and the outcomes among patients with NAFLD *vs* those without. The study findings showed that individuals with NAFLD, as compared to those without, had a higher probability of severe COVID-19 and intensive care unit admission[29]. Furthermore, NAFLD patients tended to have higher COVID-19-related mortality compared to non-NAFLD patients[6,29].

Assessment of LFT and clinical outcomes in patients with or without NAFLD showed that in the vast majority of patients, liver damage was minor and hepatocellular in type[13,45]. A higher probability of abnormal LFT from admission to discharge was recorded for patients with NAFLD[13,45]. A Chinese analysis found that patients with NAFLD had a higher incidence of severe COVID-19 than those who did not have NAFLD but only those under 60-years-old. This observation was observed even after adjusting for potentially confounding factors like obesity, diabetes and hypertension[13,52]. In contrast to that age group, there was no association between patients age 60 years and older and NAFLD and the severity of COVID-19[13,52]. It was suggested that NAFLD-induced hepatic and systemic immune

responses may worsen the severity of the cytokine storm in COVID-19 patients who are younger. Aside from that, older people often have other cardiometabolic comorbidities, which may change any link to NAFLD[13,52].

NAFLD AND OBESITY

Dysfunctional adipose tissue (AT), an organ critical for whole-body homeostasis, is a hallmark of obesity and obesity-related chronic cardiometabolic diseases[28,53-55]. Dysfunctional AT is distinguished by, among other things, hormonal/adipocytokine dysregulation, a state of chronic low-grade inflammation associated with adipocyte hypertrophy and lipid metabolism impairments (reduced capacity to buffer the daily influx of dietary lipids), resulting in ectopic fat accumulation[28,56-58]. Additionally, decreased AT blood flow, mitochondrial dysfunction and altered oxygenation are frequently present in obesity[28,59].

Several proinflammatory molecules are increased in obesity and are related to aspects of the metabolic syndrome and other metabolic dysfunctions, including tumour necrosis factor alpha, interleukin 6 (IL-6), plasminogen activator inhibitor-1, dipeptidyl peptidase 4 and monocyte chemoattractant protein-1[53,54,60-62]. IL-6 can activate macrophages and contribute to the cytokine storm seen in COVID-19[13,63]. The loss of muscle mass and its anti-inflammatory properties, which are common in sarcopenic obesity, may have a negative impact on the chronic inflammatory status, various comorbidities and COVID-19 outcomes[64].

Liver dysfunction associated with obesity and metabolic diseases, including the spectrum of NAFLD, is characterized by a multifactorial pathophysiological mechanism still under investigation involving multiple pathways[65]. It has been suggested that, in part, the inability to sufficiently increase subcutaneous AT triglyceride stores in response to excessive energy intake and weight gain causes lipids to be diverted to other organs, such as the liver and skeletal muscle, where they accumulate ectopically and cause cellular lipotoxicity. This results in insulin resistance and inflammation in these tissues[66-70].

COVID-19: AN ADDITIONAL CAUSE OF LIVER DAMAGE IN PRE-EXISTING NAFLD AND OBESITY?

The COVID-19 systemic inflammatory state is linked with the angiotensin converting enzyme 2 (ACE2) receptor expressed in a variety of tissues[2,9,11]. Many organ systems, including the lungs, liver, heart, kidney and blood vessels, contain ACE2 receptors[31]. AT of patients with obesity is estimated to exhibit higher amounts of ACE2, perhaps acting as a SARS-CoV-2 reservoir with delayed viral shedding time[13,63]. The structural spike protein, characteristic of SARS-CoV-2, predominantly promotes the host's immunological reaction[9]. The spike protein attaches to ACE2 receptor sites on the cell membrane, facilitating cell penetration[9].

In the liver, ACE2 receptor expression is significantly higher in cholangiocytes than in hepatocytes[31,41]. Direct virus cytopathogenic effects, inflammatory responses and intrahepatic immune cell stimulation, (micro)vascular thrombosis, hepatic obstruction, destabilized gut-liver axis, drug-induced toxicity and interfaces all play a part in liver damage during COVID-19 infection[31,35,71]. Interestingly, as demonstrated in a diet-induced nonalcoholic steatohepatitis (NASH) model in rodents, ACE2 hepatic expression was shown to be dramatically elevated, potentially enhancing hepatic vulnerability towards SARS-CoV-2 infection in individuals with NAFLD and/or NASH[13,72]. However, the link between NAFLD and liver-induced production of SARS-CoV-2 vital entry proteins, essentially ACE2, is still debatable[13]. A direct viral cytotoxic effect on hepatocytes appeared to induce mitochondrial and endoplasmic reticulum damage (swelling and distention accordingly), decreased glycogen granules and malfunction of the cell membrane in hepatocytes[31,33,34,42]. As in dysmetabolic conditions, the homeostasis of the liver and metabolic parameters are already impaired. This could have an additional effect on NAFLD. Finally, moderate microvesicular steatosis, along with other histopathological findings in deceased COVID-19 patients, may indicate additional pathways of metabolic derangement and liver damage[73].

In addition, the hyperinflammatory status in COVID-19 may act as a "second hit" to an inflamed fatty liver, causing "acute-on-chronic" steatohepatitis with increased aminotransferases[13,74]. Immune-mediated liver injury is caused by proinflammatory cytokines, chemokines and inflammatory cells produced against the SARS-CoV-2, which are also increased in obesity (IL-6, tumour necrosis factor)[32,34,75]. This may explain the finding that the C-reactive protein to albumin ratio was an independent risk factor for mortality in NAFLD patients with COVID-19 in one study[6]. Another significant immunological mediator of damage is viral-induced T cells (CD8)[31,32].

Another major cause of liver injury in COVID-19 appears to be coagulation disruption and endothelial damage[31,73]. Obesity is associated with hypercoagulation/thrombotic status dysregu-

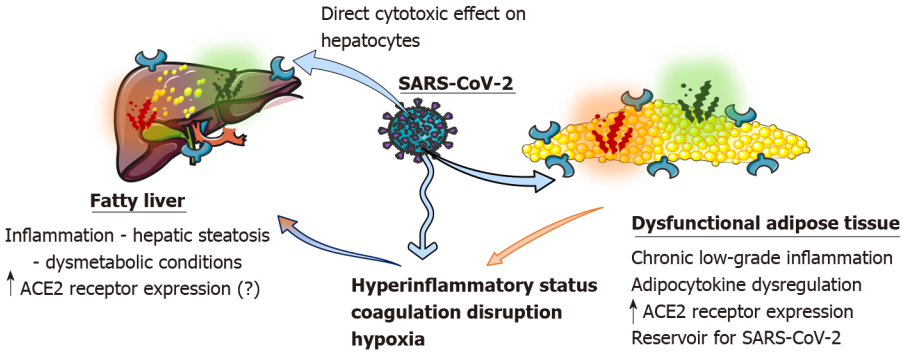

Figure 1 Potential mediators of liver damage associated to coronavirus disease 2019, fatty liver, and obesity. ACE2: Angiotensin converting enzyme 2; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2. Parts of the figure were drawn by using pictures from Servier Medical Art (smart.servier.com).

lation due to increased circulating concentrations of factor VII, von Willebrand factor and fibrinogen [13]. Ischemia-induced hypoxic liver injury most likely promotes the establishment of microvascular thrombosis[13,63]. Hypoxia caused by pneumonia is another major cause of liver damage[31]. This could be made worse in the case of COVID-19 and obesity, which is linked to obstructive sleep apnea and lower oxygen levels[28].

Ultimately, other factors may contribute to liver damage. It could be the end result of antivirals, anti-inflammatory medications, anticoagulants, antibiotics and other treatments used to treat underlying cardiometabolic chronic conditions and utilized during the COVID-19 infection, leading to liver injury [31]. Finally, dysbiosis and gut microbiota changes that usually occur in obesity could be exacerbated during COVID-19 and due to various medications[31,76]. A summary of the mechanisms can be found in Figure 1.

FUTURE PERSPECTIVES

Future studies should focus on elucidating and comparing a variety of populations with various body mass indexes (including normal weight, overweight and various degrees of obesity) because to date few studies have examined the presence of liver steatosis in patients with overweight or obesity[77]. Furthermore, the extent of underlying liver damage (NASH, liver fibrosis, or even liver cancer) should be determined in people who have pre-existing NAFLD and to monitor the severity of the COVID-19 infection outcomes. Finally, it would be of great interest to examine the potential differential impact of COVID-19 infection due to different viral variants on individuals with NAFLD and other liver manifestations, as these studies are sparse and focus on cirrhosis of various aetiologies[78].

CONCLUSION

In conclusion, the poor clinical outcomes of COVID-19 and the greater risk of pathological LFTs seen in people with obesity and/or NAFLD are likely caused by immune activation and a tendency toward a proinflammatory state during obesity as well as by metabolic and immune-mediated parameters that place the liver at risk. Thus, obesity should be prevented, especially in the context of the COVID-19 pandemic.

Abstract

Ulcerative colitis (UC) is a chronic inflammatory disease with a high impact. In order to improve patient outcomes, the clinician-patient relationship in daily practice is critical. Clinical guidelines provide a framework for UC diagnosis and treatment. However, standard procedures and the medical content focused upon medical consultations in UC patients has not yet been defined. Moreover, UC is a complex disease, given that patient characteristics and patient needs have been proven to vary during clinical consultation since establishing the diagnosis and upon the course of the disease. In this article, we have discussed the key elements and specific objectives to consider in medical consultation, such as diagnosis, first visits, follow-up visits, active disease patients, patients on topical therapies, new treatment initiation, refractory patients, extra-intestinal manifestations, as well as challenging situations. The key elements have been mentioned to comprise effective communication techniques, motivational interviewing (MI), as well as information and educational aspects, or organizational issues. The key elements to be implemented in daily practice were reported to comprise several general principles like duly prepared consultations, in addition to honesty and empathy with patients, as well as effective communication techniques, MI, information and

educational points, or organizational issues. The role of other healthcare professionals such as specialized nurses, psychologists, or the use of checklists was also discussed and commented on.

Key Words: Ulcerative colitis; Patient experience; Shared decision making; Medical consultation; Motivational interviewing; Patient education

Core Tip: Nowadays, patient-centered medical care has become accepted as a preferred care model, especially concerning chronic and heterogeneous diseases like ulcerative colitis. Clearly, medical consultations can substantially be improved by defining objectives along with the patients and adapting decisions and actions to this specific context. This comprises disease clinical features and stage, such as diagnosis, flare, and others, disease impact and patient's needs, as well as patient's opinions and preferences. Moreover, improvement can be obtained if we put into practice different resources that have demonstrated their efficacy in improving patient care such as effective communication techniques, motivational interviewing, or the use of checklists.

INTRODUCTION

Ulcerative colitis (UC) is a chronic inflammatory disease that affects approximately 250 people out of 100000[1,2]. Different studies have reported the great impact of UC on patients, health systems, and society[3-6].

Currently, patient-centered medical care is synonymous with good-quality care, and it has become accepted as a preferred care model[7]. Effective clinician-patient communication is one of the cornerstones of patient-centered care, with proven impact on treatment adherence[8] and patient outcomes[9]. Key factors of effective communication have been shown to include patient understanding, trust, and respecting patients' preferences, in addition to shared decision-making. These factors are instrumental in influencing health outcomes like increased treatment adherence or better self-care skills[10].

On the other hand, UC characteristics and needs have been shown to greatly vary since the time the diagnosis has been made and during the disease course. Indeed, a recent publication demonstrated that patient preferences with respect to the disease management, disease information, as well as other items, differs depending on the context[11]. As a consequence, clinician-patient communication and decisions should similarly be adapted in daily practice.

Taking into account all of this information, we sought to define particular clinical scenarios and key elements to be considered upon medical consultation. For this purpose, we conducted a literature review and gathered expert's opinions. Although this work is focused on UC, most of the results can be applied to patients with other types of inflammatory bowel disease (IBD).

OVERARCHING PRINCIPLES IN A MEDICAL CONSULTATION FOR UC

Along with a set of overarching principles (Table 1), we have proposed eight particular clinical scenarios for which key elements and specific attitudes should be accounted for (Table 2).

Shared decision-making is increasingly advocated as an ideal model of therapeutic decision-making. In this model, the physician has the responsibility to inform the patients and provide them advice, whereas the actual decisions on how to act on this information are being made in a collaborative work environment between the patient and physician[12].

Among overarching principles during clinical consultation (Table 1), apart from an appropriate environment and preparation to the consultation, honesty and empathy with patients are essential, as is the adaptation of the physician's language and terms to the patients' understanding by avoiding technical terms that may not be fully understood. These features should always be considered as being dynamic when providing care to UC patients.

Taking into account UC's complexity, impact, and related treatments, in addition to considering non-adherence rates, it is essential to include behavioral interventions that likely improve patient outcomes

Table 1 Overarching principles for the clinical consultation in patients with ulcerative colitis

No.	Overarching principles
1	Appropriate environment where the clinical consultation takes place (tidy, clean, a chair for accompanying person, *etc.*)
2	Motivational interviewing
3	Use of appropriate verbal and non-verbal language
4	Good manners (salutation, face to face interaction, *etc.*) and empathy
5	Be honest about what we know, what we do not know and describe actions regarding what to do/what to avoid
6	Ideally prepare and organize the clinical consultation before seeing the patient (medical history, check labs, imaging tests, *etc.*)
7	Establish the objectives of the clinical consultation:
	Adapted to each clinical scenario
	Adapted (including the message) to each patient's features
	Taking into account patient's opinion and preferences

[8,13,14]. One such intervention is motivational interviewing (MI)[15]. MI is a directive patient-centered style of counselling, designed to help people further explore and resolve ambivalence about behavior changes. MI involves providers communicating in supportive, caring, and empathic ways to resolve a patient's ambivalence in view of health behavior change[16]. Specifically, providers ask, listen, and inform their patients when attempting to elicit motivation towards changes[16]. A systematic literature review involving patients with IBD has suggested that MI can be effective in improving outcomes for individuals suffering from IBD, given that patients displayed improved adherence rates and greater advice-seeking behavior, perceiving providers as having more empathy and better communication skills [15].

CLINICAL SCENARIOS AND KEY ELEMENTS DURING CLINICAL CONSULTATION FOR THE DIAGNOSIS/FIRST VISITS

The first scenario pertains to diagnosis/first visit(s) (Table 2). The emotional impact that is conveyed to any patient and environment when being confronted with the UC diagnosis is usually huge[3,17]. In addition to the initial anxiety and uncertainty, numerous patients report experiencing depressive symptoms and mental blocks after having become aware of their diagnosis[17,18]. Therefore, it is crucial to calm down the patients and help them cope with their new situation[19]. Given this context, effective clinician-patient communication has been shown to overcome barriers, while assisting patients in the decision-making about their care[9]. Communication between clinicians and patients is an interactive process upon which clinicians should listen, be open, receptive, and non-judgmental with patients[9]. Effective communication will contribute to build confidence.

In this scenario, it is also crucial to provide a minimum of information about the disease, its extra-intestinal manifestations and treatments, which should be adapted to the patient characteristics/needs and conducted in a constructive way, while also collecting data about the patients' support, especially concerning their family. On the other hand, a reasonable selection of the information to be provided is similarly advisable, thereby giving the patient the opportunity to adequately assume each issue and learn more about it[8,11]. Similarly, the same should be done with respect to the therapeutic plan by sharing treatment decisions and providing positive messages, such as: "Currently, there are several treatment options for this disease, and our objective is to improve your situation". The concept of "chronicity" should also be introduced by using expressions like: "while this is a long-term process, we can control the disease activity and avoid disease progression and symptoms", *etc.* Regarding health education, general information about diet, hygiene, healthy lifestyle, and other features should be provided[20].

An IBD specialized nurse working in a dedicated unit is likely able to improve all the information that we provide to the patient, resolve fears and doubts, and ameliorate adherence to treatments, care, and healthy habits[21]. Often, patients leave the doctor's office with large amounts of information and they feel overloaded. Therefore, changing the environment and providing a nursing summary can be very useful[19,22]. For communication to be optimal, we should try to additionally give the information in writing, at least with respect to what is essential. Reliable sources on the Internet should also be offered. In this context, many patients seek information on the disease from the internet. However, many times this information is inaccurate and even false, which might produce a negative impact on patients[23].

Table 2 Adapting the consultation to the different clinical scenarios when managing patients with ulcerative colitis

No.	Clinical scenario	Objectives	Key elements
1	Diagnosis/first visits	To engage patients in the management of their disease (treatments, visits, labs, image techniques, contact data, *etc.*); To inform wisely patients; To collect relevant data about the disease, patients and their environment	Use open questions rather than direct questions; Practice empathy: a climate of trust will make the patient feel comfortable and more information will come out naturally; When informing patients go as far as the patient needs or wants, *e.g.*, "What do you know about UC?"; Explore people's understanding, reactions and opinions about UC information; Explain the therapeutic plan (treatment objectives and goals, available therapies including surgery, response evaluation, *etc.*); Prepare the consultation: check labs, imaging tests or other available data before seeing the patient and prepare specific attitude, procedures or messages
2	Follow-up visits	To evaluate response to treatment (induction/maintenance), safety and adherence; In the induction phase, to ensure that the patient has achieved the pre-defined objective/goal; In the maintenance phase, to assure that the patient is really in remission and adherent; To explain test results	Use open questions; Solution-focused approach; Let the patients express themselves about their life (family, partner, work/studies, social life, traveling, diet, *etc.*): *e.g.*, "How are you doing? Are you doing everything you would like to do?"; Be open to patients asking questions; Detail the therapeutic and follow-up plan (*e.g.*, colonoscopy for colon cancer surveillance as indicated); Assess sexuality and fertility issues; Assess pregnancy desire: *e.g.*, when informing about drugs; Practice empathy; Prepare the consultation (see point 1)
3	Patients with active disease	To assess carefully the impact of UC on the patient's life (family, partner, work/academic, social life, traveling, diet, *etc.*); To adapt the treatment and patient's environment	Explain the therapeutic plan in detail but mainly explain and agree on what the objectives are, treatment goals and options, including surgery (informed shared decision making); Practice empathy; Prepare the consultation (see point 1)
4	Patients on topical therapies	To look for treatment acceptance and adherence	Explain in detail and clearly that topical therapies can be very effective with few adverse events (very good risk/benefit balance); Solution-focused approach; Discuss about the costs, explain their mechanism of action and options to improve comfort; Evaluate the patient's opinion and preferences; Practice empathy
5	Start of a new treatment	To assess carefully the impact of UC on the patient's life (family, partner, work/studies, social life, traveling, diet, *etc.*); To adapt the treatment and patient's environment; To fully understand the implications of starting a new treatment (changes in daily life, *etc.*)	Explain in detail and clearly the therapeutic plan but especially safety issues and new adaptations in patient's life; Solution-focused approach; Practice empathy; Prepare the consultation (see point 1)
6	Refractory patients	To assess carefully the impact of UC on the patient's life (family, partner, work/studies, social life, traveling, diet, *etc.*); To adapt the treatment and patient's environment	Explain the therapeutic plan in detail but mainly explain and agree on how far we are going to go, which are the treatment goals and options, including surgery (shared decision making); Solution-focused approach; Be especially cautious as non-standard treatments/strategies might be considered (*e.g.*, off-label uses, clinical trials, *etc.*); Spread positivity, make the patients feel accompanied; Screen for depression/dysthymia; Practice empathy; Prepare the consultation (see point 1)
7	Extra-intestinal manifestations	To inform patients about other symptoms or diseases	Explain the therapeutic plan in detail but mainly explain and agree on how far we are going to go, which are the treatment goals and options, including surgery (shared decision making); Solution-focused approach; Introduce the concept of multidisciplinary and coordinated care; Practice empathy; Prepare the consultation (see point 1)
8	Patients with negative feelings or mistrust	To win the patient over; To be patient but solid	Consider referring the patient to a psychologist; Explore fears, insecurities, frustrations; Do not confront the patient; Practice empathy; Explain the therapeutic plan in detail but mainly explain and agree on how far we are going to go, which are the treatment goals and options, including surgery (shared decision making)

For all sections, we start from the fundamentals of shared decision-making. UC: Ulcerative colitis.

There are several phases and common emotional reactions to the diagnosis, including denial, frustration, anger, and guilt; it is therefore essential to be attentive to the patient's emotional response [24]. In addition, it must be kept in mind that the patient faces significant losses, such as loss of health, of previous lifestyle, of quality of life, *etc.*

At the first visit, the patient should be offered the possibility to access the consultation, telephone, nurse, e-mail, or walk-in visits, as this has been shown to improve the patient's confidence in the care team[25].

Finally, physicians should keep in mind patient's opinions and preferences[11]. Therefore, it could be very useful to explore their beliefs, needs, and expectations. Moreover, it is advisable to leave some time for the patients, enabling them to ask questions during the consultation and encouraging them to "make a list of questions" if necessary for the next consultations[11].

CLINICAL SCENARIOS AND KEY ELEMENTS DURING CLINICAL CONSULTATION IN FOLLOW-UP VISITS

Physicians should continue addressing UC's impact on patients during the entire course of the disease. Indeed, during follow-up visits, patients may already be more aware of the disease's impact; they may thus be more comfortable to express it[22]. Apart from negative emotions, other problems may arise, such as those related to sexuality, sleep, work, or social life. In this context, it is vital to address, in male and female patient's sexuality issues and conception wishes, in order to optimize pre-conceptional, pregnancy and post pregnancy counselling, including the monitoring and therapeutic management of these patients[26]. Assessment of emotional aspects on the other hand should be an integral part of follow-up visits.

The objectives of pharmacological UC treatments are usually focused on controlling or at least reducing physical symptoms. Nevertheless, like in any other type of chronic disease, other psychological and social factors may influence the course of the disease[27]; they thus deserve appropriate attention. A central issue at this point is the assessment of treatment response upon induction and maintenance, in addition to evaluating safety and treatment adherence. While it is crucial to ensure that the patient has achieved the treatment goal, the treatment's impact on safety must likewise be assessed. In addition, considering the high rate of poor adherence in UC[28], health professionals should clearly address this issue, while actively involving the patients in implementing effective and individualized interventions to improve adherence[8].

Similarly to the first visits, information and education are vital in daily consultations, which should be appropriately adapted to the patients' characteristics and needs[11]. These consultations could be an appropriate opportunity to explain the test results to patients, as well as the role of colonoscopy for colon cancer surveillance.

CLINICAL SCENARIOS AND KEY ELEMENTS DURING CLINICAL CONSULTATION IN PATIENTS WITH ACTIVE DISEASE

Relapses are common in UC, and they are associated with a significant impact on different aspects of patients' lives[3,18]. Thus, the impact of disease activity should be carefully assessed, and physicians should thus perform therapeutic adaptations that should be discussed with the patients. Accordingly, the patients will thus feel accompanied.

The emotional impact should be included in the information/education package as disease symptoms. Physical remission does not imply the absence of psychological comorbidity in a high percentage of patients[29]. Therefore, it is essential to provide information about physical symptoms, including diarrhea, abdominal pain, and fever; emotional symptoms like anxiety, depression, irritability, mood changes, and behavioral symptoms, such as decreased activity, restriction of social relations, and isolation[19].

On the other hand, psychological treatments exert beneficial therapeutic effects, as they decrease the worsening cycle of symptoms and positively influence the patients' general well-being[13].

The integration of psychosocial factors into routine clinical practice is likely instrumental in improving quality of life of IBD patients[19].

Considering the treatment, informed shared decision-making is especially relevant in this domain [30]. At this point, physicians may be confronted with patients who are refractory to different treatment lines or types. Apart from detailed information about different treatment options, including surgery, it is even more relevant to discuss the treatment goals and get approval about them ("What is the target we want to achieve?").

CLINICAL SCENARIOS AND KEY ELEMENTS DURING CLINICAL CONSULTATION IN PATIENTS ON TOPICAL THERAPIES

The efficacy of topical therapies, especially in patients with moderate UC, has been extensively described[31]. However, the adherence to topical therapies appears to be lower when compared with oral treatments[32]. This might be related to reluctances, taboos, or other factors. Asking patients about their feelings regarding topical therapy may help anticipate a lack of adherence, thus providing the physician with the opportunity to adapt topical therapy to each patient[8].

Discussing treatment goals with the patient and setting a temporal limit may be of help when addressing topical treatments[8].

CLINICAL SCENARIOS AND KEY ELEMENTS DURING CLINICAL CONSULTATION WHEN STARTING A NEW TREATMENT

During follow-up, a number of patients may require a change in therapy due to a lack or loss of efficacy, or safety reasons. This might be associated with changes in daily life, particularly when the first immunomodulator or biologic agent is being considered. Along with all that has been previously discussed regarding patients with active disease, it must be ensured that the patient has properly understood the implications of starting a new treatment.

When starting new treatments, false beliefs such as "if I change treatment, I will worsen" or "the disease is more serious" should be dismissed. Concerns about the limit of treatments to be used, possibility of surgery, or need for an ostomy should also be addressed.

CLINICAL SCENARIOS AND KEY ELEMENTS DURING CLINICAL CONSULTATION IN REFRACTORY DISEASE PATIENTS

In daily consultation, some patients may display several failures to treatment, including biologics; they may experience frustration and despair[22]. Therefore, it is crucial to distribute positivity but also reality, given that new treatments with different mechanisms of action are being made available[19]. In some centers, authorized treatments/strategies might be considered, including off-label uses, clinical trial participation, as well as other treatments. Screening for depression/dysthymia may be required given such a clinical scenario.

It is necessary to train non-psychologists in assessing and managing emotional aspects, such as identifying symptoms related to stress, anxiety, and depression, which are among the most common [19].

CLINICAL SCENARIOS AND KEY ELEMENTS DURING CLINICAL CONSULTATION IN PATIENTS WITH EXTRA-INTESTINAL MANIFESTATIONS

As estimated, up to 50% of IBD patients experience at least one extra-intestinal manifestation, which can even occur before the IBD is being diagnosed[33]. In view of an early detection, patients should be aware that different symptoms or signs may occur, which are actually related to UC, while deserving specific actions, including consultation with other specialists. In addition, information about multidisciplinary care and coordination among health professionals will likely help control fears and doubts[19,25].

CLINICAL SCENARIOS AND KEY ELEMENTS DURING CLINICAL CONSULTATION IN PATIENTS WITH NEGATIVE FEELINGS OR MISTRUST

Finally, some patients may experience negative emotions, as they are reluctant to accept existing problems or proposed solutions, disadvantages, insufficient answers, *etc*. Such scenarios can be particularly frustrating during the consultation. Considering these patients, one should not try to "convince them", given that they are likely to become even more isolated. Instead, making them understand that we are on their team, and that they are actually responsible for their disease management is crucial[25]. In some cases, a referral to a psychologist could be an appropriate solution[34].

Healthy lifestyle information should be based on guidelines on how to handle stressful situations. Illness is a source of stress, and stress is considered a risk factor for increased severity of physical symptoms[13]. For this purpose, it is advisable to refer to reliable web pages, brochures, conferences, workshops, or even patient associations, as some of them do provide psychological assistance.

CONCLUSION

UC is a chronic, heterogeneous, and evolving disease, whose clinical features and disease impact, as well as patients' needs, opinions, and preferences may completely differ depending on the disease status[3-6,11]. In daily practice, the clinical picture of patients at early disease stages compared with that of patients with long-standing disease is not at all the same. Therefore, the physicians' attitudes and decisions should take these facts into account during the clinical consultation. Moreover, there is growing evidence suggesting that there is improved performance in this area to the benefit of both patients and clinicians[9,35].

Effective communication has emerged as a very valuable tool to superior informed decisions by patients during the clinical consultation[9]. Communication is crucial in establishing trust with UC patients, gathering patient information, addressing patient emotions, and assisting patients in the decision-making about their care[9,35]. This article sought to discuss some guidelines for physicians about how to implement effective communication during clinical consultation, as adapted to several clinical scenarios in which the objectives, attitudes, and messages most likely differ. Simple, practical, and implementable key elements including empathy, open questions, patient-centered care and information, solution-focused approach, or MI have herein been proposed.

Along with effective communication, we also suggest other actions like preparing the consultation or using appropriate verbal and non-verbal language, which have already demonstrated an effect on patient's management[36].

Some of the strengths of this work are as follows: innovation in the treatment of UC patients, how to initiate an updated patient management model, using a check list to prepare the different consultations, as well as having a specialist nurse and psychologist as external evaluators. The article's weaknesses comprise the lack of clinical evaluation or the absence of other scenarios that would have been interesting to address, such as the transition of the child to adult unit or continuity of care during admissions. Nevertheless, we consider that these items were beyond the paper's scope of interest.

In conclusion, research in UC clearly shows that it is essential to build a physician-patient partnership, focusing on the problem at hand, laying out the treatment options available along with their benefit/risk balance, eliciting the patient's views and preferences on treatment options, and agreeing on a course of action *via* shared decision-making. For these purposes, specific communication skills are necessary; they all can be learned and should be implemented during clinical consultations. We are confident that the guide provided in this article for clinical consultation will help physicians better manage UC patients.

ACKNOWLEDGEMENTS

We would like to thank Pablo Bella and Laura Camacho for their review of the final article version. Estibaliz Loza, who works at the institute of musculoskeletal health (Instituto de Salud Musculoesquelé tica), which was funded by Pfizer, provided assistance in methodological coordination and in developing this manuscript.

FOOTNOTES

Author contributions: González-Lama Y, Ricart E, Cábez A, Fortes P, Gómez S, and Casellas F conceived the idea for the manuscript, reviewed the literature and drafted the manuscript.

Conflict-of-interest statement: Fortes P and Cábez A are employees of Pfizer (Spain). González-Lama Y, Casellas F, and Ricart E have received consultancy fees from Pfizer S.L.U. for their work in this project but have no other relevant financial relationships to disclose. The authors have no other relevant affiliations or financial involvement with any organization or entity with a financial interest in or financial conflict with the subject matter or materials discussed in this manuscript apart from those disclosed. González-Lama Y received research funding from AbbVie, Ferring, MSD, Takeda, Janssen, and Pfizer; speaker fees from AbbVie, Ferring, Gebro, Takeda, and Janssen. Casellas F received research funding from AbbVie, Ferring, MSD, Shire, Takeda, Zambon and Pfizer; speaker fees from AbbVie, Chiesi, Ferring, Gebro, MSD, Shire, Takeda, and Zambon.

Abstract

Colorectal cancer (CRC) is one of the most lethal and common malignancies in the world. Chemotherapy has been the conventional treatment for metastatic CRC (mCRC) patients. However, the effects of chemotherapy have been unsatisfactory. With the advent of targeted therapy, the survival of patients with CRC have been prolonged. Over the past 20 years, targeted therapy for CRC has achieved substantial progress. However, targeted therapy has the same challenge of drug resistance as chemotherapy. Consequently, exploring the resistance mechanism and finding strategies to address the resistance to targeted therapy, along with searching for novel effective regimens, is a constant challenge in the mCRC treatment, and it is also a hot research topic. In this review, we focus on the current status on resistance to existing targeted therapies in mCRC and discuss future developments.

Key Words: Colorectal cancer; Targeted treatment; Resistance; New development

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Colorectal cancer (CRC) is one of the most lethal and common malignancies in the world. Chemotherapy has long been the mainstay of CRC treatment. However, since chemotherapy is not a specific regimen, it will produce systemic toxicity. Following, with the advent of targeted therapy, the prognosis of CRC has been improved significantly. Although targeted therapy also develop drug resistance, more and more novel targets and combination regimens are being explored over the past 20 years. In this review, we summarized resistance to exiting targeted therapy, and discussed future developments in CRC.

INTRODUCTION

Colorectal cancer (CRC) is the third most prevalent malignancy and the second most lethal cancer worldwide[1]. Surgery is the primary treatment option and has the potential to be curative, especially for patients in the early stage of the disease[2]. However, most patients suffer from advanced/metastatic tumors, with a five-year overall survival (OS) rate of approximately 13%[3]. Systemic chemotherapy is the cornerstone of treatment for these patients, resulting in a median OS (mOS) of 17-23 mo[4-6]. The prognosis of patients with mCRC has improved with the addition of targeted therapies, such as antibodies against epidermal growth factor receptor (EGFR) and vascular endothelial growth factor (VEGF), and tyrosine kinase inhibitors (TKIs)[7,8].

CRC is a heterogeneous disease with multiple molecular features, requiring individual targeted approach for achieving effective disease control and good survival rates[9]. This review presents the standard targeted therapy options and corresponding resistance mechanisms, and discuss the promising targeted agents for mCRC.

CURRENT TREATMENT FOR COLORECTAL CANCER

Conventional treatments for CRC include 5-fluorouracil (5-FU)-based chemotherapy including leucovorin, 5-FU, and oxaliplatin (FOLFOX), leucovorin, 5-FU, and irinotecan (FOLFIRI), and capecitabine and oxaliplatin (CAPOX)[10,11]. CRC chemotherapy has certain limitations due to systemic toxicity, low population-specific selectivity, and unsatisfactory response rate. Targeted therapies, including small molecule inhibitors and monoclonal antibodies (mAbs), are effective approaches following chemotherapy. The antiangiogenic drugs bevacizumab and anti-EGFR regimens have been successively approved by the Food and Drug Administration (FDA) for both first- and second-line CRC treatment[12-15]. In the Biomarkers of Nutrition for Development (BOND) trial, cetuximab showed clinically significant activity to improve the response rate and progression-free survival (PFS) in patients with irinotecan-refractory CRC; the most frequently observed adverse events were diarrhea, asthenia, and acne-like rash[12]. Panitumumab has a lower risk of hypersensitivity reactions than cetuximab, because panitumumab is a fully humanized antibody unlike others, which are murine-human chimeric antibodies[16]. The efficacy and safety of panitumumab plus fluorouracil, leucovorin, and oxaliplatin (FOLFOX4) has been proven in the PRIME trial[15,17]. Randomized controlled trials have shown that bevacizumab with chemotherapy could significantly increase OS and PFS in patients with CRC[14,18,19], and both patients with kirsten rat sarcoma 2 viral oncogene homolog (KRAS) mutations and those with the wild-type (WT) genotype could benefit from bevacizumab[20,21]. Besides, bevacizumab is the only antiangiogenic drug approved for the first-line treatment of CRC; some other novel anti-VEGF drugs have shown favorable results in second-line treatment of CRC, such as aflibercept and ramucirumab[22-24]. The main toxic effects of bevacizumab are cardiotoxicity, including hypertension and bradycardia. In addition, TKIs, including regorafenib and fruquintinib, were also options for CRC patients, which have been approved for third-line treatment[25,26]. TAS-102 is a novel oral drug that is a combination of trifluridine and tipiracil. Trifluridine is a cytotoxic nucleic acid analog that leads to DNA dysfunction, whereas tipiracil is a thymidine phosphorylase that inhibits enzyme degradation.

RESISTANCE TO TARGETED THERAPY IN CRC

EGFR pathway

EGFR is a member of ERBB (erythroblastosis oncogene B)/HER (human EGFR) family. Overexpression of EGFR has been detected in 25%-77% of CRCs[27]. Notably, subgroup analysis from the CRYSTAL and PRIME trials revealed that anti-EGFR therapy only benefited the population with WT RAS mutation[13,15]. Patients with BRAF mutations failed to respond to anti-EGFR therapy and BRAF mutations were independent of RAS mutations. Therefore, the European Society of Medical Oncology (ESMO) and National Comprehensive Cancer Network (NCCN) guidelines recommend anti-EGFR therapy only for patients with BRAF-WT and RAS-WT. Interestingly, left-sided CRC expressed more EGFR than right-sided CRC. The American Society of Clinical Oncology recommends that populations with left-sided tumors *vs* right-sided tumors seem to benefit more from anti-EGFR therapy and are associated with better prognosis[28]. It can be seen that not all patients are suitable for anti-EGFR therapy, and even though patients respond to it, resistance develops in 3-12 mo[29,30]. Gene mutations downstream of the EGFR signaling pathways are the main causes of resistance to anti-EGFR therapy, including RAS/RAF/MEK and PI3K/AKT/mTOR[31-33]. In addition, the activation of compensatory pathways of EGFR, such as ERBB2 and MET, is also the reason for the drug resistance to anti-EGFR[34-36]. In addition to the intrinsic mechanisms mentioned above, microenvironmental plasticity also conferred cetuximab and panitumumab resistance[37].

VEGF pathway

Angiogenesis is essential for tumor initiation, development, and metastasis. Overexpression of the VEGF ligand family and their binding to tyrosine kinase receptors (VEGFR-1, VEGFR-2, and VEGFR-3) result in endothelial cell growth and migration[38]. The activation of alternative signaling pathways and production of angiogenesis-related proteins may cause resistance to antiangiogenic therapy. Investigations demonstrated that both patients with KRAS-mutated-type (MT) and those with KRAS-WT could benefit from bevacizumab, which was different from cetuximab[20,21,39]. Placental growth factor is a pivotal indicator of anti-VEGF resistance, which is part of the reason that aflibercept is more effective than bevacizumab in xenograft models[40,41]. In addition, abnormal increases in angiopoietin-2 have been observed in many types of tumors, including CRC, and have been shown to be associated with resistance to bevacizumab[42-44]. Activation of the fibroblast growth factor-1 (FGF)/FGFR pathway has the ability to promote cell survival and migration in both normal and malignant tissues, which is also seen in anti-VEGF resistant population[45,46]. The mechanism most closely associated with the loss of anti-VEGF effectiveness is compensatory stimulation of the c-MET pathway, in which case, single-agent c-MET suppression might be beneficial[47].

NEW DEVELOPMENTS IN COLORECTAL CANCER

Overcoming anti-EGFR therapy resistance

In general, strategies to overcome resistance to anti-EGFR regimens include the following: Novel EGFR-targeted drugs, multi-targeted regimen combinations, metabolic regulators, and immunotherapy.

EGFR ligands and EGFR: The expression of EGFR ligands potentially correlates with efficacy of anti-EGFR therapy[48,49]. Thus, the development of new mAbs that can target different EGFR epitopes promises to reverse anti-EGFR resistance. Among different EGFR somatic sequence changes located in the extracellular domain (ECD), S492R affects cetuximab binding, but does not interrupt panitumumab binding, suggesting a rechallenge with panitumumab in patients resistant to cetuximab and developing an S492R mutation[50]. MM-151, an mAb that engages multiple epitopes on EGFR, interferes with EGFR signaling and suppresses tumor activity in a preclinical study[51]. Sym004 is a combination of two distinct anti-EGFR mAbs and showed significant superiority in suppressing phosphorylation of EGFR ligand and inhibiting EGFR downstream pathways in a tumor xenograft model[52,53]. A multicenter, phase II clinical trial explored the efficacy of Sym004 in patients with mCRC with secondary resistance to anti-EGFR therapy. Although Sym004 did not improve prognosis compared with the control group (capecitabine, fluorouracil, and best supportive care), subgroup analysis demonstrated that patients without EGFR ECD mutations had benefited in OS with Sym004 therapy[54]. Necitumumab is another approved EGFR antibody that can integrate with S468R, the most common cetuximab resistance substitution[55]. Necitumumab plus mFOLFOX6 showed favorable survival with manageable toxicity in the first-line treatment of mCRC patients[56].

Gene mutations in downstream pathways

Targeting RAS mutant CRC: RAS mutations present in nearly half of CRC patients usually occur in KRAS, NRAS, and HRAS[33,57]. KRAS is the most frequent mutation (40%), predominantly in exon 2, codons 12 and 13, and less commonly in exons 3 and 4[57-59]. Although RAS mutations are negative predictive markers of anti-EGFR treatment activity and are associated with poor survival outcomes,

data have demonstrated that not all KRAS-mutated patients develop resistance to anti-EGFR treatment [60]. It is unclear whether patients with $KRAS^{G13D}$ gene mutations develop drug resistance[61-63].

RAS direct inhibitors: RAS proteins are small guanosine triphosphate (GTP) phosphatases (GTPases) and are turned on when GTP-bound[64]. In the activated state, RAS alters its conformation and activates downstream pathways to promote cell proliferation, migration, and survival. This is precise because of the high affinity of RAS for GTP/GDP and the lack of suitable small molecules targeting known allosteric sites[65]. Among the most common RAS mutations, $KRAS^{G12C}$ possesses a unique near-WT intrinsic GTPase activity and has recently been demonstrated to be druggable[66,67]. Sotorasib (AMG 510) is the first drug tested in clinical trials, which specifically and irreversibly inhibits $KRAS^{G12C}$. The anticancer activity of sotorasib in patients harboring the $KRAS^{G12C}$ mutation has been demonstrated in a phase I trial. In the subgroup with colorectal cancer, 3 of 42 (7.1%) patients achieved partial response (PR), 28 (66.7%) experienced stable disease (SD), and the mPFS was 4.0 mo[67,68]. Adagrasib (MRTX849) is another covalent $KRAS^{G12C}$ inhibitor that achieves an overall response rate (ORR) and disease control rate (DCR) of 17% (3/18) and 94% (17/18), respectively, in patients with $KRAS^{G12C}$ CRC [69]. In addition, a phase III trial assessed the effect of adagrasib plus cetuximab as second-line treatment for $KRAS^{G12C}$ MT mCRC[70]. Regrettably, $KRAS^{G12C}$ is found in only 4% of CRCs, and $KRAS^{G12D}$ is the most common type of CRC; thus, developing a specific effective inhibitor is of great significance in clinical practice[71]. The development of inhibitors directly targeting $KRAS^{G12D}$ is much more difficult than that targeting $KRAS^{G12C}$ because $KRAS^{G12D}$ lacks cysteine, which can covalently bind to small molecular drugs. MRTX1133 is the first noncovalent and specific inhibitor of $KRAS^{G12D}$ with preclinical data. The binding activity and selectivity of MRTX1133 were improved by optimizing the positions 2, 4, and 7 of pyrido[4,3-d] pyrimidine based on adagrasib. In the mouse models of xenograft tumors, MRTX1133 has been shown to inhibit KRAS signaling and exhibit robust antitumor activity[72]. In addition, Revolution Medicines have developed a covalent $KRAS^{G12D}$ inhibitor that targets the activated state of KRAS. RM-036 forms a tri-complex with chaperone cyclophilin A and the on-state of $KRAS^{G12D}$ and can selectively bind to aspartate of $KRAS^{G12D}$ mutants, effectively inhibiting signal transduction. Treatment with RM-036 resulted in dramatic tumor regression and a complete response in several $KRAS^{G12D}$ mutant xenograft models[73]. Overall, targeted therapies for $KRAS^{G12D}$ are in the early stages of research, and more clinical trials are needed. Recently, a pan-KRAS probe compound, BI-panKRAS3, demonstrated antitumor efficacy in CRC models with $KRAS^{G12D}$ and $KRAS^{G13D}$ mutations [74].

Targeting the downstream pathways: MAPK pathway: Inhibition of MAPK effectors is another strategy targeting RAS-MT CRC[75]. Trametinib, binimetinib, and cobimetinib, which are MEK inhibitors (MEKi), prevent MEK phosphorylation of ERK1/2, thereby preventing dimerization and nuclear translocation[76]. However, these drugs alone did not show favorable results in this subset of population[77-79]. Several studies have focused on simultaneous use of inhibitors of MEK and upstream RTK, such as combination of MEKi with anti-EGFR drugs[80,81]. Results from both *in vitro* and *in vivo* studies suggest that the combination of cetuximab and trametinib can induce KRAS-MT cell death[82-85]. Moreover, activation of the MAPK pathway may dysregulate the cell cycle *via* the cyclin-dependent kinase (CDK) pathway. Palbociclib, a CDK4/6 inhibitor, showed limited antitumor activity when used alone (0% ORR and 33% DCR)[63]. However, the combination of binimetinib and palbociclib exhibited synergistic suppression of cell growth in *in vivo* trials[86]. The efficacy of palbociclib and another CDK4/6 inhibitor, trametinib, was evaluated in a phase Ib study (NCT02065063). In a case report, a CRC patient with KRAS-MT achieved PR for up to 10.8 mo with this combination regimen[87].

Immunotherapy combination: KRAS mutations might promote cancer immune escape mechanisms, and they are also relevant to programmed cell death protein 1 (PD-1) and decrease the expression of programmed death-ligand 1 (PD-L1) in CRC with microsatellite instability (MSI)[88]. In preclinical models, sotorasib plus checkpoint inhibitor therapy (immune checkpoint inhibitors, ICIs) increased T cell infiltration and activation, thereby forming a tumor microenvironment (TME) that was highly sensitive to immune-checkpoint inhibition[89]. Similar results were observed with the combination of adagrasib and anti-PD-L[90].

Targeting RAS through metabolic pathways: KRAS mutations can drive metabolic reprogramming by increasing glucose uptake and protein content and exhibit a Warburg effect phenotype[91]. Fatty acid synthase (FASN) regulates lipid synthesis and is often upregulated in KRAS-MT tumors. A phase I trial explored the pharmacodynamic effects of TVB-2640 (a FASN inhibitor) in patients with resectable tumors (NCT02980029)[92]. Interestingly, as the first-line treatment for type 2 diabetes mellitus, metformin may have a chemo-preventive role in CRC[93]. In preclinical studies, metformin showed a synergistic effect with oxaliplatin in the *in vitro* models of colon cancer[94]. However, the effect of metformin on the survival of patients receiving chemotherapy after resection is still inconclusive[95-98]. Additional evidence from prospective randomized controlled trials is needed. It has been reported that cultured CRC cells with KRAS mutations exhibited induced energy crisis and cell death when exposed to high doses of vitamin C (AA)[99]. The favorable safety and preliminary efficacy of AA plus mFOLFOX6/FOLFIRI (irinotecan, 5-fluoruracil, and leucovorin) in mCRC have been proven in a phase I study. Relevant phase II and III studies are ongoing[100].

Targeting BRAF mutant CRC: BRAF mutations occur in approximately 12% of patients with CRC, and

more than 95% of these mutations manifest as V600E substitution[101-104]. Patients with BRAF-MT CRC are more common in women and in people diagnosed at an old age, and the primary tumors mainly occur on the right side and in advanced stages, most of which are mucinous adenocarcinomas. Moreover, BRAF-MT CRC mainly develops peritoneal and lymph node metastasis[105-107]. In addition, more than 50% of BRAF V600E mutant CRCs have a high MSI (MSI-H) status[108,109]. CRCs harboring these features are frequently sporadic and exhibit extensive DNA methylation of CpG islands[110,111]. In contrast, MSI status in the absence of BRAF V600E mutation is related to Lynch syndrome[112]. The mOS of patients with BRAF-MT is approximately 11 mo, which is lower than that of patients with BRAF-WT[106,107]. Notably, non-V600E BRAF is defined as a clinically special subgroup with a good prognosis, which occurs in 2.2% of all patients with CRC[107]. Several cases have provided evidence that patients with a non-V600 BRAF mutation can respond to EGFR inhibitors[113,114].

The NCCN guidelines recommend combination chemotherapy as the foundation of therapy for patients with BRAF-mutated CRC[8]. The Triplet plus Bevacizumab (TRIBE) study compared the effectiveness and safety of FOLFIRI plus bevacizumab *vs* FOLFOXIRI plus bevacizumab in untreated patients with mCRC. Sixteen patients received FOLFOXIRI plus bevacizumab, and 12 patients received FOLFIRI plus bevacizumab, with a median OS of 19.0 mo and 10.7 mo respectively[115]. However, these promising survival data were not confirmed in the TRIBE phase III trial[116]. In addition, a meta-analysis indicated that FOLFOXIRI with bevacizumab failed to show superiority compared to doublet combination plus bevacizumab in patients with BRAF-mutant tumors[117]. Therefore, there is insufficient evidence to suggest that triplet combination regimens are better than doublet chemotherapy as first-line treatment for BRAF V600E-mutated CRC.

Monotherapy strategies: Vemurafenib is an oral inhibitor of BRAF V600 kinase, approved by the FDA for metastatic melanoma patients, with an effective rate of 77.1%[118,119]. Nevertheless, vemurafenib as a single agent, showed limited activity in BRAF-MT mCRC, with a response rate of 5%[120]. This result illustrates that BRAF activation in mCRC is more intricate and heterogeneous than that in melanoma. The activity of BRAF inhibitors may cause feedback signaling *via* reactivation of EGFR, whereas melanoma cells express low levels of EGFR[121,122].

Concurrent blockade of BRAF and EGFR: Several studies have shown that EGFR inhibitors combined with BRAF inhibitors could be an effective strategy[122,123]. The efficacy of vemurafenib combined with panitumumab in 15 patients with chemo-resistant BRAF-MT mCRC. The results of this trial included ten cases of tumor regression and two cases of stable disease lasting over 6 mo. Additional studies exploring dual blockade of BRAF and EGFR showed response rates of 10%-39%[124]. Interestingly, adding irinotecan to the two-drug regimen can further inhibit tumor growth. In a phase I trial (NCT01787500), patients with pretreated BRAF-MT mCRC achieved sustained disease control after receiving this triple combination therapy, and the mPFS was 7.7 mo[125]. The SWOG1406 phase III trial recruited 160 patients with BRAF-MT mCRC and randomly assigned them to two treatment groups: 54 patients received irinotecan, cetuximab, and vemurafenib, while the others received cetuximab and irinotecan. The results showed that the ORR and DCR increased by 17% and 65%, respectively, with the addition of vemurafenib[126]. Accordingly, the 2018 NCCN guidelines recommended that mCRC patients with BRAF-MT could choose three-drug combination regimens: Irinotecan, anti-EGFR therapy, and anti-BRAF therapy (vemurafenib)[127]. Recently, a study found that RNF43 mutations could help prioritize patients with mCRC BRAF-V600E, who are more likely to respond to the anti-EGFR/BRAF combination. Further research is needed to explore the incorporation of this biomarker along with BRAF and microsatellite stable (MSS)/MSI status in routine testing[128].

Concurrent blockade of BRAF and MEK: The combination of BRAF and MEK inhibitors can also produce potentially favorable antitumor activity by enhancing inhibition of the MAPK pathway[129,130]. In the phase III BEACON study, 665 BRAF V600E-MT mCRC patients were enrolled and randomly divided into three groups: Encorafenib, binimetinib, and cetuximab; encorafenib and cetuximab; and irinotecan plus FOLFIRI or cetuximab (control group). The triplet therapy significantly improved the OS, with an mOS of 9.0 mo. The objective response rates of the triplet therapy, doublet therapy, and control groups were 27%, 20%, and 2%, respectively[131,132]. Based on these results, the FDA approved doublet regimens as second-line treatment for BRAF-MT mCRC therapy, while in Japan, both doublet and triplet regimens are approved[133]. The ANCHOR study is an ongoing trial to estimate the efficacy of encorafenib, binimetinib, and cetuximab for BRAF-MT mCRC in previously untreated patients and is also the first prospective study using BRAF inhibitor regimens as the first-line therapy[134]. Dabrafenib is another selective BRAF inhibitor competing against ATP[135]. Ryan *et al*[64] tested dabrafenib plus trametinib in 43 patients with BRAF V600-mutanted CRC, of whom five (12%) achieved partial response, and 24 (56%) achieved stable disease[136].

PI3K/AKT activation and PI3K/AKT inhibitors: PIK3CA encodes the p110α catalytic subunit of phosphatidylinositol 3-kinase (PI3K), found in 10%-20% of CRC patients[31]. PI3KA mutation and abnormal AKT/mTOR activation lead to reversal of EGFR-blocking effects in CRC. PIK3CA mutations usually occur in exons 9 and 20, and exon 20 mutations are associated with worse prognosis in KRAS-WT mCRC patients treated with cetuximab, whereas exon 9 mutations did not affect survival[31,137]. Experimental data suggest that aspirin suppresses prostaglandin-endoperoxide synthase 2 and

downregulates PI3K signaling activity[138]. Low-dose aspirin had a significant interactive effect on survival among patients with PIK3CA-MT CRC but not among patients with PIK3CA-WT[139]. This observation requires a prospective evaluation. PTEN (phosphatase and tensin homolog) is a negative modifier of the PI3K/AKT pathway, detected in 20%-40% of mCRC cases, the loss of which results in tumor growth by activating PI3K/AKT[140]. Tumors without mutations in KRAS, NRAS, BRAF, and PIK3CA are called "quadruple negative" CRCs, responding best to anti-EGFR therapy[80].

Compensatory feedback loop signaling

HER-2 amplification/overexpression: Amplification of the HER2 gene, which induces excessive PI3KCA/AKT/mTOR signaling, occurred in 5%-7% of CRC patients, mostly in RAS wild-type tumors [36,141,142]. The incidence of HER2 mutations was not related to patient age, sex, tumor stage, or anatomical location[143]. However, genomic profiling studies have reported that HER2 mutations are more common in high tumor mutation burden or MSI-H tumors[144,145].

Early clinical studies evaluating HER2 inhibitors with chemotherapy were terminated because of poor accrual[146,147]. It has been speculated that the low frequency of HER2 expression in CRC restricts the application of HER2-targeted therapy. Bertotti *et al*[141] found that HER2 positive patients were sensitive to dual regimens of trastuzumab and lapatinib but not to either agent alone. HERACLESA, a multicenter phase II trial, evaluated the efficacy of a combination of trastuzumab and lapatinib in mCRC patients with KRAS-WT and HER2 overexpression refractory to standard treatment[148]. HER2 positivity was defined by immunohistochemistry (IHC) and fluorescence *in situ* hybridization (FISH): Tumors with a score of IHC 3 + in more than half of the cells, or with an IHC 2 +:CEP17 ratio > 2 in more than half of the cells[149]. The study achieved an ORR of 30% and showed encouraging survival outcomes: An mPFS of 5.0 mo and an mOS of 11.5 mo[148]. Based on these results, trastuzumab and lapatinib regimens were included in the 2019 NCCN Guidelines for CRC, and more clinical research has been triggered to optimize anti-HER2 regimens in this setting[8]. In the HERACLES-B study, a single-arm phase II trial, patients were treated with pertuzumab and trastuzumab (T-DM1). A total of 31 patients were evaluable, of whom 48% had more than four lines of previous therapies. Although the study did not meet its primary endpoint, with an ORR of 9.7%[150], it demonstrated a similar mPFS to other anti-HER2 regimens with low toxicity and high disease control. In the phase II MyPathway trial, patients also received pertuzumab and trastuzumab, and the ORR was only 8% in the KRAS-MT population compared to 40% in the KRAS-WT population, suggesting that patients with KRAS-WT mCRC benefited more from the combination of pertuzumab and trastuzumab than those with KRAS-MT mCRC[151,152]. The efficacy of pertuzumab plus trastuzumab was confirmed in the TRIUMPH trial. This was the first study to define HER2-positive mCRC based on tissue or circulating tumor DNA (ctDNA) analysis and to confirm the feasibility of using ctDNA to identify HER2 expression for therapeutic targeting[153].

Trastuzumab deruxtecan (T-DXd) is an antibody-drug conjugate formed by humanized anti-HER2 antibody with a topoisomerase I inhibitor payload. Its effectiveness was demonstrated in the DESTINY-CRC01 phase II trial[154]. Phase II DESTINY-CRC02 was designed to assess the efficacy of T-DXd in patients with HER2-amplified mCRC at a lower dose (5.4 mg/kg) compared to that in other studies. Preliminary data showed that T-DXd may be effective in RAS-MT mCRC, which is different from other trials of anti-HER2 regimens[155].

Tucatinib, a selective oral small-molecule inhibitor of HER2, has shown promising efficacy in HER2 positive metastatic breast cancer[156]. In xenograft models of patients with HER positive CRC, tucatinib showed significant antitumor activity. When combined with trastuzumab, the effect of tumor growth inhibition becomes more pronounced[156]. This provided the foundation for the MOUNTAINEER study, in which 26 patients with RAS-WT HER2 positive mCRC received tucatinib with trastuzumab. The results showed an ORR of 55%, with an impressive mPFS of 6.2 mo and OS of 17.3 mo, respectively [157,158].

MET amplification/activation and MET inhibitors: The phosphorylation of MET results in the activation of PI3K/AKT and RAS/RAF/MAPK to improve tumor cell growth[159]. The dual blockade of MET and EGFR could provide a new therapeutic strategy for CRC patients with acquired MET-driven resistance to anti-EGFR. A phase II clinical study evaluated the efficacy of tivantinib and cetuximab in 41 patients with secondary resistance to anti-EGFR and MET overexpression. In the first stage, the study showed promising results with a DCR of 52.4%. However, the study did not reach the primary endpoint during the second stage, and only four patients achieved an objective response instead of five as expected. Whereas, the survival results were still encouraging, with an mPFS of 2.6 mo and mOS of 9.2 mo, respectively[160]. Crizotinib is another c-MET inhibitor that has been proven to increase sensitivity to radiotherapy in patients with cetuximab-resistant KRAS-MT mCRC[161].

Rechallenge of anti-EGFR therapy

RAS mutations and EGFR ectodomain clones that appeared during anti-EGFR treatment would subside with antibody discontinuation, resulting in a decrease in the abundance of resistance mutations in the RAS/EGFR alleles, thereby restoring sensitivity to anti-EGFR regimens. However, not all patients

would benefit from the rechallenge therapy. Utilizing ctDNA is crucial for the dynamic monitoring of acquired resistance and helps to guide treatment decisions, especially for EGFR rechallenge[20]. Khan *et al*[162] found that resistance mutations can be detected in the blood a few months before disease progression. The landmark observations were from the CRICKET and CAVE clinical trials. In the CRICKET single-arm phase II study, patients treated with first-line cetuximab plus irinotecan with at least 6 mo of PFS were recruited and achieved an ORR of 21% and DCR of 54% to anti-EGFR rechallenge, respectively. All patients with PR had baseline RAS-WT, and these patients experienced longer PFS than patients with ctDNA RAS-MT (4.0 mo *vs* 1.9 mo)[163]. In CAVE phase II, single-arm clinical trial, a combination of cetuximab and avelumab has been proved to be an effective rechallenge strategy in mCRC patients with RAS-WT, and mOS reached 17.3 mo in patients with RAS/BRAF-WT ctDNA prior to anti-EGFR rechallenge[164]. The REMARRY and PURSUIT trials confirmed that baseline plasma RAS status could be a predictive indicator of rechallenge with anti-EGFR mAbs in patients with mCRC. In addition, this study demonstrated the effect of other gene mutations on the efficacy of rechallenge with anti-EGFR mAbs, including BRAF, EGFR, HER2, MET, and PIK3CA[165].

OVERCOMING RESISTANCE TO ANTI-VEGR THERAPY

Vanucizumab targets both VEGF-A and angiopoietin-2, and has manageable safety and promising anticancer effects in a phase I study[166]. Although compensatory activation of the c-MET pathway contributes to the loss of anti-VEGF drug efficacy, evidence for dual targeting of c-MET and VEGF in mCRC is rare[47]. Famitinib is a novel TKI targeting VEGFR2, PDGFRβ, and KIT[167]. In a phase II trial from China, this drug correlated with an improvement in PFS (2.8 mo *vs* 1.5 mo) and DCR (59.8% *vs* 31.4%) compared to placebo for patients with chemo-refractory mCRC[168]. In addition, the combination of bevacizumab and trifluridine/tipiracil is currently being tested in mCRC based on the promising results of preclinical and early-phase clinical trials[168,169].

TARGETING CELL CYCLE

WEE1 is a significant part of the G2/M checkpoint through its actions on CDK1 to regulate the cell cycle [170]. Adavosertib (AZD1775) is the first small-molecule inhibitor of WEE1 kinase, which has been tested in combination with chemotherapy and radiotherapy in several tumors. In addition, the protein p53 is also a pivotal factor in cell cycle arrest, inducing the inactivation of the G1/S phase checkpoint, thereby making tumor cells more dependent on the regulation of the G2/M checkpoint. Almost all tumor cells deactivate p53, most of which is mediated by TP53 mutations[171]. A randomized trial (FOCUS4-C) evaluated adavosertib in patients with KRAS and TP53-MT mCRC. Patients with both mutations who were stable or responding to chemotherapy were randomly assigned to two groups: Adavosertib and active monitoring (AM). Patients who received adavosertib showed an advantage in PFS compared to those on AM (3.61 mo *vs* 1.87 mo), although there was no significant difference in OS between the two groups (14 mo *vs* 18 mo)[172]. In addition, the combination of adavosertib and irinotecan as second-line treatment for mCRC patients with KRAS or BRAF MT is being evaluated in a phase I trial (NCT02906059). Other WEE1 inhibitors have also been explored.

OTHER TARGETS: NEUROTROPHIC TROPOMYOSIN RECEPTOR KINASE, ANAPLASTIC LYMPHOMA KINASE, AND ROS1 FUSION

Fusions of neurotrophic tropomyosin receptor kinase (NTRK) genes have been found in 1.5% of all CRCs, mainly in right-sided, MSI-H, and RAS/BRAF-WT tumors[173,174]. Larotrectinib and entrectinib, which are highly selective inhibitors of TRKA, TRKB, and TRK, were approved by the FDA in November 2018 and August 2019, respectively[175,176]. In a study by Cocco *et al*[177], larotrectinib achieved an ORR of 75%, and entrectinib resulted in an ORR of 57%. The phase II NAVIGATE trial reported that larotrectinib generated an ORR of 50%, DCR of 100%, mPFS of 5.5 mo, and mOS of 29.4 mo in ten mCRC patients[178]. Anaplastic lymphoma kinase (ALK), proto-oncogene 1, and receptor tyrosine kinase (ROS) are common driver genes in non-small cell lung cancer, but are extremely rare in mCRC, with an incidence of ≤ 1%[179,180]. In preclinical studies, the combination of crizotinib and mitomycin C appeared to have synergistic effects in CRC[181], and a series of trials on crizotinib are in progress.

IMMUNOTHERAPY

ICIs aim to improve immune surveillance and suppression by preventing tumor evasion from T-cell detection[182]. Currently, ICIs have been investigated for the treatment of multiple solid tumors with promising outcomes. Pembrolizumab, a humanized IgG4 antibody, was the first PD-1 blocker to gain FDA approval for CRC treatment in 2017. Initial data from the randomized phase III KEYNOTE-177 study showed that pembrolizumab as first-line therapy *vs* standard chemotherapy improved PFS in patients with mismatch repair deficient (dMMR) or MSI-H CRC[183]. Recently, the study published the final results: Compared with chemotherapy, pembrolizumab did not provide a profound advantage in OS because the prespecified α of 0.025 was not achieved. However, in term of mPFS, the pembrolizumab group was superior to chemotherapy group (16.5 mo *vs* 8.2 mo)[184]. Nivolumab, another humanized IgG4-based PD-1 antibody, was approved by FDA for dMMR or MSI-H CRC in the same year on the basis of CheckMate-142 trial. The ORR reached 31.1%, regardless of the tumor PD-L1 expression, and 1-year PFS and OS rates were 50.4% and 73.4%, respectively[185]. Nivolumab combined with the CTLA-4 inhibitor ipilimumab outperforms single-agent immunotherapy with acceptable adverse events. This combination regimen helped patients with dMMR or MSI-H mCRC achieve a PFS of 77% and OS of 83% at 1 year, with an ORR of 60% and DCR of 84%. Based on these data, the FDA has approved nivolumab and ipilimumab for patients with chemotherapy-refractory mCRC[186].

Patients with MMR proficient (pMMR) or MSS mCRC, which is also called "cold" tumor, could not obtain satisfactory results from ICIs; yet this subgroup accounts for the majority of CRC. Resistance mechanisms to immune checkpoint blockade in MSS mCRC include the loss of neoantigens, abnormal cell signaling, and immunosuppression[187]. Currently, strategies to improve ICIs responses in patients with pMMR and MSS CRC, such as in combination with other approaches including chemotherapy, radiotherapy, targeted agents, and other immune checkpoint modulators, are being explored[182,188,189]. For these patients, the combination of PD-1/PD-L1 and CTLA-4-blocking antibodies may have manageable safety and empowering antitumor activity[187]. In a clinical trial (NCT02754856), 21 patients with pMMR with liver-only metastases received durvalumab and tremelimumab prior to surgery, and prolonged relapse free survival (RFS) as well as T cell activation was observed[190]. Increasing evidence indicates that chemotherapy can boost the immune system by adjusting the immune microenvironment or directly stimulating antitumor responses[191]. It was suggested that 5-FU plus oxaliplatin may be the most effective chemotherapy regimen for activating PD-L1 expression and CD8 recruitment. A phase I/II study explored the safety and efficacy of durvalumab plus tremelimumab combined with FOLFOX in mCRC patients with MSS and RAS mutated status[192]. In a phase II trial, 43 patients with mCRC with MSS RAS/BRAF-WT received chemotherapy, cetuximab, and avelumab. Among them, four patients achieved complete response; the ORR and DCR were 81% and 89%, respectively[193]. Regorafenib plus nivolumab also showed an inspiring 7.9-mo median PFS for MSS mCRC in the phase Ib trial REGONIVO (NCT03406871)[194]. Radiotherapy can also promote T cell infiltration into cold tumors and has been used to improve immunotherapy efficacy[195]. A phase II study enrolled 24 patients with chemotherapy-refractory MSS mCRC who received durvalumab, tremelimumab, and radiotherapy. The results showed that the median OS was 11.4 mo, and the median PFS was 1.8 mo[196]. However, the optimal timing for the combination of immunotherapy and radiotherapy needs to be further explored. In addition, adoptive cellular therapy (ACT), as an emerging immunotherapy, has developed rapidly in several clinical studies and has been widely proven to have therapeutic efficacy in hematological malignancies. Carcinoembryonic antigen (CEA) is the most commonly researched target of chimeric antigen receptor (CAR) T cells for the treatment of mCRC. Zhang *et al*[197] recruited ten relapsed and refractory mCRC patients to evaluate the efficacy and safety of CAR-T therapy. Nearly 70% of patients achieved stable tumor control after treatment. In long-term observations, the serum CEA level decreased dramatically in most patients[197]. Moreover, the key factor to transform "cold" tumors into "hot" tumors is to stimulate immune response, and cancer vaccine is an ideal strategy. Currently, several vaccines have been studied for CRC, including autologous vaccines, dendritic cells, viral vectors, and peptide-based vaccines[198]. Relevant clinical trials are still in their early stages, and more research is needed to demonstrate their therapeutic potential[199-201].

ROLE OF TUMOR MICROENVIRONMENT

TME plasticity is a powerful driver of drug resistance. The TME contains not only the extracellular matrix (ECM), but also immune cells, endothelial cells, fibroblasts, and signaling molecules, including exosomes, chemokines, and cytokines[202]. The ECM is the main component that is remodeled during oncogenesis and progression. Collagen plays an important role in resisting tumor invasion and is regarded as a structural barrier. It was found that enriched collagen activates the PI3K/AKT signaling pathway *via* integrin α2β1 to sustain tumor growth. Notably, the inhibitor of integrin α2β1 can prevent metastasis, and the combination of integrin α2β1 inhibitor with chemotherapy showed improved curative effects[203]. In addition, the expression of type I collagen, matrix metalloproteinase (MMP-2),

and MMP-9 is upregulated in primary CRC, which participated in the degradation and regeneration of the ECM[204]. These findings will provide new ideas for the future treatment of mCRC. Fibroblasts are mesenchymal cells that secrete mitogenic growth factors such as FGF1, FGF2, hepatocyte growth factor (HGF), transforming growth factor beta-1 (TGF-β1), and TGF-β2[205]. Luraghi *et al*[206] found that HGF binds to MET receptors and stimulates MAPK and AKT to induce cetuximab resistance. This provides a theoretical basis for the concomitant blockade of FGFR and EGFR to reverse resistance to anti-EGFR mAbs. The combination of BLU9931 (an FGFR4 inhibitor) and cetuximab showed improved antitumor activity compared to cetuximab alone[207]. Exosomes exhibit potential antigenicity and can induce powerful immune responses[208]. Several studies have indicated that exosomes can be used as vaccines for mCRC. A phase I clinical trial has shown that the combination of ascites-derived exosomes (Aex) and granulocyte-macrophage colony-stimulating factor (GM-CSF) is a feasible alternative choice in the immunotherapy of mCRC[200].

WNT SIGNALING

The Wnt protein is a member of the coiled family of transmembrane receptors consisting of multiple glycoproteins and is a co-receptor for the lipoprotein receptor-related protein (LRP) family and other downstream signaling proteins[209,210]. Wnt/β-catenin signaling is the most classical pathway in Wnt signaling, and its key steps are protein stabilization and nuclear translocation. When Wnt ligands are not activated, a complex formed by adenomatous polyposis coli (APC) protein, framework protein Axin, glycogen synthase kinase 3β (GSK3β), and casein kinase 1 (CK1) will degrade βcatenin[211,212]. In the case of Wnt activation, Wnt ligands integrate with receptors, resulting in the phosphorylation of LRP by CK1 and GSK3, and recruit proteins such as axisprotein (Axin) and dishevelled to the cell membrane, thereby disrupting the formation of the complexes that could degrade βcatenin[213,214]. Undegraded β-catenin accumulates in the cytoplasm, and when it reaches a sufficient concentration, free β-catenin is transferred to the nucleus and binds to the transcription factor/lymphocyteenhancing factor (TCF/LEF), inducing cell proliferation, differentiation, and maturation[214,215]. Normal transduction of Wnt signaling facilitates the regulation of intestinal function[216,217]. Abnormal activation of Wnt/β-catenin signaling is found in more than 80% of CRCs, which leads to the accumulation of nuclear β-catenin and is associated with a poor prognosis[218]. Studies have shown that Wnt/β-catenin signaling mediates CRC resistance *via* three pathways: Tumor stem cells, non-coding RNAs (ncRNAs), and disordered TME[219-222].

β-catenin is a crucial target of Wnt signaling, thus preventing the protein-protein connection between TCF and β-catenin suppresses tumor cell growth[223]. The earliest studies utilized high-throughput enzyme-linked immunosorbent assay (ELISA) to detect the β-catenin-TCF connection, and eight compounds were initially screened, of which PKF115-584 and CGP049090 proved to be the most potent material[223]. Moreover, PKF115-584 and CGP049090 also interfere with β-catenin-APC interaction[224-226]. Another study found that 2,4-diamino-quinazoline (Table 1) exhibited solubility, metabolic stability, and oral bioavailability by preventing the β-catenin-TCF4 pathway[227,228]. Porcupine is a member of the membrane-bound O-acyltransferase (MBOAT) family. It adds a palmitoyl group to the protein, which is involved in Wnt signaling[229]. Small molecule compounds such as IWP, C59, and ETC-159 can target porcupine, thereby inhibiting the activity of the Wnt signaling pathways[230]. In addition, many natural compounds, such as curcumin, soybean-derived isoflavone-phytoestrogen genistein, and berberine, inhibit the Wnt signaling pathway by acting on different targets[231,232]. These natural compounds have the potential to treat CRC and deserve further investigation.

CONCLUSION

The heterogeneity and molecular diversity of CRC promote drug resistance and are associated with adverse outcomes. The field of CRC has continued to develop over the last few decades, leading to a better understanding of its occurrence and development. This review summarizes the currently available targeted therapies, drug resistance mechanisms, and potential treatments for mCRC. It is not difficult to find that a wider range of molecular markers is needed to assess the efficacy of targeted therapy and obtain optimal outcomes for patients. Excitingly, high-sensitivity genome sequencing methods and the application of liquid biopsy have provided deeper insight into the molecular evolution and mechanisms of resistance to treatment. In addition to the targets mentioned in this review, there are other new targets that correlate with the prognosis of patients with mCRC. The aim is to develop more specific drugs for these targets to adopt more individualized treatments and eventually improve the prognosis of patients with mCRC.

Table 1 Strategies to reverse targeted therapy resistance in clinical trials

Target(s)	Agent(s)	Phase	Condition	Treatment	Main outcomes
EGFR ECD	Sym004	Phase I	KRAS-WT mCRC	Sym004	mOS: 12.8 mo
EGFR S468R	Necitumumab	Phase II	First-line mCRC	Necitumumab + mFOLFOX6	ORR: 63.6%
$KRAS^{G12C}$	Sotorasib (AMG 510)	Phase I	Solid tumors	Sotorasib	ORR: 7.1%; DCR: 73.8%
$KRAS^{G12C}$	Adagrasib (MRTX849)	Phase II	Solid tumors	Adagrasib	ORR: 17%; DCR: 94%
BRAF	Vemurafenib	Pilot trial	Previously treated	Vemurafenib + panitumumab	DCR: 83%
BRAF	Vemurafenib	Phase I	Previously treated	Irinotecan + vemurafenib	ORR: 35%; DCR: 88%; mPFS: 7.7m
BRAF	Vemurafenib	SWOG-S1406; phase II	Previously treated	Irinotecan + cetuximab + vemurafenib	mPFS: 4.2 mo; ORR: 17%; DCR: 65%
BRAF	Encorafenib	BEACON; phase III	Previously treated	Encorafenib + binimetinib + cetuximab	mOS: 9.3; ORR: 26.8%
BRAF	Dabrafenib	Phase I/II	BRAF-WT	Dabrafenib + trametinib	ORR: 12%
HER2	Dual-targeted drugs	HERACLE A; phase II	KRAS-WT	Trastuzumab + lapatinib	mOS: 11.5 mo; mPFS: 5.0 mo; ORR: 30%
HER2	Pertuzumab; T-DM1	HERACLE B; phase II	KRAS/BRAF-WT	Pertuzumab + trastuzumab	ORR: 9.7%; mPFS: 4.1 mo
HER2	Trastuzumab pertuzumab	MyPathway; phase II	Previously treated	Trastuzumab + pertuzumab	ORR: 32%; mOS: 11.5 mo; mPFS: 2.9 mo
HER2	Trastuzumab pertuzumab	TRIUMPH;phase II	KRAS-WT	Trastuzumab + pertuzumab	ORR: 30%; mOS: 10.1 mo; mPFS: 4.0 mo
HER2	ADC	DESTINY-CRC01; phase II	Previously treated	Trastuzumab deruxtecan (T-DXd)	ORR: 45.3%; mOS: 15.5 mo; mPFS: 6.9 mo
HER2	Tucatinib	MOUNTAINEER; phase II	Previously treated	Tucatinib + trastuzumab	ORR: 52%; mOS: 18.7 mo; mPFS: 8.1 mo
MET	Tivantinib	Phase II	KRAS WT; previously treated	Tivantinib + irinotecan + cetuximab	mPFS: 8.3 mo; ORR: 44%; mOS: 19.8 mo
EGFR rechallenge	Irinotecan	CRICKET; phase II	KRAS/BRAF WT; third-line	Irinotecan + cetuximab	ORR: 21%; DCR: 54%; mOS: 9.8 mo; mPFS: 3.4 mo
EGFR rechallenge	Avelumab	CAVE; phase II	KRAS WT; third-line	Avelumab + cetuximab	mOS: 11.6 mo; mPFS: 3.6 mo; ORR: 7.8%; DCR: 65%
EGFR rechallenge	Irinotecan	REMARRY and PURSUIT; phase II	KRAS/BRAF WT	Panitumumab + irinotecan	ORR: 14%; mPFS: 3.6 mo
VEGF	Vanucizumab	Phase I	Solid tumors	Vanucizumab	DCR: 59.8%; mPFS: 2.8 mo
VEGF	Bevacizumab	TRIBE; phase II	mCRC	Bevacizumab + FOLFOXIRI	mPFS: 12.1 mo; mOS: 30.9 mo
VEGF	Aflibercept	VALOUR; phase III	Previously treated	Aflibercept + FOLFIRI	mOS: 13.5 mo; mPFS: 6.9 mo
VEGF	Aflibercept	AFFIRM; phase II	First-line	Aflibercept + FOLFOX	mPFS: 8.48 mo; 12mPFS: 25.8%
VEGF	Ramucirumab	RAISE; phase III	Second-line	Ramucirumab + FOLFIRI	mOS: 13.3 mo
VEGF	Bevacizumab	C-TASK FORCE; phase I/II	Previously treated	Bevacizumab + trifluridine/tipiracil	16 wk PFS: 46.9%
TKI	Famitinib	Phase II	Previously treated	Famitinib	mPFS: 2.8 mo; mOS: 7.4 mo; DCR: 59.8%; ORR: 2.2%
NTRK	Larotrectinib	NAVIGATE; phase I/II	Solid tumors	Larotrectinib	ORR: 50%; DCR: 100%; mPFS: 5.5 mo;

					mOS: 29.4 mo
PD-1/PD-L1	Pembrolizumab	KEYNOTE-177; phase III	dMMR/MSI-H CRC; first-line	Pembrolizumab	mPFS: 16.5 mo; mOS: NA
PD-1/PD-L1	Nivolumab	CheckMate-142; phase II	dMMR/MSI-H CRC; previously treated	Nivolumab	ORR: 60%; DCR: 84%
PD-1/PD-L1	Durvalumab	Phase I	Solid tumors	Durvalumab + tremelimumab	DCR: 36.4%
PD-1/PD-L1	Durvalumab	Phase Ib/II	MSS RAS/BRAF WT	Durvalumab + tremelimumab + FOLFOX	ORR: 81%; DCR: 89%
PD-1/PD-L1	Nivolumab	Phase Ib	MSS	Nivolumab + regorafenib	mPFS: 7.9 mo
PD-1/PD-L1	Durvalumab	Phase II	Chemotherapy-refractory MSS	Durvalumab + tremelimumab + radiotherapy	ORR: 8.3%; mPFS: 1.8 mo; mOS: 11.4 mo

mCRC: Metastatic colorectal cancer; EGFR: Epidermal growth factor receptor; VEGF: Vascular endothelial growth factor; TKI: Tyrosine kinase inhibitors; ADC: Antibody-drug conjugate; ORR: Overall response rate; mOS: Median overall survival; mPFS: Median progression-free survival; DCR: Disease control rate; PD-1: Programmed cell death protein 1; PD-L1: Programmed death-ligand 1; MSS: Microsatellite stable; FOLFOX: Leucovorin, 5-fluorouracil, and oxaliplatin; FOLFIRI: Leucovorin, 5-fluorouracil, and irinotecan; T-DXd: Trastuzumab deruxtecan; HER: Human epidermal growth factor receptor.

Abstract

Chronic infection with the hepatitis C virus (HCV) remains a major health problem affecting approximately 58 million people worldwide. In the era of interferon (IFN)-based regimens, patients particularly infected with genotypes 1 and 4 achieved a low response rate. The implementation of direct-acting antivirals changed the landscape of HCV treatment. The increase in effectiveness provided us with the hope of eliminating HCV as a significant public threat by 2030. In the following years, there was an observed improvement in the treatment of HCV with genotype-specific regimens and highly effective pangenotypic options that are the most recent stage of the revolution. The optimization of therapy was accompanied by changes in the patient profile from the beginning of the IFN-free era over time. Patients treated with antiviral therapies were younger in successive periods, less burdened with comorbidities and comedications, more frequently treatment-naïve and had less advanced liver disease. Before the IFN-free era, specific subpopulations such as patients with HCV/HIV coinfection, those with a history of previous treatment, patients with renal impairment or with cirrhosis had lower chances for a virologic response. Currently, these populations should no longer be considered difficult to treat. Despite the high effectiveness of HCV therapy, there is a small percentage of patients with treatment failure. However, they can be effectively retreated with pangenotypic rescue regimens.

Key Words: Hepatitis C virus; Interferon; Direct-acting antiviral; Epidemiology; Chronic

hepatitis C

Core Tip: A decade ago direct-acting antiviral drugs were introduced and have greatly improved the effectiveness of treatment for patients with hepatitis C virus infection. The new drugs have increased the chances of eliminating hepatitis C virus infection as a significant public threat. This paper described changes in the therapeutic options administered over the past decade and documented the changing patient profile over the years in the interferon-free era. Special populations of difficult-to-treat patients in the interferon era currently not meeting this definition are highlighted.

INTRODUCTION

Chronic infection with hepatitis C virus (HCV) is one of the leading causes of liver disease in the world. According to the most recent estimates from the World Health Organization (WHO), 58 million people are living with chronic hepatitis C (CHC) worldwide, with the annual number of new infections reaching 1.5 million[1]. About 20% of them are at risk of developing liver cirrhosis, eventually leading to organ failure and hepatocellular carcinoma[2]. These most severe complications of the disease are the cause of death of approximately 290000 people a year. There is no effective vaccine against HCV, but currently available direct-acting antivirals (DAA) can cure more than 95% of people infected with hepatitis C regardless of the genotype (GT).

To date, six major HCV GTs have been identified that differ in more than 35% of the genome sequence[3]. The most common of these worldwide is GT1, considered the most difficult to treat in the era of interferon (IFN)-based therapies. However, this was the first GT in which very high efficacy was achieved with GT-specific therapies at the beginning of the DAA era[4]. Further evolution of antiviral therapy has led to the availability of regimens that are highly effective in infection with any HCV GT and at any stage of liver disease, including decompensated liver cirrhosis[5]. In addition to increased efficacy, safety parameters have improved, and antiviral therapy has become shorter and now lasts 8 or 12 wk in the vast majority of patients[6]. There was also a simplification of regimens by dropping the addition of ribavirin (RBV), which also translated into improved tolerability. Optimization of antiviral therapy has set the groundwork for achieving the WHO's goal of eliminating HCV infection as a public health threat by 2030. The goal to realize this target remains the diagnosis of infection in patients who are unaware of it.

CHANGES IN THERAPEUTIC REGIMENS

IFN-based therapy

Regimens without DAA: The era of IFN in the treatment of HCV infection began in 1986, even before the identification of the virus, which was then known as non-A, non-B hepatitis virus. Hoofnagle *et al*[7] documented a reduction in transaminase activity as a result of IFNα2b therapy. Despite the beneficial effect of reducing disease activity, the initial responses to treatment were transient[8]. In subsequent years, other investigators reported that the decline was related to viral clearance or a decrease in serum HCV RNA[9]. Sustained virological response (SVR) after 24-wk monotherapy with recombinant IFN ranged from 3%-6%, and IFN administered for 48 wk resulted in 13%-19% efficacy[10,11]. Adding RBV to IFN improved treatment efficacy to about 40%[10-13].

The next milestone in the antiviral treatment was the introduction of two forms of long-acting pegylated IFN (pegIFN), alfa-2a and alfa-2b, which were used once a week. This change was one of the key elements in improving treatment adherence and greater efficacy of antiviral therapy[14,15]. In randomized multicenter trials, the SVR rate with pegIFN monotherapy ranged from 15% to 39%[16,17], and the addition of RBV to the regimen increased efficacy to about 50%[15,18]. HCV GTs has been identified as the most important independent predictor of response to pegIFN + RBV treatment.

The prospective PROPHESYS study involving 7163 patients treated with pegIFN + RBV for 48 wk showed better efficacy rates of 71.4% and 60.6% in patients with GT2 and GT3 infections, respectively, compared to patients with GT1 (41.8%) and GT4 (41%) infections. The higher efficacy of therapy was also observed in patients without advanced liver fibrosis or cirrhosis[19]. The most important predictor of response to therapy regardless of HCV GT was undetectable HCV RNA at week 4 of therapy, defined as the rapid virological response as proven by a retrospective study involving 1383 patients[20]. These findings allowed the reduction of the length of treatment to less than 24 wk in GT2- and GT3-infected patients who achieved rapid virological response without a significant decrease in efficacy compared to those with detectable HCV RNA after 4 wk of treatment who required treatment for 24 wk[21]. In addition to virologic response at week 4, treatment length was determined by the response at week 12; GT1-infected patients with detectable serum HCV RNA after 12 wk of treatment benefited from extending treatment to 72 wk[22,23].

The efficacy of IFN-containing regimens was limited by safety issues; adverse events of therapy were frequent and led to treatment discontinuation in 5%-16% of cases[15,24]. Fatigue, headache, fever, malaise, myalgia, neutropenia and thrombocytopenia were reported as the most common adverse events[25]. The main side effect associated with RBV use resulting in its dose reduction in 20% of patients was hemolytic anemia[18].

Regimens with DAA: The introduction of the protease inhibitors telaprevir (TVR) and boceprevir in 2011 launched the era of the first DAAs for the treatment of HCV infection[26,27]. Initially, the new drugs were registered for use with pegIFN + RBV only in patients with GT1 infection. Cure rates following triple therapy increased to about 70% compared to previously used regimens containing only pegIFN + RBV[28]. Results from the randomized, double-blind, placebo-controlled ADVANCE trial evaluating a triple regimen with TVR in treatment-naïve GT1-infected patients showed that therapy could be shortened to 24 wk in most without reducing efficacy[29].

Among patients after previous treatment failure assessed in the randomized phase 3 REALIZE trial, patients with prior relapse achieved SVR rates of 83%-88% following treatment with pegIFN + RBV + TVR, while this was only 30% for null responders[30].

The most difficult population to treat with a triple regimen containing first-generation protease inhibitors, TVR or boceprevir, was the population of treatment-experienced patients with liver cirrhosis due to very low efficacy and a poor safety profile[31-33].

Registration of new DAAs has broadened the spectrum of clinical use of triple-drug regimens. The protease inhibitor simeprevir and the non-structural protein 5A (NS5A) inhibitor daclatasvir (DCV) combined with pegIFN + RBV could be used in GT1-infected patients and those with GT4 infection with an SVR rate exceeding 82% in treatment-naïve patients[34-36]. The addition of the polymerase inhibitor, sofosbuvir (SOF) to pegIFN + RBV enabled triple therapy for patients infected with any HCV GT[37,38].

IFN-free regimens

GT-specific options: Although triple-drug therapies have resulted in higher SVR rates compared to pegIFN + RBV treatment, there is still a major limitation related to side effects as well as contraindications to therapy when using IFN. Patients with liver cirrhosis and hematologic disorders as well as those with decompensated liver disease or severe diseases of other organs and systems were left out of treatment. These safety issues were overcome by the introduction of IFN-free therapies. These well-tolerated and highly effective regimens revolutionized the antiviral therapy of CHC[39]. The first registered DAA that could be used without IFN was SOF[37]. The combination of this drug with the inhibitor of HCV NS5A protein, ledipasvir (LDV), administered with or without RBV resulted in a GT-specific combination active against GT1 and 4 infections.

Randomized, open-label phase 3 trials, ION-1 and ION-2, documented 95%-100% efficacy in GT1-infected patients depending on treatment duration (12 or 24 wk), prior treatment history and RBV use. However, lower efficacy was observed in treatment-experienced patients with liver cirrhosis[40,41] (Table 1). The ION-3 study demonstrated that in treatment-naïve patients without liver cirrhosis even shortening SOF/LDV ± RBV therapy to 8 wk does not significantly affect efficacy[42].

The results of a retrospective real-world evidence (RWE) study conducted in a large cohort of patients in the United States confirmed the high effectiveness of this regimen with 93% of GT1-infected patients responding in 93% (n = 9912), while the cure rate in GT4-infected patients was 87% (n = 97)[43].

Another GT-specific option registered for patients with compensated liver disease was the combination of ombitasvir (OBV), an inhibitor of NS5A, and ritonavir-boosted paritaprevir (PTV/r), an HCV protease inhibitor. In cases of infection with GT4, it was used with RBV for 12 wk, while for GT1-infected patients the addition of a third DAA, dasabuvir (DSV), acting as a polymerase inhibitor, was obligatory[44]. The addition of RBV and the length of therapy depended on the subtype and the presence of liver cirrhosis.

The phase 3 clinical trials SAPPHIRE-I and SAPPHIRE-II confirmed the efficacy of the 12-wk option of OBV/PTV/r + DSV + RBV at the level of 96% in GT1-infected patients without liver cirrhosis regardless of history of previous therapy[45,46]. Results from the phase 3 PEARL-III and PEARL-IV clinical trials proved that the inclusion of RBV improved efficacy in GT1a-infected patients, while the SVR in GT1b-infected patients exceeds 99% regardless of RBV addition[47].

Table 1 Efficacy of genotype-specific regimens in phase III of clinical trials

[1]Intent-to-treat analysis (no data for modified intent-to-treat analysis).
DSV: Dasabuvir; EBR: Elbasvir; GT: Genotype; GZR: Grazoprevir; LDV: Ledipasvir; mITT: Modified intention-to-treat; OBV: Ombitasvir; PTV/r: Paritaprevir; RBV: Ribavirin; SOF: Sofosbuvir; SVR: Sustained virological response.

The findings of the phase 3b study GARNET allowing the shortening of OBV/PTV/r + DSV therapy in GT1b-infected patients without cirrhosis to 8 wk without affecting efficacy formed the basis for updating the label[48]. Patients with GT4 infection both with and without compensated cirrhosis treated with OBV/PTV/r + RBV in the multinational AGATE-I and AGATE-I part II trials and the Egyptian AGATE-II trial achieved high SVR rates of 96%-100%. The demonstration that prolonging therapy did not improve the success rate among patients with compensated cirrhosis became the basis for updating the label, and regardless of the severity of liver disease, GT4-infected patients received a 12-wk treatment course[49-51]. The high effectiveness of the OBV/PTV/r + DSV +/- RBV regimen of 95% to 100% in GT1 and GT4-infected patients regardless of the severity of liver disease[52-54] and history of prior antiviral treatment has been confirmed in numerous real-world studies[55-57].

Another GT-specific DAA regimen designed for patients with GT1 and GT4 infection without cirrhosis and with compensated cirrhosis includes combinations of the protease inhibitor, grazoprevir (GZR), and the NS5A inhibitor, elbasvir (EBR), used for 12 wk. The option to add RBV and extend therapy to 16 wk applies to GT1a and GT4-infected patients with an initial viral load > 800000 IU/mL. Efficacy in phase 3 clinical trials in treatment-naïve patients without cirrhosis and those with compensated cirrhosis was 97% and 94%, respectively, while treatment-experienced patients responded in 96.6% and 93.8%, respectively[58,59]. However, it should be emphasized that these are data calculated for intent-to-treat analysis.

Pangenotypic options: The first available DAA regimen with activity against all HCV GTs was a combination of SOF and RBV. The efficacy of 12 wk of therapy with SOF + RBV in treatment-naïve patients with GT1-3 infection evaluated in a phase 3 clinical trial was 72% in patients without cirrhosis and 47% in patients with cirrhosis, respectively[60] (Table 2). A higher response rate of 97.1% was documented in patients with GT2 infection. The efficacy of this regimen in treatment-experienced GT2 and GT3-infected patients participating in the phase 3 FUSSION study was 96% *vs* 37% for patients without cirrhosis and 60% *vs* 19% in patients with cirrhosis, respectively[61]. Extending the duration of therapy to 16 wk increased the cure rates to 100% and 62.5% in patients without cirrhosis infected with GT2 *vs* GT3, while patients with liver cirrhosis responded in 62.5% and 61.0%, respectively. A comparison of treatment duration (16 wk *vs* 24 wk) in patients with GT3 infection documented the higher efficacy followed longer therapy with SVR of 86.5% and 78.6% in patients without cirrhosis and those with cirrhosis, respectively[62].

Extending treatment to 24 wk improved the response rate, especially in the GT3-infected treatment-experienced patients with cirrhosis responding in 76%. These values were still unsatisfactory, and the regimen was considered suboptimal in this patient population[62,63,64].

The use of a 12-wk regimen with pangenotypic activity, consisting of SOF and DCV, improved SVR rates in GT3-infected patients without cirrhosis to about 97% in treatment-naïve individuals and 94% in those who failed prior therapy. However, the efficacy reported in patients with cirrhosis was much lower, approximately 63%[65].

A real breakthrough in the treatment of CHC came with the introduction of new pangenotypic options highly effective against all HCV GTs. Based on phase 3 ASTRAL registration studies, in 2016 the Food and Drug Administration approved a combination consisting of SOF and the NS5A inhibitor velpatasvir (VEL) for patients without and with liver cirrhosis, including decompensated individuals [66]. The 12-wk regimen in patients with compensated liver disease resulted in an SVR of 95%-100% regardless of the history of previous therapy, while patients with decompensated liver cirrhosis responded in 84%[67-69]. The extension of therapy to 24 wk in this patient population increased the response rate to 88% and the addition of RBV to 94% in the modified intent-to-treat analysis[69]. The lowest efficacy was achieved in GT3-infected patients, with SVR rates ranging from 50% to 85%, but it should be noted that the number of patients in this study was relatively small, 12-14 in each treatment arm.

The high efficacy of SOF/VEL was confirmed in a meta-analysis of 12 studies from routine clinical practice. Of the 5196 patients with response rate data, 99% achieved SVR[70]. The analysis revealed unfavorable factors associated with a reduction in the odds of virologic response to about 98%, such as GT3 and compensated liver cirrhosis. Importantly, patients with current or prior decompensated cirrhosis were excluded from the analysis. Another new pangenotypic option containing the protease inhibitor glecaprevir (GLE) and the NS5A inhibitor pibrentasvir (PIB) became available for patients with compensated liver disease after approval by Food and Drug Administration in 2017[71].

The efficacy of the 12-wk GLE/PIB regimen in patients with GT 1, 2, 4-6 infection without cirrhosis as well as with compensated cirrhosis participating in phase 3 clinical trials reached 100% and 99%, respectively[72-74]. An equally high efficacy of 99% was reported in GT3-infected patients without liver cirrhosis in the phase 3 ENDURANCE-3 trial[72].

[1]Intent-to-treat analysis (no data for modified intent-to-treat analysis).

[2]All analyzed patients were previously treated with a direct-acting antiviral-containing regimen.

DCV: Daclatasvir; GLE: Glecaprevir; GT: Genotype; mITT: Modified intention-to-treat; PIB: Pibrentasvir; RBV: Ribavirin; SOF: Sofosbuvir; SVR: Sustained virological response; VEL: Velpatasvir; VOX: Voxilaprevir.

Shortening therapy to 8 wk in patients infected with GT1-6 without cirrhosis evaluated in the SURVEYOR-I and -II phase 2 studies and with compensated cirrhosis participating in the EXPEDITION-8 phase 3 trial did not affect the efficacy of therapy and became the basis for updating the label[75,76]. However, the EudraCT trial showed that further reduction of therapy to 4 wk reduced efficacy to 59% (10/17) for GLE/PIB without RBV and to 73% (11/15) for GLE/PIB + RBV, and drug target-specific substitutions associated with NS5A resistance were identified as a predictor of virologic failure[77].

The registration of the GLE/PIB option for use in GT1-6-infected patients with stage 4 or 5 chronic kidney disease, including those on dialysis, was based on the results of the EXPEDITION-4 trial with a 98% SVR rate in this population of patients[78]. The high efficacy of treatment with the GLE/PIB regimen has been confirmed in everyday clinical practice. A meta-analysis of 18 RWE studies involving 12531 patients documented greater than 95% efficacy regardless of GT, presence of compensated cirrhosis and history of prior therapy[79].

In 2017, a new triple pangenotypic regimen containing SOF/VEL and the HCV protease inhibitor voxilaprevir (VOX) was also registered for patients with compensated liver disease[80]. Despite its high efficacy regardless of the history of previous therapy, in practice it is used primarily as a rescue regimen after the failure of DAA therapy, and it is discussed in detail later in this manuscript, in the section on rescue therapy.

CHANGES IN THE PROFILE OF HCV-INFECTED PATIENTS OVER TIME

The availability of safe and effective therapy has led the WHO to set a goal of eliminating HCV as a significant public threat by 2030. This goal was defined as a 65% reduction in mortality and a 90% reduction in new chronic infections compared to 2015[85]. In June 2021, the WHO presented targets to reduce the annual incidence to ≤ 5 per 100000 and annual mortality to ≤ 2 per 100000[86]. In a large model study representing 93% of the global population, the Polaris Observatory HCV Collaborators estimated a reduction in global HCV prevalence from 0.9% (63.6 million) in 2015 to 0.7% (56.8 million) in 2020. During the analysis period, 8.7 million patients worldwide were treated, and significant changes were observed in the demographic and clinical characteristics of HCV-infected patients[87].

Published data indicated that patients treated with antiviral therapy for chronic HCV infection were less burdened by comorbidities and were less likely to use comedications in the subsequent time intervals analyzed[88-91]. A decrease in the median age of treated patients was also observed. Elsharkawy *et al*[88] analyzed the data of 337042 Egyptian patients of the national CHC treatment program who started therapy from October 2014 (the first introduction of IFN-free regimens in Egypt) to March 2016. The population was divided into three-time intervals of 6 mo each. The results showed a reduction in age (mean ± SD) from 53 ± 9 years in the first cohort to 49 ± 12 years in the last group[88,92]. In the Polish cohort of 10152 patients observed between 2015 and 2018, a more pronounced reduction in median age was observed from 58 at the beginning of the analyzed period to 49 at the end [89]. Furthermore, the prevalence of comorbidities and the use of concomitant medications decreased significantly in subsequent time intervals from 68.6% to 59.5% and from 64.6% to 57.7%, respectively [89].

A study carried out in the United States documented a 9.3% increase in the proportion of HCV RNA-positive patients under the age of 50 between 2017 and 2019, while German observations covering the period 2014-2018 demonstrated an increase of 14.7% in this age group of treated patients[90,91].

In 2015, Messina *et al*[3] published a comprehensive study on the prevalence and distribution of GTs worldwide before the IFN-free era. The analysis included 1217 studies published between 1993 and 2013, and they documented GT1 as the most common HCV GT globally (46%), followed by GT3 and GT4 (30% and 9%, respectively). The prevalence of GTs showed geographic variation; the proportion of GT4 in central sub-Saharan Africa accounted for more than 97% of all HCV infections. At the end of 2015, the estimated order of GTs remained the same, with GT1 and GT3 being the dominant GTs worldwide at 44% and 25% prevalence, respectively, and GT4 continuing to rank third with a 15% prevalence[93]. Given the high efficacy of pangenotypic regimens, the need for genotyping seems to be losing ground[94], and to the best of our knowledge, no studies have been published in the last few years on the prevalence and distribution of GTs at the global level.

However, several papers have analyzed this issue in patient populations at the national level. Studies of Polish and German cohorts have shown a high proportion of GT1-infected patients among antiviral-treated patients at the beginning of the DAA era[89,95]. Over time, the proportion of these patients has declined in favor of GT3-infected patients. The explanation for this phenomenon is related to the changes in therapeutic regimens discussed above. At the beginning of the DAA era, GT1-infected patients had access to highly effective GT-specific regimens, while for patients with GT3 infection there was only one IFN-free option, the 24-wk SOF + RBV combination. Because of the suboptimal virologic response achieved with this regimen, many GT3-infected patients, especially those with non-advanced liver disease, preferred the shorter 12-wk triple-drug treatment of SOF + pegIFN + RBV or waiting for more effective IFN-free options[63]. Another IFN-free therapeutic option that was more effective in patients with GT3 infection, the SOF + DCV + RBV combination, was not widely available in many countries since it contained drugs from different manufacturers, and this made registration and reimbursement difficult.

Thus the prevalence of GT1-infected DAA-treated patients decreased by 9% in Poland between 2015 and 2018 and 12% in Germany between 2014 and 2019. A similar trend was observed among 76110 patients after the introduction of DAA regimens in China, with the percentage of GT3-infected patients increasing by almost 6% between 2016 and 2020[96].

At the beginning of the IFN-free era, the proportion of patients with advanced fibrosis and cirrhosis was significantly higher compared to subsequent years, likely related to priority access to reimbursable DAA options in this patient population[97]. A single-center RWE study of Polish patients documented that the percentage of patients on antiviral therapy who were diagnosed with cirrhosis decreased significantly from 51% in 2015-2016 to 11.8% in 2018[98].

SPECIFIC SUBPOPULATIONS OF HCV-INFECTED PATIENTS

In the era of IFN-based antiviral therapies, specific subpopulations of patients were identified and recognized as difficult to treat because of more prevalent contraindications to therapy, poorer adherence, more frequent adverse events with associated treatment discontinuation and lower efficacy [4,25]. In the era of DAA therapy, these populations are essentially no longer difficult to treat, although some researchers have noted factors that negatively affect the success of therapy, especially if they occur together.

Patients with HCV/HIV coinfection

The prevalence of HCV/HIV coinfection varies significantly across subpopulations and geographic regions. Recent estimates have shown that about 2.5% of HIV-infected patients are coinfected with HCV [99]. In the era of IFN-based regimens, HIV/HCV coinfected patients were considered more challenging compared to those with HCV monoinfection. Inferior adherence, lower SVR rates, drug interactions and unfavorable safety profiles were significant therapeutic concerns[100]. DAA therapy has revolutionized the treatment of HIV/HCV-coinfected individuals, improving adherence, efficacy and safety profile. Clinical trials using a range of DAA options have shown high rates of SVR exceeding 95% and comparable to efficacy in patients with HCV monoinfection regardless of the type of regimen used[101-104]. Similar high effectiveness has been observed in studies carried out in routine medical practice, although some authors have reported lower response rates to DAA therapy in populations with HIV coinfection than in populations with HCV monoinfection[105-109].

Treatment-experienced patients

Similar observations apply to patients with a history of prior failed therapy. Numerous clinical trials with different DAA options do not document the lower SVR rates as compared to treatment-naïve patients, while in some RWE studies this parameter has been identified as an unfavorable factor in the chances of virologic response with lower SVR rates ranging from 0.7% to 2.4% depending on the regimen used, type of GT and severity of liver disease[39,55,70,73,110].

A distinct category of treatment-experienced patients is those who have not responded to IFN-free options subjected to subsequent DAA therapy. Data from the German hepatitis C registry described an unsatisfactory 79.5% response rate in patients retreated with DAA after the failure of initial IFN-free

treatment[111]. These results were supported by findings from a Polish RWE study reporting effectiveness of 86% with GT-specific DAA retreatment in previous IFN-free nonresponders[112]. A newly published analysis also from Poland evaluated patients who failed pangenotypic therapy and underwent pangenotypic retreatment[113].

Patients with renal impairment

Chronic infection with HCV may be an independent risk factor for the development or progression of chronic kidney disease (CKD)[114]. On the other hand, due to suboptimal hygiene measures in some dialysis units, the prevalence of HCV infection in hemodialysis patients was significantly higher (3.8%-31.1%)[115]. Historically, the use of IFN + RBV therapy in patients with renal failure has been limited due to contraindications to both medications[116]. Also, the efficacy of the IFN-based regimen in this patient population was lower and the safety profile was inferior compared to patients with normal renal function. Hemodialyzed patients with CHC treated with pegIFN analyzed in a meta-analysis of 24 clinical trials achieved an SVR rate of 40%, while 14% of them discontinued treatment due to adverse events[117]. Due to the distinct metabolic pathways of DAAs, their introduction to treatment has offered an effective and well-tolerated therapy for patients with renal impairment, including hemodialysis patients with HCV infection[118].

SOF-containing regimens are approved for use in patients with estimated glomerular filtration rate > 30 mL/min/1.73 m^2 due to limited safety data in patients with severe renal impairment. However, since 2019 according to the label, these combinations can also be administered with no dose adjustment at lower estimated glomerular filtration rate values and in patients requiring hemodialysis if no other relevant treatment options are available[94,119,120]. The meta-analysis included 21 studies with 717 patients in CKD stages 4-5, demonstrating an SVR of 97% and a good safety profile of SOF-containing regimens[121]. Therapy should be used with caution, and renal parameters should be carefully monitored during the treatment course due to the possibility of worsening renal function, as demonstrated by Saxena *et al*[122].

Among GT-specific options, the OBV/PTV/r +/- DSV and GZR/EBR regimens are registered for use in patients with renal failure, including those on dialysis[44,123]. The RUBY-1 and RUBY-2 clinical trials demonstrated an SVR of 95% in HCV-infected patients in CKD stage 4-5 treated with OBV/PTV/r +/- DSV +/- RBV, while the therapy with GZR/EBR in this patient population evaluated in C-SURFER study resulted in 99% efficacy[124,125]. Of the pangenotypic options, the GLE/PIB regimen has been registered for patients with severe renal failure, including those on dialysis; the good safety profile and high efficacy of this combination were documented in clinical trials[78,126].

Patients with compensated liver cirrhosis

The efficacy achieved in compensated liver patients with cirrhosis treated with GT-specific options ranged from 92% to 96%, while clinical trials evaluating pangenotypic regimens in this patient population showed an SVR of 96% and above[67,76,127,128]. Although these results corresponded with high treatment efficacy, they were lower compared to SVR in patients without cirrhosis[67,76,129]. Data from the RWE study confirmed the worse effects of therapy in the population with cirrhosis than in patients without cirrhosis. Moreover, decompensation of liver function was identified as an independent negative predictor of SVR[69,110,130]. It should be noted that IFN-based therapies were absolutely contraindicated in patients with decompensated cirrhosis due to the side effects of this cytokine[131]. Also, not all DAA regimens are registered for use in this patient population. Combinations containing protease inhibitors are not recommended because of the risk of worsening liver function[94]. Among GT-specific regimens, the SOF/LDV option is approved for use in patients with decompensated cirrhosis. Among pangenotypic regimens, it applies to SOF ± DCV ± RBV and SOF/VEL combinations[132-134].

Other factors affecting treatment outcome

Male sex is recognized as a factor that may reduce the effectiveness of DAA therapy. Multivariate logistic regression models performed in a large retrospective analysis of 17487 United States veterans with HCV infection found that the male sex was an independent negative predictor of achieving SVR [43]. These data confirm the results of other RWE analyses conducted in numerically smaller populations[110,135].

Patients with GT3 infection, who were considered an easy-to-treat population in the era of IFN-based therapy, are less likely to respond to treatment in the era of DAAs[43,136,137].

RESCUE REGIMENS

Despite the very high efficacy of currently available DAA therapy exceeding 95%, there is still a small proportion of patients who do not respond to treatment, especially when different negative predictors of achieving SVR are present[113,138]. Failure of therapy with DAA regimens could be related to the selection of mutant-resistant strains carrying resistance-associated substitutions, and those contributing

lower sensitivity to NS5A inhibitors are the most persistent[139]. The only therapeutic option registered for treatment in such cases is a three-drug pangenotypic combination of SOF/VEL/VOX. The introduction of this regimen improved the SVR rates to 96%-98% in patients after the failure of DAA therapy evaluated in POLARIS-1 and POLARIS-4 clinical trials[84,80]. The findings from registration studies are supported by data from routine medical practice[113,140,141]. A meta-analysis of 10 cohorts including 1187 patients demonstrated that 96% of them achieved undetectable HCV RNA 12 wk after the end of treatment. However, lower effectiveness was reported for those with GT3 infection and cirrhosis[140,141].

According to the most recent European Association for the Study of the Liver and American Association for the Study of Liver Diseases guidelines, in patients who have failed SOF/VEL/VOX, extended retherapy with this regimen plus weight-based RBV or a combination of GLE/PIB + SOF + RBV is recommended, although no data from clinical trials for SOF/VEL/VOX nonresponders are available[94,142]. It was pointed out that retreatment can be optimized based on resistance-associated substitution testing[94]. A 96% efficacy of the rescue regimen of GLE/PIB in combination with SOF and RBV was evaluated in the MAGELLAN-3 clinical trial, but all 23 included participants were GLE/PIB failures[143].

Very limited data on patients receiving GLE/PIB + SOF +/- RBV retherapy are available from RWE studies. In an open-label study conducted in New Zealand, patients treated with GLE/PIB + SOF after prior DAA failure achieved a virologic rate of 98%[144].

CONCLUSION

Since the beginning of the availability of IFN-free options, we have observed changes occurring in the regimens used from GT-specific to highly potent pangenotypic options, including rescue combinations. These are accompanied by changes in the profile of the HCV-infected population, with patients starting treatment over time being younger, with less advanced liver disease and less burdened by comorbidities. Despite the very high effectiveness of current DAA options, some factors including male sex, GT3 infection, liver cirrhosis and prior failure of DAA therapy are still identified that lower the chances of a cure.

Abstract

A growing body of evidence from multiple areas proposes that periodontal disease, accompanied by oral inflammation and pathological changes in the microbiome, induces gut dysbiosis and is involved in the pathogenesis of nonalcoholic fatty liver disease (NAFLD). A subgroup of NAFLD patients have a severely progressive form, namely nonalcoholic steatohepatitis (NASH), which is characterized by histological findings that include inflammatory cell infiltration and fibrosis. NASH has a high risk of further progression to cirrhosis and hepato-cellular carcinoma. The oral microbiota may serve as an endogenous reservoir for gut microbiota, and transport of oral bacteria through the gastro-intestinal tract

can set up a gut microbiome dysbiosis. Gut dysbiosis increases the production of potential hepatotoxins, including lipopolysaccharide, ethanol, and other volatile organic compounds such as acetone, phenol and cyclopentane. Moreover, gut dysbiosis increases intestinal permeability by disrupting tight junctions in the intestinal wall, leading to enhanced translocation of these hepatotoxins and enteric bacteria into the liver through the portal circulation. In particular, many animal studies support that oral administration of *Porphyromonas gingivalis*, a typical periodontopathic bacterium, induces disturbances in glycolipid metabolism and inflammation in the liver with gut dysbiosis. NAFLD, also known as the hepatic phenotype of metabolic syndrome, is strongly associated with metabolic complications, such as obesity and diabetes. Periodontal disease also has a bidirectional relationship with metabolic syndrome, and both diseases may induce oral and gut microbiome dysbiosis with insulin resistance and systemic chronic inflammation cooperatively. In this review, we will describe the link between periodontal disease and NAFLD with a focus on basic, epidemiological, and clinical studies, and discuss potential mechanisms linking the two diseases and possible therapeutic approaches focused on the microbiome. In conclusion, it is presumed that the pathogenesis of NAFLD involves a complex crosstalk between periodontal disease, gut microbiota, and metabolic syndrome. Thus, the conventional periodontal treatment and novel microbiome-targeted therapies that include probiotics, prebiotics and bacteriocins would hold great promise for preventing the onset and progression of NAFLD and subsequent complications in patients with periodontal disease.

INTRODUCTION

Periodontal disease is an inflammatory disease that is induced by a structural and metabolic imbalance of the oral microbiome, namely an oral dysbiosis, and is characterized by significant periodontal tissue destruction and tooth loss[1-3]. Until recently, specific periodontopathic bacteria, such as the Red Complex, were thought to be the major pathogens of periodontal disease[4,5], but the success of novel methods focused on the studying the oral microbiome with next-generation sequencing approaches has revealed the possibility that a variety of previously unknown bacteria, fungi, and even viruses are associated with the periodontal disease[6-9].

Periodontal disease has also been reported to adversely affect the pathogenesis of various systemic diseases, including diabetes, coronary vascular disease, rheumatoid arthritis, and cancer[10,11]. As a major mechanism, it has been proposed that pro-inflammatory cytokines, periodontal pathogens, and their microbial components spread out from damaged periodontal tissues sites into the systemic circulation and thereby reach and affect other organ sites[1,12-14]. Another idea has also emerged in the last decade that there is enteric translocation following the development of gut dysbiosis that originates from oral bacteria, and this is another pathway linking periodontitis and systemic disease[11]. Many studies have shown that swallowed periodontopathic bacteria can pass through the gastric acid barrier and reach the gut, thereby shifting the gut microbiome to an unhealthy state[15-19]. In addition, even oral commensal bacteria that are not normally pathogenic may proliferate and become established in the

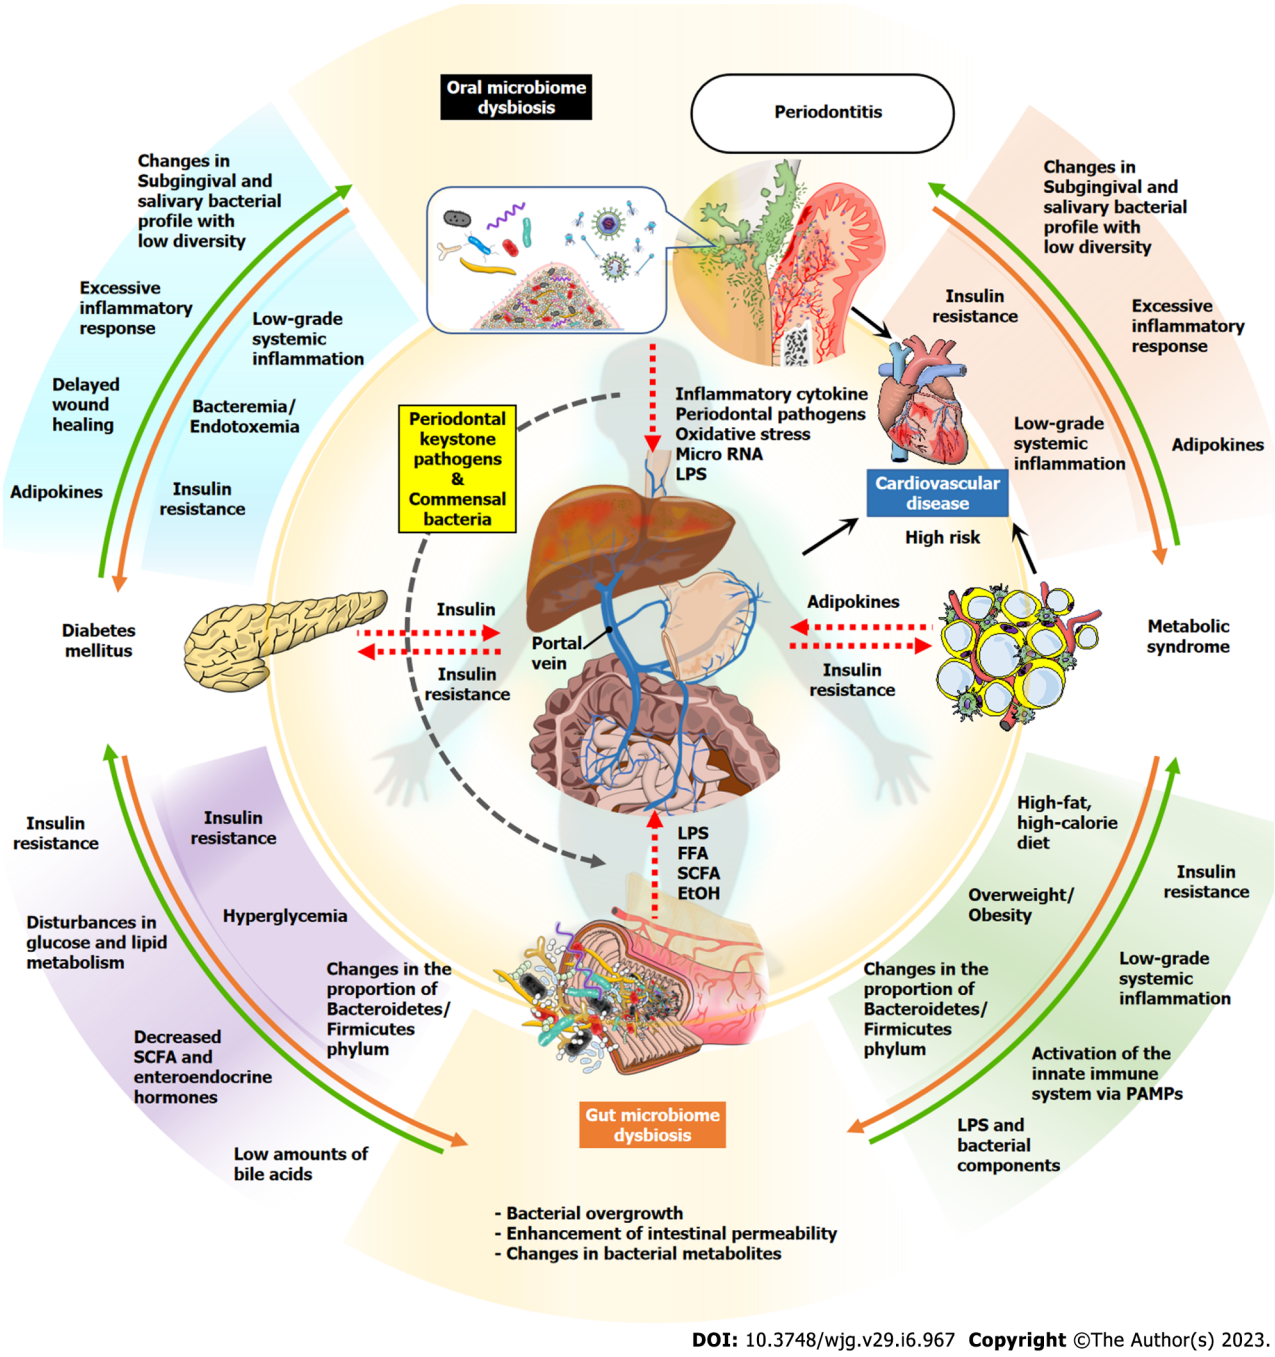
gut environment due to periodontal inflammation, and may even manifest pathogenic properties[20,21].

In the context of the association between periodontal disease and gut dysbiosis, nonalcoholic fatty liver disease (NAFLD) has received particular attention in recent years[11,22] (Figure 1). NAFLD is currently the most prevalent chronic liver disease worldwide, with a marked increase in individuals with metabolic syndrome[23], and it is defined as a fatty liver condition diagnosed upon histological observation or image analysis, but other liver diseases/conditions, such as a history of alcohol consumption, viral hepatitis, and drug-induced liver injury are excluded[24,25]. The majority of NAFLD patients (approximately 80%) have a good prognosis and simply have a fatty liver (NAFL), whereas the remaining 10%-20% have a severely progressive form, namely nonalcoholic steatohepatitis (NASH)[25]. In addition to lipid deposition, NASH is characterized by histological findings that include inflammatory cell infiltration, ballooning degeneration and fibrosis of hepatocytes, and a reported high risk of further progression to end-stage liver disease, such as cirrhosis and hepatocellular carcinoma[26,27]. NAFLD/NASH is considered a liver phenotype within various metabolic syndrome components and has a robust and bidirectional association with metabolic complications such as diabetes, obesity, and cardiovascular disease[28].

Several animal studies have demonstrated that periodontopathic bacteria, such as *Porphyromonas gingivalis* and *Aggregatibacter actinomycetemcomitans* cause increased insulin resistance and glucose intolerance through gut dysbiosis, as well as liver inflammation and fat deposition and fibrosis[29-33]. These relationships between periodontal bacteria and NAFLD are also supported by epidemiological studies[30,34-37], including cross-sectional and cohort studies, and further strengthened by clinical studies reporting that periodontal treatment improved NAFLD[36,38].

The liver is in a unique anatomic location and as such it has a dual blood supply. The liver gets blood from the systemic circulation and the gut, with the portal vein responsible for most of this blood supply, and it transports nutrients, bacterial metabolites, toxins, and drugs absorbed from the gut to liver[39,40]. In gut dysbiosis, abnormal growth and structural changes in intestinal bacteria result in an increase in hepatotoxic substances, such as endotoxin and ethanol, which reach the liver *via* the portal circulation [41-44]. In addition, increased intestinal permeability due to gut dysbiosis accelerates these hepatic exposures[45,46].

Thus, management of the oral and gut microbiome may be an important preventive strategy for patients with periodontal disease and NAFLD (Figure 2). In this regard, besides traditional therapies, the use of adjunctive therapies that include probiotics and prebiotics may be beneficial in normalizing dysbiotic microbiomes present in periodontal tissues, the liver, and the gut. This review will describe the link between periodontal disease and NAFLD with a focus on basic, epidemiological, and clinical studies. Potential mechanisms linking the two diseases and possible therapeutic approaches focused on the microbiome will also be discussed.



PERIODONTAL DISEASE AS A RISK FACTOR FOR SYSTEMIC DISEASES

Periodontitis, a chronic inflammatory disease is characterized by a microbial dysbiosis and a progressive destruction of the tooth supporting structures[47]. In the United States, Periodontitis affects 42.2% of the population over the age of 30 and 59.8% over the age of 65[48]. Periodontitis is the major cause of tooth loss in adults, according to data from the World Health Organization[49]. Periodontitis has a multifactorial pathogenesis that includes environmental, microbial, and host factors which affect disease outcomes. Several systemic diseases and conditions have been associated with periodontal disease, including cardiovascular disease, diabetes mellitus, and metabolic syndrome[11,50-54].

The impact of systemic diseases and disorders on the periodontal tissues is well known, and the evidence indicates that periodontal disease may significantly enhance the risk for certain systemic diseases or conditions or alter their natural course[55-60]. Many systemic conditions have been associated with periodontal diseases, although the level of evidence for each condition varies. Conditions for which the influence of periodontal disease is well documented include coronary heart disease and related events, diabetes mellitus, preterm and low-birth-weight delivery, and preeclampsia; and respiratory conditions, such as chronic obstructive pulmonary disease[55-57]. A smaller but growing evidence base supports an association between poor oral health, tooth loss, or periodontitis and conditions, such as chronic kidney disease and renal insufficiency[61-65]; certain forms of cancer[66-70] affecting the liver, pancreas, and colorectal region; rheumatoid arthritis[71,72] and altered cognitive function, dementia, and Alzheimer disease[22,55,73-77]. Here we will discuss the influence of periodontal disease in the context of diabetes and metabolic syndrome (Figure 1).

Diabetes

In terms of diabetes, a variety of studies have examined the effects of diabetes on the periodontal tissues, whereas others have examined the effect of periodontal disease on the control of diabetes[56]. A review of several studies including those with more than 22000 patients found that the incidence of type 2 diabetes (*i.e.*, new diagnoses) was significantly greater in individuals with periodontal disease than in those without periodontal disease[78]. Severe periodontal disease was associated with a significant

worsening of glycemic control over time in patients with type 2 diabetes[79]. Those with severe periodontitis at baseline had a greater incidence of worsening glycemic control over a 2- to 4-year period as compared with those without periodontitis at baseline. Furthermore, periodontitis was known to have preceded the worsening of glycemic control in this study. In addition, numerous systematic reviews and meta-analyses have consistently shown that periodontal therapy is associated with a significant and clinical improvement in glycemic control in patients with diabetes and periodontitis[80-82]. Furthermore, meta-analyses also indicate a higher prevalence and severity of periodontal disease in diabetic patients and vice versa[83,84].

Understanding the mechanisms that underlie other infections is helpful to understanding the mechanisms whereby periodontitis influences glycemic control. Systemic inflammation is well known to play a major role in insulin sensitivity and glucose dynamics. Periodontitis can trigger or sustain an elevated systemic chronic inflammatory state, as shown by increased levels of serum C-reactive protein (CRP), interleukin (IL)-6, and fibrinogen in individuals with periodontal disease[79,85,86]. Inflammation triggers insulin resistance, which often accompanies systemic infections. For example, acute viral and

bacterial infections can increase insulin resistance and aggravate glycemic control[87,88]. Systemic infections increase insulin resistance through several mechanisms. The insulin resistance, in turn, prevents glucose from entering target cells, causing elevated blood glucose levels. The elevated blood glucose then requires increased pancreatic insulin production to maintain normal glycemic levels. The insulin resistance can persist for weeks or months after the individual has recovered from the illness. Individuals with type 2 diabetes who already have significant insulin resistance, may experience additional tissue resistance to insulin as a result of infection, and thus exhibit an exacerbated poor glycemic control. In addition, studies suggest a relationship between the inflammatory status associated with diabetes or metabolic syndrome and the inflammatory status of periodontal disease[89,90]. Indeed chronic tissue inflammation has been recognized in the onset of metabolic diseases[91].

Chronic gram-negative periodontal infections may also lead to increased insulin resistance and poor glycemic control[92]. In individuals with periodontal disease, persistent systemic exposure to periodontopathic bacteria and their products results in an up-regulation of the immunoinflammatory response, with elevation in serum levels of proinflammatory mediators, such as IL-1β, tumor necrosis factor alpha (TNF-α), and IL-6, similar to well-recognized systemic infections, but on a more persistent, chronic basis. Increased serum levels of several cytokines, including TNF-α and IL-6, are associated with increased insulin resistance. These processes would help explain the worsening glycemic control associated with severe periodontal disease. Periodontal treatment, which is meant to decrease the bacterial insult and reduce inflammation, may lead to decreased systemic inflammation that may restore insulin sensitivity over time, and thereby result in improved metabolic control. This hypothesis would be supported by the many studies showings the improved glycemic control following periodontal therapy.

Much focus has been placed on the fact that chronic conditions can change the microbiome. As an example, individuals exhibiting obesity or type 2 diabetes demonstrate a modified gastrointestinal microbiome (reviewed by[93-96]). In addition, rodents exposed to *Enterobacter cloacae* B29, an intestinal microbe obtained from obese subjects with diabetes, develop insulin resistance and obesity[97]; indicating that bacteria can also directly induce diabetes-related symptoms. Also, modulating the microbial-mediated mucosal immunity and inflammation may help attenuate type 2 diabetes; by

mechanisms that include modulation of T lymphocytes[98,99]. Since there are associations between type 2 diabetes, periodontal disease, and changes in the gut microbiome of individuals with type 2 diabetes, additional focus has been placed on microbiome changes in the periodontal tissues of individuals with type 2 diabetes.

Studies have shown that type 2 diabetes alters the subgingival and salivary microbial profile by lowering richness and diversity[100-105]. These findings support the observations found in the gut microbiome[93-96,106]. Studies show that the subgingival microbiome diversity is not only decreased in individuals with type 2 diabetes, but when separated by adequate or inadequate glycemic control, there is a further decrease in the microbiome diversity in those with inadequate glycemic control (hemoglobin A1c 8)[107]. However, another study which assessed the microbiome present in the saliva of 17 subjects with periodontal disease and type 2 diabetes was not able to find a relationship between glycemic control and changes in the oral microbiota. Although, the study found that in individuals with type 2 diabetes, the microbial composition varied significantly between obese (body mass index = 30) and non-obese individuals with type 2 diabetes, such that obesity reduced the oral microbial diversity[108]. Furthermore, although the subgingival and supragingival microbial diversity decreases when subjects with type 2 diabetes are compared to normoglycemic individuals, the microbial shift is less in individuals with periodontal disease with type 2 diabetes subjects than in normoglycemic individuals [101,102,109].

In summary, the subgingival and salivary microbial profile is altered by type 2 diabetes by decreasing microbial diversity and richness (Figure 1). In terms of glycemic control, there is a further decrease in microbial diversity when there is inadequate glycemic control. Furthermore, the microbial shift observed in individuals with periodontal disease is less prominent in individuals with type 2 diabetes compared to normoglycemic controls. In addition, microbial diversity is further reduced in smokers. Additional research is needed to examine a potential two-way relationship between diabetes and the periodontal microbiome; namely that periodontal microbes may directly induce diabetes-related pathology, as data indicate that microbes derived from the gastrointestinal tract of obese patients with diabetes can themselves mediate symptoms related to diabetes in animal models.

Metabolic syndrome

We will next discuss the association between metabolic syndrome and periodontal disease. Metabolic syndrome is a characterized by constellation of conditions that elevate the risk for cardiovascular disease and double the risk for type 2 diabetes[110-113]. Approximately 34% of the US population[114] and 10% of US adolescents are affected by Metabolic syndrome[115]. Metabolic syndrome prevalence increases with age and varies with ethnicity and gender[116]. Metabolic syndrome is defined slightly differently by different agencies. That conveyed by the National Cholesterol Education Program Adult Treatment Panel III is the most frequently used definition; an individual has to exhibit at a minimum, three out of the five risk factors: (1) Low plasma levels of high density lipoprotein cholesterol; (2) Increased values for plasma triglycerides; (3) Increased abdominal circumference; (4) Elevated blood pressure; and (5) Elevated glucose levels[117]. Pre-diabetes is included in metabolic syndrome as it presents with insulin resistance and is highly predictive of new-onset type 2 diabetes[118].

Abdominal obesity and insulin resistance are primary risk factors for metabolic syndrome are. Physical inactivity, aging, and hormonal imbalance also contribute to metabolic syndrome[119]. A primary trigger and risk factor for the majority of mechanisms in metabolic syndrome is visceral adiposity[120]. Precise processes that underlie the systemic response seen in metabolic syndrome have not been well elucidated, but data highlight that the inflammatory response present this disease mediates endothelial dysfunction that may, in turn, promote type 2 diabetes and cardiovascular disease [121-123].

There has been a significant interest in the association between metabolic syndrome and periodontal disease, since both are characterized by insulin resistance and systemic inflammation[124,125]; common pathways whereby they could impact each other. Cross-sectional, longitudinal, and meta-analyses studies have evaluated the association between metabolic syndrome and periodontal disease. Most data indicates that there is an association between metabolic syndrome and periodontal disease[126-130]. Three meta-analyses, discussed here, found an association between periodontal disease and metabolic syndrome (odds ratio from 1.38 to 1.99)[131-133]. One meta-analysis[133] that discussed 39 studies showed an association between metabolic syndrome and periodontal disease [crude odds ratio of 1.99 (95%CI: 1.75-2.25) and an adjusted odds ratio of 1.46 (95%CI: 1.31-1.61)]. A subgroup analysis focused on different countries was also included in this study and the results showed a combined odds ratio of 1.75 (95%CI: 1.31-2.34) for the United States; 1.68 (95%CI: 1.41-2) for Japan; 1.81 (95%CI: 1.35-2.42) for Korea, and 2.29 (95%CI: 1.53-3.41) for China[133]. Another meta-analysis[131] of 26 manuscripts that included radiographic and clinical exam data reported an association between these two diseases [odds ratio of 1.38 (95%CI: 1.26-1.51)]. This suggested that patients with metabolic syndrome are 38% more likely to exhibit periodontal disease[131]. A systematic review/meta-analysis of multiple manuscripts that reported on 36,337 individuals, found a positive association between periodontal disease and metabolic syndrome [odds ratio of 1.71 (95%CI: 1.42-2.03)][132]. A comprehensive review further found a positive association between metabolic syndrome and periodontal disease[134]. Furthermore, various animal studies that employed different periodontal disease models demonstrated that rodents with

metabolic syndrome or obesity due to a high-fat diet, also exhibited exacerbated periodontal bone loss [135-139].

In terms of assessing metabolic syndrome's role in contributing to periodontal disease, two longitudinal studies found that metabolic syndrome increases the risk of periodontal disease development and progression[140,141]. Specifically, one study found that individuals with metabolic syndrome were 2.6 times more likely to develop periodontal disease. Furthermore, with increased attributes of metabolic syndrome, the periodontal disease exhibits a higher prevalence and a more extensive presentation[141,142]. Even though most studies found an association between periodontal disease and metabolic syndrome, some reports found a minimal association for these diseases[143-148]. However, most of the studies that found no association were either cross-sectional or shorter longitudinal studies (only one year), and one study was performed on a young cohort of subjects[147], that had low levels of both metabolic syndrome and periodontal disease. Furthermore, in longitudinal study of three years, researchers found that toothbrushing frequency was inversely related to the incidence of metabolic syndrome[149].

Most studies have concluded that periodontal disease may contribute to the development or exacerbation of metabolic syndrome[150-152]. In a cross-sectional study of 190 individuals, researchers found that periodontal disease and periodontal bone loss may contribute to the development of metabolic syndrome[150]. A four-year longitudinal study of 1023 adults found deeper periodontal pockets associated with a positive conversion of metabolic components (odds ratio 1.6; 95%CI: 1.1-2.2)[151]. Furthermore, another study reported that in individuals with metabolic syndrome a decrease in periodontal inflammation reduced C-reactive protein levels in those subjects[152].

There has been an increasing interest in the role of the microbiome in metabolic diseases and disturbances. Metabolic diseases change the gut microbiome (reviewed by[96]), and the oral microbiome varies significantly between individuals with a healthy periodontium and those with periodontal disease[153]. Furthermore, changes in the gastrointestinal microbiome are associated with metabolic syndrome and obesity[154]. Obesity affects the oral microbiome in the context of type 2 diabetes[108], plus it lowers the diversity of the microbiome within the distal gut[155,156]. Further, subjects with decreased microbial diversity exhibit significantly more insulin resistance, adiposity, and dyslipidemia in contrast to individuals with elevated microbial richness[156]. A study focused on 17 subjects with type 2 diabetes and with advanced periodontal disease found that the composition of the oral microbiome varied significantly between non-obese and obese (BMI = 30) subjects. Those findings suggested that obesity is related to a decreased oral microbial diversity[108]. Our research group also showed that the oral microbiome is altered in individuals with metabolic syndrome as compared to healthy individuals[157]. In addition, there are a growing number of studies suggesting potential links between the gut or oral microbiome and obesity[158-160].

In vitro and *in vivo* (animal) studies have shown how dyslipidemia (high-fat diet) compounds the effects of metabolic syndrome on periodontitis[135-139,161], and a variety of studies have assessed the role of impaired glucose in periodontal disease. A study on obese mice (metabolic syndrome model) inoculated with *P. gingivalis* and fed a high-fat diet that did not exhibit diabetes, revealed that these mice had 40% more alveolar bone loss and higher levels of *P. gingivalis* versus control mice[135]. Using the same model, another group of researchers found that the high-fat diet group exhibited metabolic syndrome, including dyslipidemia, obesity, hyperinsulinemia, and insulin-resistance. Further, the group with metabolic syndrome exhibited significantly higher osteoclast formation and alveolar bone loss. Similarly, our previous study showed that the ligature-induced periodontitis with *P. gingivalis* infection in rats fed a high-fat diet not only exacerbated the alveolar bone resorption, but also induced increase in levels of fasting blood glucose and liver damage markers, and systemic inflammation[138,139].

Moreover, lipopolysaccharide (LPS) induced-periodontitis exacerbated inflammatory cytokine expression (IL-6, monocyte chemoattractant protein-1, receptor activator of NF-kappaB ligand, and macrophage colony-stimulating factor), osteoclast formation, and alveolar bone loss[137]. Studies that used osteoblasts from obese mice showed a reduction in cell proliferation and an elevated osteoblast cell death following *P. gingivalis* treatment *vs* controls[162]. Furthermore, obese rodents with metabolic syndrome exhibited significant elevated levels of *A.actinomycetemcomitans*-LPS-induced alveolar bone loss versus the non-obese, non-metabolic syndrome animals. In addition, a cholesterol-lowering medication frequently given to patients with metabolic syndrome[163], attenuated alveolar bone loss in both groups, further supporting the role of dyslipidemia in periodontal inflammation[164]. In this regard, our research found that submucosal administration of radio-labeled *P. gingivalis* LPS to the palatal gingiva of high-fat diet-induced obese rats led to a significant accumulation of LPS in the liver and gingiva compared to other organs, including the spleen, kidney, and brain. Furthermore, the gingiva and fatty liver of obese rats demonstrated an increased level of *P. gingivalis* LPS and a prolonged accumulation time compared to mice fed a normal diet. In addition, a high-fat diet further delayed the metabolic clearance of *P. gingivalis* LPS from the gingiva and liver[165].

The role of lipids in periodontal disease was further explored using *in vitro studies*, and these studies showed that fatty acids augmented the LPS-mediated expression of markers involved in periodontal disease, for example IL1-a, IL1-b, C-X-C motif chemokine 10, cluster of differentiation (CD) 86, colony stimulating factor 2, monocyte chemoattractant protein-1, toll-like receptor 2, TNF-α, and CD14[137]. Further *in vitro* studies performed on macrophages demonstrated a significant increase in CD36, a major

fatty acid receptor, upon treatment with LPS plus palmitate in comparison to macrophages only treated with LPS or palmitate alone[161]. Periodontal disease and metabolic syndrome, independently and significantly increased the levels of CD36, and when metabolic syndrome and periodontal disease were present simultaneously, there was an additive effect. The expression of CD36 in periodontal tissues also positively correlated with osteoclast formation.

Taken in aggregate, human studies and animal models show an association between metabolic syndrome and periodontal disease, and metabolic syndrome can change the oral microbiome and potentiate the harmful effects of periodontal disease.

RELATIONSHIP BETWEEN PERIODONTAL DISEASE AND NAFLD

Periodontal disease has been associated with liver diseases, such as NAFLD, liver cirrhosis, and hepatocellular carcinoma, and even a possible worse prognosis for liver transplantation (Figure 1). The relationship between periodontitis and NAFLD is supported by a number of epidemiological studies[30,34-36,166-170]. Cross-sectional studies have also shown that the severity of periodontal disease correlates significantly with levels of blood liver injury markers [*e.g.* alanine aminotransferase (ALT), aspartate aminotransferase (AST), and gamma-glutamyl transpeptidase[171-173], hepatic imaging by ultrasound and computerized tomography, and a formula-based scoring system for estimating the degree of fatty liver and liver fibrosis[166,174,175]. Furthermore, several cohort studies have strengthened the causal relationship between periodontal disease and NAFLD. Akinkugbe *et al*[176] followed 2623 non-NAFLD subjects for more than 5 years (mean 7.7 years) in a health survey conducted in West Pomerania in Germany, and found that a history of periodontitis was an independent risk factor contributing to the development of NAFLD, which was diagnosed by abdominal ultrasonography and serum ALT levels. Compared to subjects without clinical attachment level (CAL) ≥ 3 mm, the incidence of NAFLD was significantly higher in patients with < 30% or ≥ 30% affected sites with CAL ≥ 3 mm. The adjusted incidence rate ratio for NAFLD was 1.28 for < 30% and 1.60 for ≥ 30% of affected sites with a statistically significant difference, respectively. Similarly, the incidence rate difference was statistically significant at 5.49 for < 30% of sites and 11.11 for ≥ 30% of sites. Helenius-Hietala *et al*[34] found in a 13-year cohort study of 6165 subjects participating in a Finnish population-based health study, the proportion of sites with deep periodontal pockets positively correlated with the hazard ratio for developing severe hepatic diseases. In addition, the hazard ratio was not correlated with periodontitis in those who were non-NAFLD at the study entry, whereas was 6.94 in those who were developed NAFLD with significant correlation. Based on systematic reviews and meta-analyses, this accumulating evidence highlights the potential for periodontal disease as a direct and indirect risk factor for the development and progression of NAFLD.

Periodontal disease has been reported to exacerbate metabolic diseases including diabetes, dyslipidemia and obesity through disturbance of energy homeostasis, and given the close association between NAFLD and metabolic syndrome, this underscores the importance of understanding the periodontal-metabolic relationship in the NAFLD pathogenesis. Two-thirds of patients with obesity and type 2 diabetes have been found to have fatty liver, and both excessive body mass index and visceral obesity are recognized as risk factors for NAFLD[177,178]. Metabolic syndrome is also related to an increased risk of more progressive liver disease, such as NASH, cirrhosis, and future liver failure, in patients with NAFLD[179-181]. A 5 year-follow up cohort study reported by Kuroe *et al*[182] demonstrated that in 341 Japanese subjects with NAFL without complications of liver fibrosis, stratified analysis by obesity showed that in obese subjects, severity of periodontal destruction was significantly correlated with liver fibrosis with an odds ratio of 2.87, whereas in non-obese subjects they were not correlated. Moreover, in metabolic diseases animal models induced by high-fat diet or high-cholesterol diet, the ligature-induced experimental periodontitis and periodontopathic bacterial infection exacerbated disturbances of glycolipid-metabolism in the liver and enhance the NAFLD progression[138,183,184]. Although not all mechanisms explaining the interaction between periodontal disease and NAFLD *via* metabolic diseases are known, diffusion of inflammatory mediators and periodontopathic bacteria and their components, and release of reactive oxygen species from inflamed periodontal tissues into the circulation can mediate low-glade systemic inflammation and, thereby exacerbate insulin resistance in obesity and diabetes [185].

Data over the last 10 years strongly suggest that *P. gingivalis* is involved in NAFLD and NASH. *P. gingivalis* has many virulence factors, such as collagenase, trypsin-like gingipain enzymes, LPS and fimbriae, that are also known to trigger intracellular signaling events[186]. Yoneda *et al*[36] analyzed various periodontopathic bacteria in saliva collected from non-NAFLD control subjects and NAFLD patients using polymerase chain reaction assays and showed that the detection frequency of *P. gingivalis* was significantly higher in the NAFLD patients. In addition, injection of *P. gingivalis via* the jugular vein dramatically accelerated NAFLD progression in mice fed a high fat diet. We have previously reported that *P. gingivalis* infection combined with ligature-induced periodontitis increased serum ALT and LPS levels and hepatic fat deposition in high-fat diet-induced obese rats with insulin resistance[138,139]. Conversely, hyperglycemia can promote translocation of *P. gingivalis* from the oral cavity to the liver

and reduce hepatic insulin-induced glycogen biosynthesis in mice[187]. For other periodontopathic bacteria, enteral infection with *Aggregatibacter actinomycetemcomitans* and *Prevotella intermedia* as well as *P.gingivalis* may contribute to NAFLD by altering the gut bacterial flora and metabolome in mice[30,32].

