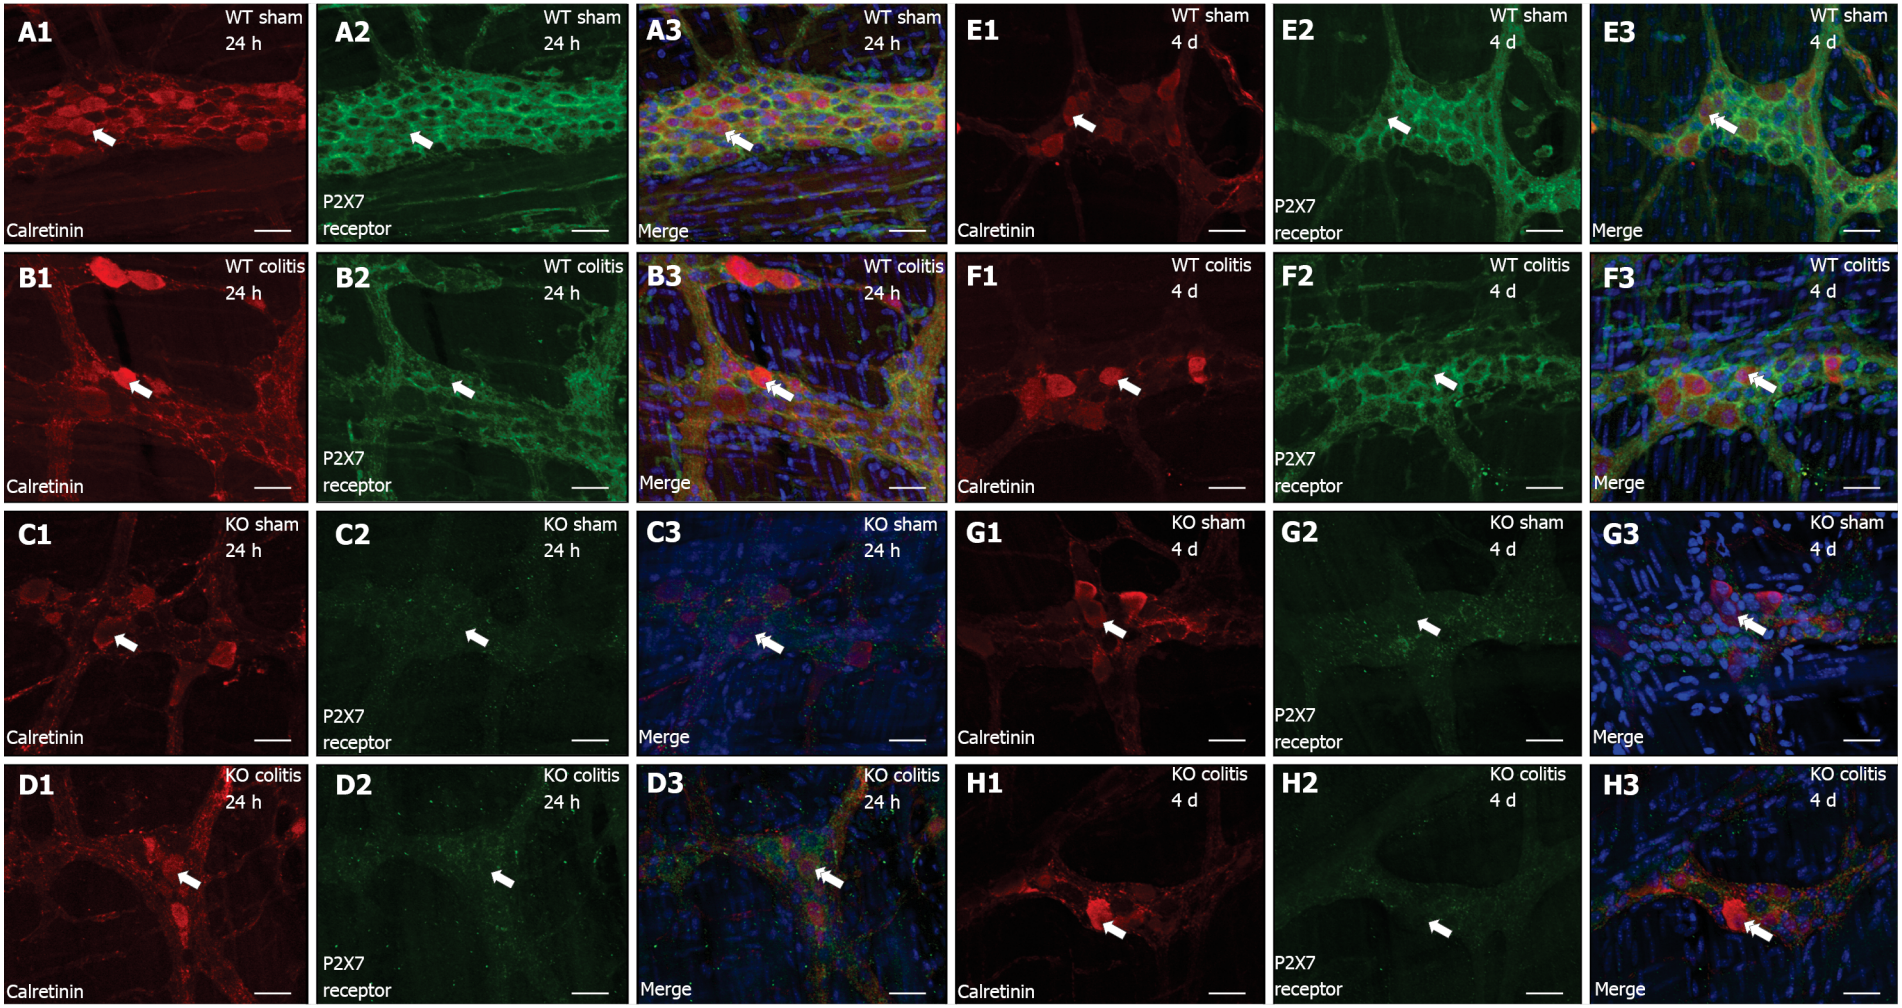
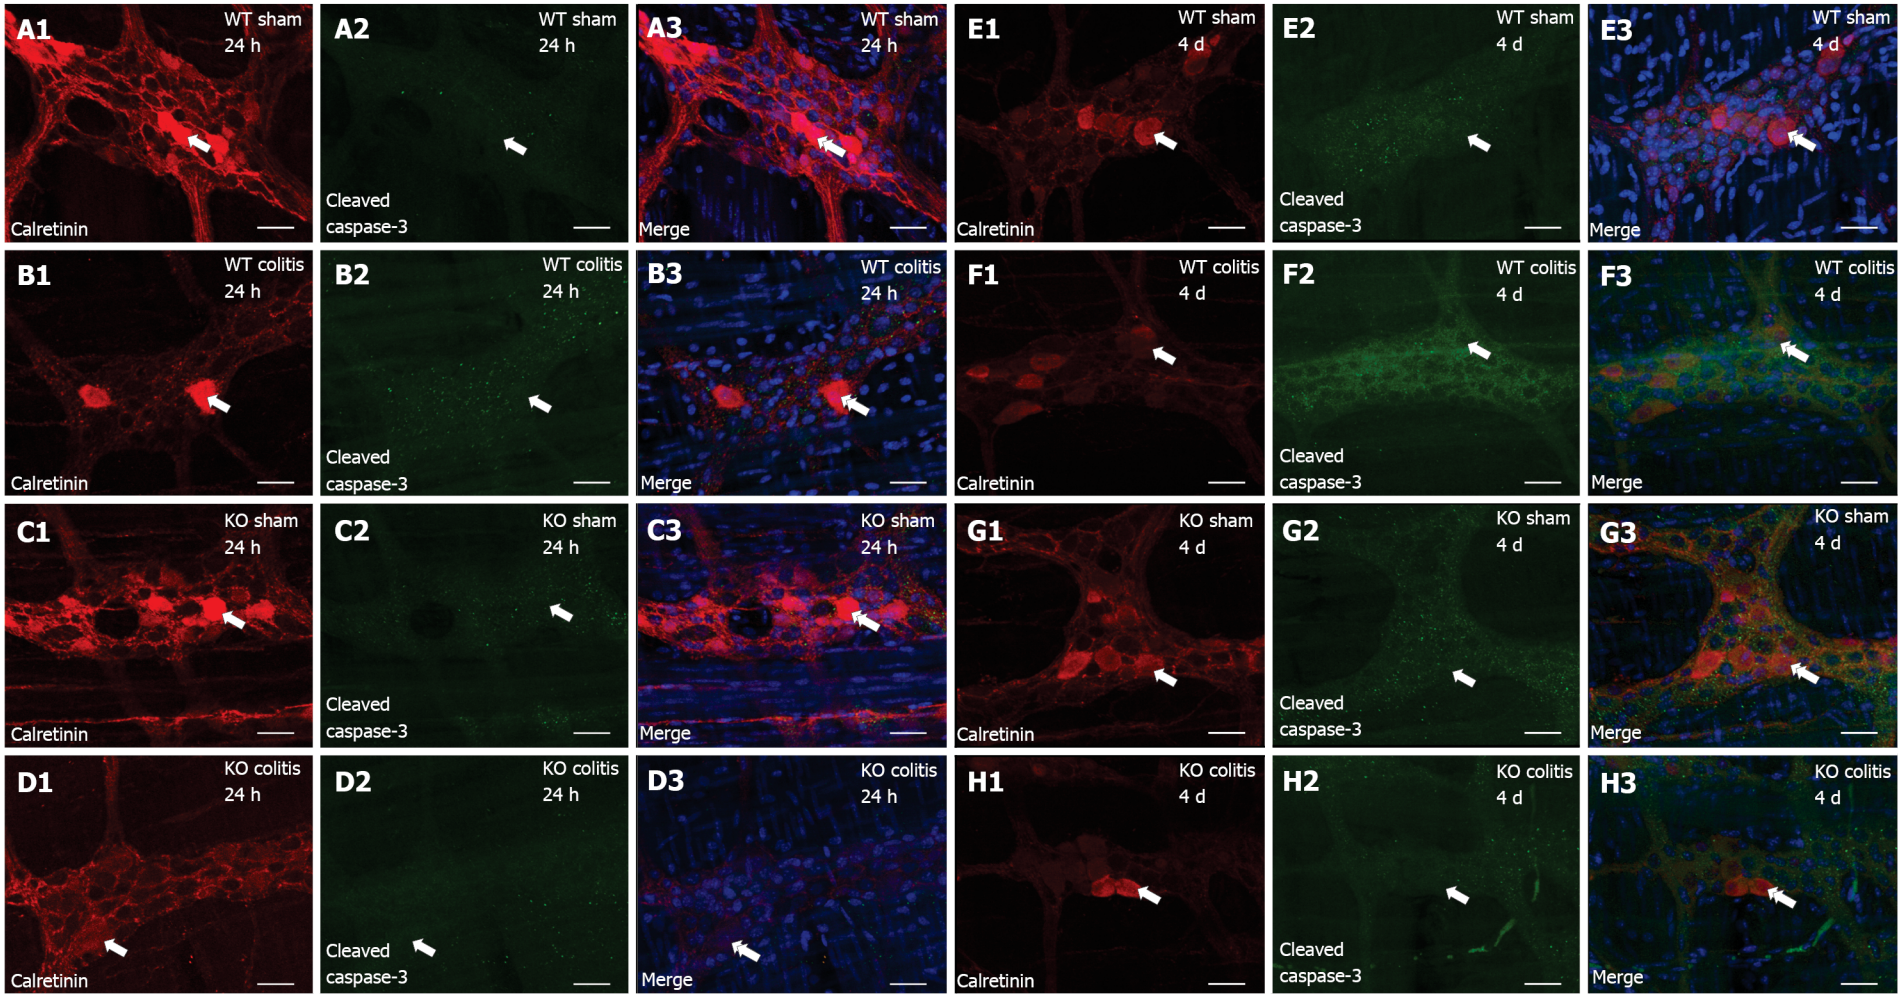
The presence of ulcers, severity of edema in the submucosal layer, and degree of inflammatory cell infiltration were assessed by histological analysis. NS: Not significant; WT: Wild-type; KO: Knockout.



Quantitative analyses

The number of calretinin-ir neurons per myenteric ganglion of the distal colon was decreased by 36.9% in the WT colitis 24 h group compared to the WT sham 24 h group (2.1 ± 0.13 *vs* 3.33 ± 0.17, $P < 0.001$) and decreased by 21.1% in the WT colitis 4 d group compared to the WT sham 4 d group (2.92 ± 0.12 *vs* 3.7 ± 0.11, $P < 0.05$). No statistically significant differences in calretinin-ir neuron density were observed between the KO colitis (24 h and 4 d) groups and the KO sham (24 h and 4 d) groups (Figure 7A).

The number of P2X7-ir receptor neurons per myenteric ganglion of the distal colon was decreased by 12.2% in the WT colitis 24 h group compared to the WT sham 24 h group (19.49 ± 0.35 *vs* 22.21 ± 0.18, $P < 0.001$) and decreased by 10.5% in the WT colitis 4 d group compared to the WT sham 4 d group (20.35 ± 0.14 *vs* 22.75 ± 0.51, $P < 0.001$). No P2X7 receptor-ir neurons were observed in the myenteric ganglia in the KO sham (24 h and 4 d) or KO colitis (24 h and 4 d) groups (Figure 7B).



The profile area of calretinin-ir neurons in the myenteric plexus of the distal colon was increased by 10.9% in the WT colitis 24 h group compared to the WT sham 24 h group (312.6 ± 7.85 *vs* 278.41 ± 6.65, $P < 0.05$) and increased by 14.6% in the KO colitis 24 h group compared to the KO sham 24 h group (302.99 ± 16.78 *vs* 258.67 ± 9.49, $P < 0.01$). The neuronal profile area was decreased by 16.4% in the WT colitis 4 d group compared to the WT sham 4 d group (277.23 ± 9.94 *vs* 331.54 ± 7.63, $P < 0.001$), and there was no difference in this measure between the KO colitis 4 d and KO sham 4 d groups (Figure 8A). The nuclear profile area in the WT colitis 4 d group was decreased by 10.9% compared to that in the WT sham 4 d group (104.63 ± 2.49 *vs* 117.41 ± 1.14, $P < 0.01$). No statistically significant differences in nuclear profile area were observed between the KO colitis (24 h and 4 d) groups and the KO sham (24 h and 4 d) groups (Figure 8B). The cytoplasmic profile area of calretinin-ir neurons in the myenteric plexus of the distal colon was increased by 15% in the WT colitis 24 h group compared to the WT sham 24 h group (195.86 ± 6.88 *vs* 166.37 ± 5.98, $P < 0.05$) and increased by 20.4% in the KO colitis 24 h group compared to the KO sham 24 h group (178.88 ± 15.52 *vs* 142.41 ± 8.62, $P < 0.05$). The cytoplasmic profile area in the WT colitis 4 d group was decreased by 19.4% compared with that in the WT sham 4 d group (172.61 ± 10.4 *vs* 214.13 ± 6.73, $P < 0.01$). No statistically significant difference in the cytoplasmic profile area was observed between the KO colitis 4 d group and the KO sham 4 d group (Figure 8C).

The profile area of calretinin-ir neurons in the myenteric plexus of the distal colon ranged from 50 μm^2 to 1050 μm^2. In the WT sham 24 h, WT colitis 24 h and KO colitis 24 h groups, 54.4%, 48.0%, and 59.5% of calretinin-ir neurons, respectively, had an area between 200 μm^2 and 300 μm^2. In the KO sham 24 h group, 58.5% of neurons had an area between 100 μm^2 and 200 μm^2 (Figure 9A). In the WT sham 4 d, WT colitis 4 d, KO sham 4 d and KO colitis 4 d groups, 58.1%, 65.6%, 62.7% and 60.6% of calretinin-ir neurons, respectively, had an area between 200 μm^2 and 300 μm^2 (Figure 9B). The nuclear profile area of these same calretinin-ir neurons ranged from 50 μm^2 to 230 μm^2. In the WT sham 24 h and KO sham 24 h groups, 57.9% and 52.6% of calretinin-ir neurons, respectively, had a nuclear area between 90 μm^2 and 110 μm^2. In the WT colitis 24 h and KO colitis 24 h groups, 62.4% and 55.5% of calretinin-ir neurons, respectively, had a nuclear area between 110 μm^2 and 130 μm^2 (Figure 9C). In the WT colitis 4 d group, 63.5% of calretinin-ir neurons had a nuclear area between 90 μm^2 and 110 μm^2, and in the WT sham 4 d, KO sham 4 d and KO colitis 4 d groups, 62.4%, 52.6% and 55% of calretinin-ir neurons, respectively, had a nuclear area between 110 μm^2 and 130 μm^2 (Figure 9D). Finally, the cytoplasmic profile area of these same calretinin-ir neurons ranged from 0 μm^2 to 840 μm^2. In the WT sham 24 h and WT colitis 24 h groups, 55.3% and 50.2% of calretinin-ir neurons, respectively, had a cytoplasmic area between 130 μm^2

Figure 8 Neuronal, nuclear, and cytoplasmic profile areas of calretinin-ir neurons in the myenteric plexus of the distal colon in mice from the wild-type sham 24 h and 4 d, wild-type colitis 24 h and 4 d, knockout sham 24 h and 4 d, and knockout colitis 24 h and 4 d groups. A: Neuronal; B: Nuclear; C: Cytoplasmic. The data are presented as the arithmetic mean ± SE. [a]*P* < 0.05 *vs* sham groups; [b]*P* < 0.01 *vs* sham groups; [c]*P* < 0.001 *vs* sham groups; NS: Not significant. WT: Wild-type; KO: Knockout.

and 230 μm². In the KO sham 24 h and KO colitis 24 h groups, 69% and 59.3% of calretinin-ir neurons, respectively, had a cytoplasmic area between 30 μm² and 130 μm² (Figure 9E). In the WT sham 4 d, WT colitis 4 d, KO sham 4 d and KO colitis 4 d groups, 59.7%, 63%, 60.5% and 60.5% of calretinin-ir neurons, respectively, had a cytoplasmic area between 130 μm² and 230 μm² (Figure 9F).

The CTCF of calretinin-ir ganglia in the myenteric plexus of the distal colon was decreased by 24.5% in the WT colitis 24 h group compared to the WT sham 24 h group (2322102 ± 154255 *vs* 3076921 ± 104235, $P < 0.001$) and was decreased by 13.7% in the WT colitis 4 d group compared to the WT sham 4 d group (2976603 ± 52989 *vs* 3452123 ± 30894, $P < 0.01$). No statistically significant differences in the CTCF of calretinin-ir myenteric ganglia were observed between the KO colitis (24 h and 4 d) groups and the KO sham (24 h and 4 d) groups (Figure 10A).

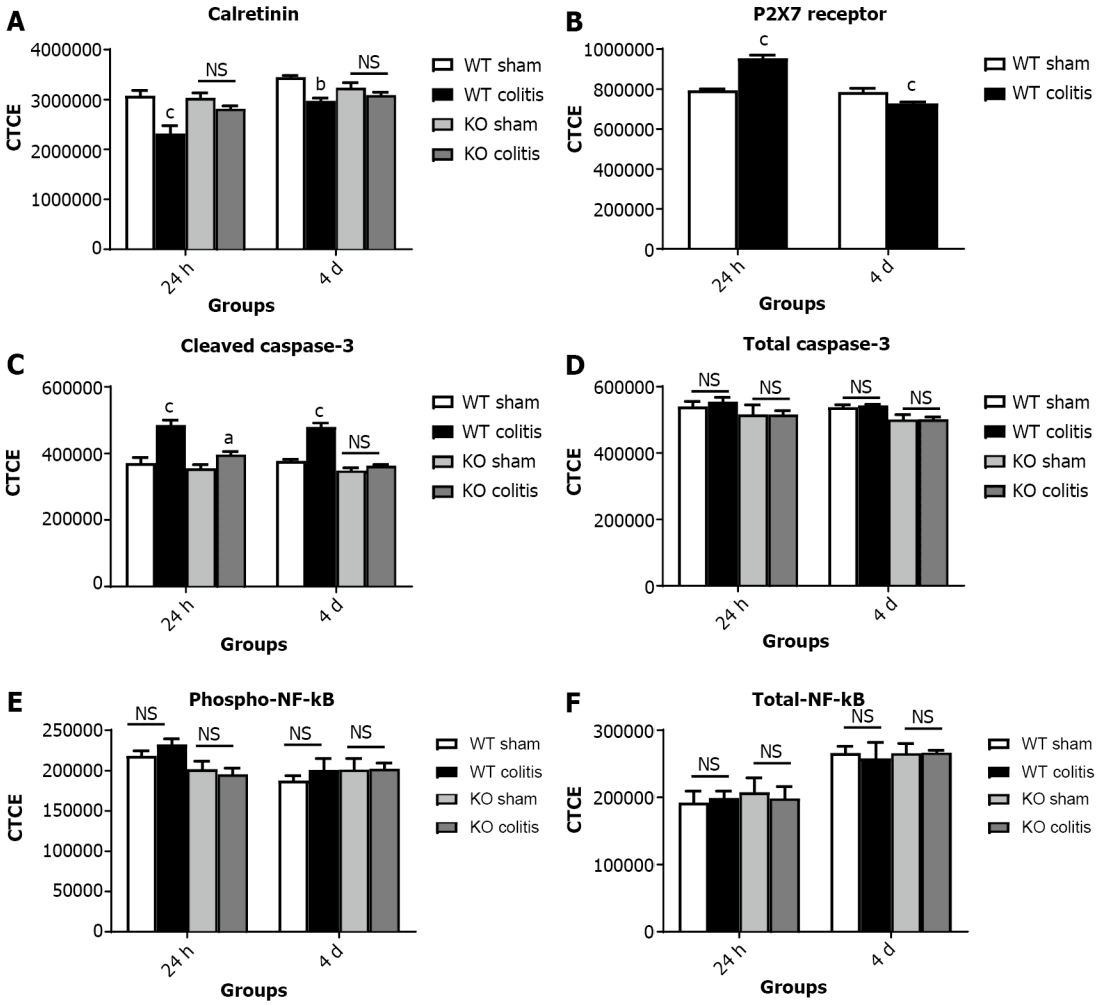

Figure 9 Distribution frequency (%) of the profile areas. A and B: Calretinin-ir neurons; C and D: Calretinin-ir nucleus; E and F: Calretinin-ir cytoplasm in the myenteric plexus of the distal colon in mice from the wild-type (WT) sham 24 h and 4 d, WT colitis 24 h and 4 d, knockout (KO) sham 24 h and 4 d, and KO colitis 24 h and 4 d groups. WT: Wild-type; KO: Knockout.

The CTCF of P2X7 receptor-ir ganglia in the myenteric plexus of the distal colon was increased by 16.8% in the WT colitis 24 h group compared to the WT sham 24 h group (953784 ± 15825 *vs* 793451 ± 6809, $P < 0.001$) and decreased by 7.2% in the WT colitis 4 d group compared to the WT sham 4 d group (728412 ± 6295 *vs* 785419 ± 18143, $P < 0.01$). P2X7 receptor expression was not observed in the myenteric ganglia in the KO sham (24 h and 4 d) and KO colitis (24 h and 4 d) groups (Figure 10B).

The CTCF of cleaved caspase-3-ir ganglia in the myenteric plexus of the distal colon was increased by 23.6% in the WT colitis 24 h group compared to the WT sham 24 h group (485949 ± 14140 *vs* 371371 ± 16426, $P < 0.001$) and increased by 10.5% in the KO colitis 24 h group compared to the KO sham 24 h group (396888 ± 8737 *vs* 355154 ± 11060, $P < 0.05$). The CTCF of cleaved caspase-3-ir myenteric ganglia was increased by 21.2% in the WT colitis 4 d group compared to the WT sham 4 d group (480381 ± 11336 *vs* 378365 ± 4053, $P < 0.001$). No statistically significant difference in the CTCF of cleaved caspase-3-ir myenteric ganglia was observed between the KO colitis 4 d group and the KO sham 4 d group (Figure 10C). In addition, no statistically significant difference in the CTCF of total caspase-3-ir (Figure 10D), phospho-NF-κB-ir (Figure 10E) and total NF-κB-ir (Figure 10F) ganglia was observed between the WT colitis (24 h and 4 d) and WT sham (24 h and 4 d) groups or between the KO colitis (24 h and 4 d) and KO sham (24 h and 4 d) groups.

Transmission electron microscopy

Transmission electron microscopy was used to assess the ultrastructural morphology of the myenteric plexus of the distal colon in mice from all groups. Myenteric neurons, neuronal nuclei and organelles, and the interaction between neurons and enteric glial cells were visualized. In the WT colitis 24 h and KO colitis 24 h groups, neurons with a necrotic phenotype characterized mainly by nuclear disruption and apparent nuclear autolysis, chromatin fragmentation and condensation, and cytoplasmic disorganization were observed. Enteric glial cells also showed morphological changes similar to those of neurons. In the WT colitis 4 d group and less frequently in the KO colitis 4 d group, neurons showed irregular nuclei and nuclear membrane invaginations. The cell membrane remained intact, and apoptotic bodies were sometimes observed. Enteric glial cells also showed features consistent with apoptosis. In the WT sham (24 h and 4 d) and KO sham (24 h and 4 d) groups, neurons showed large and round/oval nuclei and no sign of structural disruption in the cytoplasm (Figure 11).

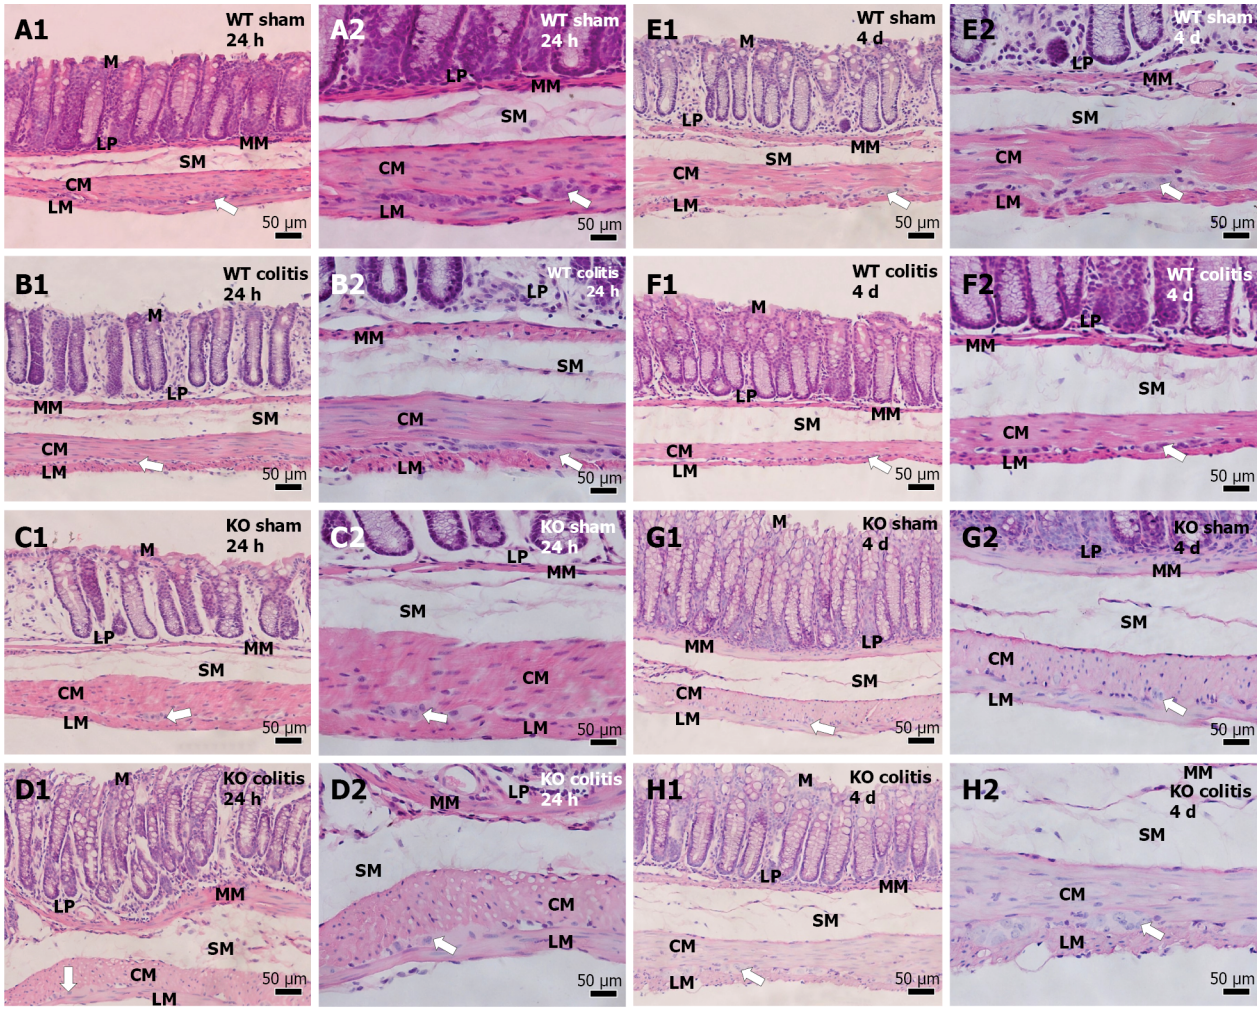
Figure 10 Corrected total cell fluorescence of myenteric neurons. A: calretinin; B: P2X7 receptor; C: Cleaved caspase-3; D: Total caspase-3; E: Phospho-nuclear factor kappa B (NF-κB); F: Total NF-κB in the myenteric plexus of the distal colon in mice from the WT sham 24 h and 4 d, wild-type (WT) colitis 24 h and 4 d, knockout (KO) sham 24 h and 4 d, and KO colitis 24 h and 4 d groups. The data are presented as the arithmetic mean ± SE. [a]*P* < 0.05 *vs* sham groups; [b]*P* < 0.01 *vs* sham groups; [c]*P* < 0.001 *vs* sham groups; NS: Not significant. WT: Wild-type; KO: Knockout; NF-κB: Nuclear factor kappa B.

Histology



Distal colon morphology was evaluated by hematoxylin and eosin staining. In the WT sham 24 h, KO sham 24 h, WT sham 4 d, and KO sham 4 d groups, the mucosa and submucosal layers, the intestinal crypts, the lamina propria, and the longitudinal and circular muscles were intact. In the WT colitis 24 h group, tissue damage characterized by cellular disruption in the mucosal layer and thickening of the lamina propria was noted. Increased infiltration of inflammatory cells in the lamina propria and evident edema in the submucosal layer were also observed. Furthermore, the distal colon architecture was better preserved, and there were fewer inflammatory cells and less severe submucosal edema in the KO colitis 24 h, WT colitis 4 d, and KO colitis 4 d groups than in the WT colitis 24 h group (Figure 12).

Picrosirius red staining revealed the presence of thick fibers (red) in the lamina propria, in the submucosal layer, intermingled with and surrounding the muscle layer, and circumscribing the myenteric ganglia, the presence of fine fibers (green under polarized light microscopy) in the lamina propria and submucosal layer, and the presence of mixed fibers (yellow under polarized light microscopy) in all regions of the intestinal tissue in the WT sham 24 h and WT sham 4 d groups. In contrast, in the WT colitis 24 h group, the number of thick collagen fibers in the submucosal layer and around the myenteric ganglia was increased, and collagen fibers were increased in number and disorganized in the lamina propria and accumulated in the subepithelial region. In the KO sham 24 h group, greater integrity and organization of collagen fibers was visualized in the submucosal layer. In the KO colitis 24 h group, there were fewer thick collagen fibers in the lamina propria and involving the myenteric ganglia and more disordered fibers in the submucosa and subepithelial region than in the corresponding sham group. The tissue in the WT colitis 4 d group was very similar to that in the WT colitis 24 h group. However, there were more thick collagen fibers around the myenteric ganglia, and they were better organized in the submucosal layer due to more discrete local edema. Tissue

Figure 12 Photomicrographs of hematoxylin-eosin-stained transverse sections of the distal colons of mice of different groups. A1 and A2: Wild-type (WT) sham 24 h; B1 and B2: WT colitis 24 h; C1 and C2: Knockout (KO) sham 24 h; D1 and D2: KO colitis 24 h; E1 and E2: WT sham 4 d; F1 and F2: WT colitis 4 d; G1 and G2: KO sham 4 d; H1 and H2: KO colitis 4 d groups. Tissue integrity was maintained in the sham groups, and cellular disruption and thickening of the lamina propria and submucosal layer were observed in the WT colitis group. Tissue was better preserved, and there were fewer inflammatory cells in the KO colitis group than in the WT colitis group. M: Mucosal layer; LP: Lamina propria; MM: Mucosal muscle; SM: Submucosal layer; ML: Muscle layer; CM: Circular musculature; LM: Longitudinal musculature; WT: Wild-type; KO: Knockout. White arrows mean myenteric ganglion.

architecture was similar between the KO sham 4 d and KO colitis 4 d groups and the KO sham 24 h and KO colitis 24 h groups (Figure 13).

Masson's trichome staining demonstrated that in the WT sham 24 h, KO sham 24 h, and WT sham 4 d groups, collagen fibers (blue) were present in the lamina propria and between the mucosal muscle and muscle layer (muscle fibers and cell nuclei shown in red) and enveloped the myenteric ganglia, and there were more collagen fibers throughout the submucosal layer. In the WT colitis 24 h and WT colitis 4 d groups, a greater number of collagen fibers was observed in the lamina propria, and collagen fibers were interspersed in the muscle layer. There were fewer collagen fibers in the submucosal layer, and the collagen fibers in this layer were hyperplastic and disorganized. The tissue structure in the KO colitis 24 h group was similar to that in the KO sham 24 h group, but there were fewer collagen fibers in the submucosal layer. Tissue architecture was similar between the KO sham 4 d and KO colitis 4 d groups and the WT sham 4 d and WT colitis 4 d groups; however, in both the KO sham and KO colitis groups, the collagen fibers in the submucosal layer were more organized (Figure 14).

Periodic acid-Schiff staining was performed to evaluate the presence and morphology of goblet cells in the distal colon. In the WT sham 24 h and WT sham 4 d groups, goblet cells in the distal colon were present throughout the epithelium, typically showed a columnar or oval shape and were circular when filled with mucus. In the WT colitis 24 h group, these cells were present in smaller quantities, were reduced in size, and presented a more rounded shape with an intumescent appearance. On the other hand, in the KO sham 24 h and KO colitis 24 h groups, the number of goblet cells was apparently increased. In the KO sham 24 h group, the cells were similar in size to those in the WT sham group, and in the KO colitis 24 h group, there was a more heterogeneous cell population. In the WT colitis 4 d group, goblet cells were apparently increased in number but still reduced in size. However, larger cells

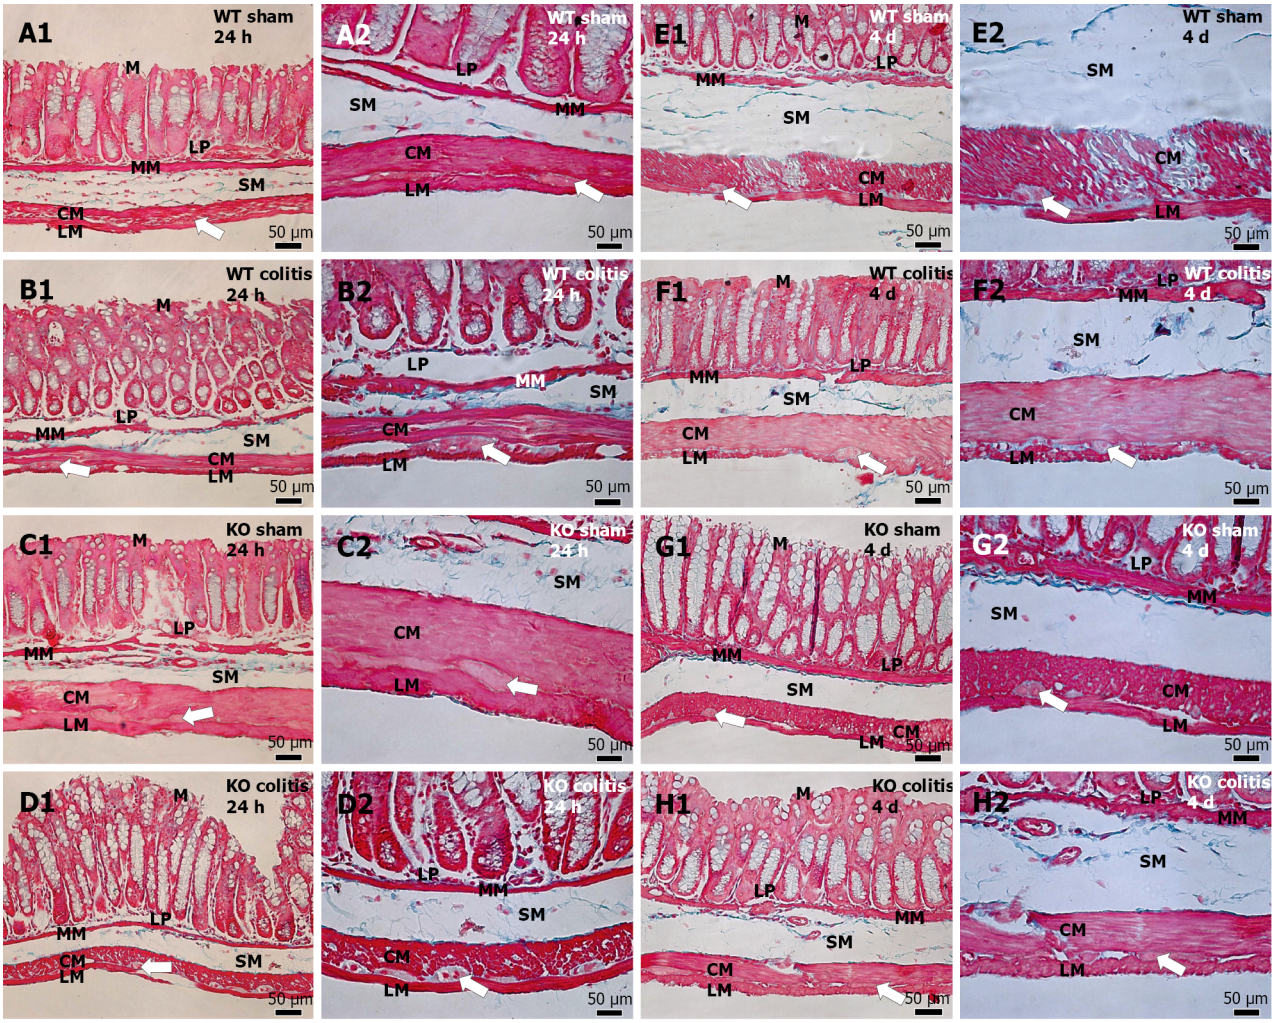

Figure 13 Photomicrograph of picrosirius red-stained transverse sections of the distal colons of mice of different groups. A1 and A2: Wild-type (WT) sham 24 h; B1 and B2: WT colitis 24 h; C1 and C2: Knockout (KO) sham 24 h; D1 and D2: KO colitis 24 h; E1 and E2: WT sham 4 d; F1 and F2: WT colitis 4 d; G1 and G2: KO sham 4 d; H1 and H2: KO colitis 4 d groups taken under an optical light (red) or polarized light (green) microscope. Thick collagen fibers (red) in the lamina propria and submucosal layer, intermingled with and involving the muscle layer, and circumscribing the myenteric ganglia were observed in the sham groups. In the WT colitis group, there was a decrease in the number of these fibers in the submucosal layer and around the myenteric ganglia, an increase in the number and disorganization of these fibers in the lamina propria and accumulation of these fibers in the subepithelial region. Tissue was better preserved in the KO colitis group. M: Mucosal layer; LP: Lamina propria; MM: Mucosal muscle; SM: Submucosal layer; ML: Muscle layer; CM: Circular musculature; LM: Longitudinal musculature; WT: Wild-type; KO: Knockout. White arrows mean myenteric ganglion.

were also observed near the surface of the intestinal crypts. Finally, there was a notable increase in the number of goblet cells in the distal colon in the KO sham 4 d and KO colitis 4 d groups (Figure 15).

Number of goblet cells per intestinal crypt: The number of goblet cells per intestinal crypt in the distal colon was decreased by 37.6% in the WT colitis 24 h group compared to the WT sham 24 h group (8.63 ± 0.43 *vs* 13.84 ± 1.00, $P < 0.01$). No statistically significant differences in the goblet cell density were observed between the KO colitis (24 h and 4 d) groups and the KO sham (24 h and 4 d) groups, but the goblet cell density was significantly different between the WT and KO groups ($P < 0.001$). In the KO groups, there was a greater number of goblet cells per intestinal crypt (Figure 16).

DISCUSSION

Despite the large amount of research on IBDs, the pathogenesis of these diseases is still unclear[74,75]. However, it is known that changes in the interaction between immune cells and the gut microbiota may contribute to the clinical progression of IBDs[76-80] and that nonimmune components may alter cellular structure and function in response to inflammation[81]. Indeed, recent evidence has indicated that colitis affects not only the intestinal mucosa but also the muscle layer and components of the ENS. Hence, gastrointestinal symptoms result from degenerative changes and a reduction in the number of

Figure 14 Photomicrographs of Masson's trichrome-stained transverse sections of the distal colons of mice in different groups. A1 and A2: Wild-type (WT) sham 24 h; B1 and B2: WT colitis 24 h; C1 and C2: Knockout (KO) sham 24 h; D1 and D2: KO colitis 24 h; E1 and E2: WT sham 4 d; F1 and F2: WT colitis 4 d; G1 and G2: KO sham 4 d; H1 and H2: KO colitis 4 d groups. Collagen fibers (blue) in the lamina propria and submucosal layer, intermingled with and involving the muscle layer, and circumscribing the myenteric ganglia were observed in the sham groups. In the WT colitis group, there was a decrease in the number of these fibers in the submucosal layer, and the collagen fibers in this layer were hyperplastic and disorganized. Moreover, the number of collagen fibers was increased in the lamina propria, and collagen fibers were intermingled in the muscular layer. Tissue was better preserved in the KO colitis group. WT: Wild-type; KO: Knockout; M: Mucosal layer; LP: Lamina propria; MM: Mucosal muscle; SM: Submucosal layer; ML: Muscle layer; CM: Circular musculature; LM: Longitudinal musculature; White arrows: Myenteric ganglion.

enteric neurons and glial cells, sometimes induced by the P2X7 receptor[35-40,48,50,62,63,82-84]. However, little is known about the cellular signaling mechanisms responsible for the loss of enteric innervation in IBDs[85].

In the present study, we hypothesized that the loss of myenteric neurons resulting from TNBS-induced colitis is related to cell death pathways mediated by caspase-3 and NF-κB-mediated transcription. In addition, we hypothesized that KO animals would be less affected by administration of an inflammatory stimulus. We compared pathological changes at two different time points after colitis induction. At both 24 h and four days post-inflammatory stimulus administration, there was a significant reduction in the number of myenteric neurons in the WT groups but not in the KO groups. In addition, the neuronal area was increased in the WT colitis 24 h and KO colitis 24 h groups, and this change was due to an increase in the cytoplasmic area; however, a decrease in the cytoplasmic area along with nuclear shrinkage was observed in the WT colitis 4 d group. We also demonstrated that when the P2X7 receptor was knocked out and at four days after colitis induction, the infiltration of inflammatory cells and microscopic tissue damage were attenuated, indicating that disease symptoms evolved during the experimental period.

According to Brenna *et al*[86], the TNBS-induced colitis model is a suitable model for studying biological processes associated with IBDs and can provide clinically relevant data; moreover, there are well-established protocols for constructing this model in both rats and mice[38-40,86-92]. Furthermore, KO animals have been used to study the onset and development of these disorders[83,86,93,94];

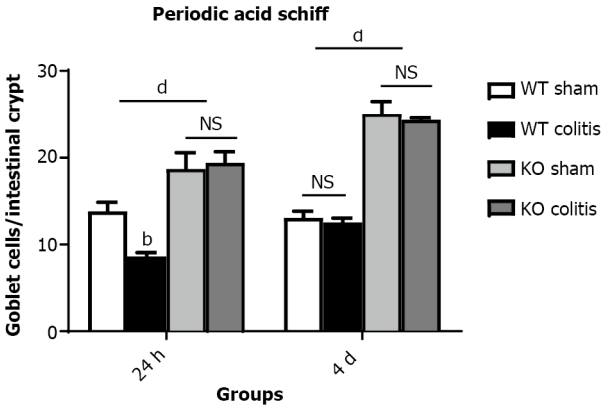

Figure 15 Photomicrograph of periodic acid Schiff-stained transverse sections of the distal colons of mice. A1 and A2: Wild-type (WT) sham 24 h; B1 and B2: WT colitis 24 h; C1 and C2: Knockout (KO) sham 24 h; D1 and D2: KO colitis 24 h; E1 and E2: WT sham 4 d; F1 and F2: WT colitis 4 d; G1 and G2: KO sham 4 d; H1 and H2: KO colitis 4 d groups. Goblet cells were observed throughout the epithelium in the sham groups, and there was an apparent reduction in goblet cell number and size in the WT colitis group. In addition, goblet cells showed a more rounded shape and an intumescent appearance in the WT colitis group. In the KO groups, an apparent increase in the number of goblet cells was noted. WT: Wild-type; KO: Knockout; M: Mucosal layer; LP: Lamina propria; MM: Mucosal muscle; SM: Submucosal layer; ML: Muscle layer; CM: Circular musculature; LM: Longitudinal musculature; white arrows: Myenteric ganglion; black arrows: Goblet cells.

however, the degree of similarity between experimentally induced colitis and spontaneous colitis in humans is still unclear[86].

In the present study, we recorded body weight and the change in DAI daily. After euthanasia, the macro- and microscopic lesions in the distal colon were characterized[64-67]. The colitis model animals lost more weight on the first day but recovered on the subsequent days. It is worth noting that in the colitis model groups, there were also greater changes in stool consistency and the presence of blood in the stool. Similarly, tissue hyperemia was noted only in the colitis groups, and the WT colitis 24 h group exhibited more severe microscopic damage. The absence of statistically significant differences in phenotype between the KO sham and KO colitis groups is consistent with previous literature showing that KO of the P2X7 receptor provides greater protection against inflammation[52,56,83,93,94].

It was previously demonstrated that intestinal inflammation induces changes in the density of neurons expressing different chemical codes in the ENS and that these changes vary between animal models and human patients. It is known that the number of neurons is reduced 24 h to seven days after the induction of colitis[35-40,62,81,89,95]. It has been reported that this decrease in the number of neurons occurs as early as six hours after colitis induction[35,81] and that, as observed in the present study, this decrease is already significant at 24 h.

According to Sanovic *et al*[81], the number of enteric neurons continues to decrease from the second to the fourth day and remains constant until day 35, suggesting that enteric neuron loss is long lasting and irreversible. Similarly, Linden *et al*[95] also reported that the number of neurons is not yet recovered at 56 d after colitis induction. In contrast, Poli *et al*[96] observed that at 30 d after inflammation

Figure 16 Number of goblet cells per intestinal crypt of the distal colon in mice from the wild-type sham 24 h and 4 d, wild-type colitis 24 h and 4 d, knockout sham 24 h and 4 d, and knockout colitis 24 h and 4 d groups. The data are presented as the arithmetic mean ± SE. $^{b}P < 0.01$ *vs* sham groups; $^{d}P < 0.001$ *vs* wild-type groups; NS: Not significant. WT: Wild-type; KO: Knockout.

induction, the myenteric plexus showed similar labeling to that in the control group. In our study, there was a slight increase in the number of calretinin-ir neurons in the WT colitis 4 d and KO colitis 4 d groups compared with the WT sham 24 h and KO sham 24 h groups, which may indicate that neurons exhibit some degree of plasticity in response to inflammatory injury. Despite this apparent alleviation of pathological changes after the inflammatory stimulus is removed, neuronal damage and activation of signaling pathways that potentially lead to cell death have already occurred.

The neuronal area was significantly increased in the WT colitis 24 h and KO colitis 24 h groups compared to the WT sham 24 h and KO sham 24 h groups, and this change was due to an increase in the cytoplasmic area. On the other hand, a significant reduction in neuronal area accompanied by a reduction in nuclear area was observed in the WT colitis 4 d group. In addition, ultrastructural analysis of myenteric neurons revealed nuclear disruption and cytoplasmic disorganization in the 24 h WT colitis and 24 h KO colitis groups and nuclear membrane folding associated with the formation of apoptotic bodies in the 4 d WT colitis group. Thus, neurons first underwent necrosis characterized by massive cell death and then, after four days, underwent apoptosis characterized by cytoplasmic condensation and nuclear shrinkage[4,6-8,10,14,35,82,97].

As reported by Martin[1] and Kanduc *et al*[2], cell death can occur either through necrosis or apoptosis and results from the activation of intrinsic death programs or passive disruption of the cell membrane resulting from damaging environmental stimuli[10]. In necrosis, the death stimulus alone causes the loss of the cell[4], whereas in apoptosis, a cascade of events that orchestrate destruction of the cell in a controlled manner is activated. The main effector of both processes is caspase-3[4,8,10,45,98], a protease that when activated fragments DNA and disrupts cellular organization and leads to cell death [4,7,98-101].

From the CTCF analysis, a greater intensity of cleaved caspase-3 was observed in the 24 h WT colitis, 24 h KO colitis and 4 d WT colitis groups, indicating a higher activation of myenteric neuron pathway death. Indeed, these results are in line with the decrease in enteric neuronal density arising from colitis. In addition, we observed a higher fluorescence of the P2X7 receptor in the WT colitis 24 h group, suggesting its greater activation during the inflammatory process[52,54,60,93,102-104].

According to North[105], Burnstock[106], and Dubyak[107], constant stimulation of the P2X7 receptor *via* ATP results in the efflux of K^+ and the influx of Ca^{2+} and Na^+ and triggers the formation of a nonselective membrane pore that makes the cell permeable to molecules of up to 900 daltons. Because of this imbalance, specific phospholipases and kinases that, in addition to exerting other effects, can trigger the caspase cascade are activated. As a result, the activation of the transcription factor NF-κB leads to the expression of proinflammatory genes and stimulates both inflammation and cell death. It has also been found that ATP is released *via* the panexin-1 channel[37,49,50], and the extracellular increase in ATP indicates exacerbation of inflammation[56,60], increased P2X7 receptor activation and severe neuronal death[37,51,52,56,103].

Consistent with the findings presented above, our results showed that in KO mice, myenteric calretinin-ir neurons were protected to a greater extent, and the loss of this receptor obviously prevented its activation, inhibiting the subsequent cascade of events culminating in cell death. Despite this, a decrease in the number of myenteric neurons was observed in the KO colitis 24 h group compared to the KO sham 24 h group, which suggests that neuronal protection and cell death also involve pathways not linked to the P2X7 receptor[4,7,8,45,47].

Our results are in line with what has been reported in the literature and confirm that neuronal death mediated by caspase-3 activation is related to purinergic signaling *via* the P2X7 receptor in the

myenteric plexus of mice with TNBS-induced colitis. However, it is worth noting that NF-κB plays a role in IBDs[108-111], but its activation is minimal during the inflammatory process[112].

Histologically, inflammatory infiltration, tissue damage, and loss of goblet cells in intestinal tissue were attenuated at four days compared with 24 h after colitis induction. This finding is consistent with the alleviation of symptoms observed in the colitis groups since the inflammatory stimulus was removed and corroborates the findings reported in the literature demonstrating that tissue recovery indicates better clinical outcomes[113,114]. Nevertheless, in the WT colitis 4 d group, collagen fibers in the lamina propria were increased in number and disorganized, indicating that the fibrosis in the mucosal layer[38,52,115,116] observed at 24 h did not decrease. On the other hand, KO animals always showed milder tissue injury and better recovery than WT animals.

It is possible that the reduction in the number of goblet cells observed in the colitis groups aggravated acute intestinal inflammation; this phenomenon has already been reported both in experimental animals and in human patients[38,52,83,117-120]. However, even though these cells play a critical role in maintaining a physical barrier by producing mucus in the gut[117,121-123], it is unclear whether the loss of their function contributes to the onset of inflammation or is a consequence of it[117]. The results of our study indicated that colitis induced the loss of these cells, and tissue recovery was observed at four days, as indicated by an increased number of goblet cells that grew as they emerged from the basal lamina and moved toward the epithelial surface. The increase in cell proliferation in the KO groups[94], which resulted in the increase in the number of goblet cells, may have also protected the mucosa by leading to increased mucus production. As reported by Van der Sluis *et al*[121], Niv[124], and Grondin *et al*[123], deficiencies in the production of diverse types of mucins favor the onset and progression of intestinal inflammation.

CONCLUSION

In conclusion, we demonstrate that although the distal colons of mice with colitis showed good histological recovery, neuronal injury occurred in the myenteric plexus and probably impaired intestinal function. Studies in which animals are maintained for a longer period of time seem to be needed to elucidate the effects of P2X7 signaling on long-term neuronal survival. Moreover, it was confirmed that the P2X7 receptor is closely associated with neuronal necrosis and apoptosis dependent on the caspase-3 pathway but not on NF-κB. KO animals were less affected by ulcerative colitis. Thus, the P2X7 receptor may be a potential therapeutic target for IBDs.

ARTICLE HIGHLIGHTS

Research background

Inflammation affects enteric neurons and has P2X7 receptor signaling.

Research motivation

The motivation of the work was to study the mechanisms of nuclear factor kappa B (NF-κB) and caspase-3.

Research objectives

To study calretinin-positive neurons and caspase-3 and NF-κB pathways in intestinal inflammation.

Research methods

Research methods of immunohistochemistry, morphometry, conventional histology and transmission electron microscopy were used.

Research results

There was a decrease in calretinin neurons in wild type colitis (WT) animals and recovery of neurons in mice deficient for the P2X7 receptor (KO). There was an increase in caspase-3 and NF-κB pathways in the WT colitis and recovery animals in the KO groups.

Research conclusions

The P2X7 receptor is involved in the decrease of neurons in the WT colitis group, and this receptor could be a therapeutic target.

Research perspectives

The perspective of the work is to use other techniques to explain other pathways of action mechanisms.

Abstract

BACKGROUND

Wild rats have the potential to hold zoonotic infectious agents that can spread to humans and cause disease.

AIM

To better understand the composition of gut bacterial communities in rats is essential for preventing and treating such diseases. As a tropical island located in the south of China, Hainan province has abundant rat species. Here, we examined the gut bacterial composition in wild adult rats from Hainan province.

METHODS

Fresh fecal samples were collected from 162 wild adult rats, including three

species (*Rattus norvegicus*, *Leopoldamys edwardsi*, and *Rattus losea*), from nine regions of Hainan province between 2017-2018.

RESULTS

We analyzed the composition of gut microbiota using the 16S rRNA gene amplicon sequencing. We identified 4903 bacterial operational taxonomic units (30 phyla, 175 families, and 498 genera), which vary between samples of different rat species in various habitats at various times of the year. In general, Firmicutes were the most abundant phyla, followed by Bacteroidetes (15.55%), Proteobacteria (6.13%), and Actinobacteria (4.02%). The genus *Lactobacillus* (20.08%), unidentified_*Clostridiales* (5.16%), *Romboutsia* (4.33%), unidentified_*Ruminococcaceae* (3.83%), *Bacteroides* (3.66%), *Helicobacter* (2.40%) and *Streptococcus* (2.37%) were dominant.

CONCLUSION

The composition and abundance of the gut microbial communities varied between rat species and locations. This work provides fundamental information to identify microbial communities useful for disease control in Hainan province.

Key Words: Hainan; Rat; Fecal microbiome; Microbial community; 16S rRNA

INTRODUCTION

The laboratory rat has been used as a useful experimental model for biomedical sciences since the last century. Rats were domesticated as early as the Edo period[1]. Gut microbiota is composed of myriad microbes (archaea, bacteria, fungi, and viruses) that interact with each other and with their host, playing important roles in the host's metabolism, physiology, homeostasis, health, and disease development[2]. There is an increase in studies of the laboratory rat gut microbiota[3-9], but very few on wild rats[10].

Wild rats pose a serious threat to public health because they are reservoirs for a number of zoonotic pathogens[11-13] and frequently and closely interact with people, domestic animals, and other animals.

Only a small number of researchers have looked into the microbial diversity in the guts of wild rats in the province of Hainan, compared to the number of researchers who have looked into the microbial communities in arthropods. Here, by 16S rRNA gene amplicon sequencing we compared the gut bacterial communities in fecal samples from 162 wild rats of three species and nine geographic locations in Hainan.

MATERIALS AND METHODS

Rat collection and morphology identification

Between December 2017 and November 2018, wild adult rats were collected using mousetraps in rat cages from nine geographic locations in Hainan province (L1-L9: L1 = Yinggeling; L2 = Huangjingjiaoling; L3 = Danzhou; L4 = Dongfang; L5 = Haikou; L6 = Jianfengling; L7 = Baisha; L8 = Sanya; L9 = Lingao) (Figure 1 and Supplementary Table 1). The trap sites we selected included mountains, residential areas, and farmland. When the team got back to the lab, they based their determination of gender on the morphology of the external reproductive organs. Based on DNA barcode analysis, a polymerase chain reaction (PCR) assay was used to confirm the identification of the species of rats. The characteristics of all rats are recorded, including acquisition time, location, sex, weight, and adult or

immaturity (Supplementary Table 1).

Molecular identification of rats

The SDS method was used for DNA extraction. The PCR assay was performed to identify rat species using the primer 5′-TACCATGAGGACAAATATCATTCTG-3′ and 5′-CCTCCTAGTTTGTTAGGGATTGATCG-3′[14]. Amplification was performed in 25 μL total volume, including DNA template (2 μL), each primer (0.5 μL), 10 × Gene Amp PCR Buffer (2.5 μL), dNTP (1.25 mmol/L) (2 μL), rTaq DNA polymerase (5 U/μL) (0.5 μL) and double distilled water (17 μL). The PCR procedure was as follows: (1) Initial denaturation 95 ℃ (5 min); (2) 35 cycles each of denaturation 94 ℃ (30 s); (3) primer annealing 51 ℃ (30 s); and (4) extension 72 ℃ (30 s). It took 5 min to complete the extension step's 35th cycle. The mouse species was determined through a blast to the NCBI nucleotide database, and the amplification products were identified using Sanger sequencing.

Tissue and fecal sampling

CO_2 was used for euthanizing rats. Intestinal tissue was dissected for each rat species, rinsing three times in sterile normal saline. In the meantime, samples of feces were taken from the intestinal tissues. Then, samples were immediately collected in a brain heart infusion medium with glycerol and subsequently stored at -80 ℃ until analysis.

16S rRNA microbial profiling preparation

Fecal samples weighing about 50 mg were used for 16S rRNA microbial profiling analyses. Following the manufacturer's instructions, microbial DNA was extracted from the fecal samples using a QIAamp Fast DNA Stool Mini Kit (Qiagen, Germany). The PCR products were examined using electrophoresis. Thermo GeneJET Gel Extraction Kit was used to recover the PCR products after running them on 2% agarose gels in TAE buffer. Until analyses, all of the extracted DNA was kept at -20 ℃.

The hypervariable regions V3-V4 of the bacterial 16S rRNA were amplified with primers 5′-CCTAYGGGRBGCASCAG-3′ and 5′-GGACTACNNGGGTATCTAAT-3′. PCR reactions were performed in a 30 μL volume consisting of Phusion® High-Fidelity PCR Master Mix with GC buffer (New England Biolabs) (15 μL), forward and reverse primers (0.2 μM), and template DNA (10 ng). The PCR reaction was done with the following conditions: (1) Initial denaturation at 98 ℃ for 1 min; (2) 30 cycles of denaturation at 98 ℃ for 10 s; (3) annealing at 50 ℃ for 30 s; (4) elongation at 72 ℃ for 30 s; and (5) final extension 72 ℃ for 5 min. Sequencing libraries were made with an Ion Plus Fragment Library Kit (48 rxns) (Thermo Scientific) according to the manufacturer's protocols. The Qubit 2.0 Fluorometer (Thermo Scientific) was used to evaluate the library's quality. Sequencing was done on the Ion S5TM XL platform last.

16S rRNA microbial profiling analysis

Based on the unique barcode, single-end reads were assigned to samples and truncated by cutting off the barcode and primer sequence. The Cutadapt quality control process involved treating the raw reads with quality filtering under specific filtering conditions in order to produce high-quality clean reads [15]. Then, we compared the reads with the Silva database, and reference database[16] using UCHIME Algorithm[17] to detect and remove chimera sequences[18] to obtain clean reads.

Uparse software performed analyses of microbial profiling[19]. Sequences with a 97% or higher similarity to one another were found to the same Operational taxonomic unit (OTU). We screened the representative sequence of each OTU for further annotation. Taxonomic data was annotated at various taxonomic levels using the Silva Database, which uses the Mothur algorithm[16]. We used the MUSCLE software to conduct multiple sequence alignment to study the difference between the dominant species in different groups[20]. We normalized OTUs abundance using the standard sequence number of the sample with the least sequences and summarized the OTU abundance in a table. Subsequently, we analyzed the alpha diversity (α-diversity) and beta diversity (β-diversity) based on this normalized data.