MECHANISMS BY WHICH PERIODONTAL DISEASE EXACERBATES NAFLD BASED ON THE ORAL-GUT-LIVER AXIS

At the present time, dual pathways have been proposed to explain the connection between periodontal disease and liver pathology, namely hematogenous and enteral diffusion of hepatotoxic components [11]. The liver is the largest parenchymal organ and, due to its unique anatomical location, it has a dual blood supply coming from the systemic circulation and the gastrointestinal tract[39], which helps explain how toxic factors diffuse from periodontal tissue and reach the liver. Eighty % of the total blood supply received by the liver is derived from the enteric portal vein, which is rich in nutrients, bacterial metabolites, and food antigens. The remaining 20% is supplied by the hepatic artery, which is the nutrient vessel of the liver and branches off the abdominal aorta. Thus, the liver is the hemodynamic confluence in the human body, and its unique characteristics allow for the maintenance of a diverse intrahepatic cell population composed of metabolically active hepatic parenchymal cells, connective tissue cells, and various immune cells[40].

One of the pathways linking the oral cavity and liver is thought to be hematogenous diffusion, which is caused by inflammatory mediators and microorganisms passing through the systemic circulation due to hyperpermeability of the pocket epithelium and micro-ulceration in the periodontal inflamed tissue [1,12]. For example, the serum levels of reactive oxygen species and inflammatory cytokines are elevated in periodontitis patients, suggesting a mild chronic inflammatory state systemically[188,189]. In fact, epidemiological studies have shown that Elevated blood level of CRP, which is secreted by hepatocytes upon stimulation of proinflammatory cytokines, are a common modifier of periodontitis and NAFLD [167,190]. With regard to microbiological invasion, mechanical injuries such as daily oral hygiene activities, chewing movements, and calculus removal as periodontal treatment have been reported to increase the frequency of bacteremia and endotoxemia in patients with periodontal disease compared to healthy subjects[191,192].

Another possible pathway linking the oral cavity to the liver is the transport of oral bacteria through the gastrointestinal tract, resulting in abnormalities in the gut microbiota[42,193,194]. Patients with periodontitis have a characteristic oral microbiome, and they continuously and unknowingly swallow pathogens present in saliva and dental plaque[19]. A part of oral bacteria can reach the intestinal tract, even in systemically healthy individuals and regardless of the harsh acidic environment in the stomach. Thus, the oral microbiome may function as an endogenous reservoir that supply novel bacteria to the gut microbiome[195]. It is widely known that gut dysbiosis is closely associated with the pathogenesis of NAFLD through changes in gut bacterial composition and metabolites[193,196,197]. In a state of gut dysbiosis, the production of choline which is an essential substance for lipolysis is decreased, whereas LPS, ethanol and volatile organic compounds (*e.g.* acetone, phenol and cyclopentane) are increased, which are potential hepatotoxin[41,42,44]. Moreover, the gut dysbiosis enhanced intestinal permeability by disrupting intercellular junctions in the intestinal mucosa, leading to increased translocation of enteric bacteria and their metabolites to the liver. Therefore, the liver is constantly exposed to various substances of intestinal derivation, which diffuse into the liver through the enterohepatic portal circulation.

A study by Lourenço *et al*[19] reported that numerous oral taxa related to periodontal inflammation and destruction were detected in the gut microbiome of individuals, regardless of periodontal condition. Patients with periodontal disease were characterized by a higher ratio of Firmicutes/Bacteroidetes, an enrichment in Euryarcheota, Verrucomicrobiota, and Proteobacteria, and a less diverse gut microbiota than those with healthy periodontal status. Kawamoto *et al*[16] found that fecal samples from patients with severe periodontitis were enriched in *Acidaminococcus, Clostridium, Lactobacillus, Bifidobacterium, Megasphaera*, and *Romboutsia*compared to those from healthy subjects. However, few studies have observed changes in the gut microbiota in patients with periodontal disease, and consistent trends in the gut dysbiosis remain unclear, with wide variations. In the future, it would be interesting to compare the modifications of the gut microbiota in the state of periodontal disease with those observed in NAFLD, diabetes, and obesity to elucidate the complex relationship between periodontal disease and systemic diseases.

Many animal studies have shown that orally administration of periodontal pathogens caused insulin resistance and hepatic fat deposition in rat and mice, accompanied by alterations in gut microbiota and glycolipid-metabolism[18,29-32]. In particular, *P. gingivalis,* known as a keystone pathogen, causes mucosal inflammation *via* contributing to oral and gut microbiome dysbiosis[29,198]. Yamazaki *et al*[32] showed that in an NAFLD mouse model fed a high-fat diet, oral administration of *P. gingivalis* or *P. intermedia* changed the composition of gut microbiota and blood metabolome, resulting in a shift in liver transcriptome expression toward the NAFLD pathogenic form. In contrast, application of commensal oral bacteria *Actinomyces naeslundii* and *Veillonella rogosae* did not affect NAFLD progression. Komazaki

et al[31] reported that oral infection with *A.actinomycetemcomitans* may contribute to NAFLD by altering the bacterial flora and glucose metabolism in mice. This result is also consistent with the fact that Anti-*A. actinomycetemcomitans* antibodies were positively correlated with visceral fat area, insulin resistance, and serum AST level in 52 Japanese NAFLD patients.

Recent studies have revealed that inflammation of periodontal tissue alters gut bacteria and metabolites even without specific periodontopathic bacterial infections[21,199,200]. Even commensal oral bacteria, which are not notably pathogenic in the oral cavity, such as *Enterobacter spp.* and *Klebsiella spp*. when stimulated to proliferate by ligature-induced periodontitis, can mediate ectopic intestinal colonization and may play an important role in the exacerbation of enteritis[21]. Therefore, future studies on the pathogenesis of NAFLD should not only focus on individual periodontal pathogens, but also comprehensively evaluate the relationship between changes in the oral and gut microbiota as a whole.

PERIODONTAL DISEASE FROM THE VIEWPOINT OF ORAL DYSBIOSIS

Polymicrobial diseases represent clinical and pathological conditions caused by 2 or more microorganisms[201]. The bacterial microbiome in the oral cavity is composed of more than 700 bacterial species [202] and is associated with the development and progression of oral diseases[203]. Periodontal diseases are representative oral polymicrobial diseases that involve a microbiome imbalance known as dysbiosis [204,205], leading to dysregulated host-microbial crosstalk that induces periodontal inflammation and alveolar bone loss[206]. The 2009–2010 and 2011–2012 cycles of the National Health and Nutrition Examination Survey reported that almost 50% of adults aged ≥ 30 years in the United States were affected by periodontitis[207]. In addition, periodontitis is associated with systemic diseases, such as type 2 diabetes, obesity, cardiovascular disease, preterm low birth weight, and NAFLD[30,208-212]. Therefore, a complete understanding of periodontal disease is essential to prevent a decline in quality of life.

The current theory suggests that gingival lesions are precursors of periodontitis[213]. Loe *et al*[214] demonstrated that the accumulation of bacterial plaque causes gingivitis in humans, and gingival inflammation is resolved by the removal of the plaque[235]. In addition, continued plaque accumulation in animal models induced gingivitis and gradually developed into periodontitis[215]. These results clearly indicate that bacterial plaque is involved in periodontitis. This belief was called the "nonspecific plaque hypothesis" which states that a sufficient accumulation of microorganisms results in destructive inflammation in periodontal tissues[216]. The contradiction between the nonspecific plaque hypothesis and actual clinical findings led scientists to propose the "specific plaque hypothesis". This hypothesis was that specific bacterial species were involved in the etiology of periodontitis[217]. However, potential periodontal pathogens could not be identified because approximately 30–100 bacterial species inhabit the periodontal pocket, and plenty of other bacterial species may have been unculturable[218].

Although culture methods have traditionally been useful for the identification of causative bacteria, DNA-based bacterial detection methods using molecular biology techniques have also contributed to the characterization of oral bacterial composition. Socransky *et al*[4] reported on findings relating to the specific plaque hypothesis where they targeted 40 subgingival bacterial species using the checkerboard DNA-DNA hybridization method. These bacteria were mainly divided into five groups: Red, orange, green, yellow, and purple complexes. *P. gingivalis*, *Tannerella forsythia*, and *Treponema denticola* were defined as periodontal pathogens and classified as the red complex because they exhibited a strong relationship with probing pocket depth and bleeding on probing. The orange complex was also associated with probing pocket depth and appeared to be closely related to the red complex. Red and orange complexes were detected more frequently in patients with periodontitis than in healthy subjects [219]. Periodontitis has been reported to be associated with many systemic diseases[220], especially diabetes caused by metabolic syndrome. The prevalence of periodontitis in diabetic subjects was higher than that in non-diabetic subjects[221]. In addition, poorly controlled diabetic subjects have more severe periodontitis[222]. In periodontitis sites, a higher quantity of *P. gingivalis* in poor controlled diabetic subjects was observed than that of non-diabetic subjects[223]. Haffajee *et al*[224] reported that a reduction in the red complex was observed at sites where periodontal treatment with scaling and root planning alone or with systemically administered azithromycin, metronidazole, or a sub-antimicrobial dose of doxycycline was performed. In another study, Duarte *et al*[225] also found a reduction in red and orange complexes after periodontal treatment. Therefore, members of the red complex are still considered periodontal pathogens; however, some inconsistency exists in this concept. Previous studies demonstrated that *Streptococcus mutans* and *Streptococcus salivarius*, which were not defined as periodontal pathogens in the complex-based classification, causing attachment loss of periodontal tissues in animal studies[226,227]. Another example of contradictory findings was that periodontal bacterial species in a complex-based classification were detected, but periodontitis was not observed [218].

Recently, high-throughput DNA sequencing technology using next-generation sequencing (NGS) methods has been used to comprehensively analyze bacterial composition in different environments

[228]. In addition, bioinformatic techniques and pipelines have been improved to analyze data obtained from NGS[229]. In particular, NGS technology is suitable for bacterial analysis because the 16S rRNA genes from bacteria critically define all bacterial species and have an approximate length of 1 kbp of nucleotide sequences that are highly conserved among bacterial species[230]. Therefore, NGS technology combined with bioinformatic techniques is a useful tool for scientists as it allows for a comprehensive evaluation of microbial composition within the microbiome. Griffen *et al*[231] compared the bacterial composition of subgingival plaque between patients with chronic periodontitis and periodontally healthy controls using 16S pyrosequencing. They reported that the proportion of red complex microbes was high at the periodontitis sites, but the microbiome included bacterial species that were not previously regarded as being involved in the etiology of periodontitis. This result showed that conventional methods, such as culture methods, real-time polymerase chain reaction, or checkerboard DNA-DNA hybridization, were limited by the number of bacteria that could be detected. However, current methods using NGS are not limited to the number of bacterial species that can be detected. A few studies using NGS with the 16S rRNA gene region suggested that several taxa, including *Filifactor alocis* and TM7, showed greater abundance in periodontitis and seemed to act as the core bacteria in the subgingival microbiome of disease in addition to the bacteria thought to be conventional periodontal pathogens[231,232]. In other words, these results suggest that bacteria other than conventional periodontal pathogens, such as red complex members, also contribute to periodontitis, and dysbiosis within the microbiome potentially induces periodontal inflammation.

Hajishengallis *et al*[241] proposed the "keystone-pathogen hypothesis," wherein a specific bacterial species is considered a keystone periodontal pathogen, such as *P. gingivalis,* which changes the microbial balance and induces inflammation through dysbiosis, despite the low abundance of the pathogen[19,233]. Several problems with DNA-based analyses alone have indicated that the 16S rDNA profile may include dead bacteria[234]. On the other hand, only viable bacteria can be analyzed by conducting experiments using 16S rRNA[235]. However, analysis of only 16S rRNA is not a reliable index for bacterial activity and may be misleading in some cases because the relationship between rRNA and growth rate differs significantly in subspecies, even if these bacteria belong to the same bacteria at the species level[236]. Therefore, the 16S rRNA/16S rDNA ratio has been useful as a bacterial activity index for detecting highly active bacterial species, which, despite the low abundance of the pathogen, can induce dysbiosis in certain environments[237,238]. Kachi *et al*[237] clarified that the activity of *P. gingivalis* was lower than that of other species in periodontitis sites, although *P. gingivalis* was abundant in both DNA and RNA. In contrast, *T. forsythia*, *Fusobacterium nucleatum* subsp. *Vincentii, Streptococcus oralis, T. denticola, F. alocis, and Streptococcus salivarius* showed high activity in periodontitis sites. By analyzing both DNA and RNA using the 16S rRNA region, it may be easier to detect keystone pathogens because this analysis can lead to the understanding of not only the abundance of each bacterium but also their activities. However, these analyses alone cannot reveal the functional composition of the microbiome. Tools such as Piphillin or Piecrust can predict the functional composition of the microbiome using the information of the 16S rRNA region[239,240]. Ikeda *et al*[241] reported that pathways for phenylpropanoid and GPI-anchor biosynthesis and metabolism of alanine, arginine, aspartate, butanoate, cyanoamino acid, fatty acid, glutamate, methane, proline, and vitamin B6 were significantly over-represented in periodontitis subjects compared with healthy subjects using Piphillin. Thus, we might understand the essence of polymicrobial disease by determining not only the composition of the microbiome but also the functional gene composition.

In terms of bacterial composition analysis, the 16S rRNA region is highly conserved among prokaryotes, such as bacteria and archaea, and the length of the 16S rRNA region is suitable to provide sufficient information for phylogenetic analysis[230]. However, the length of the 16S rRNA region is almost 1600 base pairs. Among bacteria, *Mycoplasma*, which is the smallest parasitic bacterium, has 580000 base pairs[242]. This also indicates that the 16S rRNA region alone is insufficient for a complete understanding of the microbiome. In addition, 16S rDNA and 16S rRNA sequencing has caused PCR bias[243] and the different results depend on primer type[244]. To compensate for these shortcomings, metagenomic and metatranscriptomic analyses, which decode all DNA and RNA information, have attracted attention. Both metagenomic and metatranscriptomic analyses can analyze bacterial and functional composition, but metagenomic analyses focus more on species-level profiling, metatranscriptomic analyses concentrate more on gene expression levels[245]. A report by Dabdoub *et al*[246], using metagenomic analysis, reported the microbial and functional differences between healthy and periodontal sites. *Porphyromonas, Fusobacterium, Fretibacterium, Filifactor, Parvimonas, Selenomonas, Treponema,* and *Kingella* were more abundant in periodontitis sites than in healthy sites. In addition, most functional genes in healthy sites were dedicated to energy utilization through oxidative pathways, while fermentation and methanogenesis were the predominant energy transfer mechanisms in the disease site[246]. A study using metatranscriptomic analysis reported that *T. forsythia* and *P. gingivalis* upregulated different TonB-dependent receptors, peptidases, proteases, aerotolerance genes, iron transport genes, hemolysins, and clustered regularly interspaced short palindromic repeats-associated genes in periodontitis sites. Interestingly, bacteria that have not been usually implicated in periodontitis, such as *S. oralis*, *S. mutans*, *S. intermedius*, *Streptococcus mitis*, *Veillonella parvula*, and *Pseudomonas fluorescens*, were highly active in transcribing putative virulence factors in periodontitis sites[247]. Another report using metatranscriptomic analysis revealed that bacteria, such as *Bacteroides massiliensis*

and Leptotrichia hofstadii had high transcriptional activity in addition to that of the red complex[8]. Furthermore, combining metagenomic and metatranscriptomic analyses help understand the activity or enrichment of a given gene set in the microbiome[245]. The combination of metagenomic and metatranscriptomic analyses by Duran-Pinedo *et al*[248] showed that *P. gingivalis, T. forsythia, and T. denticola* exhibited a higher mean abundance and gene expression in periodontitis sites than in healthy sites. However, *Bacteroidetes* oral taxon 274, *Corynebacterium matruchotii,* and *L. hofstadii* in periodontitis sites showed a decrease in relative abundance but represented a high proportion of gene expression, when comparing healthy and periodontitis sites. In addition, the vast majority of virulence factors upregulated in periodontitis sites originate from bacteria that are not considered major periodontal pathogens, such as *Neisseria flavescens*, *C. matruchotii, Rothia dentocariosa*. Komatsu *et al*[249] combined metagenomic and metatranscriptomic analyses with a network analysis for periodontitis. Their results showed that *Fusobacterium nucleatum* subsp. *vincentii* had the highest activity in periodontitis sites, followed by *Peptostreptococcus stomatis* and *Leptotrichia* sp. according to the RNA/DNA ratio which are similar to the 16S rRNA/16S rDNA ratio. Additionally, *Fretibacterium fastidious,* and *F. alocis*, *Eubacterium nodatum* had high activity and were core bacteria in a co-occurrence network of periodontitis sites. In addition, the virulence factors, such as translation initiation factor IF-1 and pillin subunit in metatranscriptomic data were more enriched than in metagenomic data, indicating these virulence factors have high activity in periodontitis sites. These results suggest that there are bacteria that are more active than the red complex in periodontitis sites, those bacteria are involved in the pathogenesis of periodontal disease, and bacterial activity and interaction with each other are changed in response to environmental changes.

Periodontitis is not an infectious disease caused by a single bacterium, such as diphtheria, tetanus, typhoid fever, and leprosy, but a dysbiotic disease caused by alterations in the abundance of keystone and/or accessory pathogens within the polymicrobial community, leading to inflammatory responses (Figure 1). In addition, dysbiotic microbiota further develops and stimulate inflammatory responses[6]. However, it is difficult to comprehensively understand the etiology of periodontitis, although exhaustive DNA and RNA analyses have been performed. There are several possible explanations for this reason. First, many microorganisms, including bacteria, unculturable bacteria, fungi, and viruses, are present in the oral cavity[250]. Second, the same bacteria can act as homeostatic commensals in one environment and accessory pathogens in another. Furthermore, some bacteria can act as keystone or accessory pathogens depending on their condition[6]. Recently, trans-omics has been attracting attention and has focused on connecting multi-omics data, including not only the genome and transcriptome, but also the proteome and metabolome[251]. Trans-omics has been shown to be effective in elucidating various complex mechanisms, such as insulin sensitivity in liver cells and muscle adaptation[252,253]. These techniques might be applied to unravel the full picture of periodontal disease as a polymicrobial disease.

CHARACTERISTICS OF GUT MICROBIOME IN PATIENTS WITH PERIODONTAL DISEASE

Periodontal disease is characterized by a complex relationship between the host inflammation and polymicrobial dysbiosis of the oral-dental biofilm. This leads to chronic inflammation of the periodontal tissue, ultimately leading to bone destruction and tooth loss. However, over the last several years, this dysbiosis of the oral microbiome has been also associated with multiple systemic inflammatory conditions, such as cardiovascular disease, obesity, metabolic syndrome, and rheumatoid arthritis[71,254,255]. As mentioned previously, there are two main prevailing hypotheses regarding the potential for localized chronic periodontal infection to cause systemic inflammation. Namely: (1) Periodontal dysbiosis and inflammation leads to increase bacterial translocation into the systemic circulation causing inflammatory mediators and immune complexes to be circulated to other organ systems[256,257], and (2) Chronic periodontal dysbiosis leads to disturbances and changes to the gut microbiome *via* oral ingestion of periodontopathic organisms.

The concept that the oral microbiome drives the gut microbiome space is highlighted by the fact that some of the first bacteria to colonize the gut come from the mouth[258]. Infants born from vaginal deliveries are exposed to the microbiome of the mother's vaginal tract and gastrointestinal tract during labor, while breastfeeding introduces the skin microbiome to the infant[258]. As the gut microbiome matures over time, new bacterial strains are introduced into the gut *via* the environment and foods that we are exposed to in our childhood and young adulthood.

Yet, the established gut microbiome of adults is not stagnant, but rather can be change drastically by the environment, food, and/or medications. The connection of the oral microbiome and periodontal inflammation causing changes in the gut microbiome is highlighted in several animal and human studies. In a study of 44 patients, which included 7 healthy controls, authors found that patients with either gingivitis (n = 14) or chronic periodontitis (n = 23) had lower gut bacterial diversity as compared to healthy controls[19]. Specifically, they saw that patients with chronic periodontitis had higher levels of *Firmicutes, Proteobacteria, Verrucomicrobia* and *Euryarchaeota* and lower levels of Bacteroidetes as compared to controls[19]. In patients with gingivitis, *Prevotella, Comamonadaceae* and *Lactobacillales* were

elevated and *Bacteroidales* was decreased as compared to healthy control[19]. Utilizing a random forest classifier, *Mogibacteriaceae, Ruminococcaceae,* and *Prevotella* were able to discriminate individuals with periodontal diseases from healthy controls with an accuracy of 84%. Because of the cross-sectional design of this study, causality could not be inferred. However, several animal models have shown that the oral administration of *P. gingivalis* into mice leads to significant alteration of the gut microbiome, increase in serum endotoxemia, and a reduction of gut barrier function[20,32]. The oral administration of *P. gingivalis* in mice led to increases in *Bacteroidetes* and a reduction of *Firmicutes*[29,31]. These results in mice were recently mirrored in a translational study in humans. Bao *et al*[18] took salivary and fecal samples from 16 healthy participants and 21 patients with severe periodontitis and transplanted their salivary microbiome into wildtype C57BL6 mice. The authors showed that patients with severe periodontitis had a significantly different gut microbiome than those of healthy controls, with more saliva-sourced microbiome found in the gut of patients with severe periodontitis as compared to controls[18]. When transplanted into mice, the authors showed that by using utilizing carboxyfluorescein diacetate succinimidyl ester-stained bacteria the salivary microbiota persist in the gut for at least 24 h[18]. They also showed that the salivary microbiome of patients with severe periodontitis when transplanted into mice lead to an increase in gut levels of *Porphyromonadaceae* and *Fusobacterium*, while at the same time leading to a decreased expression of gut epithelial tight junction proteins and increased levels of pro-inflammatory cytokines. These findings alongside our prior works[11,22], demonstrate the important role of the oral-gut axis in other systemic diseases.

RELATIONSHIP BETWEEN GUT DYSBIOSIS AND NAFLD

Because of the interplay between the gut microbiome and inflammation, many studies have examined the role of the gut microbiome in liver disease. As part of this review, we will only focus on the relationship between the gut microbiome and NAFLD. The term NAFLD encompasses a spectrum of diseases that range from bland steatosis or NAFL to NASH and advanced hepatic fibrosis or cirrhosis. Several studies have linked gut dysbiosis to each phase of NAFLD.

NAFL

There have been several studies linking the gut microbiome to NAFL with variable results. In adult patients with NAFL, the most common genera that have been elevated were *Lactobacillus* and *Escherichia,* and *Coprococcus* and *Prevotella* were the most common to be reduced as compared to weight matched controls[259-262]. While these studies looked only at composition, several others examined NAFL utilizing a multiomics approach, which combined sequencing data with metabolomics. Raman *et al*[43] have shown that 18 stool metabolites, including increased levels of acetic acid, butanoic acid, and propanoic acid, are associated with NAFL in adult patients. Da Silva *et al*[261] also found a characteristic enrichment of isobutyric acid and propionic acid in the feces of NAFL patients. However, one of the most convincing data that has shown the causative relationship between the gut microbiome and NAFL comes from the translational study performed by Hoyles *et al*[262]. Utilizing hepatic transcriptome, gut metagenome, and serum and urine metabolome, they saw NAFL was associated with an increased serum level of several branched-chain and aromatic compounds, including phenylacetic acid[262]. In addition, administration of phenylacetic acid into mice transplanted with human fecal microbiota caused hepatic steatosis[262].

NASH

While studies examining the profile of NAFL were slightly mixed based on the population being investigated, studies examining the profile of NASH to obese controls showed more consistent findings[263]. In adults, NASH patients had lower levels of *Faecalibacterium, Ruminococcus and Bifidobacterium*[261,264] and a higher level of *Lactobacillus*[265]. Few studies have examined the metabolomics of NASH patients separate from NAFL, likely due to the reason that a diagnosis of NASH requires a liver biopsy to confirm. However, in one study of 16 adults diagnosed with NASH by biopsy, NASH patients had an increased ratio of primary to secondary bile acids which correlated with increase hepatic injury and inflammation[266].

NAFLD-related Advanced Fibrosis.

Advanced fibrosis is defined as a fibrosis stage of 3 or more and is associated with higher risk for morbidity and mortality. In general, microbiome studies of NAFLD-related advanced fibrosis usually see a decrease in microbial diversity marked by an increase in gram-negative bacteria[267-270]. Studies have found that NAFLD-related fibrosis was associated with an increase level of *Bacteroides* and *Escherichia*[267-269] with mixed results with other genera like *Prevotella*[268,270,271]. Metabolite studies found that 3-phenylproanoate[270] and 3-(4-hydroxyphenyl) lactate[272] were associated with NAFLD-related advanced fibrosis. 3-(4-hydroxyphenyl) lactate was also strongly correlated with several bacterial species that were also associated with hepatic fibrosis, such as *Escherichia coli*, *Bacteroides caccae* and *Clostridium sp*[272].

The mechanisms by which the gut microbiome can cause steatosis, inflammation, and hepatic fibrosis is highlighted in animal models. Patients with NAFLD and obesity are associated with a microbiome that leads to decreased gut epithelial barrier function[273]. This disruption in the gut epithelium leads to increased bacterial translocation, higher levels of endotoxemia, and subsequent increased activation of toll-like receptor signaling[274,275]. However, a clinical trial utilizing toll-like receptor inhibitor did not show any benefit in patients with NASH[276]. Other mechanisms, include alterations of short-chain fatty acids[277] and bile acid metabolism[278] and signaling[279].

PERIODONTAL APPROACHES IN THE PREVENTION AND TREATMENT OF NAFLD

Management of oral microbiota with conventional periodontal treatment

Periodontal treatment is based on the mechanical and chemical removal of dental plaque and pathogenic factors from the root surfaces by the patient or by a specialist to eliminate inflammation in the periodontal tissues and promote wound healing in the host. It is known that patients who achieve good oral hygiene and a healthy morphology of periodontal tissues through periodontal treatment show a decrease in the total number of bacteria and the proportion of periodontal pathogens in saliva and plaque, as well as a change in the composition of the oral microbiota to a healthy state. Therefore, given the relationship between periodontal disease and NAFLD supported by many epidemiological studies, periodontal therapeutic interventions may be a preventive measure for NAFLD (Figure 2).

In a cross-sectional study of 6352 adults participating in the Korean National Health and Nutrition Examination Survey, Kim *et al*[280] reported that there was an inverse association between frequency of tooth brushing and NAFLD prevalence (fatty liver index ≥ 60), with a modified odds ratio of 0.56 for NAFLD in the group that brushed three or more times a day compared with the group that brushed once a day or less. A few intervention studies have examined the effect of periodontal treatment on NAFLD. Yoneda *et al*[36] reported that in a single-arm intervention study, non-surgical periodontal therapy, including oral hygiene instruction and scaling/root planing (SRP) to 10 patients with NAFLD who had 4 or more sites with periodontal pockets ≥ 5 mm led to a significant improvement in AST and ALT at 3 mo after treatment. Interestingly, a recent multicenter randomized controlled trial by Kamata *et al*[38,281] demonstrated the efficacy of periodontal therapy for patients with NAFLD and periodontal disease. The control group (n = 20) received oral hygiene instruction only, while the experimental group (n = 20) received oral hygiene instruction and SRP. Serum levels of ALT and anti-*P. gingivalis* immunoglobulin antibody titers at 12 and 60 wk after treatment were measured as primary endpoints. Results showed significant reductions in ALT levels, endotoxin levels, and liver fat content in the SRP group compared to the toothpaste group. In addition, the decrease in *P. gingivalis* immunoglobulin G (IgG) antibody titer was significantly higher in the SRP group than in the toothpaste group. These decreased ALT levels and *P. gingivalis* IgG-antibody titers in the SRP group were sustained until 60 wk from baseline. The SRP group showed significantly greater reductions in blood lipid parameters, including total cholesterol, low density lipoprotein cholesterol, and triglycerides at 12 wk post-treatment, while no significant changes in glycometabolism parameters such as glucose and insulin.

Several studies presented in this section support the potential effect of periodontal treatment in improving outcomes in NAFLD. They also strengthen the causal relationship between periodontal disease and NAFLD. However, only one high-quality randomized controlled trial has been reported to date to assess treatment efficacy, and the relationship between the two is not clear. In the future, more evidence will need to be accumulated, and these controlled trials will need to be systematically meta-analyzed.

Oral and gut microbiome-targeted therapy using probiotics, prebiotics and bacteriocins

If opportunistic pathogens and periodontopathic bacteria that predominate in oral microbiome changes cause subsequent gut microbiome dysbiosis, an approach of microbiome-targeted therapy with antibiotics, probiotics and prebiotics may help prevent the onset and progression of NAFLD for patients with periodontal disease[11,22] (Figure 2). Probiotics are defined as live cultured microorganisms that provide health benefits in humans and animals when consumed, generally by improving or restoring the gut microbiota. While, prebiotics are defined as compounds in food that induce the growth or activity of beneficial microorganisms such as bacteria and fungi by altering the composition of organisms in the gut microbiome. When probiotics and prebiotics are used in combination, this is referred to as symbiotics. On the other hand, antibiotics exert beneficial effects on metabolic disorders by non-specifically suppressing the microbiome but may be accompanied by harmful side effects and potential emergence of antibiotic-resistant bacterial strains. Thus, currently, supplementation with probiotics and prebiotics in the treatment of NAFLD and periodontal disease has been favorably accepted due to a potential improved safety for humans and the environment[282-284].

As for treatment of NAFLD, multi-strain probiotic VSL#3 (contains eight species of *Streptococcus thermophilus*,*Bifidobacteria* [*B. breve*, *B. infantis*, *B. longum*], *Lactobacillus acidophilus*, *L. plantarum*,*L. paracasei* ,*L. bulgaricus*) was originally developed to treat inflammatory bowel disease, but VSL#3 administration has also been reported to improve fatty liver and fibrosis for NAFLD[285-287]. A randomized controlled

trial by Eslamparast *et al*[288] in patients with NAFLD showed that compared to the placebo group, a symbiotic consisting of a probiotic cocktail similar to VSL#3 and fructo-oligosaccharides given twice daily for 28 wk significantly improved liver function, inflammation, and fibrosis grade. Furthermore, a systematic meta-analysis of 21 randomized clinical trial concluded that the consumption of probiotics or symbiotics in NAFLD patients is an effective treatment modality to improve liver function, liver hardness, and blood markers of liver damage[282].

The effect of probiotics on periodontal treatment have also been reported to have several benefits in animal and clinical studies[289]. In studies using probiotics as monotherapy or as adjunctive therapy, *Lactobacillus salivarius* WB21, *L. plantarum, L. reuteri*, *L. rhamnosus* SP1, *Bacillus lactis*, and various *Streptococci* showed some efficacy in suppressing periodontopathic bacteria or other anaerobic bacteria. In particular, some *Lactobacillus* spp. have been noted to play a protective role against both NAFLD and periodontal disease[290-292]. Despite limited, beneficial effects were also observed in improving clinical parameters of periodontal disease, such as plaque score, gingival inflammation, and host immune response factors.

In recent years, our research team has reported multiple times that the use of nisin, an antimicrobial peptide produced by *Lactococcus lactis*, is effective in treating periodontal disease[289,293-296]. Nisin is a type of bacteriocin that is widely used in the food industry as well as in the medical field because of its potent and broad-spectrum antimicrobial activity even in small amounts, despite its low cytotoxicity and low incidence of bacterial resistance[297-299]. Nisin is classified as a Class I bacteriocin, and is a lantibiotic (lanthionine-containing antibiotics) based on its chemical structure, because it has abnormal amino acids that are caused by translational modifications[300-302]. With regard to the mechanism of action as an antimicrobial substance, nisin attaches to lipid II present in the bacterial cell membrane, and eight molecules of nisin form a tunnel-like pore with four molecules of lipid II, thereby promoting the outflow of intracellular ions, adenosine triphosphate and other substances from the bacteria[303-306]. The production of bacteriocins, such as nisin, is strictly regulated by bacterial signaling *via* quorum sensing, which works together with the self-tolerance capacity of bacteriocin-producing bacteria to selectively control the bacterial flora[307].

Interestingly, we found that in artificial oral biofilms derived from saliva, administration of the nisin-producing probiotic *L. lactis* or nisin significantly inhibited the biofilm formation and bacterial viability, reducing periodontal pathogens while maintaining endogenous oral bacteria such as *Neisseria* spp[294]. Similarly, wild type *L. lactis* or nisin dose-dependently reduced the viability of artificial biofilms formed on titanium alloy discs mimicking peri-implantitis and shifted the composition, relative abundance, and diversity level of the biofilms toward a healthy state with improved proportions of *Proteobacteria* and *Firmicutes* phylum[295]. Furthermore, in a polymicrobial mouse model of periodontal disease infected with multiple periodontopathic bacteria, we have shown that oral administration of nisin-producing *L. lactis* or nisin suppressed periodontal inflammation and alveolar bone loss[293]. These microbial treatments improved oral dysbiosis and decreased serum antibody responses to periodontal pathogens. On the other hand, non-nisin-producing *L. lactis* also reduced the oral and systemic impacts of the periodontal polymicrobial infection, but its effects were not as pronounced as those of nisin-producing *L. lactis*. Surprisingly, nisin and the *L. lactis* probiotic also induced a reparative phenotype *in vivo* in this polymicrobial disease model of periodontal disease. These results suggest that the combined interaction of living bacteria and their bacteriocins is important for probiotic use to be effective.

However, the significance of microbiome-targeted therapy in the treatment of periodontal disease-related NAFLD has been studied to a limited degree. In this regard, we are currently exploring the prophylactic effects of nisin on periodontitis-induced gut dysbiosis and liver disease using the polymicrobial infection mouse model. Detailed analysis of NAFLD-related genes and glycolipid metabolism in the liver is still ongoing in our lab, but we found that nisin shifts the oral and gut microbial composition to a healthy state and mitigates inflammatory responses. Nisin may also prevent hepatic lipid deposition by regulating mitochondrial functions and oxidative stress production in liver tissue.

Few studies have evaluated the effects of *L. lactis* probiotics or nisin in NAFLD, but some evidence based on *in vivo* experiments has been reported[308-310]. Lee *et al*[309] (2020) showed that oral administration of *L. lactis* NZ3900 strain pre-stimulated with nisin significantly protected fatty liver formation and progression of early atherosclerosis in a rabbit model fed a high cholesterol diet. In a study by Naudin *et al*[310] (2020) using mice fed a high calorie Western diet, compared to control mice taking the beneficial bacterium *Lactobacillus rhamnosus* GGL, oral administration of *L. lactis* subsp cremoris improved glucose tolerance and reduced serum cholesterol levels, weight gain, and obesity, resulting in less hepatic lipid deposition and inflammation. Jena *et al*[308] also reported that *Lactococcus* plays a protective role against liver inflammation in mice whose intestinal environment has been compromised by a Western diet. Although human studies on this topic are very limited, Ansari *et al*[311] showed that a fermented herbal formula containing *L. lactis* effectively improved serum liver function markers and liver fat deposition.

In summary, the use of probiotics, prebiotics, and bacteriocins may be a potential therapeutic strategy for patients with periodontal disease and NAFLD. These microbiome-targeted therapies have been shown to be safe for human health and easy to use on a daily basis in an environmentally friendly manner, so they may be applied alone or in combination with periodontal therapy. The fact that adjuvant therapy with probiotics in periodontal treatment has already been applied clinically will also

support the practical application of this new strategy. However, the development of microbiome-targeted therapies for NAFLD is in its infancy and further elucidation is warranted regarding the effectiveness of microbiome-targeted therapies on host immunomodulatory mechanisms, efficient intestinal delivery methods, effective combinations of various probiotics and bacteriocins, and methods for long-term maintenance of microbial composition and functional changes.

CONCLUSION

A growing body of evidence from multiple areas proposes that periodontal disease, accompanied by oral inflammation and pathological changes in the oral microbiome, induces gut dysbiosis and is involved in the pathogenesis of NAFLD[11,22] (Figure 1). The emerging concept of periodontitis-associated oral dysbiosis strongly implicates the role of the oral-gut-liver axis in the pathogenesis of NAFLD, based on the close relationship between the gut and liver connected by the enterohepatic circulation. This is due to the advancement of innovative technologies that enable comprehensive exploration of the microbiota through the widespread use of next-generation sequencing, which has fundamentally changed the definition of periodontopathic bacteria that has persisted in periodontology, and now highlights a turning point in rethinking the relationship between periodontal disease and systemic disease.

The liver is not merely a passive organ; NAFLD itself enhances insulin resistance and increases the risk of diabetes, atherosclerosis, and myocardial infarction with exacerbation of metabolic syndrome [312-314]. This means that even if NAFLD does not lead to end-stage liver disease, such as cirrhosis or cancer in individuals with metabolic syndrome, it can promote extrahepatic complications that can lead to significant mortality-related disease. Thus, both periodontal disease and NAFLD are interrelated with various elements of metabolic syndrome, leading to a vicious cycle of systemic inflammation and metabolic disturbance through amplification of these disease triangles[315]. Furthermore, in recent years, the liver from patients with NAFLD, as in the elderly and post-cardiac arrest donors, is a marginal organ that increases the risk of poor prognosis after liver resection or liver transplantation, the main treatment modalities for liver disease[316,317]. The detailed pathomechanisms of hepatic ischemia-reperfusion injury and post-transplant rejection in these operations are not known, but periodontal disease may be a potential risk factor for these hepatotoxic events as well[316,318-320].

Thus, oral and gut microbiome-targeted therapy based on management of periodontal infections would hold great promise for preventing the onset and progression of NAFLD and subsequent complications (Figure 2). Studies suggesting the efficacy of conventional periodontal treatment and microbiome-targeted therapy in patients with periodontal disease and NAFLD are increasing each year, but these are still in their infancy. Most reports of the relationship between periodontal disease and gut microbiome are based on data from animal studies, and a few studies have been conducted in humans. However, given the high prevalence of periodontal disease in recent years and the global increase in NAFLD, this new approach appears to be of great clinical and public health importance. In the future, long-term, large sample size cohort studies and randomized controlled trials should be conducted on this topic, in addition to further accumulation of rigorously controlled basic research.

Abstract

Compelling shreds of evidence derived from both clinical and experimental research have demonstrated the crucial contribution of receptor for advanced glycation end products (RAGE) axis activation in the development of neoplasms, including gastric cancer (GC). This new actor in tumor biology plays an important role in the onset of a crucial and long-lasting inflammatory milieu, not only by supporting phenotypic changes favoring growth and dissemination of tumor cells, but also by functioning as a pattern-recognition receptor in the inflammatory response to *Helicobacter pylori* infection. In the present review, we aim to highlight how the overexpression and activation of the RAGE axis contributes to the proliferation and survival of GC cells as and their acquisition of more invasive phenotypes that promote dissemination and metastasis. Finally, the contribution of some single nucleotide polymorphisms in the RAGE gene as susceptibility or poor prognosis factors is also discussed.

Key Words: Gastric cancer; Advanced glycation end-products; Receptor of advanced glycation end-products; Alarmins; *Helicobacter pylori*; Chronic inflammation

Core Tip: During the last two decades, new evidence supported by basic and clinical research has supported the role of the receptor for advanced glycation end products (RAGE) axis as a crucial actor in gastric carcinogenesis. We herein discuss how RAGE overexpression and RAGE activation-mediated signaling mechanisms are the main contributions of the RAGE axis to tumor development, migration, and metastasis in gastric cancer.

INTRODUCTION

Gastric cancer (GC) is the fifth most common cancer and the fourth leading cause of cancer death worldwide[1]. It remains one of the most lethal neoplasms, with a 5-year survival rate of around 20%[2].

Although GC incidence and mortality rates have declined worldwide during the last decades, it still remains a very important clinical and public health issue. Important research efforts have shed new light not only on the main associated risk factors for development of GC, but also to the identification of crucial mechanistic contributors to gastric carcinogenesis[3-7]. Among these newly defined contributors to tumor growth and development of many cancer types, the receptor for advanced glycation end products (RAGE) multiligand axis has gained the attention of many research groups due to the diversity of mechanistic contributions to cancer growth and development supported by the complex signaling of the axis[5,8-11].

This review primarily highlights how the RAGE axis is involved in gastric carcinogenesis, focusing on its early contribution to the onset of a chronic inflammatory condition at the gastric epithelium and its role in tumor growth and development.

EPIDEMIOLOGY OF GC

A stated above, GC is the fourth most common cancer and the fourth leading cause of cancer death worldwide[1], despite the improvement of public health policies throughout the world to decrease the incidence and mortality rates from GC[12,13]. International reports have shown that the annual number of new GC cases is estimated to increase by 62% by 2024, especially in geographic areas of high-burden disease such as Asia, Eastern Europe, and South America[14]. The main risk factor for GC is infection by the bacterium *Helicobacter pylori* (*H. pylori*), due to this microorganism's ability to induce chronic inflammation in the gastric mucosa, atrophy of gastric glands, gastric intestinal metaplasia (IM), and carcinogenesis[14,15]. *H. pylori* infection is associated with 60%-80% of GC cases, as evidenced by extensive cohort studies of high-risk populations[16,17].

It is estimated that *H. pylori* infection is currently present in more than half of the world's population (4.4 billion people)[18]. Strikingly, only a small fraction of these *H. pylori*-infected individuals develop GC, with incidence ranging from 2% to 5%[19], strongly suggesting that GC development cannot only be explained by *H. pylori* infection. Accordingly, we must consider the role of different contributors to the sustained chronic inflammation observed in *H. pylori*-induced gastric carcinogenesis[5,20].

INFLAMMATION AND GC

In the 19th century, Rudolf Virchow outlined the putative connection between inflammation and cancer [21]. At present, there is compelling evidence supporting the role of chronic inflammation in organ-specific carcinogenesis, as is observed with *H. pylori*-induced gastric inflammation and the development of GC, gastric mucosa lymphoma[22], prostatitis and prostate cancer[23], chronic cholecystitis and gallbladder carcinoma[24], acid reflux–induced esophageal adenocarcinoma[25], and hepatocellular neoplasms associated with chronic viral hepatitis[26].

These data have increased our understanding of how chronic inflammation can promote not only the initiation of malignant transformation, but also the sculpting of the tumor microenvironment, and its transformation into a tumor-supportive niche. Through these mechanisms, inflammation can promote proliferation and survival of malignant cells, cancer cell acquisition of invasive phenotypes, dysregulation of the antitumoral immune response, and cancer cell resistance to chemotherapeutic agents[27,28]. The International Agency for Research on Cancer has recognized the bacterium *H. pylori* as a class 1

carcinogen[29]. In addition, recent evidence supports *H. pylori's* causal role in the majority of cases of cardia- and non-cardia GC[17].

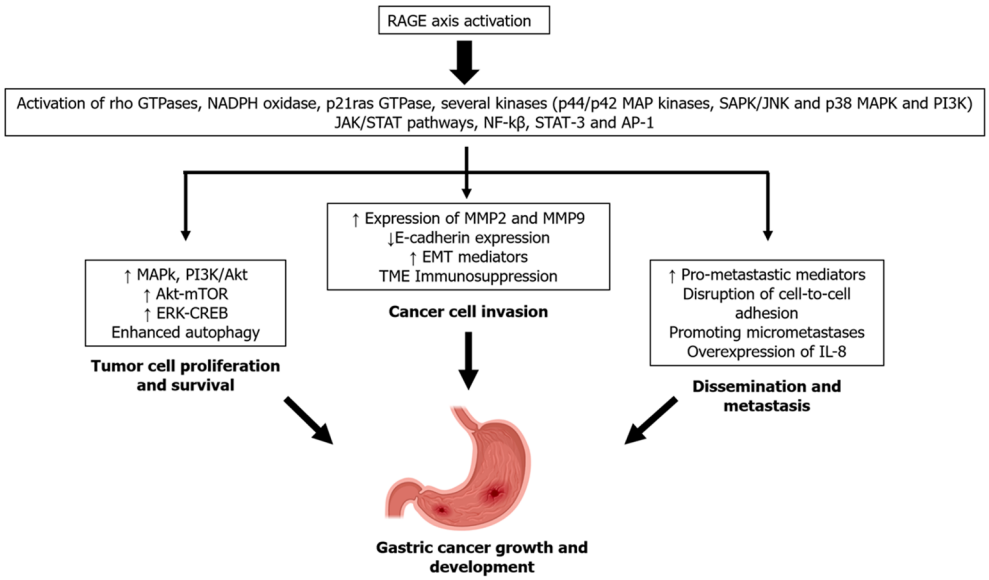
The persistent inflammation caused by chronic *H. pylori* infection in the gastric mucosal epithelium is a critical initiating factor in the multistep processes of gastric carcinogenesis, also known as Correa's cascade: (1) Chronic inflammation; (2) atrophic gastritis; (3) metaplasia; (4); dysplasia; and (5) adenocarcinoma[16].

H. PYLORI-MEDIATED INFLAMMATION

H. pylori infection incites an inflammatory reaction through myriad mechanisms in gastric epithelial cells and circulating immune cells recruited to the site of infection. Inflammation can be triggered by classical pathogenicity factors such as CagA, cagPAI, urease, and outer membrane proteins, which all play roles in nuclear factor-kappa B (NF-κB) activation[30]. Outer membrane adhesion proteins such as OipA and BabA are involved in the induction of cytokines such as tumor necrosis factor (TNF)-α, interleukin (IL)-1β, IL-6, and IL-8. CagA can also induce a marked IL-8 production, which is crucial to the recruitment of inflammatory cells and reactive oxygen species (ROS) production. Additionally, the contribution of *H. pylori* to an inflammatory milieu is supported by its induction of cyclooxygenase 2 (COX-2) and inducible nitric oxide synthase transcription, which lead to enhanced production of inflammatory mediators prostaglandin E2 and nitric oxide, respectively[31-33].

However, the earliest activation of proinflammatory pathways is associated with the sensing capacity of the innate immune response *via* pattern recognition receptors (PRRs), which can recognize evolutionarily-conserved structures found on pathogens, termed pathogen-associated molecular patterns (PAMPs)[34]. Of note, PRRs can also recognize many structures known as alarmins, or damage-associated molecular patterns (DAMPs), which are associated with cellular necrosis in the setting of noxious stimuli such as inflammation[35]. PRRs play a pivotal role in the inflammatory response to *H. pylori* infection by recognizing both PAMPs and DAMPs. A compelling body of evidence supports the relevance of several PRRs in the immune response to *H. pylori*, including Toll-like receptors, NOD-like receptors, RIG-I-like receptors, C-type lectin receptors, and more recently the RAGE[36,37].

THE RAGE AXIS



RAGE was initially recognized due to its ability to bind advanced glycation end products (AGEs). AGEs are a wide and diverse group of molecules derived *via* structural modifications of proteins, lipids, and nucleic acids, which all become non-enzymatically glycated by reducing sugars[38].

RAGE is a member of the immunoglobulin (Ig) superfamily. The human RAGE gene is located on chromosome 6p21.3, in the class II/III junction of the major histocompatibility complex locus and lies adjacent to the homeobox gene *HOX12*. The mature RAGE protein is 404 amino acids long with three major regions: an extracellular segment, a transmembrane segment, and an intracellular segment. The extracellular segment of RAGE is responsible for its ligand binding capacity and has three Ig domains, termed V-type, C1-type, and C2-type[39-42].

The integrated structural unit of the V and C1 domains is primarily responsible for interactions with a diverse group of negatively-charged RAGE ligands, including S100/calgranulins, AGEs, high mobility group box 1 (HMGB1) proteins, and Aβ-proteins[43]. The intracellular region of RAGE can also bind key molecules to activate downstream signaling, as reported in the cases of diaphanous-related formin 1 and toll-interleukin 1 receptor domain-containing adaptor protein (TIRAP)[44-46]. Soluble forms of RAGE, also known as soluble RAGE (sRAGE), have been identified and found in many fluid compartments, including serum[47,48]. These soluble variants arise from two main mechanisms: (1) Alternative splicing; and (2) enzymatic cleavage *via* the actions of matrix metalloproteinases (MMPs), disintegrin, and metalloprotease domain-containing protein 10[49]. RAGE activation by ligand binding triggers complex signaling cascades, leading to the activation of transcription factors such as NF-κB, signal transducer and activator of transcription 3 (STAT3), hypoxia-inducible factor-1α, activator protein-1, and cyclic-AMP response element binding (CREB). RAGE activation also stimulates p21ras, extracellular signal-regulated kinase (ERK) 1/2, p38 MAPK, stress-activated protein kinase/c-Jun n-terminal kinase, Rho GTPase, the PI3K and Janus kinase/STAT pathways. Accordingly, RAGE activation leads to a robust proinflammatory gene expression profile[50,51] (Figure 1).

Additionally, RAGE activation causes a positive feed-forward loop, where inflammatory stimuli activate NF-κB, which induces RAGE expression followed by sustained NF-κB activation[52].

The complexity of RAGE signaling is further expanded by its interaction at the plasma membrane with other receptors, such as the chemotactic G-protein-coupled receptors formyl peptide receptors 1 (FPR1) and FPR2, as well as the leukotriene B4 receptor 1[53]. Additionally, adaptor proteins for Toll like receptor 2 (TLR-2) and TLR-4 such as TIRAP and MyD88 also bind to the cytoplasmatic domain of RAGE, when phosphorylated at Ser 391 by PKC-zeta, following other ligand-mediated activation of RAGE[54].

Figure 1 Receptor for advanced glycation end products engagement by several ligands such as advanced glycation end products, high mobility group box 1, S-100 calgranulin family proteins, and pathogen-associated molecular patterns from *Helicobacter pylori*. Receptor for advanced glycation end products (RAGE) activation by these various ligands triggers complex signaling cascades and consequently, the activation of a gene transcriptional profile that supports growth and development of gastric cancer. Soluble forms of RAGE (sRAGE) function as decoy receptors and do not activate RAGE signaling. Some adaptor molecules, such as mDia1 and toll-interleukin 1 receptor domain-containing adaptor protein, are required for optimal signaling. AP-1: Activator protein-1; CREB: Cyclic-AMP response element binding; EMT: Epithelial-to-mesenchymal transition; ERK: Extracellular signal-regulated kinase; *H. pylori*: *Helicobacter pylori*; IL-8: Interleukin-8; JAK: Janus kinase; JNK: c-Jun n-terminal kinase; MMP: Metalloproteinases; mTOR: Mechanistic target of rapamycin; NF-κB: Nuclear factor-kappa B; SAPK: Stress-activated protein kinase; STAT: Signal transducer and activator of transcription.

The gene encoding RAGE is highly polymorphic, and several single-nucleotide polymorphisms (SNPs) within this gene have been described. Compelling data support the role of RAGE gene polymorphisms in the onset and severity of several diseases, including cancer[55].

At present, RAGE is widely recognized as a PRR[56-58]. Beyond the AGEs, RAGE also acts a signaling receptor for various DAMPs or alarmins, such as members of the S100/calgranulin family, HMGB1, amyloid-beta (β) peptide, β-sheet fibrils, lysophosphatidic acid, Mac-1, phosphatidylserine, lipopolysaccharide, the complement component C3a, CpG oligos, and nucleic acids[59,60]. The emerging role of RAGE in sensing not only DAMPs but also PAMPs has been documented[61,62]. RAGE has also been reported to mediate the adherence of some pathogens to target cells by recognizing outer membrane proteins, as reported in the case of mycobacteria[63]. Of note, RAGE not only contributes to the adherence of *H. pylori* to gastric epithelial cells, but also to the production of the inflammatory response. This increase in RAGE expression and the amplification of the inflammatory cascade therefore culminates in *H. pylori*-induced gastric inflammation[64]. This finding is particularly interesting because this pathogen also uses another PRR, TLR-4, as a receptor for binding to gastric epithelial cells[65,66].

THE RAGE AXIS: AN EMERGING ACTOR IN TUMOR BIOLOGY

In the year 2000, an article published by Schmidt *et al*[67] outlined various RAGE axis contributions to pathophysiology. This study demonstrated its active participation in tumor biology, as the blockage of RAGE was shown to decrease tumor growth and metastases *in vivo*. Since then, additional compelling pieces of evidence have also demonstrated RAGE's contribution to carcinogenesis and have highlighted its expression levels on both tumor and stromal cells, the high diversity of signaling cascades triggered upon RAGE activation, its wide repertoire, and the abundance of RAGE ligands in the tumor microenvironment[68-70]. RAGE axis activation contributes to critical processes during tumorigenesis, such as the promotion of genetic instability, the initiation of chronic inflammation, the induction of phenotypic changes in tumor cells favoring growth and dissemination, and the support of an immunosuppressive environment[71,72].

Based on the growing body of evidence supporting the crucial role of the RAGE axis in many human pathologies, including cancer, and the availability of the 1.5 Å resolution crystal structure of the receptor, the RAGE axis has become an attractive target for the development of pharmacological interventions. Notably, the design and even the virtual screening of RAGE antagonists and signaling

inhibitors (*e.g.*, small-molecule inhibitors, natural products) has demonstrated the feasibility for inhibition of RAGE signal transduction, regardless of the nature of the ligand[51,73].

RAGE AXIS CONTRIBUTION TO GC

Tumor cell proliferation and survival

HMGB1 is a classical RAGE ligand with recognized roles in tumor biology. Of note, HMGB1 is overexpressed in gastric tumors, and a recent systematic meta-analysis demonstrated that HMGB1 plays an important role in GC, and its expression significantly correlates with tumor pT stage[74].

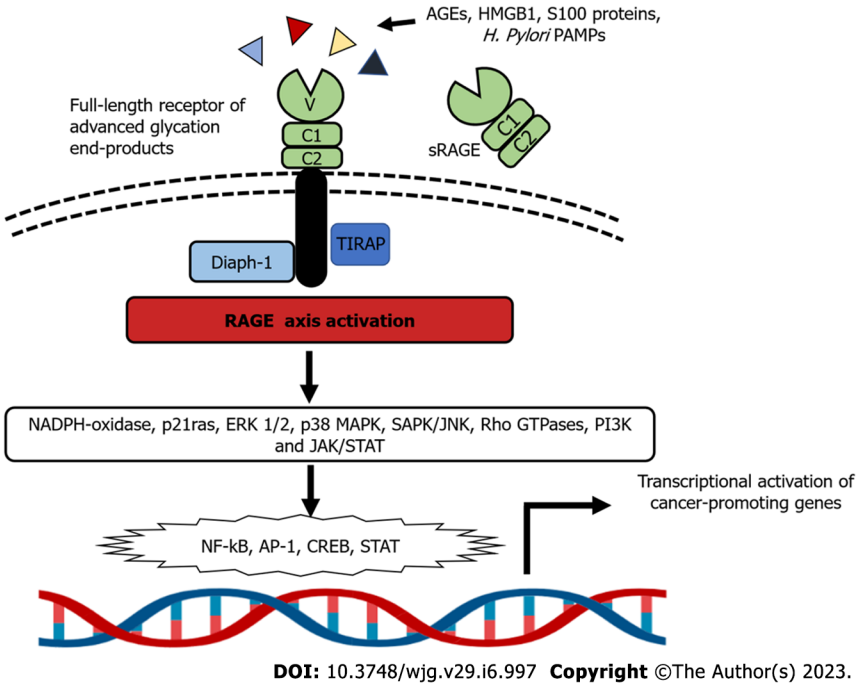
HMGB1-mediated RAGE activation triggers either MAPK or PI3K/AKT signaling and thus enhances tumor cell proliferation in different cancer cell types[75,76]. Additionally, data derived from *in vitro* experiments support the role of HMGB1 in promoting GC cell proliferation and migration *via* activation of RAGE-mediated Akt-mechanistic target of rapamycin (mTOR) and ERK-CREB signaling pathways, as well by initiation of a positive feedback loop that increases RAGE expression *via* these pathways. Furthermore, HMGB1 increases the expression levels of cyclin D1, cyclin E1, and proliferating cell nuclear antigen (PCNA), and HMGB1 knockdown reduces the expression of these proteins in GC cells [77].

The role in cancer cell proliferation of the S100 Calcium Binding Protein A16 (S100A16) remains controversial in some cancer types[78,79]. However, this alarmin is reported to promote cancer cell proliferation, migration, and invasion. *In vivo* and *in vitro* analyses revealed that S100A16 promotes both tumor cell proliferation and migration, whereas S100A16 knockdown abolished both[80]. Autophagy is a lysosome-mediated, self-degradation process that has emerged as key in protecting normal cells *via* the elimination of damaged organelles and protein aggregates and supporting bioenergetic homeostasis [81]. Autophagy can suppress the initiation of tumor development, or, in contrast, activate tumor cell survival, growth, and malignancy by facilitating access to metabolic demands during tumor progression and supporting tumor cell survival under stress[82-84].

The role of autophagy in GC progression, metastasis, and overall prognosis has been extensively documented[85,86]. Of note, HMGB1 released by autophagic GC cells through a RAGE-dependent mechanism acts as a pro-survival signal for remaining tumor cells, supporting cancer cell survival and promoting resistance to chemotherapy[87] (Figure 2).

Cancer cell invasion

Decades of research have demonstrated that the RAGE axis and its associated proinflammatory downstream pathways act as key mediators of carcinogenesis[88], especially in gastrointestinal tumor development[89].



Among different cancer cell types, RAGE overexpression has been largely recognized as a pathological feature associated with increased tumor development, high invasiveness of cancer cells, and overall poor clinical prognosis[90-92].

The first experimental evidence supporting a correlation between RAGE overexpression and increased invasive and metastatic activity of GC cells was reported in 2002 by Kuniyasu *et al*[93]. This study revealed that RAGE axis signaling in gastric tumors may promote the acquisition of an invasive phenotype by increasing MMP-2 and MMP-9 expression, decreasing E-cadherin expression, and promoting tumor growth in a MAPkinase-dependent manner.

More recently, the analysis of RAGE expression in primary GC tissue reported by Wang *et al*[94] demonstrates that the upregulation of RAGE is associated with histological grade, nodal status, metastasis status, and American Joint Committee on Cancer (AJCC) stage in GC. RAGE upregulation is also associated with shorter overall survival rates. These data suggest that RAGE expression could be considered an independent predictor of GC aggressiveness and prognosis.

RAGE axis activation can have great influence on the invasive capacity of GC tumor cells through the modulation of cellular adhesion, motility, and production of MMPs. These functions are critical for epithelial-to-mesenchymal transition (EMT)[9,10], a complex process by which epithelial cells transdifferentiate to mesenchymal phenotypes. EMT is normally present during embryogenesis, tissue morphogenesis, wound healing, and regulation of stem cell behavior[95]. During this process, epithelial cells lose basal adhesion and demonstrate downregulation of epithelial cell markers (*e.g.*, E-cadherin) and upregulation of mesenchymal markers (*e.g.*, vimentin and fibronectin). These changes are also accompanied by increased expression of MMP-2 and MMP-9, which favors the degradation of ECM proteins[96]. EMT is a key mediator of the invasive and dissemination capacities of almost all types of cancer cells[97], including GC[98,99].

RAGE ligands have also been associated with cancer cell invasion and progression[100,101]. For example, the cancer-promoting role of HMGB1 has been extensively reported as a prognostic factor in many cancer types[74]. Importantly, differential expression analysis has shown that HMGB1 is increased in gastric adenocarcinoma cells[100] and has been directly associated with higher tumor stage, lymph node metastasis, depth of invasion, macrophage infiltration in the tumor microenvironment, and antineoplastic drug resistance[102-105]. Moreover, increased HMGB1 has also been correlated with poor

Figure 2 Overview of RAGE-dependent intracellular signaling. RAGE binding triggers myriad mechanisms that support tumor proliferation and survival, invasion, and metastasis. AGE: Advanced glycation end product; AP-1: Activator protein-1; CREB: cyclic-AMP response element binding; ERK: Extracellular signal-regulated kinase; HMGB1: High mobility group box 1; JAK: Janus kinase; JNK: c-Jun n-terminal kinase; NF-κB: Nuclear factor-kappa B; PAMP: Pathogen-associated molecular patterns; RAGE: Receptor for advanced glycation end products; SAPK: Stress-activated protein kinase; STAT: Signal transducer and activator of transcription; TIRAP: Toll-interleukin 1 receptor domain-containing adaptor protein.

prognosis and overall survival in GC[106-109].

In vitro and *in vivo* assays have demonstrated that high concentrations of extracellular HMGB1 can directly impact the progression of GC cells through the induction of IL-8, which promotes tumor angiogenesis *via* increasing vascular endothelial growth factor (VEGF) and TNF-α expression[110]. Increased HMGBI also works to favor tumor invasiveness and promote EMT through RAGE-dependent activation of ERK 1/2 and NF-κB[111]. Recent experiments have also confirmed that HMGB1 activation of the RAGE axis can strongly regulate direct EMT mediators in GC cells *via* downregulation of E-cadherin, as well as by upregulation of transcription factors of Snail and Slug[111] and MMPs (*e.g.*, MMP-9 and MMP-2), whereas the knockdown of HMGB1 showed opposite effects. These results implicate HMGB1 is a key mediator of RAGE-dependent EMT, acting to favor the expression of more invasive GC cell phenotypes[77]. To this end, compelling data have revealed that RAGE knockdown in GC cells suppresses cell growth, invasion, and metastasis through the downregulation of RAGE-related pro-tumoral mediators of EMT (*e.g.*, Akt, PCNA, and MMP-2)[112]. Additionally, the knockdown of the *HMGB1* gene inhibits cell proliferation and the invasive potential of GC cells *via* suppression of RAGE-dependent NF-κB activation[113].

The S100 calcium-binding protein family member S100A8/A9 is a proinflammatory heterodimer produced by both myeloid-derived suppressor cells (MDSCs) and tumor cells[114]. S100A8 and S100A9 form a heterodimeric complex to interact with RAGE, promoting pro-tumoral signaling pathways within cancer cells[115]. Of note, serial analyses of gene expression reported significant overexpression of the genes encoding S100A8 and S100A9 in GC cells when compared to normal gastric epithelial cells [116]. In addition, *in vitro* evidence has revealed that these calcium-binding proteins are critical in promoting the invasive and migratory phenotype in GC cells through the engagement of RAGE and its pro-tumoral signaling pathways (*e.g.*, p38, MAPK, and NF-κB). These RAGE-activated pathways further mediate S100A8/A9-induced migration and invasion in GC[116,117]. For example, Yong and Moon[118] studied siRNA blockade of S100A8/A9 in a human GC cell line, and found a drastic decrease in the invasive ability of malignant cells. This finding suggests the critical role of S100A8 and S100A9 and their heterodimer in promoting progression and invasion in GC. Novel evidence has also shown a significant increase in MDSC-induced S100A8/A9 plasma levels in GC patients, which is thought to induce immunosuppressive effects through RAGE-dependent T-cell proliferation and interferon-γ production, which directly correlate with advanced cancer stage and reduced survival[119].

Interestingly, the emerging role of calprotectin as a modulator of apoptosis has been recently reported. Calprotectin has been shown to be involved in the regulation of apoptotic mediators such as Bax, Bcl-2 family proteins, and ERK signaling pathway proteins through RAGE engagement in GC cell lines[120].

Dissemination and metastasis

The dissemination of malignant cells from their primary site and the subsequent development of secondary tumors in distant organs, a process called metastasis, is a main consequence of cancer therapy failure and a major cause of cancer-related mortality[1,14]. The complex process of metastasis is supported by different mechanisms that require primary tumor cells to leave their origin, circulate within the microvasculature, escape immune surveillance, and colonize distant niches to promote the formation of secondary tumors[121].

A pivotal step in the development of secondary metastasis is the establishment of a complex interplay of tumor-derived factors, a favorable microenvironment in the distant site (*i.e.* a "pre-metastatic niche"). The pre-metastatic niche favors tumor cell colonization and promotes micro- and macrometastasis. Processes that contribute to the cultivation of the niche include inflammation, immunosuppression, neoangiogenesis, lymphangiogenesis, and organotropism[122].

Strikingly, the niche-promoting molecules described in various malignancies, including GC, are closely regulated by RAGE axis activation[71]. Examples of niche-promoting factors include S100A8/A9 ligand[39,123], VEGF-A, TNF-α, TGF-β, MMPs[43,46,124], extracellular vesicles, exosomes, and various microRNAs[5,7]; these mediators sculpt the cellular crosstalk that allows the initiation of metastatic secondary tumor formation[125,126]. In GC, it has been documented that patients with advanced stage and distant dissemination have a poor prognosis with a 5-year survival of approximately 20% depending on the population analyzed, tumor histological features, and the antineoplastic therapy used [1-3].

Experimental results suggest that RAGE overexpression is closely associated with the disruption of cell-to-cell adhesion and acceleration of GC cell motility, both of which support the metastatic activity of GC cells[93]. To this end, RAGE knockdown reduces GC cell proliferation and invasion and decreases the expression of pro-tumoral mediators (*e.g.,* Akt, PCNA, and MMP-2) consequently inducing aberrant cell apoptosis and cell cycle arrest[112]. For example, *in vivo* and *in vitro* evidence has shown that AGE binding to RAGE can accelerate gastric tumor progression and dissemination through the dose-dependent upregulation of the pro-tumoral mediators Specificity Protein 1 and MMP-2 *via* activation of ERK signaling[126,127].

In addition to its actions discussed above, HMGB1 also facilitates the progression and metastasis of various types of cancer[128], including GC[105,107]. In recent years, a growing body of evidence has begun to unravel the molecular mechanisms behind this contribution HMGB1 to CG metastasis[106]. For example, several studies have revealed increased expression of RAGE and HMGB1 in gastric tumor samples, which correlates with local and distant advanced disease and poor overall prognosis[102,107,109,110,113]. This association is accentuated under hyperglycemic conditions such as in diabetes mellitus, which enhance endogenous AGE formation and RAGE signaling[105]. Furthermore, other experimental research has shown that the overexpression of HMGB1 and the subsequent induction of IL-8 in the gastric tumor microenvironment (TME) may contribute to EMT and GC micrometastasis through the activation of downstream pathways of the RAGE axis, including ERK 1/2 and NF-κB[110]. In addition, overexpression of HMGB1 promotes the recruitment of neutrophils to the TME; this inflammation and associated production of ROS further promotes GC proliferation and metastasis[128,129].

Another recent investigation has demonstrated that the HMGB1/RAGE axis can regulate GC cell proliferation and migration *via* the enhanced expression of cyclins and MMPs, the induction of EMT, and activation of several cellular proliferation pathways including the Akt/mTOR and ERK/CREB signaling pathways[77].

Moreover, the *in vivo* or *in vitro* knockdown of HMGB1 leads to downregulation of NF-κB, PCNA, and MMP-9 expression in gastric tumor cells. This finding suggests that targeting the HMGB1 pathway may be a promising approach to inhibit the growth and metastasis of GC cells through the regulation of RAGE-dependent pathways[113]. Also, the overexpression of HMGB1 has been shown to enhance gastric tumor cell secretion of IL-8, supporting EMT during the early stages of tumor progression. Conversely, reduction in HMGB1/RAGE signaling by *in vivo* targeting of extracellular HMGB1 produces a significant reduction in tumor growth[111].

The overexpression of calgranulins in invasive GC cell lines has also been demonstrated[116]. These recognized RAGE ligands can promote not only more invasive phenotypes of the malignant cells, but can also enhance their migration capacity *via* RAGE-dependent mechanisms (*e.g.,* p38 MAPK-dependent NF-κB activation and MMP2 upregulation)[117].

RAGE polymorphisms

The expression level of RAGE has been associated with invasion, metastasis, and poor prognosis in GC [93,94]. RAGE levels also correlate with the severity of gastric mucosal lesions in patients infected with *H. pylori*, where the highest RAGE expression was observed in precancerous lesions (*e.g.*, atrophy or IM), dysplastic lesions, or *in situ* adenocarcinoma[130].

Compelling data have identified diverse polymorphisms within exons, introns, and regulatory regions of the gene encoding RAGE[131]. Interestingly, some of these polymorphisms may affect either RAGE gene transcriptional activity or the binding affinity of RAGE for its ligands[55,132]. Thus, RAGE polymorphisms are now potentially considered as susceptibility or poor prognostic factors in different cancer types. In this regard, several research groups have investigated the association between RAGE

gene polymorphisms and the risk of various cancers[133-137]. For example, studies have demonstrated the association of certain RAGE polymorphisms and GC. The pioneering work of Wang *et al*[136] demonstrated that the rs2070600 RAGE polymorphism [Gly82Ser] confers an increased risk of GC in the Chinese population[138]. Of note, this polymorphism is associated with enhanced RAGE signaling[132].

More recently, Liu *et al*[125] further confirmed that the rs2070600 variant AG genotype plays a predominant role in the development of GC. On the contrary, the rs184003 GT genotype represents a significantly reduced risk for GC. Additionally, the rs2070600 and rs184003 polymorphisms affect the serum levels of the splice variant of sRAGE, where the first is associated with a decreased level of while the latter with an increased serum level of sRAGE[139].

In addition to the protease-mediated cleavage soluble RAGE variants, sRAGE can arise from alternative splicing of the RAGE gene. These soluble variants lack the transmembrane and cytoplasmic domains, allowing them to function as decoy receptors, that do not lead to the activation of RAGE-associated signaling[46]. Reduced sRAGE has been associated with increased cancer risk and tumor progression in many other cancer types[140,141].

In summary, a diverse and compelling body of data shows the wide range of mechanistic contributions of the RAGE axis to gastric carcinogenesis (Table 1).

CONCLUSION

The RAGE axis is emerging as a relevant actor in gastric carcinogenesis. In this regard, a high expression level of RAGE and many RAGE ligands has been associated with tumor cell growth, invasion, metastasis, and poor prognosis. Furthermore, polymorphisms in the gene encoding RAGE have been linked to strengthening of RAGE ligand affinity, enhanced intracellular signaling, and modulation of

the serum levels of the soluble form of the receptor (sRAGE), which have been postulated as potential biomarkers of poor prognosis in GC patients.

However, additional research efforts are needed to fully understand the role of RAGE signaling in gastric carcinogenesis, particularly in those populations with a high prevalence of GC. Of note, increasing focus is being placed on diet and lifestyle modification as potential methods for preventing GC. This is particularly interesting, considering that in modern society, the consumption of AGEs is markedly increased (due in part to increased consumption of modern Westernized diets). Dietary intervention to restrict the intake of AGEs is recognized as a useful intervention, as demonstrated in several pathologies[10,11].

Today, clinical and experimental data demonstrate the therapeutic potential of blocking activation of the RAGE axis, as demonstrated by gene-silencing technologies, the use of aptamers, and the use of natural and synthetic molecules, all of which decrease RAGE ligand binding and/or RAGE-dependent intracellular signaling[51,70]. However, more clinical research is needed to establish the effectiveness of these promising options.

Abstract

Over the last two decades, the standard treatment for locally advanced rectal cancer (LARC) has been neoadjuvant chemoradiotherapy plus total mesorectal excision followed by adjuvant chemotherapy. Total neoadjuvant treatment (TNT) and immunotherapy are two major issues in the treatment of LARC. In the two latest phase III randomized controlled trials (RAPIDO and PRODIGE23), the TNT approach achieved higher rates of pathologic complete response and distant metastasis-free survival than conventional chemoradiotherapy. Phase I/II clinical trials have reported promising response rates to neoadjuvant (chemo)-radiotherapy combined with immunotherapy. Accordingly, the treatment paradigm for LARC is shifting toward methods that increase the oncologic outcomes and organ preservation rate. However, despite the progress of these combined modality treatment strategies for LARC, the radiotherapy details in clinical trials have not changed significantly. To guide future radiotherapy for LARC with clinical and radiobiological evidence, this study reviewed recent neoadjuvant clinical trials evaluating TNT and immunotherapy from a radiation oncologist's perspective.

Core Tip: In locally advanced rectal cancer (LARC), recent randomized controlled trials have demonstrated the benefits of total neoadjuvant treatment (TNT) in terms of oncologic outcomes and organ preservation. The results of clinical trials of immunotherapy suggest the possibility of pelvic radiotherapy in combination with immunotherapy for LARC. However, the radiotherapy details used in clinical trials have not changed significantly. This study reviewed recent neoadjuvant clinical trials evaluating TNT and immunotherapy from a radiation oncologist's perspective to guide future radiotherapy for LARC.

INTRODUCTION

Neoadjuvant chemoradiotherapy (CRT) plus total mesorectal excision (TME) has been the standard treatment for locally advanced rectal cancer (LARC) for almost two decades. Although this approach has reduced the local recurrence (LR) rate to < 5%-10%, 20%-30% patients with LARC still experience distant metastasis (DM), a major cause of death[1-3]. Although the role of adjuvant chemotherapy (CT) on survival outcomes has been investigated by several working groups[4,5], the impact of adjuvant CT after neoadjuvant CRT plus TME on survival and ideal candidates for adjuvant CT are unclear[6]. Oxaliplatin-based neoadjuvant CRT, when compared to conventional CRT, showed higher toxicity rates without survival benefit in all phase III trials except one [7-10].

Total neoadjuvant treatment (TNT) and immunotherapy are the two trending issues in the preoperative treatment of LARC. Five phase III randomized controlled trials (RCTs) evaluating the TNT approach have been reported[11-15]. All trials showed significantly higher pathologic complete response (pCR) rates in the TNT group than in the traditional neoadjuvant CRT group. Moreover, two RCTs revealed that TNT significantly improved DM-free survival (DMFS), disease-free survival (DFS), or disease-related treatment failure[13,14]. Several prospective phase I/II studies have reported promising response rates to traditional neoadjuvant treatment combined with immune checkpoint inhibitors (ICIs)[16-19] or ICI alone[20] in LARC, known as an immune-cold tumor.

However, despite these advances in multidisciplinary treatment strategies for LARC, the radiotherapy (RT) details in clinical trials have not changed significantly. Therefore, to guide future RT for LARC with clinical and radiobiological evidence, this study reviewed recent neoadjuvant clinical trials evaluating TNT and ICIs from a radiation oncologist's perspective.

SUMMARY OF RECENT NEOADJUVANT CLINICAL TRIALS

TNT

The TNT approach brings the systemic adjuvant CT to the preoperative period, which can be administered before or after RT. The TNT approach has several clinical advantages in terms of tumor response, organ preservation, distant control, and long-term survival through early administration of intensive chemotherapeutic agents with a high compliance. The treatment protocols and important findings of RCTs evaluating TNT are summarized in Table 1 and Supplementary Table 1.

Three trials compared short-course RT (SCRT) followed by consolidation CT and standard CRT (POLISH II[21], RAPIDO[13], and STELLAR[15]). Between the SCRT + CT *vs* standard CRT groups, both RAPIDO and STELLA showed a higher pCR rate with TNT, which was not different in POLISH II. Notably, 3-year disease-related treatment failure and DMFS were significantly better in the TNT arm of RAPIDO, and 3-year overall survival (OS) was significantly better in the TNT arm of STELLAR. These results support the fact that SCRT followed by consolidation CT with a sufficient RT-to-surgery interval is a good option with a high pCR rate and potential to improve DMFS and OS, although there are differences in stage distributions, duration of consolidation CT, and RT-to-surgery intervals among these trials.

Three trials evaluated the role of induction or consolidation CT in TNT regimens (PRODIGE23[14], CAO/ARO/AIO-12[22,23], and OPRA[24]). PRODIGE23 showed that induction FOLFIRINOX (6 cycles) followed by standard CRT (*vs* standard CRT) was associated with better pCR, 3-year DFS, and 3-year DMFS rates. CAO/ARO/AIO-12 and OPRA reported no differences in DFS, LR, and DM between the induction and consolidation CT groups. However, the pCR rate in CAO/ARO/AIO-12 and 3-year TME-free survival in OPRA were significantly higher in the consolidation group than in the induction group.

Table 1 Recent randomized trials evaluating the total neoadjuvant treatment approach in locally advanced rectal cancer

Trials	Identifier	Patients	Primary endpoint	Treatment arms	Results (arm A *vs* B *vs* C)
POLISH II[11,21]	NCT00833131	cT4 or fixed cT3 (primary or locally recurrent)	R0 resection	A: CRT (5-FU+LV #2) → S (→ CT); B: SCRT → FOLFOX4 #3 → S (→ CT)	R0: 71% *vs* 77% (NS); pCR: 12% *vs* 16% (NS)
FOWARC[12]	NCT01211210	cT3-4 or cN+	3 yr DFS	A: CRT (de Gramont #5) → TME → de Gramont #7; B: CRT (mFOLFOX6 #5) → TME → mFOLFOX6 #7; C: mFOLFOX6 #4-6 → TME → mFOLFOX6 #6-8	pCR: 14.0% *vs* 27.5% *vs* 6.5%; 3 yr DFS: 72.9% *vs* 77.2% *vs* 73.5% (NS); 3 yr LF: 8.0% *vs* 7.0% *vs* 8.3% (NS); 3 yr OS: 91.3% *vs* 89.1% *vs* 90.7% (NS)
RAPIDO[13,109]	NCT01558921	cT4 or MRF+ or N2 or lateral LN+ or EMVI+	3 yr DRTF[1]	A: CRT (cape) → TME → CAPOX #9 or FOLFOX4 #12; B: SCRT → CAPOX #6 or FOLFOX4 #9 → TME	3 yr DRTF: 30.4% *vs* 23.7%[2]; 3 yr DM: 26.8% *vs* 20.0%[2]; pCR: 14% *vs* 28%[2]
PRODIGE23[14]	NCT01804790	cT3-4 Nany	3 yr DFS	A: CRT (cape) → TME → mFOLFOX6 #12; B: FOLFIRINOX #6 → CRT (cape) → TME → mFOLFOX6 #6	3 yr DFS: 69% *vs* 76%[2]; pCR: 12% *vs* 28%[2]
STELLAR[15]	NCT02533271	cT3-4 or cN+	3 yr DFS	A: CRT (cape) → TME → CAPOX #6; B: SCRT → CAPOX #4 → TME → CAPOX #6	3 yr DFS: 62.3% *vs* 64.5% (NS); 3 yr OS: 75.1% *vs* 86.5%[2]; pCR: 11.8% *vs* 16.6%[2]
CAO/ARO/AIO-12[22,23]	NCT02363374	cT3-4 or cN+	pCR	A: FOLFOX #3 → CRT (5-FU+oxaliplatin) → TME; B: CRT (5-FU+oxaliplatin) → FOLFOX #3→ TME	pCR: 17% *vs* 25%[2]
OPRA[24,110]	NCT02008656	cT3-4N0 or cTanyN1-2	3 yr DFS	A: mFOLFOX6 #8 or CAPOX #5→ CRT → WW or TME; B: CRT → mFOLFOX6 #8 or CAPOX #5 → WW or TME	3 yr DFS: 76% *vs* 76% (NS); 3 yr TME-free survival: 41% *vs* 53%[2]
Tang *et al*[68] ongoing	NCT04543695	Stage II-III with at least one high-risk factors: MRF+, T4, N2, lateral LN, EMVI+	Downstaging (yp0-II, cCR)	A: CRT → TME → CAPOX #6; B: CRT → CAPOX #6 → TME or WW; C: CAPOX #6 → CRT → TME or WW	(Preliminary) yp0-II: 77.1% *vs* 84.2% *vs* 57.1%; pCR + sustained cCR: 22.9% *vs* 42.1% *vs* 28.6%
CAO/ARO/AIO-18.1[76] ongoing	NCT04246684	MRI-defined intermediate and high-risk factors: cT3 low rectal (< 6 cm from AV), cT3c/d middle rectal (≥ 6-12 cm), cT4 tumors, Tany middle/low third of rectum with N+, CRM ≤ 1 mm, EMVI+	3 yr organ preservation	A: SCRT → CAPOX #6 or mFOLFOX6 #8 → WW or TME; B: CRT (5-FU+oxaliplatin) → CAPOX #4 or mFOLFOX6 #6 → WW or TME	

[1]Disease-related treatment failure was defined as the first occurrence of locoregional failure, distant metastasis, a new primary colorectal tumor, or treatmentrelated death.

5-FU: 5-fluorouracil; AV: Anal verge; cape: Capecitabine; cCR: Clinical complete response; CRM: Circumferential resection margin; CRT: Chemoradiotherapy; CT: Chemotherapy; DFS: Disease-free survival; DM: Distant metastasis; DRTF: Disease-related treatment failure; EMVI: Extramural vascular invasion; LF: Local failure; LN: Lymph node; MRF: Mesorectal fascia; MRI: Magnetic resonance image; NS: Not significant; OS: Overall survival; pCR: Pathologic complete response; S: Surgery; SCRT: Short-course radiotherapy; TME: Total mesorectal excision; WW: Watch-and-wait.

Although the TNT approach for LARC has already been adopted in several practice guidelines[25-28], a one-size-fits-all approach would not be appropriate in many real-world clinical scenarios. Based on the results of the aforementioned RCTs of TNT, Hui *et al*[29] and Roeder *et al*[30] introduced their institutional neoadjuvant approach for LARC according to the risk of local and/or distant failure and patients' desire for organ preservation.

Immunotherapy

Radiation has immunomodulatory effects on the host immune system in addition to the direct tumor cell killing effect[31,32]. In particular, dendritic cells activated by radiation can present tumor antigens in lymph nodes (LNs) and activate CD8+ T cells, which are important for killing primary or distant tumor cells[31,33,34]. However, upregulation of programmed death ligand 1 (PD-L1) expression in tumor cells by interferon-γ produced by CD8+ T cells can lead to radioresistance[35,36]. Thus, the potential of a combination of ICIs and RT has been investigated in various cancers, including LARC [37]. In addition, neoadjuvant treatment changes colorectal cancer to an immunogenic tumor *via* loss of

the mismatch repair (MMR) protein, decrease in mRNA expression levels of MMR-related genes, and increase in the tumor mutational burden (TMB)[38-40]. Several early-phase clinical trials have reported higher response rates to neoadjuvant treatment combined with ICIs for LARC, when compared to historical rates with conventional CRT. Their treatment protocols and important findings are summarized in Table 2 and Supplementary Table 1.

Four trials evaluated tumor response to CRT combined with concurrent and/or consolidation ICIs. Five cycles of consolidation nivolumab after CRT in the VOLTAGE-A phase I/II trial achieved pCR rates of 30% in patients with microsatellite-stable (MSS) and 60% in patients with high microsatellite instability (MSI-H)[16]. Two trials reported pCR rates after CRT with concurrent and consolidation ICIs; 23% in the AVANA phase II trial[17] using 6 cycles of avelumab and 24% in the R-IMMUNE phase Ib/II trial[18] using 4 cycles of atezolizumab. The NRG-GI002 phase II RCT compared two groups of induction mFOLFOX6 (6 cycles) followed by CRT with or without concurrent and consolidation pembrolizumab; the pCR rate was not different between the groups (31.9% *vs* 29.4%)[19]. Two phase II trials evaluating SCRT followed by consolidation CT and ICIs reported the highest pCR rates; 37.5% in the AVERECTAL trial[41] using 6 cycles of mFOLFOX6 plus avelumab and 48.1% in the trial by Lin *et al*[42] using 2 cycles of CAPOX plus camrelizumab. Notably, an ongoing TORCH trial reported a preliminary clinical complete response (cCR) or pCR rate of 81.3% in 16 MSS patients who received SCRT-based induction or consolidation CAPOX plus toripalimab[43]. In addition, these studies enrolled patients regardless of the MMR status, two of which reported the pCR rate according to the MMR status [16,42]. Although these promising results should be verified in large-scale RCTs, the results indicate the potential benefits of the combination of pelvic RT and ICIs in the aspect of organ preservation and survival outcomes, especially for patients with MSS LARC.

Despite the proportion of patients with deficient MMR (dMMR) or MSI-H LARC being as low as 5%-10%, neoadjuvant ICIs with or without CRT or SCRT for dMMR/MSI-H LARC are gaining attention owing to their high response rates[44]. Most recently, Cercek *et al*[20] preliminarily reported that all 12 consecutive patients with dMMR LARC achieved cCR after 9 cycles of dostarlimab and were under watch-and-wait (WW) without CRT, surgery, or any recurrence for 6-25 mo. Several ongoing trials are evaluating the response rate and toxicities of SCRT combined with ICIs in patients with dMMR/MSI-H LARC[45-47] (Table 2 and Supplementary Table 1).

RT in clinical trials

The RT dose, field, and techniques were similar among the TNT and immunotherapy trials described above (Supplementary Table 1). The clinical target volume (CTV) included the primary tumor, regional LNs, and pelvic regions at risk, as proposed by Roels *et al*[48] and the Radiation Therapy Oncology Group[49], as long as its definition could be confirmed in the protocol or published article. A total dose of 50-50.4 Gy at 1.8-2 Gy per fraction and 45 Gy at 1.8 Gy per fraction were administered to the gross tumor volume (GTV) and elective pelvic areas during CRT, respectively. All trials using SCRT administered 25 Gy in 5 fractions to the CTV. Some studies allowed an additional boost dose to the GTV (up to a total dose of 54-56 Gy). Intensity-modulated RT (IMRT) or 3-dimensional conformal RT (3D-RT) were used. Although the treatment outcomes of the aforementioned clinical trials using these traditional target volumes and RT doses are promising, better outcomes can be achieved if RT parameters can be optimized for TNT and immunotherapy. The factors to be considered when using RT as a part of TNT or in combination with ICIs will be discussed in later sections.

CLINICAL IMPLICATIONS

Paradigm shift of neoadjuvant treatment regiments

Neoadjuvant CRT (45-50.4 Gy in 25-28 fractions concurrently with 5-fluorouracil or capecitabine) has been recommended in LARC as it improves the resectability, sphincter preservation, and local control rates. Although SCRT (25 Gy in 5 fractions without CT) with delayed surgery is considered effective as CRT in terms of sphincter preservation, R0 resection, and local control, SCRT has not been widely used because of insufficient downstaging and high toxicity[50-52]. On the other hand, many efforts have been made to omit or selectively use pelvic RT in LARC to avoid RT-related toxicities[53,54]. LARC with a low risk of LR can be successfully treated without preoperative or postoperative pelvic RT[25]. However, these approaches require radical resection, which is associated with surgery-related complications. In addition, the WW strategy became doubtful when Habr-Gama *et al*[55] reported excellent long-term outcomes of nonoperative management for patients with LARC who achieved cCR after CRT (50.4 Gy with concurrent 5-fluorouracil and leucovorin) in 2004.

Currently, the neoadjuvant treatment paradigm is shifting in several ways owing to the excellent results of TNT trials[56]. TNT regimens combined with CRT or SCRT are recommended by the National Comprehensive Cancer Network guidelines[57] and are increasingly employed in clinical practice[56]. SCRT is regaining attention because of the following advantages when combined with TNT and immunotherapy: Short treatment time, high compliance, few side effects, and potential synergistic effects with immunotherapy. The WW strategy is being accepted in patients achieving cCR after

Table 2 Recent prospective clinical trials using immune checkpoint inhibitors as a component of neoadjuvant treatment for locally advanced rectal cancer

Trials	Identifier	Patients	Primary endpoint	Treatment	Results
VOLTAGE-A [16]	NCT02948348	cT3-4 Nany (regardless of MMR status)	pCR	CRT (cape) → Nivolumab #5 → TME (→ mFOLFOX6/CAPOX)	pCR: 30% for MSS, 60% for MSI-H
AVANA[17]	NCT03854799	cN+ or cT4 or high-risk cT3 (CRM ≤ 1 mm, ≤ 6 cm from AV, or T3c/d)	pCR	CRT (cape) + Avelumab #6 → TME	pCR: 23%
R-IMMUNE [18]	NCT03127007	Stage II or III	pCR, safety	CRT(5-FU) + Atezolizumab #4 → S	pCR: 24%
NRG-GI002 [19]	NCT02921256	Stage II or III with at least 1 of the following criteria: cT3-4 ≤ 5 cm from AV, any cT4 or tumor within 3 mm of MRF, cN2, not candidates for sphincter-sparing surgery at presentation	Neoadjuvant rectal score	A: mFOLFOX6 #6 → CRT (cape) → TME; B: mFOLFOX6 #6 → CRT (cape) + Pembrolizumab #6 → TME	NAR score: 14.08 *vs* 11.53 (NS); pCR: 29.4% *vs* 31.9% (NS)
AVERECTAL [41,111,112]	NCT03503630	cT2N+ or cT3-4aNany	pCR	SCRT → mFOLFOX6 + Avelumab #6 → TME	pCR: 37.5%
Lin *et al*[42]	NCT04231552	Stage II or III	pCR	SCRT → CAPOX + Camrelizumab #2 →TME	pCR: 48.1% (13/27), 46.2% (12/26) for pMMR, 100% (1/1) for dMMR
TORCH[43, 113] ongoing	NCT04518280	cT3-4 or cN+	cCR or pCR	A: SCRT → CAPOX + toripalimab #6 → TME or WW; B: CAPOX + toripalimab #2 → SCRT → CAPOX + toripalimab #4 → TME or WW	(Preliminary) cCR + pCR: 81.3% (13/16 MSS patients); group A (n = 7): cCR 1, pCR 4, near pCR 1; group B (n = 9): cCR 4, pCR 4
Cercek *et al*[20] ongoing	NCT04165772	cT3-4 or cN+ with dMMR or MSI-H	cCR, pCR, overall response	Dostarlimab #9 → if cCR → WW; if residual+ → CRT → WW (cCR) or TME (residual+)	cCR: 100%
PRIME-RT[45] ongoing	NCT04621370	cT3b+ or EMVI+ or CRM ≤ 2 mm or a low rectal tumor requiring abdomino-perineal excision	cCR or pCR	A: (SCRT → mFOLFOX6 #6) + durvalumab #4 → S or WW; B: (CRT → mFOLFOX6 #4) + durvalumab #4 → S or WW	
EA2201[46] ongoing	NCT04751370	cT3-4 or cN+ with dMMR or MSI-H	pCR	Ipilimumab/Nivolumab #2 → SCRT → Ipilimumab/Nivolumab #2 → TME	
Qiu[47] ongoing	NCT04636008	cT2 or higher with dMMR or MSI-H	Adverse reaction after neoadjuvant treatment and perioperative complications	SCRT + Sintilimab #3 → TME or WW	

5-FU: 5-fluorouracil; AV: Anal verge; cape: Capecitabine; cCR: Clinical complete response; CRM: Circumferential resection margin; CRT: Chemoradiotherapy; dMMR: Deficient mismatch repair; EMVI: Extramural vascular invasion; MMR: Mismatch repair; MRF: Mesorectal fascia; MSI-H: High microsatellite instability; MSS: Microsatellite stable; NAR: Neoadjuvant rectal; NS: Not significant; pCR: Pathologic complete response; pMMR: Proficient mismatch repair; S: Surgery; SCRT: Short-course radiotherapy; TME: Total mesorectal excision; WW: Watch-and-wait.

neoadjuvant treatment, owing to the accumulation of clinical evidence supporting the safety of WW [58]. Although there was no difference in DFS, LR, and OS between mFOLFOX6 with or without RT in FOWARC[12] (Table 1 and Supplementary Table 1), a higher pCR rate in patients receiving RT supports the use of pelvic RT with a higher chance of organ preservation. Even in early rectal cancer with cT2-3abN0, CRT or SCRT followed by local excision or WW has achieved excellent pCR or organ preservation rates[59,60]. These trends emphasize the importance of RT in future neoadjuvant treatment regimens for rectal cancers.

Organ preservation

There is a growing demand for organ preservation to avoid surgical complications or permanent colostomy, which translates into an improved quality of life after treatment for LARC. Various efforts have been made to increase the cCR rate[61]: Escalating the radiation dose, increasing the interval between RT and surgery, and adding consolidation CT before surgery[58,62,63]. When combined with conventional CRT, these approaches increase the rate of cCR, but not survival outcomes[64-66].

A meta-analysis revealed that the TNT approach showed a better pCR rate and survival outcomes than conventional CRT[67], suggesting that the TNT approach is a good option for organ preservation with survival benefits. Based on the results of CAO/ARO/AIO-12[22,23] and OPRA[24], consolidation CT is preferred when using CRT in the WW strategy. Preliminary results of a Chinese phase II RCT also showed the highest CR rate (pCR + sustained cCR) in the consolidation group (22.9% in the CRT group *vs* 28.6% in the induction group *vs* 42.1% in the consolidation group)[68].

Although data on the WW strategy after SCRT are limited, SCRT followed by consolidation CT appears to be an option for organ preservation based on the following evidence. SCRT followed by at least 4 cycles of consolidation CT was associated with significantly better pCR and DFS rates than conventional CRT in a meta-analysis[69]. Studies using SCRT followed by consolidation CT reported similar cCR, LR, and TME-free survival rates as those reported in studies using CRT[24,70,71]. Based on the results of a meta-analysis, at least 4 cycles of consolidation CT after SCRT should be considered[69]. However, the optimal duration of consolidation CT needs to be determined to avoid undertreatment or overtreatment.

Based on the high response rates reported in the AVERECTAL[41], Lin *et al*[42]'s, and TROCH[43] trials, despite the limited data on the role of immunotherapy combined with (C)RT, SCRT-based TNT plus ICIs seems plausible for the WW strategy in MSS LARC. In patients who cannot tolerate intensive CT, CRT with concurrent or consolidation ICIs may be an option for organ preservation, given that the pCR rate (23%-30%) of these approaches seems to be higher than that of traditional CRT[16-18]. The results of ongoing trials of SCRT combined with ICIs (Table 2 and Supplementary Table 1) are anticipated because hypofractionated RT has better immunostimulatory effects than prolonged RT; this will be discussed in a later section. Induction CT combined with ICIs is discouraged based on the results of NRG-GI002[19]. Extremely high response rates (up to 100%) to immunotherapy alone, shown in retrospective[72] and prospective[20] studies, support the use of immunotherapy alone for dMMR LARC. However, in dMMR LARC with high tumor burden, immunotherapy alone may be insufficient to eliminate all the tumor cells in the body when considering the association between tumor burden and the response to immunotherapy[73]; therefore, the combination of RT and immunotherapy may be needed for dMMR LARC. To provide individualized treatment, future trials should focus on identifying the optimal combination of RT, CT, and ICIs.

RT-RELATED ISSUES

Although the treatment outcomes of the aforementioned clinical trials using traditional target volumes and radiation doses are promising, the current practice of RT for LARC may not be optimal for the combination with TNT and ICIs. The following sections provide clinical and radiobiological evidence for the RT details that would be suitable for the combination therapies in LARC.

RT dose without immunotherapy

The current guidelines typically recommend the conventional long-course RT of 50-50.4 Gy in 25-28 fractions with concurrent CT as neoadjuvant treatment for LARC, with a total dose of ≥ 54 Gy in patients with unresectable tumors or patients who desire organ preservation[25,27,57]. Appelt *et al*[74] reported a positive dose-response relationship for pathologic tumor regression, and two meta-analyses revealed a high pCR rate of 24%-28% with a total dose of ≥ 54 Gy (mostly 1.8-2.2 Gy per fraction) with or without CT intensification[66,75]. However, because no dose-response relationship or survival benefit has been proven for a total dose > 54 Gy, the impact of such high doses is unclear[66,75]. In addition, surgical complications can occur more frequently with equivalent dose in 2 Gy fractions > 58.9 Gy[66]. Thus, total doses of 54-56 Gy with induction or consolidation CT have been used in studies with the intent of organ preservation in LARC[24,62,76].

Traditionally, a total dose of 25 Gy in 5 fractions has been used for SCRT as the sole neoadjuvant treatment for LARC, with a pCR rate of approximately 10%[77]. SCRT (25 Gy in 5 fractions) followed by consolidation CT achieved a higher pCR rate (17%-28%) than conventional CRT (12%-14%)[13,15]. A single institutional retrospective study reported that SCRT (25-30 Gy in 5 fractions) followed by FOLFOX or CAPOX achieved a cCR rate of 50%, persistent cCR rate of 79% in the WW cohort, and a 2-year TME-free survival rate of 40% (69% in patients with cCR)[71]. Although the same institute reported a high 1-year cCR rate of 70% in 19 patients who were treated with dose-escalated SCRT (30 Gy to the primary tumor and 35 Gy to the extramesorectal LNs in 5 fractions) followed by FOLFOX or CAPOX [78], further studies are warranted to evaluate the benefits and toxicities of radiation dose escalation in SCRT-based TNT due to a paucity of data in this area.

RT dose with immunotherapy

Recent prospective studies combining ICIs with RT (Table 2) used traditional dose-fractionation schedules in LARC: Conventional RT (45-50.4 Gy with 1.8-2 Gy per fraction) or hypofractionated RT (25 Gy with 5 Gy per fraction). Different immunological effects between conventionally fractionated and hypofractionated schedules have been reported, mainly in murine cancer models.

In a murine colon cancer model (CT26), conventional RT (5 × 2 Gy or 18 × 2 Gy) exerted immunosuppressive effects by upregulating PD-L1 expression in tumor cells and inducing immunosuppressive myeloid cells (myeloid-derived suppressor cells and tumor-associated macrophages 2)[36,79]. The negative impact on local tumor control and survival of mice was reversed by the addition of programmed death receptor-1 (PD-1)/PD-L1 inhibitors to fractionated RT. In addition, the combination of ICIs and CRT is supported by an increase in TMB, a known predictor of response to immunotherapy [80], in patients with LARC treated with neoadjuvant CRT[40,81]. Seo *et al*[40] reported that CRT decreased the mRNA expression levels of 23 MMR-related genes in LARC. Furthermore, loss of the MMR protein has been observed after neoadjuvant CRT for LARC[38-40,82]. These results explain the high pCR rates (23%-30%) of conventional CRT (45-50.4 Gy in 25-28 fractions) combined with ICIs in VOLTAGE-A[16], AVANA[17], and R-IMMUNE[18]. With insufficient data, it is unclear whether RT dose escalation in neoadjuvant CRT for LARC is beneficial.

Hypofractionated RT using a large fractional dose appears to be more efficacious when combined with ICIs, compared with conventional RT. Preclinical studies have reported that various schedules using 5-8 Gy per fraction elicited CD8+ T cell-mediated immune responses effectively in irradiated local tumors and non-irradiated distant tumors (the abscopal effect) when combined with various immunotherapeutic agents[34,79,83]. Dendritic cells had a higher homing ability to lymphoid tissues when they received an RT dose ≥ 5 Gy than when they received 10 × 2 Gy[84]. Radiation-induced lymphopenia is a known negative prognostic factor for tumor response or oncologic outcomes in various solid tumors, including rectal cancer[85-87]. Moreover, persistent lymphocyte depletion is associated with poor treatment outcomes after immunotherapy for various solid tumors[88]. Hypofractionated schedules was associated with less lymphocyte depletion or faster recovery after treatment in several tumor sites[89-92]; this supports the use of neoadjuvant SCRT in combination with immunotherapy over protracted conventional CRT. The higher tumor response rates of SCRT followed by consolidation CT plus ICI in prospective studies[41-43] (*vs* in trials of CRT plus ICIs[16-18]) may facilitate the use of SCRT in the neoadjuvant treatment regimen for LARC, although the exact causes of this difference cannot be explained, except by the difference in the use of consolidation CT. Nonetheless, since it is unknown whether a combination of the traditional regimen of 25 Gy in 5 fractions with immunotherapy is optimal, further studies are warranted to determine the optimal dose-fractionation regimen, especially in terms of dose escalation.

RT field

Traditional RT fields include GTVs and regional lymphatics with subclinical nodal metastases. When RT is combined with immunotherapy, elective nodal irradiation (ENI) is not recommended for the following reasons. First, irradiation to tumor-draining LNs can reduce RT-mediated immune responses. Tumor-draining LNs where cytotoxic CD8+ T cells are activated by dendritic cells, are important for RT-induced immunologic cell death[33,93]. In a murine melanoma model (B16F10), irradiation to tumors (1 × 10 Gy) and tumor-draining LNs (3 × 3 Gy) reduced the response of both irradiated and non-irradiated tumors compared to tumor-only irradiation[93]. In another murine colorectal carcinoma model (MC38), a single 12-Gy ENI reduced intratumoral infiltration of functional antigen-specific CD8+ T cells[94]. Second, severe lymphopenia, which has a negative effect on immunotherapy, can occur because of the large RT field that includes the elective nodal area[95,96].

Although a CTV including the primary tumor and mesorectum below the S2/S3 interspace was safe in patients with T2 low-lying/T3, N0-N1 rectal cancers without lateral LN metastasis in a prospective phase II trial[97], there is no clinical evidence against ENI in the neoadjuvant setting of LARC. Future studies should weigh the immunologic benefit of no ENI and risk of recurrence following undertreated metastatic LNs. Nevertheless, since the tumor response to whole pelvic RT combined with ICIs is promising in early-phase clinical trials (Table 2 and Supplementary Table 1), long-term patterns of failure and survival data are anticipated.

RT planning

For a long time, radiation oncologists have tried to lower radiation doses to normal pelvic organs to reduce acute and chronic gastrointestinal and genitourinary toxicities after pelvic RT. The importance of lymphocyte-sparing RT has recently emerged in the era of immunotherapy[98]. There are several reasons supporting the need of lymphocyte sparing during the neoadjuvant pelvic RT of LARC. Approximately one-quarter of the proliferating bone marrow of the body is in the pelvis[99]. Permanent aplasia in irradiated bone may occur with irradiations > 30 Gy[100]. Fatty changes in the pelvic bone marrow are a common observation after CRT[101]. Pelvic RT for pelvic malignancies can cause prolonged lymphocyte depletion[102,103].

In addition to the dose-fractionation schedule and target volume size, the pelvic bone marrow and lymphocyte count can be influenced by the dose rate and delivery techniques such as 3D-RT and IMRT. Although IMRT can reduce acute gastrointestinal and genitourinary toxicities in LARC[104,105], it is unclear whether IMRT is superior to 3D-RT in terms of sparing of active bone marrow (or lymphocytes) [86,95]. The estimated mean dose to the entire circulating blood pool after 60 Gy in 30 fractions for glioblastoma was similar for 3D-RT and IMRT with a sliding window technique (2.4 Gy and 2.7 Gy) [95]. Patients with LARC treated with preoperative pelvic RT with helical tomotherapy showed

significantly higher rates of post-treatment neutrophil-lymphocyte ratios ≥ 4 than those treated with 3D-RT[86]. The impact of delivery techniques such as volumetric-modulated RT (VMAT) is unclear, which can deliver radiation doses faster with less low-dose spillage than other IMRT delivery modes such as step-and-shoot and sliding window techniques[106]. Kuncman *et al*[107] reported an association between the dose of active bone marrow on magnetic resonance imaging and absolute lymphocyte count nadir and platelet nadir. Huang *et al*[108] reported a lower incidence of acute hematologic toxicity with pelvic bone marrow-sparing IMRT (IMRT with sliding window or VMAT) using dosimetric constraints for the pelvic bone marrow of V10 ≤ 85%, V20 ≤ 65%, and V30 ≤ 45% (VX = volume receiving X Gy) than with non-sparing IMRT in patients with LARC treated with CRT. Therefore, it is necessary to determine the optimal dose constraints for the pelvic bone (or bone marrow) and proper dose delivery techniques to enhance the effects of immunotherapy.

CONCLUSION

Recent phase II/III RCTs have confirmed the benefits of the TNT approach combined with conventional CRT or SCRT in terms of oncologic outcomes and organ preservation in LARC. The results of prospective phase I/II studies suggest the possibility of conventional CRT or SCRT in combination with immunotherapy for LARC. Preclinical and clinical evidence suggests the RT details which may be suitable for the neoadjuvant pelvic RT as a part of TNT or in combination with immunotherapy. However, further studies are warranted to identify optimal RT strategies with the potential of maximizing the effects of neoadjuvant treatment with TNT and immunotherapy.

Abstract

One of the significant health issues in the world is the prevalence of ulcerative colitis (UC). UC is a chronic disorder that mainly affects the colon, beginning with the rectum, and can progress from asymptomatic mild inflammation to extensive inflammation of the entire colon. Understanding the underlying molecular mechanisms of UC pathogenesis emphasizes the need for innovative therapeutic approaches based on identifying molecular targets. Interestingly, in response to cellular injury, the NLR family pyrin domain containing 3 (NLRP3) inflammasome is a crucial part of the inflammation and immunological reaction by promoting caspase-1 activation and the release of interleukin-1β. This review discusses the mechanisms of NLRP3 inflammasome activation by various signals and its regulation and impact on UC.

Key Words: Ulcerative colitis; NLR family pyrin domain containing 3 inflammasome; Therapeutic strategies; Phytochemicals; Probiotics

Core Tip: Ulcerative colitis (UC) is a common chronic type of inflammatory bowel disease that affects a significant number of populations. Needing to counteract the UC prevalence, attract scientists to study its pathological mechanism deeply. NLR family pyrin domain containing 3 (NLRP3) inflammasome has been observed to have a crucial role in the pathological features of UC. Targeting NLRP3 inflammasome signals with phytochemicals, plants, probiotics, and chemical agents could be promising candidates for fixing the UC problem.

INTRODUCTION

Inflammatory bowel diseases (IBD), most referred to as Crohn's disease and ulcerative colitis (UC), are chronic, idiopathic disorders characterized by intestinal inflammation that have increased incidence and prevalence over time and in various countries worldwide[1-3]. The global prevalence is expected to impact up to 30 million by 2025[4]. Several factors are known to play a considerable role in disease pathogenesis. IBD has been linked to genetic etiology and other variables such as pathogens, appendectomy, stress, and air pollution[5,6]. UC is a chronic disorder that mainly affects the colon, beginning with the rectum and perhaps progressing to inflammation of the entire large intestine[7]. UC can begin with severe illnesses such as melena, diarrhea, and mucus production[8,9], and often between the ages of 50 years and 80 years[3,10,11].

A family history of IBD elevates the potential risk of UC, and first-degree relatives are four times more likely to acquire the disease, suggesting that genetic factors are likely related to UC[12,13]. Also, environmental factors play a crucial role in its development[14]. About 110 of the 163 susceptibility loci (67%) encode innate and adaptive immunity pathways, cytokine signaling, and immunological sensing. Several other autoimmune diseases, including psoriasis and ankylosing spondylitis, share many of these genes[15,16]. Additionally, many UC-specific genes have a role in controlling epithelial barrier function [17,18].

The gastrointestinal mucosa is susceptible to many antigens from food, the environment, and the microbiome[19]. The mucin layer that covers the epithelium, the mucosa's outer layer, serves as the gut immune system's first line of defense since it physically separates antigens from gut immune cells and has antimicrobial capabilities. Patients with active UC have been demonstrated to have a thinner mucin-containing mucosal layer in the colon, primarily due to a reduction in mucin 2 production[20]. In addition, exposure to potentially harmful stimuli such as nonsteroidal anti-inflammatory drugs and food components such as emulsifiers may prompt colitis[21,22]. Moreover, dysbiosis reduces short-chain fatty acid synthesis, which is required for epithelial energy supply and mucus formation[23]. On the same approach, UC has been attributed to a decrease in short-chain fatty acid-producing *Ruminococcaceae* and *Lachnospiraceae* and an increase in pro-inflammatory microorganisms such as Enterobacteriaceae[24,25].

When the epithelium is damaged, the mucosa becomes more permeable to luminal pathogens, increasing the absorption of these antigens and possibly activating gastrointestinal tract immunity[26,27]. Since it is the link between the host immune response repertoire and the intestinal microbiota, the intestinal epithelium plays a crucial role in the innate immune system[28]. Antigens activate the innate immune response *via* antigen-presenting cells and T cells, which evoke an inflammatory response that activates the adaptive immune system[27,29]. Mechanistically, mature dendritic cells express a lot of Toll-like receptors (TLR), which activate multiple transcription factors like nuclear factor-κB (NF-κB), which in turn causes an inflammatory response in UC[30,31]. These inflammatory cascades result in the production of pro-inflammatory cytokines such as tumor necrosis factor-alpha (TNF-α) and interleukins (IL)[26,27,29]. These pro-inflammatory cytokines have critical roles in signaling through intracellular proteins, including Janus kinase (Jak), which enhances lymphocyte activation and proliferation[32,33]. Interestingly, innate immune signaling *via* cytokine receptors, TNF receptors, and TLR-adaptor myeloid differentiation as a primary response promotes NLRP3 transcription and oligomerization through NF-kB activation[34,35]. Figure 1 outlines this inflammatory response inside the colon in IBDs, including UC.

DOI: 10.3748/wjg.v29.i6.1026 **Copyright** ©The Author(s) 2023.

Figure 1 Inflammatory response inside the colon in inflammatory bowel diseases including ulcerative colitis. Several inflammatory pathways are involved in ulcerative colitis (UC), which result in increased inflammatory mediators and cytokines and subsequent activation of inflammatory cells. First, activation of Toll-like receptors (TLR) by pathogen associated molecular pattern (PAMP), bacteria and viruses as well as tumor necrosis factor-alpha receptor (TNFR) stimulation by TNF-α, induce nuclear factor-κB (NF-κB) translocation through upregulation of MyD88 and IK-β, P50, and P65 complex. Second, along with NF-κB upregulation, interleukin receptor stimulation by interleukin (IL)-1β and/or IL-6 activates signal transducer and activator of transcription 3 signalling activation. Third, damage associated molecular pattern and/or PAMP are stimulates mitochondria to generates reactive oxygen species (ROS) which enhances inflammatory response through NF-κB activation whereas activating nuclear factor erythroid 2-related factor 2 signalling by ROS suppresses the inflammatory response by blocking NF-κB signalling and inducing antioxidants that downregulates ROS. IBDs: Inflammatory bowel diseases; UC: Ulcerative colitis; IL-(1β): Interleukin-1 beta; DAMP: Damage associated molecular pattern; PAMP: Pathogen associated molecular pattern; TNF-α: Tumour necrosis factor-alpha; ILR: Interleukin receptor; TLR: Toll-like receptor; TNFR: Tumour necrosis factor receptor; MyD88: Myeloid differentiation primary response 88; IK-β: Inhibitor *kappa*-beta; P50: Nuclear factor-kappa B P50 subunit; P65: Nuclear factor-kappa B P65 subunit; ROS: Reactive oxygen species; STAT3: Signal transducer and activator of transcription 3; NF-κB: Nuclear factor-kappa B; Nrf2: Nuclear factor erythroid 2-related factor.

NLRP3 INFLAMMASOME OVERVIEW

The innate immune system is the primary mechanism by which most organisms respond quickly to diseases or injury. Pattern-recognition receptors (PRRs) are activated by the host and identify chemicals released by infections or damaged cells. Pathogen-associated molecular patterns and damage-associated molecular patterns are the names of these molecular signals[36]. Numerous intracellular DNA sensors, TLRs, nucleotide-binding and oligomerization domain (NOD)-like receptors, C-type lectin receptors, RLRs, and NOD-inducible gene-I-like receptors are among the numerous members of the PRR family [37].

A multi-protein complex NLRP3 inflammasome is a type of PRR essential for the host's innate defenses against bacterial, fungal, and viral infections[38-41]. However, when it is dysregulated, it has been connected to the pathogenesis of many inflammatory-associated diseases, including cancer, neuroinflammation, retinopathy, stroke, diabetes, atherosclerosis, and autoinflammatory diseases[42-46]. The three protein components that make up NLRP3 are an amino-terminal pyrin domain (PYD), a NOD, and a leucine-rich repeat domain at the protein's C-terminus[47]. Apoptosis-associated speck-like protein (ASC) is composed of two proteins, pyrin and a caspase-recruitment domain (CARD), but their interaction to initiate inflammasome assembly facilitates it to recruit pro-caspase-1 to the inflammasome complex[48,49].

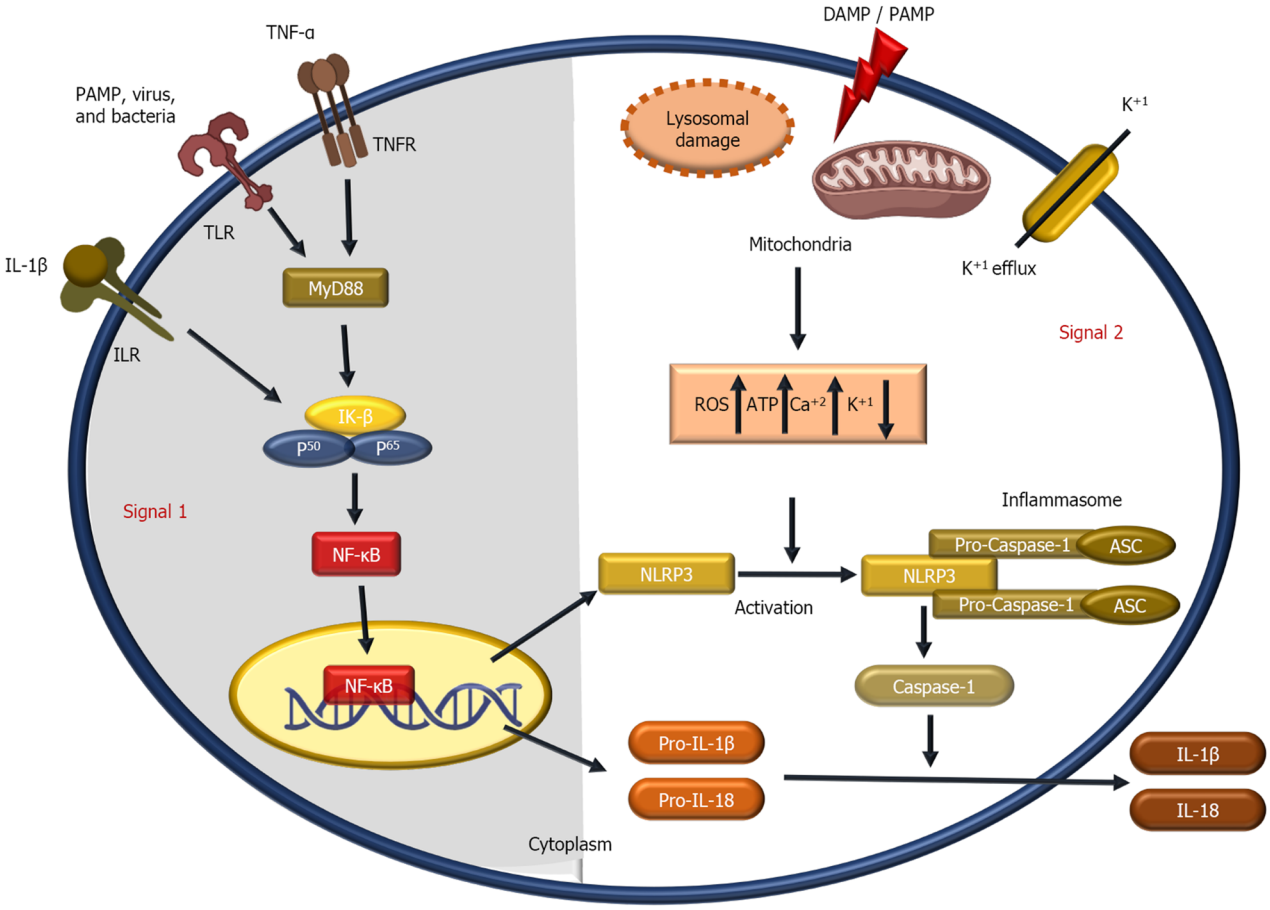
The activation of the NLRP3 inflammasome is essentially caspase-1 autocatalysis. Once turned on, NLRP3 functions as a sensor molecule that self-oligomerizes and recruits ASC through homotypic PYD-PYD interaction, causing ASC to assemble into sizable speck-like formations. Caspase-1 is then autocatalytically activated as aggregated ASC recruits pro-caspase-1 through CARD-CARD interaction. Proteolytic activation of the pro-inflammatory cytokines IL-1β and IL-18 and the soluble cytosolic protein gasdermin D (GSDMD) is the function of activated caspase-1 heterotetramers. Following

proteolysis, the oligomerized gasdermin N can bind membrane lipids and create membrane pores to mediate the release of IL-1β and IL-18 outside the normal secretory pathway. In parallel, cells go through pyroptosis, a pro-inflammatory cell death[50-53]. IL-1β stimulates endothelial cell response by allowing immune cell infiltration into infected or injured tissues *via* the activation of genes that regulate temperature, pain threshold, vasodilation, and hypotension[54]. IL-18 is a co-stimulatory cytokine necessary for mediating adaptive immunity through the influence of interferon-gamma production[54].

MECHANISMS OF NLRP3 INFLAMMASOME ACTIVATION

It is believed that several cellular signals, including ion fluxes (K^+ efflux, Cl^- efflux, Ca^{2+} influx, and Na^+ influx), mitochondrial dysfunction, and reactive oxygen species (ROS) generation, are responsible for NLRP3 inflammasome activation[55-60]. In addition, heme[61,62], particulate matter[56,63,64], pathogen-associated RNA[65-68], and bacterial and fungal toxins[69,70] are also considered NLRP3 activators.

NLRP3 activators require a priming signal (signal 1) to be activated[71]. TLRs, NOD-like receptors (*e.g.*, NOD1 and NOD2), or cytokine receptors such as TNF-α and IL-1β, bind to stimuli in the priming signal, which is crucial for macrophage stimulation. Pro-IL-1β, which is not constitutively produced in inactive macrophages, is upregulated by NF-κB. In addition, NF-κB also upregulates the expression of NLRP3, which is assumed to exist in quantities insufficient for starting inflammasome activation during rest[71,72]. In contrast, priming signals are not crucial for ASC, pro-caspase-1, and pro-IL-18 production levels[71]. Inflammasome activation and NLRP3 self-association are regulated by the priming signal's induction of Jun N-terminal 1-mediated phosphorylation of NLRP3[73].



Ca^{2+} is necessary for NLRP3 inflammasome activation by interacting with inositol 1,4,5-trisphosphate, a byproduct of phosphatidylinositol 4,5-bisphosphate hydrolysis catalyzed by phospholipase C, and the inositol 1,4,5-trisphosphate receptor on the endoplasmic reticulum, which promotes Ca^{2+} mobilization and NLRP3 inflammasome activation[60]. The NLRP3 inflammasome is activated by excessive ER Ca^{2+} release associated with mitochondrial damage and results in ROS production and an excess of Ca^{2+}[74-76]. Additionally, K^+ efflux and a reduction in intracellular K^+ are upstream events in NLRP3 activation [59,77]. The NLRP3 inflammasome also needs K^+ efflux for NLRP3 formation, according to a recently discovered component called NIMA-related kinase 7 (NEK7), which may directly bind to NLRP3 protein[78,79]. Various substances can increase ROS generation and induce NLRP3 activation without requiring K^+ efflux[80,81]. Na^+ influx-induced NLRP3 activation also relies on K^+ efflux[59]. Reducing the concentration of extracellular Cl^- activates caspase-1 and the generation of IL-β1[82]. An anion channel called the intracellular chloride channel has the potential to activate the volume-regulated anion channel. It is intriguing since the K^+ efflux-mitochondrial ROS axis was shown to be a downstream event of chloride intracellular channel-dependent chloride efflux. Intracellular chloride channel-mediated chloride efflux can encourage NEK7-NLRP3 association and subsequent ASC oligomerization[83].

ROS are one of the earliest identified triggers to engage the NLRP3 inflammasome. Lysosomal NADPH oxidase was once believed to be the source of ROS formation, even though mitochondria are the primary site of ROS production[59,84]. According to several studies, most NLRP3 inflammasome agonists have been shown to produce mitochondrial ROS in various cell types[63,85-88]. NADPH oxidase 4 (NOX4) has also been shown to influence carnitine palmitoyl transferase 1A and promote fatty acid oxidation, which aids NLRP3 activation[89].

Lysosomal destabilization contributes to NLRP3 activation in both phases (signal 2) and the priming step (signal 1); in palmitate-induced NLRP3 activation. By controlling the stability of the IL-1 mRNA, lysosomal calcium signaling controls the production of pro-IL-1β (signal 1), whereas cathepsin B, a lysosomal protease, contributes to the NLRP3 activation[90]. It has been hypothesized that acidic conditions are necessary for monosodium urate crystals to activate the inflammasome within lysosomes as the significant Na^+ release raises the cellular osmolality and water influx and lowers intracellular K^+ concentration[91].

POST-TRANSCRIPTIONAL MODIFICATIONS OF NLRP3

Protein folding, localization, and functional activity are all controlled by post-translational modifications. Numerous post-translational modifications have been shown to affect innate immunity by affecting immune cells' activation, survival, differentiation, and migration[92]. NLRP3 is ubiquitylated in dormant macrophages and deubiquitylated following activation and priming[93]. For the NLRP3 inflammasome to activate, the linear ubiquitin assembly complex must selectively ubiquitylate NLRP3 and ASC[94]. TLR priming enhances NLRP3 self-association and activation by causing Jun N-terminal kinase 1 to phosphorylate NLRP3[95]. The mechanism of NLRP3 inflammasome activation is outlined in Figure 2.

DOI: 10.3748/wjg.v29.i6.1026 **Copyright** ©The Author(s) 2023.

Figure 2 The mechanism of nod-like receptor protein-3 inflammasome activation. Nod-like receptor protein-3 (NLRP3) inflammasome activation occurs through two signals, (signal 1) toll-like receptor stimulation by pathogen associated molecular pattern (PAMP), bacteria and viruses, tumour necrosis factor receptor stimulation by TNF-α, and interleukin receptor (ILR) stimulation by IL-1β leads to activation of nuclear factor-kappa B (NF-Kb) *via* upregulation of MyD88, and Iκ-β, P50, and P65 complex. Pro-IL-1β, pro-IL-18, and inactive NLRP3 expression were all increased by the translocation of activated NF-κB into the nucleus. (Signal 2) Increased intracellular reactive oxygen species, adenosine triphosphate, and Ca^{+} levels are caused by damage associated molecular pattern and PAMP-induced lysosomal damage, and mitochondrial dysfunction, while K^{+} efflux lowered intracellular K^{+} level. The previous intracellular events lead to activates NLRP3 to inflammasome that promotes caspase-1 which begin to convert pro-IL-1β and pro-IL-18 into IL-1β and IL-18. IL-(1β): Interleukin-1 beta; DAMP: Damage associated molecular pattern; PAMP: Pathogen associated molecular pattern; TNF-α: Tumour necrosis factor-alpha; ILR: Interleukin receptor; TLR: Toll-like receptor; TNFR: Tumour necrosis factor receptor; MyD88: Myeloid differentiation primary response 88; IK-β: Inhibitor *kappa*-beta; P50: Nuclear factor-kappa B P50 subunit; P65: Nuclear factor-kappa B P65 subunit; ROS: Reactive oxygen species; ATP: Adenosine triphosphate; Ca+: Calcium ion; K+: Potassium ion; NF-Kb: Nuclear factor-kappa B; NLRP3: Nod-like receptor protein-3; ASC: Apoptosis-associated speck-like protein.

THERAPEUTIC AVENUES FOR ULCERATIVE COLITIS TARGETED NLRP3 INFLAMMASOME SIGNAL

Phytochemicals and plant extracts

Naringin: Naringin is a flavonoid glycoside, rich in citrus fruits such as grapefruit and orange[96,97]. Naringin protects mice from obesity, azoxymethane/dextran sodium sulfate (DSS)-induced carcinogenesis, and acetic acid (AA)-induced colitis[98-100]. In 2018, Cao *et al*[101] revealed that naringin protects mice from DSS-induced UC owing to its NLRP3 inflammasome and mitogen-activated protein kinase (MAPK) inhibitory effects. Furthermore, it upregulated peroxisome proliferator-activated receptor γ (PPARγ) while suppressing NF-κB activation.

Chlorogenic acid: Chlorogenic acid (CGA) is a phenolic acid found in foods and many plants[102,103]. Zeng *et al*[104] reported that CGA prevented DSS-induced mice colitis by down-regulating miR-155 expression and suppressing NLRP3 and NF-κB in macrophages. CGA downregulates caspase-1, pro-cleaved-IL-1β, and pro-cleaved-IL-18 in mice with colitis. In line with this study, CGA ameliorates NLRP3 inflammasome in different models, such as CCl_4-induced acute liver injury[105] and lipopolysaccharide (LPS)-induced mice with acute lung injury[106].

1, 25-dihydroxy vitamin D3: Vitamin D (Vit D3) is a fat-soluble vitamin that maintains calcium and phosphorus homeostasis[107]. Significantly, Vit D3 ameliorates the NLRP3 inflammasome in variant mouse models like periodontitis[108], diabetes-induced retinal vascular damage[109], nitrogen mustard-induced cutaneous inflammation[110], hyperosmotic stress-induced injury[111], cisplatin-induced acute renal injury[112], and allergy inhibition[113]. Cao *et al*[114] reported that it suppresses NLRP3 inflammasome activation, NLRP3-mediated ASC oligomerization, caspase-1 activation, and IL-1β production. Also, NLRP3 binding to NEK7 was inhibited in DSS-induced UC.

Ginsenosides: Ginsenosides are the most significant phytochemical of ginseng obtained from the *Panax* species family *Araliaceae*[115,116]. Ginsenoside Rk3 (Rk3) is a tetracyclic triterpenoid reportedly found in Radix notoginseng herbs[117]. Tian *et al*[118] revealed that Rk3 protects against DSS-induced UC by suppressing NLRP3 expression. Rk3 administration significantly attenuated myeloperoxidase (MPO), inducible nitric oxide synthase activities, and downregulated NLRP3, ASC, and caspase-1 expression. Ginsenoside Rd (Rd) is another ginsenoside that inhibits NLRP3 in UC[119]. Rd suppresses NLRP3 activation and decreases caspase-1 production and IL-1β levels in DSS-induced UC. Also, Rd inhibits MPO and inducible nitric oxide synthase activities while increasing antioxidant glutathione content [120].

Phloretin: Phloretin (PHL) is a flavonoid found in fruit, leaves, and roots of the apple tree *Malus domestica*[121,122]. Zhang *et al*[123] demonstrated that PHL suppressed DSS-induced NLRP3 inflammasome activations and regulated the NF-κB, TLR4, and PPARγ pathways. Moreover, PHL attenuated oxidative stress and regulated the expression of ZO-1 and occludin. In the same context, Wu *et al*[124] found that PHL ameliorated UC by suppressing NF-κB and NLRP3 activation. Additionally, it decreases cytokines and oxidative injury while maintaining intestinal barrier integrity.

Cinnamaldehyde: Cinnamaldehyde (CA) is the principal constituent of the bark of *Cinnamomum cassia* and *C. verum*[125]. CA suppresses NLRP3 in several models like rheumatoid arthritis[126], endotoxin-poisoned mice[127], cardiac ischemia-reperfusion[128], fructose-induced cardiac inflammation and fibrosis[129], and LPS-induced renal inflammation[130]. CA mitigates DSS-induced colitis by suppressing NLRP3 activation and miR-21, miR-155, IL-1β, and IL-6 levels. Furthermore, the suppression of NLRP3, miR-21, and miR-155 was observed in CA-treated, LPS-stimulated RAW264.7 cells. The production ROS and protein kinase B/mammalian target of rapamycin phosphorylation was also reduced[131].

Palmatine: Palmatine is an isoquinoline alkaloid found in traditional Chinese medicine (TCM), including *Fibraurea spp.*, *Corydalis spp.*, *Berberis spp.*, and *Phellodendron spp*[132-134]. Palmatine suppresses NLRP3 inflammasomes in different models, like hyperuricemia-induced kidney injury[135] and monosodium uric acid-induced gouty arthritis[136]. Mai *et al*[137] revealed that palmatine attenuates DSS-induced colitis in mice by suppressing NLRP3 inflammasomes and decreasing the colonic levels of MPO, IL-1β, and TNF-α. In 2022, Cheng and co-workers recently suggested that 8-oxypalmatine exerted an appreciable protective effect on DSS-induced colitis, suppressing the NLRP3 inflammasome and activating the nuclear factor erythroid 2-related factor 2 (Nrf2) pathway[138].

L-fucose: L-fucose, a naturally safe monosaccharide found in animals, is often utilized as a food ingredient[139,140]. L-fucose attenuates colitis by suppressing NLRP3 inflammasome and NF-κB activation, decreasing pro-inflammatory cytokines, and reducing neutrophil and macrophage infiltration[141].

Genistein: Genistein (Gen) is a significant isoflavone in soy[142]. Gen suppresses the NLRP3 inflammasome in macrophages by activating the G protein–coupled receptor 5-cAMP signal in DSS-induced UC mice. Additionally, the Gen administration boosted intracellular cAMP levels and decreased caspase-1 and IL-1β levels[143]. In agreement with this study, Gen suppressed the NLRP3 inflammasome in different models, such as cerebral ischemia in mice[144], H_2O_2-induced senescence of human umbilical vein endothelial cells[145], hippocampal neurons in aging rat brain tissue[146], and alloxan-induced diabetes in mice[147].

Sinapic acid: Sinapic acid (SA) is a phytochemical abundant in various food plants, including spices, citrus and berry fruits, cereals, and others[148-150]. SA was shown to have potential therapeutic efficacy in inhibiting NLRP3-associated inflammatory disorders[151]. In conjunction with that, SA upregulated tight junction protein-1 (ZO-1) and claudin-1 in DSS-induced UC, suppressing the NLRP3 activation and attenuating intestinal permeability. Additionally, SA attenuates oxidative injury by boosting antioxidants superoxide dismutase, glutathione peroxidase, and catalase activity while lowering MPO and pro-inflammatory cytokine mRNA levels in circulation and colonic tissue[152].

Terpinen-4-ol: Terpinen-4-ol (TER) is a primary ingredient in *Zanthoxylum bungeanum* Maxim's essential oil[153]. Zhang *et al*[154] investigated whether the protective effect of TER may be substantially related to its suppression of NLRP3 activation in DSS-induced colitis. TER balanced the amounts of *Lactobacillus* and *Escherichia coli* while lowering the plasmatic LPS content. Additionally, TER inhibited the

breakdown of the colon epithelial barrier by controlling the expression of ZO-1 and occluding and decreasing IL-1β production.

Apigenin: Apigenin (API) is a flavone found in many vascular plants' leaves, vegetables, stems, and fruits[155]. According to Márquez-Flores *et al*[156], API anti-inflammatory activity was attributed to a suppression of the NLRP3 inflammasome by lowering levels of pro-inflammatory cytokines and oxidative stress as a result of controlling the activity of cleaved caspase-1 and caspase-11 enzymes. In agreement with this study, API suppresses NLRP3 inflammasome activation in high-fat diet-induced non-alcoholic fatty liver disease[157], palmitic acid-induced liver injury[158], arteriosclerosis[159], human umbilical vein endothelial cells inflammation[160], depression in chronic unpredictable mild stress rats[161], and doxorubicin-induced renal injury[162].

Rosmarinic acid: Rosmarinic acid (RA) is a natural polyphenol found in plants from the *Labiatae* family [163]. RA down-regulates the NRLP3-inflammasome in neuroinflammation[164], acetaminophen-induced liver injury[165], and nicotine-induced atherosclerosis[166]. In 2021, Marinho *et al*[167] demonstrated that RA-loaded nanovesicles enhanced Nrf2 and heme oxygenase-1 expression while decreasing NLRP3 inflammasome, ASC, and caspase-1 protein expression and IL-1β levels. RA also reduces TNF-α and MPO activity.

Lonicerin: A flavonoid glycoside, lonicerin, is extracted from the plant *Lonicera japonica* Thunb. It treats infectious and inflammatory diseases[168,169]. Numerous investigations have shown that lonicerin is among the main ingredients with anti-inflammatory and immunomodulatory properties[170]. Lv *et al* [165] suggested that lonicerin reduces colitis through NLRP3-ASC-pro-caspase-1 complex assembly. Lonicerin has a therapeutic impact on intestinal inflammation by directly binding to the histone methyltransferase enhancer of zeste homolog 2, which promotes autophagy and speeds up the destruction of NLRP3 by autolysosomes.

Magnesium lithospermate B: Magnesium lithospermate B (MLB) is the primary ingredient of *Salviae miltiorrhizae*[171]. It has been reported that MLB treats acute colitis[172,173]. Jiang *et al*[174] found that MLB might treat acute and chronic colitis by downregulating NLRP3, ASC, and caspase-1 levels.

Fumigaclavine C: Fumigaclavine C is an indole alkaloid obtained from endophytic *Aspergillus terreus* and *Rhizophora stylosa*[175,176]. According to Guo *et al*[177], fumigaclavine C attenuates DSS-induced colitis by decreasing pro-inflammatory cytokines TNF-α, IL-1β, and IL-17A, mediated by suppressing NLRP3 inflammasome and caspase-1 activation.

Nigeglanine: Nigeglanine is a phytochemical obtained from *Nigella sativa* oil[178]. According to a study conducted in 2019 by Gao *et al*[179], nigeglanine inhibits colon epithelial cell pyroptosis by suppressing the NLRP3 inflammasome, NF-κB, and MAPK in DSS-induced colitis in mice. Surprisingly, nigeglanine supplementation enhanced ZO-1 and occludin protein levels, indicating that nigeglanine protects barrier integrity.

Mycophenolate mofetil: Mycophenolate mofetil (MMF) is a fermentation byproduct of *Penicillium stoloniferum*[180-182]. MMF is an immunosuppressant commonly used to treat systemic lupus erythematosus, lupus nephritis, and other autoimmune disorders[183]. Serrya *et al*[184] observed that MMF had coloprotective effects against AA-induced UC by suppressing the NLRP3 inflammasome and consequent release of IL-1β, IL-18, and INF-γ. In colon tissues, MMF considerably reduced oxidative stress and boosted antioxidants glutathione, catalase, and superoxide dismutase levels as well as total antioxidant capacity mediated by upregulating Nrf-2.

Evodiamine: Evodiamine (EVO), a significant alkaloidal substance discovered from *Evodia rutaecarpa*, has long been used in TCM to treat various infection-related diseases, such as diarrhea, beriberi, and oral ulcers[185,186]. Additionally, EVO effectively treats nausea and abdominal discomfort[187]. Furthermore, EVO inhibits NLRP3 inflammasome activation, indicating the application of EVO in treating IBD[188] and enhancing innate immunity against bacterial infection[189]. In DSS-induced UC mice, EVO reduced inflammation by controlling the NF-κB signal and NLRP3 inflammasome, which reduced the production of TNF-α, IL-1β, and IL-6 and altered the expression of ZO-1 and occludin[190]. Similarly, Ding *et al*[188] showed that EVO inhibits NLRP3 inflammasome activation by enhancing autophagosome degradation and inhibiting the NF-κB pathway.

Brusatol: Brusatol is a major quassinoid of *Brucea javanica* used in treating inflammatory disorders, particularly intestinal inflammation, such as colitis and dysentery[191]. Zhou *et al*[192] revealed that the anti-UC activity of brusatol is closely related to the suppression of NF-κB and NLRP3 signals and the activation of Nrf2 expression-mediated anti-oxidative effects. The TNF-α, pro- IL-1β, IL-18, prostaglandin E2, and nitric oxide levels were significantly reduced by brusatol in LPS-stimulated macrophages.

Bergenin: Bergenin, a C-glycoside produced from 4-O-methyl gallic acid, is one of the primary active components of plants in the genus *Peltophorum*[193]. Bergenin reduces palmitic acid-induced pancreatic injury by suppressing NLRP3 activation[194]. Likewise, Lopes de Oliveira *et al*[195] showed that bergenin attenuates 2,4,6-trinitrobenzene sulfonic acid-induced acute colitis in rats. Bergenin decreased inflammatory cytokines levels mediated by suppressing phosphorated signal transducer and activator of transcription 3 (STAT3), NF-κB, and NLRP3/ASC inflammasome signals.

Wedelolactone: Wedelolactone is a coumarin obtained from plants found in *Wedelia chinensis*[196,197]. Wei *et al*[198] revealed that wedelolactone administration significantly suppressed NLRP3 and caspase-1 activation to reduce IL-1β production in DSS-induced UC. Wedelolactone also successfully maintains intestinal barrier function by activating AMP-activated protein kinase (AMPK).

Walnut oil: Walnut oil is commonly recommended as a nutritious, premium food oil and is used extensively in TCM[199]. Walnut oil has anti-inflammatory and antioxidant effects[200-202]. Miao *et al*[203] explored how walnut oil inhibits the NLRP3 inflammasome activation and modifies gut microbiota in DSS-induced colitis in mice. Walnut oil enhanced the levels of short-chain fatty acids and blocked apoptosis while reducing ROS generation and pro-inflammatory cytokines release by suppressing NLRP3, ASC, and caspase-1 activation.

Nigakinone: Nigakinone is the principal active ingredient of *Ramulus et Folium Picrasmae*, and it is one of the TCM substances frequently used to treat diarrhea, colitis, and dysentery[204]. In DSS-induced colitis, nigakinone alleviated symptoms by regulating the farnesoid X receptor/NLRP3 pathway[205].

Oroxindin: Oroxindin is a natural bioflavonoid that was identified in Huang Qin. Oroxindin has been shown in several studies to have a variety of bioactivities, including anti-inflammatory, antioxidant, and anticancer effects[206-208]. According to Liu *et al*[209], oroxindin reduces inflammatory responses by suppressing NLRP3 inflammasome activation and reducing colonic IL-1β and IL-18 Levels. Oroxindin modulated the production of thioredoxin interacting protein (TXNIP), reducing LPS-induced NLRP3 inflammasome and caspase-1 activation in cultured macrophages, hence decreasing TXNIP-dependent NF-κB activation.

Schisandrin B: Schisandrin B is the most significant component in *Schisandra chinensis*[210]. Schisandrin B suppresses NLRP3 inflammasome activation in LPS-induced airway inflammation and airway remodeling[211] and propionibacterium acnes-induced pyroptosis[212]. In 2021, Zhang *et al*[213] demonstrated schisandrin B reduces NLRP3 inflammasome activation mediated by IL-1β release in intestinal epithelial cells of a colitis model.

Trifolirhizin: Trifolirhizin is a pterocarpan identified from *Trifolium pratense* and *Sophora flavescens*[214,215]. Trifolirhizin treatment successfully controlled the balance of T helper/T regulatory (Th17/Treg) cells and inflammation in DSS-induced UC mice by suppressing NLRP3 activation by TXNIP. Trifolirhizin has also been shown to control the AMPK-TXNIP pathway[216].

Sanguinarine: Sanguinarine, benzylisoquinoline alkaloids, is obtained from *Sanguinaria canadensis* and *Fumaria*[217]. According to Li *et al*[218], sanguinarine showed a potential therapeutic impact on DSS-induced UC mice by suppressing NLRP3-(Caspase-1)/IL-1β pathway and enhancing gut microbial dysbiosis. Additionally, sanguinarine decreased the expression of NLRP3 and the activation of caspase-1 and IL-1β in THP-1 cells induced by LPS[218].

Geniposide: The primary active ingredient of *Gardenia jasminoides* is geniposide, an iridoid glycoside extracted from the *Gardenia* used in TCM[219]. Geniposide was shown by Pu *et al*[220] to reduce macrophage differentiation in mice with acute colitis induced by DSS by inhibiting the NLRP3. In addition, geniposide augmented AMPK/Sirt1 signal and inhibited the NLRP3 inflammasome in LPS-induced BMDM cell or RAW264.7 cell cultures. In line with this study, geniposide suppressed the activation of the NLRP3 inflammasome in different *in vivo* and *in vitro* models, such as myocardial ischemia/reperfusion injury[221], sepsis-induced myocardial dysfunction[222], and cholestatic liver inflammatory injury[223].

Sinomenine hydrochloride: Sinomenine is a pure alkaloid derived from the plant *Sinomenium acutum* of the *Menispermaceae* family[224]. According to Zhou *et al*[225], sinomenine may reduce the symptoms of experimental colitis by altering the production of the gut microbiota and reducing the activity of the NLRP3 inflammasome and pro-inflammatory mediators levels in mice. In line with this study, sinomenine inhibits the NLRP3 inflammasome, which has a favorable effect on cartilage degradation [226], autoimmune encephalomyelitis[227], ischemic stroke[228], and others.

Picroside II: Picroside II is a kind of iridoid chemical that is used in TMC. There are now three known iridoids in *Picrorhiza scrophulariiflora* *pennell*[229]. Picroside II possesses hepatoprotective, immune-regulating, anti-inflammatory, and antioxidant properties[230-232]. Yao *et al*[233] demonstrated that picroside II alleviated DDS-induced UC by significantly suppressing NLRP3 inflammasomes and

inflammatory components *in vivo* induced by DDS.

Hydroxytyrosol: Hydroxytyrosol is a prominent and typical phenolic component in olive oil and leaves [234]. Miao[235] demonstrated that hydroxytyrosol supplementation has a coloprotective effect on DSS-induced UC by suppressing NLRP3, caspase-1, and ASC expression levels and downregulating IL-18 and IL-1β levels. Additionally, hydroxytyrosol modifies the *in vivo* gut microbiota while boosting colonic antioxidant functionality.

Trans-10-hydroxy-2-decenoic acid: The most prevalent fatty acid and main lipid in royal jelly is 10-hydroxy-2-decenoic acid, which also has antibacterial[236], antioxidant[236], immunomodulatory[237], anti-inflammatory[238] properties, and others. According to Huang *et al*[239], trans-10-hydroxy-2-decenoic acid improves colonic barrier function, decreases colonic TXNIP, ASC, caspase-1, GSDMD, IL-1β, and IL-18 Levels, and regulates the NLRP3 inflammasome-mediated pyroptosis to treat DSS-induced colitis.

PLANT EXTRACT

Canna x generalis

Canna x generalis (CG) LH Bailey is a hybrid of two closely related species that belongs to the *Canna* genus[240]. With its enormous leaves and gorgeous blooms, CG may grow without special care and can adapt to various soil conditions[241,242]. CG exhibits anti-inflammatory[243] and antioxidant[244] activities. CG extract exhibits a protective effect against DSS-induced UC mice by suppressing colonic activation of NLRP3 and NF-κB/TLR4 signals. CG extract reduces pro-inflammatory mediators, oxidative stress, and the inflammatory cascade in colonic tissues. Additionally, CG extract downregulates caspase-1, ASC, TLR4, and caspase-3 expressions[245].

Kuijieling decoction: An empirical formula known as Kuijieling decoction (KJL) has been introduced in clinical conditions for several years and is effective in treating UC[246,247]. KJL showed anti-inflammatory and antioxidant bioactivities[248,249]. KJL effectively attenuates UC symptoms in the UC rat model[250]. Jie *et al*[251] revealed that KJL suspension attenuates UC by decreasing NLRP3, caspase 1, and pro-inflammatory cytokines levels. They also showed that in DSS-induced UC mice, KJL downregulates NLRP3, caspase-1, GSDMD-N, IL-1β, and IL-18. Also, the expression levels of ASC, caspase-1, IL-1β, IL-18, and Mir-223 were downregulated in colon tissue.

Huaier: For more than 1600 years, *Trametes robiniophila Murr* (Huaier), a sandy beige fungus that grows on tree trunks, has been extensively employed in TCM[252-254]. Wang *et al*[255] showed that Huaier has anti-inflammatory activity in DSS-induced murine colitis in mice by downregulating NLRP3 expression and preventing NLRP3 inflammasome activation-induced IL-1β production and caspase-1 cleavage.

Shaoyao decoction: Shaoyao decoction (SYD) is a TCM that has demonstrated that it has anti-inflammatory[256] and anticancer[257] effects, among others. In addition, a recent study revealed that SYD had been successfully utilized to treat IBD and other disorders linked to the damp-heat syndrome in the intestines[258]. Wei *et al*[259] reported the protective effects of SYD on DSS-induced UC and pyroptosis by suppressing the NLRP3 and NF-κB/P38 signals. Moreover, SYD supplementation decreases caspase-1 activity and the release of ASC and GSDMD, preventing the formation of NLRP3 and protecting the intestinal barrier integrity.

Smilax china L.

Smilax china L. is one of the TCM that is effective in reducing inflammation[260], nociception[261], and cancer[262]. *S. china L.* polysaccharide (also known as SCLP) was isolated from the rhizome of *S. china* L. and is a TCM used to treat inflammatory disorders[263]. SCLP treats UC, according to Pan *et al*[264], by inhibiting the galectin-3 expression and its connection with NLRP3 activation and IL-1β production, which in turn decreases the release of inflammatory mediators in the DSS mice model.

Dendrobium officinale

Dendrobium officinale Kimura et Migo is the second-biggest genus of *Orchidaceae*[265,266]. Polysaccharides, the main active constituents in *D. officinale*, have received much interest due to their numerous biological activities[267-269]. Moreover, a prior investigation showed that *D. officinale* polysaccharides (DOPS) could successfully alleviate DSS-induced colitis in mice[270]. In 2018, Liang *et al*[270] found that DOPS has a notable therapeutic effect in treating DSS-induced acute UC mice. They also examined whether DOPS administration might significantly reduce the activation of the NLRP3 inflammasome and the β-arrestin1 signaling pathways. DOPS significantly decreases colonic pathological damage, relieves clinical signs and symptoms, and restores the pro- and anti-inflammatory cytokines balances.

Schisandra chinensis

As a result of its various pharmacological properties, the fruit of *Schisandra chinensis*, a member of the *Magnoliaceae* family, has long been utilized as an herbal remedy in TCM[271,272]. These fruits were often utilized as wholesome meals and pharmaceuticals for several chronic diseases, such as cancer, liver injuries, and gastrointestinal disorders[210,273]. *S. chinensis* mitigates ferroptosis and NLRP3 inflammasome-mediated pyroptosis in diabetic nephrosis[274]. Recently, Bian *et al*[275] found that *S. chinensis* extract can reduce the symptoms of DSS-induced colitis by TLR4/NF-κB and NLRP3 inflammasome suppression. Additionally, *S. chinensis* extract might correct the gut microbiota imbalance brought on by UC while maintaining gut barrier function by raising ZO-1 and occludin levels.

Tripterygium wilfordii

Tripterygium wilfordii Hook. f., commonly referred to as Lei Gong Teng, is a TCM herb frequently used to treat autoimmune and inflammatory diseases[276-278]. The root bark of *T. wilfordii* demonstrated pharmacological actions against inflammation[279], autoimmune disorders[280], Crohn's disease[281], liver cancer[282], and others. *T. wilfordii* polycoride is the primary active ingredient of *T. wilfordii*[283]. Fangxiao *et al*[284] reported the anti-inflammatory effects of *T. wilfordii* polycoride on 2,4,6-trinitrobenzenesulfonic acid-induced colitis by downregulating the NOXs-ROS-NLRP3 signal. *T. wilfordii* polycoride decreased ROS production, and NOXs' activity was mediated by downregulating colonic NLRP3, ASC, and caspase-1.

Rubia cordifolia L.

Rubia cordifolia L. is a perennial climbing vine from the Rubiaceae family[285,286]. Its aerial portion possesses a range of bioactivities, including anti-inflammatory[287], antioxidant[288,289], and others. Recent findings by Qin *et al*[290] showed that using *R. cordifolia* extract inhibits the NLRP3 inflammasome and IL-6/Jak-2/STAT3 signal activation in DSS-induced UC. *R. cordifolia* extract improves the symptoms, diminishes colonic mucosal injury and macrophage infiltration, inhibits the production of inflammatory cytokines, and lowers mortality.

Mulberry fruit extract

Mulberry fruit extract (MFE) is obtained from the fully ripened fruits of *Morus macroura*[291,292]. Salama *et al*[293] recently reported the involvement of NLRP3, miRNA-223, and the TNF-α/NF-κB pathway in the coloprotective effects of MFE against AA-induced UC in rats. MFE also reduces levels of TNFR1, NLRP3, NF-κB p65, TNF-α, IL-1β, IL-18, and caspase-1, while increases miRNA-223 expression.

PROBIOTICS

Akkermansia muciniphila

Akkermansia muciniphila, a Gram-negative and anaerobes bacterium, is a member of the *Verrucomicrobia phylum*, which has been discovered to be common in the human gut[294-296]. According to investigations, *A. muciniphila* may protect against major diseases like atherosclerosis[297], amyotrophic lateral sclerosis[298], and immune-mediated liver damage[299]. Additionally, it was reported that *A. muciniphila* improves chronic colitis[300]. Recently, Qu *et al*[301] revealed that oral treatment of *A. muciniphila* strain BAA-835 effectively reduces the signs and symptoms of DSS-induced acute colitis dependent on NLRP3 activation. The expression of NLRP3, caspase-1, and IL-1β was elevated in mouse macrophage cells in *A. muciniphila*-treated animals, as well as pro-inflammatory cytokines such as TNF-α, IL-6, and monocyte chemoattractant protein 1 (MCP-1).

Saccharomyces cerevisiae

A facultative anaerobic fungus called *Saccharomyces cerevisiae* has been extensively employed in medicine to create modified carriers and oral vaccinations[302,303]. According to a study by Sun *et al* [304], modified *S. cerevisiae* reduced the severity of DSS-induced colitis in mice by inhibiting macrophage pyroptosis and regulating the intestinal microbiota. Lactic acid-produced *S. cerevisiae* modulated macrophage polarisation, prevented the production of pro-inflammatory cytokines *in vivo* and *in vitro*, and decreased NLRP3 inflammasome and caspase-1 levels.

Lactobacillus acidophilus

Lactobacillus acidophilus is one of the most common commercial species of lactic acid bacteria, found in various dairy products and nutritional supplements with probiotic indications[305]. According to studies, *L. acidophilus* may have immunomodulatory, anti-inflammatory, and antioxidant[306-308] activities. Furthermore, it improves the intestinal epithelial barrier function[309,310]. Additionally, it was demonstrated to be efficient in preventing colitis caused by *Citrobacter rodentium*[309] and relieving DSS-induced colitis[311]. According to Li *et al*[312], *L. acidophilus* attenuates UC in rats by inhibiting the NLRP3 inflammasome pathway, increasing the short-chain fatty acids level, and promoting autophagy.

Grape seed proanthocyanidin

Grape seed proanthocyanidin extract (GSPE) is a grape seed extract that contains catechin, epicatechin gallate, and epigallocatechin[313,314]. According to Sheng *et al*[315], GSPE supplementation reduces inflammatory cytokines and oxidative stress, maintains the intestinal barrier, and enhances the microbiome in DSS-induced colitis. GSPE decreases the NLRP3 inflammasome and increases ZO-1, occludin, and claudin-1 levels. Furthermore, GSPE treatment of colon tissues resulted in a considerable decrease in TNF-α and IL-1β levels.

Brilliant blue G

Brilliant blue G (BBG) is a triarylmethane dye with a modest hydrophilicity that has been proven to stain the inner limiting membrane selectively[316]. In 2021, Saber *et al*[317] revealed that the BBG/OLT1177 combination produced complementary effects and significantly alleviated DSS-induced UC by downregulating NLRP3, caspase-1, IL-1β, and IL-18 levels. In addition to reducing purinergic receptor (P2X7R) and oxidative stress levels, BBG treatment downregulated myeloid differentiation primary response 88, NF-κB, IL-6, TNF-α, the recruitment of the NLRP3 inflammasome, and the consequent activation of caspase-1, IL-1β, and IL-18.

Forsythia suspensa extract

Forsythia suspensa (Thunb.) Vahl is well-known in TCM[318]. Chao *et al*[319] showed that *Forsythia suspensa* extract effectively reduces metabolic dysfunction and DSS-induced UC damage by suppressing the NLRP3 pathway and activating Nrf2.

Kui jie tong

Kui jie tong is a herbal extract that effectively treats UC[320]. Xue *et al*[321] reported that Kui jie tong mitigates UC by downregulating NLRP3 and caspase-1 as well as serum IL-1β, IL-18, and IL-33 and enhancing intestinal microbiota.

Jianpi Qingchang decoction

Jianpi Qingchang decoction, a TCM prescription, is composed of nine Chinese herbs and effectively attenuates moderate or beginning cases of UC[322,323]. Zhang *et al*[324] stated that Jianpi Qingchang decoction has a protective function by preventing DSS-induced NLRP3 inflammasome activation. Jianpi Qingchang decoction decreases inflammatory cytokine release.

Bovine milk

Bioactive extracellular vesicles are present in the milk of all mammalian species[325,326]. Bovine milk exosomes have been shown to support intestinal cell proliferation, boost the number of goblet cells and mucin synthesis, inhibit bacterial growth, and support the intestinal microbiota[327-329]. According to the Tong *et al*[330] study, milk-derived extracellular vesicles regulate intestinal immunological homeostasis by suppressing TLR4- NF-κB and NLRP3 signaling pathways, re-establishing the balance of Treg/Th17 cells, and altering the gut microbiota. In a mouse UC model, milk-derived extracellular vesicles were proven to have a role in the control of immunological and inflammatory pathways, which decreased intestinal epithelium disruption, blocked the infiltration of inflammatory cells, and reduced tissue fibrosis[330].

SYNTHETIC DRUGS

Mirtazapine

Mirtazapine is a well-known antidepressant medication used to treat depression, anxiety, and sleep disorders[331]. In addition, mirtazapine reduces inflammation in diabetic rat kidneys by inhibiting the NLRP3 inflammasome[332]. The same results showed that mirtazapine has a coloprotective effect against UC, which was mediated by suppressing NLRP3 and caspase-1 activation and restoring the antioxidant/oxidant balance in AA-induced UC in rats. Additionally, mirtazapine reduces the levels of NF-κB, TNF-α, IL-1β, and IL-18[333].

Paeoniflorin-6'-O-benzene sulfonate

Paeoniflorin-6′-O-benzene sulfonate is a new active monomer created by structurally altering paeoniflorin[334] and has anti-inflammatory and immunomodulatory characteristics[335,336]. According to Li *et al*[337], paeoniflorin-6′-O-benzene sulfonate has anti-colitis properties *via* suppressing TLR4-NF-κB and NLRP3 signals and G protein-coupled receptor kinase 2 translocations. Furthermore, paeoniflorin-6′-O-benzene sulfonate maintains intestinal barrier function in LPS-treated mice.

Dapagliflozin

Dapagliflozin (DPZ), a sodium-glucose cotransporter-2 inhibitor, is recommended in addition to routine medical treatment for managing type 2 diabetes mellitus that has not been effectively controlled[338]. Interestingly, DPZ modulates the NLRP3 inflammasome in different models, such as diabetic nephropathy[339], LPS-induced lung damage[340], and type 2 diabetes mellitus- induced cardiomyopathy[341]. El-Rous and colleagues reported that DPZ suppressed the activation stage (signal 2) of NLRP3 inflammasome activation and prevented the priming step (signal 1) of that activation in AA-induced UC through altering NF-κB/AMPK interaction and halting NLRP3/caspase-1 communication. Furthermore, DPZ increases the anti-inflammatory cytokine IL-10 and remarkably suppresses caspase-1 activity and IL-1β and IL-18 production[342].

Canagliflozin

Canagliflozin is a small-molecule hypoglycemic medication that lowers blood glucose levels by blocking the type 2 sodium-glucose cotransporter, which prevents the kidneys from reabsorbing glucose[343]. Nasr *et al*[344] reported that canagliflozin-loaded chitosan-hyaluronic acid microspheres significantly suppressed NF-κB and NLRP3 activation, resulting in a decrease in caspase-1 cleavage and the inhibition of several inflammatory cytokines, including IL-1β and IL-18, in AA-induced colitis.

Rosuvastatin

Rosuvastatin, an HMG-CoA inhibitor that is relatively new, has a safety and tolerability profile that is comparable to or better than the regularly prescribed dosages of other statins[345]. Rosuvastatin and *Lactobacillus* inhibit the NLRP3 inflammasome assembly, pro- IL-1β, pro-IL-18, and NF-κB, decreasing caspase-1 activity and IL-1β-driven pyroptotic activity in DSS in high-fat diet-induced colitis in rats [346].

MCC950

MCC950 is an IL-1β inhibitor and is known to be a potent inhibitor of the NLRP3 inflammasome[347]. MCC950 inhibits NLRP3 among inflammasomes[347,348] and blocks canonical, non-canonical, and alternative NLRP3 activation[80,347,349]. MCC950 showed promising therapeutic potential for inhibiting NLRP3 inflammasome in the atherosclerotic lesion[350], cholestatic liver, non-alcoholic steatohepatitis-induced liver fibrosis[351,352], LPS-induced lung inflammation[353], and others. In 2018, Perera *et al*[354] revealed that MCC950 effectively treats murine UC. MCC950 significantly suppresses NLRP3 inflammasome activation and decreases colonic cytokines, chemokines, and nitric oxide levels. Moreover, MCC950 suppresses caspase-1 activation in the colon and macrophage cells.

CONCLUSION

The incidence and prevalence of UC, a recurrent and remitting condition, are rising. The goal of treatment is to increase a patient's quality of life while achieving quick symptom alleviation and mucosal healing. There are still a lot of unsolved concerns despite the abundance of evidence pointing to genetic and host-related variables in UC. Numerous opportunities exist for further inquiry to improve our understanding of the pathogenesis of UC and uncover possible predictors of disease severity, responsiveness to medication, and novel therapeutic targets as the incidence and prevalence of UC around the world increase. The NLRP3 inflammasome plays a crucial role in the inflammation and immunological reaction by promoting caspase-1 activation and the release of IL-1β. Interestingly, phytochemicals, plant extracts, and synthetic drugs exhibit promising colon protective effects mediated by NLRP3 and caspase-1 activation suppression and, subsequently, the release of the pro-inflammatory cytokine IL-1β, which has a key role in UC-associated inflammation. However, future clinical studies are required to comprehend how NLRP3 inflammasome activation inhibition significantly treats and controls UC.

Abstract

Hepatocellular carcinoma (HCC) is one of the world's deadliest and fastest-growing tumors, with a poor prognosis. HCC develops in the context of chronic liver disease. Curative resection, surgery (liver transplantation), trans-arterial chemoembolization, radioembolization, radiofrequency ablation and chemotherapy are common treatment options for HCC, however, they will only assist a limited percentage of patients. Current treatments for advanced HCC are ineffective and aggravate the underlying liver condition. Despite promising preclinical and early-phase clinical trials for some drugs, existing systemic therapeutic methods for advanced tumor stages remain limited, underlining an unmet clinical need. In current years, cancer immunotherapy has made significant progress, opening up new treatment options for HCC. HCC, on the other hand, has a variety of causes and can affects the body's immune system *via* a variety of mechanisms. With the speedy advancement of synthetic biology and genetic engineering, a range of innovative immunotherapies, such as immune checkpoint inhibitors [anti-programmed cell death-1 (PD-1), anti-cytotoxic T lymphocyte antigen-4, and anti-PD ligand 1 cell death antibodies], therapeutic cancer vaccines, engineered cytokines, and adoptive cell therapy have all been used for the treatment of advanced HCC. In this review, we summarize the present clinical and preclinical landscape of immunotherapies in HCC, critically discuss recent clinical trial outcomes, and address future perspectives in the field of liver cancer.

Key Words: Hepatocellular carcinoma; Immunotherapy; Immune checkpoint inhibitors; Alpha-fetoprotein; Cancer vaccine; Combination therapies

Core Tip: Hepatocellular carcinoma (HCC) is a multifaceted illness with multiple faces. It avoids early discovery, which provides the best chance of cure by resection/transplant, and systemic treatments are only of marginal efficacy at best, despite recent therapeutic advances. Current advances in immunotherapy and its combinations have altered the HCC treatment landscape, and clinical studies are continuing to pave the path forward. Immunotherapy increases survival rates and provides long-term cancer control in subsets of HCC patients while also minimizing side effects. Further research into immunotherapy in combination with current treatments for HCC in the early and intermediate stages may assist a greater spectrum of patients. Continued research into programmed cell death-1/ programmed cell death ligand 1, TMB, ctDNA, microsatellite stability, DNA mismatch repair, neutrophil/lymphocyte ratio, cytokines, and cellular peripheral immune response will hopefully identify the most reliable marker for selecting and sequencing systemic treatments to achieve the best outcome in HCC patients. Despite such significant treatment advances in HCC, numerous hurdles remain. The scientific community must figure out how to appropriately sequence these medicines for the best potential response, how to control toxicities, and how to develop indicators to monitor for response and relapse.

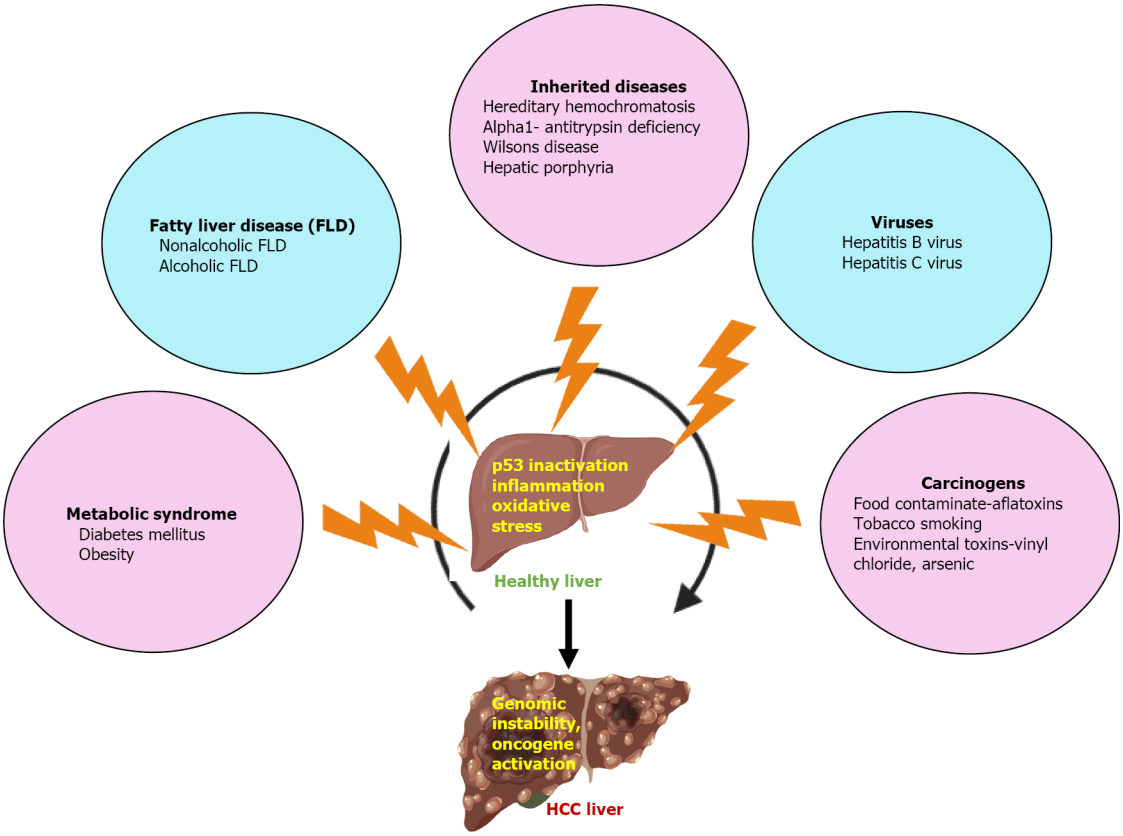
INTRODUCTION



Hepatocellular carcinoma (HCC) is the world's fifth most frequent malignancy and the third main cause of cancer death[1]. Men are slightly more likely than women to get HCC (3:1 male-to-female ratio). Globally, primary liver cancer caused an estimated 906000 new cases and 830000 fatalities in 2020; the majority of these cases (75%-85%) were HCC[2]. Underlying liver conditions including cirrhosis or chronic hepatitis frequently led to HCC. Hepatitis C virus (HCV), hepatitis B virus (HBV), fatty liver disease like non-alcoholic steatohepatitis, and alcohol consumption are the most prominent risk factors (Figure 1)[3]. The 5-year age-standardized rate of relative survival for HCC is only 18.1%, even though surgical intervention is currently the best therapy for HCC. Tumor reappearance is common after tumor removal[4]. In adult males, HCC is the second most common cancer-related killer after lung cancer because of the challenge of earlier detection, which results in the vast bulk of HCC patients receiving a higher stage diagnosis at their first visit and being ineligible for treatments like radiofrequency ablation (RFA) or hepatectomy[5]. Sorafenib and lenvatinib, the two clinically authorized targeted therapy medicines, could barely extend survival time by 2 to 3 mo[6,7]. As a result, novel HCC therapy techniques are urgently required.

Immunotherapy is successful and safe in the treatment of solid tumors, resulting in long-term survival and manageable toxicity[8,9]. The liver is a remarkable immunologically tolerant organ that is exceptional in its capacity to accept liver transplants and diminish responsiveness to antigens in bacterial and food products through the portal vein[10]. This tolerogenic trait of the liver and the immunosuppressive tumor microenvironment of HCC may jointly inhibit the formation of anti-tumor immunity against HCC. Cancer immunotherapy may be a compelling therapeutic approach for HCC, which has a metachronous, multicentric incidence due to its capacity to trigger systemic and long-lasting anti-tumor actions. For numerous forms of malignancies, along with HCC, the FDA has so far approved seven immune checkpoint inhibitors (ICIs) that target the programmed cell death protein-1 (PD-1), proteins cytotoxic T lymphocyte antigen 4 (CTLA-4), or its ligand programmed cell death-ligand 1 (PD-L1)[11,12]. Other immunotherapeutic approaches, like immune cells modified with chimeric antigen receptors, adoptive cell treatment, tailored cytokines, and cancer vaccines, are almost ready and provide HCC patients new hope[13-15]. In this review, we first provide an overview of the current state of immunotherapy for HCC (Figure 2), after which we analyze the challenges, opportunities, and potential directions of this field of study.

ANTIBODY-BASED THERAPY

Monotherapy with ICIs

Effector immune cells express inhibitory immunoreceptors called immunological checkpoints that keep the immune system from overreacting. The T cell immunoreceptor with Ig and ITIM domains (TIGIT), lymphocyte-activation gene 3 (LAG3), B and T lymphocyte attenuator, and T cell immunoglobulin and mucin domain containing-3 (TIM3) are only a few of the inhibitory receptors in this group[16]. This

Figure 1 Etiology of hepatocellular carcinoma. FLD: Fatty liver disease; HCC: Hepatocellular carcinoma.

physiological process is employed by HCC and other solid tumors to thwart anti-tumor immune reactions[17]. Monoclonal antibodies known as ICIs have the potential to prevent immunological checkpoint proteins from interacting with their ligands. This could improve the immune response against tumors by preventing T cell inactivation and reactivating immune attack and immune recognition. At the moment, ICIs' primary targets are CTLA-4, PD-1, and PD-L1[13]. Most immune cells, myeloid-derived suppressor cells, primarily activated T cells, regulatory T cells (Tregs), natural killer (NK) cells, dendritic cells (DCs), and monocytes express PD-1 and are members of the CD28 family. When PD-1 binds to its ligands, *i.e.* PD-L1 and PD-L2, that are stimulated in a variety of cancers, including HCC, it can send T cells inhibitory signals and cause tumor cells to bypass the immune system[18].

Nivolumab, a PD1 inhibitor, was given expedited approval in the United States in 2017 for this second-line treatment of patients with severe HCC following sorafenib therapy. ICIs have been used to treat HCC in several exploratory trials that have been completed so far. PD-1 and PD-L1 inhibitors pembrolizumab and atezolizumab, which target these receptors, respectively, have been steadily proposed as a clinical therapy strategy for HCC and added to the treatment recommendations of numerous nations. Nivolumab and pembrolizumab cause objective remissions of 15%-20%, which includes complete remissions of 1%-5%, and these remissions are long-lasting and linked with improved survival. Nivolumab had a median response duration of 17 mo in the dose-escalation cohort in 48 patients of the CheckMate 040 investigation, and responders had a survival rate of about 2 years of more than 80%[19]. Statistically longer survival was seen in the 413 patients who took part in phase III clinical trial KEYNOTE-240, which compared pembrolizumab after sorafenib medication to placebo. Pembrolizumab was found to have long-term advantages for some people, as seen by the overall survival curves and progression-free survival. Around 20% of patients who got pembrolizumab stayed in progression-free status for longer than a year, as opposed to merely 7% of the control group[20]. In the phase III CheckMate 459 trial, 743 patients who had never received systemic medications were compared between nivolumab and sorafenib. Patients who received nivolumab had a longer median survival time than those who received sorafenib[21]. The CheckMate 459 study's lengthier follow-up period confirmed nivolumab's better ability to sorafenib to raise the long-term rate of survival[22].

Recent studies presented at the ESMO 2021 Annual Meeting revealed that tislelizumab, a humanized monoclonal antibody (mAb) with substantial adhesion for PD-1, evidenced durable response and was well tolerated in individuals who had previously systemically treated unresectable HCC. In a global, randomized phase 3 trial, the first-line therapies for adult patients having unresectable HCC are tislel-

izumab and sorafenib (NCT03412773)[23]. The majority of activated T cells and DCs express CTLA-4, a member of the CD28 family. After binding to B7 molecules, it participates in the downregulation of the immune response[24]. The FDA approved ipilimumab, the first ICI, in 2011 for the therapy of patients with severe skin cancer. Tremelimumab is another CTLA-4 inhibitor[25].

Tremelimumab, an IgG2 mAb, has different antibody-dependent cell-mediated cytotoxicity and complement-dependent cytotoxicity activities than Ipilimumab, an IgG1 mAb[26]. Tremelimumab demonstrated a potent anti-HCC impact in a clinical trial conducted in 2013, with a 17.6% of partial response (PR) rate and 76.4% of disease control rate[27]. With the in-depth analysis of CTLA-4 inhibitors' mechanism, some researchers hypothesize that it involves the targeted eradication of Tregs from tumors rather than the immune checkpoint[28]. In human HCC, the presence of TIM3 on tumor-associated macrophages and tumor-infiltrating lymphocytes (TILs) impairs T cells' ability to operate as effector cells, while increasing the activation of Tregs' suppressor genes[29]. Less differentiated HCC is linked to the highly expressed TIM3[30]. LAG3 appearance is much greater on tumor-specific $CD4^+$ and $CD8^+$ TILs in patients with HCC compared to other immune compartments. Hepatocytes produce fibrinogen-like protein 1, another useful soluble ligand for LAG3[31]. The most recent studies published demonstrate that Siglec-15 inhibits CD44's lysosomal degradation, which encourages the migration of liver cancer cells[31,32]. T-cell immunoreceptor with immunoglobulin and ITIM domains also plays a role in TIGIT[33]. The TIGIT/CD155 pathway increases interleukin (IL)-10 synthesis and decreases IL-12 by DCs to prevent T cell activation[34]. The exploration of Siglec-15, TIM3, TIGIT, and LAG3 inhibitors in HCC in conjunction with PD1 and PDL1 inhibition is supported by the preclinical evidence presented here. According to the findings of current clinical studies, patients medicated with ICIs alone, have a lower rate of response; as a result, future therapies will combine ICIs and other therapies.

The results of the worldwide, randomized phase 3 IMbrave150 trial in 2020 showed that atezolizumab plus bevacizumab an anti-angiogenic drug considerably lowered the probability of mortality in patients with severe unresectable HCC and enhanced the rate of patient survival[35]. Lenvatinib, a tyrosine kinase inhibitor (TKI), was combined with pembrolizumab to provide an overall response rate of 46%. Patients with unresectable HCC who were enrolled in the study saw complete responses (CRs) and PR in proportions of 11% and 35%, respectively[36]. Similar to this, newer preclinical and clinical investigations have demonstrated that the administration of ICIs in combination with radiation, RFA, and transcatheter arterial chemoembolization (TACE) can enhance the effectiveness of anti-tumor immunotherapy[37,38]. In a phase, Ib/II clinical trial, camrelizumab and the chemotherapy FOLFOX4 are being used to treat advanced HCC[39].

The HIMALAYA phase 3 trial, which evaluated a single, high dose of tremelimumab, an anti-CTLA-4 antibody, added to durvalumab, an anti-PD-L1 antibody, or durvalumab alone in comparison to sorafenib as first-line treatment in 1171 patients with advanced HCC, has provided additional evidence that single-agent PD1/PD-L1 inhibition has antitumor activity (NCT03298451). Durvalumab monotherapy achieved the goal of overall survival without being inferior to sorafenib while being less toxic[40]. Regarding anti-CTLA-4 monotherapy, the research 22 revealed that tremelimumab

monotherapy in patients previously treated with sorafenib after unacceptable toxicity or rejection of sorafenib had a manageable safety profile. However, the benefit-risk ratio was often better when tremelimumab and durvalumab were used together[41].

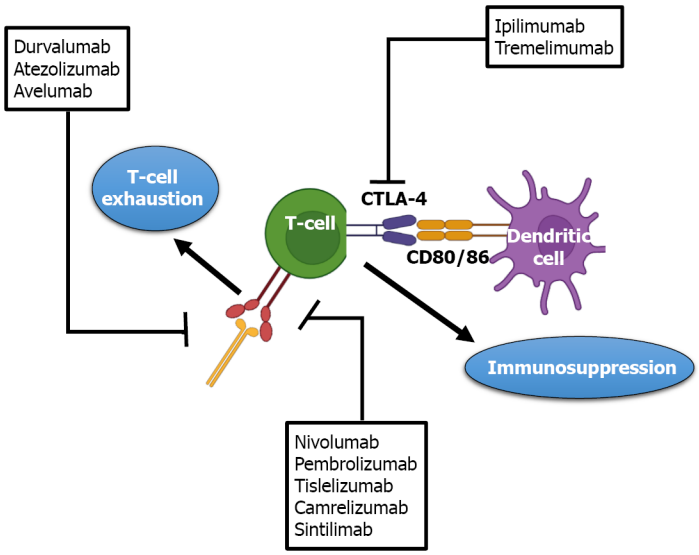
Figure 3 depicts several ICIs in HCC. Table 1 presents a summary of the clinical trials including ICIs treatment for HCC conducted during the previous 3 years.

Dual therapies with ICIs

Combining PD-1 and CTLA-4 inhibitors: The concept of combining inhibitors of several immune checkpoints, including as PD-1 and CTLA-4, is now being investigated in advanced HCC. Dual treatments combining PD-1 and CTLA-4 inhibitors have been studied in other cancer types, such as melanoma. The CheckMate 040 trial, which evaluated nivolumab and ipilimumab, an anti-CTLA-4 antibody, in 148 patients with advanced HCC who had progressed on sorafenib, provided the first clinical data[42]. Nivolumab and ipilimumab were administered to patients in three separate arms (Arm A, Arm B, and Arm C) at various doses and frequencies. The trial reported a 49% disease control rate, a 31% overall response rate, and a 17-mo median duration of response. The longest overall survival was 23 mo for patients in arm A. The patient side-effect profile was deemed acceptable. To treat side effects, more than 50% of patients required systemic steroids. Overall, the trial's findings were positive, and the FDA eventually approved the use of nivolumab and ipilimumab together. Additionally, the combination is presently being evaluated in the CheckMate 9DW phase 3 study as a first-line treatment for advanced HCC in comparison to sorafenib or lenvatinib (NCT04039607). Similar to this, durvalumab and tremelimumab together exhibited strong action in unresectable HCC, with a response rate overall of 17.5%[43].

ICIs with anti-vascular endothelial growth factor antibodies: The combination of a PD1/PD-L1 inhibitor with a vascular endothelial growth factor (VEGF) inhibitor has been established as a novel paradigm for the treatment of advanced HCC in light of the encouraging results of the IMbrave150 phase 3 trial[20]. Atezolizumab plus bevacizumab had initially shown good safety and promising anticancer activity in patients with untreated advanced HCC in a phase 1b study[44]. The next phase of the IMbrave150 trial compared sorafenib and atezolizumab in patients with advanced HCC who had never received systemic therapy and were randomly assigned (2:1) to either study arm[20]. Compared to sorafenib, the combination of atezolizumab plus bevacizumab therapy lowered the death risk by 42%. The IMbrave150 trial, which is significant, excluded patients with problems related to portal hypertension, such as severe ascites and esophageal or gastric varices at a high risk of bleeding. This atezolizumab and bevacizumab combination, which is the current standard therapy that has replaced the TKIs sorafenib and lenvatinib, were approved as a first-line treatment for unresectable HCC in the United States and Europe as a result of the IMbrave150 trial. Inhibiting PD-L1, which activates the immune system (especially T-effector cells), and inhibiting VEGF, which lessens VEGF-mediated immunosuppression and encourages T-cell infiltration in the tumor microenvironment, are probable synergistic anticancer agents that account for its effectiveness[45].

Dual therapies combining immune checkpoint with multi-kinase inhibitors: An alternative to antibody-mediated VEGF suppression may be achieved by combining ICIs with TKIs instead of anti-VEGF antibodies. The multicohort COSMIC-021 phase 1b trial is evaluating the combination of cabozantinib and atezolizumab in advanced solid tumors, including HCC (NCT03170960). Additionally, it is being evaluated in the COSMIC-312 phase 3 trial (NCT03755791) as a first-line treatment for patients with advanced HCC in comparison to sorafenib[46]. As a secondary outcome metric, cabozantinib/monotherapy is also contrasted with sorafenib in this study. A predetermined interim analysis for overall survival, however, failed to achieve statistical significance. Early 2022 is when its final analysis should produce results[47]. In 104 patients with unresectable HCC who had not previously undergone systemic treatment, the combination of lenvatinib and pembrolizumab showed reasonable results in a phase 1b trial[36]. This combination is currently being compared to lenvatinib monotherapy in the LEAP002 phase 3 trial (NCT03713593)[48]. Finally, the combination of apatinib and camrelizumab, an anti-PD-1 antibody is under clinical development. An overall response rate of 50% was found in a phase 1 study of individuals with advanced HCC[49]. Additionally, a phase 3 trial is currently comparing the combination to sorafenib in the first-line setting for patients with advanced HCC (NCT03764293).



Bispecific antibody therapy

Bispecific antibody (BsAbs), in contrast to monoclonal antibodies, are made primarily using recombinant DNA technology and may concurrently and precisely bind two antigens or epitopes[50]. BsAb can target immunological checkpoints and tumor-associated antigens (TAAs) to alter immunosuppression in the tumor environment. It can also directly increase the action of immune cells against tumors. As a result, they outperform monoclonal antibodies in aspects of synergistic effects and can mediate a wide range of particular biological effects. Most of the time, BsAbs bridge the gap between immune cells and tumor cells to attract and activate them to attack tumor cells[51]. An EpCAM/CD3 bispecific antibody called Solitomab (AMG110, MT110) is humanized. Bispecific T-cell Engager (BITE),

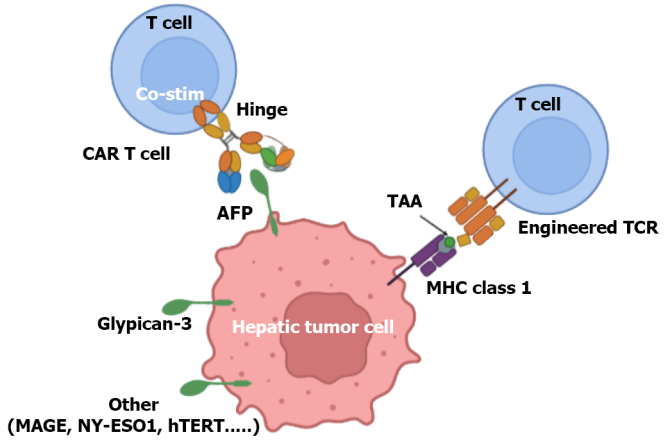
which can lyse HCC cell lines almost completely *in vitro* when it binds to gd T cells, is created by joining the anti-EpCAM single-chain variable fragment (scFv) to the anti-CD3 scFv *via* a Gly4Ser linker[52]. To remove glypican-3 (GPC3) + HCC cells, a different BsAb called GPC3/CD3 BITE is expected to entice CTL. In one work, an IgG-shaped TriFab, that can be employed to activate two antigens sequentially or for targeted delivery of tiny and large payloads, was created by joining two anti-GPC3 Fab fragments to one asymmetric third Fab-sized binding module using flexible linker peptides[53].

ADOPTIVE CELL TRANSFER

Adoptive cell transfer (ACT), an immunotherapy that harnesses the patient's immune cells or those of a healthier donor to combat cancer, has currently emerged as a crucial component of cancer treatment [54]. ACT could be stimulated and replicated *in vivo* and has a long-lasting anti-tumor impact, in contrast to antibodies or other targeted medications. As a result, the ACT is also known as a "living"

therapeutic strategy[55]. Since the majority of ACT's effector cells come from the patient, it is regarded as a highly personalized cancer therapy. ACT is more targeted than chemotherapy because enlarged or genetically altered effector cells can identify and target tumor antigens[56]. Adoptive cell transfer, as opposed to checkpoint inhibition therapy, which passively administers autologous lymphocytes after ex vivo cultivation, aims to improve the outcomes for patients with HCC[57]. Table 2 lists the ACT clinical studies for the HCC treatment that were published at clinicaltrials.gov in the previous 3 years.

Cytokine-induced killer cell: IL-2, interferon-alpha (IFN)-α, and anti-CD3 monoclonal antibodies are used to create cytokine-induced killer cell (CIK) cells, a heterogeneous population of immune cells, from human peripheral blood mononuclear cells (PBMC) in a laboratory setting[58]. NK cells, NKT cells, and CTLs make up the majority of CIK cells (CTLs). Through adhesion molecules, CIK can lyse tumor cells and recognize them without the assistance of the major histocompatibility complex (MHC). Shi *et al*[59] showed that autologous CIK cells can effectively enhance the immunological condition of HCC patients by using them to treat primary HCC in a phase I clinical study and finding that the signs and features of HCC patients were diminished without notable adverse effects. Clinical studies have also demonstrated that CIK cell treatment could be utilized to cure individuals having primary HCC that is inoperable as well as HCC patients who have had their tumors removed. Takayama *et al*[60] published the results of a 150-patient clinical trial of CIK therapy for postoperative HCC. They discovered no significant treatment adverse effects and an 18% lesser recurrence rate in the treatment group than in the control group, indicating that CIK cells treatment can lower reappearance rates and lengthen recurrence-free survival in patients with postoperative HCC[61]. Additionally, conventional therapies and CIK cell therapy have frequently been combined by researchers. As opposed to TACE alone, TACE combined with CIK cells may increase progression-free survival in HCC patients. T and NKT cells dramatically increased with the addition of CIK cells to local radio frequency hyperthermia, whereas alpha-fetoprotein (AFP) levels decreased, according to research by Wang *et al*[61]. Although 17% of patients reported experiencing pyrexia, chills, myalgia, and fatigue, these symptoms were not severe enough to require therapy to be stopped[62]. These results suggest that the combination of CIK cells having TACE or RF hyperthermia is a harmless and efficient therapy for HCC patients.



Tumor-infiltrating lymphocytes: TIL is a part of the host immune response against tumors, which also consists of Tregs, T cells, NK cells, and B cells[63]. TIL is 50-100 times more effective as compared to lymphokine-activated killer cells at curing mice with severe metastatic cancer, according to experiments [64]. A phase I clinical trial in individuals with primary HCC established the viability of TIL treatment [65]. Because TILs are derived from surgical tumor tissues and can detect several antigens, they have a stronger tumor-inhibitory effect than medications that target certain antigens or mutations. TILs in HCC are uncommon, however, prior research has shown that despite this, they can significantly affect tumor recurrence and patient prognosis[66]. Clinical research with 150 HCC patients demonstrated that adoptive TIL treatment improved recurrence-free survival following liver resection[60]. Patients who received surgical resection of their HCC and had considerable lymphocyte infiltration had a lower recurrence rate and a greater survival rate than those who did not have significant lymphocyte infiltration[67]. However, isolating TILs from HCC tumor tissues and expanding them *in vitro* is difficult. Additionally, only a small number of HCC patients could survive lymphocyte deletion, which is necessary before TIL infusion[68].

Chimeric antigen receptor T Cell: ACT research is now focused on Chimeric antigen receptor T Cell (CAR-T) treatment, novel immunotherapy for cancer wherein T cells are genetically altered to recognize particular TAA[69]. Hematological cancers can be successfully treated with CAR-T cell therapy. The FDA has approved CAR-T cells that target CD19 and B-cell maturation antigen (BCMA) for the management of acute B-cell lymphocytic leukemia, several lymphomas, and multiple myeloma[70]. CAR-T therapy for liver malignancy is currently being developed because of the variety of solid tumors, the absence of specific targets, and the liability to the tumor microenvironment[71]. Conventional T cells have a T cell receptor (TCR) structure that is reliant on MHC antigen presentation. The CAR structure is independent of MHC antigen presentation, evades MHC molecule restriction, and resolves the issue of tumor immune escape caused by MHC downregulation[72] (Figure 4). To date, an increasing series of clinical trials have been carried out to show the effectiveness of CAR-T cell treatment in solid tumors. GPC3, a 580 amino acid long heparan sulphate proteoglycan, is overexpressed in HCC yet not at all in healthy tissues[73,74]. Gao *et al*[75] created CAR-T cells targeting GPC3 for the first time and showed that GPC3 CAR-T cells can successfully eradicate the proliferation of HCC cells both *in vitro* and *in vivo*. In a recent study, researchers found that by dividing the CAR design into two parts, HCC tumors may be removed with a lower level of proinflammatory cytokines (split GPC-3 CAR-T cells)[76]. A different study used patient-derived xenograft (PDX) HCC models and showed that GPC3 CAR-T cells reduced tumor development, however to differing degrees because of variations in PDL1 expression on cancer cells[77]. This demonstrates that combining CAR-T treatment and ICIs is a workable way to increase the efficiency of curing PD-L1- +ve HCC. The secreted glycoprotein known as AFP is extensively expressed in fetuses but only modestly so in adults. However, AFP is once again expressed when HCC manifests in adults[78]. Traditional CAR-T cells are only able to identify tumor surface antigens; they are unable to identify intracellular antigens. Liu *et al*[79] developed some distinctive CAR-T cells that could bind to

Table 2 Advantages and disadvantages of vaccination strategies used in hepatocellular carcinoma

Vaccine type	Advantages	Disadvantages
Peptides	Easy to prepare; known target Ag	Adjuvants are needed; restricted Ag repertoire; restriction to human leukocyte Ag
Dendritic cells	Adjuvants are not needed	Individualized production
Peptide pulsed	Known target Ag	Restriction to human leukocyte Ag; restricted Ag repertoire
Protein pulsed	No restriction to human leukocyte Ag; known target Ag	Protein synthesis is more interesting; restricted Ag repertoire
Tumor lysate pulsed	Not human leukocyte Ag restricted full Ag repertoire; available	Tumor samples not always available; the predominance of self-Ags that may eclipse tumor Ags
Cell line pulsed	Not human leukocyte Ag restricted; unlimited Ag source	Responses against cell line-specific Ag

Ag: Antigen.

the AFP158-166 peptide-MHC complex and then damage HLA-A*02:01+/AFP+ tumor cells because all intracellular antigens are delivered by MHC class I molecules. A phase I clinical trial (NCT03349255) assessing the security and performance of CAR-T cells in patients with AFP-expressing HCC was successfully finished in the interim. As a result, using CAR-T cells to target intracellular antigens is an effective way to treat HCC. The c-Met tyrosine kinase receptor could promote hepatocyte survival, regeneration, and proliferation[80].

HCC development and progression can be aided by c-Met overexpression. As a result, c-Met is being evaluated as a possible target for the therapy of HCC. Jiang *et al*[81] developed CAR-T cells that simultaneously targeted c-Met and PD-L1, and they discovered that these cells significantly cytotoxic attacked c-Met+ PD-L1+ HCC cells. NKG2DL ligands (NK group 2 member D ligands) are present in a variety of primary malignancies, along with HCC, yet not found in healthy tissues[82]. Therefore, NKG2DL might be a good candidate for HCC immunotherapy. Innovative NKG2D-CAR-T cells that specifically target NKG2DL expressed on HCC cells were developed by Sun *et al*[83]. They also discovered that NKG2D-CART cells only targeted ruptured HCC cells with elevated NKG2DL expression and had no effect on the NKG2DL negative cell line. The xenograft model further demonstrated that NKG2D-CAR-T cells may prominently limit *in vivo* tumor growth. Type I transmembrane glycoprotein CD147 was discovered in high levels in HCC and various solid tumors [84]. When Tet-On inducible CD147-CART cells were administered Dox, Zhang *et al*[85] found that Tet-On inducible CD147-CART cells can successfully rupture numerous HCC cell lines *in vitro* and reduce the development of cancer cells in the HCC xenograft model. The safety of hepatic artery infusions (HAI) of CD147-CART cells for severe HCC was recently evaluated in a phase I trial (NCT03993743). Mucin 1[86], EpCAM[87], and CD133 are further potential targets antigens for HCC CAR-T treatment [88,89]. The majority of the above-stated targets, though, are TAAs, which are expressed at low levels in

both cancerous and healthy cells, leading to both on- and off-target toxicities in normal tissue. The most significant objective for future researchers will be to identify new targeted antigens and improve the effectiveness and safety of CAR-T treatment for HCC.

Chimeric antigen receptor NK cells: The distribution of NK cells in the liver is substantially greater as compared to the peripheral blood and spleen. As a result, NK cells are thought to be important in the prevention of HCC and are assumed to be a promising source for cell therapy in the treatment of HCC [90]. The technique utilized to produce CAR-T cells could likewise be employed to generate CAR-NK cells from NK cells. Furthermore, because CAR-NK cells have a shorter lifespan as compared to CAR-T cells, they can lower the danger of autoimmune response and tumor transformation[91]. CAR-NK cells could also be generated from various resources, such as the peripheral blood mononuclear cells (PBMC), NK92 cell line, umbilical cord blood (UCB), and induced pluripotent stem cells (IPSC). Since CAR-NK cells could be delivered "off-the-shelf", abolishing the requirement for customized and patient-specific products, so is the case with CAR-T therapies currently, the danger of syngeneic xenograft responses and graft-versus-host (GVHD) sickness is reduced[92]. The therapeutic potential of GPC3-specific CAR-NK cells for HCC was investigated by Yu *et al*[93] in 2018. *In vitro* co-culture experiments with $GPC3^+$ HCC cells revealed considerable cytotoxicity and cytokine generation by GPC3-specific CAR-NK cells. Additionally, cytotoxicity was unaffected by soluble GPC3 and TGF-b, and hypoxic (1%) conditions did not significantly alter anti-tumor efficacy. In a different study, Tseng *et al*[94] developed CD147-specific CAR-T and CAR-NK cells to treat HCC using CD147 as the target antigen. The results indicated that numerous malignant HCC cell lines *in vitro*, as well as HCC tumors in xenograft and PDX animal models, could be successfully eliminated by CD147-specific CAR-NK cells. In a human CD147 transgenic mouse model, GPC3-synNotch-inducible CD147-specific CAR-NK cells preferentially destroy $GPC3^+CD147^+$ however not $GPC3^-CD147^+$ HCC cells and don't induce substantial on-target/off-tumor damage. The lack of effective gene transfer techniques in primary NK cells is one of the fundamental obstacles to CAR-NK immunotherapy. Numerous current investigations have shown that retroviral vectors may successfully transduce larger NK cells with efficiency ranging around 27% to 52% after just one round of transduction[95]. The insertional mutations linked to retroviral transduction and the detrimental actions on primary NK cell survival, however, are the most significant drawbacks of this strategy in a clinical setting.

TCR-engineered T Cell: TCR-Engineered T Cell (TCR-T) cells are created by altering T cells with the exogenous TCRs gene to precisely identify tumor antigen peptides-MHC complexes[96]. All tumor-derived proteins could indeed be broken down *via* proteasomes and displayed by MHC, allowing TCR-T cells to target both tumor surface and intracellular antigens. TCR-T therapy should therefore be more widely applicable compared to CAR-T therapy. HCV infection affects 130-150 million people worldwide and could result in conditions like HCC[97]. Spear *et al*[98] engineered T cells with a high affinity, HLA-A2-restricted, HCV NS3:1406-1415-reactive TCR to create HCV-specific TCR-T cells. The findings demonstrated that HCV-specific TCR-T cells may cause a relapse of established HCV+ HCC *in vivo*, indicating that HCV-specific TCR-T therapy might be an efficient technique for curing HCV-associated HCC. A lesser proportion of HCC tissues produced from HBV infection detain HBV gene expression, which may become TCR-T targets. In 2011, Gehring *et al*[99] identified TCR-T cells specific for the HBV surface antigen in PBMC of patients with chronic HBV and HBV-related HCC. These HBV-specific TCR-T cells may recognize HCC tumor cells and have a variety of uses.

Additionally, a phase I clinical experiment was carried out to assess the safety and efficiency of HBV-specific TCR-T in stopping HCC reappearance following transplantation of the liver[100] (NCT02686372). As previously stated, AFP is another TAA linked to HCC. Docta *et al*[101] recently mentioned the discovery of a human HLAA2/AFP158-specific TCR, and AFP-specific TCR-engineered autologous T cells from HCC patients are now being used in a clinical investigation (NCT03132792). In 2018, we found a large number of HLA-A2/AFP158-specific TCRs from HLA-A2 transgenic mice using an immunization technique that comprised recombinant lentiviral priming and peptide boosting[102]. These TCRs were expressed on human T cells, and both *in vitro* and *in vivo* tests revealed strong anti-tumor efficacy. Additionally, the outcomes of comprehensive X-scans showed that there is little to no cross-reactivity between these TCR T cells and human cells. A clinical trial including these TCRTs for the treatment of HCC patients has begun (NCT03971747). GPC3[103], New York esophageal squamous cell cancer 1 (NY-ESO-1)[104], and human telomerase reverse transcriptase (hTERT) are further options for HCC TCR-T treatment[105]. However, because TCRs are promiscuous, TCR-T cells might cross-react with healthy tissue MHC-peptide complexes, resulting in off-target damage. TCRs produced in mice and humans can both cause off-target harm.

Despite being produced in humans, the melanoma-associated antigen (MAGE)-A3/HLA-A1TCR induced severe cardiac damage *via* targeting the cardiac muscle protein titin[106]. However, while NY-ESO-1 TCRT has demonstrated clinical anti-tumor efficacy, the majority of similar TCRTs haven't been confirmed to be useful for patients. Various aspects could be addressed to increase the anti-tumor efficacy of TCR-T therapy, such as extending TCR-T *in vivo* survival, enhancing tumor infiltration, and preventing T cell depletion.

CYTOKINES RELATED TO ADVANCED HCC

Key elements of the immune system, cytokines are crucial in the immunological response to cancer. Recently, there has been a lot of interest in using cytokines to treat cancer as the immune system is competent in identifying and eliminating cancer cells[107]. In 1986, the United States FDA approved the use of IFN-α as the first cytokine for the treatment of hairy cell leukemia (HCL)[108]. In 1992, the use of high-dose IL-2 as a therapy for metastatic renal cell carcinoma (mRCC) and metastatic melanoma was approved (MM). Besides its original approval, IFN-α has been used to treat a variety of cancers, including mRCC, melanoma, follicular lymphoma when combined with bevacizumab, and Kaposi's sarcoma linked to the AIDS virus. Numerous factors can be used to categorize advanced diseases in HCC. The major liver disease societies approve the BCLC staging, which has been well verified[109]. In the BCLC staging system, level C is the advanced stage, and stage D is the final stage[110]. Multiple cytokines and stimulatory substances have been linked to the likelihood of progressive disease in HCC patients.

Interleukin-10: IL-10 is a highly effective anti-inflammatory cytokine[111]. The majority of activated immune cells, along with macrophages and monocytes, secrete IL-10, which reduces the secretion of inflammatory mediators, prevents the formation of antigens, and controls several other immunological properties[112]. While its significance in viral infections is widely known, its function in HCC is less clear. Interpreting IL-10 data for HCC is complicated by the finding that HCC patients have greater levels of IL-10 than cirrhotic patients and healthy controls, although not in viral hepatitis patients[113]. In one investigation, it was discovered that patients with IL-10 levels of more than 12 pg/mL had inferior post-operative results. It has also been investigated how IL-10 affects HCC which is incurable. IL-10 levels in serum were revealed to be a poor prognostic predictor in a prospective analysis of 74 patients with unresectable HCC, with a considerably poorer median survival (3 mo *vs* 12 mo; $P = 0.02$) [114]. Patients with elevated IL-10 levels in serum performed markedly worse than patients with decreased IL-10 levels in a larger trial of 222 patients with unresectable HCC (mainly related to HBV) [hazard ratio (HR) 2.2][114]. Elevated IL-10 levels dramatically decreased overall survival in patients with advanced disease (BCLC stage C) from 10.2 mo to 3.5 mo, compared to those with low IL-10 levels, who exhibited average mortality of 10.2 mo[115].

Interleukin-37β: The wideset of the 5 distinct isoforms of IL-37β (named IL-37a-e) is IL-37β[116]. This cytokine, which is generated by epithelial cells, macrophages, and monocytes inhibits the production of pro-inflammatory cytokines as well as EMT by activating the STAT3/IL-6 pathway[117]. Additionally, recombinant IL-37β studies *in vivo* on mice showed that the tumor volume was lowered compared to the untreated controls[118]. IL-37 β serum levels were found to be negatively correlated with the survival of advanced HCC in a study of HBV-related HCC patients. Higher levels of IL-37β in the subjects' bodies led to prolonged overall survival and disease-free survival[119]. Similarly, in a cohort with a high percentage of HBV-HCC, higher IL-37β expression in HCC tissues was linked with better DFS and survival[118]. These HCC findings, along with decreased IL-37β expression and production in metastatic tumors, suggest that IL-37β is implicated in signaling pathways that control metastasis and may have an impact on histopathologic prognosis[119].

CC Chemokine Ligand 20: CC Chemokine Ligand 20 (CCL20) (also known as macrophage inflammatory protein-3 alpha) links with CC chemokine receptor 6 (CCR6), causing immune cells to be chemoattracted to the zone of inflammation. CCL20 have been demonstrated to play several functions in rheumatoid arthritis, general inflammation, and various cancers[120]. *In vitro* and *in vivo* studies have revealed a function for the CCL20-CCR6 axis in HCC generation, development, and invasion[121]. Furthermore, in an investigation of 33 specimens from 22 patients, CCL20 overexpression was detected in tumors, indicating a function in hepatocarcinogenesis[122]. A role in tumor invasion, angiogenesis, and the development of hepatic malignancies has been suggested by several studies that have detected significant amounts of CCL20 and its receptor CCR6 in HCC and colorectal cancer liver metastases. The relationship between CCL20 expression and tumor grading, however, was only identified in one small study including 11 HCC patients (TNM stage 3 *vs* 2)[123]. Tumor-infiltrating regulatory T cells may be preferentially attracted to the tumor *via* the CCR6-CCL20 axis, according to an investigation of 293 HCC patients. This study found a favorable correlation between the number of regulatory T cells infiltrating the tumor and CCL20 expression in the tumor. Significantly, patients with HCC who had larger levels of tumor-infiltrating regulatory T cells had a worse prognosis[124].

IL-6: The predictive importance of pre-treatment blood IL-6 levels in the condition of advanced HCC was examined in research on 128 sorafenib-treated HCC patients divided into a finding and validating cohort. In both groups, a high level of serum IL-6 before therapy was a reliable indicator of poor overall survival. The time to progression and progression-free survival were comparable independent of pretreatment IL-6 levels, hence there was no association with sorafenib efficacy. Furthermore, pretreatment IL-6 levels were not associated with macrovascular invasion or extrahepatic dissemination [125]. Although promising, further research which is presently being undertaken, is required to establish the function of IL-6 in HCC therapeutic response. Interestingly, recent research in cellular

models has shown that blocking IL-6-related pathways reduces sorafenib resistance[126].

Angiopoietin-2: A major regulator of vascular development, angiopoietin-2 (ANG-2) is nearly entirely generated by epithelial cells and supports the actions of other endothelial-acting cytokines[127]. Superior pretreatment in the SHARP research, the first randomized placebo-controlled experiment to assess the effect of sorafenib in advanced HCC as well as the prognostic significance of multiple cytokines, ANG-2 levels were associated with shorter overall survival in the overall cohort as well as in the sorafenib arm. However, no link was discovered between sorafenib-associated survival and therapy interaction analyses. Nonetheless, those with higher plasma ANG-2 levels at week 12 had a smaller total survival and time to progression than those who did not have an increase in plasma levels[128]. A year after, the Okayama Liver Group (Japan) then performed a longitudinal analysis and retrospective investigation of serum cytokines in 2 independent sorafenib-treated advanced HCC cohorts. Increased pretreatment ANG-2 levels, as in the SHARP research, were linked to a worse overall survival rate[129]. Furthermore, when the researchers assessed ANG-2 in a prospective cohort, the difference was not statistically significant, most likely because there were fewer patients, even though patients with progressive disease had higher ANG-2 levels at the beginning of treatment than those having the non-progressive disease. ANG-2 levels, on the other hand, increased only in patients with worsening disease over time[129].

Hepatocyte growth factor: *In vitro* and animal models have revealed that hepatocyte growth factor (HGF) could either promote or prevent the development of HCC[130]. In both the sorafenib arm and the overall cohort of the SHARP trial, increased pretreatment plasma HGF levels were a significant independent predictor of worse overall survival. Surprisingly, sorafenib was linked with a greater benefit in terms of total survival and time to progression in patients with reduced HGF amount at the start of therapy. Additionally, in the therapy arm, a reduction in median HGF plasma levels at 12 wk was not associated with overall survival but was associated with a lengthier duration of progression [128]. In a prospective cohort, the Okayama Liver Group discovered pretreatment serum HGF levels to be a potential independent marker of overall survival, albeit significance was lost following multivariate analysis. Additionally, only in the retrospective cohort, HGF pretreatment levels were higher in patients with the progressive disease compared to non-progressive disease[131].

VEGF: Multityrosine kinase inhibitors, such as Sorafenib, target VEGF signaling as a major cytokine causing angiogenesis. The SHARP study looked at VEGF as a predictive marker in addition to ANG-2 and HGF. Similar to ANG-2, higher pretreatment VEGF amounts were linked to reducing survival. Nevertheless, the Sorafenib arm did not convert its predictive value. Interesting, the Sorafenib group's average plasma VEGF levels were significantly greater than those of the placebo group[128]. Furthermore, VEGF levels were shown to be higher in individuals than those later experienced disease advancement compared to non-disease progression in a retrospective study on HCC patients administered with sorafenib by the Okayama Liver group. Furthermore, higher baseline VEGF levels were linked to shorter overall survival and progression-free survival, which is consistent with the results of the SHARP trial. Nevertheless, the multivariate analysis failed to identify VEGF as a predictor of total survival[131]. Later, the same study team verified this finding in a prospective cohort of HCC patients receiving sorafenib therapy[129]. A decrease in plasma VEGF levels at 8 wk from baseline was shown by Tsuchiya *et al*[132] to be an independent predictive factor linked with 1-year survival following Sorafenib therapy in a small cohort of HCC patients.

THERAPEUTIC VACCINE

Tumor vaccines are substances that boost particular immune reactions to tumor antigens. For patients whose tumors don't have a lymphocytic infiltration that can be treated with ICI, immune-enhancing techniques may be helpful. One of the earliest immunotherapeutic methods applied in HCC among these methods is vaccination. In comparison to studies looking at adoptive cellular therapies and checkpoint inhibitors, clinical trials for such tumor vaccines in HCC are presently being conducted far less frequently. This is partly due to earlier disappointing trial results as well as the relative ineffectiveness of other tumor vaccines. This could be because it was formerly challenging to identify the proper tumor antigens, but that is now possible because of recent technology advancements permitting huge parallel DNA sequencing. Therefore, inducing an immune response remains a promising treatment strategy for HCC, either by itself or more likely in combination including an immune modulator. To date, several agents have been looked at in this area.

The high recurrence rate cannot be avoided by current treatments for advanced-stage HCC due to their insufficient efficacy. Vaccines have already been suggested as potential solutions to this problem, able to enhance clinical results when used in conjunction with existing recognized systemic treatments. Though they are harmless and have immunologic effects, the few trials that have been undertaken so far have only shown disappointing/poor clinical results/efficacy[133]. The majority of them are quite old,

and they are all phase I or II trials (Table 1). Peptide-based or DC-based vaccines are two categories of HCC vaccination methods now in use (Table 1). Additionally, this could be further divided into peptide-loaded and tumor lysate-pulsed DCs. Epitopes from the oncofetal antigens AFP[134,135], glypican 3 (GPC-3)[136], and the hTERT peptide GV1001 are the principal antigens used for peptide-based vaccinations in HCC[137]. Additionally, peptides from AFP and AFP coupled with MAGE-1 and GPC3 have been tested in clinical trials utilizing DCs loaded with peptides[138]. HepG2 (a hepatoma cell line) and autologous tumor lysates have both been employed in clinical trials[138,139]. All of these vaccination methods are risk-free, and even though clinical outcomes were subpar, the majority of them produced antigen-specific immune reactions without inducing toxic or autoimmune reactions. The various characteristics of HCC tumors and the vaccine's design, or even the combination of the two, may be to blame for this poor performance.

TAA-based vaccines are prone to tolerance mechanisms because they are not entirely tumor specific, which is reflected in the dearth of highly reactive clones against them[140]. As a result, responses are typically insufficient to stop tumor development. Additionally, as previously mentioned, the immunosuppressive HCC environment is not favorable for immune responses since it is a clear, prominent reflection of the intrinsic hepatic environment[141]. In addition, the restricted amount of TAAs expressed in HCC tumors makes it possible for immune evasion through Ag loss. Regarding their manufacturing, antigenic repertoire, and the variety of patients to be cured, the various vaccination modalities employed in HCC patients each have their benefits and drawbacks, which are listed in Table 2. Clinical trials for HCC have not yet fully utilized all vaccine strategies. Vaccination clinical trials in HCC with reported results are shown in Table 3. By changing the vaccination platform or adding new tumor antigens, vaccines may be improved. The first entails techniques like tumor cell fusion and *in vivo* DC-targeted immunization[140,141]. The assumption behind targeted vaccines is that by linking the antigen to antibodies, ligands, or viruses, non-target cell Ag delivery is prevented, potentially reducing any negative effects. In a recent preclinical model, we showed that this tactic increases the therapeutic effectiveness of ICI if it is paired with other treatments[142]. WT-1, ROBO1, FOXM1, and NY-ESO-1 are additional TAAs that may be utilized in upcoming clinical studies about a larger antigenic repertoire [143,144]. Finally, future HCC anticancer vaccination strategies should take into account neoAgs because of their tumor selectivity and possible increased immunogenicity[145].

DCs

DCs are expert antigen-presenting cells with a wide range of responsibilities, including the processing, presentation, and absorption of TAAs. Allogeneic DCs make up a significant portion of vaccines because they provide the antigen as well as the secondary co-stimulation required to effectively elicit a T cell activation. DCs from peripheral blood are isolated, grown ex vivo, and activated with cytokines like granulocyte-macrophage colony-stimulating factor (GM-CSF) to produce primed DCs for reinfusion. Another appealing, targeted strategy involves injecting such cells to cause the activation of effector cells, trigger a cascade of tumor rupture, and cause more TAA secretion[146]. To boost the effectiveness of the vaccine and optimize this TAA priming, a variety of approaches may be used. DCs might be cultured with tumor lysate or the fusion of DCs and tumor cells, or they may be transduced with DNA or RNA encoding recognized TAAs[141]. Ilixadencel (pro-inflammatory allogeneic DCs activated by GM-CSF and IL-4) was injected intratumorally in a newly published phase I trial, where 17 patients received it either alone or in conjunction with sorafenib. Tolerability evaluation was the main goal. There was just one grade 3 adverse event noted. Enhanced tumor-specific $CD8^+$T cells were seen in the peripheral blood of 73% of the 15 evaluable patients, indicating at least a successful immune-provoked response [147].

Peptide vaccines

An alternate choice for eliciting a powerful immune response is peptide vaccinations. However, despite immunological surrogates, like the generation of GPC-3 reactive cytotoxic T cells in one phase I trial, being successful, this has not led to clinical results[148]. GPC-3 and MRP3 have shown any efficacy in inducing a T cell response rate over 70%, while other TAAs such as SSX-2, NY-ESO-1, hTERT, and MAGE-A all induce considerably lower rates. This is despite a plethora of TAAs being found in HCC trials using AFP[149].

Oncolytic viruses

A more recent development in the arena of tumor vaccines is the use of oncolytic viruses. These therapeutically useful viruses are targeted to preferentially replicate in cancer cells. To date, they have been predominantly introduced by intra-tumoral injection. The modified poxvirus JX-594 remains the lead oncolytic virus of interest in clinical trials about HCC. As an immunotherapeutic agent, it piqued considerable interest when it conferred a dose-related survival benefit (median of 14.1 mo compared to 6.7 mo) in a phase II dose-finding trial of 30 patients[150,151]. The global, randomized, open-label, phase III study of Pexa-Vec (JX-594; an oncolytic vaccinia virus which selectively targets cancer cells) is currently recruiting patients with advanced HCC to two arms of vaccination with sorafenib *vs* sorafenib alone[152]. We excitedly await the results of this, particularly as a combination therapy.

Table 3 Vaccination clinical trials in hepatocellular carcinoma with reported results

Vaccine	Patient inclusion criteria	Patients, *n*	Immune response, %	Observations	Ref.
AFP HLA-A*02 restricted peptides + IFA	AFP + tumors from (stage IV patients)	6	66	Increased CTL response	[134]
DCs pulsed with autologous tumor lysate	Unresectable HCC	8	62	Immune response generation	[152]
DCs pulsed with autologous tumor lysate	Advanced HCC	31	0	Improved survival	[138]
DCs pulsed with AFP HLA-A*02 restricted peptides	Stage IV patients with surgery chemotherapy	10	60	No clinical responses	[135]
DCs pulsed with hepatoma cell-line (HEP-G2) lysate	No other therapeutic option	35	11.4	Evidence of antitumor efficacy	[139]
Gv1001 peptide + GM-CSF + cyclophosphamide	Advanced-stage HCC with no previous antitumor treatment	37	0	The immunological response is not detected	[137]
GPC3 HLA-A*24:02 and HLA-A*02-restricted peptides + IFA	Metastatic HCC or advanced HCC	33	91	Antitumor efficacy	[148]
DCs pulsed with fused recombinant proteins (AFP, MAGE-1 and GPC-3)	Surgical resection and locoregional therapy	12	92	Improved survival	[65]
GPC3 HLA-A*24:02 and HLA-A*02-restricted peptides + IFA	Vaccines as adjuvant therapy	41	85	Improved recurrence rate	[136]
AFP HLA-A*24:02 restricted peptides + IFA	Stage B/C tumors	15	33	Increased CTL response	[154]

Clinical trials with no published results have been excluded from the review. Incomplete Freund's Adjuvant, *immunologic response measurement was not appropriate. AFP: Alpha-fetoprotein; CTL: Cytotoxic T lymphocyte; DC: Dendritic cell; HCC: Hepatocellular carcinoma; GPC-3: Glypican-3; IFA: Incomplete Freund's Adjuvant; MAGE: Melanoma-associated antigen.

Immunotherapy toxicities and management

Immune-related adverse events: Immune checkpoint molecules serve an important function in immune homeostasis. Inhibitory immune checkpoint molecules, like PD-1 and CTL-4, are particularly important for balancing activation of T-cell and self-tolerance[153-155]. ICIs targeting PD-1 or CTL-4 may thereby produce a range of immune-related adverse events (IrAEs) by increasing self-immunity. IrAEs can affect every organ system and can range from a minor rash to life-threatening consequences. IrAEs caused by PD-1/PD-L1 inhibition are dose-independent[156]. Unlike anti-PD-1/PD-L1 agents, the risk of antiCTL-4-related adverse events is dose-dependent[157]. The gastrointestinal tract and skin were the most often affected organ systems by both anti-CTLA-4 and PD-1/PD-L1 inhibitors, whereas the endocrine systems and liver were less frequently affected[156,157]. In meta-analysis of phase 2/3 trials patients treated with ICIs, found that a rash was the most prevalent all-grade IrAE, with colitis and an increase in aspartate aminotransferase level being the most common high-grade IrAEs. Ipilimumab was related with a significantly greater incidence of rash and colitis when compared to anti-PD-1/PD-L1 drugs[158].

Management of IrAEs: Because IrAEs are linked with a wide range of aggravating factors in the context of HCC, hepatologists face significant hurdles in detecting and managing them. First, liver cirrhosis causes progressive immunological dysfunction, including immune deficiency as well as systemic inflammation[159]. Thus, in these patients, the liver-related immune homeostasis is already significantly disrupted. Second, cirrhosis-related hepatic and extrahepatic problems may overlap with or intensify symptoms caused by IrAEs, hampered early and rapid detection, which is compulsory concerning the consequence of potentially life-threatening episodes. Thus, before starting ICI therapy, individuals with HCC should be carefully selected and evaluated. In general, IrAE management is built on three pillars. First, close monitoring is required, including weekly clinical controls and, depending on the severity of the incidents, hospitalization. Importantly, individuals with severe IrAEs should be referred to a specialized center as soon as possible. This is especially important in patients with liver cirrhosis because distinguishing between cirrhosis-associated complications and IrAEs can be difficult, and premature discontinuation of an effective antitumor therapy or starting of steroid therapy in cirrhotic patients can have serious consequences[160]. Second, depending on the type and severity of IrAEs, ICI therapy may need to be either interrupted or permanently discontinued. Apart from PD-1/PD-L1-driven rash, adrenal insufficiency, nephritis and hypothyroidism, which recover after 1 mo of cessation, permanent termination of ICI therapy should be considered for higher grade IrAEs[160]. Re-exposure to ICI therapy after withdrawal, on the other hand, is associated with a significant risk of IrAE recurrence

[161]. Third, for IrAEs of greater than grade 2, glucocorticoids (0.5 to 2 mg/kg/d prednisone oral or intravenous depending on the type and severity of IrAEs) may be needed. Cutaneous IrAEs are treated with topical, oral, or intravenous glucocorticoids and topical or oral antihistamines, depending on the severity of clinical presentation. Cutaneous IrAEs range from commonly observed rash or pruritus to very less common but more severe disorders such as Stevens-Johnson syndrome[160]. Steroids should be continued for at least 3 d and then tapered over a period of 1 wk to 4 wk[162,163].

Differential diagnosis is required for gastrointestinal IrAEs, notably colitis and/or diarrhea, in order to rule out infectious disorders and pharmacological side effects[160]. In the event of glucocorticoid failure, immunosuppressive medication (such as vedolizumab or infliximab) should be started as soon as possible[164]. The diagnosis and management of immune-related hepatitis in HCC patients receiving ICI therapy is particularly difficult[160]. As a result, seeking the advice of an experienced hepatologist as soon as possible is strongly advised. Intrahepatic tumor growth, hepatitis B virus and/or hepatitis C virus or newly acquired viral hepatitis, cytomegalovirus reactivation, hepatotoxic medication side effects, cholestasis, and ascites should all be ruled out before diagnosing immune-related hepatitis[160]. A liver biopsy should also be considered prior to steroid therapy. For severe cases of immune-related hepatitis, oral or intravenous steroids may be used[160]. After the toxicity has subsided, tapering should be done over a period of 4-6 wk[162,163].

Pneumonitis is a potentially life-threatening IrAE. As a result, the pneumonitis should be followed by a prompt and thorough differential diagnosis, including the elimination of viral etiologies, hepatopulmonary syndrome and porto-pulmonary hypertension[160]. Steroids should be started, and tapering should take 4-6 wk[163]. Following glucocorticoid failure, infliximab or mycophenolate mofetil may be administered[160]. Thyroid-related IrAEs include hypothyroidism and hyperthyroidism caused by thyroiditis. A progressive reduction in thyroid-stimulating hormone in conjunction with normal or decreasing thyroxine levels should trigger repeated cortisol assessments to rule out immune-related hypopituitarism. In the case of hypothyroidism, thyroxine substitution is only recommended in symptomatic patients[162]. Thyroid antibodies and uptake should be assessed in symptomatic hyperthyroid patients, and beta-blockers and/or carbimazole should be investigated. Asymptomatic patients do not require any special treatment, and ICI therapy should be continued. Patients on ICI therapy should have regular thyroid stimulating hormone and free thyroxine tests. If central hypothyroidism is suspected, each pituitary hormone axis should be examined[160]. Cortisol, corticotropin-releasing hormone, adrenocorticotropic hormone, luteinizing hormone, thyroid stimulating hormone, free thyroxine, follicle-stimulating hormone, estradiol (premenopausal women), testosterone (men), insulin-like growth factor 1, and electrolytes are examples of these hormones[162,163].

CONCLUSION

Finally, HCC is a multifaceted illness with multiple faces. It avoids early discovery, which provides the best chance of cure by resection/transplant, and systemic treatments are only of marginal efficacy at best, despite recent therapeutic advances. Current advances in immunotherapy and its combinations have altered the HCC treatment landscape and clinical studies are continuing to pave the path forward. Immunotherapy increases survival rates and provides long-term cancer control in subsets of HCC patients while also minimizing side effects. Further research into immunotherapy in combination with current treatments for HCC in the early and intermediate stages may assist a greater spectrum of patients. Continued research into PD-1/PD-L1, TMB, ctDNA, microsatellite stability, DNA mismatch repair, neutrophil/lymphocyte ratio, cytokines, and cellular peripheral immune response will hopefully identify the most reliable marker for selecting and sequencing systemic treatments to achieve the best outcome in HCC patients. Despite such significant treatment advances in HCC, numerous hurdles remain. The scientific community must figure out how to appropriately sequence these medicines for the best potential response, how to control toxicities, and how to develop indicators to monitor for response and relapse.

ACKNOWLEDGEMENTS

We want to thank you, Dr. A. P. Pawar, Principal, Poona College of Pharmacy, Bharati Vidyapeeth (Deemed to be University), for providing the necessary facilities to carry out this research work.

ORIGINAL ARTICLE

Retrospective Study

Clinical-radiomics nomogram for predicting esophagogastric variceal bleeding risk noninvasively in patients with cirrhosis

Rui Luo, Jian Gao, Wei Gan, Wei-Bo Xie

Specialty type: Gastroenterology and hepatology

Provenance and peer review: Unsolicited article; Externally peer reviewed.

Peer-review model: Single blind

Peer-review report's scientific quality classification

Grade A (Excellent): 0
Grade B (Very good): B, B
Grade C (Good): C, C
Grade D (Fair): D
Grade E (Poor): 0

P-Reviewer: Chen SH, Taiwan; Paparoupa M, Germany; Tai DI, Taiwan

Abstract

BACKGROUND

Esophagogastric variceal bleeding (EGVB) is a serious complication of patients with decompensated cirrhosis and is associated with high mortality and morbidity. Early diagnosis and screening of cirrhotic patients at risk for EGVB is crucial. Currently, there is a lack of noninvasive predictive models widely available in clinical practice.

AIM

To develop a nomogram based on clinical variables and radiomics to facilitate the noninvasive prediction of EGVB in cirrhotic patients.

METHODS

A total of 211 cirrhotic patients hospitalized between September 2017 and December 2021 were included in this retrospective study. Patients were divided into training (n = 149) and validation (n = 62) groups at a 7:3 ratio. Participants underwent three-phase computed tomography (CT) scans before endoscopy, and radiomic features were extracted from portal venous phase CT images. The independent sample t-test and least absolute shrinkage and selection operator logistic regression were used to screen out the best features and establish a radiomics signature (RadScore). Univariate and multivariate analyses were performed to determine the independent predictors of EGVB in clinical settings. A noninvasive predictive nomogram for the risk of EGVB was built using independent clinical predictors and RadScore. Receiver operating characteristic, calibration, clinical decision, and clinical impact curves were applied to evaluate the model's performance.

RESULTS

Albumin (P = 0.001), fibrinogen (P = 0.001), portal vein thrombosis (P = 0.002), aspartate aminotransferase (P = 0.001), and spleen thickness (P = 0.025) were selected as independent clinical predictors of EGVB. RadScore, constructed with five CT features of the liver region and three of the spleen regions, performed well in training (area under the receiver operating characteristic curve (AUC) = 0.817) as well as in validation (AUC = 0.741) cohorts. There was excellent predictive performance in both the training and validation cohorts for the clinical-radiomics model (AUC = 0.925 and 0.912, respectively). Compared with the existing noninvasive models such as ratio of aspartate aminotransferase to platelets and Fibrosis-4 scores, our combined model had better predictive accuracy with the Delong's test less than 0.05. The Nomogram had a good fit in the calibration curve (P > 0.05), and the clinical decision curve further supported its clinical utility.

CONCLUSION

We designed and validated a clinical-radiomics nomogram able to noninvasively predict whether cirrhotic patients will develop EGVB, thus facilitating early diagnosis and treatment.

Core Tip: Esophagogastric variceal bleeding (EGVB) is a life-threatening complication of liver cirrhosis. Currently, no noninvasive prediction models for bleeding risk are widely used in clinical practice. Our study extracted radiomics features from computed tomography and identified portal vein thrombosis, fibrinogen, aspartate aminotransferase, albumin, and spleen thickness as independent clinical predictors. Consequently, we established a novel clinical-radiomics model for noninvasive prediction of EGVB. This model exhibits superior diagnostic performance and can assess bleeding risk early. It has the potential to facilitate early prevention and treatment of possible bleeding in cirrhotic patients with esophagogastric varices.

INTRODUCTION

In liver cirrhosis, esophagogastric variceal bleeding (EGVB) is among the most common complications associated with portal hypertension, characterized by acute life-threatening sequelae and high mortality rates[1]. Approximately 50% of patients with cirrhosis develop esophagogastric varices (EGV) and approximately 10%–15% of these rupture and hemorrhage annually. Almost 12% – 20% of patients die within 6 wk of acute variceal bleeding, and 60% are likely to rebleed within a year, thus endangering their lives and degrading their quality of life[1-3]. Therefore, the early identification of cirrhotic patients at risk of EGVB is essential.

Endoscopy is the gold standard for detecting patients with EGVB, which is recommended by guidelines for diagnosing and screening EGV as well as for assessing bleeding risk[4]. However, some patients refuse upper gastrointestinal endoscopy due to its invasiveness and poor tolerance. Furthermore, repeated examinations may reduce long-term compliance and thereby confound clinical observation. Moreover, endoscopy has the potential to provoke EGVB in low-risk patients, and carries the attendant risks of anesthesia. Consequently, regular follow-up through endoscopy is difficult.

The Baveno VII consensus workshop recommended that patients with compensated cirrhosis whose liver stiffness and platelet counts meet cut-off points may be spared endoscopic screening[3]. However, because the Baveno criteria have a low specificity for ruling out high-risk varices, some patients still require a subsequent endoscopy[5]. Ultrasound elastography is impeded by ascites, obesity, bowel gas, and other clinical issues. The above reasons limit the application of the Baveno criteria in clinical practice. Measurement of the hepatic venous pressure gradient serves as the gold standard for the diagnosis of portal hypertension and to assess treatment response, which is an effective tool for predicting the risk of bleeding at the EGV[3]. However, its measurement entails an invasive procedure that requires specialized operators and equipment, as well as high economic costs that limit its availability in clinical practice.

Conversely, the widespread use of computed tomography (CT) in cirrhotic patients facilitates the diagnosis and evaluation of complications. Typical CT manifestations of cirrhosis include disproportionate sizes of hepatic lobes, marked widening of hepatic fissures, wavy patterns of hepatic edges, visible gallbladder displacement, and heterogenous hepatic parenchymal density[6]. In addition, CT images can visualize cirrhosis-related complications such as portal vein widening, portal hypertension, collateral circulation, and splenomegaly[7]. All of these manifestations can facilitate the diagnosis of cirrhosis. Nonetheless, the utility of CT-based screening depends highly on the experience and subjective judgement of the radiologist.

Recent studies on the noninvasive assessment and prediction of EGV have made progress. Radiomics is an emerging image analysis technology that focuses on extracting high-throughput and quantitative features from medical images, using data mining algorithms to detect associations between radiographic features and diseases, and to then develop corresponding models for each feature[8]. It is used primarily for tumor diagnosis, efficacy evaluation, and prognosis[9]. Only a few studies have utilized it to assess non-neoplastic liver diseases and portal hypertension[10-14]. The CHESS team from China established the first model for predicting clinically significant portal hypertension based on radiomics features of liver and spleen, and demonstrated good diagnostic performance (area under the receiver operating characteristic curve (AUC) = 0.894)[11]. Additionally, Lin *et al*[15] evaluated the safety and efficacy of predicting high-risk EGV by combining esophageal and gastric radiomics features. By extracting CT features from hepatic, splenic, and lower esophageal regions of interest (ROIs), Liu *et al*[12] combined radiomics signature with clinical indicators to establish a prediction model to identify the likelihood esophageal variceal bleeding. Yang *et al*[14] integrated radiomics from the liver region with clinical variables to estimate the bleeding risk of EGV in cirrhosis related to hepatitis B.

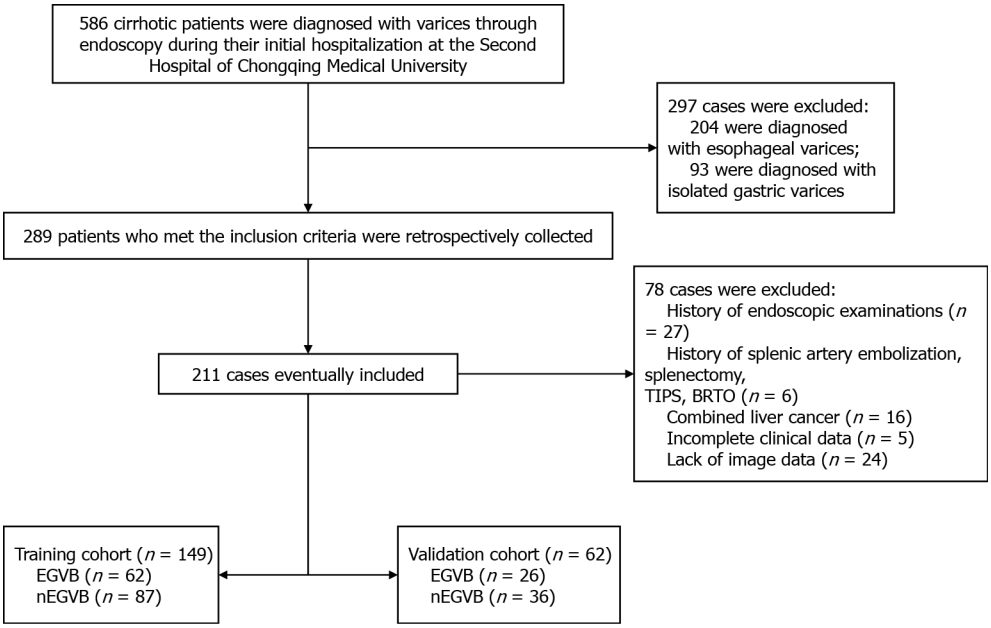
However, previous radiomics models have not explored the risk of EGVB in patients with cirrhosis of varied etiologies. Furthermore, their performance has not been compared to existing noninvasive models. The establishment of a noninvasive prediction model may reduce the frequency of endoscopic examinations in patients without EGVB, while patients at risk of EGVB may receive more timely diagnosis and treatment, which is of great significance for guidance of follow-up treatment and review. Therefore, our study sought to develop a noninvasive predictive model that combines radiomics features of the liver and spleen as well as clinical indicators for predicting the risk of EGVB in patients with cirrhosis, and to evaluate its clinical utility.

MATERIALS AND METHODS

This was a retrospective study conducted at a single center, with an informed consent waiver granted by the Institutional Review Board.

Patients

Patients diagnosed with liver cirrhosis and EGV between September 2017 and December 2021 were included in our study by retrospective review. The following were the criteria for inclusion: (1) Diagnosis of cirrhosis through histopathologic examination or a combination of clinical, laboratory, and radiologic findings; (2) Completion of a triple-phase enhanced CT scan within one week prior to endoscopy; and (3) All patients diagnosed with EGV through endoscopy. Exclusion criteria were: (1) Previous endoscopic therapy, trans jugular intrahepatic portosystemic shunt, splenectomy, splenic artery embolization, balloon occlusion, retrograde transvenous occlusion, or liver transplantation; (2) Patients with liver neoplasms; and (3) Incomplete clinical or imaging data.



As a random assignment in a 7:3 ratio, patients were divided into training and validation cohorts. Finally, there were 149 patients included in the training set, as well as 62 in the validation one. A flowchart of our study is shown in Figure 1.

Endoscopy

Endoscopies were performed by experienced gastroenterologists. The diagnosis of EGVB-positive was based on one or more of the following signs: (1) Bleeding or exudation of the variceal region; (2) Fresh blood, with the exclusion of non-variceal hemorrhage; and (3) Signs of recent variceal bleeding (stain), such as a white thrombus or an overlying blood clot[4,16]. Ulcers, portal hypertensive gastropathy, and other non-variceal factors may also lead to upper gastrointestinal bleeding. When patients had a recent history of bleeding and endoscopy failed to find evidence of variceal hemorrhage, we considered other etiologies of bleeding such as portal hypertensive gastropathy and ulcers.

CT Scan

CT examinations were performed using a Siemens SOMATOM Force dual-source CT scanner (Siemens Healthcare). Patients were instructed to fast for more than four hours without consuming any solid food or liquids. They were allowed to drink up to 800 mL of water before scanning. Iohexol (350 mg/mL) was injected under high pressure into the cubital vein at a dose of 1.5 mL/kg and at a flow rate of 4.5 mL/s, followed by flushing with 30 mL of a saline solution. Siemens CT used contrast agent concen-

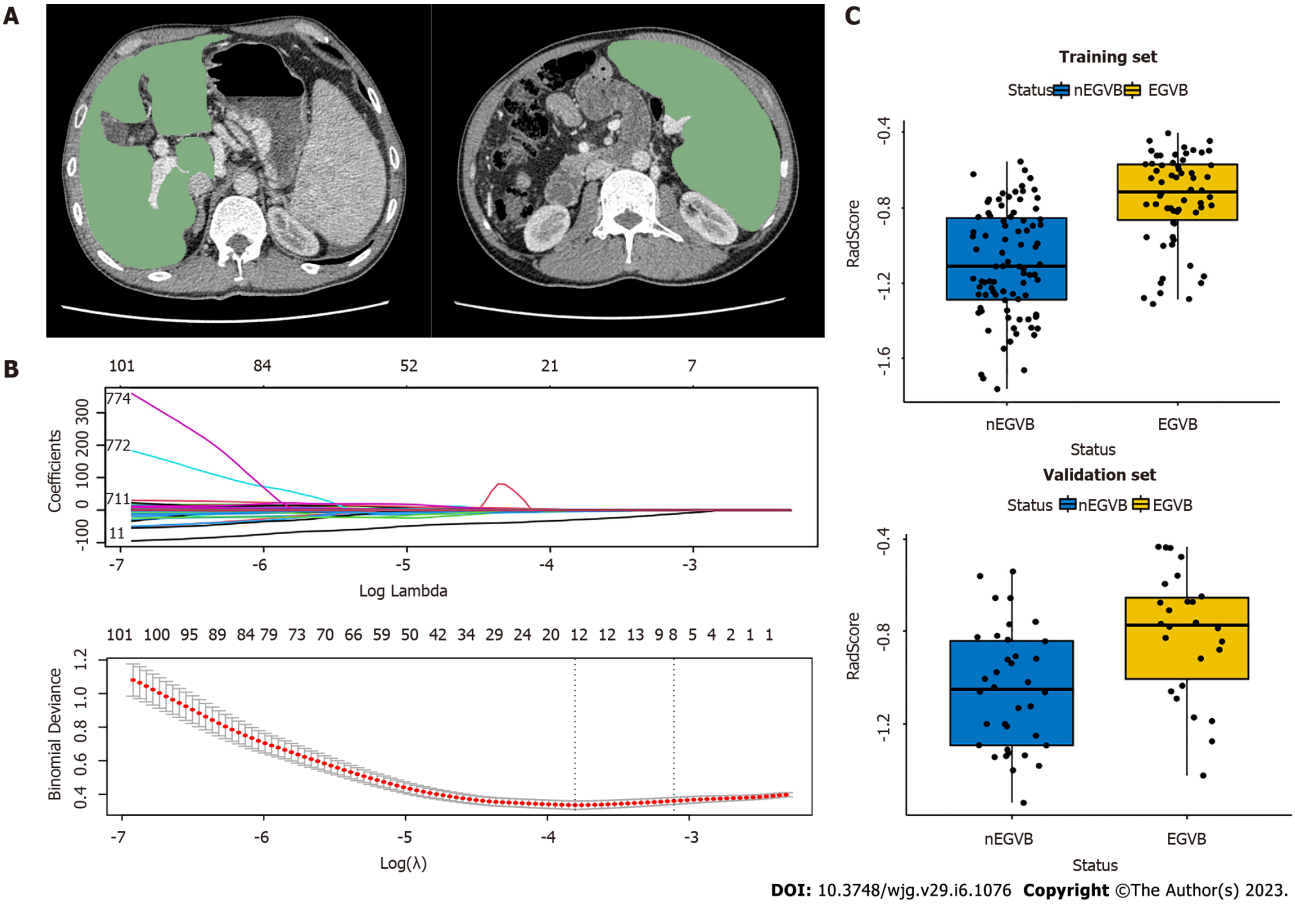
tration tracking technology to obtain standard three-phase images of the abdominal aorta after setting a threshold of 100HU and triggering delays of 10 s, 20 s, and 15 s. Scan parameters were: tube voltage, 120 kV or 70 kV; tube current, 148 mAs; slice thickness, 1 mm; slice interval, 0 mm; and pitch ratio, 0.6. Feature extraction was performed on all images and exported in Digital Imaging and Communications in Medicine format.

Measurements of related parameters from CT images[17] were: (1) Portal vein thrombosis: endovascular filling defect of the portal vein; (2) Splenorenal/gastrorenal shunts: tortuous and thick vessels between the lesser curvature of the stomach, the splenic hilum, and left renal hilus, which may dilate and communicate with the left renal vein; (3) Upper and lower splenic diameters: The vertical distance from the upper to the lower margin of the spleen, *i.e.*, the lower pole window minus the upper pole window of the spleen; (4) Spleen diameter: The longest diameter of the spleen at the central level of the splenic hilum (antero-posterior straight line); and (5) Spleen thickness: The shortest diameter from the inner margin to the outer margin of the spleen at the central level of the splenic hilum.



CT image preprocessing and ROI segmentation

After retrieving CT images from all patients, the radiologist used the 3Dslicer (V4.13.0, https://www.slicer.org/) to delineate ROI in the portal venous phase. ROIs of the liver and spleen were set at the levels of the hepatic and splenic hila, respectively (Figure 2A), excluding the large blood vessels. The radiologist was blinded to the endoscopic results.

Feature extraction and selection in radiomics

Before the extraction of radiomic features, images were normalized by Gaussian filtering, wavelet bandpass filtering, and isotropic resampling. Based on ROIs, we could extract radiomics features through the Pyradiomics-based extension package Radiomics of 3Dslicer. There were 1130 radiomic features extracted for each ROI, totaling 2260 per patient.

To analyze inter- and intra-observer reliability, 30 cases were selected randomly from the total sample. After two months, two radiologists experienced in abdominal CT interpretation repeated segmentation and feature extraction for these cases. Reliability was assessed by the intraclass correlation coefficient (ICC), and was considered strongly reproducible and dependable when ICC values exceeded 0.75. Features above the ICC threshold of 0.75 were included in subsequent studies. To reduce the overfitting caused by a great number of redundant features, an independent sample t-test was applied to features and classification labels to screen out highly correlated features. Next, the least absolute shrinkage and selection operator (LASSO) regression was conducted to obtain dimensionality reduction, retain the most relevant features, and construct radiomic features from non-zero coefficient features within one standard deviation of the optimal penalty parameter lambda. A radiomics signature (RadScore) was calculated and constructed for each patient through a linear combination of selected features weighted by their respective LASSO coefficients.

Statistical analysis

Quantitative data from normal distribution are represented by X (standard deviation), from non-normal distribution by M (P25-P75), and count data by percentage. Both univariate logistic and multiple logistic regressions with backward stepwise selection were used for the selection of independent risk factors for clinical variables. For the training and validation cohorts, we calculated the AUC the receiver operating characteristic curves to evaluate the predictive accuracy of clinical-radiomic models. Furthermore, the clinical-radiomics nomogram was subjected to decision curve and clinical impact curve analyses to determine its clinical utility and net benefit. There were two statistical analysis software programs carried out for this study: R (version 4.1.3) and Python (version 3.9.7). Statistical tests were all two-way, and it was considered statistically significant when the *P*-values were less than 0.05.

RESULTS

Patient characteristics

In our study, there were a total of 211 patients diagnosed with cirrhosis and EGV (131 men and 80 women), 123 of whom were identified as EGVB-negative (nEGVB) and 88 were EGVB-positive. Thirteen were diagnosed with cirrhosis by histological examination, and the remaining 198 patients were diagnosed with cirrhosis by a combination of history, clinical manifestations, laboratory findings, and CT examination. Of these, some were hospitalized for acute decompensation events such as bleeding, ascites, and hepatic encephalopathy in a short-term period. Hemorrhage occurred primarily in the EGVB-positive group, while ascites and hepatic encephalopathy were present in both EGVB-positive and -negative groups.

From electronic medical record systems, we obtained the complete demographic and clinical data about patients. Table 1 summarizes the baseline characteristics of patients.

Radiomics Feature Selection and Radiomics Signature Construction

Based on an independent sample t-test and LASSO regression, eight radiomics features were selected, five from the liver and three from the spleen (Figure 2B). Through weighting the LASSO coefficients of the selected features, we established a radiomics signature (RadScore). The specific formula of RadScore

is shown in the supplementary material. The boxplots in the training and validation cohorts indicated that RadScores differed remarkably ($P < 0.001$) (Figure 2C).

Model Construction and Evaluation

Univariate analysis screened out clinical features that were significantly related to EGVB ($P < 0.05$). To minimize the effects of multicollinearity, we performed a multivariate backward stepwise regression to confirm portal vein thrombosis, aspartate aminotransferase (AST), albumin, fibrinogen, and spleen thickness as independent risk factors for EGVB ($P < 0.05$) (Table 2). The variance inflation factor was less than 4.

By combining independent clinical predictors with RadScore, a clinical-radiomics nomogram was established by generalized linear regression (Figure 3). The calibration curve performed well in both training and validation groups, with Hosmer-Lemeshow test results of $P = 0.775$ (Figure 4A) and $P = 0.391$ (Figure 4B) respectively, indicating that the nomogram's predictive power and the actual risk of developing EGVB did not differ significantly. As shown in the training set (Figure 5A), the clinical-radiomics nomogram demonstrated excellent predictive performance with an AUC of 0.925 (95%CI: 0.883-0.967) and 0.912 (95%CI: 0.845-0.98) as shown in the validation set (Figure 5B). Furthermore, compared with other noninvasive methods such as APRI and FIB-4 reported in studies previously, our clinical-radiomics nomogram exhibited the highest diagnostic accuracy, with Delong test of less than 0.05. Decision curve analysis showed that the clinical-radiomics nomogram had a high clinical applicability that exceeded those of existing noninvasive serum-based predictive models such as APRI and FIB-4 in both the training (Figure 6A) and validation (Figure 6B) sets. Moreover, the clinical impact curve of the nomogram was constructed based on 1,000 simulated samples, which revealed that the nomogram yielded an event probability that corresponded closely to actual high risk when the risk threshold was between 0.4 and 0.8, and consistently when it exceeded 0.8 (Figure 7).

DISCUSSION

With a high mortality and morbidity rate, EGVB is among the most serious complications related to decompensated cirrhosis[1]. A routine endoscopic examination is recommended as a diagnostic method for assessing the grade and bleeding risk of EGV[4]. However, the bleeding risk of invasive procedures, contraindications to anesthesia, and unnecessarily excessive endoscopic examinations limit its clinical application and, to some extent, lead patients to forego their follow-ups. In recent years, there has been an increasing demand for noninvasive methods to estimate the risk of EGVB in cirrhotic patients. Noninvasive diagnostic methods such as ultrasonography, magnetic resonance imaging, and CT have both advantages and disadvantages[18-20], and there are no standardized noninvasive models for EGVB that can be used widely in clinical practice.

Radiomics is an emerging diagnostic tool that has the ability to extract numerous image features noninvasively and describe modules for quantitatively evaluating gray scales and pixel distribution in medical images, which are undetectable by the naked eye[21]. It has yielded satisfactory results, and has become increasingly popular in diagnosis, assessment of treatment response, and prognosis in recent years[8]. It can comprehensively describe ROIs from the perspectives of morphology, histogram, texture, and higher-order features such as texture features extracted through Gaussian, wavelet, and other filtration methods[22].

We constructed a RadScore based on five liver features and three spleen features. Among them, 5 texture and 3 histogram features were extracted, 7 of which were higher-order filtered features. Small Area Low Gray Level Emphasis, Size Zone Non Uniformity Normalized, Short Run High Gray Level Emphasis, Cluster Shade, and Imc1 are texture features[23]. As crucial components of radiomics features, they combine pixels and shapes, and thereby describe the spatial relationships of adjacent pixels. Kurtosis, Skewness and Maximum are histogram features that emphasize the distribution pattern of gray-level pixel values within ROIs[23]. RadScore can accurately predict EGVB risk as evidenced AUCs of both the training and validation sets, and performed better in the validation group in comparison to Yang *et al*[14]'s previous study that only included liver ROIs.

There is no single radiomics model which is capable of fully reflecting the characteristics of the disease. Consequently, multiparametric, multi-omics, and multivariate models have generated increasing interest. By incorporating readily available independent clinical predictors and RadScore, diagnostic performance has been further enhanced, with an AUC of 0.925 (95%CI: 0.883-0.967) and 0.912 (95%CI: 0.845-0.98) in the training and validation sets, respectively. Meanwhile, our combined model performed better in predicting EGVB than other noninvasive methods (such as APRI and FIB-4) that have been fully validated in previous studies. Decision curve analysis showed that the clinical-radiomics nomogram can yield a good net benefit in clinical applications. The reduced AUCs of all models in the validation cohort are readily apparent, and may have been caused by the small sample size. In addition, the EGVB group included 29 patients with variceal bleeding at the esophagogastric junction and 27 at the gastric fundus. To some extent, our model could predict the overall risk of variceal bleeding in the esophagogastric junction and gastric fundus. However, no radiomics-related

HE: Hepatic encephalopathy; PLT: Platelet; PT: Prothrombin time; APTT: Activated partial thromboplastin time; INR: International prothrombin ratio; Fib: Fibrinogen; Tbil: Total bilirubin; DBil: Direct bilirubin; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; SL: Spleen upper and lower diameter; SD: Spleen diameter; ST: Spleen thickness.

studies have specifically addressed the risk of variceal bleeding at these two anatomic sites. Prospective exploration and analysis in follow-up studies are necessary.

Cirrhosis features fibrosis and regenerative hepatic nodules that compress sinusoids, resulting in sinusoidal narrowing that promotes vascular collateralization[1]. Furthermore, portal hypertension predisposes to branched splenic vein obstruction, leading to congestive splenomegaly and hypersplenism. Numerous studies have confirmed associations between liver, spleen, and portal hypertension [18,24]. In earlier studies of radiomics models for predicting variceal bleeding in cirrhosis, Liu's research only examined esophageal variceal bleeding[12], and Yang *et al*'s study only included liver ROIs[14]. In contrast to previous reports, we included patients with cirrhosis of multiple etiologies and extracted hepatic and splenic features simultaneously. Additionally, our combined model showed a better performance in comparison with other multivariate ones.

Our study found that portal vein thrombosis, fibrinogen, AST, albumin, and spleen thickness were independent risk factors for EGVB in patients with cirrhosis. According to previous studies, portal vein thrombosis is one of the risk factors for EGVB in liver cirrhosis, which may be related to the increased portal pressure to some extent[25,26]. Impaired hepatic synthetic capacity disturbs procoagulant (*e.g.*, fibrinogen) and anticoagulant balance, resulting in coagulopathies. The decrease of fibrinogen may result in an inefficient removal of activated coagulation factors and ultimately increase the risk of bleeding. AST is a functional hepatic enzyme that can indirectly reflect hepatocellular injury. Albumin and spleen thickness are significantly correlated with the presence of EGV, and were considered as risk factors in previous research[27-29]. In contrast to several previous studies, we found that platelet count was not an independent clinical predictor and may be related to its predisposing factors such as hypers-

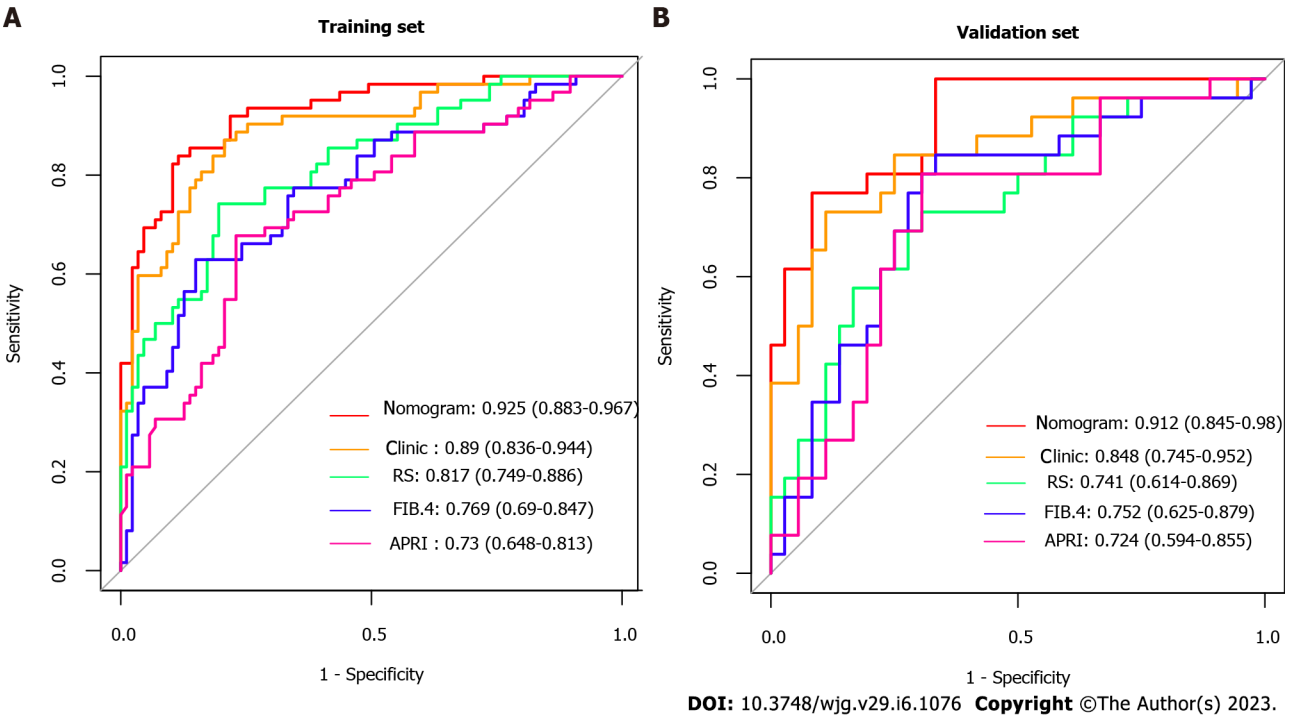
Figure 3 The construction of a clinical-radiomics prediction model for esophagogastric variceal bleeding. The clinical-radiomics nomogram for predicting bleeding risk. The scores of the different variables in the nomogram were summed to obtain the total score, and a line was drawn from the axis of the total score to the bottom line to determine the probability of bleeding risk. Fib: Fibrinogen; AST: Aspartate aminotransferase; ST: Spleen thickness; EGVB: Esophagogastric variceal bleeding.



plenism, antibody-mediated destruction (primarily during viral hepatitis), reductions in thrombopoietin, and bone marrow toxicity caused by hepatitis viruses and alcohol. The Child Pugh score can reflect hepatic functional reserve, often as a prognostic indicator in patients with cirrhosis. Most of the patients in our retrospective study had splenomegaly and hypersplenism, and Child Pugh scores were predominantly grade B in both the EGVB and nEGVB groups. Child Pugh scores, platelet counts, and total bilirubin levels were similar between the two groups ($P > 0.05$). Similar results were also shown previously[30,31].

Several limitations have been identified in our study. Firstly, this is a small-scale single-center retrospective study. Large, multicenter and prospective studies will be required to verify the model's feasibility in the future. Moreover, there is no relevant study to explore the performance of models in predicting the risk of bleeding in patients with different Child Pugh class. Our study has demonstrated that there was no significant difference in the Child Pugh scores between the EGVB and nEGVB group, and the prediction model performed well in assessing the risk of bleeding on the whole. Exploring the diagnostic performance of the model for bleeding risk in patients with different Child Pugh class can facilitate further refining the risk stratification of patients and achieve precision medicine, which should be investigated in subsequent research. Secondly, elastography can predict portal hypertension and EGV to some extent by measuring liver and spleen stiffness. Lin *et al*[15] compared a radiomics nomogram with liver stiffness measurement through transient elastography in a subgroup of 42 patients, showing the nomogram was superior in predicting high-risk EGV. However, comparisons of elastography with radiomics models to predict variceal bleeding are lacking. In our retrospective study, most patients did not undergo elastography. We failed to retrieve the relevant data, which we see as a shortcoming of our study. The comparison of elastography with radiomics models is crucial, and should be conducted in the later studies. Thirdly, more in-depth investigations of multi-image and multi-omics (such as metabolomics, genomics, *etc*.) were not conducted. For subsequent studies of EGVB, multimodal and multi-omics models, deep learning, and other methods should be fully employed.

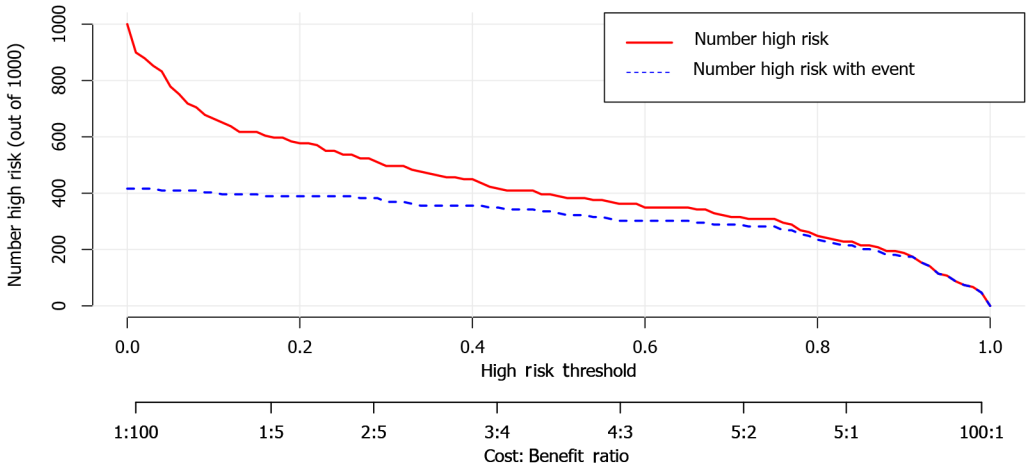
Figure 5 The receiver operating characteristic curves in the study. A: The receiver operating characteristic curves (ROC) in the training cohort; B: The ROCs in the validation cohort. Clinic: The model based on clinical individual indicator; RS: Radiomics Signature (RadScore); APRI: Ratio of aspartate aminotransferase to platelets; FIB-4: Fibrosis-4 scores.



CONCLUSION

We established a multivariate prediction model based on CT radiomics features and clinical characteristics, which demonstrated good performance for predicting EGVB in cirrhotic patients. Aided by clinical-radiomics nomogram, clinicians can base therapeutic decisions on fewer invasive procedures while personalizing follow-up treatment.

Figure 6 The clinical decision curves for bleeding prediction. A: The training cohort; B: The validation cohort. A threshold probability is the point at which the expected benefits of a treatment equal those of not receiving treatment. As shown by the different lines in the diagram, red indicates the clinical-radiomics nomogram, green indicates Fibrosis-4 scores (FIB-4), yellow indicates Ratio of aspartate aminotransferase to platelets (APRI), pink indicates the hypothesis of patients without esophagogastric variceal bleeding (EGVB), and blue indicates that all patients developed EGVB. They indicate that the clinical-radiomics nomogram is superior to the non-invasive serum predictive model's APRI and FIB-4 in terms of clinical utility. APRI: Ratio of aspartate aminotransferase to platelets; FIB-4: Fibrosis-4 scores.

Figure 7 Clinical impact curve of the nomogram for 1,000 simulated samples. The blue dashed line is the actual high-risk number, and the red line is the high-risk number based on the nomogram. The nomogram predicted a probability of the event that corresponded closely to its actual high risk when the risk threshold was between 0.4 and 0.8, and consistently when it exceeded 0.8.

ARTICLE HIGHLIGHTS

Research background

Esophagogastric variceal bleeding (EGVB) is a fatal complication of liver cirrhosis, which requires aggressive intervention. Prediction of bleeding risk in cirrhotic patients with esophagogastric varices (EGV) is beneficial to individualized treatment and improve prognosis. Radiomics, an emerging field, has a good performance in disease diagnosis and efficacy evaluation.

Research motivation

Currently, there is still a lack of noninvasive models that can be widely used in clinical practice to predict the risk of bleeding in liver cirrhosis.

Research objectives

Our study aimed to develop and validate a novel predictive model based on radiomics extracted from contrast-enhanced computed tomography (CT) and clinical indicators to noninvasively assess the risk of bleeding in cirrhotic patients with EGV.

Research methods

211 patients were divided into training and validation cohorts in a 7:3 ratio. Radiomics features were extracted from the portal venous phase CT images, and a radiomics signature (RadScore) was constructed through further feature dimension reduction and screening. The univariate and multivariate logistic regression analyses were preformed to select independent clinical predictors. Finally, a combined model was established based on RadScore and clinical variables. The receiver operating characteristic curves, calibration curves, clinical decision curves and clinical impact curves were applied to evaluate the performance of the model.

Research results

The RadScore was constructed from 8 radiomics features. Albumin, fibrinogen, portal vein thrombosis, aspartate aminotransferase, and spleen thickness were selected as independent predictors. The nomogram, combining RadScore and clinical variables, demonstrated good diagnostic performance in both the training and validation cohorts (area under the receiver operating characteristic curve (AUC) = 0.925 and 0.912, respectively), which outperformed existing non-invasive models such as ratio of aspartate aminotransferase to platelets and Fibrosis-4 scores (Delong test < 0.05).

Research conclusions

The combined model based on radiomics features and clinical indicators shows good predictive accuracy and can contribute to noninvasively assessing the risk of EGVB in patients with cirrhosis.

Research perspectives

Radiomics has shown good diagnostic performance in the assessment of portal hypertension and the identification of high-risk esophageal varices. Our study demonstrated that the model combined clinical variables and radiomics features has the potential utility for non-invasive prediction of EGVB. Further large-scale, multi-center prospective studies are still required to verify its performance in the future.

Abstract

BACKGROUND

The impact of racial and regional disparity on younger patients with gastric cancer (GC) remains unclear.

AIM

To investigate the clinicopathological characteristics, prognostic nomogram, and biological analysis of younger GC patients in China and the United States.

METHODS

From 2000 to 2018, GC patients aged less than 40 years were enrolled from the China National Cancer Center and the Surveillance Epidemiology and End Results database. Biological analysis was performed based on the Gene Expression Omnibus database. Survival analysis was conducted *via* Kaplan-Meier estimates and Cox proportional hazards models.

RESULTS

A total of 6098 younger GC patients were selected from 2000 to 2018, of which 1159 were enrolled in the China National Cancer Center, and 4939 were collected from the Surveillance Epidemiology and End Results database. Compared with the United States group, younger patients in China revealed better survival outcomes ($P < 0.01$). For race/ethnicity, younger Chinese cases also enjoyed a better prognosis than that in White and Black datasets ($P < 0.01$). After stratification by pathological Tumor-Node-Metastasis (pTNM) stage, a survival advantage was observed in China with pathological stage I, III, and IV (all $P < 0.01$), whereas younger GC patients with stage II showed no difference ($P = 0.16$). In multivariate analysis, predictors in China involved period of diagnosis, linitis plastica, and pTNM stage, while race, diagnostic period, sex, location, differen-

tiation, linitis plastica, signet ring cell, pTNM stage, surgery, and chemotherapy were confirmed in the United States group. Prognostic nomograms for younger patients were established, with the area under the curve of 0.786 in the China group and of 0.842 in the United States group. Moreover, three gene expression profiles (GSE27342, GSE51105, and GSE38749) were enrolled in further biological analysis, and distinctive molecular characteristics were identified in younger GC patients among different regions.

CONCLUSION

Except for younger cases with pTNM stage II, a survival advantage was observed in the China group with pathological stage I, III, and IV compared to the United States group, which might be partly due to differences in surgical approaches and the improvement of the cancer screening in China. The nomogram model provided an insightful and applicable tool to evaluate the prognosis of younger patients in China and the United States. Furthermore, biological analysis of younger patients was performed among different regions, which might partly explain the histopathological behavior and survival disparity in the subpopulations.

Core Tip: The impact of racial and regional disparity on younger patients with gastric cancer (GC) is not clear. A total of 6098 younger GC patients were selected from 2000 to 2018, of which 1159 were enrolled in the China National Cancer Center, and 4939 were collected from the Surveillance Epidemiology and End Results database. Compared with the United States group, younger patients in China revealed better survival outcomes and a better prognosis. Three gene expression profiles from the Gene Expression Omnibus database were enrolled in further biological analysis, and distinctive molecular characteristics were identified in younger GC patients among different regions.

INTRODUCTION

Gastric cancer (GC) is the fourth leading cause of cancer-related deaths worldwide[1], with the highest incidence among individuals aged 50-70 years. Only 2.0%-6.2% of documented cases are among patients younger than 40 years[2,3]. Although the incidence of GC has gradually declined, important age-specific details may be obscured by the overall trend[4]. During the last decades, the incidence of younger GC patients has remained stable or even increased in both Western and Eastern populations[5-7].

It was long thought that younger patients with GC had aggressive behavior and serious prognosis[8]. Further insight into which subpopulations were at the highest risk of dying remained a crucial requisite so that interventions could be initiated appropriately. Recently, several studies have demonstrated a wide survival discrepancy of GC in different regions or races[9,10]. Notably, GC patients in Asia had more favorable prognoses than patients in Western countries. The important difference has also been found in certain subtypes of GC, including sex and anatomic location[9,10]. For younger GC patients, however, knowledge concerning the regional and racial disparity is scarce. Chen *et al*[11] reported that younger patients in China have a longer survival time than younger patients in the United States, whereas Strong *et al*[12] showed no difference between the United States and Chinese cohorts. The inconsistent findings from these studies might derive from the small sample sizes, with the population records ranging from 336 to 1075.

As such, based on a unique combination of the Surveillance Epidemiology and End Results (SEER) database in the United States and a high-volume National Cancer Center Database in China, we sought to compare the clinicopathological features, survival outcomes, and prognostic nomograms in younger Chinese and United States patients. Moreover, biological analysis of younger GC patients was further evaluated, which might partly explain the histopathological behaviors and survival disparity among different regions and races.

MATERIALS AND METHODS

Data source and patient selection

The study queried clinical data from 2000 to 2018 based on the two large independent cohorts. The histologically confirmed GC cases in China were selected through the China National Cancer Center Gastric Cancer Database (NCCGCDB). As a single but high-volume cohort, NCCGCDB included more than 18000 patients from all regions of China over the past 20 years. Meanwhile, the United States group was identified from the SEER database. The SEER database, supported by the National Cancer Institute, constituted approximately 27.8% of the United States population[13]. Younger patients were defined as GC cases younger than 40 years of age, which remains consistent with the majority of previous studies [14,15]. Clinical data abstracted from the NCCGCDB and SEER databases included younger patients' demographics, clinicopathological characteristics, and survival variables. The stage of GC was assessed according to the 8th edition of the American Joint Committee on Cancer Tumor-Node-Metastasis (TNM) staging system. The primary endpoint of the study was overall survival (OS). Moreover, the gene expression sets evaluated in the study were obtained from the Gene Expression Omnibus (GEO) database (https://www.ncbi.nlm.nih.gov/geo/). The study protocol was approved by the ethics committee of National Cancer Center/National Clinical Research Center for Cancer/Cancer Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College (No. 17-156/1412), and all methods were carried out in accordance with relevant guidelines and regulations in the ethics approval and consent.

Statistical analysis

The line chart was plotted to analyze the changing ratios of younger GC patients from 2000 to 2018. Categorical variables were compared using the χ^2 test. Comparisons were performed using the *t*-test for normally distributed continuous variables and the Mann-Whitney *U* test for variables not normally distributed. Survival curves for different regions and races were calculated with the Kaplan-Meier method, while the log-rank test estimated the relevant survival disparity. Univariate and multivariate Cox proportional hazards models were used to determine the prognostic factors for younger patients, while the corresponding hazard ratio and 95% confidence interval (CI) were generated. The covariates with a *P* value of < 0.10 in the univariate models were included in the multivariate analysis[16]. Statistical significance was set at a two-sided *P* value less than 0.05. The survival nomogram for China and the United States was formulated based on the multivariate analysis. Younger cases were randomized 7:3, which were adopted in the training set and the validation set, respectively. The area under the curves (AUC), the concordance index (C-index), and the calibration plots were performed to measure the effectiveness of nomograms. All statistical analyses in the study were conducted using R software v.3.6.3 (http://www.r-project.org/).

Bioinformatics analysis

Based on the GEO database, the differentially expressed genes (DEGs) analysis was further performed to evaluate gene discrepancy for younger patients among different regions, while genes that met the cutoff criteria, adjusted *P*-value < 0.05 and |logFC| > 2.0, where FC represents fold change, were considered as DEGs. A heatmap was constructed with 50 differential genes from the DEGs analysis. The Search Tool for the Retrieval of Interacting Genes database (http://string-db.org/) was designed to analyze the protein-protein interaction (PPI) network, which was subsequently visualized by Cytoscape software (www.cytoscape.org/). As a plugin in Cytoscape, CytoHubba was used to calculate the degree of protein node, and the top 10 genes were identified as hub genes.

RESULTS

Demographic and clinicopathological features

From 2000 to 2018, a total of 6098 younger GC patients were selected, of which 1159 were enrolled in NCCGCDB, and 4939 were collected from the SEER database. The mean age of younger patients was 33.77 ± 4.53 in China, and 32.91 ± 5.38 in the United States ($P < 0.0001$). As shown in Figure 1, time trends of younger patients from 2000 to 2018 have remained stable in both China and the United States sets (range 3.9%-6.7%, range 3.4%-3.8%, respectively). Compared to the United States group, the China group had a higher ratio of younger patients over periods.

Notably, compared to the United States, younger GC patients in China predominantly had distal tumor location (83.7% *vs* 66.7%, $P < 0.0001$), poor differentiation (82.5% *vs* 78.5%, $P < 0.0001$), and signet ring cell carcinoma (52.9% *vs* 28.9%, $P < 0.0001$). Conversely, relatively higher percentages of proximal location (33.3% *vs* 16.3%, $P < 0.0001$), well differentiation (7.5% *vs* 1.2%, $P < 0.0001$), and pTNM stage IV tumors (52.5% *vs* 21.4%, $P < 0.0001$) were revealed in the United States patients (Table 1). As for treatment, the percentage of surgery (75.1% *vs* 41.4%, $P < 0.0001$), lymphadenectomy (67.4% *vs* 19.1%, $P < 0.0001$), and lymphadenectomy with at least 15 examined lymph nodes (ELNs ≥ 15) (52.4% *vs* 10.6%, *P*

< 0.0001) were higher in China than those in the United States. In addition, nearly 60.6% of the patients in the United States cohort received chemotherapy compared with only 36.9% in the Chinese cohort (P < 0.0001).

Survival analysis in different regions and races

Survival trends of younger GC patients are summarized in Table 2 and Figure 2. Compared to the stable prognosis of the United States, a noticeable survival increment was shown in younger Chinese patients. The 3-year OS increased from 54.5% (95%CI: 41.7%-71.4%) in 2000-2003 to 66.5% (95%CI: 60.8%-72.7%) in 2014-2018, while the 5-year OS improved from 47.7% (95%CI: 35.0%-65.0%) in 2000-2003 to 51.6% (95%CI: 46.6%-57.2%) in 2009-2013.

Figure 3 depicts the Kaplan-Meier curves for different regions and races. The survival outcomes were much better in Chinese patients or patients diagnosed in China, compared with other races (mentioned in SEER dataset) or the United States patients (all P < 0.0001). To avoid the bias of pathological stage, further analysis was performed to evaluate prognosis of younger cases divided by pTNM stage. The left column of Figure 3 shows the survival curves of younger patients in China and the United States diagnosed as all pTNM stages (Figure 3A), pTNM stage I (Figure 3B), pTNM stage II (Figure 3C), pTNM stage III (Figure 3D), and pTNM stage IV (Figure 3E), while the right column evaluated the OS among different races/ethnicities. Except for stage II GC patients (P = 0.16, P = 0.22, respectively), all other Kaplan-Meier curves revealed obvious survival advantages in patients who were Chinese or diagnosed in China (all P < 0.01).

Moreover, the univariate and multivariate analyses were performed to investigate the prognostic factors for younger GC patients in the China group and the United States group (Tables 3 and 4).

AJCC: American Joint Committee on Cancer; CI: Confidence interval pTNM: Pathological Tumor-Node-Metastasis.

Significant variables on univariate analysis were enrolled in the multivariate modeling, followed by region, race, period of diagnosis, sex, location, differentiation, linitis plastica, signet ring cell carcinoma, pTNM, surgery, chemotherapy, ELNs ≥ 15 (all $P < 0.05$). For younger GC patients, the independent prognosis factors included region, period of diagnosis, poorly differentiated, linitis plastica, pTNM stage, surgery, chemotherapy, and ELNs ≥ 15 (all $P < 0.05$). However, significant predictors in China only involved period of diagnosis (all $P < 0.05$), linitis plastica ($P = 0.0005$), and pTNM stage (all $P < 0.0001$). For the United States patients, Black ethnicity, poorly differentiated, linitis plastica, signet ring cell, and later pathological stage were related to serious prognosis (all $P < 0.01$), whereas recent period, female, distal location, surgery, and chemotherapy emerged as protective factors (all $P < 0.05$).

Nomogram of younger GC patients

To predict OS of younger patients with GC, nomograms for China and the United States group were established separately based on the results of the Cox regression analysis. As illustrated in Figure 4, a total of four clinical parameters (including linitis plastica, surgery, ELNs ≥ 15, and pTNM stage) were included in the Chinese models, while the nomogram for the United States identified the following parameters: Race, sex, tumor location, differentiation, pTNM stage, linitis plastica, signet ring cell, surgery, and chemotherapy.

According to the results of the validation set, the C-index for the China and United States models was 0.814 and 0.787, respectively. The AUC that was applied to evaluate the discernment of the nomogram models was 0.786 in the China group and 0.842 in the United States group (Supplementary Figure 1). In addition, high-quality calibration plots in both China and the United States models had been demonstrated (Supplementary Figure 2).

DEGs analysis, PPI network, and hub gene identification from GEO database

To evaluate gene disparities according to different races, we performed DEGs analysis for younger GC patients from the GEO database. Three gene expression profiles (GSE27342, GSE51105, and GSE38749), which contained 8 younger cases from China, and 12 samples from the Americas and Oceania, were included in this study. After DEGs analysis was performed among different regional sets, 50 significant DEGs were selected (Figure 5). Compared to other regions, certain genes were downregulated in China (Figure 5A), while *C11orf58, TLK1, ARHGAP5, MRPL2,* and *RBMX2* were upregulated. Moreover, the PPIs among the DEGs were performed with the Search Tool for the Retrieval of Interacting Genes. A total of 200 nodes and 245 edges were involved in the PPI network (Figure 5B and C). The top 10 genes evaluated by connectivity degree in the PPI network were as follows: *CTNNB1, APP, CTSB, UBA52, RHOA, ATP5B, EEF2, FN1, RPL11,* and *CTSD*.

DISCUSSION

Our study compared younger GC patients in China and the United States at clinical and biological levels. Survival advantages of younger GC patients in China were demonstrated from two high-volume databases. These data were stronger than previous studies[17], and high-quality nomograms were further constructed for younger patients according to different regions. Compared to western regions, DEGs in China were confirmed, which might partly explain the histopathological behaviors and survival disparity.

Staying in line with the previous results[11,18], our conclusions showed that younger patients in China were more prominent in the distal location, while GC in the proximal location was more common in the United States. The above discrepancy was presumably related to certain predisposing factors[19-21]. In Western countries, obesity and gastroesophageal reflux were associated with proximal GC[20], whereas *Helicobacter pylori* infection in China may partially account for a high incidence of the distal location[21]. Additionally, Chinese cases were more likely diagnosed with an early pathological stage than those in the United States. This might partially be due to the improvement of cancer screening and

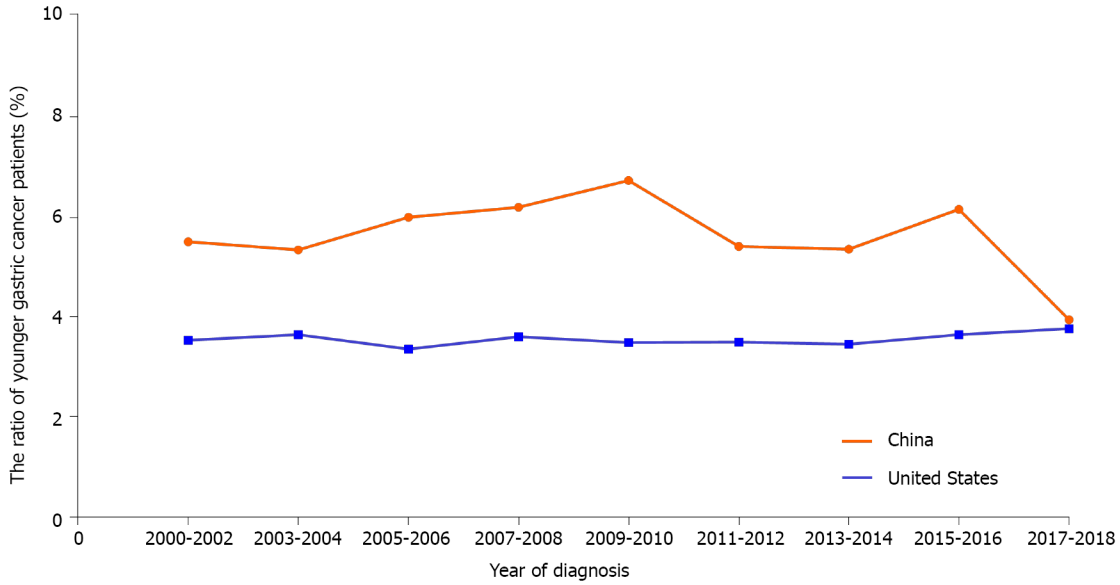
early detection programs in China, which have expanded to 31 provinces since 2015[22,23]. When considering surgical patterns, it was thought that gastrectomy with D2 lymphadenectomy was the standard treatment for GC in Eastern Asia[24]. However, most patients in Western countries undergo D1 lymphadenectomy, and D2 lymphadenectomy was only recommended rather than the therapeutic norm[25,26]. These treatment differences might explain the higher percentage of ELNs ≥ 15 and the larger number of nodes examined for Chinese younger patients in our study.

With a direct comparison from a high-volume GC cohort in China and the SEER database, we reported significant survival differences for younger GC patients. Consistent with the previous studies [11,18], our findings revealed that younger cases had a better prognosis in China than in the United States. With the exception of pTNM stage II, significantly better OS was observed in the China group with stages I, III, and IV. Notably, the survival advantage of younger Chinese patients could partially be attributed to a remarkable improvement in the quality of clinical services, such as improved access to primary healthcare, early cancer screening, and individual multimodal therapies[22,23,27]. Moreover, it was well known that gastrectomy with D2 lymphadenectomy was common in Asian areas, while the vast majority of GC cases in Western countries undergo D1 lymphadenectomy[24]. The above type of surgical procedures might be associated with the survival disparity among different regions. In addition, the later tumor stage and some other factors including lifestyle and high body mass index in the United States patients might also in part explain the poor prognosis[28].

As a convenient statistical predictive tool, nomograms have been widely applied for physicians to clarify a diagnosis and predict survival[29,30]. To our best knowledge, the present study, which used the largest sample sizes, constructed survival nomograms for younger GC patients in China and the United States. Compared with previous models[18], nomograms not only avoid the bias of regions but also achieve reliable predictive performance, which was reflected by an AUC of 0.786 for China and 0.842 for the United States. In addition, the calibration plots of the training set and validation set (Supplementary Figure 1) illustrated great agreement between nomogram prediction and actual observation, thus further suggesting a robust predictive ability of nomograms in the present study.



Although specific gene expression among regions and races was not yet fully ascertained, several studies demonstrated a strong association between regional/racial-related genes and the prognosis of GC[31,32]. Loh *et al*[31] reviewed the genetic polymorphisms of GC among different races/ethnicities. The results showed that 37 polymorphisms across 27 genes were significantly related to GC in Asians,

Figure 2 The survival trends of younger patients with gastric cancer based on the China National Cancer Center and Surveillance Epidemiology and End Results databases. A: Trends of the 3-year overall survival; B: Trends of the 5-year overall survival.

transcription pathways. Black ethnicity with GC was mainly enriched in cell structural changes, and *DNAJC5*, *HDAC10*, *NEO1*, and *SMG5* were identified. For Asian patients, *TMSB4Y*, *UTY*, *ZFY*, and *ZNF787* were screened based on the relationship between gene expression and DNA methylation. In our study, we first evaluated the race/ethnicity-associated genes for younger GC patients. After the construction of PPI networks and screening according to the degree of the protein node, the hub genes of younger GC patients were as follows: *CTNNB1*, *APP*, *CTSB*, *UBA52*, *RHOA*, *ATP5B*, *EEF2*, *FN1*, *RPL11*, and *CTSD*. Further mechanistic studies are warranted to confirm the related signaling and action mechanisms.

Our study has certain strengths. First, two high-volume databases based on the SEER and the NCCGCDB were comprehensively evaluated for the regional and racial disparity of younger GC patients. Second, our study, utilizing the largest sample sizes globally, constructed prognostic nomograms for younger GC patients in China and the United States, thus providing an intuitive accessible tool for physicians to predict survival and develop resurvey schedules. Moreover, to our best knowledge, it was the first study to perform biological analysis for younger patients among different

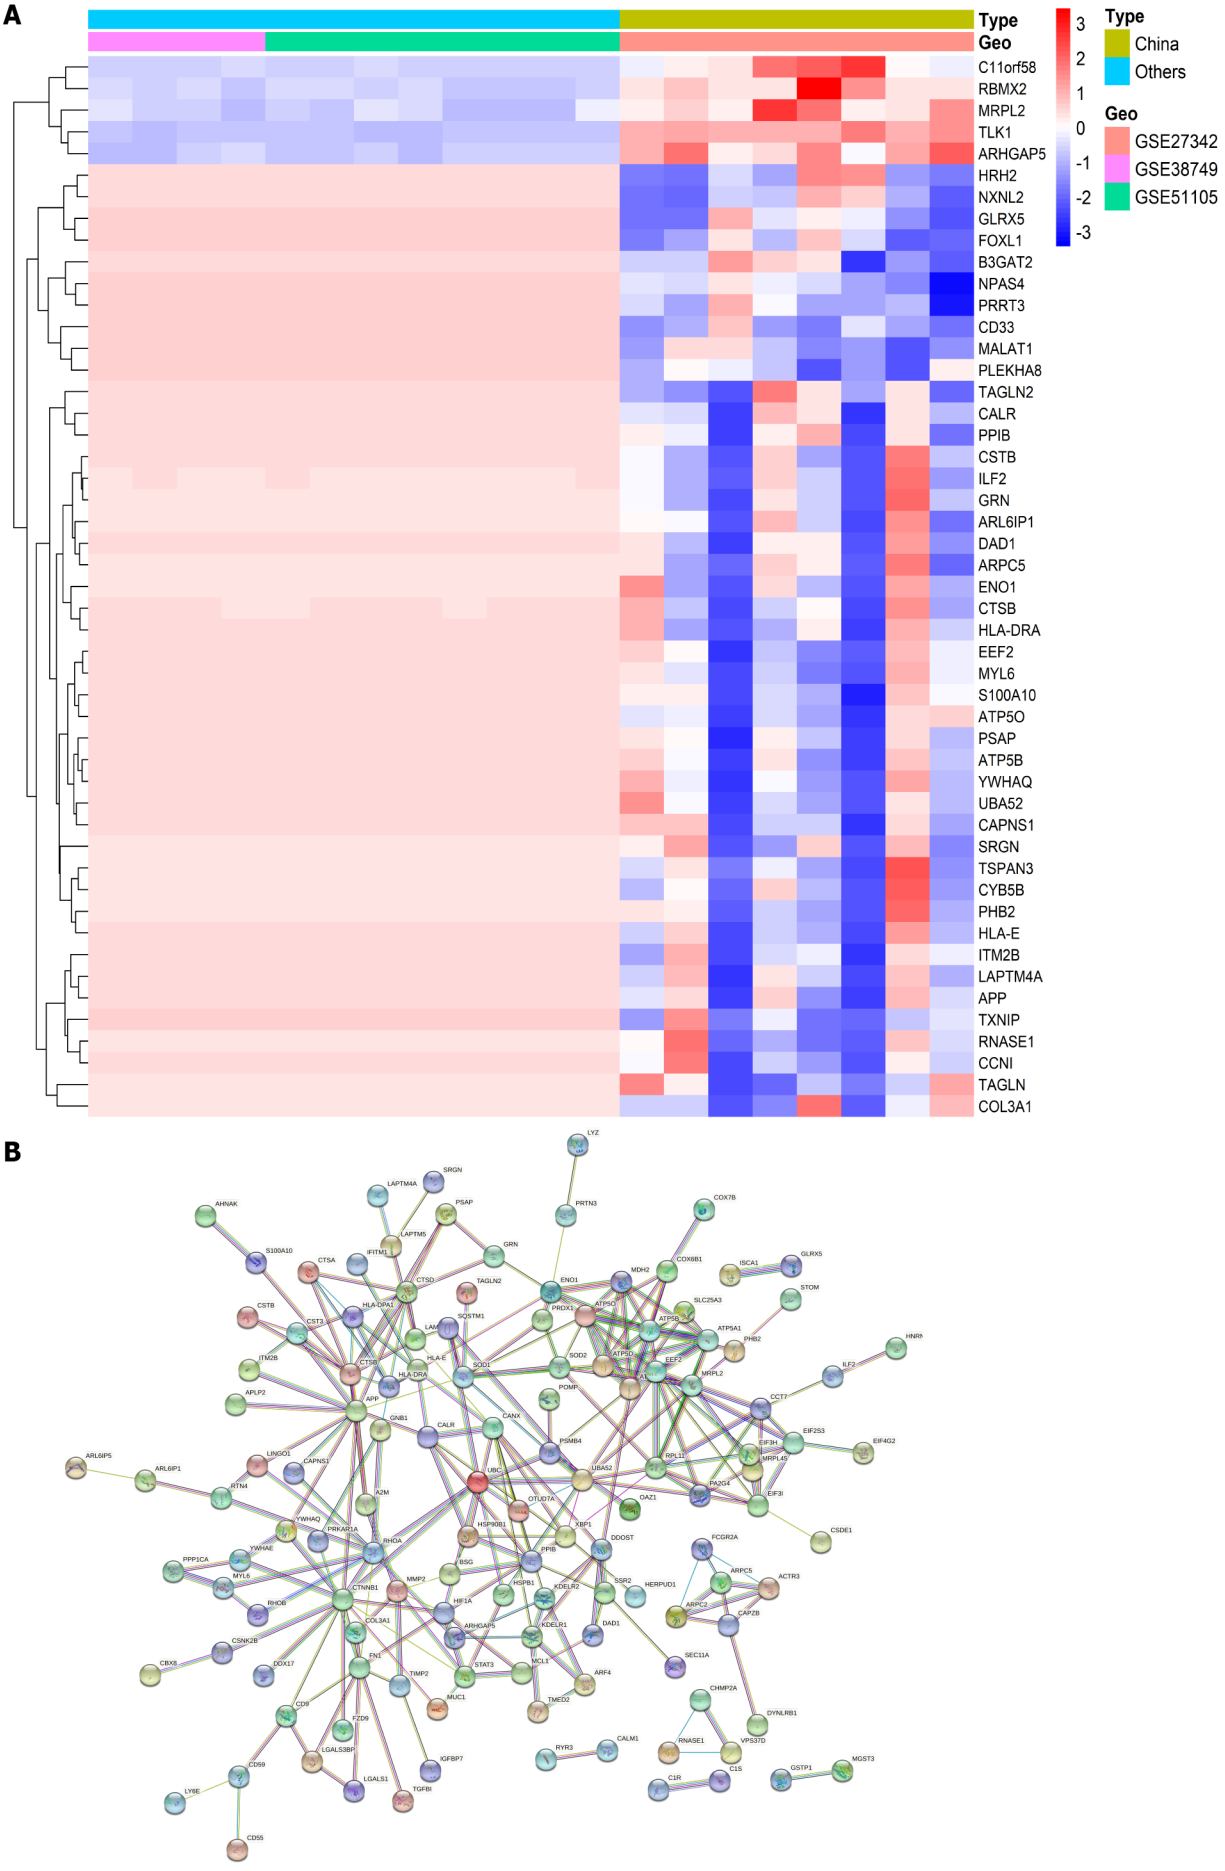
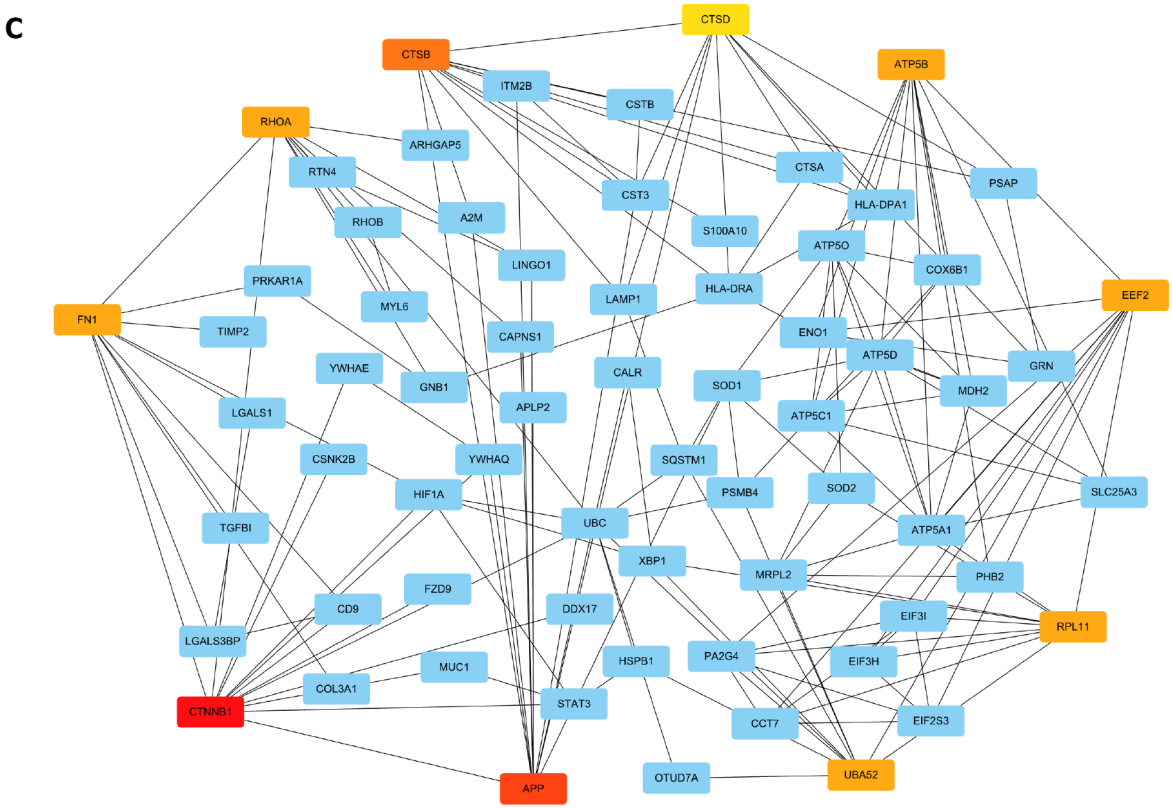
Figure 3 Kaplan-Meier survival curves of different regions and races from the China National Cancer Center and Surveillance Epidemiology and End Results databases from 2000 to 2018. A: All gastric cancer; B: Gastric cancer diagnosed as Tumor-Node-Metastasis (TNM) stage I; C: Gastric cancer diagnosed as TNM stage II; D: Gastric cancer diagnosed as TNM stage III; E: Gastric cancer diagnosed as TNM stage IV.

regions, which provided a molecular interpretation for the survival discrepancy. Despite all this, several limitations need to be considered in the present study. Some of the key baseline prognostic factors, including body mass index, smoking, drinking, and the efficacy of neo/adjuvant therapy were absent in the SEER database. In addition, as a high-volume single center, some findings from NCCGCDB might not be strongly generalizable to China, which should be replicated in a larger multicenter experience. Lastly, even after correcting by batch effects (Supplementary Figure 3), there was also potential bias during encoding samples from GEO database. These factors might affect the accuracy of the results.