Bacterial diversity analysis

In the complexity of species diversity, we applied α-diversity through 6 indices (Observed-species, Chao1, ACE, Shannon, Simpson, Good's coverage). Chao1 and ACE were selected as the Chao1 and ACE estimators to determine richness. The Shannon index and Simpson index were used to calculating Shannon diversity and Simpson diversity. Using Good's coverage, Coverage was chosen to describe the depth of the Sequencing.

We applied β-diversity for evaluating the similarity of different samples rather than describing within-sample diversity like α-diversity. We calculated β-diversity on both Weighted and Unweighted unifrac. The dimension of the original variables was reduced using principal component analysis. Principal coordinate analysis (PCoA) was performed to visualize complex, multidimensional data and was displayed to visualize microbial community structure relationships. Firstly, we obtained a distance matrix among samples in weighted or unweighted unifrac. Secondly, we transformed the distance matrix to a new set of orthogonal axes. Finally, the first principal coordinate demonstrated the maximum variation factor, and the second principal coordinate demonstrated the second maximum

one, and so on. We performed Adonis analysis to know to what extent location explained variation in microbial composition. For significant difference analysis, either the USEARCH software (https://www.drive5.com/usearch) or R software (version 4.0.3) was used.

RESULTS

Rat species from different sampling areas

Among the 162 wild rats collected by traps from nine district areas which covered almost half of Hainan province (Figure 1), three rat species (*Rattus norvegicus*, *Leopoldamys edwardsi*, and *Rattus losea*) were predominant (Table 1 and Supplementary Table 1). These rat species showed distinct geographic distributions. *Rattus norvegicus* (brown rat) was mainly found in farmland (Danzhou, Dongfang, Baisha, and Sanya) and residential areas (Haikou); *Leopoldamys edwardsi* (Edward's long-tailed rat) was exclusively found in mountain areas in Yinggeling, Huangjingjiaoling, and Jianfengling; *Rattus losea* (Lesser rice-field rat) was only found from mountains in Lingao area (Table 1).

Gut bacterial species composition among rat species

A total of 162 fecal samples (one from each rat) were collected from the field-collected wild adult rats and subjected to bacterial profiling analyses, and estimating the bacterial community composition of these samples involved 16S rRNA gene amplicon sequencing. A total of 13326753 raw reads (mean ± SE = 82263.91 ± 8277.45 per sample) were obtained from the 162 samples that were sequenced (Supplementary Table 2). Among them, 12537453 clean reads (mean ± SE = 77391.69 ± 7604.97 per sample) remained for subsequent analyses after quality control processing. These sequences were divided into 4903 OTUs that belonged to 30 phyla, 175 families, and 498 genera (Supplementary Table 3). Among those OTUs that were defined to species level (Supplementary Table 3), some notoriously famous bacteria were found, such as *Bacillus anthracis* (OUT_426), *Bacteroides pyogenes* (OUT_3846), *Clostridium perfringens* (OUT_8), *Streptococcus suis* (OUT_410), and *Vibrio cholerae* (OUT_3092).

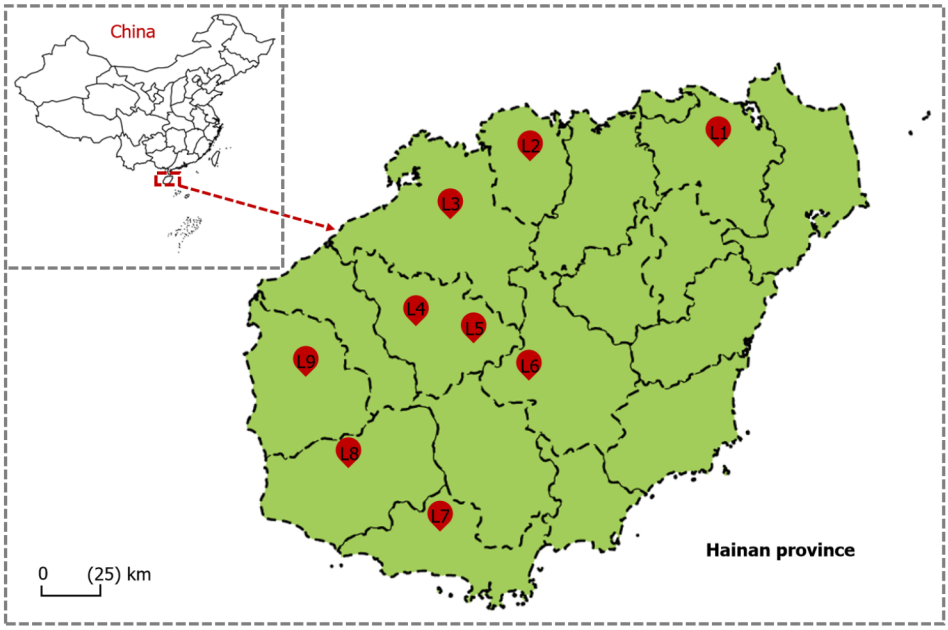
As shown in Figure 2A, sequences originating from Firmicutes (average 65.76%, Supplementary Table 4) were dominant, followed by Bacteroidetes (15.55%), Proteobacteria (6.13%), Actinobacteria (4.02%), Unclassified bacteria (3.68%), Tenericutes (1.93%), Fusobacteria (1.00%), Spirochaetes (0.88%), Chlamydiae (0.27%), Melainabacteria (0.17%), and so on (detailed in Supplementary Table 4, those < 0.15% were pooled together as "Others" in Figure 2A). Although Bacteroidetes were the second most abundant on average, this was not the case for samples from Danzhou, Haikou, Baisha, and Lingao (Supplementary Table 4).

Following a similar trend, Clostridia (averaged 32.72%) and Bacilli (averaged 26.48%) were the top two classes of bacteria in most samples (Figure 2B), but Clostridia only ranked fourth in samples from the Jianfengling area, and Bacteroidia was the 2nd most abundant in samples from Yinggeling, Huangjingjiaoling and Sanya (Supplementary Table 5).

According to the average value, the most abundant family was Lactobacillaceae (20.08%), followed by Ruminococcaceae (12.03%), Lachnospiraceae (8.11%), Muribaculaceae (6.33%), Peptostreptococcaceae (5.61%), unidentified_Clostridiales (5.58%), Erysipelotrichaceae (5.50%), Bacteroidaceae (3.66%), Enterobacteriaceae (3.25%), and Streptococcaceae (2.71%) (detailed in Supplementary Table 6, those < 2.5% were pooled together as "Others" in Figure 2C). Compared to the profiles for the bacterial phylum and class, the profiles for the actual values were more complex. Lactobacillaceae was the most abundant in samples from five areas (Danzhou, Dongfang, Jianfengling, Baisha, and Lingao), Ruminococcaceae was most abundant in samples from Yinggeling and Huangjingjiaoling, and Peptostreptococcaceae and Bacteroidaceae were the richest in samples from Haikou and Sanya, respectively (Supplementary Table 6).

As illustrated in Figure 2D and detailed in Supplementary Table 7, the genus with the highest OTU abundance in the feces of rats was those (with relative abundance less than 0.5%) designated as 'others' (average 26.80%), followed by *Lactobacillus* (20.08%), unidentified_*Clostridiales* (5.16%), *Romboutsia* (4.33%), and so on. In samples from eight different areas, "Others" or *Lactobacillus* ranked first and second, but not in samples from the Haikou area, which had the highest concentrations of unidentified *Clostridiales* and *Romboutsia*.

As shown in Figure 3, the heatmap color-coded the different OUT compositions in samples of the nine groups (Figure 3A); all of the samples contained unique bacterial OTUs, according to the upset plot (Figure 3B), but those from the Jianfengling region had the highest numbers of both (618 for unique and 153 for common with the Lingao area).



Gut bacterial diversity of rat

Alpha diversity indices were performed to detect whether bacterial diversity and richness significantly varied among samples of different rat species and geographic locations. The bacterial species richness, represented by Chao1 and ace denoting the number of species rather than the abundance of each species was highest for samples from the Yinggeling area (Table 2). Statistics were conducted for the Chao1 values because the values of both indices (Chao1 and ace) changed in a remarkably similar way across

Table 1 Location, species, number, season, and habitat of trapped rats

Site	Rat species	Number of midgut samples	Sampling season	Trap sites

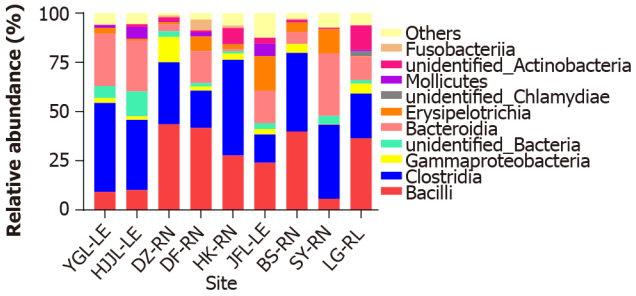
Figure 1 Sketch map of Hainan province. The map shows the locations of the nine collection study sites. L1 = Yinggeling, mountain; L2 = Huangjingjiaoling, mountain; L3 = Danzhou, residential areas; L4 = Dongfang, residential areas; L5 = Haikou, residential areas; L6 = Jianfengling, mountain; L7 = Baisha, residential areas; L8 = Sanya, residential areas; L9 = Lingao, farmland.

the nine groups. Except for Lingao and Jianfengling, samples from Yinggeling and Huangjingjiaoling, the two highest among all, had significantly more bacteria than the other five samples (Figure 4A). Taking Yinggeling as an example, it was most significantly higher ($P < 0.0001$) than those from Danzhou, Dongfang, Haikou, Sanya and Baisha, and significant ($P < 0.05$) compared to Lingao and Jianfengling (Figure 4A). In addition, samples from the Jianfengling area had higher bacterial richness compared to those from Danzhou and Sanya, and those from the Lingao area had higher richness than those from Danzhou and Sanya. There was no significant difference between other groups if not mentioned above.



Species diversity, represented by Shannon diversity and Simpson diversity, indicates species richness and evenness in the community. As the two indices changed accordingly (Table 2), values of the Shannon diversity were used to do the statistics. In comparison to samples from Danzhou ($P < 0.0001$), Dongfang ($P < 0.01$), Haikou ($P < 0.001$), and Sanya ($P < 0.05$), samples from the Yinggeling area showed significant differences. Although similar in its bacterial composition pattern to those from the Yinggeling area, the species diversity of samples from the Huangjingjiaoling area was less significant with samples from Danzhou ($P < 0.001$) and Haikou ($P < 0.05$). In contrast to the insignificant results

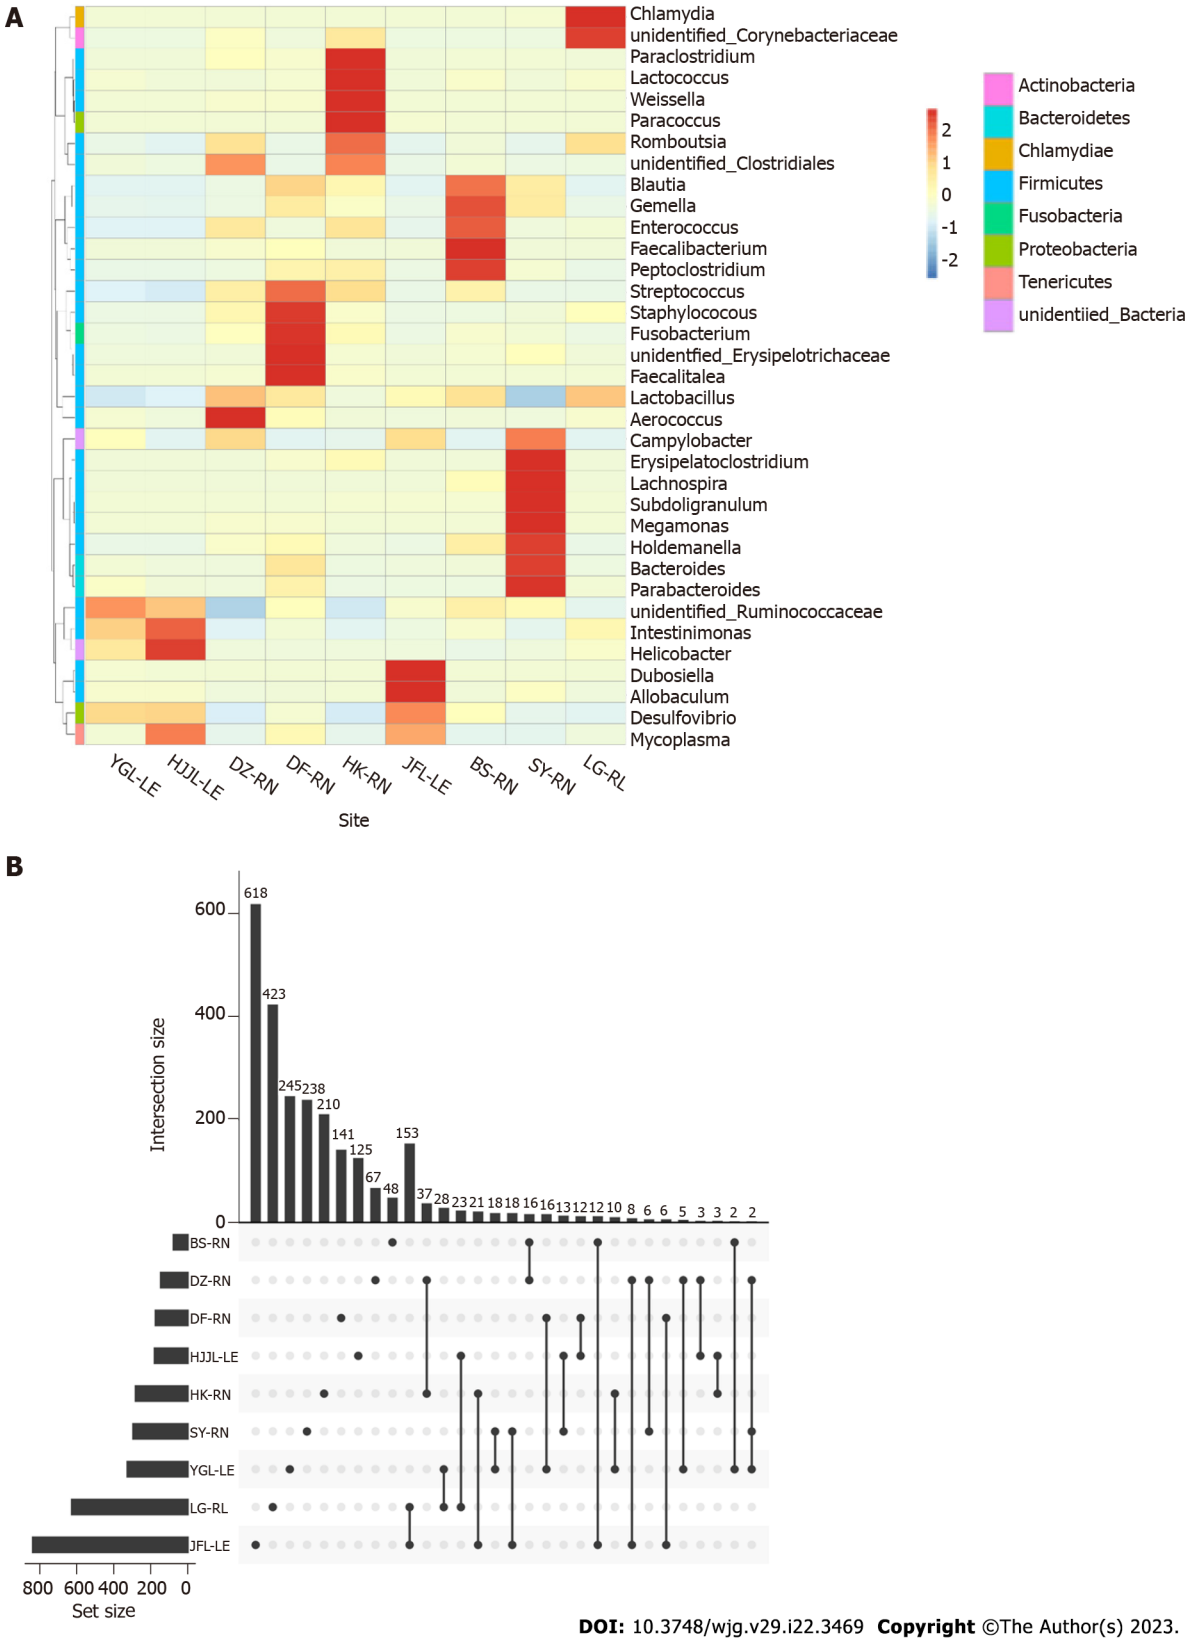

Figure 2 Mean relative abundances of bacterial phylum, class, family, and genus associated with three rat species at different sites. A: Phylum; B: Class; C: Family; D: Genus. Families with an abundance of less than 2.50% and Phyla with an abundance of less than 0.15% were combined to form the category "Others." YGL: Yinggeling; HJJL: Huangjingjiaoling; DZ: Danzhou; DF: Dongfang; HK: Haikou; JFL: Jianfengling; BS: Baisha; SY: Sanya; LG: Lingao; LE: Leopoldamys edwardsi; RN: Rattus norvegicus; RL: Rattus losea.

among sample groups not mentioned above, the species diversity of samples from the Danzhou area was significantly different ($P < 0.05$) from those from the Lingao area (Figure 4B).

Variation of gut bacterial communities among study locations

Distance metrics were used to estimate differences between rat species and geographical locations in bacterial community profiles. The results showed a significant difference in microbiota among the three rat species and nine locations based on unweighted unifrac and weighted unifrac distances. When analyzing the fecal microbiota from various study sites, we used PCoA plots to visualize its composition. Using Unweighted Unifrac distance, two PCoA coordinates percent variation explained PCo1 (21.33%) and PCo2 (6.98%) of the total variation, respectively. We observed significant differences in fecal microbial β-diversity among communities from different locations, including *Leopoldamys edwardsi* from Yinggeling, Huangjingjiaoling, and Jianfengling; *Rattus norvegicus* from Danzhou, Baisha, and Sanya. *Rattus norvegicus* from the Dongfang area does not cluster tightly. There were no observable differences between Rattus norvegicus from Danzhou and Haikou (Figure 5A). Two PCoA coordinates based on Weighted Unifrac distance percent variation revealed PCo1 (44.41%) and PCo2 (10.69%), respectively (Figure 5B). These differences were mainly due to the geographical location, which included a plethora of variables (rat species, habitat, season, diet, *etc.*).

Heatmaps based on Bray-Curtis distances and Weighted unifrac distances, respectively, showed the diversity and similarity of microbial communities (Figure 5C and D). As shown in Figure 5C, the most similar (0.508, the lowest in Supplementary Table 8) intestinal bacterial community structure was between samples from Jianfengling and Huangjingjiaoling (highlighted with blue triangles in

Figure 5C), followed by that between Baisha and Dongfang (0.57), and those of Danzhou area (0.61-0.63, Supplementary Table 8) with Baisha, Dongfang, Haikou, and Lingao (Figure 5C). Conversely, samples from the Sanya area were most dissimilar to those from Huangjingjiaoling (0.91), Lingao (0.89), and Haikou (0.88). As shown in Figure 5D, the lowest difference (0.16, Supplementary Table 9) was observed between samples from Yinggeling and Huangjingjiaoling (highlighted by the blue triangles), suggesting the bacteria in these two groups of samples were evolutionary more similar. Conversely, the bacteria in the samples from the Sanya area were evolutionary most distant (highlighted by the stars in Figure 5D) to those from Danzhou and Haikou (0.51 and 0.57, respectively; Supplementary Table 9).

DISCUSSION

Through the same procedure from sample collection and processing to sequencing, the gut bacterial communities differed at all levels (phylum, class, family, and genus) among fecal samples of wild rats from nine geographical locations, three different habitats, and rat species, and two seasons (winter *vs* summer). According to scant research, diet uncontrollable for wild rats is a significant determinant of gut bacterial composition[21-23], which differs for rats living in diverse habitats in every location at all

Figure 5 Principal coordinate analysis plot based on unweighted Unifrac distance and weighted Unifrac distance matrix depicting differences in the composition of the gut microbiota from different rat species and locations. A: unweighted Unifrac distance; B: Weighted Unifrac distance; C and D: Colors represent community profiles of location. Matrix heatmap of the Bray-Curtis distances (C) and the weighted unifrac beta diversity (D) between the microbial communities of rats from nine different areas. YGL: Yinggeling; HJJL: Huangjingjiaoling; DZ: Danzhou; DF: Dongfang; HK: Haikou; JFL: Jianfengling; BS: Baisha; SY: Sanya; LG: Lingao; LE: Leopoldamys edwardsi; RN: Rattus norvegicus; RL: Rattus losea.

seasons. There were quite a few striking findings from our study. As the only representative samples of residential area (Haikou) rats, their gut bacterial composition was different at the family and genus level, richest with *Peptostreptococcaceae* and unidentified_*Clostridiales* at the family level, and with unidentified_*Clostridiales* and *Romboutsia* at the genus level. Although collected from the same rat species (*Rattus norvegicus*) during the same winter season, the bacterial profiles of the four groups of samples from different areas (Baisha, Dongfang, Danzhou, and Haikou) were distinctly different at the class, family, and genus level, revealing the complexity of factors (*e.g.*, habitat, farmland *vs* residential area) behind the bacterial community. The general bacterial profile of samples taken from the same species of rat (*Leopoldamys edwardsi*) in the summer in one mountain area (Yinggeling) varied from samples taken in the winter from the other two mountain areas (Huangjingjiaoling and Jianfengling), indicating that season (and thus a variety of factors) played a significant role in determining their gut bacterial composition.

Several studies report that Firmicutes, Bacteroidetes, and Proteobacteria are the most abundant phyla, and *Lactobacillus* is the predominant genus in fecal samples from both wild (*Rattus norvegicus*) and laboratory (Sprague-Dawley) rats[7,9], a pattern similar to our results. Fusobacteria was interestingly

the fourth most prevalent phylum in[10], which is most consistent with findings from one of our nine groups (Dongfang) (Figure 2B). Although of the same species (*Rattus norvegicus*), sample size (12), and similar climate, rats from the Dongfang area of this study were trapped in January from farmland on an isolated island contrasting to all year round (one mouse per month) from a residential area in an inland metropolitan city[10].

Although we identified some potential bacterial pathogens by their species names and reputation in the samples (Supplementary Table 3), a profile distinct from the results of other studies[11,12], they still need to be tested for virulence and pathogenesis. Because wild rats carry some bacteria (*Bacillus anthracis*, *Vibrio cholerae,* and *Yersinia pestis*)[11,12] and this study] can cause a serious outbreak or even a pandemic, it would be prudent to start a regular survey program at some strategic points to monitor the distribution of sentinel rodents and the target pathogens the animals may transmit.

The ideal comparison should only have one factor, but this seems like an impossible task for our current research. Admittedly our study had some limitations, to name a few: (1) As some variables, like sex, age, and so on, were difficult, if not impossible, to control as a baseline investigation; (2) despite the interesting findings (having the highest *Corynebacteriaceae* in all samples) of the gut bacterial composition in *Rattus losea*, it was from only one area (Lingao); (3) the summer samples were collected from two different rat species (*Rattus norvegicus vs Leopoldamys edwardsi*,) in two different habitats (farmland *vs* mountain) from only one area each, making the results less conclusive and comparable; and (4) samples from residential rats were only from Haikou area, making some of the results less comparable.

CONCLUSION

The study revealed the structure of gut bacterial communities by sampling wild rats' feces. In general, the gut microbiota was different in both composition and abundance in samples from the nine areas of Hainan of three wild rat species, three habitats (mountain, farmland, and residential area), and two seasons (summer and winter). This study provides fundamental information for identifying microbial communities that will be useful for disease control in Hainan Province.

ARTICLE HIGHLIGHTS

Research background

Wild rats are potential reservoirs for zoonotic infectious agents which can be transmitted to and cause diseases in humans.

Research motivation

As a tropical island locating in the south of China, Hainan province has abundant rat species.

Research objectives

To better understand the composition of gut bacterial communities in rats is essential for preventing and treating such diseases. Here, we examined the gut bacterial composition in wild adult rats from Hainan province.

Research methods

Fresh faecal samples were collected from 162 wild adult rats, including three species (*Rattus norvegicus*, *Leopoldamys edwardsi*, and *Rattus losea*), from nine regions of Hainan province between 2017-2018.

Research results

We analyzed the composition of gut microbiota using the 16S rRNA gene amplicon sequencing. We identified 4,903 bacterial operational taxonomic units (30 phyla, 175 families, and 498 genera), which is different among samples of different rat species in different habitat during different season. In general, Firmicutes were the most abundant phyla, followed by Bacteroidetes (15.55%), Proteobacteria (6.13%) and Actinobacteria (4.02%). The genus *Lactobacillus* (20.08%), unidentified_*Clostridiales* (5.16%), *Romboutsia* (4.33%), unidentified_*Ruminococcaceae* (3.83%), *Bacteroides* (3.66%), *Helicobacter* (2.40%) and *Streptococcus* (2.37%) were dominant.

Research conclusions

Among locations for rat species, the gut microbial communities were different in composition and abundance. This work provides fundamental information to identify microbial communities useful for disease control in Hainan province.

Research perspectives

The study revealed the structure of gut bacterial communities by sampling wild rats' feces. In general, the gut microbiota was different in both composition and abundance in samples from the nine areas of Hainan of three wild rat species, three habitats (mountain, farmland and residential area), and of two seasons (summer and winter). This work provides fundamental information to identify microbial communities which will be useful for disease control in Hainan province.

Abstract

BACKGROUND

Due to the poor prognosis of gastric cancer (GC), early detection methods are urgently needed. Plasma exosomal circular RNAs (circRNAs) have been suggested as novel biomarkers for GC.

AIM

To identify a novel biomarker for early detection of GC.

METHODS

Healthy donors (HDs) and GC patients diagnosed by pathology were recruited. Nine GC patients and three HDs were selected for exosomal whole-transcriptome RNA sequencing. The expression profiles of circRNAs were analyzed by bioinformatics methods and validated by droplet digital polymerase chain reaction. The expression levels and area under receiver operating characteristic curve values of plasma exosomal circRNAs and standard serum biomarkers were used to compare their diagnostic efficiency.

RESULTS

There were 303 participants, including 240 GC patients and 63 HDs, involved in the study. The expression levels of exosomal hsa_circ_0079439 were significantly higher in GC patients than in HDs ($P < 0.0001$). However, the levels of standard serum biomarkers were similar between the two groups. The area under the curve

value of exosomal hsa_circ_0079439 was higher than those of standard biomarkers, including carcinoembryonic antigen, carbohydrate antigen (CA)19-9, CA72-4, alpha-fetoprotein, and CA125 (0.8595 *vs* 0.5862, 0.5660, 0.5360, 0.5082, and 0.5018, respectively). The expression levels of exosomal hsa_circ_0079439 were significantly decreased after treatment ($P < 0.05$). Moreover, the expression levels of exosomal hsa_circ_0079439 were obviously higher in early GC (EGC) patients than in HDs ($P < 0.0001$).

CONCLUSION

Our results suggest that plasma exosomal hsa_circ_0079439 is upregulated in GC patients. Moreover, the levels of exosomal hsa_circ_0079439 could distinguish EGC and advanced GC patients from HDs. Therefore, plasma exosomal hsa_circ_0079439 might be a potential biomarker for the diagnosis of GC during both the early and late stages.

Core Tip: Gastric cancer (GC) remains a prevalent disease worldwide. Due to its atypical clinical manifestations, GC is usually diagnosed at late stages in most patients and has a poor prognosis. Therefore, early detection of GC is of great importance. Based on the results of exosomal whole-transcriptome RNA sequencing, we performed bioinformatic analysis and droplet digital polymerase chain reaction (dd-PCR) tests. As validated by dd-PCR, exosomal hsa_circ_0079439 had a higher area under the curve value than standard biomarkers. Therefore, plasma exosomal hsa_circ_0079439 could serve as a novel biomarker for the early detection of GC.

INTRODUCTION

Gastric cancer (GC) is the fifth most commonly diagnosed cancer and the fourth leading cause of cancer-related death; it accounted for 1089103 new cases and 768793 deaths in 2020 globally[1]. The prognosis of advanced GC (AGC) patients is poor[2]. Early detection of GC and identification of individuals who might benefit from a given treatment are of great importance. Unfortunately, the most common symptoms associated with GC are nonspecific, such as weight loss, poor appetite, and abdominal pain [2]. Based on the abovementioned conditions, the diagnosis of GC is often at a late stage[2]. Therefore, accurate early detection of GC is one of the most urgent issues in its management.

A previous study showed that carcinoembryonic antigen (CEA), carbohydrate antigen (CA)19-9, and CA72-4 levels are significantly associated with tumor stage and patient survival[3]. In addition, some studies have shown that CA125 and alpha-fetoprotein (AFP) are linked to GC[4,5]. However, the widespread use of less invasive detection methods has resulted in a number of inaccurate diagnoses due to their low sensitivity and specificity[6-8]. Therefore, it is necessary to identify novel biomarkers with higher accuracy for the early detection of GC.

Exosomes, a subset of nanometer-sized (50-150 nm) extracellular vesicles, can be secreted by almost all kinds of cells[9,10]. In addition, exosomes comprise diverse components, including proteins, DNAs, circular RNAs (circRNAs), long noncoding RNAs (lncRNAs), microRNAs (miRNAs), messenger RNAs (mRNAs), and lipids[10-13]. An increasing number of studies have shown that exosomes are involved in mediating intercellular communication and many pathological processes[9,10,14]. Therefore, they have great potential to become novel biomarkers in liquid biopsy. CircRNAs, a class of lncRNAs, were first discovered by electron microscopy more than 40 years ago[15-17]. Because of the exosomal phospholipid bilayer membrane structure, circRNAs are stable within exosomes.

Furthermore, a number of studies have demonstrated that circRNAs play an important role in GC progression, invasion, and metastasis. However, the utility of exosomal circRNAs for early detection of GC is largely unknown. Profiling circRNAs in exosomes could be useful for identifying molecular markers for early detection and prognosis prediction for various types of cancers[14,18-20].

In this study, we analyzed the expression levels of plasma exosomal circRNAs from GC patients in different clinical stages. The findings of this study support the notion that plasma exosomal circRNAs could serve as biomarkers for the diagnosis of early GC (EGC). Moreover, they might be considered as new therapeutic targets as well as effective prognostic markers for GC.

MATERIALS AND METHODS

Definitions

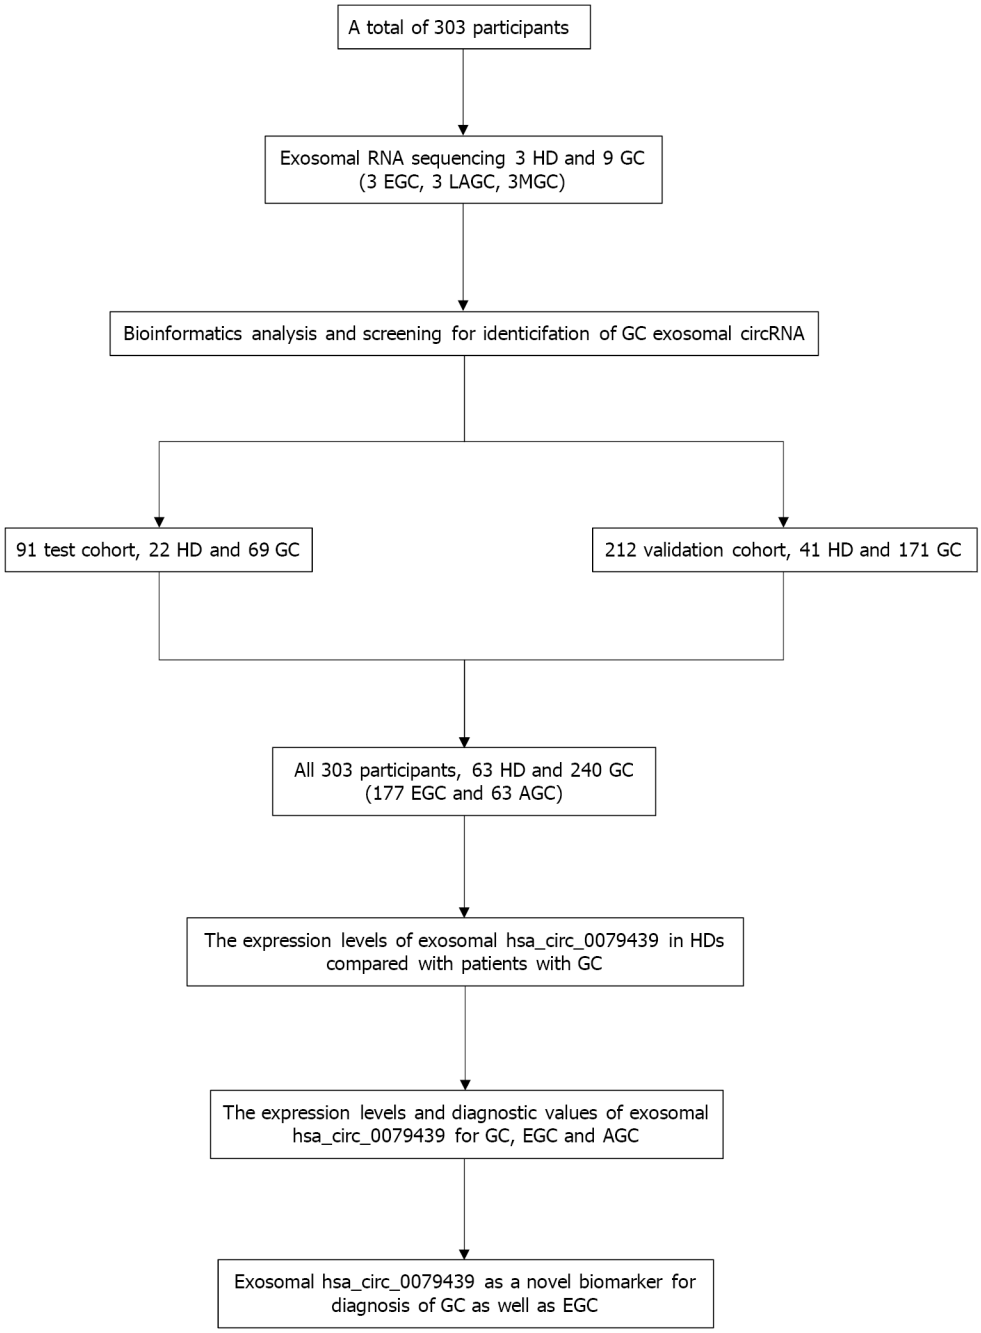
EGC is defined as GC confined to the mucosal and submucosal layers. Locally AGC (LAGC) was defined as stages T2-4aN0-3M0 GC, corresponding to stages Ib to IIIc and excluding T1 or T4b tumors [21-23]. Metastatic GC (MGC) refers to the invasion of GC cells into other tissues or organs. AGC includes LAGC and MGC[24].

Patients and plasma sample collection

A total of 240 GC patients (including 177 EGC patients and 63 AGC patients) and 63 healthy donors (HDs) were enrolled in our study from April 2018 to October 2022 (Figure 1). All of the GC patients had been diagnosed with adenocarcinoma after surgery. Patients who had been treated by chemoradiotherapy, targeted therapy, or cytotoxic therapy were excluded. HDs had undergone gastric endoscopy, and they did not have GC or any other gastric disease. We selected plasma exosomal samples obtained from nine GC patients (3 EGC, 3 LAGC, and 3 MGC) and three HDs for whole transcriptome RNA sequencing (nine GC patients were included in the validation cohort, and the expression levels of circRNA were verified). None of these GC patients had received any previous treatment before their first blood samples were obtained.

All participants were divided into a test cohort and a validation cohort. There were 69 GC patients and 22 HDs in the test cohort from April 2018 to December 2018. Another 171 GC patients and 41 HDs were included in the validation cohort from January 2019 to October 2022. According to the American Joint Committee on Cancer 8th edition[22,23], the clinical stage and TNM classification of GC in all patients were assessed and analyzed. All patients underwent endoscopic submucosal dissection or minimally invasive surgery to remove the lesions, which meant that accurate pathology results could be confirmed. In addition, plasma samples were acquired from GC patients 7 d after treatment.

Blood samples were collected from GC patients or HDs in K2-EDTA Blood Collection Tubes (Becton, Dickinson and Company). Blood samples were centrifuged at 500 × *g* for 15 min, and the supernatant collected was plasma. Plasma was transferred to a new tube and a unique classification number was written on the tube, which was then stored at -80 °C.



Cell culture

GC cells (GCCs) (AGS and HGC-27) were obtained from Shanghai Gaining Biological Technology Company (http://www.shgnsw.com). KATO III was obtained from the American Type Culture Collection (ATCC, http://www.atcc.org). Other GCCs (SNU-1, SGC-7901, MGC-803, and BGC-823) were obtained from the BeNa Culture Collection (BNCC, http://www.bncc.org.cn). Normal gastric epithelial cells (NGECs) were obtained from the Shanghai Qincheng Biological Technology Company (http://www.shqcsw.com). The culture methods used for the cell lines are shown in Supplementary Table 1.

Isolation and purification of exosomes

For whole-transcriptome RNA sequencing, exosomes were isolated by size-exclusion chromatography. We used a procedure described in a previous study with a few minor modifications[25]. PBS was used to perform a 1.5-fold dilution of 1 mL of each plasma sample (0.8 μm filtered). Then, the mixture was purified using Exosupur® columns (Echobiotech, China) and more PBS was used to perform elution, which resulted in a total of 2 mL of eluate. Finally, by using 100 kDa molecular weight cutoff Amicon® Ultra spin filters (Merck, Germany), the fractions obtained during the previous step were concentrated to 200 μL.

For droplet digital polymerase chain reaction (dd-PCR) test, plasma exosomes were isolated according to the manufacturer's instructions for the ExoQuick™ Exosome Precipitation Solution (SBI). Briefly, 16 μL of thrombin was added to 1000 μL of plasma at a final concentration of 5 U/mL. The mixture was incubated at room temperature for 5 min and centrifuged at 10000 rpm for 5 min, and a visible pellet was observed at the bottom of the tube. The supernatant was transferred to a new tube and centrifuged at 3000 × *g* for 5 min to remove cells and other debris. The supernatant was transferred to a new tube; 63 μL of ExoQuick Exosome Precipitation Solution was added, and the mixture was incubated at 4 °C for 30 min. After centrifuging the mixture at 1500 × *g* for 30 min, the fluid was removed. The pellet at the bottom of the tube, which contained exosomes, was collected.

Figure 1 Study design. HD: Healthy donor; GC: Gastric cancer; EGC: Early gastric cancer; LAGC: Locally advanced gastric cancer; MGC: Metastatic gastric cancer; circRNA: Circular RNA; AGC: Advanced gastric cancer.

Transmission electron microscopy

Exosomes isolated from plasma were diluted. Ten microliters of exosome solution was added to a copper mesh and incubated for 10 min. After cleaning the mesh with sterile distilled water, filter paper was used to absorb the liquid. Ten microliters of 2% phosphotungstic acid was added to the copper mesh and incubated for 1 min. Then, the copper mesh was dried with filter paper. The copper mesh was kept dry for several minutes at room temperature. And transmission electron microscopy (TEM) was performed.

Nanoparticle tracking analysis

After the instrument qualification test, the diameter and quantity of the exosomes isolated from plasma were measured by ZetaView PMX 110 (Particle Metrix, Meerbusch). The movement of particles was analyzed by nanoparticle tracking analysis (NTA) software (ZetaView 8.02.28) by taking 60 s of video at a rate of 30 frames/s.

Western blot analysis

After total protein extraction from exosomes, the protein concentration was measured with the Pierce BCA Protein Assay kit (Thermo). Western blot (WB) analysis was performed to measure protein expression in the extracts. The positive markers of exosomes that were used included CD9 (Abcam), TSG101 (Abcam), and CD81 (Abcam). The negative marker was calnexin (Abcam).

Total RNA extraction of exosomes and RNA analysis

Total RNA was extracted from plasma exosomes and purified with the miRNeasy Serum/Plasma Advanced Kit (Qiagen). The concentration and purity were evaluated with the RNA Nano 6000 Assay Kit and an Agilent Bioanalyzer 2100 System (Agilent Technologies).

Whole-transcriptome RNA library preparation and sequencing

According to the instructions of the SMARTer Stranded Total RNA-Seq Kit V2 (Takara), a total amount of 250 pg-10 ng RNA per sample was used as input material for RNA-seq library preparation. For small RNA libraries, a total amount of 1 ng-500 ng RNA per sample was used as input material for the QIAseq miRNA Library Kit (Qiagen). The quality of RNA-seq libraries and small RNA libraries was assessed with an Agilent Bioanalyzer 2100 (Agilent Technologies). Based on the acBot Cluster Generation System, the index-coded samples were clustered using TruSeq PE Cluster Kitv3-cBot-HS (Illumina). Then, the prepared libraries were sequenced on an Illumina NovaSeq 6000 platform. Paired-end reads were generated at EchoBiotech Co. Ltd., Beijing, P. R. China.

Bioinformatics analysis

The R package DESeq2 was used for the differential expression analysis of circRNAs, lncRNAs, miRNAs, and mRNAs between HDs and GC patients. The criteria were set as $|\log_2 FC| > 1$ and $P < 0.01$. The R package pheatmap was used for clustering analysis of these differentially expressed circRNAs, lncRNAs, miRNAs, and mRNAs. The Cancer-Specific CircRNA Database (CSCD) and CircInteractome databases were used to predict the target miRNAs of circRNAs. The TargetScan, miRDB, and miRTarBase databases were used to predict the target genes of miRNAs. Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway enrichment analysis and Gene Ontology (GO) functional enrichment analysis were performed with R 4.1.1 software to identify the enriched genes.

Verification of circRNA expression by dd-PCR

Dd-PCR was performed on a QX200 Droplet System using dd-PCR EvaGreen Supermix (Bio-Rad). The divergent primers overlapping the splice junction of hsa_circ_0079439 were designed by Primer-BLAST (Supplementary Table 2).

Statistical analysis

Statistical analyses were performed with SPSS 26.0 and GraphPad Prism 8.0. The expression levels of plasma exosomal hsa_circ_0079439 and standard serum biomarkers, including CEA, CA19-9, CA72-4, AFP, and CA125, were compared between the test cohort and validation cohort, and the differences were analyzed by the *t* test. The data are shown as the mean (SD). The expression levels and area under the receiver operating characteristic (ROC) curve (AUC) values of plasma exosomal hsa_circ_0079439 and standard serum biomarkers were used to assess their diagnostic efficiency for GC, EGC, and AGC. The results with $P < 0.05$ were considered significant.

RESULTS

Clinical characteristics of patients

There were 303 participants, including 63 HDs and 240 GC patients, enrolled in our study (Table 1). There were 177 patients (73.75%) with GC at T1 stage, 7 (2.92%) with GC at T2 stage, 37 (15.42%) with GC at T3 stage, and 19 (7.91%) with GC at T4 stage. Among these GC patients, 47 (19.58%) had lymph node metastasis, and 9 (3.75%) had distant metastasis. Most GC cases were in stage I (180, 75.00%), and others were in stage II (16, 6.67%), stage III (35, 14.58%), and stage IV (9, 3.75%). The median age (range) of the HD group was 53 years (24-81 years) and that of the GC group was 64 years (34-94 years). The ratio of males to females was 43/20 in the HD group, and 187/53 in the GC group.

Isolation and identification of exosomes

To characterize exosomes and confirm their isolation from GC patients and HDs, TEM, NTA, and WB analysis were performed. The exosomes appeared to be almost round in shape according to electron microscopy images (Figure 2A). NTA indicated that the diameter of exosomes ranged from 40 nm to 200 nm, which was consistent with previous research results[26] (Figure 2B). WB results showed that exosomes expressed typical markers, including CD9, TSG101, and CD81. The negative marker calnexin was not expressed (Figure 2C).

Bioinformatic analysis of whole-transcriptome RNA sequencing results

There were 14976 circRNAs, 3061 lncRNAs, 1629 miRNAs, and 12830 mRNAs identified by whole transcriptome RNA sequencing of exosomes. Clustering analysis was performed to reveal the differentially expressed circRNAs, lncRNAs, miRNAs, and mRNAs between HDs and GC patients. Unlike the relatively ambiguous clusters observed for the latter three RNA types (Supplementary Figure 1A-C), circRNAs were clearly clustered into five groups (Figure 2D). Based on data obtained from CSCD and CircInteractome, 2262 miRNA response elements were predicted. By intersecting the results obtained from TargetScan, miRDB, and miRTarBase, 8145 common potential target genes were identified. Then, we performed differential expression analyses of GC patient samples *vs* HD samples by using The Cancer Genome Atlas (TCGA) and identified 2512 genes (1072 upregulated, 1440 downregulated); 998 of these genes were also identified as potential targets in the abovementioned analysis. KEGG pathway analysis demonstrated that these genes were enriched in pathways in cancer, the cell cycle, and the PI3K-Akt signaling pathway (Supplementary Figure 2A). GO enrichment analysis indicated that these genes were associated with nuclear division, organelle fission, and cell cycle G1/S phase transition (Supplementary Figure 2B).

To further investigate the function of cluster 5 (68 circRNAs, marked in Figure 2D), similar analysis methods were used. These circRNAs were significantly upregulated in all GC samples, and 1731 target miRNAs were predicted. To identify potential miRNAs related to GC, we performed differential expression analyses based on TCGA and identified 64 miRNAs that were downregulated in GC samples *vs* HD samples. Thirty-one miRNAs were selected by taking the intersection of the two groups of results. These miRNAs were predicted to bind 1578 target genes. KEGG pathway analysis demonstrated that these genes were enriched in five pathways, including pathways in cancer, the PI3K-Akt signaling pathway, the MAPK signaling pathway, miRNAs in cancer, and cellular senescence (Figure 2E). GO enrichment analysis indicated that these genes were associated with nuclear division, organelle fission

and cell cycle G1/S phase transition (Figure 2F).

We generated a circRNA-miRNA-mRNA regulatory network related to the genes enriched in the top 5 KEGG pathways. Ultimately, we found that six circRNAs (hsa_circ_0113953, hsa_circ_0076179, hsa_circ_0007353, hsa_circ_0012823, hsa_circ_0001470, and hsa_circ_0079439) were included in all the networks (Supplementary Figure 3A-E).

Similar to a previous study, the expression levels of ncRNAs in exosomes were consistent with those in GCCs or tissues[27]. Then, we assessed the expression levels of the six circRNAs in NGECs and GCCs (AGS, MGC-803, SGC-7901, HGC-27, SNU-1, KATO III, and BGC-823) (Supplementary Figure 4A-F). The results showed that the expression levels of hsa_circ_0079439 in the GCCs were obviously higher than those in NGECs. Thus, hsa_circ_0079439 was selected for further validation by dd-PCR. The primers used to measure the levels of the six circRNAs are shown in Supplementary Table 1.

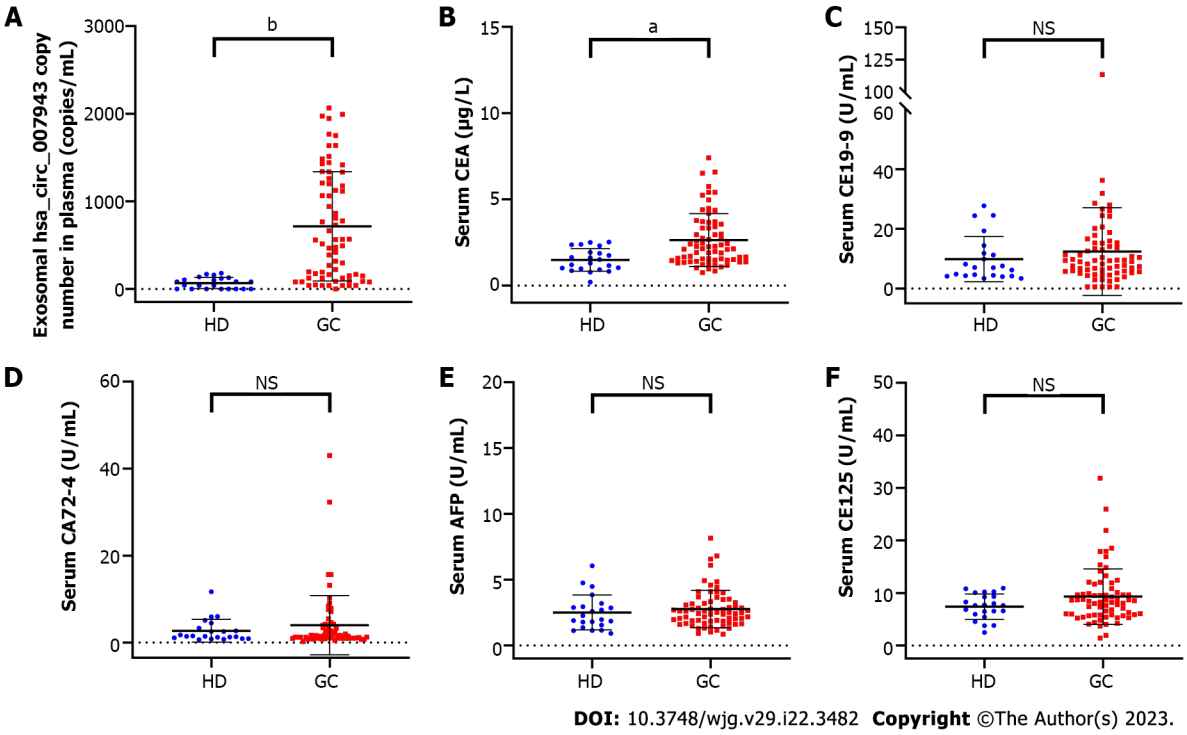
Expression levels of exosomal hsa_circ_0079439 in test and validation cohorts

In the test cohort, the expression levels of exosomal hsa_circ_0079439 were significantly higher in GC patients than in HDs ($P < 0.0001$) (Figure 3A). In addition, the levels of serum CEA in GC patients were higher than those in HDs ($P < 0.001$) (Figure 3B). However, the expression levels of CA19-9, CA72-4, AFP, and CA125 were not significantly different between GC patients and HDs (Figure 3C-F).

Furthermore, in the validation cohort, we again found that the expression levels of exosomal hsa_circ_0079439 were significantly higher in GC patients than in HDs ($P < 0.0001$) (Figure 4A). However, the expression levels of standard serum biomarkers between GC patients and HDs were not significantly different (Figure 4B-F).

Expression of exosomal hsa_circ_0079439 and its value in diagnosing GC, EGC, and AGC

To evaluate the diagnostic value of exosomal hsa_circ_0079439 for GC, EGC, and AGC, we combined the data obtained from the test cohort and validation cohort. We compared the expression levels and analyzed the ROC curves of exosomal hsa_circ_0079439, CEA, CA19-9, CA72-4, AFP, and CA125. The expression levels of exosomal hsa_circ_0079439 were significantly higher in GC patients than in HDs ($P < 0.0001$) (Figure 5A). However, the levels of standard serum biomarkers showed no significant difference between GC patients and HDs (Figure 5B-F). The AUC value of exosomal hsa_circ_0079439 was higher than those of CEA, CA19-9, CA72-4, AFP, and CA125 (0.8595 *vs* 0.5862, 0.5660, 0.5360, 0.5082, and 0.5018, respectively) (Figure 5G). To investigate the changes in the expression levels of exosomal hsa_circ_0079439 before and after treatment, we analyzed 30 paired plasma samples obtained from GC patients. The expression levels of exosomal hsa_circ_0079439 were significantly decreased after treatment (Figure 5H) ($P < 0.05$).



To determine whether the results were similar in EGC patients, all GC patients were divided into two groups (EGC patients and AGC patients). The expression levels of exosomal hsa_circ_0079439 were obviously higher in EGC patients ($P < 0.0001$) and AGC patients ($P < 0.0001$) than in HDs (Figure 6A). However, the serum levels of CEA, CA19-9, CA72-4, AFP, and CA125 could not be used to distinguish EGC patients from HDs (Figure 6B-F). The AUC value of exosomal hsa_circ_0079439 was obviously higher than those of CEA, CA19-9, CA72-4, AFP, and CA125 (0.8433 *vs* 0.5732, 0.5362, 0.5203, 0.5024, and 0.5352, respectively) (Figure 6G).

In addition, the serum levels of CEA, CA19-9, and CA125 were apparently higher in AGC patients than in HDs ($P < 0.05$) (Figure 6B, C and F). However, when comparing the levels of CA72-4 and AFP, there was no significant difference between AGC patients and HDs (Figure 6D and E). The AUC value of exosomal hsa_circ_0079439 was obviously higher than those of CEA, CA19-9, CA72-4, AFP, and CA125 (0.9050 *vs* 0.6228, 0.6497, 0.5801, 0.5379, and 0.6058, respectively) (Figure 6H).

DISCUSSION

Although the incidence and mortality rates of GC have declined over the past century, GC is still a major health problem worldwide, especially in East Asian countries[2,28]. GC has a poor prognosis in most patients due to late detection. Currently, the overall survival rate of EGC patients treated by endoscopy can exceed 90%[28,29]. Nonetheless, the 5-year survival rate of AGC patients with distant metastases is lower than 5%[30]. However, a screening program carried out by the Shanghai Research Institute in ten medical centers showed that the rate of EGC diagnosis is only 9.61%[28].

The clinical symptoms of EGC are atypical in most patients, and these symptoms include anorexia, malnutrition, and stomachache[2]. The methods of early diagnosis of GC include detection of standard serum biomarkers, barium radiography, computerized tomography, and endoscopic biopsy[31]. Over

time, the role of liquid biopsy in GC has received close attention. Furthermore, liquid biopsy has emerged as a revolutionary strategy for the early diagnosis of cancers, detection of therapeutic targets, prediction of prognosis, monitoring of therapeutic efficacy, and analysis of drug resistance; it also has the advantage of being minimally invasive[14,32-34]. Although numerous studies have investigated biomarkers for the early detection of GC, there are still many limitations regarding the use of these biomarkers for the early diagnosis of GC. For example, CEA and CA72-4 are standard clinical biomarkers, but both lack sensitivity and specificity.

In recent years, exosomes have been found in nearly all types of human body fluids, such as blood, urine, breast milk, saliva, ascites, and cerebrospinal fluid. Because of their phospholipid bilayer membrane structure, they can protect bioactive cargos from degradation. There are many metabolites and products in exosomes produced by all kinds of cells. These cargoes include nucleic acids, proteins, lipids, and metabolites[35].

CircRNAs are a class of single-stranded noncoding RNAs[36]. Initially, circRNAs were considered to be the result of splicing errors. However, with the development of bioinformatics and high-throughput sequencing technologies, more circRNAs have been identified, and they have been found to be involved in the occurrence and development of many human diseases. Many studies have demonstrated that circRNAs are abundant, stable and conserved rather than random products of RNA splicing[36]. Due to their high stability, circRNAs have many important biological functions, including noncoding and coding functions. The most widely studied function is their role in the regulation of miRNA target genes as miRNA sponges or decoys. They can protect target mRNAs from miRNA-dependent degradation. Moreover, it has been found that circRNAs may function as protein sponges or decoys, enhancers of protein function, protein scaffolds, protein recruiters, and templates for translation[17,37].

For instance, Zhang *et al*[38] reported that exosomal circNRIP1, as a tumor promoter, sponges miR-149-5p to regulate the expression level of AKT1 in GC. Similarly, exosomal circSHKBP1 may be a promising circulating biomarker for GC diagnosis and prognosis[39]. Exosomal circSHKBP1 regulates the miR-582-3p/HUR/vascular endothelial growth factor pathway and suppresses HSP90 degradation to promote GC progression[39]. In addition, Lu *et al*[40] found that exosomal circ-RanGAP1 facilitates GC invasion and metastasis by targeting miR-877-3p to regulate vascular endothelial growth factor-A expression, suggesting that circ-RanGAP1 may act as a tumor promoter in GC.

Figure 4 Expression levels of exosomal hsa_circ_0079439, carcinoembryonic antigen, carbohydrate antigen 19-9, carbohydrate antigen 72-4, alpha-fetoprotein, and carbohydrate antigen 125 in the validation cohort. A: Absolutely quantitative detection of exosomal hsa_circ_0079439 copy number in plasma from healthy donors (HDs) (n = 41) and gastric cancer (GC) patients (n = 171) by droplet digital polymerase chain reaction; B-F: Expression levels of standard serum biomarkers in GC patients and HDs, including carcinoembryonic antigen (B), carbohydrate antigen (CA)19-9 (C), CA72-4 (D), alpha-fetoprotein (E), and CA125 (F). And all the results are shown as mean (SD). [a]P < 0.0001, NS: Not significant. HD: Healthy donor; GC: Gastric cancer; CEA: Carcinoembryonic antigen; CA19-9: Carbohydrate antigen 19-9; CA72-4: Carbohydrate antigen 72-4; CA 125: Carbohydrate antigen 125; AFP: Alpha-fetoprotein.

In this study, we performed cluster analysis of exosomal circRNAs, lncRNAs, miRNAs, and mRNAs based on the results of whole-transcriptome RNA sequencing. The results showed that circRNAs could be used to distinguish GC patients from HDs better than lncRNAs, miRNAs, and mRNAs. Then, we investigated the expression of exosomal hsa_circ_0079439 in HDs and GC patients, including EGC and AGC, by dd-PCR. The expression levels of exosomal hsa_circ_0079439 were significantly higher in GC patients.

In recent years, dd-PCR has become the latest technology used for DNA quantification. The reaction volume containing the nucleic acids is divided into thousands of nanosized droplets, each of which either contains the gene of interest or does not. After PCR amplification, each droplet is detected one by one. A droplet with a fluorescence signal is interpreted as a 1, and a droplet without a fluorescence signal is interpreted as a 0. According to the Poisson distribution principle and the number and proportion of positive droplets, the initial copy number or concentration of the gene of interest can be obtained. There is no suitable reference gene in exosomes for normalization of the expression levels of circRNAs in real-time PCR (RT-PCR) experiments. Previous studies have shown that dd-PCR can be used to accurately quantify the copy numbers of specific nucleotides in plasma without external calibrators and has higher sensitivity than RT-PCR[41-44]. Therefore, we compared the diagnostic efficiency of exosomal hsa_circ_0079439 in GC patients, especially EGC patients, with standard clinical biomarkers, by dd-PCR. We found that exosomal hsa_circ_0079439 had higher sensitivity and specificity than standard clinical biomarkers. The findings of this study support the notion that plasma exosomal circRNAs could serve as biomarkers for the diagnosis of EGC and might be new therapeutic targets as well as effective prognostic markers for GC.

However, there are still some limitations to our study. First, the main limitation of this study is that since it was conducted at a single center, selection bias may have affected the results. This may indicate that this method is suitable for the early diagnosis of GC in Asians but not necessarily in other populations. Second, some groups had relatively few samples, so the generalizability of our study results may be affected. Third, since there is no standard isolation method for exosomes, the use of different isolation methods may result in differences in detection efficiency for the early diagnosis of GC [45-47]. Fourth, although circulating exosomal circRNAs serve as good candidates for blood-based biomarkers, it will take some time before they can be applied in the clinic. Therefore, multicenter studies with larger sample sizes are encouraged to obtain more accurate results for the early diagnosis of GC.

Figure 5 Diagnostic value and expression levels of exosomal hsa_circ_0079439, carcinoembryonic antigen, carbohydrate antigen 19-9, carbohydrate antigen 72-4, alpha-fetoprotein, and carbohydrate antigen 125 in total participants for gastric cancer. A: Absolutely quantitative detection of exosomal hsa_circ_0079439 copy number in plasma from healthy donors (HDs) (n = 63) and gastric cancer (GC) patients (n = 240) by droplet digital polymerase chain reaction; B-F: Expression levels of standard serum biomarkers in GC patients and HDs, including carcinoembryonic antigen (B), carbohydrate antigen (CA)19-9 (C), CA72-4 (D), alpha-fetoprotein (E), and CA125 (F); G: Receiver operating characteristic curves of hsa_circ_0079439, carcinoembryonic antigen, CA19-9, CA72-4, alpha-fetoprotein, and CA125 in distinguish GC patients (n = 240) from HDs (n = 63); H: Changes of expression levels of exosomal hsa_circ_0079439 before and after treatment. And all the results are shown as the mean (SD). $^{a}P < 0.05$, $^{b}P < 0.0001$, NS: Not significant. HD: Healthy donor; GC: Gastric cancer; CEA: Carcinoembryonic antigen; CA19-9: Carbohydrate antigen 19-9; CA72-4: Carbohydrate antigen 72-4; CA 125: Carbohydrate antigen 125; AFP: Alpha-fetoprotein.

CONCLUSION

Based on whole-transcriptome RNA resequencing data, we found that circRNAs have greater potential than other RNA types as novel biomarkers for the detection of GC, especially EGC. To our knowledge, this study is the first to discover and verify that the levels of exosomal hsa_circ_0079439 are higher in GC patients than in HDs. In addition, exosomal hsa_circ_0079439 performs better in distinguishing EGC patients from HDs than standard clinical biomarkers. Overall, exosomal hsa_circ_0079439 is a prospective biomarker for the diagnosis of GC, including EGC and AGC.

ARTICLE HIGHLIGHTS

Research background

Gastric cancer (GC) is a major health problem worldwide, especially in East Asian countries, and GC has a poor prognosis in most patients due to late detection. Therefore, accurate early detection of GC is one of the most urgent issues in its management.

Research motivation

A number of studies have demonstrated that circular RNAs (circRNAs) play an important role in GC progression, invasion, and metastasis. However, the utility of exosomal circRNAs for early detection of GC is largely unknown.