CONCLUSION



In conclusion, younger GC patients diagnosed in China had a better prognosis than those in the United States. Except for younger cases with pTNM stage II, a survival advantage was observed in the China group with pathological stages I, III, and IV. Moreover, utilizing the largest sample sizes globally, prognostic nomograms in China and the United States were constructed and showed robust predictive performance. Further large-scale studies are warranted to investigate more molecular characteristics and related mechanisms for younger GC patients among different regions and races.

ARTICLE HIGHLIGHTS

Research background

The impact of racial and regional disparity on younger patients with gastric cancer (GC) remains unclear.

Research motivation

This study aimed to provide a national view of younger GC patients in China and the United States.

Research objectives

To investigate the clinicopathological characteristics, prognostic nomogram, and biological analysis of younger GC patients in China and the United States.

Research methods

From 2000 to 2018, GC patients aged less than 40 years were selected from the China National Cancer Center and the Surveillance Epidemiology and End Results database. Biological analysis was enrolled from the Gene Expression Omnibus database.

Research results

A total of 6098 younger GC patients were selected from 2000 to 2018, of which 1159 were enrolled in the China National Cancer Center, and 4939 were collected from the Surveillance Epidemiology and End Results database. Compared with the United States group, younger patients in China revealed better survival outcomes ($P < 0.01$). For race/ethnicity, younger Chinese cases also enjoyed a better prognosis than that in White and Black subsets ($P < 0.01$). Prognostic nomograms for younger patients were established, with area under the curves of 0.786 for China and 0.842 for the United States. Moreover, three gene expression profiles (GSE27342, GSE51105, and GSE38749) were enrolled in further biological analysis, and distinctive molecular characteristics were identified in younger GC patients in different regions.

Research conclusions

Except for younger cases with pathological Tumor-Node-Metastasis stage II, a survival advantage was observed in the China group with pathological stages I, III, and IV. Biological analysis of younger patients was performed among different regions, which might partly explain the histopathological behaviors and survival disparity in the subpopulations.

Research perspectives

Further large-scale studies are warranted to investigate more molecular characteristics and related mechanisms for younger GC patients among different regions and races.

ACKNOWLEDGEMENTS

We thank Da-Wei Zhou (Qilu Hospital, Cheeloo College of Medicine, Shandong University) for assistance with data analysis.

Abstract

BACKGROUND

The impact caused by the coronavirus disease 2019 (COVID-19) on the Portuguese population has been addressed in areas such as clinical manifestations, frequent comorbidities, and alterations in consumption habits. However, comorbidities like liver conditions and changes concerning the Portuguese population's access to healthcare-related services have received less attention.

AIM

To (1) Review the impact of COVID-19 on the healthcare system; (2) examine the relationship between liver diseases and COVID-19 in infected individuals; and (3) investigate the situation in the Portuguese population concerning these topics.

METHODS

For our purposes, we conducted a literature review using specific keywords.

RESULTS

COVID-19 is frequently associated with liver damage. However, liver injury in COVID-19 individuals is a multifactor-mediated effect. Therefore, it remains

unclear whether changes in liver laboratory tests are associated with a worse prognosis in Portuguese individuals with COVID-19.

CONCLUSION

COVID-19 has impacted healthcare systems in Portugal and other countries; the combination of COVID-19 with liver injury is common. Previous liver damage may represent a risk factor that worsens the prognosis in individuals with COVID-19.

Key Words: COVID-19; Healthcare systems; Liver; Portuguese individuals; Comorbidities; Clinical outcomes

Core Tip: This review analyzes how the coronavirus disease 2019 (COVID-19) affects health care and clinical practice in Portugal and the possible causes of liver injury in COVID-19 individuals, including the direct effect of severe acute respiratory syndrome coronavirus 2 on the liver and drug-induced liver injury, and how preexisting liver diseases affect the treatment of COVID-19.

INTRODUCTION

The coronavirus disease 2019 (COVID-19) caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is usually characterized by cough, headache, fever, muscle pain, general weakness, difficulty breathing, fatigue, and loss of taste and smell[1,2]. More severe cases may present pneumonia with fever, cough, dyspnea, and respiratory failure[1,2].

These symptoms may be aggravated by preexisting health conditions or comorbidities, which have been addressed in studies on the clinical characteristics and outcomes of COVID-19 individuals[2-4] published since the official declaration of the pandemic outbreak of COVID-19 on March 11, 2020[5].

Some of the most frequent comorbidities described in these studies are hypertension, diabetes mellitus, chronic obstructive pulmonary disease, cardiovascular disease, chronic kidney disease, and cancer[2-4]. In addition, despite not being among the most frequent comorbidities, the pathologies associated with the liver are hardly ever missing from the list of preexisting health conditions in COVID-19 individuals[6]. For example, a study that associated comorbidities with COVID-19 severity and hospitalization found that, concerning liver diseases, similarly to other studies[7,8], individuals with previous hepatic disorders (HD) were at a higher risk of developing symptoms when infected with SARS-CoV-2[9].

In Portugal, several studies have also focused on characterizing the clinical manifestations and outcomes of COVID-19[10-13], and some others have synthesized the clinical manifestations of COVID-19, for example, in the gastrointestinal system[14], in organs like the lungs, heart, kidney, and brain[15], or target specific population like children[16].

However, to date and the best of our knowledge, only one study has been published with a review of the impact of COVID-19 on the liver in the Portuguese population since 2020[17]. Data on individuals with COVID-19 who were also living with liver diseases and the implications and outcomes of this co-occurrence of health problems in the Portuguese population is ostensibly scarce. Likewise, the alterations in the healthcare system due to the pandemic and their association with COVID-19 and liver diseases have received little attention. Therefore, in this study, by reviewing the available research, we aimed to study the incidence of preexisting liver-associated diseases and liver injuries induced by COVID-19 in adults in Portugal and investigate the relationship of COVID-19 with liver diseases. On the other hand, we also seek to analyze how the COVID-19 pandemic affected access to healthcare systems and reflect on how societies should prepare for other pandemic crises in the future, thus contributing to the general and clinical body of knowledge on this topic.

MATERIALS AND METHODS

Literature search

The protocol used in this review included the following elements: (1) Research objective as specified in the introduction; (2) Eligibility criteria; (3) Search strategy and selection of studies; (4) Ethical considerations; (5) Quality assessment; and (6) Data extraction and analysis.

Eligibility criteria and data extraction and analysis

All the studies assessed in this review comply with the following inclusion criteria established beforehand by the authors: (1) Studies reporting original research published in Portuguese or English; (2) Targeting the Portuguese adult population, *i.e.*, 18 years old or older; (3) From any period since the official diagnosis of the first case of COVID-19 in Portugal on March 2, 2020[18]; and (4) Reporting any liver-associated clinical manifestation or outcome.

Any study that: (1) Was duplicated; (2) Was not an original research article, *i.e.*, was a case report, a conference article or an abstract-only article, a comment, a letter or editorial, an expert opinion, *etc.*; (3) Was not the final, and definite publication of the article (pre-print or accepted stage of the editorial process); or (4) Did not have data or did not refer to liver-associated diseases, was excluded.

First, the authors discussed the keywords to be used in the search, agreeing upon the following string and operators: ["Portugal" or "Portuguese patients" AND "COVID" OR "SARS-CoV-2" OR "coronavirus" AND "liver" or "hepatic condition" OR "chronic hepatitis" AND "clinical manifestations" OR "outcomes" AND "COVID-19 treatment"] to be found either in the titles, abstracts, or keywords of the articles.

The analysis began with a search of the literature available using the software *Publish or Perish*[19] to survey the databases *PubMed*, *Scopus*, *CrossRef*, *Google Scholar*, and *Web of Science*. Any study containing the string and operators mentioned before, either in the title or the abstract, was to be examined. The search was carried out on June 17, 2022, and the results of the search were exported to an *Excel* table.

A two-stage approach was used to assess the retrieved studies. First, only the titles and abstracts were scanned to determine eligibility according to the research objective and criteria. Second, the full texts of the selected papers were read and thoroughly analyzed. All the authors participated in these analyses.

Additionally, several other sources were examined to develop and elaborate on the results obtained. Some of these sources are other papers on the main topics of this review and the Portuguese National Health System (NHS), which was consulted for official information on COVID-19 and the health services at the time of the pandemic.

This study reports the review of published original research articles. Each assessed study addressed ethical specifications and approvals required by deontological practices and the law to be carried out and published. We did not recruit participants or request any information on any individual. Therefore, no formal consent or approval from any ethics committee was required.

The design of the protocol included meetings to discuss procedures and results. Cases of disagreement between the reviewers would have been resolved by resorting to two other independent researchers in the field. However, a consensus was reached about the studies to be included and excluded and the results of the analyses.

Likewise, all studies considered in this review were assessed methodologically to determine if biases were minimized or excluded. Finally, all the results are reported narratively and using tables.

RESULTS

We retrieved 804 articles from the database search. Of those, eight articles were duplicated and, therefore, eliminated. Then, the title and abstract of the 796 studies selected were screened, and 748 articles were excluded for: (1) Not referring to Portugal (n = 747); and (2) Not having the full text of the article available (n = 1) (Figure 1).

The remaining articles (n = 48) were equally distributed among the authors to assess based on the inclusion criteria. Of those, 42 articles were excluded for: (1) Not referring to the liver but instead covering comorbidities in the Portuguese population related to areas such as the cardiovascular system [20], kidney pathologies[13], respiratory system[10,21], mental health in the elderly[22], and a survey to parents on the use of healthcare services during the COVID-19 pandemic[23] (n = 27); (2) Due to lack of information to verify if the inclusion criteria were met (n = 11); (3) Not referring to data related to the liver or COVID-19 (n = 3); and (4) Referring to data on the liver but not under COVID-19 conditions (n = 1).

Finally, six studies complied with the inclusion criteria. Figure 1 shows the selection process flowchart, and the reviewed articles' characteristics are described in Table 1 of the section: *Liver diseases and COVID-19 in Portuguese individuals*.

COVID-19, healthcare, and clinical practice in Portugal

COVID-19 has greatly affected the Portuguese population's life, modifying their lifestyle, especially consumption habits[24]. Socialization with friends and family was reduced due to measures such as

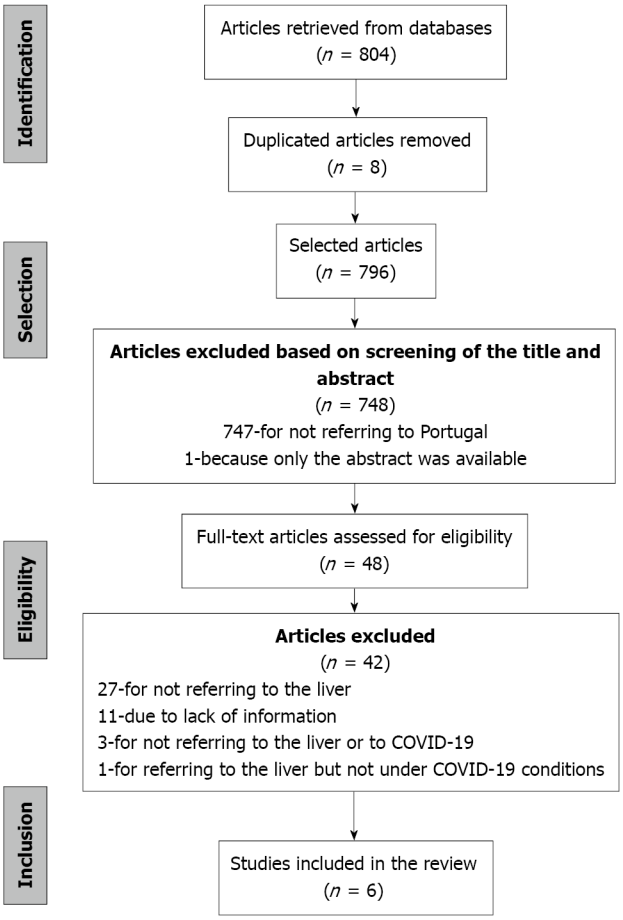

Table 1 Coronavirus disease 2019 studies in Portuguese individuals with preexisting liver disease

Ref.	Breadth and type of study	Analyzed individuals (*N*)	Data source	Period of data collection	Age range (yr)	Preexisting liver disease (%)	Study findings
[63]	National Retrospective (observational) study	20.293	SINAVE (DGS)	January 1-April 21, 2020	[0 to > 86]	0.53%	Risk of mortality: (1) Higher in the male gender; (2) Higher in older age groups; and (3) Increases with the presence of comorbidities
[61]	National Retrospective observational study	36.244	DGS	March 2–June 30, 2020	[18 to > 80]	0.57%	The presence of simultaneous diseases is significantly associated with negative outcomes in individuals with COVID-19
[60]	National Retrospective cohort study	38.545	DGS	March 2–June 30, 2020	[0 to > 70]	0.60%	Risk of hospitalization: (1) Lower in females; (2) Increases with age; and (3) Increases with the presence of comorbidities
[62]	National Retrospective cohort study	20.293	DGS	March 1-April 28, 2020	[0 to > 90]	0.50%	Risk of hospitalization, ICU admission, and death: (1) Higher in males; (2) Increases with age; and (3) Increases with the presence of comorbidities
[64]	National Retrospective (observational) study	6.701	SICO DGS)	The year 2020	[0 to > 0]	No information available	The risk of hospitalization and lethality is higher in males and increases with age
[59]	A retrospective cohort study in a university hospital center	317	University Hospital Center of Porto (CHUP)	March 2-May 4, 020	[18 to 5]	4.42%	Hepatic enzyme changes in COVID-19 individuals were frequent but mostly mild; AST, unlike ALT, was associated with worse clinical outcomes, such as the severity of COVID-19 and mortality

All results are represented in frequency (N, number of individuals) and percentage (%). General Health Directorate of Portugal–DGS (Direção geral de Saú de de Portugal)/National e-Death Certificates Information System–SICO (Sistema de Informação do Certificados de Óbito) (SICO)/National System for Epidemiological Surveillance–SINAVE (Sistema Nacional de Vigilância Epidemiológica). COVID-19: Coronavirus disease 2019; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ICU: Intensive care unit.

social distancing and restriction of access to many public services adopted to break the COVID-19 transmission chains. In Portugal, the National Health Service also enforced the suspension of all elective and non-urgent health care[25]. This measure had long-term consequences, such as an impact on the waiting lists for hospital medical specialties for first evaluation or other complex procedures/treatments (for example, surgeries and physiotherapy). During that period, all laboratories were exclusively dedicated to testing for COVID-19, reducing non-urgent activities and re-organizing their tasks.

Primary health services were also impacted, and many appointments were canceled or modified. A Portuguese study by Vieira *et al*[26] investigated all medical appointments in a primary care unit in the central region of Portugal from March 1 to July 31, 2020, and in the same period of 2019 and 2018. The authors observed that, contrary to what was expected, there was an increase (about 14% when compared with 2018 and 4% when compared with 2019) in the number of medical appointments in 2020 compared with the same period of 2018 and 2019. However, most of these appointments were teleconsultations performed by e-mail or phone compared with previous years (71.6% in 2020, 42.6% in 2019, and 35.2% in 2018). On the other hand, there was also a decrease in most follow-up and routine appointments and an increment in psychiatric diagnoses, mainly anxiety-related disorders[26]. Although this study demonstrated that the total number of medical appointments increased in 2020, mostly due to teleconsultations, this increase may not have reflected the general situation in other primary health units across the country. One reason for this hypothesis is that the central region in Portugal was less affected by the COVID-19 pandemic in the period when the study was performed. If the same study had been replicated in the northern region, the results would have been different. Data from the NHS revealed that in March 2020, a reduction of 16% in speciality medical appointments in public hospitals was observed compared with the same period of 2019. This negative variation was even greater in the following months, April and May, when it increased to 25% and 31%, respectively[27]. The first specialty medical appointment in the hospital was also reduced in these months in 2020 when compared with 2019. However, telemedicine appointments (not face-to-face appointments) increased [27]. The number of scheduled and urgent surgeries also decreased in these months by 15%, 38%, and 32% compared with March, April, and May of 2019, respectively. The emergency cases arriving at the hospital also decreased during this period[28].

DOI: 10.3748/wjg.v29.i6.1109 **Copyright** ©The Author(s) 2023.

Figure 1 Flowchart of the studies selection process.

When the data from January to July 2019 and 2020 were compared, a reduction in face-to-face appointments, an increase in telemedicine, and a reduction in medical tests were observed. Regarding the latter, pathological anatomy tests decreased by 36%, and tests concerning surgery medical specialties, which may study the liver, decreased by 32%[27].

More face-to-face nursing consultations occurred in 2019 compared with 2020, and the same was observed regarding face-to-face medical consultations. However, regarding cancer screening, in 2020 compared with 2019, fewer women got mammographies in the previous 2 years, fewer women updated their Pap smears, and fewer individuals got their colorectal cancer screening[29].

Portugal was not the only country whose health services were affected by the COVID-19 pandemic. Other European and non-European countries also suffered adjustments and had similar results to those observed in Portugal in primary care health services during COVID-19[30]. In this regard, some authors have proposed lessons on the COVID-19 pandemic for primary care professionals worldwide[31]. The main aspects that these authors consider essential for health services to learn and adapt are: (1) Rapidly changing and innovating by redirecting patient flow like primary care; (2) Maintaining access to primary care and managing all health problems that impact the local population; and (3) Collecting and disseminating information that is sufficiently fitted for the purpose[31].

The alterations in the operation of laboratories were studied mainly in the laboratories dedicated to diagnosing malignant pathologies.

In the cytopathology laboratories of 23 countries (including Portugal), the number of samples analyzed during 2020 compared with the same period in 2019 was reduced by 45.3%[32]. While the number of samples from the cervicovaginal tract, thyroid, and anorectal region decreased significantly, and the percentage of samples from the urinary tract, serous cavities, breast, lymph nodes, respiratory tract, salivary glands, central nervous system, gastrointestinal tract, pancreas, liver, and biliary tract increased[32].

Also, lab facilities were adapted to work in COVID-19-free environments. Glasbey *et al*[33] compared hospitals with and without COVID-19-free surgical pathways to investigate if implementing these pathways could be associated with lower postoperative pulmonary complication rates. This study demonstrated that COVID-19-free surgical pathways should be established within available resources to provide safer elective cancer surgery during current and future COVID-19 outbreaks. As health

providers resume elective cancer surgery, they should prevent harm by investing in dedicated COVID-19-free surgical pathways tailored to local resources[33].

COVID-19 and liver disease

The SARS-CoV-2 infection is frequently associated with acute liver injury (ALI), evidenced by increased transaminases in individuals with and without prior liver disease. Elevated transaminases affected up to 50% of SARS-CoV-2 infected subjects and correlated with the severity of the disease[34].

Transaminase elevation during COVID-19 is mostly mild and reversible (*i.e.*, < 5 times higher than the normal limit). Severe ALI is uncommon, occurring in 0.1% on admission and 2% during hospitalization, with alanine aminotransferase (ALT) values 20 times higher than the normal limit. These individuals had abnormal liver tests before being hospitalized[35].

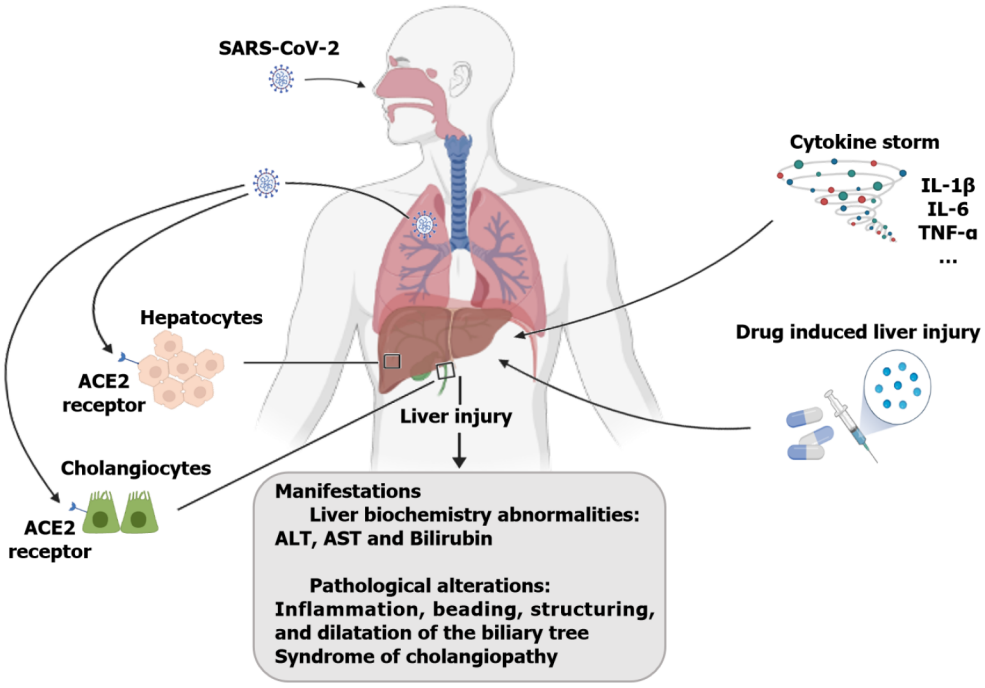
ALI reflected by increased transaminases and bilirubin was related to disease severity and poor outcome of COVID-19[36]. Increases in gamma glutamyl transferase (γGT) and alkaline phosphatase (AP), also liver-related enzymes, are less observed and found more frequently in the later course of the disease. In contrast, moderate increases in aspartate aminotransferase (AST), ALT, and bilirubin are very common features in COVID-19[37].

Cholangiopathy, which is focal or extensive damage to bile ducts due to an impaired blood supply, has been reported as a late complication of severe COVID-19, and some persons have developed progressive biliary injury and liver failure[38,39]. In a study with 2047 patients hospitalized for COVID-19, 12 (approximately 0.58%) with severe COVID-19 developed a syndrome of cholangiopathy characterized by cholestasis and biliary tract abnormalities[38]. The mean time from COVID-19 diagnosis to cholangiopathy was 118 d. Imaging findings included inflammation, beading, stricturing, and dilation of the biliary tree.

Angiotensin-converting enzyme 2 (ACE2) receptor and the SARS-CoV-2 co-receptor transmembrane serine protease 2 seem to be the key host receptors for this virus and are expressed on diverse liver cells such as hepatocytes, immune cells, cholangiocytes, and liver progenitor cells. The levels of ACE2 are very low in liver cells, accounting for 2.6% of the total number of cells, but it is highly expressed in bile duct cells (59.7%)[40] (Figure 2).

The liver may undergo several injuries during the infection period. According to several authors, these aggressions may result from: (1) A direct virus attack on the different types of liver cells; (2) A magnified immune response (cytokine storm); and (3) Toxicity of the drugs used to treat COVID-19 symptoms. Whether one or the sum of these insults contributes to liver disruption has yet to be clarified. The 'cytokine storm' that occurs in COVID-19 is common to other viral infections and involves a massive acute phase reaction that results from the release of huge amounts of proinflammatory cytokines, such as interleukin (IL)-1, tumor necrosis factor, and IL-6, as well as an increased concentration of C reactive protein and ferritin. The bulk of these cytokines is released by macrophages and monocytes, assumed to be the main players of the 'cytokine storm' that occurs in SARS-CoV-2 infection [41,42] (Figure 2).

Whether individuals with chronic liver disease (CLD) are more susceptible to COVID-19 is uncertain. CLD, in the absence of immunosuppressive therapy, is not known to be associated with an increased risk of acquiring COVID-19[36]. However, the liver may be susceptible to SARS-CoV-2 because of ACE2 receptors in the biliary and liver epithelial cells[40].



Data have suggested that preexisting liver disease was associated with worse outcomes in individuals with COVID-19. In a study of 2780 persons with COVID-19, those with CLD (n = 250) had higher rates of mortality as compared with those without liver disease (12% *vs.* 4%; risk ratio: 2.8, 95%CI: 1.9-4.0)[9,43,44]. Similarly, research carried out in Bangladesh on the relation of comorbidities, the severity of COVID-19, and hospitalization found that 43.6% of the individuals with HD (n = 39 in a sample of 1025) had more serious, *i.e.*, moderate to severe, symptoms of COVID-19[9]; in another study in the same country on the relation of comorbidities and health outcomes in COVID-19 persons, the authors concluded that several comorbidities, including liver diseases, influence the severity of outcomes and fatality in these individuals[6].

Subsequently, a large French retrospective cohort of > 259000 individuals with COVID-19, including > 15000 with preexisting CLD, demonstrated that those with decompensated cirrhosis were at an increased adjusted risk for COVID-19 mortality[45].

Acute-on-chronic liver failure is also well recognized, being reported in up to 12%–50% of people with decompensated cirrhosis and COVID-19. Although acute hepatic malfunction induced by the SARS-CoV-2 virus may aggravate decompensated cirrhosis, in most cases, this liver aggravation did not contribute to the death of individuals, which occurred mostly due to respiratory failure (71%), followed by liver-related complications (19%)[44].

Hepatic conditions affecting COVID-19 treatment

CLD is considered a serious problem worldwide. Liver injuries like cirrhosis, chronic viral hepatitis, alcohol-related liver disease, non-alcoholic fatty liver disease, and autoimmune hepatitis affect approximately 50 thousand people in Portugal, most of which are still undiagnosed[46]. Therefore, it is important to carefully evaluate how different existing liver diseases influence liver damage in persons with COVID-19[47,48].

DOI: 10.3748/wjg.v29.i6.1109 **Copyright** ©The Author(s) 2023.

Figure 2 Mechanisms that may lead to liver injury in individuals with coronavirus disease 2019. An infection by severe acute respiratory syndrome coronavirus 2 may result in liver injury due to viral entry through angiotensin-converting enzyme 2 receptors on hepatocytes and cholangiocytes, pharmacological treatment, or an exaggerated immune response. ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2; ACE2: Angiotensin-converting enzyme 2; IL: Interleukin; TNF-α: Tumor necrosis factor-α.

Individuals with chronic hepatitis B (CHB) treated with nucleoside analogs for long periods are in a phase of immune tolerance. Therefore, the virus that causes hepatitis is inhibited. However, when infected with SARS-CoV-2, they can suffer severe liver injury[48].

Previous studies[47,48] have shown that for persons with hepatitis B undergoing antiviral therapy, stopping drug administration may lead to reactivation and replication of the hepatitis B virus (HBV) after treatment against SARS-CoV-2 infection is done. It has also been previously reported[47,48] that CHB patients infected with SARS-CoV-2 may take longer to clear the virus from their bodies. Zha *et al* [49] found a correlation between chronic HBV infection and the time required to eliminate SARS-CoV-2 from the individual. This association may have to do with T-cell dysfunction in people with chronic HBV infection fighting other viruses, but the link between them requires future investigations.

Other clinical studies have noted that the combination of lopinavir and ritonavir in the treatment of individuals infected with SARS-CoV-2 may increase liver damage in those with hepatitis B or hepatitis C[47], so the use of these drugs in the treatment of COVID-19 may promote or worsen liver injury in people with preexisting liver disease[47,48].

Another risk factor that may be related to disease severity and mortality and is common in persons with COVID-19 is dysfunction in the immune system[47,48]. In persons with autoimmune hepatitis who have been infected with SARS-CoV-2, special attention should be paid to the effect of glucocorticoid administration on the prognosis of the disease[47,50]. Considering the high level of ACE2 receptor expression in bile duct cells, individuals with cholangitis infected with SARS-CoV-2 may see their cholestasis worsen, resulting in increased levels of AP and γGT[48]. Moreover, persons with cirrhosis and liver cancer with systemic immunodeficiency might be more susceptible to SARS-CoV-2 infection, as their immune function is relatively lower[47,50].

For individuals with COVID-19 and mildly abnormal liver function, the administration of anti-inflammatory and hepatoprotective drugs is generally not required[48]. Still, if necessary, the initial disease should be treated with antiviral and supportive drugs that inhibit viral replication, reduce inflammation, and enhance immunity. Additionally, the pre-emptive application of liver-protective and liver enzyme-lowering drugs is not recommended[47].

In people with COVID-19 and acute liver damage, clinicians should analyze and judge the most probable cause of liver injury and then take the appropriate action[47,48]. Routinely, these persons should be treated with anti-inflammatory, hepatoprotective drugs, and jaundice-reducing agents such as polyene phosphatidylcholine, glycyrrhizic acid, bicyclol, and vitamin E[48]. In critically ill patients, the therapy should be chosen according to liver function injury, the types of drugs administered should not be more than two, and the dosage should not be too high to avoid worsening liver damage and drug interactions[49].

In persons with COVID-19 suspected of having liver damage caused by drugs, stopping or reducing the amount of the drug should be considered. Besides that, liver function indicators should be closely monitored to prevent acute liver failure[47,48]. Respiratory and circulatory support should be reinforced in individuals with critical and severe COVID-19 disease with liver damage since the clinical status should be caused by cytokine storms and microcirculation ischemia and hypoxia[47]. If necessary, extracorporeal membrane oxygenation should be performed to improve the blood oxygen saturation of patients[47].

In this way, control and prevention of the inflammatory response in the early phase of the disease not only helps to reduce nonspecific inflammation in the liver but also prevents the occurrence of a systemic inflammatory response as a way to mitigate the likelihood of mild disease developing into severe or critical illness[47,48].

The main drugs used to treat COVID-19 in individuals with severe or strong symptoms, *i.e.*, hydroxychloroquine[51,52], lopinavir/ritonavir[53], and remdesivir[54-58], have adverse effects in the liver (Table 2). Such effects limit the use of these drugs in persons with previous liver diseases who may experience an aggravation of COVID-19 symptoms (as explained before).

Liver diseases and COVID-19 in Portuguese individuals

The impact of SARS-CoV-2 infection on the liver and the hypothesis that having liver injury may represent a risk factor for the worsening of COVID-19 prognosis have been addressed by several authors[47,48,59].

In Portugal, an epidemiological study by Tenreiro *et al*[60], in a sample of 35117 individuals with COVID-19, demonstrated that the risk of hospitalization increases with the presence of comorbidities and that preexisting pathologies, such as CLDs, are associated with worse prognosis in people with COVID-19 (Table 1). In agreement, Froes *et al*[61] (2020) and Ricoca Peixoto *et al*[62] (2021) observed that the presence of concurrent comorbidities is significantly associated with negative outcomes when the person is infected with SARS-CoV-2 (Table 1).

In the different studies (Table 1), it was also possible to observe that in the Portuguese population, the risk of hospitalization and lethality associated with COVID-19 in infected individuals is higher in males and increases with age[60-64]. Furthermore, Musa[65] also noted that people at high risk of severe COVID-19 are generally older and/or have associated complications such as diabetes, hypertension, cardiovascular disease, and liver disease.

However, the existing literature has shown contradictory data. Although some reports have shown that persons with comorbidities, such as liver failure, had longer hospitalization lengths and were at a higher risk of progressing to severe disease[58,66], which is in line with the data found in Portuguese individuals, other studies have demonstrated that the COVID-19-related liver injuries are usually temporary and mild, with minor clinical significance[59,67].

Liver biochemical indicators, mainly shown by abnormal ALT and AST levels complemented by a slight increase in total bilirubin levels and prolonged prothrombin time, have also been used as a predictor of the severity and prognosis of COVID-19 patients[47,59,68,69].

In a study performed by Guan *et al*[68] (2020), which included 1099 patients, elevated AST levels were observed in 18.2% of patients with non-severe disease and 39.4% with severe disease. In addition, the proportion of patients with abnormal ALT in severe cases (28.1%) was higher than that in mild cases (19.8%)[68]. Other studies, however, have found different results. Wang *et al*[70] and Wu *et al*[50] reported no significant differences in liver function tests when comparing severe and mild/moderate patients.

In the Portuguese literature, there is still scarce information regarding the global etiology of preexisting liver disease in individuals with COVID-19. Garrido *et al*[59], in a study of 317 individuals with COVID-19 at the University Hospital Center of Porto, observed that at the time of hospitalization, 50.3% of patients had abnormal changes in liver enzymes, with 41.5% showing elevated levels of aminotransferases. AST and AP were associated with the severity of COVID-19, intensive care unit (ICU) admission and increased mortality. In contrast, ALT and γGT were associated with patient admission to the ICU[59]. In the same study, the authors reported that of the 14 patients with CLD, 21.4% had a critical level of COVID-19, the average duration of disease was 36.6 d, hospitalization 11.5 d, and mortality 28.6%, increasing to 66.7% in patients with liver cirrhosis[59].

Portugal participated in the European study from the European Hematology Association Survey (EPICOVIDEHA) that aimed to investigate the characteristics of hematological malignancies in individuals developing COVID-19 and analyzed predictors of mortality[71]. The authors concluded that increased age, active disease, chronic cardiopathy, liver disease, renal impairment, smoking history, and ICU were significantly associated with higher mortality[71].

Recently, we published a study on the Portuguese population, with more than 2000 participants, reporting the medical and legal implications of COVID-19 in life habits[24]. We observed that the subjects increased alcohol consumption, a change that can contribute to liver diseases. On the other hand, we also analyzed all participants' comorbidities, and none indicated having a liver disease (unpublished results). It is possible that in some cases, the individuals do not even know that they have liver malfunction, or the liver disease is discovered after the SARS-CoV-2 infection and treatment.

Table 2 Drugs used in the treatment of coronavirus disease 2019 that have adverse effects on the liver

Drug(s)	Mechanism of action	Adverse effects on the liver	Ref.
Hydroxychloroquine	Increases intracellular pH and inhibits lysosomal activity in antigen-presenting cells	Liver failure	[51,52]
Lopinavir/Ritonavir	Inhibition of 3-chymotrypsin-like protease	Hepatoxicity	[53]
Remdesivir	Inhibits viral transcription and replication by blocking the RNA polymerase enzyme	Increased aminotransferase levels	[54-57,70]

However, as concluded in other reports[58,59,68], it remains unclear whether these changes in laboratory tests are associated with a worse prognosis in individuals with COVID-19 because the cause of these alterations could be explained by several factors like the virus or the percussion of a severe inflammatory response from a liver injury such as hypoxic hepatitis, drug toxicity, immune response, and alterations in the gut vascular barrier and microbiota[47,48,59].

DISCUSSION

We surveyed several databases and screened several papers to review the clinical manifestations and outcomes of Portuguese individuals with COVID-19 and liver injury. However, only six studies reported original observational and retrospective research on the Portuguese adult population concerning liver-associated clinical manifestations or outcomes and COVID-19.

Because of the relatively small number of articles analyzed in this review, further studies were considered to develop and elaborate on the results obtained. Data from the Portuguese NHS on COVID-19 was also included. In this second round of literature search, we found information about the implications of COVID-19 in healthcare. Therefore, we broadened the scope of this review, although this was not initially planned.

We examined topics essential to understanding the relationship between COVID-19, liver injury, and patients' clinical outcomes. We discussed: (1) How COVID-19 affected health care and clinical practice in Portugal; (2) The relationship between COVID-19 and liver diseases; (3) Hepatic conditions that affect the treatment of COVID-19; and (4) What is known regarding liver diseases and COVID-19 in Portuguese individuals.

Our results demonstrated the implications of the COVID-19 pandemic in Portugal's health care and clinical practice. We observed that the number of face-to-face consultations decreased during the pandemic, specifically, during the first semester, of 2020, compared with the same period of the last 2 years (2018/2019). However, virtual medical assistance, *i.e.*, medical and nurse teleconsultations, increased. Besides these changes in medical appointments, we also observed adjustments in the activity of diagnostic laboratories. A European study involving Portugal demonstrated that the percentage of analyzed samples increased during the pandemic, specifically from the liver, urinary tract, serous cavities, breast, lymph nodes, respiratory tract, and others. On the contrary, the percentage of analyzed samples of the cervicovaginal tract, thyroid, and anorectal region decreased[32].

While exploring the role of liver injury and COVID-19, we observed that COVID-19 affects liver activity, changing the enzymatic activity[37]. These enzymatic alterations were observed in half of the infected individuals[34]. On the other hand, preexisting liver disease was associated with worse outcomes in persons with COVID-19. For this reason, in Portugal, having a liver disease (chronic disease) was enough to be included in priority groups for vaccination during the first campaign of the Portuguese NHS.

The liver and COVID-19 are interrelated. On the one hand, liver function affects COVID-19 status. On the other hand, drugs such as lopinavir, ritonavir, hydroxychloroquine, and remdesivir, used to treat COVID-19, may cause adverse effects on the liver and affect its function (Table 1).

According to our search, the clinical outcome in Portuguese individuals with COVID-19 was aggravated by liver injury, old age, and other comorbidities leading to treatment in intensive care and increased mortality.

CONCLUSION

COVID-19 was a pandemic that had many implications for people's health, life quality, and lifestyle and their access to public or "social" services, such as primary healthcare services. The global dimension of COVID-19 consequences is almost unmeasurable. However, our lives have changed, and these alterations may be permanent. Not so much time ago, before the COVID-19 pandemic, teleconsultations were unthinkable. During the pandemic, telemedicine became a form of access to medical assistance.

Figure 3 Alterations in people's quality of life and healthcare systems due to coronavirus disease 2019.

Furthermore, all health systems had to adapt during COVID-19, prioritizing healthcare. According to this evidence, we conclude that societies should define strategies to be implemented during pandemic situations to ensure that all individuals have guaranteed access to health care (Figure 3). In Portugal, we observed that the alterations that occurred in the healthcare system during the pandemic seem to have been effective in providing care to the population.

Concerning the relationship between liver diseases and COVID-19, we conclude that COVID-19 may alter the function of the liver. The worsening of the COVID-19 status depends on the age of the individuals and the presence of other comorbidities, albeit the papers analyzed in this review do not discuss if the liver function is age-dependent. Moreover, the drugs used to treat COVID-19 have adverse effects on the liver and affect liver function.

ARTICLE HIGHLIGHTS

Research background

Coronavirus disease 2019 (COVID-19) may be asymptomatic or cause mild to severe symptoms exacerbated by preexisting health conditions like liver diseases. However, the relation between hepatic diseases and the effect and prognosis of COVID-19 individuals is unclear, and information concerning the Portuguese population is scarce.

Research motivation

To understand how hepatic disorders may have been affected by COVID-19 and how this infection impacted the Portuguese healthcare system.

Research objectives

To investigate the association between COVID-19 and liver diseases and their impact on the prognosis of patients and explore the effect of COVID-19 on healthcare systems.

Research methods

A review of the relevant literature was performed.

Research results

People with liver diseases who were COVID-19-positive had a worse prognosis than individuals without hepatic diseases. Due to COVID-19, most countries altered the normal activity of healthcare systems, increasing teleconsultations.

Research conclusions

The interaction between liver diseases and COVID-19 in people's prognosis is unclear, but there is evidence of its existence. As observed in other countries, the normal activity of the national healthcare system in Portugal was modified due to the pandemic situation created by COVID-19.

Research perspectives

To promote the development of studies about the interaction and relation between liver diseases and COVID-19 and generate critical thinking about how healthcare systems should function in case of a

pandemic.

ABOUT COVER

Editorial Board of *World Journal of Gastroenterology*, Chun-Feng Qu, MD, PhD, Director, Professor, Department of Immunology, National Cancer Center/Cancer Hospital, Chinese Academy of Medical Sciences & Peking Union Medical College, No. 17 Panjiayuan South Lane, Chaoyang District, Beijing 100021, China. quchf@cicams.ac.cn

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

The risk of liver injury in patients with coronavirus disease 2019 (COVID-19) infection is quite evident. Furthermore, liver function test abnormalities are still detected in COVID-19 patients despite the development of antivirals and the availability of several types of vaccines. This editorial describes liver involvement during COVID-19 infection in patients with or without preexisting liver injury, such as chronic liver disease, to elucidate COVID-19-induced liver function abnormalities and their severity, pathophysiology, clinical manifestations, and clinical and laboratory outcomes. We also discuss the effect of vaccination against COVID-19 to better understand host factors, such as age, gender, and race, on the incidence and severity of liver dysfunction at initial presentation and during the illness. Finally, we summarize the results of relevant meta-analyses published to date and highlight the importance of adequate liver function monitoring in the current climate of the overwhelming COVID-19 pandemic.

Key Words: COVID-19; SARS-CoV-2; Liver injury; Transaminases; Hyperbilirubinemia; Pathophysiology

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Recent evidence confirmed coronavirus disease 2019-induced liver function test abnormalities in patients with or without preexisting liver injury. Understanding the mechanism and recognizing the clinical picture, as well as identifying the risk factors for developing such abnormalities, will pave the way for early diagnosis and better management of such cases.

INTRODUCTION

The continuing evolution of coronavirus disease 2019 (COVID-19) has led to the identification of a wide spectrum of associated symptoms, ranging from asymptomatic disease to severe manifestations that resulted in acute respiratory distress syndrome, respiratory failure, or multiple organ dysfunctions with risk of thrombosis and death[1,2]. Accumulating evidence indicates an association between COVID-19 infection and liver function test (LFT) abnormalities, and there have been many reports of liver injury, even in those without pre-existing liver disease[3-5]. It was shown that COVID-19 binds to angiotensin-converting enzyme 2 (ACE2) receptors (part of the renin–angiotensin system) to gain entry and damage the target organ[2]. Since ACE2 receptors are found in both bile duct epithelial cells (cholangiocytes) and liver cells (hepatocytes)[4], the liver is a potential target for direct infection. COVID-19 liver infection is related to disease severity and older age[5], and LFTs usually reveal a cholestatic or hepatocellular pattern[6]. Thus, a more detailed understanding of host factors including underlying comorbidities, in addition to adequate monitoring of patients with liver damage, is mandatory in the current overwhelming COVID-19 pandemic[7].

INCIDENCE OF COVID-19-INDUCED LIVER DYSFUNCTION

Sun *et al*[8] defined COVID-19-related liver injury as any liver damage occurring during disease progression and treatment in patients with or without pre-existing liver disease. The reported incidence of LFT abnormalities observed with COVID-19 is variable. A recent meta-analysis of 107 studies consisting of 20874 COVID-19-positive patients reported the pooled incidence of elevated liver enzymes at presentation as 23.1%[9]. A similar frequency was reported in another meta-analysis, where abnormal aminotransferase levels were present in 24% of 17776 patients[10]. Most enzyme elevations associated with COVID-19 infection are transient and self-limited[8]. Notably, elevated aminotransferase levels were reported in 14%–58% of hospitalized patients with COVID-19[4,11]. Additionally, the pooled prevalence of elevated alanine transaminase (ALT), aspartate transaminase (AST), and total bilirubin were evaluated as 21% (14%–29%),18% (13%–25%), and 6% (3%–11%), respectively[12]. Males are at high risk of getting acute liver injury related to COVID-19 than females since it was reported that bilirubin, ALT, alkaline phosphatase (ALP), and gamma-glutamyl transferase values were higher in male patients with COVID-19[13,14]. Regarding age, a meta-analysis by Kulkarni *et al*[10] revealed that the incidence of elevated liver enzymes in children (> 10 years) was 17.8% [95% confidence interval (CI): 9.9–29.8] among 283 patients, meanwhile, in adults it was 24.1% (95%CI: 20–28.8) among 12756 patients. There was also a significant difference in the prevalence of liver injury among different races and ethnicities. On adjusted analyses, white patients were less likely to develop liver injury compared with Asian patients (OR: 1.65, 95%CI: 1.37–2.02) and multiracial patients (OR: 1.65, 95%CI: 1.37–2.02). Those with a non-Hispanic ethnicity had a lower association with sustaining liver injury (OR: 0.77, 95%CI: 0.75–1.03)[15].

PATHOPHYSIOLOGY

The detailed mechanism of liver injury in COVID-19 infection remains unclear. Several possibilities involving a combination of direct viral-mediated effects due to viral replication within hepatocytes[8,9,16] and the viral-induced cytokine storm have been postulated[8,17]. Remarkably, severe acute respiratory syndrome coronavirus-1 RNA was detected in liver tissue from SARS-infected patients, although viral inclusions were not detected under electron microscopy[18]. Viral entry occurs through ACE2 receptors, which are expressed on many cell types, including hepatocytes and cholangiocytes[9,19]. Increased ACE2 expression in cholangiocytes (59.7% of cells) and, to a lesser extent, hepatocytes

(2.6% of cells) confirms that severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) infection alters liver function by direct cytotoxicity due to continuous viral replication[20]. However, severe SARS-CoV-2 infection results in a clinical state resembling sepsis due to the massive release of cytokines, which may progress to apoptosis and necrosis of infected cells, resulting in multiorgan failure late in the course of the disease[21]. Immune-mediated injury is supported by a marked rise in serum ferritin, lactate dehydrogenase, interleukin (IL)-2, and IL-6[6,19]. Pneumonia-associated hypoxia or ischemic hepatitis due to prolonged hypotension/shock is also speculated[5,6,8,9,16]. Exposure to hepatotoxic agents must be considered since drug-induced hepatotoxicity varies with age, sex, and race [22]. Antiviral agents directed against COVID-19 (*e.g.*, lopinavir or ritonavir), antibiotics used against bacterial infections, antipyretics, anticoagulants, and steroids may also cause liver function deterioration [23,24]. Additionally, underlying liver disease is considered a risk factor.

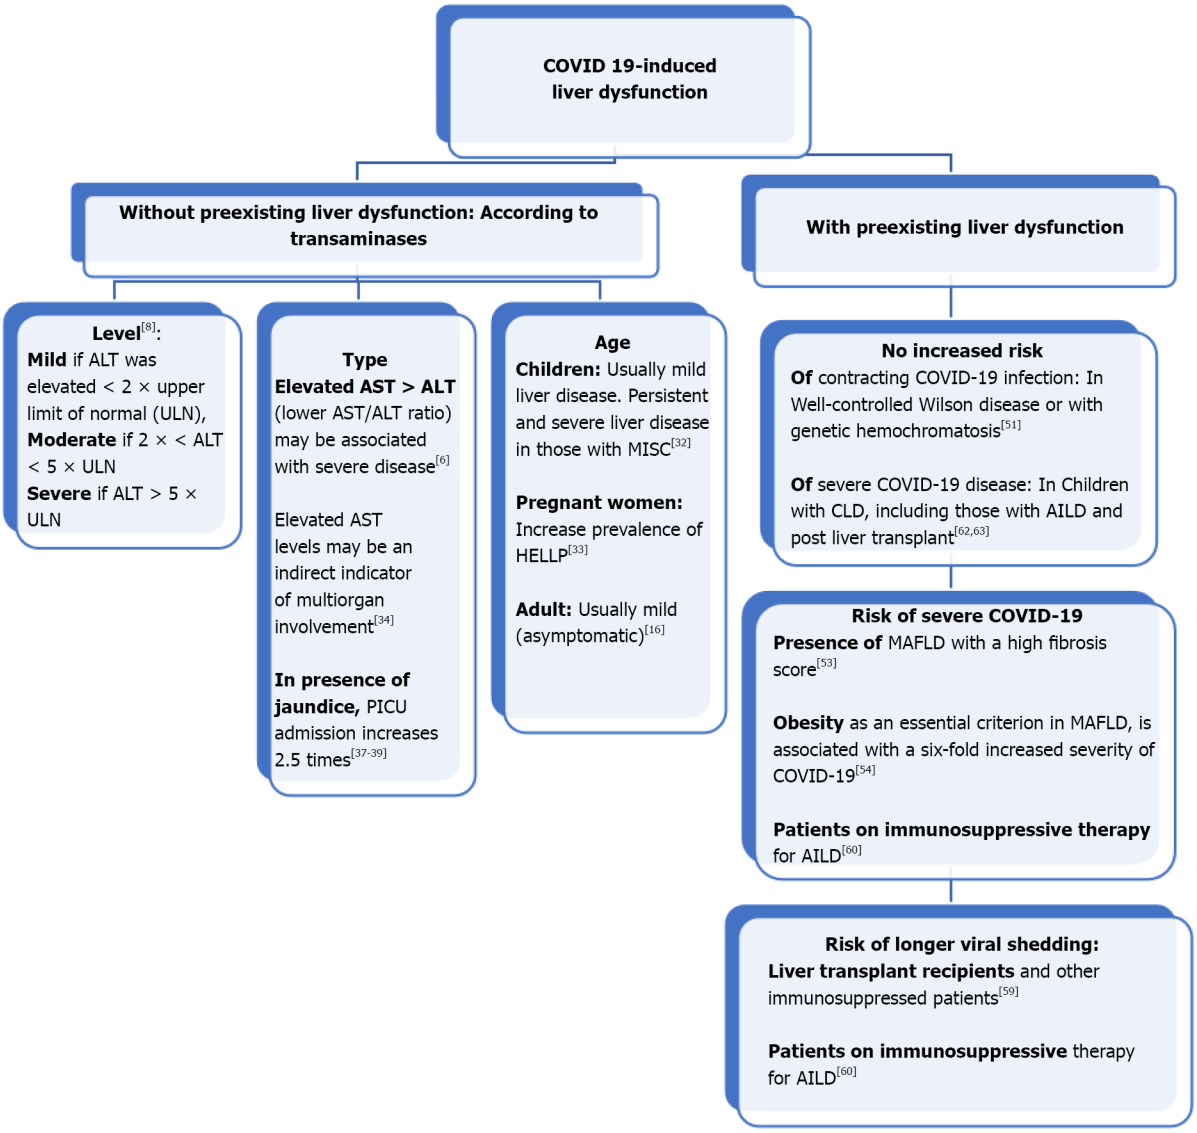
CLINICAL/LABORATORY MANIFESTATIONS

COVID-19-related liver injury may manifest as hepatobiliary symptoms and elevated liver enzymes. Among patients with COVID-19, liver symptoms are not atypical and may be present without any respiratory symptoms. Furthermore, hepatic symptoms are associated with worse clinical outcomes and an increased risk of mortality[25]. The incidence of a worse clinical outcome is high in hospitalized COVID-19 patients who suffer from jaundice. Additionally, the intensive care unit (ICU) admission rate is approximately 2.5 times higher for patients with hepatic jaundice ($P < 0.001$), mainly due to complicated bacterial sepsis or severe systemic inflammation[26].

Patients with COVID-19, both with and without pre-existing liver disease, may have elevated aminotransferase levels. A mixed pattern of both hepatocellular and cholestatic affection, without significant liver synthetic dysfunction has been reported, although ACE2 receptors are more frequently expressed on cholangiocytes than hepatocytes[4,27]. There is usually a greater elevation of AST than ALT levels, and this pattern has been associated with disease severity. Additionally, both ALT and AST are more usually elevated than bilirubin or ALP[28,29]. Sun *et al*[8] categorized the degree of liver damage as mild if ALT was elevated < 2 × upper limit of normal (ULN), moderate if 2 × < ALT < 5 × ULN, and severe if ALT > 5 × ULN. However, lower AST/ALT ratios may be more specific for hepatic injury[6]. A retrospective study evaluating the levels of hepatic enzymes of 1827 COVID-19 patients at admission and during hospitalization demonstrated abnormal levels of AST (66.9%), ALT (41.6%), and ALP (13.5%) at admission with peaks of AST (83.4%), ALT (61.6%), and ALP (80%) during hospitalization[30]. Another retrospective cohort study on 230 Covid-19 positive patients showed that the prevalence of abnormal liver enzymes among those with severe COVID-19 infection were as follows: AST (77%), ALT (49%), gamma glutamyl transpeptidase (GT) (37%), and ALP (12%). A severe COVID-19 infection was more likely present in patients with abnormal levels of AST ($P = 0.015$), gamma GT ($P = 0.022$), and ALP ($P = 0.03$)[31].

Regarding age, children appear to have a milder illness with significantly less need for inpatient admission or respiratory support and are less likely to have the multiple comorbidities present in older adults. Hepatitis is common in children with multisystem inflammatory syndrome and is associated with a more severe presentation and persistent elevation of LFTs in many patients[32]. Furthermore, older patients are more likely to develop more severe COVID-19 and at greater risk of abnormal liver function. The latter is more common in patients with severe or critical presentations of COVID-19[5]. In pregnant women with COVID-19, observational studies showed an increased prevalence of preeclampsia and hemolysis, elevated liver enzymes and low platelet (HELLP) syndrome. Despite a possible pathophysiology linkage between COVID-19 and HELLP syndrome, the evidence on temporality to prove a causal association between SARS-CoV-2 infection and HELLP syndrome is still insufficient[33].

A cohort study reported that acute liver injury with a hepatocellular pattern was common in patients who tested positive for SARS-CoV-2 but was usually mild[16]. However, 6.4% of patients had a severe liver injury with a severe disease course, where elevated AST levels may be indirect indicators of multiorgan involvement[34]. There is also a recent case report of a young male with COVID-19 who suffered from acute icteric hepatitis with a marked rise in bilirubin and liver transaminase levels without any respiratory symptoms[6]. Another case report found that COVID-19 infection could be a risk factor or comorbidity of acute liver failure, with only isolated hyperbilirubinemia indicating liver involvement[17]. Moreover, severe infections with COVID-19 followed by death were more often associated with hypertransaminasemia and high bilirubin levels compared with mild and moderate infections[14,35]. Patients with severe liver injury were more likely to need ICU-level care, intubation, and renal replacement therapy and showed a greater risk of in-hospital mortality[6,16,36]. A high bilirubin level and liver stiffness (measured using shear wave elastography) have been reported as correlated with more severe outcomes[37-39]. Liver injury and failure are frequently observed in critically ill cases, and their occurrence is associated with high morbidity and mortality[40-42]. Recently a potential link between Omicron variant infection and severe hepatitis of unknown etiology in children was observed, where it was postulated that previous infection or co-infection with SARS-CoV-2



increases the susceptibility to adenovirus infection[43]. Figure 1 summarizes the clinical and laboratory presentation of COVID-19-induced liver dysfunction.

COVID-19 IN- PATIENTS WITH PRE-EXISTING LIVER DISEASE

The impact of COVID-19 on chronic liver disease (CLD) is variable. Several studies have reported that patients with CLD, regardless of its etiology, may be at higher risk for severe illness from COVID-19[44-47]. A systematic review of 40 studies with 908032 participants (most of them from China and United States) showed that COVID-19 cases with CLD had significantly higher chance of having a severe form of COVID-19 (pooled OR: 2.44; 95%CI: 1.89–3.16) and death (pooled OR: 2.35; 95%CI: 1.85–3.00) when compared with COVID-19 cases without CLD[48]. A United States-based multicenter study reported a mortality rate of 12% in COVID-19 patients with pre-existing liver disease compared with 4% in those without[49]. Li *et al*[5] found that patients with underlying chronic hepatitis B virus infection suffered from a higher rate of severe or critical COVID-19 illness than mild/moderate illness ($P < 0.0001$). However, it remains unclear whether COVID-19 infection causes an already susceptible liver to fail or is just a risk factor for fulminant hepatic failure[21]. Acute and chronic liver failure related to COVID-19 infection has been shown in patients with decompensated alcoholic and non-alcoholic liver cirrhosis[50,51]. Whether cases with cirrhosis and COVID-19 are at higher risk of decompensation or development of acute-on-chronic liver failure, as has been reported for influenza infection, remains undetermined [52]. Notably, existence of metabolic-associated fatty liver disease (MAFLD) was considered an independent factor for the severity of COVID-19 in a series of non-diabetic COVID-19 infected cases, indicating an injurious bidirectional relationship between liver disease and COVID-19 infection[53]. Obesity is an essential criterion in MAFLD[54], and it was reported that the severity of COVID-19 showed a six-fold increase in obese patients with MAFLD[28]. Furthermore, patients with MAFLD and a high fibrosis score were more liable to suffer from severe COVID-19 disease, regardless the existing metabolic abnormalities[55]. Large amounts of IL-6 are produced in patients with severe COVID-19, particularly those with obesity, and this is considered a primary factor in triggering a systemic inflammatory response and cytokine storm, as well as multiple organ dysfunctions[53,56]. Moreover, there is altered secretion of inflammatory lipid mediators and a reduction in adiponectin levels in obese patients with MAFLD[57]. In patients with underlying advanced CLD, SARS-CoV-2 infection could lead to hepatorenal syndrome and liver transplantation[50]. Liver transplant recipients and other immunosuppressed patients who have COVID-19 may have a longer duration of viral shedding than non-immunosuppressed patients[58]. Additionally, Center for Disease Control and Prevention considers patients on immunosuppressive therapy for autoimmune liver diseases (AILD) are at high risk for severe COVID-19 disease and have prolonged viral shedding[59]. Meanwhile, patients with well-controlled Wilson disease or with genetic hemochromatosis showed no increased risk of having COVID-19 infection[60]. On the other hand, children with CLD, including those with AILD and post liver transplant, do not have an increased risk for severe COVID-19 disease, with little or no liver dysfunction [61,62]. It was found that the risk of mortality in COVID-19 patients is associated with the severity of the underlying liver diseases[45,57]. A recent meta-analysis based on confounding cofactors-controlled data demonstrated that cirrhosis was an independent risk factor for prediction of mortality associated with SARS-CoV-2 infection[63].

SARS-COV-2 VACCINATION AND LIVER DISEASE

Patients with CLD can receive a COVID-19 vaccination, although the immunogenicity and effectiveness of these vaccines have not been fully evaluated in this group of patients. However, vaccination has been associated with a lower risk of COVID-19-related infection and mortality in patients with cirrhosis[4,64]. Following COVID-19 vaccination, immune-mediated liver injury (ILI) is not well-characterized. A recent meta-analysis of 23 patients (mean age, 55.3 years) showed jaundice as the most common symptom (78.3%). Peak bilirubin, ALT, and ALP levels were 10.8 (6.8–14.8) mg/dL, 1106.5 (757.0–1702.5) U/L, and 229 (174.6–259.6) U/L, respectively. Histological examination showed intense portal lymphoplasmacytic infiltrate with interface hepatitis. The mean duration between receiving the vaccine dose (either first or second) and subsequent development of liver injury was 17.3 (11.2–23.4) d. Steroids were used in 86.9% of cases, and complete response, recovery, and death were reported in 56.5%, 39.1%, and 4.3% of cases, respectively. A temporal course between vaccination and the onset of liver injury was reported. Shroff *et al*[65] noted that most cases of severe liver injury were described after SARS-CoV-2 mRNA vaccines. Most cases occurred following the first vaccination dose, and two developed ILI following the second dose. Interestingly, there was one case of ILI after both doses of vaccine. It is also notable that pre-existing comorbidities (69.6%) were common, including liver disease in 26.1% and thyroid disorders in 13% of patients[66].

DOI: 10.3748/wjg.v29.i7.1123 **Copyright** ©The Author(s) 2023.

Figure 1 Summary of coronavirus disease 2019-induced liver dysfunction. MAFLD: Metabolic-associated fatty liver disease; AILD: Autoimmune liver diseases; COVID-19: Coronavirus disease 2019; ALT: Alanine transaminase; ULN: Upper limit of normal; AST: Aspartate transaminase; PICU: Pediatric intensive care; CLD: Chronic liver disease; HELLP: Hemolysis, elevated liver enzymes and low platelet; MISC: Multisystem inflammatory syndrome of children.

CONCLUSION

This editorial sheds light on liver involvement in COVID-19 patients with and without pre-existing liver injury. Further studies are necessary to elucidate the etiology and mechanism(s) of liver dysfunction associated with COVID-19 infection, particularly in patients aged less than 18 years. Liver function should be monitored carefully during COVID-19 infection.

Abstract

Small bowel angiodysplasia (SBAD) is reported to account for nearly 50% of cases of small bowel bleeding. When SBAD occurs frequently, it is difficult to treat all the angiodysplasias endoscopically, and gastrointestinal bleeding often recurs. Hormone therapy, somatostatin analogs, thalidomide and vascular endothelial growth factor (VEGF)-neutralizing antibodies have been reported to reduce gastrointestinal angiodysplasia (GIAD) bleeding. However, there is no strong evidence to recommend them. Also, there are no guidelines for their use. Hereditary hemorrhagic telangiectasia (HHT) is a hereditary disease caused by abnormalities in VEGF, resulting in multiple GIADs. A treatment guideline has been created for GIAD in HHT, and the use of tranexamic acid, an antifibrinolytic agent, is the first recommendation pharmacotherapy for GIAD with gastrointestinal bleeding that is difficult to treat endoscopically. It has been reported that fibrinolysis is accelerated in GIAD patients who are not HHT, similar to HHT patients. The use of tranexamic acid for gastric antral vascular ectasia in GIAD has been reported to be useful. However, there are very few reports of its use for SBAD. There are concerns with tranexamic acid use regarding the development of thrombosis/embolism, but there are few reports of such side effects. Future clinical trials including tranexamic acid for SBAD are desired.

Key Words: Angiodysplasia; Intestine; Hereditary hemorrhagic telangiectasia; Tranexamic acid; Endoscopic treatment; Pharmacotherapy

Core Tip: It is difficult to treat all multiple small bowel angiodysplasias (SBAD) endoscopically. Four main types of drugs, including somatostatin analogs, hormone therapy, thalidomide, and vascular endothelial growth factor-neutralizing antibodies, have been reported for use in gastrointestinal angiodysplasias (GIAD). However, there is no recommended pharmacotherapy for SBAD. Tranexamic acid is recommended for patients with GIAD in hereditary hemorrhagic telangiectasia who are difficult to treat endoscopically. Investigation of the use of tranexamic acid for SBAD is desired.

INTRODUCTION

Gastrointestinal angiodysplasia (GIAD) is a benign vascular malformation of the GI tract and is a frequent source of GI bleeding. AD has been reported under various names, such as vascularectasia, angioectasa, and angiectasia, but since all of these generally present with the same lesions, they are collectively referred to here as AD. GIAD patients include patients with isolated AD in the stomach, small bowel, and large bowel; gastric antral vascular ectasia (GAVE) secondary to cirrhosis; and Heyde's syndrome secondary to aortic stenosis. GIAD causes 10% of all GI bleeding cases and 50% of small bowel bleeding cases[1]. GIAD has also been reported to cause approximately 4%-7% of upper nonvariceal bleeding, 30%-40% of occult small bowel bleeding, and 3%-40% of colonic bleeding episodes [2].

GIAD diagnosed as a source of GI bleeding often causes rebleeding even after endoscopic treatment, and subsequent treatment is difficult in these cases. After hospitalization and treatment in patients diagnosed with GIAD as the source of GI bleeding, the rate of rebleeding reaches 20% 30 d after discharge, and medical expenses are high[3]. In addition, a systematic review showed that 42.7% (209/490) of small bowel AD (SBAD) patients had rebleeding even after endoscopic treatment, and subsequent treatment is difficult in cases of rebleeding[4].

A major reason for rebleeding is that ADs tend to occur frequently. Even gastric ADs such as GAVE occur so frequently that endoscopic treatment is difficult. In addition, it has been reported that 2 or more ADs in the small bowel were observed in more than 63% of patients[5]. It is difficult to perform enteroscopy frequently for multiple SBADs, and it is difficult to find all the ADs in the long length of the small bowel. In other words, even if one lesion is treated, the other lesions bleed. Some types of pharmacotherapies are desirable for patients with SBAD whose overt bleeding or anemia progresses even after multiple endoscopic treatments. There are no established pharmacological treatments for SBAD. However, several pharmacological treatments for GIAD have been proposed, such as somatostatin analogs, hormone therapy, thalidomide and angiogenesis inhibitors.

Hereditary hemorrhagic telangiectasia (HHT) is a congenital disease in which AD occurs frequently in various organs. In HHT, GIADs occur so frequently that endoscopic treatment is difficult. Therefore, the pharmacotherapy of HHT has been studied for a long time, many reports have been published, and guidelines have been established. In this paper, the GI bleeding section of the HHT guideline is outlined, the pharmacotherapy options for GIAD that have been performed thus far are introduced, and finally, the treatment policy for SBAD is considered based on the HHT guideline.

GUIDELINE FOR HHT

HHT is a multiorgan disease in which AD occurs frequently in the skin, mucous membranes, and GI tract, causing recurrent bleeding and arteriovenous malformations (AVMs) in the brain, spinal cord, lungs, and liver[6,7]. HHT is inherited in an autosomal dominant manner and is caused by abnormalities in vascular endothelial growth factor (VEGF)[8]. The gene associated with HHT type 1 is a transforming growth factor-beta binding protein of endothelial cells[9]. HHT types 1 and 2 arise from mutations in endoglin and activin receptor-like kinase 1, respectively[10].

Epistaxis is a serious problem in HHT patients, but GI bleeding due to multiple GIADs is also a major problem. HHT has international guidelines, updated in 2020[11]. The guidelines recommend endoscopic treatment for GIAD in patients with HHT first. Second, antifibrinolytic therapy is encouraged as pharmacotherapy for endoscopic treatment resistant cases. However, the degree of encouragement is weak. This guideline is due to a recent report that showed that the antifibrinolytic agent tranexamic acid reduced the need for endoscopic management in patients with HHT[12]. The latest report summarizing the main points of the guideline recommends using tranexamic acid as the first step after performing

argon plasma coagulation of actively bleeding lesions at the initial diagnosis. Systemic antiangiogenic agents are recommended as a next step if no improvement is seen with administration of tranexamic acid[13]. The guideline committee states that, where possible, the use of dual antiplatelet therapy and/or a combination of antiplatelet therapy and anticoagulation should be avoided in patients with HHT. If anticoagulation is not tolerated in HHT patients with atrial fibrillation, discontinuation of anticoagulation with alternative approaches, such as left atrial appendage closure, is recommended[14]. Since the bleeding in HHT patients tends to be serious, the use of anticoagulant therapy and antiplatelet therapy is recommended with the minimum amount that is necessary.

Patients with multiple SBADs often have fewer ADs than patients with HHT. However, SBAD is a similar pathology, and HHT is a reference for SBAD treatment. There are no trials of tranexamic acid in the pharmacological treatment of SBAD in non-HHT patients, nor does tranexamic acid appear in various reviews as a treatment for SBAD. The next section considers the drug treatment of GIAD, especially SBAD, with reference to HHT.

PHARMACOLOGICAL TREATMENT OF GIAD

According to an analysis of the MEDLINE, Cochrane, Scopus and Embase databases, there are four main pharmacological therapies for GIAD that have been reported: Somatostatin analogs, hormone therapy, thalidomide and angiogenesis inhibitors[15]. These drugs are discussed first, followed by a discussion of tranexamic acid, which is used in the treatment of HHT.

Hormone therapy

Studies of oral contraceptives have shown that there is a risk of thrombosis with hormonal therapy with estrogens and progestogens[16]. It has been reported that this hormone therapy affects blood clotting ability and shortens bleeding time[17], which leads to its use as a hemostatic agent. Activated protein C resistance was reported to be involved in this coagulation enhancement[18]. On the other hand, postmenopausal hormonal therapy has been reported to increase plasma fibrinolytic activity, plasma levels of D-dimer and tissue plasminogen activator activity[19]. Thus, the therapy does not appear to increase coagulability in postmenopausal women. The increase in plasma fibrinolytic activity due to postmenopausal hormone therapy may be considered a secondary phenomenon of hypercoagulability. Fundamentally, hormone therapy for GIAD is considered to be an attempt to utilize the enhancement of blood coagulability for hemostasis against GI bleeding.

In a double-blind, placebo-controlled, crossover trial using estrogens and progestogens in 10 patients with GIAD requiring frequent blood transfusions, it was reported that hormone therapy reduced the amount of transfusion[20]. Various studies have originated from this Lancet report in 1990. In a prospective observational study with an average follow-up period of 535 d in 43 patients with obscure GI bleeding, all 38 who received concomitant hormonal therapy were bleeding-free. In contrast, all 5 patients treated with estrogen alone had episodes of rebleeding[21]. However, a double-blind randomized control trial (RCT) was conducted in 72 noncirrhotic patients with hemorrhages of GIAD-probable origin; rebleeding occurred in 46% of the 35 patients; and no significant difference was observed[22]. As a result of this study, the number of reports on hormone therapy has decreased, but reports on treatment using hormone therapy have been published recently. For example, when comparing 6 mo before and after hormone therapy for GIAD, anemia improved, and the number of blood transfusions decreased[23]. Hormone therapy has side effects peculiar to hormone drugs, but it is generally safe and has the advantage of being inexpensive. For these reasons, the search for a hormone therapy treatment for difficult-to-control GI bleeding continues.

Somatostatin analogs

Since the 1990s, attempts have been made to use the somatostatin analogs octreotide and lanreotide to treat hemorrhagic GIAD. Somatostatin analogs for GIAD are thought to inhibit angiogenic promoters by affecting chemical factors such as VEGF, basic fibroblast growth factor, and insulin-like growth factor 1 and to stimulate relaxation of intestinal smooth muscle, relieve chronic submucosal vein occlusion, and reduce the intravascular pressure on the arterial side[24]. There are many reports showing that somatostatin analogs are effective in patients with GIAD, but most have a small number of patients and are retrospective studies[1]. The usefulness of somatostatin analogs was reported in an RCT targeting 70 patients in which the actuarial probability of remaining free of rebleeding at 1 and 2 years of follow-up was 77% and 68%, respectively, in the octreotide group and 55% and 36%, respectively, in the placebo group ($P = 0.030$)[25].

Recently, a systematic review of 212 patients from 11 studies investigating the usefulness of somatostatin analogs for patients with GIAD, with a median duration of treatment of 12 mo, was reported. Somatostatin analogs were reported to reduce the number of red blood cell transfusions by an incidence rate ratio of 0.18 ($P < 0.0001$). The most common side effects of somatostatin reported in this study were loose stools (3%), cholelithiasis (2%), flatulence (2%), and administration site erythema (2%)[26]. Another systematic review and meta-analysis suggested that somatostatin analogs are more useful

in patients with GIAD than hormone therapy[27]. Based on the above, somatostatin analogs are thought to be useful for the treatment of patients with GIAD. However, since most somatostatin analogs are a daily subcutaneous injection and are expensive, there is a high possibility that the number of patients that can be treated with them are small.

Thalidomide

Thalidomide was reported to inhibit angiogenesis by suppressing VEGF[28]. Recently, it was reported that EGF-like domain multiple 6 (EGFL6) is overexpressed in patients with SBAD, and *in vitro* and *in vivo* assays reveal that thalidomide can act as an anti-angiogenic agent through the regulation of EGFL6 in a proteasome-dependent manner[29].

One RCT showing the efficacy of thalidomide for patients with GIAD has been published. The study randomized 55 patients with GIAD to receive either thalidomide 100 mg (n = 28) or iron 400 mg (n = 27, controls) daily for 4 mo. The treatment was considered to be effective when patients showed a 50% or greater reduction in bleeding episodes (fecal occult blood) in the first year of follow-up; the response rates in the thalidomide group and the control group were 71.4% and 3.7%, respectively (P < 0.001)[30].

Thalidomide is also considered useful in patients with HHT[31]. Therefore, thalidomide is listed as one of the systemic antiangiogenic therapies in the HHT guidelines[11]. However, thalidomide is highly teratogenic, and since it was developed as a sleeping drug, it has been shown to cause neurological symptoms such as somnolence in a drug-dependent manner. These issues limit its use.

VEGF-neutralizing antibodies

As previously mentioned, HHT is caused by abnormalities in VEGF. First, a VEGF-neutralizing antibody was reported to prevent cutaneous AVM formation and ameliorate the internal bleeding in Alk1-deficient adult HHT model mice[32]. In animal experiments, sorafenib and a pazopanib analog were reported to be effective against a mouse model of HHT, and there have been many case reports of the effectiveness of bevacizumab for HHT[33-39]. However, since these are all case reports, generally, VEGF-neutralizing antibodies cannot be judged to be effective, and further investigation is needed.

On the other hand, patients with GIAD did not show any abnormalities in their VEGF levels. In patients with GIAD, angiopoietin-2 was increased, but VEGF did not increase[40]. Similarly, when the serum from patients with SBAD, portal hypertensive gastropathy, and GAVE was compared with the serum from nonbleeding, nonanemic control patients, angiopoietin-2 was increased, but there was no difference in the blood VEGF concentration[41]. Although the relationship between GIAD and VEGF is not clear, there are reports that VEGF-neutralizing antibodies are effective in patients with GIAD. A study reported that bevacizumab was effective for treating GIAD in two patients with Heyde's syndrome[42]. There is one case report involving Heyde's syndrome[43] and another case report showing that bevacizumab is useful for patients with GIAD[44]. Since the number of reports is still small, VEGF-neutralizing antibodies cannot be judged to be effective, and further examination is necessary. Even if effective, VEGF-neutralizing antibody preparations are extremely expensive and difficult to use in many patients.

Tranexamic acid

Plasma hyperfibrinolysis has been reported to occur in both patients with HHT[45] and patients with hemorrhagic GIAD[46]. The latter report suggests that intrinsic ischemia may be the cause of GIAD, which may result in increased fibrinolytic activity in patients with GIAD. This plasma hyperfibrinolysis may promote GI bleeding in patients with GIAD. Tranexamic acid has been widely used as a hemostatic agent for many bleeding disorders by utilizing its anti-hyperfibrinolysis action. Tranexamic acid is a synthetic derivative of the amino acid lysine and exerts antifibrinolytic effects through reversible blockade of the lysine binding site on the plasminogen molecule[47].

A comparative study published in 1973 showed that tranexamic acid is effective in stopping bleeding in the upper GI tract[48]. Gastric juice has been reported to induce marked fibrinolysis, and tranexamic acid was expected to stop bleeding, especially in gastric lesions[49]. In a meta-analysis, tranexamic acid was shown to reduce mortality in patients with upper GI bleeding by 5%-54% and by 40% compared to placebo and is expected to be effective in a variety of nongastrointestinal bleeding disorders[47]. Tranexamic acid was also used for GAVE in patients with cirrhosis that was unresponsive to propranolol therapy and transjugular intrahepatic portosystemic shunt and was reported to reduce bleeding by 20%-30% and the need for surgery by 30%-40%[50-52].

As mentioned above, although the recommendations for it are weak, tranexamic acid is considered to be the first-choice drug for GI bleeding in patients with HHT that is difficult to treat endoscopically. For GIAD, it was reported for the first time in 1998 that tranexamic acid is effective for treating chronic bleeding from colonic AD in dialysis patients[53]. Jejunal AD with persistent bleeding is called Bernard-Soulier, and it was reported in 2013 that tranexamic acid is an effective treatment[54]. Tranexamic acid was reported to be very effective in a patient with multiple duodenal and jejunal ADs who had a medical history of ineffective hormone therapy; discontinued thalidomide treatment due to side effects such as nausea, dizziness, and severe fatigue; and discontinued octreotide treatment after one dose due to a hypoglycemic episode[55]. However, there are still only a few reports of the use of tranexamic acid

Table 1 Mechanisms of drugs used to treat gastrointestinal angiodysplasia and the main studies

Drug/therapy	Mechanism	Leading clinical trial	No. of cases	Result	Ref.
Hormone therapy	Enhanced coagulability				
		Double-blind, placebo-controlled, crossover trial for GIAD	10	Effective	[20]
		Prospective observational study for OGIB	43	Effective	[21]
		Double-blind RCT for GIAD	72	Not effective	[22]
		Systematic review for GIAD	63	Not effective	[27]
		Comparing before and after therapy for GIAD	12	Effective	[23]
Somatostatin analogs	Inhibition of angiogenic promoters				
	Relaxation of intestinal smooth muscle	RCT for gastrointestinal bleeding due to GIAD	70	Effective	[25]
		Systematic review for GIAD	72	Effective	[27]
		Systematic review for GIAD	212	Effective	[26]
Thalidomide	Anti-angiogenic agent				
		RCT for GIAD	55	Effective	[30]
VEGF-neutralizing antibodies	Angiogenesis inhibition				
		Only case reports			
Tranexamic acid	Antifibrinolytic effects				
		Observational study for GAVE	8	Effective	[51]
		Retrospective study for HHT	42	Effective	[12]

OGIB: Obscure gastrointestinal bleeding; GAVE: Gastric antral vascular ectasia; HHT: Hereditary hemorrhagic telangiectasia; GIAD: Gastrointestinal angiodysplasia; RCT: Randomized control trial; VEGF: Vascular endothelial growth factor.

for patients with SBAD.

Since tranexamic acid is an antifibrinolytic agent, there are concerns about thrombosis and embolism, and the following reports have been published. First, there are reports of ischemic episodes and pulmonary embolisms with the use of tranexamic acid[52]. In addition, there is a case report in which tranexamic acid was used to treat SBAD in dialysis patients for whom endoscopic treatment was difficult, and thrombosis of the arteriovenous fistula occurred[56]. In contrast, a meta-analysis of 4747 patients undergoing cesarean section or vaginal delivery found no association between tranexamic acid and deep vein thrombosis[57]. Additionally, in an RCT conducted in patients undergoing bilateral total knee arthroplasty, adverse effects such as deep vein thrombosis and pulmonary embolism were not significantly different between 245 patients who received tranexamic acid and 271 who did not[58]. Furthermore, a review of short-term tranexamic acid use in postdental surgery patients on anticoagulant therapy found no complications, such as thrombosis, in 125 tranexamic acid-treated patients[59]. Based on these reports, tranexamic acid appears to be relatively safe for short-term use. However, there have been no reports on the long-term use of tranexamic acid, especially during anticoagulant or antiplatelet therapy for myocardial infarction or cerebral infarction, and caution should be exercised when using tranexamic acid in patients with these high-risk diseases. Although there are concerns about the risks described above, tranexamic acid is an inexpensive drug that can be expected to reduce the amount of GI bleeding in patients with SBAD who are difficult to treat by endoscopy. Future reports are needed.

CONCLUSION

Table 1 summarizes the drugs currently being studied for use in patients with GIAD, including SBAD. There are several reports that hormone therapy, somatostatin analogs, thalidomide and VEGF-neutralizing antibodies are useful for SBAD for which endoscopic treatment is difficult. Hormone therapy is a good choice considering its less side effects and costs, but there are negative reports. Due to the small number of reports, it is not possible to decide which drug to strongly recommend. Tranexamic

acid has been adopted as a first-line pharmacological treatment in the guidelines for GIAD in HHT patients who are difficult to treat endoscopically. It is also effective for GAVE in non-HHT patients. Although there are concerns about the risk of thrombosis and embolism, tranexamic acid is expected to reduce the amount of GI bleeding in patients with SBAD in whom endoscopic treatment is difficult. Future reports are expected, as tranexamic acid could be a first-line drug for patients with SBAD.

Abstract

This review summarizes the evidence about telemonitoring in patients with inflammatory bowel disease (IBD). To give an overview of the advances performed, as well as the enablers and barriers which favoured/hindered telemonitoring implementation. We performed a literature search in PubMed, EMBASE, MEDLINE, Cochrane Database, Web of Science and Conference Proceedings. Titles and abstracts published up to September 2022 were screened for a set of inclusion criteria: telemonitoring intervention, IBD as the main disease, and a primary study performed. Ninety-seven reports were selected for full review. Finally, 20 were included for data extraction and critical appraisal. Most studies used telemonitoring combined with tele-education, and programs evolved from home telemanagement systems towards web portals through mHealth applications. Web systems demonstrated patients' acceptance, improvement in quality of life, disease activity and knowledge, with a good cost-effectiveness profile in the short-term. Initially, telemonitoring was almost restricted to ulcerative colitis, but new patient reported outcome measures, home-based tests and mobile devices favoured its expansion to different patients´ categories. However, technological and knowledge advances led to legal, ethical, economical and logistic issues. Standardization of remote healthcare is necessary, to improve the interoperability of systems as well as to address liability concerns and users´ preferences. Telemonitoring IBD is well accepted and improves clinical outcomes at a lower cost in the short-term. Funders, policymakers, providers, and patients need to align their interests to overcome the emerging barriers for its full implementation.

Key Words: Inflammatory bowel disease; Telemedicine; Telemonitoring; Information and

communication technology; Crohn´s disease; Ulcerative colitis

Core Tip: In this review we focus on the advances performed in telemonitoring of patients with inflammatory bowel disease, taking into consideration the elements which enabled its use and how technological achievements led to other barriers for its full implementation. We detail the impact of telemonitoring on health outcomes and its cost-effectiveness. We also describe the advances on new patient-reported outcome measures, home-based tests and wearables which improve the ability to manage new patients´ profiles remotely. However, during the pandemic, e-mail and telephone still represented the main resources used. Then, we describe the emerging barriers which explained the limited application of mature telemonitoring programs.

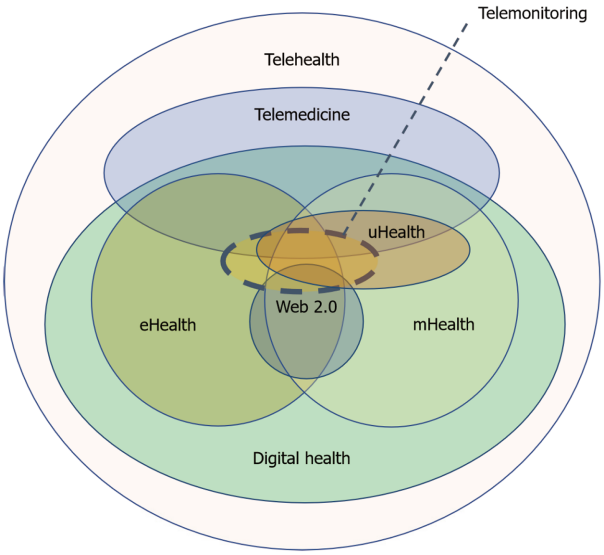
INTRODUCTION



Inflammatory bowel disease (IBD) is a group of disorders characterized by the chronic and recurrent inflammation of different segments of the gastrointestinal tract, which usually associates extraintestinal manifestations and complications due to sustained activity. Unlike other chronic pathologies, IBD mainly affects young individuals in their optimal period of personal and professional development. As such, IBD is related to high levels of school absenteeism and work disability[1], interference with social activities, and impaired health-related quality of life (QoL)[2]. Therefore, IBD has a significant medical, social, and financial impact, further increased by the global increase in its incidence and prevalence in recent years[3].

It is suggested that the "treat-to-target" strategy leads to better outcomes[4]. However, in the conventional management of IBD, scheduled outpatient visits show difficulties to address the disease evolution in each patient, with frequent discrepancies between medical practice and guideline recommendations. Furthermore, patients have little involvement in decision-making, and nearly 50% of adults[5] and an even higher percentage of adolescents with IBD[6,7] are nonadherent to treatment. All these factors prevent the effectiveness of traditional interventions in disease control and increase health expenses[8], especially considering that patients with IBD use health care resources more often than patients with other conditions[9].

Nowadays, health systems are facing financial problems, and telemedicine has been proposed as an alternative to provide an efficient and equitable use of health resources. Information and communication technologies (ICTs) have the potential advantages of providing better communication between healthcare providers and patients, as well as educational resources adapted to patients´ needs. On the one hand, communication improvements could overcome limitations of health access in remote areas, also developing telementoring systems and contact between different specialists in centres where multidisciplinary teams are not available. On the other hand, educational elements could favour patients' empowerment and treatment optimization throughout the disease course[10,11], also addressing behavioural and psychological factors related to nonadherence[5].

Telemedicine has been successfully used in other chronic diseases such as congestive heart failure[12,13], diabetes mellitus[14,15] or chronic obstructive pulmonary disease[16,17] and showed excellent acceptance by patients, improvement in health related QoL and a reduction in hospitalizations[12,16,18]. Owing to these positive results, telemedicine systems have been evaluated in patients with IBD, especially in mild to moderate ulcerative colitis (UC)[19,20]. Telemedicine in IBD started with the adaptation of telemonitoring programs previously used in other chronic pathologies[21], but these were subsequently replaced by web and m-health systems, which represented more attractive options to maintain patients adherence to remote follow-up.

Telemonitoring is the main form of telemedicine in IBD. It is based on the provision of health services at a distance, related to diagnosis, treatment, follow-up or education. It is characterized by the structured and continuous monitoring of clinical data that is self-reported by patients in their usual environment, and then sent to health providers. The objective is the early detection and intervention on complications related to the disease itself or its treatment. It usually includes tele-education interventions and shares many features with other domains of use of ICTs in the health-care setting (Figure 1). Web telemonitoring in IBD is safe and reduces the duration of disease flares[22]. Moreover,

Figure 1 Telemonitoring in relation to other domains associated with the use of information and communication technologies in the health context.

patients´ empowerment has been related to a reduction in outpatient visits and hospitalizations[23-26], which represent potential cost savings[22,24,27].

The development of more sophisticated telemonitoring programs and point of care (PoC) testing during recent years provided additional value to remote follow-up in the IBD context, improving the ability to cover different patients' profiles more objectively. These advances gained special interest after the advent of coronavirus disease 2019 (COVID-19) outbreak, as distance management offered new elements to overcome healthcare challenges posed during the pandemic[28]. However, telemedicine was represented mainly by telephone and e-mail, previously available in many centres[29,30], but the development of mature telemedicine programs integrated with electronic health records were still the exception, due to a series of remaining barriers.

In this review we focus on the advances performed in telemonitoring of patients with IBD, taking into consideration the elements which enabled its use and how technological achievements led to other barriers for its full implementation. The search strategy is detailed in the Supplementary material.

TELEMEDICINE IN CHRONIC DISEASES

There is a wide heterogeneity of telemedicine programs considering the different types of technological resources used, the different diseases and populations in which they are applied, and the objectives pursued with their use. The variability in the quality and design of the published studies (randomized clinical trials, before-and-after studies, qualitative studies, *etc*.) can partially explain the variable results obtained. Furthermore, in some studies these systems are part of wider interventions, rendering the comparability between programs even more difficult. These factors limit the quality of evidence regarding the efficacy of telemedicine to improve outcomes in chronic diseases.

Despite this, ICTs have been used in a wide range of pathologies, with improvement of patients´ empowerment and with good acceptance[31]. With the aim of giving response to the rise in chronic diseases and multimorbidity worldwide, different projects in Europe have studied the use of telehealth, mainly in diabetes mellitus, cardiovascular diseases, depression, and chronic obstructive pulmonary disease (COPD).

There is moderate evidence about the efficacy of telehealth systems in the improvement of glycaemic control, mainly in terms of HbA1c in patients with type 2 diabetes mellitus. Active telemonitoring including providers´ feedback, as well as tele-education have shown positive results compared with usual practice[14]. In fact, the highest impact was seen in the combination of telemonitoring and tele-education for both patients and providers, allowing for shared decision-making[15].

In patients with heart failure, telemonitoring has been shown to reduce global mortality and hospitalizations compared to usual care[12]. Many telemonitoring systems were part of multidisciplinary programs managed by specialized nurses and incorporated tele-education and action plans before hospital discharge[13]. Interactive monitoring with healthcare providers has also shown to improve blood pressure in hypertensive patients, weight control and lipidic profile[32]. Video consultation and biosensors are especially useful in cardiovascular diseases, with reduced costs compared with other

pathologies[33].

Most digital resources used in the mental health context refer to the application of cognitive behavioural therapy (CBT) in patients with depression. Both traditional and e-Health CBT are effective [34], but its use with telemedicine programs could offer additional advantages, such as better accessibility. However, many studies with psychotherapies show a high rate of nonadherence to follow-up [35]. Similarly, in patients with IBD one clinical trial showed a significant improvement in QoL after 12 wk of self-administered computerized CBT, but this outcome was not maintained at 6 mo, with a high rate of dropouts[36].

In patients with asthma, the use of multiplatform programs combining tele-education, telemonitoring and individualized action plans reduced hospitalizations compared with traditional care, mainly in more severe patients[18]. In patients with COPD, the use of telemedicine also reduces hospitalizations, but without an improvement of global mortality[16]. With the development of mHealth, the use of SMS combined with telephone support is associated with an improvement in respiratory function and QoL in patients with asthma[32], but telemonitoring in COPD has not demonstrated any improvement in these outcomes[17,37]. Telemonitoring of patients with COPD is more expensive due to associated multimorbidity[33].

The use of telemedicine in digestive diseases is more limited, and most studies focused on IBD and irritable bowel syndrome. Unlike other chronic diseases such as diabetes mellitus, IBD implies the consideration of many clinical, biological, endoscopic, and even histologic variables to reach disease control. However, early detection of complications usually requires invasive tests in IBD. The absence of validated tools with adequate cost and accuracy to measure disease activity at a distance have represented an important limitation.

Most studies about telemedicine in IBD have emerged in the last decade. The development of mHealth, the validation of patient reported outcome measures (PROMs), PoC and home-based tests to measure fecal calprotectin (FC) near the patient improved the ability to evaluate more types of patients with IBD at a distance, even in more complex cases.

PROGRAMS FOR TELEMONITORING IBD

The increase in the capacity of data transmission and storage, as well as the evolution of wireless communications provided many resources that are easy to use and adaptable to IBD telemonitoring.

Initially, telemonitoring systems for IBD allowed communication between health centres and patient´s home using computers. Afterwards, the development of web-based systems permitted easy-to-use and cheaper telemonitoring programs. In the last years, mobile devices (Smartphone, Tablet, *etc.*) made it possible to establish the communication process with the patient during his/her daily activities. Furthermore, in other settings (such as cardiovascular diseases) the transmission of continuous physiological data through biotelemetry has evolved with the incorporation of wearables.

In the IBD setting, telemonitoring is a safe, acceptable, and effective option to improve clinical outcomes[38,39], but the results of studies are still variable. In this context, telemonitoring has mainly used programs requiring home installation or web-systems, although e-mail and telephone have supported some of these programs. The main telemonitoring platforms used in IBD are summarized in Table 1.

Home telemanagement systems

The Cross group was the first to apply ICTs in adult patients with IBD, mainly with UC. This research team developed a remote-control system (home automated telemanagement system: HAT system) made up of 3 stations, adapted from a program previously used in self-management of patients with asthma [40]. The Home Unit was made up of a portable computer that collected patients' information (symptoms, adverse effects, medication, *etc.*), and these data were then sent to a decision-support server connected to a provider's PC[21]. The computer created alerts if the values collected in a web portal surpassed pre-established thresholds. Moreover, the HAT system incorporated educative elements.

Different exploratory studies showed good acceptance with the use of this system. In 2 studies with 10 and 23 patients with IBD, all of them considered that the HAT system was simple and increased patients´ knowledge[21,41]. To confirm the acceptability and adherence to follow-up with this program, the authors performed a subsequent study with 25 patients followed-up over 6 mo. Adherence to the weekly questionnaire was 91% and 86% had a prescribed medication adherence over 80%. This good adherence corresponded to a trend towards improvement in disease activity and QoL levels, together with a statistically significant improvement in understanding the disease (P = 0.0015). These good results led to the hypothesis that the HAT system could be feasible for telemonitoring patients with IBD.

Subsequently, the same group designed a randomized clinical trial including 47 patients with mild to moderate UC. Twenty-five patients were controlled with the HAT system and 22 followed usual in-person visits together with educational support and individualized action plans to make groups more comparable[42]. The groups had similar baseline characteristics, except for the use of immunosuppressants in 56% of the study group and 27% of the control group (P = 0.05), which would indicate a

Table 1 Studies of Telemonitoring in inflammatory bowel disease

Ref.	Disease	Type of study	*n*	Application	Outcomes
Cross *et al*[21]	IBD	Noncontrolled, clinical trial	10	Telemonitoring, home unit-server PC provider	Feasible method Excellent patient acceptance

Bonnaud *et al* [51]	IBD	Controlled randomized clinical trial	54	Telemonitoring through the web (mHealth)	Significant improvement in QoL A trend to reduce outpatient visits Satisfaction
McCombie *et al*[50]	IBD	Controlled randomized clinical trial	100	Telemonitoring through the web (mHealth) and home-based FC	Non-inferiority of QoL and symptoms Reduced outpatient visits

IBD: Inflammatory bowel disease; UC: Ulcerative colitis; CD: Crohn's disease; QoL: Quality of life

higher level of disease activity in the experimental group. There were no statistically significant differences for improvement of disease activity, treatment adherence, and quality-of-life values between both groups at 12 mo. These results could be related to the small sample size as well as a higher dropout rate in the intervention group, possibly due to the platform design, which required installation and eventual repairs at home.

To avoid these problems, Cross and cols developed web telemonitoring using mobile devices[25].

Web-based systems

In the last decade, telemonitoring systems have progressively evolved with web programs and mHealth solutions. Web applications are less expensive, safe, and feasible in the management of IBD not only in adults but also in adolescents[43-45], and they are associated with a reduction in outpatient visits and hospitalizations[22,24,27,43,45].

A Danish group developed telemonitoring through the web under the concept of "Constant-care". The system was developed through the web http://www.constant-care.dk, which also incorporated an educational centre. These investigators designed a randomized controlled trial with 333 UC patients treated with 5-aminosalicylates (5-ASA) from different hospitals in Denmark and Ireland[22]. The intervention group introduced clinical data and analytic results in the web to guide changes in the follow-up schedule and treatment. This intervention was compared to usual care.

After 12 mo of follow-up, in both the Danish and Irish population 88% of patients showed good acceptance with the web telemonitoring. There was a statistically significant improvement in adherence to treatment after 4 wk and a lower duration of disease flares. This was related to the use of high doses of 5-ASA in 100% of patients from the intervention group in Denmark, who also had improved QoL and disease knowledge. However, these outcomes were not reproduced in the Irish population. Moreover, in the Danish population telemonitoring reduced outpatient and emergency department visits, which led to direct cost-savings of 189 euros per patient-year, but also to an increase of e-mails and telephone contacts.

The use of this web-system in paediatric patients also reduced outpatient visits and school absenteeism, without differences in disease activity, QoL and adherence to treatment compared to the control group[43]. In another study developed in the University of California with a telemonitoring program combined with tele-education, patients followed remotely used less corticosteroids and suffered less hospitalizations and emergency department visits, with cost reductions of 16%[23]. In short, these studies show that web-telemonitoring is feasible, safe and could reduce health costs, although there are reproducibility differences depending on the population in which telemonitoring is applied[19].

Moreover, web-systems have been used to individualize the treatment according to the disease course. In a prospective study with 95 patients with mild to moderate UC, web control allowed the adjustment of 5-ASA doses and improved adherence. This was related with a significant improvement in clinical activity and FC values after 3 mo of follow-up[11]. Telemonitoring has even been used to individualize the treatment schedule with infliximab. After 1 year of follow-up, there were no significant changes in disease activity and QoL, although there was an estimated cost-saving of 699 euros/patient, compared with a historic control group[10].

In the same line and to avoid problems generated with the HAT system in the pioneering studies, the Cross group developed a web system for the management of patients with IBD (TELE-IBD) through text messages. In a randomized clinical trial with 3 parallel groups (TELE-IBD weekly, TELE-IBD every other week and control group) in 3 reference centres for IBD, they included 348 patients who had at least one disease flare in the last 2 years. Seventy-five percent completed the study, with an improvement in disease activity and QoL in the 3 groups, but without a higher improvement in these outcomes, depressive symptoms, or self-efficacy in the web control group, although in another study self-efficacy improved when tailored counselling was associated[46]. Moreover, telemonitoring was associated with a change in the profile of health expenses. Less hospitalizations were seen in the telemonitoring group but with higher use of non-invasive tests and telephone or e-mail[25,47,48].

The largest clinical trial with a telemonitoring program to date was performed with the Dutch web myIBDcoach (http://www.mijnibdcoach.nl). This web allows distance monitoring of disease activity, treatment adherence and side effects, as well as nutritional status, smoking habits, QoL, fatigue, stress,

anxiety and depression. As other platforms, it provides educational elements to improve empowerment. Patients showed good acceptance with its use in a pilot study[49]. In a clinical trial including 909 patients with different disease characteristics, the use of this system reduced outpatient visits and hospitalizations compared to standard care after 12 mo of follow-up[24]. Similarly, a reduction in outpatient visits was also obtained in adolescents[43,45] and in adults who used home-based tests to measure FC[50]. In a pilot study performed in France with the EasyMICI-MaMICI® platform, a reduction in outpatient visits was also associated with a significant improvement in QoL and satisfaction[51].

Our study group evaluated the impact on health outcomes of the telemonitoring web platform TECCU (Telemonitorización de la Enfermedad de Crohn y Colitis Ulcerosa or Telemonitoring of Crohn's Disease and Ulcerative Colitis), as compared to standard care and telephone care. In a 3-arm randomized clinical trial, 63 patients (21 per arm) with complex IBD were managed with each follow-up method over 24 wk. At the end of the study, the percentage of patients in remission was higher in the TECCU group (17/21, 81%) compared to nurse assisted telephone care (14/21, 66.7%) and standard care (15/21, 71.4%). The telemonitoring group had more improvement in disease activity, and this was associated with a larger reduction in FC values. All completers adhered to treatment in the TECCU group, while QoL, social activities, and satisfaction improved in all 3 groups[52].

Telephone and e-mail support in web-systems

Telephone and e-mail are resources attended by both medical doctors and specialized nurses in some IBD units, with high capacity to solve problems at less cost[53-55]. These tools have also been used to coordinate action plans in telemonitoring systems.

In Spain, the Crohn´s and Colitis Care Unit model has been used since 1999 as a multidisciplinary model of continuous care for patients with IBD. This model manages health demands with distance management mainly through telephone or e-mail with the support of a web page, which includes educational elements. The number of users has risen over the years, with a reduction of in-person care [56]. In Illinois, the Sonar Project is based on monthly web monitoring of symptoms in patients with IBD. Nurses exert a central role and use telephone contact for those patients who send results out of normal ranges, and together with medical health providers management adjustments are performed. This system also reduced hospitalizations, emergency visits and costs[57].

Therefore, beyond the use of telephone and e-mail in units which work as centres for resource coordination, telemedicine in IBD is expanding through the use of web and mHealth systems. These include telemonitoring, tele-education and videocalls in some cases. Its application allows the development of projects to provide health resources in remote areas[58,59], mainly with the use of mobile apps and the integration of some of these platforms into the electronic medical records, as is the case of the app HealthPROMISE and mynexuzhealth[60,61]. These models promote collaboration and mentoring between specialists, which could reduce variability in medical practice and modify the structure of future health systems if they demonstrate to be cost-effective.

Cost-effectiveness of telemonitoring IBD

Although many data about cost-savings have been published, they refer almost exclusively to direct costs[22,27], without considering costs of installation and maintenance of platforms or indirect costs.

In the IBD setting, our research group published the first cost-effectiveness and cost-utility analysis of a telemonitoring program compared to telephone and standard care[62,63]. The differences between groups and statistical uncertainty in disease activity, quality-adjusted life-years, and costs were calculated using nonparametric bootstrap estimations. Even though our trial only included 63 patients, we imputed the original dataset 5 times, and the bootstrapping estimations allowed us to extract 1000 random samples (of 21 patients per arm) from each of the 5 imputations, thus generating 5000 bootstrap replications.

We concluded that there is a high probability (79.96%) that the use of the TECCU web platform for telemonitoring complex IBD patients produces a greater improvement in disease activity at a lower societal cost, compared with standard care. Telemonitoring through the TECCU platform saved €2250 per additional patient in remission (95%CI: €–15363 to 11086) *vs* telephone care, and telephone care saved €538 compared with standard care (95%CI: €–6475 to 5303). Moreover, the use of the TECCU platform and telephone care showed an 84% and 67% probability, respectively, of producing a cost saving per additional quality-adjusted life-year (QALY) compared with usual care, even considering the simulations that involved negative incremental QALYs.

With a similar methodology, our results were reproduced by de Jong *et al*[64] who concluded that telemedicine with myIBDcoach is cost-saving and has a high probability of being cost-effective, without a decline in QoL. In this study, telemedicine resulted in lower mean annual costs of €547/patient (95%CI: €1029-2143) without changing quality adjusted life years. At the Dutch threshold of €80000 per quality adjusted life year, the intervention had an increased incremental cost-effectiveness over standard care in 83% of replications.

The authors included all subtypes of IBD, whereas our study with the TECCU platform recruited complex patients with IBD who needed to start immunosuppressants and/or biologic agents. According to our conclusions, the big sample size recruited in this article is useful to confirm our prior results, and

the reproducibility of the favourable cost-effectiveness profile of telemedicine applied in IBD across countries and patients' characteristics. In fact, during the COVID-19 pandemic, similar cost-savings with a higher gain of QALYs have been observed with the use of telemonitoring for IBD in Hong Kong[65].

ENABLERS AND BARRIERS FOR THE IMPLEMENTATION OF TELEMONITORING IN IBD

Unlike the use of ICTs in other fields (streaming entertainment services, grocery delivery, e-banking, *etc.*), telemonitoring interventions deal with a series of barriers which hinder their definitive implementation to reorganize health systems, despite other associated advantages (Table 2)[66-71]. The factors which favoured and limited these changes can be classified in 5 groups: technological, organizational, legal, acceptability and costs[72].

MODELS OF TELEMONITORING IN IBD

Telemonitoring theoretically include three different diagnostic models: patient self-diagnosis, remote providers´ diagnosis and computer-assisted diagnosis. They usually work as triage systems but, beyond diagnostic capabilities, telemonitoring platforms allow for remote management of other aspects such as disease treatment or education. In the IBD setting, they usually combine self-management, remote providers´ management and computer-assisted telemanagement[10,11,21,22,24,25,42,43,45,47,48,50-52].

Patient self-management

Self-management refers to a dynamic, interactive, and daily process in which individuals engage to manage a chronic illness[73]. This process includes the ability to deal with their own symptoms, treatment, physical and social consequences, and lifestyle changes to maintain a satisfactory QoL[74]. In this sense, telemonitoring platforms for IBD have incorporated PROMS and home-based tests that allowed patients to self-report their health status. This information has been even used to guide treatment adjustments by themselves[22].

Resources for patients´ self-management: PROMs, home-based tests and wearable devices

Considering the "treat-to-target" strategy, the Selecting Therapeutic Targets in Inflammatory Bowel Disease (STRIDE) project recognized different evidence and consensus-based recommendations to optimize outcomes in patients with IBD. Among the different targets proposed, clinical remission and endoscopic healing were confirmed in the STRIDE-II actualization, while normalization of serum and fecal markers of inflammation have been determined as short-term targets[4]. There was agreement to evaluate disease remission with clinical indexes, PROMs and endoscopic criteria [or also radiologic criteria in Crohn's disease (CD)].

Usually, endoscopic disease activity has been considered the gold standard to measure inflammation and to consider mucosal healing, but endoscopy is invasive and expensive.

In this sense, with the aim of measuring inflammation non-invasively, different PROMs and PoC tests have been developed over last years. Moreover, some of these tools have been specifically validated for their use in telemedicine programs.

PROMs: A PROM is a measurement of any aspect of a patient's health status that comes directly from the patient, without the interpretation of the patient's responses by healthcare providers and without the need of laboratory tests[75]. PROMs are designed for screening of disease activity, and then they need to be sensitive enough, especially if it implies more false positive results.

The Simple Clinical Colitis Activity Index (SCCAI) has shown a high correlation and good agreement between patient and clinician reported versions[76]. Compared to UC, PROMs used in the context of CD have shown worse correlation with other markers of clinical or endoscopic activity. The Harvey-Bradshaw index (HBI) had high correlation but only moderate agreement between versions registered by the patient or the clinician[77], although a recent version of the HBI self-administered by the patient through a mobile app showed a high percentage of agreement with in-clinic physician assessment, with a remarkably high PPV for remission[78]. Both SCCAI and HBI show good agreement between paper and online versions[78-80], and represent attractive tools for telemonitoring IBD.

Few PROMs have had their correlation with endoscopic activity evaluated. The global assessment of the patient, based on an analogic visual scale about how they felt regarding their UC during the previous 2 d, only showed moderate correlation with endoscopic activity[81]. The subscore of the global medical assessment and the 6-point Mayo index (which includes stool frequency and rectal bleeding) have a high correlation with the whole Mayo index[82]. Moreover, the 6-point Mayo index has an AUC of 0.80 compared to the endoscopic subscore[83].

Recently, the mobile Health Index was validated to monitor IBD activity through mHealth systems. In patients with CD, it showed high correlation and agreement with the Crohn´s Disease Activity Index and the HBI, as well as in patients with UC when it was compared to the partial Mayo index[84]. The

Table 2 Enablers and barriers for the implementation of telemonitoring in inflammatory bowel disease

	Enablers	Barriers
Technological	Adequate support	Lack of EMR integration
	Sufficient training	System maintenance required to avoid malfunction
	Fast internet connections	
	5G network	
Organizational	Continuous monitoring	Multidimensional nature: complex comparability between programmes
	Overcome geographic barriers	
	Safe assistance during COVID-19 pandemic	Lack of robust data: small studies, short-term follow up periods
	Structured data collection	
	Favours experimental studies and epidemiological surveillance	Lack of standardized remote medical practice (Interstate Mecial Licensure compact in the United States)[66]
	Multicentric access to data	Reimbursement limitations
	Telementoring: professional support and education	
Legal		Lack of legal framework[67,68]
		Data security
Acceptability/accessibility	Patient empowerment	Technological knowledge[69-71]; Some demographic factors increase the likelihood of a telematic encounter failure
	Wide use of smartphones	High drop-out rate in some clinical trials
	Wide use of wearable devices	
	Cheap internet plans	
Costs	Potential decrease of direct and indirect costs	High initial investment
		Limited cost-effectiveness data

intraclass correlation coefficient for test-retest reliability was high for CD and for UC. Nevertheless, its agreement with endoscopic scores was poor in CD and moderate in UC.

QoL and absence of disability are other targets of the STRIDE-II initiative. The Inflammatory Bowel Disease Questionnaire (IBDQ) was specifically validated in patients with IBD and has a moderate to high correlation with treatment response and the endoscopic Mayo index. However, their 32 and 36 items versions require a lot of time for their interpretation, so the reduced versions of 9 and 10 questions were subsequently validated[85,86]. On the other hand, the IBD disability index predicts active disease, nonadherence, and treatment with corticosteroids when high disability values are obtained[87]. Finally, health-related fatigue was incorporated in the Monitor IBD At Home index, but it is still not considered a specific target.

Probably the accuracy of PROMs increases when used in combination with FC. Thus, the Monitor IBD At Home index was developed to predict the endoscopic activity in patients with IBD. The association of FC to both the CD and UC versions showed high sensibility and NPV to rule out endoscopic activity[88]. The development of home-based FC tests that can be measured by the patient represent a potential option to measure disease activity in telemonitoring programs.

PoC tests and home-based tests: The use of PoC tests refers to patient specimens assayed at or near the patient with the assumption that test results will be available instantly or in a very short timeframe to assist caregivers with immediate diagnosis and/or clinical intervention[89]. In the IBD setting, the interest has centered on FC, and even though lactoferrin tests have been developed with adequate accuracy[90], FC offers better sensibility at certain cutoffs[90,91].

FC has good correlation with endoscopic activity in both UC[92,93] and CD[94-96]. FC helps to differentiate between functional and inflammatory diseases in patients with digestive symptoms. Moreover, in patients already diagnosed of IBD it allows the evaluation of disease activity, response to treatment, post-surgical recurrence and it predicts relapses after the withdrawal of anti-TNF agents[97,98]. These features, its non-invasiveness and a relative low cost makes FC tests in a useful tool in the diagnosis, monitoring and treatment adjustment in IBD.

Furthermore, the diagnostic accuracy of FC in different clinical scenarios has increased the interest in its use in telemonitoring IBD programs. In line with a patient-centered care and to favour empowerment, during the last years and the COVID-19 pandemic, different home-based FC tests have

been developed as an additional tool for a home-based follow-up[99]. These tests are based on kits that analysed faecal samples through immunochromatography. Then, the results are read with a smartphone camera, and they are sent through a specific app to a server accessible by providers (Figure 2).

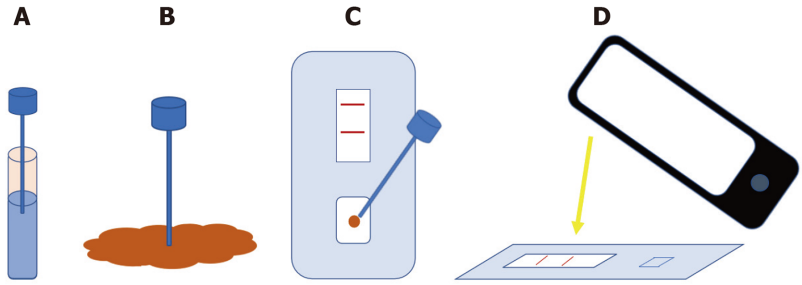
Comparison between different home-based FC tests: Three main FC tests have been developed for its use by patients at home: CalproSmart, IBDoc and QuantonCal.

In a recent study, these 3 tests were compared with the ELISA method of the same manufacturer [100]. Considering the importance of obtaining good agreement in the low range of FC values (ruling-out disease activity), IBDoc, QuantonCal and CalproSmart have an 87%, 82% and 76% agreement, respectively, compared with their corresponding ELISA readings.

However, and similarly to its validation study[101], CalproSmart showed a trend to overestimate FC values with a mean bias of +141 μg/g (95%CI: -316 to 598 μg/g), while IBDoc tended to underestimate FC values with a mean bias of -105 μg/g (95%CI: -576 to 366 μg/g). This could generate more false positive results when using CalproSmart, but misclassification in the low (< 250 μg/g), medium (250-500 μg/g) or high (> 500 μg/g) range of FC values with this test showed large differences (*i.e.*, to classify as > 500 with CalproSmart and < 250 with ELISA, and viceversa) in only 2% of measures, compared to 5% in IBDoc and 8% in QuantonCal.

In any case, the error range between FC measured with home-based tests and their corresponding ELISA method was high. This happens especially when FC values are > 500 μg/g. With values ≤ 500 μg/g, differences were also over the acceptable range of 200 μg/g (+/-100 μg/g), but they were not wide enough to induce errors in the interpretation of inflammatory activity. Therefore, home-based tests are considered useful to rule-out inflammation at a distance when FC values are < 500 μg/g, but when values are > 500 μg/g disease activity should be evaluated with other methods.

Home-drug monitoring: Home therapeutic drug monitoring of monoclonal antibodies appears to be an innovative possibility to improve and simplify IBD management. To date, these tests are performed only in some hospital laboratories and results are not immediate. This delay, of months in some cases, impairs drug monitoring and dose adjustment, compromising its utility.



To solve this issue, home drug monitoring using dried blood samples is being evaluated in different inflammatory diseases. The first data were published by Kneepkens *et al*[102] in patients with rheumatic inflammatory diseases. Adalimumab and anti-adalimumab antibodies concentration measurements in finger prick dried blood spots were compared with simultaneous serum measurements. They found that both drug levels and antibody concentrations from the finger prick method correlated well with serum measurements (correlation coefficient > 0.87). However, some disadvantages should be considered, such as loss in precision, workload and elevated costs.

Berends and colleagues did a similar study with 40 IBD patients, comparing infliximab concentrations in dried blood samples and serum. Home-based test infliximab concentrations showed a good correlation (correlation coefficient: 0.671) with serum measurements[103]. This author also published data with adalimumab treatment one year later. A high correlation was found (Pearson's correlation: ≥ 0.96) between dried blood test and venipuncture results when performed at the same time during the outpatient clinic. Moderate correlation (Pearson coefficient = 0.51) was reported between home self-performed finger test and estimated adalimumab concentrations[104]. Larger studies are needed to confirm the reliability, accuracy, and cost effectiveness of home-based testing as a new telemonitoring tool in IBD.

Wearable devices: Wearable devices are electronic gadgets that consumers wear to track health-relevant physiological data to monitor and improve health[105]. IBD patient preferences and interest in wearable technology were evaluated by Hirten and colleagues using a 28-question survey. Four hundred patients completed the survey. Of these, 42.7% reported prior or current use of wearable devices, mainly smart watches (34.5%) and wrist band devices (29.1%). Almost 90% of subjects believed these gadgets could provide important information about their health and 93.8% reported that they would use them if it could help doctors manage their disease[106].

In the last few years, several studies have tried to demonstrate the utility of wearable devices in IBD telemonitoring[107]. The first available data was published by Yvellez *et al*[108] in 2018. They prospectively assessed daily health-related QoL, pain and sleep data using validated indexes through a mobile application and a Fitbit® device. Fitbit® compliance was almost 80%, suggesting this technology is feasible[108]. The Fitbit® device has also been used to predict disease activity. In one study a significant reduction in daily steps has been shown over the week before CRP or FC elevation, but without differences in daily resting heart rate[109]. Two years later, however, Hirten *et al*[110] demonstrated that significant changes in heart rate variability measured using VitalPatch® were observed before the development of symptomatic or inflammatory flare in ulcerative colitis patients.

Step count and sleep monitoring have also been used, not to predict flares but the intent to determine post-operative length of stay. Overall, step count and sleep duration/efficiency did not predict length of stay. However, in a multivariable linear regression model, significant interaction was found between postoperative complications and step count, suggesting that increased physical activity was associated with a reduction in duration of hospital stay[111].

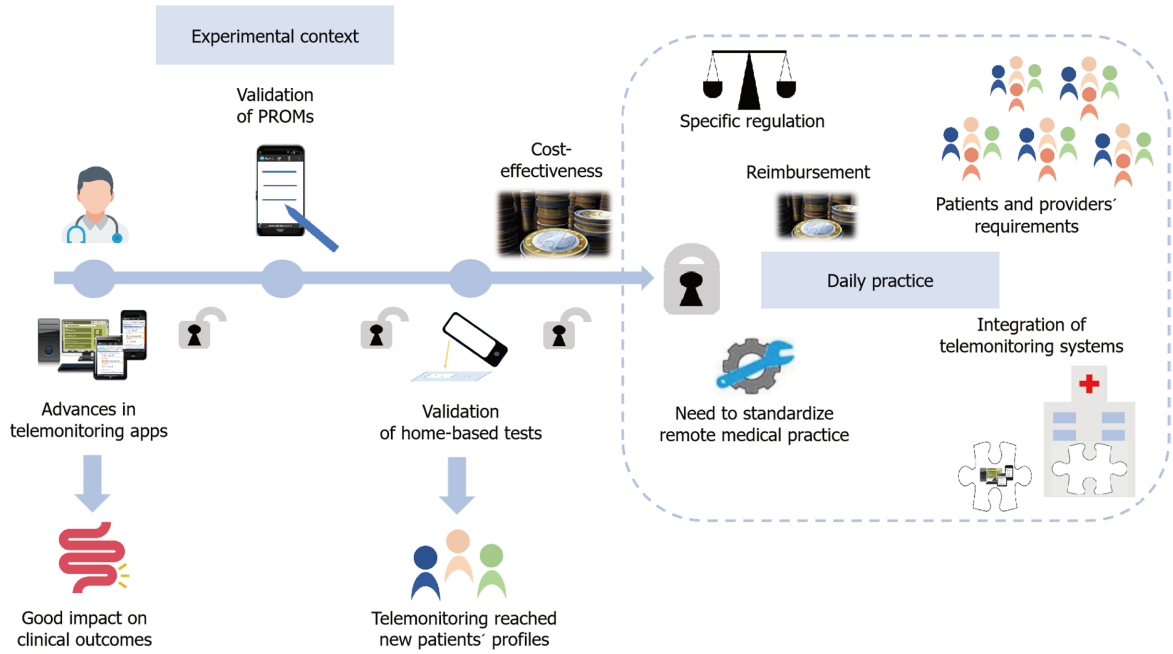
Remote providers´ management

All the telemonitoring interventions in IBD reported in this review comprise healthcare providers´ advice. Most systems employ store and forward programs, where nurses acquire a central role in tracking the information received and making contact between patients and specialists to set up healthcare plans. Communication is established through websites, usually with the support of telephone and e-mail, as reported above.

Computer-assisted telemanagement

Computerized systems have been used for telemonitoring IBD and they usually work as a triage system to identify which patients might require further evaluation. Many of them can generate automatic action plans through the integration of different monitorable indicators in decision-making algorithms. In most telemonitoring programs tested thus far, these tools are combined with self-management and the remote providers´ management models seen above.

Telemonitoring systems in IBD are integrated by personal computers or mobile devices used by patients, a decision support server and a website for staff and providers. The website provides an interface to collect data from testing sessions, and these platforms usually generate automated reminders to favour adherence to follow-up. The structure of most eHealth tools in IBD are based on a traffic light system[10,11,22,25,27,43,45,52,112]. Patients usually enter their symptoms in scheduled online controls, mainly in a structured manner through PROMS, but many apps also include a comment box to freely express anything outside the questionnaires. Then, the patient´s status appears as red, yellow or green when disease is highly, moderately active, or quiescent, respectively.



Some systems combine self-reported symptoms with the level of FC in a total inflammation burden score. In fact, recent clinical trials have incorporated FC tests performed by patients at home[45,50,112]. This status is sometimes supplemented with disease activity and QoL graphs[10,11,22]. Depending on the level of alert, simultaneous action plans and email alerts are sent to the participant and providers, who review the information to decide if further management changes are necessary.

Altogether, these new models and resources for patients´ self-management represent advances to reach the implementation of telemonitoring in daily practice, but still some legal, ethical, economical and logistic barriers need to be solved (Figure 3).

DISCUSSION

Telemonitoring is about communication, and the development of faster and wireless systems at a lower cost has supported the use of proactive remote monitoring. As well, the increase in data storage also favoured the incorporation of tele-education in most telemonitoring programs in the IBD setting. However, during the pandemic, e-mail and telephone still represented the main resources used[29,30], while the application of mature telemonitoring programs was the exception. As different enablers encouraged advances of telemonitoring in IBD, many other barriers emerged and hindered its full implementation in daily practice.

Pioneering studies evaluated telemonitoring programs previously used in other chronic diseases[21,42,113,114]. Feasibility and patients´ acceptance of these applications was excellent. Yet, they were not able to clearly demonstrate an improvement in QoL, disease activity, and treatment adherence. These systems were based on remote monitoring through computers, they needed to be adapted to the IBD context and required eventual repairs at home, which were time expensive. Telemonitoring subsequently evolved towards the use of web-based systems, which were cheaper and easy to use. Remote monitoring through the web demonstrated its feasibility and excellent patients' acceptance, with an improvement in QoL, disease activity, and disease knowledge[22,115].

Figure 3 Advances in telemonitoring of inflammatory bowel disease related to the enablers and barriers for its implementation in daily practice. PROMs: Patient reported outcome measures.

In the last few years, telemonitoring prioritized the use of mHealth resources[24,25,116]. Beyond the improvement in clinical outcomes, mHealth telemonitoring associated cost-savings in outpatient visits and hospitalizations[23-26]. Almost parallel to the mHealth evolution, many PROMs have been validated to self-report disease activity. In line with patient-centered care, empowered patients can use new home-based calprotectin tests, which are accurate enough and useful to rule-out disease activity at low FC values[100,101]. In fact, new home drug monitoring is being developed to measure levels of monoclonal antibodies near the patient[103,104]. Furthermore, the development of mobile devices even enabled the increasing use of wearables to monitor physiological predictors of disease activity and postoperative length of stay[110,111]. These new tools could represent one of the first steps towards ubiquitous Health in IBD, and in a near future machine learning may allow the integration of large data sets in personalized algorithms.

Despite the technological and knowledge advances reached, the effect of telemonitoring on health outcomes is not consistent in different populations and health systems[22,24,25,42,44,45,52]. Initially, remote monitoring was mostly restricted to UC patients, while the design of new apps, PROMs and home-based tests allowed to progressively expand its use to a broad range of patients´ profiles. However, telemonitoring has not been demonstrated to improve QoL or clinical/endoscopic remission in the long-term. In addition, biomarkers in IBD are less accurate compared to other chronic diseases such as diabetes mellitus, and the early recognition of complications in IBD still require invasive tests in many cases.

On the other hand, although telemedicine has been traditionally considered cost-effective, cost-saving data previously published referred almost exclusively to direct costs[22,27]. The implementation of telemonitoring services represents a short-term high initial cost, not only from a technological point of view, but also by changes in the organization of the IBD units. Thus, decision-makers have had difficulties to support the implementation and investment in telemedicine due to a lack of solid evidence so far. In addition, these decisions become even more complicated in areas where reimbursement is an important factor in the setup of clinical activity. In this regard, recent studies suggested a good cost-effectiveness profile of telemonitoring[62-65], even after considering the costs of installation and maintenance of platforms, as well as indirect costs.

The availability of more powerful and cheaper communication tools turned technical challenges into legal, ethical, economical, and logistic issues[28]. To standardize remote medical practice, in the US the Interstate Medical Licensure Compact was created to increase efficiency in multistate licensing of physicians[66] but such a proposal is lacking in Europe. Besides, only a few examples of full integration of telemonitoring programs into electronic medical records are available to date[60,61]. In this sense, interoperability of systems while maintaining the confidentiality of data cannot be guaranteed in many centres. Moreover, the provision of remote health safely also requires a specific European regulation to protect remote medical practice and to lift some existing legal barriers. Finally, to keep adherence to follow-up, it is essential to adapt telemedicine programs according to patients' and providers´ character-

istics, because some demographic factors such as increasing age, commercial insurance status and racial differences increase the likelihood of a telematic encounter failure in some contexts[117].

CONCLUSION

Therefore, telemonitoring IBD is well accepted and improves clinical outcomes at a lower cost in the short-term. The advances performed on new PROMS, home-based tests and wearables improved the ability to manage new patients´ profiles remotely. However, it is still necessary to overcome many legal, ethical, economical and logistic barriers. Funders, policymakers, providers and patients need to align their interests to successfully implement telemonitoring, and further collaborative efforts based on teamwork between centres are essential to help reorganize health systems.

Abstract

Mucosal healing (MH) is vital in maintaining homeostasis within the gut and protecting against injury and infections. Multiple factors and signaling pathways contribute in a dynamic and coordinated manner to maintain intestinal homeostasis and mucosal regeneration/repair. However, when intestinal homeostasis becomes chronically disturbed and an inflammatory immune response is constitutively active due to impairment of the intestinal epithelial barrier autoimmune disease results, particularly inflammatory bowel disease (IBD). Many proteins and signaling pathways become dysregulated or impaired during these pathological conditions, with the mechanisms of regulation just beginning to be understood. Consequently, there remains a relative lack of broadly effective therapeutics that can restore MH due to the complexity of both the disease and healing processes, so tissue damage in the gastrointestinal tract of patients, even those in clinical remission, persists. With increased understanding of the molecular mechanisms of IBD and MH, tissue damage from autoimmune disease may in the future be ameliorated by developing therapeutics that enhance the body's own healing response. In this review, we introduce the concept of mucosal healing and its relevance in IBD as well as discuss the mechanisms of IBD and potential strategies for altering these processes and inducing MH.

Key Words: Inflammation; Injury/repair; Mucosal healing; Mucosal barrier; Therapeutics; Colitis

Core Tip: Mucosal healing (MH) is vital in maintaining intestinal homeostasis and protecting against infection and injury. MH has emerged as an important clinical criterion in effective treatment of inflammatory bowel disease (IBD). However, there remains a relative lack of therapeutics that can restore MH due to the complexity of the disease and healing processes. Through increased understanding of the molecular mechanisms of MH, tissue damage from IBD may be ameliorated by developing novel therapeutics. Here, we introduce the concept of MH and its relevance in IBD, and discuss the mechanisms of IBD and potential strategies for altering these processes for inducing MH.

INTRODUCTION

Mucosal healing (MH) is a process of wound repair that restores the integrity of damaged epithelial barrier and homeostatic function after an injury compromises barrier integrity[1]. It is a complex process regulated by multiple cell types, through distinct mechanisms in response to highly specific stimuli within multiple signaling and cytokine pathways[1]. For simplification, the MH process is considered to have three phases: Epithelial restitution, proliferation, and differentiation and maturation[1]. Restitution consists of epithelial cells migrating into a wound within hours, followed by proliferation of epithelial cells in hours to days, and finally differentiation of intestinal stem cells into all mature intestinal cell types[1-3]. Each phase is induced and regulated by multiple cytokines, growth factors, and cell types reviewed in[1] and can be influenced by many factors that enhance or prevent wound healing as well as by the source of barrier injury. When the homeostatic process of wound healing is slowed or delayed by external or genetic factors, chronic inflammation may develop because repair of the intestinal epithelial barrier (IEB) and subsequent reduction of inflammation will not occur unless wound healing mechanisms are present[3]. Due to inflammation and chronic immune response, the consequences of impaired MH are chronicity of autoimmune diseases, including Inflammatory Bowel Disease, (IBD) and its progression to colorectal cancer.

INFLAMMATORY BOWEL DISEASE OVERVIEW AND PATHOGENESIS

Inflammatory Bowel Disease (IBD) is a term that represents autoimmune inflammatory diseases of the gut, with ulcerative colitis (UC) and Crohn's Disease (CD) being the major disease types; however, the etiology of IBD remains unclear. IBD is known to have genetic and environmental risk factors, but the mechanisms by which these factors induce IBD are not well-understood[4]. Common symptoms include abdominal pain, diarrhea, weight loss, malnutrition, and particularly in CD, nausea, vomiting, intestinal blockages, fistulae, and abscesses[4,5]. IBD is an increasingly common and often debilitating disease, affecting up to 200 individuals *per* 100000 people in the United States[4]. Onset of IBD often occurs before the age of 30, and patients experience poor quality of life along with high risk of developing colorectal cancer due to the chronic and progressive symptoms and persistent inflammatory state[1,4]. Though multiple treatment mechanisms exist, including corticosteroids, anti-inflammatory medications, monoclonal antibodies, stem cell treatments, and surgery, IBD cannot currently be cured[4]. Therefore, continued research into the mechanisms of pathogenesis and development of new pharmaceuticals and treatment methods is vital to decrease mortality and improve quality of life for IBD patients.

Autoimmune disease pathogenesis is difficult to study due to the multifactorial causes of disease and complex molecular mechanisms, as well as the predicament of patients not presenting to the clinic until late in the disease development process. Although the disease complexity and difficulty in identifying the initial molecular instigators has thus far precluded full understanding of the specific molecular mechanisms of IBD pathogenesis, the general overarching processes have been elucidated. During IBD pathogenesis, the IEB and mucosal layers become damaged and inflamed due to injury and/or infection, which can develop into a state of chronic inflammation and reduced IEB integrity. Genetic factors can also play a role in pathogenesis, particularly in CD through genes such as a variant that impairs autophagy and dysregulates the IEB and gut microbiota[6,7]. The damage to the IEB results in microbial and antigen exposure in the intestinal lumen, leading to an inflammatory cascade and disturbed homeostasis[8,9]. Multiple cytokines and immune cell types are also thought to contribute to the pathogenesis of or protection against IBD; therefore, further study of the complex interactions governing the maintenance or breakdown of gut barrier homeostasis is imperative to deeper

understanding of IBD pathogenesis and the development of effective treatments.

MUCOSAL HEALING AND PATHOLOGICAL RELEVANCE IN IBD

The main goals of IBD treatment are two-pronged: Reducing symptoms and preventing new inflammation and intestinal injury through traditional treatment methods, and recently a new, ambitious goal of inducing wound healing of existing inflammation and damage[8]. Some current treatments may contribute to both treatment goals; however, many existing clinical treatments are more targeted toward the traditional goal of preventing inflammation and damage. Even with the advent of some newer MH-focused treatments, additional avenues of further enhancing MH should be explored. Although clinical remission or preventing new inflammation is possible, patients may still have residual disease symptoms during remission due to the defective wound healing process leaving previous intestinal damage unrepaired. Additionally, up to half of IBD patients experience non-response or loss of response to standard therapeutics, leading to relapse[10]. Hence, MH induction presents an attractive goal in effective long-term treatment of IBD and prevention of relapse, and thus also prevention of progression to colitis-associated colon cancer. In this review, we will summarize the main current and prospective treatments of IBD, as described in Table 1, and their benefits and limitations towards the goal of reducing inflammation and achieving MH. More detailed analysis of the mechanisms of action, safety, and efficacy profiles of current IBD therapies and clinical trials can be found in Neurath *et al*[11]. However, in this review, we will emphasize areas that have not yet been as extensively clinically explored, including the temporal control of gut immune function, which presents novel potential for fine-tuning of the immune system in MH and restoration of gut homeostasis. We will examine three major factors contributing to the pathogenesis and tissue damage of IBD, as shown in Figure 1: Gut barrier dysfunction, gut dysbiosis, and inflammatory cytokine responses. Specifically, we will focus on the prospect of altering these factors and associated pathways summarized in Table 2 for both the reduction of inflammation and induction of MH.

CURRENT STATUS OF IBD THERAPIES AND FOCUS ON ENHANCED MUCOSAL HEALING

Traditional Therapies

Historically, there has been a disconnect between the expectation of IBD treatment promoting MH and real treatment outcomes, as many therapies for UC and CD primarily target symptom relief and reduction of chronic inflammation[12]. Corticosteroids, Methotrexate, and surgery are typically utilized to achieve these goals, but they do not promote MH as the primary therapeutic endpoint[13,14]. Because UC and CD are progressive diseases, patients may still experience intestinal damage even during periods without physical symptoms, and disease progression is typically only slowed by these treatments, not stopped[12,15]. However, achieving MH may help stop disease progression as well as decrease symptom severity. New treatment plans broaden the therapeutic focus to include inducing MH through a variety of mechanisms, such as by altering the gut microbiome and altering inflammatory and anti-inflammatory cytokines with antibodies or exogenous cytokine therapies.

Inflammation Reduction and Immune Modulation Therapies

One such mechanism for emphasizing MH includes suppressing specific parts of the patient's immune system to decrease the main contributors of chronic inflammation. When new inflammation is reduced, it may then be possible for the wound healing process to begin to keep up with the rate of tissue damage. Methods of achieving this goal include enteral nutrition (EN), partial EN (PEN), 5-aminosalicylates (5-ASA), and Azathioprine treatments, which focus on decreasing IBD-associated inflammation by suppressing the host immune system in a less global manner than corticosteroids or preventing the production of inflammatory molecules. EN is a dietary treatment for IBD patients that can either totally (with EN) or partially (with PEN) replace solid food intake with specialized formula[16]. Although the mechanism by which EN induces MH is currently unknown, microbiome changes are implicated and are hypothesized to aid in decreasing chronic inflammation[17]. While typically a pediatric treatment, a pilot study shows MH in adults following EN and PEN treatment as well[16]. Currently, the largest drawback of EN treatment is low patient compliance, especially in adults[16]. 5-ASA drugs, which are used to induce remission in early IBD, are shown to induce MH in 43.7% of patients[18]. Azathioprine is a purine analog inhibiting purine metabolism and blocking T cell activation and co-stimulation, therefore functioning by suppressing the immune system and decreasing inflammation in IBD[11,19-21]. It is shown to achieve MH independently in some cases (30.1%) alone but is more successful when used in conjunction with anti-TNF-α antibodies such as Infliximab (44%)[22]. Other immunomodulating drugs shown to induce MH when given with monoclonal antibodies include Cylosporine and Tacrolimus[23].

Table 1 Summary of inflammatory bowel disease therapeutics

Treatment type	Available therapeutics	Mucosal healing relevance/ Success
Corticosteroids	Prednisone/ Prednisolone/ Methylprednisone	Prednisone treatment for 14 d (20 mg/day) decreased mucosal inflammation indicating a possible role in developing short-term MH[139]. 29% of patients in one study displayed endoscopic remission after steroid treatment[140].
Nutritional therapy	Enteral nutrition (EN)/ Partial enternal nutrition (PEN)	EN/PEN induce MH in both adults and children[14].
Aminosalicylates (5-ASA)	Sulfasalazine/ Mesalamine/ Olsalazine/ Balsalazide	On average induce MH in 43.7% of patients[141].
Immunomodulators	Azathioprine/ 6-mercaptopurine	Azathioprine alone has achieved MH in 16.5% of cases and in 43.9% when used in combination with antibody therapies[18]. After 16 wk of mercaptopurine treatment, patients in remission showed a 47.1% rate of MH[142].
	Cyclosporine	Shown to induce MH when used in conjunction with Vendolizumab[143].
	Tacrolimus	Shown to induce MH when used in conjunction with Vendolizumab[143].
	Methotrexate	After 36 wk, methotrexate treatment had a MH rate of 47.4%[142].
Monoclonal antibody/ Biologic therapies	Adalimumab	Induced MH in 24% of patients treated[24].
	Certolizumab	Clinical response rate at weeks 2 and 12 was 29.7% and 52.8% (respectively) in CD[25].
	Infliximab	Treatment induced MH in up to 60.3% of patients in phase 2 clinical trials[23].
	Natalizumab	MH achieved by 42.3% of patients after 14.1 mo of treatment[144].
	Risankizumab-rzaa	Endoscopic response and deep remission observed in 55% and 29% of patients (respectively), indicating MH[27].
	Ustekinumab	Treatment of individuals with moderate to severe CD showed MH *via* a reduced disease score after 8 wk[19].
	Vedolizumab	Has shown to induce MH in up to 50% of UC patients and 29% of CD patients in clinical trials[26,27].

MH: Mucosal healing; EN: Enteral nutrition; PEN: Partial enteral nutrition; 5-ASA: Aminosalicylates; CD: Chron's Disease; UC: Ulcerative colitis.