Research objectives
To analyze the expression levels of plasma exosomal circRNAs from GC patients in different clinical stages to identify a novel biomarker for early detection of GC.

Research methods
Healthy donors (HDs) and GC patients diagnosed by pathology were recruited. Based on the results of whole-transcriptome RNA sequencing, the expression profiles of circRNAs were analyzed by bioinformatics methods and validated by droplet digital polymerase chain reaction. Then we compared the diagnostic efficiency of plasma exosomal circRNAs and standard serum biomarkers.

Research results
The expression levels of exosomal hsa_circ_0079439 were obviously higher in GC patients than in HDs ($P < 0.0001$). And the area under the curve value of exosomal hsa_circ_0079439 was obviously higher than those of carcinoembryonic antigen, carbohydrate antigen (CA)19-9, CA72-4, alpha-fetoprotein, and CA125 (0.8433 *vs* 0.5732, 0.5362, 0.5203, 0.5024, and 0.5352, respectively).

Research conclusions
Plasma exosomal hsa_circ_0079439 is a prospective biomarker for the diagnosis of GC.

Research perspectives
Multicenter studies with larger sample sizes are encouraged to obtain more accurate results for the early diagnosis of GC.

Abstract

BACKGROUND

Per-oral endoscopic myotomy (POEM) is emerging as a prefer treatment option for pediatric achalasia. However, data are limited on the long-term efficacy of POEM in children and adolescents with achalasia.

AIM

To evaluate the safety and long-term efficacy of POEM for pediatric patients with achalasia and compare those outcomes with adult patients.

METHODS

This retrospective cohort study was conducted in patients with achalasia who underwent POEM. Patients aged under 18 years were included in the pediatric group; patients aged between 18 to 65 years who underwent POEM in the same period were assigned to the control group. For investigation of long-term follow-up, the pediatric group were matched with patients from the control group in a 1:1 ratio. The procedure-related parameters, adverse events, clinical success, gastroesophageal reflux disease (GERD) after POEM, and quality of life (QoL) were evaluated.

RESULTS

From January 2012 to March 2020, POEM was performed in 1025 patients aged under 65 years old (48 in the pediatric group, 1025 in the control group). No significant differences were observed in the occurrence of POEM complications between the two groups (14.6% *vs* 14.6%; P = 0.99). Among the 34 pediatric patients (70.8%) who underwent follow-up for 5.7 years (range 2.6-10.6 years), clinical success was achieved in 35 patients (35/36; 97.2%). No differences were

observed in post-POEM GERD occurrence (17.6% *vs* 35.3%; P = 0.10). QoL was significantly improved in both groups after POEM.

CONCLUSION

POEM is safe and effective for pediatric patients with achalasia. It can achieve significant symptoms relief and improve QoL.

Key Words: Achalasia; Pediatric; Per-oral endoscopic myotomy; Long-term outcomes

Core Tip: Per-oral endoscopic myotomy (POEM) is widely accepted in adult patients with achalasia. However, there is limited data on the application of POEM in pediatric patients, particularly regarding the long-term outcomes. In this study, we evaluated the safety and long-term efficacy of POEM in pediatric patients and compared those results with adult patients. The results show that POEM is safe and effective for pediatric patients with achalasia.

INTRODUCTION

Achalasia is a rare disorder of the esophageal smooth muscle characterized by impaired relaxation of the lower esophageal sphincter (LES) and absent or spastic contractions in the esophageal body[1]. Recent studies have estimated that the annul incidence of achalasia in pediatric population is approximately 0.02-0.31 per 100000 individuals[2-4]. Despite this modest incidence rate, the disease burden of achalasia in pediatric patients is substantial owing to the extreme disruption caused to the patients' childhood and education. Children with achalasia suffer from dysphagia, regurgitation, vomiting, chest pain, weight loss, and respiratory symptoms (nocturnal cough, aspiration), with frequent emergency department visits, hospitalizations, and malnutrition caused by decreased dietary intake of these children[5].

The traditional management of achalasia includes medication, endoscopy, and laparoscopic Heller myotomy (LHM)[6]. Per-oral endoscopic myotomy (POEM) is a minimally invasive method of myotomy first applied in clinical since 2010[7]. Since then, numerous large scales, retrospective and prospective with long-term follow-up studies have shown that POEM is safe and effective in the treatment of achalasia in adult patients[8,9]. However, studies on the safety and long-term effectiveness of POEM in the treatment of pediatric population are limited[10-13]. Owning to the low incidence of achalasia in pediatric population, the sample sizes that can be included in studies are usually small which may affect the credibility of the results. POEM has been proved to be safe and effective in adult patients, comparing the results in pediatric patients with adult patients may further validated the effectiveness of POEM in pediatric patients. Furthermore, the long-term outcome of POEM is needed to be studied as children have a long-life expectancy. Therefore, the aim of this study was to comprehensively evaluate and analyze the safety and long-term outcomes of POEM in pediatric patients and compare with those in adults.

MATERIALS AND METHODS

Study design

We performed a retrospective cohort study to evaluate the outcome of pediatric patients with achalasia who underwent POEM in comparison to the outcome of all adult patients who underwent POEM within the same period. Written informed consent was obtained from each patient, and the study was approved by the Medical Ethics Committee of The First Medical Center of Chinese PLA General Hospital. Informed consent for patients aged less than 18 years was provided by their guardian.

Patients and data collection

The inclusion criteria in this study included: (1) Achalasia diagnosed by Eckardt score ≥ 4 and further confirmed by esophagogastroduodenoscopy (EGD), barium esophagram, and/or esophageal manometry; and excluding others secondary to tumor, autoimmune diseases, *etc.*; and (2) Patients with age ≤ 65 when performing POEM. Those patients with severe cardiopulmonary disease, blood coagulation disorders, or other underlying diseases were excluded from this study.

Patients aged less than 18 years who underwent POEM in The First Medical Center of Chinese PLA General Hospital, Beijing, China from January 2012 to March 2020 were included in the pediatric group, whereas patients between the ages of 18-65 who underwent POEM in the same period were assigned to the control group. Demographic data and the disease course of the achalasia, including the manifestations, diagnosis, and prior treatments, were recorded in detail upon admission to the hospital. In addition, the Urbach scale questionaries were completed to assess the quality of life (QoL) of achalasia patients[14].

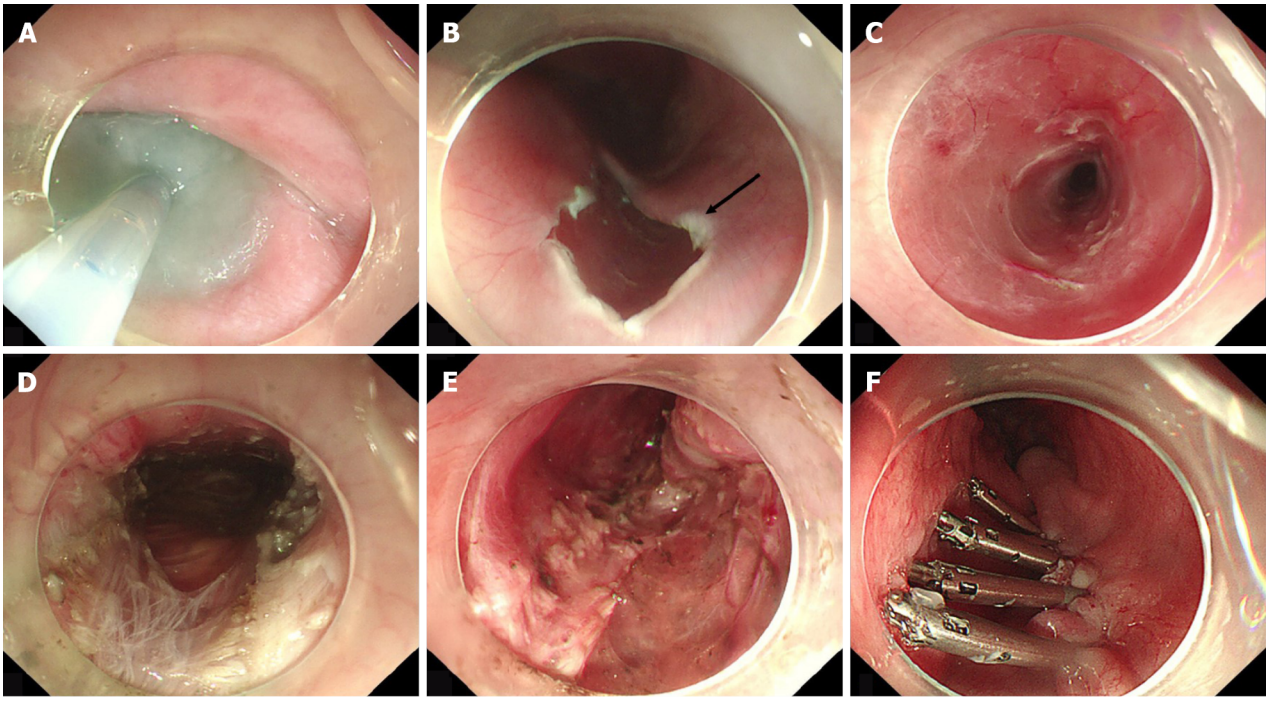
To evaluate the long-term outcomes of POEM in pediatric patients, we matched the pediatric group with patients from the control group in a 1:1 ratio. The matching principles were based on identical gender, the same type of Chicago classification and Ling classification, a surgery date that did not differ by more than three months, and the involvement of the same operating physician.

Patients were scheduled for follow-up visits at 3 mo, 6 mo, and 1 year after POEM, then yearly. EGD was performed to assess wound healing and to determine whether or not post-POEM reflux esophagitis existed. Moreover, esophageal high-resolution manometry, an X-ray barium meal, and 24-h esophageal pH monitoring were performed if possible. Patients were also contacted *via* telephone and the post-POEM complications, Eckardt score and the Urbach questionaries were recorded.

POEM procedure

POEM was performed after the patients fasted for 48 h and underwent EGD to ensure that no food residue remained in the esophageal lumen. The standard POEM procedure was performed as previously described and generally consisted of the following major steps: First, a submucosal injection of methylene blue saline solution (1:10000) was administered, then a mucosal incision was made approximately 6–10 cm above the gastroesophageal junction (GEJ); second, a submucosal tunnel was established, passing over the GEJ and 2–3 cm into the proximal stomach; third, a myotomy started 2 cm distal to the incision and extended 2–3 cm into the stomach; and finally, after assuring hemostasis and verifying that the endoscope could easily pass the cardia, the mucosal incision was closed with clips (Figure 1). Adequate extension of the submucosal tunnel across the GEJ was confirmed by visualizing blanched gastric mucosa and a vascular pattern. Carbon dioxide gas was used for insufflation with a CO_2 insufflator (UCR; Olympus) during procedures.

All patients were kept fasting for 3 d after the procedure. A liquid diet was started for an additional day. Antibiotics and proton pump inhibitor (PPI) were administered intravenously during the fasting period. An oral PPI was required for at least 4 wk subsequently. X-ray or chest and abdominal computed tomography was performed to evaluate gas-related adverse events.



Endoscopic classifications and definitions

The Ling classification was based on the endoscopic morphology of the esophageal lumen[15]. According to multiring structures, crescent-like structures, and diverticula, the Ling classification was recorded as Ling I, Ling IIa, Ling Ib, Ling IIc, and Ling III.

Perioperative outcomes and clinical follow-up were evaluated. Perioperative outcomes included technical success, and perioperative adverse events. Technical success was defined as the successful completion of the entire POEM procedure; if the procedure was not completed, it was defined as technical failure. Perioperative adverse events include mucosa injury, gas-related adverse events (pneumothorax, pneumoperitoneum and subcutaneous emphysema), pleural effusion, and bleeding. Procedure time was defined as the time from submucosal injection to the end of incision closure with clips. Clinical success was defined as a post-POEM Eckardt score ≤ 3. QoL was accessed by Urbach questionaries.

Statistical analysis

Depending on the distributional properties, outcome measures were expressed as the mean ± SD or as median values with ranges. For normally distributed continuous data, statistical significance was assessed by the Student's *t*-test; for categorical data, significance was assessed by the χ^2 test with Yates' correction when appropriate or by the Fisher's exact test; and for non-normally distributed continuous data, statistical significance was assessed by the Wilcoxon test. A P value of < 0.05 was established as the significance level.

The black arrow points to the inversed T-shaped incision; C: The submucosal tunnel establishment; D and E: Myotomy in the submucosal tunnel; F: Mucosal incision was closed with clips.

RESULTS

From January 2012 to March 2020, POEM was performed in 1073 patients aged under 65 years old (48 in the pediatric group and 1025 in the control group).

Baseline characters

The demographic and clinical characteristics of the patients in the two groups are shown in Table 1. There was no significant difference in gender distribution between the two groups. The median age of the pediatric patients who underwent POEM in our hospital was 16 years (range 7-18 years). Compared with control group, body weight index of pediatric group was significantly lower (17.7 *vs* 20.9, $P < 0.001$). Although the median disease course was significantly shorter in the pediatric group (median 17.5 mo *vs* 48 mo, $P < 0.001$), no significant differences were observed between the two groups regarding the type of Chicago classification, type of Ling classification and residual LES pressure. Twelve pediatric patients and 183 adult patients had undergone prior treatments, including botulinum toxin injection, pneumatic balloon dilation, endoscopic stent placement, POEM and LHM. In terms of prior treatment history, there were 4 (8.3%) patients received botulinum toxin injection, 5 (10.4%) patients received pneumatic balloon dilation, 1 (2.1%) patient had POEM and 2 (4.2%) patients had more than one treatment method in pediatric group. While 46 (4.5%) patients had botulinum toxin injection, 92 (9.0%) patients had pneumatic balloon dilation, 9 (0.9%) patients had POEM, 10 (1.0%) had LHM, 14 (1.4%) patients had endoscopic stent placement, and 12 (1.2%) had more than one treatment method in control group.

Procedure-related characteristics and safety

The procedure results in the two groups are shown in Table 2. All pediatric patients successfully underwent POEM. Of the 1025 patients in control group, 1016 (99.1%) had technique success; nine patients could not complete the POEM procedure because of serious submucosal adhesions. No significant differences were observed between the pediatric and control groups regarding the length of tunnel, length of esophageal myotomy, length of gastric myotomy, types of myotomy and procedure time. The mean lengths of the tunnel were 10.8 cm (range, 7–14 cm) and 11.2 cm (range, 5-20 cm), respectively, whereas the length of the esophageal and gastric tunnels were 5.3 cm (range, 1-9 cm) and 1.9 cm (range, 0-4 cm) in pediatric group and were 5.2 cm (range, 3-15 cm) and 1.9 cm (range, 0-4 cm) in control group. A progressive full-thickness myotomy was the most common type of myotomy in both group (87.5% in pediatric group and 78.0% in control group). The types of myotomy in the remaining pediatric patients involved full thickness muscle myotomy (6.3%), circular muscle myotomy (2.1%), and other types (4.2%). In the control group, full-thickness myotomy accounted for 9.6%, circular myotomy

accounted for 5.5%, and other incision types accounted for 6.9%. The mean procedure time was 43.9 min (range, 24-116 min) and 47.1 min (14-160 min) respectively.

No significant differences were observed between the pediatric and control groups regarding the overall complications of POEM (14.6 % *vs* 14.6 %; *P* = 0.997). All of the mucosa injuries were closed with titanium clips and porcine fibrin glue. Patients with pneumoperitoneum treated by puncture with a 10-mL syringe intra-operatively and patients with subcutaneous emphysema gradually absorbed the gas without special intervention. In the pediatric group, three complications of POEM occurred in seven patients (7/48; 14.6%), with three of these patients presenting with mucosa injury, two presenting with

[1]Other types of myotomy include circular muscle incision plus balloon plasty and glass-style anti-reflux myotomy.

pneumoperitoneum, and two presenting with subcutaneous emphysema. In control group, in addition to mucosa injury and gas-related complications, a 27-year-old male patient had delayed bleeding with hematemesis 11 d after the POEM and he underwent gastroscopic hemostasis. The patient with pleural effusion was treated with closed thoracic drainage. None of the patients with complications required surgical intervention or intensive care unit (ICU) transfer.

Efficacy

The median follow-up period was 5.7 years (range 2.6-10.6 years) for the pediatric group and 14 patients were lost for long-term follow-up. Significant differences were shown in the Eckardt score, QoL, height, weight, residual LES pressure and numbers of months absent from school of the pediatric patients before and after POEM (Table 3). The Eckardt score after median 5.7 years of follow-up was significantly declined compared with the score before POEM (8.0 *vs* 1.1, $P < 0.001$) and all symptom component of the Eckardt score decreased significantly. QoL was assessed by Urbach scale questionaries, which is a 10-item measure of disease-specific health-related QoL that sampled the concepts of food tolerance, dysphagiarelated behavior modifications, pain, heartburn, distress, lifestyle limitation, and satisfaction. Scores on the Urbach scale questionaries range from 10-33, and lower scores indicate better QoL. Urbach scores were significantly lower in pediatric patients at long-term follow-up after POEM treatment compared with pre-treatment scores (24.7 *vs* 12.8, $P < 0.001$). The height and weight of pediatric patients also improved significantly at follow-up (163.7 cm *vs* 170.5 cm and 49.9 kg *vs* 64.3 kg, $P < 0.001$). Moreover, the absences from school decreased significantly (median 3.3 mo *vs* 0.1 mo, $P < 0.001$).

To compare the long-term outcomes of POEM in pediatric patients and adult patients, we matched the pediatric group with patients from the control group in a 1:1 ratio. The matching principles were based on identical gender, the same type of Chicago classification and Ling classification, a surgery date that did not differ by more than three months, and the involvement of the same operating physician. The long-term outcomes of POEM in pediatric patients and matched adult patients were shown in Table 4. The median follow-up time in pediatric group and matched adult group was 5.7years (range 2.6-10.6 years) and 6.0 years (range 2.7-10.7 years) respectively. Patients in both groups had clinical symptoms relief and QoL improvement after POEM. No significant differences were observed between the two groups regarding the Eckardt scores, Urbach scores, clinical failure and clinical reflux evaluation. Before POEM treatment and at post-operative follow-up, the body mass index (BMI) of matched control group was significantly greater than that of pediatric group (17.7 *vs* 20.0; 20.8 *vs* 24.0).

Table 3 The long-term outcomes of per-oral endoscopic myotomy in pediatric patients

	Pre-POEM	Post-POEM	*P* value
Eckardt score, mean (range)	8.0 (4-11)	1.1 (0-4)	< 0.001
Dysphagia, mean ± SD	2.8 ± 0.7	0.6 ± 0.7	< 0.001
Regurgitation, mean ± SD	1.7 ± 0.8	0.1 ± 0.2	< 0.001
Chest pain, mean ± SD	1.0 ± 0.9	0.4 ± 0.6	< 0.001
Weight loss, mean ± SD	1.5 ± 1.2	0.0 ± 0.0	< 0.001
Urbach score, mean (range)	12.8 (10-20)	24.7 (18-30)	< 0.001
Height, mean (range), cm	163.7 (120-184)	170.5 (159-185)	< 0.001
Weight, mean (range), kg	49.9 (22.2-82)	64.3 (47-100)	< 0.001
Number of months absent from school, mean (range), months	3.3 (0.5-24)	0.1 (0-1)	< 0.001

POEM: Per-oral endoscopic myotomy.

Table 4 The long-term outcomes of per-oral endoscopic myotomy in pediatric group and matched control group

	Pediatric group (*n* = 34)	Matched control group (*n* = 34)	*P* value
Follow-up time, median (range), years	5.7 (2.6-10.6)	6.0 (2.7-10.7)	0.954
Pre-POEM, Eckardt score, mean (range)	8.0 (4-11)	7.9 (4-12)	0.975
Post-POEM (3 mo), Eckardt score, mean (range)	0.3 (0-3)	0.3 (0-2)	0.978
Post-POEM, Eckardt score, mean (range)	1.1 (0-4)	1.4 (0-3)	0.088
Eckardt score[1] (pre-post), mean (range)	6.9 (2-10)	6.4 (0-12)	0.578
Pre-POEM BMI, median (range), kg/m^2	17.7 (11.2-26.8)	20.0 (16.4-28.7)	< 0.001
Post-POEM BMI, median (range), kg/m^2	20.8 (15.8-29.5)	24.0 (19.5-29.4)	< 0.001
BMI (Post-pre)[2], median (range), kg/m^2	3.7 (-1.7-13)	3.5 (0.7-12.9)	0.502
Pre-POEM, Urbach score, mean (range)	12.8 (10-20)	12.7 (10-20)	0.842
Post-POEM, Urbach score, mean (range)	24.7 (18-30)	25.7 (17-33)	0.221
Urbach score[3] (pre-post), mean (range)	11.9 (1-18)	13.0 (4-23)	0.254
Clinical success, *n* (%)	33 (97.1)	34 (100.0)	> 0.999
Clinical reflux evaluation	6 (17.6)	12 (35.3)	0.099
Reflux esophagitis by gastroscopy	2 (5.9)	2 (5.9)	
Symptomatic reflux	4 (11.8)	10 (29.4)	

[1]Eckardt score: The Eckardt score before per-oral endoscopic myotomy (POEM) minus the Eckardt score at last follow-up.
[2]Body mass index (BMI): The BMI value at the last follow-up minus the BMI value before POEM.
[3]Urbach score: The Urbach score before POEM minus the Urbach score at last follow-up.
POEM: Per-oral endoscopic myotomy; BMI: Body mass index.

However, the difference in BMI before and after POEM was similar in both groups (3.7 *vs* 3.5, $P = 0.502$).

All adult patients in matched group received clinical success. One pediatric patient was considered clinical failure because his Eckardt score was 4. The patient mainly has substernal pain and need to drink water to when eating dry food without weight loss and chest pain.

Gastroesophageal reflux disease (GERD) is the most common adverse event after POEM treatment [16]. Reflux esophagitis identified by EGD and assessed by the Los Angeles classification. A GerdQ score of GERD with a score of > 7 was defined as symptomatic reflux[11,13]. At median 5.7 years follow-up, 6 patients (6/34, 17.6%) were suffered from symptomatic reflux, with 2 patients (5.9%) showed reflux esophagitis (1 Los Angeles type A, 1 Los Angeles type B) on endoscopy and 4 patients (11.8%) were suffered from clinical reflux. In matched control group, 2 patients (5.9%) showed reflux esophagitis (1 Los Angeles type A, 1 Los Angeles type C) on endoscopy, 10 patients (29.4%) were suffered from clinical reflux. All patients were well controlled with medical therapy.

DISCUSSION

In this study, we included 48 pediatric patients and 1025 adult patients with achalasia and patients had a median 5.7 years followed-up. The risk of complications relating to POEM was not increased in pediatric patients, and the long-term efficacy of POEM in pediatric patients were similar to the results of adult group. Our results indicated that POEM is a safe and effective procedure for the management of pediatric achalasia.

Achalasia is a primary esophageal motility disorder with unknown etiology. While adults and children both present with progressive dysphagia initially to solids and in some cases to liquids, the manifestations can be more protean and challenging to diagnose in children. A majority of pediatric patients, especially those under 6-7 years of age, are often misdiagnosed as GERD and given acid-suppressive therapy[17]. Patients have dysphagia due to esophageal motility disorder, and some children may show reluctance to eat and be misdiagnosed as anorexia[18]. Up to 50% of children are treated with antacids or prokinetics before the diagnosis of achalasia is identified[19]. Dysphagia and regurgitation are the main symptoms of achalasia, and patients often suffer from malnutrition due to insufficient intake[20]. Upon majority of patients present normal BMI or even obese, there are almost 50% of patients to be at moderate or high risk for malnutrition at presentation[21]. Compared with adult patients, malnutrition in a pediatric patient may negatively affect long-term growth and development. Furthermore, psychology of children is immature, and the decline in QoL caused by achalasia can lead to a series of mental illnesses in pediatric patients such as low self-esteem, depression, anxiety, school stress or decreased performance[22]. Therefore, it is urgent to find an effective treatment method to relieve the symptoms of achalasia in pediatric patients. POEM is a is a less invasive therapy with promising treatment effect. Since the clinical application of POEM in 2010, a large number of studies have been conducted and shown that POEM is a safe and effective method for the treatment of achalasia in adult patients[7,23,24]. However, data of POEM for pediatric patients are limited. Due to the low incidence of achalasia in children and adolescents, the sample size is small in most studies which is difficult to systematically evaluate and avoid statistical bias. Therefore, comparing its outcomes with those in adults seems particularly necessary. In addition, pediatric patients have a long-life expectancy and the long-term outcomes of POEM should be investigated. To our best knowledge, this is the first study evaluated the safety and long-term efficacy of POEM in children and compared those with adults with the median follow-up time over 5 years.

In our study, we compare 48 pediatric patients with 1025 adults with a median follow-up over 5 years. The technique success achieved 100% in pediatric group and 99.1% in control group. Standard tunnel and the length of myotomy were applied during POEM procedure in both groups. According to the previous studies, pediatric patients were all received standard tunnel and myotomy length[11,13,25]. POEM-related parameters such as length of tunnel, length of myotomy, types of myotomy and operation time were similar to those of adult patients.

Our results showed that there are no significant differences between the pediatric and control groups regarding the overall complications of POEM. All pediatric patients who developed complications recovered with conservative management. While one adult patient had delayed bleeding with hematemesis need another endoscopic invention and one pleural effusion which treated with closed thoracic drainage. Liu *et al*[13] showed only five children (3.8%) experienced major adverse events, which were resolved by conservative treatment[13]. Peng *et al*[11] found two children (8.3%) developed perioperative subcutaneous emphysema during the procedure and were spontaneously absorbed without any intervention[11]. Wood *et al*[25] showed that among 21 pediatric patients who received POEM, one had mucosa injury and one had pneumoperitoneum. None of them need for reintervention [25]. Choné *et al*[26] indicated that 1 case (1%) of significant per-procedure bleeding, 7 cases (6%) had postoperative adverse events. None of them need surgery or transfer to ICU[26]. All these results indicate that POEM is a safe treatment method for pediatric patients.

In our study, all the pediatric patients with preoperative dysphagia and regurgitation reported improved or resolved symptoms at the median 5.7 years follow-up. All of them were free from the further intervention for achalasia after POEM. Compared with adult patients, POEM also achieved satisfactory long-term outcomes in pediatric patients. One pediatric patient was considered clinical failure at last time follow-up as his Eckardt score was 4. The patient began to experience intermittent dysphagia symptoms again in the second year after POEM and at last time follow-up the patient mainly has substernal pain and need to drink water to when eating dry food every day. In this patient, a submucosal tunnel of standard length was established, but the end of the tunnel was located at the EGJ, and only esophagomyotomy was performed. Studies had showed that in order to ensure the curative effect of POEM, the length of myotomy is routinely 8-10 cm, at least 2 cm below the EGJ[27]. Therefore, symptom recurrence of the patient may be related to insufficient myotomy and we suggested him could receive a re-POEM.

Several factors could limit the extent to which the results can be generalized in our study. First, we did not analysis the risk factors for complications of POEM in pediatric patients due to the small sample size. Second, the mean age was slightly older in pediatric group (median age was 16). This shortage is due to younger children tend to receive treatment in children's hospitals in China. Third, the study was retrospective and a single-center analysis.

CONCLUSION

In summary, POEM is safe treatment method and could achieve satisfactory long-term outcomes in pediatric patients. Furthermore, prospective, multicenter, and large sample studies are warranted to validate our conclusions.

ARTICLE HIGHLIGHTS

Research background

Achalasia is a rare disorder of the esophageal smooth muscle which cause dysphagia, regurgitation, chest pain and weight loss. In recent years, per-oral endoscopic myotomy (POEM) is emerging as a prefer treatment option for patients achalasia.

Research motivation

Although POEM was proved to be safe and efficacy for adult patients with achalasia, data of POEM in pediatric patients are limited.

Research objectives

To evaluate the safety and long-term efficacy of POEM for pediatric patients with achalasia.

Research methods

We performed a retrospective cohort study to evaluate the outcome of pediatric patients with achalasia who underwent POEM in comparison to the outcome of all adult patients who underwent POEM within the same period. To evaluate the safety of POEM, we compare the operation-related parameters and complications in the two groups. To evaluate the long-term efficacy of POEM, we compare the body mass index, clinical symptoms, quality of life in pediatric group before and after POEM; and we also compare those outcomes in pediatric group and matched adult group.

Research results

The risk of complications relating to POEM was not increased in pediatric patients, and the long-term efficacy of POEM in pediatric patients were similar to the results of adult group.

Research conclusions

POEM is safe treatment method and could achieve satisfactory long-term outcomes in pediatric patients.

Research perspectives

POEM can be an an effective treatment option for achalasia in pediatric patients.

Abstract

BACKGROUND

Although highly effective as a component of *Helicobacter pylori* (*H. pylori*) treatment regimen, tetracycline is associated with a high incidence of medication-related adverse events. Modified dosing of tetracycline as part of quadruple therapy may improve safety while providing comparable eradication rates.

AIM

To evaluate the efficacy and safety of modified dosing of tetracycline in patients receiving tetracycline and furazolidone-containing quadruple therapy in patients with *H. pylori* infection.

METHODS

Consecutive patients (10/2020-12/2021) who received tetracycline and furazolidone quadruple therapy for *H. pylori* infection at Sir Run Run Shaw Hospital were identified. All patients received tetracycline, furazolidone, proton pump inhibitor, and bismuth for 14 d as primary or rescue therapy. Modified tetracycline dose group received tetracycline 500 mg twice daily while standard group received 750 mg twice daily or 500 mg three times daily.

RESULTS

Three hundred and ninety-four patients [mean age = 46.3 ± 13.9, male = 137 (34.8%), and 309 (78.4%) primary therapy] completed tetracycline and furazolidone quadruple therapy for *H. pylori* infection including those who received modified tetracycline dose in 157 and standard doses in 118 (750 mg twice daily) and 119 (500 mg three times daily). Eradication rates in the modified tetracycline dose group were 92.40% and in the standard groups, eradication rates were 93.20% for 750 mg twice daily group and 92.43% for 500 mg three times daily group, respectively, without statistical difference (P = 0.959). The incidence of adverse events was lower in the modified tetracycline dose (15.3% *vs* 32.3% and 29.4%; P = 0.002) compared to the standard dose group.

CONCLUSION

In a real-world experience, modified tetracycline dosing as part of tetracycline and furazolidone quadruple therapy for 14 d demonstrated high efficacy, comparable to standard tetracycline dose regimens, with a favorable safety profile.

Key Words: *Helicobacter pylori*; Tetracycline; Furazolidone; Eradication; Penicillin allergy; Bismuth quadruple therapy

INTRODUCTION

Helicobacter pylori (*H. pylori*) infection is associated with the development of chronic gastritis, peptic ulcer, and gastric cancer. Approximately 75% of gastric cancers worldwide can be attributed to *H. pylori*-induced inflammation and injury[1]. China is in a geographic area with high prevalence of *H. pylori* infection which parallels to high incidence of gastric cancer. Prevalence of *H. pylori* infection is estimated to be as high as 50%, and the number of incident cases of gastric cancer accounts for about 44% all patients newly diagnosed with gastric cancer globally[2,3]. Following the recognition of *H. pylori* gastritis as an infectious disease in 2015, guideline recommend that all patients diagnosed with infection should receive eradication therapy. Unless there are competing considerations such as comorbidities, re-infection rates in their communities, competing health priorities of society and financial cost[4].

With the alarming rise in the prevalence of clarithromycin-resistant *H. pylori* infection, increased incidence of treatment failure has been observed[5,6]. In addition, other proposed causes of treatment failure of *H. pylori* eradication therapy include poor patient adherence, host genetics (low gastric pH and metabolism-enhancing phenotypes of CYP2C19), and high bacterial load[7,8]. A systematic review and meta-analysis that included data from 45 countries, found that secondary resistance rates by regions ranged from 15% to 67% for clarithromycin, 19% to 30% for levofloxacin, and 30% to 65% for metronidazole[9]. However, resistance rate remains low for tetracycline, generally occurring in less than 5%. The proportion of strains with dual resistance to tetracycline and furazolidone was 0.5%[10]. Given high efficacy, tetracycline-based bismuth quadruple therapy is the preferred first-line therapy in China [3]. All major society guidelines including Maastricht VI/Florence Consensus Report[11], Toronto Consensus[12], and American College of Gastroenterology guidelines[9] recommend tetracycline-based quadruple therapy as first-line therapy in areas with high (> 15%) prevalence of clarithromycin resistance or in patients with previous macrolide exposure.

Tetracycline exhibits activity against *H. pylori* by binding reversibly to a pocket in the 30S subunit of bacterial ribosomes containing 16S rRNA, causing bacteriostatic and bactericidal effects by inhibiting protein synthesis and bacterial growth[13]. Furazolidone is a nitrofuran antibiotic with activity against *H. pylori* with a high absorption and distribution profile[14]. Tetracycline and furazolidone-based quadruple therapies have achieved high eradication rates in China of 91.7% and 95.2% on intention-to-

treat (ITT) and per-protocol (PP) analyses[15]. However frequent dosing requirements (three to four times daily) and high incidence of antibiotic related adverse events have resulted in reduced adherence and treatment failure[15,16], limiting effectiveness in clinical practice.

The aim of the study is to compare the efficacy and safety of modified twice daily dosing of tetracycline compared to standard tetracycline, furazolidone-containing bismuth quadruple therapy in *H. pylori* infection patients. Our goal is to determine whether lower and simplified dosing of tetracycline can achieve similar eradication rate as standard tetracycline, furazolidone quadruple therapy in a real-world setting.

MATERIALS AND METHODS

Study design and participants

Consecutive patients age > 18 years of age who were diagnosed with *H. pylori* infection and received tetracycline, furazolidone-containing quadruple therapy for 14 d at Sir Run Run Shaw Hospital (Hangzhou, China) between October 2020 to December 2021 were identified. This study was approved by the Institutional Review Board of Sir Run Run Shaw Hospital, Medical School, Zhejiang University, Hangzhou (SRRSH: 2022-431).

All patients were diagnosed as *H. pylori* infection by positive ^{13}C-urea breath test (UBT) and ^{13}C-UBT was performed again one month after completion of the planned treatment. Patients who had prior use of PPI, bismuth, or antibiotics one month prior to initiation of tetracycline, furazolidone-containing quadruple therapy were excluded. Furthermore, patients who had previous surgical history of upper gastrointestinal diseases; pregnant, severe medical comorbidities, allergies to any component of the tetracycline, furazolidone-containing quadruple regimen, or incomplete information were excluded for the analysis.

Diagnosis of H. pylori infection and treatment regimen

H. pylori infection was diagnosed by positive 13C-UBT (75 mg 13C-urea, Shenzhen Zhonghe Headway Bio-Sci & Tech Co., Ltd.) and 13C collection time was 30 min. Eradication was defined as negative urea breath test (< 0.4%; 0.4% as the cutoff value) according to previous Chinese studies[17-19]. Three treatment groups consisting of tetracycline-furazolidone-PPI and bismuth for 14 d with differing doses and frequency of tetracycline administration were examined. Tetracycline was given as 500 mg twice daily in the modified tetracycline dose group, and 750 mg twice daily or 500 mg three times daily in the standard tetracycline dose group[3]. Tetracycline and furazolidone were prescribed half an hour after meals; proton pump inhibitors (PPIs) included esomeprazole, rabeprazole, lansoprazole, and pantoprazole, were given 30 min before morning and evening meals; colloidal bismuth pectin capsules and bismuth potassium citrate capsules were also prescribed 30 min before morning and evening meals. Specific drugs dosage information is as follows: Furazolidone 100 mg twice daily, colloidal bismuth pectin capsules 400 mg twice daily, bismuth potassium citrate capsules 600 mg twice daily, esomeprazole 20 mg twice daily, rabeprazole 10 mg twice daily, lansoprazole 30 mg twice daily, pantoprazole 20 mg twice daily.

Medication adherence and adverse events

13C-UBT result medication adherence and adverse events were obtained by reviewing electronic medical records and telephone surveys when patients were at completion of 14-d *H. pylori* therapy and 4 wk after completion of the treatment. Medication adherence was defined as poor when they had taken < 80% of the total medication.

Endpoint

The primary outcome was the eradication rate of *H. pylori* infection in each treatment group, the secondary endpoint was the incidence of adverse events and medication adherence rate.

Statistical analysis

Continuous variables were expressed as the mean ± SD, and categorical variables were expressed as numbers and percentages. Continuous variables were evaluated using one-way ANOVA and categorical variables using Pearson χ^2 or Fisher's exact test. Furthermore, adjusted for age, gender, education, smoking, alcohol drinking, hypertension, hyperlipidemia, diabetes, treatment line, bismuth type, PPI type, and treatment regimen into multivariate logistic regression model to identify independent risk factors associated with eradication failure. Two-sided $P < 0.05$ was considered significant. IBM SPSS Statistics SPSS 26.0 software (IBM Corp.,) was used for all analysis.

RESULTS

Patients enrolled and baseline characteristics

During the study period, 394 patients received tetracycline, furazolidone-containing quadruple therapy for *H. pylori* infection met study criteria. The mean age was 46.3 ± 13.9, male = 137 (34.8%), and 309 (78.4%) received treatment as primary therapy for *H. pylori* infection. Of the 85 patient who had prior *H. pylori* therapy, 72 (18.3%) had one and 13 (3.3%) had two or more previous therapies. Most common failed *H. pylori* regimens among those with available data included amoxicillin-furazolidone in 25 (34.7%) and furazolidone-clarithromycin in 8 (11.1%) (Supplementary Table 1).

In this study, eradication of *H. pylori* infection was successful in 365 patients and failed in 29 patients. Patients with successful or failed eradication did not differ between groups in demographic characteristics such as age, sex, smoking history, drinking history, educational background, and family history of gastric cancer. A total of 316 patients completed gastroscopy, of which 67.7% and 12.3% were endoscopy diagnosed with gastritis or peptic ulcer in the successful eradication group, respectively, with no difference between the two groups (P = 0.597). Pathological diagnosis of intestinal metaplasia was present in 30.9% and 24.1% of patients between the two groups, respectively, with no difference between groups (P = 0.557). A total of 157 patients received low-dose tetracycline and 237 patients received standard-dose tetracycline, including 118 and 119 patients in the 750 mg twice daily and 500 mg three times daily groups, respectively. There was no difference in the distribution of treatment regimens between eradication success or failure groups (P = 0.959). Initial treatment was achieved in 79.7% of patients in the eradication success group and 66.7% of patients in the failure group. Specific patient demographics and clinical data are presented in Table 1.

When stratified by tetracycline dose, 157 (39.8%) patients received modified tetracycline dose and 237 (60.2%) received standard tetracycline dose including 118 (49.8%) and 119 (50.2%) who received 750 mg b.i.d. and 500 mg t.i.d. dosing, respectively (Supplementary Table 2). Demographic data including age, gender, education, and alcohol/tobacco use were similar among the three groups (Supplementary Table 2). However, a higher proportion of patients who received modified tetracycline dose (87% *vs* 57% and 79%, P = 0.003) compared to standard tetracycline dose received primary therapy for *H. pylori.*

Eradication of H. pylori infection

The eradication rates in the modified tetracycline dose group were 92.4% compared to 93.2% in the 750 mg b.i.d. group and 92.4% in the 500 mg t.i.d. group without difference (P = 0.959).

Eradication of *H. pylori* infection as primary or rescue therapy: Of the 309 patients naïve to prior *H. pylori* treatment, eradication rates for those receiving 500 mg b.i.d., 750 mg b.i.d., and 500 mg t.i.d. dosing were 93.4%, 97.5%, and 92.6%, respectively, without difference P = 0.338) (Table 2).

Of the 85 patients who had prior *H. pylori* treatment as rescue therapy, eradication rates for those receiving 500 mg b.i.d., 750 mg b.i.d., and 500 mg t.i.d. dosing were 85.7%, 84.6%, and 92.0%, respectively, with difference P < 0.0001).

Among subgroup of patients who previously received amoxicillin-furazolidone regimen, eradication rates for those receiving 500 mg b.i.d., 750 mg b.i.d., and 500 mg t.i.d. dosing were 83.3%, 88.2%, and 83.3%, respectively, without difference (P = 0.918) (Supplementary Table 1).

Eradication of *H. pylori* infection with penicillin allergy: Of the 76 (19.3%) patients with penicillin allergy, eradication rates for those receiving 500 mg b.i.d., 750 mg b.i.d., and 500 mg t.i.d. dosing were 91.7%, 95.5%, and 93.1% by ITT analysis, respectively, without difference (P = 0.770) (Table 3).

Of the 63 patients with penicillin allergy naïve to *H. pylori* therapy, eradication rates for those receiving 500 mg b.i.d., 750 mg b.i.d., and 500 mg t.i.d. dosing were 95.0%, 100%, and 90.0%, respectively, without difference (P = 0.372) (Supplementary Table 3).

Eradication rates of removing the discontinued treatment population: Of all 394 patients, a total of 14 discontinued treatment due to serious adverse events or arbitrarily, including 5, 3, and 6 in the three treatment groups, respectively. Five patients in the 500 mg twice daily group and six patients in the 500 mg three times daily group discontinued treatment due to adverse reactions, but eradication of *H. pylori* infection was eventually successful. Three patients in the 750 mg twice daily group discontinued treatment, and eventually two patients failed eradication therapy. After removing these 14 patients, the eradication efficacy of the population was re-counted. The eradication rates in the three treatment groups were 92.10% (140/152), 95.65% (109/115), and 92.04% (104/113), respectively, with no statistically significant difference (P = 0.447).

Of the 298 patients naïve to prior *H. pylori* treatment, eradication rates among those 500 mg b.i.d., 750 mg b.i.d., and 500 mg t.i.d. dosing were 93.1%, 97.4%, and 92.1%, respectively, without difference (P = 0.310). Of the 82 patients who had prior *H. pylori* treatment as rescue therapy, eradication rates those receiving 500 mg b.i.d., 750 mg b.i.d., and 500 mg t.i.d. dosing were 85.7%, 89.2%, and 91.7%, respectively, with difference P < 0.0001). Of the 75 patients with penicillin allergy, eradication rates those receiving 500 mg b.i.d., 750 mg b.i.d., and 500 mg t.i.d. dosing were 91.7%, 95.5%, and 93.1%, respectively, without difference (P = 0.870).

500mg b.i.d.: Tetracycline twice daily; 750 mg b.i.d.: Tetracycline twice daily; 500 mg t.i.d.: Tetracycline three times daily.

Medication adherence and adverse events

Of 394 patients, 380 (96.4%) demonstrated good adherence to prescribed therapy. Furthermore, 79 patients (20.1%) experienced at least one adverse event with a cumulative number of 98 adverse events during the treatment period (Table 4). Subsequently, 14 (3.6%) patients discontinued the treatment.

The rates of adverse events among those receiving 500 mg b.i.d., 750 mg b.i.d., and 500 mg t.i.d. dosing was 5.3%, 32.3%, and 30.3%, respectively. The incidence of adverse events in the modified dose group was lower than the standard dose group ($P = 0.002$). The most frequent adverse event was fever in 18 (4.7%), bitter taste in 16 (4.1%), nausea in 12 (3.0%), and rash in 10 (2.5%) (Table 4).

Predictors of failed H. pylori eradication

On univariate analysis, age > 50 years (OR = 1.821, 95%CI: 0.841-3.943, $P = 0.128$), male gender (OR = 2.314, 95%CI: 0.998-4.564, $P = 0.051$), smoking status (OR = 2.245, 95%CI: 0.800-6.296, $P = 0.124$), alcohol use (OR = 1.899, 95%CI: 0.804-4.484, $P = 0.144$), rescue therapy (OR = 2.403, 95%CI: 1.088-5.307, $P = 0.03$), type 2 diabetes (OR = 4.016, 95%CI: 1.373-11.752, $P = 0.011$), hyperlipidemia (OR = 6.937, 95%CI: 2.720-17.691, $P < 0.0001$), and hypertension (OR = 6.964, 95%CI: 3.163-15.333, $P < 0.0001$) were associated failed *H. pylori* eradication. On multivariate analysis model, hyperlipidemia (aOR = 3.697, 95%CI: 1.149-11.899, $P = 0.028$) and hypertension aOR = 7.885, 95%CI: 2.582-24.081, $P < 0.0001$) were associated with failed *H. pylori* eradication (Supplementary Table 4).

DISCUSSION

To our knowledge, this is the first real-world study to evaluate the effectiveness and safety of modified dosing of tetracycline as part of tetracycline and furazolidone-containing bismuth quadruple therapy in patients with *H. pylori* infection. Our study demonstrated high *H. pylori* eradication rates of in the modified tetracycline dose of utilizing tetracycline 500 mg twice daily were 92.4%, similar to standard dosing utilizing tetracycline 750 mg twice daily or 500 mg three times daily regimens. Furthermore, the incidence of adverse events was lower in the modified tetracycline dosing (15.3% *vs* 32.3% and 29.4%; $P = 0.002$) compared to the regimen with standard tetracycline dosing.

Previous studies demonstrated that tetracycline and furazolidone quadruple therapy provide high eradication rates of 91.7% and 95.2% per ITT and PP analysis[15]. A randomized trial performed China demonstrated robust eradication rates of tetracycline and furazolidone quadruple therapy, even as rescue therapy of 77.5% and 85.0% per ITT and PP analysis[16]. Lower eradication rates may be

[2]The symptoms of a single adverse reaction are counted as 1, and a patient may have multiple adverse events.

P values were from two-side comparisons the differences among three treatment group. N: Total patient number; n: Patient number with side effects; 500 mg b.i.d.: Tetracycline twice daily; 750 mg b.i.d.: Tetracycline twice daily; 500 mg t.i.d.: Tetracycline three times daily.

attributed to clinical or agricultural overuse of antibiotics in northwest China where the primary resistance rates of *H. pylori* for furazolidone and tetracycline reached 21.0% and 19.3%[10]. Another study using Lactobacillus acidophilus (1 g t.i.d.) for 2 wk followed by bismuth-containing quadruple regimen (tetracycline 750 mg b.i.d. + furazolidone 100 mg b.i.d.) for 10 d as rescue therapy in patients showed eradication rates of 92.0% and 91.8% in ITT and PP analysis, respectively, suggesting that patients with refractory infection may benefit from tetracycline-containing bismuth quadruple regimen therapy[20].

Tetracycline exert bacteriostatic activity by binding bacterial ribosome and inhibit protein synthesis [13]. Pharmacokinetic properties including time over MIC (T > MIC) and maximum concentration (Cmax/MIC) are vital to antimicrobial activity of tetracycline leading to recommendations for frequent dosing regimens[21]. Interestingly our results demonstrated that tetracycline twice a day dosing was comparable to three times a day dosing. Our findings are consistent with a previous Korean study[22] that demonstrated that comparable high eradication rates of 93.9% with twice a day dosing of tetracycline comparable to four times a day dosing of 92.9% when maintaining a total tetracycline dose of 2 g a day utilizing tetracycline and metronidazole quadruple therapy. Furthermore, tetracycline concentrations in blood follow a plateau-shaped course with a slow rise and a slower drop, the serum half-life (t1/2) being in the range 6 h to 10 h. Although sparse data, previous study demonstrated that tetracycline dose of 300 mg produced a consistent and robust areas under the serum time curves of 26.9 mg × h/L ± 6.0 mg × h/L[23]. Our study demonstrated no appreciable difference in *H. pylori* eradication with tetracycline 750 mg and 500 mg twice daily dosing regimens. However, studies evaluating pharmacokinetics and pharmacodynamics of tetracyclines in *H. pylori* infection is limited and are mainly derived from treatment of primary or secondary syphilis[21].

Previously studied explored the optimal dose and interval of tetracycline as a component of tetracycline and furazolidone triple therapy for *H. pylori* infection. For example, an Iranian study of 52 patients receiving tetracycline 500 mg twice a day combined with furazolidone and PPI for 14 d resulted in an eradication rate of 96.3% with only occasional serious side effects[24]. Furthermore, a Chinese study of 60 patients evaluating 7-d therapy tetracycline 500 mg twice daily with furazolidone, ranitidine, and bismuth citrate demonstrated eradication rate of 85% in the ITT analysis and 91% in the PP analysis[25]. Studies evaluating tetracycline twice a day dosing as a component of tetracycline and metronidazole quadruple therapy resulted in high eradication rates of over 90%[22,26,27]. However, they were not comparative studies[22,27] or agents at doses different from that of standard BQT[26]. A

Korean study comparing tetracycline twice a day compared to four times a day as part of tetracycline and metronidazole quadruple therapy demonstrated eradication rate of 90.1%, similar to four times a day dosing but also similar adherence and incidence of adverse events (32.4% and 43.1%, $P = 0.254$)[28]. This study raised the possibility that dose reduction of tetracycline to improve adherence and reduce adverse events is possible while maintaining high eradication rates.

The minority (22.6%) of patients in our study population received tetracycline and furazolidone quadruple therapy for previous failed treatment. As expected, eradications appeared reduced among patients receiving rescue therapy. This may be related to development of resistance to furazolidone with recent study in China demonstrating alarming prevalence of 63.1% (736/1167) of furazolidone-resistance *H. pylori* strains among those who experienced prior treatment failure[29].

Safety of tetracycline-containing regimen have raised concern given high incidence of adverse events including gastrointestinal symptoms, allergies, asthma, and hemolytic anemia, loss of appetite, and severe liver injury. Early studies have reported impaired bone growth and maturation as well as deposition in teeth with tetracycline leading to avoidance of use in the pediatric population[30]. In previous studies evaluating tetracycline-containing bismuth quadruple regimens used as rescue therapy in penicillin-allergic patients, approximately one-third developed adverse events leading to discontinuation on therapy in tenth despite high (> 90%) eradication rates[15]. Standard dose of tetracycline in tetracycline and metronidazole regimens are generally lower than the doses utilize in tetracycline and furazolidone regimens given concern for compounded risk of adverse events associated with furazolidone. Our study confirmed that modified dosing and frequency of tetracycline as part of tetracycline and furazolidone therapy had a lower incidence of adverse events (15.3%) compared to the groups that received standard dosing (750 mg twice a day) or frequency (500 mg three times a day) of tetracycline of 32.3% and 29.4%, respectively. Previous studies showed similar incidence of overall adverse events (26%-32%) with *H. pylori* therapy containing standard dosing of 500 mg three times a day [15,16]. Furthermore, 14 (3.6%) patients discontinued therapy due to adverse reactions including 5 in the 500 mg twice a day group (3.2%). Previous studies have suggested as development of serious adverse effects of furazolidone (*i.e.*, fever, fatigue, and dizziness) led to discontinuation of the therapy related to high dose (*i.e.*, 200 mg twice a day) or longer duration (> 7 d) of therapy[31-33]. A recent randomized trial demonstrated that furazolidone had higher incidence of adverse events (37.6% *vs* 20.2%; $P = 0.003$) compared to tetracycline containing amoxicillin quadruple therapy[34]. Although unclear, some of the adverse events in the study are likely driven by the use of furazolidone rather than tetracycline.

There were limitations in our study mostly related to retrospective study design. Although categorized tetracycline and furazolidone doses were consistent across groups, variation in bismuth and PPI types and dose were observed. The differences in pharmacodynamic effects of different PPIs driven by CYP2C19 genetic polymorphism and higher proportion of patients receiving standard compared to modified dosing of tetracycline among those receiving rescue therapy may have introduced bias in the results. The treatment and eradication testing time taken in this study was 4 wk apart, but many previous studies have suggested that more accurate results can be obtained with a duration of 6-8 wk [35], and shorter testing intervals may have an impact on the results. Furthermore, lack of *H. pylori* culture and antibiotic sensitivity testing precluded determine for reasons for failed therapy.

CONCLUSION

Modified tetracycline dosing as a component of tetracycline and furazolidone quadruple therapy for 14 d demonstrated high and comparable *H. pylori* eradication rate while reducing the incidence of adverse events compared to standard tetracycline dose regimen. Randomized controlled studies comparing difference doses of tetracycline as a component of tetracycline and furazolidone quadruple therapy are needed to confirm our findings in patients with *H. pylori* infection.

ARTICLE HIGHLIGHTS

Research background

Although highly effective as a component of *Helicobacter pylori* (*H. pylori*) treatment regimen, tetracycline is associated with a high incidence of medication-related adverse events. Modified dosing of tetracycline as part of quadruple therapy may improve safety while providing comparable eradication rates.

Research motivation

To evaluate the efficacy and safety of modified dosing of tetracycline in a quadruple therapy in patients with *H. pylori* infection.

Research objectives
To compare the efficacy and safety of modified twice daily dosing of tetracycline compared to standard tetracycline, furazolidone-containing bismuth quadruple therapy in *H. pylori* infection patients. Our goal is to determine whether lower and simplified dosing of tetracycline can achieve similar eradication rate as standard tetracycline, furazolidone quadruple therapy in a real-world setting.

Research methods
Consecutive patients (10/2020-12/2021) who received tetracycline and furazolidone quadruple therapy for *H. pylori* infection at Sir Run Run Shaw Hospital were identified. All patients received tetracycline, furazolidone, proton pump inhibitor, and bismuth for 14 d as primary or rescue therapy. Statistical analysis was applied to analyze the eradication rate and the occurrence of adverse events in this population.

Research results
Eradication rates in the modified tetracycline dose group were 92.40% and in the standard groups, eradication rates were 93.20% for 750 mg twice daily group and 92.43% for 500 mg three times daily group, respectively, without statistical difference (P = 0.959). The incidence of adverse events was lower in the modified tetracycline dose (15.3% *vs* 32.3% and 29.4%; P = 0.002) compared to the standard dose group.

Research conclusions
In a real-world experience, modified tetracycline dosing as part of tetracycline and furazolidone quadruple therapy for 14 d demonstrated high efficacy, comparable to standard tetracycline dose regimens, with a favorable safety profile.

Research perspectives
Randomized controlled studies comparing difference doses of tetracycline as a component of tetracycline and furazolidone quadruple therapy are needed to confirm our findings in patients with *H. pylori* infection.

Abstract

BACKGROUND

It is controversial whether transjugular intrahepatic portosystemic shunt (TIPS) placement can improve long-term survival.

AIM

To assess whether TIPS placement improves survival in patients with hepatic-venous-pressure-gradient (HVPG) ≥ 16 mmHg, based on HVPG-related risk stratification.

METHODS

Consecutive variceal bleeding patients treated with endoscopic therapy + nonselective β-blockers (NSBBs) or covered TIPS placement were retrospectively enrolled between January 2013 and December 2019. HVPG measurements were performed before therapy. The primary outcome was transplant-free survival; secondary endpoints were rebleeding and overt hepatic ence-phalopathy (OHE).

RESULTS

A total of 184 patients were analyzed (mean age, 55.27 years ± 13.86, 107 males; 102 in the EVL+NSBB group, 82 in the covered TIPS group). Based on the HVPG-

guided risk stratification, 70 patients had HVPG < 16 mmHg, and 114 patients had HVPG ≥ 16 mmHg. The median follow-up time of the cohort was 49.5 mo. There was no significant difference in transplant-free survival between the two treatment groups overall (hazard ratio [HR], 0.61; 95% confidence interval [CI]: 0.35-1.05; P = 0.07). In the high-HVPG tier, transplant-free survival was higher in the TIPS group (HR, 0.44; 95%CI: 0.23-0.85; P = 0.004). In the low-HVPG tier, transplant-free survival after the two treatments was similar (HR, 0.86; 95%CI: 0.33-0.23; P = 0.74). Covered TIPS placement decreased the rate of rebleeding independent of the HVPG tier (P < 0.001). The difference in OHE between the two groups was not statistically significant (P = 0.09; P = 0.48).

CONCLUSION

TIPS placement can effectively improve transplant-free survival when the HVPG is greater than 16 mmHg.

Key Words: Hepatic venous pressure gradient; Transjugular intrahepatic portosystemic shunts; Cirrhosis; Variceal rebleeding; Survival

Core Tip: Hepatic venous pressure gradient helps clinicians to assess the prognosis of decompensated cirrhotic patients. The study included 184 patients showed that hepatic-venous-pressure-gradient (HVPG) before therapy as a risk stratification provides prognostic value. Treatment can be given with greater confidence with the management of patients by HVPG.

INTRODUCTION

As a result of portal hypertension related to cirrhosis, variceal bleeding (VB) has been the leading cause of death in cirrhotic patients[1]. More than 50% of cirrhotic patients who undergo the recommended hemostatic treatments are readmitted due to rebleeding within a year. Among them, the mortality rate is nearly 33%[2]. In view of the high rebleeding rate, further therapy to prevent rebleeding, which is defined as secondary prophylaxis, should be performed for patients surviving acute VB. Nonselective beta-blockers (NSBBs) can decrease the portal venous pressure by reducing the cardiac output and splanchnic vasodilation. In addition, to render varices ischemic and necrotic, some endoscopic treatments for VB have been developed. It is advocated that endoscopic variceal ligation (EVL), combined with NSBBs, should be the first line of therapy for the secondary prevention of VB, while transjugular intrahepatic portosystemic shunt (TIPS) placement should be performed in rebleeding patients and preemptive TIPS placement should only be performed for high-risk patients[3,4]. TIPS placement is a fluoroscopy-guided procedure in which a conduit is built between the systemic and portal venous systems with the intent of decreasing the portal pressure[5]. A study with a median follow-up of 16 mo concluded that early TIPS placement could reduce treatment failure and mortality among high-risk patients[6]. Preemptive treatment could also improve the survival of patients with acute-on-chronic liver failure and acute VB, as suggested in a European observational study[7]. However, diversion of the portal flow could also lead to hepatic encephalopathy (HE) resulting from hepatic hypoperfusion and liver failure[6,8]. Holster *et al*[5] noted that TIPS placement was associated with higher rates of early HE (within one year). Thus, it is not clear whether TIPS placement offers a survival benefit.

The hepatic venous pressure gradient (HVPG) has been shown to have prognostic value in both compensated and decompensated cirrhosis[3,4,9]. In patients with HVPG ≥ 16 mmHg, the mortality rate of acute variceal hemorrhage is increased[10]. Moreover, HVPG ≥ 20 mmHg has been a clinically effective predictor of early rebleeding[11]. In our previous study[12], which had a 1-year follow-up period, we concluded that covered TIPS placement was more effective than standard therapy in preventing rebleeding but that it did not improve survival.

On the basis of our earlier findings, we compared TIPS placement with EVL+NSBBs to assess whether TIPS placement improves survival in cirrhotic patients with VB based on HVPG-related risk stratification over a long-term period to obtain more precise individual treatments and better treatment

effects.

MATERIALS AND METHODS

Study design and patients

The study protocol was approved by the ethics committees of the Nanjing Drum Tower Hospital (Nanjing, Jiangsu Province, China). We retrospectively screened clinically stable cirrhotic patients with VB who were admitted to the Department of Gastroenterology of Nanjing Drum Tower Hospital from January 2013 to December 2019 in the prospectively maintained database (Figure 1). The included patients were diagnosed with liver cirrhosis by clinical, radiologic, and endoscopic examinations[13], and signed the informed consent form. The HVPG measurement was performed before therapy. Based on the HVPG-guided risk stratification (with the HVPG as a scale variable), patients with HVPG ≥ 16 mmHg were considered high-HVPG patients, and those with 10 mmHg ≤ HVPG < 16 mmHg were considered low-HVPG patients. The exclusion criteria of the study were as follows: (1) Non-standardized sequential endoscopic therapy; (2) previous secondary preventive intervention; (3) concomitant malignant tumors; (4) failure of sequential endoscopic therapy, *i.e.*, rebleeding before the eradication of varices; (5) severe heart failure (New York Heart Association stage IV), respiratory failure (PaO_2 < 60 mmHg) or severe kidney dysfunction (stage 5 chronic kidney disease); (6) pregnancy or lactation; and (7) missing follow-up data.

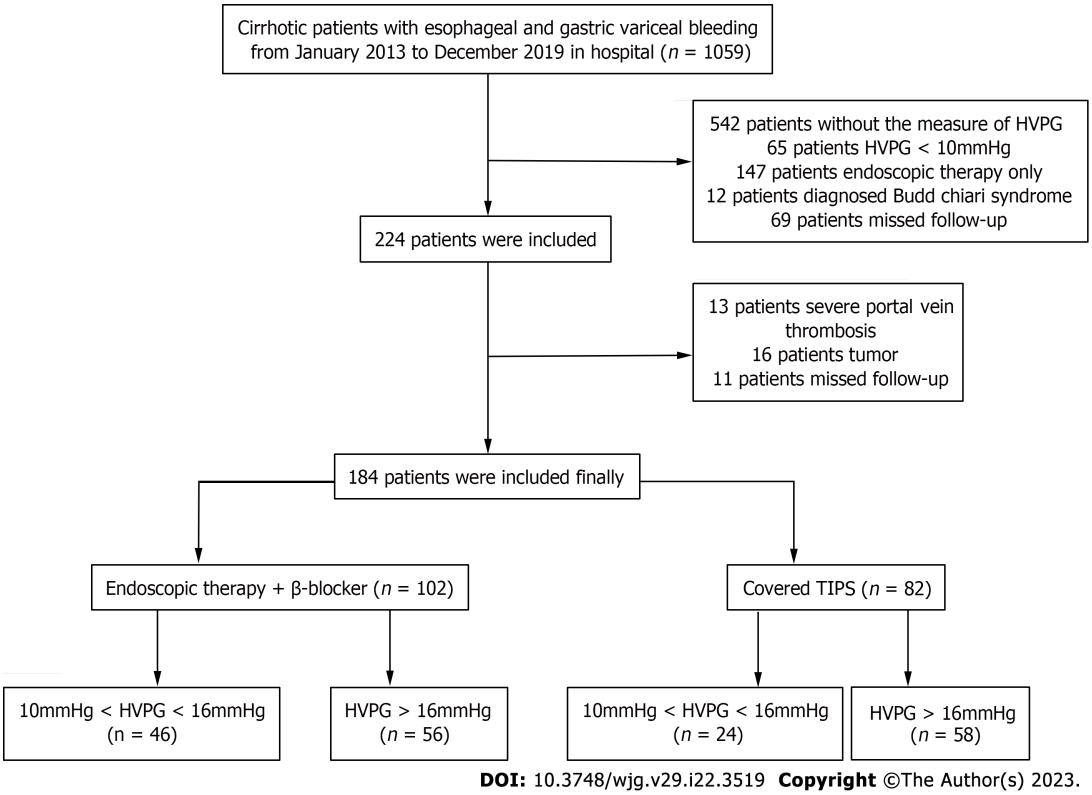
Finally, we included 184 patients in our study. All patients signed the informed consent form. Data for 83 of the 184 patients have been previously reported[12]. The prior article examined the effect of covered TIPS placement *vs* EVL+β-blockers in patients with HVPG ≥ 16 mmHg after 1 year, whereas in this study, which included all patients with HVPG ≥ 10 mmHg, we report the long-term outcomes after covered TIPS placement.

HVPG measurement

All included patients underwent preoperative examinations to rule out contraindications followed by HVPG measurements, which were performed under local anesthesia after 6-8 h of fasting (Figure 2). Briefly, the external zero reference point was set at the midaxillary line of the patient. Puncture through the right internal jugular vein was performed. In the TIPS group, a Cobra catheter (RUPS-100, COOK, Bloomington, IN, United States) was introduced into the right or middle hepatic vein, and hepatic venography was performed first to confirm whether stenosis or an obvious lateral shunt was present in the surrounding area. Measurements indicating large shunts were considered meaningless, while measurements indicating small or no shunts were considered meaningful. A 5.5-7 F balloon-tipped catheter (Edwards Lifesciences, Irvine, CA, United States) was guided into the hepatic vein. The free hepatic venous pressure (FHVP) was read after the pressure value stabilized. Air was injected to dilate the balloon to fully block hepatic vein blood flow. The wedged hepatic venous pressure (WHVP) was read after the pressure value stabilized for at least 40 s. The WHVP, FHVP, and inferior vena cava pressure were measured three times. Differences among the WHVP or FHVP measurements should not exceed 1 mmHg. The average of the 3 measurements was taken. After the pressure measurements were completed, a contrast agent was injected to confirm whether the obstruction was complete and whether hepatic vein-to-vein communications were present. The HVPG was calculated according to the following formula: HVPG=WHVP-FHVP.

Therapy

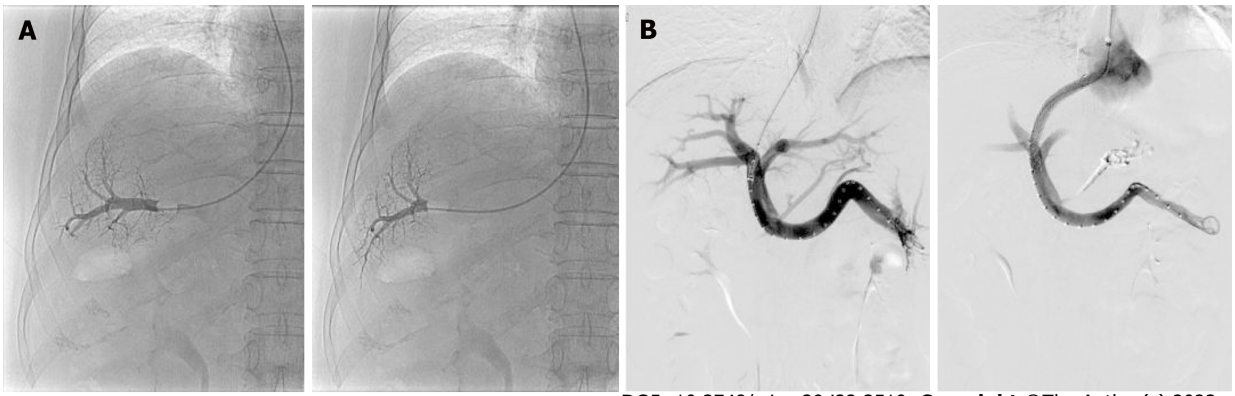
After the HVPG measurements were acquired, the details of the two therapies were explained to the patients, including the procedures, adverse reactions, cost, and so on. Doctors provided professional medical advice based on the patient's performance status, past bleeding history, vascular conditions, and HVPG, among other factors. The final treatment was selected by the patients.



Endoscopic therapy and NSBB usage were the same as described in our previous article[12]; specific details are provided in the Supplementary Methods.

Eighty-two patients underwent covered TIPS placement (Figure 2). Briefly, the process of TIPS placement was the same as described in our previous article[12]; specific details are provided in the Supplementary Methods. All operations were completed by a professional gastroenterology interventional therapy team to avoid surgical complications as much as possible.

Etiological treatment was followed throughout the study.



Follow-up and endpoints

Outpatient follow-up was performed 1, 3, 6 and 12 mo after treatment and once a year thereafter. Follow-up examinations included postoperative history collection, routine blood tests and abdominal ultrasound. Any patients with complications during the follow-up period were admitted to the hospital for active treatment.

Figure 2 Images taken in hepatic venous pressure gradient measurement and transjugular intrahepatic portosystemic shunts. A: A 68-year-old male received endoscopic therapy with non-selective β-blockers, whose hepatic venous pressure gradient (HVPG) is 16mmHg; B: A 57-year-old female received covered transjugular intrahepatic portosystemic shunts, whose HVPG is 19.6 mmHg.

The primary endpoint of the study was the transplant-free survival time. The secondary endpoints were: (1) Rebleeding; and (2) the development of overt HE (OHE) diagnosed according to the American Association for the Study of Liver Diseases guidelines[14]. The patients were followed up until November 2021 or until death or liver transplantation. Two physicians regularly reviewed the data to detect errors. Two physicians assessed the accuracy of the data. After verification of the collected clinical variables in our study, statistical analysis was performed.

Statistical analysis

Our long-term observational study followed the Strengthening the Reporting of Observational Studies in Epidemiology guidelines[15]. Data are described as frequencies and percentages, means and standard deviations, or medians and interquartile ranges, as appropriate. Baseline characteristics were compared using Fisher's exact test for categorical variables, *t* test for continuous variables, and the Wilcoxon rank-sum test for ordinal and continuous variables. Survival was estimated using the cumulative incidence function. Kaplan–Meier curves were used to illustrate the cumulative rates of survival and variceal

Figure 3 Comparison of transplant-free survival rates between the patients with endoscopic therapy+non-selective β-blockers and covered transjugular intrahepatic portosystemic shunts during the whole follow-up period. A: The total cohort; B: Patients on low-hepatic venous pressure gradient (HVPG) tier; C: Patients on high-HVPG tier; D: Patients with viral cirrhosis or alcoholic cirrhosis; E: Patients with viral cirrhosis or alcoholic cirrhosis on low-HVPG tier; F: Patients with viral cirrhosis or alcoholic cirrhosis on high-HVPG tier; TIPS: Transjugular intrahepatic portosystemic shunt; NSBBs: Non-selective β-blockers.

rebleeding, and differences were assessed by the log-rank test. Associations of the risk factors with mortality were assessed by univariate and multivariate Cox proportional hazards regression models, and forward regression analysis was used to select the variables included in the multivariate model. All analyses were performed using GraphPad software (version 9.0), Statistical Package for Social Sciences (version 22.0) and R studio (version 4.0.1), and a level of significance was established at the two-sided 5% level.

RESULTS

According to the inclusion and exclusion criteria, 184 patients were analyzed. Based on the HVPG-guided risk stratification, 70 patients were in the low-HVPG tier, and 114 were in the high-HVPG tier. The patient characteristics are shown in Table 1. The median follow-up time was 49.5 mo. Patients who were lost to follow-up were excluded. The average time from registering to the end of research was not significantly different between the two groups. There were some differences in the baseline characteristics, which reflected the more severe conditions of the patients undergoing covered TIPS placement.

Transplant-free survival

In general, the mortality rate was not significantly different between the two therapies in the whole cohort of patients who were admitted with VB (P = 0.07) (Figure 3A). In the low-HVPG tier, few differences were observed between the two groups (P = 0.74) (Figure 3B). Interestingly, in the high-HVPG tier, covered TIPS placement markedly improved survival. In patients with HVPG ≥ 16 mmHg, 14 (24.1%) patients in the TIPS group and 19 (33.9%) in the EVL+NSBB group died during the follow-up period; 3 (5.4%) patients in the TIPS group and 3 (5.2%) in the EVL+NSBB group underwent liver transplantation. The transplant-free survival rate was higher in the TIPS group (hazard ratio [HR], 0.44;

HVPG: Hepatic venous pressure gradient; NSBBs: Non-selective β-blockers; TIPS: Transjugular intrahepatic portosystemic shunts; PLT: Platelets; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; Tbil: Total bilirubin; INR: International normalized ratio; MELD: The model for end-stage liver disease; WHVP: Wedged hepatic venous pressure; FHVP: Free hepatic venous pressure; IVCP: Inferior vena cava pressure; RAP: Right atrium pressure; EV: Esophageal varices; GOV: Gastroesophageal varices; IGV: Isolated gastric varices; PPG: Portal pressure gradient.

95% confidence interval [CI]: 0.23-0.85; P = 0.004) (Figure 3C). Similar trends were found among patients without a shunt in the hepatic vein (Supplementary Figure 1).

A subgroup analysis was performed according to etiology. For cirrhotic patients with viral hepatitis and alcoholic hepatitis, the difference in transplant-free survival was negligible (HR, 0.53; 95%CI: 0.26-1.06; P = 0.07) (Figure 3D). Among these patients, TIPS placement did not improve transplant-free survival in the low-HVPG tier (HR, 0.91; 95%CI: 0.23-3.61; P = 0.89) (Figure 3E) but did improve transplant-free survival in the high-HVPG tier (HR, 0.41; 95%CI: 0.18-0.94; P = 0.04) (Figure 3F). For cirrhotic patients who had etiologies unrelated to viral and alcoholic hepatitis, TIPS placement did not confer a significant transplant-free survival benefit, as shown in Supplementary Figure 1.

Subgroup analysis was performed according to the endoscopic appearance of varices, whether there were cardiofundal varices or type 2 isolated gastric varices (IGV)[16]. Among patients suffering only from esophagogastric varices and/or type 1 gastroesophageal varices (GOV1), during the follow-up period, TIPS placement showed a significant transplant-free survival advantage in the high-HVPG tier (HR, 0.29; 95%CI: 0.11-0.71; P = 0.007) (Supplementary Figure 1), while there was no significant difference between the two groups (HR, 0.75; 95%CI: 0.22-2.54; P = 0.64) (Supplementary Figure 1). Among 57 patients with GOV2 and/or IGV, TIPS placement did not improve survival, as shown in Supplementary Figure 1.

In the univariate analysis, baseline age, total bilirubin (Tbil), aspartate aminotransferase, HVPG tier and therapy were included as candidate variables for the multivariate model. The final multivariate Cox regression model showed that age (HR, 1.03 per year of age; 95%CI: 1.02-1.07), Tbil (HR, 1.03 per mol/L of Tbil; 95%CI: 1.00-1.06), HVPG tier (HR, 2.01 compared with low-HVPG tier; 95%CI: 1.04-3.89), and therapy (HR, 0.45 compared with EVL+NSBBs; 95%CI: 0.25-0.81) were independent risk factors for mortality (Table 2).

Uncontrolled rebleeding, HE and multiple organ dysfunction syndrome were the most common causes of death (Table 3).

Rebleeding

In the whole cohort, covered TIPS placement significantly reduced rebleeding, as previous studies[17] have reported (P < 0.001) in both the low-HVPG and high-HVPG tiers (Figure 4). The same trends were found for the patients without stents and in the subgroup analyses (Supplementary Figure 2). TIPS placement definitely reduced rebleeding, even when ignoring the etiology and endoscopic appearance. The causes of rebleeding are shown in Table 4.

OHE

Thirteen patients (16.30%) experienced OHE, including 12 (13.33%) patients in the EVL+NSBB group and 18 (28.12%) in the covered TIPS group (Table 5). The occurrence of OHE was consistently similar between the two groups over the long term, while a significant difference was observed in the occurrence of OHE at 1 year (2.90% *vs* 10.98%, P = 0.02).

Jaundice and hyperbilirubinemia

Changes in Tbil after therapy occurred in 184 patients (EVL+NSBB group *vs* covered TIPS group, 102 *vs* 82) at baseline, 156 patients at the 1-year follow-up (92 *vs* 74), and 141 patients at the 2-year follow-up (77 *vs* 64). The TBIL values for 181 patients were registered at the end of follow-up.

Among the included patients (n = 184), excluding those without complete follow-up examinations (n = 43), the changes in the actual values and in the P values after Bonferroni correction at each point are shown in Figure 5A and B. TIPS placement did not induce hyperbilirubinemia (Tbil > 34 μmol/L[18]) in the low-HVPG tier (Figure 5C and D), while in the high-HVPG tier, more patients who underwent TIPS placement experienced hyperbilirubinemia (Figure 5E and F), as shown in Table 5.

Ascites

Changes in the depth of ascites after therapy were obtained, as described for Tbil.

The average of the actual values and the P values after Bonferroni correction at each point are shown in Figure 6 and Table 5. In our research, the depth of ascites in the patients after covered TIPS placement decreased, while after endoscopy therapy with NSBBs, it did not, which agreed with the previously reported findings[19].

Table 2 Cox regression evaluation of factors associated with mortality

Univariate analysis		Multivariate analysis

	Covered TIPS (*n* = 24)	3	0	0	0	0	0

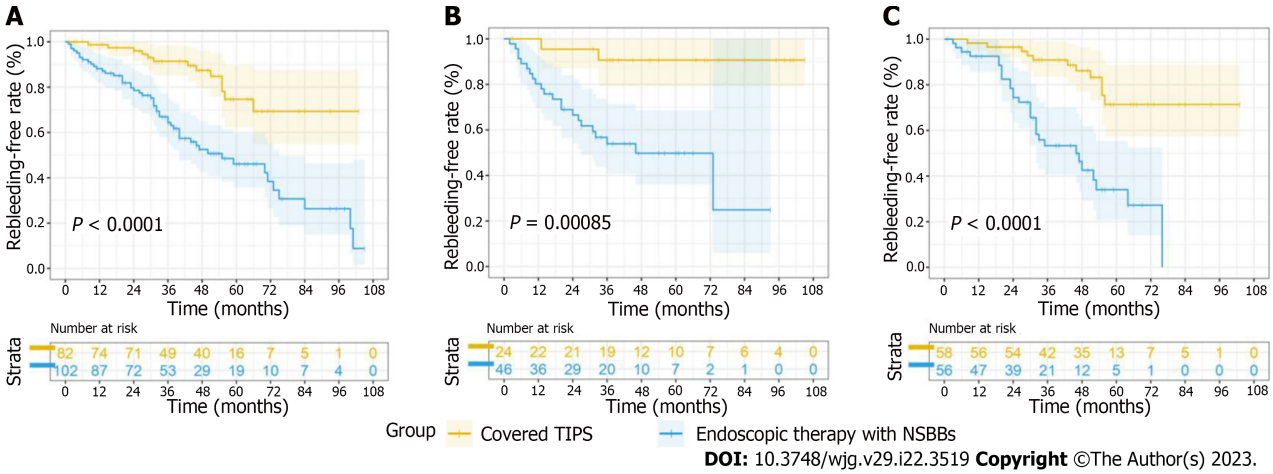
HVPG: Hepatic venous pressure gradient; NSBBs: Non-selective β-blockers; TIPS: Transjugular intrahepatic portosystemic shunts; EGVB: Esophageal and gastric varices bleeding; HCC: Hepatocellular carcinoma.

Hypercreatinemia, hyponatremia and hepatorenal syndrome

The changes in serum creatine and Na^+ after therapy were the same as the changes in Tbil.

TIPS placement had no effects on hypercreatinemia (creatine > 110 μmol/L for males, > 100 μmol/L for females) or hyponatremia (Na^+ < 135 mmol/L) compared with EVL+NSBBs (Supplemental Figure 3), ignoring the HVPG.

Changes in the model for end-stage liver disease score



Changes in the model for end-stage liver disease score after therapy were determined the same as described for changes in the Tbil level[20].

In the whole cohort, the scores gradually increased over follow-up after both of the therapies (Figure 7A and B). The patients treated with EVL+NSBBs in the low-HVPG tier showed increased scores after the second year (Figure 7C), while those treated with covered TIPS placement did not. the scores of patients in the high-HVPG tier increased earlier (Figure 7E and F).

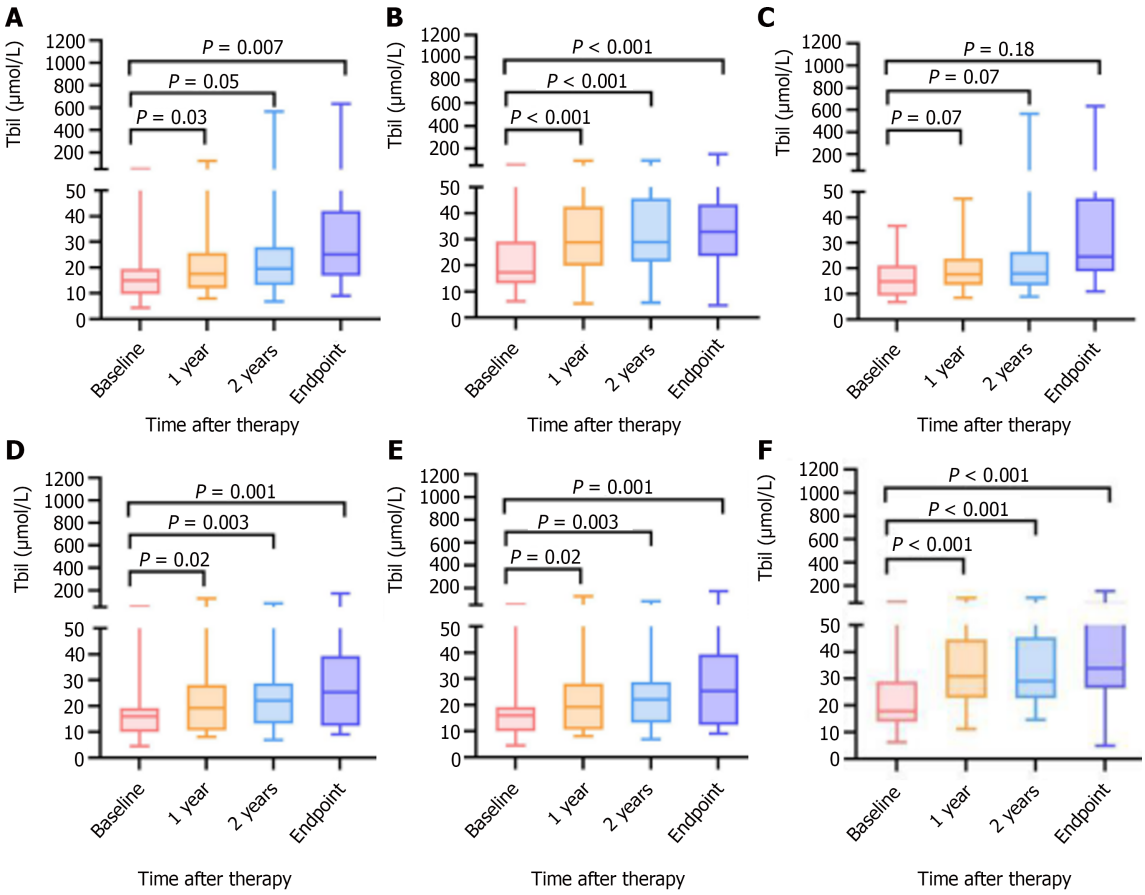

Figure 4 Comparison of the rebleeding-free rate between the patients with endoscopic therapy+non-selective β-blockers and covered transjugular intrahepatic portosystemic shunts. A: The total cohort; B: Patients on low-hepatic venous pressure gradient (HVPG) tier; C: Patients on high-HVPG tier; TIPS: Transjugular intrahepatic portosystemic shunt; NSBBs: Non-selective β-blockers.

Shunt dysfunction

In our study, stent loss occurred in 12 of 82 patients, including 3 (12.50%) in the low-HVPG tier and 9 (16.07%) in the high-HVPG tier. Stent dysfunction was discovered in 6 (66.67%) patients in the high-HVPG tier due to rebleeding or ascites, while stent dysfunction was discovered in patients in the low-HVPG tier during regular follow-up.

DISCUSSION

It would be extremely helpful to be able to distinguish patients with a high risk of uncontrolled

Figure 5 Changes in total bilirubin after therapy at baseline, 1-year follow-up, 2-year follow-up and the endpoint of follow-up. A: Patients received endoscopy therapy + non-selective β-blockers (NSBBs); B: Patients received covered transjugular intrahepatic portosystemic shunt (TIPS); C: Patients received endoscopy therapy + NSBBs in the low-hepatic venous pressure gradient (HVPG) tier; D: Patients received covered TIPS in the low-HVPG tier; E: Patients received endoscopy therapy+NSBBs in the high-HVPG tier; F: Patients received covered TIPS in the high-HVPG tier.

rebleeding. Risk stratification is pivotal for secondary prophylaxis in VB. A recent expert consensus has suggested that HVPG-guided treatment is a reasonable clinical strategy[4]. A study in 2015 concluded that HVPG measurement was useful for making decisions in selecting therapies for secondary prophylaxis[21]. However, the HVPG cutoff for risk stratification has not been clearly demonstrated. In 1991, a study demonstrated that the lowest pressure associated with continued bleeding or rebleeding was 16 mmHg[22]. Furthermore, Villanueva *et al*[23] pointed out that HVPG > 16 mmHg was a predictor of treatment failure. The latest expert consensus is that early TIPS placement reduces treatment failure in patients with HVPG ≥ 20 mmHg[4]. There is established evidence for an HVPG-stratified approach to treatment among compensated cirrhotic patients but very limited data for decompensated patients. On the basis of earlier findings[12], at the beginning of our study and according to the present guidelines, the included patients were divided into 2 groups: the high-HVPG (≥ 16 mmHg) and low-HVPG (10 mmHg ≤ HVPG < 16 mmHg) groups. Consequently, if there were no contraindications, TIPS placement improved survival in patients with HVPG ≥ 16 mmHg (HR, 0.4385; 95%CI: 0.2255-0.8525; P = 0.0037), even though patients who underwent TIPS placement had worse baseline clinical indicators.

A previous study could not conclude whether there were any beneficial effects of TIPS placement on transplant-free survival in all patients. Notably, the median follow-up in all previous studies was shorter than 24 mo, while our median follow-up was 49.5 mo. In our study, the survival benefit can be viewed in the long term. Moreover, the main causes of death were significantly different. Rebleeding in patients treated with covered TIPS placement, which was generally due to stent dysfunction, was controlled in most patients, providing an opportunity for further therapy, while rebleeding in some patients treated with EVL+NSBBs was turbulent.

Our study of HVPG-guided treatment indicated that patients with high HVPG values have a high risk of rebleeding despite treatment with EVL+NSBBs, and in patients with HVPG ≥ 16 mmHg, percutaneous transhepatic variceal embolization or TIPS placement may be a favorable alternative to EVL+NSBBs.

Figure 6 Changes in the depths of ascites after therapy at baseline, 1-year follow-up, 2-year follow-up and the endpoint of follow-up. A: Patients received endoscopy therapy + non-selective β-blockers (NSBBs); B: Patients received covered transjugular intrahepatic portosystemic shunt (TIPS); C: Patients received endoscopy therapy + NSBBs in the low-hepatic venous pressure gradient (HVPG) tier; D: Patients received covered TIPS in the low-HVPG tier; E: Patients received endoscopy therapy + NSBBs in the high-HVPG tier; F: Patients received covered TIPS in the high-HVPG tier.

Considering the high rate of OHE in patients treated with covered TIPS placement mentioned in previous research[8,24], we opted for the placement of small-diameter (8 mm) stents, which can provide adequate bleeding prophylaxis and decrease the OHE rate. Regarding the patients in the low-HVPG tier, there was a trend of growth in the rate of OHE among patients treated with covered TIPS placement, and these results are in accordance with earlier findings. Covered TIPS placement did not increase the rate of OHE among patients in the high-HVPG tier. The differences in encephalopathy between the two treatment groups were the largest in the first year, and this result is in accordance with that of a previous study[6]. A Chinese study proposed that the HVPG is a risk factor for liver failure after TIPS placement[24]. Therefore, we assessed hyperbilirubinemia after therapy. Our results were in accordance with those of a previous study[24].

Based on the HVPG-guided risk stratification, patients with a high HVPG were more likely to benefit from TIPS placement in our study. For patients with a low HVPG, the significant reduction in rebleeding did not improve survival outcomes due to the complications of TIPS placement. Furthermore, HVPG-guided risk stratification may be applied in the evaluation of OHE and hyperbilirubinemia syndrome after TIPS: Patients with a high HVPG have a higher probability of OHE and hyperbilirubinemia than those with a low HVPG. Rebleeding and ascites might occur earlier in patients with a high HVPG who underwent TIPS placement and developed stent dysfunction, but this needs further study. Further research is needed to evaluate whether HVPG-guided risk stratification should be performed before splenectomy.

Notably, our results cannot be extrapolated to older patients or patients with occlusive portal vein thrombosis or hepatocellular carcinoma, as these populations were not included in our study. Additionally, in our study, the numbers of patients with IGV and/or GOV2 were not sufficient, which contributed to the fact that the differences between the two therapies were not significant; as such, the findings could not confirm previous research[25]. Due to the nature of single-center observational studies, an inherent risk of selection bias is inevitable. Another potential bias may be the lower-than-expected attention to the clinical symptoms in patients. Furthermore, selection bias could not be ignored because the therapy was ultimately chosen by the patient. Even with these limitations, this study produced robust data. Further randomized controlled trials need to be performed to prove the benefit of covered TIPS placement in the secondary prevention of VB.

Figure 7 Changes in the model for end-stage liver disease scores after therapy at baseline, 1-year follow-up, 2-year follow-up and the endpoint of follow-up. A: Patients received endoscopy therapy + non-selective β-blockers (NSBBs); B: Patients received covered transjugular intrahepatic portosystemic shunt (TIPS); C: Patients received endoscopy therapy + NSBBs in the low-hepatic venous pressure gradient (HVPG) tier; D: Patients received covered TIPS in the low-HVPG tier; E: Patients received endoscopy therapy + NSBBs in the high-HVPG tier; F: Patients received covered TIPS in the high-HVPG tier.

CONCLUSION

In conclusion, covered TIPS placement increases long-term transplant-free survival in patients with HVPG ≥ 16 mmHg who are admitted with VB, but this advantage may not be observed in patients with 10 mmHg ≤ HVPG < 16 mmHg. More appropriate management and treatment of cirrhotic patients may be achieved by stratification according to HVPG measurements obtained before therapy.

ARTICLE HIGHLIGHTS

Research background

It is controversial whether transjugular intrahepatic portosystemic shunt (TIPS) placement can improve long-term survival.

Research motivation

To clarify the feasibility of hepatic venous pressure gradient (HVPG) as a risk stratification strategy for patients with decompensated cirrhosis.

Research objectives

To assess whether TIPS placement improves survival in patients with HVPG ≥ 16 mmHg based on HVPG-related risk stratification.

Research methods

Consecutive variceal bleeding patients treated with endoscopic variceal ligation (EVL) + nonselective β-blockers (NSBBs) or covered TIPS placement were retrospectively enrolled between January 2013 and

December 2019. HVPG measurements were performed before therapy. The primary outcome was transplant-free survival; secondary endpoints were rebleeding and overt hepatic encephalopathy (OHE).

Research results

A total of 184 patients were analyzed (mean age, 55.27 years ± 13.86, 107 males; 102 in the EVL+NSBB group, 82 in the covered TIPS group). Based on the HVPG-guided risk stratification, 70 patients had HVPG < 16 mmHg, and 114 patients had HVPG ≥ 16 mmHg. The median follow-up time of the cohort was 49.5 mo. There was no significant difference in transplant-free survival between the two treatment groups overall (hazard ratio [HR], 0.61; 95% confidence interval [CI]: 0.35-1.05; P = 0.07). In the high-HVPG tier, transplant-free survival was higher in the TIPS group (HR, 0.44; 95%CI: 0.23, 0.85; P = 0.004). In the low-HVPG tier, transplant-free survival after the two treatments was similar (HR, 0.86; 95%CI: 0.33, 0.23; P = 0.74). Covered TIPS placement decreased the rate of rebleeding independent of the HVPG tier (P < 0.001). The difference in OHE between the two groups was not statistically significant (P = 0.09; P = 0.48).

Research conclusions

TIPS placement can effectively improve transplant-free survival when the HVPG is greater.

Research perspectives

Further randomized controlled trials need to be performed to prove the benefit of covered TIPS placement in the secondary prevention of decompensated cirrhosis.

ACKNOWLEDGEMENTS

The authors would like to thank several researchers from Nanjing Medical University, Nanjing University, Jiangsu University and Southeast University for their help in data collection for the *DCDT COHORT STUDY* since 2012, Nurse Qin Yin from the Department of Gastroenterology of Nanjing Drum Tower Hospital for help in patient follow-up, Dr. Hao Han and Prof. Jian Yang from the Department of Ultrasound Imaging of Nanjing Drum Tower Hospital for their help in collecting abdominal ultrasound images, Dr. Hao Zhang from the Department of Internal Medicine of Nanjing Drum Tower Hospital for his guidance on visualization, and Dr. Taishun Li from the Department of Biomedicine Statistics of Nanjing Drum Tower Hospital for providing statistical suggestions.

Abstract

BACKGROUND

Alterations in plasma and intestinal metabolites contribute to the pathogenesis and progression of alcohol-related liver cirrhosis (ALC).

AIM

To explore the common and different metabolites in the plasma and feces of patients with ALC and evaluate their clinical implications.

METHODS

According to the inclusion and exclusion criteria, 27 patients with ALC and 24 healthy controls (HCs) were selected, and plasma and feces samples were collected. Liver function, blood routine, and other indicators were detected with

automatic biochemical and blood routine analyzers. Liquid chromatography-mass spectrometry was used to detect the plasma and feces metabolites of the two groups and the metabolomics of plasma and feces. Also, the correlation between metabolites and clinical features was analyzed.

RESULTS

More than 300 common metabolites were identified in the plasma and feces of patients with ALC. Pathway analysis showed that these metabolites are enriched in bile acid and amino acid metabolic pathways. Compared to HCs, patients with ALC had a higher level of glycocholic acid (GCA) and taurocholic acid (TCA) in plasma and a lower level of deoxycholic acid (DCA) in the feces, while L-threonine, L-phenylalanine, and L-tyrosine increased simultaneously in plasma and feces. GCA, TCA, L-methionine, L-phenylalanine, and L-tyrosine in plasma were positively correlated with total bilirubin (TBil), prothrombin time (PT), and maddrey discriminant function score (MDF) and negatively correlated with cholinesterase (CHE) and albumin (ALB). The DCA in feces was negatively correlated with TBil, MDF, and PT and positively correlated with CHE and ALB. Moreover, we established a P/S BA ratio of plasma primary bile acid (GCA and TCA) to fecal secondary bile acid (DCA), which was relevant to TBil, PT, and MDF score.

CONCLUSION

The enrichment of GCA, TCA, L-phenylalanine, L-tyrosine, and L-methionine in the plasma of patients with ALC and the reduction of DCA in feces were related to the severity of ALC. These metabolites may be used as indicators to evaluate the progression of alcohol-related liver cirrhosis.

Key Words: Alcohol-related liver cirrhosis; Plasma; Feces; Metabolites; Deoxycholic acid; Amino acids

Core Tip: Metabolites in enterohepatic circulation play an important role in cross-talk between liver and gut. More than 300 common metabolites were identified in the plasma and feces of patients with alcohol-related liver cirrhosis (ALC) by liquid chromatography-mass spectrometry. And we found bile acid and amino acid were distributed differently in plasma and feces. More importantly, increased glycocholic acid, taurocholic acid, L-phenylalanine, L-tyrosine, and L-methionine in plasma and decreased deoxycholic acid in feces of patients with ALC were related to the severity of ALC. These metabolites have the potential to evaluate the progression of ALC.

INTRODUCTION

Alcohol abuse is one of the major factors causing cirrhosis. According to the research data on global disease burden in 2017, 25% of deaths from liver cirrhosis were caused by alcohol-related liver diseases (ALD)[1]. Several clinical studies have found altered plasma or serum metabolites in patients with alcohol-related liver cirrhosis (ALC)[2]. Previous studies have focused on serum or plasma metabolomics in patients with ALC and demonstrated that alcohol alters the levels of amino acids and bile acids in the plasma or serum[3]. The common changes in plasma or serum include decreased levels of glutamine and increased levels of tyrosine and alanine[4,5]. A few studies on fecal metabolomics showed that fecal metabolomics in patients with alcoholic cirrhosis was changed, while some studies revealed that the fecal amino acids, such as glutamine, isoleucine, phenylalanine, and serine, are reduced[6]. In addition, the production of secondary bile acid, such as deoxycholic acid (DCA), was reduced[6]. Also, intestinal microbiota can metabolize bile acids, aromatic amino acids, carbohydrates, and polysaccharides to produce secondary bile acids, indoles, phenol derivatives, short-chain fatty acids, and polysaccharides[7]. These metabolites can also influence other organs through the gut-liver axis[8]. Therefore, the metabolites in the blood can be either from other organs' metabolites outside the intestine or from intestinal[9]. The metabolites in the blood or the feces may have homogeneity but may also have specific characteristics related to their respective environments. These products participate in the metabolism of glycogen, amino acid, and exogenous substances and exert anti-inflammatory effects

directly in the intestine[10]. However, the correlation between intestinal metabolites and metabolites in plasma for patients with ALC, which might be helpful for the diagnosis and treatment of ALC, has not yet been elucidated. Therefore, the present study aimed to investigate the common and different characteristics of the metabolites in the plasma and feces of patients with ALC, their clinical correlation between plasma metabolomics and fecal metabolomics, and their value in the evaluation of the severity of ALC. This might provide a new direction for understanding the progression of ALC and the diagnosis and treatment of ALD.

MATERIALS AND METHODS

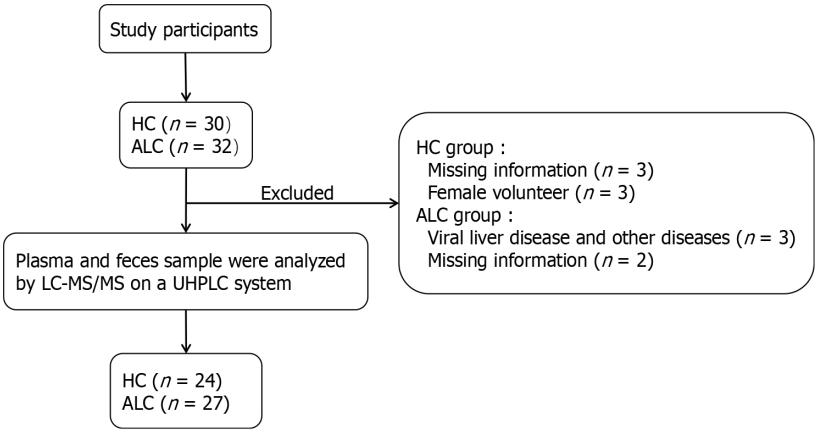
Study design and patients

This was a case-controlled observation study. We prospectively enrolled two groups of subjects: individuals with ALC and healthy controls (HCs). ALC subjects were selected from male inpatients admitted to the Liver Disease Center of Ditan Hospital (Beijing, China) from September 30, 2020 to December 31, 2021. The flow-chart demonstrates the selection of study participants (Figure 1). According to the International Clinical Guidelines[11], individuals with ALC were diagnosed if they met the following criteria: (1) Regular drinking and have a prior or ongoing heavy alcohol intake of > 5 years (males >36 g alcohol/day); and (2) ultrasonography, computed tomography, or magnetic resonance imaging should exhibit liver cirrhosis. Additionally, we recruited age-matched healthy males as controls through recruitment advertisements. These controls met the following criteria after clinical assessment and blood and imaging examinations: (1) Normal physical examination (heart rate, blood pressure, and respiratory rate) and body mass index (BMI) < 30 kg/m^2; (2) no history of alcohol intake; (3) blood routine, liver function, kidney function, tumor maker, and abdominal ultrasound with normal limits; and (4) no sign of any disease, including liver and heart diseases. The following criteria were excluded for all participants: (1) Liver diseases except for alcohol etiologies, such as hepatitis B virus or hepatitis C virus infection, drug-induced liver diseases, and autoimmune hepatitis; (2) Complications except for ascites, such as hepatic encephalopathy, hepatorenal syndrome, hepatopulmonary syndrome, and esophageal and gastric variceal bleeding; (3) human immunodeficiency virus infection; (4) other digestive diseases (colitis, pancreatitis, and cholecystitis); (5) kidney, heart, lung, neurological, and metabolic diseases (diabetes, thyroid, and adrenal diseases); (6) all types of cancers; and (7) systematically using antibiotics, probiotics, and proton pump inhibitors within 1 mo before enrollment.

Clinical information, including demographic indicators, was collected. Moreover, the plasma and feces of all participants were collected and frozen at -80 °C for subsequent biochemical and hematological indexes tests and untargeted metabolomics detection.

This research scheme was approved by the Ethics Committee of Ditan hospital based on the ethical principles of the Declaration of Helsinki and registered at http://www.chictr.org.cn/ (ChiCTR-2000038216). Written informed consent was obtained from all the participants.

Biochemical and hematological indexes examination



White blood cell, neutrophilic granulocyte percentage, red blood cell (RBC), hemoglobin (HGB), hematocrit (HCT), mean corpuscular volume (MCV), and platelet (PLT) levels were detected on automatic blood routine analyzers (Sysmex, Kobe, Japan). Alanine aminotransferase (ALT), aspartate transaminase (AST), total bilirubin (TBil), albumin (ALB), albumin/globulin (A/G), g-glutamyl transpeptidase (GGT), alkaline phosphatase (ALP), cholinesterase (CHE), total bile acid (TBA), total cholesterol, urea nitrogen, and creatinine (Cr) were detected on automatic biochemical analyzers (Hitachi, Tokyo, Japan). Prothrombin time (PT) was detected by automatic coagulation analyzers (Werfan, Barcelona, Spain), and alpha-fetoprotein (AFP) was detected by chemiluminescence immunoassay analyzer (Abbott, Chicago, IL, United States).

Untargeted metabolomics detection

Plasma or feces sample was mixed with an extract buffer and homogenized in an ice-water bath. The homogenization and sonication cycle was repeated three times. The supernatant was collected by centrifugation of the homogenates and analyzed by liquid chromatography-mass spectrometry (LC-MS/MS) on a UHPLC system (Thermo Fisher Scientific, Waltham, MA, United States) with a UPLC BEH Amide column coupled to Q Exactive HFX mass spectrometer from Thermo Fisher Scientific. The QE HFX mass spectrometer was used for its ability to acquire MS/MS spectra in information-dependent acquisition (IDA) mode using the acquisition software (Thermo Fisher Scientific, Waltham, MA, United States). The acquisition software continuously evaluates the full scan MS spectrum in this mode. The quality control (QC) sample was prepared by mixing an equal aliquot of the supernatants from all the samples.

Statistical analysis

The raw data were converted to the mzXML format using ProteoWizard and processed with an in-house program developed using R and based on XCMS for peak detection, extraction, alignment, and

Figure 1 Flow chart demonstrating the selection of study participants. HC: Healthy control group; ALC: Alcohol-related liver cirrhosis group; LC-MS/MS: Liquid chromatography-mass spectrometry.

integration. Then, an in-house MS2 database (Biotree DB, Shanghai, China) was applied to metabolite annotation. The cutoff for the annotation was set at 0.3. All variables were normalized in MetaboAnalyst 5.0 (https://www.metaboan-alyst.ca) after preprocessing using the Masshunter Profinder software. R script can view details and download them from the website of MetaboAnalyst (https://www.metaboanalyst.ca/MetaboAnalyst/docs/RTutorial.xhtml). The results of the patients' clinical and biochemical characteristics for continuous variables are expressed as median (upper quartile, lower quartile), and categorical variables are expressed as numbers and percentages. The between-group comparisons were made with Kruskal-Wallis *H* test. All statistical analyses were performed using SPSS 26.0 software. The significance level for all statistical tests was set at 0.05. Based on the metabolome profile, the phenotype-associated fingerprint metabolites were projected to one eigen metabolite by the first principal component in the unsupervised principal component analysis (PCA). Fold change (FC): the quantitative ratio of the two groups of experimental substances by comparing the ALC group to the HC group. Furthermore, we analyzed significant differences ($P < 0.05$ and FC > 2 or $P < 0.05$ and FC < 0.5) by comparing the ALC and HC groups and marked them as ALC/HC. We also detected the metabolic pathways of phenotype-associated fingerprint metabolites. PCA was conducted on the MetaboAnalyst website based on R. Furthermore, the *P*- and FC values were obtained from the MetaboAnalyst website. Then, the original variables were narrowed down to fingerprint based on *P*-value and FC.

RESULTS

Clinical characteristics of the study cohort

The clinical characteristics and laboratory tests of participants are shown in Table 1. A total of 51 subjects were included in this study, including 24 HCs and 27 patients with ALC, and all subjects were males. No significant differences were detected in age and BMI between the two groups. The levels of ALT, AST, TBil, GGT, ALP, TBA, and PT were higher in the ALC group than in the HC group, while the number of RBCs and the levels of HGB, HCT, ALB, CHE, PLT, and T-CHO were lower in ALC than in HCs. Compared to HCs, there were no significant differences in UREA, CREA, AFP, and GLU in ALC patients.

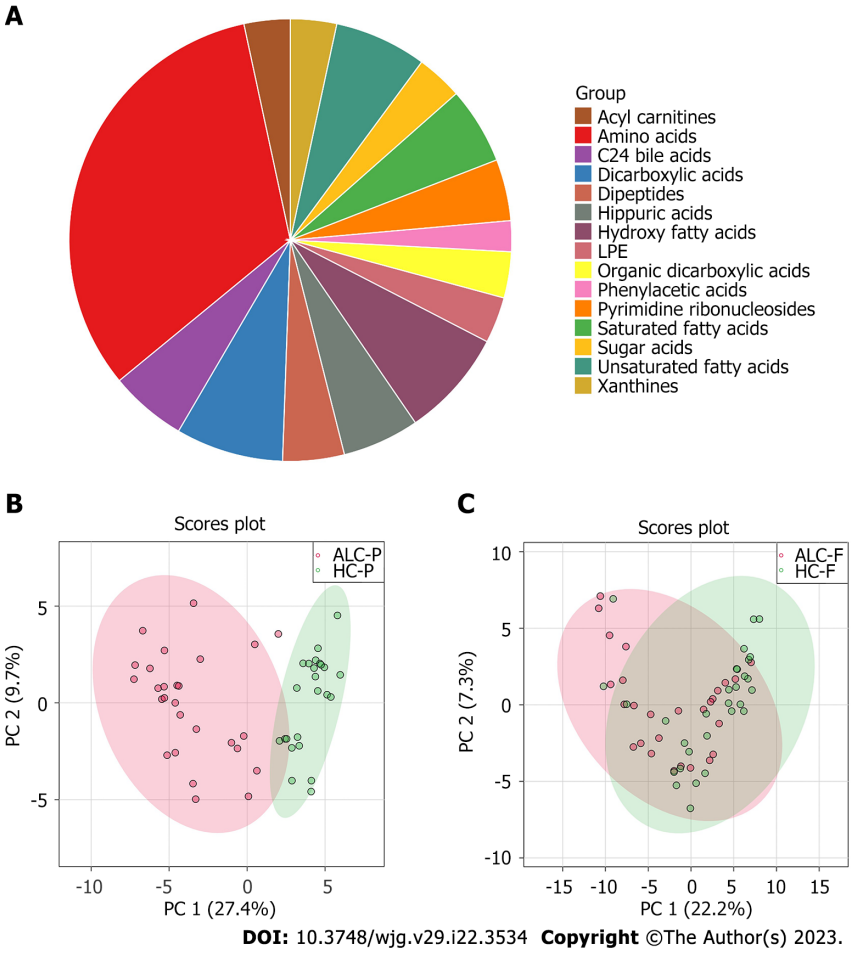
Amino acids and derivatives were the most common metabolites in the plasma and feces of patients with ALC

More than 8000 plasma metabolites and more than 10,000 fecal metabolites were detected in this study. HMDB identified > 300 types of co-metabolites in plasma and feces. Amino acids and their derivatives accounted for the largest proportion of co-metabolites in plasma and feces. The remaining metabolites included bile acids, dicarboxylic acids, hydroxy fatty acids, saturated fatty acids, and unsaturated fatty acids (Figure 2A). Principal component analysis on the plasma and feces of patients with ALC showed (Figure 2B and C) that the metabolites in the plasma were clearly distinguished between the two groups based on the first and second principal component scores, while the metabolites in the feces were discretely distributed within the two groups, rendering difficulty in distinguish them between the groups. These findings indicated obvious individual differences in the types and content of fecal metabolites in ALC or HCs.

Table 1 Clinical characteristics of the study cohort

Characteristic	HC (*n* = 24)	ALC (*n* = 27)	*P* value
Age (yr)	53 (48, 57.75)	51 (43, 60)	0.527
BMI (kg/m^2)	22.92 (22.04, 24.09)	24.22 (22.94, 24.94)	0.101
Clinical lab index			
WBC (10^9/L)	5.82 (5.30, 6.76)	4.57 (3.60, 6.62)	0.023
NEU (%)	56.20 (52.1, 60.55)	56.60 (46.60, 67.90)	0.678
RBC (10^{12}/L)	4.83 (4.52, 5.02)	3.66 (2.90, 4.58)	< 0.01
HGB (g/L)	148.00 (144.00, 156.00)	117.00 (100.00, 147.00)	< 0.01
HCT (%)	43.25(41.85, 46.8)	33.60 (29.50, 42.50)	< 0.01
MCV (fl)	91.50 (88.35, 94.68)	97.00 (92.2, 104.00)	0.001
PLT (10^9/L)	246 (223.25, 268.00)	86.00 (46.00, 123.00)	< 0.01
ALT (U/L)	17.35 (12.75, 22.5)	25.7 (15.1, 36.9)	< 0.01
AST (U/L)	19.7 (17.78, 21.73)	36.7 (24.90, 74.20)	< 0.01
TBil (μmol/L)	13.95 (11.75, 15.20)	47.3 (28.70, 115.70)	< 0.01
ALB (g/L)	46.48 (45.68, 47.68)	34.27 (28.4, 39.5)	< 0.01
A/G	1.80 (1.63, 1.80)	1.10 (0.80, 1.60)	< 0.01
GGT (U/L)	14.7 (10.28, 17.50)	94.3 (25.00, 243.80)	< 0.01
ALP (U/L)	58.7 (53.05,70.05)	97.9 (68.40, 137.50)	< 0.01
CHE (U/L)	8326.00 (7251.50, 9304.25)	3547 (1700.00, 5735.00)	< 0.01
TBA (μmol/L)	1.90 (1.45, 2.50)	66.1 (29.30, 174.20)	< 0.01
T-CHO (mmol/L)	4.40(3.72, 4.86)	3.27 (2.54, 4.78)	< 0.05
UREA (mmol/L)	5.04 (4.12, 5.87)	5.05 (4.29, 6.21)	0.734
CREA (mmol/L)	75.5 (72.18, 84.93)	68.8 (60.5, 75.50)	0.051
GLU (mmol/L)	5.27 (4.94, 5.76)	5.24 (4.57, 6.08)	0.977
PT(s)	11.45 (11.20, 11.8)	17.1 (12.10, 22.80)	< 0.01
AFP (ng/mL)	2.37 (1.97, 3.34)	4.01 (2.70, 6.97)	0.002

All clinical information in the table indicates data collected at the time closest to blood collection. Median and quartile values are provided as Median (upper quartile, lower quartile), unless otherwise noted as *n* (%). ALC: Alcohol-related liver cirrhosis; HC: Healthy control; CA: Cholic acid; TCA: Taurocholic acid; WBC: White blood cell; NEU: Neutrophilic granulocyte percentage; RBC: Red blood cell; HGB: Hemoglobin; HCT: Hematocrit; MCV: Mean corpuscular volume; PLT: Platelet; ALT: Alanine aminotransferase; AST: Aspartate transaminase; TBil: Total bilirubin; ALB: Albumin; A/G: Albumin/glubumin; GGT: γ-glutamyl transpeptidase; ALP: Alkaline phosphatase; CHE: Cholinesterase; TBA: Total bile acid; T-CHO: Total cholesterol; UREA: Urea nitrogen; CREA: Creatinine; PT: Prothrombin time; AFP: Alpha-fetoprotein.

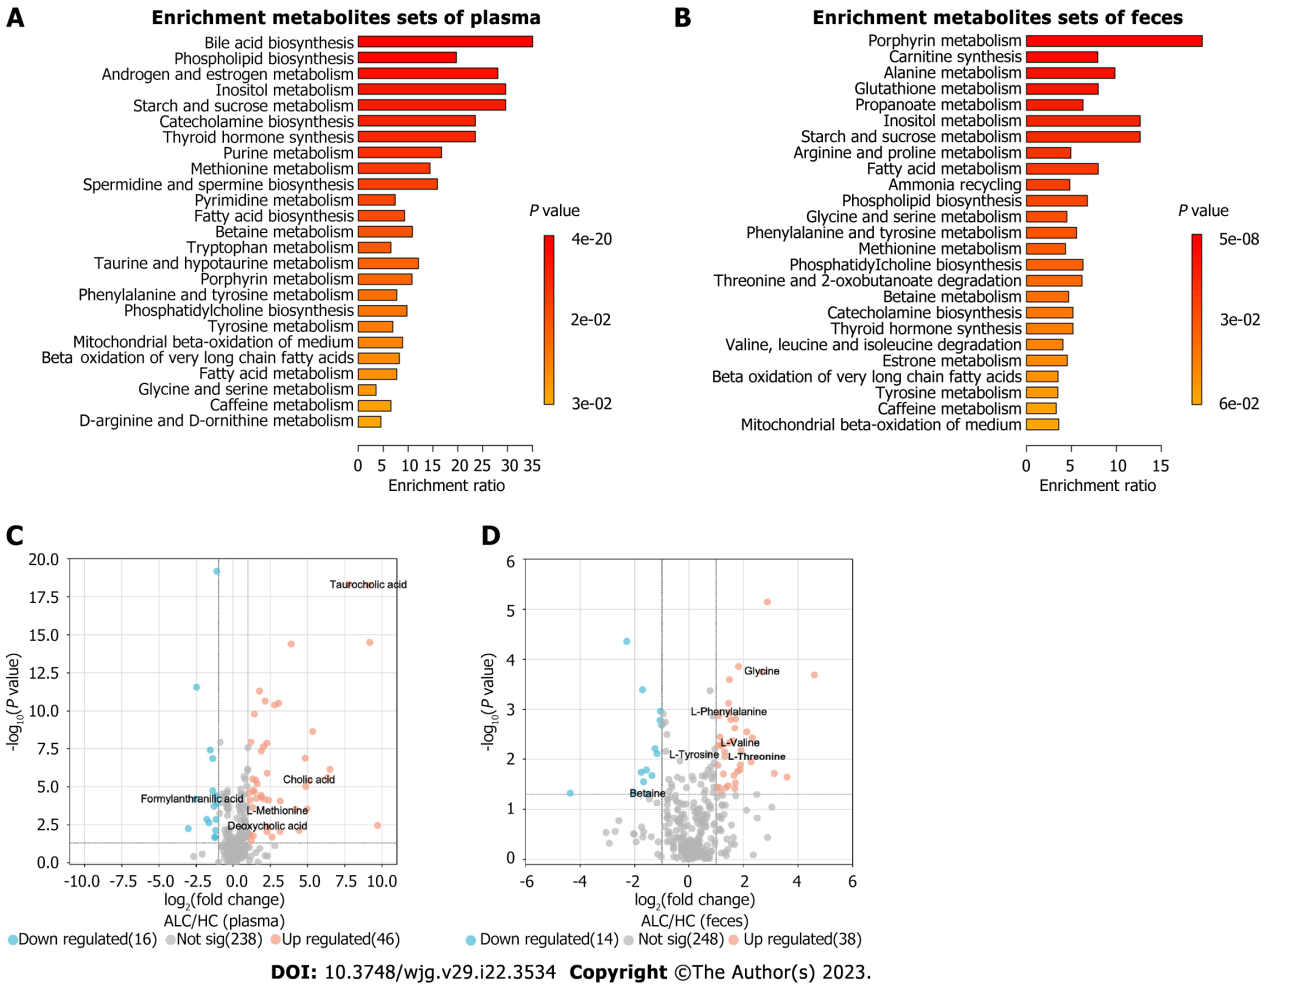


Differences in bile acid and amino acid metabolism pathways in plasma and feces of patients with ALC

The common metabolites were analyzed in plasma and feces, respectively, and compared to HCs after *t*-test and difference analysis. A total of 150 differential metabolites in plasma and 106 differential metabolites in the feces of patients with ALC were screened based on FC > 2 or FC < 0.5. The results showed that 46 metabolites were upregulated and 16 were downregulated in plasma, while 38 metabolites were upregulated and 14 were downregulated in feces (Table 2, Supplementary Tables 1 and 2). Similarly, metabolic pathway analysis showed that the metabolites in plasma and feces of patients with ALC were involved in porphyrin metabolism, phospholipid biosynthesis, inositol metabolism, sugar and starch metabolism, catecholamine biosynthesis, thyroid hormone synthesis, estrone metabolism, betaine metabolism, beta-oxidation of very long chain fatty acids, fatty acid metabolism, caffeine metabolism, and phosphatidylcholine synthesis. The bile acid metabolism pathway was significantly enriched in plasma, while the porphyrin metabolism pathway was significantly enriched in feces (Figures 3A and B). Strikingly, the amino acid metabolism was significantly enriched in both plasma and feces. However, the types of amino acids involved in plasma and feces were

Table 2 Number of altered metabolites

ALC/HC	*P* < 0.05	Up (FC > 2)	Down (FC < 0.5)
Plasma	150	46	16
Feces	106	38	14



Compared to healthy controls, there were different number of differential metabolites in plasma or feces of patients with alcohol-related liver cirrhosis (ALC) by *t*-test. Fold change: The quantitative ratio of the two groups of experimental substances by comparing ALC group with healthy control (HC) group, and marked them as ALC/HC. ALC: Alcohol-related liver cirrhosis; HC: Healthy control; FC: Fold change.

Figure 2 Subclass and distribution of common metabolites in the plasma and feces of patients with alcohol-related liver cirrhosis. A: Subclass of common metabolites in plasma and feces of patients with alcohol-related liver cirrhosis (ALC); B: Principal component analysis (PCA) of plasma metabolites in two groups; C: PCA of fecal metabolites in two groups. Green dots represent healthy control group, and red dots represented patients with ALC group. Abscissa PC 1 and ordinate PC 2 represent the scores of the first and second principal components respectively, each scatter point represented a sample, the closer the distribution of sample points, it indicates that the types and contents of metabolites in the samples are more similar. On the contrary, the farther the sample is, the greater the difference in its overall metabolic level. The sample is basically within the 95% confidence interval (Hotelling's T-squared ellipse). HC: Healthy control group; ALC: Alcohol-related liver cirrhosis group.

different. The metabolic pathways of methionine, phenylalanine, tyrosine, glycine, and serine were significantly enriched in both plasma and feces; however, the metabolic pathways of tryptophan, taurine, hypotaurine, D-arginine, and D-ornithine were enriched in the plasma, while alanine, valine, leucine, isoleucine, arginine, and proline metabolic pathways were significantly enriched in feces. Various substances were involved in the above-mentioned enrichment pathways (Supplementary Tables 3 and 4). Differential analysis and screening of FC > 2 or FC < 0.5 with $P < 0.05$ showed that nine substances, such as cholic acid (CA), taurocholic acid (TCA), DCA (DCA), and L-methionine were upregulated in plasma, and three metabolites, such as formylanthranilic acid, were down-regulated in ALC. Thirteen metabolites, such as glycine, L-threonine, L-phenylalanine, L-valine, L-tyrosine were upregulated, and betaine was downregulated in feces (Figure 3C and D, Supplementary Table 5).

Common and differential bile acids, amino acids, and related metabolites in the plasma and feces of patients with ALC

Compared to HCs, metabolites involved in the above metabolic pathways differed in the plasma and stool of ALC (Table 3). In the bile acid metabolism pathway, primary bile acids, including CA, TCA, and glycocholic acid (GCA), increased in the plasma of patients with ALC, while CA, TCA, and GCA did not change significantly in feces. Additionally, secondary bile acid DCA decreased in feces but did not differ in plasma. In the amino acid metabolism pathway, L-threonine, L-phenylalanine, L-tyrosine, and choline increased in both plasma and feces, while betaine decreased concomitantly. GCA, L-methionine, and taurine increased, while sarcosine decreased only in plasma. Glycine elevated only in feces, while L-valine decreased in plasma but increased in feces.

For patients with ALC, the differential enrichment analysis of bile acid and amino acid metabolites in plasma and feces revealed that the distribution of the above-mentioned metabolites differed in the plasma and feces. In the plasma of patients with ALC, betaine, TCA, GCA, sarcosine, and taurine were significantly enriched, while CA, DCA, and formylanthranilic acid, L-threonine, L-phenylalanine, L-tyrosine, L-methionine, and glycine were markedly enriched in feces (Figure 4).

Association of amino acid or bile acid in plasma or feces with clinical features

Spearman's correlation analysis revealed that plasma amino acids L-methionine, L-phenylalanine, and L-tyrosine in patients with ALC were positively correlated to TBA, MDF, TBil, and PT and negatively correlated with CHE and ALB. L-methionine had the highest correlation with TBA, and L-phenylalanine had the highest correlation with MDF, TBil, and PT. Nonetheless, no correlation was established between L-methionine, L-phenylalanine, L-tyrosine and TBA, MDF, TBil, PT in feces (Figure 5).

Primary bile acids GCA and TCA in plasma exhibited a positive correlation with TBil in clinical practice to varying degrees, with GCA having the strongest correlation with a coefficient of 0.86. However, no correlation was established between DCA in feces and clinical TBil. The levels of both

Compared to healthy controls, variation trend of bile acid and amino acid in plasma or feces of patients with alcohol-related liver cirrhosis. NS: Not significant; ALC: Alcohol-related liver cirrhosis; HC: Healthy control.

GCA and TCA in plasma showed a positive correlation with TBil, MDF, and PT and a negative correlation with CHE and ALB. Conversely, DCA in feces demonstrated a negative correlation with TBil, MDF, and PT but a positive correlation with CHE and ALB. Compared to a single index, the ratio of all primary bile acids in the blood, including GCA and TCA to DCA in the feces (recorded as P/S BA ratio) showed a higher correlation with MDF, TBil, CHE, PT, and ALB (Figure 5).

DISCUSSION

In patients with ALC, the stability of the intestinal microbiota and the integrity of the intestinal barrier were compromised, altering the intestinal microbiota and their metabolites. Both exogenous molecules, such as amino acids, and endogenously produced molecules from intestinal microorganisms can be transported to the liver *via* the portal vein. The liver secretes bile acids and other biologically active mediators into the biliary tract and bloodstream, affecting the intestinal microbiota and their metabolites [12]. This raises questions about the similarities and differences between plasma and intestinal metabolites and their implications in the progression of ALD. In order to gain an in-depth understanding of the primary metabolic pathways involved in enterohepatic circulation and their correlation with ALD, we conducted a metabolomics study that analyzed both plasma and feces metabolites. The current comparative analysis was based on the Human Metabolome Database and identified > 300 metabolites, although their distribution varied between plasma and feces. Notably, bile acid and amino acid metabolism pathways were significantly concentrated in both plasma and feces, which might participate in the progression of the disease.