Monoclonal Antibody Therapies

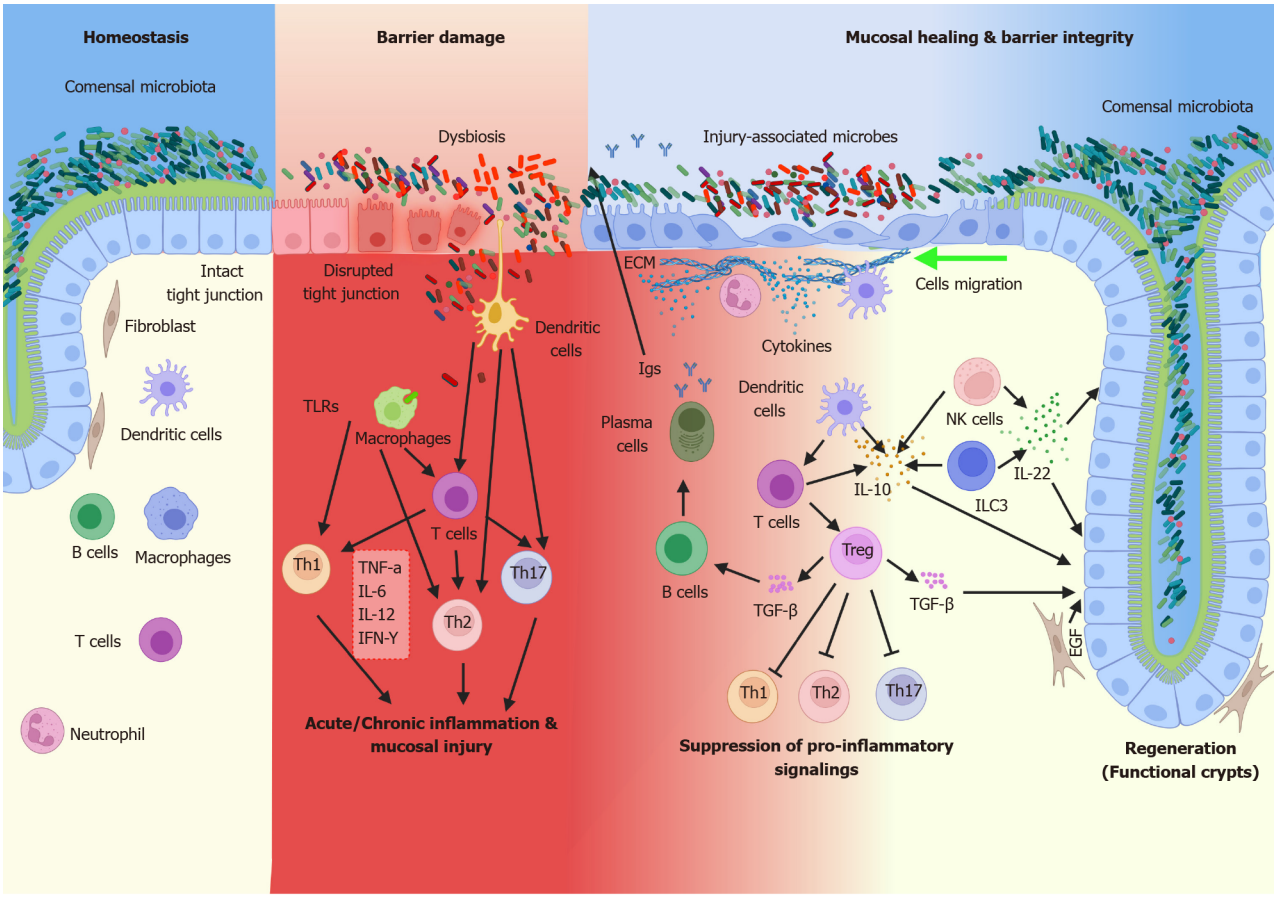
Monoclonal antibodies targeting inflammatory cytokines are an emerging class of IBD therapies that more directly focus on permitting or inducing MH and are an attractive method of IBD treatment. Monoclonal antibody drugs targeting multiple cytokines are approved or in trials, and function by removing inflammatory cytokines. Anti-tumor necrosis factor-alpha (TNF-α) antibody-based drugs such as Infliximab, Adalimumab, and Certolizumab are biologic therapies that have achieved significant clinical success and are now widely used as front-line treatments for IBD, with the goal of reducing inflammation and promoting MH. The target of anti-TNF-α therapies is a pro-inflammatory cytokine contributing to the chronic and severe inflammatory response observed in UC and CD, and the monoclonal antibody functions by downregulating pro-inflammatory molecules and restoring IEB integrity, allowing the body to begin to heal[8,24-26]. Infliximab is an Immunoglobulin G1 anti-TNF-α antibody that is shown to induce MH. Active phase 1 and 2 clinical trials of Infliximab in UC patients find that, respectively, 45.5% of patients and 60.3% of patients exhibit MH[27]. Adalimumab is another anti-TNF-α antibody presenting some indication of MH effects. In the double blind, randomized, placebo controlled clinical trial, 24% of patients display MH at week 52 compared to 0% in the placebo group[28]. Certolizumab pegol is an anti-TNF-α antibody fragment targeting soluble and trans-membrane TNF. Its role in promoting MH is not yet well-investigated, but it demonstrates symptom relief and remission at week 8[29]. In some patients, anti-TNF-α treatments are ineffective or lose efficacy over time. In these patients, biologics targeting other inflammatory cytokines are employed as IBD treatment options. For example, Ustekinumab is a monoclonal antibody that targets interleukin (IL)-12 and IL-23 pro-inflammatory cytokines. Ustekinumab significantly reduces SES-CD (Simplified Endoscopic Activity Score for Crohn's Disease) scores in patients over 44 wk, implying its ability to enhance MH[30]. Similarly, Risankizumab, an IL-23 antibody, induced remission in 45% of patients, with an endoscopic response rate of 29%[31]. Additionally, Natalizumab, an anti-α4-integrin antibody, induces MH in 42.3% of patients[32]. Vedolizumab, on the other hand, is an $\alpha_4\beta_7$ integrin receptor antagonist and biologic medication, with potential immunosuppressive effects localized to the colon. In a clinical trial, 50% of UC patients and 29% of CD patients display MH following long-term use[33,34].

Although inflammation reduction and monoclonal antibody treatments have greatly enhanced the quality of IBD treatment in recent years, lack or loss of response occurs with concerning frequency, and even in patients who respond well to treatments, complete resolution of the disease has not been

Table 2 Summary of molecular pathways involved in mucosal healing

Pathways/ Mechanism of action	Associated models studied	Ref.
EGFR signaling	*In vitro*, colorectal cancer mice, EGFR mutant mice	[43,116]
Hippo/YAP signaling	*In vitro*, YAP-1 transgenic mice	[36,59]
Notch signaling	Villin-Claudin-1 transgenic mice	[41,42]
Wnt/β-catenin signaling	*In vitro* and *In vivo models of injury/repair*	[44,60,61]
Vitamin D receptor (VDR) signaling	*In vitro*, VDR knockout mice	[45]
Src/focal adhesion kinase	*In vitro*, Mechanical colonic wound in mice, Nox1 and AnxA1 knockout mice, oral gavage in mice	[76-78]
Autophagy/ATG16L1	Patient biopsies; ATG16L1 T300A knock-in mice; Atg5-manipulated mice	[6,7,104]
SCFA-mediated signaling [acetate, propionate, butyrate, *etc.*]	*In vitro*, Patient biopsies, oral gavage in mice. T-cell induced colitis, trinitrobenzenesulphonic acid (TNBS) colitis	[83-85,91,93,100,101,114]
TLR-mediated signaling	DSS colitis	[109,110,112]
MyD88 mediated bacterial sensing	Mechanical colonic wound, MyD88 knockout mice	[111]
Prostaglandin-endoperoxidase synthase 2 enzyme (PGE2)	*In vitro*, mechanical colonic wound, Ptgs2 knockout mice, Ptger4 knockout mice	[111,112]
Mucin 2 signaling	*In vitro*, DSS colitis, EGFR mutant mice	[80,116]
IL-6/IL-22/IL-23/STAT3 signaling	DSS colitis, Th2-mediated colitis, cytokine deficient mice, bone marrow transplant mice, T-cell induced colitis, human and mouse intestinal organoid culture	[94,97,98,136-138]
TGF-β signaling	*In vitro*, DSS colitis, TGF-β transgenic mice	[50,130,131]
IL-10 signaling	*In vitro*, mechanical colonic wound in mice, IL-10-deficient mice	[132,133]

EGFR: Epidermal growth factor receptor; YAP: Yes-associated protein 1; ATG16L1: Autophagy related 16 like 1 protein; Atg5: Autophagy related 5; SCFA: Short chain fatty acid; TNBS: Trinitrobenzenesulphonic acid; TLR: Toll-like receptor; DSS: Dextran sodium sulfate; PGE2: Prostaglandin-endoperoxidase synthase 2 enzyme; IL: Interleukin; STAT3: Signal transducer and activator of transcription 3; TGF-β: Transforming growth factor-β.



achieved[10]. This is due to the complex nature of disease development through many aberrant proteins and signaling pathways, as well as the multi-faceted process of MH that must be approached from many angles to restore complete IEB homeostasis. Overall, while current therapies offer evidence of permitting MH in IBD, some of these therapies do not directly promote MH through enhancing the processes of restitution, proliferation, or differentiation, but rather by simply inducing immune suppression to decrease inflammation and associated injury. Subsequently, there is a critical need to better understand the processes of inflammation and MH in IBD to aid in the development of actively MH-inducing IBD therapies.

IBD TISSUE DAMAGE MECHANISMS AND IMPLICATIONS FOR MH INDUCTION

Gut Barrier Functions and Mucosal Healing

A major role of the intestinal epithelium is its function as a barrier against the luminal environment and antigens; a role that is critical in maintaining normal mammalian homeostasis[35]. Accordingly, IEB dysregulation is a major factor in gut inflammation; thus, reinforcement of IEB integrity is a key consideration when developing more effective treatments for gut inflammatory diseases, including IBD. The MH process has been shown to help reinforce barrier integrity[36]. A complex and dynamic coordination between epithelial and immune factors facilitates MH, however, the 'paradoxical' role of the barrier-integral proteins in promoting MH remains ill-understood. Here, we summarize the key components of IEB regulation to illustrate the dynamic causal relationship between MH and the proteins comprising the structural and functional units of the gut barrier.

The physical component of the IEB consists of a single layer of epithelium, with cells linked by junctional complexes along the apicobasal axis. Excellent reviews have described the types and roles of junctional complex proteins in barrier integrity, thus here we focus on mechanisms by which regulation of these proteins influences inflammation and MH[35-39]. Tight junctions, the most apical cell-cell adhesions are considered the "gate" of the IEB and consist of multiple proteins, including the Claudin family of proteins, Occludin, junctional adhesion molecule (JAM) and the zonula occludens (ZO)-proteins[40]. Studies in cell and mouse models demonstrate through genetic manipulation that tight

Figure 1 Pictorial depiction of inter-connection between the immune system, inflammation, and microbiota in mucosal inflammation, associated injury, and healing. Left: normal mucosal homeostasis; Middle: Inflammatory lesions damage the mucosal barrier between the gut lumen and the rest of the body. Barrier damage leads to immune cell activation, cytokine release, and feedback cycles of deteriorating inflammation driven by microbes crossing the damaged barrier; Right: Migration of circulating restitutive immune cells to the wound area, the release of repairing cytokines; crosstalk among extracellular matrix and epithelial cells for proliferation and migration; switching of microbiota and cytokines for mucosal healing and functional crypt regeneration.

junction proteins are not merely static structural entities of the IEB; they perform additional non-canonical roles of regulating epithelial cell proliferation, survival, differentiation, and migration, which are the same processes integral to MH. In this regard, ZO-1 regulates expression and nuclear localization of the transcription factor ZO-1-associated nucleic-acid-binding protein to influence cell proliferation in a density dependent manner[41,42]. Recent studies also show that the ZO-proteins modulate Hippo/Yes-associated protein 1 signaling, a critical regulator of crypt growth and MH[43]. A similar role of JAM in regulating intestinal epithelial cell (IEC) proliferation has been reported[44,45]. Occludin, on the other hand, is shown to regulate IEC apoptosis and survival[46,47]. Recent studies demonstrate that the Claudin family of proteins is integral to tight junction structure and function and plays a complex role in gut inflammation and regenerative processes. For example, Claudin-1 overexpression in the intestinal epithelium of mouse models of IBD induces significant dysregulation of Notch/Wnt signaling and severe colitis, resulting in delayed recovery from colitis-associated injury[48,49]. Claudin-2 is unique among the Claudin proteins expressed in the intestine, as it is primarily expressed at the crypt base among proliferative undifferentiated cells and associates inversely with the differentiation state of IECs[48]. Of note, Claudin-2 is a direct target of Epidermal Growth Factor Receptor (EGFR), Wnt/β-catenin, and Vitamin D receptor signaling, all of which promote intestinal MH [50-52]. Claudin-3 on the other hand, which functions as a receptor for *Clostridium perfringens*, is sharply downregulated in the biopsies of the IBD patients, and loss of its function in the mouse gut promotes colitis-associated cancer[53-55]. We have also previously reported that Claudin-3 Loss enhances gp130/IL-6/STAT3 (signal transducer and activator of transcription 3) signaling, which promotes colitis-associated injury/repair[50]. Interestingly, the loss of intestinal Claudin-7 expression results in spontaneous inflammation due to dysregulation of epithelial-extracellular matrix interactions[56,57]. Claudin-7 also regulates intestinal stem cell function in association with the Epithelial Cellular Adhesion Molecule protein[58,59]. Conversely, Claudin-15 Loss in the IEB results in a mega-intestine[60]. Hence, dysregulation of tight junction protein expression in the IEB results in IBD, indicating that restoration of tight junction homeostasis is a vital component of MH and a promising target for treatment

development.

Like tight junction component proteins, adherens junction proteins contribute significantly to gut inflammation and MH. Here, E-cadherin, a protein whose expression indicates an epithelial phenotype, contributes to inflammation-associated epithelial repair by regulating the epithelial-to-mesenchymal transition, a process associated with cell proliferation and migration[58,61,62]. Specifically, E-cadherin expression inhibits migration of IECs and wound healing[63]. Contrastingly, complete E-cadherin loss causes a severe inflammatory phenotype characterized by villus blunting, which is a marker of premature epithelial death, and incomplete brush border development[64]. The stabilization of E-cadherin expression is facilitated partly by binding with the cytoplasmic domain of p120-cadherin. Accordingly, p120 knockout mice displayed disrupted intestinal integrity and early death from intestinal injury[65]. Other heterodimeric adherens junction proteins, α- and β-catenin, are key players in the regulation of Hippo and Wnt signaling[66,67]. Although α- and β-catenin expression dictates IEC proliferation and differentiation during injury repair, their expression counter-acts each other. Moreover, ubiquitination of β-catenin by α-catenin aids the degradation of β-catenin, balancing the Wnt signaling pathway[68]. Taken together, these findings support a complex and dynamic interdependence between gut barrier regulation and MH, which should be considered for therapeutic potential.

Gut Dysbiosis, IBD, and Mucosal Healing

Aberrant microbiome-immune interactions can lead to improper immune activation and are potentially responsible for the clinical and endoscopic observations in IBD patients. Mechanisms of microbial involvement in IBD include production of short-chain fatty acids (SCFAs), interaction with autophagy pathways, activation of immune cells, TLR signaling, and prostaglandin pathways[69-73]. Excellent reviews have covered the details of such interactions and the dynamic association with gut inflammatory processes[71-75]. Thus, here we focus primarily on how gut microbiota may contribute to MH processes under normal and/or inflammatory conditions.

Gut dysbiosis is mediated by pathogenic microbes harboring genes encoding toxin proteins, which disrupt the IEB *via* disassembly or redistribution of tight junction proteins. For example, human epithelial cells treated with *Escherichia coli* or *Salmonella typhimurium* demonstrate downregulation of ZO-1 and Occludin proteins while by contrast, Claudin-2 is upregulated[76-78]. *Shigella flexneri* and *Campylobacter jejuni* are involved in deregulating E-cadherin, as well as activating IL-8 and nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB), thereby inducing barrier dysfunction and inflammation[79,80]. Overall, studies suggest that pathogenic gut bacteria promote chronic mucosal inflammation by dysregulating IEB integrity.

On the other hand, commensal gut bacteria seem to promote the initial stage of epithelial restitution, as studies in germ-free mice show impaired rates of epithelial cell migration, which is dependent on the formation of focal adhesions[81,82]. In this context, a commensal bacterium activates the focal adhesion kinase, thereby enhancing epithelial restitution and promoting mucosal wound repair in a redox-dependent manner[83-85]. In a mouse colonoscopy-based wound healing model, an abundance of anaerobic bacteria such as *Akkermansia spp* augmented early stages of MH[86]. The selection of mucin-producing bacteria from the mucin layer also helps close mucosal wounds[87,88]. These microbes help generate SCFAs such as acetate, propionate, and butyrate, which are considered the primary energy sources of gut colonocytes and are therefore critical supporters of IEB restoration and integrity following tissue damage[89-92]. The major producers of SCFAs include the genus *Bacteroides*, *Clostridium* clusters IV and XIVa, and *Bifidobacterium*, though they use diverse mechanisms to achieve homeostatic outcomes[89,93,94]. For example, *Bacteroides ovatus* decreases lipopolysaccharide-induced inflammation and produces indole-3-acetic acid that likely promotes IL-22 production by immune cells, yielding beneficial effects in epithelial regeneration[95,96]. SCFAs produced by fiber-fermenting commensal microbes are also linked to upregulation of Foxp3+ T regulatory (Tregs) cell development, which have a widely documented role in protection against epithelial injury and colitis [97]. Inhibition of histone deacetylases and/or activation of the latent form of transforming growth factor-β (TGF-β) to act as a potent inducer of Tregs are potential mechanisms of SCFAs[98,99]. SCFAs also mediate activation of STAT3 which plays a vital role in mucosal homeostasis[100,101]. *Clostridia*-related segmented filamentous bacteria promote IL-23 production by antigen-presenting cells, which activate type 3 innate lymphoid cells (ILCs) to initiate an IL-23R/IL-22/STAT3 loop, thereby producing serum amyloid A which promotes IL-17 production by Th17 cells[102-105]. The importance of the SCFA propionate is the augmentation of dendritic cell and macrophage hematopoiesis precursors that impact intestinal immunity to control the growth of invading mucosal pathogens[106,107]. A breach in this regulation is a central mechanism in triggering, maintaining, and exacerbating IBD. Supplementation with another important SCFA, butyrate, rescues deficiencies in mitochondrial respiration and increases autophagy in the colonocytes of germ-free mice compared to conventionally raised mice[108]. Due to the critical role in repair of gut dysbiosis, the regulation of specific gut bacteria and SCFAs may therefore possess significant potential for clinical treatment of IBD.

As introduced above, accumulating evidence suggests a causal interdependence between autophagic flux in the intestinal epithelium and gut microbiota colonization. In this regard, CD patients who are homozygous for the ATG16L1^{T300A} gene variant exhibit higher abundance of Enterobacteriaceae, Bacteroidaceae and Fusobacteriaceae in the inflamed ileum compared with patients homozygous for the wild

type ATG16L1 allele[6]. Similar findings have been obtained from mice where expression of the autophagy gene Atg7 is genetically knocked out in the gut epithelium, as these mice display altered microbial composition with enrichment in *Clostridium septum*, *Eubacterium cylindroides*, and *Bacteroides fragilis* compared to wild type mice[109]. ATG16L1^{T300A} variant mice also show changes in fecal microbiota composition compared to wild type mice, displaying an increase in the order Bacteroidales, which is associated with increased Th17 and Th1 cells in the colon and ileum lamina propria without the development of intestinal inflammation[7]. However, Atg5 deficient mice display reduced bacterial diversity, as observed in IBD patients, and contain a low number of the Lachnospiraceae, Ruminococcaceae, and Akkermansia families that control inflammatory responses[110]. Of note, a role of autophagy in regulating intestinal stem cell function and mucosal injury/repair has been demonstrated by several recent studies[111,112]. Taken together, these studies highlight a complex causal integration between host cell autophagy processes and intestinal microbial communities in regulating intestinal homeostasis and injury/repair.

Additionally, infiltrating immune cells such as macrophages and neutrophils responding to gut dysbiosis comprise essential components of intestinal wound healing by altering aberrant physiological parameters of the local microenvironment, such as microbe-associated molecular patterns (MAMPs) and decreased oxygen levels from the formation of reactive oxygen species[86,113-115]. Of note, Toll-like receptors (TLRs) expressed on multiple immune cell lineages induce signaling pathways upon binding by MAMPs and improve outcomes in experimental mouse colitis models *via* the promotion of wound healing[116,117]. Specific microbes in proximity to the wound bed also activate host epithelial proliferative signaling through a formyl peptide receptor pathway[83,84]. Studies employing a mechanical colonic wound method further disclose a protective role for prostaglandin E2 (PGE2) in re-establishment of the IEB through a TLR2/MyD88-dependent manner[118,119]. A follow-up study from the same group shows that in the early repair phase, a TLR2/PGE2 axis is required for barrier establishment; however, PGE2 must then decrease to allow for epithelial proliferation and regeneration [118]. In this context, Jain *et al*[120] elegantly demonstrates that temporal regulation of the bacterial metabolite PGE2/deoxycholate during colonic repair is critical for crypt regeneration[120]. The highly specific and time-dependent switching of microbial colonization and signaling pathways can therefore act to promote MH in a localized manner.

Several therapeutic approaches have been examined by administration of prebiotics or probiotics to regulate the microbiota. For example, butyrate enemas are effective in treating experimental colitis and UC patients[121,122]. Also, p40, a protein produced by *Lactobacillus rhamnosus GG* (LGG), activates host epithelial EGFR signaling and mediates wound healing[123]. Of note, the mechanism of MH promotion by LGG is *via* a positive effect on epithelial barrier maturation by upregulation of Claudin-3[124]. Recently, genetically modified probiotic bacteria–based precision delivery of human EGF also appears to be a promising intervention against mucosal inflammation through crypt-derived MH and barrier restoration[125,126]. Firmicutes, such as *Faecalibacterium prausnitzii* play an essential role in mucosal barrier homeostasis by regulating NF-κB activation and IL-8 production[125,126]. In another study, oral gavage with *Faecalibacterium prausnitzii* during dextran sodium sulfate (DSS) colitis improves outcomes compared to mice treated with DSS alone, likely due to participation of Claudin-1 and Claudin-2[125]. The probiotic mixture known as VSL #3, containing 4 strains of *Lactobacilli*, 3 strains of *Bifidobacteria*, and one strain of *Streptococcus* is effective in preventing pouchitis and in treating UC flareups[127]. This probiotic functions by partially upregulating mucin production and restoring the IEB by stimulating ZO-1 and Occludin expression while decreasing Claudin-2[127]. Taken together, a complex interdependence exists between gut microbiota and MH processes in the promotion of barrier integrity that should be fully explored for its intriguing potential in improving clinical outcomes.

Inflammatory Cytokines in IBD and Mucosal Healing

Due to dysregulation of many cytokines and growth factors in IBD and the regulatory importance of many of these same molecules in MH, we discuss the potential of altering immune signaling and inflammatory cascades in restoring proper intestinal homeostatic balance. Increasing knowledge of the coordination of these pathways will contribute to the development of more effective and targeted therapies to ameliorate disease while preserving essential immune system function.

Major cytokines and growth factors that are considered pro-inflammatory in IBD include IL-1β, interferon-gamma (IFN-γ), TNF-α, and IL-6. During an infection in the gut, IL-1β, TNF-α, and IFN-γ are shown to be produced by inflammatory monocytes, among which IL-1β and TNF-α are associated with increased IEB permeability[2]. TNF-α and IFN-γ are also produced by ILCs and serve to recruit and activate additional inflammatory cells[3]. TNF-α is particularly well-studied and often targeted in the treatment of autoimmune diseases as detailed in our discussion of monoclonal antibody therapies above. Although necessary for innate immune responses against acute pathogens and acute DSS colitis, when produced chronically by T cells TNF-α can be a major contributing factor to the loss of epithelial barrier and development of autoimmune disease[128-130]. IFN-γ has been shown to be regulated during wound healing of skin epithelium by Tregs, where lack of Tregs resulted in increased IFN-γ, accumulation of pro-inflammatory macrophages, and hindered wound healing[131]. Gut microbiota can also impact immune system activation through cytokine signaling. Kuhn *et al*.[132] demonstrates that intraepithelial lymphocytes (IELs) must interact with commensal Bacteroidales order microbes to produce IL-

6 in response to acute *C. rodentium* colitis infection, aiding in repair of the IEB *via* increased Claudin-1 expression[132]. Despite the necessary effects of pro-inflammatory cytokines for immune system response and homeostasis, each also possesses drawbacks. When the location, amount, or duration of cytokine production becomes dysregulated, chronic inflammation and disease can result. IFN-γ, TNF-α, and IL-6 are upregulated after secretion by immune cells in the chronic inflammatory state associated with IBD[3,130,132]. These cytokines are known to increase gut permeability by altering tight junction protein expression[132-134]. In particular, increased IL-6 in the IECs and lamina propria mononuclear cells increases Claudin-2, which promotes intestinal permeability and is known to be upregulated in IBD[134,135]. Interestingly, it is IELs that produce IL-6 in a protective manner during acute infection through the c-Jun N-terminal Kinase pathway, rather than the Mitogen-activated protein kinase/extracellular signal-regulated kinase pathway, suggesting both duration and cell type-specific layers of complexity in the role of IL-6[132,134]. It is likely that similar multi-layer and highly context-specific pathways exist for other inflammatory cytokines as well. Therein lies the challenge of harnessing pro-inflammatory cytokines and signaling pathways in the immune system for MH: Targeting modifications toward the decrease of detrimental chronic effects without impairing their beneficial and homeostatic functions. Continuing in the discussion of IL-6, global reduction of IL-6 expression can decrease chronic inflammation in IBD and enhance MH, but may also increase susceptibility to infection[132,136]. It would therefore be ideal to develop a method of reducing IL-6 production in IECs while leaving expression in IELs intact to avoid increasing the risk of dangerous infections in patients. The potential in fine-tuning inflammatory cytokine expression to promote MH is great, but much work remains to ensure it can be accomplished safely without severe detrimental effects to other functions of the immune system.

Conversely, several other cytokines, growth factors, and cell types function primarily in an anti-inflammatory role in IBD and intestinal homeostasis and offer additional mechanisms to enhance MH by resolving chronic inflammation. Growth factors and cytokines considered to be anti-inflammatory include TGF-β, IL-10, IL-22, and IL-17. TGF-β is a well-studied growth factor that has been demonstrated by Beck *et al*[137]. to play a role in the restitution, or IEC migration, phase of MH, evidenced by the lack of IEC migration and impaired wound healing after TGF-β inhibition in DSS colitis[8,137]. Additionally, TGF-β when produced by a macrophage secretome called SuperMApo aids in removal of apoptotic cells and resolution of inflammation in IBD models[57,138]. Importantly, since this secretome produces TGF-β from a singular cell type, rather than globally, its administration can provide the context- and location-dependent production of beneficial TGF-β while avoiding potential opposing or off-target effects. Macrophages and Th2 cells also produce IL-10, which enhances the proliferation phase of MH, maintains immune tolerance to the many antigens encountered by the IEB, and promotes barrier integrity[139,140]. Similarly, the production of IL-17 by anti-inflammatory Tregs helps with IEC proliferation and blockage of detrimental microbiota in colitis models, providing protection against IBD[141]. One of the major players in protection against IBD is IL-22, which is produced by multiple cell types and promotes MH by more than one mechanism, as reviewed in[142]. Most importantly in IBD, IL-22 is produced by ILCs, CD4+ T cells, and NK cells, demonstrating activation of both the innate and adaptive immune system[143,144]. IL-22 primarily acts on intestinal stem cells (ISCs) and IECs and functions by activating STAT3 signaling, which induces IEC proliferation and therefore MH[101,142,143,145]. Regarding ISCs, IL-22 both protects them from depletion during intestinal inflammation and induces regeneration[101,143,145]. Though some of these cytokines and growth factors can be inflammatory under certain circumstances, in the context of IBD they function in an anti-inflammatory manner and are beneficial in promoting MH. Some cytokines even demonstrate potential to be produced or administered selectively in only beneficial locations or cell types. Therefore, anti-inflammatory cytokines and growth factors present promising options for treatment of IBD through selectively reducing inflammatory signals and inducing or enhancing the MH process.

CONCLUSION

In recent years, IBD has become increasingly common in the United States and abroad. As progressive and debilitating diseases, UC and CD have long-term negative implications on health. In the past, treatments have focused on reducing the clinical manifestations of the disease, often leaving underlying disease mechanisms active in the gut[12,15]. With increased understanding of the mechanisms and complex pathogenesis of IBD, further innovation in treatment approaches must occur to improve patients' long-term outcomes. Subsequently, instead of merely hoping to reduce symptoms, doctors now desire therapies that actively aid in healing and regeneration of damaged tissue. MH has therefore emerged as the main goal for research and treatment end points to ensure long-term remission, survival, and a good quality of life for patients. Going forward, understanding the interactions regulating the breakdown and regeneration of the IEB, as well as overarching gut homeostasis processes, will be paramount to treating and curing patients with IBD. Monoclonal antibody therapies offer a promising start to revolutionizing treatment, aiming not only to reduce clinical manifestations, but also to interrupt disease activity on a cellular and molecular level. However, even newly developed antibody therapies

cannot by themselves completely resolve IBD and restore total gut homeostasis. Therefore, the three approaches to targeting the molecular machinery governing IBD of restoring the IEB, regulating the gut microbiota, and altering the cytokine signaling-mediated immune response are all being studied as potential mechanisms for achieving MH. Optimal future treatment protocols for IBD will ideally include a combination of these approaches, with the intent of restoring intestinal homeostasis by balancing expression of multiple proteins and repairing several of the many dysregulated pathways involved in IBD pathogenesis.

Abstract

Post-surgical leaks and fistulas are the most feared complication of bariatric surgery. They have become more common in clinical practice given the increasing number of these procedures and can be very difficult to treat. These two related conditions must be distinguished and characterized to guide the appropriate treatment. Leak is defined as a transmural defect with communication between the intra and extraluminal compartments, while fistula is defined as an abnormal communication between two epithelialized surfaces. Traditionally, surgical treatment was the preferred approach for leaks and fistulas and was associated with high morbidity with significant mortality rates. However, with the development of novel devices and techniques, endoscopic therapy plays an increasingly essential role in managing these conditions. Early diagnosis and endoscopic therapy initiation after clinical stabilization are crucial to success since clinical success rates are higher for acute leaks and fistulas when compared to late and chronic leaks and fistulas. Several endoscopic techniques are available with different mechanisms of action, including direct closure, covering/diverting or draining. The treatment should be individualized by considering the characteristics of both the patient and the defect. Although there is a lack of high-quality studies to provide standardized treatment algorithms, this narrative review aims to provide a summary of the current scientific evidence and, based on this data and our extensive experience, make recommendations to help choose the best endoscopic approach for the management of post-bariatric surgical leaks and fistulas.

Core Tip: Post-surgical leaks and fistulas are the most feared complications of bariatric surgery. Endoscopic therapy is essential for effective management of these conditions. Several endoscopic techniques are available, and this review aims to clarify their mechanisms of action, basic principles, and optimal approach for each situation based on a detailed literature review as well as the authors' personal experience.

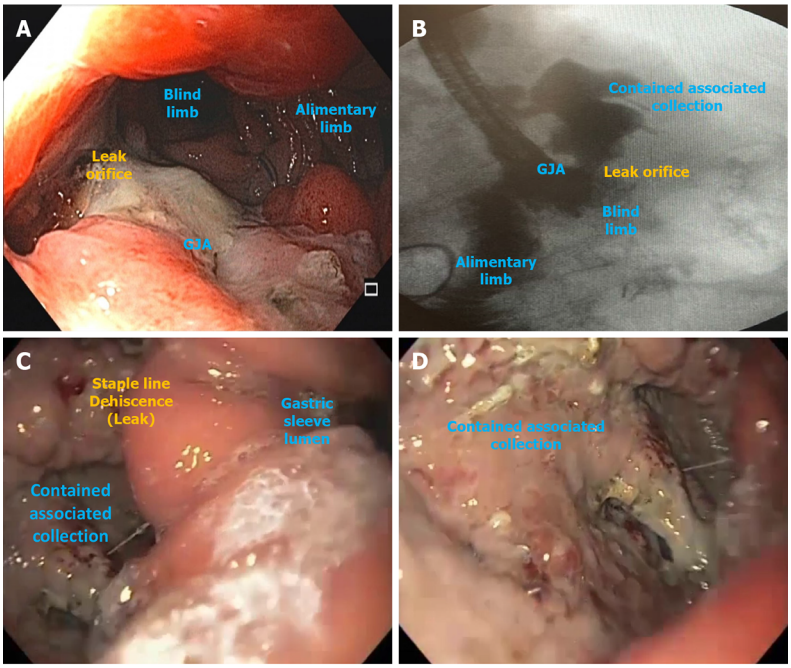
INTRODUCTION

Obesity is now a pandemic, and the prevalence of people living with obesity continues to increase. As a chronic and multifactorial disease with several associated comorbidities, a multidisciplinary approach is required to prevent, treat, and reverse obesity-related complications and to improve quality and length of life for people with obesity[1].

Bariatric and metabolic surgery (BMS) remains the most effective and durable therapy for weight loss and improvement of associated comorbidities. Unsurprisingly, the number of bariatric surgeries performed has grown progressively worldwide. In 2019, about 256000 BMS were performed in the United States. The most performed procedure is laparoscopic sleeve gastrectomy (LSG) followed by Roux-en-Y gastric bypass (RYGB), and revisional surgery[2]. With the increasing number of BMS, familiarity with management of procedure related complications is increasingly important for endoscopists.

Although rare, especially in referral centers, complications can occur, such as leaks and fistulas[3]. Traditionally, leaks and fistulas were treated with surgery. However, surgical management of these defects is usually challenging and has been associated with high morbidity and mortality rates[4]. Less invasive approaches are preferred, when possible, to reduce associated morbidity. Endoscopic therapies play an essential role in the management of leaks and fistulas. Several endoscopic devices and techniques, with different mechanisms of action have been developed, with considerable clinical success for what is often morbid and refractory disease[3,4].

In this narrative review we discuss the pathophysiology, characteristics, diagnosis, and management of post-bariatric surgical leaks and fistulas, focusing on endoscopic therapies. We include descriptions of the mechanism of action, indications, contraindications, tips, tricks, and outcomes for different techniques, in order to facilitate choosing the best approach for each unique case.



DEFINITIONS

Leak is defined as a transmural defect with communication between the intra and extraluminal compartments (Figure 1). A fistula is defined as an abnormal communication between two epithelialized surfaces. Fistulas can be divided into internal and external. An internal fistula occurs between two internal epithelialized organs, whereas an external fistula is a communication between an internal organ and the skin surface (Figure 2)[5].

EPIDEMIOLOGY

Despite the increasing number of BMS, the rate of mortality and adverse events (AEs), including leaks and fistulas, has decreased over the past two decades[6] due to improvement in surgical techniques, such as laparoscopy and robotic surgery, improved materials, and surgeons' expertise.

Leaks and fistulas occurred with similar incidence among the most common bariatric surgeries, ranging from 0.4% to 5.6% in RYGB and 1.9% to 5.3% in LSG, with higher rates after revisional surgeries

DOI: 10.3748/wjg.v29.i7.1173 **Copyright** ©The Author(s) 2023.

GJA: Gastrojejunal anastomosis.

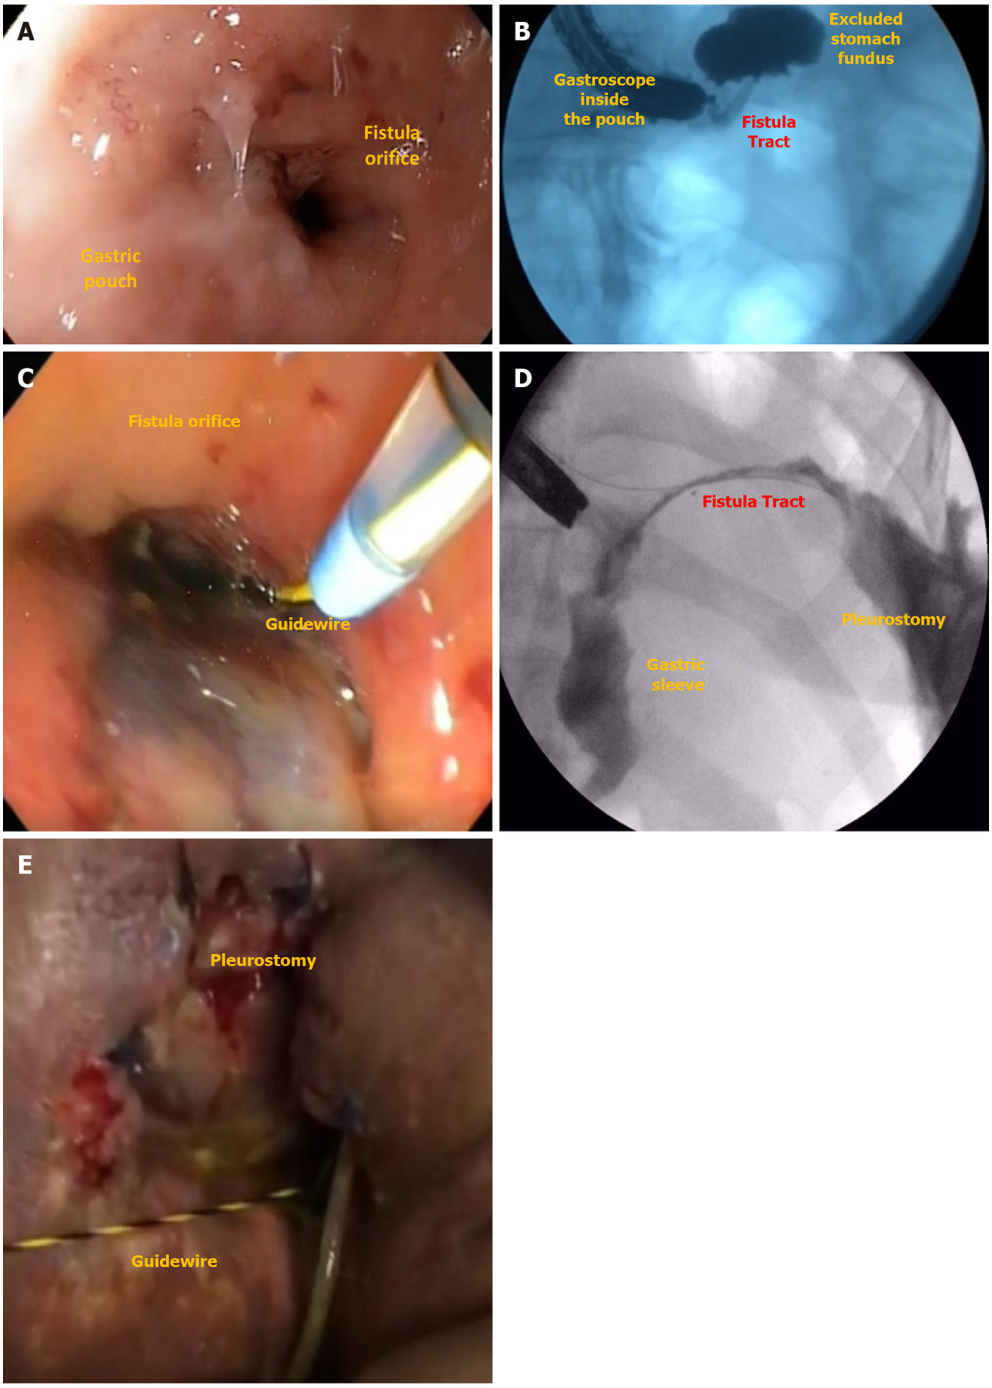
[7-10]. This incidence is considerably lower in high-volume specialized centers; as low as 0.5%[11]. Post-BMS mortality is very low, ranging from 0.2% to 0.4%, and is mainly related to late diagnosis and management of complications[7-10].

CAUSES AND PREVENTION



Leaks usually occur after surgery and are often located at the suture (staple) line and/or anastomosis, while fistulas are mainly caused by untreated leaks[5].

The causes of transmural defects after BMS are related to several factors, including the patient related risk factors and technical risk factors. Patient related risk factors for transmural defects include high body mass index, age, smoking, alcohol use, malnutrition, and other related comorbidities [*e.g.*, type 2 diabetes mellitus (T2DM)][12]. Technical risk factors include mechanical or ischemic insults, both of which contribute to a mechanism of high intraluminal pressure that overcomes the integrity of the tissue. Meticulous surgical technique, with careful attention to tissue handling and inadvertent excessive tension on anastomoses, luminal narrowing, suturing/stapling ischemic areas, and torsion of blood vessels or organs is mandatory to avoid undesirable outcomes such as downstream stenosis, leaks, and fistulas. Additionally, stapling failure is also a cause of BMS leaks[13,14].

The pathophysiology of leaks and fistulas after RYGB and LSG differ; given distinct technical and anatomic particularities of each surgery. Most commonly in LSG, the creation of a long and narrow conduit combined with pylorus preservation creates a high-pressure region proximally leading to stress on the proximal staple line. In RYGB, the gastric pouch is a low-pressure system with low resistance to gastric emptying through the gastrojejunal anastomosis (GJA) into the small bowel, though high-pressure areas can develop in cases of GJA stenosis or excluded stomach gastroparesis. The anatomy of LSG favors leak and fistula formation at the proximal portion of the staple line, especially near the angle of His. Here the thin gastric wall, high pressure, and borderline vascularization secondary to take down of the short gastric arteries all contribute to comprised wall integrity[14-16].

Of note, for both LSG and RYGB, it has been shown that laparoscopic surgery reduces the incidence of leaks and fistulas as well as mortality rates compared to open surgery[6,17]. Intraoperative leak assessment using methylene blue, endoscopy, or air insufflation allows for immediate repair of defects though this practice has never been proven to reduce the incidence of leak or fistula formation after surgery[14,18].

Stapling technology has evolved in recent years with the development of different staple heights capable of accommodating variable gastric wall thickness according to the anatomic portions of the stomach. To take advantage of this technology, the surgeon must be aware of which one is the most appropriate in each case to avoid mismatch[14]. Moreover, several techniques of staple line reinforcement have been studied, from oversewing the staple line with different suture techniques to

Figure 2 Post-bariatric surgical fistulas illustrations. A and B: Gastrogastric fistula after Roux-en-Y gastric bypass; C, D, and E: Gastropleural fistula after laparoscopic sleeve gastrectomy.

the use of biologic or synthetic materials, such as glues and tissue sealants, but none of these interventions have been proven to reduce the incidence of post-surgical leaks and fistulas[19-22].

The routine placement of drains near the anastomosis is controversial and there is no consensus in the literature and between surgeons on whether this intervention prevents the development of uncontrolled leakage or increases the risk of developing leaks[23,24].

CLASSIFICATION

Leaks and fistulas can be classified based on several parameters, including time of onset and location.

The definition of acute *vs* chronic leaks and fistulas varies between 30 and 45 d in the literature (acute < 30-45 d and chronic > 30-45 d)[25,26]. In our practice, we use the classification described in the

international LSG consensus, which classified the defects into acute (< 7 d), early (between 7 d and 6 wk or 45 d), late (between 6 wk or 45 d and 3 mo or 90 d), and chronic (> 3 mo or 90 d)[27]. Up to 20% of acute and early leaks and fistulas become late and chronic leaks and fistulas, mainly when the defect is untreated[26,28].

Based on the location, post-RYGB leaks are classified into Type I to VI. The locations include: The gastric pouch (Type I), GJA (Type II), blind jejunal stump (Type III), jejunojejunal anastomosis (Type IV), excluded stomach (Type V), and the blind stump of the biliopancreatic limb (Type VI). The first three topographies are easily accessible by endoscopy and can be treated with endoscopic techniques, unlike the others[29].

LSG leaks mostly occur at the level of the angle of His due to poor vascularization (more than 90% of the cases) but can also occur in the distal body and antrum. Both locations can be treated with an endoscopic approach[27].

DIAGNOSIS

The diagnosis of leaks and fistulas is based on clinical history and physical examination. Complementary studies, including laboratory tests and imaging are usually required to establish a precise diagnosis.

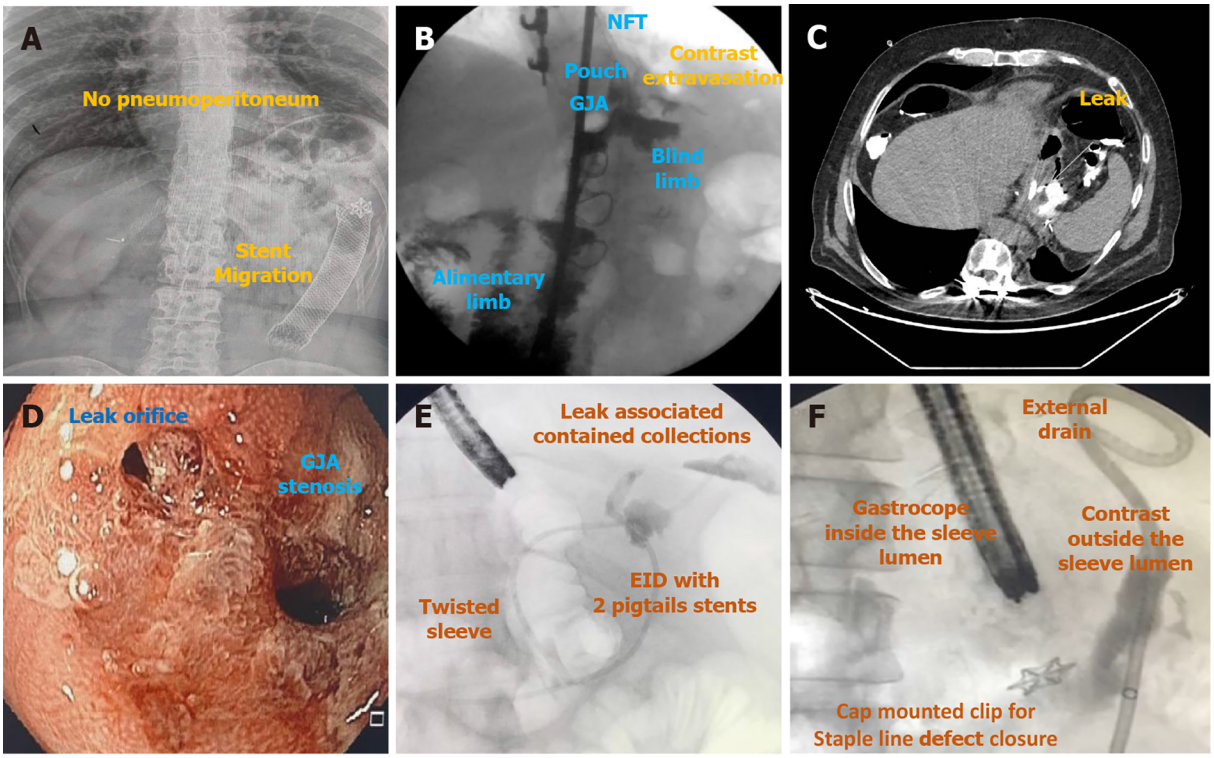
Clinical manifestations vary according to individual factors related to the level of inflammatory response as well as particularities of the leak or fistula, such as the onset time, defect location, and the placement of a post-surgical drain. If an external drain is placed, the leak can be identified early due to increased drainage[5]. On the other hand, patients without external drainage usually present with infectious manifestations, from mild signs and symptoms, such as low-grade tachycardia, fever, and abdominal pain, to sepsis[30].

Clinical manifestations of fistulas depend on the location of the defect. Respiratory symptoms should be an alarm to consider gastrointestinal (GI)-respiratory fistulas, although patients with peritonitis can also present with pleural effusion[31]. GI-cutaneous fistulas are easily diagnosed if secretions are observed coming out through the skin[32]. Gastrogastric fistula is usually a late complication of RYGB and should be investigated in patients with weight regain and/or gastroesophageal reflux[33].

Laboratory tests are important in acute infection and include leukocytosis, elevated C-reactive protein, and changes indicating organ dysfunction[14]. Additionally, it may be important in patients with long-term fistulas to evaluate nutritional state or electrolyte depletion, for example, in chronic gastrocolic fistulas.

Once suspicion is established, diagnosis is usually confirmed with imaging exams, including radiography of the abdomen, upper gastro-intestinal transit (upper GI series) and computed tomography (CT) scan with administration of water-soluble oral contrast, esophagogastroduodenoscopy (EGD), and/or fistulogram[34] (Figure 3).

Radiography of the abdomen is frequently requested as it can rapidly evaluate for pneumoperitoneum (Figure 3A).



Upper GI transit should be performed with water-soluble contrast if leak or fistula are suspected (Figure 3B). It is important to locate the fistulous orifice and to understand the post-surgical anatomy, including the presence of downstream stenosis for successful treatment. The use of barium is not recommended as it may delay endoscopic treatment. When GI transit findings are doubtful or clinically discordant, CT scan should be used to clarify the results due to its lower sensitivity[35,36].

CT scan allows the evaluation of a fistulous path as well as indirect signs of the source of a leak or fistula, presence of associated collections, pneumoperitoneum, and free fluid. Additionally, it provides a broad evaluation of the intracavitary organs for procedural planning (Figure 3C)[4,37].

EGD is needed to evaluate the fistulous orifice (Figure 3D) surrounding tissue, presence of foreign bodies, and downstream stenosis. Fluoroscopy can be critically useful, especially for orifices smaller than the diameter of the gastroscope. In these cases, a fistulogram can be performed by injecting water-soluble contrast through a catheter or the gastroscope working channel (Figure 3E). Additionally, injection of water-soluble contrast, methylene blue, or a bubble test can be performed if there is an external drain (Figure 3F)[5]. In patients with LSG and suspicion of a leak or fistula without an evident defect, an important reminder is to follow the staple line superiorly looking for small orifices as these can be difficult to locate. A fistulogram can also be performed percutaneously in cases of GI-cutaneous fistulas allowing for a better understanding (size and location) of the fistula tract.

PRINCIPLES OF TREATMENT

The treatment of leaks and fistulas is based on four pivotal principles: (1) Clinical management; (2) Drainage; (3) Treatment of associated factors; and (4) Closure of the transmural defect.

DOI: 10.3748/wjg.v29.i7.1173 **Copyright** ©The Author(s) 2023.

Figure 3 Imaging exams for diagnosis of leaks and fistulas after bariatric surgery. A: Abdominal radiograph showing an esophageal fully covered metal stent fixed with a cap mounted clip at its proximal edge used for the treatment of a gastrojejunal anastomosis (GJA) leak after Roux-en-Y gastric bypass (RYGB) migrated to distal jejunum with no signs of pneuperitoneum; B: Upper gastrointestinal (GI) transit for suspicious leak after RYGB showing contrast extravasation; C: Computed tomography scan confirming the GJA leak suspected in the upper GI series (Figure 3B); D: Endoscopic visualization of a GJA stenosis associated with a leak; E: Fluoroscopy image during esophagogastroduodenoscopy (EGD) with injection of water soluble contrast through a catheter showing two leaks in the sleeve staple line with associated collections treated with endoscopic internal drainage with pigtail stents; F: Fluoroscopy image during EGD with injection of water soluble contrast through the external drain showing no extravasation for the intraluminal compartment, confirming the successful defect closure. GJA: Gastrojejunal anastomosis; EID: Endoscopic internal drainage; NFT: Nasoenteral feeding tube.

First, unstable patients must be clinically stabilized, including fluid resuscitation, packed blood cells transfusion when indicated, and administration of vasoactive drugs if necessary.

Infectious source control including intravenous antibiotic therapy and drainage must be performed to control sepsis. Drainage can be performed surgically, percutaneously by image guidance, or endoscopically. For unstable patients with peritonitis and free infected fluid in the cavity, surgical lavage and drainage, with or without defect repair, is the preferred approach.

Nutrition is also key for defect healing and is often neglected as most patients are kept nil *per* os initially. Therefore, enteral or parenteral nutrition should be introduced as early as feasible. Enteral nutrition is the preferred option, through a nasoenteral feeding tube placed distal to the defect[5].

Defect related factors must be treated to achieve successful closure, such as dilation of downstream stenosis, and foreign body removal (staples, suture, and drains, *etc.*)[38,39].

After clinical stabilization, endoscopic evaluation is recommended. The endoscopist must communicate with other specialty teams and review the operative report thoroughly before performing the initial endoscopic evaluation. The role of endoscopy in the management of leaks and fistulas includes both diagnosis and treatment. Early diagnosis and endoscopic management are key for success, with closure efficacy as high as 90% when defects are treated within 3 wk of surgery and about 70% after this period[25,26]. Endoscopic treatment of leaks is associated with higher rates of successful closure when compared to fistulas[40]. Despite the lower efficacy of endoscopic treatment for chronic leaks and fistulas compared to acute and early transmural defects, it should be attempted exhaustively before referral for definitive surgical treatment as surgery is often challenging and associated with more morbidity[41]. In this setting, the most commonly proposed revision surgeries are fistulojejunostomy, conversion of LSG to RYGB (without gastrectomy), and total/near total gastrectomy with esophagojejunal anastomosis. Direct surgical repair of the fistula site is not effective and not advised.

ENDOSCOPIC MANAGEMENT

Endoscopic evaluation of leaks must be performed under carbon dioxide insufflation or underwater to reduce the risk of pneumoperitoneum or pneumomediastinum, especially when there is no external drainage. Careful endoscopic assessment is essential to avoid wall rupture of a contained collection[37].

The procedure can be performed in the operating room, endoscopy suite, or at the bedside[4]. The endoscopy suite is preferable due to its lower costs when compared to the operating room and greater resources when compared to the bedside. However, for unstable patients, the operating room or at bedside in an intensive care unit may be preferred.

General anesthesia with orotracheal intubation to reduce the risk of aspiration during fluoroscopy is advised, especially in the initial evaluation. General anesthesia often allows a more detailed inspection of the transmural defect, including defect size, fistula path, and presence of extraluminal collection[4]. The need for general anesthesia and fluoroscopy is not mandatory but can be tailored to the case at hand.

ENDOSCOPIC TECHNIQUES

Endoscopic therapies utilize several mechanisms of action and can be classified into closure, covering, and draining techniques[5].

Closure techniques include clips [through-the-scope clips (TTSC) and cap mounted clips], endoloop, endoscopic suture, and tissue sealants/glues. Despite some studies[42,43] reporting successful closure of leaks and fistulas using the widely available and simple-to-place TTSC, sometimes combined with endoloop, this technique requires robust and healthy tissue around the defect for successful primary closure. Therefore, this approach is not effective in closing leaks and fistulas and should not be recommended[5]. Hence, this closure technique will not be discussed in this review. Common closure techniques are summarized in Table 1.

Covering techniques utilize cardiac septal defect occluders (CSDO) or self-expandable metal stents (SEMS), including conventional (esophageal) stents and custom (bariatric) stents (Table 2). Closure and covering techniques do not allow internal drainage; thus, external drainage is required when an associated collection or intracavitary infected fluid is identified.

Endoscopic drainage techniques include endoscopic vacuum therapy (EVT), endoscopic internal drainage (EID) with double pigtail stent (DPS), and septotomy (Table 3).

All endoscopic techniques are summarized in Tables 1, 2, and 3 discussed in detail below.

Cap-mounted clips

Cap-mounted clips (Figure 4) are usually referred to as over the scope clips (OTSC®, Ovesco Endoscopy GmbH, Tübingen, Germany) as this is the commercial name of the first cap mounted clip. However, it is important to state that the name OTSC® is trademarked and other devices are available.

Cap mounted clip use is increasing due to its benefits compared to the TTSC, including the ability to close leaks and fistulas as it can approximate a larger volume of tissue.

The device is placed into the distal tip of the endoscope and deployment is similar to band ligation, a procedure widely performed by endoscopists, helping to shorten the learning curve[44]. It can only be used in defects smaller than 20 mm.

A meta-analysis including 73 patients from 9 studies evaluating cap-mounted clips for treatment of leaks and fistulas after LSG, including both acute and chronic defects showed a clinical success rate of 63.5% when used as a single therapy and 86.3% when combined with other therapies[45].

In our experience, cap-mounted clips can be used in patients with small orifices without undrained associated collection and always combine with other therapy (Figure 4A). Additionally, cap-mounted clips can be used for stent fixation (Figure 4B and C).

Tissue sealants/Glues

Tissue sealants (Figure 5A) and glues (Figure 5B) include fibrin glue, acellular matrix biomaterial (SurgiSIS® – Cook Medical, Winston-Salem, North Carolina, United States), and cyanoacrylate. These materials are primarily used to close fistulous tracts and are usually used as an adjunctive therapy.

Despite the closure effect of both glues and tissue sealants, the last group also play a role in tissue healing. Fibrin glue induces a cellular response, extracellular matrix formation and neovascularization, while acellular matrix biomaterial induces fibroblast proliferation[46,47].

Although these techniques have a well-established safety profile, reported clinical success is variable and multiple applications are usually required. In a recent meta-analysis evaluating 10 case series involving 63 patients, the number of sessions needed for treatment ranged from 1 to 9, with a pooled successful closure rate of 96.8%[48]. Regardless of the excellent result shown in this meta-analysis, our experience does not reflect this high efficacy. It is important to analyze this data with care given significant limitations and risk of bias for retrospective case series. Furthermore, clinical success is related to the characteristics of the leak or fistula, including defect site, chronicity, and size. Therefore,

Table 1 Endoscopic closure techniques

Endoscopic techniques	Indications/advantages	Not indicated/disadvantages	Authors experience
Cap-mounted clips	(1) Acute/ early/ late/ chronic; (2) Small orifices (< 20 mm); and (3) Safe	(1) Orifices > 20 mm; (2) Need for external drainage; and (3) Variable efficacy	(1) Acute/ early/ late/ chronic; (2) Safe; (3) < 10 mm: > efficacy; (4) > 10mm: very low efficacy; (5) Combined therapy improves its efficacy; and (6) Can be removed when fails to close the defect (not easy to remove)
Glues/ tissue sealants	(1) Acute/ early/ late/ chronic; (2) Diameter < 10 mm; (3) Low drainage (< 200 ml/24 h); and (4) Safe	(1) Multiple sessions are usually required; (2) Need for external drainage; and (3) Variable efficacy	(1) Late/ chronic; (2) Low efficacy; (3) Safe; (4) Helpful as an adjunctive therapy; (5) Never use it as a single therapy; (6) Multiple sessions; (7) Cytology brushing or APC is useful to loosen granulation tissue before application; (8) Delivery *via* endoscopic or percutaneous access; and (9) High cost (tissue sealants)
Endoscopic suturing	(1) Acute/ early/ late/ chronic; (2) High technical success; and (3) Safe	(1) Need for external drainage; (2) Low efficacy (need for robust and healthy tissue for primary closure); (3) Challenging: Previous experience with the device is needed; and (4) High costs (most countries)	(1) Very poor long-term clinical success; (2) Helpful for other devices fixation; (3) Not recommended for chronic defects; and (4) High cost

APC: Argon plasma coagulation.

Table 2 Endoscopic covering techniques

Endoscopic techniques	Indications/advantages	Not indicated/disadvantages	Authors experience
Conventional (esophageal) stents	(1) Acute/ early; (2) Satisfactory efficacy; (3) Very popular; (4) Widely available; (5) International guidelines support; (6) Easy placement; (7) Early oral intake; and (8) Low number of repeated procedures	(1) Late/ chronic; (2) High migration rates; (3) Need for external drainage; (4) Mild symptoms related to the stent; and (5) Possible "surprise" when removing it	(1) Acute/ early; (2) Satisfactory efficacy; (3) Easy placement/ not expensive; (4) Helpful for complete dehiscence; (5) PCSEMS > FCSEMS (challenging removal – do not keep it for > 3 wk); and (6) High migration rates (FCSEMS)
Bariatric stents	(1) Acute/Early; (2) Satisfactory efficacy; (3) "Perfect" shape for LSG leaks; (4) Low number of repeated procedures ; and (5) Easy placement	(1) Late/ chronic; (2) High migration rates; (3) Need for external drainage; (4) Severe symptoms related to the stent; and (5) Possible "surprise" when removing it	(1) Acute/ early; (2) Similar efficacy to the conventional stent; (3) More expensive than the conventional stent; (4) Helpful for downstream stenosis and complete dehiscence; (5) Pre-pyloric position: more symptoms; (6) Post-pyloric position: more migration; (7) High rates of adverse events (ulcers and perforations); and (8) Intolerance due to symptoms related to the stent (GERD, pain, and emesis)
Cardiac septal defect occluder	(1) Late/ chronic; (2) High efficacy; (3) Safe; and (4) Epithelialized surface is required for device fixation	(1) Need for external drainage; (2) Off-label use; (3) High cost; and (4) Acute and early: enlargement and migration if no epithelialized surface	(1) Very high efficacy for late/ chronic defects with epithelialized tract without associated collection; (2) Safe; (3) High cost; (4) Off-label; (5) Indicated after conventional techniques failure; and (6) Size selection based on defect size (2:1)

FCSEMS: Fully covered self-expandable metal stents; GERD: Gastroesophageal reflux disease; LSG: Laparoscopic sleeve gastrectomy; PCSEMS: Partially covered self-expandable metal stents.

all these variables should be considered in a treatment plan.

In our experience, the best indication for tissue sealants and glues are GI-cutaneous fistulas, with thin tract and low output and always combined with additional therapies[31]. Tissue sealants and glues can be delivered *via* endoscopic or percutaneous tract, facilitating the procedure[49]. Cytology brushing or ablation of the epithelialized (chronic) tract to induce granulation is recommended.

Endoscopic suturing

Endoscopic suturing (Figure 6) allows for full-thickness closure. However, similar to TTSC, any type of suturing (surgical or endoscopic) needs robust and healthy tissue around the defect for primary closure. Therefore, this technique is not effective in closing most leaks and fistulas and should not be recommended[5]. In a multicenter study evaluating fistula closure by endoscopic suturing, 56 patients underwent the procedure with 100% technical success. Despite the high technical success, only 22.4% of patients achieved clinical success at one year follow-up[50]. Additionally, endoscopic suturing is expensive in most countries and requires specialized training.

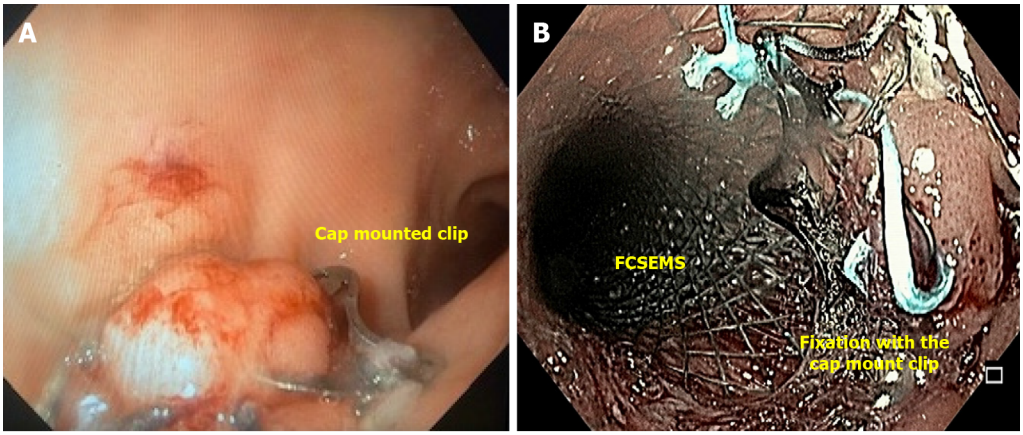
Table 3 Endoscopic draining techniques

Endoscopic techniques	Indications/advantages	Not indicated/disadvantages	Authors experience
Endoscopic vacuum therapy	(1) Acute/ early/ late/ chronic; (2) High efficacy in leaks and fistulas with or without associated collection; (3) No need for external drainage; (4) Superior to stent in upper GI tract; and (5) Unique mechanism of action: macro-deformation/ micro-deformation, changes in perfusion/ angiogenesis/exudate control/bacterial clearance	(1) Inability to achieve negative pressure; (2) No endoscopic access; (3) Patient discomfort related to nasogastric tube; (4) Usually repeated procedures are needed (especially when traditional sponge is used); and (5) Longer hospital stay/ high costs (?)	(1) Acute/ early/ late/ chronic; (2) Very high clinical success rates; (3) You must place the EVT system in intracavitary position when an associated collection is identified; (4) Placement of both intracavitary and intraluminal EVT appears to be the best approach; (5) Traditional sponge: challenging placement and removal (mouth), prolonged procedures, and need for multiple exchanges (6) Low-cost modified EVT: easy placement and removal, reduction in procedure time, longer interval between EVT system exchanges, low cost, and low AEs rates; and (7) Modified triple-lumen EVT: drainage and nutrition with one tube through the nares
Endoscopic internal drainage with double pigtail stent	(1) Acute/early/late/chronic; (2) High efficacy; (3) No need for external drainage; (4) Need of an associated collection; (4) Easy placement (7fr – gastroscope); (5) Small or large orifices; and (6) Short hospital stay	(1) Defects without an associated collection; (2) No place to accommodate the DPS (small collection: < 2 cm); (3) Long period for complete healing; (4) Risk of migration, perforation and bleeding; and (5) Usually, fluoroscopy is needed	(1) Acute/ early/ late/ chronic; (2) High clinical success rates; (3) Small orifices with associated collection; (4) Easy placement; (5) Shorter hospital stay/ electives procedures for DPS exchanges; (6) Faster oral intake (start with clear liquids); (7) Better patient acceptance – no symptoms; (8) Long period for complete healing; and (9) Ureteral stents appear to be safer with similar efficacy
Septotomy	(1) Early/late/chronic (> 15 d); (2) High efficacy; (3) Safe; (4) Septum between the orifice/ collection and the gastric lumen; and (5) Must do it when a septum is identified	It is only performed when a septum is identified	(1) Early/late/chronic (> 15 d); (2) Very high clinical success; (3) Usually more than 1 session is required; (4) Cut until the staple line; (5) APC or Knife (APC < bleeding); (6) Always dilate after septotomy; (7) Outpatient procedure; and (8) Septum is the cause of most late/chronic refractory defects treated in a center without experience

APC: Argon plasma coagulation; DPS: Double-pigtail stents; EVT: Endoscopic vacuum therapy; GI: Gastrointestinal.

In our experience, we only use endoscopic suturing as an adjunctive therapy, for example to fix a stent aiming to reduce the risk of migration.

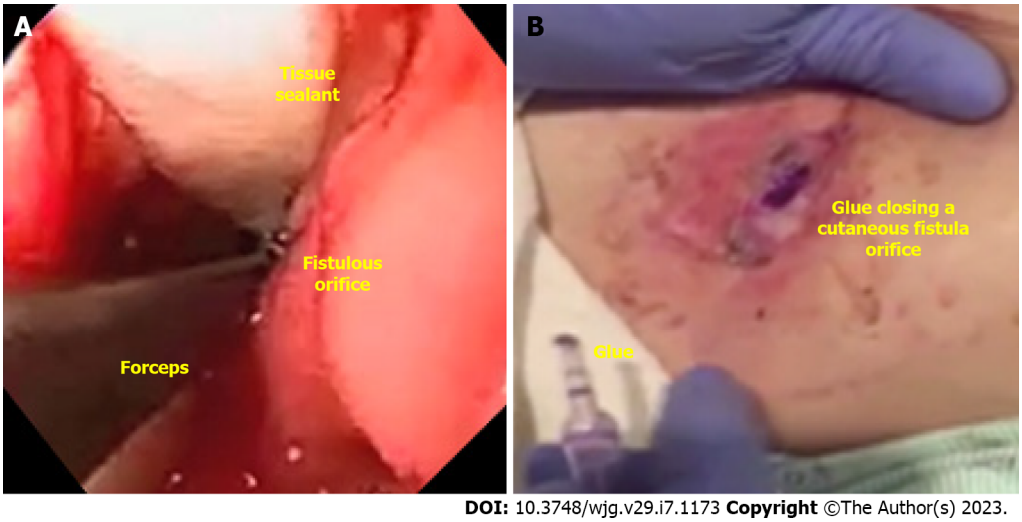
Self-expandable metal stents



SEMS (Figure 7) are the most used technique for the treatment of post-bariatric surgical leaks and fistulas worldwide and is recommended by the American Society for Metabolic and Bariatric Surgery in a position statement from 2015[14]. SEMS are widely available, easy to place and usually with a low cost.

SEMS are indicated for acute and early leaks and should be avoided in late and chronic defects and late stenosis due to reduced efficacy and increased AE rates, especially migration[51]. The American Gastroenterology Association suggests the use of SEMS for leaks and fistulas earlier than 6 wk, preferably in defects < 10 mm[15].

Despite satisfactory efficacy in acute and early leaks as shown in a recent meta-analysis (RYGB: 76.1% and LSG: 72.8%), high migration rates (RYGB: 30.5% and LSG: 28.2%) must be considered, as an urgent surgery due to device migration may be catastrophic[52]. It is important to remember that SEMS placement requires drainage of any associated collections before or promptly after stent placement.



Choosing the correct SEMS facilitates successful therapy. Fully-covered SEMS (FCSEMS) are easy to remove but have a high rate of migration (Figure 7A). Fixation of the FCSEMS with suturing, cap mounted clips or the nasal bridle technique is recommended[53]. On the other hand, partially-covered SEMS (PCSEMS) are associated with low rates of migration, with challenging removal, particularly after 3 wk due to tissue ingrowth (Figure 7B). Nevertheless, some groups argue that the PCSEMS may be better than the FCSEMS as tissue ingrowth prevents leakage between the esophageal wall and the stent. In cases of stent removal failure, several rescue techniques may be used such as the stent in stent technique, ablation and/or endoscopic resection of the tissue ingrowth[15].

Recently, due to the non-negligible migration rate of the esophageal SEMS (Figure 7C), novel models of stents (longer and with a larger diameter) have been developed, focused on the gastric sleeve anatomy. These are customized bariatric stents (Figure 7D). In a retrospective multicenter study[26], 37 patients with early and acute post-LSG leaks were treated with the 24-cm length customized bariatric stent showing similar efficacy and migration rates reported with conventional esophageal SEMS[52]. However, more severe AEs were reported, including two urgent surgeries due to stent migration[54], esophageal perforation[55], contained gastric perforation, and symptoms such as pain and gastroesophageal reflux. In this study, post-pyloric position was associated with high rates of migration and pre-

pyloric position with more stent related symptoms[26]. In a meta-analysis comparing conventional esophageal SEMS and the customized bariatric stents, there were no statistical difference in terms of efficacy (93% *vs* 82%) and migration (15% *vs* 32%) rates[56]. Therefore, this novel customized bariatric stent should be used with caution, preferably in specialized centers with close follow up[57].

In our experience, SEMS are best applied in acute and early leaks with complete dehiscence and/or with associated downstream stenosis, always in conjunction with external drainage. Moreover, we

prefer the esophageal PCSEMS with dwell time of no more than 3 wk, over customized bariatric stents.

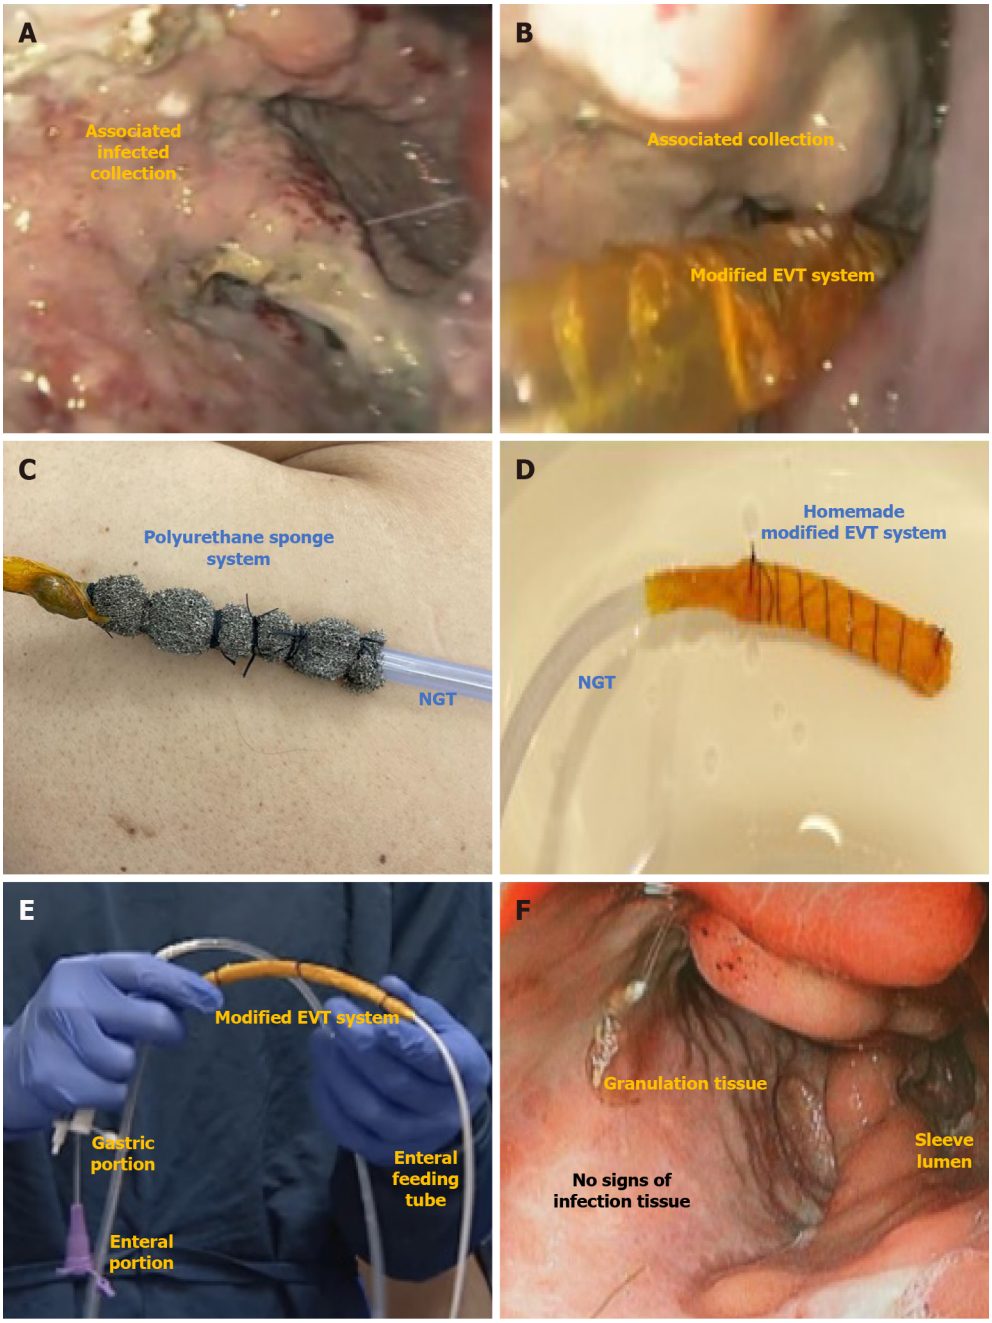
Cardiac septal defect occluder

The non-surgical closure of a cardiac septal defect was first described in 1976 and was considered a revolution in the treatment of cardiac defects[58]. Although developed for the closure of cardiac defects, the off-label use of the CSDO has been reported for the management of bronchopleural and GI fistulas [59].

The CSDO is a self-expanding, double-disc closure device composed of nitinol and polyester, with shape-memory and impressive expansion force (Figure 8)[28,59]. The thick waist portion serves to self-center the device during deployment to close the defect. The disc diameter varies from 9 mm to 54 mm, and the waist size varies from 4 mm to 38 mm.

DOI: 10.3748/wjg.v29.i7.1173 **Copyright** ©The Author(s) 2023.

Figure 8 Cardiac septal defect occluder for the treatment of chronic fistulas after bariatric and metabolic surgery. A: Endoscopic imaging of a successful closure of a gastrocutaneous fistula after cardiac septal defect occluder (CSDO) placement in a distal staple line leak after laparoscopic sleeve gastrectomy; B: Methylene blue test showing no leakage to the skin; C: CSDO migration after placement in an early leak after Roux-en-Y gastric bypass surgery. CSDO: Cardiac septal defect occluder.



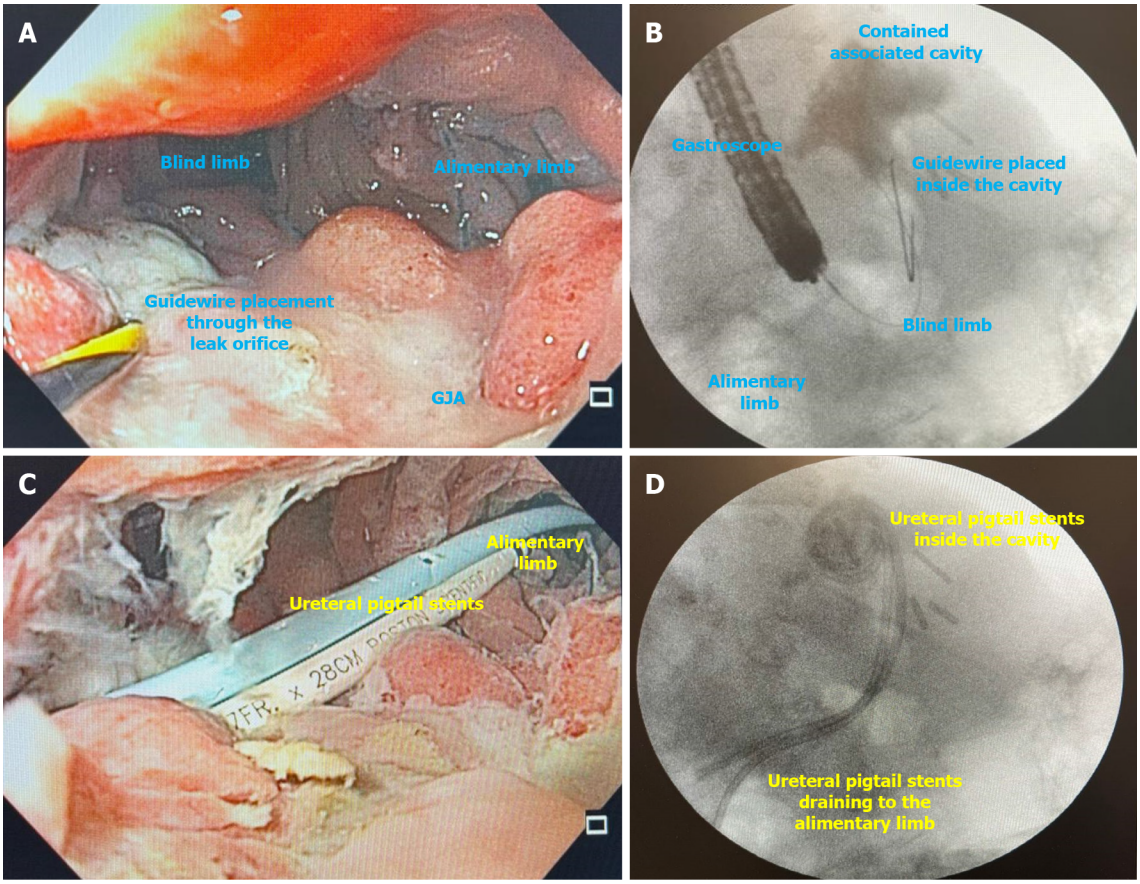
The appropriate device size ("waist diameter") should be 50% larger than the defect orifice. Regarding placement, first, the distal flange is released either into the GI lumen (percutaneous placement) or the fistula tract (endoscopic placement), then, after adequate position is confirmed, the proximal flange is deployed[28].

In a multicenter study, clinical success rate for late and chronic defects after BMS was 97.1% *vs* 62.5% in acute and early scenarios[28]. Due to its expansion force, immediate contrast study or methylene blue test after the procedure usually confirms complete occlusion of the fistulous tract allowing hospital discharge after anesthesia recovery (Figure 8A and B)[32]. If immediate, complete closure fails, adjunctive therapies such as glues/tissue sealants can be performed[31]. Therefore, CSDO is recommended for late and chronic defects as an epithelialized tract is needed for device accommodation. The device should not be used in acute and early leaks or fistulas as it can increases the size of the defect due to its significant expansion force (Figure 8C)[3].

In our experience, the CSDO is the best approach for epithelialized fistulas (Figure 5B) tracts but as an off-label high-cost device, we only use it after conventional technique failure. Regarding long-term follow-up, some devices stay in place and other migrate after complete healing of the defect[28,60].

Endoscopic vacuum therapy

EVT is indicated for GI transmural defects (Figure 9). Its high efficacy is associated with its mechanism of action that involves micro-deformation, macro-deformation, changes in perfusion (angiogenesis), exudate control, and bacterial clearance[4]. The traditional technique involves the use of a polyurethane sponge connected to a nasogastric tube placed into the extraluminal compartment (intracavitary position) or into the GI lumen (intraluminal position). The nasogastric tube is then connected to a vacuum machine with continuous negative pressure (between -125 and -175 mmHg). It is important to understand that, when an associated collection is identified (Figure 9A), the EVT system must be placed inside the collection (intracavitary) (Figure 9B). Despite the high efficacy, the traditional system (Figure 9C) is associated with challenging placement and removal (through the mouth) leading to a prolonged procedure, and the need for frequent exchanges due to tissue ingrowth.



DOI: 10.3748/wjg.v29.i7.1173 **Copyright** ©The Author(s) 2023.

Figure 9 Endoscopic vacuum therapy for the treatment of a post bariatric and metabolic surgery leak. A: Leak associated collection after laparoscopic sleeve gastrectomy; B: Intracavitary modified endoscopic vacuum therapy (EVT) placement; C: Traditional (polyurethane) sponge system; D: Homemade modified EVT; E: Triple lumen tube used for intraluminal EVT allowing for drainage and nutrition with one tube through the nares; F: Complete tissue healing showing granulation tissue and no signs of infection after EVT treatment. EVT: Endoscopic vacuum therapy; NGT: Nasogastric tube.

To overcome these limitations, the open pore film system was developed showing several benefits compared to the traditional sponge system, maintaining a high efficacy and safety profile. These advantages include easy placement (through the nares), reduction in procedure time, longer interval between EVT system exchanges, and a lower rate of AEs[61]. Despite these improvements, the high cost and limited availability of the open pore film remain barriers to its use and widespread adoption. Recently, a cost-effective modified-EVT manufactured from widely available materials and utilizing wall suction was described with promising results (Figure 9D)[62-65]. Furthermore, the use of intraluminal EVT *via* a triple-lumen tube was reported that allowed both drainage (gastric fenestrations) and nutrition (enteral portion) using a single tube through the nares (Figure 9E)[64,66].

Previous studies had already demonstrated very positive outcomes for EVT in the management of general upper GI leaks and fistulas, including with higher success rates and lower AEs rates when compared to SEMS[67]. A recent meta-analysis evaluated the use of the EVT in the management of leaks and fistulas after BMS demonstrating a pooled clinical success rate of 87.2% with 6% AE rate. In this

GJA: Gastrojejunal anastomosis.

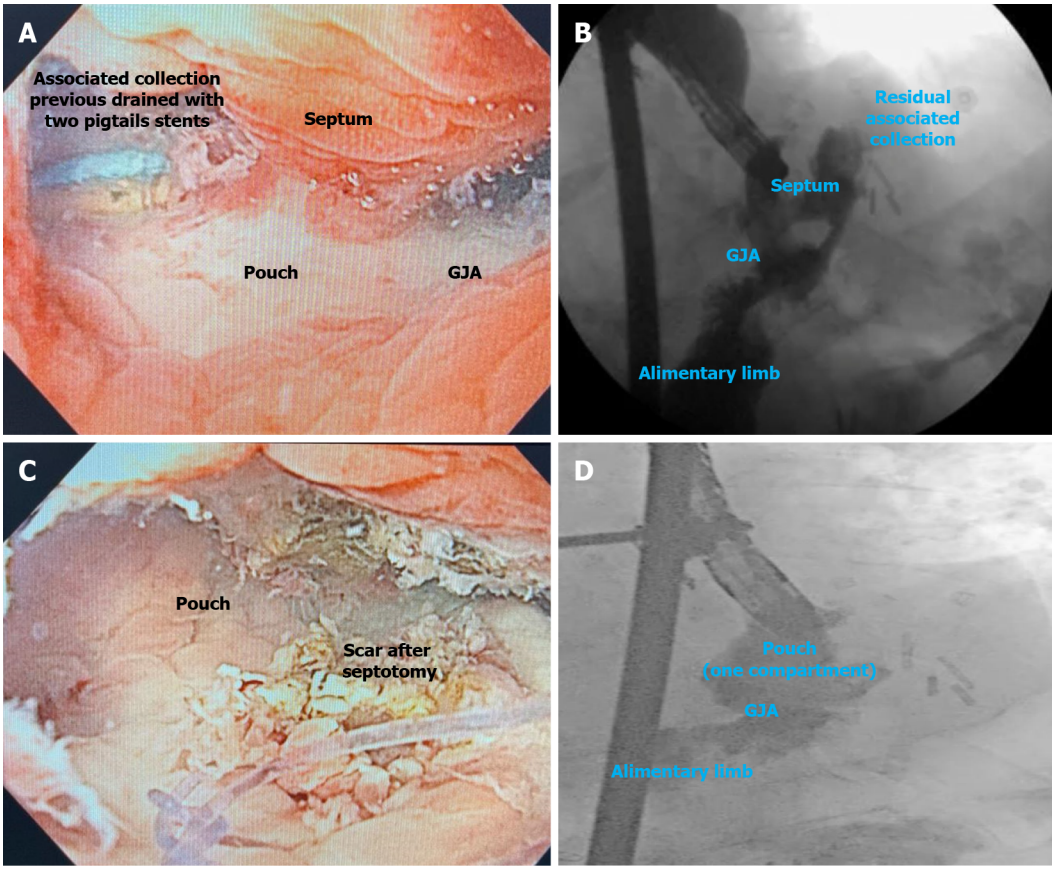
study, the mean number of EVT system exchanges was 6.47 with a mean interval of 4.39 d[68]. Despite the satisfactory results, there is a concern regarding patients' complaints due to the nasogastric tube and a possible prolonged hospital stay. Additionally, the risk of major bleeding related to the development of a fistula between the wound cavity and major blood vessels, including the aorta or its branches is a reported concern from some experts[4,69,70].

In our practice, the cost-effective modified EVT is the preferred approach due to its high efficacy, satisfactory patient acceptance, and safety benefit of avoiding sponge dislodgement and exchange related bleeding[71]. Based on our experience, the best indication for EVT is acute and early leaks with associated infected collections. In these cases, after clinical improvement and collection clearance associated with granulation tissue (Figure 9F), we do change the intracavitary EVT for EID with DPS allowing earlier hospital discharge or when the associated cavity is smaller than 3 cm, we change the intracavitary EVT for intraluminal EVT.



Endoscopic internal drainage with double pigtail stent

EID with DPS (Figure 10) is indicated for leaks and fistulas with associated fluid collections after BMS. The principle for internal drainage is based on the concept that when the pressure within the gastric lumen is lower than that of the perigastric collection, flow will be directed into the GI tract. Additionally, oral contents will preferentially flow through the gastric lumen.

For EID with DPS to be effective as a sole strategy, the following conditions should be absent: (1) Uncontained perigastric collections; (2) High intragastric pressure secondary to downstream stenosis; and (3) Existence of a gastropleural fistula. With drainage, the perigastric cavity, will typically contract until it is obliterated, resolving the leak. When evaluating the response to therapy, the ability to tolerate diet as well as a decrease in the size of the perigastric cavity are indicative of clinical success[72,73].

EID has been widely adopted, especially in Europe, with high clinical success rates for both acute and chronic leaks and fistulas and a low rate of AEs, allowing a shorter hospital stay.

The largest study evaluating EID with DPS for the treatment of complications after BMS included 617 patients, with a clinical success rate of 89.5% for leaks and 78.5%, for fistulas[74].

Figure 11 Septotomy. A: Septum between the associated collection and the leak orifice at the gastrojejunal anastomosis staple line after Roux-en-y gastric bypass surgery; B: Fluoroscopy showing a septum between the leak associated collection and the gastric pouch; C: Endoscopic image after septotomy; D: Fluoroscopy showing a gastric pouch without associated collections as the septotomy transformed the pouch and the associated collection in one compartment. GJA: Gastrojejunal anastomosis.

Placement of DPS is easy to learn (Figure 10A and B), demonstrated by high clinical success when performed by an endoscopist with (84.71%) or without (83.41%) experience in EID as demonstrated by a recent systematic review[72]. Additionally, it also presents satisfactory clinical success as a rescue therapy (78.05%)[72].

Defect closure is usually achieved after a long period of treatment. However, as most patients are not hospitalized, present no symptoms, receive oral diet, and return to their daily activities, the long treatment time is not considered an issue when compared to other techniques which are associated with symptoms related to the therapy, such as bariatric stents, or need for hospital stay, such as EVT[72].

AEs are reported in about 13.8% of patients, mostly due to stent migration, but also including perforation and bleeding[72].

In our experience, EID with DPS is the best approach for defects with associated collections in patients with no signs of sepsis. As most patients are not hospitalized, close follow-up is needed to avoid complications. Additionally, to minimize the risk of AEs related to the DPS, we prefer to use ureteral stents as they are more flexible and softer than biliary DPS, avoiding damage to tissue and vessels (Figure 10C and D)[75].

Septotomy

Septotomy (Figure 11) must be performed when a septum between the defect orifice/associated collection and the GI lumen is identified (Figure 11A and B). The principle of this therapy is similar to the Zenker´s diverticulotomy. The septum is sectioned to match the pressure of the leak or fistula orifice within the gastric chamber, providing better drainage (Figure 11C and D). The septotomy can be performed with endoscopic electrosurgical knives, through the scope scissors or argon plasma coagulation (APC), until the depth of the suture line without exceeding this limit (the cut must not extend beyond the base of the perigastric cavity) to avoid perforation[3,76]. It is important to state that in most cases, several sessions are needed.

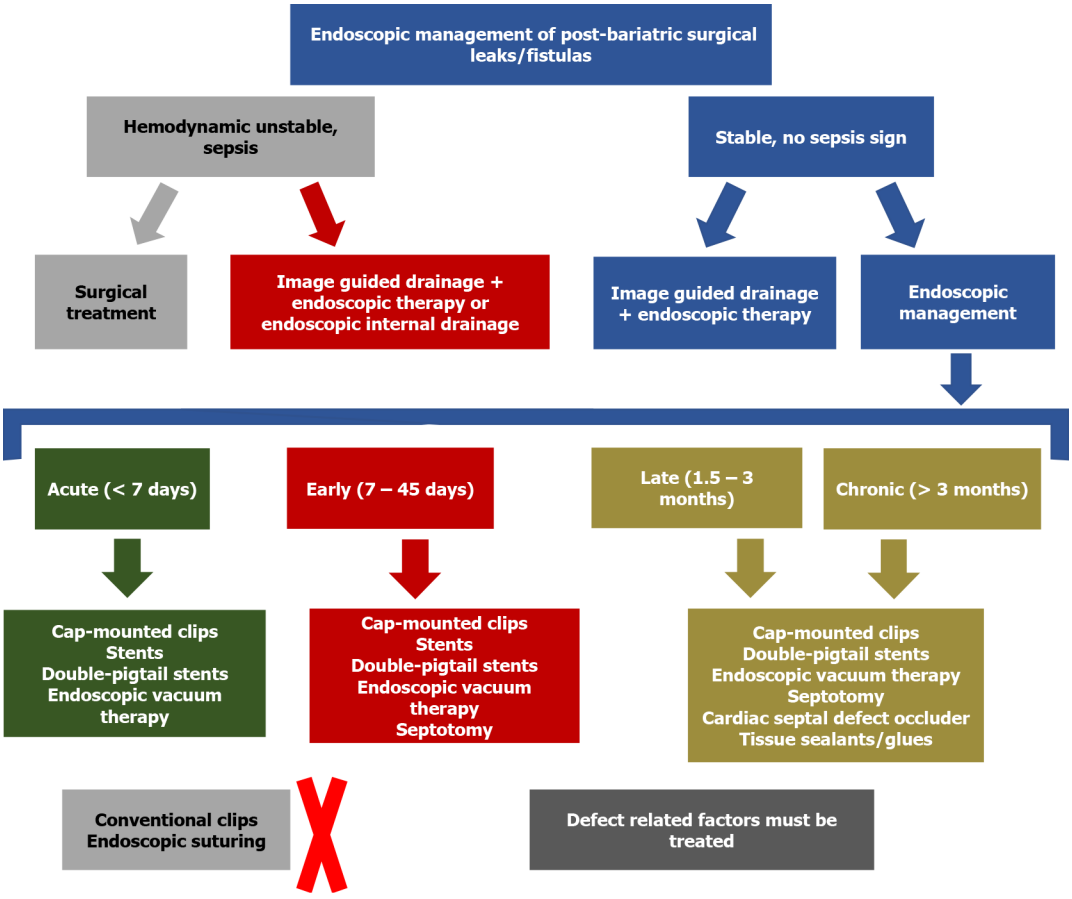
Septotomy is associated with high clinical success rates and with low AEs in expert hands. In a study involving 27 patients with leaks and fistulas after BMS, including RYGB, LSG, and duodenal switch, the clinical success rate after one to six septotomies was 100%, with an average treatment time of 18.11 d

Table 4 Suggested recommendations on management of post bariatric surgical leaks and fistulas

Leak or fistula characteristics + patient clinical condition	Recommended management (first line approach)	Possible therapy (second line approach)	Possible endoscopic therapies based on defect characteristics
Acute and early leaks with undrained uncontained collection in unstable patients	Surgical lavage + external drainage (surgical placement) ± surgical repair ± endoscopic therapy (see column 4)	Image-guided external drainage + endoscopic therapy (see column 4) OR Intracavitary EVT	Defect < 2 cm: Cap mounted clips OR stents OR intraluminal EVT; Defect > 2 cm: Stents OR intraluminal EVT; If a septum is diagnosed (early): Septotomy must be performed
Acute and early leaks with undrained uncontained collections in stable patients (rare condition as most patients with undrained uncontained collections presents with peritonitis/sepsis)	Image-guided external drainage + endoscopic therapy (see column 4)	Surgical lavage + external drainage (surgical placement) ± surgical repair ± endoscopic therapy (see column 4) OR Intracavitary EVT	Defect < 2 cm: Cap mounted clip OR stents (prefer stents if associated with downstream stenosis) OR intraluminal EVT; Defect > 2 cm: Stents OR intraluminal EVT; If a septum is diagnosed (early): Septotomy must be performed
Acute and early leaks with undrained contained collections (both unstable or stable patients - most of these patients are stable due to the contained collection)	Endoscopic drainage techniques: Intracavitary EVT OR EID with DPS; If a septum is identified, septotomy must be performed	Image-guided external drainage + endoscopic therapy (see column 4)	Defect < 2 cm: Cap mounted clips OR stents (prefer stents if associate with downstream stenosis) OR intraluminal EVT; Defect > 2 cm: Stents OR intraluminal EVT; If a septum is diagnosed (early): Septotomy must be performed
Late and chronic leaks (both unstable or stable patients - most of these patients are stable as uncontained collection are extremely rare in late and chronic leaks)	Endoscopic drainage techniques: EID with DPS OREVT (intracavitary if associated collection > 3 cm); If a septum is identified, septotomy must be performed	Image-guided external drainage + endoscopic therapy (see column 4) OR Surgical approach	Defect < 2 cm: Cap mounted clips OR CSDO OR tissue sealants/glues (as an adjunctive therapy); Defect > 2 cm: CSDO OR tissue sealants/glues (as an adjunctive therapy)
Late and chronic fistulas (both unstable or stable patients - most of these patients are stable)	Endoscopic therapy (see column 4); Cytology brushing or APC to loosen granulation tissue before endoscopic therapy is helpful; If a septum is identified, septotomy must be performed	Surgical approach	Defect < 2 cm: CSDO ± tissue sealants/glues OR tissue sealants/glues ± cap mounted clips OR tissue sealants/glues + intraluminal EVT; -Defect > 2 cm: CSDO ± tissue sealants/glues OR tissue sealants/glues + intraluminal EVT,
Late and chronic gastro-gastric fistula	Defect < 10 mm: Endoscopic therapy (see column 4); Defect > 10 mm: Surgical approach	Surgical approach after endoscopic management failure	APC ± CSDO ORAPC + suturing OR APC + cap mounted clip

APC: argon plasma coagulation; CSDO: Cardiac septal defect occluder; DPS: Double pigtail stents; EID: Endoscopic internal drainage; EVT: Endoscopic vacuum therapy.

[77]. Our experience reflects the results of this study. We do prefer to use APC as it is associated with a low rate of bleeding.



In our practice, the presence of a septum is the most common cause of late and chronic leaks and fistulas refractory to endoscopic treatment in non-specialized centers referred to our institution. Therefore, when treating a leak or fistula after BMS, attention to the presence of a septum and need for septotomy is required to achieve clinical success.

CHOOSING THE BEST APPROACH

Based on the pathophysiology of leaks and fistulas after BMS, the appropriate therapy should be individualized, considering the patient´s clinical condition, defect characteristics (size, chronicity, associated collections, and health of the surrounding tissue), device availability, cost, patient preference, mechanism of action of each endoscopic therapy, one's personal experience and comfort and local availability of experienced physicians. Although there is a paucity of high-quality studies to provide standardized treatment algorithms, we summarize our recommendations on the management of these challenging conditions in Table 4 and Figure 12 based on our large referral volume, and review of the available literature.

DISCUSSION

The management of post bariatric surgery complications is challenging as patients have obesity-mediated chronic pro-inflammatory state and are in a catabolic state related to weight loss. Additionally, most patients have comorbidities, such as T2DM, arterial hypertension, among others. The most feared complication is leak, as an infection in these patients can be life-threatening or severely

DOI: 10.3748/wjg.v29.i7.1173 **Copyright** ©The Author(s) 2023.

Figure 12 Suggested algorithm for the management of post bariatric surgical leaks and fistulas.

morbid, especially when early identification and management is not achieved. Although laboratory tests and imaging are important for diagnosis, patient clinical conditions must be the primary consideration. If a patient presents with tachycardia, fever, and intense abdominal pain, a surgical revision should not be postponed.

In cases of acute and early leaks associated with infection, there can be a need for admission to an intensive care unit and long-term hospital stay is often needed. Additionally, some patients cannot take an oral diet and there is a need for enteral nutrition or parenteral nutrition. Unfortunately, long-term inpatient related diseases such as pneumonia, deep venous thrombosis, healthcare-associated infections, and others, can affect these patients. Therefore, multidisciplinary care is required, including surgeons, endoscopists, radiologists, intensivists, infectious disease experts, nutrition experts, nurses, physiotherapists, and other specialists contributing to successful outcomes. Ideally, these patients should be treated in a tertiary referral center given the complexity and relative rarity of this disease state.

For late and chronic leaks and fistulas, almost all patients present in a stable condition, most of them need several procedures and longer treatment time to achieve defect closure. Despite the need for more sessions, as these patients are stable, they do not need to be hospitalized in most cases and can be discharged to attend subsequent elective endoscopic procedures while they carry on with their normal activities.

Endoscopy has evolved to become first line therapy for the treatment of post-bariatric leaks and fistulas, except in unstable patients with undrained, uncontained collections (peritonitis) where a surgical approach is preferred. There are several available endoscopic devices and techniques with different mechanisms of actions, including closing, covering, and draining therapies. When determining the appropriate endoscopic technique, fundamental principles must be considered, such as draining of associated collections and treatment of related factors such as dilation of downstream stenosis and foreign body removal. It is mandatory that endoscopists incorporating management of BMS complications into their clinical practice have expertise in several advanced therapeutic endoscopic techniques as well as knowledge in using fluoroscopy, managing percutaneous drains, and also understanding of post-surgical anatomy and pathophysiology concepts for origin and maintenance of leaks and fistulas. It is also important to understand that there is no gold standard approach for these patients and usually more than one endoscopic intervention is required, especially in a chronic scenario. Furthermore, combined therapies may be required for some patients to achieve clinical success.

CONCLUSION

In summary, a multidisciplinary team and individualized evaluation considering patient and defect characteristics, available resources, local and personal experience, and knowledge of fundamental principles and mechanisms of action of each technique is essential to choosing the best approach for the management of post-bariatric surgical leaks and fistulas. With a committed approach, high rates of leak and fistula closure can be achieved.

Abstract

Acute pancreatitis (AP) and chronic pancreatitis are the third leading gastrointestinal causes for admissions and readmissions to hospitals in the United States. This review of articles published between 2019-2022 (December) from international sources identified four categories of crucial new findings: The report includes (1) New genetic pathogenic mutations (*TRPV6*); expected genetic outcomes in a Northern European population; (2) a new serum diagnostic marker for AP-fatty acid ethyl esters-distinguishing acute pancreatitis associated with alcohol; explanations of the impact of monocytes/macrophages on the inflammatory process that defines their future in diagnosis, staging, and treatment; (3) innovations in timing of per os low-fat, solid food intake immediately on admission; resolution of concepts of aggressive parenteral fluid intake; dramatic shifts to nonoperative from operative treatment of infected pancreatic necrosis. Each modification reduced interventions, complications, and lengths-of-stay; and (4) authoritarian recommendations for medical treatment of chronic pain. These advances offer opportunities to initiate newly proven treatments to enhance outcomes, alter the natural history, and envision the future of two diseases that have no known cure.

Key Words: Genetics; New diagnostics; Macrophage regulation; New approaches to early feeding; Fluid management

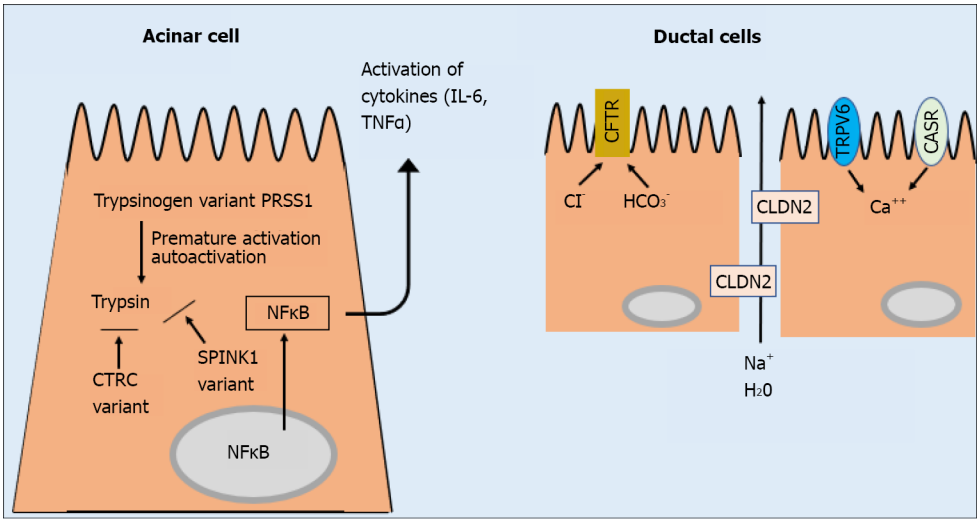
INTRODUCTION

Acute pancreatitis (AP) and chronic pancreatitis (CP) are two of the most common causes for gastrointestinal-related office visits and admissions to hospital[1-3]. AP and CP are multifactorial diseases in which the former may progress to the latter as chronic inflammation and autodigestion lead to fibrosis and atrophy. Information that improves understanding of the diseases is critical to advancing therapy. The objective of this review was to identify pivotal studies that directly impart usable information relative to pathophysiology, diagnosis, preventative and other treatments.



METHODS

The information in this review was obtained between 2019 through December 2022 from PubMed, Ovid, International Guidelines, expert opinion, and personal contact with experts. We looked specifically for well-designed, randomized, controlled original research, systematic reviews, meta-analyses, expert guidelines, and professional association guidelines addressing changes favorably affecting outcomes. Case reports, case series and others considered irrelevant to the study were excluded as were most articles outside the inclusive dates, although some were included for supporting information. Over 400 articles were reviewed for possible relevance, with primary selections based on new information considered important and usable for health care workers.

OBSERVATIONS AND DISCUSSION

Pathophysiology: Genetic risks and clinical characterization

The landmark discovery of mutations in the pancreatic digestive genes coding for trypsinogen (*PRSS1* and *PRSS2*[4] catalyzed a search for additional pathologic variants in pancreatic digestive genes. The search has been rewarded with the discovery of a sufficient number of genetic variants to permit a mechanistic classification suggesting their pathogenic effect[5-7]. These include genetic variants in: (1) The trypsin-dependent pathway, including *PRSS1*, *PRSS2*, *SPINK1*, and chymotrypsin C (*CTRC*) genes; (2) the ductal physiology pathway including the cystic fibrosis transmembrane conductance receptor (*CFTR*), *claudin* 2 (*CLDN2*), possibly the *calcium sensing receptor* (*CASR*); proposed, and offered on many testing panels, but still controversial), plus newly discovered variants in the calcium channel coding genes (*TRPV6*, not yet on most testing panels)[8]; and (3) the misfolding-dependent pathway including a distinct subset of *PRSS1* variants, carboxypeptidase A1 (*CPA1*), and rare variants of carboxyl ester lipase (*CEL*) (Figure 1). The *TRPV6* variants are important new additions to the ductal-pathway genes, which alter calcium concentration in ductal fluid. The *TRPV6* variant is identified in 4.3% of nonalcoholic CP patients in Japan and 2.0% in Europe, indicating a substantial global risk gene for CP. Most of the carriers were heterozygous for the variant, implicating the potent pathogenic effect of certain *TRVP6* variants (*i.e.*, haploinsufficiency). Furthermore, 20% with defective *TRPV6* variants were transheterozygous for *SPINK1* variants, an unusually high association[8,9]. More than half of the *TRPV6* variants cause subtle functional defects with loss-of-function for removing calcium from the ductal fluid, leading to increased ductal calcium concentrations. This discovery offers a possible novel target for therapeutic intervention since *TRPV6* expression is regulated by 1-alpha,25-dihydroxyvitamin D3, and partial correction of *TRPV6* dysfunction in heterozygous carriers might be feasible with vitamin D supplements[9]. Collateral laboratory studies demonstrate that much of the injury in acute and chronic

Figure 1 Diagrammatic depiction of fundamental events contributing to the complex molecular pathways resulting in pancreatitis. Although a unifying concept is not available for all events, recent literature has provided a clearer description of the complexity of pathologic events which is briefly summarized. A proposed first step is injury to cytoplasmic organelles from external stressors, including prolonged, high intake of ethanol and smoking. These injuries result in endoplasmic reticulum stress, mitochondrial depolarization, inadequate ATP production, vacuole accumulation, protein misfolding, and disordered autophagy leading to activation of trypsinogen and inflammatory pathways. Disruption of the normal pathways may be augmented by genetic mutations at key functional sites responsible for trypsinogen activation, trypsin inhibition, Ca^{++} concentrations, and $HCO3^-$ and H_2O movement[4-9,20,21]. CTRC: Chymotrypsin C; CFTR: Cystic fibrosis transmembrane conductance receptor; NF-Kb: Noncanonical nuclear factor-kappaB; TNF-α: Tumour necrosis factor alpha; IL: Interleukin.

pancreatitis evolves from alterations of acinar and ductal digestive function by these pancreatitis-susceptibility mutants, culminating in disruption of the protease-antiprotease interaction in the serine protease trypsinogen pathway within pancreatic acinar and ductal cells[5-9].

Recent studies by Lewis *et al*[10] provide clinical characterization of genetic risks for CP in a North American population of European ancestry. Patients with early-onset (< 35 years) idiopathic CP and no alcohol exposure had significantly more pathogenic variants in 49% of cases compared to no more than 26% in those with late-onset idiopathic CP or CP associated with light-to-moderate or heavy-to-very heavy drinking. Likewise, the early-onset group was significantly more likely to have pathogenic variants in *SPINK1* (24%) or *CFTR* (36%) than patients with late-onset idiopathic CP (9% and 15%) or CP associated with light-to-moderate drinking (7% and 19%) or heavy-to-very heavy drinking (9% and 13%). Evidence supporting pathogenicity of the mutants included a younger age of onset of symptoms in which the *SPINK1* mutation decreased the age at onset to 12 years from 24 years in early-onset idiopathic CP ($P = 0.004$) and to 24 years from 50 years in the light-to-moderate drinkers ($P < 0.001$). The *CFTR* mutation dropped the age at onset to 41 years from 50 years in the light-to-moderate drinkers ($P = 0.030$). Sixty-one cases of early-onset ICP were characterized by persons with an average age of 20 years, incessant pain, pancreatic calcifications, and genetic variants in the *SPINK1*, *CTRC*, or *CFTR* genes in almost half the cases. These collective findings reclassified as many as 23%-49% of cases of ICP to those with potential genetic causes.

CFTR was the most common gene with pathogenic variants in 13%-36%. It is important to recognize that interactions between incompletely penetrant genetic variants-including several working synergistically (*i.e.*, epistasis) and a pronounced exposure to alcohol, smoking, or other toxins are frequently involved in the final pathways leading to acute and chronic pancreatitis. More often than not, multiple factors are responsible. The pathologic progression then gradually leads to well-recognized complications of chronic inflammation with fibrosis, ductular calcifications, pain, steatorrhea, insulin insufficiency, fluid collections, disability, and premature death.

Along with appropriate counseling, testing for the six (or seven including the newly described *TRPV6* variants) commercially evaluable genetic causes of acute and chronic pancreatitis is recommended in cases that have age of onset < 35 years, relapsing pancreatitis, or are idiopathic. The results offer valuable information regarding diagnostic probability of a genetic predisposition, a prediction as to probable cofactors, how to initiate available treatment as early in the process as possible, and do not require repetitive testing. Persons who have extensive comorbidities or are elderly may not benefit from genetic investigation.

Acute pancreatitis: New tools for diagnosis

AP, a disease with a variety of etiologies and risk factors is diagnosed by blood levels of amylase and lipase, abdominal pain, and imaging abnormalities of the pancreas[11-13]. A new diagnostic test has produced intriguing results. Vela and colleagues conducted a prospective, blinded trial comparing

blood levels of fatty acid ethyl esters (FAEEs), nonesterified fatty acids, and ethanol in 175 patients at the time of hospitalization with alcoholic pancreatitis, alcoholic intoxication, nonalcoholic pancreatitis, and normal controls[14]. Distinguishing differences were that median FAEEs were similarly elevated in alcoholic pancreatitis (103 nmol/L) and alcoholic intoxication (205 nmol/L), whereas there was no significant elevation in nonalcoholic causes of AP (8 nmol/L) or controls (1.7 nmol/L). By its unique ability to demonstrate diagnostic elevations of FAEEs in association with alcohol intake, this test could become an efficient tool for identifying alcohol as the cause in alcohol-associated pancreatitis when present and eliminating alcohol as the culprit when caused by other factors. That alcohol intoxication without AP raises the level of FAEEs is explained by a well-known effect of excessive ethanol ingestion on cell membranes. The study did not distinguish between AP and alcohol-induced AP superimposed on CP, although the latter would be suspected in most of the latter cases.

In a similar vein, Manohar *et al*[15] have presented data defining the complex role of immune responses in monocytes and macrophages using single-cell mass Cytometry by Time Of Flight in two experimental models and in patients with acute, recurrent, and severe AP. As inflammatory cells determine disease severity and pancreatic damage is increased by tissue-derived neutrophils, macrophages are the predominant immune cell in the early phases of AP. Their report explains the role of the immune response in AP, provides insight toward the biological significance of novel Ly6Gc+/CD206+ monocytes and macrophages, and shows how these cellular components may be used to diagnose AP, define its severity, and target potential treatment[15,16].

Chronic pancreatitis: Alcohol and smoking

CP is diagnosed by imaging scans showing glandular atrophy, ductal distortion, and calcifications, or by biopsy demonstrating widespread fibrosis, and is, like AP, characterized by a variety of similar etiologies and risk factors, excepting gallstones and medications[2,3,13]. The relationship of ethanol and smoking to CP is indisputable. Both the amount and duration of exposure matter, and the exposures may vary with time and gender. A contemporary analysis of daily ethanol consumption in persons with alcoholic CP revealed a median of 5.1 drinks/d, in which 12.0 g/drink = 61.5 g/d of ethanol[17]. Consumption of up to 110-277 g/d over 5-25 years may transpire by the time of diagnosis of alcoholic CP[2,3,17-19]. A lower intake of < 50 g/d is implicated where the disease progresses more slowly, and persons are older at the time of diagnosis with less pain and fewer complications[10]. Evidence substantiating the role of ethanol and tobacco intake in perpetuating the fibro-inflammatory phase is exemplified by unabated progression even if ethanol and tobacco intake are discontinued, although at a slower pace when compared with continued usage of both[2,3,10], implicating ethanol and tobacco activating subclinical pancreatic stellate cell fibrosis for years before becoming clinically apparent[19-21].

Recently, models ranging from necroptosis to pyroptosis show how a pathogenic metabolic pathway can provoke inflammation, often initiated by premature intrapancreatic activation of trypsinogen, and be perpetuated by synergy between genetic, epigenetic, immune and environmental factors[5-9] as clinical and post-mortem studies of chronic alcoholics without a sentinel AP event show pathologically recognizable CP in the form of fibrosis and/or ductal calcifications in 47%-68%, indicating extensive damage present before diagnosis[19,22,23].

NEW TREATMENTS

Early feedings in acute pancreatitis

Initiating early feeding per os or *via* nasogastric/nasojejunal routes beginning after the onset of AP is supported by multiple randomized controlled trials and has replaced prior practices of resting the gastrointestinal tract until pain subsides. This approach increases bowel motility and reduces rates of organ failure, infection, length of stay and mortality, substantiating the suspicion that an idle intestine leads to bacterial overgrowth, increased permeability and bacterial translocation[2,3,11,24]. Questions regarding preferred timing had remained but new results from a randomized controlled trial of 131 patients with mild-moderate AP provide clarity. The study compared those fed a low-fat, solid diet immediately upon decision for admission, regardless of symptoms or laboratory parameters, to those receiving conventional feeding with progressive diet as clinical and laboratory parameters improved. The results indicate that immediate feeding is safe and feasible with significantly decreased complications (4.2% *vs* 18.3%) and shorter length of stay (3.4 d *vs* 8.8 d) at one-half the costs[25].

Fluid resuscitation in acute pancreatitis

A major question addressing the appropriateness of early, aggressive hydration was just answered in an important multicenter, randomized, controlled trial from India, Italy, Mexico, and Spain that assessed the efficacy and safety of aggressive fluid resuscitation as compared with moderate resuscitation using lactated Ringer's solution in patients with AP; patients with moderate to severe disease or heart failure at baseline were excluded[26]. The primary outcome was the development of moderately severe or severe acute pancreatitis and secondary outcomes included organ failure and local complications

occurring after randomization and during the hospitalization. The aggressive-group received a bolus of 20 mL/kg body weight over 2 h, followed by an infusion rate of 3 mL/kg/h, and the moderate-group a dose of 1.5 mL/kg/h, with a bolus of 10 mL/kg/h if hypovolemic. Oral feeding was started at 12 h if the intensity of abdominal pain permitted. The first interim analysis included 249 of the planned sample size of 744 patients and uncovered significant fluid overload in the aggressive-resuscitation group at 20.5% *vs* 6.3% (P = 0.004), and the trial was stopped[26]. Significant differences were not reached for the primary or secondary endpoints, although the results tended to favor the moderate resuscitation group. An editorial analysis concluded that the trial results were stunning and irrefutable and that clinicians should follow an infusion rate of the moderate group with careful monitoring of volemic status, adding fluid if underhydrated or diuresis if overhydrated[27].

Pancreatic fluid collections

New data have created a decisive shift in treatment of infected necrotizing pancreatitis, in which antibiotics without drainage are replacing the long-held concept of antibiotics and immediate drainage of infection developing after AP[28]. The crucial substantiation came from a randomized, superiority trial in the Netherlands that compared immediate drainage of infected necrotizing pancreatitis *vs* postponement of drainage in patients with infected tissue occurring within 35 d from onset of initial symptoms of AP. Infection was documented by gram stain, culture, or clinical deterioration and both groups received antibiotics. The Dutch study enrolled 104 qualifying patients; complications and mortality were similar for both groups. However, the mean number of interventions was 4.4 for the immediately drained group compared to only 2.6 (40% less) for the deferred group; 37% (19/52) of patients in the deferred group did not require drainage, and the number of hospital days was shorter by 15% (51 d *vs* 59 d). The rationale for the study had been supported by retrospective studies that showed apparent safety in postponing intervention with drainage, although none have demonstrated superiority[28-30].

Current concepts for pain management in chronic pancreatitis

Pain affects most persons with CP and is the most significant obstacle to successful treatment.

Pain is the major cause of morbidity, disability, and impaired quality of life. Pain syndromes are complex, widely variable and range from severe and chronic to absent[31,32]. An up-to-date study of pain patterns in 1131 persons in 30 Dutch hospitals revealed continuous pain in 52%, intermittent pain in 20%, and no pain in 28%[33]. Patients with continuous pattern had more severe pain, used more opioids and neuropathic medications, and had lower quality of life.

Current concepts emphasize that pain may arise from origins other than the pancreas. Persistent, severe pain can transfer centrally in association with cerebral cortical thinning, central sensitization, central pain processing, or other neuropathology, and becomes less likely to respond to conventional measures. Pancreatic quantitative sensory testing that interrogates nociception and sensory response could help unmask irreversible central neuropathic changes that make interventional treatment of pancreatic pain less likely to be successful. During the course of disease, pain severity may increase or decrease as disease progresses over 10-25 years[31-33]. The initial treatment of choice for those who drink and/or smoke is complete abstinence to reduce the pain, prevent further episodes of AP, forestall progressive damage to the pancreas and lessen cancer risk to the pancreas and other organs[2,3,18,19,28-32]. Early diagnosis of the cause represents the first chance to initiate treatment to retard the progress of a disease that no one can cure. In cases of mild or intermittent pain, non-narcotic oral analgesics including NSAIDS, acetaminophen, tricyclic antidepressants, mirtazapine, and cognitive behavioral therapy may be helpful. Treatment with antioxidants may produce a small improvement, but pancreatic enzyme supplementation does not. Opioids are not recommended, due to their frequent and rising association with addiction and hyperalgesia, but may be considered after other reasonable options are exhausted[2,3,31-34].

In recognition that the longer pain is present, the more difficult it is to treat, a recent randomized surgical study of 88 patients (ESCAPE trial) compared early pancreatic ductal drainage by surgery for those with strong to weak pain of less than 2-6 mo *vs* conventional medical and endoscopic treatment. The initial results indicated a lower pain score in the surgical group of 37 *vs* 49 (P = 0.02)[35], similar to data from Cahen[35]. Additional endoscopic and surgical approaches have been addressed[36-41] but are beyond the scope of this review.

CONCLUSION

This narrative review captures the highlights of a number of significant articles published between January 2019 and December 2022 bearing new concepts in pathophysiology, diagnosis, and treatment of AP and CP. The major findings include clinical identification and application of new genetic information, newly identified serum biomarkers-FAEEs, for diagnosis of alcohol-related AP, novel concepts regarding monocyte/macrophage participation in the immune reaction, important acceleration in timing of early per os feedings in AP, answers to major questions concerning the appropriateness of

early, aggressive parenteral hydration, decisive shifts in non-operative management of infected pancreatic fluid, and updated, expert approaches to medical management of pain in CP. These advances are evaluated in the context of enhancing outcomes for these two acute and chronic inflammatory diseases.

Abstract

BACKGROUND

Helicobacter pylori and the stomach microbiome play a crucial role in gastric carcinogenesis, and detailed characterization of the microbiome is necessary for a better understanding of the pathophysiology of the disease. There are two common modalities for microbiome analysis: DNA (16S rRNA gene) and RNA (16S rRNA transcript) sequencing. The implications from the use of one or another sequencing approach on the characterization and comparability of the mucosal microbiome in gastric cancer (GC) are poorly studied.

AIM

To characterize the microbiota of GC using 16S rRNA gene and its transcript and determine difference in the bacterial composition.

METHODS

In this study, 316 DNA and RNA samples extracted from 105 individual stomach biopsies were included. The study cohort consisted of 29 healthy control individuals and 76 patients with GC. Gastric tissue biopsy samples were collected from damaged mucosa and healthy mucosa at least 5 cm from the tumor tissue. From the controls, healthy stomach mucosa biopsies were collected. From all biopsies RNA and DNA were extracted. RNA was reverse transcribed into cDNA. V1-V2 region of bacterial 16S rRNA gene from all samples were amplified and sequenced on an Illumina MiSeq platform. Bray-Curtis algorithm was used to

construct sample-similarity matrices abundances of taxonomic ranks in each sample type. For significant differences between groups permutational multivariate analysis of variance and Mann-Whitney test followed by false-discovery rate test were used.

RESULTS

Microbial analysis revealed that only a portion of phylotypes (18%-30%) overlapped between microbial profiles obtained from DNA and RNA samples. Detailed analysis revealed differences between GC and controls depending on the chosen modality, identifying 17 genera at the DNA level and 27 genera at the RNA level. Ten of those bacteria were found to be different from the control group at both levels. The key taxa showed congruent results in various tests used; however, differences in 7 bacteria taxa were found uniquely only at the DNA level, and 17 uniquely only at the RNA level. Furthermore, RNA sequencing was more sensitive for detecting differences in bacterial richness, as well as differences in the relative abundance of *Reyranella* and *Sediminibacterium* according to the type of GC. In each study group (control, tumor, and tumor adjacent) were found differences between DNA and RNA bacterial profiles.

CONCLUSION

Comprehensive microbial study provides evidence for the effect of choice of sequencing modality on the microbiota profile, as well as on the identified differences between case and control.

Key Words: Gastric cancer; Microbiome; *Helicobacter pylori*; 16S rRNA gene; 16S rRNA transcript; 16S rDNA

Core Tip: In this study, we aimed to characterize the microbiota of gastric cancer (GC) on two levels: 16S rRNA gene and its transcript. Our study showed that only a small portion of bacterial sequences overlapped using those two approaches. Moreover, our study revealed that obtained results comparing the case group with the controls depend on the chosen modality. We also showed that *Reyranella* and *Sediminibacterium* was associated with the Lauren classification and RNA level was more sensitive to detect low abundant bacteria. This study provides novel insights into microbiome study as well as new founding related to complex GC pathogenesis.

INTRODUCTION

Microbiota analyses are becoming increasingly relevant in scientific and clinical studies. Most modern microbiome studies use 16S rRNA gene sequence analysis at the DNA level, thereby enabling the identification of bacteria at all stages of their existence (active, dead, and inactive bacteria in the form of endospores) simultaneously. However, some of the more recent studies use RNA samples, which are subsequently reverse transcribed into cDNA for sequencing, giving us knowledge about the metabolic state of the microbial community[1]. RNA has a shorter half-life than DNA and turns over in cells more rapidly, providing a deeper look at bacterial activity[2].

The stomach has long been considered an almost sterile organ due to its acidic environment and enzymatic effects[3]. Since its identification, it is known that *Helicobacter pylori* (*H. pylori*) is perfectly adapted not only to survive in the acidic environment of the stomach, but also to colonize this part of the gastrointestinal tract[4]. *H. pylori* is the major cause of peptic ulcer disease and the most significant risk factor for gastric cancer (GC). GC remains one of the most common cancers in the world and the fourth leading cause of cancer-related death[5]. However, only a minority of people infected with *H. pylori* develop GC, which may be linked to non-*H. pylori* microbiota-associated alterations in the stomach[6]. Studies in insulin-gastrin (INS-GAS) mice and in humans indicated the importance of other members of the stomach bacterial community in the development of gastric carcinogenesis[7-10].

There is only one study that has compared DNA and RNA profiles of the stomach microbiota[11]. However, the profiles of the active and standing microbiota in GC have not been studied. In this study,

we systematically characterized the microbiota of GC on both levels using the 16S rRNA gene (DNA level) and its transcript (RNA level). GC tumor and tumor adjacent tissue samples, as well as healthy mucosa samples from the young control group, were used for the comparison. We obtained detailed data on bacterial composition within groups depending on study modality (DNA or RNA) and performed association analysis with clinical characteristics to question the potential impact of approach on the outcome.

MATERIALS AND METHODS

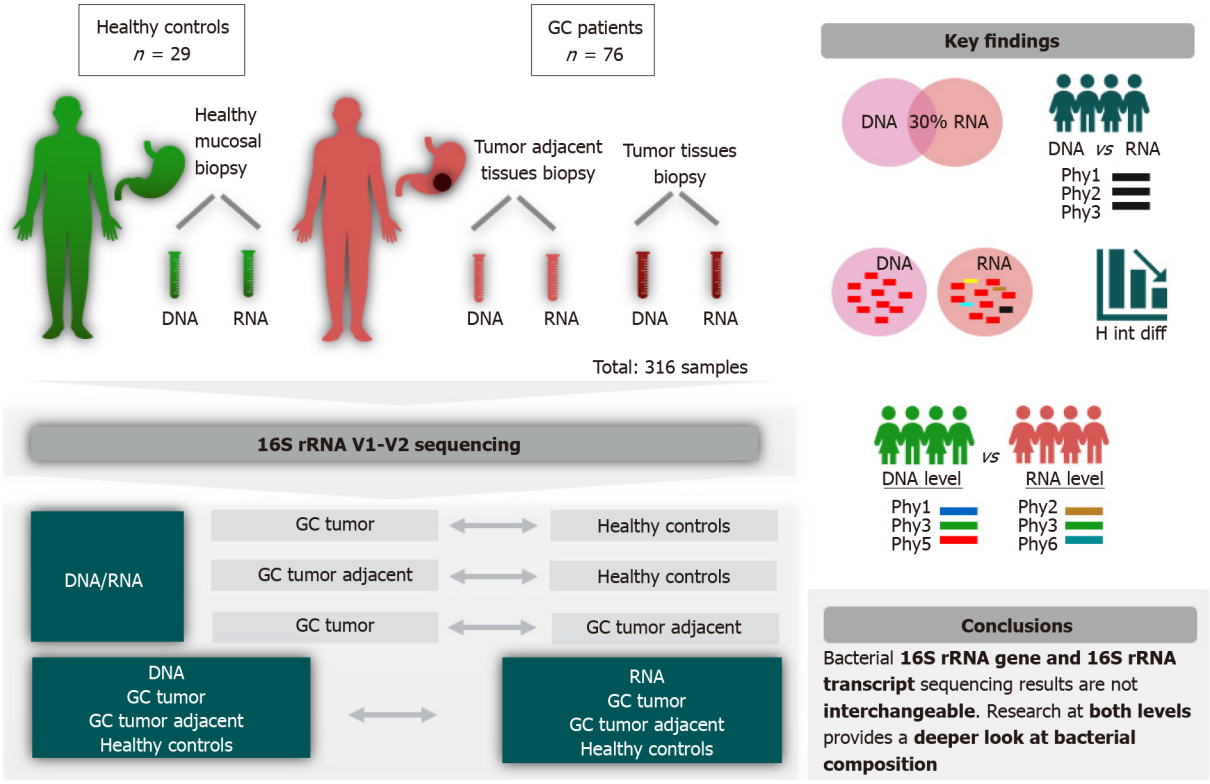
Study cohort

In total, 316 DNA and RNA samples from a group of 105 individuals were included in the study (Figure 1). The study cohort consisted of 29 healthy control individuals and 76 patients with GC. Participants did not report any antibiotic intake at least a month before endoscopy. Gastric tissue biopsy samples from damaged mucosa and healthy mucosa at least 5 cm from the tumor tissue were collected from GC patients using single-bite biopsy forceps. From the controls, healthy stomach mucosa biopsies were collected. Tissue samples were placed in sterile cryotubes (Thermo Fisher Scientific, United States), snap-frozen in liquid nitrogen, and stored at -86 °C until further study. Clinical data obtained from histological examination, such as tumor size, number of lymph nodes damaged by tumor cells, presence of metastases (TNM classification), cell differentiation (grading), type of GC (Lauren classification) and stage of GC, were included in the analysis. An overview of the demographic and clinical characteristics of the study cohort is given in Supplementary Table 1.

Study individuals were recruited at the Department of Gastroenterology at the Hospital of Lithuanian University of Health Sciences Kaunas Clinics during the years 2012-2018. This study was approved by the local ethics committee (BE-2-10), and all participants gave their written informed consent.

DNA, RNA extraction, cDNA synthesis and amplicon library preparation

Total DNA and RNA were extracted from gastric biopsy samples using an AllPrep DNA/RNA Mini kit (Qiagen, Germany) according to the manufacturer's recommendations. RNA was reverse transcribed into cDNA using the Superscript IV First-Strand Synthesis System Purification Kit (Invitrogen, Carlsbad, CA) and random hexamer primers, following the manufacturer's instructions. Amplicon libraries were generated as described previously[12,13]. The bacterial 16S rRNA gene V1-V2 region was amplified using the 27F and 338R polymerase chain reaction primers and sequenced on a MiSeq (2 × 250 bp; Illumina, Hayward, CA).



Bioinformatic and statistical analysis

Bioinformatic processing was performed as described previously[14]. FastQ files were analyzed using the dada 2 package[15], version 1.10.1, in R. In total, 7735281 paired-end reads were received, with an average of 22953 per sample. Samples that did not reach 5000 reads were discarded from the analysis (21 samples out of initial 337). All samples were rarefied to an equal sequencing depth of 5047 reads using the phyloseq package[16], with returning 10496 phylotypes (Supplementary Table 2). Phylotypes were annotated to a taxonomic affiliation based on the naive Bayesian classification[17] with a pseudo-bootstrap threshold of 80%. The relative abundances (expressed as percentages) of different microbial communities' phylogenetic ranks (from phylum to class, order, family, genus and phylotype) were used for downstream analyses.

The phylogenetic tree was built using the online tool iTOL[18], after hierarchical clustering using the Bray-Curtis algorithm[19] at the phylotype level in Past 3[20]. Bacterial richness and Shannon diversity indices were calculated using the vegan[21] package from R. The data matrices comprising the percentage of abundances of each of the abovementioned taxa were used to construct sample-similarity matrices by the Bray-Curtis algorithm, where samples were ordinated by principal coordinate analysis (PCoA) at the phylotype level using the patchwork[22] package from R.

Differences in relative abundance of detected bacteria (at all taxonomic ranks) between study groups were evaluated by PERMANOVA and ANOSIM statistical tests, using 9999 permutations. Groups were considered significantly different if the P value was < 0.05, considering an estimate effect-size F values for PERMANOVA and R values for ANOSIM tests. Calculation was made by Past 3 program. The distributions of taxa abundance values were compared by Mann-Whitney test followed by Benjamini-Hochberg correction for multiple comparisons, named as false discovery rate value. Differences were considered significant when the corrected p value (q value) was < 0.05.

The bacterial networks were visualized using Cytoscape 3.8.0[23], after the Spearman correlation test performed with the psych[24] package from R, with threshold of 0.2 in absolute value and P value < 0.05. Phylotypes that accounted for at least 1% of the total number of phylotypes and at least 10% of the samples in each group were used for correlation analysis.

Figure 1 Study design illustration. GC: Gastric cancer.

RESULTS

General cohort

The bacterial contents of 180 biopsy samples taken from 105 individuals were characterized as described above (Supplementary Table 1). After sequencing and rarefying library size to the minimum sequencing depth, 10496 different phylotypes belonging to 23 phyla, 40 classes, 82 orders, 169 families, and 463 genera were retrieved and taxonomically annotated.

The global bacterial profiles were grouped into two clusters based on their Bray-Curtis similarities as percentages (Figure 2A). Analyzing all samples together, the main factor for clustering was bacterial heterogeneity. The first cluster consisted of samples with a more heterogeneous microbiome profile, where the most abundant bacteria accounted for less than 30%. All control samples (except T10_2) were located in this cluster. The second cluster - where the most abundant bacteria accounted for more than 30% of GC patient samples - was shaped by the most abundant bacteria *Helicobacter*, the abundance of which reached 98%-100% in some samples (Figure 2A, Supplementary Table 2).

Distinct profile of the gastric tissue microbiome at the RNA and DNA levels

Further PERMANOVA and ANOSIM analyses showed that DNA and RNA groups of the same study individuals were significantly different in all taxonomic ranks (Figures 3A-C; Supplementary Table 3). Differences between DNA and RNA samples were noticeable even at the phylum level. Although *Firmicutes*, *Bacteroidetes*, *Actinobacteria*, *Proteobacteria*, and *Fusobacteria* were the main bacterial phyla in all groups, *Bacteroides* and *Fusobacteria* were significantly more abundant at the DNA level. However, in the control group, *Firmicutes* and *Proteobacteria* were more abundant at the RNA level. Bacterial profile analysis indicated that only a portion of phylotypes (18%-30%) were common between bacterial profiles obtained from DNA and RNA samples (Figure 3D). PCoA supported the distinction of bacterial communities at the DNA and RNA levels, especially in the control group (Figure 3E). *Firmicutes*, *Bacteroidetes*, *Proteobacteria*, and *Fusobacteria* were major phyla determinants for sample differentiation.

More detailed analysis revealed that DNA and RNA samples differed from each other by 12, 10, and 30 phylotypes and by 18, 17, and 35 genera in the tumor, tumor adjacent, and control groups, respectively (Table 1, Supplementary Table 4). In all study groups, bacteria such as *Neisseria*, *Peptostreptococcus*, *Prevotella*, *Veillonella*, and *Oribacterium* were significantly more abundant at the DNA level, while *Staphylococcus*, *Methyloversatilis*, *Pseudomonas*, *Reyranella*, *Corynebacterium*, and *Sediminibacterium* were significantly enriched at the RNA level. Interestingly, most of these bacteria founded in the RNA samples were not observed in the DNA samples at all, or their relative abundance was low. Some

changes in the relative abundance of bacteria between DNA and RNA samples were specific for the study group. For instance, in the control group, *Helicobacter*, *Gemella*, and *Streptococcus* were enriched at the RNA level, while *Actinomyces* and *Alloprevotella* were enriched at the DNA level. In the GC groups (tumor and tumor adjacent), *Fusobacterium*, *Granulicatella*, *Solobacterium*, and *Porphyromonas* were enriched at the DNA level. No bacteria were enriched at the RNA level in this group.

Nevertheless, despite the found differences between DNA and RNA, samples of the same origin tended to cluster together in each of the study groups (Figure 2). Paired samples, 46 pairs out of 64 (72%) in the tumor group and 38 pairs out of 58 (66%) in the tumor adjacent tissue group, clustered next to each other, indicating their global similarity (Supplementary Figure 1). Paired samples from the control group were not added to this analysis due to the small number of paired samples.

Revealed microbiome alterations in GC depend on the chosen sequencing modality

The GC samples had lower bacterial richness and diversity compared to control samples (Figures 3F and 3G). While differences in diversity were found both at the DNA and RNA levels, differences in bacterial richness were found only at the RNA level. Group-average agglomerative hierarchical clustering analysis showed that it was possible to distinguish patients with GC from controls by their bacterial profile, as samples tended to cluster based on clinical status (both at the DNA and RNA levels) (Figures 2B and 2C). These results were supported by the phylogenetic analysis of global stomach bacteria, which revealed significant differences between the GC group and control groups at all taxonomic ranks (Figures 3A-C, Supplementary Table 3).

Bacterial abundance differential analysis revealed 15 phylotypes and 17 genera that differed between the GC and control groups at the DNA level (Table 2, Supplementary Figure 2, Supplementary Table 4). Meanwhile, at the RNA level, there were twice as many differences: 40 at the phylotype level and 27 at the genus level. Half of the differences detected at the DNA level were also found at the RNA level (58%

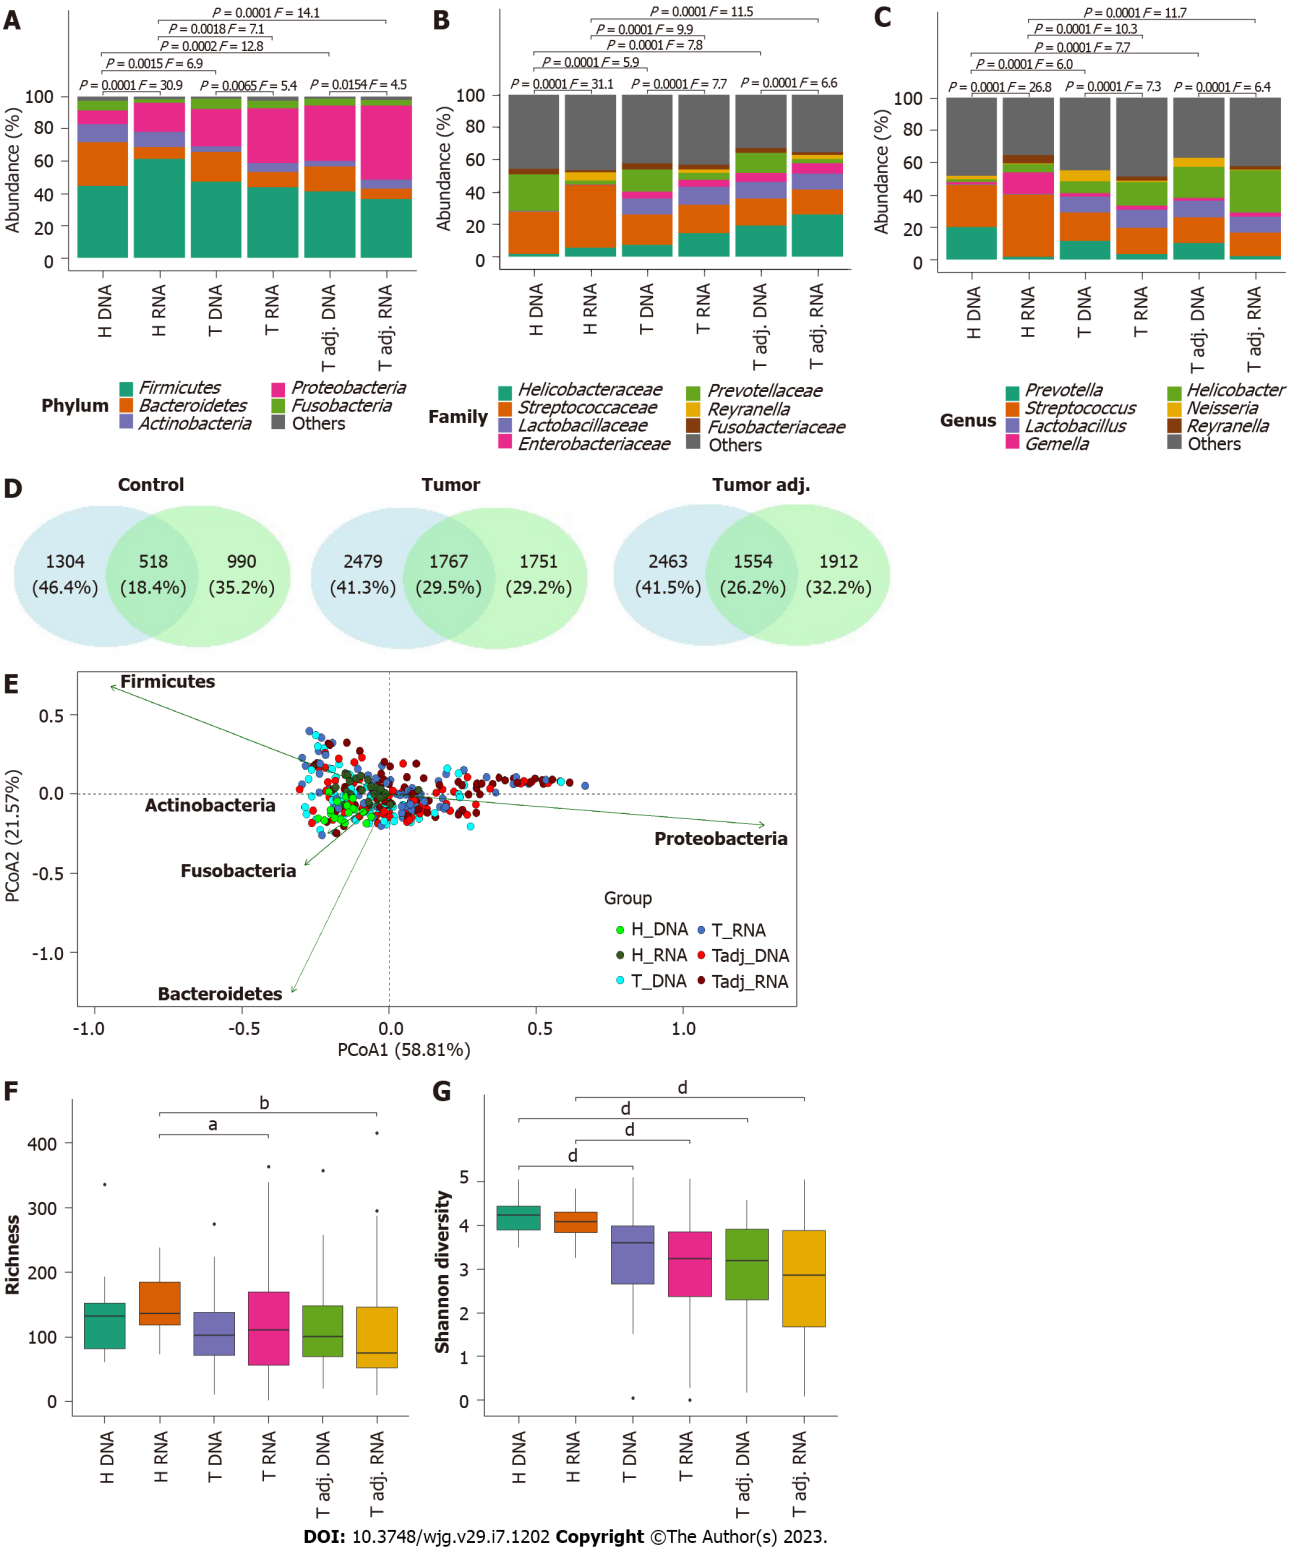
of genera and 46% of phylotypes). These bacteria include previously described bacteria, such as *Lactobacillus, Propionibacterium, Streptococcus,* and *Veillonella,* among others[25-29].