Bile acid is a critical metabolic substance for maintaining the homeostasis of the gut-liver axis[13]. Primary and secondary bile acids (synthesized by the liver and produced by bacterial metabolism, respectively) performed various functions in the small intestine and played critical roles in lipid

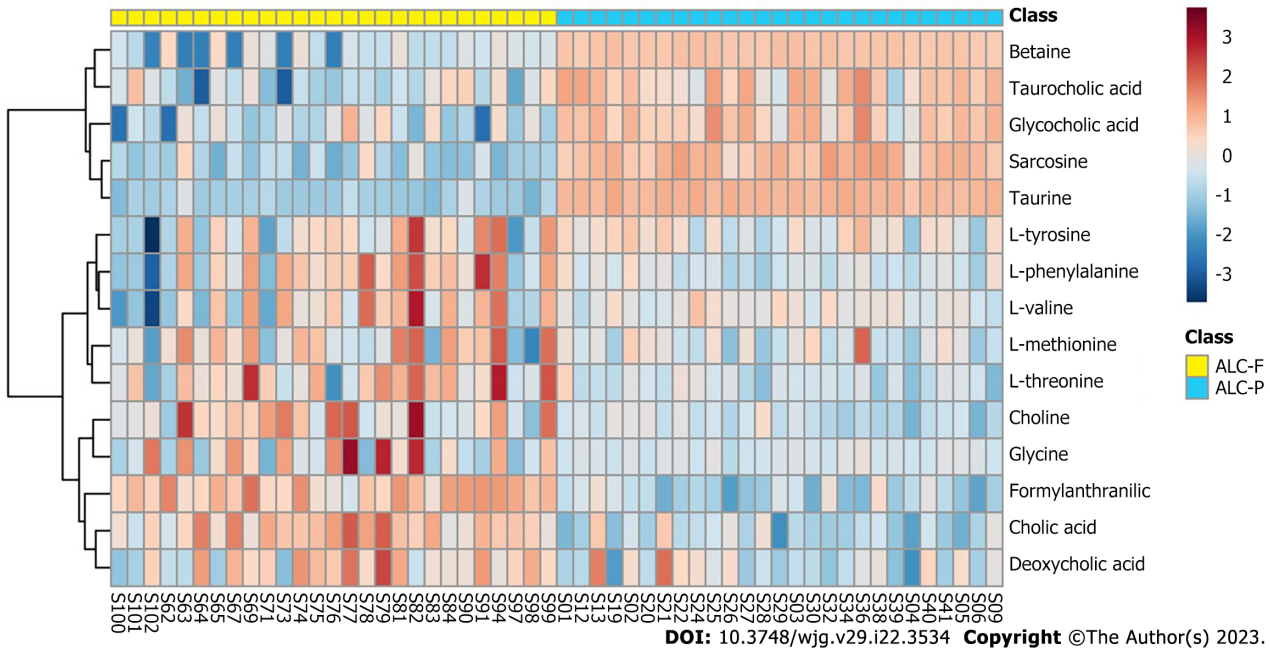

Figure 4 Distribution of bile acids and amino acid and related metabolites in plasma and feces of patients with alcohol-related liver cirrhosis**.** Numerous data basically conformed to the normal distribution after normalizing and scaling. The darker the color, the higher the relative content. ALC-P: Mean metabolites in the plasma of patients with alcohol-related liver cirrhosis; ALC-F: Mean metabolites in the feces of patients with alcohol-related liver cirrhosis.

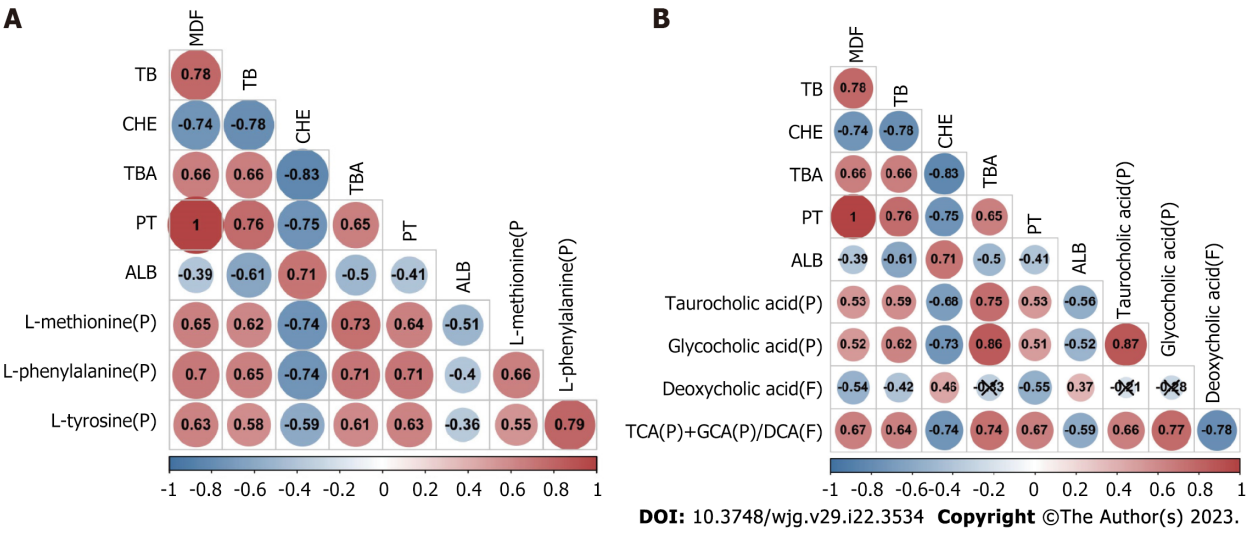

Figure 5 Correlation heatmap of amino acid or bile acid with clinical index. A: Correlation of amino acid with clinical index; B: Correlation of bile acid with clinical index. Relative coefficient in circle were calculated by spearman correlation analysis ($P < 0.05$). "×" in the circle mean no statistical difference ($P > 0.05$). TCA(P)+GCA(P)/DCA(F) also marked as P/S BA ratio represented sum of glycocholic acid and taurocholic acid in plasma divided by deoxycholic acid in feces. absorption, cholesterol homeostasis, and hormonal effects *via* their steroid structure[14]. Firstly, pathway enrichment analysis in patients with ALC showed substantial enrichment of bile acid metabolism in plasma. Next, we found that primary bile acids, including CA, TCA, and GCA of patients with ALC increased in plasma but showed no apparent differences in feces, while secondary bile acid DCA decreased in feces but increased in plasma. Ethanol stimulates bile acid formation in primary human hepatocytes[15]. Moreover, liver cirrhosis affects bile acid secretion, and patients suffer from cholestasis. This phenomenon might be the reason for the increase of CA, TCA, and GCA in the plasma of patients with ALC. Kakiyama *et al*[16] reported different levels of serum DCA in ALC with varied amounts of alcohol consumption, and the volume of serum binding DCA in ALC was higher than in HCs. These findings indicated that plasma DCA increased in patients with ALC; this phenomenon was associated with alcohol consumption status. However, several studies have demonstrated that fecal DCA and other secondary bile acids in patients with ALD decreased[17,18], which was in agreement

with our findings. DCA is the most common bile acid in human feces and cecum samples[19]. Most of the DCA in the intestine is only produced by cholic acid transformed by 7α-dehydroxylation-producing bacteria, and the currently known DCA-producing bacteria include very few *Clostridia* and closely related bacteria of other genera[20]. Previous studies demonstrated that *Clostridiales* XIV decreased in the feces of ALC patients[21], which might be related to alcohol-induced dysbiosis and inflammation of the intestine, and *Clostridiales* XIV was predictive of 90-d hospitalizations. This could be one of the mechanisms for the decrease in fecal DCA, which is presented to the colon[6]. On the other hand, due to the impact of DCA on the stability of intestinal epithelial cell membrane, intestinal permeability increased, which might result in the resorption of DCA in the blood[22]. This further suggested that intestinal microbiota play a significant role in bile acid metabolism and disease progression.

Moreover, our analysis of the correlation between bile acids with clinical indicators showed that GCA and TCA in plasma were positively correlated with TBil, PT, and MDF and negatively correlated with ALB and CHE, while fecal DCA was negatively correlated with TBil, PT, and MDF and positively correlated with ALB and CHE. The ratio of primary bile acids in the plasma to secondary bile acids in the feces was correlated with MDF, TBil, CHE, ALB, and PT. Additionally, a positive correlation was established between fecal DCA and T-CHO in blood, suggesting that secondary bile acids in feces might be closely related to cholesterol homeostasis in the blood. TBil, PT, ALB, and MDF reflect the severity of diseases, while CHE reflects the liver's composition function. The current results suggested that plasma GCA and TCA and fecal DCA might be related to the severity of diseases. Furthermore, we calculated the ratio of primary bile acids in the plasma to secondary bile acids in feces (P/S BA ratio) and found that the P/S BA ratio is correlated with MDF, TBil, CHE, ALB, and PT, which might be an alternative indicator of the severity of the diseases. In addition, we found a positive correlation between DCA in feces and T-CHO in the blood, which further suggested that secondary bile acids in feces might be closely related to cholesterol homeostasis in the blood. In conclusion, bile acid metabolism plays a significant role in enterohepatic circulation, and a combined analysis of primary bile acids in the plasma and secondary bile acids in feces might provide valuable insights into the progression of ALD.

The current study also revealed that both plasma and feces exhibit a substantial concentration of amino acid metabolism, yet the specific types of amino acids involved in each vary significantly. Branched-chain amino acids and aromatic amino acids partake in the progression of cirrhosis, as shown previously[23,24]. These findings showed a decrease in the plasma concentration of the branched-chain amino acid L-valine and an increase in its concentration in feces. Some studies have shown that the concentration of L-valine in the plasma of ALC patients decreased[25], and supplementing with L-valine could improve the survival rate of cirrhosis patients[26]. The decrease in *Faecalibacterium prausnitzii* in the feces of cirrhosis patients, which coded for branched-chain amino acid translocators [27], can obstruct the transport of branched-chain amino acids and increase L-valine in feces but decrease it in the plasma. The content of valine in feces is also affected by the dietary intake of branched-chain amino acids. The amino acids with simultaneous changes in plasma and feces are L-phenylalanine, L-tyrosine, and L-threonine, of which L-phenylalanine and L-tyrosine are aromatic amino acids. The elevated levels of aromatic amino acids in cirrhotic patients are linked to the progression of liver disease and the development of hepatic encephalopathy[28]. Previous studies have demonstrated that hydroxylation of L-phenylalanine and L-tyrosine flux is increased in the blood of patients with liver cirrhosis[29]. Phenylalanine is decomposed and hydroxylated to tyrosine, which might explain the elevated levels of L-phenylalanine and L-tyrosine in the plasma. Also, L-phenylalanine and L-tyrosine were raised in feces through enterohepatic circulation, while L-methionine was increased in the plasma but not feces in ALC patients. A previous study by Marchesini *et al*[30] suggested that the increase of plasma methionine in patients with cirrhosis could be attributed to the damage of liver cells and the decrease in methionine's metabolic function. In addition, the NMR-based metabolomics analysis by Kumar *et al*[31] showed increased serum methionine in patients with acute-on-chronic liver failure. Moreover, our study found that plasma L-phenylalanine, L-tyrosine, and L-methionine were positively correlated with TBil and MDF, suggesting that these three amino acids may be related to the severity of diseases, and are designated as markers of disease progression in the blood.

Furthermore, our analysis detected the presence of betaine, a crucial component in the metabolism of amino acids, such as glycine, serine, and methionine, in the enterohepatic circulation. In patients with ALC, betaine decreased in both plasma and feces. It plays a vital role in methylating homocysteine into methionine, a process that is crucial for maintaining liver function stability, cell replication, and detoxification. The reduction in betaine levels in patients with ALC could be due to its depletion or insufficient supply during the disease process. A study by Schofield *et al*[32] showed that changes in betaine were associated with the development of ALC. Previous studies have shown that supplementing betaine can prevent acute alcoholic liver injury[33], and measuring fecal or plasma betaine levels in patients with ALC can assess its insufficiency and is expected to serve as an indicator for evaluating the severity of disease or a therapeutic target for treatment.

In addition, glycine and taurine play crucial roles in both amino acid metabolism and bile acid metabolism. Alcohol consumption may increase in the proportion of secondary bile acids, the total concentration of bile acids, and the proportion of bile acids bound to glycine rather than taurine[10,13]. Bajaj *et al*[6] found that the conjugated bile acids in the duodenal fluid and feces turned into toxic

glycine-conjugated bile acids from harmless taurine-conjugated bile acids in ALC patients. Our study also observed that taurine was concentrated in the plasma of patients with ALC, while glycine was concentrated in their feces. Taurine/glycine ratio was decreased in the serum and feces of patients with ALC. The imbalance in the taurine/glycine ratio may be due to dysbiosis caused by liver cirrhosis, the subsequent reduction of taurine bioavailability, and an increase in the intestine-liver circulation rate[10, 14]. This phenomenon suggested that regulating taurine/glycine ratio might improve the intestinal microecology of ALC patients and alleviate liver diseases.

Taken together, understanding the similarities and differences between plasma and feces metabolites holds significant potential in advancing molecular diagnosis in disease progression. The detection of these metabolites highlights the diversity of substances that can be detected in both plasma and feces. Fecal metabolites are more complex than those in plasma, which might be influenced by several factors, such as race, environment, diet, and medicine. Additionally, changes in intestinal and colon microbiota and their metabolism can alter the fecal metabolites, with secondary metabolites produced by the intestinal microbiota potentially playing a role in disease progression. Thus, further studies with larger samples are required to validate and evaluate bile acid and amino acids as potential markers for disease progression in cirrhosis. Moreover, integrating intestinal microbiome omics and metabonomics analysis is essential to decipher the molecular mechanisms underlying ALC. Since LC-MS analysis used in this study has limitations, further comparisons with other detection methods and complementary studies are required. The analysis of metabolites in plasma and feces provides an in-depth insight into ALC.

CONCLUSION

Bile acid and amino acid metabolism play a very important role in the progression of ALC. The enrichment of GCA, TCA, L-phenylalanine, L-tyrosine, and L-methionine in the plasma of patients with ALC and the reduction of DCA in feces was related to the severity of ALC. These metabolites may be used as indicators to evaluate the progression of ALC.

ARTICLE HIGHLIGHTS

Research background

Alterations in plasma and intestinal metabolites contribute to the pathogenesis and progression of alcohol-related liver cirrhosis (ALC).

Research motivation

Metabolites in enterohepatic circulation play an important role in cross-talk between liver and gut. The metabolites in the blood or the feces may have homogeneity but may also have specific characteristics related to their respective environments. The correlation between intestinal and plasma metabolites in patients with ALC, which might be helpful for the diagnosis and treatment of ALC, has not yet been elucidated.

Research objectives

To explore the common and different metabolites in the plasma and feces of patients with ALC and evaluate their clinical implications.

Research methods

This was a case-controlled observation study. We prospectively enrolled two groups of subjects: individuals with ALC and healthy controls (HCs). We recruited age-matched healthy males as controls through recruitment advertisements. According to the inclusion and exclusion criteria, 27 patients with ALC and 24 HCs were selected. The plasma and feces samples were collected. Liver function, blood routine, and other indicators were detected with automatic biochemical and blood routine analyzers. Liquid chromatography-mass spectrometry was used to detect the plasma and feces metabolites. Also, the association of metabolites with clinical features was analyzed.

Research results

More than 8000 plasma and more than 10000 fecal metabolites of patients with ALC were detected. Among them, More than 300 metabolites were found both in the plasma and feces. Enrichment analysis showed that these common metabolites are enriched in bile and amino acid metabolic pathways. Moreover, patients with ALC had a higher level of glycocholic acid (GCA) and taurocholic acid (TCA) in plasma and a lower level of deoxycholic acid (DCA) in the feces, while L-threonine, L-phenylalanine, and L-tyrosine increased simultaneously in plasma and feces. These results was consistent with previous studies and have indeed confirmed the disorder of bile acid and amino acid metabolism in

patients with ALC. Besides, GCA, TCA, L-methionine, L-phenylalanine, and L-tyrosine in plasma were positively correlated with total bilirubin (TBil), prothrombin time (PT), and maddrey discriminant function score (MDF) and negatively correlated with cholinesterase (CHE) and albumin (ALB). The DCA in feces was negatively correlated with TBil, MDF, and PT and positively correlated with CHE and ALB. AP/S BA ratio of plasma primary bile acid (GCA and TCA) to fecal secondary bile acid (DCA), which was relevant to TBil, PT, and MDF score was established, which may be used as a biomarker of the severity of ALC.

Research conclusions

Bile acid and amino acid metabolism play a very important role in the progression of ALC. The enrichment of GCA, TCA, L-phenylalanine, L-tyrosine, and L-methionine in the plasma of patients with ALC and the reduction of DCA in feces was related to the severity of ALC. The P/S BA ratio of plasma primary bile acids (GCA and TCA) to fecal secondary bile acid (DCA), was relevant to TBil, PT, and MDF score.

Research perspectives

Integrating intestinal microbiomics and metabolomics analysis is essential to decipher the molecular mechanisms underlying ALC. Since LC-MS analysis used in this study has limitations, further comparisons with other detection methods and complementary studies are required.

ACKNOWLEDGEMENTS

The authors would like to thank all patients and healthy volunteers for their participation in this study.

Abstract

BACKGROUND

Non-alcoholic fatty liver disease (NAFLD) is becoming a major health problem, resulting in hepatic, metabolic and cardio-vascular morbidity.

AIM

To evaluate new ultrasonographic tools to detect and measure hepatic steatosis.

METHODS

We prospectively included 105 patients referred to our liver unit for NAFLD suspicion or follow-up. They underwent ultrasonographic measurement of liver sound speed estimation (SSE) and attenuation coefficient (AC) using Aixplorer MACH 30 (Supersonic Imagine, France), continuous controlled attenuation parameter (cCAP) using Fibroscan (Echosens, France) and standard liver ultrasound with hepato-renal index (HRI) calculation. Hepatic steatosis was then classified according to magnetic resonance imaging proton density fat fraction (PDFF). Receiver operating curve (ROC) analysis was performed to evaluate the diagnostic performance in the diagnosis of steatosis.

RESULTS

Most patients were overweight or obese (90%) and had metabolic syndrome (70%). One third suffered from diabetes. Steatosis was identified in 85 patients (81%) according to PDFF. Twenty-one patients (20%) had advanced liver disease.

SSE, AC, cCAP and HRI correlated with PDFF, with respective Spearman correlation coefficient of -0.39, 0.42, 0.54 and 0.59 (P < 0.01). Area under the receiver operating characteristic curve (AUROC) for detection of steatosis with HRI was 0.91 (0.83-0.99), with the best cut-off value being 1.3 (Se = 83%, Sp = 98%). The optimal cCAP threshold of 275 dB/m, corresponding to the recent EASL-suggested threshold, had a sensitivity of 72% and a specificity of 80%. Corresponding AUROC was 0.79 (0.66-0.92). The diagnostic accuracy of cCAP was more reliable when standard deviation was < 15 dB/m with an AUC of 0.91 (0.83-0.98). An AC threshold of 0.42 dB/cm/MHz had an AUROC was 0.82 (0.70-0.93). SSE performed moderately with an AUROC of 0.73 (0.62-0.84).

CONCLUSION

Among all ultrasonographic tools evaluated in this study, including new-generation tools such as cCAP and SSE, HRI had the best performance. It is also the simplest and most available method as most ultrasound scans are equipped with this module.

Key Words: Non-alcoholic fatty liver disease; Ultrasonography; Steatosis assessment; Magnetic resonance imaging; Controlled attenuation parameter

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Among all ultrasonographic tools evaluated in this study, including new-generation systems such as continuous controlled attenuation parameter and sound speed examination, hepato-renal index had the best performance. It is also the simplest and most available method as most ultrasound (US) scans are equipped with this module. The presence of an hyperechogenic liver on US also performed well, confirming that US should remain the first-line screening tool for steatosis.

INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD), considered as the liver manifestation of the metabolic syndrome, has become a major public health issue, affecting around 25% of people in western societies. Its presence has been associated with an increased risk of both cardiovascular, hepatic and cancer-related morbidity[1]. Therefore, identifying steatosis among individuals with increased metabolic risk is crucial for primary care.

Hepatic steatosis is the key manifestation of NAFLD and refers to the excess of fat within the hepatocytes, histologically defined by the presence of at least 5% of hepatocytes containing fat. Histological assessment of steatosis is the gold standard for the diagnosis of liver steatosis but is an invasive procedure and cannot be performed for all patients with metabolic risk factors[2].

Ultrasound (US) is currently the first-line screening test, but several studies have shown that US is lacking the necessary sensitivity to assess mild steatosis < 20%, particularly in obese patients with body mass index (BMI) > 35 kg/m^2[3-7]. It is also subject to inter-observer and intra-observer variabilities[8].

Magnetic resonance imaging (MRI) has demonstrated excellent performances for the diagnosis and grading of steatosis using either spectroscopy, in-phase and opposed-phase technique or multiecho gradient sequences but this process is expensive, with limited access[9-11].

Controlled attenuation parameter (CAP) is a promising technique for steatosis assessment and grading. The interpretation of CAP values remains difficult in practice for several reasons: many cutoffs have been published, the influence of the chosen probe is still debated and solid quality criteria of measures are unavailable[12-17]. A new CAP method called continuous CAP (cCAP) is emerging. The major difference with the alternative method is that it uses ultrasound data continuously acquired during the imaging phase examination[18].

Other non-invasive techniques including B-mode image-guided US attenuation parameter or hepato-renal index (HRI) have been developed in the past years[19-23].

Recently, a new US technique based on sound speed estimation (SSE) demonstrated accurate performances for the detection of steatosis. The speed of sound decreased as the fat content in liver

increased. SSE could be used to detect, quantify and grade liver steatosis. However, the evaluation of steatosis was not specifically done in overweighted/obese patients suffering from NAFLD and SSE needs further investigations in this indication[24-26].

In a monocentric prospective study, we aimed at evaluating diagnosis performances of various US tools compared to MRI proton density fat fraction assessment (PDFF).

MATERIALS AND METHODS

Participants

Study participants were consecutively and prospectively recruited from the University Hospital of Clermont-Ferrand, France, from January 2021 to October 2021 by physicians of the hepatology department. Inclusion criteria were: Age over 18 years, patients with known or suspected NAFLD, referred for non-invasive fibrosis evaluation using impulse elastography, with willingness and ability to participate. Exclusion criteria were clinical, laboratory, or histologic evidence of a liver disease other than NAFLD (chronic hepatitis B or C, autoimmune liver disease, excessive alcohol consumption defined by WHO criteria, Wilson's disease or other), hepatocellular carcinoma and all other liver tumors, secondary causes of liver steatosis (genetic disease, steatogenic or hepatoxic medication use) and contraindications to MRI.

Demographic and anthropometric data were recorded. Biological data collected included platelets, prothrombin time (PT), international normalized ratio (INR), albumin, bilirubin, transaminases (aspartate aminotransferase, AST and alanine aminotransferase, ALT), gamma-glutamyltransferase (GGT), alkaline phosphatase (ALP), total cholesterol, high density lipoprotein (HDL) cholesterol, low density lipoprotein (LDL) cholesterol, triglycerides, fasting glucose, fasting insulinemia.

The study design was approved by local ethic committee (study M210401, Clermont-Ferrand University Hospital) and informed consent was obtained for all participants.

US examinations

All participants underwent US liver examinations using the Aixplorer MACH 30® US system (Supersonic Imagine, Aix-en-Provence, France). Participants were asked to fast for at least 3 h prior to US examinations. They were positioned in the dorsal decubitus position with the right arm at maximum abduction for intercostal stretching. A 3.5 MHz abdominal curved transducer (C6-1X probe) was used. Acquisitions were performed during neutral respiratory apnea as follows: (1) Right intercostal (between the 7th and 9th intercostal space) and subcostal view was considered for every patient; (2) US transducer was placed so that the hepatic capsule was parallel to the US transducer; and (3) Care was taken to avoid the presence of large hepatic vessels or artifacts in the image (ultrasound reflection caused by abdominal gas or by rib interposition). For HRI, the probe was placed to obtain an adequate visualization of the liver and the right kidney in a sagittal or oblique image with minimal artifacts. HRI was calculated using the region of interest (ROI) measure tool, with average brightness ratio between two ROI at least 3 mm wide placed at the same depth in hepatic parenchyma and in renal cortex (Figure 1).

For each patient, 5 measures of sound speed, 5 of attenuation coefficient (AC) and 3 of HRI acquisitions were performed by the same physician. The mean values were used for statistical analysis.

Simultaneously, liver stiffness and cCAP measurements were performed using FibroScan SmartExam® (Echosens, Paris, France) by experienced operators. All patients were measured using either an M- or an XL-probe, according to the device automatically-selected probe.

A liver US was also performed by a radiologist at patient's discretion, in any radiological center, unaware of the study, in the standard clinical care of NAFLD. The presence of a hyperechogenic liver described on the US report was noted (steatosis vs. no steatosis or not mentioned).

MRI PDFF technique

Within the month following US examinations, all participants underwent a chemical shift-encoded liver MRI using a 3.0 Tesla MAGNETOM Vida® system (Siemens Medical Solutions, Erlangen, Germany). A gradient echo dedicated sequence developed by the manufacturer to measure hepatic PDFF was systematically included in MRI acquisition protocols. This sequence is characterized by a low flip angle to reduce T1 bias and six echoes to correct for T2* effect. Images were acquired during a single breath hold. In and out-phases imaging was used prior to fat quantification to assess homogeneity of fat distribution. PDFF (%) estimation was obtained by placing three large regions of interest in the liver parenchyma. Steatosis was regarded as fat fraction ≥ 5.6 %, as defined by EASL. Steatosis grading was not evaluated because correspondence between the steatosis histologic grading and PDFF value has not yet been standardized in the literature[27]. Iron content was also measured using this technique.

Statistical analysis

Patients data were recorded in e-case report form *via* a secure web platform (REDCap® version 9.3.7, Vanderbilt University, United States) where these data were monitored and a database extraction was

Figure 1 Hepato-renal index measurement with 6 mm wide regions of interest, at a depth of 9.4 cm in liver right lobe and right kidney, University Hospital of Clermont-Ferrand.

performed.

Data were expressed as descriptive statistics (mean ± SD, median with IQR or number with corresponding percentage as appropriate). The normality assumption was assessed using the Shapiro-Wilk's test. Chi-Square and Student *t*-test were used to compare categorical and continuous variables. If normality was not ascertained, the Mann-Whitney test was used for continuous variables. Receiver operating curve (ROC) analysis was performed to evaluate the diagnostic performance of US tools compared to MRI PDFF. Optimal cutoff values were identified by maximizing the Youden index, and corresponding sensitivities, specificities, likelihood ratios (LR) were derived. Comparison of areas under receiver operating characteristic curves was made according to Hanley and McNeil. Pearson and Spearman linear correlation coefficients were used to evaluate the relationship between continuous variables, respectively when normality was assessed or not. A non-linear regression analysis was also conducted to assess the relationship between SSE AC, cCAP, HRI and PDFF. All tests were considered statistically significant in the case of $P < 0.05$. Statistical analysis were performed and graphs were designed using GraphPad Prism® (v8, GraphPad Software, La Jolla, California, United States). Multivariable linear regression was used to evaluate the influence of anthropometric parameters and fibrosis severity on US measures (R Software, R Foundation for Statistical Computing, Vienna, Austria).

RESULTS

Clinical, biological and radiological characteristics of the study population

One hundred and five patients were included in this study. Main characteristics are presented in Table 1. Median BMI was 31 kg/m². Most patients were overweight or obese (90%) and had metabolic syndrome (70%). One third suffered from diabetes. Steatosis was identified in 85 patients (81%) according to PDFF. Twenty-five patients (20%) were suspected to have advanced liver disease according to shear-wave elastography.

Mean AST and ALT were respectively 35 (± 28) U/L and 65 (± 49) U/L. Mean GGT was 120 (± 125) U/mL. Only ALT levels correlated significantly but moderately with PDFF (Spearman's ρ = 0.4, $P < 0.001$). One patient failed to receive Fibroscan® and HRI measurement due to poor US signal.

Patients characteristics according to the presence of steatosis are shown in Table 2. Steatotic patients had significantly higher BMI and waist circumference. As expected, metabolic syndrome was more prevalent in patients with steatosis. Mean SSE, AC and cCAP values significantly differed between non-steatotic and steatotic patients, but not liver stiffness.

Relationship between SSE, AC, HRI and cCAP with MRI PDFF

SSE, AC, HRI and cCAP correlated with PDFF, with respective Spearman correlation coefficient of -0.39, 0.42, 0.59 and 0.54 ($P < 0.01$) (Figure 2). SSE, AC, cCAP and HRI specifically displayed a significant non-linear relationship with PDFF as previously demonstrated (Supplementary Figure 1)[28].

Performances of SSE and AC

Intercostal SSE performed moderately for the diagnosis of steatosis with an area under curve (AUC) of 0.73 [0.62-0.84] (P = 0.001) (Figure 3A). Using the manufacturer cutoff of 1537 m/s resulted in a sensitivity and specificity of 80% and 45%. The best cutoff identified in our work was 1518 m/s but performances remained modest with sensitivity and specificity of 60% and 80% respectively. Of note,

[1]Data are mean ± SD.

BMI: Body mass index; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; GGT: Gamma glutamyl transferase; PDFF: Proton density fat fraction; cCAP: Continuous controlled attenuation parameter; SSE: Sound speed estimation; AC: Attenuation coefficient; HRI: Hepato-renal index; NS: Non-significant.

using 5 measures of SSE compared to 3 measures did not improve performances (data not shown).

Intercostal AC performed well for the diagnosis of steatosis with an AUC of 0.82 (0.70-0.93) (P = 0.001) (Figure 3B). The best cutoff identified in our work was 0.42 dB/cm/MHz with sensitivity and specificity of 84 % and 75 % respectively.

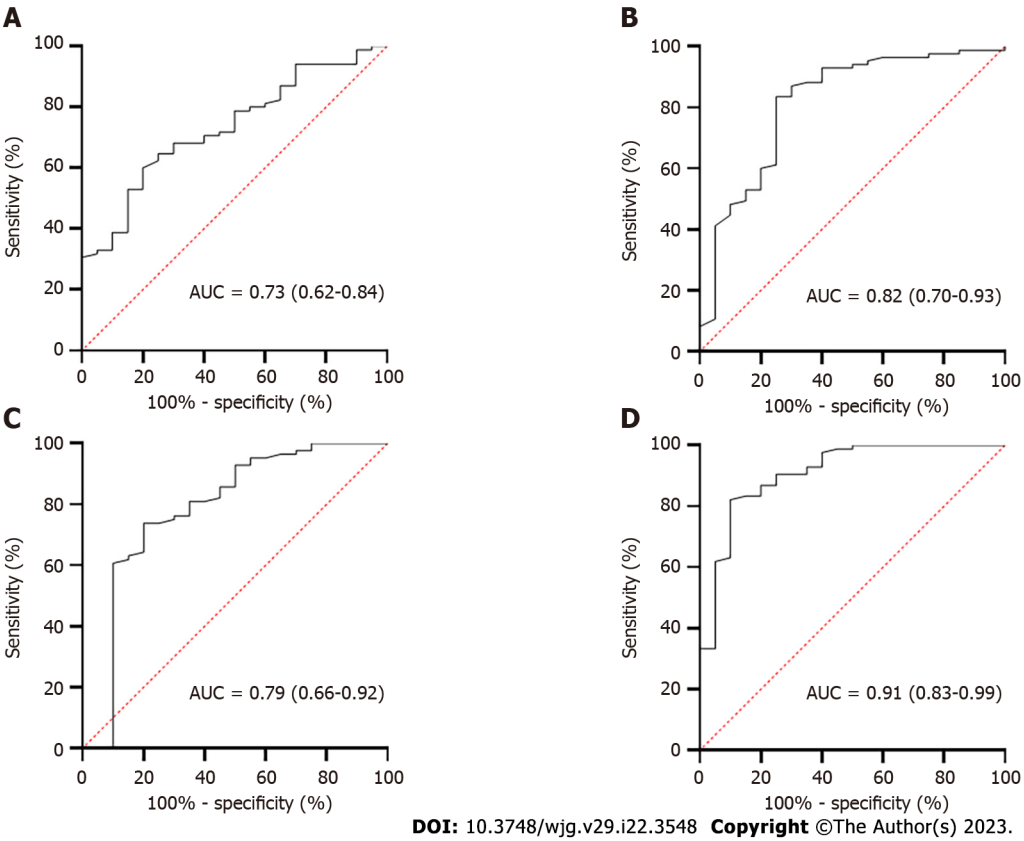
Figure 2 Scatterplots. A-D: Scatterplots showing linear relationship between sound speed estimation (A), attenuation coefficient (B), hepato-renal index (C) and continuous controlled attenuation parameter (D) with magnetic resonance imaging-proton density fat fraction using 6-echo gradient ($P < 0.001$). PDFF: Proton density fat fraction; cCAP: Continuous controlled attenuation parameter; SSE: Sound speed estimation; AC: Attenuation coefficient; HRI: Hepato-renal index.

Performances of cCAP

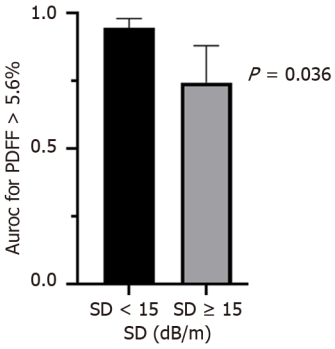
cCAP was accurate for the diagnosis of steatosis with AUC of 0.79 (0.66-0.92) but did not perform better than AC. The best cutoff identified in our work was 275 dB/m but lacked sensitivity and specificity (respectively 72% and 80%) (Figure 3C).



As expected, using cCAP resulted in low coefficient variation with 96% of patients having a coefficient of less than 10%. The diagnostic accuracy of cCAP was significantly improved when SD of cCAP was < 15 dB/m with an AUC of 0.91 (95% confidence interval: 0.83-0.98, $P < 0.01$) resulting in a sensitivity and specificity of 74% and 92%. In this work, one third of patients had an SD > 15 dB/m (Figure 4).

Performances of HRI

HRI performed the best with an AUC of 0.91 (0.83-0.99) ($P < 0.0001$) (Figure 3D). Using a cutoff set at 1.3 resulted in a sensitivity of 82% and specificity of 98%. In other words, only 2 patients had an increased hepatorenal gradient without having liver steatosis. The first patient had borderline steatosis (4% on MRI) and severe fibrosis on elastography (19 KPa) which could explain the increased HRI. For the other patient, moderate iron overload may have increased hepatorenal gradient. Among the 15 false negative patients, two third had mild steatosis on MRI (defined as PDFF < 10%).



Performances of standard ultrasound

Hyperechogenic liver was described in 73/85 steatotic patients (Figure 5). It showed a sensitivity of 86% and specificity of 70%. Among the 6 patients presenting a hyperechogenic liver on US but no steatosis on MRI, none had severe fibrosis (assessed using Fibroscan) or iron overload. Among the 12 patients with no hyperechogenic liver but steatosis on MRI, 7/12 (58%) had mild steatosis based on PDFF. No other steatosis sign was described by radiologists.

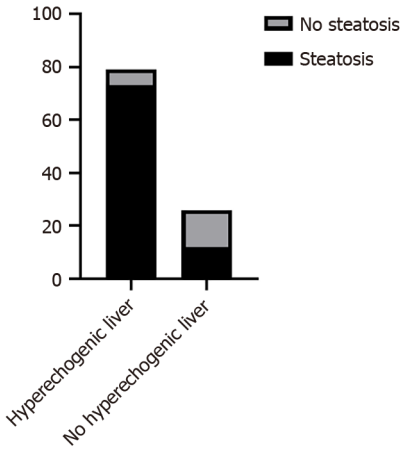

Figure 4 Continuous controlled attenuation parameter area under the receiver operating characteristic curve for the diagnosis of steatosis according to SD. PDFF: Proton density fat fraction; AUROC: Area under the receiver operating characteristic curve.

Intercostal or subcostal access

SSE and AC measurements were made for every patient using intercostal and subcostal view. However, if intercostal access was successful in every patient (success rate: 100% for SSE and AC), subcostal access showed a lower success rate (94% for SSE, 92% for AC) and lower performances (data not shown).

Influence of BMI and severity of fibrosis

Using multivariable linear regression, we demonstrated that both HRI, cCAP, AC and SSE were associated with the presence of steatosis on MRI, independently from BMI, waist circumference elastography, iron overload and the presence of diabetes or metabolic syndrome.

Figure 5 Ultrasound finding according to liver steatosis based on proton density fat fraction.

DISCUSSION

Standard ultrasound is widely used as first diagnostic exam for NAFLD. Our results confirmed past studies reporting poor sensitivity for mild steatosis[3,5]. Furthermore, BMI and fibrosis negatively influence US performances[6,7], and it suffers from inter- and intra-observer variability[8]. Our study collected US report from various radiologists, unaware of the study, chosen at patient's discretion. Steatosis was only described according to parenchyma hyperechogenicity. No other steatosis sign, like vessels blurring, gallbladder blurring or inability to visualize the diaphragm, nor steatosis scoring system, was used by radiologist, even if it proved to improve its diagnostic performance.

HRI calculation is a simple way to improve capabilities, as most US devices or radiology systems propose a dedicated module[21,29,30]. It can be easily performed by someone already familiar with US scan evaluation. Webb *et al*[31] proved that the known limitation of sonography to detect high grade steatosis of more than 30% of hepatocytes is resolved by HRI. In our study, HRI performed the best with a cut-off of 1.30. Previously described cut-off for the detection of any grade steatosis may vary in the literature from 1.22 to 1.49, influenced by system settings and different gold standards, and thus limiting HRI reproducibility and applicability[21,28,30-32].

It was the most reliable technique in our work, permitting an objective and quantitative assessment of steatosis better than cCAP and SSE. Furthermore, B-mode guidance permits to suspect heterogenous steatosis and adapt the location of measurement, which cannot be done with cCAP.

cCAP demonstrated promising performances for diagnosis of steatosis. This confirms a pilot study, which showed that cCAP outperformed significantly conventional CAP for the diagnostic of steatosis [33]. Indeed, the continuous method allows for larger volume sampling, reducing intraindividual variability and increasing correlation with MRI-PDFF. Caussy *et al*[34] described an IQR-based validity criteria significantly improving CAP performances. CAP results were generally expressed as the median and interquartile range of several manually triggered sequential attenuation measurements. Individual measurements collected with the cCAP method being much numerous, its results are expressed as the mean and SD. Thus, we proposed a quality criteria based on SD. In our work, cCAP proved to be perform significantly better for the diagnosis of steatosis when SD < 15 dB/m, reaching HRI measurement performances.

One main advantage of cCAP is to be combined with simultaneous fibrosis measurement, rapidly and without additional capabilities. This is of particular interest considering that the degree of fibrosis is the main prognosis factor in patients suffering from NAFLD[35]. However, on a practical level, not all medical structures have access to this device. This a major issue knowing that the growing prevalence of NAFLD worldwide cannot be fully handled by tertiary-care centers.

SSE and AC measurement on Aixplorer MACH 30 system are new non-invasive tools to quantify liver fat content, which may be useful in patient follow-up or therapeutic studies[36]. Using MRI-PDFF as reference, our study proved mixed performances for detection or exclusion of steatosis, with AUC ranging from 0.73 to 0.82.

SSE is a novel, understudied technique, based on the decrease of US speed as liver fat increases. Dioguardi Burgio *et al*[25] showed that SSE could be used for the detection and quantification of liver steatosis. However, in this study, SSE was acquired during US exam but calculated off-site. This resulted in invalid measurements in almost one quarter of patients due to poor signal quality. Moreover, this study included patients presenting liver diseases of various etiologies, and NAFLD-patients are not the only one known to present a poor echogenicity.

AC uses the same physical principles as cCAP but is performed under B-mode visual control. Several studies demonstrated promising performances, using various devices[19,37]. Nevertheless, optimal thresholds values slightly differ among different published studies, probably due to the use of different US scans and different reference standards (biopsy or MRI). A recent meta-analysis explored performances of AC for the detection of any grade steatosis, compiling 11 studies and more than 1400 patients: AUC was 0.83, close to what was assessed in our work[38].

SSE and AC intra-individual variability with 5 measures per patient was too low to suggest any validity criteria assessing better correlation to PDFF. Using three instead of five measures did not result in significant lower performances. To be noted, even if technical success was high (99% to 100%) with both cCAP and SSE/AC, these last tools were the most difficult to tame as they require a stable position, the strict absence of large hepatic vessels or artifacts in the image.

We found no influence of BMI, waist circumference elastography, iron overload or presence of diabetes or metabolic syndrome on the correlation between MRI-PDFF and both HRI, cCAP, AC and SSE. Previous studies reported unsure influence[37,39].

Several scores have also been developed to detect steatosis: fatty liver index, hepatic steatosis index and NAFLD liver fat score, which combine various clinical and biological parameters[40-42]. These algorithms demonstrated modest performances for the detection of steatosis and were inaccurate for the staging of steatosis[43]. They do not provide add-on features compared to standard clinical and biological data and are mainly used as epidemiological tools.

One limit of this study is that AC, SSE and HRI were assessed by two different examinators. As both examinators did not perform US liver examinations for all patients, we are unable to report an interobserver comparison or concordance.

Although our sample size is quite small, this work is the first one to prospectively evaluate diagnosis performances of various new generations US tools using MRI as gold standard on an exclusively-NAFLD population. Our study population contained patients with high BMI and weight, with a low fibrosis prevalence and moderate hepatic biological abnormalities, representing NAFLD-patients in real life situations.

These results should be validated in a population with a different prevalence of steatosis and in a multicenter study.

CONCLUSION

Among all ultrasonographic tools evaluated in this study, including new-generation systems such as cCAP and SSE, HRI had the best performance. It is also the simplest and most available method as most US scans are equipped with this module.

The presence of an hyperechogenic liver on US also performed well, confirming that US should remain the first-line screening tool for steatosis.

ARTICLE HIGHLIGHTS

Research background

Non-alcoholic fatty liver disease (NAFLD) is the most common liver disease worldwide, ranging from simple steatosis to aggressive hepatitis leading to liver fibrosis, cirrhosis and hepatocellular carcinoma.

Research motivation

Diagnose fatty liver disease and assess its severity during follow-up and after treatment is a key in clinical practice. Liver biopsy can deliver this information, but it is an invasive procedure with potentially severe. Therefore, non-invasive techniques were developed to stage steatosis. Ultrasound is the primary imaging modality in the assessment of patients with confirmed or suspected NAFLD.

Research objectives

We wanted to evaluate new ultrasonographic tools to detect and measure hepatic steatosis.

Research methods

One hundred and five patients underwent ultrasonographic measurement of liver sound speed estimation (SSE) and attenuation coefficient (AC) using Aixplorer MACH 30 (Supersonic Imagine, France), continuous Controlled Attenuation Parameter (cCAP) using Fibroscan (Echosens, France) and standard liver ultrasound with hepato-renal index (HRI) calculation. Hepatic steatosis was then classified according to MRI proton density fat fraction (PDFF) as gold standard.

Research results

SSE, AC, cCAP and HRI correlated with PDFF, with respective Spearman correlation coefficient of -0.39, 0.42, 0.54 and 0.59 ($P < 0.01$). Area under the receiver operating characteristic curve (AUROC) for detection of steatosis with HRI was 0.91 (0.83-0.99), with the best cut-off value being 1.3 (Se = 83%, Sp = 98%). The optimal cCAP threshold of 275 dB/m, corresponding to the recent EASL-suggested threshold, had a sensitivity of 72% and a specificity of 80%. Corresponding AUROC was 0.79 (0.66-0.92). The diagnostic accuracy of cCAP was more reliable when standard deviation was < 15 dB/m with an AUC of 0.91 (0.83-0.98). An AC threshold of 0.42 dB/cm/MHz had an AUROC was 0.82 (0.70-0.93). SSE performed moderately with an AUROC of 0.73 (0.62-0.84).

Research conclusions

HRI had the best performance. It is also the simplest and most available method as most US scans are equipped with this module.

Research perspectives

Measurement quality criteria need to be defined and validated for a wider use of theses techniques. Their improvement could open the way to efficient and easily accessible non-invasive steatosis grading.

Abstract

BACKGROUND

Recently, artificial intelligence (AI) has been widely used in gastrointestinal endoscopy examinations.

AIM

To comprehensively evaluate the application of AI-assisted endoscopy in detecting different digestive diseases using bibliometric analysis.

METHODS

Relevant publications from the Web of Science published from 1990 to 2022 were extracted using a combination of the search terms "AI" and "endoscopy". The following information was recorded from the included publications: Title, author, institution, country, endoscopy type, disease type, performance of AI, publication, citation, journal and H-index.

RESULTS

A total of 446 studies were included. The number of articles reached its peak in 2021, and the annual citation numbers increased after 2006. China, the United States and Japan were dominant countries in this field, accounting for 28.7%, 16.8%, and 15.7% of publications, respectively. The Tada Tomohiro Institute of Gastroenterology and Proctology was the most influential institution. "Cancer" and "polyps" were the hotspots in this field. Colorectal polyps were the most concerning and researched disease, followed by gastric cancer and gastrointestinal bleeding. Conventional endoscopy was the most common type of examination. The accuracy of AI in detecting Barrett's esophagus, colorectal polyps and gastric cancer from 2018 to 2022 is 87.6%, 93.7% and 88.3%, respectively. The detection

rates of adenoma and gastrointestinal bleeding from 2018 to 2022 are 31.3% and 96.2%, respectively.

CONCLUSION
AI could improve the detection rate of digestive tract diseases and a convolutional neural network-based diagnosis program for endoscopic images shows promising results.

Key Words: Bibliometric analysis; Artificial intelligence; Endoscopy; Publications; Research trends

Core Tip: Gastrointestinal tumors diagnosed at an early stage had a better prognosis than those diagnosed at a late stage, and performing endoscopy is the most effective approach to detect gastrointestinal tumors. In recent years, artificial intelligence (AI) has been widely used in gastrointestinal endoscopy examinations and it represents a fundamental breakthrough in the field of diagnostic endoscopy by assisting endoscopists with the detection of gastrointestinal tumors. This study aimed to provide a comprehensive analysis of AI applied in diagnostic endoscopy. A basic literature analysis was performed, as well as a subgroup analysis of AI-assisted digestive endoscopy in diagnosing various diseases.

INTRODUCTION

Gastrointestinal cancers (esophageal cancer, gastric cancer, colorectal cancer, *etc*.) account for 26% of global cancer incidence and 35% of all cancer-related deaths, which seriously threaten the health of global populations[1]. Gastrointestinal tumors diagnosed at an early stage had a better prognosis than those diagnosed at a late stage. For example, the 5-year survival rates of early gastric cancer and advanced gastric cancer were > 90% and < 30%, respectively. Performing endoscopy is the most effective approach to detect gastrointestinal tumors. More than 100 million subjects receive gastrointestinal endoscopy examinations each year. However, the current challenge is that the early diagnosis rate of tumors is low, and many lesions cannot be found in routine digestive endoscopy because of the large area of gastrointestinal mucosa, unobvious characteristics of early lesions, the existence of blind zones and uniform quality of examinations conducted by different endoscopists[2]. It is of great importance to improve the quality of endoscopy examinations to discover the lesions.

Artificial intelligence (AI) is intelligence processed by machines, as opposed to intelligence of humans and other animals, which emerged as a powerful and novel technology influencing many aspects of health care. In recent years, image recognition technology of AI has been dramatically improved and widely used in the medical field of diagnostic imaging[3-6]. AI represents a fundamental breakthrough in the field of diagnostic endoscopy by assisting endoscopists with the detection of gastrointestinal tumors[7]. Deep learning networks represented by convolutional neural network (CNN) systems are a hot research topic at present and have been widely applied in the fields of pathology, radiology and endoscopy[8]. The first study focusing on gastrointestinal endoscopy and computer simulation was reported in 1990, which showed that computer simulation was used as a tool to train endoscopists by constructing a model describing the three-dimensional structure of the appropriate parts of the gastrointestinal tract[9]. With the development of AI, it has been extensively used in gastrointestinal endoscopy examinations, such as upper gastrointestinal endoscopy, colonoscopy, wireless capsule and ultrasonic endoscopy.

Bibliometric analysis refers to a statistical approach that helps to comprehensively analyze the hotspots, trends and each unit and scholar's cooperation of published articles in this field[10,11]. In this study, we aimed to analyze the research hot spots and trends in the field of AI and endoscopy from 1990 to 2022 using a quantitative method. We also explored the application of AI-assisted endoscopy in detecting different digestive diseases to provide assistance for the research and clinical application of AI and endoscopy.

MATERIALS AND METHODS

Search strategy

All relevant and qualified data were collected from the Web of Science database. The search strategy was a combination of the following keywords and terms: ("artificial intelligence" OR "AI" OR "deep learning" OR "machine learning" OR "machine intelligence" OR "computer" OR "computational intelligence" OR "neural network" OR "knowledge acquisition" OR "automatic" OR "automated" OR "feature extraction" OR "image segmentation" OR "neural learning" OR "artificial neural network" OR "data mining" OR "data clustering" OR "big data") AND ("endoscopy" OR "endoscope"). Moreover, only publications written in English between 01 January 1990 and 01 November 2022 were considered.

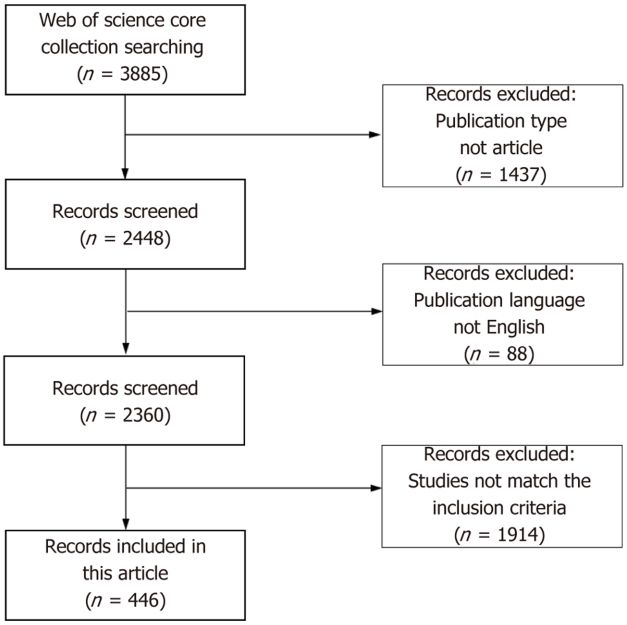
Study selection

Two authors (Ren-Chun Du and Yao-Bin Ouyang) independently evaluated all relevant articles in two stages, and a full discussion was held to resolve any differences and conflicts (the inclusion of literature, classification of disease and endoscopy, and weight of different studies, *etc*) with the third author (Yi Hu). At the first stage of evaluation, basic research, reviews, case reports and meta-analysis were excluded. In the second stage, the contents of the remaining articles were carefully assessed according to the patient, intervention, comparison, outcomes (PICOs) criteria. "P" (patient): Patients with digestive diseases or health care; "I" (intervention): AI-assisted endoscopic examination; "C" (comparison): Routine endoscopic examination; "O" (outcome): The accuracy of AI and routine endoscopic examination in detecting digestive diseases; and "S" (study design): Retrospective studies, prospective randomized controlled trials (RCTs) and non-RCTs.

Data extraction

The included articles were assessed and downloaded into various file formats for analysis by the two investigators. The following data were extracted: Author, institution, country, endoscopy type, disease type, performance of AI (including sensitivity, specificity, and accuracy), citations, year of publications, and H-index. Each study was weighted according to the number of test samples and the weighted average of the performance data of AI in diagnosing diseases was calculated. Any discrepancy was evaluated by the kappa value to assess the agreement between two investigators.

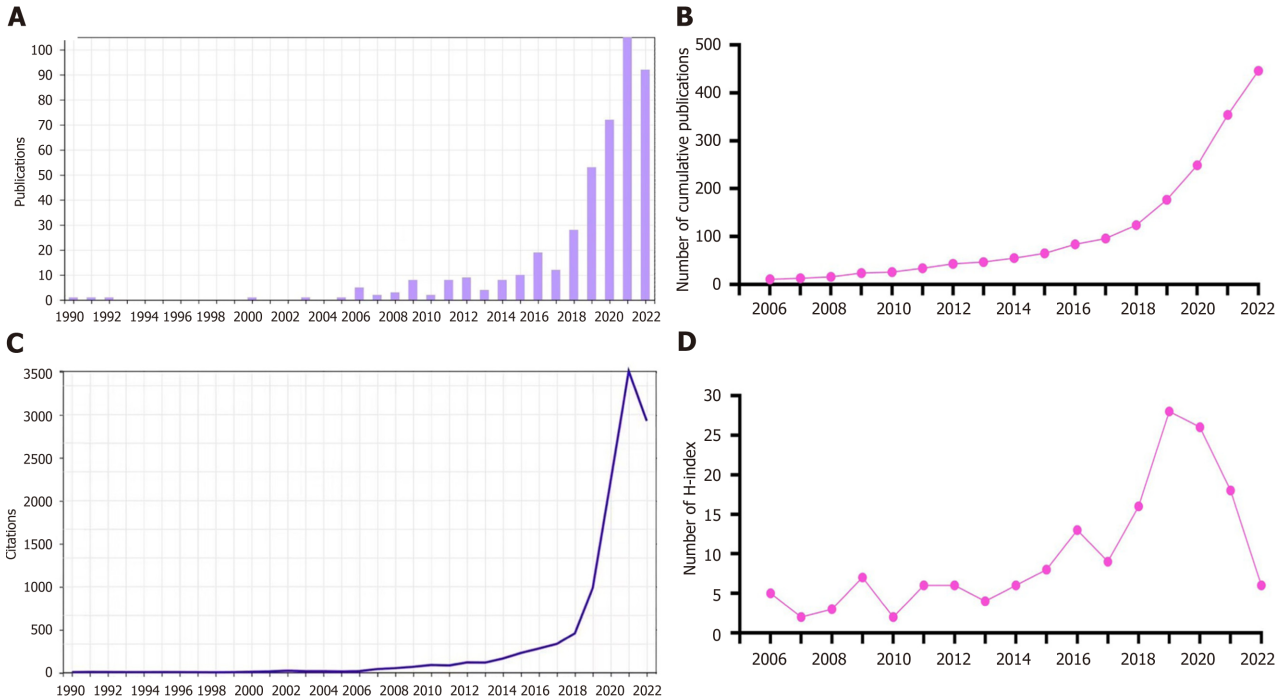
Data analysis



The data were imported into VOSviewer software (version 1.6.18), GraphPad Prism (version 8) and CiteSpace (version 6.1.R3) to generate the visual graphs. CiteSpace and VOSviewer were used to perform the quantitative and qualitative analyses. The cluster network was generated by VOSviewer to assess the most productive and cooperative authors, countries and institutions. Each dot of the visual graphs represents an author, institution and country, and these dots were clustered into various groups based on their cooperations. The size of the dots corresponded to the number of articles, while the strength of the connection was based on the frequency of cooperations. The options used in CiteSpace included a time slice set to "1990-2022," with 1 year per slice and the selection criteria set to "g-index." The scale factor k was set to "25", and "pathfinder" was selected to preserve the optimal structure while reducing the total links[12]. Keywords were used to label clusters and show cluster labels by a latent semantic indexing algorithm.

RESULTS

Study selection and characteristics



As shown in Figure 1, 3885 papers were enrolled from the Web of Science through our search strategy. At the first stage of selection, 1437 publications were excluded because of publication type, and 88 publications were excluded because of language. The contents of the remaining 2360 articles were carefully assessed. Ultimately, 446 articles meeting the inclusion criteria of this study were included.

Next, we summarized the characteristics of the included articles. The chronological distribution of annual publication numbers from 1990 to 2022 is shown in Figure 2A. The first study we obtained was published in 1990[9]. Less than 10 annual publications were reported in this field before 2015. As depicted in the diagram, the number of publications rapidly increased after 2015, and peaked in 2021, accounting for 23.5% of all publications. Figure 2B displays the cumulative number of publications. The number of annual publications gradually increased after 2013 except for a decrease in 2017. The number of annual citations is shown in Figure 2C, which was relatively low from 1990 to 2010 (below 100 citations for each year). It increased slowly after 2006 and quickly after 2018, remaining at a high number after 2020 (over 2000 citations). The annual H-index is shown in Figure 2D, which was relatively low (< 10) before 2016, but then increased rapidly and peaked at 28 in 2019, followed by a slight decrease from 2020 to 2022.

Figure 2 The annual number and H-index values. A: Annual number of published articles; B: Number of annual cumulative articles; C: Global annual number of the publications; D: Annual H-index values of the publications.

Analysis of country, institution and authors

The cooperation network of publication countries is displayed in Figure 3A, including a total of 50 countries and 524 co-operations. Next, the H-index, total citations and publications of the top 10 most productive countries were analyzed and presented in Supplementary Table 1. China emerged as the most productive country with 128 publications, 4089 citations and an H-index of 36. Figure 3B shows the cooperation cluster network of institutions, with a total of 106 institutions and 708 cooperations displayed. These institutions were clustered into different groups according to their cooperations. The top 10 most productive institutions were further analyzed for their publications, citations and H-index, and the results are presented in Supplementary Table 2. The Tada Tomohiro Institute of Gastroenterology and Proctology had the highest number of publications (22), citations (1454), and H-index (17).

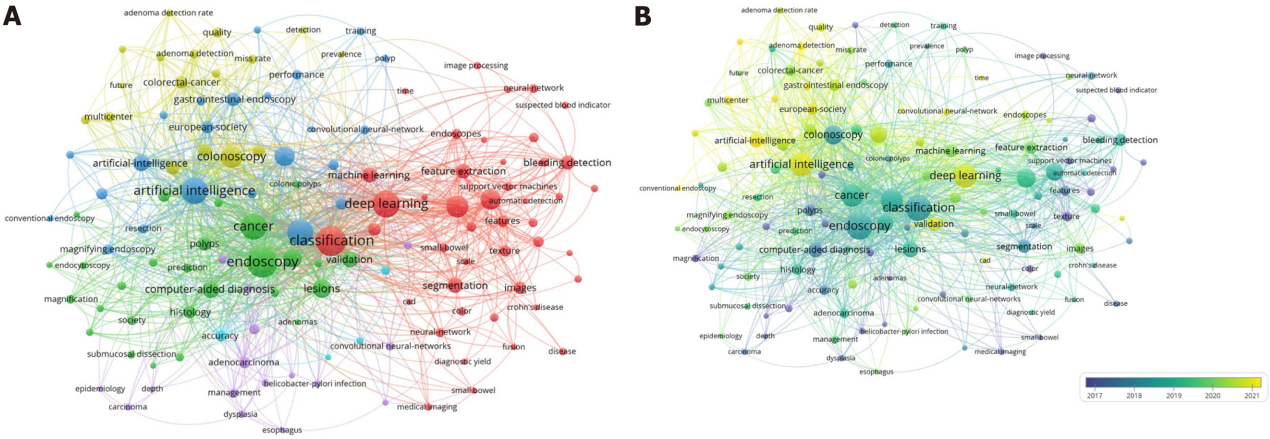
Figure 3 Cooperation network. A-C: Cooperation network of countries (A), institutions (B), and authors (C) in the field of artificial intelligence and endoscopy from 1990-2022.

Next, the publications, citations, H-index and co-operations of the 10 most productive authors were also analyzed. A total of 63 authors and 996 co-operations are shown in Figure 3C. As shown in Supplementary Table 3, Tada Tomohiro was the most productive author with 23 publications, an H-index of 17 and 1456 citations, followed by Yu HG, Wu LL, and Ishihara S.



Analysis of keywords and burst detection of publications

To obtain a comprehensive understanding of the popular topics in the realm of AI and endoscopy, a study is conducted utilizing keyword co-occurrence analysis. The analysis involves examining the relevant keywords associated with each paper, based on their titles and abstracts. A total of 131 keywords, appearing at least 5 times, are identified and represented using a bubble graph to visualize citation data. VOSviewer is employed to generate a comprehensive keyword co-occurrence visualization map, where the keywords are grouped into a distinct clusters market with a unique color code. Three categories were identified: AI, deep learning and endoscopy (Figure 4A). The co-occurrence visualization map based on the average year of publication is shown in Figure 4B. "Magnification" and "adenomas" mainly appeared before 2017. The keywords "classification", "endoscopy", and "cancer" became more common after 2017. Keywords colored in yellow are the latest, such as "AI", "deep learning", and "CNN".

Burst detection is a method employed for detecting a sudden surge in the occurrence of novel concepts during a specific period. As shown in Figure 4C, wireless capsule endoscopy ranked first in terms of outbreak intensity (4.83) over the past three decades, followed by color (3.82) and texture (3.82). Computer-assisted diagnosis became the focus of research after 1993. It is worth noting that AI, neoplasia, upper gastrointestinal endoscopy, society, and endoscopic imagine were the strongest bursts since 2022.

Analysis of cocited reference cluster

A network of references that are cocited by publications is referred to as a cocited network. When a group of references are repeatedly cited, it could generate a cluster network diagram (Figure 5A) and a literature cocitation diagram (Figure 5B). The "Pathfinder" and "Pruning Networks" options were utilized to conduct the optimal network. Each node on the network signifies a cited article and the size of it is based on the total cited frequency of pertinent articles. The literature that was cocited was then categorized into 10 major labels: Wireless capsule endoscopy, deep learning, AI, machine learning, CNN, response evaluation, capsule endoscopy, endoscopy imagine, gastrointestinal tract, and small

bowel (Figure 5A). Figure 5B shows a timeline view of distinct cocitations. Deep learning, CNN and response evaluation have always been popular research topics. Wireless capsule endoscopy, AI, and machine learning have been popular research topics since 2000.

Analysis of the most cited studies

Table 1 shows the specifics of the 10 most cited studies from 1990 to 2022. Each study was cited between 145 and 323 times. Three of these studies were published in *Gastroenterology*, and the remaining 7 studies were published in *Gastric Cancer*, *GUT*, *Gastrointestinal Endoscopy*, *IEEE Journal of Biomedical, Health Informatics*, *Lancet Gastroenterology*, and *Hepatology*. The most cited article was the application of AI using a CNN for detecting gastric cancer in endoscopic images. Five articles focused on AI applied in the detection of polyps. Another 5 articles focused on AI applied in cancer detection.