Although fewer unique bacteria were identified only at the DNA level (8 phylotypes and 7 genera), they were more studied and more frequently discussed in the literature as being associated with various human health conditions (Supplementary Table 4). These bacteria include *Campylobacter*, *Clostridium sensu stricto*, *Prevotella*, and *Saccharibacteria,* among others. Of the listed bacteria, *Clostridium sensu stricto* was enriched, and others were decreased in GC patients. Uniquely, only at the RNA level were 33 and 17 differences at the phylotype and genus levels, respectively, found between the GC and control groups (Supplementary Table 4). Essentially, this group included such bacteria that were not established or their abundance at the DNA level was negligible, for example, *Limnohabitans*, *Methylobacterium*, *Methyloversatilis*, *Pseudomonas*, *Reyranella*, *Rhodoluna*, *Sediminibacterium*, and *Staphylococcus*. Of the listed bacteria, only *Pseudomonas* and *Staphylococcus* were more abundant in GC samples, while all the others were more abundant in healthy individuals.

Bacterial diversity and profile comparison analysis between tumor and tumor adjacent tissues did not reveal significant differences at either the DNA or RNA level (Figures 3A-C, 3F and 3G). Moreover, assemblages of approach from each individual typically clustered together irrespective of tissue type (tumor or tumor adjacent tissue) (Figure 2A).



Bacterial networks in GC patients have fewer components and integrated connections

Analysis of the bacterial network similarity revealed that the main network holding bacteria with the highest betweenness centrality score was different between DNA and RNA levels in all study groups (Supplementary Figure 3). In the bacterial network of the control group at the DNA level, phylotypes depending on the *Streptococcus, Prevotella,* and *Actinomyces* genera accounted for 68% (58 out of 85) of the total number of bacteria and formed the core network keeping bacteria, while at the RNA level, core bacteria were *Streptococcus* and *Gemella*, making up to 62% (47 out of 75) (Supplementary Figures 3A and 3B). The GC groups showed different DNA/RNA networks as well: The main network forming bacteria in the tumor adjacent tissue at the DNA level was *Prevotella*, *Gemella*, and *Granulicatella*, while the RNA network was shaped by *Streptococcus, Reyranella,* and *Fusobacterium* (Supplementary Figures 3C and 3D). The most critical network-forming bacteria in tumor tissue were: *Granulicatella*, *Veillonella*, and *Neisseria* at the DNA level and *Reyranella*, *Acinetobacter*, and *Prevotellaceae* at the RNA level (

Supplementary Figures 3E and 3F).

Two common bacterial clusters (one at the DNA level and another at the RNA level) with strong positive correlations for tumor and tumor adjacent tissues were discovered (Supplementary Figures 3C-F), which confirms the absence of significant differences between tumor and tumor adjacent tissue microbiome profiles. At the DNA level, the common cluster consisted of Phy6 (*Neisseria*), Phy15 (unclas-

sified *Prevotellaceae*), Phy23 (*Neisseria perflava*), Phy29 (*Prevotella melaninogenica*), Phy87 (*Solobacterium*), and Phy98 (*Prevotella*). The common cluster at the RNA level included phylotypes such as Phy7 (*Reyranella*), Phy33 (*Sediminibacterium*), Phy46 (*Propionibacterium acnes*), Phy94 (*Methyloversatilis*), Phy107 (*Pseudomonas aeruginosa*), and Phy108 (*Sphingomonas echinoides*). Detected clusters were not found in the control group.

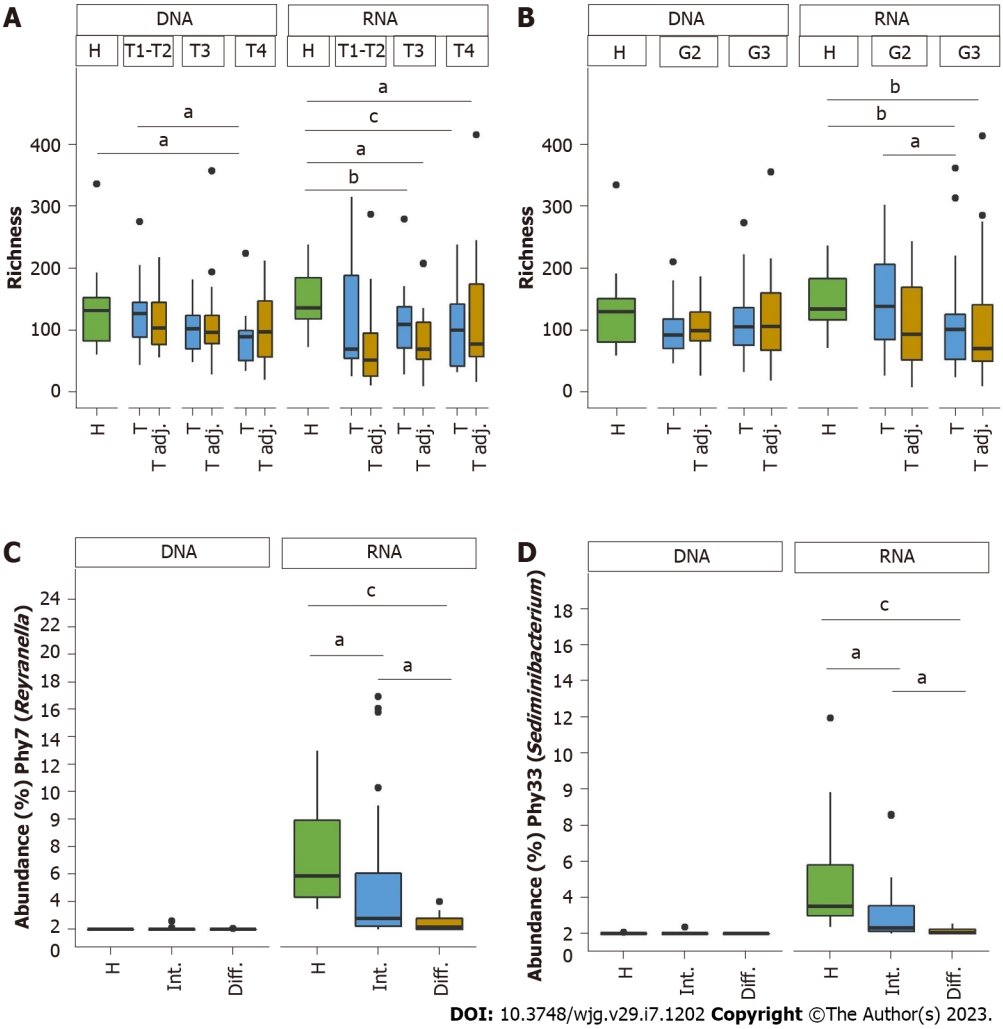
Generally, under the same analysis conditions, GC patients displayed a simpler bacterial network at both the DNA and RNA levels. At the DNA level, control, the tumor, and tumor adjacent groups had 85, 25, and 23 bacteria, respectively; at the RNA level, they had 75, 21, and 18, respectively. Moreover, analysis of bacterial interactions in controls had not only positive but also negative correlations, while GC analysis showed mostly positive correlations.

GC microbiota alterations and clinical parameters

At the DNA level, according to clinical parameters, statistically significant differences were found only in the decrease in bacterial richness between smaller tumors (T1-T2) and extended tumors (T4). The RNA level turned out to be more sensitive and allowed us to detect richness differences between grade II and grade III (Figures 4A and 4B). Moreover, at the RNA level, the relative abundance of the Phy7 (*Reyranella*) and Phy33 (*Sediminibacterium*) phylotypes was lower in the diffuse type of GC than in the intestinal type (Figures 4C and 4D). No differences were found between subgroups at the DNA level.

The effect of H. pylori infection on stomach microbiota

PCoA showed *Helicobacter* to be the major determinant for differentiating samples based on their bacterial composition in the stomach (Supplementary Figure 4). Overall, *H. pylori* was detected in 115 and 117 DNA and RNA samples, respectively. In the control group, *H. pylori* was lower than that in the GC groups at both the DNA and RNA levels (Figure 5A). The tumor adjacent sample group showed the highest number of samples with high *H. pylori* abundance (Figure 5B). Both in tumor and tumor adjacent groups the mean abundance of *H. pylori* was increased at the RNA level, although no significant differences between DNA and RNA samples were found.



High *H. pylori* relative abundance (> 15%) led to an increase in the relative abundance of *Proteobacteria* and a decrease in other major bacterial phyla, such as *Firmicutes*, *Bacteroidetes*, and *Fusobacteria* (Figure 5C). In tumor tissues analyzed at the DNA and RNA level, *Helicobacter* was only one genus which changed significantly between samples with high and low *H. pylori* abundance (Figure 5D, Supplementary Table 5). On the other hand, in tumor adjacent tissues, more bacteria were found, the number of which changed together with *Helicobacter*. At the DNA level, as the relative abundance of *H. pylori* increased, the abundance of *Porphyromonas* and *Prevotella* significantly decreased. In line with our previous results, more significant differences were found at the RNA level: *Staphylococcus* significantly increased and seven bacteria (*Campylobacter*, *Fusobacterium*, *Prevotella*, *Pseudomonas*, *Reyranella*, *Sediminibacterium*, *Streptococcus*) decreased (Figure 5C, Supplementary Table 5). *Porphyromonas* tended to decrease in tumor adjacent RNA samples as well, although it did not reach a statistically significant level (Supplementary Table 5).

DISCUSSION

Despite growing interest in the study of microbiota, there is still limited agreement on the most appropriate standard for such studies, especially using 16S rRNA sequencing. Here, we performed systematic analysis of bacterial communities at both the 16S rRNA gene and 16S rRNA transcript levels. To estimate the impact of the different approaches, we used the GC model and considered not only healthy gastric tissues but also GC tumor and adjacent tissues.

The analysis of the study results showed that there were significant differences in the relative abundance of the gastric tissue microbiome between 16S rRNA gene transcript and 16S rRNA gene levels in all study groups (control, tumor, and tumor adjacent). This is the first GC study indicating that active and standing gastric microbiomes are distinct even at the largest taxonomic levels.

Differences in bacterial communities at the DNA and RNA levels could be explained by several possibilities. Using DNA as a research material summed up all bacteria, both biologically active passive in the form of endospores, and DNA sequences of already destroyed and dead bacteria[2,30]. The presence and number of ribosomes in bacteria reflects their metabolic activity; thus, the analysis at the RNA level shows the metabolic activity of live and active bacteria in the community[31-33]. For instance, previously GC-associated bacteria such as *Prevotella*, *Veillonella*, and *Neisseria* in our study were present in high abundance in all analyzed groups at the DNA level but were greatly reduced at the RNA level. In contrast, *Pseudomonas*, *Reyranella*, and *Staphylococcus* were present in higher abundance at the RNA level in all groups. However, it is erroneous to assume that only active bacteria can influence host responses. Many studies have shown that inactivated bacteria or parts of their cells can also influence inflammatory processes or other responses in host tissues. For example, Rabie *et al*[34] showed that thermally inactivated *Salmonella*, *Staphylococcus*, *Escherichia*, and *Pseudomonas* strains with unchangeable surface proteins cause colon and breast cancer cell proliferation. In Suprewicz *et al*[35]'s

study, heat-inactivated *Enterococcus faecalis*, *Actinomyces odontolyticus*, and *Propionibacterium acnes* caused cell proliferation changes in lung, breast, and ovarian carcinoma. Postbiotics work based on the same principle. To avoid possible bacterial infection during therapy, instead of active bacteria, their metabolites, which are involved in anti-inflammatory and anticancer mechanisms, are used[36].

It is also cannot be excluded that the shift in bacterial abundance between DNA and RNA levels might stem from varying numbers of copies of the 16S rRNA gene[37] or target sequence quantity inequality[38]. Bacterial rRNAs (16S rRNA, 23S rRNA and 5S rRNA) are typically organized into one operon, and their transcription occurs together, with the number of such operons varying from 1 to 15 [38]. In the case of active bacteria, an increase in 16S rRNA gene copies proportionally increases the pool of 16S rRNA transcripts. However, in the case of inactive bacteria, a larger number of 16S gene copies enables the detection of some bacteria, which could not be detected at the RNA level.

The amount of target sequences using the 16S rRNA gene and its transcript are not the same. Of all types of RNA molecules present in the cell, the most common (80%-90%) are included in the ribosome structure rRNAs[39]. 16S rRNAs make up one-third of the total rRNAs. On the other hand, when analyzing the microbiota using the 16S rRNA gene, only one gene is amplified out of the total number of genes, which in different bacteria varies from 1500 to 7000[37]. Thus, the initial larger amount of the bacterial target sequence at the RNA level makes it possible to increase the depth of sequencing and detect more rare bacteria that would be lost during DNA-level analysis. In addition, a shift toward DNA or RNA levels can also be caused by ingestion of bacterial parts from the higher parts of the digestive tract.

Our analysis revealed that the profile of differences found between GC and control tissue depended on the chosen modality: At the DNA level, 17 bacterial genera were detected, and at the RNA level, 27 bacterial genera were detected. Ten of those bacteria (*Actinomyces*, *Alloprevotella*, *Atopobium*, *Granulicatella*, *Lactobacillus*, *Megasphaera*, *Propionibacterium*, *Rothia*, *Streptococcus*, *Veillonella*) were found to be different from the control group at both levels of sequencing; seven bacterial taxa (*Campylobacter*,

Figure 5 Comparison of gastric microbiota alterations at the DNA and RNA levels depending on high *Helicobacter pylori* abundance (> 15%). A and B: Relative mean abundance of *Helicobacter pylori* (*H. pylori*) in all study groups and the number of patients with high *H. pylori* abundance; C and D: Comparison of the relative abundance of the top 5 microbiota at the phylum and top 11 microbiota at the genus levels. [a]$q < 0.05$.

Clostridium sensu stricto, *Leptotrichia*, *Oribacterium*, *Prevotella*, *Saccharibacteria genera incertae sedis*, *Stomatobaculum*) were found uniquely only at the DNA level; and 17 (*Anaerococcus*, *Corynebacterium*, *Eubacterium* , *Flavobacterium*, *Gemella*, *Legionella*, *Limnohabitans*, *Massilia*, *Methylobacterium*, *Methyloversatilis*, *Parvimonas*, *Pseudomonas*, *Reyranella*, *Rhodoluna*, *Sediminibacterium*, *Solobacterium*, *Staphylococcus*) were found uniquely only at the RNA level. These results confirm the importance of unifying the procedures for studying the microbiota.

Although our study focused on differences in methodology, it did reveal several important findings for the GC study as well. Fourteen bacteria genera were identified to be decreased in patients with GC. Eleven of these bacteria (*Actinomyces*, *Atopobium*, *Propionibacterium*, *Streptococcus*, *Granulicatella*, *Veillonella*, *Rothia*, *Parvimonas*, *Gemella*, *Prevotella*, *Leptotrichia*) were previously established in the stomach of healthy people in the absence of gastrointestinal diseases[40]. Most of them are common members of the upper gastrointestinal tract and have strong enzymatic activities. Our study also found four bacteria genera, which were significantly increased in GC patients' stomach biopsy: *Lactobacillus*, *Clostridium sensu stricto*, *Staphylococcus*, and *Pseudomonas*.

Lactobacillus is commonly used as a probiotic; however, it has been verified in multiple studies to be enriched in GC[41]. *Lactobacillus* strains, as well as *Clostridium* and *Staphylococcus*, can reduce nitrate to nitrite[42,43]. During the nitrate-reducing process, many N-nitroso compounds are formed that inhibit cell apoptosis and promote mutagenesis and protooncogene expression[44-47]. *Clostridium* is part of the

normal gastrointestinal tract; however, in several previous studies, as in ours, an increase in the number of *Clostridium sensu stricto* was found[48-50]. Interestingly, Lertpiriyapong *et al*[9] showed earlier onset and faster progression of GC in INS-GAS mice with restricted microbiota (including *Clostridium*, *Lactobacillus,* and *Bacteroides*), highlighting a possible role of these bacteria in GC. Additionally, several studies have detected increased levels of *Staphylococcus* in patients with upper gastrointestinal diseases[51-53]. One of the reasons for this may be that stains of *Staphylococcus* have the enzyme urease, and are able to catalyze the hydrolysis of urea to carbon dioxide and ammonia, which can neutralize gastric hydrochloric acid, thus promoting bacterial existence. Although we found an increased number of *Pseudomonas*, this bacterial infection affects people with weakened immune systems (including patients with cancer), and thus, it is more likely that this finding is the result of already developed pathological processes.

We did not detect significant bacterial abundance, richness, or diversity alterations at either the DNA or RNA level between tumor and tumor adjacent tissues. This result is consistent with two previous studies[54,55] but contradicts recent GC studies where significant differences between tumor-affected and nearby healthy tissues were found[27,56]. Moreover, we found the same clusters of bacterial networks in tumor and tumor adjacent tissues at both the DNA and RNA levels. These results may suggest that with the onset and development of carcinogenic processes, local changes in stomach tissues lead not only to a change in the bacterial composition but are also precise uniformity between cancer-affected and still healthy tissues (at least within a radius of 5 cm from the tumor area).

Studying GC samples at the RNA level, we managed to identify microbiome associations with clinical data. Analysis revealed two phylotypes (Phy7 and Phy33) related to *Reyranella* and *Sediminibacterium*, respectively. The relative number of those phylotypes gradually decreased from healthy to GC patients through intestinal growth type (considered as less aggressive cell growing type) to GC patients with diffuse growth type of cancer cells with worse outcome prognosis. To our knowledge, this is the first mention of these bacteria associated with the GC cell growth type. *Reyranella* is part of *Proteobacteria* and has previously been associated with the main chemokine expression, which is involved in T-cell attraction during cancerogenesis[57,58]. In another study, it was shown that there are significantly lower amounts of circulating natural killer and Treg cells in patients with diffuse/mixed-type GC compared to intestinal-type GC[59]. Taken together, these results suggest that *Reyranella* may be involved in the decrease in T-cell number and thus stimulation of cell growth of diffuse-type GC. *Sediminibacterium* was reported to be associated with GC, but there is no knowledge about the possible role of this bacteria in the pathophysiological processes[60,61]. Therefore, more detailed research on the effects of *Reyranella* and *Sediminibacterium* on GC cells is needed to be able to use these bacterial phylotypes as potential biomarkers.

H. pylori is the most common bacterial infection worldwide, as well as the main risk factor for GC [40]. It has been shown that during the transition from *H. pylori*-induced inflammation to the growth and development of carcinogenic cells, *H. pylori* is no longer detected in the affected areas in such large abundance[62]. Our results, showing that more *H. pylori* were found in tumor adjacent tissue than in tumor tissue, both at the DNA and RNA levels, confirm this. According to some previous reports, infection with *H. pylori* promotes the proliferation of non-*Helicobacter* bacteria from *Proteobacteria*, *Spirochetes*, and *Acidobacteria* and limits the spread of bacteria such as *Actinobacteria*, *Bacteroidetes* and *Firmicutes*[63,64]. Although most of the bacteria we found with altered numbers in GC were not associated with *H. pylori*, changes in the number of bacteria, such as *Granulicatella*, *Lactobacillus*, *Rothia*, *Pseudomonas*, *Gemella*, *Prevotella*, *Leptotrichia*, *Clostridium sensu stricto*, and *Fusobacterium,* were associated with high *H. pylori* abundance.

The question regarding the causality in the gastric microbiome is still partially unanswered. On the one hand, alterations in gastric microbiota have a causal role in the progression of carcinogenesis (*e.g.*, *H. pylori*). On the other hand, the role of other bacteria is less understood. However, there are new studies that strongly suggest the impact of the gastric microbiome on inflammation and carcinogenesis. For instance, a recent study by Kwon *et al*[65] showed that intestinal metaplasia or GC patient gastric microbiome transplantation contributes to changes in the phenotype of premalignant lesions. In this regard, a detailed understanding of the output of different sequencing technologies and comparability between RNA/DNA-based analyses is critical.

Since systematic analysis to assess the differences with respect to GC has not been performed before, we would like to point out some limitations of this work. While the primary focus of the work was related to technical differences, thus food preferences, sex, and aging can be potential contributing factors that have not been thoroughly considered in this study. Overall, the focus was on providing a truly confirmed healthy cohort for the most precise comparison to strengthen the differences. Nevertheless, PERMANOVA and Mann-Whitney analyses performed in each of the study groups (tumor DNA, tumor RNA, tumor adjacent DNA, tumor adjacent RNA, control DNA, control RNA) did not reveal significant differences between the sexes and age (divided by median) (Supplementary Tables 6 and 7). Furthermore, due to the sample size, we did not consider the newly proposed TCGA classification for subsequent analysis nor to assess the impact of 4 subtypes on bacterial composition in tumors.

CONCLUSION

In conclusion, our study provides evidence that the tumor microbiome of GC patients has a distinct pattern compared to healthy controls, while the difference analyzed from adjacent tissue was rather low. Despite some overlap between the data obtained from the 16S rRNA transcript and 16S rRNA gene, our results showed the critical importance of the chosen study material on the resulting bacterial profile. Thus, researchers comparing their results with previous studies might take into consideration which initial material was used, either the 16S rRNA gene or 16S rRNA transcript. Our results showed that the RNA level was more sensitive for detecting low abundance bacteria and allowed us to detect differences according to GC clinical data.

ARTICLE HIGHLIGHTS

Research background

There is currently no gold standard for analyzing the microbiome in 16S rRNA studies. Two common modalities are: Sequencing of DNA (16S rRNA gene) and sequencing of RNA (16S rRNA transcript). Gastric cancer (GC) remains one of the most common cancers in the world and microbiome takes important place in its carcinogenesis.

Research motivation

Microbiota studies are becoming more relevant and widespread. Comparison of different approaches for microbiome studying is necessary for correct interpretation of other studies results, as well as for a deeper understanding of bacterial composition.

Research objectives

To investigate how the choice of sequencing modality affects the bacterial profile of differences between case and controls as well as to characterize the microbiota of GC tissues using 16S rRNA gene and its transcript.

Research methods

The study included healthy tissues from the control group, as well as tumor and tumor adjacent tissues from GC patients. From all biopsies RNA and DNA were extracted. 16S rRNA V1-V2 region was sequenced for all samples. For significant differences between groups permutational multivariate analysis of variance and Mann-Whitney test followed by false-discovery rate test were used.

Research results

Only a small portion of bacterial sequences overlapped on DNA and RNA levels in all groups. Differences between GC and control groups also only partially overlayed on DNA and RNA levels. RNA sequencing was more sensitive for detecting differences in bacterial richness, low abundance bacteria, and changes in the relative abundance of *Reyranella* and *Sediminibacterium* according to the type of GC. In each study group differences between DNA and RNA bacterial profiles were identified.

Research conclusions

Chosen study material (16S rRNA transcript or 16S rRNA gene) greatly affects detectable microbiome profile as well as the differences between cases and controls.

Research perspectives

This study provides microbiome analysis applying two different methodologies using GC gastric tissues as example and could serve as a reference for future research.

ACKNOWLEDGEMENTS

We would like to thank Justina Arstikyte, Ilka Kramer, and Susan Engerlberg for the technical assistance in this study. The authors would also like to thank Prof. Martin Zenker and Dr. Denny Schanze for their support in sequencing the samples. Additionally, we are grateful to the Team of Data Integration Center of University Medicine Magdeburg for local data-analysis solutions, supported by MIRACUM and funded by the German Federal Ministry of Education and Research (BMBF) within the "Medical Informatics Funding Scheme" (FKZ 01ZZ1801H).

Abstract

BACKGROUND

Dietary methyl donors might influence DNA methylation during carcinogenesis of colorectal cancer (CRC). However, whether the influence of methyl donor intake is modified by polymorphisms in such epigenetic regulators is still unclear.

AIM

To improve the current understanding of the molecular basis of CRC.

METHODS

A literature search in the Medline database, *Reference Citation Analysis* (https://www.referencecitationanalysis.com/), and manual reference screening were performed to identify observational studies published from inception to May 2022.

RESULTS

A total of fourteen case-control studies and five cohort studies were identified. These studies included information on dietary methyl donors, dietary components that potentially modulate the bioavailability of methyl groups, genetic variants of methyl metabolizing enzymes, and/or markers of CpG island methylator phenotype and/or microsatellite instability, and their possible interactions on CRC risk.

CONCLUSION
Several studies have suggested interactions between methylenetetrahydrofolate reductase polymorphisms, methyl donor nutrients (such as folate) and alcohol on CRC risk. Moreover, vitamin B_6, niacin, and alcohol may affect CRC risk through not only genetic but also epigenetic regulation. Identification of specific mechanisms in these interactions associated with CRC may assist in developing targeted prevention strategies for individuals at the highest risk of developing CRC.

Core Tip: Dietary methyl donors might influence DNA methylation during the carcinogenesis of colorectal cancer (CRC). However, whether the influence of methyl donor intake is modified by polymorphisms in such epigenetic regulators is still unclear. We conducted a systematic review on this topic to improve the current understanding of the molecular basis of CRC. Several studies have suggested interactions between methylenetetrahydrofolate reductase polymorphisms, methyl donor nutrients (such as folate) and alcohol on CRC risk. Moreover, vitamin B_6, niacin, and alcohol may affect CRC risk through not only genetic but also epigenetic regulation.

INTRODUCTION

Colorectal cancer (CRC) is the third most frequent type of cancer and is responsible for the second highest mortality rate in cancer patients worldwide[1]. Although screening for early detection of CRC is effective to help decrease the trends in mortality rates, understanding daily life factors is also important to prevent this type of cancer[2]. The main factors which may help prevent CRC are those associated with diet, lifestyle, and prevention of metabolic diseases[3].

With regards to the dietary component, nutrients associated with one carbon (1C) metabolism [including folate, other B vitamins, methionine (Met), and choline] have been recognized as anticarcinogenic and chemotherapeutic agents in the 1C metabolic network[4]. Folate has shown to play a preventive role in CRC, probably because of its involvement in the processes of DNA methylation and synthesis[5]. Other nutrients, such as Met and vitamins B_6 and B_{12}, which interact metabolically with folate in this process, may also influence the risk of CRC[6]. Moreover, in some of those studies, the observed inverse association between folate status and CRC risk was further modified by genetic polymorphisms of the enzymes involved in folate metabolism, most notably methylenetetrahydrofolate reductase (*MTHFR*).

A common C677T substitution in the *MTHFR* gene results in a protein with valine instead of alanine, yielding a more thermolabile enzyme with decreased activity[7]. Numerous studies have shown that this variant (TT) is associated with a decreased risk of CRC, but only when folate status is normal or high. *MTHFR* polymorphism is possibly the best-known gene polymorphism that switches from being a risk factor to a protective one depending on nutrient status. In any case, it is also important to evaluate the joint influence that other polymorphisms in genes involved in folate metabolism might exert. Thus, for example, Met synthase requires vitamin B_{12}, as methylcobalamin, as a cofactor. A variant in this gene, A2756G [in methionine synthase (*MTR*) gene], has been described and results in the substitution of aspartate by glycine. Some studies have shown that the MTR 2756 GG genotype is associated with a decreased risk of CRC; however, the association with diet is still unclear[8,9].

Another relevant example of a mutation in a polymorphism associated with CRC risk, but not consistent with nutrients, is the case of serine hydroxymethyltransferase, a pyridoxal phosphate (B_6)-dependent enzyme, in particular the polymorphism C1420T[10]. An additional relationship between 1C metabolism-related nutrients and CRC risk is related to its influence on DNA methylation. Thus, low folate status or intake is related to a decreasing methylation level[11,12], whereas colonic mucosal DNA methylation increased globally as a result of folate supplementation[13]. A sufficient intake of methyl

donors may also prevent aberrant CpG island promoter hypermethylation. The promoter CpG island hypermethylation that characterizes the CpG island methylator phenotype (CIMP) in CRC is common [14]. Moreover, polymorphisms in enzymes involved in folate metabolism may change the potential impact of methyl donor consumption on DNA methylation[15].

According to the molecular subtype, chromosomal instability, and microsatellite instability (MSI) represent the major pathways for CRC[16]. The inactivation of DNA mismatch repair (MMR) genes, which are responsible for correcting mismatched bases during DNA replication, results in MSI[17]. Microsatellites are short sequences that are dispersed across the genome and are likely to undergo MMR machinery-induced deletion or insertion. Defects in the MMR machinery are associated with CRC[18] and can be affected by epigenetic alterations and deregulation of methylation[19]. In this sense, the associations between methyl donor nutrient intake and CRC risk have been extensively studied, although evidence on their effect is limited[20]. However, whether they act as effect modifiers against a background of deficient DNA repair capacity is unknown.

Until now, there have been few studies on the influence of methyl group donors as epigenetic regulators in CRC[21]. In the present work, we reviewed previous studies that have investigated this matter to improve the current understanding of the molecular basis of CRC, which could contribute to a better design of future research and to better preventive nutritional management in this type of cancer.

MATERIALS AND METHODS

Search strategy

The search terms and search strategy were developed by two researchers. To guide this research, we formulated the following question as the starting point: What is the influence of methyl donor nutrients as epigenetic regulators in CRC? For this purpose, a systematic search in the Medline (through PubMed) database, *Reference Citation Analysis* (https://www.referencecitationanalysis.com/, an artificial intelligence technology-based open multidisciplinary citation analysis database), and a manual reference screening were performed to identify observational studies published from inception to May 20, 2022. A search for relevant keywords and medical subject heading terms related to dietary methyl donors, dietary components that potentially modulate the bioavailability of methyl groups, genetic variants of methyl-metabolizing enzymes, markers of CIMP and/or MSI, in combination with keywords related to CRC events was conducted.

The search was amplified through citation chaining (forward and backward) of the included studies. Reference lists of all identified articles and other related review articles, systematic reviews, and meta-analyses were hand-searched for additional articles. The present search was developed according to the "PRISMA Statement" guidelines (see the PRISMA checklist) (www.prisma-statement.org). For this review, a protocol was not prepared or registered. The search strategy is detailed as follows: (1) Colorectal neoplasms/exp or [(colorectal* or rect* or anal* or anus or colon* or sigmoid) adj3 (cancer* or carcinoma or tumour* or tumor* or neoplas* or adenoma or adenocarcinoma)], abstract (ab), keyword hearing word (kf), original title (ot), title (ti), text word (tw); (2) (observational or case-control or cohort), ab, kf, ot, ti, tw; (3) (incidence or prevalence or risk or odds ratio or hazard ratio), ab, kf, ot, ti, tw; (4) (one-carbon metabolism-related nutrient* or dietary methyl donor* or alcohol), ab, kf, ot, ti, tw; and (5) [gen* or single-nucleotide polymorphism (SNP)* or polymorphism* or methyl metabolizing enzyme* or diet–gene interaction* or hypermethylation* or microsatellite instability*], ab, kf, ot, ti, tw.

Review process and selection criteria

Two researchers independently screened the titles and abstracts of the articles to identify potentially relevant studies. Studies that passed the title/abstract review were retrieved for full-text review. The inclusion and exclusion criteria and the quality of the study were assessed by two researchers with the use of a data extraction form especially designed for this study.

The inclusion criteria consisted of studies: (1) With an observational design (case-control or cohort); (2) that evaluated the exposure to at least one of the following dietary components (dietary nutrient intake and/or plasma levels): Folate, other B vitamins, Met, choline, betaine, and/or alcohol; (3) that included genotyping analyses of methyl-metabolizing enzymes (*MTHFR, MTR,* Met synthase reductase), DN methyltransferase 3 b, euchromatin histone methyltransferase 1 and 2, PR domain zinc finger protein 2; (4) CIMP defined by promotor hypermethylation (calcium voltage-gated channel subunit a1 G, insulin-like growth factor 2, neurogenin1, runt-related transcription factor 3, suppressor of cytokine signalling 1), human *MutL* homolog 1 (*hMLH1*) hypermethylation; (5) MSI using markers [such as mononucleotide microsatellites with quasi-monomorphic allele length distribution in healthy controls but unstable (Bat-26 and/or Bat-25), NR-21, NR-22, NR-24)]; (6) in which the outcome of interest was CRC, colon, or rectal cancer (studies investigating benign adenomas or polyps were excluded); (7) that provided estimates of the adjusted odds ratios or relative risks or hazard ratios with 95% confidence intervals (95%CI); (8) conducted in humans (≥ 18 years old); and (9) written in English or Spanish.

The following types of publications were excluded: (1) Nonoriginal papers (reviews, commentaries, editorials, or letters); (2) meta-analysis studies; (3) off-topic studies; (4) studies lacking specific CRC data; (5) nonhuman research; (6) studies conducted in children, adolescents, or pregnant women; (7) duplicate publications; and (8) low-quality studies (Newcastle-Ottawa scale (NOS)[22] < 4 indicating insufficient study quality).

Study quality assessment

To evaluate the validity of the individual studies, two reviewers worked independently to determine the quality of the included studies based on the use of the NOS for case-control or cohort studies[22]. The maximum score was 9, and a high score (≥ 6) indicated high methodological quality; however, given the lack of studies on the subject under study, it was agreed to select those that had a score equal to or greater than 4. A consensus was reached between the reviewers if there were any discrepancies.

Data extraction

The data extracted for each individual study included the following: Name of the first author, study design, characteristics of the study population (age range or mean age, sex, country), dietary exposure, dietary assessment instrument used, outcomes (including cancer site), comparison, odds ratio or relative risk or hazard ratio (95%CI), adjusted variables, and NOS. For case-control studies, the following additional information was extracted: Number of cases and number of controls. For cohort studies, the following additional information was extracted: Number of participants at baseline, number of CRC cases, and length of follow-up. These variables were judged to be most relevant to the outcome studied. Where multiple estimates for the association of the same outcome were used, the one with the highest number of adjusted variables was extracted. Template data collection forms and data extracted from the included studies will be made available upon request from the corresponding author.

RESULTS

Figure 1 shows the PRISMA flow diagram summarizing the identification and selection of the relevant publications. A total of nineteen studies were included in this systematic review: Fourteen case-control studies[23-36] and five cohort studies[9,37-40]. In total, the case-control studies included 7055 cases and 9032 controls. The cohort studies included 256914 participants, with 1109 cases recorded during follow-up periods that ranged from 7.3 to 22 years. Amongst the case-control studies, nine articles were conducted in the United States, two in the United Kingdom, two in Korea and one in Portugal. With regard to the cohort studies, three were conducted in the Netherlands and two in the United States.

Tables 1 and 2 summarize the main characteristics and findings of the case-control and cohort studies, respectively, on the interactive effect between single-nucleotide polymorphisms in genes encoding methyl-metabolizing enzymes, dietary methyl donors and dietary components that potentially modulate the bioavailability of methyl groups on CRC risk. Tables 3 and 4 show the effects of dietary methyl donors and dietary components that potentially modulate the bioavailability of methyl groups on CRC risk, according to SNPs in genes encoding methyl-metabolizing enzymes and/or mutations in oncogenes, CIMP and/or MSI, in the case-control studies and cohort studies, respectively. Table 5 provides a summary of the results of the studies included in the systematic review.

DISCUSSION

This review summarizes previous studies that have investigated the influence of methyl donor nutrients as epigenetic regulators in CRC. The dietary components that showed a higher association with CRC risk were folate and alcohol. Thus, high folate intake was considered a protective factor, while high alcohol consumption proved to be a risk factor. Several studies have investigated the association between methyl donor nutrients and/or methyl antagonists (*e.g.*, alcohol) and *MTHFR* polymorphisms and have reported significant interactions[23,24,26,29,36]. In one of those case-control studies, those with the *MTHFR* 677 TT genotype, who consume low folate diets, had a greater chance of developing CRC than people with the CC or CT genotype[24]. Two other case-control studies reported that *MTHFR* 677 TT carriers with high (above mean) or adequate folate intake had a low risk of CRC[26,29].

Two case-control studies found that alcohol consumption increased CRC risk among *MTHFR* 677 TT carriers[23,26]. The decreased *MTHFR* enzyme activity among those who carried the T allele, and consumed low methyl donor nutrients and large amounts of alcohol can be utilised to explain the increased CRC risk[25,30]. These dietary habits may alter folate metabolism, especially in people with folate deficiencies[41]. In contrast, several studies have not found an association between *MTHFR* polymorphisms and either folate intake or alcohol intake and CRC risk[25,27]. It has been hypothesized that the differences in folate status among various populations may have influenced the contradictory results on the contribution of *MTHFR* genetic variants in CRC[25]. In addition to *MTHFR* poly-

morphisms, de Vogel *et al*[9] also investigated the modifying effects of polymorphisms of Met synthase reductase, *MTR*, DN methyltransferase 3 b, euchromatin histone methyltransferase 1 and 2, and PR domain zinc finger protein 2 but found no interactions, although some *P-trends* were significant.

Regarding the methylation abnormalities of genes, de Vogel *et al*[37] found that high vitamin B_6 intake was associated with an increased CRC risk caused by hypermethylation of the *hMLH1* promoter among men. Therefore, these authors suggest that vitamin B_6 may have had a tumour-promoting effect by increasing promoter methylation. However, the intake of folate, vitamin B_2, Met and alcohol was not associated with the risk of tumours showing *hMLH1* hypermethylation. In any case, other studies

showed inverse associations between vitamin B_6 intake and CRC risk, both when the intake level was higher[6] and when it was similar[42] to that in the study of de Vogel *et al*[37]. Therefore, further attention should be given to this association in future studies.

Another interesting finding in this review is the inverse association between dietary folate and Met and B-Raf proto-oncogene mutations among men[37]. A previous study showed that folate may increase the risk of tumours harbouring truncating adenomatous polyposis coli mutations in men[43]. Apparently, relatively high folate intake may confer a growth advantage to mutated tumours independent of the type of mutation. Nevertheless, the occurrence of MSI does not seem to be sensitive to methyl donor intake or to that of alcohol[36-37,44].

In one of the case-control studies that we analysed, an interaction was observed between a high- or low-risk diet and *MTHFR* 1298A>C (but not 677C>T) with regard to CIMP status[32]. This result suggests that a genetic polymorphism at *MTHFR* 1298A>C interacts with the diet (with a low folate and Met intake and a high alcohol consumption) increasing the risk of highly CpG-methylated colon tumours. S-adenosylmethionine binds as an allosteric inhibitor in the *MTHFR* regulatory region, which is where the 1298A>C variant is found. This gives some justification for the stronger associations between *MTHFR* 1298A>C and CIMP rather than the 677C>T SNP, which has an opposite effect on the stability of the enzyme. Due to their high linkage disequilibrium, the *MTHFR* 677C>T and 1298A>C polymorphisms should not be viewed separately. van Engeland *et al*[40] also discovered that people

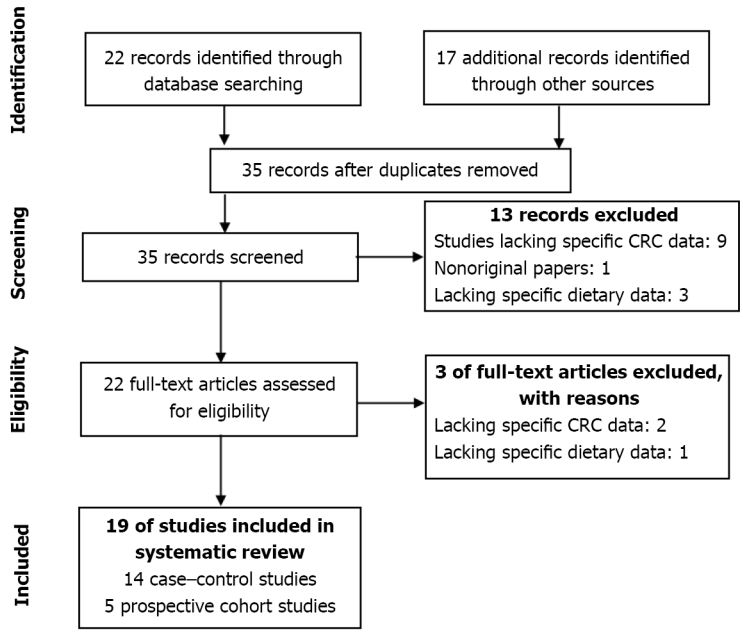
diagnosed with CRC, with low intake of folate and high consumption of alcohol, had a greater prevalence of promoter hypermethylation; however, the difference was not statistically significant due to limited power. Therefore, it was proposed that stratification for functionally significant SNPs in the genes encoding folate metabolism enzymes could strengthen the observed effect of folate deficiency on promoter methylation[40].



Additionally, Curtin *et al*´s study[32] found an interaction between alcohol consumption and *MTHFR* 1298A>C in association with CIMP status. Relative to the AA genotype in non-drinkers, the *MTHFR* 1298 AA genotype was linked to a higher risk of CIMP+ in drinkers. In a previous study by Slattery *et al* [35], in which associations between CIMP status and alcohol use were assessed without taking into regard to genotype, no association was observed. These results imply that the activity of the 1C-metabolism enzyme may alter the risk associated with alcohol in determining the CIMP status of colon cancer. In any case, to date, few published studies have evaluated, CIMP in CRC for possible relationships with 1C-metabolism SNPs[32,45,46]. Moreover, these data raise the possibility that more investigation is required to clarify the function of genetic SNPs in relation to CIMP status and the promoter hypermethylation of particular genes.

In one case-control study[36], an association between long-term alcohol consumption and increased likelihood of having a CIMP-low or B-Raf proto-oncogene-mutated tumour was observed. Among those with unstable tumours, they observed that alcohol was more likely to be associated with CIMP-low rather than CIMP-high tumours. A previous study of these same authors showed that alcohol increased the risk for MSI+ tumours in general[35]. Therefore, these findings suggest that the increased risk of MSI associated with alcohol is limited to those tumours that are unmethylated rather than methylated.

Table 5 Summary of results of the studies included in this systematic review

Figure 1 PRISMA flow diagram summarizing the identification and selection of the relevant publications assessing the influence of methyl donor nutrients as epigenetic regulators in colorectal cancer. CRC: Colorectal cancer.

Finally, regarding the interaction between MMR SNPs and methyl donor nutrient intake on CRC based on MSI status, in a case-control study[34], a strong inverse association was observed for *hMSH3* AG or GG carriers with a high intake of niacin, particularly among patients with CC and microsatellite stability or proficient MMR status. However, to ascertain the processes behind this association with CRC risk, the precise roles of this SNP must be identified.

The importance of interactions between modifiable factors, such as methyl donor nutrients and CRC, is suggested by evidence that colorectal carcinogenesis is generated by numerous molecular pathways in parallel with MSI status, which is caused by a defect in the MMR machinery. In this sense, it is worth

remembering the article mentioned by de Vogel *et al*[37], in which it was reported that high consumption of vitamin B_6 was linked to an increased risk of sporadic CRC with *hMLH1* hypermethylation, indicating that vitamin B_6 affects CRC risk through both genetic and epigenetic mechanisms. Based on the findings of Kim *et al*[34], it may be possible to explain the interactions between dietary methyl donor nutrients, such as niacin, and *hMSH3* genetic variants as predictors of CRC risk.

DNA methylation and microRNA expression levels may be regulated by the MMR machinery's epigenetic relationships with methyl groups[47]. Through the methylation of CpG islands in the promoter region, 1C metabolism mediated by methyl donor nutrients can change how the DNA MMR system is activated. A adequate DNA MMR system with methyl groups may control the equilibrium between the repair and accumulation of short repeat sequences, preventing extensive DNA damage that supports colorectal carcinogenesis.

This systematic review has several strengths: (1) Cohort and case-control studies were identified through a systematic search; (2) a quantitative NOS scale was used to assess the quality of the studies; and (3) most studies (twelve of nineteen) used a validated questionnaire to assess dietary intake. To our knowledge, this is the first systematic review regarding the influence of methyl donor nutrients as epigenetic regulators in CRC.

The limitations of this review include the following: (1) Case-control studies, which are susceptible to recall and selection bias, made up the bulk of the research. However, most studies were based on community controls; thus, they might be a good representation of the frequency of genetic variants or of dietary habits of the overall population; (2) the heterogeneous nature of studies, including the study population characteristics, sample size, study design, and follow-up periods; (3) potential residual confounding because of the observational nature of the studies included or the possibility that not all the studies were adjusted for important nutrient variables; (4) some of the dietary assessments were self-reported, which may affect the reliability of the reported intakes, although the use of validated questionnaires in most studies could reduce this bias; (5) some studies had a relatively limited sample size or effect size, which made it difficult for them to detect the interactions between genetic and nutritional information, which could explain, in part, the lack of results with a statistically significant level; and (6) despite the fact that some research have found differential interactions based on the CRC subtype[34], the majority of studies lacked stratified analysis. Considering these limitations, the conclusions from these researchers should be taken carefully. Consequently, it is difficult for this review to explain the gene-diet interactions and their effects on the development of CRC.

CONCLUSION

In this systematic review of observational studies, some interactions between *MTHFR* polymorphisms, methyl donor nutrients (such as folate) and alcohol on CRC risk are suggested. Moreover, some studies show that vitamin B_6, niacin and alcohol may affect CRC risk through not only genetic but also epigenetic regulation. In any case, this review was not able to clarify which mechanisms underlie the influence of methyl donor nutrients on DNA methylation, as well as the efficacy of methyl uptake, transportation, and the final involvement in methyl-related gene expression. Further prospective studies with large samples and long follow-up periods, as well as clinical trials that take into account the long latency period of CRC, are needed to clarify the influence of methyl group donors as epigenetic regulators, with particular emphasis on differences in CRC subsite-specific risk. Such studies may provide valuable insight into the biological mechanisms with the goal of identifying at-risk subpopulations and promoting primary prevention of CRC.

ARTICLE HIGHLIGHTS

Research background

Colorectal cancer (CRC) is the third most frequent cancer and is responsible for the second-highest mortality rate in cancer patients worldwide. The main factors which may help prevent CRC are those associated with diet, lifestyle, and prevention of metabolic diseases. With regards to the dietary component, one-carbon metabolism-related nutrients have been considered anticarcinogenic and chemotherapeutic agents in the one-carbon metabolic network. However, it is still unclear whether the influence of methyl donor intake is modified by polymorphisms in these epigenetic regulators.

Research motivation

Although screening for early detection of CRC is effective to help decrease the trends in mortality rates, understanding daily life factors is also important to prevent this type of cancer. A better understanding of the molecular basis of CRC could contribute to a better design of future research and better preventive nutritional management in this type of cancer.

Research objectives

In the present work, we reviewed previous studies that have investigated this matter to improve the current understanding of the molecular basis of CRC.

Research methods

A literature search in the Medline database, *Reference Citation Analysis* (https://www.referencecitation-analysis.com/, an artificial intelligence technology-based open multidisciplinary citation analysis database), and manual reference screening were performed to identify observational studies published from inception to May 2022. A search for relevant keywords and medical subject heading terms related to dietary methyl donors, dietary components that potentially modulate the bioavailability of methyl groups, genetic variants of methyl-metabolizing enzymes, markers of CpG island methylator phenotype and/or microsatellite instability, in combination with keywords related to CRC events was conducted. The present search was developed according to the "PRISMA Statement" guidelines. To evaluate the validity of the individual studies, two reviewers worked independently to determine the quality of the included studies based on the use of the Newcastle-Ottawa scale for case-control or cohort studies.

Research results

A total of fourteen case-control studies and five cohort studies were identified. In total, the case-control studies included 7055 cases and 9032 controls. The cohort studies included 256914 participants, with 1109 cases recorded during follow-up periods that ranged from 7.3 to 22 years. The dietary components that showed a higher association with CRC risk were folate and alcohol. Thus, high folate intake was considered a protective factor, while high alcohol consumption proved to be a risk factor. Several studies have investigated the association between methyl donor nutrients and/or methyl antagonists (*e.g.*, alcohol) and methylenetetrahydrofolate reductase (*MTHFR*) polymorphisms and have reported significant interactions. In one of those case-control studies, those with the *MTHFR* 677 TT genotype, who consume low folate diets, had a greater chance of developing CRC than people with the CC or CT genotype. Two other case-control studies reported that *MTHFR* 677 TT carriers with high (above mean) or adequate folate intake had a low risk of CRC.

Research conclusions

In this systematic review of observational studies, some interactions between *MTHFR* polymorphisms, methyl donor nutrients (such as folate), and alcohol on CRC risk are suggested. Moreover, some studies show that vitamin B_6, niacin, and alcohol may affect CRC risk through not only genetic but also epigenetic regulation.

Research perspectives

This review was not able to clarify which mechanisms underlie the influence of methyl donor nutrients on DNA methylation, as well as the efficacy of methyl uptake, transportation, and the final involvement in methyl-related gene expression. Further prospective studies with large samples and long follow-up periods, as well as clinical trials that consider the long latency period of CRC, are needed to clarify the influence of methyl group donors as epigenetic regulators, with particular emphasis on differences in CRC subsite-specific risk.

Abstract

BACKGROUND

Pancreatic neuroendocrine neoplasms (PNENs) are a rare group of neoplasms originating from the islets of the Langerhans. Portal vein tumor thrombosis has been reported in 33% of patients with PNENs. While the histopathological diagnosis of PNENs is usually based on percutaneous biopsy or endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA), these approaches may be impeded by gastric varices, poor access windows, or anatomically contiguous critical structures. Obtaining a pathological diagnosis using a gastroscope biopsy forceps *via* percutaneous transhepatic intravascular pathway is an innovative method that has rarely been reported.

CASE SUMMARY

A 72-year-old man was referred to our hospital for abdominal pain and melena. Abdominal contrast-enhanced magnetic resonance imaging revealed a well-enhanced tumor (size: 2.4 cm × 1.2 cm × 1.2 cm) in the pancreatic tail with portal vein invasion. Traditional pathological diagnosis *via* EUS-FNA was not possible because of diffuse gastric varices. We performed a percutaneous transportal biopsy of the portal vein tumor thrombus using a gastroscope biopsy forceps. Histopathologic examination revealed a pancreatic neuroendocrine neoplasm (G2) with somatostatin receptors 2 (+), allowing systemic treatment.

CONCLUSION

Intravascular biopsy using gastroscope biopsy forceps appears to be a safe and effective method for obtaining a histopathological diagnosis. Although well-designed clinic trials are required to obtain more definitive evidence, this procedure may help improve the diagnosis of portal vein thrombosis and related

diseases.

Core Tip: Endoscopic ultrasound-guided fine-needle aspiration or percutaneous biopsy of pancreatic neuroendocrine neoplasms patients can be impeded by gastric varices and poor access windows. In this patient, we faced the challenge of obtaining biopsy of the pancreatic mass which had invaded the portal vein. We performed a percutaneous transportal biopsy of the portal vein tumor thrombosis using a gastroscope biopsy forceps. Our experience suggests that gastroscope biopsy forceps is a viable alternative to obtain biopsy in the portal vein system. Our work expands the use of diagnostic transhepatic portal catheterization. This method may also help prevent repeated liver puncture, reducing the risk of complications.

INTRODUCTION

Pancreatic neuroendocrine neoplasms (PNENs) are rare tumors accounting for approximately 2% of all pancreatic tumors[1]. Portal vein tumor thrombosis (PVTT) was reported in approximately 33% of patients with non-functioning PNENs (NF-PNENs)[2]. Tumor thrombosis in such cases may cause splenoportomesenteric hypertension, potentially resulting in life-threatening upper gastrointestinal bleeding. Computed tomography (CT) or magnetic resonance imaging (MRI) is useful for diagnosis. Tissue samples are usually obtained *via* imaging-guided percutaneous fine-needle aspiration biopsy or core needle biopsy, endoscopic retrograde cholangiopancreatography, or endoscopic ultrasound-guided fine-needle aspiration/biopsy (EUS-FNA/B)[3]. This report describes the first diagnostic case of percutaneous transhepatic intravascular biopsy of PVTT caused by PNEN invasion using a gastroscope biopsy forceps in a patient with severe gastric varices in whom diagnosis could not be made through percutaneous or endoscopic approaches.

CASE PRESENTATION

Chief complaints

A 72-year-old man was referred to a local hospital for upper abdominal pain with melena for 10 d.

History of present illness

He was diagnosed with pancreatitis and gastric varices. The abdominal pain was relieved after somatostatin treatment for 2 d. The patient was referred to our hospital for further treatment.

History of past illness

Six months ago, he was diagnosed with gastric varices after undergoing gastroscopy as part of routine medical checkup; however, he did not undergo further evaluation.

Personal and family history

He had no family history of malignant tumors, psychological, or genetic disorders.

Physical examination

Physical examination showed pallor.

Laboratory examinations

Laboratory investigations showed three lineage pancytopenia (hemoglobin 66 g/L, WBC count: 2.4 × 10^9

/L, platelet count: 83.0 × 10^9/L). Serum transaminases, bilirubin, and amylase levels were normal. Urine routine, stool routine and occult blood test were negative. Serum tumor markers (AFP, CEA, CA199, and NSE) were all within the normal reference range.

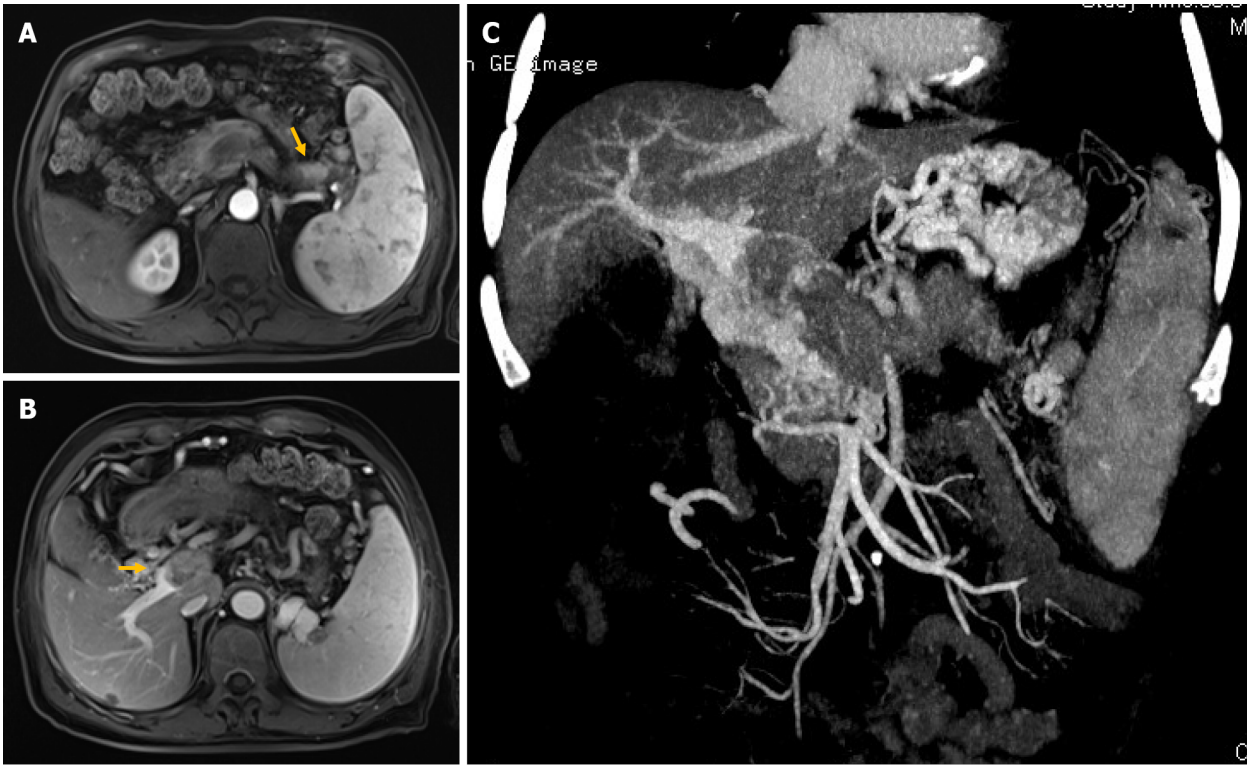
Imaging examinations

Abdominal contrast-enhanced MRI revealed a well-enhanced tumor (size: 2.4 cm × 1.2 cm × 1.2 cm) in the pancreatic tail (Figure 1A), with portal vein invasion (Figure 1B and C), and the presence of many collateral vessels indicative of portal stenosis (Figure 1C). The mass inside the portal vein was enhanced too, suggesting that it was a tumor rather than a thrombus. Splenomegaly was also observed, which was considered as a secondary change. No metastasis was found in other organs, including the lymph nodes, liver parenchyma, and lungs.

FINAL DIAGNOSIS

Histopathologic examination revealed a NEN (G2) with somatostatin receptors 2 (SSTR2) (+) (Figure 2A-D).

TREATMENT



A multidisciplinary team meeting was held to discuss the case. Diagnosis of PNEN with portal vein invasion was highly suspected. Surgical resection was considered risky because of the involvement of adjacent organs and sinistral portal hypertension. Interventional therapy to prevent upper gastrointestinal hemorrhage and chemotherapy were suggested. However, pathological diagnosis *via* EUS-FNA seemed infeasible because of diffuse gastric varices (Figure 3A). The possibility of percutaneous CT/ultrasound-guided fine-needle aspiration biopsy was also excluded since no adequate access was identified. Finally, we performed percutaneous transportal biopsy of the PVTT using a gastroscope biopsy forceps. After percutaneous transhepatic puncture of the right-portal vein under sonographic guidance, 7F "crossover sheath" catheter was introduced into the right-portal vein and the biopsy forceps was inserted into the catheter. Under X-ray guidance, the biopsy forceps was pushed close to the thrombus and 3 samples were obtained (Figure 2E and F; Figure 4; Supplementary material) and fixed immediately. Subsequently, partial splenic embolization (PSE) was performed for treating the gastric varices. After obtaining the histopathologic results, the patient received octreotide long-acting release (LAR) injection. There were no postoperative complications, and the patient was discharged on postoperative day 8. Owing to the high risk of gastric varices hemorrhage, the patient received repeat PSE treatment.

OUTCOME AND FOLLOW-UP

Follow-up gastroscopy performed after one month showed significant alleviation of gastric varices (Figure 3B). Subsequently, the patient regularly received octreotide LAR injection at a local hospital. He experienced weight loss and fatigue for the following 2-4 mo and recovered gradually. He received no chemotherapy or CT/MRI re-examination for some personal reasons. As of 8-mo follow-up, the patient is alive and showed no discomfort.

DISCUSSION

Histological diagnosis is essential for the treatment of patients with PNEN and can be carried out using resection samples, while core biopsies can be performed in patients with advanced disease[4]. ^{68}Ga-DOTATOC-PET-CT, with high sensitivity (92%) and specificity (83%), has been recommended as part of tumor staging, preoperative imaging, and restaging[4]. The EUS features (size and irregular lesion margins) associated with malignancy/aggressiveness of iso- and hypervascular solid pancreatic lesions have also been reported[5]. However, a definitive diagnosis cannot be established based on imaging findings alone. Biopsy can be performed by EUS-FNA/B or percutaneous ultrasound/CT-guided biopsy. Currently, EUS-FNA/B represents the gold standard for diagnosis of pancreatic lesions[6]. This technique provides pathological diagnosis as well as mitotic rate and Ki-67 index which defines grading, with an overall accuracy of approximately 92%[5], leading to its fundamental role in PNENs. However, these approaches may be hampered by gastric varices, poor access windows, target mobility, adjacent critical structures, and skin-to-target remoteness.

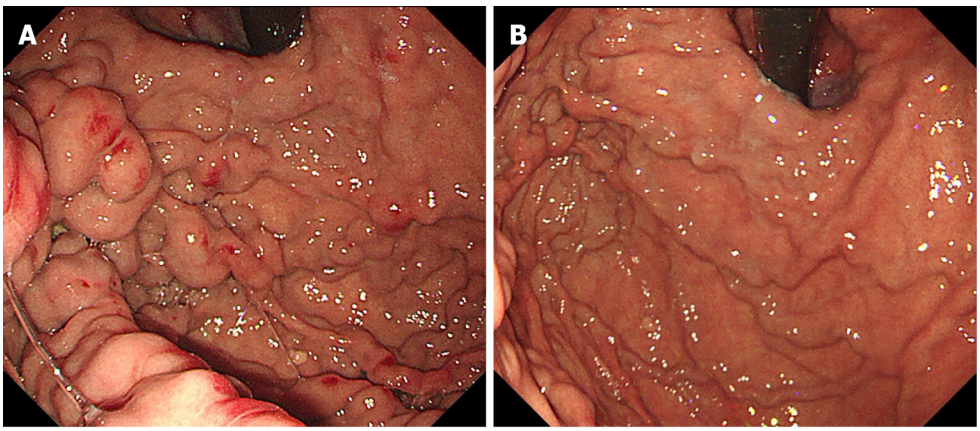
PNENs originate in the endocrine cells of the pancreas, and some of them can secrete specific hormones. Thus, PNENs can be classified as functional PNENs or non-functioning PNENs (NF-PNENs). Due to the lack of symptoms, NF-PENs tend to remain occult until a late stage of disease. In the study by Balachandran *et al*[2], venous tumor thrombus was detected by CT in 29 out of 88 (33%) patients with NF-PNEN. Six of these 29 patients showed invasion of portal vein. Portal venous tumor thrombus (PVTT) is a typical complication of hepatocellular carcinoma and is associated with a poor prognosis[7]. Other causes of PVTT include gastrointestinal and abdominal-pelvic malignant tumors[8]. Pancreatic neoplasms, especially neuroendocrine tumors, represent a possible but uncommon etiology of portal venous invasion[9,10].



Due to the PVTT in the present case, a gastroscope biopsy forceps-assisted intravascular biopsy was a safe and effective procedure for obtaining samples for histopathology, allowing the initiation of targeted drugs and chemotherapy. Portal vein catheterization has a certain learning curve, and the biopsy device must be introduced into the lesion by transhepatic approach using a large enough catheter (7 Fr). This would lead to a high risk of bleeding due to hepatic tract puncture. To prevent this complication, the puncture tract was embolized with coils, and the patient recovered well without any complications. Clinical use of percutaneous transhepatic portal catheterization was first described in 1970[11,12]. Since then, this has been proven to be a safe technique with few complications[13,14]. It is widely used to control gastroesophageal variceal bleeding[15-17] and to localize gastrointestinal hormone-producing tumors[18-21]. In hormone-producing tumors, percutaneous transhepatic portal catheterization has usually been performed for blood sampling from the portal vein. Here we expanded the use and value of transhepatic portal catheterization for diagnostic purposes.

The use of endoscopic biopsy forceps in intravenous biopsy has been reported. Guirola *et al*[22] reported an intravascular biopsy using a bronchoscopy forceps for facilitating the diagnosis of pulmonary artery intimal sarcoma. Chick JFBreported a transbiliary intravascular ultrasound-guided diagnostic biopsy of an inaccessible pancreatic head mass using core biopsy needle[3]. Sherk *et al*[23] reported a single-center retrospective analysis of 36 patients who underwent transvenous biopsy using cutting biopsy forceps; one of the patients in their study underwent a PVTT biopsy *via* transhepatic portal vein access, which is similar as our work. Apart from this, the use of biopsy forceps in portal vein biopsy has rarely been reported, let alone gastroscope biopsy forceps. Dodd GD III and Vilana R both performed Doppler-guided percutaneous portal vein thrombi biopsy using aspiration needle[24,25]. The potential side effects of percutaneous portal vein sampling include severe biliary or vascular injury. The potential complications include hepatic arterial or portal venous bleeding, bile duct laceration, and

formation of biliary-vascular fistula, arterio-venous fistula, or pseudoaneurysm. EUS-FNA of portal venous thrombi represents an alternative approach which might overcome these limitations. Compared with fine needle aspiration, our method may help avert the need for repeated liver puncture, and reduce the risk of injury.

Currently, dual-tracer (^{68}Ga-DOTATOC and ^{18}F-FDG-)-PET/CT scan is a powerful imaging modality for the diagnosis and evaluation of PNET[26]. We did not perform the PET/CT scan owing to the patient's financial constraints. Moreover, the final therapeutic choice for the inoperable tumor would

not have changed regardless of the tumor stage. The validity of our method was uncertain prior to this case. Lack of malignant cells in the specimen obtained from a malignant thrombus may lead to a false-negative diagnosis. We tried to prevent false-negative result by obtaining samples for 3 times. Our positive result suggests that tumor cells can be obtained from the PVTT. Our work suggests that the gastroscope biopsy forceps of an appropriate size and function is a suitable substitute to obtain biopsy in the portal vein system. There is still a need for well-designed clinic trials, but this procedure may improve the diagnosis of portal vein thrombosis and related diseases.

CONCLUSION

Percutaneous transhepatic intraportal biopsy is valuable for the diagnosis of portal thrombosis and related diseases. Using gastroscope biopsy forceps through the sheath for tissue sample appears to be safe and effective, and can be performed in the context of other interventional procedures. More clinical trials are required to verify the safety and efficacy of this technique.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Ragesh Babu Thandassery, MD, Assistant Professor, Doctor, Department of Medicine, Central Arkansas Veterans Healthcare Systen, Little Rock, AR 72205, United States. doc.ragesh@gmail.com

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

Hepatocellular carcinoma (HCC) is the most frequent liver neoplasm, and its incidence rates are constantly increasing. Despite the availability of potentially curative treatments (liver transplantation, surgical resection, thermal ablation), long-term outcomes are affected by a high recurrence rate (up to 70% of cases 5 years after treatment). HCC recurrence within 2 years of treatment is defined as "early" and is generally caused by the occult intrahepatic spread of the primary neoplasm and related to the tumor burden. A recurrence that occurs after 2 years of treatment is defined as "late" and is related to de novo HCC, independent of the primary neoplasm. Early HCC recurrence has a significantly poorer prognosis and outcome than late recurrence. Different pathogenesis corresponds to different predictors of the risk of early or late recurrence. An adequate knowledge of predictive factors and recurrence risk stratification guides the therapeutic strategy and post-treatment surveillance. Patients at high risk of HCC recurrence should be referred to treatments with the lowest recurrence rate and when standardized to combined or adjuvant therapy regimens. This review aimed to expose the recurrence predictors and examine the differences between predictors of early and late recurrence.

Key Words: Hepatocellular carcinoma; Early recurrence; Late recurrence; Predictors; Liver transplant; Liver resection; Thermal ablation

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Hepatocellular carcinoma is burdened by a high rate of both early and late recurrence. The knowledge of the predictive factors of recurrence and its risk stratification should allow optimization of the management of the patient with hepatocellular carcinoma.

INTRODUCTION

Liver cancers represent the fifth neoplasm by incidence and the fourth cause of cancer-related deaths worldwide, with a higher incidence in men than in women[1] and an epidemiological distribution that results from the variations of etiological factors for liver disease (with a current reduction in viral hepatitis and an increase in metabolic etiologies)[2,3]. Hepatocellular carcinoma (HCC) accounts for about 90% of liver cancer cases, with an increasing incidence of 75% from 1990 to 2015[1,4]. The onset of HCC generally follows chronic liver damage resulting in the development of fibrosis and especially liver cirrhosis, although cases of HCC in the absence of liver damage are possible and are generally related to aflatoxin exposure[5].

The main risk factors for HCC are represented by: liver cirrhosis and chronic hepatitis; chronic hepatitis B virus (HBV) infection (with or without hepatitis D virus)[6,7] or hepatitis C virus (HCV)[8,9]; chronic alcohol abuse; metabolic syndrome[10]; diabetes mellitus[11]; and obesity[12]. In particular, 1% to 8% of patients with liver cirrhosis develop HCC annually[13]. Low platelet count, severe portal hypertension, certain comorbidities (*e.g.*, obesity, diabetes mellitus), cigarette smoking, concomitant alcohol consumption, older age and male sex are factors closely associated with the development of HCC in patients with liver cirrhosis[13-17].

The mortality rate of HCC patients, although improving, still appears to be extraordinarily high[18]. An early diagnosis and an appropriate therapeutic approach contribute to higher overall and disease-free survival rates. In particular, when diagnosed at an early stage, HCC can be effectively treated by liver transplantation (LT) or loco-regional techniques, including liver resection (LR) and radio-frequency ablation (RFA). Optimal treatment choice is based on both tumor burden and residual liver function[19-21]. HCC recurrence rates after LT accounts for about 13% of cases[22], and these rates appear significantly higher after loco-regional treatment, reaching 70% of cases at 5 years[4]. The recurrence of the neoplasm may reflect both the presence of intrahepatic metastases ("true" or "early" recurrence) and the development of de novo tumors ("late" recurrence). A 2-year cutoff is generally used to define the two entities[4].

There are numerous factors (related to the patient, the tumor and the type of treatment) able to predict the risk of recurrence after loco-regional treatment or LT. Although many predictors are common to early and late recurrence, other factors may be exclusive to one form due to the different pathogenesis. An adequate recurrence risk stratification would allow personalization of the therapeutic strategy for each patient, optimization of the surveillance program and ideally encourage the study, validation and use of adjuvant therapy in high-risk patients.

The aim of this review was to examine the predictors of HCC recurrence after LT and loco-regional treatment and discuss the differences between predictors of early and late recurrence.

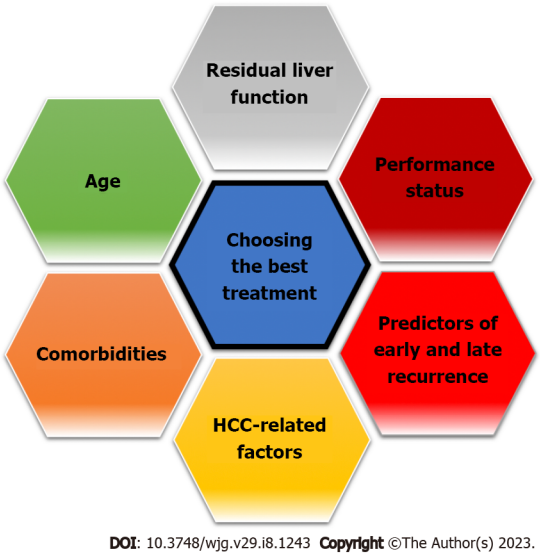
STRATEGIES OF HCC RADICAL TREATMENT

In order to define the most appropriate therapeutic strategy able to maximize outcomes and reduce the risk of recurrence, HCC requires appropriate staging that considers cancer-related factors and residual liver function. The Barcelona Clinic Liver Cancer (BCLC) staging system is the most used to predict patient prognosis and establish treatment allocation[4]. It divides patients into 5 categories (0, A-D) based on tumor characteristics (uni- or multifocality, vascular invasion, size and extrahepatic spread) and liver function (assessed by Child Pugh score).

"Very early HCC stage" (BCLC 0) is defined as patients with preserved liver function and carcinoma in situ (single HCC lesion < 2 cm without vascular invasion), whereas "early stage" (BCLC A) is defined as patients with preserved liver function and a single lesion > 2 cm or 3 lesions with diameters < 3 cm. Patients at BCLC stage 0 and A are optimal candidates for a radical therapeutic strategy (LT, ablation, surgical resection). Patients in more advanced states (BCLC B-D) are candidates for palliative (chemoembolization, systemic therapy) or supportive treatment[4,21].

Due to the excellent long-term outcomes achievable, LT is considered the gold standard for the treatment of HCC[22,23]. It is indicated as the first-line therapy in patients with HCC who meet the Milan criteria (single tumor ≤ 5 cm or multiple tumors as ≤ 3 nodules size ≤ 3 cm) without vascular invasion and/or extrahepatic involvement[24]) but are not eligible for LR[4]. Recent evidence also suggests that patients beyond the Milan criteria could be reconsidered for LT after adequate downstaging of the tumor[25]. LR is the treatment of choice in HCC patients with or without cirrhosis with well-preserved liver function, solitary tumors and clinically mild portal hypertension (hepatic vein to portal system gradient ≤ 10 mmHg)[4,26], with the possibility (not standardized yet) to extend the indication to multicentric tumors or to tumors > 2 cm[4]. It is still one of the main local-regional curative-intent treatments, with a 5-year survival between 40% and 70%[27].

Thermal ablation with RFA or microwaves is the standard of care for HCC patients with BCLC 0 and A stage not suitable for surgery (LT or LR) or as an alternative to LR in very early HCC stage with favorable localization also in patients eligible for surgery[4]. Thermoablation is also indicated as a neoadjuvant therapy in patients who are candidates for LT (pre-transplant) in order to reduce the risk of recurrence. Selected patients with intermediate HCC-BCLC B (solitary > 3 cm or > 3 nodules < 3 cm or advanced liver failure not clinically decompensated) can be reasonably treated with RFA, even if medium- and long-term outcomes appear worse than patients with HCC BCLC 0 or A[28].



Transarterial chemoembolization (TACE) is the most widely used treatment for unresectable HCC and offers significant overall survival advantages over best supportive care[4], although it has no clear curative purposes and cannot be considered a radical approach. In particular, the survival rates after TACE are 70.3% at 1 year, 51.8% at 2 years, 40.4% at 3 years and 32.4% at 5 years[29]. The rationale of the technique is based on the intermediate HCC intense arterial neo-angiogenic activity and consists in the intra-arterial administration of cytotoxic agents (doxorubicin or platinum derivatives) followed by the embolization of peritumoral vessels inducing a cytotoxic and ischemic effect of the tumor mass. Combination treatments (*e.g.*, TACE + RFA) and neoadjuvant or adjuvant systemic treatments are currently being studied.

EARLY OR LATE RECURRENCE

The recurrence of HCC represents a relevant clinical issue, affecting up to 70% of patients undergoing curative treatment[4]. Although many factors are involved in the decision-making process of the best possible treatment (Figure 1), the assessment of baseline risk recurrence significantly influences the choice of treatment type and its timing. Moreover, the treatment of a relapse is generally more complex than the treatment of the first lesion, due to the change in anatomical or functional liver conditions and a more advanced age. Patients at high risk of early recurrence are candidates for close surveillance and potentially adjuvant therapy, which has not yet been standardized[30,31].

The "true" recurrence (secondary to the presence of occult intrahepatic metastases) is generally "early" and accounts for more than 70% of tumor recurrence. It derives from an intrahepatic dissemination of the neoplasm through the portal circulation. A 2-year cutoff is used to distinguish it from late recurrence, generally resulting from de novo development of the neoplasm. However, this cutoff remains arbitrary and not universally accepted. Yamamoto *et al*[32], for example, identified 17 mo as the best cutoff to distinguish early and late recurrence on a cohort of 252 patients with recurrence of HCC after hepatectomy. Previously Hayashi *et al*[33] had hypothesized a 1 year cutoff instead. A further shorter observation period has recently been hypothesized by Xing *et al*[34] who identify 8 mo as the ideal threshold to define a recurrence of HCC as early or late. Although the temporal criterion is used to distinguish a pathogenesis related to the presence of occult intrahepatic metastases or to a de novo neoplasm, a precise differentiation would require the study of recurrence clonality by genetic/genomic analyzes[35].

The two types of recurrence are two distinct entities associated with different risk factors. Early recurrence is associated with tumor-related factors, whereas late recurrence is related to underlying liver disease. They have a substantially different clinical and biological profile and are burdened by different morbidity and mortality. In fact, an early recurrence represents a significant negative prognostic factor and has a far greater impact on overall survival than a late recurrence[32,36]. Xing *et al*[34] demonstrated that patients with early recurrence showed a median of survival free from cancer of 8.4 mo (7.5-10.0 mo) compared to a median of 21.3 mo (17.9-23.8 mo) for patients with late recurrence. In particular, an early recurrence, mainly determined by the aggressiveness of the primary tumor, is characterized by larger dimensions, higher rates of multifocality and intrahepatic spread, higher probability of vascular invasion and higher levels of alpha-fetoprotein (AFP) compared to a recurrence that develops later[36]. Conversely, late recurrence is generally related to etiology and cirrhosis, risk factors for hepatocarcinogenesis, and not to the primary tumor[37].

Figure 1 Determinants of therapeutic decision making for hepatocellular carcinoma. HCC: Hepatocellular carcinoma.

EARLY RECURRENCE PREDICTIVE FACTORS

The factors affecting the possibility of early HCC relapse after LT or loco-regional treatment can be classified into three categories: those related to the tumor (size, number of nodules, differentiation, oncological markers); to the patient (*e.g.*, age, comorbidity, liver function, possible viral load, presence and activity of hepatitis, presence and activity of liver cirrhosis); and treatment (type of treatment, margins, characteristics of resection) (Table 1)[38,39].

Predictors of early recurrence related to HCC characteristics

Several factors related to the characteristics of HCC are able to predict the risk of early recurrence (Table 1). This risk is closely related to the tumor burden and its aggressiveness, which increases the probability of occult intrahepatic spread and affects the radicality of the treatment[40].

Preoperative radiological imaging can already provide first indications about the risk of relapse. In this regard, the size of the tumor represents a relevant predictor of the risk of early recurrence. Jung *et al*[36] showed that a maximum diameter of HCC greater than 3 cm before a curative LR represented an independent risk factor for early recurrence (defined by the authors as occurring within 1 year of treatment). These results have recently been confirmed by Lee *et al*[41]. Zhu *et al*[42] identified a 4.77-fold higher risk of early recurrence after an LR for cancers with a maximum diameter greater than 2.6 cm compared to those with a smaller maximum diameter[42]. Similarly, the multifocality of HCC seems to be another significant risk factor for early recurrence[41]. Tumor size and number of lesions represents together the aforementioned Milan criteria. As expected, being beyond the Milan criteria represents an independent risk factor for early HCC recurrence[43].

At histological evaluation, the most predictive factors of the risk of early HCC recurrence are the presence of microvascular invasion, the integrity of the capsule and the degree of differentiation. In light of the fact that early recurrence is generally due to intrahepatic dissemination of the neoplasm through the portal circulation, it is not surprising that vascular invasion has been identified many times as an independent predictor of recurrence. If the involvement of the major vessels (*e.g.*, portal vein, inferior vena cava) can be evaluated radiologically and often excludes the possibility of loco-regional treatment for radical purposes, microvascular invasion needs to be evaluated by histopathological analysis of the intraoperative sample. Microvascular invasion, although dependent upon the operator and influenced by possible sampling errors, represents an independent risk factor for early recurrence[34,44,45] affecting approximately one-third of HCC cases that underwent LR[37]. Since a qualitative and/or quantitative classification of microvascular invasion is not yet available, its only presence/absence is generally considered in the histopathological evaluation. However, in this regard, Roayaie *et al*[46] proposed a risk system based on histological features of microvascular invasion that includes invasion of a vessel with a muscular wall and invasion of vessels ≥ 1 cm away from the tumor capsule. According to the authors, this system stratifies patients into three distinct groups with significantly different risks of recurrence and death. In particular, patients with microvascular invasion and the aforementioned risk factors show outcomes (tumor recurrence rate, mortality rate) comparable to patients with macroscopic vascular invasion.

The integrity of the HCC capsule would instead represent a protective factor for the risk of recurrence [42]. The capsule would act as a barrier to the spread and metastasis of cancer cells. This function is lost

Table 1 Predictors of early hepatocellular carcinoma recurrence after curative treatment

Predictors related to HCC characteristics	Ref.	Predictors related to patient characteristics	Ref.	Predictors related to treatment	Ref.
Size		Liver cirrhosis	[37,41]	RFA (*vs* LR)	[41,88,89]
> 2.6 cm	[42]				
> 3 cm	[36,41]				
Multifocality	[41]	Liver insufficiency (CPS, MELD, ALBI)	[37,56-58]	LR:	
				Liver resection margins invasion	[44]
				Liver resection margins < 1 cm	[43,86]
				Non-anatomical resection[1]	[45]
Beyond Milan criteria	[43]	High total bilirubin	[42]	RFA: ablation margins < 1 cm	[91]
Microvascular invasion	[34,36,38,40,44,45]	Male sex	[37]		
Lack of capsule integrity	[34,42]	High PLR	[49,59,60]		
Poor histological differentiation	[36,43,47]	High NLR	[49,60]		
High AFP	[36,41,50]	DAAs therapy			
> 10 ng/mL	[48]	Predictor	[62,63]		
> 32 ng/mL	[45]	Non-predictor	[64-76]		
> 400 ng/mL	[40]	Protective	[77-83]		
High PIVKA-II	[41,52,55]	High viral load in HBV infected patients	[109]		
> 46.0 mAU/mL	[38]				
> 375.5 mAU/mL	[51]				

[1]Available data are contradictory and not conclusive.

AFP: Alpha-fetoprotein; ALBI: Albumin-Bilirubin score; CPS: Child-Pugh score; DAA: Direct antiviral agent; HBV: Hepatitis B virus; HCC: Hepatocellular carcinoma; LR: Liver resection; MELD: Model for end-stage liver disease; NLR: Neutrophil-to-lymphocyte ratio; PIVKA-II: Protein induced by vitamin K absence or antagonist II; PLR: Platelet-to-lymphocyte ratio; RFA: Radio-frequency ablation.

in non-capsular HCC or those with a ruptured capsule[34,42]. Zhu *et al*[42] showed that non-capsular HCC was associated with a higher rate of poorer differentiation and vascular invasion than capsular HCC.

Histological differentiation is considered an independent risk factor for early HCC recurrence. It is classified according to the Edmonson-Steiner criteria: 1st and 2nd degree correspond to well differentiated neoplasms; and 3rd and 4th degree correspond to poorly differentiated neoplasms. In particular, grades 3 and 4 are related to a significantly increased risk of early recurrence[36,43]. In patients without microvascular invasion, the degree of differentiation seems to be the best histological predictor of the risk of early recurrence and overall survival[47].

In light of the growing evidence of the efficacy in predicting the risk of recurrence, histological evaluation will become crucial in choosing the optimal therapeutic strategy for each patient, allowing the implementation of the stratification of the basal recurrence risk with the postoperative one. Patients at high risk of recurrence should undergo an aggressive surveillance strategy and ideally adjuvant therapy.

Among the predictors of early recurrence, the markers expressed by the neoplasm are certainly the most studied. In particular, AFP, a glycoprotein physiologically produced by the liver and fetus, can increase in pathological conditions, such as liver cancer. In addition to the diagnostic phase, it plays an important role as a predictor and monitoring tool in the context of HCC recurrence. There is almost unanimous agreement on the predictive value of elevated AFP levels for the risk of early HCC recurrence after treatment[36,48,49], but there are no standardized cutoffs pre- and post-treatment.

Jung *et al*[36] showed that high AFP values both pre- and post-hepatectomy were associated with a higher risk of early recurrence (which the authors defined as < 1 year after treatment) but without a standardized threshold value. Using a retrospective data analysis, Kim *et al*[48] showed that preoperative AFP values > 10 ng/mL were a predisposing factor of disseminated HCC recurrence

within 3 mo after hepatectomy for solitary HCC [odds ratio: 5.333; 95% confidence interval (CI): 1.095–25.985]. Fang *et al*[40] showed instead that preoperative AFP > 400 ng/mL correlated independently with the risk of early recurrence. Recently, AFP levels at 12 wk after achieving sustained virological response with direct antiviral agents (DAAs) treatment in chronic HCV patients have also been independently associated with a risk of HCC recurrence[50].

The protein induced by vitamin K absence or antagonist II (PIVKA-II) is an immature form of prothrombin, a cofactor of vitamin K that is synthesized by the liver when the latter is not produced or antagonized. Evaluation of PIVKA-II has been shown to be useful in diagnosing HCC and in stratifying the risk of recurrence[38,41,51,52]. In fact, it acts as a growth factor, promoting cell proliferation and tumor angiogenesis in HCC patients[52,53]. The evaluation of PIVKA-II appears to be complementary to AFP[54]. Low values of both AFP and PIVKA-II are associated with a better prognosis compared to elevated levels of AFP and/or PIVKA-II[55]. Serial measurements of both proteins allow a prompt diagnosis of early recurrence. In fact, pre- and post-treatment levels of PIVKA-II are good predictors of early HCC recurrence[38,41,51] since they are related to greater aggressiveness of the neoplasm, such as the presence of vascular invasion and intrahepatic metastasis of HCC cells[52].

Similarly to what is highlighted for AFP, there is no agreement on a PIVKA-II cutoff that is useful as a guide for assessing the risk of recurrence. In this regard, Wang *et al*[51] showed that in patients with a low risk of recurrence (tumor size < 5 cm, single tumor, absence of satellite lesions, absence of vascular invasions, high degree of histological differentiation, BCLC stage 0-A), a preoperative value of PIVKA-II > 375.5 mAU/mL was the strongest independent prognostic factor for the risk of early recurrence [hazard ratio (HR): 2877; 95%CI: 1524-5429]. Furthermore, patients who expressed high levels of PIVKA-II showed lower 1-year time-to-progression than patients with low levels (54.8% *vs* 20.2%, respectively). More recently, Hong *et al*[38] identified a cutoff of 46 mAU/mL for PIVKA-II for predicting an increased risk of early recurrence.

Predictors of early recurrence related to patient characteristics

Predictors related to patient characteristics are associated with the risk of late recurrence. In fact, they represent the substrate for the risk of hepatocarcinogenesis and generally do not correlate with the aggressiveness of the primary tumor, which is strongly associated with early recurrence instead. However, some studies have shown a certain impact of the patient's basal phenotype on HCC recurrence that occurs in the first 2 years after treatment (Table 1).

In this regard, the presence of liver cirrhosis and the degree of hepatic dysfunction are the factors that most increase the risk of early recurrence after curative treatment[37,41]. In the models used for risk stratification in patients undergoing hepatectomy, the degree of hepatic dysfunction is quantified by the Child Pugh score[56,57], the model for end-stage liver disease[41] or by the Albumin-Bilirubin score[37,58]. The latter in particular seems to have better discriminatory power in this setting since it helps to further stratify stage A of the Child-Pugh score, which includes almost all patients undergoing LR[58]. Total bilirubin levels, an expression of the degree of hepatic dysfunction, also correlate with the risk of early recurrence[42]. Furthermore, according to Chan *et al*[37] male patients undergoing hepatectomy show a higher risk of early recurrence than female patients.

The predictive value on outcomes (mortality and recurrence) of the neutrophil-to-lymphocyte ratio (NLR) and platelet-to-lymphocyte ratio (PLR) in HCC patients has been extensively studied. These scores are an expression of the systemic inflammatory response, a known preoperative risk factor for HCC outcomes[49,59,60]. High PLR has been shown to predict lower overall survival (HR: 1.63, 95%CI: 1.34-1.98) and earlier HCC recurrence (HR: 1.52, 95%CI: 1.21-1.91)[59]. Similar results were also highlighted for NLR[49,60]. In addition, both the NLR and PLR were identified as independent risk factors for predicting overall survival and recurrence-free survival (RFS) in HCC patients[59,60].

In recent years, a heated scientific debate has been carried out on the hypothesis of an increased risk of HCC incidence and recurrence in chronic HCV patients treated with DAAs. Unlike interferon (IFN)-based therapeutic regimens, which have been proven to reduce the incidence and recurrence of HCC in cases of sustained virological response[61], some data indicated that after DAA therapy HCC risk may remain high[4,62]. In particular, the retrospective analysis of some patient cohorts revealed an unexpectedly high rate of early HCC recurrence in patients undergoing antiviral treatment with DAAs [62,63]. It has been hypothesized that the rapid fall in viral load induced by DAAs could lead to an altered immune surveillance, promoting the growth of already existing cancer clones[4]. However, the higher number of patients eligible for antiviral treatment with DAAs could influence the apparent raise in early recurrence rates. In fact, due to the manageability and safety profile of these therapeutic regimens, a larger number of patients with advanced liver disease at high risk of HCC (*e.g.*, liver cirrhosis, advanced age, multiple morbidity) have undergone antiviral treatment than those who were candidates for IFN-based schemes. Subsequent prospective studies underlined that although the rates of early HCC recurrence remain high in patients who have obtained viral clearance by DAAs, these rates are comparable to those reported in the literature for patients not treated with these regimens[64-66].

Waziry *et al*[67], in a meta-analysis, concluded that there is no evidence that DAA therapy was associated with higher HCC recurrence and that the available data do not suggest differentiated surveillance pathways for HCC among patients receiving IFN-free therapeutic regimens or receiving DAA treatment. However, the heterogeneity of the studies included in this analysis limited the power of

its results. Although there is no conclusive evidence at the moment in favor or against an increased risk of early HCC recurrence in patients undergoing treatment with DAAs, it is clear that the risk of early HCC recurrence in patients with HCV-related cirrhosis remains high despite viral eradication.

The latest guidelines of the European Association for the Study of the Liver (published in 2018) suggested a more intensive surveillance strategy (3-4 mo imaging intervals for the first 2 years that can be extended to 6-mo intervals thereafter) in this patient setting[4]. However, the updated literature available after the publication of these guidelines almost unanimously confirmed that DAA therapy was not associated with an increase in early HCC recurrence rates and that both recurrence rates and tumor patterns after initiation of antiviral therapy did not differ between patients who received IFN-based or IFN-free therapy[68-76]. On the contrary, there is now increasing evidence of a reduction in the risk of early (as well as late) HCC recurrence after viral eradication achieved by DAA[77-83].

Predictors of early recurrence related to HCC treatment

The choice of treatment for HCC depends on the characteristics of the patient (in particular the residual liver function and the performance status) and the neoplasm characteristics (size, single or multifocal, vascular invasion, distant metastasis) as well as the indication and eligibility for LT.

In terms of recurrence risk, no conclusive data are available in the literature about which type of loco-regional treatment is more advantageous. In the absence of liver cirrhosis, LR probably offers the best prognostic prospects, with an early recurrence rate of approximately 10%[36]. Including patients with liver cirrhosis, the early recurrence rates of post-hepatectomy HCC reported in the literature range from 25% to 50%[34,84,85]. Metachronous HCC, new postoperative lesions and intrahepatic metastasis from primary HCC are in fact relatively common following hepatectomy[42]. In this regard, the resection margins after hepatectomy appear to be closely related to the risk of recurrence. In particular, neoplastic invasion of the resection margins represents a significant predictor of the risk of recurrence[44]. A resection margin < 1 cm also seems to be an independent risk factor for early HCC recurrence[43,86]. Some evidence also suggests that a non-anatomic hepatic resection (resection or enucleation without regard to sectoral structure) could lead to an increase in early recurrence rate[45]. In fact, an anatomic resection (resection of the entire liver parenchymal tissue supplied by the portal venous system draining the HCC tissue, independent of margin length) could hinder cell dissemination, reducing tumor cell flow throughout the portal circulation and consequently reduce the risk of intrahepatic metastasis and improve RFS. However, the absence of randomized clinical trials comparing anatomical and non-anatomical hepatic resection do not provide conclusive indications[87].

As previously mentioned, a maximum tumor diameter greater than 2.6 cm (according to Zhu *et al*[42]) or 3.0 cm (according to Jung *et al*[36]) before a curative LR is predictive of a high rate of early recurrence. The risk of early HCC recurrence with a diameter greater than 2.6 cm appears 4.77-fold higher than neoplasms with a diameter ≤ 2.6 cm[42]. Furthermore, high preoperative total bilirubin levels also correlate with an increased risk of recurrence[42]. In particular, this risk would be increased by 6% for every 1 mmol/L increase in preoperative bilirubin. Chan *et al*[37] in a large multicenter study provided pre- and post-hepatectomy risk stratification models (ERASL-pre and ERASL-post, respectively) with the ability to identify three early recurrence risk classes, with a 2-year malignancy free survival rate of 64.8%, 42.5% and 20.7% in low, intermediate and high risk patients, respectively. In these models male sex, large tumor size, multifocal tumor, high Albumin-Bilirubin score and high serum AFP represented the factors closely related to early recurrence after LR. Ideally, these models, once validated, would optimize the therapeutic strategy for patients with high baseline risk of early recurrence after hepatectomy (revaluating the possibility of LT or providing adjuvant therapy) and intensify the surveillance program.

Compared to LR, RFA treatment shows significantly higher recurrence rates[41,88,89]. In particular RFA results in shorter overall survival and time to recurrence (5-year overall survival of 71.1%, 5-year recurrence time of 63.8%) than LR (5-year overall survival of 61.1%, 5-year recurrence time of 71.7%) [88]. The HR for death (0.84, 95%CI: 0.74-0.95) and recurrence (0.74, 95%CI: 0.68-0.79) was significantly lower in patients undergoing LR than in those undergoing RFA. Recently, Lee *et al*[41], through a retrospective study comparing the two methods, showed that in patients with BCLC stage A HCC treatment with RFA was associated with a 1.8 times higher probability of HCC recurrence than hepatectomy (95%CI: 1541-2216). While confirming higher overall survival rates after LR compared to RFA, other data were unable to demonstrate significant differences in RFS between the two methods [90]. Finally, similar to what was shown for LR, an ablation margin ≥ 10 mm away from the tumor lesion guarantees better outcomes and a lower rate of recurrence compared to an ablation margin ≥ 5 mm and < 10 mm[91].

PREDICTIVE FACTORS OF LATE RECURRENCE

Conventionally, HCC recurrence is defined as late when it occurs 2 years after treatment of the primary tumor. Late recurrence is generally related to de novo development of the neoplasm and does not depend on the characteristics of the previous tumor. About 90% of late relapses consist in exclusively

intrahepatic localization, whereas the remaining cases show both intrahepatic and extrahepatic localizations[92]. Therefore the risk factors are mainly related to underlying liver disease (Table 2).

Predictors of late recurrence related to patient characteristics

Among the predictive factors of late recurrence related to the basal characteristics of the patient, it is easily understood that the main predictive factor is the presence of liver cirrhosis, a fertile substrate for hepatocarcinogenesis[93-96]. In particular, the presence of liver cirrhosis increases the risk of late HCC recurrence by 3 or 4 times[41,93]. In fact, liver cirrhosis is a pre-malignant condition that due to an accelerated hepatocyte turnover induced by the chronic inflammatory state promotes the accumulation of gene aberrations and cell transformations. The high rate of gene errors and the subsequent uncontrolled cell proliferation therefore favor the development of HCC[97]. However, patients with liver cirrhosis undergoing curative treatment for HCC show a late recurrence rate significantly higher compared to de novo incidence rate in patients with no history of prior HCC[41]. This implies that the presence of liver cirrhosis is not the only factor that elicits the cancer risk in patients with late recurrence.

As highlighted by Lee *et al*[41], Xu *et al*[92] and Yang *et al*[93], the age and sex of the patient also contribute to the late recurrence risk stratification. Older and male patients show an increased risk of late HCC recurrence after curative treatment. The sex difference in the late recurrence rate could be explained by the potential protective role of estrogen on the development of HCC[98,99], resulting in more than 3 times higher probability of late recurrence in men compared to women[93].

The predictive role of liver stiffness (LSM) in the risk of HCC occurrence is well documented in the literature[100,101]. Since occurrence and late recurrence show similar pathogenesis (de novo hepatocarcinogenesis), it seems reasonable to believe that LSM can also represent a risk factor for late recurrence. In this regard, Jung *et al*[102] had already highlighted how the presence of liver cirrhosis assessed by LSM ≥ 13.5 kPa was associated with an increased overall risk of recurrence. More recently, Marasco *et al*[43] demonstrated that LSM but even more the splenic stiffness (surrogate for the degree of portal hypertension) were associated with an increased risk of late HCC recurrence. Late RFS was significantly different according to the splenic stiffness cutoff of 70 kPa.

These data find further evidence in the literature. Fang *et al*[40] in fact showed how the splenic volume (evaluated through automated volumetry software from preoperative computed tomography images) correlated independently with the probability of HCC recurrence 2 years after hepatic resection. In particular, for each 1 mL increase in splenic volume, the risk of late recurrence increased by 0.3%. In addition, patients with high splenic volume (> 165 mL) showed a lower 5-year RFS (5-year RFS 36%) than patients with low splenic volume (< 165 mL, 5-year RFS 71%). The correlation between stiffness/splenic volume and the risk of late HCC recurrence probably comes from the close association with the severity of liver disease and portal hypertension, both involved in hepatocarcinogenesis. The correlation that some studies showed between the risk of late recurrence and platelet counts or the presence of esophageal varices, which are also surrogates of the degree of portal hypertension and severity of liver damage[43,103,104], is therefore easily explained.

In patients with chronic HBV infection, the presence of viral replication increases the risk of late recurrence[105-108]. In particular, patients undergoing LR for HCC with high preoperative HBV-DNA levels show lower median overall survival and RFS compared to those with low viral load[106]. Patients with high viremia are characterized by higher Ishak inflammatory and fibrosis scores, favoring hepatocarcinogenesis[105]. The liver inflammatory activity induced by the high viral load may lead to necrosis and regeneration of hepatocytes, increasing the rate of gene errors and neoplastic transformation.

Recently, it was hypothesized that a high viral load (HBV-DNA > 10^4 copies/mL) was a risk factor also of early recurrence[109]. In fact, high preoperative levels of HBV-DNA increased the risk of microvascular invasion by about 40%[110]. In patients with high preoperative viral load, the initiation of antiviral treatment after surgical resection reduced both early and late HCC recurrence rates[106,109,110]. However, a similar effect on late recurrence rates was also found in patients with low preoperative viral loads[111]. Despite comparable efficacy in obtaining virological response, recent evidence suggested that tenofovir disoproxil fumarate (TDF) treatment was associated with a significantly lower risk of both HCC occurrence[112] and early and late recurrence[113] compared to treatment with entecavir (ETV). In particular, the HCC recurrence rate at 5 years from surgical resection was 33.6% in patients treated with TDF and 44.5% in those treated with ETV[113]. Unlike ETV, TDF induced the synthesis of high serum levels of IFN-lambda 3 (IFN-λ3)[114], which has been shown to exert a strong antitumor activity[115,116]. The antitumor effect of IFN-λ3 induced by TDF would therefore be additive to the capacity of breaking down viral replication and turn off necroinflammatory activity, which is common to both nucleoside (ETV) and nucleotide (TDF) analogs.

Increasing evidence is also available on the predictive role of hepatitis B surface antigen (HBsAg) levels on the rate of late HCC recurrence. In patients undergoing LR, preoperative HBsAg levels > 200 IU/mL were independent predictors of late recurrence (HR: 1778)[84,103]. If the role of the predictor is well defined, there is nevertheless a significant heterogeneity of the cutoffs used. Huang *et al*[86] in fact highlighted how in patients with low viral load the risk for HCC recurrence significantly increased with HBsAg levels ≥ 1000 IU/mL (5-year RFS rate of 46.1% in HBsAg ≥ 1000 IU/mL group *vs* 34.1% in HBsAg < 1000 IU/mL group). According to Sohn *et al*[107], HBsAg levels ≥ 4000 IU/mL were associated

Table 2 Predictors of late hepatocellular carcinoma recurrence after curative treatment

Predictors related to HCC characteristics	Ref.	Predictors related to patient characteristics	Ref.	Predictors related to treatment	Ref.
Size > 5 cm	[92]	Liver cirrhosis	[32,41,43,84,93-96]	RFA (*vs* LR)	[41,88,117-119]

with late recurrence after curative resection in HBV-related HCC.

Predictors of late recurrence related to HCC treatment

Several studies suggested that RFA treatment increases the risk of early and late recurrence (HR: 1872; 95%CI: 1290-2717) compared to LR[41,88,117-119]. Furthermore, the overall survival at 3 years and 5 years of patients undergoing LR appeared significantly higher than patients undergoing RFA[117,118]. In particular, the 5-year overall survival rates were 80% *vs* 66%, and 5-year RFS rates were 48% *vs* 18% for LR and RFA groups, respectively[118]. Because the choice of treatment is influenced by both tumor- and liver disease-related factors, some authors hypothesize that the correlation between RFA treatment and the risk of late recurrence could reflect both. In fact, patients undergoing RFA are generally older, have a greater number of comorbidities and a worse degree of liver function than patients undergoing LR. As noted above, these factors are closely related to the risk of both late and early recurrence. Therefore, the higher risk of late recurrence in patients who received RFA compared to those treated with resection could depend on more severe underlying liver disease.

Predictors of late recurrence related to HCC characteristics

Some evidence suggested (which was different from what was expected[95,96]) that factors related to tumor burden (size, multifocality) determined an increase in the risk of late and early recurrence[45,93,105]. Recently, Xu *et al*[92] confirmed in a multicenter retrospective analysis of patients who underwent curative LR for HCC that multifocality, dimensions greater than 5 cm and the presence of satellite nodules or vascular invasion (macroscopic or microscopic) represented independent risk factors of late recurrence. The presence of multifocal HCC at baseline increased the risk of a late recurrence after curative treatment by more than 3 times (HR: 3766, 95%CI: 2287–6201)[93]. In this regard, Cheng *et al*[94] also showed that pre-hepatectomy AFP levels > 400 ug/L were related to the risk of late (as well as early) recurrence. Given the dichotomy between early and late recurrence, these factors should correlate with an increased probability of occult intrahepatic dissemination (and therefore early recurrence) rather than an increased risk of hepatocarcinogenesis (late recurrence). These data suggest that the dichotomy between early and late recurrence is probably not so clear-cut, and pathogenetic mechanisms and clinical features may overlap. Therefore, the temporal criterion alone is not able to discriminate the pathogenesis and aggressiveness of a recurrence of HCC with certainty.

LIVER TRANSPLANT AND HCC RECURRENCE RISK

LT represents the most radical approach for HCC in patients with liver cirrhosis and is able to treat

simultaneously the neoplasm and the underlying liver disease while minimizing the risk of both early and late recurrence when candidate selection is adequate[120]. In fact, a therapeutic strategy that provides for early listing for transplantation and a loco-regional bridging therapy in patients with HCC at high risk of recurrence has proven to be extremely valid and associated with excellent long-term outcomes[121]. The presence of occult extrahepatic dissemination and the persistence of the cause of liver damage (*e.g.*, HBV infection or HBV/hepatitis D virus coinfection) account for the residual risk of early and late HCC recurrence, respectively. Overall, the estimated HCC recurrence rate in patients undergoing LT is between 12% and 20%[22,122,123].

The most important predictor of the risk of early post-transplant recurrence is certainly the tumor burden. Size and number of lesions closely correlate with this risk, although not in a linear way. In fact, in multifocal HCC, starting from three or more lesions, the increase in the risk of recurrence appears to be attenuated[124]. Conversely, this risk is proportional to the size of the tumor. In particular, the recurrence rate increases by 36% for each additional centimeter of HCC diameter[125]. The microvascular invasion is another determining factor in the risk of recurrence and HCC-related death [126,127]. Its presence increases the risk of recurrence by approximately 2.4 times and significantly reduces the 5-year rates of RFS (44% *vs* 64% in the absence of microvascular invasion)[126]. Similarly, the histological finding of poorly differentiated (grade 3 or 4) HCC determines an increased risk of recurrence (39.3% *vs* 13.0% for grade 1 and 2 tumors) and reduction of 5-year RFS (39.9% *vs* 57.7%)[127]. In this setting, the prognostic role of AFP is also relevant with an inverse relationship with the post-transplant survival rate[128]. An increase in AFP greater than 7.5 ng/mL per month is associated with the presence of microvascular invasion and is predictive of post-transplant recurrence[129].

Beyond the characteristics and aggressiveness of the tumor, the etiology of liver disease also affects the rate of recurrence, especially late recurrence. In particular, the highest recurrence rate was found in patients with chronic HBV infection (18%) compared to other etiologies (11%, 10% and 8% for HCV, alcoholic liver disease and nonalcoholic steatohepatitis, respectively). In this regard, preliminary evidence suggested that an increase in RFS for HCC patients following LT can be obtained by administering anti-HBV prophylaxis and/or anti-HBV immunoglobulins[130].

Finally, some comorbidities may also influence the risk of recurrence in HCC patients undergoing LT. In particular, obese patients show a significantly higher frequency of microvascular invasion and recurrence rates and lower RFS than normal weight patients[131,132]. This correlation could be explained by a more pronounced tumor neoangiogenesis in obese patients, secondary to the increased expression of vascular endothelial growth factor. Furthermore, in obese patients the reduction of adiponectin levels and the simultaneous increase of leptin induced a pro-oncogenic state and stimulated neoplastic proliferation[131,132].

The central theme in managing the risk of recurrence is the selection of patients eligible for LT. Currently, the strongest evidence identifies the Milan criteria as the best strategy to optimize the selection of LT candidates, stratifying the risk of early recurrence, strongly correlated to tumor size and number of focal lesions[22]. These criteria suggest the presence of single tumors ≤ 5 cm or multiple tumors ≤ 3 nodules sized ≤ 3 cm, without vascular invasion and/or extrahepatic involvement as boundaries for transplant eligibility[24]. The application of these criteria guarantees a post-transplant survival rate comparable to that of patients undergoing transplants for non-neoplastic causes[133]. On the other hand, patients undergoing organ transplantation beyond the Milan criteria show significantly higher HCC recurrence rates than patients within these criteria[22].

However, growing evidence suggests that these criteria, developed in 1996, may be excessively restrictive to date, leading to the exclusion of a subgroup of patients who could benefit from transplantation[120]. Yao *et al*[134] showed that expansion of the tumor size limits (solitary tumor ≤ 6.5 cm or ≤ 3 nodules with the largest lesion ≤ 4.5 cm and total diameter ≤ 8 cm-UCSF criteria) does not adversely impact survival post-transplant. Subsequently, the same authors validated these criteria, confirming a 5-year RFS rate of 81%[135]. The extension of the Milan criteria suggested by Yao *et al*[135] made the 5%-20% of previously excluded patients eligible for LT, guaranteeing comparable long-term survival rates. Also Mazzaferro *et al*[124] attempted to overcome the previous limits through the up-to-seven criteria: HCC with seven as the sum of the size of the largest tumor (in centimeters) and the number of tumors. They showed that in the absence of microvascular invasion patients who met these criteria demonstrated survival rates comparable to patients who met the original Milan criteria (5-year overall survival of 71.2%). Conversely, the presence of microvascular invasion doubled the likelihood of recurrence and significantly reduced the overall post-transplant survival rates in these patients (up-to-seven patients 5-year overall survival of 53.6% *vs* Milan criteria patients 5-year overall survival of 73.3%). Microvascular invasion was observed in 16.6% of patients who met the Milan criteria and in over half of patients beyond the Up-to-seven criteria[124].

Recently, Mazzaferro *et al*[136] attempted to identify factors associated with HCC-related deaths of patients who underwent LT and to provide a predictive model of survival. The number of lesions and their size, as well as the levels of AFP, were significantly associated with HCC-specific deaths. To ensure an HCC-specific post-transplant survival rate of at least 70%, the authors suggested that the sum of the number and size of tumors (in centimeters) should not exceed 7 when the level of AFP was < 200 ng/mL, should not exceed 5 when the level of AFP was 200-400 ng/mL and should not exceed 4 when the level of AFP was 400-1000 ng/mL. Several studies confirmed the predictive value of pretransplant

AFP levels for HCC recurrence[22,137]. A similar role has also been demonstrated for PIVKA-II (5-fold increased risk for recurrence after transplantation)[138].

An approach independent of the size of the HCC and the number of lesions has been hypothesized through the "extended Toronto criteria"[137]. The eligibility for LT included tumors that do not have extrahepatic spread and/or macrovascular invasion and that have a low histological grade on preoperative biopsy and the patient enjoys a high performance status. The post-transplant survival rates in this case were shown to be independent of the patient's status within or beyond the Milan criteria (5-year overall survival of 69% and 78% for patients who met or did not meet the Milan criteria, respectively, $P = 0.3$) and therefore independent of the size of HCC and the number of lesions[139].

Furthermore, growing evidence suggests that an effective and sustained tumor downstaging with locoregional, surgical or systemic therapies from beyond to within the Milan criteria favorably impact overall and tumor-free survival[25,140,141]. In particular, the success rate of downstaging reported in the literature was higher than 40%[142]. Patients eligible for LT who met the Milan criteria after HCC downstaging showed 5-year tumor event-free and overall survival of 76.8% and 77.5%, respectively, compared to 18.3% ($P = 0.003$) and 31.2% ($P = 0.035$) of patients who underwent standard of care (non-transplantation therapies)[25]. Regardless of the Milan criteria, in patients with HCC eligible for LT, a pretransplantation loco-regional therapeutic approach (neoadjuvant, thermal ablation) reduced the risk of recurrence[4].

CONCLUSION

HCC is currently a potentially curable disease. However, recurrence rates still appear to be extraordinarily high. Although several factors are involved, the identification of predictive factors for both early and late HCC recurrence could optimize treatment strategies (LT, LR, thermal ablation) and surveillance. High-risk patients should be referred to treatments with the lowest recurrence rate (*e.g.*, LT [121]) and/or combination therapies, as well as intensive surveillance programs. The combination of multiple treatments or use of adjuvant or neoadjuvant therapeutic schemes (*e.g.*, immunotherapy) could reduce the recurrence rate and improve overall survival[143]. Research should therefore aim to validate these combined therapeutic strategies, particularly in patients with strong pre- and postoperative predictors of early or late recurrence.

Abstract

Functional constipation (FC) is considered the most common functional gastrointestinal disorder in children with a pooled global prevalence of 14.4% (95% confidence interval: 11.2-17.6) when diagnosed based on the Rome IV criteria. Its pathophysiological mechanisms are thought be multifactorial and complicated, resulting in difficult management. Currently, the most effective medication, when used in parallel with toilet training, is osmotic laxatives. Children's adherence to medication and parental concern regarding long-term laxative use are the main contributors to treatment failure. Recently, novel therapies with a high safety profile have been developed, such as probiotics, synbiotics, serotonin 5-hydroxytryptamine 4 receptor agonists, chloride channel activators, and herbal and transitional medicines; nonetheless, well-designed research to support the use of these therapies is needed. This review aims to focus on multiple aspects of FC in children, including global prevalence, pathogenesis, diagnostic criteria, tools, as well as conventional and novel treatment options, such as non-pharmacological management, including adequate fiber and fluid intake, physiotherapy, or neuromodulators. We also report that in very difficult cases, surgical intervention may be required.

Key Words: Constipation; Children; Laxative; Treatment; Toilet training; Herbal

Core Tip: Functional constipation (FC) is a typical symptom of functional gastrointestinal disorders in children and its prevalence is high worldwide. Since the pathophysiology of FC in children is associated with stool withholding behavior, successful toilet training in combination with osmotic laxatives is crucial for the treatment childhood FC. Additionally, promising and innovative drugs can also aid in treatment success.

INTRODUCTION

Functional constipation (FC) is considered a great disease burden in children that needs early screening and detection. The prognosis of FC is better in children with prompt and proper management. General physicians and pediatricians are usually the first person who take care these children hence understanding the pathophysiology of FC can lead to the proper management and satisfied outcome. In this chapter, the content will be covered all aspect the physician should know about FC for better patient care.

EPIDEMIOLOGY

Globally, up to 25% of visits to pediatric gastroenterologists and 3% of all general pediatric outpatient visits are due to FC[1]. It is difficult to determine the true prevalence of FC in children due to the heterogeneity of the studies in terms of target population sampling, diagnostic criteria, participant ethnicity and environment, method of data acquisition, and life style and psychological factors among others[2]. The primary reasons for the global diversity in prevalence among published studied may be due to the lack of agreement on diagnostic standards and cultural differences[3]. A systematic review and meta-analysis published by Koppen *et al*[4] reported that the worldwide prevalence of FC according to the Rome III criteria was 9.5% [95% confidence interval (CI): 7.5%-12.1%], with significantly more American and European children being affected than Asian ones. Additionally, geographical region, diet, and exposure to traumatic life events were linked to FC in children.

We determined that the pool global prevalence of FC in children was 14.4% (95%CI: 11.2-17.6) using the Rome IV criteria. According to continent, Africa had a highest prevalence of constipation (31.4%), followed by America (12.1%, 95%CI: 9.1%-15.1%), Europe (8.3%, 95%CI: 3.7%-12.9%), and Asia (6.2%, 95%CI: 1.3%-11%). Moreover, the factors significantly associated with FC from these studies are summarized in Figure 1 and Table 1.

NORMAL DEFECATION AND FC

Frequency of toileting habits in infants and children varies with age. To reduce parental worry and prevent needless testing and treatment, knowing the typical toilet routines for all age groups is important[5]. The frequency of stool passage per day gradually decreases from more than four times per day during the first week of life to three times per day at 4-6 wk of life and one to two times per day by the age of 4 years[6,7]. Healthy infants who are exclusively breastfed will have infrequent stool passage at 1-2 mo of life, with a mean duration of 6 days per stool passage (2-28 d per stool passage) without any abnormalities[8]. This condition will normalize at a mean age of 3.9 mo (range 1-7 mo)[9]. Hence, if the stool is soft, the infrequent stool passage in this age group requires neither intervention nor treatment. From the age of five, the majority of children pass stools daily or every other day without straining or withholding[3]. In early newborns, the average intestinal transit time is around 8.5 h, whereas intestinal transit times after puberty range from 30 to 48 h[5].

FC in adults had been first defined in 1999 according to the Rome II criteria and was mostly based on expert opinion. The diagnostic criteria of FC in children was subsequently established and integrated in Rome III criteria by Rome foundation in 2006. In 2016, the Rome III criteria had been replaced by the Rome IV criteria, with only minor changes being made as shown in Table 2[10]. Children who are not yet toilet trained do not need to include fecal incontinence (FI) and clogged toilet in the diagnostic criteria. In addition, the duration of symptoms in children had been changed from 2 mo in the previous Rome III criteria to 1 mo in the current Rome IV criteria[10,11] to promote early recognition and timely

Table 2 Rome IV criteria for pediatric functional constipation[6,7,9]

Child's age	Diagnostic criteria
< 4 years old	Two or more criteria for at least 1 mo[1]: (1) Two or fewer defecations per week; (2) History of excessive stool retention; (3) History of painful or hard bowel movements; (4) History of large diameter stools; (5) Presence of a large fecal mass in the rectum; (6) At least one episode of fecal incontinence per week after the acquisition of toileting skills; and (7) History of large-diameter stools that may obstruct the toilet in toilet trained children
≥ 4 years old	Two or more symptoms for at least 1 mo in children at least 4 yr[2]: (1) Two or fewer defecations per week; (2) At least one episode of fecal incontinence per week; (3) History of retentive posturing or excessive stool retention; (4) History of painful or hard bowel movements; (5) Presence of a large fecal mass in the rectum; (6) History of large-diameter stool that may obstruct the toilet; and (7) Additional criteria: Without fulfilling irritable bowel syndrome criteria

treatment. Although there are some changes of the diagnostic criteria in Rome IV, the prevalence of FC in children was similar using either the Rome IV or Rome III criteria.

FI in children is defined as the involuntary passage of stool into the underwear either as unintentional seepage of small amounts of liquid stools (generally referred to as "soiling" or "leakage") in a child older than 4 years of age or in a toilet-trained child[12,13]. Irrespective of the amount of stool, this is one of the most unpleasant and embarrassing things for a growing child apart from being an upsetting and mentally distressing issue that has a negative impact on children's quality of life. FI was divided into 2 types; retentive and nonretentive FI. It is critical to distinguish between retentive and nonretentive FI given their different etiologies and approaches to treatment[14]. Hospital and community studies have shown retentive FI occurs in constipated children with fecal impaction[1,15,16], whereas the nonretentive type could be found in children with psychological problems[3].

PHYSIOLOGY OF DEFECATION AND PATHOGENESIS

The act of defecation is a process related to the pelvic floor muscles, anal sphincter complex, enteric nervous system, and central nervous system (Figure 2). Normally, children over 18 mo old can initially control defecation through this complicated process, with nearly all of them succeeding in controlling defecation by the age of 4.

The etiology of constipation can be classified into functional and organic causes, which account for 90% and 10% of the cases, respectively[12]. Regarding FC, the pathophysiological mechanism might be multifactorial, including stool withholding behavior, anorectal dysfunctions, diet, physical activity,

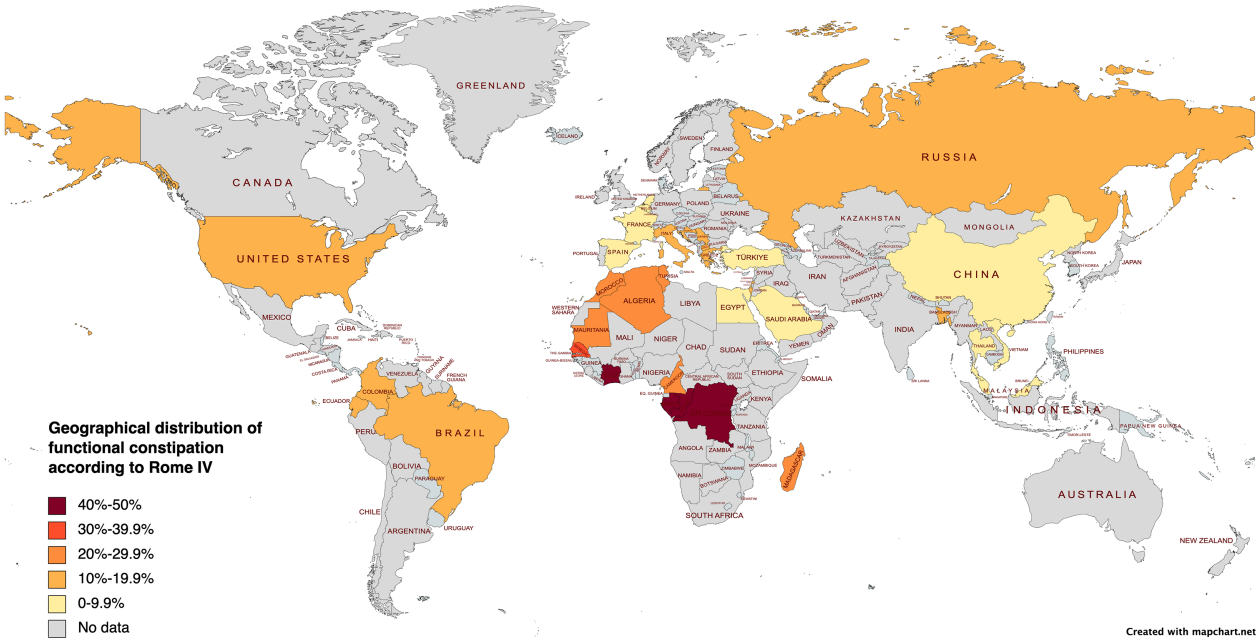

Figure 1 Geographical distribution of functional constipation in children worldwide, according to Rome IV.

genetic predisposition, and psychological issues. Stool withholding behavior is the main pathophysiological mechanism especially in toddlers and young children. Faulty toilet training, painful defecation from hard stool and frequent rectal enema contribute to fear and bad experiences related to defecation, which can cause purposeful or subconscious stool withholding behavior. Instead of relaxing the pelvic floor muscle when feeling the urge to defecate, children will defecate in the standing position and contract the pelvic floor and gluteal muscles, a phenomenon called "retentive posture or defecation in standing position". This behavior promotes the retention of stool in rectum and causes the stool to become lumpier and harder, making it quite difficult to evacuate, due to water absorption by rectal mucosa. This phenomenon leads to a vicious cycle of difficult defecation. Once large stools are retained in the rectum, the rectal wall stretches and develops into a megarectum[17] with decreased sensation to defecate[12]. Moreover, liquid stool can penetrate the hard stool and leak out of the anus, causing fecal soiling (Figure 3). According to pathophysiology, withholding behavior, palpable fecal mass on abdominal examination, and fecal soiling were reported in 37%-91%, 33%-68%, and 33%-77% of in children with FC, respectively[18-21]. Hence, two of the three characteristics were integrated into the Rome IV criteria.

CLINICAL MANIFESTATIONS OF AND EXAMINATIONS FOR FUNCTIONAL AND ORGANIC CONSTIPATION

FC is diagnosed based on symptoms detailed in the Rome IV criteria. However, some examinations may help pediatricians in cases with uncertain symptoms and signs[22]. Moreover, in cases that are difficult to treat or have alarm features (Table 3), examinations to exclude organic cause are necessary. Here we will review the clinical manifestations and examinations that can helpful general pediatricians and specialists diagnose functional and organic constipation (Table 4).

Patient history

When obtaining the medical history of children, it is important to inquire about when the child had their first bowel movement after delivery. Normally, during the first 24 h of life, more than 90% of term newborns pass meconium[23,24]. This period may be longer in preterm infants due to the delayed maturation of the intestinal motor function[25]. If the passage of meconium is delayed after birth, worrisome diseases, such as Hirschsprung's disease (HD) and cystic fibrosis, should be excluded[6,26]. Age of onset, frequency, consistency and size of the stool, painful or difficult defecation, and presence of blood coating the stool are all crucial details to note when recording a patient's history. In addition, frequent clogging of the toilet might reflect a large fecal mass in rectum. Anal fissures should be examined in children with a history of difficult defecation (Figure 4A) and those with blood coating the stool (Figure 4B) or the toilet paper. It is necessary to gather information regarding incontinence or soiling during the day and night. FI can be mistaken for diarrhea by their guardians[1,6] (Figure 4C).

Table 3 Alarm signs and symptoms of constipation[37]

Alarm signs	Symptoms of constipation
History	Constipation starting in neonatal period, delay pass meconium (> 48 h of life), family history of Hirschsprung's disease
Stool characteristics	Ribbon stools, blood in the stools in the absence of anal fissures
Gastrointestinal features	Bilious vomiting, severe abdominal distension
Back	Sacral dimple, tuft of hair on spine, gluteal cleft deviation
Anus	Perianal fistula, abnormal position of anus, anal scar, absent anal/cremasteric reflex
Neurological features	Decreased lower extremity strength/tone/reflex
Others	Abnormal thyroid gland, fever, faltering of growth

Table 4 Organic causes of constipation[1]

Organic causes	
Abnormalities of colon and rectum	Anal or colonic stenosis. Imperforate anus. Anteriorly displaced or ectopic anus. Cloacal malformations. Chronic intestinal pseudo-obstruction
Systemic disorders	Hypothyroidism. Hypercalcemia. Hypocalcemia. Diabetes mellitus. Panhypopituitarism. Cerebral palsy. Myotonia congenita. Scleroderma. Amyloidosis. Mixed connective tissue disease. Myotonic dystrophy. Progressive systemic sclerosis
Others	Cystic fibrosis. Celiac disease. Heavy metal ingestion (lead, mercury)
Spinal cord abnormalities	Meningomyelocele. Spinal cord tumor. Sacral agenesis. Tethered cord
Neuropathic intestinal disorders	Hirschsprung's disease. Intestinal neuronal dysplasia. Chagas disease. Abnormal muscle of abdomen. Prune belly syndrome. Gastroschisis
Drugs	Opiates. Anticholinergics. Antacids. Antihypertensives. Antimotility agents. Cholestyramine. Psychotropics. Diuretics

Evidence of fecal impaction in children suspected of FI is crucial, and physicians could obtain this information through abdominal palpation of a fecal mass, digital rectal examination, or rarely through plain abdominal radiography in noncooperative children. Importantly, physicians must define how a child defecates. Withholding behaviors are considered the main pathogenesis of FC and have been defined by guardians as defecation in the "standing position". This can also be described as stiffening up, buttock clenching, walking on tip toes, crossing one leg over the other, bracing against furniture, being in the all-fours position or curling up in a ball, and sitting with legs straight out (Figure 4D)[27,28]. Withholding behaviors also help clinicians determine that the constipation should be of functional etiology without any organic problems. Other factors, such as significant life events like a family member's death, the birth of a sibling, difficulties in school, sexual abuse, and others, can contribute to retentive behaviors and FC and should be evaluated in detail[1,6].

Although the abdominal pain caused by FC is typically nonspecific and poorly localized, constipation was the cause of acute abdominal pain in 50% of children who presented for a primary care visit and should be considered in this context[1]. Physicians should identify alarm features (Table 4) and other signs and symptoms, including appetite loss, fever, nausea, vomiting, reduced weight gain, issues with neuromuscular development, and behavioral or psychological problems[6,26,29]. Poddar *et al*[18] reported that children with symptoms such as delayed passage of meconium, growth failure, lack of retentive posturing, and absence of fecal impaction may likely have organic FC. Furthermore, urinary tract infections have been reported in a significant number of children suffering from constipation and FI[30,31]. Dietary and constipation treatment history should be investigated to predict the long-term outcomes of FC in affected children[1,6,32].

Physical examination

Assessing children's physical development through weight and height measurements should be the first step[6]. Abdominal examination should obtain information on the rectal fecal mass, particularly its height above the pelvic brim, through bimanual palpation on either side of the rectus sheath[7]. With careful abdominal and digital rectal examination, fecal masses can be detected in 30%-75% of children with FC[1,18]. The perineum should be examined given that it can reveal important details regarding the anal position, evidence of FI, skin irritation, eczema, fissures, and signs of possible sexual abuse[6].

Measuring the anogenital index (Figure 5) is important given that it might be considered a factor associated with FC. The anogenital index can be calculated using the formula presented below[33-36]. The normal anogenital index in males and females is 0.54 ± 0.03 and 0.40 ± 0.04, respectively[35].

history of delayed meconium passage after birth, intractable constipation, an uncertain diagnosis according to the Rome IV criteria, suspicion of an anatomic problem, and assessment of fecal impaction after disimpaction. Although neurological disease causing organic constipation is very rare, dedicated neurological examination still has merit (Figure 6).

Laboratory examinations

It is necessary to emphasize that FC is a clinical diagnosis based on a detailed medical history and physical examination. The goal of laboratory testing is to determine the presence of a rare organic

etiology in children with constipation showing alarm features[37] (Table 3) or confirm the diagnosis of FC in complicated or unclear cases. Hence, further diagnostic interventions are sometimes warranted. Investigations that might be useful for determining organic causes of constipation are described below.

Laboratory testing: Thyroid function and serum calcium tests can be used in children with intractable constipation or chronic constipation who are quite difficult to treat. In countries with a high prevalence of celiac disease and cystic fibrosis, specific tests for these diseases might be considered. Although the prevalence of food allergies in children presenting to tertiary clinics with chronic constipation who are unresponsive to traditional treatment vary from 28% to 78%[38], conflicting data support the use of allergy testing to identify cow's milk protein allergy (CMPA) in constipated children[39-41]. Therefore, according to the recommendations of the European Society of Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) and North American Society of Pediatric Gastroenterology, Hepatology and Nutrition (NAPSGHAN), routine allergy testing is not recommended in constipated children suspected for CMPA[37]. Oral food avoidance and rechallenge is the gold standard for diagnosing CMPA that manifests with intractable constipation.

Abdominal radiography: Abdominal radiography can be help pediatricians determine the presence fecal masses in some cases where physical examination is limited (Figure 7), such as obese children, patient refusal, or noncooperation, or exclude some causes of acute abdominal pain.

According to systematic reviews, abdominal radiography can identify constipation with a sensitivity and specificity of 60%-80% and 43%-99%, respectively[42,43]. There was inconsistent evidence to support the diagnostic relationship between constipation symptoms and fecal loading in abdominal radiographs from children; hence, the results should be interpreted with caution. In line with this, three scoring systems have been developed, namely the Barr score[44], Leech score[45], and Blethyn score [46]. However, further validation is needed before they can be widely used in clinical practice.

Abdominal ultrasonography: Abdominal ultrasonography can assess stool retention and estimate the size of the rectum and colon based on the supposition that fecal retention is one of the primary characteristics of constipation in both children and adult[6,47]. Given that ultrasound scanning is noninvasive and radiation-free, it is usually used for assessment in primary and secondary clinical care[1,6]. Rectal diameter measurements were correlated with the results of digital rectal examination and therefore seems to accurately assess fecal impaction[43]. Evidence suggests that digital rectal examination might be replaced by ultrasound scanning given that the latter is less unpleasant[48]. Even though there was a good correlation of transverse rectal diameter with FI and long-term constipation[49], the transverse diameter cannot be used to predict fecal impaction or constipation[37]. Furthermore, the results are largely operator dependent, and patient cooperation is also needed.

Radiopaque marker for colonic transit study: Based on the distribution of markers throughout the colon, the radiopaque marker (ROM) for colonic transit time (CTT) study is one method for distinguishing between different types of colonic function, including normal colonic transit, slow-transit constipation, and obstruction of the rectal outlet. Given its accessibility and strong concordance with scintigraphic methods, the ROM for CTT study has become the most popular method for determining both total and segmental CTT[50]. The sensitivity and specificity of the ROM for CTT study were 71% (95%CI: 57%-83%) and 95% (95%CI: 82%-99%), respectively[51]. The mean transit time in healthy persons has been reported to range from 15.6 to 37.7 h, with a review by Southwell *et al*[52] revealing that the normal CTT was < 32 h (upper 95th centile: 54 h).

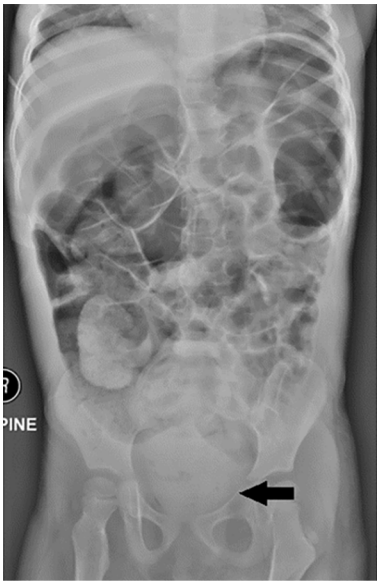

Figure 7 Abdominal radiography of a 3-year-old girl with a chief complaint of chronic diarrhea for 4 mo shows fecal impaction in the rectum. Citation: Palittiya Sintusek. Chronic constipation. The ESPGHAN and NAPSGHAN recommend that these tests only used to distinguish FC from functional non-retentive fecal incontinence or, where the diagnosis is unclear, provide clarity and allow the selection of alternative diagnostic procedures due to the widespread use of the Rome criteria for the diagnosis of FC and the potential risks caused from repeated radiation exposure from abdominal radiography[37,50].

Colonic manometry: To determine the neuromuscular function of the colon in children with intractable constipation, colonic manometry is regarded as the gold standard[50]. Evidence suggests that colonic manometry is most useful in providing subsequent guidance for further therapy, including pharmacological and surgical management, in intractable constipation. According to a review by the ESPGHAN motility group, high amplitude propagating contractions are the most easily recognizable and reliable motor pattern (Figure 8). They are initiated usually in the proximal colon and expected to stop at the recto-sigmoid junction. However, colonic manometry can be difficult for children given its invasive nature and necessity for general anesthesia. Moreover, age can be a potential limiting factor depending on the size of the catheter and endoscope. Additionally, only a few specialist centers globally offer this test.

Wireless motility capsule: The wireless motility capsule (WMC) is a novel, nonradioactive, and minimally invasive tool for the assessment of colonic motor function. Several investigations have reported on the safety and tolerability of WMC. In recent years, an increasing number of studies have used WMC to diagnose children with functional gastrointestinal diseases (FGIDs)[53,54]. This test could provide information on gastrointestinal motility that is similar to information obtained *via* nuclear medicine gastric emptying time and/or ROM. Moreover, WMC can provide additional information on regional and entire-gut transit[53], which can not only add to our knowledge of colon physiology but also be used as a parameter to tailor treatment[54]. Considering its safety and low invasiveness, the ESPGHAN motility working group recommended that more research be done to assess the effectiveness of the WMC in predicting outcomes among children with intractable constipation[50].

Magnetic resonance imaging: Cine magnetic resonance imaging (cMRI) is a noninvasive tool that uses a high-resolution spatiotemporal approach to facilitate dynamic MRI, which would allow the observation of the gut lumen diameter. The assessment of stomach accommodation and emptying, terminal ileum motility, and the small bowel using cMRI has been documented in the literature[43].

In both adults and children, cMRI can be used to assess colonic motility for various gastrointestinal disorders[55]. However, data on the application of this method in children with intractable FC are currently scarce.

Vriesman *et al*[56] published the first pediatric study comparing the identification of colonic motility patterns on cMRI with that on colonic manometry, proving potential evidence regarding the feasibility of the technique. cMRI has the advantage of being noninvasive, precluding the need for general anesthesia; however, given that this is still a research-based modality, additional studies are required to establish objective and systematic measurements.

Barium enema and others: A barium enema is used to coat the lining of the colon and rectum in order to create clearer images of the colon (Figure 9A). A contrast enema is often used in the diagnostic workup of HD, in which a transition zone between the aganglionic and ganglionic bowel may be observed in histopathology study[6] (Figure 9B). A 24-h delayed barium enema film could offer comprehensive data on colon transit function in young children, especially those under 4 years old who often cannot undergo CTT study[57]. Moreover, delayed retention of contrast at 48 h provides the strongest negative predictive value to exclude HD. Nonetheless, a limitation of barium enema is that it cannot be used to diagnose ultrashort HD; instead, anorectal manometry is required wherein absence of the anorectal inhibitory reflex is pathognomonic for HD (Figure 9C).

TREATMENT OPTIONS

The goals of treatment include establishing regular defecation (ideally once a day, passing soft stools and without difficulties) and preventing relapses[1,6,58]. Oral laxatives and structured toilet training are the main tools of a successful treatment. FC in children is typically managed across four important phases: (1) Education; (2) Fecal disimpaction; (3) Preventing fecal reaccumulation; and (4) Follow-up.

Education

Education is an important initial step of treatment[59] given its association with adherence and the successful of management of constipated children. In fact, studies by Steiner *et al*[60] and Koppen *et al*[61] reported that 38% and 37% of patients adhered to therapy, respectively. Inconvenience, dissatisfaction with treatment, and emotional impact of symptoms were linked to low adherence, all of which require attention[61].

Therefore, education should include an explanation of the physiological dynamics of defecation; associated factors of constipation; and the related shame, embarrassment, and social issues to the guardians and their children. In particular, the doctor needs to make it clear to the family that withholding behavior is crucial to the pathophysiology of FC. Furthermore, physicians should create a thorough plan to eliminate the frustration of guardians and children and increase cooperation required for prolonged treatment. Moreover, the timing of a successful treatment is frequently unpredictable, and guardians must understand that there is no quick fix for this problem. Recovery is only feasible with a sufficient, frequent, and prolonged care[1,6,59]. In some complex cases, such as in children with

intractable constipation or in those suffering from other comorbidities such as urinary problems, it is necessary to involve a multidisciplinary team that includes pediatric specialist nurses, pediatric research nurses, psychiatrists, urotherapists, and urologists for long-term follow-ups. Hence, such children require customized care.

Fecal disimpaction

Fecal disimpaction is crucial before the start of maintenance therapy in order to maximize the success of treatment. If fecal impaction is not eliminated beforehand, maintenance therapy can lead to worsening FI[1,6,59]. Oral drugs, rectal enema, or a combination of both can effectively treat fecal impaction. Two randomized controlled trials (RCTs) showed that polyethylene glycol (PEG) and enemas are equally effective for fecal disimpaction[62,63]. The use of 1-1.5 g/kg/d of PEG with or without electrolytes orally for 3-6 d is recommended as the first-line treatment for constipated children with fecal impaction [37]. However, a RCT study reported that both lactulose and PEG treatment successfully promoted disimpaction and were safe and well tolerated, although PEG achieved disimpaction significantly faster at day 2 (P = 0.001)[64]. Lactulose may be a useful PEG substitution for treating fecal impaction, particularly in areas wherein the availability of PEG is limited.

The oral route is typically less intrusive, better tolerated, and provides children with a better sense of control than rectal enema; however, successful disimpaction can take a few days, with compliance also being an issue. In contrast, the rectal approach (enema) is faster (effect occurs within minutes) but more invasive and traumatic. It may be useful for removing fecal impaction in patients with severe abdominal pain or large fecal mass on abdominal examination. Common side effects of enema include anorectal discomfort and abdominal pain; hence, it should be avoided in scared and resistant children to avoid anal fissures[58]. Recently, a study on the efficacy of olive oil enemas for childhood constipation showed that 79.6% and 66.7% of FC cases in the olive oil and lubricant groups were effectively treated for fecal impaction, respectively[65] (Table 5).

Maintenance therapy

Following disimpaction, maintenance therapy should be started immediately. The goals of maintenance therapy are to produce soft and painless stools, avoid stool reimpaction, and stop the reemergence of stool withholding behavior. This can be accomplished by combining pharmacological and nonpharmacological interventions.

Pharmacological management

Osmotic laxatives: Osmotic laxatives, including PEG, lactulose, and milk of magnesium hydroxide (MOM), are a type of osmotically active ions or molecules that are rarely absorbed in the small intestine. As such, they stimulate water retention in the colon, consequently softening stools.

PEG has been demonstrated to be more effective at increasing bowel movement frequency than lactulose, making it the first option for maintenance therapy in constipated children[66-68] or MOM [69]. However, limited evidence of its the utilization and safety has been available in infants, especially for long-term usage[66,70]. Moreover, data from a 10-year survey revealed that 645 children using PEG 3350 between the ages of 0-21 reported 1564 adverse symptoms. Among these adverse symptoms, 58.75% were neurological or neuropsychiatric, such as anxiety, anger, abnormal behaviors, and others [71]. However, the data source from this survey had significant limitations, including sampling bias, lack of verification, inability to seek clarifications, and lack of follow-up data. Comparing the efficacy of lactulose and MOM, one study found a significant difference in the frequency of stool passage per week,

Table 5 Laxatives used for functional constipation in children[1,6,37,58]

Agent	Child's age	Dosage	Side effects
Osmotic laxatives			
PEG	Any age	0.4-0.8g/kg per day for maintenance; 1-1.5g/kg per day for fecal disimpaction	Diarrhea, bloating, flatulence, nausea, vomiting, abdominal cramps
Lactulose (70% solution)	Any age	1 mL/kg once or twice daily (max 120 mL per day)	Bloating, flatulence, abdominal cramps, fecal, incontinence
Sorbitol (70% solution)	1-11 yr	1 mL/kg once or twice daily (max 30 mL per day)	Bloating, abdominal cramps
	> 12 yr	15-30 mL once or twice daily	
Milk of magnesium	> 2 yr	1-3 mL/kg per day once or twice daily	Abdominal pain, fecal incontinence, hypermagnesaemia, hypocalcaemia, hypophosphataemia (with excess use in children with renal disease)
Stimulant laxatives			
Senna (antraquinone)	> 2 yr	7.5-15 mg/kg per day once daily	Abdominal cramps, idiosyncratic hepatitis, melanosis coli in prolong used, nephropathy, neuropathy, hypertrophic osteoarthropathy
Bisacodyl	> 2 yr	5-10 mg per day once daily	Diarrhoea, abdominal cramps
Sodium picosulphate	4-5 yr	3 mg per day	Nausea, vomiting, bloating, abdominal cramps, diarrhea, headache, taste impairment
	> 6 yr	4-6 mg per day	
Glycerine suppository	< 1 yr	Half for pediatric suppository once daily	Rectal irritation, bloating, abdominal cramps, diarrhea
Rectal laxatives/enemas			
Sodium phosphate	> 1 yr	2.5 mg/kg	Rectal discomfort, diarrhea, abdominal cramps, electrolyte imbalance
Bisacodyl	2-12 yr	5 mg/dose once daily	Rectal discomfort, diarrhea, abdominal cramps, hypokalemia
	> 12 yr	5-10 mg/dose once daily	
Saline enema	Neonate	< 1 kg: 5 mL, > 1 kg: 10 mL	Rectal discomfort, bloating
	> 1 yr	6 mL/kg once or twice daily	
Lubricant			
Mineral oil	> 1 yr	1-2 mL/kg daily (max 90 mL per day)	Rectal discomfort, lipoid pneumonitis

PEG: Polyethylene glycol.

favoring MOM over lactulose (MD: 1.51, 95%CI: -2.63 to -0.39, 50 patients). Besides PEG, lactulose and MOM have been used as second-line drugs, with MOM being very cheap and widely available in some Asian countries such as Thailand[72]. However, the main limitation of MOM is its terrible palatability as opposed to lactulose. The concerning adverse effect of MOM is just only awareness of hypermagnesemia, especially with long-term usage in children with chronic renal disease. Conversely, lactulose can used safely even among preterm infants[73], with the only common adverse effect being abdominal distension. Though PEG is the most effective osmotic laxative for the treatment of function constipation in children, in areas or situations where availability is limited, MOM or lactulose might be used as the standard medication for FC instead of PEG[6,37].