Research trends in AI applied in disease diagnosis

The proportion of the number of diseases in the field of AI and endoscopy was counted. As shown in Figure 5C, gastrointestinal polyps accounted for the largest proportion of disease in this area (14.6%), followed by gastric cancer (13.5%). The proportion of the endoscopy type was also counted. As shown in Figure 5D, conventional endoscopy accounted for the largest proportion in this area (42.3%), followed

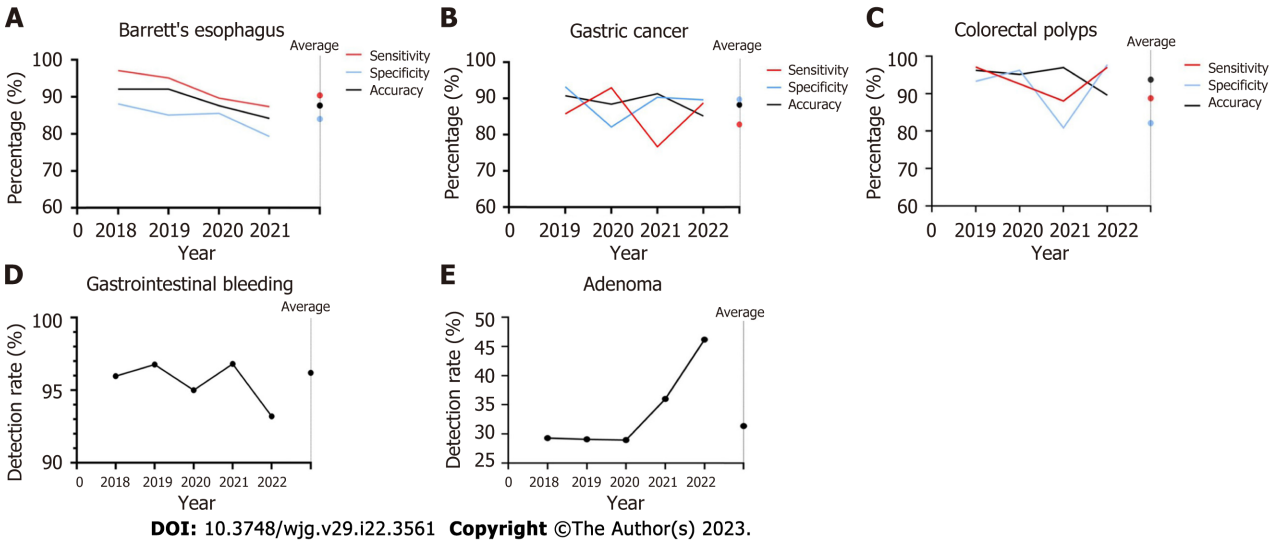
by capsule endoscopy (35.5%).

We further analyzed the temporal variation in the diagnostic performance of AI-assisted endoscopy for digestive diseases. The sensitivity, specificity and accuracy of AI-assisted endoscopy in Barrett's esophagus, gastric cancer and polyps are shown in Figure 6A-C. For Barrett's esophagus, the studies published in 2018 showed the highest sensitivity (97.0%), specificity (88.0%) and accuracy (92.0%). The weighted average sensitivity, specificity and accuracy of AI in detecting Barrett's esophagus from 2018 to 2021 were 90.4%, 84.0%, and 87.6%, respectively. In terms of gastric cancer, the studies in 2019 showed the highest accuracy (90.8%) and specificity (93.3%), and the studies in 2020 showed the highest sensitivity (92.3%). The weighted average sensitivity, specificity and accuracy of AI in detecting gastric cancer from 2019 to 2022 are 82.8%, 89.8%, and 88.3%, respectively. For detecting colorectal polyps, the studies in 2019 showed the highest sensitivity (97.1%), the studies in 2022 showed the highest specificity (97.7%), and 2021 showed the highest accuracy (96.9%). The weighted average sensitivity, specificity and accuracy of AI in detecting polyps from 2019 to 2022 are 89.6%, 82.1% and 93.7%, respectively. As shown in Figure 6D-E, the detection rate of gastrointestinal bleeding remained stable above 95% from 2018 to 2021 (weighted average: 96.2%). The adenoma detection rate remained stable at approximately 29% from 2018 to 2020. A higher detection rate (46.2%) was achieved in 2022 (weighted average: 31.3%).

DISCUSSION



To the best of our knowledge, this is the first bibliometric analysis to comprehensively illustrate the application of AI-assisted digestive endoscopy in digestive diseases. A basic literature analysis was performed, as well as a subgroup analysis of AI-assisted digestive endoscopy in diagnosing various diseases.

The term "AI" was first proposed in 1956[13]. Cortes *et al*[14] suggested the first algorithm for pattern recognition 60 years ago. In 2006, a fast-learning algorithm for deep belief networks was proposed[15].

Figure 6 Temporal variation in the diagnostic performance of artificial intelligence-assisted endoscopy for digestive diseases. A-C: Temporal variation in the sensitivity, specificity and accuracy of artificial intelligence (AI)-assisted endoscopy in Barrett's esophagus (A), gastric cancer (B), and polyps (C); D and E: Temporal variation in the detection rate of AI-assisted endoscopy in bleeding (D) and adenoma (E).

Since then, the number of publications and citations in this field has risen steadily. Machine learning is one of the fastest growing areas of technology[16]. Deep learning is an important branch of machine learning and is further divided into deep neural networks, recurrent neural networks and CNNs[17]. The best results were achieved by CNN in the field of image analysis[18]. In this study, we analyzed the most influential authors, institutions and countries regarding AI and endoscopy. Among these countries, China had the largest number of publications, citations and H-index. Moreover, China, United States, and Japan are the centers of the co-occurrence map. Wireless capsule endoscopy is one of

the most effective endoscopic techniques used in the examination of gastrointestinal diseases such as polyps and ulcers[19] and has been a research hot spot and topic since 2014.

AI-assisted endoscopy for disease detection covers almost all endoscopy in the field of digestive endoscopy. Colorectal cancer is the world's fourth most deadly cancer, with almost 900000 deaths annually[20]. AI-assisted colonoscopy has broad prospects in the screening and diagnosis of colorectal cancer. In our study, colorectal cancer accounted for 9.19% of the total disease. Urban *et al*[21] showed excellent performance in AI-assisted colonoscopy studies using CNN based on the deep learning method. The CNN identified polyps with an accuracy of 96.4%. Similarly, Shin *et al*[22] compared two different approaches named the hand-crafted feature method and CNN based on the deep learning method, and the results demonstrated that the CNN-based deep learning framework had better performance for detecting polyps, achieving over 90% accuracy, sensitivity, and specificity. The detection rate of adenoma reflects the quality of colonoscopy. A prospective cohort study was conducted to develop an automatic polyp detection system based on deep learning, and the detection rate of polyps and adenomas could be improved from 29% to 45% and 20% to 29%, respectively[23]. Wang *et al*[24] also studied the development and validation of a deep-learning algorithm for the detection of polyps during colonoscopy, which proved that AI could assist endoscopists efficiently in discovering colorectal adenomas and polyps with high accuracy (per-image sensitivity: 94.4%, per-image specificity: 95.5%). Moreover, Pfeifer *et al*[25] evaluated a newly developed deep CNN with a large sample size (15534 test images), and the deep CNN's sensitivity and specificity for detecting polyps were 90% and 80%, respectively.

Gastric cancer, Barrett's esophagus and *Helicobacter pylori* (*H. pylori*) infection are common upper gastrointestinal diseases. Hirasawa *et al*[26] first reported that AI using a CNN applied in conventional endoscopic images could achieve a diagnostic sensitivity of 92% for gastric cancer in 2018. It is worth noting that the CNN system only required 47 s to analyze 2296 images, which is faster than analyses completed by endoscopists. Ikenoyama *et al*[27] constructed a CNN to detect early gastric cancer with 2940 test samples, and the sensitivity was 58.4%. The prognosis of esophageal cancer is relatively poor. The first report of AI-assisted endoscopy applied in the diagnosis of esophageal cancer was conducted by Horie *et al*[28]. A CNN was trained to diagnose esophageal cancer using 8284 conventional endoscopic images, and eventually, high sensitivity and accuracy were achieved. The weighted average specificity of AI in detecting Barrett's esophagus from 2018 to 2021 was 84.0%. In 2020, a study with 20 samples achieved a specificity of 85.5%[29]. Another study in the same year with a sample size of 100 achieved a specificity of 78%[30]. *H. pylori* is the main pathogenic factor of gastric diseases. Shichijo *et al*[31] reported 89% sensitivity and 87% specificity for the diagnosis of *H. pylori* infection using CNN, and the diagnostic accuracy was significantly higher than that achieved by endoscopists. A consistent result was also achieved by another study[32].

Many studies have shown that cooperation between AI and endoscopists could improve the diagnostic ability to diagnose gastrointestinal diseases. Ikenoyama *et al*[27] compared the performance of endoscopists with an AI classifier based on CNN in detecting early gastric cancer through 2940 test images. Eventually, the results showed that AI had a significantly higher sensitivity than endoscopists. Niikura *et al*[33] obtained similar results in another study, and the diagnostic rate of gastric cancer per image in the AI group was higher than that in the group of experts. Yen *et al*[34] showed a higher accuracy of AI than experts in detecting peptic ulcer bleeding. Zhang *et al*[35] compared a CNN-based image recognition system with visual inspection by endoscopists in identifying polyps. The results showed a significant improvement in accuracy with the application of AI.

Certain limitations existed regarding the use of AI. First, algorithm performance could be different when using endoscopy equipment manufactured by different companies[23,24]. Second, as AI algorithms are highly dependent on the integrity of the database, the number of training images might result in a different diagnostic ability of AI[26]. Third, data privacy and security considerations are also critical, which could be of great concern to endoscopists[36,37]. The potential ethical and legal issues of this technology in clinical application should not be underestimated.

A bibliometric analysis was previously conducted to examine AI applied in digestive endoscopy[38]. A basic analysis of bibliometric indicators was performed. Our study recorded the data of each article in detail. We also analyze the effectiveness of AI-assisted endoscopy in disease detection, specific analysis of digestive endoscopy, and gastrointestinal diseases and evaluate the accuracy of AI.

Our study aimed to provide a comprehensive analysis of AI applied in diagnostic endoscopy: (1) The emergence of deep belief networks contributed to an increase in research in this field; (2) the intelligent detection and recognition of colorectal polyps is the most concerning and researched area at present; (3) capsule endoscopy is one of the most influential keywords; (4) the accuracy of AI in detecting Barrett's esophagus, colorectal polyps and gastric cancer from 2018 to 2022 is 88.08%, 93.71%, and 88.29%, respectively, and the detection rates of adenoma and gastrointestinal bleeding from 2018 to 2022 are 31.38% and 96.20%, respectively; and (5) AI-assisted digestive endoscopy could improve the diagnosis rate of endoscopists in disease detection, and CNN-based diagnosis programs for endoscopic images showed promising results. However, there are some limitations which existed in this study. First, the search for publications was limited to the Web of Science core collection database, which may result in incomplete literature searches of other databases. Second, a number of studies that were not in English might be missed. Third, several bias may affect the results, such as publication bias.

CONCLUSION

In conclusion, AI could improve the detection rate of digestive tract diseases and has been applied widely in the field of endoscopy. Multicenter prospective studies with larger samples should be conducted in the future to further explore the accuracy of AI based on different methods.

ARTICLE HIGHLIGHTS

Research background

Recently, artificial intelligence (AI) has been widely used in gastrointestinal endoscopy examinations.

Research motivation

More than 100 million subjects receive gastrointestinal endoscopy examinations each year. It is of great importance to improve the quality of endoscopy examinations to discover the lesions. With the development of AI, it has been extensively used in gastrointestinal endoscopy examinations.

Research objectives

To provide a comprehensive analysis of AI applied in diagnostic endoscopy.

Research methods

Relevant publications from the Web of Science published from 1990 to 2022 were extracted using a combination of the search terms "AI" and "endoscopy".

Research results

AI-assisted digestive endoscopy could improve the diagnosis rate of endoscopists in disease detection, and convolutional neural network-based diagnosis programs for endoscopic images showed promising results.

Research conclusions

AI could improve the detection rate of digestive tract diseases and has been applied widely in the field of endoscopy. Multicenter prospective studies with larger samples should be conducted in the future to further explore the accuracy of AI based on different methods.

Research perspectives

Gastrointestinal cancers seriously threaten the health of global populations. Gastrointestinal tumors diagnosed at an early stage had a better prognosis than those diagnosed at a late stage. AI represents a fundamental breakthrough in the field of diagnostic endoscopy by assisting endoscopists with the detection of gastrointestinal tumors and it has been extensively used in gastrointestinal endoscopy examinations.

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJG* as 4.3; IF without journal self cites: 4.1; 5-year IF: 5.3; Journal Citation Indicator: 0.82; Ranking: 32 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.3 and Scopus CiteScore rank 2022: Gastroenterology is 22/149.

Abstract

Follicular lymphoma (FL) is the most common low-grade lymphoma, and although nodal FL is highly responsive to treatment, the majority of patients relapse repeatedly, and the disease has been incurable with a poor prognosis. However, primary FL of the gastrointestinal tract has been increasingly detected in Japan, especially due to recent advances in small bowel endoscopy and increased opportunities for endoscopic examinations and endoscopic diagnosis. However, many cases are detected at an early stage, and the prognosis is good in many cases. In contrast, in Europe and the United States, gastrointestinal FL has long been considered to be present in 12%-24% of Stage-IV patients, and the number of advanced gastrointestinal cases is expected to increase. This editorial provides an overview of the recent therapeutic advances in nodal FL, including antibody-targeted therapy, bispecific antibody therapy, epigenetic modulation, and chimeric antigen receptor T-cell therapy, and reviews the latest therapeutic manuscripts published in the past year. Based on an understanding of the therapeutic advances in nodal FL, we also discuss future possibilities for gastroenterologists to treat gastrointestinal FL, especially in advanced cases.

Key Words: Nodal and gastrointestinal follicular lymphoma; Antibody-based therapy; Bispecific antibody therapy; Phosphatidylinositol-3 kinase inhibitor; Epigenetic modulator; Chimeric antigen receptor-T cell therapy

INTRODUCTION

Follicular lymphoma (FL) is a typical indolent B-cell lymphoma that accounts for 10%-20% of all non-Hodgkin lymphomas (NHLs)[1]. Its incidence is increasing rapidly in Western and Asian countries[2]. In particular, the number of FL cases in Japan has recently increased[3]. FL is histopathologically classified as grades 1, 2, 3a, or 3b, with grade 3b usually treated as aggressive (intermediate/high-grade) lymphoma. Most patients present with enlarged lymph nodes, and 70%-85% of patients have advanced clinical stage III or IV disease at diagnosis, with a high rate of bone marrow involvement. The gastrointestinal tract is the most common site of extranodal NHL, accounting for 30-40% of primary extranodal NHL cases[4,5]; however, gastrointestinal FL (GI-FL) is rare, with a frequency of approximately 2% of GI-NHL[6-8]. However, in recent years, the number of patients with primary GI-FL has increased because capsule and double-balloon endoscopies of the small intestine have become common in Japan. Most GI-FL cases are stage I, but there are 3.4%-40.0% with metastasis or invasion to intra-abdominal lymph nodes (stage II), extensive extranodal organ (stage IV) to extensive extranodal organs or beyond the diaphragm (12%-24%) have been reported[9], and the number of advanced cases of GI-FL (stage III, IV) is expected to increase in the future. Hiddemann *et al*[10] reported the efficacy and prolonged overall survival (OS) of rituximab, an anti-CD20 monoclonal antibody, in combination with cyclophosphamide, doxorubicin, vincristine, and prednisolone (CHOP) in patients with advanced FL. Prior to the introduction of rituximab, the 50% survival period for FL patients was 7-10 years, recent reports have indicated that the 50% survival period exceeds 20 years for patients under 40 years of age at diagnosis[11]. Furthermore, progress has been made in the studies and clinical trials of combination therapies using other monoclonal antibodies and conventional chemotherapy combinations. In the last decade, new therapeutic agents for nodal FL have been developed, including antibody-targeted therapy, bispecific antibody therapy, epigenetic mutation, and chimeric antigen receptor (CAR)-T cell therapy, and many clinical trials of monotherapy and various combinations of two or three of these agents have been conducted, showing high response rates, progression-free survival (PFS). Many clinical trials have been conducted to evaluate the efficacy of single agents and combinations of two or three of these drugs, and have shown high response rates, PFS, and OS. However, the large number of new drugs has led to the creation of many combinations of these drugs, so there is still no definitive conclusion as to which combination is the best in terms of efficacy and safety, and what the optimal order of these therapies should be. We reviewed and summarized the recently reported therapeutic advances in nodal FL, especially the most recent therapeutic publications during the past year. We then discuss the possibilities and directions in which gastroenterologists should utilize and reflect on recent advances in the treatment of nodal FL in primary GI-FL.

Recent advances in the treatment of nodal FL

Radiation therapy used to be the first choice for the treatment of nodal FL when the lesions were localized or multiple but few in number, however, the choice of radiation therapy has been greatly reduced in recent years due to its strong adverse reactions, and chemotherapy, which has advanced significantly in the past 20 years, immunotherapy, which has fewer side effects, or their combination therapies have emerged.

This editorial describes recent advances in the treatment of advanced FL, primarily stage III or IV, with reference to tables summarizing them.

ANTIBODY-BASED THERAPY

Monoclonal antibody-based therapy

Immunotherapy with rituximab and other anti-CD antibodies is highly effective in the treatment of FL and is superior and still central to current FL therapy. The objective response rate (ORR) with single-agent rituximab was 67% in untreated FL patients and 46% in previously treated relapsed FL patients [12].

A German Low-Grade Lymphoma Study Group conducted a randomized trial of CHOP alone *vs* rituximab plus CHOP (R-CHOP) in untreated advanced FLs. In a randomized comparison of CHOP monotherapy and R-CHOP combination therapy, the R-CHOP group significantly outperformed the CHOP group not only in time to failure but also in OS[13]. This evidence is important because it heralds the subsequent progress of combination therapy using anti-CD monoclonal antibody immunotherapy and other novel agents, in addition to conventional chemotherapy. Following rituximab administration, new antibody-based agents have been developed, including tafasitamab, an anti-CD19 antibody; polatuzumab vedotin, an anti-CD79b antibody-drug conjugate (ADC); loncastyximab tesirine, an ADC composed of a humanized antibody targeting the protein CD19; magrolimab, an anti-CD47 antibody; and obinutumab, a humanized anti-CD20 monoclonal antibody. Obinutumab, a humanized anti-CD20 monoclonal antibody, has been developed (Table 1).

Tafasitamab plus lenalidomide, which enhances NK cell activity and antibody-dependent cytotoxicity (ADCC), has been shown to be superior to the monotherapy[14].

Polatuzumab vedotin is a CD79b-directed ADC. In the phase II ROMULUS trial of relapsed and refractory (r/r) FL and diffuse large B-cell lymphoma (DLBCL), patients with FL were treated with rituximab plus polatuzumab (CD79-directed ADC) or rituximab plus pinatuzumab (CD22-directed ADC), and their efficacy was compared[15].

Loncastuximab tesirineis (ADCT-402) is a noble antibody-drug conjugated to a cytotoxic dimer. After bindig to the tumor cells the antibody is internalized, the cytotoxic drug is released, and the cancer cells are killed. The ORR in patients with FL in a phase I study was 78.6%; phase II findings (LOTIS-2 study) of loncastaximab tecilin in r/r DLBCL patients showed a good and sustained antitumor effect with an ORR of 48.3% and complete response rate (CRR) of 24.2%[16]. Clinical trials are currently underway for other carcinomas; a phase II study in combination with rituximab for r/r FL patients is ongoing in Florida, United States.

Magrolimab is a CD47-directed antibody, and a phase I study of its combination with rituximab in r/r lymphoma has been reported[17].

Obinutumab is a humanized anti-CD20 monoclonal antibody with low fucose content in the Fc region through glycosylation technology and the unique properties of a type-2 antibody. Phase 3 trials have shown improved efficacy in indolent non-NHL (iNHL) and chronic lymphocytic leukemia (CLL), and phase 2 trials of these therapeutic regimens have shown promising results in CLL, FL, and mantle cell lymphoma (MCL)[18].

Results of a phase I study of the combination of venetoclax plus obinutumab in previously untreated FL patients ORR and CRR were 87.5% and 25.0%, respectively, by CT evaluation; 84.2% and 68.4%, respectively, by PET/CT evaluation; 1-year PFS was 77.8% and 79%, respectively; 30-mo PFS was 73.2% and 79.0%, respectively and showed efficacy of the combination of venetoclax plus obinutumab[19]. However, in the GALLIUM trial, obinutuzumab had a better PFS than rituximab when combined with conventional chemotherapy as frontline therapy in previously untreated advanced FL patients[20]. Furthermore, transformed-FL (t-FL) patients with more aggressively transformed, more malignant potential had worse survival than r/r FL patients (2-year rate: 55.9% *vs* 83.1%). t-FL relapsed earlier than FL (median observation time: 0.8 years *vs* 2.3 years)[21].

Finally, we discuss the key points regarding recent rituximab biosimilars. In recent years, four rituximab biosimilars have been approved to date in Europe and the United States. CT-P10 is the first Rituximab biosimilar approved CT-P10 is as effective and safe as Rituximab in untreated FL with small tumor volume[22]. They also reported no statistically significant differences in efficacy and serious adverse events between the Rituximab biosimilar group and the reference drug, Mabusera[23]. The Japanese government's policy for 2022 also states that biosimilar will be steadily promoted with a target value set by the end of 2022 based on the effect of medical cost optimization. It is expected that the use of rituximb biosimulators will be recommended and increased worldwide from the viewpoint of cost benefit in reducing the enormous medical costs in the future.

Antibody therapies against novel targets, such as CD19, CD79b, and CD47, as well as rituximab, an anti-CD20 monoclonal antibody and obinutumab, a humanized anti-CD20 monoclonal antibody, have been developed and have demonstrated efficacy in FL. Antibody targeted therapies to FL are innovative immunotherapy medication that offers great efficacy and safety for FL treatment. We have high expectations for improved outcomes in the near future.

Bispecific T cell binding antibody = bispecific antibody therapy

Bispecific T-cell binding antibodies (BTEs) = bispecific antibodies are molecules designed to bind to two or more different antigens, a powerful therapy that allows T cells to more precisely target specific tissues and cells. Summary of clinical trials of BTE treatment for FL is shown in Table 2.

Table 1 Summary of clinical trial results of monoclonal antibody-based therapies

Study	Target disease	No. of patients	Objective response rate	Complete response rate	Median progression-free survival	Overall survival	Adverse events or other subjects	Ref.
Tafasitamab plus lenalidomide phase-II L-MID	r/r DLBCL (no FL) > 35 mo follow up	*n* = 80	57.5% (*n* = 46/80)	40.0% (*n* = 32/80)	11.6 mo	33.5 mo	No unexpected toxicity	[14]
Phase-II ROMULUS, rituximab-polatuzumab *vs* rituximab-pinatuzumab	r/r FL	*n* = 42, *n* = 20, *n* = 21	70% (*n* = 14/20); 62% (*n* = 13/21)	45% (*n* = 9/20); 5% (*n* = 1/21)	Unknown	Unknown		[15]
Loncastuximab tesirine (ADTC-402) frontline therapy	Untreated FL	Total, DLBCL, MZL, FL	45.6%, 42.3%, 46.7%, 78.6%	26.7%	Unknown	Unknown	Median duration response: 5.4 mo	[16]
Magrolimab plus rituximab phase-Ib	r/r DLBCL; r/r FL	*n* = 22; DLBCL:15; FL: 7	50% (CR or PR); 40%, 71% (*n* = 5/7)	33%, 43% (*n* = 3/7)	Unknown	Unknown	90% response were on going, a median follow-up of 6.2 (DLBCL)/8.1 (FL) mo	[17]
Venetoclax plus obinutumab phase-I	Untreated FL	CT, PET/CT	87.5%, 84.2%	25.0%, 68.4%	77.8% (at one yr); 79.0% (at one yr); 73.2% (at 30 mo); 79.0% (at 30 mo)	Unknown; unknown		[19]
GALLIUM trial obinutuzumab + CTx rituximab + CTx	Untreated FL	*n* = 1202, *n* = 601, *n* = 601	88.5%, 86.9%	Unknown, unknown	80.0% (at 3 yr); 73.3% (at 3 yr)	Unknown, unknown	Obinutuzumab is better	[20, 21]

"Unknown" means data not shown, unknown information or not reached. r/r: Refractory and relapsed; FL: Follicular lymphoma; DLBCL: Diffuse large B-cell lymphoma; MZL: Marginal zone lymphoma; (R-)CHOP: (Rituximab plus) cyclophosphamide, doxorubicin, vincristine, and prednisolone; CT: Computed tomography; PET/CT: Positron emission tomography/computed tomography; CTx: Traditional chemotherapy.

The BTEs most commonly used for FL treatment are CD3 and CD20, with Mosunetuzumab and Glofitamab being pioneering representative novel BTEs.

A phase I trial of single-agent mosunetuzumab in patients with r/r iNHL (including FL and t-FL) showed an ORR of 66% and a CRR of 49%, with grade 3 or higher adverse events in 71% of patients with low-grade lymphoma (r/r and t-FL, 96%)[24]. Mosnetuzumab, a CD20 × CD3 bispecific monoclonal antibody, showed a significantly higher CRR of 60% than that of the control group with copanlisib of 14%, when administered to patients with r/r FL, indicating high efficacy[25]. Mosunetuzumab was also studied in combination with lenaridomide; a phase I study of combination therapy in r/r FL patients showed an ORR of 92%, CR of 77%, and grade 3 or higher adverse events in 30% of patients in the abstruct.

Glofitamab was observed to have a better response rate at higher dose levels in the r/r B-NHL (including indolent lymphoma of 25.7%) phase I trial, with an ORR of 65.7% and a CRR of 57.1%. CRS occurred in 50.3% of cases[26]. The results of a study comparing glofitamab with or without obinutuzumab in r/r FL showed an ORR of 81% and a CRR of 70% for glofitamab alone and 100% and 74% for the combination group in the Abstruct.

The results of a phase I/II trial of epcoritamab, an anti-CD3 and anti-CD20 BTE, in r/r NHL patients showed an ORR of 90% and a CRR of 50% in FL patients[27]. The results of a phase I/II study of epcoritamab in combination with lenaridomide and rituximab in patients with r/r FL showed high efficacy, with an ORR of 100% and a CRR of 93%[28].

Odronextamab is a hinge-stabilized fully human IgG4-based CD20 × CD3 bispecificity antibody that binds to CD3 on T cells and CD20 on B cells. In the Odronextamab ELM-1 phase I study, patients with r/r FL who received 5 mg or more of odronextamab had an ORR of 91% and a CRR of 72%; Odronextamab monotherapy showed promising preliminary activity, especially in patients with long-standing previously treated BCL with sustained response[29,30].

BTE is a novel immunotherapy agent that shows high efficacy and safety for FL treatment. We would like to greatly anticipate further improvements in outcomes through future clinical trials.

Anti-programmed death ligand 1 antibody

Programmed death ligand 1 (PD-1) blockade enhances anti-tumor T cell function and ADCC in NK cells. Recntly, the efficacy of the anti-PD-1 ligand (PD-L1) antibodies, atezolitumab and pembrolizumab, in FL has also attracted attention (Table 3).

Table 2 Summary of clinical trial results of bispecific T cell binding antibody therapies

Study	Target disease	No.of patients	Objective response rate	Complete response rate	Median progression-free survival	Overall survival	Adverse events or other subjects	Ref.
Mosunetuzumab alone, phase-I	r/r NHL (including FL and t-FL)	*n* = 157	66.2% (i B-NHL)	48.5% (i B-NHL)	Median duration of response 20.4 mo (i B-NHL	Unknown	G3 and higher in 71% of iNHL patients	[24]
Mosunetuzumab alone, phase-II	r/r FL (Grade 1-3a)	*n* = 90 (median follow-up was 18.3 mo)	Unknown	60% (*n* = 54/90) (14% higher than CRR with copanlisib), high efficacy	Unknown	Unknown	High efficacy	[25]
Mosunetuzumab with lenaridomide, phase-I	r/r FL	Unknown	92%	77%	Unknown	Unknown	G3 and higher in 30% of patients	In abstruct
Glofitamab alone, phase-I	r/r B-NHL (including r/r FL)	*n* = 155	65.7% (at the recommended phase-II dose)	57.1% (at the recommended phase-II dose)	Unknown	Unknown	CRS occurred in 50.3% of patients	[26]
Glofitamab alone *vs* glofitamab with obinutuzumab	r/r FL	Unknown	81%, 100%	70%, 74%	Unknown	Unknown	Combination has a better response rate	In Abstruct
Epcoritamab, phase-I/II	r/r B-NHL	*n* = 68	90% (full dose)	50% (full dose)	Unknown	Unknown	Pyrexia 69%, CRS 59%	[27]
Epcoritamab with lenaridomide and rituximab	r/r FL	Unknown	100%	93%	Unknown	Unknown	High efficacy is revealed	[28]
Odronextamab alone phase-I ELM-1 trial	r/r B-NHL (including r/r FL)	*n* = 145	91% (r/r FL)	72% (r/r FL)	Unknown	Unknown	CRS 28%	[29]

"Unknown" means data not shown, unknown information or not reached. r/r: Refractory and relapsed; (i)NHL: (Indolent) non-Hodgkin lymphoma; i B-NHL: Indolent B-cell non-Hodgkin lymphoma; FL: Follicular lymphoma; t-FL: Transformed follicular lymphoma; G: Grade; CRS: Cytokine release syndrome.

Table 3 Summary of clinical trial results of anti-programmed death ligand 1 antibody-based therapies

Study	Target disease	No. of patients	Objective response rate	Complete response rate	Median progression-free survival	Overall survival	Adverse events or other subjects	Ref.
Atezolitumab (anti-PD-1 antibody) plus obinutumab	Total	*n* = 49				Unknown		[31]
phase-I	r/r FL	*n* = 26	54%	23%	9 mo			
	r/r DLBCL	*n* = 23	17%	4%	3 mo			
Pembrolizumab(anti-PD-1antibody) plus rituximab	r/r FL (one or more prior therapy)	*n* = 30	67%	50%	12.6 mo	97% (at 3 yr)	23% in remission at medianfollow-up of 35 mo	[32]

"Unknown" means data not shown, unknown information or not reached. r/r: Refractory and relapsed; FL: Follicular lymphoma; DLBCL: Diffuse large B-cell lymphoma; PD-1: Programmed death ligand 1.

The results of a phase I study of the combination of atezolizumab, an anti-PD-L1 antibody, and obinutumab showed an ORR of 54% (CRR: 23%) for r/r FL and r/r DLBCL and 17% (CRR: 4%) for DLBCL; PFS was 9 mo in the FL group and 3 mo in the DLBCL group[31]. In addition, a clinical trial of pembrolizumab, an anti-PD-1 monoclonal antibody, in combination with rituximab, an anti-CD20 monoclonal antibody, in r/r FL patients showed an ORR of 67% and CRR of 50%; median PFS was 12.6 mo, 3-year OS was 97%, and at a median follow-up of 35 mo 23% of patients were in remission[32]. Pembrolizumab in combination with rituximab as a novel therapeutic agent for r/r FL showed high efficacy and remission maintenance.

PD-1 blockade enhances anti-tumor T cell function and ADCC in NK cells, and its mechanism of action is more fundamental and makes more sense. We expect further improvement of the therapeutic effect of anti-PD-1 antibody therapy for FL patients.

IMMUNOMODULATORS

Lenaridomide is a typical oral immunomodulatory drug (IMiD) used to treat FL. Lenaridomide is a derivative of thalidomide with a similar structure. Lenaridomide is a derivative of thalidomide with a similar structure. It has both a "tumor-killing" effect by inhibiting the growth of hematological malignancies and inducing apoptosis, and an "immunomodulatory" effect by acting on immune cells and activating their immunity[33]. The combination of lenaridomide and CD20 antibody was initially tested as a salvage therapy for r/r FL in combination with an anti-CD20 antibody; however, owing to its high efficacy, it was recently tested as a frontline therapy for patients with advanced, untreated FL, with good results. Table 4 lists clinical trials in which lenaridomide was administered.

A phase II study comparing lenaridomide alone with R2 (lenaridomide plus rituximab) in patients with r/r FL showed an ORR favoring the R2 group (35% *vs* 24%), with a median follow-up of 2.5 years. The time to progression (median) was also superior in the R2 group (2.0 years *vs* 1.1 years), but there was no significant difference in OS[34].

The results of the phase III AUGMENT study evaluating R2 (lenaridomide plus rituximab) in r/r FL and marginal zone lymphoma (MZL) showed a median PFS of 39 mo in the R2 group compared to 14 mo in the rituximab group, with no difference in OS[35].

The phase IIIb MAGNIFY trial investigated extended R2 treatment in patients with r/r FL and MZL. After 12 cycles of R2 treatment, patients were randomized to receive an additional 18 mo of R2 treatment or rituximab maintenance therapy. The R2 cohort had ORR of 69% and CRR of 40%. The median PFS was 40 mo, similar to that observed in the AUGMENT trial[36].

In a single-arm phase II GALEN trial of patients with r/r FL, Obinutuzumab and lenaridomide were studied[37]. The patients received lenaridomide and obinutuzumab for 18 mo, followed by 1 year of obinutuzumab maintenance therapy[37]. After a median follow-up of 2.6 years, the ORR was 95%, 2-year PFS was 65%, and OS was 87%. No clinical trials have directly compared rituximab and obinutuzumab in combination with lenaridomide, and it is unclear which combination is superior in efficacy.

The phase III RELEVANCE trial of R2 as frontline therapy for advanced FL was conducted[38]. Patients were randomized to receive 18 cycles of R2 therapy plus 6 cycles of rituximab maintenance therapy or a chemoimmunotherapy regimen including rituximab [R-CHOP, bendamustine plus rituximab (BR), or rituximab plus cyclophosphamide, vincristine, and prednisone (R-CVP)]. The primary endpoints of the CR rate (48%-53%) and 3-year PFS (77%-78%) at 120 wk were similar; no superiority of R2 over chemoimmunotherapy in the front-line treatment of FL has been demonstrated [38].

The phase II E2408 trial randomized untreated FL patients into BR induction and R2 maintenance, BR induction and rituximab maintenance, or BR and the proteasome inhibitor boltezomib plus rituximab maintenance, and compared the efficacy among the three groups[39]. The three groups had similar (approximately 90%) and high CRRs, and the 1-year disease-free survival was higher in the rituximab maintenance group (85%) than in the R2 group (67%), possibly due to a higher discontinuation rate due to adverse events in the R2 group.

A clinical trial of lenaridomide plus obinutuzumab as frontline therapy for patients with advanced untreated FL showed very good results, with an ORR of 98%, CR of 92%, and 2-year PFS of 96% after a median follow-up of 22 mo[40]. In the future, the combination of lenalidomide and CD20 antibodies is expected to be the mainstay of front-line therapy for FL.

With the introduction of bendamustine, obinutuzumab, and lenalidomide, which have shown high efficacy in maintenance therapy, front-line treatment of FL has improved and developed. However, how they can be combined to provide the best treatment has recently been studied by network meta-analysis of randomized controlled trials to compare treatment efficacy[41].

With lenaridomide, a further improvement in the therapeutic effect in FL patients was obtained when used in combination with other main agents. As one of the important combination drugs, it is expected to improve treatment outcomes in the future.

MOLECULAR TARGETED THERAPIES (SMALL MOLECULE CONPOUNDS)

Bruton's tyrosine kinase inhibitor

Bruton's tyrosine kinase (BTK) is a type of protein kinase that exists in immune cells and regulates B cell differentiation and activation upon stimulation from the B cell receptor (BCR). Since BCR signaling plays an important role in blood cancers such as B-cell NHL and CLL, BTK inhibitors have been expected to have therapeutic effects in these blood cancers including FL. The results of the clinical trials

Table 4 Summary of clinical trial results of immunomodulator-based therapies

Study	Target disease	No.of patients	Objective response rate	Complete response rate	Progression-free survival	Overall survival	Adverse events or other subjects	Ref.
Randomized phase-II; lenaridomide alone (L) lenaridomide + rituximab (LR)	r/r FL	*n* = 91, *n* = 45 (L); *n* = 46 (LR)	53%, 76%	20%, 39%	Median time to progression: 1.1 yr (at 2.5 yr); 2.0 yr (at 2.5 yr)	Unknown		[34]
Phase-III AUGMENT lenaridomide + R (R2) *vs* lenaridomide + placebo	r/r FL; r/r MZL	*n* = 358; *n* = 180; *n* = 178	Unknown	Unknown	Median duration: 39.4 mo; 14.1 mo	Unknown	Grade 3 neutropenia of R2 is higher than L	[35]
Phase-IIIb MAGNIFY trial; R maintain after R2 additional lenarimide + rituximab (R2) 18 mo after R2	r/r FL; r/r MZL	*n* = 393	69% (R2)	40% (R2)	40 mo (similar to AUGMENT trial)	Unknown		[36]
Phase-II GALEN study; lenarimide + obinutuzumab (R2) 18 mo followed by obinutuzumab alone maintenance therapy 1 year	r/r FL	*n* = 68; evaluable	95% (at 2.6 yr)	38% (*n* = 33/86)	65% (at 2 yr)	87% (at 2 yr); 81% (*n* = 70/86); 84% (*n* = 72/86)		[37]
Phase-III RELEVANCE study, lenaridomide + rituximab (R2) + Rituximab maintenance therapy *vs* CTx (R-CHOP, BR, or R-CVP)	Untreated advanced FL	*n* = 1030; R-maintenance, *n* = 513; CTx, *n* = 517	Unknown	48%-53%, about the same	3 years-PFS 77%-78%, almost equal to superiority of R2 in F2 frontline not proven	Unknown		[38]
	Untreated advanced FL		Unknown	All 3 groups approximately 90%, about the same	3 yr PFS (5 yr median follow-up); -R 77%, BVR-R 82%, BR-LR 76% (higher in the R-maintenance group than in the R2 group) because of more discontinuations in the R2 group)	3 yr PFS (5 yr median follow-up), BR-R 87%, BVR-R 90%, BR-LR 84%		[39]
Single center phase-II frontline therapy; lenaridomide plus obinutuzumab	Untreated advanced FL	*n* = 90	98% (after a median follow-up of 22 mo)	92% (after a median follow-up of 22 mo)	2 yr-PFS 96 (after a median follow-up of 22 mo)	Unknown		[40]

"Unknown" means data not shown, unknown information or not reached. r/r: Refractory and relapsed; FL: Follicular lymphoma; MZL: Marginal zone lymphoma; L: Lenaridomide; R: Rituximab; LR: Lenaridomide plus rituximab; R2: Lenaridomide plus rituximab; (R-)CHOP: (Rituximab plus) cyclophosphamide, doxorubicin, vincristine, and prednisolone; BR: Bendamustine plus rituximab; (R-)CVP: (Rituximab plus) cyclophosphamide, vincristine and prednisolone; BR-R: BR induction followed by 2-year rituximab maintenance; BVR-R: BR with bortezomib and rituximab maintenance; BB-LR: BR followed by lenalidomide (1 year) with rituximab maintenance; CTx: Traditional chemotherapy.

of BTKi treatments for FL are listed in Table 5.

Representative BTKi include, in order of oldest to youngest, first-generation ibrutinib, second-generation acalabrutinib and zanubrutinib, and third-generation piltobrutinib. These BTKi have shown high efficacy in B-cell NHL and CLL[42-46].

The efficacy of zanurutinib monotherapy in patients with r/r FL was sluggish, with an ORR of 36.4% and CR of 18.2%. After a median follow-up of 33.9 mo, the median PFS was 10.4 mo[42]. On the other hand, a phase II study in r/r MCL showed that after a median follow-up of 35.3 mo, the ORR was 83.7%, the CRR was 79.9%, and the median PFS was 33.0 mo[43]. Zanurutinib alone was highly effective in r/r MCL, however, limited in r/r FL.

The phase II DAWN trial evaluated the therapeutic efficacy of single-agent ibrutinib in patients with r/r FL; the ORR was 21% and did not meet the primary endpoint[47]. Frontline therapy was administered to investigate a combination of Ibrutinib and Rituximab. This phase II trial included two arms, both with ibrutinib 560 mg/d, with Rituximab in arm-1 starting at week 1 for four cycles per

Table 5 Summary of Clinical Trial Results of Bruton's Tyrosine Kinase inhibitors

Study	Target disease	No. of patients	Objective response rate	Complete response rate	Progression-free survival	Overall survival	Adverse events or others	Ref.
Zanubrutinib (other BTKi) alone	r/r FL		36.4%	18.2%	Median PFS 10.4 mo (median follow-up 33.9 mo)	Unknown		[42]
Zanubrutinib phase-II	r/r MCL	83.7%	77.9%	Unknown	33.0 mo	Unknown		[43]
	r/r FL	n = 100	21.0% (poor)	Unknown	Unknown	Unknown		[47]
Ibrutinib with rituximab phase-II trial	Untreated FL, r/r FL	n = 13, n = 27	85% (arm-1), 75% (arm-2)	Unknown	62% of untreated FL, 26% of r/r FL, continued treatment	Unknown		[48]

"Unknown" means data not shown, unknown information or not reached. r/r: Refractory and relapsed; FL: Follicular lymphoma; MCL: Mantle cell lymphoma; PFS: Progression-free survival.

week, and Rituximab in arm-2 starting at week 9. The ORR was 85% in arm-1 and 75% in arm-2[48].

Acalabrutinib is an effective BTKi for r/r MCL Results of a phase I trial comparing acalabrutinib with or without rituximab as frontline therapy for untreated FL and salvage therapy for r/r FL, after a median follow-up of 22 mo, 62% of untreated FL patients and 26% of r/r FL patients remained on therapy and showed high tolerability[49].

Results of the randomized phase II ROSEWOOD trial in patients with r/r FL showed that combination therapy with zanubrutinib had better PFS than obinutuzumab alone. Zanubrutinib suggested to be more effective against r/r FL when used in combination with Obinutuzumab[50].

Although the single-agent activity of BTKis in FL is modest, their activity may be demonstrated when used in combination, and there is hope for their efficacy. We will keep a close eye on the future improvements in combination therapy with various combinations of new BTKs and other drugs in patients with FL.

Pro-apoptotic pathway inhibitors (BCL2 inhibitor)

Venetoclax selectively binds with strong affinity to BCL2, an anti-apoptotic protein involved in many blood cancers, and liberates apoptosis-promoting proteins, thus rapidly and irreversibly promoting apoptosis of blood cancer cells because BCL2 is overexpressed in FL, Venetoclax, a BCL2 inhibitor, has shown great promise. A phase I trial of venetoclax monotherapy was conducted in patients with FL, with an ORR of 38% and a median PFS of 11 mo[51]. The phase II CONTRALTO trial compared three groups of patients with r/r FL: Venetoclax plus rituximab, venetoclax plus BR, and BR in combination with venetoclax[52]. The CRR were 17%, 75%, and 69%, respectively; grade 3 or higher adverse events were extremely common in the venetoclax plus BR group (94%). r/r FL was included. In addition, combination therapy with ibrutinib was tested in a phase I/II study of venetolax plus ibrutinib with an ORR of 69% and a CRR of 25%[53].

Since BCL2 is overexpressed in FL, BCL2 inhibitors are expected to have a fundamental antitumor effect on FL tumor cells in terms of their mechanism of action. We look forward to improving the therapeutic outcome of BCL2 inhibitors for FL patients in the near future.

Epigenetic regulator

Progress has been made in drug development that is active against blood cancers through the epigenetic regulation of gene expression, such as DNA methylation. The results of clinical trials of EZH2 treatments in patients with FL are listed in Table 6.

Tazemetostat is a small molecule that inhibits the activity of enhancer of zeste homolog 2 (EZH2), a methyltransferase of histones, *etc.* Tazemetostat inhibits the methylation activity of mutant EZH2, thereby inhibiting the methylation of lysine residue 27 of histone H3 and other methyltransferases. A phase II study of tazemetostat in EZH2-mutant and wild-type r/r FL patients showed a higher ORR in the EZH2-mutant cohort (69% *vs* 35%)[54]. It is important to note that higher activity was observed in patients with FL with high-risk characteristics. Currently, combination therapy for r/r FL with tazemetostat is under investigation in the phase II SYMPHONY-2 trial in combination with rituximab and in the phase Ib/III trial in combination with R2. Tazemetostat as a third, fourth, and subsequent treatment for FL and DLBCL patients, especially r/r FL, has a reduced risk of adverse events compared to the PI3K inhibitors ideralisib, duvelisib, copanlisib, and umbralisib, while the therapeutic efficacy and benefit were comparable[55-57].

More than 10 EZH2 inhibitors have recently entered clinical trials, including tazemetostat[56], and we look forward to improved outcomes in the future.

Table 6 Summary of clinical trial results of epigenetic regulators

Study	Targeted disease	No. of patients	Objective response rate	Complete response rate	Progression-free survival	Overall survival	Adverse events or others	Ref.
Tazemetostat alone, phase-II	r/r FL, EZH2-mut; FL, EZH2-wt. FL	*n* = 99, mut FL *n* = 45; wt FL *n* = 54	69% (EZH2 mut); 35% (EZH2 wt)	Unknown; unknown	Median PFS: 13.8 mo (EZH2 mut); 13.1 mo (EZH2 wt)	Unknown	G3 or higher 27%+, treatment discontinued at 8%	[54]
Tazemetostat (first EZH2 inhibitor) *vs* inderalisib, duvelisib, copanlishib, umbralisib	r/r FL, systematic literature review		Tazemetostat *vs* inderalisib 43% *vs* 56; duvelisib 48% *vs* 47; Kopanlisib 49% *vs* 61; umbralisib 57% *vs* 47; no significant difference in either case	Unknown	Unknown	Unknown	Predominantly reduced risk of adverse events compared to PI3Ki	[57]
Vorinostat (HDACi), phase-II	r/r Inhl + MCL, median with one or more prior treatment	*n* = 39 (r/r FL)	49%	Unknown	Median PFS, 20 mo	Unknown	G3 or higher 8%	[58]
Vorinostat + rituximab, phase-II	Untreated and r/r FL (4 or less prior treatment)	*n* = 22	46% (all patients); 67% (untreated pts); 41% (r/r FL)	Unknown	Median PFS, 29.2 mo (all patients); not reached (untreated pts); 18.8 mo (r/r FL)	Unknown		[59]
Mocetinostat, phase-II	r/r DLBCL, r/r FL	*n* = 41, *n* = 31	18.9% (r/r DLBCL), 11.5% (r/r FL)	Unknown	1.8-22.8 mo (DLBCL); 11.8-26.3 mo (FL)	Unknown	Fatigue (75.0%); nausea (69.4%); diarrhea (61.1%)	[60]

"Unknown" means data not shown, unknown information or not reached. r/r: Refractory and relapsed; FL: Follicular lymphoma; EZH2: Enhancer of zeste homolog 2; mt: Mutant; wt: Wild type; (i)NHL: (Indolent) non-Hodgkin lymphoma; DLBCL: Diffuse large B-cell lymphoma; MZL: Marginal zone lymphoma; MCL: Mantle cell lymphoma; G: Grade; PI3Ki: Phosphoinositide 3 kinase inhibitor.

Vorinostat is a histone deacetylase inhibitor (HDACi). A phase II study of vorinostat in patients with r/r FL reported an ORR of 49%, with a median PFS of 20 mo. Grade 3 or greater adverse events were observed in 80% of the patients, mostly cytopenia[58]. Vorinostat was also evaluated in combination with rituximab, with an ORR of 50% and a CR of 41% in a phase II study of 22 untreated and r/r FL patients[59]. Another HDACi, mocetinostat, has shown poor efficacy, with an ORR of only 12% in patients with FL (*n* = 31) evaluated in a phase II trial of patients with r/r FL[60].

EZH2 inhibitors demonstrate effectiveness as an epigenetic regulator by the mechanism that inhibits the activity of methyltransferase of histones, *etc*. These agents are expected to further improve their therapeutic outcomes in the future, especially as a treatment for t-FL.

Phosphatidylinositol-3 kinase inhibitor

The BCR-mediated signaling pathway has been found to be permanently activated in B cell tumor cells, and inhibitors targeting molecules in the BCR signaling pathway are being developed.

Phosphatidylinositol-3 kinaseb (PI3K) is a lipid kinase that mediates the phosphorylation of the inositol ring 3 of inositol phospholipids, a membrane component[61]. Class I PI3Ks are heterologous. Class I PI3Ks are heterodimers that play important roles in signal transduction. Class 1 kinases are further divided into α, β, ϒ, and δ isoforms. For example, p110α and β are expressed in all cells, their knock out mouse is embryonic lethal[62]. p110γ is involved in neutrophil and macrophage migration [63] and mast cell degranulation[64]. This pathway is important in cancer, including B cell malignancies, and several small-molecule PI3K inhibitors (PI3Ki) have been developed for its treatment. The results of clinical trials of PI3K inhibitors in patients with r/r FL are listed in Table 7.

Idelalisib, a selective inhibitor of the delta isoform, was the first PI3Ki developed for the treatment of FL. In the European phase II DELTA study, idelalisib demonstrated the highest efficacy to date in r/r/ FL patients, with a median treatment duration of 10 mo (range 1-43) and an overall response rate of 73% [65].

In addition, a phase II open-label study of idelalisib in r/r iNHL, including FL, in the United.States. confirmed a response rate of 57% and a median PFS of 11 mo[66]. While idelalisib showed high efficacy against r/r FL, grade 3 or higher adverse events were observed in most participants (54%). Higher rates of adverse events have been observed in relatively young patients with less severe prior therapy, fewer complications, and stronger immune responses[67,68]. Fatal adverse events complicate the use of PI3K inhibitors.

Table 7 Summary of Clinical Trial Results of phosphoinositide 3 kinase inhibitors

Study	Target disease	No. of patients	Objective response rate	Complete response rate	Progression-free survival	Overall survival	Adverse events or others	Ref.
Indelalisib, phase-II DELTA trial	r/r FL	*n* = 55	73% (highest ever reported)	Unknown	72% disease-free after 12 mo	80% alive after 12 months	54% of G3 or higher	[65]
Indelalisib phase-II open-labeled trial	r/r NHL (including FL), median of 4 lines prior therapy	iNHL, *n* = 72; FL, *n* = 42)	57%	Unknown	11 mo	Unknown	54% of G3 or higher	[66]
Duvelisib	iNHL (including FL)	*n* = 187	70% good	Unknown	Unknown	Unknown	63% of G3 or higher	[63, 69]
Conpalisib, phase-II CHRONOS-1 trial	r/r FL, median 3-lines of prior therapy	*n* = 142	59%	12%	11 mo (median)	43 mo (median)	G3 84%, 6 cases of G5 events	[70, 71]
Umbralisib, phase-II trial	iNHL (including FL) median 3-lines or more of prior therapy	*n* = 208 (FL = 117)	47.1% of (after a median follow-up of 27.7 mo)	Unknown	10.6 mo (median PFS)	Unknown		[74]
Parsaclisib, phase-Ib, CITADEL-111 trial	Japanease: r/r FL; r/r MZL; r/r DLBCL	*n* = 9; *n* = 2; *n* = 6	9 cases (= 100%); 2 cases (= 100%); 1 case (= 16.7%)	22.2% (*n* = 2/9); 100% (*n* = 2/2); 16.7% (*n* = 1/6)	Unknown	High incidence of adverse events-need to carefully select target patients	Neutropenia above G3 interrupted in 58.8% and reduced in 29.4%	[75]
Parsaclisib, phase-I/II (phase-II trial is ongoing)	r/r B-NHL	*n* = 72	71% (r/r FL); 78% (r/r MZL); 67% (r/r MCL); 30% (r/r DLBCL)	Unknown	Unknown	Unknown	G3/4 neutropenia occurred in 19%	[76]
Zandelisib (ME-401), phase-I trial	Japanese, r/r iNHL	*n* = 9	100% (*n* = 9/9)	22% (*n* = 2/9), median duration of response 7.9 mo; median time to response 1.9 mo		Unknown	G3 or higher neutropenia 6/9 (55.6%) diarrhea 3/9 (33.3%) and many events	[77]
Zandelisib alone *vs* zandelisib + rituximab	r/r FL	*n* = 12	92% (*n* = 11/12) in the 60 mg group; 83% (*n* = 5/6) in the 180 mg group	Unknown	Unknown	Unknown		[78]
	r/r iNHL, median 3-lines of prior therapy	*n* = 30 + BR (*n* = 19) *vs* + R-CHOP (*n* = 11)	90% (+ BR) *vs* 100% (+ R-CHOP)	Unknown	Unknown	Unknown	G3 or higher, high rate of 70% (BR), 91% (R-CHOP)	[79]

"Unknown" means data not shown, unknown information or not reached. r/r: Refractory and relapsed; FL: Follicular Lymphoma; B-NHL: B-cell non-Hodgkin lymphoma; (i)NHL: (Indolent) non-Hodgkin lymphoma; DLBCL: Diffuse large B-cell lymphoma; MZL: Marginal zone lymphoma; MCL: Mantle cell lymphoma.

Duvelisib is the first FDA-approved oral dual inhibitor of PI3K-δ and PI3K-γ. Wang *et al*[69] reported on the safety and efficacy of duvelisib, a dual PI3K-δ and γ inhibitor, in patients with relapsed and refractory lymphoid neoplasms in a systematic prospective clinical trial reviews and meta-analyses have been reported[63,69]. Although the ORR of 187 patients with iNHL including FL showed a good efficacy of 70%, the relatively high rate of grade 3 or higher adverse events (63%) is still a safety concern[63,69].

The high rate of adverse events associated with these two drugs has made it difficult to gain general acceptance for FL treatment. In such a situation, only conpalisib has been approved for r/r FL after more than two lines of therapy. The phase II CHRONOS-1 study[70,71] of copanlisib in patients with r/r iNHL showed an ORR of 59%, CR of 12%, median PFS of 11 mo, and median OS of 43 mo. There was no increase in serious adverse events during the long-term follow-up period, although the rate of grade 3 or higher adverse events was as high as 84%, including 6 grade 5 events[70,71].

Umbralisib (TGR-1202) is an orally available, effective, potent and selective PI3-K δ and casein kinase-1-ε (CK1ε) inhibitor[72]. Umbralisib is a fourth-generation, late-stage PI3Ki that may play an important role in therapeutic algorithms[73]. The results of a phase II trial of r/r iNHL showed an ORR of 45% and

median PFS of 10.6 mo in a cohort of patients with FL after a median follow-up period of 27 mo[74]. Most recently, a phase II trial of Frontline with umbralisib and ubrituximab in untreated advanced FL patients was completed in Florida, the United States.

Parsaclisib is a potent δ isoform of the PI3Ki. The results of CITADEL-111, a phase Ib study in Japanese patients with relapsed/refractory B-cell lymphoma, showed an ORR of 100% in r/r FL and CR in two patients (22.2%), indicating efficacy. The results for MZL and DLBCL are shown in Table 7. Although potent, adverse events were frequent, requiring careful patient selection and implementation [75]. The Phase I/II trial of parsaclisib in patients with r/r FL showed an ORR of 71%. Grade 3 or higher adverse events were observed in 19% of all participants, and phase II trial is ongoing[76].

Zandelisib (ME-401) is a novel PI3-Kδ inhibitor, and phase I trials have recently been reported in Japanese patients with r/r iNHL. ORR was 100% and CR was 22% in 9 Japanese patients with r/r iNHL, and the median duration of response, progression-free survival, and time to response were 7.9 mo, 11.1 mo, and 1.9 mo, respectively. Neutropenia was the most common adverse event, with 55.6% (6/9) of the patients having neutropenia, and thrombocytopenia was the most common adverse event. In Japanese patients with r/r iNHL, zandelisib showed good antitumor efficacy[77]. The results of a study comparing zandelisib monotherapy with zandelisib plus rituximab combination therapy for r/r FL showed an ORR of 92% in the 60 mg group and 83% in the 180 mg group. Serious adverse events occurred in 21% and 8% of patients in the continuous- and intermittent-dose groups, respectively. There were no treatment-related deaths. The 60 mg once-daily intermittent dose was safe, with a low incidence of grade 3 or higher adverse events[78].

PI3Ki has also been considered in combination with conventional chemotherapy, immunotherapy, and other targeted therapies to achieve more potent therapeutic effects. Results of the phase III CHRONOS-4 trial comparing the efficacy and safety of Conpalisib in combination with BR or R-CHOP in patients with r/riNHL showed an ORR of 90% in the BR group and 100% in the R-CHOP group, with grade 3 or higher adverse events occurring in 70% of the BR group and 91% of the R-CHOP group[79]. Early clinical trials of PI3Ki in combination with other immune checkpoint inhibitors and IMiDs are currently underway.

Inderalisib-induced acute liver injury has also been reported and has been noted to be severe and potentially fatal[80]. In a phase I trial in patients with FL or MCL, the triple combination of inderalisib with lenaridomide and rituximab was discontinued early because of the excessive toxicity of all three drugs[81]. Combination therapy with other drugs, including inderalisib, is complicated for future treatment because of significant safety concerns owing to overtoxicity.

PI3K inhibitors were initially expected to have therapeutic effects, and various types of agents were developed, but due to the large number of adverse reactions, only zandelisib remains in Japan, for example, and clinical trials are continuing. We hope that the treatment effect for FL patients will improve in the future.

PI3K/mechanistic target of rapamycin inhibitor

Numerous studies have shown that somatic mutations in PI3K/Akt/mechanistic target of rapamycin (mTOR)-related genes may induce homeostatic activation of various types of cancer pathways, leading to dysregulation of tumor cell growth, growth, differentiation, metabolism, apoptosis, and other functions supporting tumor cell survival It has been shown[82].

Recently, dual inhibitors targeting two targets of the PI3K/PKB/mTOR signaling pathway have been developed and investigated for their therapeutic effects; PI3K/mTOR inhibitors not only inhibit cell proliferation but also promote cell apoptosis. They are also expected to be promising anticancer agents because of their high efficacy at low doses and low drug resistance[83].

The TOR inhibitors, temisirolimusm (TEM) and lenaridomide (LEN) combination therapy, overlapped within the PAM axis and were expected to have synergistic effects. the FL cohort was discontinued early due to low case numbers. the ORR and CRR of the DLBCL and exploratory cohorts were 26% and 13%, 64% and 18%, respectively. The ORR and CRR of the exploratory cohort for classical Hodgkin lymphoma (CHL) patients were 80% and 35%, respectively. Forty percent of CHL patients could be transferred to allogeneic transplant after TEM/LEN therapy. Grade 3 or higher hematologic adverse events were common, and three grade 5 adverse events occurred; TEM/LEN combination therapy was highly effective in advanced untreated lymphomas and especially in r/r CHL[84].

We look forward to the further development of new PI3K/Akt/mTOR dual inhibitors, and to the improvement of therapeutic results and progress as FL treatment agents through the accumulation of clinical trials.

CELL THERAPY

CAR-T cell therapy uses autologous T cells genetically engineered to attack cancer and other cells by introducing CARs.

CAR-T cell therapy is a highly effective, innovative, and revolutionary treatment for patients with r/r hematologic malignancies and shows great promise. When reinjected into the same patient, these CAR-

T cells trigger a T-cell-mediated immune response against the antigen-expressing malignancy and induce cell death. CAR-T cell therapy has recently been used in the treatment of iNHL such as FL and MCL. However, CAR T-cell therapy has a unique hematological toxicity, and post-treatment cytopenia is a major side effect[85,86].

Recent clinical trials have compared the efficacy and safety of three cell therapy modalities (autologous transplantation, allogeneic transplantation, and CAR-T with respect to their validity and rationale as therapeutic modalities[87]. In addition, there are various issues and barriers to the realization of CAR-T therapy, including complex logistics, manufacturing limitations, toxicity concerns, and economic burdens, which must be addressed and remedy[88]. The results of clinical trials on CAR-T cell therapy are summarized in Table 8.

Clinical trials of the autologous anti-CD19 CART agents axicabtagene ciloleucel (Axi-cell), tisagenlecleucel (Tisa-cell), and lisocabtagene maraleucel (Liso-cell) for r/r DLBCL containing approximately 20% transformed FL (Liso-cell) have shown high efficacy, with ORRs ranging from 52% to 82%[89-91]. Long-term follow-up has shown sustained remission in approximately 40% of the patients and high remission maintenance against t-FL[92]. The results of the Phase II ZUMA-5 trial showed that Axi-cells in r/r FL had a median follow-up of 18 mo, with an ORR of 94%, a CRR of 79%, and an estimated PFS of 66% at 18 mo, although the median PFS and OS were not reached. Grade 3 or higher adverse events were observed in 86%, with Grade-5 adverse events in 3%[93,94].

The results of the phase II ELARA trial showed an ORR of 86% and a CR of 69% after a median follow-up of 17 mo for Tisa-cell r/r FL. The results of the Phase II ELARA trial of Tisa-cell therapy for r/r FL showed an ORR of 86% and CR of 69% at a median follow-up of 17 mo[95-97]. It is important to note that the results of these trials showed that Tisa-cells had a higher sustained response in higher-risk patients with refractory, relapsed, and heavily pretreated FL[98].

Liso-cells are autologous anti-CD19 CAR-T cells. The results of a clinical trial as a second-line therapy for patients with r/r DLBCL not scheduled for hematopoietic stem cell transplantation showed high efficacy, with a median follow-up of 12.3 mo and an ORR of 80%. Grade 3 or higher adverse events ranged from 20%-48% for thrombocytopenia and 21% for serious adverse events[99]. Based on these results, Liso cells have the potential for future use in patients with r/r FL.