Stimulant laxatives: Stimulant laxatives, such as senna and bisacodyl, increase intestinal motility and interfere with water and electrolyte transport across the epithelial layer. Therefore, stimulant laxatives might result in cramping and abdominal discomfort[1,6,74]. When osmotic laxatives alone are ineffective in treating chronic constipation, stimulant laxatives are often considered. Although stimulant laxatives are thought to be safe and beneficial for treating childhood constipation, limited high-quality RCTs have evaluated their use[66,74,75]. Based on expert opinion, the use of stimulant laxatives may be considered as an additional or second-line treatment[37].

Lubricants: The most popular lubricant laxative is mineral oil, often known as liquid paraffin. Mineral oil works by coating and lubricating stools, lowering fecal water absorption in the colon, and making it easier to pass feces. Given that mineral oil has no chemical activity, severe negative impacts are rarely common. The effectiveness of mineral oil and oral laxatives in treating childhood constipation has been compared in a few low-quality trials. Accordingly, mineral oil promoted significantly greater bowel

movement frequency compared to lactulose[66,76,77], but no significant difference in treatment response was observed when compared to PEG[78]. Moreover, liquid paraffin was found to induce significantly better defecation frequency and FI episodes compared to senna; however, the evidence was of low quality[79]. Given the risk of aspiration and severe lipoid pneumonitis, mineral oil is not recommended for infants under the age of 1 year[80].

Promising pharmacological therapies

Probiotics/prebiotics: Probiotics are live microorganisms that, when administered in adequate amounts, confer health benefits to the host. Probiotics have been used in the treatment of FC based on the hypothesis that they alter the intestinal microbiota and colonic pH, thereby improving gastrointestinal motility. Studies reported that constipated children have higher amounts of *Lactobacillus spp.*[81,82] and lower amounts of *Bacteroides*[83] compared to healthy children, implying that gut dysbiosis in the pathogenesis of constipation. So far, however, strong evidence to support the benefits of probiotics in the treatment or prevention of constipation has been limited[84-87]. However, some studies have demonstrated significantly increased stool frequency or softer stools after receiving probiotics. These findings might imply the significant impact of the pathogenesis of stool withholding in constipated children and that probiotics cannot be expected to overcome withholding behaviors. Therefore, future well-designed studies are needed.

5-HT$_4$ receptor agonists: Serotonin controls gut motility, visceral sensitivity, and intestinal secretion through serotonin 5-HT$_4$ receptors, which are primarily expressed by enteric nervous system interneurons[6].

5-HT$_4$ receptor agonists cisapride and tegaserod, which showed similar benefits for treating childhood constipation, were discontinued due to their increased risk for cardiovascular accidents and prolonged QT interval. Prucalopride is a new generation of selective, high-affinity 5-HT$_4$ receptor agonists that stimulate gastrointestinal motility and act primarily on parts of the lower gastrointestinal tract[6,74,88]. Current research on the benefit of prucalopride for constipated children has been contradictory. In an open-label pilot study, prucalopride had favorable effects on stool frequency, stool consistency, and frequency of FI in children with FC[89]. However, a recent multicenter RCT in 213 constipated children found no significant improvement of symptoms compared to placebo[90]. Common side effects include headache, nausea, abdominal pain, and diarrhea.

Chloride channel activators: Lubiprostone is a prostaglandin E$_1$ derivative that activates the chloride channel, thereby stimulating intestinal fluid secretion without increasing serum electrolyte levels[6,74,88]. A study on 127 children (3-17 years old) with constipation showed that lubiprostone was effective and well tolerated, with only minimal side effects like nausea and vomiting[91]. Another study evaluating the safety and tolerability of oral lubiprostone over the course of 24 wk for the treatment of childhood FC in patients aged 6-17 years old showed that lubiprostone was well tolerated and the frequency of treatment-emergent adverse events was similar to that seen in previous clinical trials and adults[92]. However, a double-blind, placebo-controlled, multicenter study on 606 children aged 6-17 years old (202 placebo; 404 Lubiprostone) with FC who satisfied the Rome IV criteria showed no significant difference in the total spontaneous bowel movements response rate between the lubiprostone and placebo groups. Frequently reported side effects include nausea, vomiting, diarrhea, and stomach pain[93].

Linaclotide and plecanatide bind to and act as an agonist of guanylate cyclase-C receptors, causing an increase in the production of chloride and bicarbonate the intestinal lumen. This increase in intestinal fluid causes an acceleration of the gastrointestinal transit while simultaneously decreasing visceral pain by reducing pain sensation[6,74]. Although no pediatric trials have been conducted, studies in adults showed that plecanatide treatment significantly improved constipation. The use of linaclotide in children with FC (0-18 years old) was only reported in a retrospective study, which showed that 45% patients with FC had a positive clinical response and approximately one-third of children experienced negative side effect, such as diarrhea, abdominal pain nausea, and bloating. Eventually, 27% patients stopped using linaclotid due to adverse events[94].

Herbal and traditional medicine: Stool withholding behavior is the main pathogenesis of FC in children. Given that successful toilet training takes time, normally more than 3-6 mo, osmotic laxatives have been the mainstay of treatment during toilet training. However, the majority of guardians and children wanted to withdraw the medication due to their concerns, sometimes with the taste or the amount of osmotic laxatives, which worsened the constipation. In several countries such as Iran, China, Vietnam, and Thailand, herbal medicine is usually integrated into some parts of the treatment as the main or additional therapy. Furthermore, while developing a new drug is a time-consuming and costly process, traditional drugs can be used to treat FC in children instead.

Several herbal and traditional medicines have been used for managing constipation in children, such as glucomannan[95,96], cocoa husk[97], AFPFF (combined acacia fiber, psyllium and fructose)[98], cassia fistula emulsion[99], inulin[100], black stap molasses[101], XiaojiDaozhi Decoction[102], damask roses[103,104], and other herbal medicines[105]. However, only a small number of herbal remedies for

FC have been well supported by RCTs in children (Table 6).

Most studies have reported that herbal and traditional medicine had significant effects on childhood constipation without significant adverse effects. Nonetheless, more high-quality studies are needed. This also suggests the need for studies that identify the active ingredients of herbal and traditional medicine responsible for their beneficial effects against FC in children. With more evidence, herbal or traditional medicine therapies can be integrated into standard treatments for childhood.

Nonpharmacological management

Diet (fiber and water): A low dietary fiber intake has been considered a risk factor for the development of FC[1,6,106]. The recommended adequate dietary fiber intake in children older than 2 years of age is equivalent to age (in years) plus 5-10 g/d[1,107]. However, there is still insufficient evidence from RCTs to support the routine use of fiber supplements to reduce constipation in children[108]. While some studies have shown that constipated children have lower fiber intake compared to healthy controls[96,109], other studies do not support this[95,110]. Regarding to fluid intake, lower water intake has been associated with a higher risk for intestinal constipation[111-113]. Hence, adequate water intake may be beneficial for the prevention of FC. The recommended water intake for children is based on the National Institute for Health and Care Excellence Guideline (Table 7).

Physiotherapy: FC in children is thought to be influenced by dysynergic defecation, which refers to pelvic floor dysfunction[88]. Studies have shown the effectiveness of pelvic muscle exercises as part of a combined treatment intervention[59,88]. A multicenter RCT comparing standard medical care (SMC), which includes education, toilet training, and laxatives, with pelvic physiotherapy (PPT) + SMC in constipated children aged 5-16 years old showed that PPT and PPT + SMC were effective in 63% and 92.3% of the children, respectively. Treatment success (based on the global perceived effect) were achieved in 88.5% and 33.3% of subjects receiving PPT + SMC and SMC, respectively ($P < 0.001$)[114]. A significant study in a primary care environment, however, found no additional benefits of PPT in 134 children aged 4-18[115] and that adding physiotherapy to SMA as a first-line treatment for all children with FC offered no cost benefits compared to SMA alone[116].

Toilet training: Toilet training aims to reduce symptoms, the child's defecation anxiety, and toileting avoidance[1,6]. There are four main methods for toilet training, including the child-oriented toilet training method, Azrin and Foxx method, Dr. Spock's toilet training method, and early elimination toilet training method[117-119]. The most friendly, accepted, and practical methods recommended by the American Academy of Pediatrics and Canadian Pediatric Society is the child-oriented toilet training method, in which the proper age for toilet training is between 18 and 24 mo[120,121]. Parents should be encouraged to be positive and supportive throughout the toilet training. Children should be encouraged to participate in toilet training, which consists of five sequential steps: know, dare, can, will, and do [122]. The child is taught to sit on the toilet for up to 5 min, one to three times a day, following meals to take advantage of the gastrocolic reflex[6]. The position of defecation is necessary to open the anorectal angle (the angle between the longitudinal axis of anal canal and the posterior rectal line, parallel to the longitudinal axis of rectum) and facilitate stool expulsion (Figure 10). To track improvement and compliance, keeping a daily journal of bowel movement, fecal and urine incontinence, and medication is beneficial. Providing stickers or small gifts as positive reinforcement for good behavior might further motivate children[6,122]. Through this process, children gain the ability to perceive their urge to defecate, consequently developing the habit of using the toilet instead of holding it in[59].

Biofeedback: Biofeedback training is a technique for teaching children how to control their perianal muscles for more efficient bowel movements. This technique involves bringing a typically unfamiliar physiological process to the patient's attention and allowing them to measure it[1,6]. In line with this, a recent meta-analysis incorporated three studies contrasting conventional treatment with add-on biofeedback treatment. Accordingly, two studies showed that treatment success rates were higher in the biofeedback group, whereas one study found no difference. In addition, one study found that the addition of biofeedback training at home offered no benefit in terms of defecation frequency compared to biofeedback at the laboratory[106]. Accordingly, biofeedback therapy is not advised for the regular treatment of children with FC based on the most recent research[59,106].

Abdominal massage: The mechanisms by which abdominal massages reduce constipation are most likely a combination of local stimulation and relaxation, as well as stimulation of the parasympathetic nervous system. Direct pressure over the abdominal wall alternately compresses and releases sections of the digestive tract, briefly distorting the lumen size and activating stretch receptors that can reinforce the gastrocolic reflex and trigger intestinal and rectal contraction[106,123,124]. A meta-analysis including a total of 23 RCTs and 2005 children showed that traditional Chinese medicine (TCM) infant massage had a superior effect on infant FC than drug therapy alone. Moreover, a clinical investigation found that children with FC may defecate more frequently and experience less constipation symptoms when receiving TCM infant massage[123]. There is little evidence to support the idea that using Chinese herbs in combination with other therapies might be beneficial[106,123]. Abdominal massage might be a promising additional therapy to manage FC.

Table 6 Characteristics of randomized controlled trials assessing the effects of herbal medications in children with constipation

Ref.	Country	Age (yr)	Study design	No. case (intervention/ control)	Intervention protocol	Probably pharmacological effect of herbal medicine	Duration of treatment/follow-up/end point and outcome measurement	Treatment effect
Esmaeilidooki *et al*[99], 2016	Iran	2-15	Open label, RCT, single center	109 (52/57)	CFE 1 mL/kg per day in three-divided doses (equivalent to 0.1 g of dried pulp of fruits of Cassia fistula). PEG 0.7-0.8g/kg per day	Phenolic antioxidants such as flavonoids, flavan-3-ol derivatives and anthraquinones: Stimulant laxative	Treatment for 4 wk. Primary outcome: Frequencies of defecation, severity of pain, consistency of stool, fecal incontinence and retentive posturing. Secondary: The safety and compliance of therapy	After 4 wk: 86.5% of children in CFE group and 77.1% in PEG group exited from the criteria of FC (RR = 1.121, CI95%: 0.939-1.338). Frequency of defecation that in CFE group (10.96 ± 5.7 stools per week) was significantly more than PEG group (6.9 ± 3.5 stools per week) (P < 0.001). No serious adverse effects in both groups (25% diarrhea and 3.8% abdominal pain)
Cai *et al*[161], 2018	China	1-14	Double-bline RCT, multicenter	480 (120/360)	XEBT: (1) 1-3 years old: 2.5 g, 3 times a day; (2) 4-6 years old: 5 g, 2 times a day; and (3) > 7 years old: 5 g, 3 times a day. Placebo	Seven herbs (Houpo contains magnolol, JueMingZi contain anthraquinones, LuHui contains reactive Aloe-emodin, BaiZhu contains Atractylodes japonica, LaiFuZi, XingRen, ZhiQiao): Promote small bowel peristalsis and work against atropine-induced small intestine suppression in mice	Treatment for 14 daysPrimary outcome: Frequency of SBM for 14 d. Secondary outcomes: Effectual time of defecation, mean symptom scores, disappearance rate of symptoms, recurrence rate and safety outcomes	The mean value of SBM for 14 d were 8.89 and 5.63 in the XEBT and placebo group (P < 0.05). The median effectual time of defecation, main symptom score and disappearance rate of symptoms were significant improved in XEBT group without the significant minor adverse effects between groups
Dehghani *et al* [101], 2019	Iran	4-12	Double-blind RCT, single center	92 (45/47)	BSM (sugarcane extract) 1 mL/kg per day. PEG 1 g/kg per day	The BSM naturally contained polyphenols (960 μg/mL), potassium (12430 μg/mL), iron (10 μg/mL), calcium (3320 μg/mL), zinc (22 μg/mL), sucrose (296000 μg/mL), triterpenoids (11230 μg/mL), phytosterols (7 μg/mL), flavonoids (2 μg/mL and polysaccharides (1250 μg/mL): Polysaccharide act as bulk forming agent, flavonoids/phytosterols and polyphenolic compounds act as natural antioxidants and anti-inflammatory agents	Treatment for 4 wk: Primary outcome: Response rate improvement in frequency of defecations per week, absence of lumpy or hard stools, abdominal pain and retention, soiling and blood-stained stool, sensation of anorectal obstruction/blockage. Secondary outcome: Patients' body weigh was measured in every visit and serological parameters (count blood cells, BUN, creatinine, calcium, phosphorus, sodium and potassium)	Defecation per week was significantly improved in both groups. Symptoms including volitional stool retention, large diameter stool, painful or hard stool and large fecal mass in the rectum decreased significantly two and four weeks after intervention (P < 0.05). No significant difference between the groups. No adverse effects were observed
Qiao *et al*[102], 2021	China	4-14	Double-blind RCT, multicenter study	200 (100/100)	Mixture of 12 herbs[1] (XiaojiDaozhi Decoction) and placebo (5% drug ingredients and 95% dextrin). All received fiber 20 g per day and toilet training)	12.5% *Raphanus sativus L.* (facilitating intestinal motility), 8.33% *Areca catechu L.* (stimulating gastrointestinal cholinergic receptor), 6.67% *Fructus aurantll immaturus* (stimulate gastrointestinal smooth muscle), *Citrus aurantium L.* (stimulate gastrointestinal smooth muscle), 6.67% *Crataegus pinnatifida* (stimulate gastrointestinal smooth muscle), *Magnolia officinalis Rehd* (stimulate gastrointestinal smooth muscle), *Cannabis sativa L.* (moistening the bowel and purging the stools), *Atractylodesmacrocephala Koidz.*	Treatment for 8 wk and follow-up for 12 wk. Primary outcome: Complete SBM (≥ 3 per week) and satisfaction with bowel function. Secondary outcome: Safety and adverse effect (blood measurement of liver and kidney function and lead level)	After 8 wk: 56% of CHM group and 25% of placebo satified with bowel movement (P < 0.05). 40% of CHM group and 19% of placebo had complete spontaneous bowel movement (P < 0.05). No serious adverse effects in both groups

					(stimulate gastrointestinal smooth muscle), *Semen armeniacae amarum* (purgative effect), *Paeonia lactiflora Pall*, *Radix et rhizoma rhei*, (purgative stool)0 and honey (moistening the bowel and purgative effect)		
Tavassoli *et al* [162], 2021	Iran	4-10	Open label RCT, single center	133 (66/67)	Viola flower syrups 5 mL, 3 times a day. PEG 4000 1 g/kg per day	Viola flower contains crude methanolic extract, butanolic and aqueous extracts the stimulate gastrointestinal motility	Treatment 4 wk. Primary outcome: Response off treatment (ROME III criteria). Secondary outcome: Stool consistency, defecation frequency, hard stools, painful defecation, fecal retention, and fecal soiling	Both groups demonstrated significant improvement in stool consistency, number off defecation, hard stool, painful defecation, fecal retention and fecal soiling at the end of the study compared to baseline ($P < 0.001$). No significant difference was observed between the two groups at baseline or at the end of the study ($P > 0.05$)
Nasri *et al* [163], 2021	Iran	2-15	Open-lable RCT	120 (60/60)	LaxaPlus Barij Syrup 1 mL/kg divided into 3 doses. PEG 0.7 g/kg	NA	Treatment and follow-up 8 wk. Primary outcome: Stool consistency, number of defecations, intensity of pain, fecal incontinence. Secondary outcome: Satisfaction rate	After 8 wk follow-up: Bowel movements in the intervention group was significantly higher than in the control group ($P < 0.05$). Pain intensity, and abdominal pain in the group LaxaPlus Barij® decreased significant than control group. No different about satisfaction rate between 2 group
Saneian *et al* [103], 2021	Iran	2-15	Double-blind RCT	60 (30/30)	Goleghand (including honey and Rosa damascene) 0.5 g/kg in three divided dose. PEG: 0.7 g/kg	NA	Treatment and follow-up 8 wk. Primary outcome: The number and consistency of stools per day, painful defecation, abdominal pain, and fecal incontinence. Secondary outcome: Adverse effects and parental satisfaction	After 8 wk: The number of fecal defecations in Goleghand group was higher than PEG ($P < 0.05$). The decrease of defecations after following was more significant in the PEG group than in the Goleghand® group ($P = 0.001$). Parental satisfaction scores did not change in either group ($P > 0.05$)
Imanieh *et al* [104], 2022	Iran	1-18	Double-blind RCT	100 (50/50)	Rosa damascena + brown sugar 1-2 mL/kg (1 mL composed of 0.1 g damask rose and 0.85 g brown sugar). PEG 1-2 mL/kg. All received high fiber diet and hydration	Damask rose: Osmotic laxatives and prokinetic effect. Brown sugar: Osmotic laxatives effect. Possible active ingredients might be phenolic compounds and aqueous fraction (terpenes, glucosides, flavonoids, anthocyanins, kaempferol and quercetin)	Treatment and follow-up 4 wk. Primary outcome: the effective of herbs with PEG. Secondary outcome: Adverse effects	After 4 wk: The cure rate was 100% in the R. damascena group and 91.7% in the control group. Adverse effect of intervention group was the taste which was too sweet

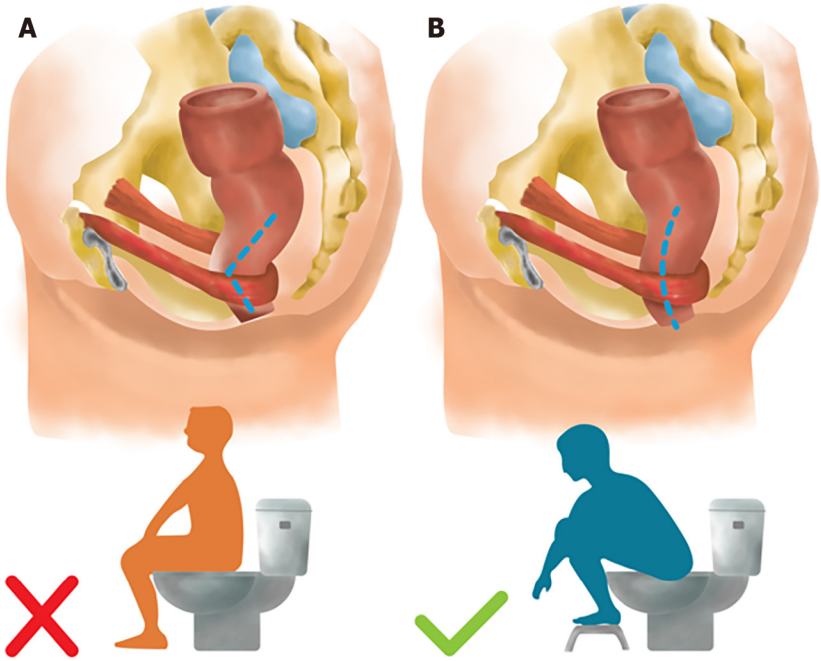
[1]LaxaPlus Barij® Syrup- an herbal medicine that includes *jujube, rose, asparagus, violet flower, borage, quince seeds, and Cordia myxa fruit*. CFE: Cassia fistula emulsion; PEG: Polyethylene glycol; FC: Functional constipation; RR: Risk ratio; RCT: Randomized controlled trial; XEBT: Xiao'er Biantong granules; SBM: Spontaneous bowel movements; BSM: Black strap molasses; BUN: Blood urea nitrogen; CHM: Chinese herbal medicine.

Retrograde enemas: There is insufficient evidence to support the role of retrograde enemas in the maintenance phase of FC in children. Hence, this procedure is reserved for intractable constipation, especially in cases with slow-transit constipation or megarectum. An RCT comparing to the clinical efficacy of supplemental treatment with rectal enemas against conventional treatment alone in 100 children between the ages of 8 and 18 who had symptoms of constipation for at least 2 years revealed that defecation frequency normalized after 1 year of treatment in both groups but was significantly

higher in the intervention group compared to controls at 26 and 52 wk (5.6/wk *vs* 3.9/wk, $P = 0.02$, and 5.3/wk *vs*. 3.9/wk, $P = 0.02$, respectively). Enemas as maintenance therapy for severely constipated children had no substantial side effects compared to oral laxatives alone[125].

Transanal irrigation: Transanal irrigation (Figure 11A) can be an option for children with FC who do not respond to pharmacological treatment[126,127]. It involves inserting a catheter or cone into the rectum to inject water into the colon, cleaning it completely[126]. This treatment has been previously well established for patients with neurogenic bowel disorders and anorectal malformations[127]. Moreover, evidence has suggested its safety and effectiveness, with an average success rate of 78% for both FI and constipation[127,128]. In addition, 86% of the parents were satisfied with the results of transanal irrigation, and 67% reported that they would continue using transanal irrigation for the treatment of their child's symptoms[129]. Therefore, transanal irrigation can be considered an effective therapeutic option for severely constipated children with FI who do not respond to conventional therapy[6,127,128].

Botulinum toxin A injection: Botulinum toxin A (Botox) injections into the anal sphincter can be considered in cases suspected of anorectal dysfunction or functional outlet obstruction[59]. Botox injections, which temporarily reduce anal sphincter muscle contraction, serves as both a diagnostic test, indicating whether the obstructive symptoms are being caused by internal anal sphincter hypertonia, and treatment for intractable constipation. Children who exhibit significant withholding behavior or anal sphincter dysfunction may benefit from Botox injections[6,59]. A RCT and systematic review found that Botox injections were as equally effective as internal sphincter myectomy on short-term follow-up [130,131]. However, a retrospective study on 164 children over 7 years old with intractable constipation showed that Botox injections into the internal anal sphincter of children had an overall response rate of 70%. Moreover, anorectal manometry studies in children with normal and abnormal sphincter dynamics observed similar response rates to this therapy[132].



Neuromodulation: Sacral neuromodulation (SNM) is a promising option for the treatment intractable constipation. SNM involves percutaneous placement of an electrode into the third sacral foramen and implantation of a stimulating device under the skin covering the buttocks[6]. The exact working mechanism of SNM remains largely unknown, although evidence has suggested that SNM stimulates anorectal function at a more central level. SNS can affect multiple physiological functions of the pelvis and lower abdomen and supports the propulsive peristalsis of the intestine, which is of special interest in slow-transit constipation[133]. One study in 30 constipated children reported a significant improvement in defecation frequency and abdominal pain after 3 wk of SNM treatment, with the effects being sustained over 22 mo of follow-up in 42% of children. Another study on the treatment of intractable constipation with SNM for over 2 years found that defecation frequency did not change after SNS; however, patients reported that FI decreased from 72% to 20% ($P < 0.01$) and urinary incontinence decreased from 56% to 28% ($P = 0.04$). Minor complications include pain after implantation, displacements of the leads, and infection[134,135]. A recent pilot study that assessed noninvasive SNS in 17 constipated children also found it effective in improving symptoms of constipation[136]. Additionally, abdominal transcutaneous electrical stimulation and posterior tibial nerve stimulation, two skin stimulation techniques, have been used to neuromodulate the bowel to treat constipation with promising outcomes[6].

Surgery: Although almost all patients with FC are successfully treated with conventional therapy, a few continue to have intractable symptoms without any organic problems. In such cases, surgical interventions may be beneficial.

Apart from transanal irrigation, there are also surgical treatment options to achieve stool expulsion, such as antegrade colonic irrigation or antegrade continence enemas (ACEs)[59]. When maximal conventional therapy fails, ACEs have been considered a successful therapeutic option for constipated children[1,6]. ACEs allow fluid to be flushed through the entire colon *via* an external opening into the colonic lumen, which is usually located at the cecum. The most well-established ACE procedures are percutaneous cecostomy and Malone appendicocecostomy (Figures 11B and C). The success rate of ACEs for the management of FC varies from 15% to 100% among studies[130,137,138]. Various enema solutions can be used, including saline and PEG. Complications include skin abrasion, stoma stenosis, granulation tissue, enema fluid leaks, and tube dislodging[137,138]. Regarding other surgical management, there are no clear guidelines on surgical colonic resections and ostomies for children with FC, with such surgical management only reserved for severely constipated children who do not respond to conventional therapy and surgical ACE. These surgical procedures are performed in specialized centers by a multidisciplinary team due to their complexity and potential for problems[6,59].

Table 7 Recommend water intake per day[164]

	Total water intake per day, including water contained in food (mL)
Infants 0-6 mo	700 (water is assumed to be from breast) milk
7-12 mo	800 (milk and complementary foods and beverages)
1-3 yr	1300
4-8 yr	1700
Boys 9-13 yr	2400
Girls 9-13 yr	2100
Boys 14-18 yr	3300
Girls 14-18 yr	2300

CONCLUSION

FC is the most common FGID in children and it affects the quality of life and psychological health of both the child and the family. Stool withholding behavior is the main etiological agent of FC and successful toilet training is the most effective treatment measure as it also prevents FC recurrence in the long term. Nonetheless, osmotic laxatives and lifestyle modifications, along with adequate fiber and fluid intake, are also crucial as first line therapy during toilet training. Even though extensive history taking and physical examination might enable a diagnosis of FC according to Rome IV criteria, children with intractable constipation may require multiple investigations to confirm the diagnosis or to exclude organic causes. Apart from osmotic laxatives, other promising herbal and alternative therapies have been reported to yield satisfactory outcomes in FC with minimal short-term adverse effects; nevertheless, more evidence is needed before these strategies can be adopted worldwide. Children with intractable constipation typically requires a multidisciplinary team approach and the physician should refer the child to a pediatric specialist for re-evaluation and further management (Figure 12).

Abstract

Colorectal cancer (CRC) is one of the most prevalent malignancies worldwide. Although most prevalent among older people, its incidence above 50 years old has been decreasing globally in the last decades, probably as a result of better screening. Paradoxically, its incidence in patients below 50 years old [early-onset CRC (EO-CRC)] has been increasing, for reasons not yet fully understood. EO-CRC's increasing incidence is genre independent but shows racial disparities and has been described to occur worldwide. It follows a birth-cohort effect which probably reflects a change in exposure to CRC risk factors. Its incidence is predicted to double until 2030, which makes EO-CRC a serious public health issue. Both modifiable and non-modifiable risk factors have been identified - some are potential targets for preventive measures. EO-CRC is often diagnosed at advanced stages and histological features associated with poor prognosis have been described. EO-CRC presents some distinctive features: Microsatellite instability is common, but another subtype of tumours, both microsatellite and chromosome stable also seems relevant. There are no age-specific treatment protocols and studies on EO-CRC survival rates have shown conflicting data. Due to the higher germline pathological mutations found in EO-CRC patients, an accurate genetic risk evaluation should be performed. In this review, we summarize the current evidence on epidemiological, clinical, histopathological and molecular features of EO-CRC and discuss the contribution of genetics and lifestyle risk factors. We further comment on screening strategies and specific dimensions to consider when dealing with a younger cancer patient.

Key Words: Colorectal cancer; Early-onset; Adenocarcinoma; Hereditary; Birth-cohort effect; Risk factors

Core Tip: The incidence of early-onset colorectal cancer (EO-CRC) has been surprisingly increasing worldwide and it has become a public health issue. Its clinical, genetic, molecular and histological characteristics suggest that this may be a distinct entity, with a more aggressive behaviour. However, both genetic and environmental risk factors seem to contribute to this observed epidemiological shift in CRC incidence. More evidence is needed in order to clarify EO-CRC aetiology and to develop screening and management strategies.

INTRODUCTION

Colorectal cancer (CRC), the most common gastrointestinal cancer, is the third most common malignancy and the third leading cause of cancer-related death globally[1]. Once perceived as an elderlies' disease, CRC incidence among the younger population [early-onset CRC (EO-CRC)] has been gaining more relevance. Recent epidemiological data show that, probably due to interventions on risk factors, screening programs implementation and better treatment[2], the incidence and mortality of CRC in patients older than 50 have been decreasing for the past decades[3]. On the contrary, from 1939, when the first case-reports of CRC in the young were published[4], the incidence of EO-CRC has been increasing and is expected to double by 2030[5].

Efforts have been made to characterize EO-CRC, questioning if this is a different entity from CRC in the older. As consensus is lacking, the authors review the existing knowledge, namely epidemiology, risk factors, clinical, molecular and genetic characteristics as well as treatment and overall survival (OS). EO-CRC has become a global health issue and there is a need to raise awareness for it, aiming at lowering the suspicion diagnostic threshold for symptomatic young patients.

EPIDEMIOLOGY

CRC belongs to the top 3 of the most prevalent cancers worldwide, representing, in 2020, 10% of the global cancer incidence and 9.4% of all cancer-related deaths[1,6]. Globally, both CRC incidence and mortality have been decreasing in the last decades[3,5], which is consistently associated to screening programs implementation, thus allowing the detection and removal of adenomatous polyps and consequently interrupting the adenoma-carcinoma sequence[7]. In fact, the inflection time point when CRC incidence began to decrease occurred in the 1990s, coincident with the adoption and diffusion of colonoscopy for screening of average-risk CRC patients in several countries[8].

CRC incidence follows a heterogeneous geographical distribution. The highest incidences have been reported to occur in China, United States of America and Japan. Studies suggest that Human Development Index (HDI) is positively correlated with CRC incidence[9], meaning that countries with high HDI have a CRC incidence about 4-folds higher than low HDI countries. Currently, developed countries show a stabilizing or declining incidence rate whereas developing countries have an increasing incidence rate. The later is probably related to the increase in exposure to CRC risk factors[1], reflecting the adoption of a western lifestyle that accompanies economic transition[10].

Current data implies that CRC is going through an epidemiological change. In fact, based on data from the United States Surveillance, Epidemiology, and End Results program, Galloway *et al*[11] concluded that, although CRC incidence is decreasing by 3.1% per year among people above 50 years old, the incidence of EO-CRC is increasing by 1.4% per year. EO-CRC patients currently account for a percentage that ranges from 0.4% to as high as 35.6% with a median of 7% between the considered reports - such high values should be interpreted carefully as they may reflect institutional biases due to cancer centres that probably receive a high referral of EO-CRC patients[12]. Undoubtedly, CRC has become an increasingly more common diagnosis in younger patients.

One problem potentially leading to controversial research results is the lack of an agreed definition of EO-CRC patients. Some authors use a cut-off of 40 years old[12,13], but most reports in the literature apply a 50 years old limit[10,14,15], this later being consistent with the Amsterdam criteria, that identify patients more likely to have an hereditary predisposition for CRC[16]; 50 years old also coincides with the starting age of most screening programs in the general risk population.

Most studies found no significant difference in gender distribution in CRC[12,17] and the available evidence on EO-CRC prevalence found it to be independent of gender as well[13]. Racial disparities in EO-CRC incidence have however been described, namely with a higher proportion of Black patients,

who also have a worse OS rate[18] - the same occurs for CRC in general in the United States[19]. A recent study, that suggested that the EO-CRC incidence has increased in all racial groups, reported the most elevated rise in Non-Hispanic White People. However, the overall incidence of EO-CRC in the United States remains higher for African Americans[20]. In an Israeli study, racial differences were also found, with the highest EO-CRC incidence in the Arabic population[21].

The reasons for the increased incidence of EO-CRC are not fully understood. Some authors suggest that the common use of colonoscopy is responsible for a proportion of the detected CRCs in young adults. This may have happened as a consequence of the diffusion of colonoscopy as a screening method as well as of an increased endoscopic capacity and efficiency, which may have unintentionally lowered the threshold for performing colonoscopy in younger patients[22].

Another important factor to consider when reflecting about EO-CRC incidence is the globally described existence of a strong birth-cohort effect. This is considered to occur when age-specific incidence rates vary by generation as a result of changes in people's exposure to factors associated to disease risk. This is the opposite concept of period effect, when incidence varies at the same time for all generations[23].

A report based on the incidence of CRC in people from 20 European countries, aged 20 to 49 years old and including data from 1990 to 2016, elucidates on this effect. It showed that the CRC incidence for people aged 30-39 years old started to increase exactly 10 years earlier than in the 40-49 years old group and that, although the CRC incidence also increased for 20-29 years old patients, the study period (> 1980) did not cover the time inflection for that group. This suggests that the turning point possibly occurred before 1990. Additionally, the biggest incidence rise occurred in patients 20-39 years[24], which is consistent with results from an American study[5].

This recent rise in EO-CRC has been observed globally. A report including data from 20 European countries found that EO-CRC incidence has raised significantly in 14 of them, in 5 of them was stable and decreased only in Italy[24]. Another study about EO-CRC incidence among 36 countries from 5 continents reported that EO-CRC incidence was stable in 14 countries, decreased in 3 countries (Austria, Italy and Lithuania) and increased in 19 countries. From these 19 countries, 9 presented an isolated increase in EO-CRC incidence rate - in 5 of them CRC incidence was declining in the older population and in the remaining 4 countries it was stable[17].

Additionally, authors concluded that the most rapid increase in EO-CRC happened in countries where incidence rates were already the highest, such as South Korea[10]. This may be justified by the modernization process that occurred earlier in South Korea in comparison with other Asian countries and the consequently rapid dietary transition that took place following the Korean war[25]. The obesity increase that has been occurring worldwide, both for adults and children, may also play an important role, particularly because Asian countries have been experiencing some of the largest relative increases in body mass indexes[26].

In terms of future predictions, it is expected that the incidence rate for EO-CRC will double by 2030, while in older patients incidence it will probably decline by more than one-third. Meaning that, compared to 2010, when only 4.8% of all colon and 9.5% of all rectal cancers were diagnosed in younger patients, by 2030 they will sum up to 10.9% of all colon and 22.9% of all rectal cancers[5]. These findings explain why EO-CRC is clearly becoming an important public health issue.

RISK FACTORS

CRC is a very heterogeneous disease that results from an interaction between genetic and environmental factors. The majority of CRCs are sporadic (70%), a small proportion of cases are caused by inherited syndromes (5%) and the remaining (25%) have an associated hereditary component, which has not yet been well established and is known as familial CRC[27]. Based on current knowledge, both modifiable and non-modifiable factors may also contribute to EO-CRC.

Modifiable risk factors

There is substantial controversy about results from studies concerning risk factors for CRC, and for EO-CRC in particular, especially concerning preventable risk factors. The majority of data about CRC risk factors is based on older age cohorts' evidence and mainly represents mid- to late-life exposures. But when it comes to EO-CRC, early-life exposures may have a predominant role[28].

One of the most consensual risk factors for CRC is excess body weight. This has been associated with an increased risk for CRC[29] and has become more relevant since obesity prevalence has increased in the last decades[30], paralleling the tendency of EO-CRC[31]. In fact, recent data show that obesity is responsible for a 20% higher risk of EO-CRC[32].

Early-age exposures and weight are also suggested to influence CRC risk. A meta-analysis concluded that higher body fatness at an early age is associated with a higher risk of colon cancer in men and women, the same not applying to rectal cancer[33]. This correlation is probably explained by the effect of proinflammatory cytokines produced by the adipose tissue and by the chronic exposure to hyperinsulinemia and insulin-like growth factor 1 (IGF-I), that may contribute to carcinogenesis[34].

Another consistently associated risk factor for CRC is diabetes mellitus, with an increased relative risk of 30%[35]. In fact, a Swedish study concluded that a diabetic patient reaches the 10-year cumulative risk for CRC that justifies the general screening program 5 years earlier than a non-diabetic patient[36]. Its impact on EO-CRC has already been proved as well[37].

Both alcohol[38] and tobacco[39] are independent risk factors for CRC. A recent study also showed their contribution to EO-CRC, particularly when concomitantly present[40,41]. The protective role of physical activity has been described in different studies that demonstrated an inverse relationship between physical activity and risk of colon cancer. This probably happens due to decreased inflammation, reduced intestinal transit time, decreased IGF-I levels, reduced hyperinsulinemia and modulated immune function, that come with physical activity[42].

Conflicting data exists regarding the role of dyslipidaemia in CRC risk. While some studies suggest a protective one[43], others associate it to a higher risk[44]. The association between diet and CRC has been extensively studied. Some of the proposed elements associated to a higher risk of CRC are processed and red meat[45-47] and sugar sweetened beverages[48] - these are believed to influence gut immune response and inflammation[49]. On the contrary, a diet rich in fiber, dairy, fruits, vegetables [45], fish, beta-carotene, vitamin C, vitamin E, vitamin D and folate has shown a protective effect[41,50].

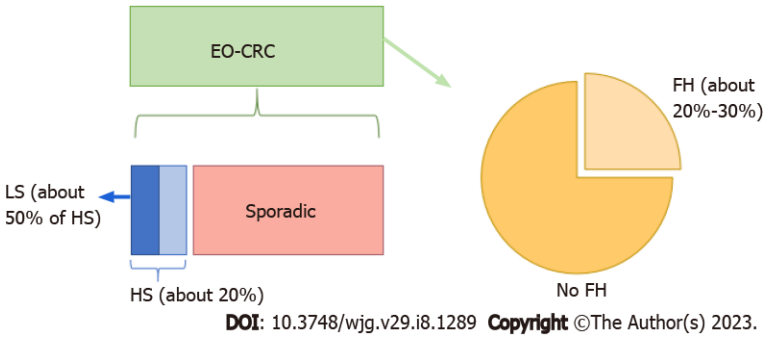
Aspirin and nonsteroidal anti-inflammatory drugs also exert a dose-dependent protective effect for CRC, through inhibition of the cyclooxygenase pathway[51]. Some of these interactions may account for the older onset/EO-CRC findings[41]. The importance of including fiber in the diet is mainly due to the production of short chain fatty acids during fiber fermentation. These have anti-inflammatory and anti-tumor properties[52] and their levels are inversely related with CRC occurrence[53].

The Western diet, typically rich in red and processed meat and poor in fiber, may be implicated on some of the differences found in incidence among populations[49]. Currently, the increasing incidence of EO-CRC is mostly observed in high-income economies or countries transitioning to a high-income economy and thus adopting Westernized lifestyle habits such as a western diet, weight excess and less activity level - all these may contribute to the increase in EO-CRC[10].

Microbiota has been recently proposed to also play a role in CRC pathogenesis. After comparing the colonic bacterial flora of populations considered to be at high and low risk for CRC[54], differences in microbiota composition were described - this may be a consequence of dietary habits and could harbour a risk for the development of CRC. Besides diet, the use of antibiotics may also affect the microbiota composition and it has been showed that the use of antibiotics, especially when used repeatedly[55] or for long periods during early to middle adulthood[56], is associated with an increased risk of developing CRC. From this point on, further research is needed before a microbiota modifying approach is considered. Current data shows conflicting results on prebiotic and probiotic therapy in CRC patients[57,58]. Based on the already mentioned birth-cohort effect, it seems that modifiable risk factors may play an important role in EO-CRC pathogenesis. The majority of the already known modifiable factors for CRC in general are believed to also apply to EO-CRC[41]. However, conflicting and limited evidence demands more studies.

Non modifiable risk factors

The most consensual risk factor for CRC is a positive family history[17]: First-degree relatives (FDR) have an increased risk of developing CRC, especially when the proband was diagnosed at a younger age. In fact, having a FDR diagnosed under the age of 50 increases the risk of developing CRC by more than three-fold[59]. This risk is also increased for people with more than one affected relative[59], and for family history among distant relatives[60]. Additionally, a history of advanced adenomas or even a family history of any kind of adenomas also increases CRC risk[61,62].



Other known conditions that increase the risk for EO-CRC are Lynch syndrome (LS) and familial adenomatous polyposis, among other hereditary CRC syndromes, with a larger proportion of EO-CRC being hereditary compared with older CRC patients[12,63] (Figure 1). Additional risk of EO-CRC has also been described for patients treated with pelvic radiation at young age[17,64].

Finally, patients with inflammatory bowel disease (IBD) are also known to be at increased risk for CRC[54], due to long-term inflammation. The highest risk is associated with extensive long duration colitis and/or a concomitant primary sclerosing cholangitis diagnosis. The association with EO-CRC, especially for ulcerative colitis, has been clearly demonstrated[15].

Conflicting data has been published about the correlation between breast cancer and CRC. Several studies have suggested an increased risk of CRC for patients with breast cancer at younger ages, and this relationship has also been suggested for EO-CRC[15].

CLINICAL AND HISTOPATHOLOGICAL CHARACTERISTICS

Evidence from different studies found some differences between EO-CRC and older patients CRC, concerning clinical presentation, location and histological characteristics, suggesting it might be a distinct entity. Most studies have agreed on the clinical features of EO-CRC, namely on the most common presentation symptoms, with abdominal pain, rectal bleeding, weight loss, anaemia, decreased

Figure 1 Genetic risk in early-onset colorectal cancer. HS: Hereditary cancer syndromes; LS: Lynch syndrome; FH: Family history of colorectal cancer; EO-CRC: Early-onset colorectal cancer.

appetite and change in bowel habits[12,52,65], as well as on the more frequent presentation with bowel obstruction[66]. These common clinical symptoms are in accordance with the most common location of EO-CRC in the left colon, more precisely the rectum and the sigmoid colon, as described in the United States[12,23,67-69]. However, global data regarding location are conflicting.

A delay in the diagnosis of EO-CRC has been consistently described, with one series showing an average delay of 4[70] to 6 mo[71] and even with case-reports of a 2 years delay[72]. This represents a 1.4-fold increase in time when compared to older patients[70]. Various reasons can justify this, both doctor and patient related. There is probably both a lower suspicion by the clinicians, hence assuming that the symptomatology is associated to other benign and more common pathology (such as irritable bowel syndrome or haemorrhoids) and consequently not investigating further, and a younger patients' delay in seeking medical attention, out of fear, denial, absence of information about alert symptoms, difficult access to health care or financial reasons[17,72,73].

Several studies consistently demonstrated that younger patients present more often with stage III or IV disease[10,66,74]. In fact, one multicentre retrospective study found that 61.2% of EO-CRC compared to 44.5% of older patients presented metastatic disease at diagnosis[12,13,75]. A plausible explanation for this relates to the absence of screening programs for younger patients but it may also be due to aggressive histopathological characteristics of EO-CRC and to its potential genetic basis, that may predispose to accelerated carcinogenesis in young patients. The diagnostic delay in younger patients may also contribute to more advanced disease at EO-CRC diagnosis[76], although this is not completely explained by the longer time to diagnosis[70].

Furthermore, synchronous or metachronous tumours more frequently arise in EO-CRC[76] but precursor adenomatous lesion are less frequently identified in the EO-CRC groups compared with older ones[13,52] - this also favours the accelerated carcinogenesis hypothesis. Histological predictors of bad prognosis have also been often found in EO-CRC. Young patients' tumours more frequently display adverse histologic features compared with older CRC patients, such as mucinous or signet cell differentiation and poorly differentiated tumours[13,66,68,77]; lymphovascular, venous, and perineural invasion have also been described to be more common[13,66].

MOLECULAR AND GENETIC FEATURES

Since the classical sequence adenoma-carcinoma implicated in the carcinogenesis of CRC has been proposed, our understanding of its biology has evolved and currently CRC and particularly EO-CRC is believed to be an heterogenous disease, including cases with a strong hereditary component as well as sporadic disease[78]. For every CRC patient, a genetic aetiology should be considered, and this is particularly important for EO-CRC patients. In the EO-CRC group, even if we exclude LS (the most common hereditary CRC syndrome) patients, there is still a clear familial component, stronger than for older patients[78].

It is estimated that 20%-30% of CRC are associated with a family history of colorectal polyps or cancer, and that up to 3%-5% of CRC are attributed to an identifiable inherited CRC syndrome, such as LS, familial adenomatous polyposis, MUTYH-associated polyposis, juvenile polyposis syndrome, Peutz-Jeghers syndrome or others[79]. Recent studies concluded that 1 in 5 of EO-CRC cases is attributed to hereditary cancer syndromes[63], and half of those particularly to LS[80] (Figure 1).

Observing mutational profiles of left-sided CRCs, EO-CRC patients were found to have higher rates of mutations in genes related to cancer-predisposing syndromes, such as *MSH2* and *MSH6* (LS), neurofibromatosis type 1, *PTEN* hamartoma tumours syndrome or Cowden's syndrome, tuberous sclerosis complex (*TSC*)*1* and *TSC2*, and *BRCA2* (hereditary breast and ovarian cancer syndrome)[81].

Due to the fact that a larger proportion of EO-CRC seems to be hereditary compared with older patients CRCs, the diagnosis of EO-CRC is currently an indication for referral for genetic evaluation [82]. Additionally, the variability in clinical presentations and potential for phenotypic overlap in CRC justifies the recommendation for genetic testing using a multigene panel for all individuals with an age below 50 years old[83]. This next-generation genetic tests identify pathogenic germline variants in 16%-20% of EO-CRC cases, including genes with moderate to high penetrance in cancer syndromes[63,80].

The diagnosis of a hereditary cancer syndrome frequently influences therapeutical options. In fact, it determines the surgical approach (*e.g.*, subtotal colectomy instead of segmental resection), the chemotherapy regimen choice, colonoscopy surveillance intervals, and management of potential extracolonic cancers[84]. Furthermore, genetic testing is also important to identify relatives that may benefit from anticipation of colonoscopy screening[85].

Although germline genetic alterations can be implicated in 20% of individuals with EO-CRC, hereditary syndromes continue to account for only a minority of cases and the majority of EO-CRC are sporadic, in patients with no family history of CRC[86,87]. CRC represents a heterogenous group of cancers, although its majority can be divided in a few molecular subtypes, that influence treatment options such as chemotherapy regimens and correlate with cancer survival. Interestingly, current evidence suggests a different proportion of molecular tumour subtypes between older and EO-CRCs[68,78,88,89].

CRC usually follows one of the three main molecular subtypes: Chromosomal instability (CIN) or suppressor pathway subtype (80%-85%), CpG island methylator phenotype (CIMP) or serrated pathway (40%) or microsatellite instability (MSI) or mutator pathway subtype (10%-15%). The later is characterized by MSI due to loss of DNA mismatch repair (MMR), occurring both in a sporadic manner or in association with germline alterations in MMR genes (LS), as reviewed in Currais *et al*[84]. These subtypes are not mutually exclusive and can frequently overlap, with a minority of CRCs exhibiting both microsatellite and chromosome stability (MACS)[78,89].

The currently available studies addressing the molecular profile in EO-CRC have reached conflicting results. Some authors present evidence that EO-CRC tumours present more frequently with MSI (MSI-H)[81,90]. MSI tumours in these patients are mostly related to LS[91] and rarely to inactivation of MLH1 (which commonly occurs in older patients) but are more frequently associated with MSH2 inactivation [92]. They are associated with a better prognosis than microsatellite stable (MSS) tumours[93]. Other reports describe that the majority of EO-CRC are rather MSS, lacking DNA repair mechanism abnormalities[94,95]. EO-CRC MSS tumours are typically localized in the left colon, rarely associate with other primary neoplasms and have a strong familial component, features that distinguish them from MSS CRC in older patients[94].

MMR status has potential therapeutical implications. For example, CRCs exhibiting MMR deficiency typically have poor response to fluorouracil-based adjuvant chemotherapy[93]. Interestingly, however, patients with MMR-deficient tumours tend to exhibit better OS, attributed to the more immunogenic nature of these tumours[89]. Additionally, metastatic tumours with MMR deficiency are candidates for immune checkpoint inhibitors[88].

The CpG island methylator phenotype, seems to play a modest role in EO-CRC. EO-CRC are frequently CIMP-low except for EO-CRC LS patients, for whom a higher proportion will be CIMP-high, compared to those who develop LS-related CRC later in life[94]. A more recently described subset of CRC, defined by MACS, because of their diploid DNA content and lack of MMR deficiency, may account for 30% of all sporadic CRCs. These affect younger patients more commonly and have been identified frequently in the left distal colon and rectum. Moreover, this molecular subtype has been associated with poor differentiation, early occurrence of metastasis, disease recurrence and lower survival than patients with MSI or CIN. This can be related to its lack of immune response, opposite to the immunogenic favourable properties of MSI-H CRC[89]. There is still an incomplete understanding of the molecular profile of MACS. Silla *et al*[78] reviewed its main features: MACS tumours are usually CIMP-low, are rarely associated with *BRAF* mutations, lack MLH1 expression, and present a different pattern of hypomethylation than MSI and CIN CRC. Some published studies suggest that MACS may be related to familial CRC syndromes, based on observed increased frequency in young patients[96].

LINE-1 hypomethylation is another feature implied in EO-CRC and is considered to be a surrogate marker for genome-wide hypomethylation. It is associated with increased CIN[97]. Evidence shows that the degree of LINE-1 hypomethylation is an independent factor for increased cancer related mortality and overall mortality in CRC[98]. Antelo *et al*[91] compared this marker in EO-CRC and older CRC and concluded that the first group presented lower levels of LINE-1 methylation, which suggests a distinct molecular subtype of these tumours. Additional studies are needed in order to confirm this association and properly assess the prognostic value of LINE-1 in young-onset CRC.

As for the consensus molecular subtypes classification, EO-CRC tumours are more likely to have subtypes CMS1 or CMS2 tumours compared with CMS3 or CMS4 tumours[68]. From a mutational perspective, despite some conflicting data, the most consensual results show that EO-CRC has lower prevalence of *BRAF* V600, *NRAS*, *KRAS* and *APC* mutations in comparison with late-onset CRC[13,68].

In order to rigorously determine if the described characteristics are sufficient to consider EO-CRC as a distinct molecular profile, more and larger trials are needed. In fact, although lifestyle factors and exposure are believed to contribute to the EO-CRC incidence increase, germline and molecular data also

provide clues to a different CRC pathogenesis.

TREATMENT

EO-CRC does not have specific evidence-based treatment protocols. The subset of EO-CRC patients that present an inherited CRC syndrome, such as LS and polyposis syndromes, should follow their respective guidelines. This is important as the surgical approach is generally more radical and there is a need to manage the risk for other syndrome related malignancies by appropriate screening[3,99].

For the majority of the patients, although there are no age specific recommendations, current studies show that different therapeutic strategies are being implemented according to the patient's age. Surgery is the main curative treatment for CRC, but for high-risk stage II and stage III there is a role for adjuvant chemotherapy[100]. When comparing EO-CRC with an older cohort (65-75 years old), various studies have found that more patients with early-stage EO-CRC are treated with adjuvant therapy for stage II and III disease. In fact, stage II low-risk EO-CRC patients receive adjuvant therapy 50% of the time, compared with 19.1% in the older cohort[101,102]. Curiously, these regimens were not associated with increased survival in stage I or stage II cancers and offered only marginal benefit in stage III and stage IV diseases[102].

Additionally, EO-CRC patients have better chances of receiving surgical treatment either for early-stage or for metastatic disease[66,103], of receiving radiotherapy at all disease stages and also of being offered more aggressive adjuvant treatment, including multi-agent chemotherapy[102]. Another study found that EO-CRC patients with stage I or II were more likely to receive adjuvant or neoadjuvant therapy, compared to older patients[66].

These studies may reflect the fewer comorbidities of EO-CRC patients, a better performance status and fewer adverse reactions to systemic treatment leading to a better tolerance to multiagent regimens than the older patients[66]. However, they may also show a bias towards offering more treatment to younger patients and there is a question of whether they are being victims of overtreatment with no proven benefit. According to current knowledge, equal treatment should be offered to EO-CRC (without a hereditary syndrome). More studies on the putative molecular differences between EO-CRC and older age CRC may in the future bring new molecular treatment targets, allowing specific treatment[11].

SURVIVAL

Some authors, supported by population-based studies, suggest that EO-CRC presents a better survival at every stage[77,103] and even that 5 years after curative treatment, EO-CRC survivors present the same main causes of death than the general population[104]. Other studies demonstrated that, after adjusting for stage, the prognosis is not influenced by CRC age[13,66], with no difference in stage-specific 5-year disease free survival and OS rates[66].

On the contrary, there also reports from single institution studies that showed poor clinical outcomes for EO-CRC and some authors suggest that the worse survival described for EO-CRC is caused by adverse histopathological features[105,106]. O'Connell *et al*[12]'s review found the average overall 5-year survival for young patients to be 33.4%, consistent with other reports[107,108]. When comparing stage-for-stage survival for younger *vs* older patients with CRC, it seems that young patients with earlier stages have better survival than older patients with the same stage disease. On the contrary, EO-CRC patients with advanced stages do the same or worse than older patients with the same advanced stage. This may justify the described overall lower 5-year survival for EO-CRC because these patients frequently present advanced disease, possibly as a consequence of the delayed diagnosis and/or the more aggressive underlying nature of the disease[12].

Regarding advanced and metastatic disease, studies found that EO-CRC patients have a lower progression-free survival although this does not impact the relative risk of death or OS compared with older CRC patients[109]. As for the mortality rate, although CRC mortality is declining overall and, from 2000 to 2014, CRC death rates decreased by 34% in individuals older than 50 years old, it increased by 13% in EO-CRC patients[110]. One limitation of the studies is that survival outcomes for EO-CRC are often confounded by the inclusion of hereditary colorectal carcinomas, such as LS related CRCs, that are believed to present a better survival compared with non-syndromic colorectal carcinomas[111,112].

SCREENING

CRC incidence and mortality for people older than 50 years old have been declining and the main proposed reason for that is the successful implementation of CRC screening, with a possible contribution of a change in lifestyle. Screening programmes have mostly emerged over the past few decades and generically apply to adults starting from 50 to 60 years old[113]. A recent study shows that from 36

countries from 5 continents, only 4 (Costa Rica, Cyprus, India and Philippines) lack any form of screening programmes[10]. Additionally, only 4 from the 36 mentioned countries have an earlier age cut-off for screening: Italy, beginning at 44 years; China, Japan and Austria, where it begins at 40 years old[113].

On the contrary, prevalence of EO-CRC is increasing. Although one reason for this increase could be over detection through screening, that seems unlikely since screening before age 50 is rare in the general population in most countries[113]. This was the reality until the most recent publication of the American Cancer Society (ACS) guidelines that, for the first time, recommend starting CRC screening at 45 years old for the standard-risk population. The previous CRC screening recommendations have been based on randomized controlled trials and prospective cohort studies. Since there is a lack of data on screening below 50 years old, this recommendation was a result of simulation modelling analyses of screening outcomes, that showed a favourable balance between benefits of screening from 45 years old with its potential life-years gained and the related burdens[114].

Although the absolute risk for EO-CRC is still low, it is expected to increase and the disease burden for younger patients is already substantial and potentially long-term. Additionally, current data show that 40-45 years old adults have the same prevalence of adenomas - CRC precursor lesions[115] - than adults 50-54.5 years old and people aged 40-49 years old account for 75% of the EO-CRC patients[116]. This questions the current age threshold and supports the ACS recommendation.

The debate about lowering the screening age is ongoing, as reviewed in Anderson and Samadder [117]. Those who are favourable to this approach prioritize the need to control the increase in EO-CRC. A study on screening worldwide, showed that two (Austria and Italy) of the only three countries where EO-CRC has declined have screening programs that begin below 50 years old (Italy at 44 and Austria at 40)[113]. Curiously, in Austria, the decreasing incidence of EO-CRC has only occurred in the 40 to 49 years age group[10]. Although another study showed that the same happened in Italy, other described an incidence decrease among the 20-39 years old patients[24].

Reasons for opposing the new 45 years old age threshold are diverse. One argument is that studies have shown that the biggest increase rate in EO-CRC was observed for people aged 20 to 39 years old, an age sector still not included in the suggested screening program. Another argument is that, although increasing, the absolute numbers of EO-CRC are still low, not relevant enough for a screening strategy change. Other concerns are related to the risk of augmenting health inequities related to access to health care services as well as for excessive financial health care costs, especially considering most European countries are still struggling to finance the current screening programs or are still in the process of implementing them[24].

Other authors suggest waiting for adequate randomized screening studies to test the ACS recent recommendation before adopting it and even question if the screening strategy should be applied to a malignancy whose biological and molecular substrate is not fully understood[95], which could mean that standard screening methods and prevention may not even be appropriate for it.

Another small study, based on the evidence that EO-CRC affects predominantly the left side of the colon, suggests a screening strategy with flexible sigmoidoscopy to be applied to people from 40 to 49 years old, as their study group observed that 80% to 83% of those tumours were theoretically within the reach of a flexible sigmoidoscopy[67]. From a different angle, another important factor when reflecting on EO-CRC diagnosis is that only half of the EO-CRC patients with germline pathogenic mutations reported a CRC diagnosis in a FDR and, consequently, were not eligible for high-risk CRC screening [63]. This contributes to the recommendation of performing genetic testing in all EO-CRC. Moreover, tumour testing for MSI or immunohistochemistry for MLH1, MSH2, MSH6, and PMS2 is recommended for all EO-CRC patients, even in countries where universal CRC MSI screening is still not implemented [3].

Another important aspect is the need to alert the medical community for the increasing incidence of EO-CRC and the consequent need for a rigorous assessment of CRC family risk trough detailed and complete family history in medical records, namely reviewing the familiar history of cancer including first- and second-degree relatives as well as personal and familiar history of advanced polyps[82]. Such systematic evaluation may be difficult to reliably execute in real world clinical practice, but it allows an appropriate determination of the patient risk for CRC and the identification of high-risk patients who should be offered earlier screening. Additionally, existing genetic risk models can also be employed and help identifying patients that benefit from genetic testing[118].

Another debatable option is to offer EO-CRC patients next-generation sequencing technology for genetic germline testing. Multigene panel testing has increased detection of germline mutations[79] in a feasible and more cost-effective way than single gene testing[82]. Recently, the National Comprehensive Cancer Network guidelines proposed offering multigene panel testing to all EO-CRC, aiming to increase opportunities for primary and secondary cancer prevention[83].

The disadvantage of this approach is that by testing more genes there is a higher risk of finding genetic variants of unknown significance or without a clear management evidence-based guideline[3]. As so, a multidisciplinary discussion with the active participation of a genetics specialist is recommended to appropriately offer and interpret genetic results, hence providing an appropriate counselling to EO-CRC patients and their families[3].

SPECIFIC CONSIDERATIONS IN THE YOUNG

When dealing with younger patients with a malignancy, there are some extra needs that should be remembered and appropriately managed. EO-CRC patients, as older ones, may need to deal with adverse effects of the different treatment modalities. They face a higher rate of sexual dysfunction than the general population and report to be less sexually active after surgery[119]. Although surgery for CRC does not generally affect fertility[3], chemotherapy, particularly fluorouracil, may reduce sperm count or cause amenorrhea and radiotherapy may also reduce fertility in both men and women[120].

Fertility may play a central concern in the management of EO-CRC patients since they may still be in the reproductive age and have incomplete reproductive plans. As so, patients should be referred to reproductive specialists because options for fertility preservation such as banking of cryopreservation of sperm/oocytes/embryos is recommended prior to gonadotoxic chemotherapy and should be discussed, ahead of starting treatment[121].

Other aspect to consider in EO-CRC patients is the possibility of the diagnosis and/or treatment to be coincidental with a pregnancy, especially with the common delay in childbearing age in the developed world. In that scenario, a multidisciplinary approach, weighting the risks and benefits for both the mother and the foetus should be employed. Although studies in pregnant women are missing, it is consensually agreed that the first trimester is the most vital period to avoid, if possible, systemic agents [122]. Besides fertility, another concern for EO-CRC is to cope with the eventual need for transient or permanent ostomy. The present or past history of an ostomy can contribute to worse sexual function and body image[123].

Additionally, EO-CRC patients, especially the ones submitted to multimodality therapy, will live the rest of their lives under the threat or burden of long-term sequelae. Long-term survivors have reported sustained functional deficits and symptoms, such as sexual disfunction, anxiety, worse body image, embarrassment with bowel movements and faecal incontinence[124], with an impact on their quality of life. Concerning the psychosocial dimension, higher depression and anxiety diagnosis have been described for CRC survivors[125]. Concordantly, the American Society of Clinical Oncology recommends that all cancer survivors should be periodically evaluated for symptoms of depression and anxiety using validated measures and adequately managed, if necessary with the referral for psychological or psychiatric consultation[126]. All of these afore-mentioned factors contribute to the EO-CRC burden of disease, diminish patients' quality of life and should be appropriately addressed throughout patients' life.

CONCLUSION

By 2030, previsions are that more than 1 in 10 colon cancers and 1 in 4 rectal cancers will be diagnosed in patients younger than 50 years old[5]. These numbers are alarming and, consequently, as EO-CRC incidence increases, many studies have tried to shed light on this entity, especially comparing it to the traditional older patient CRC. Evidence suggests that EO-CRC differs from older-onset CRC in its clinical characteristics, pathological features, aggressive behaviour, and molecular profiles. These may be responsible for different responses to treatment and survival, although further studies are needed.

Although a higher proportion of cases, comparing to older patients, is genetic or familial, the majority of EO-CRC cases is still probably related to somatic genetic mutations or epigenetic alterations induced by modifiable risk factors. This is consistent with the birth-cohort effect observed. The contribution of lifestyle risk factors stands as an opportunity for implementing primary prevention measures for CRC, such as the practice of physical activity, having a healthy diet, quitting smoking and limiting alcohol consumption, also preventing obesity and diabetes. A study showed that risk factor modification could diminish CRC-related mortality in about 12% over 20-years[2].

This paper also aims at raising awareness of all the clinicians for the need to lower the suspicion threshold for young patients presenting with alarming gastrointestinal symptoms. We also stress the need to obtain complete clinical information, such as history of polyps, familial history (first- and second-degree relatives) and personal diseases history, namely previous radiation therapy or IBD. Only with this information can the genetic risk of EO-CRC be properly evaluated and subsequent genetic consultation be asked for, when indicated.

EO-CRC patients have some peculiarities and clinicians should be conscious of them. Financial burden and treatment sequelae such as sexual dysfunction, incontinence, anxiety and depression must be considered and managed. Patient's reproductive plans should also be discussed. To conclude, although currently we already have some important data about EO-CRC, larger studies with longer follow-up of these patients are needed in order to reach consensus about the nature and pathogenesis of this disease.

Namely, ongoing studies and clinical trials, by our group and several others across the world, on the impact on survival of increasing clinician awareness on EO-CRC, on the definition of potentially specific phenotypes of EO-CRC, or on their specific responses to radio-, chemo- or immunotherapy will shed light on the subject. Hopefully, by improving young patients' diagnosis, diminishing its observed delay,

tailoring its treatment and follow-up and implementing modifications in lifestyle risk factors, in the future EO-CRC incidence will follow CRC incidence pattern and both entities' burden will decrease.

Abstract

Hereditary polyposis syndrome can be divided into three categories: Adenomatous, serrated, and hamartomatous polyps. Hamartomatous polyps, malformations of normal tissue presenting in a disorganized manner, are characterized by an autosomal dominant inheritance pattern. These syndromes exhibit hamartomatous gastrointestinal polyps in conjunction to extra-intestinal manifestations, which require conscientious and diligent monitoring. Peutz-Jeghers syndrome, Cowden syndrome, and juvenile polyposis syndrome are the most common displays of hamartomatous polyposis syndrome (HPS). Diagnosis can be pursued with molecular testing and endoscopic sampling. Early identification of these autosomal dominant pathologies allows to optimize malignancy surveillance, which helps reduce morbidity and mortality in both the affected patient population as well as at-risk family members. Endoscopic surveillance is an important pillar of prognosis and monitoring, with many patients eventually requiring surgical intervention. In this review, we discuss the diagnosis, surveillance, and management of HPS.

Key Words: Hamartomatous polyps; Peutz-Jegher syndrome; Cowden syndrome; Juvenile polyposis syndrome

INTRODUCTION

The national cancer institute defines a harmartoma as, "a benign growth made up of an abnormal mixture of cells and tissues normally found in the area of the body where the growth occurs"[1,2]. Diagnosis may be pursued based on personal or family history, endoscopic evaluation, and histopathology identified on endoscopic tissue sampling. The most common disease processes associated with hamartomatous polyps include Peutz–Jeghers syndromes (PJS), Cowden syndrome (CS), and juvenile polyposis syndrome (JPS). While hamartomatous polyps themselves are benign, diligent surveillance is imperative as a significant risk of malignant transformation exists. Additionally, the disease process is often associated with an increased risk of other additional malignancies. As a result, management often requires multidisciplinary evaluation[1,3]. In this review, we discuss the diagnostic considerations, clinical manifestations, gastrointestinal (GI) and extra-intestinal surveillance recommendations, and management options of the most common syndromes associated with hamartomatous polyps.

PJS

Diagnosis

PJS is an autosomal dominant mutation of the mammalian target of rapamycin (mTOR) pathway as a result of a germline mutation of the serine-threonine kinase (*STK11/LKB1*) tumor suppressor gene[4]. The *STK11/LKB1* gene is located on chromosome 19p13.3 and plays an important role in the secondary messenger pathway, which modulates cellular proliferation, responds to cellular energy deficits, and controls cellular polarity[5-7]. The incidence of PJS is estimated to range between approximately 1:8300 and 1:200000 with nearly 70% of cases demonstrating familial inherence and 30% of cases arising from a sporadic mutation[3,8,9]. Although there is often variable penetrance and clinical heterogeneity, diagnostic clinical criteria include: Any number of polyps with a family history of PJS, two or more Peutz-Jeghers polyps (PJPs), mucocutaneous pigmentations with family history of PJS, or any number of PJPs with mucocutaneous pigmentation[4,8,10]. While endoscopically similar to other polyps, PJPs have a characteristic phyllodes appearing epithelial component and a cystic glandular component which extends into the submucosa and muscular propria on hematoxylin and eosin staining[7,11-13]. Notably, PJPs are exclusively located within the small bowel. Gastric polyps associated with PJS have similar characteristics to hyperplastic gastric polyps and are not considered PJPs[7,12]. The median age of initial polyp development is 12 years-old, with nearly half of patients experiencing symptoms by the age of 20 [7,14]. The primary clinical manifestation of PJS is chronic bleeding from GI polyps leading to anemia. Small bowel obstruction secondary to an intussusception from a hamartomatous polyp of the GI tract occurs in up to 70% of patients, with the average age of diagnosis being 23 years-old[7]. Patients also characteristically present with mucocutaneous hyperpigmentation surrounding the oral cavity, eyes, nostrils, or surrounding the anus[15].

Surveillance

Due the increased risk of GI and extra-intestinal malignancies, a multidisciplinary approach to screening is encouraged. While the mean age of index cancer diagnosis is 41 years old, PJS is associated with an overall cumulated malignancy rate of 90% by the age of 70[4,8]. GI malignancies commonly associated with PJS include gastric, intestinal, and the pancreatic. Additional extra-intestinal malignancy manifestations include breast, endometrial, ovarian, and lung[11]. Multiple studies have been pursued in order to further characterize the malignancy risk that is associated with PJS (Table 1). The National Comprehensive Cancer Network, European Hereditary Tumour Group, and the American College of Gastroenterology (ACG) provide surveillance recommendations for patients[16-19]. A meticulous regimen of lifelong malignancy surveillance is imperative (Table 2).

Management

Endoscopy is an essential modality of surveillance and management of polyps associated with PJS. Polypectomy during esophagogastroduodenoscopy (EGD) and colonoscopy is particularly appropriate for patients with a limited number of polyps ranging from 0.5-1 cm in size. If the polyposis that is encountered is too large or numerous to be managed endoscopically, surgical resection of the diseased segment may be pursued[18,20].

Table 1 Studies investigating the malignancy risk associated with Peutz-Jeghers syndrome

Ref.	*N*	Location	Outcome
Chen *et al*[80]	336	China	Patients with PJS possess a 50% cumulative malignancy risk by the age of 60, with the most common malignancy being colorectal cancer at a median age of 41
Hearle *et al* [81]	419	United Kingdom	The risk of developing a malignancy is 85% at the age of 70 in patients with PJS, most common being gastrointestinal in origin
Ishida *et al* [82]	583	Japan	Patients with PJS possess a cumulative malignancy risk of 83% by the age of 70, with an increased rate of gynecologic malignancy in comparison to previously reported data
Korsse *et al* [83]	144	Netherlands	The cumulative risk of pancreatico-biliary malignancy is 32% by the age of 70 in patients with PJS
Mehenni *et al* [84]	149	Switzerland	Patients with PJS have a cumulate malignancy risk of 67% at age 70, particularly with *STK11/LKB1* mutations in exon 6. Malignancies most commonly occur in the GI tract
Resta *et al*[11]	119	Italy	The *STK11/LKB1* mutation is associated with a relative overall cancer risk of 15.1, with pancreatic and cervical malignancies being the most common; median age of diagnosis noted to be 41 yr
Van Lier *et al* [8]	133	Netherlands	Patients with PJS possess a cumulative malignancy rate of 76% by the age of 70; malignancies most commonly occur in the GI tract and in women

GI: Gastrointestinal; PJS: Peutz-Jeghers syndrome.

Table 2 Malignancy screening for Peutz-Jeghers syndrome[4,8,10,16-18,85,86]

Malignancy	Screening
Breast	Annual self-breast exam beginning at the age of 18. Annual breast exam with MRI or mammography beginning at the age of 25, and as needed
Cervical	Cervical smear annual beginning at the age of 20, and as needed
Colon	Colonoscopy every 1-3 yr beginning at the age of 8, and as needed. Routine surveillance at 18 if baseline endoscopy at age 8 is negative
Pancreas	Annual endoscopic ultrasound or MRCP/ERCP beginning at the age of 30, and as needed
Stomach	EGD every 1-3 yr beginning at the age of 8, and as needed. Routine surveillance at 18 if baseline endoscopy at age 8 is negative
Small bowel	Capsule endoscopy or CT/MRI enterography every 2-3 yr, beginning at the age of 8, and as needed
Testicular	Annual testicular exam and ultrasound beginning at birth
Uterus	Annual pelvic ultrasound and exam beginning at the age of 25, and as needed; consider total hysterectomy once complete with child-bearing

MRI: Magnetic resonance imaging; CT: Computed tomography; MRCP: Magnetic resonance pancreatography; ERCP: Endoscopic retrograde cholangiopancreatography; EGD: Esophagogastroduodenoscopy.

Management of small bowel polyps includes double balloon enteroscopy (DBE) or surgery. DBE allows for diagnosis and treatment of polyps located in the jejunum and the ileum. The device possesses a 200 cm long enteroscope with a 145 cm long overtube. There are two latex balloons attached to the tip of the endoscope and overtube, which are managed with a pressure-control pump system serving to prevent redundancy of the small bowel[21-23]. With this approach, manipulation and advancement of the scope may be occasionally impaired in patients who have previously undergone abdominal surgery secondary to intraabdominal adhesions, warranting intraoperative enteroscopy[24,25]. The European Society of Gastrointestinal Endoscopy (ESGE) recommends elective polypectomy for small bowel polyps that are > 15-20 mm in size to reduce the risk of intussusception. In symptomatic patients, polyps that are < 15 mm should be removed, as well[19]. Complications from DBE occur in less than < 1% of cases, but include perforation, post-procedure hemorrhage, pancreatitis and aspiration[23,26]. DBE is an effective method for early detection and non-operative removal of polyps located in the small bowel[18,27]. Similar to polyposis of the colon, surgical resection may be required in the setting of numerous or large polyposis of the small bowel[19].

Surgical intervention is required for patients with PJS who present with intussusception, a phenomenon where the proximal segment of bowel telescopes into a distal segment of bowel with the polyp acting as a lead point. If no intervention is pursued, bowel ischemia and perforation may occur [4]. Patients with PJS possess a cumulative risk of intussusception reaching nearly 44% by the age of 10,

which increases to nearly 50% by the age of 20[20]. The risk of intussusception is greatest with polyps that are 15 mm or larger[28]. Intraoperatively, frankly ischemic bowel evidently must be removed; however, polypectomy without bowel resection is recommended in cases of reversible ischemia. As the risk of recurrent intussusception is present especially in younger patients, some authors have recommended further evaluate the bowel through manual palpation or enteroscopy *via* an intraoperative enterotomy in order to remove any additional polyps greater than 15 mm[20,29].

According to the ESGE, pancreatic lesions should be addressed with partial pancreatectomies in the case of: (1) Solid lesions ³10 mm unless known to be benign; or (2) intraductal papillary mucinous neoplasms with high-risk features including mural nodules, enhanced solid component, obstructive symptoms, enhanced cyst wall, abrupt changes to duct size, and main pancreatic duct ³10 mm[19,30].

Breast lesions should be managed based on current breast cancer guidelines, as no therapeutic strategy specific to PJS is presently available. A mastectomy for the purpose of risk reduction should be discussed in a multi-disciplinary setting accounting for additional patient risk factors and family history [19]. Similarly, while an established malignancy risk exists between PJS and cervical, uterine, and testicular cancer, no formal intervention guidelines specific to the correlation exists.

Studies have also demonstrated that the immunosuppressant agent Sirolimus (Rapamycin) has led to reduction in the number and size of polyps in a mouse model, which is largely attribute to the anti-angiogenic properties of the drug[31-33]. Currently, phase 4 prospective study for characterization of the drug in patients with PJS is being undertaken.

CS

Diagnosis

CS is an autosomal dominant mutation in the *phosphatase and tensin homolog* (*PTEN*) gene impacting the downregulation of the mTOR pathway. Consequently, the *PTEN* regulation of cellular proliferation and survival is impaired[34,35]. The incidence of CS is estimated to be roughly 1:200000[36]. CS characteristically presents with hamartomatous polyps which may appear in any organ. Nearly all patients exhibit some type of skin lesion including trichilemmomas, acral keratoses, and papillomatous papules. Additionally, nearly 80% of patients demonstrate GI hamartomatous polyps and 80% of patients exhibit macrocephaly. Diagnosis is based on the guidelines established by the International CS Consortium: Patients must possess two major criteria one of which must be either macrocephaly or Lhermitte-Duclos disease (LDD), one major criteria with three minor criteria, or four minor criteria (Table 3)[37]. 40% of CS is associated with LDD-a rare, slow growing dysplastic gangliocytoma of the cerebellum manifesting with a broad range of clinical findings. The presentation of LDD may range from being asymptomatic to exhibiting signs of ataxia, cranial nerve palsy, vertigo, mental impairment and deterioration, intracranial hypertension, and hydrocephalus. The wide spectrum of clinical manifestations is attributable to the slow growing nature of the neoplasm[38,39].

Surveillance

The majority of patients with CS are at risk for developing breast, thyroid, renal, endometrial, colorectal, and skin malignancies (Table 4). Given this established predisposition, attentive multidisciplinary surveillance and screening is an essential component of disease management (Table 5). The purpose of these surveillance recommendations is early detection in order to allow curative oncologic treatment.

Management

There is no available curative treatment for CS. Rather, management is geared towards early detection of malignancy and timely oncologic treatment. Genetic counseling is also prudent in order to promote early detection and surveillance for kindred. Options for treatment of cutaneous lesions include, surgical excision, 5-Flurouracil, carbon dioxide laser treatments, isotretinoin[40,41]. Polyps found on endoscopy may be removed endoscopically, if amenable. Otherwise, identified malignancies should be addressed utilizing the most up-to-date therapeutic regimens.

Associated syndromes

PTEN hamartoma tumor syndrome (PHTS) is a broad category of hamartomatous pathologies arising as pathogenic *PTEN* mutation variants identified by gene-targeted testing and comprehensive genomic testing. PHTS classically includes CS, Bannayan-Riley-Ruvalcaba Syndromes (BRRS), PTEN-related Proteus Syndromes (PS), and *PTEN*-related Proteus-like syndromes (PLS). Notably, however, segmental overgrowth lipomatosis arteriovenous malformation epidermal nevus (SOLAMEN) syndrome also shares the same mutation[42,43]. It has been proposed that CS and BRRS may simply be varying spectrums of the same syndrome[44]. While formal diagnosis criteria are not present for BRRS, patients often present with macrocephaly, penile mucocutaneous lesions, delayed psychomotor development, and visceral hamartomas[44,45]. Approximately half of patients with BRRS have GI polyposis, with an analogous histopathologic presentation[44]. Nearly 60% of patients with BRRS possess a germline *PTEN*

Table 3 Major and minor criteria for the diagnosis of Cowden syndrome[37]

Major criteria	Minor criteria
Breast malignancy	Fibrocystic changes of the breast
Lhermitte-Duclos disease	Fibromas
Macrocephaly	Gastrointestinal hamartomas
Thyroid malignancy	Genitourinary tumors or malformations
	Lipomas
	Mental retardation
	Thyroid lesions, *i.e.* goiter

Table 4 Studies investigating the malignancy risk associated with *phosphatase and tensin homolog* mutation

Ref.	*N*	Location	Outcome
Tan *et al*[87]	3399	North America, Europe, and Asia	Patient with *PTEN* mutations possess a lifetime breast cancer risk of 85%, thyroid cancer risk of 35%, renal cell carcinoma of 35%, endometrial cancer risk of 28%, colorectal cancer risk of 9%, and melanoma risk of 6%
Fackenthal *et al*[88]	2	United States	There is an increased risk of male breast cancer in patient with *PTEN* mutations and CS
Harach *et al* [89]	11	Argentina	Patients with CS have increased likelihood of developing benign thyroid lesions, with increased risk of malignant transformation
Ngeow *et al* [90]	2723	United States	CS and CS-like phenotypes possess standardized incidence rate for thyroid cancer of 72%, particularly follicular thyroid cancer
Heald *et al*[91]	127	North America and Europe	*PTEN* mutations are associated with early-onset (age < 50) colorectal malignancy; routine colonoscopy should be encouraged

PTEN: *Phosphatase and tensin homolog*; CS: Cowden syndrome.

Table 5 Malignancy screening for *phosphatase and tensin homolog* mutation[92]

Malignancy	Screening
Breast	Annual self-breast exam at the age of 18; annual clinical breast exam at the age of 25; annual MRI at the age of 30
Colon	Colonoscopy every 5 yr at the age of 35, and as needed
Endometrial	Annual exam with biopsy at the age of 35, and as needed. Hysterectomy upon childbearing completion
Kidney	Annual renal ultrasound at the age of 40; CT or MRI as indicated
Skin lesion	Annual dermatologic exams, no consensus on initiation age
Thyroid	Annual thyroid ultrasound at the age of 7

MRI: Magnetic resonance imaging; CT: Computed tomography.

mutation[46]. SOLAMEN syndrome is also associated with hamartomatous polyps, macrocephaly, lipomas, and hemangiomas. These patients further possess an increased risk of skin, GI, thyroid, breast, brain, and genito-urinary malignant neoplasms[47,48]. Surveillance is advised to be similar to CS, given the mutual *PTEN* mutation association (Table 5). Treatment is predominantly symptomatic and often requires a multidisciplinary approach[49].

PS and PLS are similar pathologic processes that may be associated with a *PTEN* mutations[50]. PS has been associated with *AKT1* and *PTEN* mutations, both of which influence the PI3KCA/AKT pathway[51]. Pulmonary embolism secondary to a hypercoagulable state and pneumonia are noted to be contributing factors to early mortality in this patient population. Other complications include scoliosis, central nervous system abnormalities, ophthalmic complications, abnormal bone growth, and pulmonary malformations[52]. Treatment is often targeted toward the correction of the functional limitations caused by the skeletal deformities associated with the disease. Patients should be closely monitored for the development of venous thrombosis; however, no recommendations for prophylactic anticoagulation currently exist[3,53]. Patients that have presentations similar to PS, but do not possess

all the diagnostic criteria are deemed to have PLS.

JPS

Diagnosis

JPS is an autosomal dominant condition resulting from a germline mutation of the *SMAD4* or *BMPR1A* genes in 60% of the affected population. These genes impact the transforming growth factor-beta signaling pathway[54,55]. The estimated incidence of JPS is approximately between 1:100000 to 1:160000 [56,57]. Clinical diagnosis is based on the presence of one of the following: 5+ juvenile polyps in the colorectal region, 2+ juvenile polyps in the GI tract, or any number of juvenile polyps with a family history of juvenile polyposis[18,56,58,59]. Juvenile polyps refer to the histopathology of the polyps, rather than the age of onset. Juvenile polyps are hamartomas demonstrating a dense stroma with a smooth surface and mucin-filled cystic lamina propria[60]. Macroscopically, these pedunculated polyps have an erosive surface ranging from 5 mm to 50 mm in size. While distinction with sporadic juvenile polyps is difficult to make, JPS polyps frequently demonstrate epithelial neoplastic transformation, reduced stroma, reduced dilated glands, and increased proliferative glands[61].

Subtypes of JPS include JPS of infancy, generalized JPS, and juvenile polyposis coli. JPS of infancy is characterized by sessile or pedunculated polyps diffusely throughout the GI tract ranging from 1-30 mm. Although further investigation must be pursued, some sources have reported JPS of infancy is caused by mutations resulting in the continuous deletion of *BMPR1A* and *PTEN*[62]. The disease process is plagued with early mortality secondary to hemorrhage, malnutrition caused by diarrhea, and intussusception[61,63]. Considered to be a variable spectrum of penetrance of the same disease, generalized JPS occurs diffusely throughout the GI tract while juvenile polyposis coli is limited to the colorectal region[64]. Nearly half of the patients with generalized JPS or juvenile polyposis coli possess a heterozygous germline mutation of the *SMAD4* or *BMPR1A* gene[64].

Extra-intestinal manifestations are present in up to 15% of patients including midgut rotation, cardiac abnormalities, and craniofacial abnormalities. JPS may also be present in conjunction to hereditary hemorrhagic telangiectasia (HHT) syndrome[65,66]. Patients with HHT have a characteristic increased risk of bleeding secondary to greater rates of arteriovenous malformations of the lung, liver, brain, and GI tract. HHS is an autosomal dominant disorder also associated with a *SMAD4* gene mutation[65,67,68]. Patient may demonstrate varying degrees of disease qualities when they have both disorders simultaneously. However, the combination of both disorders results in a higher risk of colorectal malignant neoplasms and anemia[68,69]. Although further studies are required, the current perspective on the malignant pathogenesis of JPS includes the "landscaper mechanism" and the "gatekeeper" model. The "landscaper mechanism" postulates that genetic alterations lead to an abnormal stromal environment, which leads to malignant transformation of neighboring epithelium. A de novo study by Haramis *et al*[70] demonstrated that bone morphogenetic protein (*BMP*)-4 inhibition, a common JPS pathway mutation, results in ectopic crypt units adjacent to the crypt-villus axis supporting the "landscaper mechanism"[70]. A "gatekeeper" model has also been proposed, where the biallelic *SMAD4* mutation contributes to malignant transformation and progression[71,72].

Surveillance

JPS has an established increased risk of GI malignancy, with a cumulative lifetime risk reported to range between 39%-63%[73,74]. The *SMAD4* gene has been associated with a greater risk of GI malignancies as well as a greater number of polyps in comparison to the *BMPR1A* mutation[54,75,76]. JPS is associated with an elevated risk of colorectal and gastric malignancies (Table 6). Therefore, a combination of colonoscopy and EGD is recommended for appropriate screening and surveillance[77] (Table 7).

Management

Endoscopic management is typically feasible for patients with a limited number of polyps[18]. EGD may be utilized for surveillance and endoscopic removal of polyps located in the stomach and duodenum. In the setting of extensive polyposis, advanced dysplasia, or malignancy, a partial or complete gastrectomy may be pursued[44,78] Jaoude *et al*[55] recommended proposed prophylactic gastrectomy in patients with symptomatic JPS, asymptomatic patients with a *SMAD4* mutation, or patients with unmanageable polyposis defined as > 50-100 polyps[55]. Certainly, morbidity and mortality are greater with surgical intervention. However, surgical intervention must be weighed against the possibility of inadequate surveillance and treatment with endoscopy, particularly in the setting of an elevated likelihood for sporadic gastric malignancy associated with the *SMAD4* gene mutation. Further investigation should be pursued to determine the optimal parameters for surgical intervention, particularly in the prophylactic setting.

Small bowel polyps should be evaluated periodically with enteroscopy. Patient with limited small bowel polyps may be managed with endoscopic polypectomy but will require surgical treatment in the event of obstructive symptoms associated with intussusception. Colonoscopy is an essential screening and management tool for colonic polyps. However, in the setting of numerous polyps, advanced

Table 6 Studies investing the malignancy risk associated with juvenile polyposis syndrome

Ref.	N	Location	Outcome
Brosens *et al*[73]	84	United States	Patients with JPS possess a lifetime cumulative risk of 38.7% for development of colorectal cancer, with the average age of diagnosis being 43.9
Latchford *et al*[56]	44	United Kingdom	The *SMAD4* gene is a poor prognostic indicator for development of gastric malignancy. Colonic polyps have predominance to ascending colon
Howe *et al*[93]	117	United States	Kindred of patients with JPS possess approximately 50% cumulative risk of developing gastric malignancy

JPS: Juvenile polyposis syndrome.

Table 7 Malignancy screening for juvenile polyposis syndrome[18,77,94-96]

Malignancy	Screening
Colorectal	Colonoscopy every 1-3 yr between the ages of 12-15; screening should be initiated sooner if earlier onset of symptoms
Gastric	Esophagogastroduodenoscopy every 1-3 yr between the age of 12-15; screening should be initiated sooner if earlier onset of symptoms
HHT mutation	Brain MRI, cardiac echocardiogram, testing for lung arterio-venous malformations

HHT: Hereditary hemorrhagic telangiectasia; MRI: Magnetic resonance imaging.

dysplasia, or malignancy, a colectomy may be pursued. Surgical options include proctocolectomy with ileal pouch anal anastomosis (IPAA) or colectomy with ileorectal anastomosis (IRA) based on rectal involvement. Nearly half of patients who elect to undergo IRA will require additional proctocolectomy with IPAA secondary to the development of rectal polyposis[18,44,78].

An area of potential emerging investigation includes the utility of chemoprevention in patients with JPS. Van Hattem *et al*[79] determined an increased expression of cyclooxygenase-2, particularly in patients with a *BMPR1A* gene mutation. Further investigation should be pursued in order to determine the clinical implications of this expression profile[79]. Ultimately, additional studies should be pursued regarding the optimal management of these patients.

CONCLUSION

Hamartomas polyps result from hyperproliferations of normal tissues and are often associated with genetic mutations. While patients experience symptoms from the hamartomas themselves, there also exists an established malignancy risk associated with these disorders. Therefore, patient education regarding surveillance is imperative, and a multidisciplinary approach is often required for comprehensive management. First degree relatives should also be investigated for the diagnosis due to the dominant inheritance patterns that these disease processes possess. Due to the rarity of the disorders, limited studies are available on the clinical and molecular aspects of the disease processes, and further investigation should be dedicated to understanding the pathology associated with these syndromes.

Abstract

BACKGROUND

Stress granules (SGs) could be formed under different stimulation to inhibit cell injury.

AIM

To investigate whether SGs could protect hepatocytes from hypoxia-induced damage during acute liver failure (ALF) by reducing endoplasmic reticulum stress (ERS) mediated apoptosis.

METHODS

The agonist of SGs, arsenite (Ars) was used to intervene hypoxia-induced hepatocyte injury cellular model and ALF mice models. Further, the siRNA of activating transcription factor 4 (ATF4) and SGs inhibitor anisomycin was then used to intervene in cell models.

RESULTS

With the increase of hypoxia time from 4 h to 12 h, the levels of HIF-1α, ERS and apoptosis gradually increased, and the expression of SGs marker G3BP1 and TIA-1 was increased and then decreased. Compared with the hypoxia cell model group and ALF mice model, the levels of HIF-1α, apoptosis and ERS were increased in the Ars intervention group. After siRNA-ATF4 intervention, the level of SGs in cells increased, and the levels of HIF-1α, ERS and apoptosis decreased. Compared with the siRNA-ATF4 group, the levels of G3BP1 in the siRNA-ATF4+anisomycin group were decreased, and the levels of HIF-1α, ERS and apoptosis were increased. Moreover, compared with the ALF group, the degree of liver injury and liver function, the levels of HIF-1α, ERS and apoptosis in the Ars intervention group were decreased, the level of SGs was increased.

CONCLUSION
SGs could protect hepatocytes from hypoxia-induced damage during ALF by reducing ERS-mediated apoptosis.

Key Words: Acute liver failure; Stress granules; Hypoxia; Endoplasmic reticulum stress; Apoptosis

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Hepatocytes were damaged by hypoxia and ischemia injury in the process of acute liver failure. At this time, the content of HIF-1α in cells increased, which inhibited the formation of stress granules (SGs) mediated by G3BP1 and promoted the expression of endoplasmic reticulum stress (ERS) marker molecules activating transcription factor 4 (ATF4) and CCAAT/enhancer-binding protein-homologous protein. The activated ERS pathway further promotes hepatocyte apoptosis. Promoting SGs synthesis can inhibit the level of hepatocyte apoptosis by inhibiting the ATF4-mediated ERS pathway.

INTRODUCTION

Acute liver failure (ALF) is a common clinical syndrome in intensive care units, with a high mortality due to various causes, such as drugs, toxic exposure, viral hepatitis, *etc*[1]. ALF can be preliminarily diagnosed in patients with no history of basic liver disease, with rapid deepening of jaundice in a short period of time. It has the typical symptom, such as poor appetite, vomiting, diarrhea, abdominal distension and hepatic encephalopathy. Advanced high bilirubin or aminotransferase, and prothrombin activity of coagulation item ≤ 40% can be the basic diagnosis[2]. For such patients, it is extremely important to be transferred to intensive care unit as soon as possible for mechanical ventilation to improve oxygenation. The comprehensive medical treatment, blood purification (artificial liver) and maintenance of homeostasis in human body should be carried out throughout the treatment. For patients with ALF, liver transplantation is the only completely effective treatment option. However, the development of liver transplantation is limited by shortage of liver source, strict transplantation conditions, huge treatment cost and rejection after transplantation[3].

Endoplasmic reticulum stress (ERS) plays an important role in the regulation of inflammatory response and apoptosis, and severe ERS promotes the occurrence and development of ALF[4]. When cells undergo ERS, they can be induced by type-1 ER transmembrane protein kinase (IRE1), double-stranded RNA-dependent protein kinase-like ER kinase (PERK) and activating transcription factor 6 (ATF6), induce unfolded protein response (UPR)[5]. Unfolded proteins can alter cellular transcription and translation programs to regulate protein synthesis, secretion, and degradation to relieve endoplasmic reticulum stress, thereby protecting cells[6]. When ERS exceeds the controllable range of the body, cells will undergo apoptosis. CCAAT/enhancer-binding protein-homologous protein (CHOP) is a transcription factor that controls gene-encoded components in apoptosis[7]. The activation of ERS of the three pathways will eventually induce the expression of the apoptotic factor CHOP[7]. Among them, PERK can activate eIF2a and further induce the expression of ATF4. ATF4 can promote the activation of CHOP, and the highly expressed CHOP triggers the bax/bad system to activate caspase9 and caspase3, which in turn leads to apoptosis[8].

Stress granules (SGs) refer to the fact that when eukaryotic cells are subjected to various environmental stimuli, such as oxidative stress, heat shock, ultraviolet radiation, and viral infection. Aids in the transport of dense granular material formed into the cytoplasm, which is an adaptive regulation mechanism of cells[9]. SGs are a protective mechanism of cells, which is the product of the host's response to external stress. The production mechanism of SGs is related to neurological diseases[10], viral infections[11], and cancers[12], *etc*. There is no study on the relationship between SGs, ERS and hepatocyte apoptosis in ALF. This experiment investigates the effect and mechanism of SGs on the apoptosis process induced by ERS during the hypoxic injury of hepatocytes in ALF.

MATERIALS AND METHODS

Chemicals and reagents

The normal human liver L02 cell line was purchased from the China Center for Type Culture Collection (Wuhan University). DMEM medium and fetal bovine serum (FBS) were purchased from GIBCO (NY, United States). Lipopolysaccharide (LPS), D-galactosamine (D-Gal), arsenite (Ars) and anisomycin were purchased from Sigma (St. Louis, United States). Rabbit anti-human/ mouse G3BP1, T-cell restricted intracellular antigen-1 (TIA-1), ATF4, CHOP, BAX, BCL2, GAPDH antibodies, Cy3-labeled goat anti-rabbit secondary antibody were purchased from Proteintech (Wuhan, China). Rabbit anti-human/ mouse cleaved caspase3 (c-cas3), c-cas9 antibodies were purchased from Cell Signaling Technology (Boston, United States). Goat anti-rabbit fluorescent secondary antibody IRDye800 was purchased from LI-COR Biosciences (Lincoln, United States). Human and mouse lactate dehydrogenase (LDH) and HIF-1α enzyme-linked immunosorbent assay kits were purchased from Elabscience (Wuhan, China). RNAiso Plus, PrimeScript™, RT reagent and SYBR Premix Ex Taq kit were purchased from TaKaRa (Dalian, China). The Annexin V-phycoerythrin/7-aminoactinomycin D (Annexin V-PE/7AAD) apoptosis kit Apoptosis kit was purchased from BD (San Diego, United States). The transfection reagent Lipo200 was purchased from Invitrogen (CA, United States).

Cell culture and treatment

After receiving the L02 cells, they were centrifuged to remove the cell cryopreservation solution. The cells were then added DMEM complete medium (containing 10% FBS), and cultured in a 37 °C 5% CO_2 constant temperature incubator in a suitable humidity environment. The adherence and growth of the cells were observed under a microscope, and the cells were in the logarithmic growth phase for experiments. The hypoxia-treated cell group was placed in a three-gas incubator at 37 °C with a volume fraction of 95% N_2 + a volume fraction of 5% CO_2 for hypoxia treatment for 4 h, 8 h, and 12 h, respectively. Hepatocytes treated with hypoxia for 12 h were used as model group. The Hypoxia + Ars group was first treated with Hypoxia for 12 h, followed by hypoxia treatment for 12 h. Hypoxia + anisomycin + siRNA-ATF4 group cells were first transfected with siRNA, then intervened with anisomycin for 12 h, and finally treated with hypoxia for 12 h. The sequence of siRNA-ATF4 was 5'-TCC CTC AGT GCA TAA AGG A-3'. And the sequence of non-targeting control siRNA was 5'-UUC UCC GAA CGU GUC ACG A-3'. The siRNA was transfected into cells using Lipo2000 according to the manufacturer's instructions.

Animal groups and treatment

All animal experimental procedures were evaluated and approved by the Laboratory Animal Care and Committee of Renmin Hospital of Wuhan University (WDRM20181018) and followed institutional guidelines as well as ARRIVE guidelines. Thirty male C57BL/6 rats were randomly divided into 3 groups, namely the normal group, the model group, and the Ars group, with 10 rats in each group. All mice were acclimated to feeding for 1 wk before the experiment. Referring to the previous modeling method[13,14], the mice in the model group and Ars group were injected with D-Gal 400 mg/kg and LPS 100 μg/kg intraperitoneally. The mice in Ars group were given Ars (1 mg/kg) intraperitoneal treatment 3 d before modeling, once a day, until 24 h after modeling. The rats in the normal group and the model group were given normal saline by gavage every day. 12 h after modeling, the survival of mice in each group was observed and recorded. Body weights and health of the animals were monitored every other day. If the mice were unable to eat or drink, showed any abnormal behavior, or signs of toxicity, pain, or distress, they would be removed from the study. At the end of the experiment, the mice were euthanized by sodium pentobarbital, and death was confirmed by the absence of a heartbeat. About 1 mL of ocular venous blood was collected. Liver tissue was taken, washed with normal saline, and then stored in -80 °C freezer for tissue homogenate, protein and mRNA extraction. The rest of the liver tissue specimens were fixed with 4% paraformaldehyde, embedded in paraffin, and used for hematoxylin-eosin (HE) and transferase-mediated deoxyuridine triphosphate-biotin nick end labeling (TUNEL) staining.

Cell apoptosis, HIF-1α and LDH detection

Referring to the previous method[15], the apoptosis level of L02 cells in each group was detected by flow cytometry using Annexin V-PE/7AAD apoptosis kit. After intervention in each group, 1.0×10^5 cells were added to 400 μL buffer solution for staining. 5 μL of Annexin V-PE and 5 μL of 7AAD were then added to the cell suspension. The cell was incubated in the dark for 15 min at 37 °C. The apoptosis rate of early and late cells was detected by flow cytometry (BD, United States). According to the description in the previous experiments[16], the cell supernatant, homogenates of cells and liver tissues in each group were taken. Then the HIF-1α and LDH detection kits were used to evaluate the content of HIF-1α in cell or tissue homogenates, LDH in cell supernatant or serum according to the kit instructions.

Determination of G3BP1 expression by immunofluorescence

The cells in each group were modeled and intervened by the above method. After 24 h of incubation, they were fixed with cell fixative for 25 min, and then washed with PBS for 3 times. 0.2% Triton was permeabilized for 20 min, and 0.5% BSA was blocked for 30 min. G3BP1 primary antibody (1:1000) was incubated overnight. The next day, the secondary antibody was incubated for 1 h, nuclei were stained with DAPI for 3 min, washed with PBS for 5 times. The anti-fluorescence quencher was added dropwise, and the slides were mounted and observed under an upright microscope.

Detection of ATF4 mRNA by quantitative real-time polymerase chain reaction

The total RNA of each group of cells was extracted by RNAiso Plus kit. The cDNA was further amplified using Prime-Script RT reagent kit. The amplified cDNA was subjected to quantitative polymerase chain reaction (qPCR) by real-time PCR (RT-PCR) using SYBR Premix Ex Taq kit. The PCR program was set as: initial 95 °C for 10 s; 95 °C for 5 s and 60 °C for 20 s, 40 cycles. ATF4 primer sequences: forward 5'-TCAAACCTCATGGGTTCTCC-3' and reverse 5'-GTGTCATCCAACGT-GGTCAG-3'. GAPDH primer sequences: forward 5'-ACCACAGTCCATGCCATCAC-3', reverse 5'-TCCACCACCCTGTTGCTGTA-3'. The relative gene expression of ATF4 was calculated by $2^{-\Delta\Delta CT}$. The above methods refer to previous reports[17].

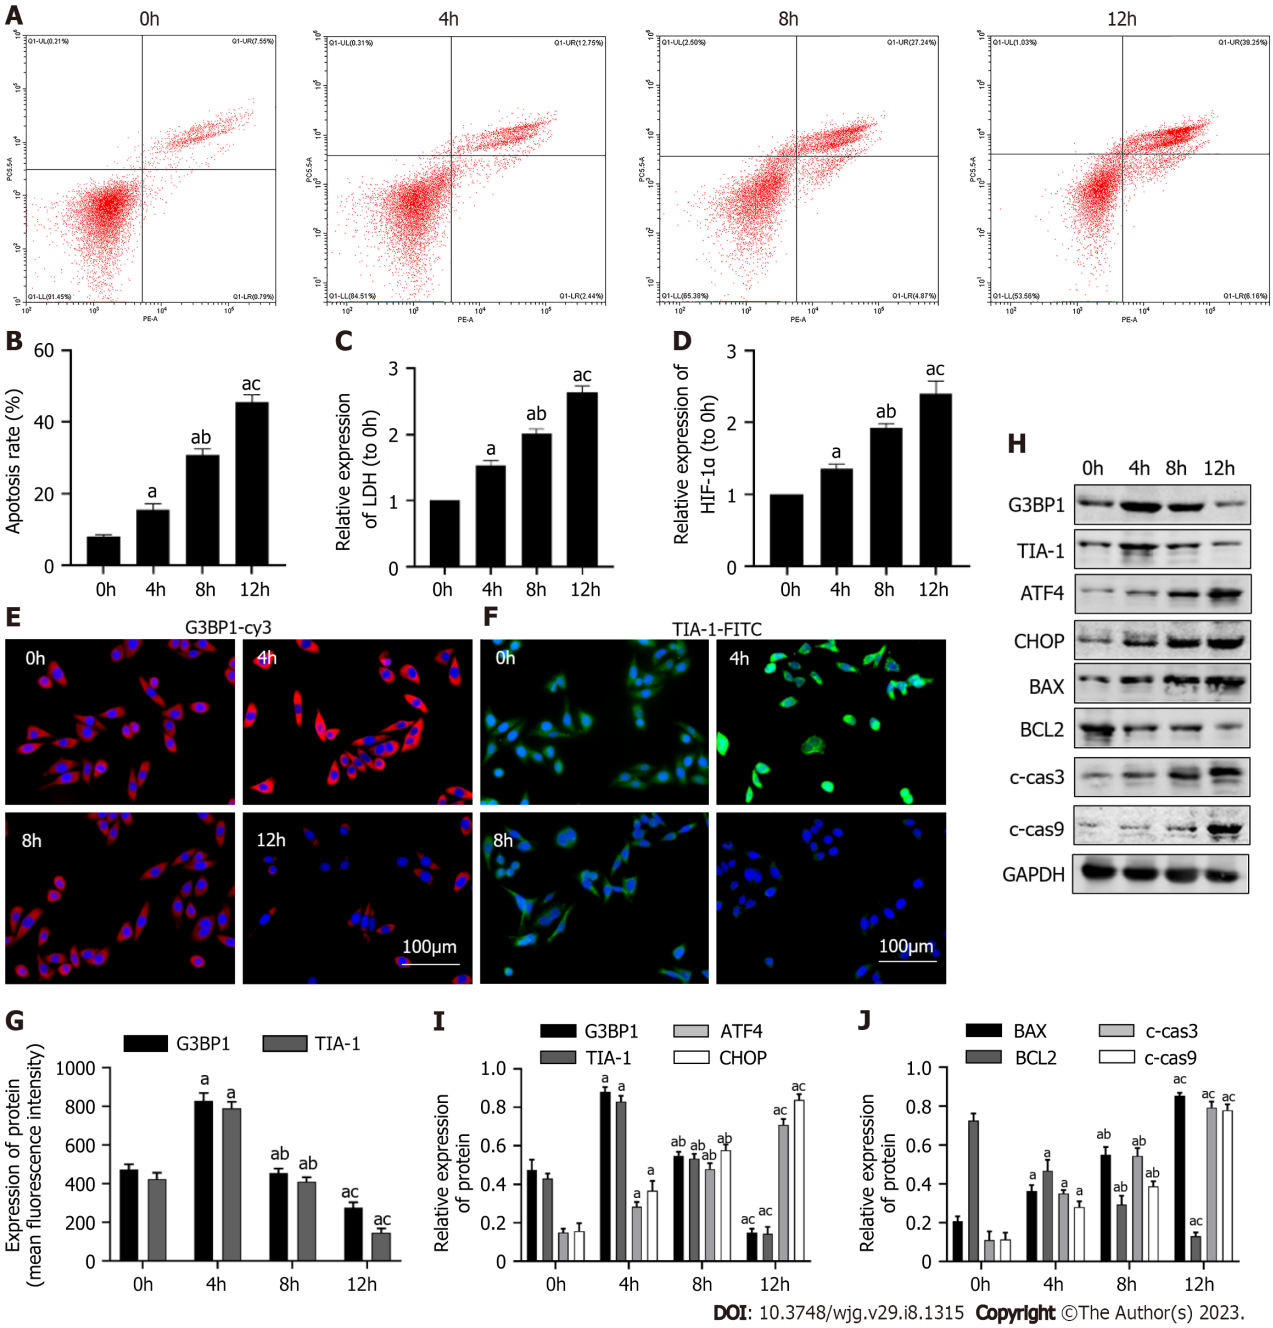
Protein expression was detected by western blot

Referring to the previous experimental method[18], the cells or liver tissues of each group were collected into the centrifuge tube, and were broken under ice bath by ultrasound. After centrifugation at 4 °C, the supernatant was taken. Total protein was determined by bicinchoninic acid method and protein concentration was adjusted. It was then added protein loading buffer, mixed well, and boiled for 10 min. Electrophoresis was performed with 10% sodium dodecyl sulfate polyacrylamide gel electrophoresis. 10 μL sample to each well was then add. Electrophoresis was performed at 80 V and then at a constant current of 200 mA. PVDF membranes were sealed with 5% skim milk powder at room temperature for 1h. Then primary antibody (G3BP1, 1:1,000; TIA-1, 1:1000; ATF4, 1:1000; CHOP, 1:1000; BAX, 1:1000; BCL2, 1:1000; c-cas3, 1:1,000; c-cas9, 1:1000; GAPDH, 1:3000) was used to incubated the membranes overnight at 4 °C. After the membranes were washed, fluorescent secondary antibody (1:10000) was used to incubate at room temperature without light for 1 h. Finally, the membranes were scanned with Odyssey system to detect and compare the relative protein expression levels of each group.

Biochemical tests and histological studies

The levels of alanine aminotransferase (ALT), aspartate aminotransferase (AST) and total bilirubin (TBIL) in serum in each group were detected by automatic biochemical analyzer. Liver tissues fixed by formaldehyde and embedded in paraffin were taken from each group. The paraffin blocks were sectioned. Hematoxylin and eosin were used to stain the slices. The slices were dehydrated and dried in turn. The histopathological changes of liver in each group were observed under inverted microscope. The slices were stained with TUNEL and incubated away from light. After washing with PBS, DAPI was dropped and incubated away from light. Cell morphology was observed under fluorescence microscope, and apoptosis index in each tissue was calculated according to the method described previously[19].

Statistical analysis

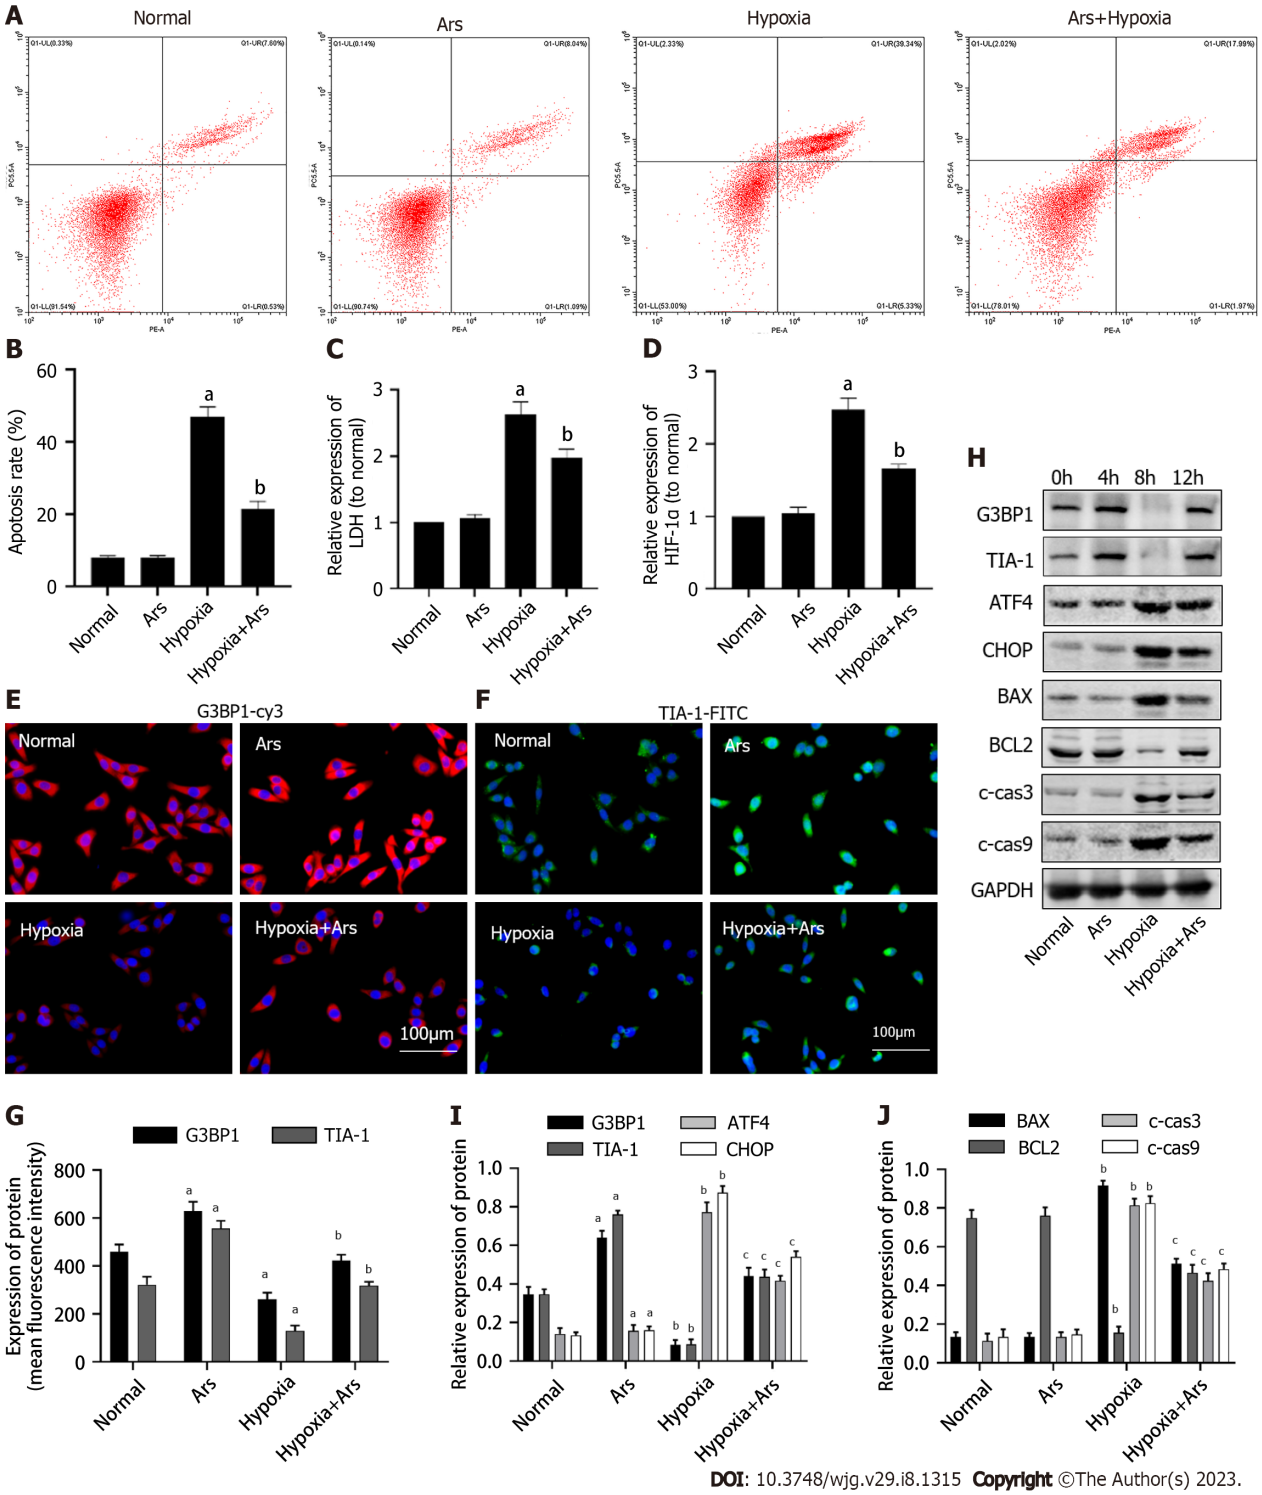


SPSS 19.0 statistical software was used for statistical analysis. All data were expressed as mean ± SD. *t*-test was used for comparison between two groups, and analysis of variance test was used for comparison between three groups and more than three groups. $P < 0.05$ means the difference was statistically significant.

RESULTS

Changes of SGs, ERS and apoptosis levels with the change of hypoxia time

The histopathological examination of liver failure revealed massive necrosis and extensive intrahepatic inflammatory reaction, resulting in the embolization of micro vessels and the structural destruction of hepatic sinuses. The microcirculation disturbance could lead to obvious hepatic perfusion obstruction, reflecting ischemic hypoxic injury[20]. The ischemia-hypoxia and ischemia-reperfusion (IR) could further activate local inflammatory response or aggravate local perfusion disorders through platelet activation pathway[21].



In this part, the model of hepatocyte hypoxia *in vitro* was used to simulate the ischemic hypoxia injury during ALF. It was firstly observed how the levels of SGs, ERS and apoptosis changed over time. As shown in Figure 1A-D, compared with the normal group, the apoptosis rate, HIF-1α and LDH contents in the hypoxia group for 4 h were increased ($P < 0.05$). Compared with the 4 h group, the apoptosis rate and the contents of HIF-1α and LDH in hypoxia group for 8 h and 12 h was furtherly

Figure 1 Changes of stress granules, endoplasmic reticulum stress and apoptosis levels with the change of hypoxia time. A and B: The level of apoptosis was detected by flow cytometry; C and D: The detection kits were used to evaluate the content of HIF-1α in homogenates, lactate dehydrogenase in cell supernatant; E: The expression of G3BP1 in cells was detected by immunofluorescence; F: The expression of TIA-1 in cells was detected by immunofluorescence; G: The histogram displays the amount of molecules expression; H-J: The protein expression levels of G3BP1, TIA-1, ATF4, CHOP, BAX, BCL2, c-cas3 and c-cas9 was detected by western blot. $n = 3$. Data was shown mean ± SD. $^{a}P < 0.05$ *vs* 0 h group; $^{b}P < 0.05$ *vs* 4 h group; $^{c}P < 0.05$ *vs* 8 h group.

increased ($P < 0.05$). As shown in Figure 1E-G, compared with the normal group, the expression levels of G3BP1 and TIA-1, the marker molecules of SGs, were increased in the hypoxia group for 4 h ($P < 0.05$). The expression of G3BP1 decreased in the hypoxia groups of 8 h and 12 h compared with the hypoxia group of 4 h ($P < 0.05$). As shown in Figure 1H-J, compared with the normal group, the protein expression levels of ATF4, CHOP, BAX, c-cas3 and c-cas9 in the hypoxia group for 4 h increased ($P < 0.05$), the expression of G3BP1, TIA-1, BCL2 was decreased ($P < 0.05$). After 8 h and 12 h hypoxia, the protein expression levels of ATF4, CHOP, BAX, c-cas3 and c-cas9 were further increased ($P < 0.05$), the expression of G3BP1, TIA-1, BCL2 was further decreased ($P < 0.05$). In conclusion, after 12 h hypoxia treatment, ERS and apoptosis levels of L02 cells were the highest, while SGs content was the lowest. Therefore, the cells treated with hypoxia for 12 h were used as cell models for subsequent research, which was consistent with reported studies[22].

Effects of SGs on ERS and apoptosis in hepatocyte hypoxia model

Arsenite can induce SGs formation by promoting e-IF2α phosphorylation[23], but arsenite has certain hepatotoxicity[24,25]. Refer to the reported studies, the 10 μmol/L intervention dose was used[25,26]. In this part, the Ars intervention group was set to observe that Ars could induce the formation of SGs without causing hepatocyte damage and related molecular changes.

As shown in Figure 2, we first verified the effect of SGs agonist Ars on normal L02 cells. Compared with the normal group, the expression level of G3BP1 was increased in the Ars group, while the level of

ERS and apoptosis did not change significantly. Subsequently, we used Ars to intervene the L02 hepatocyte model treated with 12 h hypoxia. As shown in Figure 2A-D, compared with the Hypoxia group, the apoptosis rate, HIF-1α and LDH contents in cells in the Hypoxia + Ars group were decreased ($P < 0.05$). As shown in Figure 2E-G, compared with the Hypoxia group, the expression levels of G3BP1 and TIA-1 were increased in the Hypoxia + Ars group ($P < 0.05$). As shown in Figure 2H-J, compared with the Hypoxia group, the protein expression levels of ATF4, CHOP, BAX, c-cas3 and c-cas9 in the Hypoxia + Ars group was decreased ($P < 0.05$), the expression of G3BP1, TIA-1, BCL2 was increased ($P < 0.05$).

Effect of SGs on apoptosis in hypoxia model through ERS

ATF4 plays a key role in the process of ERS, which negatively regulates Bcl-2 by promoting the expression of CHOP, leading to the transport of Bax from cytoplasm to mitochondria and the initiation of mitochondrial apoptosis pathway[27]. When excessive ERS occurs, PERK, IRE1, and ATF4 activate and activate the corresponding downstream factors, and up-regulate the expression of ATF4 at the transcriptional and translational levels, resulting in the destruction of the endoplasmic reticulum membrane, the efflux of Ca^{2+}, and the occurrence of apoptosis[28]. The knockdown of ATF4 and the SGs inhibitor anisomycin showed an antagonistic effect on the protective cells. In this part, the groups were set to show that SGs can affect hepatocyte injury through the ATF4-mediated ERS pathway.

We first verified the intervention effect of siRNA-ATF4. As shown in Figure 3A, compared with the normal group, the level of ATF4 mRNA in the normal control group did not change, while the level of ATF4 mRNA in the siRNA-ATF4 group decreased significantly ($P < 0.05$). As shown in Figure 3B-E, compared with the Hypoxia group, the apoptosis rate, HIF-1α and LDH contents in cells of the Hypoxia + siRNA-ATF4 group were decreased ($P < 0.05$). Compared with the Hypoxia + siRNA-ATF4, the apoptosis rate, HIF-1 α and LDH contents in cells of the Hypoxia + siRNA-ATF4 + anisomycin group were increased ($P < 0.05$). As shown in Figure 4A-C, compared with the Hypoxia group, the expression of G3BP1 and TIA-1 in Hypoxia + siRNA-ATF4 group was increased ($P < 0.05$). Compared with the Hypoxia + siRNA-ATF4, the expression of G3BP1 and TIA-1 in Hypoxia + siRNA-ATF4 + anisomycin group was decreased ($P < 0.05$). As shown in Figure 4C-F, compared with the Hypoxia group, the protein expression levels of ATF4, CHOP, BAX, c-cas3 and c-cas9 in the Hypoxia + siRNA-ATF4 group was decreased ($P < 0.05$), the expression of G3BP1, TIA-1, BCL2 was increased ($P < 0.05$). Compared with the Hypoxia + siRNA-ATF4 group, the protein expression levels of ATF4, CHOP, BAX, c-cas3 and c-cas9 in the Hypoxia + siRNA-ATF4 + anisomycin group was increased ($P < 0.05$), the expression of

BCL2 was decreased ($P < 0.05$).

Effects of SGs on ERS and apoptosis levels in liver of ALF mice

In the *in vivo* experiment, we first detected whether the ALF mouse model was successfully established, and then detected the effects of Ars on liver pathological changes and serum biochemical indexes. As shown in Figure 5A, the liver lobules in the normal group were clearly structured and the hepatocytes were neatly arranged. The lobule structure of liver tissue in ALF group was not clear, hepatocyte was necrotic around with inflammatory cells infiltrate. Compared with ALF model group, the hepatic lobule structure in Ars group was clearer and the infiltration of inflammatory cells was reduced. As shown in Figure 5B and F, compared with the normal group, the apoptosis level in liver tissues of mice in model group was significantly increased ($P < 0.05$). After Ars intervention, apoptosis level of liver tissue was significantly reduced ($P < 0.05$). As shown in Figure 5C-E, the serum levels of ALT, AST and TBIL in model group were higher than those in normal group ($P < 0.05$). Compared with model group, ALT, AST and TBIL levels in Ars group were significantly decreased ($P < 0.05$). In addition, as shown in Figure 5G, the 24 h survival rate of mice was observed in each group. The results showed that 90% of mice survived in Ars group, whereas only 70.0% in model group.

As shown in Figure 6A and B, compared with the normal group, the expression of G3BP1 and TIA-1 in model group was decreased ($P < 0.05$). Compared with the model group, the expression of G3BP1 and TIA-1 in Ars group was increased ($P < 0.05$). As shown in Figure 6C-G, compared with the normal group, the level of HIF-1α and LDH, the protein expression of ATF4, CHOP, BAX, c-cas3 and c-cas9 in the model was increased ($P < 0.05$), the expression of G3BP1, TIA-1, BCL2 was decreased ($P < 0.05$). Compared with the model group, the level of HIF-1α and LDH, the protein expression of protein expression levels of ATF4, CHOP, BAX, c-cas3 and c-cas9 in the Ars group was decreased ($P < 0.05$), the expression of BCL2 was increased ($P < 0.05$).

DISCUSSION

Liver is very sensitive to ischemic hypoxic injury because of its high aerobic tissue and metabolism. Ischemia-hypoxia and IR injury induce a large number of ERS and mitochondrial apoptosis pathway. ERS can be induced under ischemia and hypoxia through HIF-1α[29,30]. The complex functions of ERS in hepatocytes can regulate inflammation, oxidative stress, *etc*., which are closely related to the pathogenesis of liver failure. A large number of experimental studies have confirmed that ERS occurs in the liver of various types of ALF animal models. In the liver of ALF mice/rats induced by N-acetaminophen (APAP)[31], LPS combined with D-Gal[32], and carbon tetrachloride[33] induced liver, p-eIF2α, ATF4 and CHOP GRP78 markedly increased. The ERS inhibitors 4-phenylbutyric acid[34] and TUDCA[35] can alleviate the up-regulation of endoplasmic reticulum stress markers CHOP, XBP1, p-eIF2α, and reduce inflammation in liver tissue. damage, alleviate the up-regulation of serum transaminases. At the same time, inhibiting of ERS had a protective effect on APAP-induced liver injury, can reduce liver necrosis, and improve mouse survival[36]. It can be seen that ERS-related molecules can be used as new targets, and the development of drugs targeting ERS provides new ideas for the treatment of ALF.

ERS is an important homeostatic device during liver disease progression, which can assist cells to resist stress, but excessive stress can also lead to cell damage. In the early stage of stress, the endoplasmic reticulum reduces the cell load caused by the accumulation of wrong proteins by inhibiting protein synthesis and accelerating protein transport and degradation, and maintains cell stability[37]. However, when the stress intensity continues to increase, ERS will initiate cell apoptosis pathway. Among them, ATF4 induces the production of endoplasmic reticulum oxide protein and activates the inositol triphosphate receptor, which is a key way to induce apoptosis[38].

SGs are formed by RNA and protein aggregates that control RNA metabolism, signaling, and cell survival under stress. When translation is inhibited, polysomes lose their mRNAs, and "naked" mRNAs assemble with SG nucleating proteins for liquid-liquid phase separation[39]. SGs are dynamically complex and variable biomolecular condensates whose composition and structure undergo dramatic changes under different types of stress. The ability of cells to respond rapidly to various environmental stresses[40,41]. Therefore, the dynamic process of SGs and their regulation are crucial for cells to cope with stress. Studies have shown that the process of SGs formation is stalled by the accumulation of translation initiation complexes in response to various stresses[42]. G3BP1 bind mRNA and aggregate to form SGs. While large SGs aggregates are formed by smaller aggregates through post-translational

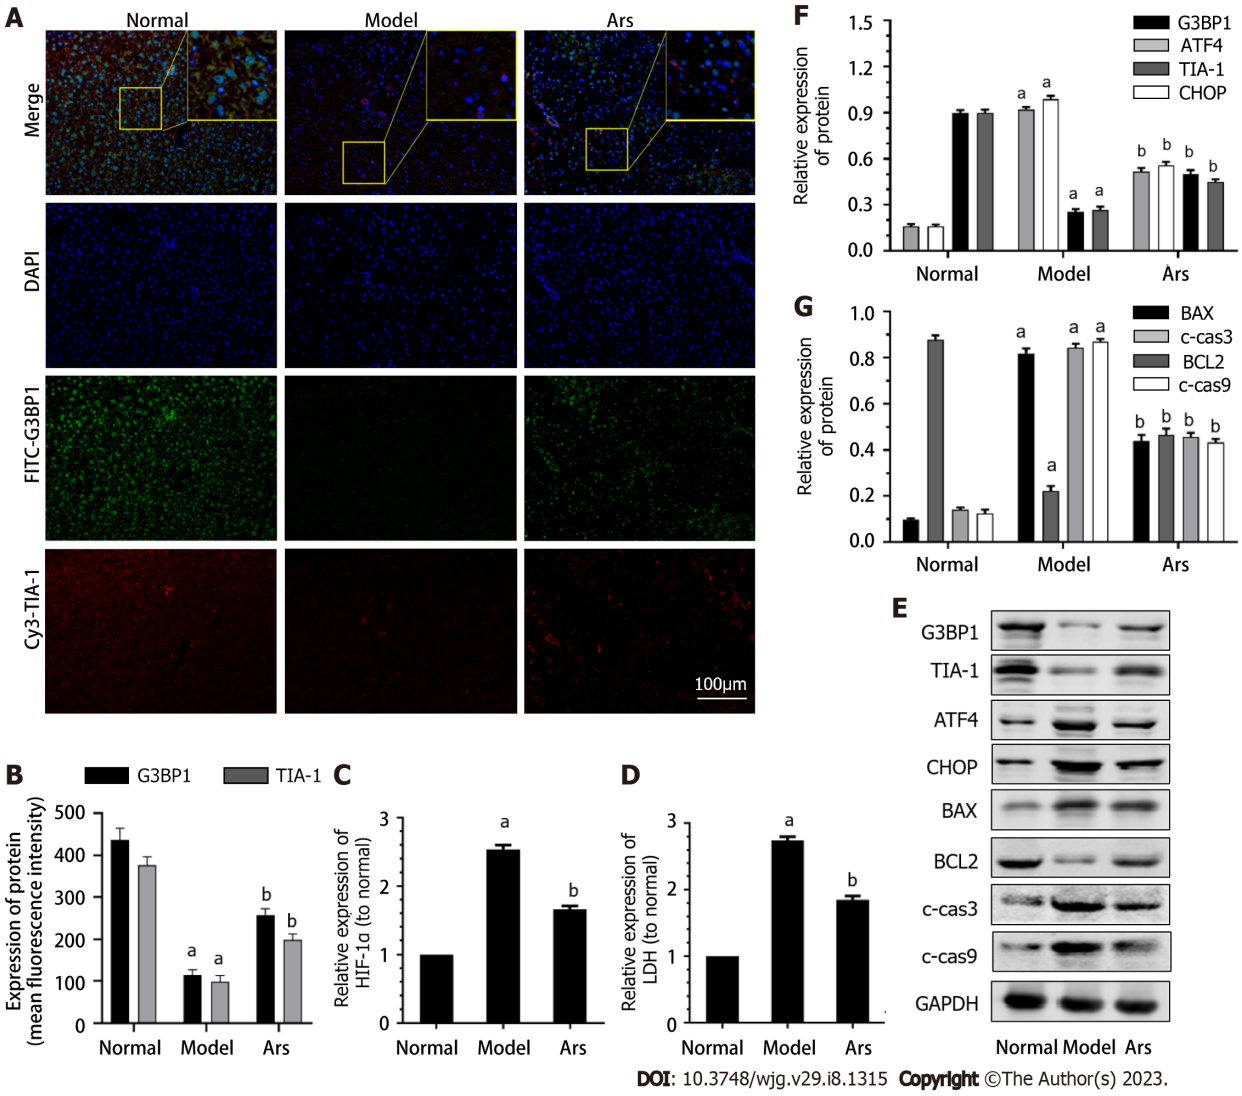

Figure 6 Effect of stress granules agonist on G3BP1, HIF-1α, lactate dehydrogenase and endoplasmic reticulum stress related molecules in acute liver failure mice liver. A: The expression of G3BP1 and TIA-1 in liver was detected by immunofluorescence; B: The histogram displays the amount of molecules expression; C and D: The detection kits were used to evaluate the content of HIF-1α in liver tissue homogenate, lactate dehydrogenase in serum; E-G: The protein expression levels of G3BP1, TIA-1, ATF4, CHOP, BAX, BCL2, c-cas3 and c-cas9 was detected by western blot. n = 10. modification and microtubule transport[43]. Another typical SGs maker, TIA-1 RNA-binding protein packet TIA-1 binds to mRNA, causing mRNA to stop translation and aggregate to form SGs[44,45]. Therefore, G3BP1 and TIA-1 were selected as markers for SGs in this study. Therefore, G3BP1 and TIA-1 were selected as markers for SGs in this study.

There is no relevant report on the relationship between SGs, ERS and hepatocyte apoptosis in the process of hepatocyte ischemia and hypoxia for ALF. In the *in vitro* study, we firstly observed how the levels of SGs, ERS and apoptosis changed over time. With the prolongation of hypoxia time, the levels of ERS and apoptosis in hepatocytes increased. The level of SGs increased at 4h and then decreased. Therefore, hepatocyte treated with hypoxia for 12 h were used as cell models for subsequent research. This suggested that SGs were stress-increased in the early stage of hepatocyte hypoxia to protect cells from damage. However, with the prolongation of hypoxia time, the production of SGs would decrease, and the effect of protecting hepatocytes will be weakened. Then the effects of SGs on ERS and apoptosis in hepatocyte hypoxia model was observed. Compared with the Hypoxia group, the apoptosis rate and ERS level decreased in SGs hepatocyte Ars treated group. However, Ars could elevate the level of SGs. In the next, it was verified the effect of SGs on apoptosis level of hepatocyte hypoxia model through ERS. It was verified the intervention effect of siRNA-ATF4. Compared with the normal group, the level of ATF4 mRNA in the siRNA-ATF4 group was decreased significantly. Compared with the Hypoxia group, the apoptosis rate, HIF-1α and LDH contents in cells, the level of ERS was decreased in the siRNA-ATF4 treatment group. Moreover, on the basis of siRNA-ATF4 intervention group, it was found that the apoptosis rate, HIF-1α and LDH contents in cells, the level of ERS was decreased.

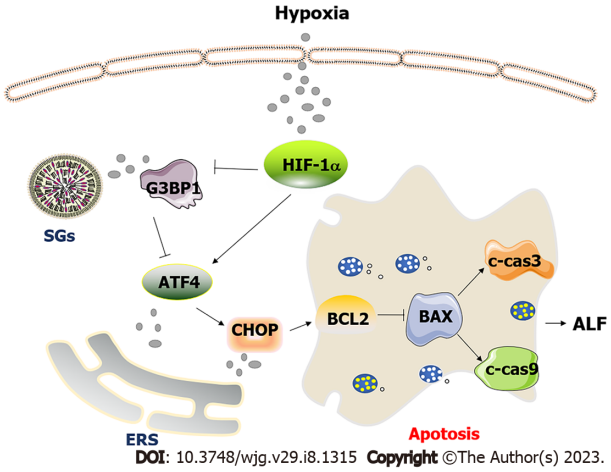

Figure 7 Graphical abstract. In the process of acute liver failure, hepatocytes were damaged by hypoxia and ischemia injury. At this time, the content of HIF-1α in cells increased, which inhibited the formation of stress granules (SGs) mediated by G3BP1 and promoted the expression of endoplasmic reticulum stress (ERS) marker molecules ATF4 and CHOP. The activated ERS pathway further promotes hepatocyte apoptosis. Promoting SGs synthesis can inhibit the level of hepatocyte apoptosis by inhibiting the ATF4-mediated ERS pathway. SGs: Stress granules; ERS: Endoplasmic reticulum stress; ALF: Acute liver failure.

According to previous studies, the criteria for success in animal modeling of ALF include liver histopathological damage, serological changes, especially elevated levels of transaminase and bilirubin [13,16,46]. In this study, LPS injection combined with D-Gal simulates acute inflammatory liver injury model, which is widely accepted and used to explore and develop new liver protective reagents for inflammatory liver injury[47]. LPS is in the outer membrane of the gram-negative bacteria[48], and can combine with myeloid differentiation factor 2 and cluster of differentiation 14 to form a complex. This complex is recognized by the toll-like receptor 4 on the membrane of Kupffer cells (KCs) in the liver. KCs can produce the inflammatory mediators, such as TNF-α, IL-1β, IL-6, *etc.*, leading to liver cell damage[49,50]. However, LPS has a low specificity for liver injury, so it is often combined with DGal to establish an animal model of acute inflammatory liver injury to simulate human hepatitis[48]. Studies have shown that D-Gal can inhibit protein synthesis by depletion of uridine triphosphate through the galactose pathway, and reactive oxygen species production can induce liver injury. Therefore, D-Gal can be used as a sensitizer in LPS-induced liver injury[51]. In the course of occurrence and development of liver failure, a large number of liver cell death is the most core event.

So, In the *in vivo* experiment, it was first detected whether the ALF mouse model was successfully established. HE staining showed that the liver tissue structure of mice in the normal group was regular, and the liver cells were neatly arranged in the hepatic lobules. No necrosis of liver cells and inflammatory cell infiltration. The liver lobule structure of the ALF model group was destroyed by LPS combined with D-Gal, accompanied by a large number of necrotic liver cells and infiltrating inflammatory cells. Compared with normal group, ALT, AST and TBIL levels in serum of model group were increased. The above studies indicate that the mouse model of ALF has been successfully constructed in this study, which is consistent with previous reports[13,16]. After Ars intervention, the degree of infiltration of necrotic liver cells and inflammatory cells in mouse liver tissue was reduced, and the levels of ALT, AST and TBIL in serum were decreased.

Moreover, compared with the normal group, the apoptosis level in liver tissues of mice in model group was significantly increased. The expression of G3BP1 in model group was decreased. The expression of G3BP1 in model group was decreased. Moreover, compared with the normal group, the level of HIF-1α and LDH, the protein expression of ATF4, CHOP, BAX, c-cas3 and c-cas9 in the model was increased, the expression of BCL2 was decreased. Compared with the model group, the level of HIF-1α and LDH, the protein expression of protein expression levels of ATF4, CHOP, BAX, c-cas3 and c-cas9 in the Ars group was decreased, the expression of BCL2 was increased.

CONCLUSION

In conclusion, as shown in Figure 7, hepatocytes were damaged by hypoxia and ischemia injury in the process of ALF. At this time, the content of HIF-1α in cells increased, which inhibited the formation of SGs mediated by G3BP1 and promoted the expression of ERS marker molecules ATF4 and CHOP. The activated ERS pathway further promotes hepatocyte apoptosis. Promoting SGs synthesis can inhibit the level of hepatocyte apoptosis by inhibiting the ATF4-mediated ERS pathway. However, the inhibition of ERS-mediated hepatocyte apoptosis pathway by SGs still needs to be further studied. Despite the use of Ars and anisomycin in the intervention of SGs, there is still no direct evidence to prove the influence of

SGs on hepatocyte apoptosis. In the next studies, we will use more appropriate methods to directly detect the influence of SGs on hepatocyte. At the same time, this paper provides potential targets and ideas for clinical treatment of ALF.

ARTICLE HIGHLIGHTS

Research background

There is no relevant report on the relationship between stress granules (SGs), endoplasmic reticulum stress (ERS) and hepatocyte apoptosis in the process of hepatocyte ischemia and hypoxia for acute liver failure (ALF).

Research motivation

This paper provides potential targets and ideas for clinical treatment of ALF.

Research objectives

This study was to investigate whether SGs could protect hepatocytes from hypoxia-induced damage during ALF by reducing ERS mediated apoptosis.

Research methods

The agonist of SGs, arsenite (Ars) was used to intervene hypoxia-induced hepatocyte injury cellular model and ALF mice models. Further, the siRNA of ATF4 and SGs inhibitor anisomycin was then used to intervene in cell models.

Research results

In the *in vitro* study, we firstly observed how the levels of SGs, ERS and apoptosis changed over time. With the prolongation of hypoxia time, the levels of ERS and apoptosis in hepatocytes increased. The level of SGs increased at 4h and then decreased. Therefore, hepatocyte treated with hypoxia for 12 h were used as cell models for subsequent research. This suggested that SGs were stress-increased in the early stage of hepatocyte hypoxia to protect cells from damage. However, with the prolongation of hypoxia time, the production of SGs would decrease, and the effect of protecting hepatocytes will be weakened. Then the effects of SGs on ERS and apoptosis in hepatocyte hypoxia model was observed. Compared with the Hypoxia group, the apoptosis rate and ERS level decreased in SGs hepatocyte Ars treated group. However, Ars could elevate the level of SGs. In the next, it was verified the effect of SGs on apoptosis level of hepatocyte hypoxia model through ERS. It was verified the intervention effect of siRNA-ATF4. Compared with the normal group, the level of ATF4 mRNA in the siRNA-ATF4 group was decreased significantly. Compared with the Hypoxia group, the apoptosis rate, HIF-1α and lactate dehydrogenase (LDH) contents in cells, the level of ERS was decreased in the siRNA-ATF4 treatment group. Moreover, on the basis of siRNA-ATF4 intervention group, it was found that the apoptosis rate, HIF-1α and LDH contents in cells, the level of ERS was decreased. In the *in vivo* experiment, it was first detected whether the ALF mouse model was successfully established. HE staining showed that the liver tissue structure of mice in the normal group was regular, and the liver cells were neatly arranged in the hepatic lobules. No necrosis of liver cells and inflammatory cell infiltration. The liver lobule structure of the ALF model group was destroyed by LPS combined with D-Gal, accompanied by a large number of necrotic liver cells and infiltrating inflammatory cells. Compared with normal group, alanine aminotransferase (ALT), aspartate aminotransferase (AST) and total bilirubin (TBIL) levels in serum of model group were increased. The above studies indicate that the mouse model of ALF has been successfully constructed in this study, which is consistent with previous reports. After Ars intervention, the degree of infiltration of necrotic liver cells and inflammatory cells in mouse liver tissue was reduced, and the levels of ALT, AST and TBIL in serum were decreased.

Research conclusions

Hepatocytes were damaged by hypoxia and ischemia injury in the process of ALF. At this time, the content of HIF-1α in cells increased, which inhibited the formation of SGs mediated by G3BP1 and promoted the expression of ERS marker molecules ATF4 and CHOP. The activated ERS pathway further promotes hepatocyte apoptosis. Promoting SGs synthesis can inhibit the level of hepatocyte apoptosis by inhibiting the ATF4-mediated ERS pathway.

Research perspectives

SGs could protect hepatocytes from hypoxia-induced damage during ALF by reducing ERS-mediated apoptosis.

Abstract

BACKGROUND

This was an observational, descriptive, and retrospective study from 2011 to 2020 from the Department of Informatics of the Brazilian Healthcare System database.

AIM

To describe the intestinal complications (IC) of patients with ulcerative colitis (UC) who started conventional therapies in Brazil´s public Healthcare system.

METHODS

Patients ≥ 18 years of age who had at least one claim related to UC 10th revision of the International Statistical Classification of Diseases and Related Health Problems (ICD-10) code and at least 2 claims for conventional therapies were included. IC was defined as at least one claim of: UC-related hospitalization, procedures code for rectum or intestinal surgeries, and/or associated disease defined by ICD-10 codes (malignant neoplasia of colon, stenosis, hemorrhage, ulcer and other rectum or anus disease, megacolon, functional diarrhea volvulus, intussusception and erythema nodosum). Descriptive statistics, annual incidence, and

incidence rate (IR) [per 100 patient-years (PY)] over the available follow-up period were calculated.

RESULTS

In total, 41229 UC patients were included (median age, 48 years; 65% women) and the median (interquartile range) follow-up period was 3.3 (1.8-5.3) years. Conventional therapy used during follow-up period included: mesalazine (87%), sulfasalazine (15%), azathioprine (16%) or methotrexate (1%) with a median duration of 1.9 (0.8-4.0) years. Overall IR of IC was 3.2 cases per 100 PY. Among the IC claims, 54% were related to associated diseases, 20% to procedures and 26% to hospitalizations. The overall annual incidence of IC was 2.9%, 2.6% and 2.5% in the first, second and third year after the first claim for therapy (index date), respectively. Over the first 3 years, the annual IR of UC-related hospitalizations ranged from 0.8% to 1.1%; associated diseases from 0.9% to 1.2% - in which anus or rectum disease, and malignant neoplasia of colon were the most frequently reported; and procedure events from 0.6% to 0.7%, being intestinal resection and polyp removal the most frequent ones.

CONCLUSION

Study shows that UC patients under conventional therapy seem to present progression of disease developing some IC, which may have a negative impact on patients and the burden on the health system.

Core Tip: This population-based study investigated intestinal complications (ICs) in patients with ulcerative colitis (UC) undergoing therapy available in the public healthcare system (Sistema Único de Saúde) of Brazil over the last decade. Our results showed that some patients with UC undergoing conventional therapy, seem to present an active and progressive disease and develop relevant ICs, which demand important resources of the healthcare system and have a negative impact on their lives.

INTRODUCTION

Ulcerative Colitis (UC) is an idiopathic inflammatory disease of the mucosa and colon that commonly involve colonic regions both proximal to and distal from the site of the primary lesion[1]. The typical presentation includes symptoms such as bloody diarrhea, rectal urgency, and abdominal pain[2]. UC is a component of inflammatory bowel diseases (IBD), which are chronic, immune-mediated inflammatory diseases of the gastrointestinal tract. The etiopathogenesis is multifactorial involving different environmental, genetic, immune-mediated and intestinal microbial factors[3].

Although epidemiological studies are still scarce in developing countries, the incidence and prevalence of UC is increasing worldwide, along with IBD[4]. A systematic review showed that the incidence and prevalence of UC in Latin America varied between regions and studies, ranging from 0.04 to 8.00/100000 and 0.23 to 76.1/100000, respectively, and generally increased over the period from 1986 to 2015[5].

Many patients have long periods of complete remission, but the cumulative probability of remaining relapse-free for two years is only 20%, decreasing to less than 5% in 10 years[6]. Chronic inflammation of the colorectal mucosa, as is typically found in UC, is a proven risk factor for neoplasm of colon. The development of neoplasm of colon in patients with UC is related to several factors: Duration, extent, activity, severity and family history of the disease. The progression from UC inflammation to neoplasm and/or surgery is a multi-step process in which the accumulation of symptoms and sequential mucosal changes gradually transition to a low-grade change to neoplasm[7]. Indications for emergency surgery include refractory toxic megacolon, perforation, and ongoing severe colorectal bleeding[8].

UC is a progressive disease that can lead to other serious complications and/or even life-threatening complications. One of the most common UC disease progressions are: anorectal dysfunction (50%)[9], proximal extension (25%) with the greatest proximal extension occurring during the first 10 years[10, 11], pseudopolyposis (16%)[12] and other such as impaired permeability in remission or with mucosal healing, stenosis and dysmotility[10]. Thus, complications related to UC represent a substantial burden in terms of costs and patient quality of life, with hospital admissions, operations and treatments being the most relevant burdens[13].

The treatment of UC currently aims to monitor indicators of disease activity and to adjust therapy, aiming to achieve clinical remission and prevent long-term complications, such as dysplasia, colorectal cancer, hospitalizations and colectomy[14]. In 2021, the STRIDE-II study confirmed STRIDE-I's long-term goals of clinical remission, histological remission, and endoscopic mucosal healing[15] and added absence of disability, restoration of quality of life, and normal growth in children. Symptomatic relief and normalization of serum and fecal markers were determined as short-term targets[16].

Treatment will vary depending on the severity and location of the UC. For proctitis, topical therapy with 5-aminosalicylic acid (5-ASA) compounds is used. For more severe UC, oral and local 5-ASA compounds and corticosteroids are indicated to induce remission. For patients who do not respond to these treatments, intravenous steroids are used. When refractory to this, calcineurin inhibitors (cyclosporine, tacrolimus), tumor necrosis factor-α antibodies or immunomodulators are then used[17].

For patients with moderate to severe UC, drugs such as thiopurines and biologics are indicated to control symptoms and heal the intestinal mucosa. Anti-tumor necrotizing factor (TNF) drugs include infliximab, adalimumab and golimumab. Of the anti-integrin drug, vedolizumab can be mentioned. And the anti-p40 antibody targeting interleukin (IL)-12 and IL-23, we can mention ustekinumab and small molecules (Janus Kinase inhibitor - tofacitinib)[18]. Biologics were not available in the public healthcare system during the study period in Brazil. Studies have observed an association between the administration of biologics therapies such as anti-TNF-α within the first 2 years of diagnosis and several beneficial effects, including reduction risk of intestinal surgery[4,5,19].

There are few population-based studies documenting the evaluation and progression of the conventional therapy-using patient of the UC disease phenotype. Thus, this study aims to describe the intestinal complications (IC) of patients with UC who started treatment with conventional therapies between January 2011 and January 2020 in the Brazilian healthcare system.

MATERIALS AND METHODS

Data source

For this study, data were collected from two Department of Informatics of the Brazilian Healthcare System (DATASUS) databases: Hospitalizations Information System (SIH), which contains hospitalization data[20] and the Outpatient Information System (SIA), which contains data on outpatient care [21,22].

The causes of hospital admissions are coded according to the 10th revision of the International Statistical Classification of Diseases and Related Health Problems (ICD-10). The SIH was used to identify the number and causes of hospital admissions related to UC and/or its IC.

The SIA is the system that allows local managers to process outpatient care information recorded in outpatient care capture applications by public and private providers contracted/agreed by the public healthcare system (SUS). Most SIA subsets have an ID code that enables linking the outpatient procedures to a single patient. Because SIH does not have patient ID information, a probabilistic record linkage (RLK) was performed allowing longitudinal assessment in SIH and SIA at a patient-level. The RLK relied on multiple steps with different combination of patient information from both databases, such as date of birth, gender and ZIP code, making it possible to identify patients in both systems.

Data is presented as procedure codes from billing records and includes demographic information, all procedures such as inpatient and outpatient performance, number of procedures, and other additional information.

Study design

The present study is a descriptive, observational, retrospective study of secondary data collected between 2011 and 2020, which used the DATASUS to characterize IC in patients with UC.

We considered UC patients those who had at least one report of UC ICD-10 code (K51). The date of the first request for UC conventional therapy was considered as the index date. Conventional therapies used for UC treatment were based on procedures codes available at DATASUS, according to the following list: Sulfasalazine; Mesalazine; Azathioprine; Methotrexate; Cyclosporine. UC patients must had at least two claims of conventional therapy to be included in the study. They were followed from the index date until the last information available in the DATASUS regardless of being under conventional treatment or not. One or more conventional therapies could had been used at the same time and/or in sequence by the patient, due to that line of treatment and comparisons between different conventional therapies were not assessed in this study.

We also assessed sociodemographic, such as age, sex and location of residency of the patient. Measurements of IC information in UC patients were extracted, including procedures performed, hospitalization causes, and diseases developing in the study sample. Each pre-defined claim of IC reported after conventional therapy initiation was considered as a progression of the UC disease.

Pre-defined claims of ICs were validated based on four independent medical expert opinions and literature about the natural history and evaluation of UC[23]. Patients who progressed from UC to malignant neoplasm of colon, stenosis, hemorrhage, ulcer or other specified diseases or symptoms of anus and rectum, functional diarrhea, megacolon, volvulus, intussusception or erythema nodosum or any intestinal surgery or hospitalization related to the disease was considered to have experienced an IC.

The following claims were considered as proxy of ICs: any claim for anus, rectum or intestinal surgeries for procedures, any claim of hospitalization reporting UC ICD-10 codes for hospitalization and/or any claim of ICD-10 code pre-defined for associated diseases [Table 1, list of diseases (ICD-10 code) considered as IC in consequence of underlying UC disease].

Overall ICs could reflect one or more type of ICs, so, in an attempt to represent them, IC analyses sets were stratified into 3 groups based on the type of IC: (1) Procedures: If claim of procedure code for anus, rectum or intestinal surgeries; (2) Hospitalizations: If claim of hospitalization for UC (reported UC ICD-10 in inpatient setting); and (3) Associated disease: If claim of ICD-10 code for diseases pre-defined as UC complications, such as C18 (malignant neoplasm of colon), K62.4 (stenosis of anus and rectum), K62.5 (hemorrhage of anus and rectum), K62.6 (ulcer of anus and rectum), K62.8 (other specified diseases of anus and rectum), K62.9 (disease of anus and rectum, unspecified), K59.1 (functional diarrhea), K59.3 (megacolon, not elsewhere classified), K56.2 (volvulus), K56.1 (intussusception), or L52 (erythema nodosum). Thus, to be considered a case of IC, patients must have at least one medical complaint in one or more of the sub-groups of ICs previously described.

In the data analysis, the annual IC in UC patients per each calendar year, and the incidence per 100 people of ICs were evaluated throughout the study. Patients whose UC progressed after the conventional treatment initiation timeframe were recorded as an IC annual rate and expressed year (from 1 to 5 years) according to the number of claims (total and mean) and the number of patients (total and percentage according to the number of patients in follow-up at the database at the respective year Also, the mean ICs per each patient were assessed and expressed by calendar year. The incidence of IC was converted into units per patient/year by dividing them for all patients by the person-years of follow-up, because each individual attends a different time in the database. Thus, the incidence rate was calculated as the number of intestinal events divided by the total person-time at risk. Considering that one patient could present one or more types of IC, we also expressed the total of ICs found in the study.

The most frequent ICs related to procedures in UC population were assessed according to the number of patients with at least one procedure for anus, rectum or intestinal surgeries during the study period. The most frequent ICs related to associated disease in UC population was assessed according to the number of patients with at least one ICD-10 code of pre-defined associated-disease.

Study population

Patients were included in the study if they were aged ≥ 18 years old, if they had evidence of UC [at least one ICD-10 claim of UC (K51.0, K51.2, K51.3, K51.4, K51.5, K51.8 or K51.9)] and if they had at least one claim of conventional treatment of UC. The UC conventional therapies (synthetic) considered in the present study were sulfasalazine, mesalazine, azathioprine, methotrexate and cyclosporine.

To capture the initial stage of treatment, patients must have had no claims for conventional and/or anti-TNF therapy prior to the index date. Thus, the period from January 2010 to December 2011 was considered only for the evaluation of the medical history of patients who had the index date in 2011.

Considering that fissure and fistula of anal and rectal regions (K60) and/or abscess of anal and rectal regions (K61) are considered an uncommon IC in UC patients, but common in other IBD, we excluded patients with at least one ICD-10 claim of these diseases after index date (first claim of UC conventional treatment code). Additionally, patients with less than 6 months of follow-up in the database and patients who were not exclusive to the SUS were excluded. Non-SUS exclusive was defined as patients who used the SUS only to obtain high-cost medications and who carried out the rest of the treatment and medical care through their private health plan[24]. Thus, they are patients who had claims related to medications only.

Statistical analysis

Although only descriptive analyses were performed, a statistical review of the study was performed by a statistician. Results were described as measures of central tendency (means, medians) and spread (variance, range) for continuous variables (*e.g.*, age); absolute number and percentage for categorical variables (*e.g.*, sex) and Kaplan Meier Curve for time to event data. Ninety-five percent confidence intervals (95%CI) were calculated according to the variable, normal distribution for continuous variable, normal approximation to binominal distribution for proportion and Poisson distribution for incidence rate, as applicable.

Table 1 Description of most common intestinal complications related to associated diseases (International Statistical Classification of Diseases and Related Health Problems) or procedures (codes), *n* (%)

ICs	Description of ICs	Patients (*n* = 1273)	%	Procedure-related complications		Patients (*n* = 1125)	%
Associated disease (ICD-10–related complications)				0407020403	Abdominal rectosig-moidectomy	167	15
K62	Other diseases of the anus and rectum	1070	78	0407020390	Body removed – rectum or colon polyps	145	13
C18	Malignant neoplasms of the colon	255	19	0407020063	Partial colectomy	135	12
K59	Other functional intestinal disorders	66	5	0407020209	Enteroctomy and/or resection	128	11
L52	Erythema nodosum	27	2	0407020101	Colostomy	105	9
K56	Paralytic ileus and intestinal obstruction without hernia	3	0.2	0407020128	Dilatation of the anus and/or rectum	91	8
K51	Ulcerative colitis	2	0.1	0407020098	Abdominal colporrhaphy	51	5
C63	Malignant neoplasms of other and unspecified male genital organs	1	0.1	0407020241	Enterostomy closure	50	4
				0407020187	Enteroanastomy	41	4

Enterotomy is surgical incision into the intestine. ICs: intestinal complications; ICD: International Classification of Diseases.

The age variable was calculated based on the difference between the date of birth and the first conventional therapy claim reported (index date). The age was described as continuous variable, including the mean, standard deviation, median and quartiles. For the sex and race variables, they were described as categorical variables, with absolute frequencies and percentage.

Time of follow-up was calculated based on the difference between date of first claim of conventional therapy (index date) and the last date of patient information available at database. Conventional treatment profile of UC patients was evaluated and expressed by the percentage of patient who had at least one claim of UC therapy. Patients could change, add or stopped some of the conventional therapies (sulfasalazine, mesalazine, azathioprine, methotrexate and cyclosporine) during the treatment approach, therefore, the patient may have used one or more conventional therapies during the study period. Conventional treatment initiation was expressed as the number of patients (absolute and percentage) per calendar year (2011-2020) according to the first claim of the conventional therapy in the database. Timing using conventional therapy was calculated based on the first and the last claim of the therapy presented by the patient regardless of gaps. Switch conventional therapy was considered when it had at least one claim of different conventional therapy than the previous one. The time between one conventional therapy to another conventional therapy was described as continuous variable, including the mean, standard deviation, median and quartiles of the mean.

The main outcomes were regarding ICs in patients who initiated on conventional treatment between 2011 and 2020 in the SUS. Since each individual attended different amount of time in the database, some ICs parameters were analyzed as the frequency per person-years of follow-up. For incidence rate, confidence interval was estimated by Poisson rate confidence interval. The number of claims and the number of patients with at least one claim were expressed to address the total number of claim [patient could present more than one IC (claim) for the respective group of IC] and the total number of patients with at least one IC (claim).

Missing values were reported as missing information and imputation methods were not used. When needed, patient was censored for IC analyses. For Kaplan-Meier curve the last information available of the patient or the end of the study period was considered as censored for patients who did not present IC. IC was not assessed according to the conventional treatment received and neither if patient discontinued or not discontinued the conventional therapy treatment. Data was analyzed using Python version 3.6.9.

RESULTS

In the present study, a total of 41229 patients with UC meeting the inclusion criteria were exposed to conventional medications between 2011 to 2020 in DATASUS. Most patients were female (65%) and

were reported as white (56%). The mean ± SD age was 48 ± 15.42 years old, with a mean ± SD follow-up of 3.65 ± 2.27 years. Most patients (56%) were in the Southeast region of Brazil, followed by South (21%), and Northeast (14%) (Table 2).

All patients with UC had received conventional therapy and the mean ± SD time using each was 2.64 ± 2.29 years. Regarding the conventional treatment profile for patients with UC, mesalazine had the highest proportion (87%). Azathioprine was the second (16%) and sulfasalazine the third (15%) most frequent drugs among patients with UC. Methotrexate was reported only by 1% of the patients and cyclosporine by less than 1% (Table 2).

Table 3 shows the incidence rate of bowel complications in patients with UC exposed to conventional treatment. The overall IR was 2.55 (2.46-2.63) per 100 patients. The IR of associated diseases (ICD-10-related), procedures-related and UC hospitalizations were 0.93 (0.89-0.98), 0.76 (0.71-0.80) and 0.97 (0.92-1.02), respectively. Considering that one patient could present more than one IC, a total of 6711 bowel complications claims were reported over the study period in these patients (Table 3).

Regarding the annual IC (overall and segregated types) in patients with UC, during the study period (≤ 1 year and 5 years), the overall complications rates were 2.90% at one year and 2.36% at 5 years. Segregated by type, complications related to the associated diseases (ICD-10) were1.18% and 0.88%; the procedure-related complications were 0.71% and 0.68%; and the complications related to hospitalizations due to colitis was 1.10% and 0.84%, respectively (Table 4). The mean number of events per patient was also similar over the years for both the overall and the segregated IC types in patients with UC (Table 4). A description of the time to event for overall and segregated IC type in the population with UC is shown in Figure 1. In the Kaplan-Meier analysis, the probability to present any type of ICs (overall) was approximately 20% by the end of the study period. The segregated IC types had a comparable probability to present an event (less than 10% for procedures, hospitalization and associated disease) by the end of the study period (Figure 2).

From the 1273 patients with IC due to disease associated to UC found in the study, the categories Other diseases of the anus and rectum (78%), Colon malignant neoplasm (19%), Other functional intestinal disorders (5%) were the most common ones (Table 1).

Additionally, for the 1125 patients with IC due to procedures performed in consequence of the UC progression, it was found that abdominal rectosigmoidectomy (15%), body removed-rectal or colon polyps (13%) and partial colectomy (12%) were the most common ones (Table 1).

The length of hospitalization stay was 6.62 ± 6.62 d and the number of procedures performed during a hospitalization was 0.32 ± 0.28. The most common hospitalization procedure was the treatment of non-infectious enteritis and colitis (77%), followed by diagnosis and/or emergency care at a medical clinic (7%) and treatment of other intestinal diseases (4%) (Table 5).

DISCUSSION

The present study described some specific categories of ICs in patients with UC treated with conventional therapies available in the public health system in Brazil between January 2011 and January 2020. Women, who were reported as white and from the Southeast region were the patients with the highest proportions in this study. The mean time of use of conventional therapy was 2.64 years and mesalazine was the most conventional therapy used. The mean age of UC patients treated with conventional medication in SUS was 48.86 years. This finding is similar to another database study, which reported that the highest proportion of patients with UC was in the 45-54 age group[25].

UC is considered a global burden due to its high prevalence and incidence in developed countries. Lima Martins *et al*[26], in 2014, carried out a study in Brazil, presenting a UC incidence of 5.3/100000 inhabitants/year. In São Paulo, Brazil the incidence of UC was 8/100000 inhabitants per year in 2015 [27]. A study carried out in an underdeveloped region of Northeastern in Brazil found an incidence of UC of approximately 0.6/100000 inhabitants per year in 2012[28].

Demographic characteristics of patients with UC in DATASUS showed that the large proportion of patients were from the Southeast region and the minority from the North region of Brazil. Although these regions represent one of the highest and lowest densities in the country, respectively, the number of UC cases in each region may also be due to social differences and inequalities in access to health services found in the country, in line with previous Brazilian perspectives findings reported in the literature[29].

Several studies have shown that uncontrolled UC is associated with structural damage and impaired gastrointestinal functioning[30]. This population-based study in Brazil depicted the year-by-year proportion of patients with IC under conventional therapy in SUS. During the first year and the last 5 years of follow-up, about 2.90% and 2.36%, respectively, of the patients had one or more IC in consequence of the UC progression. The rate of IC also appeared not to be high, similarly found in another international study. Thus, the proportion of patients with some complication seems to be constant over time even under treatment. It is known that continuing conventional therapy in some cases may delay more effective therapy and place patients at risk for worsening disease and complications[31].

Table 3 Incidence of intestinal complications (overall and segregated types) in patients with ulcerative colitis considering all population at risk

	Total of events	First event[1] (*n*)	PY[2]	IR (95%CI)
Overall	6711	3616	141997.40	2.546 (2.464-2.628)
Associated disease (ICD-10-related)	3766	1372	146806.44	0.934 (0.885-0.983)
Procedure-related	1324	1125	148326.75	0.758 (0.714-0.802)
Colitis-related Hospitalization	1791	1426	147412.62	0.967 (0.917-1.017)

Incidence rate = *n* of patients with event/patient year × 100.
[1]Counted only the first intestinal complication (claim), but the patient could present with more than one IC (represented by the sum of the first claim).
[2]Patient year = sum of time of all patients under risk, since index date up to first IC or last available data.
ICs: Intestinal complications; IR: Incidence rate; ICD: International Classification of Diseases; PY: Patient year; UC: Ulcerative colitis.

Although the rates of ICs in the present study might be underestimated due to intrinsic limitation of the method applied, the impact of the progression of UC disease with consequent complication for the health system and patient might be significant, especially due to the severity and type of the complication generated for the patient. We found that almost 4% of the UC patients performed a surgery and/or procedure of anus or rectum during the study period. Surgical complications represent a substantial burden in terms of cost and quality of life, with reoperations, medical fees and additional hospital admissions being the main cost factors[13].

The associated diseases observed in the present study were mainly represented by other diseases of rectum and anus (78%) followed by the malignant neoplasm of colon (19%). Literature shows that UC patients with severe and persistent inflammation have an increased risk of developing neoplasm of colon[32]. In the United States, the prevalence of neoplasm of colon in a patient with UC was about 3.7% [33], in Spain was 11.7%[34]. It is well known that cancer is more likely to develop in patients with extensive colitis lasting 8-10 years or more[35]. In our investigation, the average follow-up period was only 3.65 years. Thus, it is possible that our results would be improved by a longer follow-up period.

Although no direct statistical comparison was performed, the incidence rates of ICs found in the present study indicate that ICs related to diseases associated to UC (ICD-10 code) were the highest, followed by those related to the procedure and finally hospitalization for UC. Only hospitalization related to ICD-10 of UC was considered in this study, which may imply underestimated rates. That is, if the patient was hospitalized due to the progression of the disease, other ICDs-10 codes were probably used and, therefore, was not counted in this study. Even though, we might assume that conventional therapy was not able to control the inflammatory process for all patients leading them to seek urgent and emergency services, or even been hospitalized and/or require surgeries procedures.

Conventional medical treatment for UC may have limited efficacy or serious adverse reactions[36]. Currently, 20% to 40% of patients with UC do not respond to conventional therapies and may receive secondary drug treatment or even colectomy. Anti-TNF agents were the first biologics to be used in the treatment of IBD, including infliximab and adalimumab. Other biologics therapies that target specific immune pathways has been implemented in several countries, including in Brazil, as potential therapeutics for UC[37,38]. In this line, Vedolizumab was recently approved by ANVISA for the treatment of adult patients with moderate to severe UC[39] who are not responding to one or more conventional treatments, such as steroids, immunosuppressive agents or TNF blockers[36]. However, during the study period, there was no biological therapy available in the SUS.

Table 4 Annual incidence of intestinal complications (overall and segregated type) in patients with ulcerative colitis over the study period (January 2011-February 2020)

	Overall				Associated disease (ICD-10–related)				Procedure-related				UC-related hospitalization

n of patients: Counted only the number of patients with intestinal complications (ICs) (first IC), but patients could present with more than one IC. *n* of claims: Counted the total number of claims. ICs: Intestinal complications; ICD: International Classification of Diseases; IR: Incidence rate; UC: Ulcerative colitis.

The treatments available in the SUS until 2020 involved the use of aminosalicylates (sulfasalazine and mesalazine), corticosteroids (hydrocortisone and prednisone), immunosuppressants (azathioprine, 6-mercaptopurine and (intravenous cyclosporine), and antibiotics[40]. Biological therapy was included in the national protocol of UC treatment in early 2020[40,41]. Before that period, patients who needed biological therapy had to find other strategies besides the SUS to get biologic therapies for UC treatment, such as out of pocket, private healthcare and/or even judicial action.

Limitations

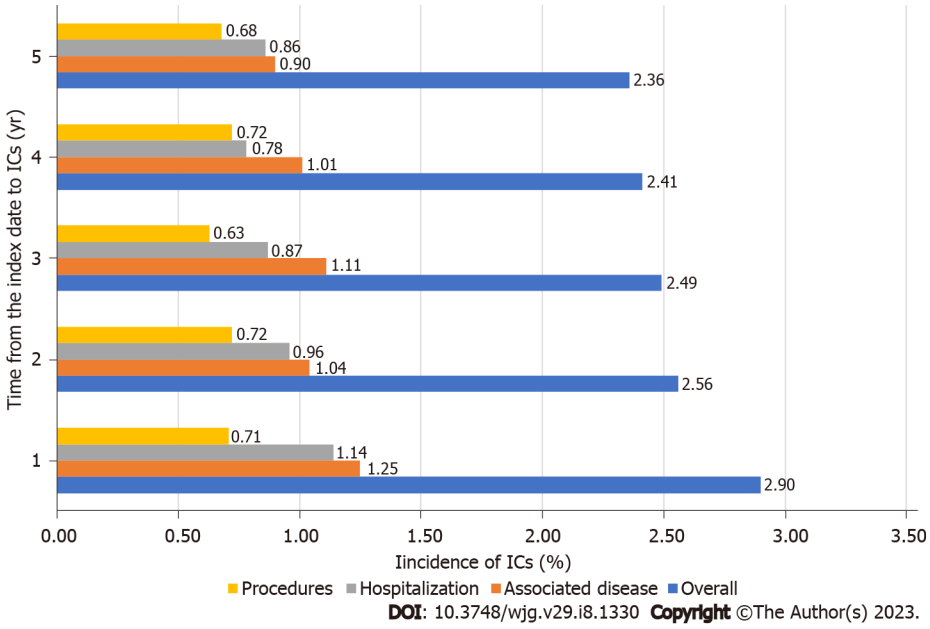
The main limitations of this study are related to the retrospective design of the study and the potential information biases and attrition of this study. With regard to information bias, the lack of information can lead to underestimation of results. Longitudinal and time-dependent analyzes of data correction are more accurate, however, DATASUS data end up being limited by this. Another limitation refers to the availability of medicines by the SUS, which are not always available and/or are available at different times during the period of this study, such as corticosteroids. Use of conventional therapy was an assumption based on the first claim of each drug at the database, so the patients could have not been under treatment during all the study period. However, as a real word study, this scenario reflects the daily life of UC patients. The severity of the disease was not considered in the analyses due to methodological limitations.

Additionally, for data analysis, the inpatient database (SIH) does not have patient identification and the use of probabilistic RLK, event rates may be underestimated, as they are mainly captured in outpatient databases (SIA). As it is a descriptive observational study, it is prone to confounding factors that are difficult to control or assess. In an attempt to reduce these biases, broad terms of procedures and ICD-10s related to possible complications were used. Although the ICD-10 codes used, procedures and hospitalization were predefined as ICs, other diseases and/or procedures related to UC could be codes could have been studied as ICs proxy, however, we were not able to predict all ICD-10.

Table 5 Length of hospitalization and most common procedures performed during hospitalization

Length of hospitalization and procedures	mean ± SD	Median (IQI)	Procedures (inpatient most common procedures[1])		Patients (*n* = 1426)	%
			ICs	Description of ICs		
Hospitalization (inpatient)			303070099	Treatment of enteritis and colitis not infectious	1103	77
Length of hospital stay, d (PPPY)	6.62 ± 6.62	4.60 (2.63-8.11)	301060088	Diagnose and/or emergence care in medical clinic	102	7
Number of procedures performed (PPPY)	0.32 ± 0.28	0.23 (0.15-0.38)	303070110	Treatment of other intestinal diseases	56	4
			301060070	Diagnosis and/or emergence care in surgery clinic	47	3
			415010012	Treatment with multiple surgeries	44	3
			415020034	Other procedures with following surgeries	30	2
			407020071	Total colectomy	29	2
			303070102	Treatment of digestive tract disease	23	2
			407020330	Total proctocolectomy	12	1
			303010061	Exploratory laparotomy	9	1

[1]Inpatient procedures reported with ulcerative colitis disease International Statistical Classification of Diseases and Related Health Problems codes.
ICs: Intestinal complications; ICD: International Classification of Diseases; IQI: Interquartile interval; PPPY: Per patient per year; UC: Ulcerative colitis.



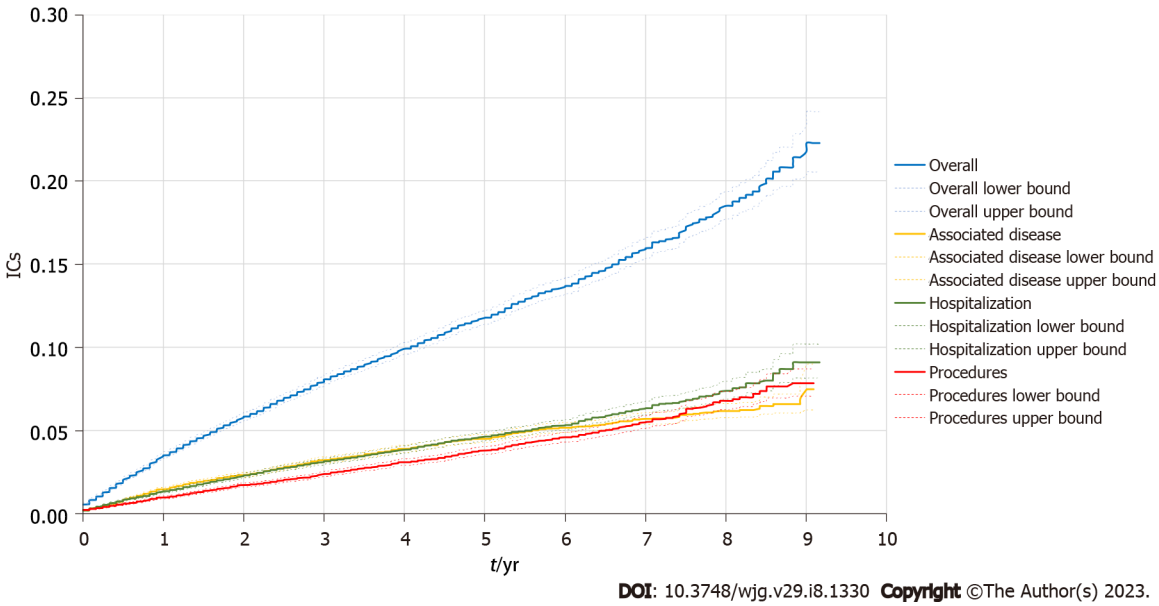


Figure 1 Annual intestinal complication (overall and segregated types) in ulcerative colitis patients over the study period (January 2011-February 2020). ICs: Intestinal complications.

CONCLUSION

UC have impact both for the population and public system (SUS) due to its clinical management and development of comorbidities and associated diseases. The results of this study highlight some issues regarding the progression of UC in patients who were treated with conventional therapies in the Brazilian public system showing that a percentage of UC patients have presented IC during the history of the disease. Most of the IC represent an important demand to the health system, with a need for health support and hospitalization. Current UC therapies, as well as innovative therapies that effectively alleviate UC symptoms, along with the implementation of an adequate program to access

Figure 2 Kaplan-Meier curve depicting time to intestinal complication in ulcerative colitis patients. ICs: Intestinal complications.

and manage therapy for patients with UC, may improve the control or progression of UC and consequently decrease the negative the impact of the disease.

ARTICLE HIGHLIGHTS

Research background

This was an observational, descriptive, and retrospective study from 2011 to 2020 from the Department of Informatics of the Brazilian Healthcare System database.

Research motivation

To understand the real world situation of patients with ulcerative colitis (UC) in the public healthcare system.

Research objectives

Describe the intestinal complications (IC) of patients with UC who started conventional therapies.

Research methods

Patients ≥ 18 years of age who had at least one claim related to UC International Statistical Classification of Diseases and Related Health Problems (ICD-10) code and at least 2 claims for conventional therapies were included. IC was defined as at least one claim of: UC-related hospitalization, procedures code for rectum or intestinal surgeries, and/or associated disease defined by ICD-10 codes.

Research results

In total, 41229 UC patients were included. Overall IR of IC was 3.2 cases per 100 PY. Among the IC claims, 54% were related to associated diseases, 20% to procedures and 26% to hospitalizations. The overall annual incidence of IC was 2.9%, 2.6% and 2.5% in the first, second and third year after the first claim for therapy (index date), respectively. Over the first 3 years, the annual IR of UC-related hospitalizations ranged from 0.8% to 1.1%; associated diseases from 0.9% to 1.2%.

Research conclusions

Study shows that UC patients under conventional therapy seem to present progression of disease developing some IC, which may have a negative impact on patients and the burden on the health system.

Research perspectives

Biologics were implemented in the public healthcare system after the study period, it would be interesting to verify the IC impact of this implementation in patients with UC.

FOOTNOTES

Author contributions: Martins AL, Galhardi Gasparini R, Sassaki LY, Saad-Hossne R, Barreto TB, Marcolino T and Yang Santos C participated in designed, interpretation of the data and revised the article critically for important intellectual content; Ritter AMV participated in the acquisition, analysis and draft the initial manuscript.

Institutional review board statement: In alignment with Brazilian ethical resolution number 510, 2016, ethical approval was not necessary since this is a secondary study using anonymized data.

Conflict-of-interest statement: Martins AL served on the advisory board of Takeda, AbbVie, Janssen, Pfizer and Amgen and is a speaker for Amgen and Janssen. Galhardi Gasparini R is a speaker for Janssen, Takeda and AbbVie. Sassaki LY is a speaker for Janssen and Takeda and participated in the advisory boards of Takeda and AbbVie. Saad-Hossne R is a speaker and on the advisory boards for AbbVie, Takeda, Janssen, Pfizer, Fresenius and Amgen, as well as a speaker for Novartis. AMVR is an employee of IQVIA Brazil. Marcolino T, Barreto TB and Yang Santos C are employees of Takeda Pharmaceutical Brazil.

Data sharing statement: No additional data are available.

STROBE statement: The authors have read the STROBE statement, and the manuscript was prepared and revised according to the STROBE statement.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. Abstract

BACKGROUND

Cervical cancer is one of the most common gynecological malignant tumors. Radiation enteritis (RE) leads to radiotherapy intolerance or termination of radiotherapy, which negatively impacts the therapeutic effect and seriously affects the quality of life of patients. If the incidence of RE in patients can be predicted in advance, and targeted clinical preventive treatment can be carried out, the side effects of radiotherapy in cervical cancer patients can be significantly reduced. Furthermore, accurate prediction of RE is essential for the selection of individualized radiation dose and the optimization of the radiotherapy plan.

AIM

To analyze the relationships between severe acute RE (SARE) of cervical cancer radiotherapy and clinical factors and dose-volume parameters retrospectively.

METHODS

We included 50 cervical cancer patients who received volumetric modulated arc therapy (VMAT) from September 2017 to June 2018 in the Department of Radiotherapy at The First Affiliated Hospital Soochow University. Clinical and dose-volume histogram factors of patients were collected. Logistic regression analysis was used to evaluate the predictive value of each factor for SARE. A nomogram to predict SARE was developed (SARE scoring system ≥ 3 points) based on the multiple regression coefficients; validity was verified by an internal verification method.

RESULTS

Gastrointestinal and hematological toxicity of cervical cancer VMAT gradually increased with radiotherapy and reached the peak at the end of radiotherapy. The main adverse reactions were diarrhea, abdominal pain, colitis, anal swelling, and blood in the stool. There was no significant difference in the incidence of gastrointestinal toxicity between the radical and postoperative adjuvant radiotherapy groups ($P > 0.05$). There were significant differences in the small intestine V_{20}, V_{30}, V_{40}, and rectal V_{40} between adjuvant radiotherapy and radical radiotherapy after surgery ($P < 0.05$). Univariate and multivariate analyses revealed anal bulge rating (OR: 14.779, 95%CI: 1.281-170.547, $P = 0.031$) and disease activity index (DAI) score (OR: 53.928, 95%CI: 3.822-760.948, $P = 0.003$) as independent predictors of SARE.

CONCLUSION

Anal bulge rating (> 0.500 grade) and DAI score (> 2.165 points) can predict SARE. The nomogram shows potential value in clinical practice.

Core Tip: Radiation enteritis (RE) not only seriously affects the quality of life of patients, but it also leads to radiotherapy intolerance or termination of radiotherapy. The aim of our study was to determine the cumulative incidence of acute RE associated with cervical cancer radiotherapy in patients with RE in organs at risk and changes in dose-volume histogram indices. The nomogram of severe acute RE (SARE) was further developed according to the clinical factors, cumulative incidence of SARE and dosimetric parameters of volumetric modulated arc therapy patients, which may be useful for individualized risk assessment and accurate prediction of SARE to guide clinical treatment strategies.

INTRODUCTION

Cervical cancer is one of the most common gynecological malignant tumors, ranking fourth among malignant tumors in females worldwide[1]. Radiotherapy plays an important role in the postoperative adjuvant treatment of cervical cancer patients and the radical treatment of patients who are ineligible for surgery. Radiation enteritis (RE) is a common and potentially dose-limiting toxic reaction of pelvic radiotherapy. The clinical manifestations include nausea, vomiting, abdominal pain, bloody stool, mucous stool, diarrhea, tenesmus, and urinary incontinence. RE not only seriously affects the quality of life of patients, but it also leads to radiotherapy intolerance or termination of radiotherapy, which negatively impacts the therapeutic effect. If the incidence of RE in patients can be predicted in advance, and targeted clinical preventive treatment can be carried out, the side effects of radiotherapy in cervical cancer patients can be significantly reduced. Furthermore, accurate prediction of RE is essential for the selection of individualized radiation dose and the optimization of the radiotherapy plan.

Many studies have shown that the occurrence and development of RE are related to intestinal radiotherapy technology, total dose, total volume, fraction dose, ratio of dose to volume, and uniformity of radiation dose distribution[2-6]. RE is also influenced by factors such as inflammatory bowel disease [7], collagen vascular disease[8], history of abdominal and pelvic surgery[9], history of pelvic inflammatory disease, diabetes mellitus[10], and acquired immunodeficiency syndrome[11]. However, there is no consensus on the relative importance of these predictors. Only a few studies have explored the dosimetric risk factors for RE in cervical cancer patients[12]. How to predict RE and reduce adverse reactions is the core issue of clinical radiotherapy for cervical cancer. Notably, a single predictor has limited predictive power and cases can show substantial differences in heterogeneity of RE; these issues should be addressed in further research[13]. To specifically and accurately identify RE, there is an urgent need for an accurate predictive model that combines multiple factors.

The initial objective of this study was to determine the cumulative incidence of acute RE associated with intensity modulated radiation therapy (IMRT) for cervical cancer in patients with RE in organs at risk (OAR) and changes in dose-volume histogram indices. The severe acute RE scoring system (SARE-

SS) was defined by integrating clinical factors and dosimetric physical parameters. Finally, the nomogram of severe acute RE (SARE) was further developed according to the clinical factors, cumulative incidence of SARE and dosimetric parameters of volumetric modulated arc therapy (VMAT) patients. This nomogram may be useful for individualized risk assessment and accurate prediction of SARE to guide clinical treatment strategies.

MATERIALS AND METHODS

Patient selection

Fifty patients with cervical cancer who received pelvic local radiotherapy in the Department of Radiation Oncology of The First Affiliated Hospital of Soochow University from August 2017 to August 2018 were selected. The inclusion criteria were as follows: (1) 18-80 years old; (2) cervical cancer confirmed by pathology; (3) no history of intestinal diseases or metabolic diseases; and (4) good understanding and communication skills. The exclusion criteria were as follows: (1) Severe heart, liver and kidney dysfunction; (2) termination of treatment because of serious complications during and after radiotherapy (such as cardiopulmonary, hepatic and renal insufficiency, severe infection, severe bone marrow suppression, massive hemorrhage, vaginorectal fistula and vaginovesical fistula); and (3) refusal to participate in the study.

This study was approved by the ethics committee of The First Affiliated Hospital of Soochow University Medical Ethics Committee [approval No. 2016(100)]. All enrolled patients provided signed informed consent.

External irradiation method for cervical cancer

Radiotherapy simulation positioning: On the night before radiotherapy, all patients took laxatives to clean the intestinal track. One hour before positioning, the bladder was emptied and patients drank 800 mL of water to fill the bladder. The patients then took the supine position. A Philips [Brilliance computed tomography (CT) Big Bore] large aperture CT machine was used for simulated CT localization, and enhanced CT scanning was performed with a slice thickness of 5 mm. The scanning range was from the upper edge of T11 vertebral body to 5 cm below the ischial tuberosity. The CT localization images were transferred to the treatment planning system (V5.1.1, Elekta, Monaco, Sweden).

Radiotherapy target delineation: Magnetic resonance imaging (MRI), CT or positron emission tomography-CT (PET-CT) examinations were routinely performed during the pre-radiotherapy evaluation. The target volume and OAR were delineated according to the standards of Radiation Therapy Oncology Group and Japan Clinical Oncology Group.

Radiotherapy plan design: The Monaco treatment planning system was used to design the 7-field reverse dynamic VMAT plan using unified parameters. The X-ray beam energy was 6 MV. At least 95% of the pelvic lymphatic drainage (PTV) is required to reach the prescribed dose, and no hot spot of ≥ 110% dose can occur outside the PTV. The OAR dose limit was uniform (OAR dose limitation: Bladder $V_{40} < 0\%$, rectum $V_{40} < 40\%$, colon $V_{40} < 30\%$, small intestine $V_{40} < 20\%$, femoral head $V_{45} < 5\%$).

Prescription dose of the VMAT target volume after operation: We administered 45 Gy/25 fractions for moderate risk included lymph node metastasis, paracytal invasion, and positive margin) PTV1 and 50 Gy/25 fractions for high risk PTV1 50. 4 Gy/28 fractions, the prescription dose of the remaining target volume can be executed according to the radical external irradiation scheme.

Prescription dose of the radical VMAT target volume: We administered the following doses: PTV1 45 Gy/25 fractions, parametrial area (PTV2) 50 Gy/25 fractions, and positive lymph nodes (PGTVnd) 56 Gy/28 fractions. In cases with para-aortic area, the dose for the para-aortic lymphatic drainage area (PTV3) was 36-40 Gy/20 fractions.

Implementation of the VMAT plan: VMAT was performed using the Elekta Synergy linear accelerator. All patients were treated five times a week, with one treatment a day. Cone-beam CT (Elekta) image-guided VMAT was performed at least once a week, and the error of each treatment was kept within 3 mm.

Chemotherapy for cervical cancer

Of the 50 cervical cancer patients included in this study, 18 were treated with concurrent chemoradiotherapy (CCRT) and 32 received sequential chemoradiotherapy (SCRT). All doses and adjustments of the chemotherapy regimen followed the NCCN guidelines[14].

End point definitions

General data collection: Data on age, weight, height, body mass index (BMI)[15], age-adjusted Charlson Comorbidity Index (aCCI), pathological data, HPV, squamous cell carcinoma antigen, risk rating, FIGO

2018 staging information, surgery, radiotherapy and chemotherapy were collected.

Data collection of acute RE: The adverse reactions of all patients were monitored at baseline and 2 wk, 4 wk, and 6 wk after the start of radiotherapy. Adverse reactions included diarrhea, abdominal pain, colitis, anal distension, hematochezia and bone marrow suppression. The diagnosis and classification of RE were determined following the National Institutes of Health Common Adverse Events Evaluation Criteria (CTCAE 5.0).

We established the SARE-SS to reflect the adverse reaction score as follows: SARE-SS = the sum of CTCAE scores of diarrhea + abdominal pain + colitis + anal bulging + hematochezia. A score of ≥ 3 indicated the presence of SARE. The diagnosis of SARE was determined by at least two experienced radiation oncologists on the basis of clinical symptoms and changes in the results of ancillary tests.

Disease activity index determination: The disease activity index (DAI) is based on scores that reflect the weight loss of patients (weight unchanged is 0, 1%-5% is 1 point, 5%-10% is 2 points, 10%-15% is 3 points, more than 15% is 4 points), stool viscosity (normal is 0 points, loose stool is 2 points, diarrhea is 4 points) and stool bleeding (normal is 0 points, occult blood positive is 2 points, dominant bleeding 4 points). The sum of the three scores is divided by 3 to obtain the final DAI score.

Radiotherapy planning parameter collection: Statistics of different OAR dose-volume relationship (percentage of PTV volume receiving prescription dose), recorded as V_x.

Statistical analysis

Statistical analysis was performed using SPSS 20.0. The quantitative data of normal distribution were expressed as (mean ± SD), and *t* test was used for comparisons between groups. The data of skew distribution were tested by Mann-Whitney *U* test. Qualitative data were expressed as number of cases and percentage; Fisher's exact probability method or χ^2 test was used to compare unordered categorical data, and Mantel-Haenszel χ^2 and Mann-Whitney *U* test were used to compare ordered categorical data. $P < 0.05$ was considered to indicate statistical significance. Receiver operating characteristic curve (ROC curve) was used to analyze the specificity and sensitivity of OAR dose-volume parameters in predicting RE. Two-factor repeated-measures ANOVA was used to analyze the relationship between DAI scores and time in different groups, and one-way ANOVA was used to compare the differences of DAI scores among four time points in each group.

To establish the prediction model, univariate logistic regression model was used to evaluate the predictive ability of each factor for SARE. Multivariate analysis was performed for significant factors from the univariate analysis. Kendall correlation analysis was used to avoid multicollinearity between factors. Factors with significant predictive value in the multivariate analysis were used to construct a nomogram. The area under the ROC curve (AUC), calibration curve and decision curve analysis (DCA) were used for nomogram validation. Data analysis was performed using R software (software version 4.0.2, R package version rmda 1.6).

RESULTS

Clinical characteristics of patients

This study included 50 patients with cervical cancer. Among the 50 patients, 14 patients received radical radiotherapy, 35 patients received postoperative adjuvant pelvic radiotherapy and 1 patient received pelvic radiotherapy combined with after loading vaginal radiotherapy because the vaginal margin was 2 cm away from the tumor boundary. The specific clinical factors are detailed in Table 1. The mean age of the postoperative adjuvant radiotherapy group was significantly lower than that of radical radiotherapy group ($P < 0.05$) (Table 2). The BMI of the postoperative adjuvant radiotherapy group was also significantly lower ($P < 0.05$), but there was no significant difference in weight, pathological type, cumulative incidence of RE and SARE and irradiation of para-aortic extension field between the two groups ($P > 0.05$).

Dose-volume comparison of OAR in the VMAT plan between the postoperative adjuvant radiotherapy group and radical radiotherapy group

Patients in the radical radiotherapy group were treated with total pelvic and parauterine local radiotherapy, and patients in the postoperative adjuvant radiotherapy group were treated with total pelvic prophylactic radiotherapy. The dose and volume of small intestine in the radical radiotherapy group were significantly reduced compared with that in the postoperative adjuvant radiotherapy group, and the decrease of V_{20}, V_{30} and V_{40} were statistically significant ($P < 0.05$) (Table 3). Rectal V_{30}, V_{35}, and V_{40} in the radical radiotherapy group were significantly higher than those in the postoperative adjuvant radiotherapy group. The increase of V_{40} was statistically significant ($P < 0.05$). There was no significant difference in the dose-volume relationship of colon, bladder and femoral head between the two groups ($P > 0.05$).

Comparison of the cumulative incidence of VMAT-related acute RE in cervical cancer between the postoperative adjuvant radiotherapy group and the radical radiotherapy group

The main radiotherapy-related adverse reactions included diarrhea, abdominal pain, colitis, anal distension, hematochezia and bone marrow suppression. All adverse reactions were grade 1 to 3; no adverse reactions above grade 3 occurred. RE was monitored as follows (Table 4). There was no significant difference in the incidences of adverse reaction between the radical radiotherapy group and postoperative adjuvant radiotherapy group ($P > 0.05$).

Evaluation of the specificity and sensitivity of OAR dose-volume parameters in the IMRT plan for predicting acute/SARE

ROC curve was used to analyze the specificity and sensitivity of small intestine V_{20}, V_{30}, V_{40} and rectum

Table 3 Organs at risk dose-volume comparison between adjuvant radiotherapy (*n* = 36) and radical radiotherapy (*n* = 14) after cervical cancer surgery (%)

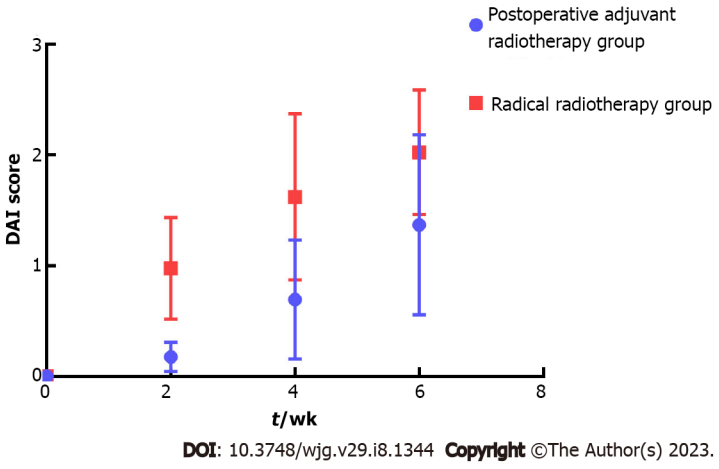
	P value	0.342	0.353	0.320	0.353	0.326

OAR: Organs at risk.

V_{40} in predicting acute/SARE. The AUC was less than 0.60 and $P > 0.05$. These results suggest that a single OAR dose-volume parameter is not enough to predict the occurrence of acute/SARE.

DAI score changes

The DAI scores of the radical radiotherapy group were higher than those of the postoperative adjuvant radiotherapy group at the second week, fourth week and the end of radiotherapy (Figure 1). There was an interaction effect between different groups and time ($\chi^2 = 77.238$, $P < 0.01$). The DAI scores of the two groups showed an increasing trend over time ($P < 0.05$), and the DAI scores of the radical radiotherapy group increased the most.



Establishment of the SARE prediction model

Univariate analysis showed that abdominal pain, colitis, anal bulging, hematochezia, DAI score, age, and CCRT were significantly correlated with the occurrence of severe acute RE (all $P < 0.05$) (Table 5). Kendall analysis showed a relatively strong correlation between abdominal pain, hematochezia and DAI score ($R = 0.715$, 0.622, $P < 0.001$); the correlation between other factors was very weak (Figure 2A). To avoid multicollinearity, abdominal pain, hematochezia, and DAI scores were included in the multivariate analysis. Multivariate logistic regression analysis was conducted to analyze the factors of colitis, anal bulge, DAI score and age. In multivariate analysis, anal bulge rating (OR: 14.779, 95%CI: 1.281-170.547, $P = 0.031$) and DAI score (OR: 53.928, 95%CI: 3.822-760.948, $P = 0.003$) were independent predictors of SARE (Table 6). These factors were used to construct the nomogram. The constant in the logistic regression equation was -10.039, and the logistic regression equation was Logit (P) = 3.988 × DAI + 2.693 × anal bulge rating -10.039.

Table 4 Comparison of the incidence of acute radiation enteritis in patients with cervical cancer treated with adjuvant radiotherapy (*n* = 36) and radical radiotherapy (*n* = 14), *n* (%)

Figure 1 Disease activity index score during volumetric modulated arc therapy in 50 patients with cervical cancer.

Development and validation of the nomogram

Based on the multivariate logistic regression coefficients, the prediction model was visually represented as a nomogram (Figure 2B). The ROC curves for the anal bulge rating, DAI score and nomogram are shown in Figure 2C. ROC analysis showed that the AUC of the prediction model was 0.950 (95%CI: 0.891-1.000), which was much higher than that of each parameter alone (anal bulge rating: 0.805, 95%CI: 0.651-0.959; DAI score: 0.892, 95%CI: 0.873-1.000). The MAL thresholds for anal bulge rating and DAI score were 0.5 and 2.165 points. The nomogram had a high predictive efficiency (sensitivity: 80.0%, specificity: 91.4%). In addition, the calibration curve showed good agreement between the predicted severe acute RE and the actual observations (Figure 2D). In most threshold probabilities, DCA showed a positive net benefit with a satisfactory nomogram, indicating a good potential clinical effect of the model (Figure 2E).

DISCUSSION

Nearly 80% of patients receiving pelvic radiotherapy for cervical cancer have early acute toxicity and 20% have late toxicity[16]. Acute RE often occurs in the second week after the start of radiotherapy and reaches a peak in the fourth to fifth week. The clinical manifestations are nausea, vomiting, abdominal pain, bloody stool, mucous stool, diarrhea, tenesmus, and incontinence. In gynecological tumor radiotherapy, the clinical application of IMRT shows an increasing trend. This radiotherapy technology can not only obtain satisfactory target coverage dose, but also effectively reduces the radiation dose of OAR[17,18], such as V45 of rectum and small intestine[19,20], and reduces the toxic reaction of bone marrow[21,22]. Although the incidence and severity of RE have decreased under the current radiotherapy technology, these issues cannot be ignored. In addition, mild RE is often underestimated or ignored due to the lack of clinical records and inadequate assessment of toxicity[23].

In this study, we preliminarily demonstrated the close relationship between the anal bulge rating and the DAI score and SARE. More importantly, this study is the first to develop and validate an easy-to-understand visual nomogram prediction model for cervical cancer radiotherapy patients and doctors, providing more personalized and accurate SARE prediction for cervical cancer patients undergoing radiotherapy. Many studies have reported that the most important factor affecting radiation proctitis is the total dose received by the rectum, and it is also affected by the radiotherapy technique, fraction dose, total dose received by the rectum/total volume, dose volume ratio of rectum to radiation dose,

Figure 2 Development and validation of the nomogram. A: Kendall's rank correlation analyses among factors with $P < 0.05$ in univariate logistic regression; B: Nomogram predicting the occurrence of severe acute radiation enteritis (SARE). For each individual patient, two lines are drawn upward to determine the points received from the two variables in the nomogram; the sum of these points is located on the "Total Points" line, and a line is drawn downward to determine the likelihood of this patient to have SARE; C: Receiver operating characteristic curves of anal bulge rating. Disease activity index score *vs* the predictive model; D: Calibration curves of the nomogram predicting the occurrence of SARE. The x-axis and y-axis indicate the predicted and actual probabilities of having SARE, respectively; E: Decision curves of the nomogram predicting the occurrence of SARE. The x-axis shows the threshold probabilities. The y-axis measures the net benefit, which was calculated by adding the true positives and subtracting the false positives. NOMO: Nodal modulator; AUC: Area under the receiver operating characteristic curve; DAI: Disease activity index.

and uniformity of radiation dose distribution[4-6]. According to Seppenwoolde *et al*[24], rectal V40 ≥ 80% is a physical dose factor predicting VMAT-related rectal incontinence and diarrhea in patients with locally advanced cervical cancer. Ballari *et al*[25] suggested that small bowel V45 has predictive value for acute RE. In addition, individual factors such as IBD, collagen vascular disease, history of abdominal and pelvic surgery, history of pelvic inflammatory disease, diabetes mellitus, and acquired immunodeficiency syndrome affect the determination of radiation dose and volume[7-11]. In patients with cervical cancer, CCRT exerts radiosensitization and increases gastrointestinal toxicity by a factor of 3[18]. However, there is currently no consensus on the relative importance of these relevant predictors. In our study, the dose-volume of the small intestine receiving 20-40 Gy in the radical radiotherapy group of cervical cancer was significantly reduced compared with that in the postoperative adjuvant radiotherapy group, and the reduction of V_{20}, V_{30}, and V_{40} was statistically significant ($P < 0.05$), which was considered to be related to the anatomical displacement of organs after hysterectomy. After the removal of the tumor bed and uterus, part of the intestinal loop falls into the pelvic cavity[9], resulting in increased secondary toxicity of radiotherapy. In addition, the rectal V_{30}, V_{35}, and V_{40} in the radical radiotherapy group were significantly higher than those in the postoperative adjuvant radiotherapy group, and the increase of V_{40} was statistically significant ($P < 0.05$). The cervical cancer patients treated with radical radiotherapy in this study were FIGO IIB-IVA. CT or MRI showed obvious parametrial infiltration, and mesorectal invasion occurred in some patients, resulting in a relative increase in the volume of PTV to the left, right and dorsal side. Although we found dose-volume differences in the small intestine and rectum between groups, we were unable to demonstrate that a single physical parameter independently predicted RE or SARE. Therefore, more prospective, well-designed randomized controlled trials with larger sample sizes are needed for validation.

Acute RE is self-limited, and not all acute RE will be classified as chronic RE. The prevalence of chronic RE after 10 years of radiotherapy is 10%-20%[26]. In terms of pathogenesis, inflammation and cell death occur in the intestinal mucosa during the acute phase of RE, and sustained cytokine activation

in the submucosa leads to progressive ischemia, fibrosis, and stem cell loss[27]. In contrast, chronic RE is associated with progressive endarteritis obliterans, secondary to capillary fibrosis, leading to chronic ischemia and fibrosis of the affected bowel segments[28]. The outcome of chronic RE often induces intestinal obstruction, which is similar to the Koenig syndrome observed in Crohn's disease and is considered to be related to ileal stenosis. In view of the similarities between RE and IBD, we innovatively adopted the IBD evaluation index-DAI score. Univariate and multivariate logistic regression analysis confirmed that DAI score was independent of other physical parameters and clinical factors and could be used as a new predictor of SARE. In univariate analysis, abdominal pain, colitis, anal distension, hematochezia, DAI score, age, and CCRT were statistically correlated with the occurrence of severe acute RE ($P < 0.05$). Kendall analysis showed a relatively strong correlation between abdominal pain, hematochezia, and DAI scores. Therefore, DAI score is a convenient, non-invasive and highly beneficial diagnostic system for SARE.

The clinical manifestations of SARE are complex, and it is difficult for doctors, even with extensive clinical experience, to predict and diagnose the disease early, comprehensively and accurately. If cervical cancer can be identified and treated early before, during or after radiotherapy, the toxic and side effects of pelvic radiotherapy may be improved, and the probability of radiotherapy intolerance or even termination of radiotherapy may be reduced. The multi-factor prediction model is helpful to further improve the prediction of RE. Several prediction models have been described in previous studies, but they are still not used in clinic due to the low recognition ability of RE and the neglect of heterogeneity among different patients[29,30]. In this study, we established a SARE-SS evaluation system and found that anal bulge rating and DAI score were independent predictors of SARE through multivariate statistical analysis. The above predictors were further integrated into the nomogram to allow precise individualized SARE risk assessment for each patient. The AUC of the predictive model was 0.950, which was much higher than the two independent factors of DAI score and anal bulge score. The MAL thresholds for anal bulge rating and DAI score were 0.5 grade and 2.165 points, respectively, indicating an advantage over previous models in predicting RE. We adopted the Bootstrap validation method (including drawing the calibration curve and DCA curve), which showed a statistical advantage in a relatively small sample size statistic[31,32]. In later studies, we will expand the sample size, carry out prospective cohort studies, and use external validation methods to reduce data selection bias and increase test power.

Although our study has many advantages, there are still several limitations to be addressed. First, our sample size is small, so a large cohort is needed to further develop and validate the nomogram for predicting RE. Second, since this was a retrospective study, our study may have had a selection bias. Third, we only integrated the most important and commonly used parameters in clinic. From the perspective of precision medicine, we need to combine biological factors in the future including individual genomics, proteomics, metabolomics, microbiomics, real-time dosimetry and a wider range of clinical parameters to establish a comprehensive prediction model to improve the accuracy of RE prediction. Therefore, we will add biological factors to the analysis of related studies in later studies and need to establish a more comprehensive and specific prediction model of RE.

CONCLUSION

Our findings showed that during VMAT for cervical cancer, gastrointestinal and hematological system toxicity gradually increased with radiotherapy treatment and reached the peak at the end of radiotherapy. The main adverse reactions were diarrhea, abdominal pain, colitis, anal bulging and hematochezia. There were significant differences in V_{20}, V_{30}, V_{40} of small intestine and V_{40} of rectum between postoperative adjuvant radiotherapy and radical radiotherapy, which may be related to intestinal anatomical displacement caused by surgery and primary disease. However, there were no significant differences in the cumulative incidence of adverse reactions between the two groups. Anal bulge rating (> 0.500) and DAI score (> 2.165) were identified as independent predictors of SARE by multivariate analysis. The validity of our established nomogram was verified by the internal verification method. Although further external validation is needed, our results indicate that the nomogram has clinical value for the prediction and evaluation of SARE.

ARTICLE HIGHLIGHTS

Research background

Radiation enteritis (RE) not only seriously affects the quality of life of patients, but it also leads to radiotherapy intolerance or termination of radiotherapy. However, data on the clinical efficacy and side effects of volumetric modulated arc therapy (VMAT) for cervical cancer are limited.

Research motivation

If the incidence of RE in patients can be predicted in advance, and targeted clinical preventive treatment can be carried out, the side effects of radiotherapy in cervical cancer patients can be significantly reduced. Furthermore, accurate prediction of RE is essential for the selection of individualized radiation dose and the optimization of the radiotherapy plan.

Research objectives

To analyze the relationships between severe acute RE (SARE) of cervical cancer radiotherapy and clinical factors and dose-volume parameters retrospectively.

Research methods

We included 50 cervical cancer patients who received VMAT from September 2017 to June 2018 in the Department of Radiotherapy at The First Affiliated Hospital Soochow University. Clinical and dose-volume histogram factors of patients were collected. Logistic regression analysis was used to evaluate the predictive value of each factor for SARE. A nomogram to predict SARE was developed (SARE scoring system ≥ 3 points) based on the multiple regression coefficients; validity was verified by an internal verification method.

Research results

Gastrointestinal and hematological toxicity of cervical cancer VMAT gradually increased with radiotherapy and reached the peak at the end of radiotherapy. The main adverse reactions were diarrhea, abdominal pain, colitis, anal swelling, and blood in the stool. There was no significant difference in the incidence of gastrointestinal toxicity between the radical and postoperative adjuvant radiotherapy groups ($P > 0.05$). There were significant differences in the small intestine V20, V30, V40, and rectal V40 between adjuvant radiotherapy and radical radiotherapy after surgery ($P < 0.05$). Univariate and multivariate analysis revealed anal bulge rating (OR: 14.779, 95%CI: 1.281-170.547, $P = 0.031$) and disease activity index (DAI) score (OR: 53.928, 95%CI: 3.822-760.948, $P = 0.003$) as independent predictors of SARE.

Research conclusions

Anal bulge rating (> 0.500 grade) and DAI score (> 2.165 points) can predict SARE. The nomogram shows potential value in clinical practice.

Research perspectives

From the perspective of precision medicine, it will also be necessary to combine biological factors, such as individual genomics, proteomics, metabolomics, microbiomics, real-time dosimetry, and a wider range of clinical parameters to establish comprehensive predictive models. This study is a prospective study with a small sample size. In the later stage, we will expand the sample size, conduct prospective cohort studies, and use external validation methods to reduce data selection bias and increase test efficiency.

Abstract

BACKGROUND

Serum protein induced by vitamin K absence or antagonist-II (PIVKA-II) is a promising biomarker for hepatocellular carcinoma (HCC) surveillance.

AIM

To identify the contributing factors related to the abnormal elevation of PIVKA-II level and assess their potential influence on the performance of PIVKA-II in detecting HCC.

METHODS

This study retrospectively enrolled in 784 chronic liver disease (CLD) patients and 267 HCC patients in Mengchao Hepatobiliary Hospital of Fujian Medical University from April 2016 to December 2019. Logistic regression and the area

under the receiver operating characteristic curve (AUC) were used to evaluate the influencing factors and diagnostic performance of PIVKA-II for HCC, respectively.

RESULTS

Elevated PIVKA-II levels were independently positively associated with alcohol-related liver disease, serum alkaline phosphatase (ALP), and total bilirubin (TBIL) for CLD patients and aspartate aminotransferase (AST) and tumor size for HCC patients (all $P < 0.05$). Serum PIVKA-II were significantly lower in patients with viral etiology, ALP ≤ 1 × upper limit of normal (ULN), TBIL ≤ 1 × ULN, and AST ≤ 1 × ULN than in those with nonviral disease and abnormal ALP, TBIL, or AST (all $P < 0.05$), but the differences disappeared in patients with early-stage HCC. For patients with TBIL ≤ 1 × ULN, the AUC of PIVKA-II was significantly higher compared to that in patients with TBIL > 1 × ULN (0.817 *vs* 0.669, $P = 0.015$), while the difference between ALP ≤ 1 × ULN and ALP > 1 × ULN was not statistically significant (0.783 *vs* 0.729, $P = 0.398$). These trends were then more prominently perceived in subgroups of patients with viral etiology and HBV alone.

CONCLUSION

Serum PIVKA-II has better performance in detecting HCC at an early stage for CLD patients with normal serum TBIL.

Key Words: Protein induced by vitamin K absence or antagonist-II; Chronic liver disease; Total bilirubin; Hepatocellular carcinoma; Diagnosis; Hepatitis B virus

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This study demonstrated that elevated serum protein induced by vitamin K absence or antagonist-II (PIVKA-II) were positively associated with serum total bilirubin (TBIL) in patients with chronic liver disease (CLD), and the levels of PIVKA-II in CLD patients with normal serum TBIL were significantly lower than those in CLD patients with abnormal serum TBIL. Serum PIVKA-II has better performance in detecting hepatocellular carcinoma (HCC) at an early stage for CLD patients with normal serum TBIL, which was more prominently perceived in patients with viral etiology and hepatitis B virus alone. These findings may be important for surveillance counseling of early-stage HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC), a serious issue for global health, is still the sixth most prevalently diagnosed cancer and the third highest cause of cancer death worldwide[1,2]. Chronic liver disease (CLD) induced by viral and nonviral factors has been identified as the main cause of HCC, including chronic infection with hepatitis B virus (HBV) or hepatitis C virus (HCV), alcohol-related liver disease (ALD), nonalcoholic fatty liver disease (NAFLD), autoimmune liver disease (AILD), and so on, with the major risk factors varying from region to region[1-3].

In recent years, although great progress has been achieved on cancer treatment with the development by surgical resection, molecular targeted therapy, and immunotherapy[2,4-6], 5-year survival rate of HCC remains not satisfactory, with only 15%-17% as reported[7,8]. The main cause of this extremely poor prognosis is that more than half of HCC patients present with advanced stages once at diagnosis[7,8]. Detecting HCC at an early stage is an efficacious way for the improvement of long term survival of HCC patients[2,9,10].

Serum HCC biomarkers as surveillance tools remain controversial because the diagnostic accuracy of the traditional biomarker for HCC, serum alpha-fetoprotein (AFP), is unsatisfactory[8,11,12]. Serum AFP is frequently influenced by many noncancerous factors and is falsely raised in non-HCC patients who have active chronic viral and advanced liver disease[13-15]. Hence, protein induced by vitamin K absence or antagonist-II (PIVKA-II), has gained increasing attention in recent years since it was first

reported for the diagnosis of HCC in 1984[2,8,9,16]. PIVKA-II is poorly related to AFP, and the diagnostic performance of HCC by combining the two biomarkers was higher compared to AFP alone[8, 17]. In addition, the guidelines of the Japan Society of Hepatology has recommended serum PIVKA-II as one of the HCC surveillance markers in at-risk populations[18,19].

PIVKA-II could also be employed to monitor HCC prognosis, treatment response, and recurrence because of its possible associations with the tumor size, HCC progression and recurrence[20,21]. Serum PIVKA-II levels have also been reported to be influenced by several noncancerous factors, such as vitamin K deficiency[22], ALD[23-26], acute hepatic failure[27], and the use of warfarin or antibiotics[26, 28] by leading to serum PIVKA-II elevation in non-HCC patients.

However, it remains unclear what the factors are regarding different liver disease etiologies, the liver injury severity, and disease activity degree associated with abnormal PIVKA-II levels in patients with CLD and HCC. Therefore, we aimed to identify the potential contributing factors and evaluate their influence on serum PIVKA-II levels and the performance of PIVKA-II for the diagnosis of HCC in different populations.

MATERIALS AND METHODS

Patients selection

This study eventually retrospectively registered 1051 patients after excluding 80 patients from 1131 registered patients. The mean age of the total cohort was 48.93 years ± 13.70 years, and 73.6% of them were male (n = 773). Supplementary Figure 1 shows the selection flowchart and the analysis process. All patients were recruited in Mengchao Hepatobiliary Hospital of Fujian Medical University from April 2016 to December 2019.

The patients included following the criteria as: (1) With CLD or HCC of clear etiology diagnosed by clinical or histological evidence, including chronic hepatitis B (CHB), chronic hepatitis C (CHC), ALD, NAFLD, and AILD; (2) CHB and CHC were defined as patients with positive hepatitis B surface antigen (HBsAg) and positive hepatitis C virus (HCV) antibodies and/or HCV RNA for at least 6 months; and (3) complete and detailed laboratory and clinical information, including serum PIVKA-II, relevant laboratory tests, and other clearly clinical characteristics and records. The patients excluded following the criteria as: (1) Patients diagnosed with CHB and ALD simultaneously; (2) patients with liver failure, esophageal and gastric variceal bleeding, or drug-induced liver disease; (3) patients without sufficient information on relevant laboratory tests and clinical records; (4) patients without a certain clinical diagnosis of HCC; (5) patients accepting warfarin or long-term treatment with antibiotics at the time of enrollment; and (6) patients with other malignant tumors or a prior history of antitumor treatment in HCC.

According to the Milan criteria, early-stage HCC is defined as a nodule with the diameter less than 5 cm or two to three nodules with the diameter each less than 3 cm and do not have significant vascular invasion or extrahepatic metastases[2,15,29], and beyond the Milan criteria was considered as late-stage HCC. A positive lesion discovered by the suggested imaging techniques and contrast agents or histopathological confirmation were used to determine the diagnosis of HCC[2,3,9,15,30]. For CLD patients at enrollment, the lack of an HCC was determined through that there were no any suspicious hepatic masses in clinical and imaging evidence, and if with an abnormal PIVKA-II level, a continuous imaging surveillance within the subsequent months was appropriate.

The existence of cirrhosis was generally determined *via* imaging, laboratory and clinical characteristics, or liver biopsy without a routine examination.

The ethics committee of Peking University Health Science Center granted this study approval (IRB00001052-19081). All procedures carried out in this study had followed the Helsinki declaration or equivalent ethical principles.

Study variables

Serum PIVKA-II level was quantitatively detected through the chemiluminescence enzyme immunoassay (LUMIPULSE® G1200, FUJIREBIO INC, Japan) by using Lumipulse® G PIVKA-II reaction cartridges in the clinical laboratory of Mengchao Hepatobiliary Hospital of Fujian Medical University, according to manufacturer's instructions. The lower limit of detection is > 0 mAU/mL, and the upper is 75000 mAU/mL. The upper limit of normal (ULN) was 40 mAU/mL[9]. Furthermore, abnormal elevation of serum PIVKA-II was defined as its values elevated above 40 mAU/mL (ULN).

Liver-related laboratory tests, including liver enzyme and function and routine blood, were performed in the clinical laboratory using commercially available kits by manufacturers' instructions. Test values would be reviewed if judged as unusual in order to ensure their accuracy.

Statistical analysis

SPSS 24.0 software (New York, NK, United States) was applied to finish the basic statistical analyses. The mean ± SD or median and interquartile range (IQR), as the continuous variables, were analyzed by t or Mann-Whitney test between two groups or Kruskal-Wallis test among three or more groups; χ^2 test

for categorical variables. Univariate and multivariate (forward) analyses of logistic regression were constructed to investigate factors associated with the abnormal elevation of serum PIVKA-II for non-HCC and HCC patients, respectively. Then, GraphPad Prism 7 (California, CA, United States) was used to plot the distributions of the levels of PIVKA-II in different subgroups and further compare them. The area under receiver operating characteristic (ROC) curve (AUC) and 95% confidence interval (CI), which reflecting the PIVKA-II's performance for HCC, were conducted and calculated by MedCalc version 18.2.1 (Ostend, Belgium). The best cutoff value, sensitivity, specificity, positive likelihood ratio (LR+), and negative likelihood ratio (LR-) of PIVKA-II levels were also calculated and shown. $P < 0.05$ was deemed statistically significant, and all tests and power analyses of significance were two-tailed.

RESULTS

Patient characteristics

The comprehensive clinical and laboratory characteristics of the study population are listed in Table 1. A total of 595 viral liver disease patients, 189 nonviral liver disease patients, 127 early-stage HCC patients, and 140 late-stage HCC patients were enrolled in. Compared to viral liver disease patients, patients with nonviral liver disease had significantly older mean age and higher median serum platelet (PLT) and GGT levels ($P < 0.05$); however, their male proportion and median serum ALT, AST and TBIL levels were significantly lower ($P < 0.05$). Interestingly, the abnormally elevated proportion of PIVKA-II > 40 mAU/mL (ULN) in patients with nonviral liver disease was significantly higher than that in patients with viral liver disease (20.6% *vs* 13.9%, $P < 0.050$), as well as the substantially higher median levels of serum PIVKA-II (27.0 *vs* 23.0, $P < 0.001$).

The median serum ALT, AST, ALP, GGT, and PLT levels in patients with early-stage HCC were significantly lower compared to those in patients with late-stage HCC ($P < 0.01$); and the significantly smaller tumor size and proportion of the number of tumors ≥ 2 were also observed in early-stage HCC patients (both $P < 0.001$), but they had a higher median level of serum ALB ($P < 0.05$). Furthermore, patients with early-stage HCC had a significantly lower abnormal proportion of PIVKA-II > 40 mAU/mL (ULN) than patients with late-stage HCC (60.6% *vs* 93.6%, $P < 0.001$), as well as significantly lower median serum PIVKA-II level (58 *vs* 5124, $P < 0.001$).

Identify the independent factors related to the abnormal elevation of PIVKA-II level (> 1 × ULN) in non-HCC and HCC patients

Then, we further analyzed and identified the independent factors related to the abnormal elevation of PIVKA-II level in non-HCC and HCC patients through logistic regression analyses, respectively. Table 2 and Figure 1A summarize the results of non-HCC patients. ALD etiology (OR: 9.883, 95%CI: 2.216-44.086, $P < 0.001$) was an independent positive factor associated with the abnormal elevation of serum PIVKA-II in non-HCC patients, as well as the factors of ALP/ULN (OR: 2.146, 95%CI: 1.429-3.221, $P < 0.001$) and TBIL/ULN (OR: 1.162, 95%CI: 1.080-1.250, $P < 0.001$). Table 3 and Figure 1B summarize the results of HCC patients. AST/ULN (OR: 1.759, 95%CI: 1.072-2.887, $P = 0.025$) was an independent positive factor associated with the abnormal elevation of serum PIVKA-II in HCC patients, as well as the factor of tumor size (OR: 1.349, 95%CI: 1.175-1.549, $P < 0.001$). These findings implied that there were obvious differences in the factors associated with the abnormal elevation of PIVKA-II level between non-HCC and HCC patients.

Serum PIVKA-II levels were different among different subgroups of patients with non-HCC, early-stage HCC, and late-stage HCC

The distributions and comparisons of serum PIVKA-II were further investigated according to the above results of independent factors associated with the abnormal elevation of PIVKA-II level.

According to Figure 2A, the median PIVKA-II levels among subgroups of different etiologies were significantly different ($P < 0.0001$); for viral liver disease without HCC, no difference was observed between HBV and HCV (23.8 *vs* 21.5, $P > 0.05$), but among nonviral liver diseases of NAFLD, ALD and AILD (28.0 *vs* 34.5 *vs* 20.0, $P < 0.0001$), the differences were significant. Further analysis showed that compared to CLD patients with HBV or HCV, the median PIVKA-II level in ALD was substantially higher (both $P < 0.0001$), and also in NAFLD (both $P < 0.05$). Meanwhile, AILD patients had significantly lower PIVKA-II levels than HBV patients ($P < 0.05$), whereas no difference was observed between HCV and AILD ($P > 0.05$). For patients with HCC (Figure 2B), the median PIVKA-II levels gradually significantly increased as the tumor size changed by ≤ 2 cm, > 2 cm and ≤ 5 cm, > 5 cm and ≤ 10 cm to > 10 cm (39.5 *vs* 135.5 *vs* 1811.0 *vs* 30987.0, $P < 0.0001$).

Further analysis revealed that viral liver disease patients had a significantly lower median level of PIVKA-II than patients with nonviral liver disease (23.0 *vs* 27.0, $P < 0.0001$) in non-HCC (Figure 2C), and there were also similar trends between ALP ≤ 1 × ULN and ALP > 1 × ULN (23.0 *vs* 30.0, $P < 0.0001$) (Figure 2D), TBIL ≤ 1 × ULN and TBIL > 1 × ULN (23.0 *vs* 27.0, $P < 0.0001$) (Figure 2E), AST ≤ 1 × ULN and AST > 1 × ULN (23.0 *vs* 26.0, $P < 0.01$) (Figure 2F) in non-HCC. However, similar tendencies were

Table 1 Clinical characteristics of patients with non-hepatocellular carcinoma and hepatocellular carcinoma

HCC: Hepatocellular carcinoma; HBV: Hepatitis B virus; HCV: Hepatitis C virus; NAFLD: Nonalcoholic fatty liver disease; ALD: Alcohol-related liver disease; AILD: Autoimmune liver disease; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ALP: Alkaline phosphatase; GGT: Gamma-glutamyltranspeptidase; TBIL: Total bilirubin; ALB: Albumin; PLT: Platelet; PIVKA-II: Protein induced by vitamin K absence or antagonist-II.

not observed in early-stage HCC patients, and the PIVKA-II levels between the above subgroups did not differ significantly. Furthermore, for late-stage HCC, the median level of PIVKA-II of ALP ≤ 1 × ULN was significantly lower compared to that of ALP > 1 × ULN (2129 *vs* 11992, $P < 0.01$), and also between AST ≤ 1 × ULN and AST > 1 × ULN (593.0 *vs* 15164, $P < 0.0001$); however, between viral and nonviral liver disease, a significant difference was not observed, nor between TBIL ≤ 1 × ULN and TBIL > 1 × ULN.

Additionally, Supplementary Table 1 shows that irrespective of the subgroups of etiology (viral and nonviral liver disease), ALP (≤ 1 × ULN and > 1 × ULN), TBIL (≤ 1 × ULN and > 1 × ULN), AST (≤ 1 × ULN and > 1 × ULN), serum PIVKA-II levels differed significantly among non-HCC, early-stage and late-stage HCC.

Significant influence of serum TBIL on the performance of PIVKA-II in diagnosing early-stage HCC but not for late-stage HCC

The above findings suggested that abnormally elevated PIVKA-II level was independently positively associated with etiology, ALP, and TBIL for non-HCC patients and AST and tumor size for HCC patients. Then, the AUCs of serum PIVKA-II for the diagnosis of early-stage HCC and late-stage HCC were further analyzed for each subgroup of patients by etiology, ALP, TBIL, and AST.

HCC: Hepatocellular carcinoma; OR: Odds ratio; CI: Confidence interval; M: male; HBV: Hepatitis B virus; HCV: Hepatitis C virus; NAFLD: Nonalcoholic fatty liver disease; ALD: Alcohol-related liver disease; AILD: Autoimmune liver disease; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ALP: Alkaline phosphatase; GGT: Gamma-glutamyltranspeptidase; TBIL: Total bilirubin; ALB: Albumin; PLT: Platelet; ULN: Upper limit of normal; LLN: Lower limit of normal.

In Table 4, serum PIVKA-II had the best performance for diagnosing early-stage HCC in TBIL ≤ 1 × ULN subgroup, and the AUC of PIVKA-II in TBIL ≤ 1 × ULN subgroup was significantly higher than that in TBIL > 1 × ULN subgroup (0.817 *vs* 0.669, $P = 0.015$). When compared with the subgroup of nonviral liver disease, the AUC of PIVKA-II in the subgroup of viral liver disease for diagnosing early-stage HCC was only marginally higher (0.783 *vs* 0.736, $P = 0.678$), the difference was not significant, nor was the difference between ALP ≤ 1 × ULN and ALP > 1 × ULN (0.783 *vs* 0.729, $P = 0.398$). However, the AUC of PIVKA-II in AST ≤ 1 × ULN subgroup was almost the same to AST > 1 × ULN subgroup (0.774 *vs* 0.778, $P = 0.941$) in diagnosing early-stage HCC. Figure 3 shows the corresponding ROC curves of PIVKA-II for diagnosing early-stage HCC in different subgroups.

However, subsequent analysis of Supplementary Table 2 showed that the above factors, including etiology, ALP, TBIL, and AST, had almost no influence on the performance of PIVKA-II for the diagnosis of late-stage HCC. The AUCs of PIVKA-II did not differ significantly between subgroups in etiology (viral *vs* nonviral), ALP (≤ 1 × ULN *vs* > 1 × ULN), TBIL (≤ 1 × ULN *vs* > 1 × ULN) and AST (≤ 1 × ULN *vs* > 1 × ULN) (P all > 0.05). Supplementary Figure 2 also shows the corresponding ROC curves of PIVKA-II for diagnosing late-stage HCC in different subgroups.

Furthermore, we also analyzed the AUCs of PIVKA-II for HCC between viral and ALD etiologies. Supplementary Figure 3 shows that compared to the subgroup of viral etiology, the AUC of PIVKA-II for early-stage HCC was lower in ALD etiology (0.783 *vs* 0.655, $P = 0.470$), and also for late-stage HCC (0.970 *vs* 0.909, $P = 0.361$).

Serum PIVKA-II had better performance in diagnosing early-stage HCC for patients with TBIL ≤ 1 × ULN, both of viral etiology and HBV alone

Different etiologies of liver disease might induce diverse progression of liver injuries and changes in indicators of liver function, such as serum ALP and TBIL. Then, we further analyzed the AUCs of ROC curves of PIVKA-II by each subgroup of ALP and TBIL in patients of viral etiology and HBV alone, respectively, but not in patients with nonviral etiology on account of the limited cases of HCC.

Figure 4 shows that patients with TBIL ≤ 1 × ULN of viral etiology had substantially higher AUC of PIVKA-II for diagnosing early-stage HCC (0.837 *vs* 0.677, $P = 0.012$) than patients with TBIL > 1ULN.

Table 3 Factors associated with abnormally elevated protein induced by vitamin K absence or antagonist-II by univariate and multivariate logistic analyses in hepatocellular carcinoma patients

HCC: Hepatocellular carcinoma; OR: Odds ratio; CI: Confidence interval; M: Male; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ALP: Alkaline phosphatase; GGT: Gamma-glutamyltranspeptidase; TBIL: Total bilirubin; ALB: Albumin; PLT: Platelet; ULN: Upper limit of normal; LLN: Lower limit of normal.

Also, for patients with viral etiology, the AUC of PIVKA-II in ALP ≤ 1 × ULN was higher (0.800 *vs* 0.731, $P = 0.318$) than that in ALP > 1 × ULN, but no statistical significance was found. Supplementary Table 3 further shows the detailed value of AUC, best cutoff value, sensitivity, specificity, LR+, and LR- in each subgroup.

Furthermore, similar tendencies were also validated in patients with HBV alone. As shown in Supplementary Table 4, for patients with HBV alone, the AUCs of PIVKA-II were 0.832 and 0.676 ($P = 0.015$) in TBIL ≤ 1 × ULN and TBIL > 1 × ULN, and 0.794 and 0.732 ($P = 0.368$) in ALP ≤ 1 × ULN and ALP > 1 × ULN, respectively.

When the cutoff value of PIVKA-II for detecting early-stage HCC was set at 40 mAU/mL (ULN), the sensitivity, specificity, LR+, and LR- were further analyzed in patients with viral etiology and HBV alone. As shown in Table 5, compared to TBIL > 1 × ULN of viral etiology, the sensitivity of PIVKA-II in TBIL ≤ 1 × ULN of viral etiology increased from 30.30% to 57.47%, and the LR+ increased from 3.80 to 6.66, without compromising the corresponding specificity (92.02% *vs* 91.37%). Similarly, for patients with HBV alone, the sensitivity of PIVKA-II in TBIL ≤ 1 × ULN was also significantly higher than that in TBIL > 1 × ULN (57.14% *vs* 30.77%), as well as LR+ (6.16 *vs* 3.73), with similar specificity (90.72% *vs* 91.76%). Noticeably, the sensitivities in TBIL ≤ 1 × ULN have consistently been greater than those in ALP≤ 1 × ULN, both for patients with viral etiology (57.47% *vs* 52.88%) and HBV alone (57.14% *vs* 53.00%), and the corresponding specificities were almost the same. However, this tendency disappeared, and the sensitivities tended to be the same between TBIL > 1 × ULN and ALP > 1 × ULN, regardless of viral etiology (30.30% *vs* 30.61%) and HBV alone (30.77% *vs* 30.61%).

DISCUSSION

In the current study, 1051 patients in total were analyzed, and we determined the independent variables linked to elevated serum PIVKA-II levels in CLD and HCC patients, with the purpose of expounding their influence on the PIVKA-II performance for early-stage HCC and late-stage HCC detection. For patients with CLD, abnormally increased PIVKA-II levels were independently positively associated with ALD etiology, serum ALP and TBIL, but serum AST and tumor size for HCC patients. Compared to subgroups of nonviral etiology, ALP > 1 × ULN, TBIL > 1 × ULN and AST > 1 × ULN, serum PIVKA-II levels were significantly lower in subgroups of viral etiology, ALP ≤ 1 × ULN, TBIL ≤ 1 × ULN, and

AST ≤ 1 × ULN in CLD patients; however, these differences disappeared in early-stage HCC. Furthermore, serum PIVKA-II in a subgroup of TBIL ≤ 1 × ULN always had the highest AUCs and the best performance in detecting early-stage HCC than TBIL > 1 × ULN, irrespective of all patients, viral etiology or HBV alone. However, the above factors, including etiology, ALP, TBIL, and AST, had almost no influence on PIVKA-II performance for late-stage HCC detection.

Four previous studies found that ALD patients had higher levels of PIVKA-II compared to viral hepatitis-related CLD patients[23-26], and ALD was also verified to be a significant factor related to positive serum PIVKA-II by a retrospective case-control study[26]. Consistently, in this study, patients with CLD with ALD etiology had the highest median level of PIVKA-II compared to those with other etiologies of HBV, HCV, NAFLD, and AILD, and was demonstrated to be independently associated with abnormally elevated PIVKA-II levels. A recent study enrolled 130 cases and showed that patients with CHB, CHC, and nonviral CLD had no significant differences in PIVKA-II levels (32 mAU/mL *vs* 35 mAU/mL *vs* 35 mAU/mL, any two $P > 0.05$)[31]. In the current study, however, a significant difference was observed in PIVKA-II levels between viral and nonviral CLD patients; meanwhile, PIVKA-II levels in NAFLD and ALD patients were significantly higher compared to those in HBV and HCV patients,

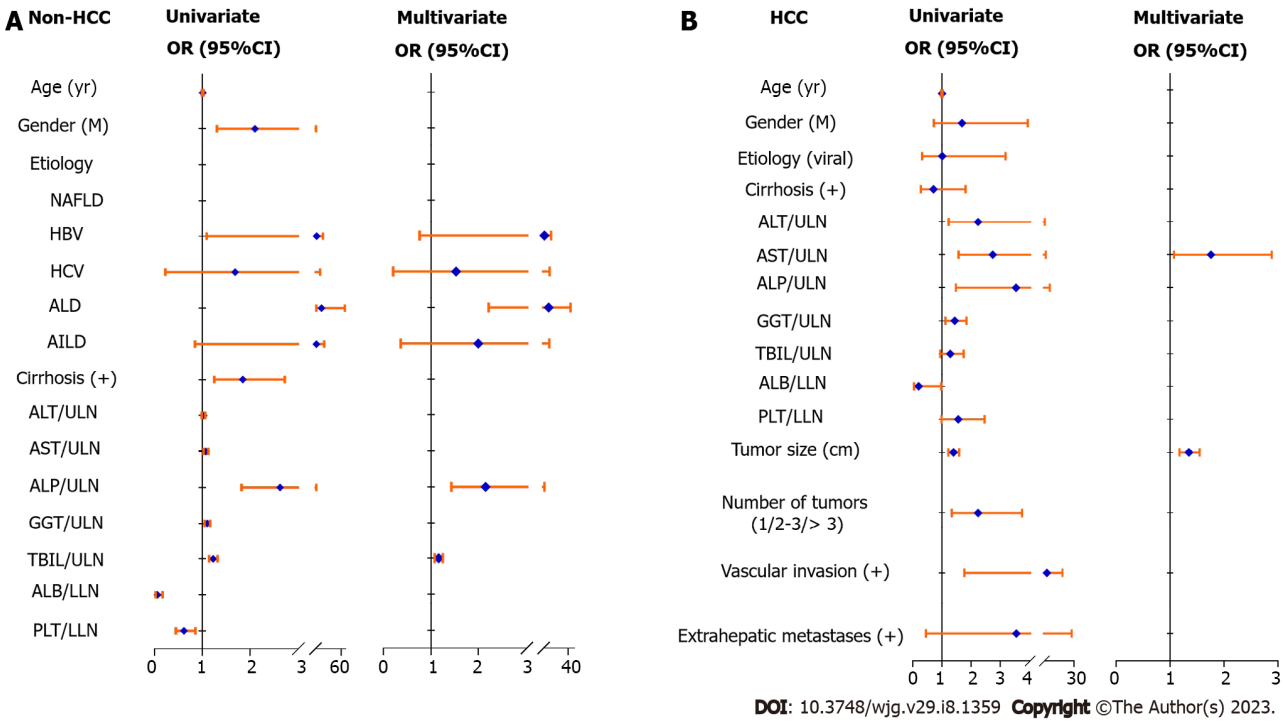

Figure 1 Forest plots of factors associated with abnormally elevated protein induced by vitamin K absence or antagonist-II by univariate and multivariate logistic analysis in patients with non-hepatocellular carcinoma and hepatocellular carcinoma. A: In non- hepatocellular carcinoma (HCC) patients; B: In HCC patients. HBV: Hepatitis B virus; HCV: Hepatitis C virus; NAFLD: Nonalcoholic fatty liver disease; ALD: Alcohol-related liver disease; AILD: Autoimmune liver disease; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ALP: Alkaline phosphatase; ULN: Upper limit of normal; TBIL: Total bilirubin; PLT: Platelet; LLN: Lower limit of normal; 95%CI: 95% confidence interval; OR: Odds ratio.

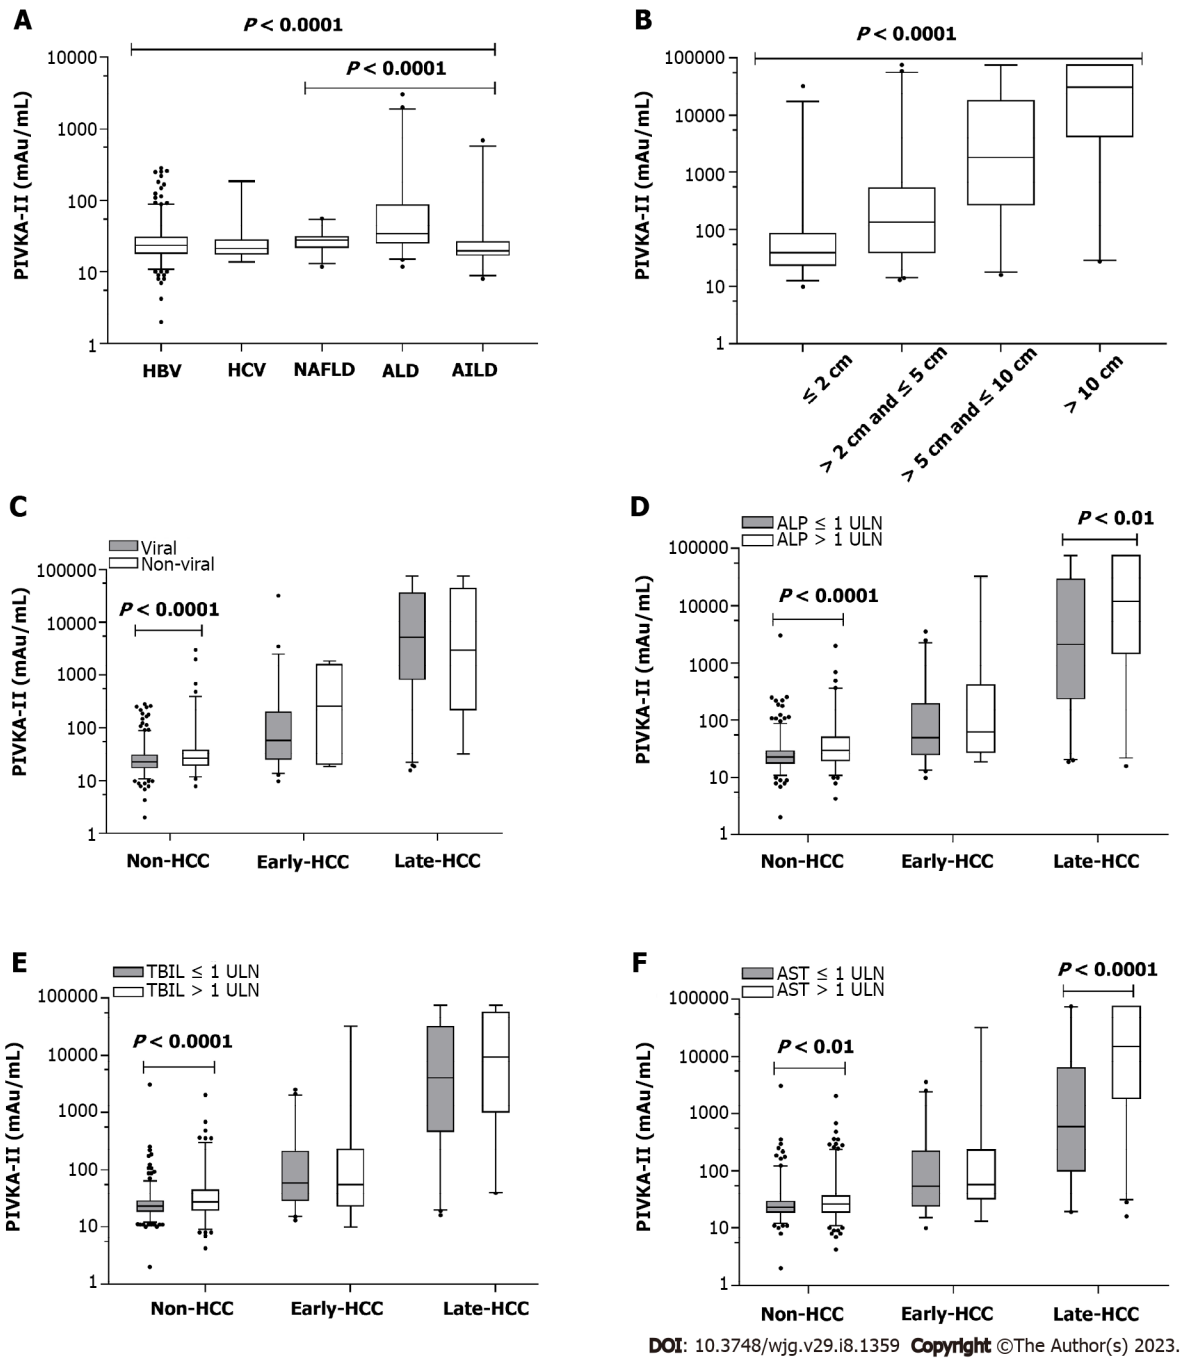

and AILD patients had the lowest PIVKA-II levels than those of other CLD patients.

In this study, tumor size was an independent factor relevant to abnormally elevated PIVKA-II levels in HCC patients, and the median levels of PIVKA-II gradually significantly increased as the tumor size changed by ≤ 2 cm, > 2 cm and ≤ 5 cm, > 5 cm and ≤ 10 cm to > 10 cm, which was consistent with the results of previous studies[32,33]. Moreover, the number of tumors and vascular invasion were associated with the abnormal elevation of PIVKA-II level which was only perceived in the univariate analysis. The results imply that tumor size had more influence on the PIVKA-II level than the number of tumors and vascular invasion.

Prior researches had reported that PIVKA-II serum levels are not elevated in hepatic flares and are influenced by liver regeneration triggered by necroinflammation in patients with active CLD, and have paid little attention to the confounding factors of liver injury and function that influence the levels of PIVKA-II[12,31]. Nonetheless, this is the first study to our knowledge to demonstrate that the abnormal PIVKA-II levels are significantly associated with serum ALP and TBIL in CLD patients and serum AST in HCC patients. Furthermore, in patients with CLD, the median PIVKA-II levels differed significantly between the subgroups of ALP ≤ 1 × ULN and ALP > 1 × ULN, as well as between TBIL ≤ 1 × ULN and TBIL > 1 × ULN; and in patients with late-stage HCC, the differences in PIVKA-II median levels were also observed between the subgroups of ALP and AST classified by 1 × ULN. However, these changes in PIVKA-II serum levels disappeared in early-stage HCC patients in the same situation.

Regretfully, the underlying mechanism behind the associations of ALD, ALP, and TBIL with elevated PIVKA-II levels in CLD patients remains unclear. Although vitamin K insufficiency may arise in chronic alcoholics[34], prior studies[23,25] found there was no direct correlation between PIVKA-II serum levels and vitamin K serum concentration. For ALP and TBIL, one likely explanation is that abnormalities in serum ALP and TBIL were always seen in all types of liver disorders and cholestasis. Vitamin K deficiency, as one of the fat-soluble vitamin deficiencies, is also a typical complication in chronic cholestasis patients, and vitamin levels were inversely correlated with serum TBIL levels[35-37]. Interestingly, one recent study also reported that hepatitis E patients in the raised PIVKA-II subgroup had significantly greater TBIL levels than those in the normal PIVKA-II subgroup ($P < 0.05$), and the trend of changes in serum PIVKA and TBIL were similar and related to the disease course[38].

It has been reported that the PIVKA-II's AUC for HCC in the CHB group was the highest compared to those in CHC and nonviral CLD patients (0.833 *vs* 0.732 *vs* 0.806)[31]. Similarly, in the current study, the AUC of PIVKA-II was slightly higher in patients with viral etiology compared to that in patients with nonviral etiology, irrespective of whether the HCC is in its early or late stages. Patients with ALD etiology had much lower AUCs of PIVKA-II for detecting HCC than patients with viral etiology,

especially for early-stage HCC. However, in previous literature, the influences of serum ALP and TBIL on the performance of PIVKA-II for the detection of HCC have not been evaluated. In this study, we provided evidence that patients in TBIL ≤ 1 × ULN subgroup had the best performance of PIVKA-II for detecting early-stage HCC, and the AUC of PIVKA-II in TBIL ≤ 1 × ULN subgroup was significantly higher compared to that in TBIL > 1 × ULN subgroup. Between ALP ≤ 1 × ULN and ALP > 1 × ULN, a similar trend was also observed, although the difference was not significant. However, no significant influences of serum ALP and TBIL were observed on the performance of PIVKA-II for late-stage HCC.

Further analysis also showed that the above changes and differences in the performance of PIVKA-II for the detection of early-stage HCC still existed between different subgroups of ALP and TBIL in patients with viral etiology and HBV alone. Moreover, when 40 mAU/mL (ULN) was set as the cutoff

value of PIVKA-II, for patients with TBIL ≤ 1 × ULN, serum PIVKA-II had the highest sensitivities in detecting early-stage HCC than other subgroups and enough high specificities at the same time, irrespective of viral etiology or HBV alone. These results strongly suggest that serum PIVKA-II would have better performance in detecting HCC at an early-stage for patients with normal serum TBIL.

The current study had a number of limitations. Firstly, it was a retrospective design, and some unidentified potential biases might exist, although we completely ruled out the possible interferences on serum PIVKA-II by the potential confounding factors in the exclusion criteria. Then, the limited sample size, including HCC patients with CHC, ALD, NAFLD, and AILD, does not allow us to independently evaluate the influences of these factors on the performance of PIVKA-II in HCC patients with CHC, NAFLD, and AILD, and decrease the reliability of that in HCC patients with ALD. Finally, further

multicenter research with more participants are required to validate the above findings.

CONCLUSION

The present study suggests that abnormally elevated PIVKA-II levels were independently positively associated with ALD etiology, serum ALP and TBIL for non-HCC CLD patients and serum AST and tumor size for HCC patients. Better performance of PIVKA-II for discriminating HCC at an early stage from patients with CLD would be achieved in patients with normal TBIL, and more attention should be given to the availability of PIVKA-II in HCC surveillance for at-risk patients with elevated serum TBIL.

ARTICLE HIGHLIGHTS

Research background

Serum protein induced by vitamin K absence or antagonist-II (PIVKA-II) is a promising biomarker for hepatocellular carcinoma (HCC) surveillance.

Research motivation

Investigate those unclear factors regarding different liver disease etiologies, the liver injury severity, and disease activity associated with the abnormal levels of serum PIVKA-II in chronic liver disease (CLD) and HCC patients.

Research objectives

Identify the potential contributing factors and evaluate their influence on serum PIVKA-II levels and the performance of PIVKA-II for the diagnosis of HCC in different populations.

Research methods

This study retrospectively enrolled in 784 CLD patients and 267 HCC patients in Mengchao Hepatobiliary Hospital of Fujian Medical University from April 2016 to December 2019. Logistic regression and the area under the receiver operating characteristic curve (AUC) were used to evaluate the influencing factors and diagnostic performance of PIVKA-II for HCC, respectively.

Research results

Elevated PIVKA-II levels were independently positively associated with alcohol-related liver disease (ALD), serum alkaline phosphatase (ALP), and total bilirubin (TBIL) for CLD patients and aspartate aminotransferase (AST) and tumor size for HCC patients (all $P < 0.05$). Serum PIVKA-II were significantly lower in patients with viral etiology, ALP ≤ 1 × upper limit of normal (ULN), TBIL ≤ 1 × ULN, and AST ≤ 1 × ULN than in those with nonviral disease and abnormal ALP, TBIL, or AST (all $P < 0.05$), but the differences disappeared in patients with early-stage HCC. For patients with TBIL ≤ 1 × ULN, the AUC of PIVKA-II was significantly higher compared to that in patients with TBIL > 1 × ULN (0.817 *vs* 0.669, $P = 0.015$), while the difference between ALP ≤ 1 × ULN and ALP > 1 × ULN was not statistically significant found between ALP ≤ 1 × ULN and ALP > 1 × ULN (0.783 *vs* 0.729, $P = 0.398$). These trends were then more prominently perceived in subgroups of patients with viral etiology and HBV alone.

Research conclusions

Abnormally elevated PIVKA-II levels were independently positively associated with ALD etiology, serum ALP and TBIL for non-HCC CLD patients and serum AST and tumor size for HCC patients. Better performance of PIVKA-II for discriminating HCC at an early stage from patients with CLD would be achieved in patients with normal TBIL.

Research perspectives

More attention should be given to the availability of PIVKA-II in HCC surveillance for at-risk patients with elevated serum TBIL, which may be important for surveillance counseling of early-stage HCC.

Abstract

BACKGROUND

Bone disease is an under-recognized cause of morbidity in chronic pancreatitis (CP). Over the past decade, publications of original studies on bone disease in CP has warranted synthesis of the evidence to ascertain the true burden of the problem.

AIM

To quantify the prevalence of osteopenia, osteoporosis, and fragility fractures in CP patients and investigate the associated clinical features and outcomes.

METHODS

A systematic search identified studies investigating bone disease in CP patients from Cochrane Library, Embase, Google Scholar, Ovid Medline, PubMed, Scopus, and Web of Science, from inception until October 2022. The outcomes included prevalence of osteopenia, osteoporosis, and fragility fractures, which were meta-analyzed using a random-effects model and underwent metaregression to delineate association with baseline clinical features.

RESULTS

Twenty-one studies were included for systematic review and 18 studies were

included for meta-analysis. The pooled prevalence of osteopenia and osteoporosis in CP patients was 41.2% (95%CI: 35.2%-47.3%) and 20.9% (95%CI: 14.9%-27.6%), respectively. The pooled prevalence of fragility fractures described among CP was 5.9% (95%CI: 3.9%-8.4%). Meta-regression revealed significant association of pancreatic enzyme replacement therapy (PERT) use with prevalence of osteoporosis [coefficient: 1.7 (95%CI: 0.6-2.8); $P < 0.0001$]. We observed no associations with mean age, sex distribution, body mass index, alcohol or smoking exposure, diabetes with prevalence of osteopenia, osteoporosis or fragility fractures. Paucity of data on systemic inflammation, CP severity, and bone mineralization parameters precluded a formal meta-analysis.

CONCLUSION

This meta-analysis confirms significant bone disease in patients with CP. Other than PERT use, we observed no patient or study-specific factor to be significantly associated with CP-related bone disease. Further studies are needed to identify confounders, at-risk population, and to understand the mechanisms of CP-related bone disease and the implications of treatment response.

Key Words: Chronic pancreatitis; Fractures; Osteoporosis; Osteopenia; Bone disease

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Bone disease is an under recognized cause of morbidity in chronic pancreatitis (CP). This systematic review and meta-analysis demonstrate substantial burden of bone disease (osteopenia and osteoporosis) and fragility fractures in CP patients. In addition, metaregression has demonstrated a significant association of osteoporosis with pancreatic enzyme replacement. The study is powered by high-quality studies with large sample size and clearly defined study population and outcome measures.

INTRODUCTION

Chronic pancreatitis (CP) is a progressive, multifactorial fibro-inflammatory syndrome, which arises from persistent pathological response to noxious stimuli[1]. It is characterized by chronic abdominal pain, exocrine and endocrine insufficiency. Over time, nutritional deficiencies, systemic inflammation, and etiological factors like alcohol or smoking may disrupt the balance between bone formation and resorption[2]. These maladaptive alterations may subsequently cause bone disease *i.e.*, osteopenia and osteoporosis, leading to fractures which result from low energy trauma, called fragility fractures, and have significant implications on quality of life[3].

Osteoporosis is a public health hazard with a substantial economic burden[4]. Recent data from the National Health and Nutrition Examination Survey found its age-adjusted prevalence among adults older than 50 years to be 12.6% affecting more women than men (19.6% *vs* 4.4%). In view of the burden of bone disease and subsequent fracture risk in individuals affected by CP, various consensus guidelines have recommended baseline bone health assessment[5,6]. The adherence to guidelines has been low and studies have demonstrated that less than a quarter of CP patients are screened for bone disease, suggesting that bone disease is an underappreciated source of morbidity in CP[7,8].

A previous systematic review by Duggan *et al*[9] estimated the prevalence of osteopenia and osteoporosis in patients with CP to be 39.8% and 23.4%, respectively. The analysis was based on a limited number of studies ($n = 11$) and did not quantify fragility fractures which are complications of CP-related bone disease. Over the last decade, multiple large-sized studies including those from multicenter cohorts have investigated bone disease in CP as well as the nutritional, anthropometric, and inflammatory parameters which may impact bone health outcomes. Thus, with quantitative data on covariates and fragility fractures available, an updated synthesis of evidence is pertinent. This systematic review and meta-analysis aims to quantify the prevalence of osteopenia, osteoporosis, and fragility fractures in CP patients and to delineate clinical parameters which impact their occurrence.

MATERIALS AND METHODS

Protocol registration

This systematic review was performed in accordance with PRISMA guidelines[10]. The review methodology was pre-registered at open-source forum[11].

Search strategy

A systematic search of the literature was conducted by a medical librarian in the following databases: Cochrane Library, Ovid Embase, Google Scholar, Ovid Medline, PubMed, Scopus, and Web of Science Core Collection to find articles published from the inception of the database to October 20, 2022. The search was performed using a combination of controlled and free text terms for CP and bone diseases (strategy outlined in Supplementary Table 1). The search was not limited to publication type or date. the search was peer-reviewed by a second librarian using peer review for electronic search strategies[12]. Citations were imported into an Endnote 20 Library (Version 20.2, Clarivate Analytics, Philadelphia), and after removal of duplicates, the remaining studies were imported into Covidence (Melbourne, Australia) for screening and data extraction.

Study selection

Two co-authors (MJ, AC) independently used the inclusion and exclusion criteria to assess titles and abstracts. Eligibility decisions and disagreements were reconciled through discussion with the senior author (SS). Full-text articles included by two reviewers underwent data extraction and quality assessment.

Inclusion criteria: This systematic review included original cross-sectional and cohort studies, which were of prospective and retrospective design. CP patients were diagnosed based on specific codes related to CP per the International Classification of Diseases (ICD-9/10) and through predefined clinical, radiologic and/or histologic findings (described in Table 1).

Exclusion criteria: The studies which did not report bone diseases in CP patients were ineligible for the systematic review. We also excluded studies published in foreign languages, associated with animal research, reviews, abstracts, letters, case reports, and series with a sample size of less than 10 patients were excluded (Figure 1).

Data extraction

We noted data on study design, population characteristics such as age, gender, method of CP diagnosis (ICD-code based *vs* systematic clinical-radiologic features), body mass index (BMI), and exposure to alcohol and smoking. These data were independently extracted by two authors (MJ and AC). The outcome of interest included the prevalence of osteopenia, osteoporosis, and fragility fractures among the CP patients. The definitions of these bone outcome measures were also noted and have been outlined in Table 2.

Meta-analysis methodology

Prevalence rates were pooled using random-effects meta-analysis and calculated using the score method [13]. Between-study heterogeneity was estimated using I^2 statistics wherein 25%, 50%, and 75% were considered to indicate low, moderate, and high heterogeneity, respectively. Sensitivity analysis was conducted by sequentially removing individual studies. Statistical analysis was performed using Stata/IC, version 17 (StataCorp, College Station, TX). Metaregression, subgroup analysis and publication bias assessment could not be performed for analyses including < 10 studies[14].

Metaregression

Metaregression using the restricted maximum likelihood method was also performed using variables of mean age, sex, BMI, smoking or alcohol exposure, diabetes, serum parathyroid hormone (PTH), percentage population with vitamin D deficiency, and pancreatic enzyme replacement therapy (PERT).

Study quality and publication bias assessment

The quality of observational studies was independently assessed using the Newcastle-Ottawa Scale by two investigators (SN and AA) and recorded in a Microsoft Excel spreadsheet (XP Professional Edition; Microsoft Corp, Redmond, WA, United States)[15]. Any discrepancy was resolved by the senior author (SS). Publication bias were assessed by inspection of a funnel plot and Egger's test[16].

RESULTS

Literature search

The literature search yielded 2081 results and after the removal of 20 duplicates, 2061 citations underwent title and abstract screening. The exclusion of 1979 citations due to lack of relevance to the research question resulted in 82 citations for full-text review. The review of their full texts enabled exclusion of 61 citations and finally 21 studies were included[7,8,17-35] (Supplementary Table 2). The excluded studies had incorrect study design (n = 27), wrong outcomes (n = 17), ineligible patient population (n = 8), non-English language (n = 6), wrong setting (n = 3), and duplicate center or overlapping populations (n = 1) (Supplementary Table 3). The search and selection processes are summarized in Figure 1.

Study design

All the eligible studies were observational studies and included 14 cross-sectional and 7 cohort studies (described in Table 1). Among the cohort studies, four were performed prospectively[25,26,31,33], and remaining three had retrospective design[7,8,35]. Most of the studies originated from European

countries (n = 9), while the remaining were from the United States (n = 6), India (n = 4), China (n = 1), and Argentina (n = 1). Multicenter collaboration was noted in two eligible studies whereas the remaining 19 were performed at single centers. The controls of matched patients were also analyzed in seven studies which were from a healthcare system (n = 3)[20,22,24]; healthy community population (n = 3)[21,26,27]; or were not defined (n = 1)[28].

Population characteristics

The qualitative review of 21 studies included 20155 CP patients and 2007278 control patients (from seven controlled studies). The patients with CP were identified based on the combination of clinical, radiologic, endoscopic and/or histologic findings in 17 studies[7,8,17-19,21-23,25,27-34], and diagnosed through ICD-9/10 codes in four studies[20,24,26,35] (Table 1).

Prevalence of bone disease

We performed meta-analysis of 21 eligible studies which included 20155 CP patients evaluated for bone disease.

Prevalence of osteopenia in CP patients: In adult CP patients, the pooled prevalence of osteopenia was 41.2% (95%CI: 35.2%-47.3%, P < 0.0001; χ^2 = 63.0, df = 14, P < 0.0001; I^2 = 77.8%, τ^2 = 0.04)[7,8,17-19,23,25,27-32,34,35] (Figure 2A). All of the studies prevalence estimates had high heterogeneity since I^2 > 75%.

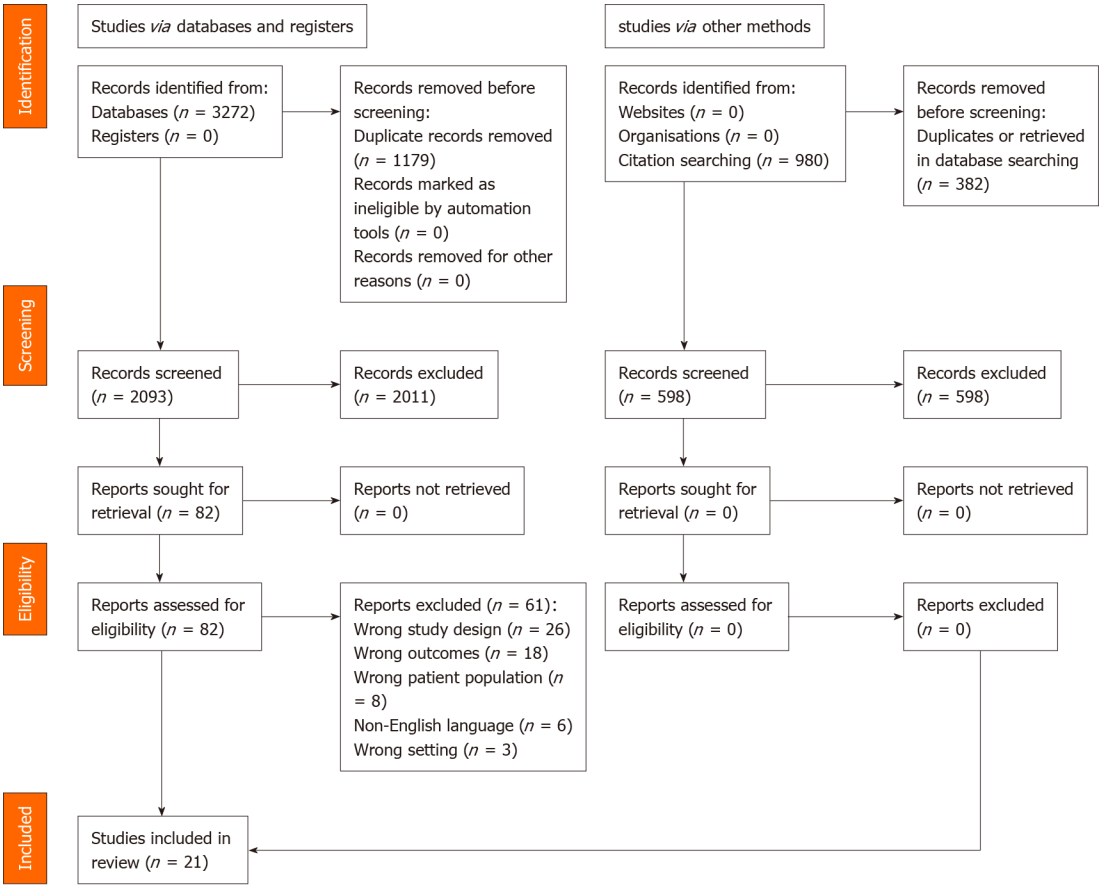

Figure 1 PRISMA flow diagram describing study selection.

Prevalence of osteoporosis among CP patients: The pooled prevalence of osteoporosis in CP patients was 20.9% (95%CI: 14.9%-27.6%; $P < 0.0001$; $\chi^2 = 290.33$, $df = 18$, $P < 0.0001$; $I^2 = 93.8\%$, $\tau^2 = 0.1$)[7,8,17-19,21-23,25-35] (Figure 2B). The pooled prevalence of osteoporosis in CP patients had high heterogeneity since $I^2 > 75\%$.

Prevalence of fragility fracture among CP patients: The pooled prevalence of fragility fracture was 5.9% (95%CI: 3.9%-8.4%, $P < 0.0001$; $\chi^2 = 186.0$, $df = 8$, $P < 0.0001$; $I^2 = 95.7\%$, $\tau^2 = 0.02$)[7,19-21,24,26,32,34,35] (Figure 2C). All of the studies prevalence estimates had high heterogeneity since $I^2 > 75\%$.

Factors impacting bone disease in CP patients: Various covariates underwent qualitative assessment for their association with CP related bone disease (Table 3).

Baseline patient characteristics: Female population was excluded in three studies[17,22,28] whereas 6376 (31.6%) female subjects were incorporated in the remaining 18 studies. In addition, three studies excluded post-menopausal females[19,25,33]. The race of CP patients was described in only five studies [7,20,24,33,34]. Its association with bone disease was investigated only by Hart and colleagues and they observed significantly higher burden among Caucasian population[34].

CP activity: The impact of CP severity on the bone outcomes was investigated in only one third of the eligible studies[17,19,27,28,31,32,34]. These studies observed no correlation with CP severity and alteration in bone mineral density. Moreover, the association of bone disease with duration of CP was also studied and lacked statistically significance[18,29,32,33,34,35]. The studies by Sikkens *et al*[25], and Kuhlman *et al*[30], observed a significant association of bone disease with exocrine insufficiency. Improved bone disease outcomes were observed in patients receiving PERT based on four large sized studies[8,26,30,34]. PERT usage and CP-related bone disease lacked statistical significance in five observational studies[17,22,23,28,32].

Inflammatory factors: Inflammation-based biomarkers such as C-reactive protein and interleukin (IL)-6 levels also yielded non-significant results in the investigation by two groups[27,32].

Endocrine factors: Among the eligible studies, hormones which regulate calcium metabolism have been widely studied. Serum 25-OH cholecalciferol had a positive correlation with bone density in three

[1]Number of subjects who consented to Dual-energy X-ray Absorptiometry scan if detailed in the studies.

CP: Chronic pancreatitis; EPI: Exocrine pancreatic insufficiency; PTH: Parathyroid; PERT: Pancreatic enzyme replacement; BMI: Body mass index; CRP: C-reactive protein; IL-6: Interleukin 6.

studies[21,27,30], whereas the remaining reported no significant associations[17,18,22,28,29,32]. Similarly, alkaline phosphatase and calcium had non-significant correlation with bone mineral density in two studies[17,28]. Serum PTH level did not correlate with bone disease in three studies[17,18,28], in contrast to the significant association found by Stigliano *et al*[32], Duggan *et al*[27], and Tang *et al*[35]. Novel bone turnover-based biomarkers *i.e.*, carboxy-terminal telopeptide of type I collagen, osteocalcin, procollagen 1 amino-terminal propeptide also had non-significant results in limited observational studies[27,35]. Thyroid-stimulating hormones and Insulin-like growth factors 1 were considered by Munigala *et al*[24], but no correlation was found with bone mineral density (BMD). Although hypogonadism was higher in subjects with low BMD in the study by Gupta e*t al*[33], no statistically significant difference was found. Exogenous hormone uses or replacement therapy was not investigated in any of the included studies.

Nutritional factors: The evidence linking BMI with bone disease outcomes has been conflicting. Whereas six studies described higher BMI as a protective factor[19,21-23,30,32,35], others reported an increased risk or non-significant findings[17,31,33,34]. Serum albumin was also explored in two studies with no mention of outcome association[17,21]. Min and colleagues studied the Malnutrition Universal Screening Tool, a validated nutritional assessment tool and observed that a score of 1 or more had significant association with osteopenia and osteoporosis ($P = 0.004$)[31]. Three studies described calcium supplement intake but did not study its relationship with bone disease[21,22,30].

Lifestyle factors: The definitions for exposure to alcohol and/or smoking were heterogeneous with limited evidence on their impact on bone outcomes[7,8,17,19,21,23-28,30,32-35]. Outdoor activity and sunlight exposure was only investigated by Joshi *et al*[21], and although correlated positively with vitamin D levels, their impact on osteoporosis was not studied.

Meta-regression

Meta-regression revealed significant association of PERT use with prevalence of osteoporosis [coefficient: 1.7 (95%CI: 0.6-2.8); $P < 0.0001$] but not with osteopenia or fragility fractures. No associations with mean age, sex distribution, BMI, alcohol or smoking exposure, vitamin D deficiency, PTH levels, and diabetes with prevalence of osteopenia, osteoporosis or fragility fractures (Table 4).

Sensitivity analysis

Sensitivity analysis through forest plot calculation was performed using the "remove one study" method as described above. Confidence intervals and heterogeneity was measured through I^2 and no significant alterations were observed after removal of one particular study (Supplementary Table 4).

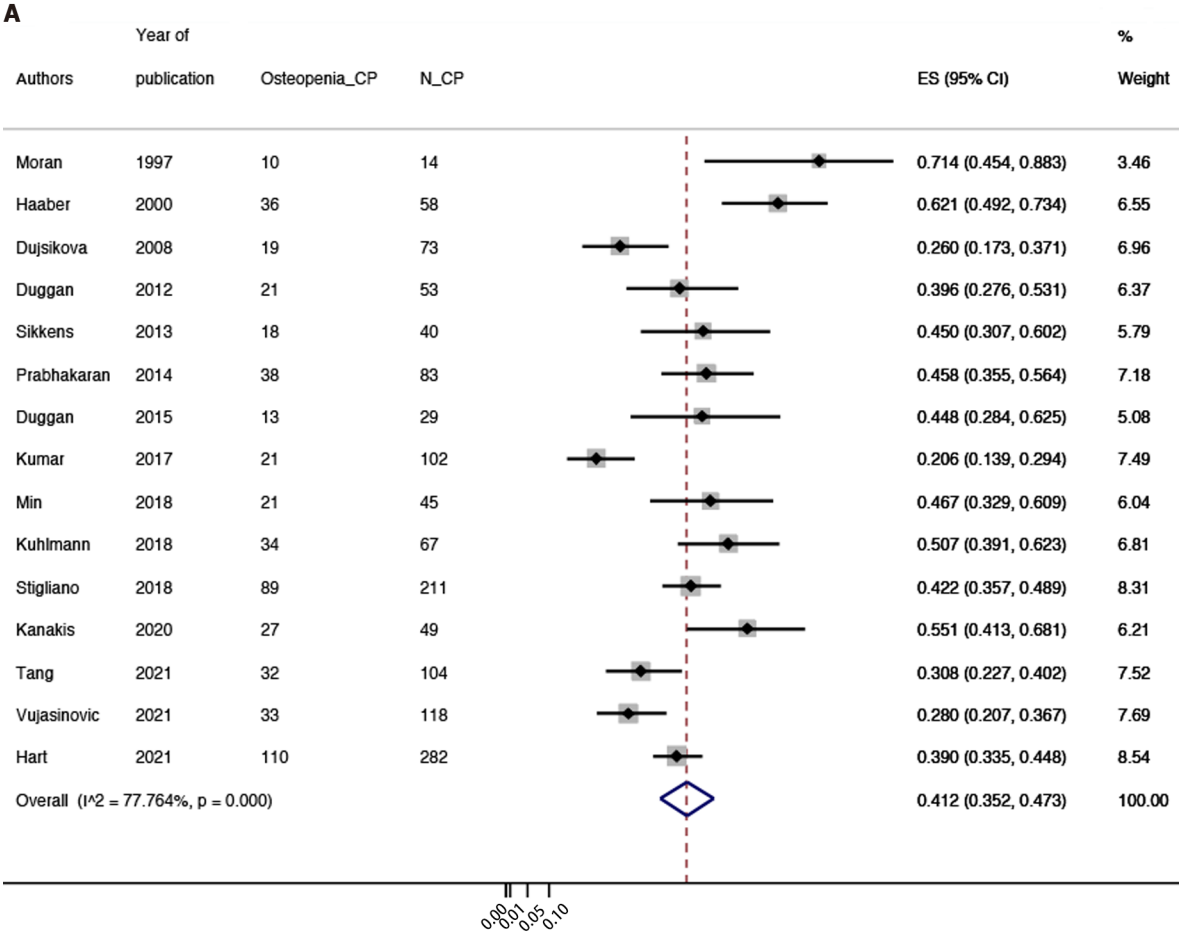
Study quality and publication bias assessment

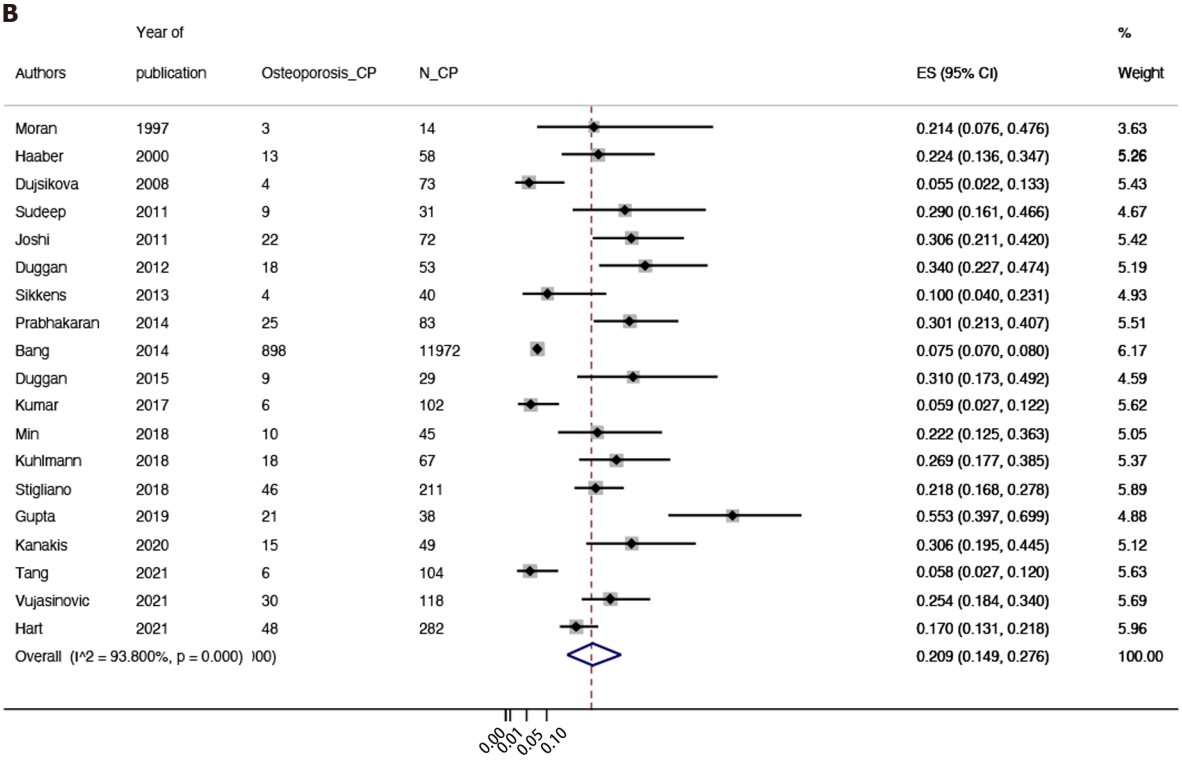
All the observational studies were assessed for quality in selection, comparability, and outcome/exposure domain and their scores ranged from 5-8 and were in good agreement (93% agreement, Cohen's κ = 0.87) (Supplementary Table 5). The comparability domain was variable based upon the presence or absence of controls. Visual inspection of funnel plot and Egger's regression for studies describing osteopenia ($P = 0.003$), and osteoporosis ($P < 0.001$) demonstrated significant publication bias (Figure 3).

DISCUSSION



Through this systematic review we present the burden of osteopenia, osteoporosis, and fragility fractures in CP patients. The majority of the studies used bone mineral density to quantitate bone disease, which is a validated tool for use in the general population[36]. Our meta-analyses revealed osteopenia and osteoporosis to be prevalent in 41.2% and 20.9% of the CP population, respectively. We also observed a fracture risk of 5.9% among CP patients, which includes low trauma fractures predominantly in the hip, vertebrae and distal radius. These may cause pain, falls, and hospitalizations which may significantly impair the lives of CP patients along with pre-existing morbidities like malabsorption and chronic abdominal pain[37].

Although dedicated studies among CP patients are lacking, reduced bone mass and resultant fractures cause significant pain, reduced functionality, and quality of life in both men and women[38]. Chronic inflammatory conditions affecting the gastrointestinal tract, such as inflammatory bowel disease, celiac disease and chronic liver disease have been known to disrupt the balance between bone resorption and formation and cause bone disease. Histomorphometric analysis among alcohol related CP patients has revealed low cortical and trabecular bone thickness and endocortical apposition and growth rate as compared to controls[39]. Similarly, increased bone turnover and mineralization defects due to malnutrition have been observed in CP[27,40]. Although recent CP guidelines in the United States and Europe have suggested surveillance of bone-related disorders, studies report poor adherence to these guidelines, suggesting CP-related bone disease is an underappreciated clinical entity[7,8].



CP-related bone disease has been quantified previously by Duggan *et al*[9] in 2014 who observed similar prevalence of osteopenia and osteoporosis *i.e.*, 39.8% and 23.4%, respectively. Since this publication, over the past decade, several additional observational studies have investigated bone mineral density and metabolism in CP patients[7,8,24,25,27-31,33,34], and therefore, provide a unique opportunity to further investigate the evidence in this clinical domain. Hence, we appraised all the available literature, including the most recent publications, in an effort to contribute evidence for future by also uniquely quantifying fragility fractures which are significant complications of CP-related bone disease.

The current systematic review is powered by high-quality studies with large sample size and clearly defined study population and outcome measures. In addition, strengths of the study include a clearly articulated a priori analysis plan, a thorough search strategy and a conservative analysis. However, our study is limited by variability in the CP definitions from centers worldwide and spanning over 2

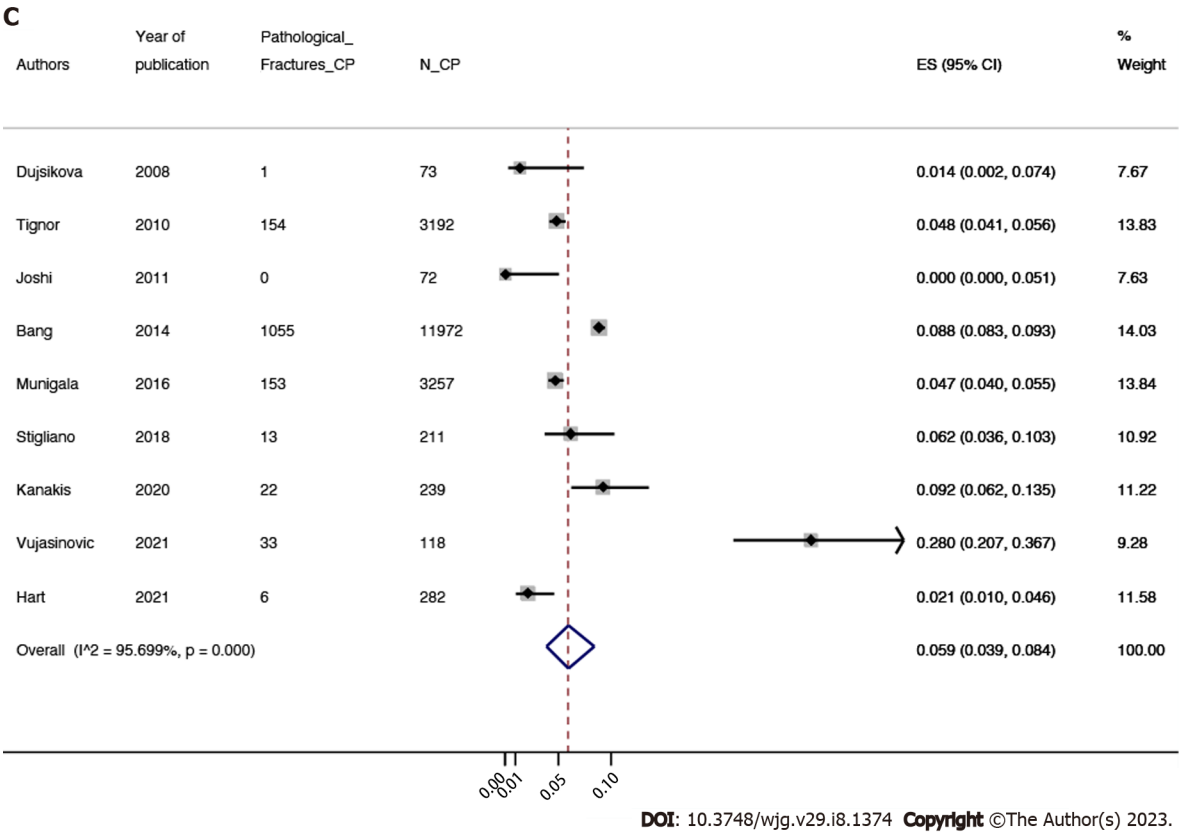

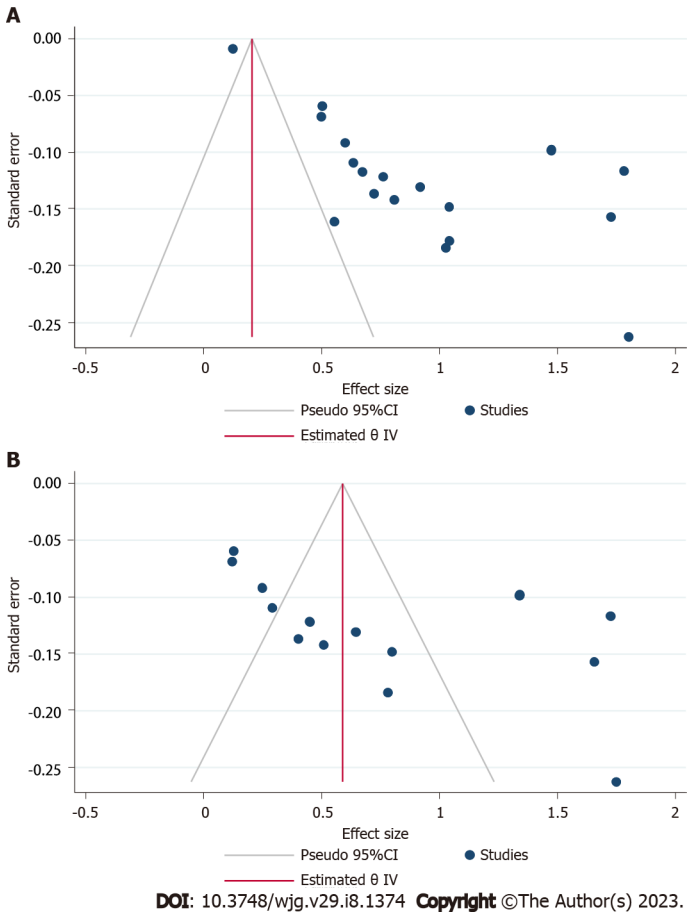

Figure 2 Forest plot demonstrating pooled prevalence of bone disease in chronic pancreatitis. A: Forest plot demonstrating pooled prevalence of osteopenia in chronic pancreatitis (CP); B: Forest plot demonstrating pooled prevalence of osteoporosis in CP; C: Forest plot demonstrating pooled prevalence of fragility fractures in CP. ES: Effect size; N: Total chronic pancreatitis population.

decades. Besides inconsistencies in definitions, high heterogeneity in the effect sizes is evident from I^2 mandated performance of metaregression and sensitivity analysis. The heterogeneity was not attributable to any specific study as demonstrated by sensitivity analysis. We observed significant association of osteoporosis with patients with PERT use on metaregression analysis. Although PERT use signifies severe disease, this association doesn't not establish causality and this in conjunction with limited information on the dosage of PERT or nutritional outcomes prevent substantial inferences to be drawn from this association[41]. We acknowledge significant publication bias, and a priori exclusion of studies in foreign language and conference abstracts[42]. These limitations prevent making categorical recommendations to patients.

Various mechanisms have been hypothesized to cause CP-mediated bone disease. Risk factors for CP such as cigarette smoking and alcohol exposure have been proven to alter the PTH-vitamin D axis and gonadal hormones and cause oxidative stress[39,43-46]. This clinical entity is also hypothesized to be driven by RANK ligand-induced osteoclastogenesis typically stimulated by inflammation-mediated nuclear factor-kappa B ligand[47]. Prior studies have also evaluated the relation of CP with inflammatory markers, such as IL-6, IL-1, and tumor necrosis factor-alpha[48]. Protein malnutrition lowers bone mass whereas deficiency of fat-soluble vitamins contributes to defects in mineralization and thus causes osteoporosis and resultant stress fracture[49,50]. CP is also characterized by low skeletal muscle, weight loss, and low mobility, all of which negatively impacts bone mass[51-53].

CP-related bone disease warrants further investigation to answer a few clinical queries. While CP patients are at risk, the impact of disease severity and duration on bone outcomes are unknown. Additionally, poor correlation between clinical symptomatology, severity and imaging findings in CP patients presents challenges for research[54]. We also systematically assessed various confounders including baseline clinical features and impact of bone turnover and inflammatory markers, albeit our results were unremarkable. The evidence on calcium supplements, hormone levels and outdoor activity among included studies was lacking. The studies that investigated mechanisms of systemic inflammation, bone turn over and malabsorption were underpowered, whereas those pertaining to vitamin D had conflicted evidence[17,18,21,22,27-30,32]. Among this at-risk group, efficacy of preventative therapy for osteoporotic fracture, drug interactions, and adverse effect also remain elusive.

Figure 3 Funnel plots showing the publication bias assessment in studies describing patients with osteopenia and osteoporosis. A: Osteopenia ($Z = 2.9$, $P = 0.003$); B: Osteoporosis ($Z = 4.7$, $P < 0.001$).

CONCLUSION

In summary, this meta-analysis confirms significant bone disease in patients with CP. We observed significant association of PERT with CP related osteoporosis. Our study calls for improved methodology dedicated at delineation of confounders and studies targeting identification of at-risk CP patients, deeper understanding of mechanisms of CP related bone disease and their implications of treatment response. Fragility fractures are an important consequence of bone disease, which we have found to be increased in patients with CP. Screening strategies in this at-risk population with CP are needed as well as evaluating quality of life due to consequences of bone disease.

ARTICLE HIGHLIGHTS

Research background

Chronic pancreatitis (CP) is a multifactorial fibro-inflammatory syndrome is characterized by nutritional deficiencies, systemic inflammation, and etiological factors like alcohol or smoking may disrupt the balance between bone formation and resorption. These maladaptive alterations may cause osteopenia and osteoporosis, resulting in fragility fractures which result from low energy trauma and have significant implications on quality of life.

Research motivation

Multiple large-sized studies on CP patients including those from multicenter cohorts have investigated the burden of bone disease in CP as well as their association with nutritional, anthropometric, and inflammatory parameters. Thus, with quantitative data on covariates and fragility fractures available, a synthesis of evidence is pertinent.

Research objectives

This systematic review and meta-analysis sought to quantify the prevalence of osteopenia, osteoporosis,

and fragility fractures in CP patients and delineate clinical parameters which impact their occurrence.

Research methods

The study included systematic review and then metanalysis of studies describing bone disease in CP patients. A preregistered systematic search enabled identification of original studies from Cochrane Library, Embase, Google Scholar, Ovid Medline, PubMed, Scopus, and Web of Science, from inception until October 2022. The metanalysis was performed using random effect model and the outcomes of interest included prevalence of osteopenia, osteoporosis, and fragility fractures. To assess the association of these outcomes with covariates metaregression using random effect model was performed.

Research results

Twenty-one studies were included for systematic review and 18 studies were included for meta-analysis. The pooled prevalence of osteopenia and osteoporosis in CP patients was 41.2% (95%CI: 35.2%-47.3%) and 20.9% (95%CI: 14.9%-27.6%), respectively. The pooled prevalence of fragility fractures described among CP was 5.9% (95%CI: 3.9%-8.4%). Meta-regression showed no associations of bone outcomes in CP patients with mean age, sex distribution, body mass index, alcohol or smoking exposure, diabetes, serum parathyroid levels, and vitamin D deficiency with prevalence of osteopenia, osteoporosis or fragility fractures. A significant association of pancreatic enzyme replacement therapy use with prevalence of osteoporosis [coefficient: 1.7 (95%CI: 0.6-2.8); $P < 0.0001$]. Due to sparse data on systemic inflammation, CP severity, and bone mineralization parameters a formal meta-analysis was not feasible.

Research conclusions

This meta-analysis confirms significant bone disease: Osteopenia, osteoporosis, and fragility fractures in CP patients. Although pancreatic enzyme use had significant association with osteoporosis, the link between osteopathy and various patient or study-specific factors remains unclear. Further investigation is needed for delineation of at-risk population, to understand the mechanisms of CP-related bone disease, and assess the therapeutic response to treatment modalities.

Research perspectives

Our study calls for dedicated studies targeting delineation of confounders and identification of at-risk features in CP patients. There is also a knowledge gap in therapeutic response among CP patients with bone disease.