The TRANSFORM and PILOT trials demonstrated the high efficacy of Liso-cell in the second-line treatment of r/r large B-cell lymphoma. As a result, Liso-cell was approved as a third-line agent for aggresive B-cell lymphoma[100].

Expectations are high for the future development of CAR-T cell therapy as a fundamental therapeutic tool for FL.

MOLECULAR RESPONSE ADAPTIVE THERAPY RESPONSE-ADOPTED POST-INDUCTION STRATEGY

The FOLL12 study compared a standard 2-year rituximab maintain therapy arm with an experimental post-remission induction arm in patients with FL who responded to induction immunochemotherapy. In the experimental arm, post-induction treatment consisted of observation for patients with complete metabolic response (CMR) and minimal residual disease (MRD)-negative disease, four doses of rituximab for patients with CMR and MRD-positive disease until MRD-negative, and one dose of ibritumomab tixetan for non-CMR patients, followed by three standard treatments with RM. Results showed that After a median follow-up of 53 mo, patients in the standard arm had significantly better PFS than those in the experimental arm (3-year PFS, 86% *vs* 72%; $P < 0.001$). All subgroups except non-CMR patients confirmed the superior PFS of the standard group *vs* the experimental group, with 3-year OS rates of 98% and 97% (95%CI, 95-99) in the reference and experimental groups, respectively[101]. In FL patients who benefited from induction therapy, standard 2-year rituximab maintenance therapy prolonged PFS after the induction of remission.

Future prospects for nodal FL treatment

Although FL progresses slowly and can be effective if treated, it is prone to recurrence and has been considered an incurable disease. Recently, however, research and progress in various new treatment modalities have been remarkable, and improvements in treatment outcomes have been confirmed. In addition, the direction of research is beginning to turn toward how to combine two or more of these anticancer agents, immune agents, immunomodulators, and CAR-T cell therapy, which have different mechanisms of action, and how to arrange the order of treatment in such combinations to obtain the best results. After discussing this important topic, I will conclude this section with the hope that the era of complete cure of FL will arrive in the future.

Prospects for GI-FL treatment

Based on an understanding of the recent advances in the treatment of nodal FL that have been discussed, the current status and future of GI-FL treatment and how gastroenterologists should treat

Table 8 Summary of clinical trials results of chimeric antigen receptor T-cell therapies

Study	Target disease	No. of patients	Objective response rate	Complete response rate	Progression-free survival	Overall survival	Adverse events and others	Ref.
Axicabtagene ciloleucel (Axi-cell), phase-II	r/r DLBCL, t-FL	*n* = 101	82%	40%	Unknown	52% (overall survival rate at 18.8 mo)	Neutropenia 78%; anemia 43%; thrombocytopenia 38%	[90]
Tisagenlecleucel (Tisa-cell), phase-II JULIET trial	r/r DLBCL	*n* = 93	52%	40%	65% (relapse-free survival rate)	Unknown	CRS 22%; neurologic events 12%; infections 20%	[91]
Axicabtagene ciloleucel (Axi-cell), phase-II	r/r iNHL (FL and MZL) after 2 or more treatment	*n* = 148, *n* = 124 (FL), *n* = 24 (MZL)	92%	74%	Unknown	Unknown	Serious adverse events (any grade) occurred in 50% of all	[93]
Tisagenlecleucel (Tisa-cell), phase-II ELARA trial	r/r FL (with 2 and more prior treatments)	*n* = 97	86.2%	69.1%	Unknown	Unknown	CRS 48.5% (> G3) neurological events 37.1% (> G3)	[96]
Lisocabtagene maraleucel (Liso-cell), phase-II	r/r large BCL	*n* = 61	80% (median follow-up 12.3 mo)	Unknown	Unknown	Unknown	Neutropenia 48%, thrombocytopenia 20%, CRS 38%	[99]

"Unknown" means data not shown, unknown information or not reached. r/r: Refractory and relapsed; FL: Follicular lymphoma; t-FL: Transformed follicular lymphoma; (i)NHL: (Indolent) non-Hodgkin lymphoma; DLBCL: Diffuse large B-cell lymphoma; BCL: B-cell lymphoma; MZL: Marginal zone lymphoma; CRS: Cytokine release syndrome.

gastrointestinal FL in the future will be discussed.

FL is the most common low-grade lymphoma, and although nodal FL is highly responsive to treatment, the majority of patients relapse repeatedly, and the disease has been said to be incurable with a poor prognosis. In contrast, primary GI-FL has been detected and treated in a larger number of cases in Japan, especially due to recent advances in small bowel endoscopy and increased opportunities for endoscopic examinations, such as health checkups, diagnostic imaging equipment, endoscopist examination techniques, and endoscopic diagnostic procedures. However, many cases are detected at an early stage, and many of them are at a later stage than those detected at an early stage, owing to the bias of reported cases, and the prognosis is excellent. Therefore, there is still a mainstream view that "watch and wait" is preferable, taking into account the adverse effects of treatment and the decline in patient quality of life. Schmatz *et al*[102] compared the progression of 63 stage I GI-FLs in the treatment, watch, and wait groups and reported no significant difference in PFS or OS. Tari *et al*[103] also reported no difference in prognosis in a study of GI-FL patients with low tumor volume divided between the "watch and wait" groups and the rituximab combination chemotherapy group. GI-FL is considered a potential candidate for "watch and wait" in many cases because of its pathological characteristics: The lesions are widely distributed and not amenable to local therapy, many patients are asymptomatic in the localized stage, and the degree of tumor extension and invasion is lower than that of nodal FL. The number of patients with nodal FL was high, and the degree of tumor progression and invasiveness was low. Yamamoto *et al*[104] have reported that 128 (66.3%) of 193 cases of GI-FL in Japan were stage I and 52 (26.9%) were stage II. The authors attribute this to the higher frequency of grade 1 lymphoma. However, we think that the reported cases may not necessarily represent the overall picture of GI-FL cases in Japan due to a large bias arising when they selected. In a Japanese multicenter study by Takata *et al*[105] in 125 patients with localized GI-FL, CR was observed in 61 (49%) out of 125 patients treated with Watch and Wait (33 patients), combination chemotherapy including rituximab (42 patients), rituximab alone (29 patients), surgical resection (4 patients), radiation therapy (1 patient), and *Helicobacter pylori (H. pylori)* eradication therapy (3 patients). pylori eradication therapy in three cases, 61 cases (49%) achieved CR, and by treatment method, 39/42 cases (93%) were treated with multi-agent chemotherapy including rituximab, 20/29 (69%) with rituximab alone, 1/4 (25%) with surgical resection, 0/1 case (0%) with radiation therapy, *H. pylori* eradication in 1/3 (33%), and Watch and Wait 1/33 (3%). The median follow-up was 40 mo (6-148 mo), with no primary deaths, a 5-year survival rate of 100%, a progression-free survival rate of 93 %, and very good results[105]. It should be noted that the Watch and Wait group had a CR rate of 3%, which was lower than the CR rate in the treatment group, excluding radiotherapy. Damaj *et al*[9] reported that most GI-FL are Stage I, but metastasis or invasion of intra-abdominal lymph nodes (Stage II) is 3.4%-40.0%, and extensive extranodal dissemination or transdiaphragmatic invasion (Stage IV) is reported in 12%-24% of GI-FL cases. The number of reports of advanced GI-FL cases (stages III and IV) is expected to increase further in the future. To understand the recent advances in the treatment of nodal FL, how should gastroenterologists treat gastrointestinal FL in the future? In early stage I cases, endoscopic resection of the gastrointestinal tract or surgical resection plus R-CHOP is the

standard of care. The prognosis was good and the PFS and OS were excellent. The number of refractory and advanced GI-FL cases, grade 3b or higher at the cellular level, and stage II or higher are expected to increase in the future. These cases will likely be treated with the same advanced and recent therapeutic modalities for nodal FL, such as antibody-targeted therapy, bispecific antibody therapy, epigenetic mutation, and CAR T-cell therapy, as described previously. The importance of nodal and Gastrointestinal-FL treatments is expected to increase. The difference is that when GI-FL is treated, the risk of perforation of the gastrointestinal tract must always be considered because if perforation develops due to a decrease in tumor volume, subsequent peritonitis may develop, making the disease more severe, and subsequent treatment impossible to continue. After careful consideration of the risk of gastrointestinal perforation, surgical resection of the gastrointestinal lesion should be performed first, followed by adjuvant therapy. For postoperative recurrence, lymph node metastases outside the gastrointestinal tract, and other distant metastases, it is necessary to collaborate with hematology and gastrointestinal surgery departments to predict possible complications and changes in disease status due to treatment, such as in the treatment of nodal and r/r-FL, and to discuss a royal policy in collaboration with these departments. We look forward to the future development and progress of GI-FL treatment.

Differences in treatment strategies between nodal FL and GI-FL

Staging of nodal FL is determined using the Ann-Arbor clinical staging classification, while GI-FL is classified according to the Lugano staging classification[106], a modified version of the Ann-Arbor staging classification. Basically, the Lugano staging classification[106] should be followed to determine a treatment strategy similar to that for nodal FL. However, due to the characteristics of the gastrointestinal tract, a treatment strategy specific to gastrointestinal FL may be considered in the following cases, which differ from nodal FL.

First, and most importantly, one must be very mindful of gastrointestinal perforation due to the loss of tumor tissue associated with the mass reduction effect of treatment. Careful consideration should be given to the risk of gastrointestinal tract perforation before initiating any type of treatment.

In GI-FL cases, whether the distribution of lesions is unifocal or multifocal is important in the choice of treatment; Yamamoto *et al*[104] reported that in more than 70% of GI-FL patients with lesions in the gastrointestinal tract other than the small bowel, new secondary lesions were found in the small bowel. If the disease is found to be multifocal, immunochemotherapy may be the treatment of choice.

Primary FL in the gastrointestinal tract should be treated with surgical resection first, followed by postoperative chemotherapy (or combination chemotherapy and immunotherapy), depending on the extent of extension and invasion, if the lesions arise from deep submucosal layers and are localized within the wall, lumen, or regional lymph nodes. However, if the disease has invaded or spread beyond the gastrointestinal tract or has distant metastasis beyond the diaphragm, it is stage-4 according to the Lugano classification, and if there is no or little deterioration in quality of life due to gastrointestinal obstruction, local surgical resection is of course not indicated, and combination chemotherapy plus immunotherapy or immunomodulators is the chemotherapy plus immunotherapy or immunomodulators is the first choice.

In cases of extra-gastrointestinal primary disease with gastrointestinal involvement, surgical resection or radiotherapy should be considered if the disease is localized. If there are metastases in multiple organs or bone marrow, the disease is basically stage-4, and chemotherapy (plus immunotherapy) is the first choice.

In addition, other factors such as age, gender, site of disease, and extent of spread should determine the best overall treatment for each case of gastrointestinal FL that is most appropriate for the patient and that offers a better prognosis, especially longer treatment-free period and improved patient quality of life. Because gastrointestinal FL is an organ with "gastrointestinal" characteristics, the treatment strategy is often more controversial than that for nodal FL, and in a sense, the range of treatment options is wider.

In addition, the underlying nature of FL itself, which as a tumor is indolent in its extension, growth, and invasion, responds well to chemotherapy, but is prone to relapse and is currently incurable, further complicates and complicates the treatment options for gastrointestinal FL. The differences in treatment strategy between nodal FL and gastrointestinal FL are described in the author's previous review[107], which should also be consulted.

In the future, the number of advanced-stage, multifocal GI-FL cases will increase more and more, and the treatment strategy should be carefully determined by cooperating multiple physicians in each department, including gastroenterology, surgery, hematology, and radiology.

CONCLUSION

Treatment with Nodal-FL improved the ORR, CRR, PFS, and OS with the addition of rituximab, an anti-CD20 monoclonal antibody, to CHOP therapy, which was the standard chemotherapy regimen for malignant lymphomas 20 years ago. Maintenance therapy with an anti-CD20 antibody prolongs

remission. The last decade has seen remarkable progress with the addition of new therapeutic modalities such as antibody-targeted therapy, bispecific antibody therapy, epigenetic modulator therapy, CAR-T cell therapy, and conventional chemotherapy. The combination of lenaridomide and anti-CD20 antibodies was effective in r/r FL treatment. In contrast, lenaridomide shows good results as frontline therapy for untreated patients with advanced FL and may become a mainstay treatment modality. Antibody therapies against novel targets, such as CD19, CD79b, and CD47, as well as obinutumab, a humanized anti-CD20 monoclonal antibody, have been developed and have demonstrated efficacy in FL. More recently, anti-PD-L1 antibodies such as atezolitumab and pembrolizumab have also demonstrated efficacy in relapsed FL. PI3Kinase inhibitors are effective for treating FL and multiple relapsed lesions. However, the high number of adverse events associated with its toxicity complicates its future use as a combination therapy. As an epigenetic modulator treatment, tazemetostat showed more activity in r/r FL patients with higher risk characteristics. Vorinostat, a histone deacetylase inhibitor HDACi, is also a potential treatment for r/r FL patients. CAR-T cell therapy for FL and T-cell immune attack with bispecific antibodies have shown remarkable efficacy and are expected to become a fundamental therapy, as evidenced by the current approval of CAR-T cell therapy for relapsed and refractory FL in the United States. In Europe and the United States, Damaj *et al*[9] have reported that most GI-FL cases are stage I, but metastasis or invasion of intra-abdominal lymph nodes (stage-II) is present in 3.4%-40.0% and extensive extranodal organ dissemination or involvement beyond the diaphragm (stage-IV) in 12%-24%. The number of advanced GI-FL cases (stages III and IV) is expected to increase further in the future. The number of refractory and advanced GI-FL cases, grade 3b or higher at the cellular level, and stage II or higher are expected to increase in the future. For these cases, recent advances in nodal FL, such as antibody-targeted therapy, bispecific antibody therapy, epigenetic mutation, and CAR-T cell therapy, as described above, should be considered as treatment options, but with careful attention to gastrointestinal perforation and cooperation among the departments of gastroenterology, hematology, and gastroenterological surgery need to work together.

Abstract

The majority of patients affected by Crohn's disease (CD) develop a chronic condition with persistent inflammation and relapses that may cause progressive and irreversible damage to the bowel, resulting in stricturing or penetrating complications in around 50% of patients during the natural history of the disease. Surgery is frequently needed to treat complicated disease when pharmacological therapy failes, with a high risk of repeated operations in time. Intestinal ultrasound (IUS), a non-invasive, cost-effective, radiation free and reproducible method for the diagnosis and follow-up of CD, in expert hands, allow a precise assessment of all the disease manifestations: Bowel characteristics, retrodilation, wrapping fat, fistulas and abscesses. Moreover, IUS is able to assess bowel wall thickness, bowel wall stratification (echo-pattern), vascularization and elasticity, as well as mesenteric hypertrophy, lymph-nodes and mesenteric blood flow. Its role in the disease evaluation and behaviour description is well assessed in literature, but less is known about the potential space of IUS as predictor of prognostic factors suggesting response to a medical treatment or postoperative recurrence. The availability of a low cost exam as IUS, able to recognize which patients are more likely to respond to a specific therapy and which patients are at high risk of surgery or complications, could be a very useful instrument in the hands of IBD physician. The aim of this review is to present current evidence about the prognostic role that IUS can show in predicting response to treatment, disease progression, risk of surgery and risk of post-surgical recurrence in CD.

Key Words: Intestinal ultrasound; Crohn's disease; Postoperative recurrence; Bowel wall thickness; Remission; Intestinal surgery

Core Tip: Intestinal ultrasound (IUS) and magnetic resonance enterography are better tolerated and safer than endoscopy, with IUS more easily available and less expensive than magnetic resonance imaging. Moreover, IUS allows complete visualization of the small-bowel even in patients with stenoses and/or severe inflammation, and can assess for extraintestinal disease. In addition, IUS may predict outcomes better than endoscopic mucosal assessment, possibly identifying more relevant therapeutic targets. This review discusses the role of IUS in Crohn's disease not only as first line investigation but as an extremely useful instrument in predicting response to medical treatment, disease evolution and risk of recurrence before and after surgery.

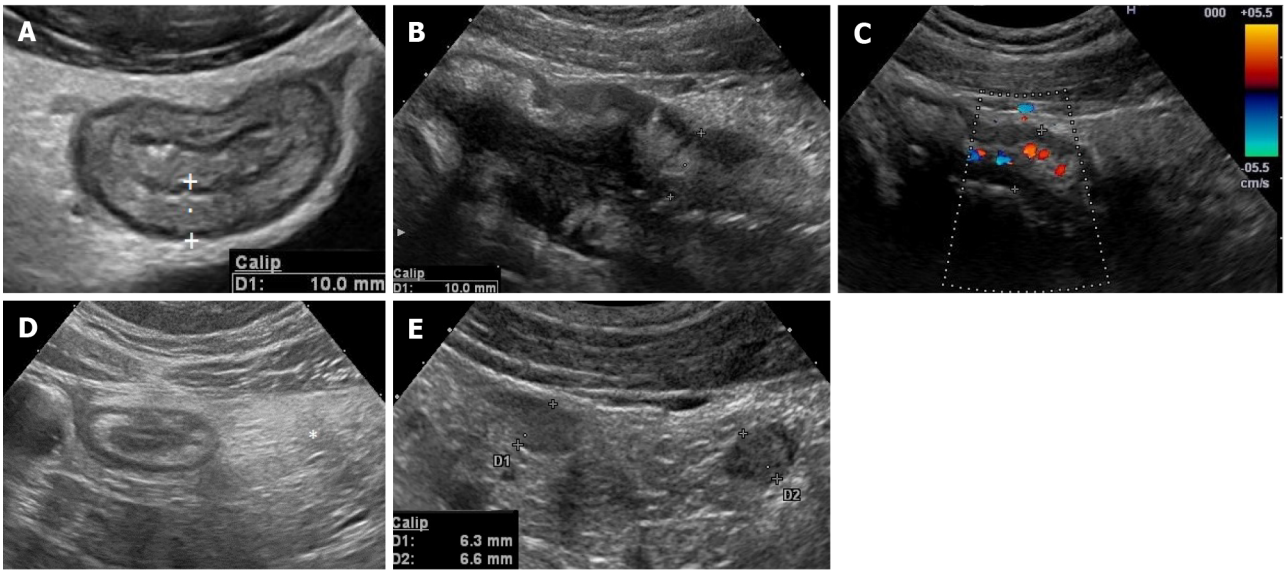
INTRODUCTION

Crohn's disease (CD) is a chronic inflammatory condition that can affect the whole gastrointestinal tract, more frequently involving the ileum and colon, usually presenting in its active phases with abdominal pain, diarrhoea (bloody or non-bloody), urgency, fatigue and weight loss[1]. The majority of patients affected by CD show chronic relapsing disease with potential chronic continuous abdominal symptoms after diagnosis[2].

The available treatments often fail to achieve disease remission or lose their efficacy over time. Moreover, in CD, chronic inflammation and relapses may cause progressive and irreversible damage to the bowel[3], which results in stricturing or penetrating complications in approximately 50% of patients during the natural history of the disease, with a high risk of surgery or repeated surgery[4].



It has been realized that patients' symptoms in CD do not necessarily reflect the underlying inflammatory burden of the disease and that, independent of clinical symptoms, patients can have different rates of disease progression and outcomes[2]. Most CD patients at the time of diagnosis have a disease with inflammatory features, but in some patients, it can evolve to a stenosing or penetrating pattern during follow-up[5]. Therefore, the possibility of identifying which patients are nonresponsive to medical treatment and prone to develop stricturing and penetrating CD would be very important to properly address the treatment. Prognostic factors for favourable or unfavourable outcomes of CD have been extensively researched and assessed with both invasive and noninvasive methods.

Intestinal ultrasound (IUS) is a non-invasive, cost-effective, radiation free and reproducible method for the diagnosis and follow-up of CD, with an accuracy comparable to magnetic resonance imaging and computed tomography[6,7]. IUS can assess several features of the bowel wall and surrounding tissue: Bowel wall thickness (BWT) (Figure 1A), bowel wall stratification (echo-pattern) (Figure 1B), vascularization (Figure 1C) and elasticity, as well as mesenteric hypertrophy (Figure 1D), lymph-nodes (Figure 1E) and mesenteric blood flow. IUS is also able to assess complications such as stenosis, dilations, fistulas and abscesses[8]. During the follow-up of CD patients undergoing biological therapy, IUS features have been correlated with clinical activity, endoscopic activity, laboratory markers (faecal calprotectin and C-reactive protein) and drug serum levels[9-13]. However, IUS specific features have also been suggested as predictive factors for evaluating the response to medical treatment, the risk of clinical relapse or surgery, and the risk of postoperative recurrence[14-17]. We present the current evidence on the prognostic value of IUS and especially the IUS features of the bowel wall in predicting response to treatment and risk of relapse in CD.

LITERATURE REVIEW

Search strategy and selection criteria

Two authors (Manzotti C and Maconi G) searched the literature using the PubMed database from January 2000 to January 2022. The search used the following terms in different combinations: "intestinal ultrasound", "bowel ultrasound", "transabdominal ultrasound", "IUS", "bowel wall thickness", "Doppler", "CEUS", "transmural healing", "Crohn", "Crohn's disease", "IBD", "inflammatory bowel disease", "surgery", "clinical remission", "remission", "predictive value", "outcome", and "post-surgical recurrence". In particular, the following string was used: [(ultrasound OR sonography) AND (bowel OR intestinal) AND (Crohn's disease OR IBD) AND (remission OR response OR transmural OR outcome OR predictive)].

DOI: 10.3748/wjg.v29.i23.3595 **Copyright** ©The Author(s) 2023.

Figure 1 Intestinal ultrasound assess several features of the bowel wall and surrounding tissue. A: Bowel wall thickness should be measured perpendicular to the anterior wall of the bowel (or where it is better visible) avoiding haustrations and mucosal folds. The cursor/calipers should be placed at the end of the interface echo between the serosa and the proper muscle to the start of the interface echo between the lumen and the mucosa; B: Bowel wall stratification. The wall layers in case of active disease may appear focally or extensively disrupted (disrupted or hypoechoic echo pattern); C: Bowel wall vascularity. Bowel wall vascularity can be determined both by colour Doppler or power Doppler signal at the level of the most thickened segments, using special presets optimized for slow flow detection; D: Mesenteric hypertrophy. Mesenteric hypertrophy also called fat wrapping or creeping fat appears on ultrasound (US) as hyperechoic tissue or "mass effect" encircling the diseased bowel; E: Lymphnodes. Enlarged inflammatory mesenteric lymph nodes related to Crohn's disease are usually described at US as oval or elongated with lesser diameter > 5 mm and seem to be correlated with young age, early disease, or disease with shorter duration, and with the presence of fistulae and abscesses.

Additional potentially eligible articles were manually searched through the bibliography of relevant articles. Eligible articles were randomized controlled trials, prospective or retrospective cohort studies, reviews, and systematic reviews with a meta-analysis; duplications and studies in languages other than English were excluded. In each eligible paper, we searched for information on the predictive value of IUS for patients affected by active or quiescent CD in terms of response to treatment, disease course, transmural healing, risk of surgery, and risk of postsurgical recurrence. Two authors (Manzotti C and Maconi G) screened the title and abstract of potentially eligible papers, followed by a full-text analysis of relevant articles. Starting from a total of 1040 articles, 49 were considered suitable and were included in this review.

DISCUSSION

Active disease

Intestinal US, before and early after the start of biologic treatment, showed high accuracy in predicting long-term clinical and endoscopic remission and response[17,18]. Although few data have shown that pretreatment IUS features may predict the outcome and somewhat drive the choice of treatment, much more data have shown that sonographic improvement of BWT, echopattern and vascularization as early as weeks 2-4 of biologic treatment may predict a better long-term response compared to those of patients without an early treatment response[19]. Studies considering predictive value of IUS parameters for response to treatment and course of CD are shown in Table 1.

Intestinal US to predict response to treatment and disease course

Increased BWT and bowel wall vascularity assessed by colour Doppler or IV contrast-enhanced ultrasound (CEUS), variably powered in bowel US scores, was identified as an independent predictor of a negative disease course, namely, the need for steroids, change of therapy, treatment intensification, hospitalization, or need for surgery through 6-12 mo[20,14]. In addition, increased echopatterns coupled with disrupted echopatterns of the bowel wall or lack of bowel wall stratification were independent predictors for the need for subsequent therapeutic optimization[20].

Sonographic response and clinical response

It seems that sonographic response after 12 or 14 wk of therapy with anti-tumor necrosis factor (TNF)

Table 1 Predictive value of intestinal ultrasound parameters for response to treatment and course of Crohn's disease

Ref.	Treatment	Timing of IUS after start of treatment	IUS parameter	Predictive value for
Albshesh *et al*[18], 2020	Anti-TNF	> 14 wk	BWT > 4 mm	Treatment failure
			BWT < 4 mm	Duration of failure-free response
Calabrese *et al*[52], 2022	Anti-TNF, vedolizumab, ustekinumab	Baseline	"Higher BWT"	Low risk of TR
			Colonic localization	High risk of TR
Chen *et al* [19], 2022	Anti-TNF	Baseline-2 wk	Reduction in BWT, vascularization, SWE	Response to treatment
De Voogd *et al*[17], 2022	Anti-TNF	Baseline-4/8 wk	BWT reduction > 18%	Endoscopic response and remission at 12-34 wk
Helwig *et al* [32], 2022	All available biological therapies	Baseline-12 wk	BWT reduction > 25%	Clinical remission and no therapy change at 52 wk
Les *et al*[20], 2021	5-ASA, budesonide, AZA, anti TNF		Worsened BWT, echopattern, vascularization	Need for treatment escalation, negative disease course
Orlando *et al* [29], 2018	Anti-TNF	Baseline	SWE strain ratio > 2	Surgery
Paredes *et al* [53], 2019	Anti-TNF	12 wk	BWT ≤ 3 mm	"Good outcome" (no treatment intensification, no surgery) at 1 yr
Ripollés *et al* [21], 2016	Anti-TNF	Baseline-12 wk	Sonographic response (BWT decrease > 2 mm, diminution of one grade of ECD, decrease > 20% of mural enhancement, disappearance of transmural complications or stenosi	1-yr sonographic response and further 1-yr clinical response and treatment efficacy
Smith *et al* [22], 2022	All available biological therapies and thiopurines	Baseline-14 wk	Sonographic response (BWT decreasing > 0.5 mm and vascularity improvement by ≥ one grade)	Treatment response at 46 wk
Zorzi *et al* [23], 2020	Anti-TNF, budesonide, thiopurines	Baseline-18 mo	Normalization of SICUS (BWT, disease extension, complications)	Long term lower cumulative probability of need for surgery, hospitalization, and need for steroids
Laterza *et al* [54], 2021	Anti-TNF	12 wk	CEUS increased PI and Pw	Clinical relapse within 6 mo
Ungar *et al* [55], 2020	Adalimumab	NA	Terminal ileum BWT < 4 mm	Therapy retention
Quaia *et al* [56], 2019	Anti-TNF	Baseline-6 wk	CEUS pretreatment values and % variations of peak enhancement, AUC, AUC during wash-in, AUC during wash-out	Long term response to therapy

IUS: Intestinal ultrasound; BWT: Bowel wall thickness; ECD: Eco-color-doppler; SWE: Shear wave elastography; UEI: Ultrasound elastography imaging; TR: Transmural remission; CEUS: Contrast enhanced ultrasound; AUC: Area under the curve; TNF: Tumor necrosis factor; NA: Not available; 5-ASA: 5-aminosalicylic acid; AZA: Azacitidine.

drugs predicts the 1-year sonographic response, which in turn correlates with the 1-year clinical response, predicts efficacy of further treatment and inversely correlated with the need for surgery. Stricturing behaviour, namely, the detection of strictures with prestenotic dilatation, seems to be the only sonographic feature associated with a long-term negative predictive value of clinical response[21, 22].

Similar results were demonstrated by using small intestinal contrast US (SICUS), which is used to monitor patients undergoing anti-TNF therapy. An improvement in BWT, a reduction of disease extension, or the absence of intestinal complications as detected by SICUS predicted a better response after 1 year of therapy, as well as a reduction in steroid therapy and hospital admissions[23].

Monitoring BWT with IUS also showed predictive value for patients starting therapy with ustekinumab. A decrease in BWT > 1 mm at week 8 after the start of therapy was a helpful parameter for selecting patients with an early response to ustekinumab and for providing assistance in terms of further treatment intervals[24]. The thickening of each single layer of the bowel wall and its clinical significance in CD have been poorly investigated thusfar. It seems that the thickening of the proper muscle layer in active CD patients is correlated with poor clinical and sonographic responses to vedolizumab treatment[25]. In this regard, smooth muscle hyperplasia has been underlined as a central

contributor to the stricturing phenotype, whereas fibrosis is less significant, and the 'inflammation-smooth muscle hyperplasia axis' seems to be the most important step in the pathogenesis of Crohn's strictures[26].

Additionally, the assessment of bowel wall vascularity by CEUS seems to provide relevant prognostic information regarding treatment efficacy in patients with CD. The improvement of several perfusion parameters, such as peak contrast enhancement, rate of wash-in and wash-out and the area under the time intensity curve of the intestinal wall 4-6 wk after starting anti-inflammatory treatment (anti-TNF-alpha), were correlated with a favourable response[25,27,28]. Finally, the evaluation of ultrasound elasticity of the bowel wall may have a predictive role as well, correlating with therapeutic outcomes for CD patients treated with anti-TNF[29].

With regard to extra bowel findings, especially mesenteric lymphadenopathy and mesenteric fat hypertrophy, their prognostic role in response to treatment remains controversial. Regional mesenteric lymphadenopathy detected by IUS is a common but nonspecific sonographic finding in early CD and could be linked to young age, early disease, and the presence of abscesses or fistulae[30]. However, its prognostic significance remains poorly investigated. Mesenteric fat hypertrophy is associated with clinical and biochemical disease activity, and it may disappear or improve in patients who have responded to medical treatment[31]. However, its prognostic value in predicting response to therapy and risk of relapse is debatable[16,31].

IUS to predict transmural remission

Transmural remission (TR) or transmural healing with different definitions in literature, is now considered as an objective and relevant target in CD. It may be assessed by IUS taking into account BWT normalization (≤ 3 mm) with or without normalization of Doppler vascular signs and peri-intestinal inflammatory signs[32]. It is correlated with improved clinical outcome, such as a reduced demand of medication escalation, corticosteroid use, hospitalization and CD-related surgery.

The rate of TR, with more or less extensive definitions, in patients undergoing biological therapy was obtained from 12% to 46.2% of patients after 12 wk to 2 years of therapy (see Table 2). TR was strictly correlated with time, being higher at later assessments compared with early assessments. Moreover, it is more prevalent in colic CD than in ileal CD and it is associated with lower BWT and lower shear wave elastography strain ratio at baseline (see Table 2). However, a few studies have evaluated baseline or early IUS factors predictive of TR. Further prospective trials are needed to reach more consistent evidence on IUS predictive value, to help in properly selecting the right treatment for the right CD patient and plain maintenance therapy.

IUS to predict the risk of surgery

The ileal localization and stricturing and perforating behaviour of CD are well-known risk factors for surgery both in children and in adults. Children with ileal CD requiring surgical resection may have more severe IUS manifestations (such as loss of mural stratification and severe fibrofatty proliferation) associated with both active inflammation and chronic fibrosis than those managed medically[33].

Even in adults, the routine use of IUS in CD patients may identify a subgroup at high risk of surgery, taking into account that nearly half of patients with CD may require surgery within 10 years of diagnosis[1]. Irrespective of the treatment performed, BWT > 7 mm at IUS, altered bowel wall echopattern, and the presence of complications such as fistulas or stenosis are risk factors for intestinal resection over a short period of time[34-36]. In particular, the presence of strictures, fistulae, and abscesses at baseline bowel US seems to predict the need for surgery through 12 mo[14].

The assessment of fibrosis by means of strain elastography may identify patients who are nonresponsive to anti-TNF and need surgery. Orlando *et al*[29] in a small series of patients, showed that the strain ratio of the thickened bowel wall may predict surgery much better than the degree of its thickening and vascularization and that a strain ratio ≥ 2 before starting anti-TNF was the cut-off value correlated with poor lack of improvement, surgery and worst outcome. Likewise, the lack of improvement or the increase in BWT after the start of treatment is correlated with a high risk of surgery[21,34]. It is debatable whether in selected populations at high risk of surgery, such as CD patients with well-known strictures and fistulas, the features of BWT may suggest the response to treatment and ultimately surgery. In the STRIDENT study, 77 CD patients with a *de novo* or postoperative anastomotic intestinal stricture with symptoms consistent with chronic or subacute intestinal obstruction were randomly assigned to receive adalimumab alone or combined with thiopurines. IUS at 12 mo showed improvement (> 25%) in BWT in 45% of patients, with no significant difference between the two groups of patients and an overall low risk of surgery, but no predictors of improvement were given[10].

IUS to predict post-surgical recurrence

Several studies and systematic reviews have assessed the role of IUS in postoperative follow-up, showing that a BWT > 3 mm of the anastomosis or neoterminal ileum is an accurate indicator for recurrence[11]. In this regard, prospective studies have shown that the use of PEG solution (SICUS)[37] and colour Doppler or CEUS[38] can increase the sensitivity, albeit with a decrease in specificity in detecting postoperative recurrence at 1 year after surgery. Moreover, both IUS and SICUS, adopting

Table 2 Rate of transmural remission and intestinal ultrasound parameters predictive of transmural remission in Crohn's disease patients treated with biologics

Ref.	Patients, *n*	TR definition	Study drug	Treatment duration	Rate of TR	IUS parameters predictive of TR
Calabrese *et al*[52], 2022	188	Normalization of BWT, no ECD, no extra bowel signs of inflammation	Adalimumab, infliximab, vedolizumab, ustekinumab	52 wk	27.5% (26.8% adalimumab; 37% infliximab; 27.2% vedolizumab; 20% ustekinumab	Colonic localization, lower BWT at baseline
Castiglione *et al*[57], 2013	66	NA	Anti-TNF	2 yr	25%

TR: Transmural remission; BWT: Bowel wall thickness; ECD: Eco-color-doppler vascular signal; I: Ileal Crohn's disease; C: Colonic Crohn's disease; UEI: Ultrasound elastography imaging; SICUS: Small intestine contrast ultrasonography; IUS: Intestinal ultrasound; TNF: Tumor necrosis factor; NA: Not available.

different cut-off levels for bowel thickness (> 5 mm for conventional sonography and > 4 mm for SICUS), can suggest severe endoscopic postoperative recurrence and could accordingly replace endoscopy in postsurgical follow-up[37] (for detection of recurrence).

IUS is accurate not only in detecting postoperative clinical recurrence but also in predicting endoscopic and surgical recurrence. IUS assessment 3 mo after surgery showed high sensitivity in predicting postoperative recurrence at 12 mo, with lower sensitivity[38] but higher specificity than calprotectin[39]. A retrospective study showed that in postoperative CD patients, independent of the

time elapsed from earlier surgery, patients with BWT > 3 mm had a doubled risk of surgical recurrence compared with patients with BWT < 3 mm, and that the absolute incidence of new surgical interventions positively correlated with increased BWT[40]. In this respect, the prognostic value of increased BWT, as assessed by IUS several years after surgery, needs further confirmation, and in particular, the usefulness of therapy escalation for these patients remains unconfirmed[12].

Additionally, in CD patients treated with conservative surgery (*e.g.*, strictureplasty or minimal bowel resections), IUS is useful for monitoring the postoperative behaviour of BWT and can provide prognostic information: US detection of unchanged or worsened wall thickness 6 mo after surgery or the postoperative persistence of wall thickness > 6 mm is predictive of a high risk of recurrence[41].

In this subset of patients, the estimated 5-year survival probability of symptomatic CD recurrence was 90% and 33%, respectively, for unchanged/worsened BWT *vs* improved BWT at 12 mo after surgery. A BWT > 6.0 mm at 12 mo after surgery was directly associated with the risk of CD recurrence. Hence, systematic IUS follow-up of diseased bowel walls after conservative surgery seems to allow the early identification of patients at high risk of clinical/surgical recurrence[42].

Clinical remission

In CD patients, bowel wall changes such as increased BWT and vascularization may persist after therapy and despite clinical remission. The meaning and prognostic significance of these IUS findings have been widely investigated. In quiescent CD, increased vascularity, detected either by colour Doppler or CEUS, after treatment may suggest an increased risk of relapse[21,43,44].

Vascularization and BWT currently represent the main features of sonographic activity scores, and the investigation on prognostic significance of these scores in clinical studies is still ongoing. However, it is clear that normalization of the bowel wall (the so-called TR), namely, a BWT < 3 mm[45] or a more stringent definition such as the combination of BWT < 3 mm, normalization of vascularity and wall stratification, absence of mesenteric fat hypertrophy, node enlargement, or disease complications (*i.e.*, strictures, fistulas)[46,47], is associated with favourable prognostic long-term outcomes[40,43,46,48,49].

Indeed, it has been demonstrated that sonographic remission evaluated after one year of anti-TNF therapy is associated with a longer remission without the need for a therapy change and a reduced need for surgery[21]. In patients with CD in clinical remission, achieving TR is associated with reduced clinical complications, including medication escalation, corticosteroid use, hospitalization, and surgery. When examining clinical complications occurring more than 90 d following IUS, sonographic inflammation remains associated with an increased risk of clinical complications such asmedication escalation, hospitalization, and surgery[46,50,51].

CONCLUSION

IUS is a useful imaging method to assess CD disease activity and can have a prognostic role in predicting response to treatment, disease progression, risk of surgery and risk of postsurgical recurrence. Response to treatment may be predicted by increased BWT and vascularization, reduced elasticity and absence of CD complications. Disease progression or risk of surgery may be predicted by increased BWT, loss of bowel stratification and the presence of CD complications. Postoperative clinical and surgical relapse may be predicted by increased BWT. As more biological therapies become available in the coming years, further prospective trials will be needed to reach definite evidence on IUS predictive value at baseline, to recognize which patients are more likely to respond to a specific therapy and which patients are at high risk of surgery or complications, needing early intensive treatment.

Abstract

BACKGROUND

Activated hepatic stellate cells (aHSCs) are the major source of cancer-associated fibroblasts in the liver. Although the crosstalk between aHSCs and colorectal cancer (CRC) cells supports liver metastasis (LM), the mechanisms are largely unknown.

AIM

To explore the role of BMI-1, a polycomb group protein family member, which is highly expressed in LM, and the interaction between aHSCs and CRC cells in promoting CRC liver metastasis (CRLM).

METHODS

Immunohistochemistry was carried out to examine BMI-1 expression in LM and matched liver specimens of CRC. The expression levels of BMI-1 in mouse liver during CRLM (0, 7, 14, 21, and 28 d) were detected by Western blotting (WB) and the quantitative polymerase chain reaction (qPCR) assay. We overexpressed BMI-1 in HSCs (LX2) by lentivirus infection and tested the molecular markers of aHSCs by WB, qPCR, and the immunofluorescence assay. CRC cells (HCT116 and DLD1)

were cultured in HSC-conditioned medium (LX2 NC CM or LX2 BMI-1 CM). CM-induced CRC cell proliferation, migration, epithelial-mesenchymal transition (EMT) phenotype, and transforming growth factor beta (TGF-β)/SMAD pathway changes were investigated *in vitro*. A mouse subcutaneous xenotransplantation tumor model was established by co-implantation of HSCs (LX2 NC or LX2 BMI-1) and CRC cells to investigate the effects of HSCs on tumor growth and the EMT phenotype *in vivo*.

RESULTS

Positive of BMI-1 expression in the liver of CRLM patients was 77.8%. The expression level of BMI-1 continued to increase during CRLM in mouse liver cells. LX2 overexpressed BMI-1 was activated, accompanied by increased expression level of alpha smooth muscle actin, fibronectin, TGF-β1, matrix metalloproteinases, and interleukin 6. CRC cells cultured in BMI-1 CM exhibited enhanced proliferation and migration ability, EMT phenotype and activation of the TGF-β/SMAD pathway. In addition, the TGF-βR inhibitor SB-505124 diminished the effect of BMI-1 CM on SMAD2/3 phosphorylation in CRC cells. Furthermore, BMI-1 overexpressed LX2 HSCs promoted tumor growth and the EMT phenotype *in vivo*.

CONCLUSION

High expression of BMI-1 in liver cells is associated with CRLM progression. BMI-1 activates HSCs to secrete factors to form a prometastatic environment in the liver, and aHSCs promote proliferation, migration, and the EMT in CRC cells partially through the TGF-β/SMAD pathway.

Key Words: BMI-1; Hepatic stellate cells; Colorectal cancer; Liver metastasis; Epithelial-mesenchymal transition

Core Tip: This study revealed that BMI-1 was upregulated in liver cells during colorectal cancer (CRC) liver metastasis. BMI-1-activated LX2 hepatic stellate cells (HSCs) promoted CRC cell proliferation, migration, and the epithelial-mesenchymal transition both *in vitro* and *in vivo*. Mechanistically, transforming growth factor beta 1 was increased in BMI-1 overexpressed LX2 HSCs, and triggered the phosphorylation of downstream SMAD2/3 in CRC cells and the interaction of activated HSCs and CRC cells, thereby further promoting CRC progression.

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer and ranks second in terms of cancer mortality worldwide[1,2]. Liver metastasis (LM) is the primary cause of death in CRC patients, and the liver plays a major role in survival as it is often the only site of metastasis. In CRC patients, approximately 14%-35% have LM at diagnosis, and about 70% have LM in the late stage of the disease[3]. In colorectal cancer (CRC) liver metastasis (CRLM) patients, liver resection is the primary curative treatment option, with a 5-year survival rate of 20%-50%[4]. Although treatments have advanced in recent years, the rate of intrahepatic recurrence is still high.

During CRLM, CRC cells can orchestrate a premetastatic niche by changing the tumor microenvironment[5,6]. For example, tumor cells secrete cytokines and extracellular vesicles containing microRNAs (miRNAs), integrins, and cytokines, which can modulate distant niches[7]. Zhao *et al*[8] found that CRC-derived miRNA-181a-5p-rich extracellular vesicles induced the activation of hepatic stellate cells (HSCs)[8]. The hepatic microenvironment has numerous signaling factors in liver cells, which consist of parenchymal and nonparenchymal cells, and the interaction between cancer cells and stromal cells facilitates the development of LM[9,10]. Cancer-associated fibroblasts (CAFs), comprising the major stromal cell type, are fibroblast populations found in primary and metastatic cancers and are related to tumor initiation, progression, and metastasis by regulating extracellular matrix (ECM) remodeling and the immune response[11-13]. HSCs are the major nonparenchymal liver cells, which store retinol and

play a role in liver repair, liver fibrosis, and hepatocellular carcinoma (HCC)[14-17]. HSCs contribute 85%–95% of fibroblasts in the liver[18]. HSCs are activated to CAFs by cancer cells to support tumor growth and metastasis[8,19]. Hepatic CAFs are thought to come primarily from HSCs and to a lesser extent from bone marrow-derived precursors, portal fibroblasts, and endothelial cells[20]. In intrahepatic cholangiocarcinoma, HSC-derived CAFs are the main tumor-interacting population[21]. Although CRC is the most common primary cancer that metastasizes to the liver, the mechanisms by which HSCs interact with CRC cells to promote LM are largely unclear.

BMI-1, one of the polycomb group protein family members, plays a critical role in negatively regulating the Ink4a/Arf locus which encodes $p16^{INK4a}$ and $p19^{ARF}$[22]. BMI-1 regulates self-renewal of stem cells and participates in the carcinogenesis of human cancers including CRC[23-25]. We previously reported that BMI-1 was overexpressed in CRLM and contributes to LM by regulating the epithelial-mesenchymal transition (EMT) of CRC cells *in vitro* and *in vivo*[26]. Interestingly, we observed BMI-1-positive staining in liver cells both in human and mouse specimens of CRLM. Studies have shown that quiescent HSCs can be activated by cancer cells and transformed into CAFs, and in turn activated HSCs (aHSCs) promote cancer cell invasion and the EMT[8,19]. Thus, we speculated that BMI-1 plays a role in the crosstalk between HSCs and CRC cells during LM.

In this study, both CRLM patients and mice showed increased BMI-1 expression in liver cells. BMI-1 overexpressed HSCs were activated and transformed into CAFs. CRC cells cultured in conditioned medium (CM) from BMI-1 overexpressed HSCs showed enhanced proliferation, migration, and EMT ability. The experimental *in vivo* subcutaneous xenotransplantation tumor model also showed increased tumor proliferation and EMT of CRC cells cocultured with BMI-1 overexpressed HSCs. These findings may provide a potential new target for the treatment of CRLM.

MATERIALS AND METHODS

Immunohistochemistry analysis of CRLM patients

LM and adjacent normal liver tissues from 18 clinically diagnosed patients with CRLM were collected from the Pathology Department (from 2013 to 2020), Sir Run Run Shaw Hospital, Hangzhou, China. The expression of BMI-1 was investigated by immunohistochemistry (IHC) staining. Anti-BMI-1 (1:100; Cell Signaling Technology, Danvers, MA, United States) was used as the primary antibody before secondary antibody incubation.

Cell culture and treatment

The high metastatic human CRC cell line (HCT116), low metastatic human CRC cell line (DLD1), mouse CRC cell line (CT26), and human HSC line (LX2) were purchased from the American Type Culture Collection (Manassas, VA, United States). Cells were cultured in Dulbecco's Modified Eagle's Medium (Gibco, Waltham, MA, United States) with 10% fetal bovine serum and 1% penicillin/streptomycin in a 5% carbon dioxide humidified incubator at 37 °C. The BMI-1 overexpressed lentiviral construct (pGC-FU-GFP-*BMI-1*) and negative control (pGC-FU-GFP) were obtained from Genechem (Shanghai, China). The control (LX2 NC) and stable BMI-1 overexpressed LX2 (LX2 BMI-1) cells were established by lentivirus transfection following the manufacturer's instructions. In addition, to prepare the CM, we first cultured transfected LX2 cells in a 10 cm plate at a density of 1×10^6 cells. We then used 6 mL serum-free DMEM to culture the cells for 24 h. The supernatants were collected, centrifuged at 1000 × *g* for 10 min, and filtered through a 0.22 mm filter unit (Millex, Duluth, GA, United States). CM from NC LX2 (NC CM) and BMI-1 LX2 (BMI-1 CM) was prepared by mixing the different supernatant with complete medium (1:1). Then the CRC cells were cultured in CM for 24 h. All CM was used within 2 d. CRC cells were pretreated with SB-505124 (0.05 μM) for 1 h to inhibit SMAD2 phosphorylation, and then the cells were incubated with BMI-1 CM for 24 h.

Western blotting

Whole proteins from the tissue and cell samples were extracted using RIPA buffer with a 1% protease/phosphatase inhibitor. After centrifugation of the extraction solutions, the BCA Protein Concentration Assay Kit (Solarbio, Beijing, China) was used to quantify the proteins. Following sodium dodecyl sulfate-polyacrylamide gel electrophoresis, the proteins were electrotransferred to polyvinylidene fluoride membranes. Antibodies against BMI-1, glyceraldehyde-3-phosphate dehydrogenase, β-actin, vimentin, SMAD2/3, phosphorylated SMAD3 (1:1000; Cell Signaling Technology), alpha smooth muscle actin (α-SMA), transforming growth factor beta 1 (TGF-β1), phosphorylated SMAD2 (1:1000; Abcam, Cambridge, MA, United States), fibronectin (1:1000; BD Biosciences, San Jose, CA, United States), E-cadherin, zinc finger E-box-binding homeobox 1 (ZEB-1), Twist-1 (1:1000; Novus Biologicals, Centennial, CO, United States), and Snail (1:1000; Proteintech Group, Rosemont, IL, United States) were used as primary antibodies. After washing with Tris-buffered saline with 0.1% Tween 20 three times every 10 min, goat anti-rabbit/mouse immunoglobulin G (Abcam) was used as the secondary antibody. The Bio-Rad CD Touch Detection System (Hercules, CA, United States) with enhanced chemiluminescence detection reagents was used to detect protein bands.

Quantitative polymerase chain reaction

Whole RNAs from the tissue and cell samples were extracted using Trizol reagent (Cwbio, Dalian, China). HiScript II Q RT SuperMix (Vazyme Biotech, Nanjing, China) was subsequently used for reverse transcription. ChamQ Universal SYBR quantitative polymerase chain reaction (qPCR) Master Mix (Vazyme Biotech) was used for qPCR. The Bio-Rad CFX-96 Real-Time PCR System was utilized to analyze the results. The sequences of all primers are listed in Supplementary Table 1.

Immunofluorescence staining

Immunofluorescence staining was performed in 96-well plates. Cells were fixed in paraformaldehyde and permeabilized with Triton X-100. Before incubation with secondary antibody, antibodies against vimentin (1:100; Cell Signaling Technology) and Snail (1:100; Proteintech Group) were used as primary antibodies. The Zeiss AXIO Observer A1 inverted fluorescence microscope system (Jena, Germany) was used to obtain images.

Cell viability assay

Cells were cultured in CM separately for 24, 48, 72, and 96 h. After treatment, Cell Counting Kit-8 (CCK-8) reagent (Yeasen Biotechnology, Shanghai, China) was added and incubated for 2 h. A spectrophotometer (Thermo Fisher Scientific, Waltham, MA, United States) was used to detect the optical density value (450 nm).

Colony formation assay

CRC cells were cultured in CM for 2 wk. Cells were fixed in paraformaldehyde and stained with crystal violet. Colonies were viewed with the Olympus CKK53 microscope (Tokyo, Japan), and photos were taken. ImageJ software was utilized to measure the number of colonies.

Wound healing assay

CRC cells were cultured until they reached 90% confluence. Following the creation of a linear wound, cells were cultured in CM for 48 h. Wounds were viewed with the Olympus CKK53 microscope, and photos were taken at 0, 24, and 48 h. ImageJ software was used to measure the migration rate.

Transwell migration assay

Transwell chambers were purchased from Corning Inc. (Corning, NY, United States). CRC cells were plated in the upper chambers with serum-free DMEM, while CM was placed in the lower chambers. After 48 h, cells in the upper chambers were removed, and cells on the lower membrane surface were fixed and stained. The migrated cells were viewed with the Olympus CKK53 microscope, and photos were taken. ImageJ software was used to measure the number of cells.

IHC

Tissue samples were fixed, dehydrated, paraffin-embedded, and sectioned. After deparaffinization, the sections were blocked in goat serum and incubated with primary antibodies for 24 h. The sections were incubated with secondary antibody for 30 min, followed by counterstaining with Mayer's hematoxylin. The Olympus CKK53 microscope was used to view and photograph the stained sections.

Animal experiments

All animal experimental procedures were approved by the Committee on the Ethics of Animal Experiments of Zhejiang University (No. ZJU20220447; Hangzhou, China).

Treatment protocol 1

Five-week-old male BALB/c mice (19-20 g) were randomly divided into five groups (n = 3). Isoflurane (inhalation) was utilized to anesthetize the mice. The spleen was then exteriorized through a left flank incision. CT26 cells (2×10^6) were injected intrasplenically to establish the tumor, and then the injection site was pressed for 5 min. Surgical thread was used to close the peritoneum and skin. The mice were sacrificed at 0, 7, 14, 21, and 28 d after inoculation of CT26 cells. Resected liver tissues were collected for qPCR, Western blotting (WB), and the IHC assay.

Treatment protocol 2

Five-week-old male BALB/c nude mice (17-18 g) were randomly divided into four groups (n = 5): (1) HCT116 cells (5×10^6) were mixed with LX2 NC cells (1×10^6); (2) HCT116 cells (5×10^6) were mixed with LX2 BMI-1 cells (1×10^6); (3) DLD1 cells (5×10^6) were mixed with LX2 NC cells (1×10^6); and (4) DLD1 cells (5×10^6) were mixed with LX2 BMI-1 cells (1×10^6). The mixed cells were subcutaneously injected into mouse flanks to establish the tumors. When measurable, tumor sizes were estimated every 2 d. The mice were killed 28 d after cell inoculation. Resected tumor tissues were collected for qPCR, WB, and the IHC assay. Total tumor volume (mm^3) = $L \times W^2/2$ (L = length and W = width).

Table 1 Correlation between clinicopathological characteristics of colorectal cancer patients and *BMI-1* expression in the liver

Characteristics	Cases, *n* = 18	*BMI-1* expression		*P* value

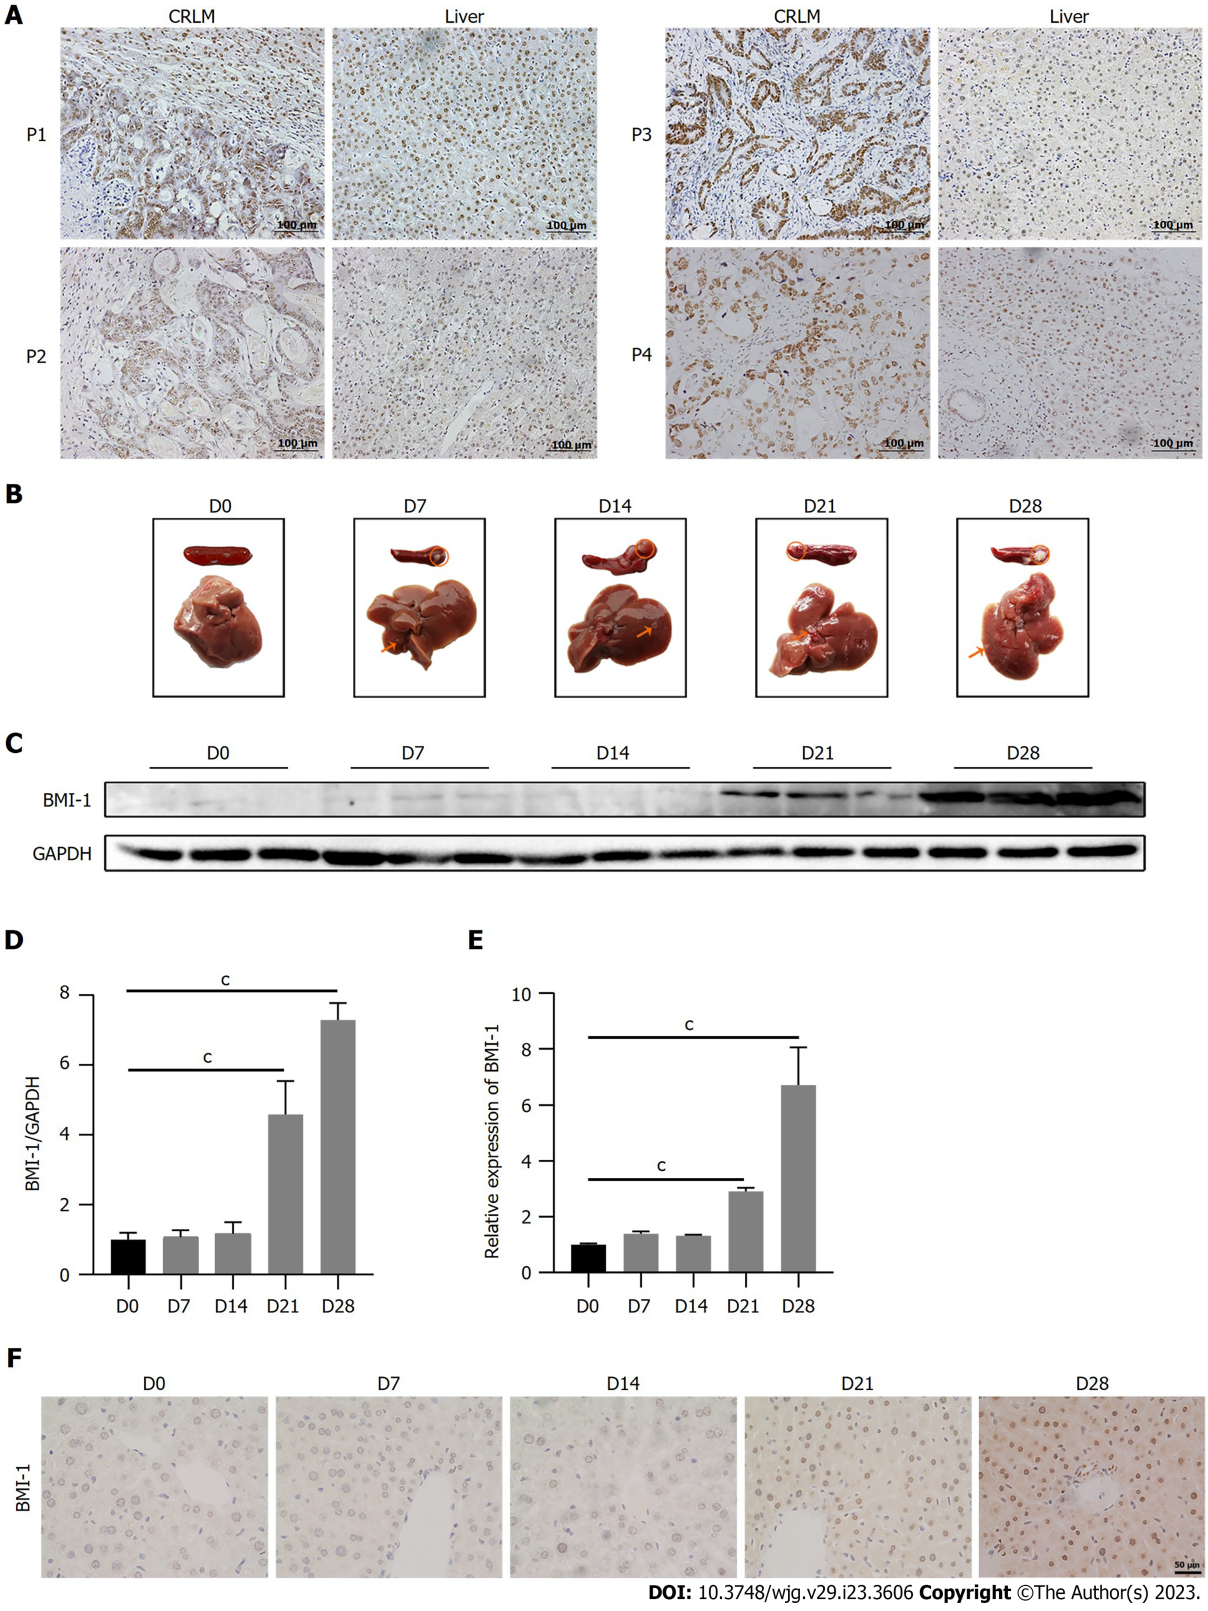
[a]$P < 0.05$.

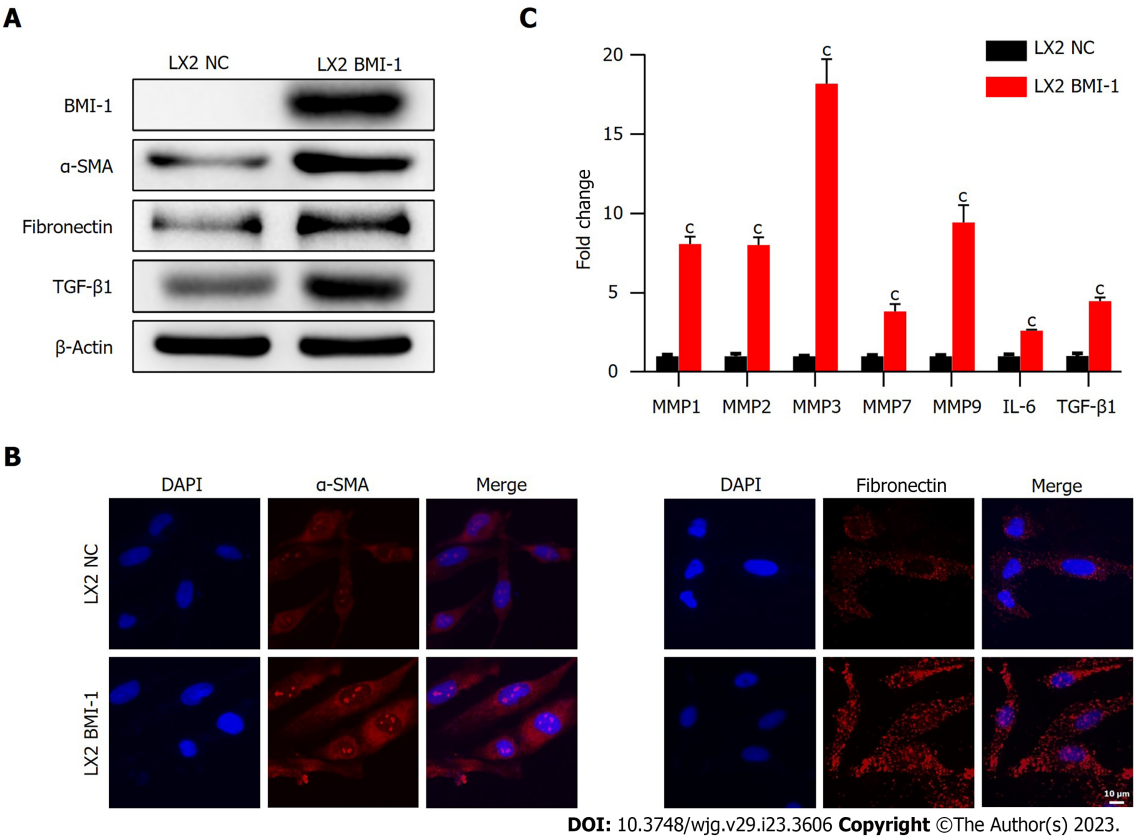


Statistical analyses

In all experiments, the data are shown as the mean ± standard deviation based on three independent experiments. The difference between the groups was analyzed by the χ^2 test, Fisher's exact probability, Student's *t*-test, or one-way analysis of variance using GraphPad Prism 8 software or SPSS 25.0. $P < 0.05$ was considered statistically significant.

RESULTS

BMI-1 expression is upregulated in liver cells during CRLM



In our previous research, it was found that BMI-1 was overexpressed in LM of human CRC[26]. Interestingly, although normal liver cells were BMI-1-negative, 77.8% of liver cells from CRLM patients (14 of 18 samples; Figure 1A) were BMI-1-positive. The positive expression of BMI-1 was not strongly related to the clinical pathological characteristics (including tumor size and tumor number in the liver, differentiation degree, T stage, N stage) except the tumor site (Table 1). Positive BMI-1 expression in the liver cells of patients with rectal cancer LM was significantly higher (100%) than in patients with CRLM (60%). To investigate BMI-1 expression level in liver cells during CRLM, we measured BMI-1 expression at 0, 7, 14, 21, and 28 d following intrasplenic injection of CT26 cells in mice (Figure 1B). As shown in Figure 1C, small LM had formed by day 7. Compared with healthy control mice, the protein expression level of BMI-1 did not significantly change at 7 and 14 d, but markedly increased 4.58-fold at 21 d and

continued increasing up to 7.29-fold at 28 d (Figure 1D). The mRNA expression level of BMI-1 accordingly increased 2.92-fold at 21 d and 6.71-fold at 28 d (Figure 1E). The IHC results also showed that few nuclei in liver cells were BMI-1-positive in CRLM mice from 14 d, but the BMI-1-positive rate and intensity increased markedly at 21 and 28 d (Figure 1F). These results suggest that BMI-1 was

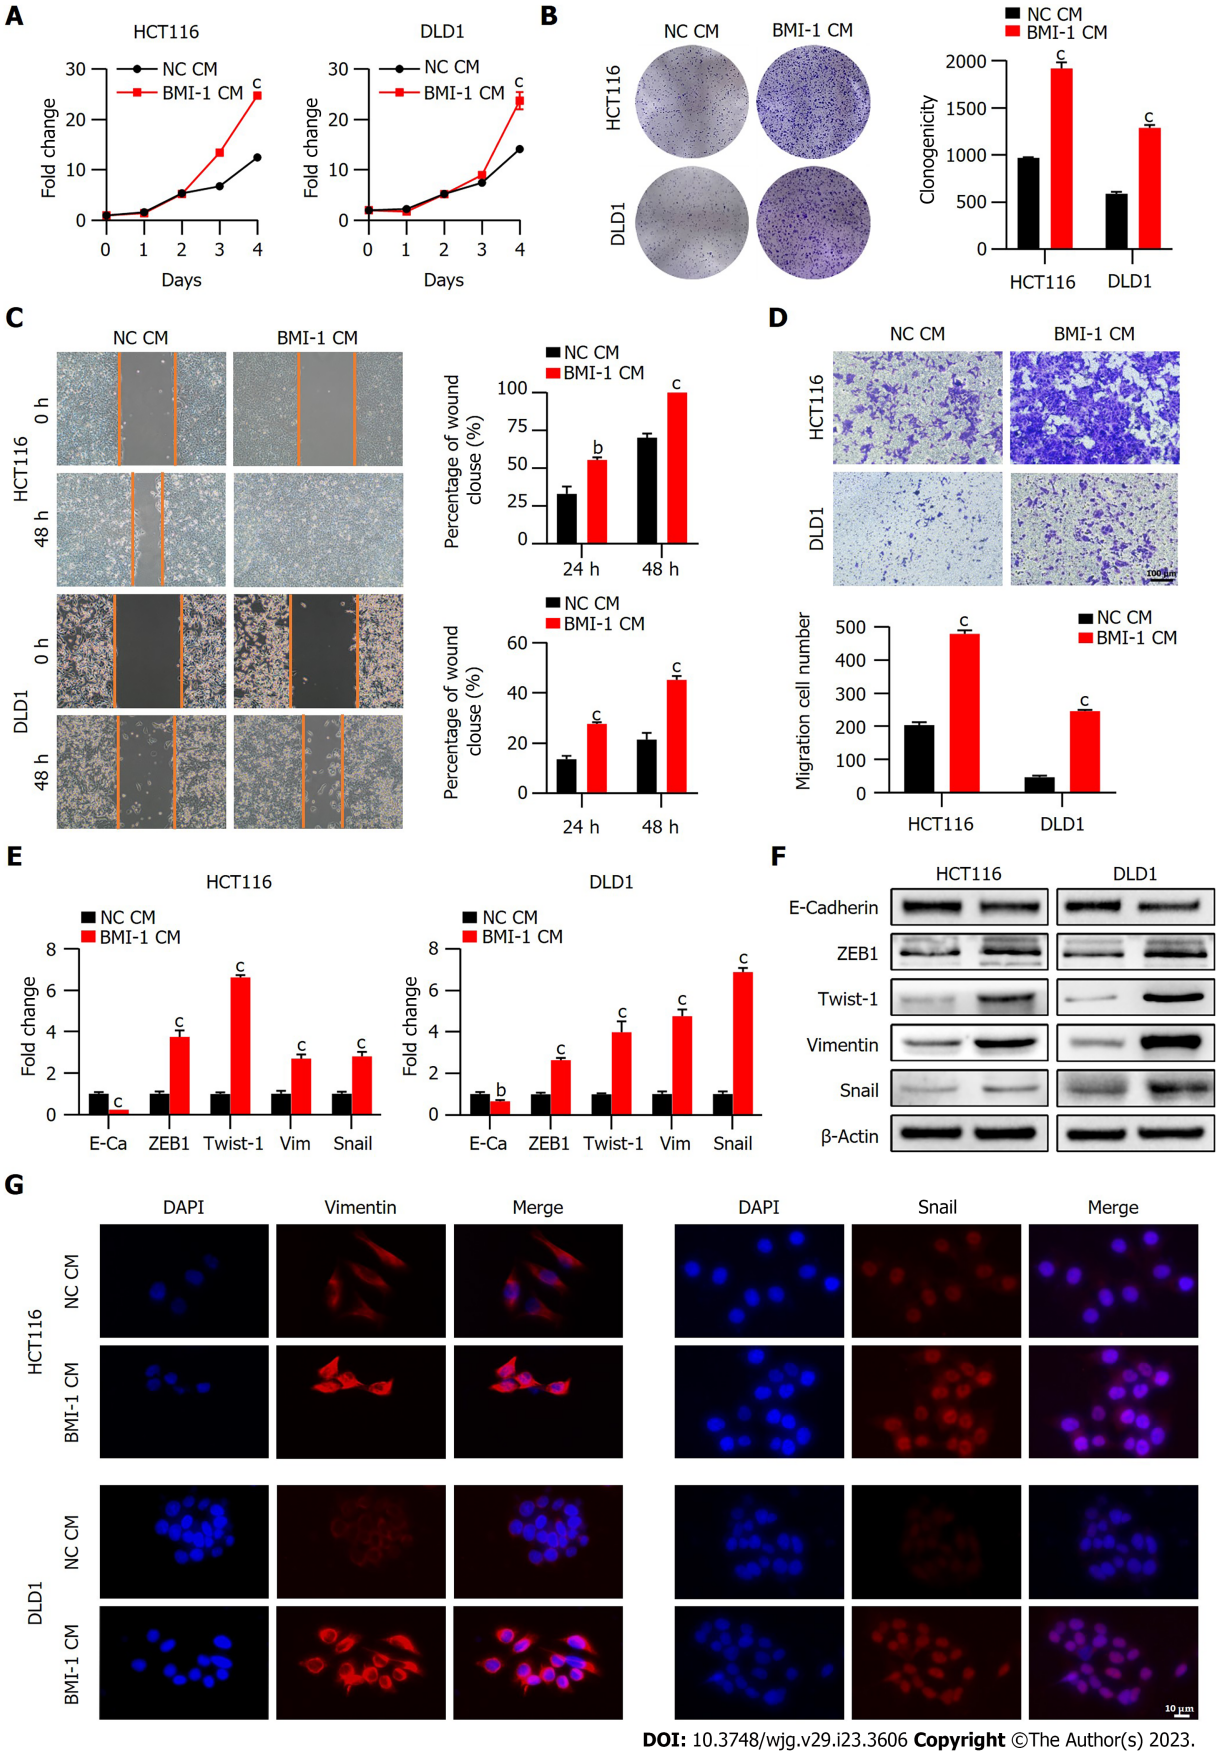
Figure 2 BMI-1 activates LX2 hepatic stellate cells. A: Western blot analysis of BMI-1 and activated hepatic stellate cell (aHSC)-related markers (alpha smooth muscle actin [α-SMA], fibronectin and transforming growth factor beta 1) in control (LX2 NC) and LX2 BMI-1 HSCs; B: Quantitative polymerase chain reaction detection of matrix metalloproteinases (MMPs) and cytokines in LX2 HSCs, $^{c}P < 0.001$; C: Immunofluorescence analysis showed that α-SMA and fibronectin expression levels were increased in LX2 BMI-1 HSCs. DAPI: 4',6-diamidino-2-phenylindole; IL: Interleukin; NC: Negative control.



upregulated in liver cells after CRC cells metastasized to the liver, and may play a role in CRLM.

BMI-1 activates HSCs

To investigate the effects of BMI-1 on liver cells, we overexpressed BMI-1 in LX2 HSCs and confirmed the overexpression by WB (Figure 2A). High expression of α-SMA, a myofibroblast marker, is a key marker of aHSCs. aHSCs highly secrete the key cytokine TGF-β1 and promote hepatic fibrosis with fibronectin expression[27]. Compared with control quiescent HSCs, BMI-1 overexpressed LX2 HSCs showed a significant increase in α-SMA expression. Fibronectin and TGF-β1 expression were also markedly increased in BMI-1 overexpressed LX2 HSCs. Immunofluorescence staining also confirmed that the expression of α-SMA and fibronectin was significantly increased in LX2 cells overexpressing BMI-1 (Figure 2B). It was also observed that the transcript levels of matrix metalloproteinases (MMP1, MMP2, MMP3, MMP7, MMP9) and inflammatory cytokines (TGF-β1 and interleukin 6 [IL-6]) were markedly increased (Figure 2C). Thus, LX2 HSCs were activated by the overexpression of BMI-1.

BMI-1 overexpressed HSC CM enhances CRC cell proliferation and migration

To examine the effect of BMI-1 on the interaction between HSCs and CRC cells, CRC cells (HCT116 and DLD1) were cultured in control LX2 CM (NC CM) or BMI-1 overexpressed LX2 CM (BMI-1 CM). We first measured cell proliferation using the CCK-8 assay. Compared with cells cultured in NC CM, the proliferation of CRC cells cultured in BMI-1 CM was markedly enhanced on day 4 (Figure 3A), and the colony formation ability of CRC cells cultured in BMI-1 CM also significantly increased (Figure 3B). In addition, CRC cells cultured in BMI-1 CM showed higher wound healing rates (Figure 3C). Transwell migration assays showed the same results (Figure 3D). Then we investigated EMT-related molecular changes. Consistent with the above results, the mRNA and protein expression levels of ZEB-1, Twist-1, vimentin, and Snail in CRC cells cultured in BMI-1 CM were significantly increased while E-cadherin was decreased (Figure 3E and F). Immunofluorescence staining further demonstrated that Snail and vimentin expression was obviously increased in CRC cells cultured in BMI-1 CM (Figure 3G). Therefore, BMI-1 may be an important regulator in aHSCs, which promoted the malignant phenotype of CRC cells.

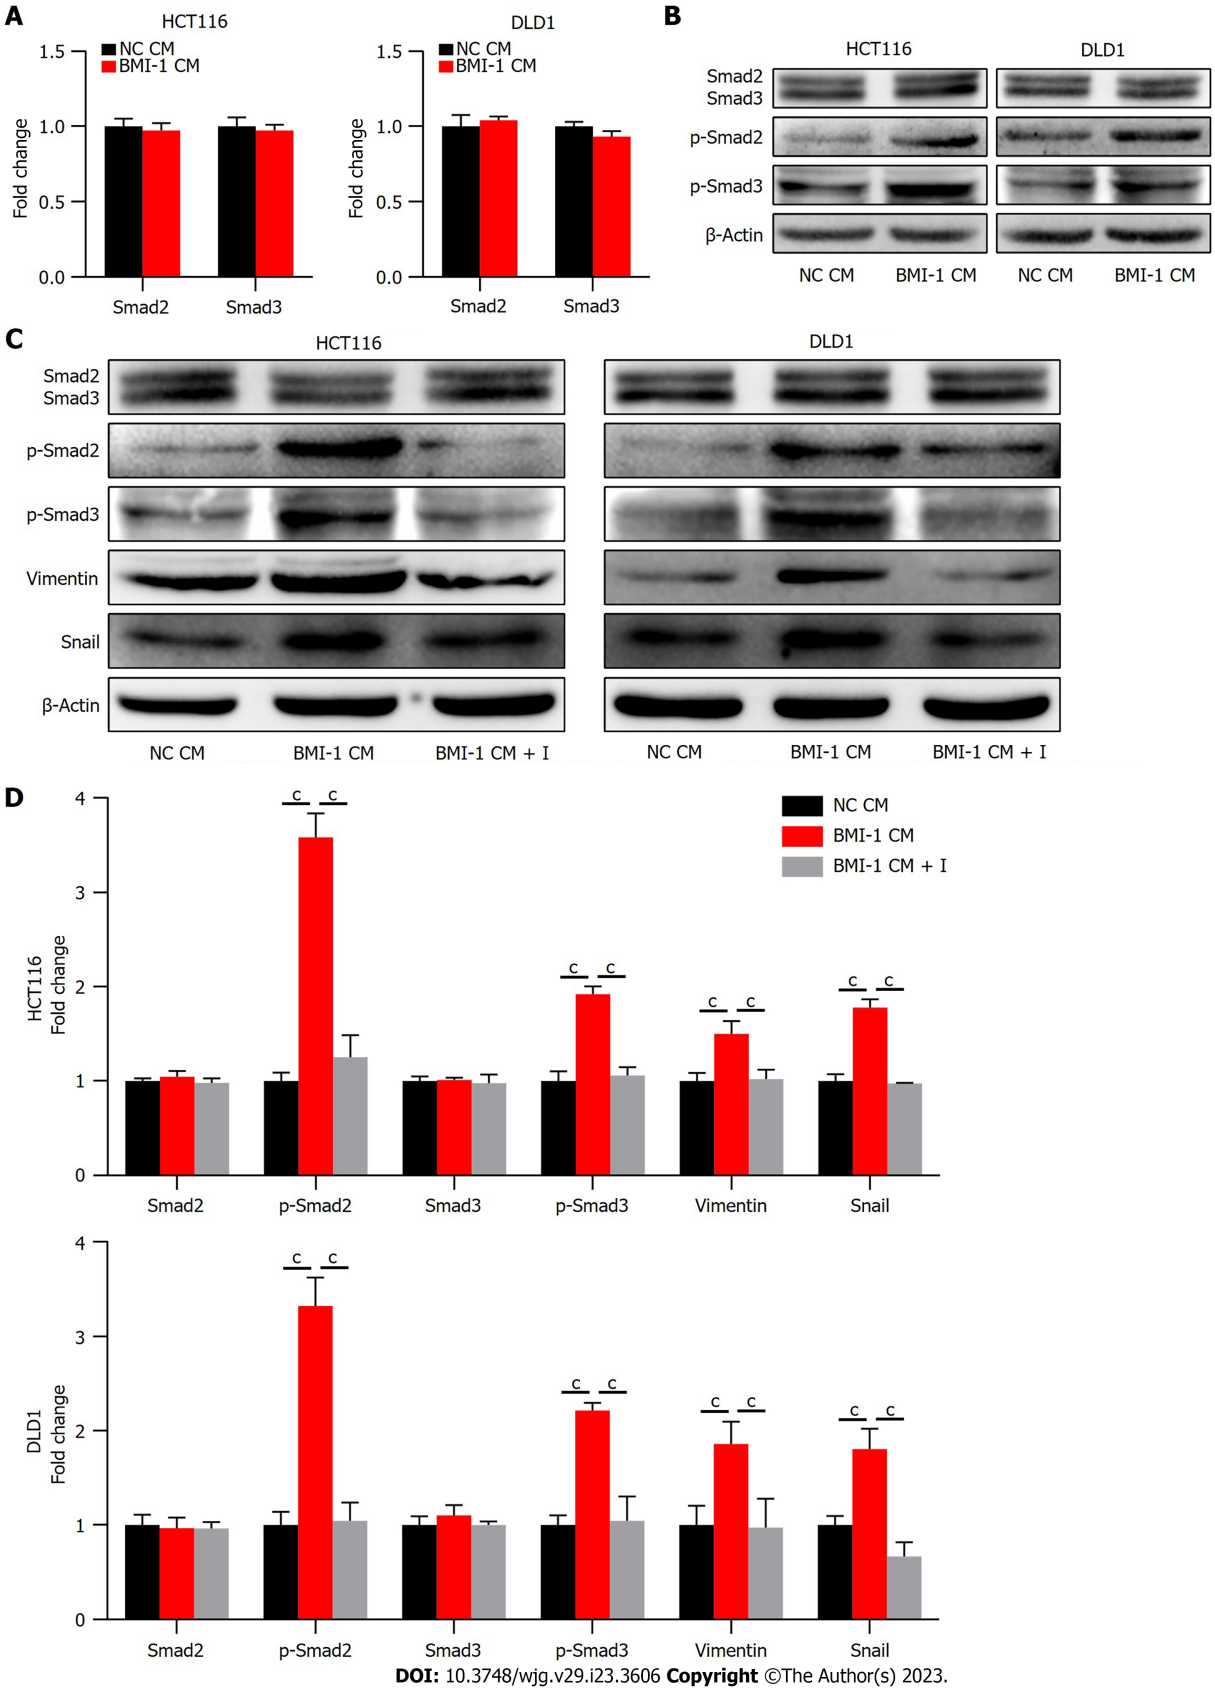
Figure 3 Effects of BMI-1 overexpressed hepatic stellate cell conditioned medium on cell proliferation and migration of colorectal cancer cells. A: Viability of HCT116 and DLD-1 cells cultured in conditioned medium (CM) from negative control (NC) LX2 (NC CM) or CM from BMI-1 overexpressed LX2 (BMI-1 CM) was confirmed by the Cell Counting Kit-8 assay; B: Colony formation assay of colorectal cancer (CRC) cells cultured in NC CM or BMI-1 CM; C: Wound healing assay of CRC cells cultured in NC CM or BMI-1 CM, the healing percentages were calculated at 24 h and 48 h; D: Transwell migration assay of CRC cells

cultured in NC CM or BMI-1 CM, the numbers of cells which migrated were counted; E: Quantitative polymerase chain reaction assay of the expression of epithelial-mesenchymal transition (EMT)-related markers in CRC cells cultured in NC CM or BMI-1 CM; F: Western blot assays of the expression of EMT-related markers in CRC cells cultured in NC CM or BMI-1 CM; G: Immunofluorescence analysis showed that vimentin and Snail expression levels were increased in CRC cells cultured in BMI-1 CM. $^{b}P < 0.01$, $^{c}P < 0.001$ *vs* NC CM. DAPI: 4',6-diamidino-2-phenylindole.

BMI-1 overexpressed HSC CM promotes CRC cell EMT by activating the Smad2/3 pathway

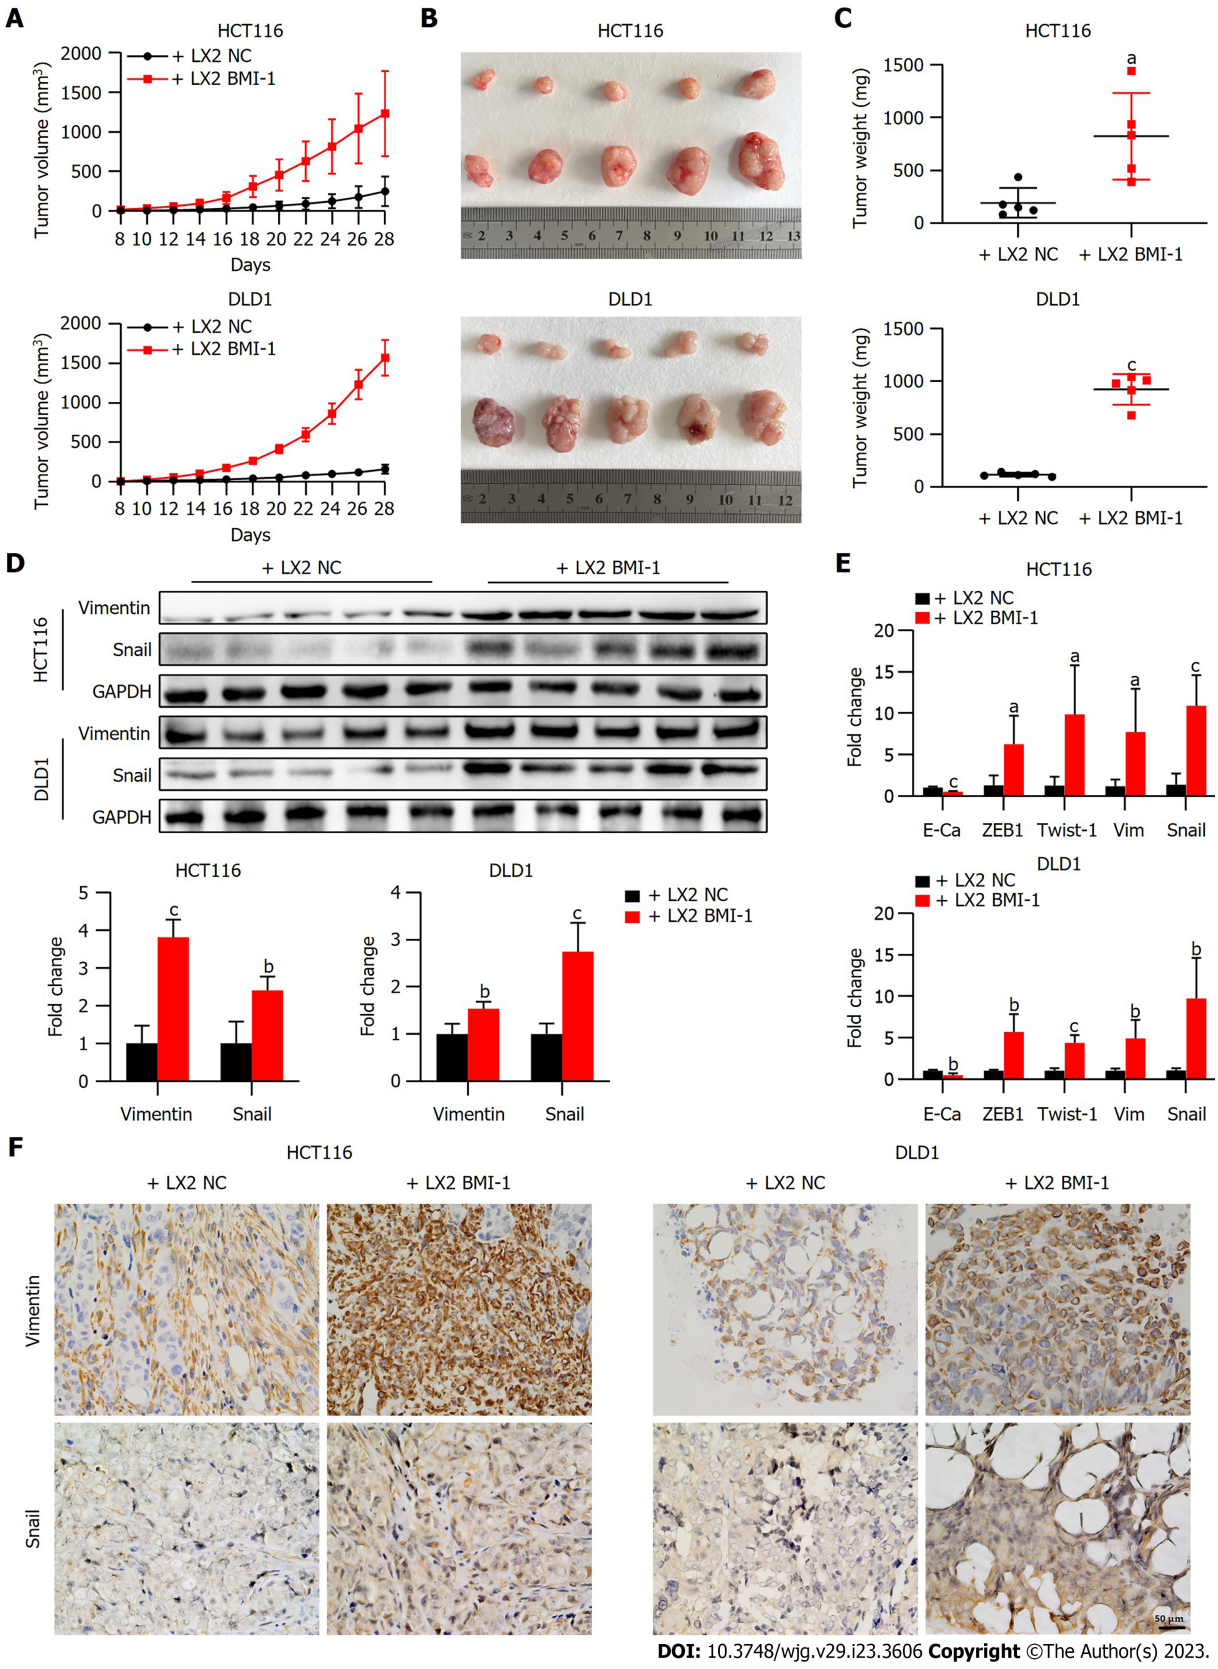
As previously mentioned, TGF-β1 was upregulated in BMI-1 overexpressed LX2 HSCs (Figure 2A). The TGF-β/SMAD signal pathway plays an important role in metastasis by modulating the EMT process[28,29]; therefore, we hypothesized that BMI-1 CM induces EMT in CRC cells by activating SMADs. We first determined the expression levels of SMAD2/3. As shown in Figure 4A and B, although the mRNA and protein expression levels of SMAD2 and SMAD3 showed no changes in CRC cells cultured in BMI-1 CM, SMAD2 and SMAD3 phosphorylation was significantly increased compared with CRC cells cultured in NC CM. We then used SB-505124 (a TGF-β receptor [TGF-βR] inhibitor, which inhibits SMAD2 phosphorylation) to further confirm the involvement of SMADs in the pro-EMT effects of BMI-1 CM. SB-505124 markedly decreased BMI-1 CM-induced SMAD2 and SMAD3 phosphorylation in CRC cells (Figure 4C and D). In addition, the downstream target proteins (Snail and vimentin) of the TGF-β/SMAD pathway accordingly decreased in SB-505124-treated CRC cells cultured in BMI-1 CM (Figure 4C and D). These results confirmed that BMI-1 CM induces EMT in CRC cells partially by activating SMAD2/3.



BMI-1 overexpressed HSCs promotes tumor growth in vivo

We further evaluated the effects of BMI-1 overexpressed LX2 HSCs on CRC cell growth *in vivo*. A subcutaneous xenotransplantation tumor model was established by co-implantation of HSCs (LX2 NC or LX2 BMI-1) and CRC cells (Figure 5A). Compared with mice co-implanted with LX2 NC, tumors grew faster and larger in mice co-implanted with LX2 BMI-1 HSCs and CRC cells as shown by increased tumor volume and weight (Figure 5B and C). Moreover, consistent with the *in vitro* results, we found that Snail and vimentin were upregulated in mice co-implanted with LX2 BMI-1 HSCs and CRC cells as shown by the qPCR and WB results (Figure 5D and E). Furthermore, the increased expression of Snail and vimentin in mouse liver co-implanted with LX2 BMI-1 HSCs and CRC cells was confirmed by IHC (Figure 5F). These results showed that LX2 BMI-1 HSCs promoted CRC tumor growth and EMT in the mouse model.

DISCUSSION



The liver is the most common target organ in terms of CRC metastases. Accumulating evidence suggests that the interactions between cancer cells and the liver microenvironment promote the progression of LM. In the liver microenvironment, HSC-derived CAFs are the main tumor-interacting population and play a vital role in cancer cell metastasis[8,30]. During the development of CRLM, HSC activation was found to be the most common biological process. Tumor-derived factors such as TGF-β and platelet-derived growth factor can activate HSCs[31]. BMI-1 has been proved to promote tumorigenesis and tumor progression in different types of cancers including CRC and HCC[24,26,32-34]. We previously reported that BMI-1 was abnormally highly expressed in CRLM and inhibition of BMI-1 in CRC cells dramatically reduced LM *in vivo*[26]. Normal liver cells were BMI-1-negative, and we observed that BMI-1-positive liver cells were common in CRLM samples from humans and mice. In particular, the mRNA and protein expression levels of BMI-1 in liver cells gradually increased during the development of CRLM in mice, suggesting that BMI-1 also participates in regulating liver cells during the course of CRLM. In this study, we found that BMI-1 had a novel function as a regulator in activating HSCs and plays an important role in the crosstalk between HSCs and CRC cells.

Quiescent HSCs normally resident in the space of Disse become activated with a myofibroblast-like phenotype (α-SMA^{+}) in response to inflammatory stimuli and liver damage[27]. Studies have shown that cancer cells can also activate HSCs to release cytokines and chemokines to promote LM[8,35]. aHSCs reportedly orchestrate a premetastatic and prometastatic niche, which accelerate CRLM[5,6,36]. In this study, we found that BMI-1-positive liver cells appeared on day 14 and increased on days 21 and 28 after injection of CT26 cells, while small LM had formed on day 7. We further confirmed that BMI-1 overexpressed HSCs were activated to α-SMA^{+} myofibroblasts with increased expression of fibronectin, TGF-β1, MMPs, and IL-6. These secreted components can maintain the activated status of HSCs by enhancing the autocrine signaling loop[37]. aHSCs are the major source of ECM, and aHSC-secreted factors play a pivotal role in remodeling the ECM during tumor invasion and metastasis[38]. TGF-β1 is the most potent fibrogenic cytokine and is a fibrotic marker[39,40]. Fibronectin and MMPs are important ECM regulators in the liver fibrosis process[41]. ECM deposition by aHSCs provides a prometastatic environment. Thus, BMI-1 activates HSCs to secrete factors to form a prometastatic environment in the liver.

Figure 6 Schematic summary of BMI-1-activated hepatic stellate cells, which promote colorectal cancer cell epithelial-mesenchymal transition and liver metastasis. CRC: Colorectal cancer; HSC: Hepatic stellate cell; TGF-β1: Transforming growth factor beta 1.

The interactions between cancer cells and aHSCs promote tumor growth and metastasis. CRC cells can stimulate aHSCs to release cytokines and chemokines, which in turn promote CRC growth and invasion[8,35]. In addition, aHSCs can secrete ECM components, induce angiogenesis, and modulate immunity to facilitate tumor growth and metastasis[31]. We found that high-metastatic HCT116 and low-metastatic DLD1 CRC cells cultured in CM from BMI-1 overexpressed HSCs showed the same enhanced proliferation and migration ability, and both HCT116 and DLD1 cells co-implanted with BMI-1 overexpressed HSCs showed increased tumor growth *in vivo*. These results demonstrated that BMI-1 aHSCs promote CRC cell proliferation and migration regardless of their ability to metastasize.

TGF-β signaling is important in tumor-stroma crosstalk. The TGF-β/SMAD pathway can act as both a tumor suppressor and promoter in CRLM[42,43]. The effect of the TGF-β/SMAD pathway in most malignant tumors is toward migration, the EMT or stemness, thereby promoting LM[44-46]. CRC cells are able to recruit and activate HSCs into CAFs by secreting TGF-β, and aHSCs lead to secretion of TGF-β which influences CRC cells[7]. LM has been found to be dependent on TGF-β signaling in liver stroma [47-50]. TGF-β1 is a key inducer of EMT transcription factors, which can promote EMT through the TGF-β/SMAD pathway[28,29]. The markers of EMT, including vimentin, Snail, ZEB-1, and Twist-1, were upregulated in CRC cells cultured in CM from BMI-1 overexpressed HSCs. The TGF-β/SMAD signaling pathway was activated and the phosphorylation of SMAD2/3 was induced in CRC cells cultured in CM from BMI-1 overexpressed HSCs, and treatment with the TGF-βR inhibitor SB-505124 attenuated the effect of BMI-1. Moreover, CRC cells co-implanted with BMI-1 overexpressed HSCs showed increased expression of EMT markers *in vivo*. Taken together, these findings indicate that BMI-1 overexpressed HSCs promote CRC cell growth and migration partly by activating the TGF-β/SMAD pathway and enhancing the EMT.

CONCLUSION

We propose a novel mechanism for BMI-1 involvement in promoting CRLM. BMI-1 was upregulated in liver cells during CRLM. BMI-1 aHSCs released cytokines and chemokines (fibronectin, TGF-β, MMPs, *etc*) to form a prometastatic environment in the liver, and promoted CRC cell proliferation, migration, and the EMT partially by activating the TGF-β/SMAD pathway (Figure 6). These findings provide a potential target for the treatment of CRLM.

ARTICLE HIGHLIGHTS

Research background

Hepatic stellate cells (HSCs) are an important component of liver tissue and are a major source of

cancer-associated fibroblasts. Cancer cells can activate HSCs, and in turn activated HSCs (aHSCs) promote tumor growth and metastasis. However, the mechanisms by which HSCs interact with colorectal cancer (CRC) cells to promote liver metastases (LM) are largely unknown.

Research motivation

We previously discovered that the expression of BMI-1 was abnormally high in LM of CRC. We speculated that BMI-1 plays an important role in the interaction between HSCs and CRC cells.

Research objectives

To examine the role of BMI-1 in HSC activation, and investigate the potential mechanisms of BMI-1 in the interaction between HSCs and CRC cells.

Research methods

The expression of BMI-1 in liver tissue of patients with CRC liver metastasis (CRLM) was determined by immunohistochemistry analysis. We established a mouse LM model to assess the expression of BMI-1 during CRLM. We used lentiviral vectors to overexpress BMI-1 in LX2 HSCs (LX2 BMI-1) and evaluated the molecular markers of aHSCs. The proliferation and mobility of CRC cells in LX2 BMI-1 conditioned medium (CM) was detected. The epithelial-mesenchymal transition (EMT) and transforming growth factor beta (TGF-β)/SMAD pathway in CRC cells treated with LX2 BMI-1 CM were investigated by Western blot analysis and quantitative polymerase chain reaction. A mouse xenograft model was established to investigate the effects of co-implantation of LX2 BMI-1 and CRC cells on tumor growth, and the EMT phenotype of CRC.

Research results

BMI-1 expression was upregulated in liver cells during CRLM. Overexpression of BMI-1 induced the activation of LX2 HSCs. CRC cells cultured in LX2 BMI-1 CM showed higher proliferation, migration, and EMT ability compared with cells cultured in NC CM. LX2 BMI-1 CM induced activation of the TGF-β/SMAD pathway in CRC cells, and the TGF-βR inhibitor SB-505124 diminished the effect of BMI-1 CM. In addition, LX2 BMI-1 HSCs promoted CRC tumor growth and EMT in the mouse model.

Research conclusions

BMI-1 aHSCs promoted the proliferation and migration of CRC partly *via* the TGF-β/SMAD pathway.

Research perspectives

Targeting BMI-1 in liver tissues may have potential therapeutic implications for the treatment of CRLM.

Abstract

BACKGROUND

Gastric cancer (GC) is a common gastrointestinal malignancy worldwide. Based on cancer-related mortality, the current prevention and treatment strategies for GC still show poor clinical results. Therefore, it is important to find effective drug treatment targets.

AIM

To explore the molecular mechanism of 18β-glycyrrhetinic acid (18β-GRA) regulating the miR-345-5p/TGM2 signaling pathway to inhibit the proliferation of GC cells.

METHODS

CCK-8 assay was used to determine the effect of 18β-GRA on the survival rate of GES-1 cells and AGS and HGC-27 cells. Cell cycle and apoptosis were detected by flow cytometry, cell migration was detected by a wound healing assay, the effect of 18β-GRA on subcutaneous tumor growth in BALB/c nude mice was inves-

tigated, and the cell autophagy level was determined by MDC staining. TMT proteomic analysis was used to detect the differentially expressed autophagy-related proteins in GC cells after 18β-GRA intervention, and then the protein-protein interaction was predicted using STRING (https://string-db.org/). MicroRNAs (miRNAs) transcriptome analysis was used to detect the miRNA differential expression profile, and use miRBase (https://www.mirbase/) and TargetScan (https://www.targetscan.org/) to predict the miRNA and complementary binding sites. Quantitative real-time polymerase chain reaction was used to detect the expression level of miRNA in 18β-GRA treated cells, and western blot was used to detect the expression of autophagy related proteins. Finally, the effect of miR-345-5p on GC cells was verified by mir-345-5p overexpression.

RESULTS

18β-GRA could inhibit GC cells viability, promote cell apoptosis, block cell cycle, reduce cell wound healing ability, and inhibit the GC cells growth *in vivo*. MDC staining results showed that 18β-GRA could promote autophagy in GC cells. By TMT proteomic analysis and miRNAs transcriptome analysis, it was concluded that 18β-GRA could down-regulate TGM2 expression and up-regulate miR-345-5p expression in GC cells. Subsequently, we verified that TGM2 is the target of miR-345-5p, and that overexpression of miR-345-5p significantly inhibited the protein expression level of TGM2. Western blot showed that the expression of autophagy-related proteins of TGM2 and p62 was significantly reduced, and LC3II, ULK1 and AMPK expression was significantly increased in GC cells treated with 18β-GRA. Overexpression of miR-345-5p not only inhibited the expression of TGM2, but also inhibited the proliferation of GC cells by promoting cell apoptosis and arresting cell cycle.

CONCLUSION

18β-GRA inhibits the proliferation of GC cells and promotes autophagy by regulating the miR-345-5p/TGM2 signaling pathway.

Core Tip: Gastric cancer (GC) is a global health problem that seriously endangers human life, so it is urgent to find drugs to treat it. 18β-glycyrrhetinic acid (18β-GRA), as one of the main components of glycyrrhiza, has a strong antitumor effect. In this paper, the inhibitory effect of 18β-GRA on GC was verified by *in vitro* and *in vivo* experiments. In addition, it was found that 18β-GRA promoted autophagy and inhibited the proliferation of GC cells through the miR-345-5p/TGM2 signaling pathway. These findings provide the theoretical basis for the GC clinical treatment of 18β-GRA.

INTRODUCTION

The fourth most common cause of cancer-related death worldwide is gastric cancer (GC)[1]. Environment, diet, genetic factors, and *Helicobacter pylori* infection are the main causes of GC. Because there are no specific diagnostic indicators, the majority of patients ignore their early symptoms because they are inconspicuous. By the time the body shows obvious discomfort, the disease has progressed to intermediate or advanced cancer, and the disease has worsened significantly, allowing the best opportunity for treatment to pass. The existing treatment methods for GC are mainly drug therapy, chemotherapy and surgery[2,3]. But the drug resistance and toxic side effects of anticancer drugs, the low compliance of patients during chemotherapy and the low survival rate after surgery all suggest that we can find a natural, effective and low-toxic active ingredient to treat GC.

18β-glycyrrhetinic acid (18β-GRA) is a compound extracted from licorice[4]. Studies have revealed that 18β-GRA has multiple pharmacological effects, like anti-inflammatory, anti-viral, anti-tumor, liver protection and so on[5-9]. In recent years, the therapeutic effect of 18β-GRA on lung cancer[7], breast

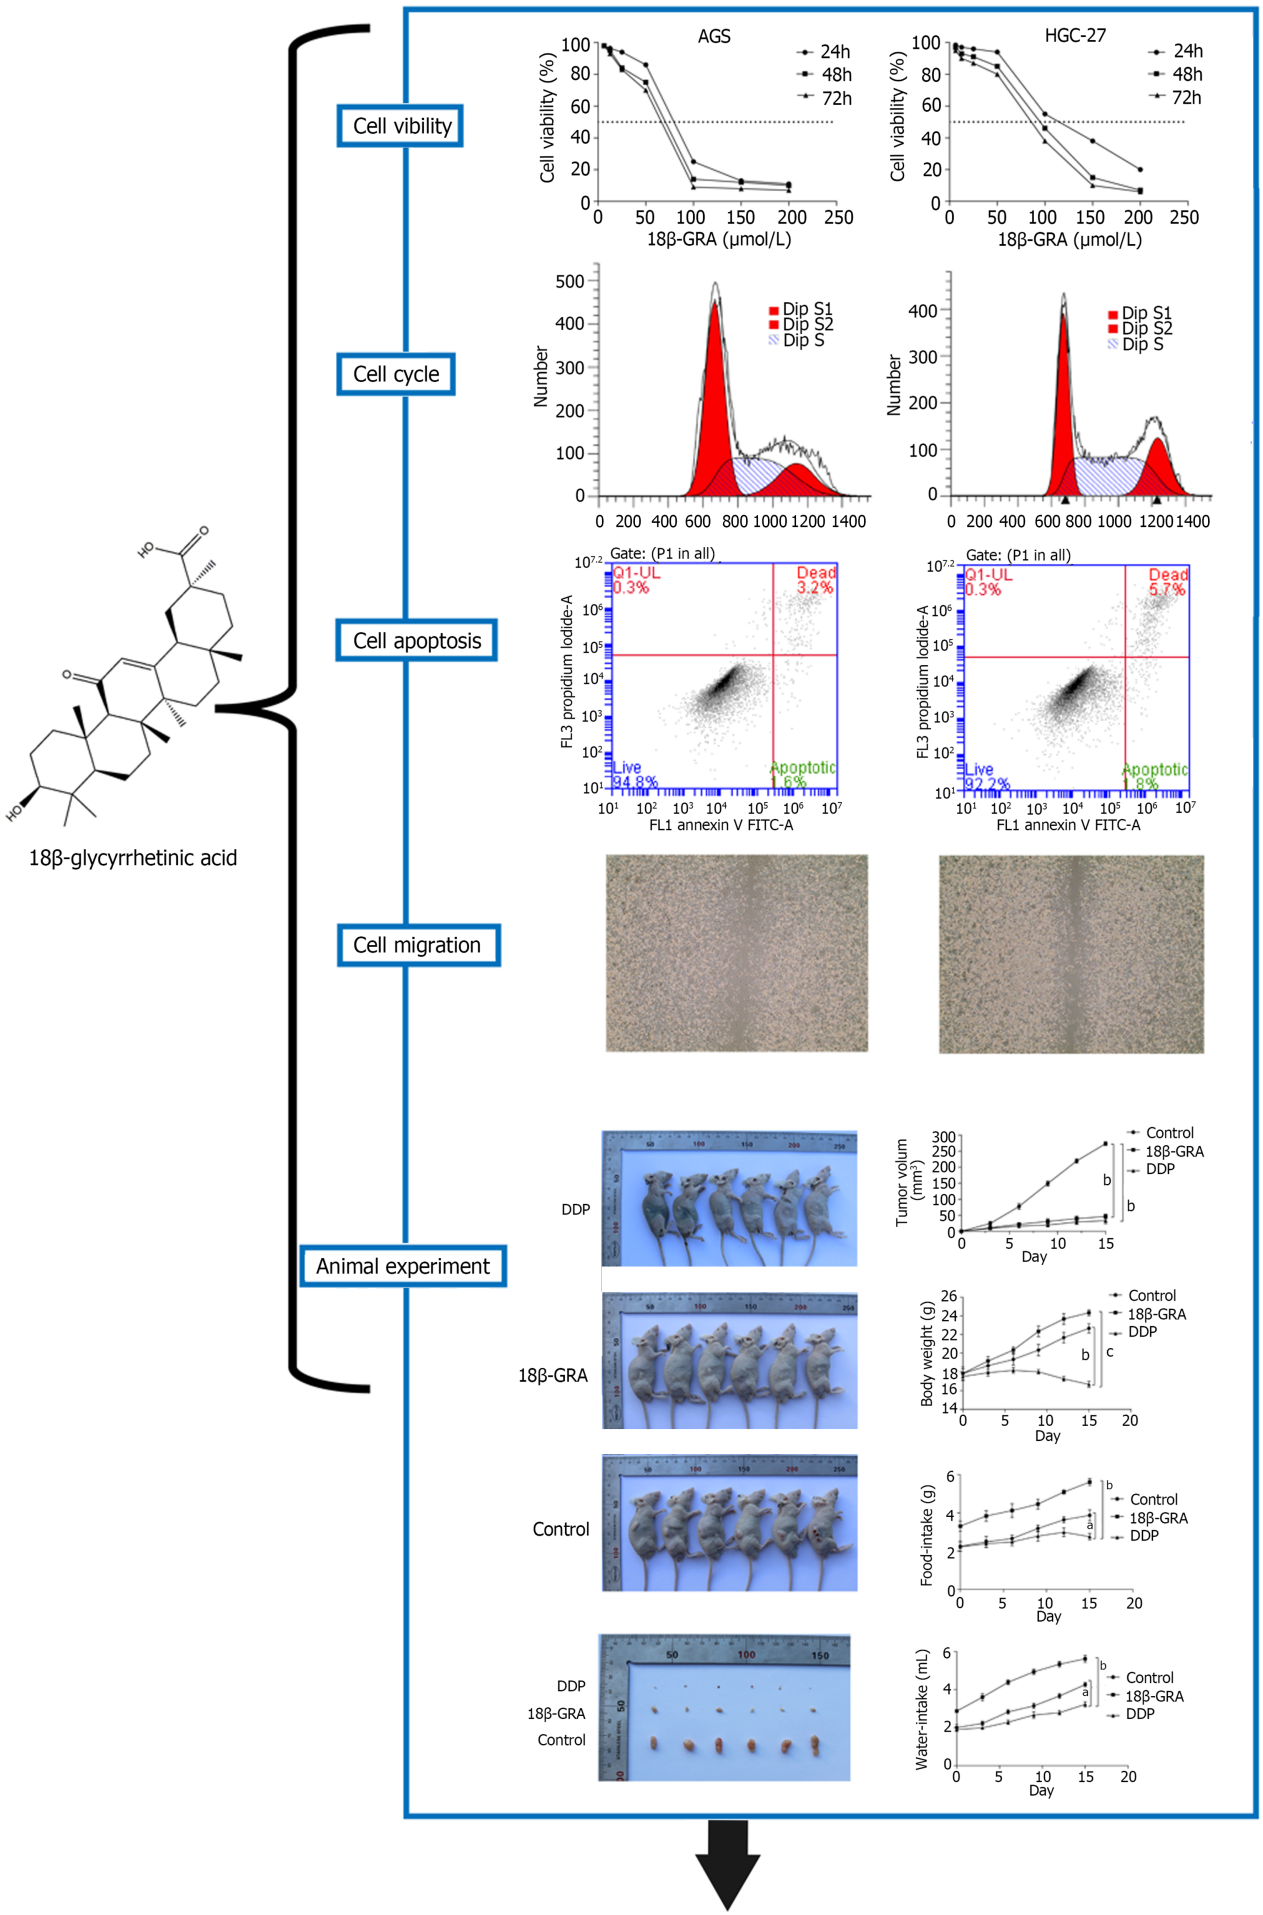
cancer[10], ovarian cancer[11], prostate cancer[12] and other cancers has been confirmed. Cao *et al*[13] revealed that 18β-GRA inhibited GC cells proliferation, energy metabolism and carcinogenesis by down-regulating toll-like receptor 2. Through reactive oxygen species/protein kinase C-α/extracellular signal-regulated kinase pathway, as well as matrix metalloproteinase MMP2 and MMP9 activity, 18β-GRA inhibited GC cells migration and invasion[14]. And our previous study found that 18β-GRA inhibited GC cells proliferation by regulating MRPL35[15]. These results indicated that 18β-GRA may be a useful drug for the prevention and treatment of GC.

MicroRNAs (miRNAs) are highly conserved non-coding RNA molecules, that take part in the occurrence and development of cancer[16]. Many sequences of human miRNAs associated with cancer mechanisms have been identified. They regulate protein expression levels by their target mRNA, and participate in vital cellular processes and pathways[17]. There is growing evidence that the difference in miRNAs expression exists not only between normal and cancer tissues and between different cancer types and subtypes, but also between early and advanced cancers[18,19]. Komatsu *et al*[20] found that up-regulation of miR-148a inhibited the GC cells proliferation, invasion and EMT. The researchers revealed that *Helicobacter pylori* infection reduced miR-1298-5p expression in GC cells, while low-expressed miR-1298-5p could promote GC cells proliferation, migration and invasion[21].

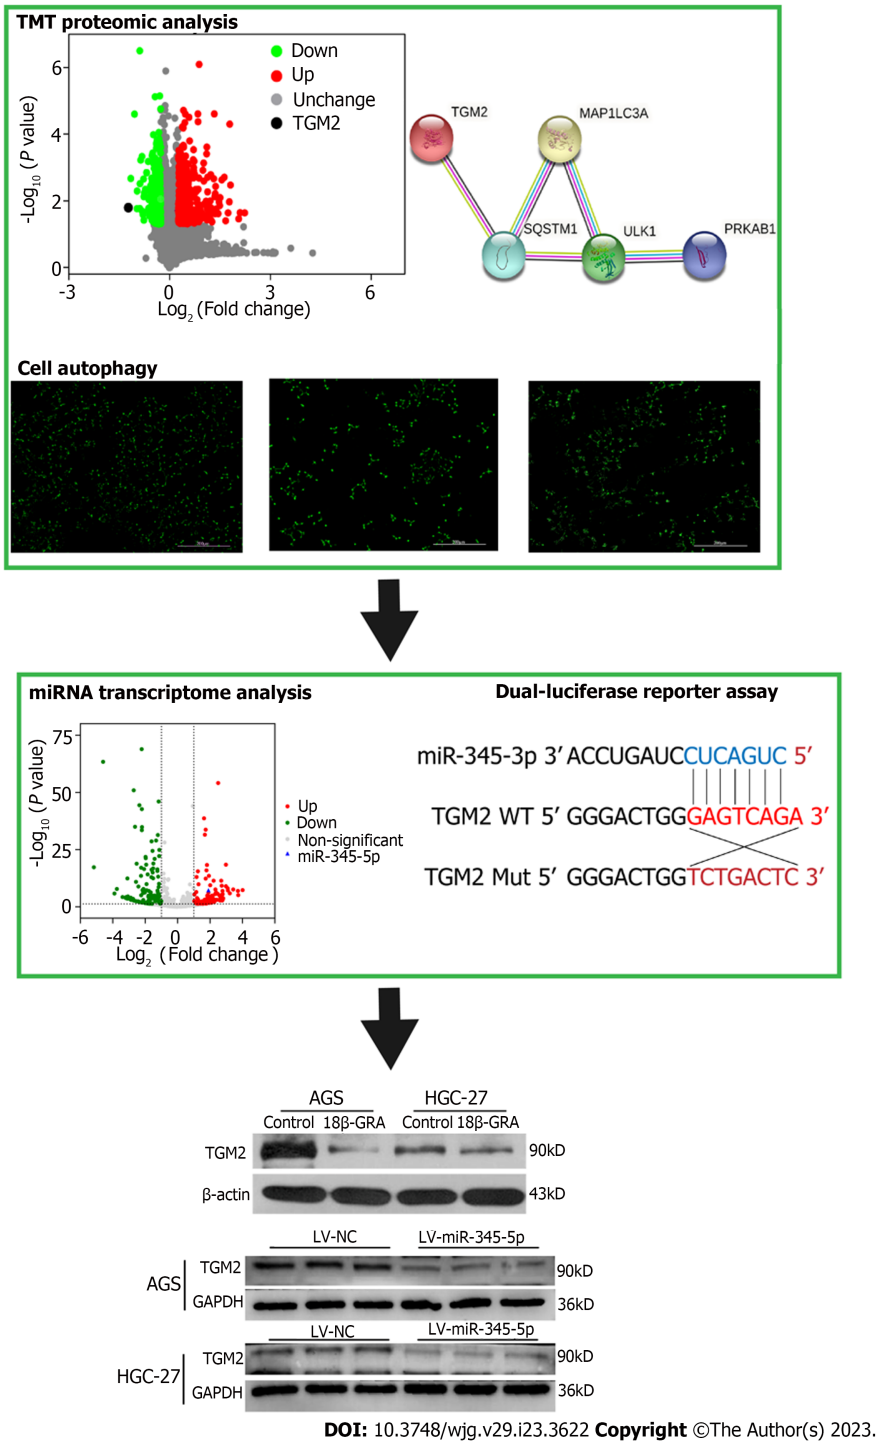
Autophagy is a biological process that occurs in cells[22]. A lot of research has found that it plays a key role in physiological processes and disease occurrences, including development, metabolism, inflammation and cancer[23]. Dysfunctional autophagy results in incorrect organelles and protein breakdown, which kill autophagic cells and affect tumor cell survival. Wei *et al*[24] revealed that miR-183 induced GC cells autophagy and inhibited proliferation *via* targeted inhibition of mechanistic target of rapamycin (mTOR) expression.

In our study, we revealed 18β-GRA's effect on GC cells phenotype and tumor formation in nude mice, and 18β-GRA's effect on GC cells autophagy. We used TMT proteomic analysis and the STRING database to predict the differentially expressed autophagy-related proteins and their interactions. The differentially expressed miRNAs were analyzed using miRNAs transcriptome analysis, and the corresponding miRNAs and complementary binding sites of autophagy-related proteins were predicted using the miRBase and TargetScan databases. Later, we verified the link between miR-345-5p and TGM2 using a dual-luciferase reporter assay. Quantitative real-time polymerase chain reaction (qRT-PCR) was used to detect expression of miR-345-5p, western blot was used to detect autophagy-related proteins, and lentivirus transfection technique verified the effect of miR-345-5p on TGM2. We concluded that 18β-GRA can inhibit GC cells proliferation and promote autophagy *via* regulating the miR-345-5p/TGM2 signaling pathway, which may afford a theoretical basis for GC treatment with 18β-GRA. The research idea is shown in Figure 1.

MATERIALS AND METHODS



Experimental materials



Human gastric epithelial cell GES-1 was purchased from BNCC (Cat. No. BNCC353464, Beijing, China). Human GC cell lines AGS, HGC-27 and MKN-45 were purchased from Procell (Cat. No. CL-0022/CL-0107/CL-0292, Wuhan, China). Fetal bovine serum (FBS) was purchased from Corning (Cat. No. 35-076-CV, United States). DMEM, DMEM/F-12 and RPIM-1640 mediums were purchased from Gibco. The dual-luciferase reporter assay system was purchased from Promega (United States). Shanghai Gene Biotechnology Co., Ltd. (China) provided the plasmid and lentiviral expression vector. The MDC kit, cell apoptosis kit and cell cycle kit (Cat. No. KGATG001/KGA1026/KGA512, Jiangsu, China) were purchased from Jiangsu KeyGEN Bio TECH Corp., Ltd. TaKaRa provided the PrimeScript™ RT reagent kit and TB Green Premix Ex Taq II (Cat. No. RR047A/RR82LR, Japan). Thermofisher provided Trizol. MedChemExpress provided cisplatin (DDP) and 18β-GRA (Cat. No. HY17394/HY-N0180, United States). Immunoway provided TGM2, AMPK, p62, ULK1, LC3I/II, GAPDH and β-actin antibodies, while CST provided anti-mouse/rabbit immunoglobulin G antibodies.

BABL/c nude mice (male, 18-22g, SPF) were provided by the Animal Laboratory Center of Ningxia Medical University. All animals were fed standard laboratory feed and water in 12 h light/dark cycle environment. The animal protocols (IACUC-NYLAC-2022-108) were approved by the Institutional Animal Care and Use Committee of Ningxia Medical University. All animals were euthanized by CO_2.

Cell culture and cell transfection

GES-1 cells were cultured in DMEM medium, HGC-27 cells were cultured in RPIM-1640 medium, and AGS and MKN-45 cells were cultured in DMEM/F-12 medium, and 10% FBS and 1% penicillin-streptomycin liquid were added into all mediums to. The cell culture flask was placed in an incubator with a constant temperature of 37 °C and 5% CO_2. The GFP-labeled miR-345-5p overexpression lentiviral vector (LV-miR-345-5p) and empty lentiviral vector (LV-NC) were then transfected into HGC-27 and AGS cells using the tool virus user manual as a guide.

Figure 1 Flow chart. In this study, we revealed 18β-glycyrrhetinic acid (18β-GRA)'s effect on gastric cancer (GC) cells phenotype and tumor formation in nude mice, and 18β-GRA's effect on GC cells autophagy. We used TMT proteomic analysis and the STRING database to predict the differentially expressed autophagy-related proteins and their interactions. Later, we verified the link between miR-345-5p and TGM2 using a dual-luciferase reporter assay. Quantitative real-time polymerase chain reaction was used to detect expression of miR-345-5p, western blot was used to detect autophagy-related proteins, and lentivirus transfection technique verified the effect of miR-345-5p on TGM2. LV-NC: Empty lentiviral vector.

Cell viability assay

The cells were inoculated into 96-well plates at 4000 cells per well and treated with 18β-GRA (12.5 μmol/L-200 μmol/L) for 24 h, 48 h and 72 h. Next, 10 μL CCK-8 was added to each well, and the absorbance was detected at 450 nm.

Cell cycle and cell apoptosis assay

The cells were treated with 18β-GRA at concentrations of 30, 60 and 120 μmol/L or 45, 90 and 135 μmol/L for 48 h, respectively. Next, the cells were collected and fixed with 70% pre-cooled ethanol. The fixative solution was washed off with PBS. 500 μL pre-configured working solution (RNase A:PI = 1:9)

was added. The percentage of cell cycle was determined by flow cytometry after 30 min. The cells in each group were collected, 500 μL binding buffer, 5 μL Annexin V-FITC and 5 μL PI or 500 μL binding buffer, 5 μL Annexin V-APC and 5 μL 7-AAD were added and mixed. Cell apoptosis was determined after 15 min using flow cytometry.

Wound healing assay

The cells were inoculated into the 6-well plates at the appropriate concentration and cultured for 24 h. Next, we made a scratch in the central part of each hole, and 18β-GRA at concentrations of 30, 60, 120 μmol/L or 45, 90, 135 μmol/L was added for 48 h. Finally, the cells were washed and photographed with a microscope. Cell migration area was calculated by Image J.

MDC staining assay

The cells were treated with 18β-GRA at concentrations of 30, 60 and 120 μmol/L or 45, 90 and 135 μmol/L for 48 h, respectively. Next, the cells were gently washed twice with a wash buffer, stained with MDC and incubated away from light for 15-45 min. Photographs were taken under a fluorescence microscope after washing twice with 1 × wash buffer.

Tumor formation experiment in BALB/c nude mice

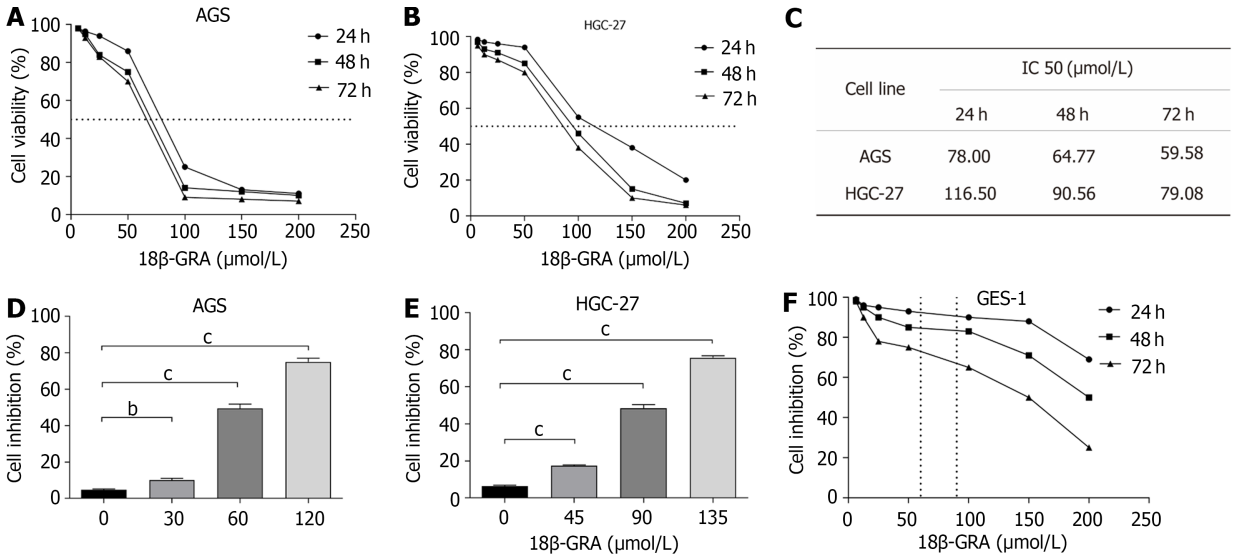
The BALB/c nude mice were fed for 1 wk, then 200 μL MKN-45 cells suspension containing 4×10^6 cells were inoculated subcutaneously into nude mice using a microsyringe. The experiment was divided into three groups: Control, cisplatin group (DDP) and 18β-GRA groups. After 5 d of subcutaneous inoculation, the 18β-GRA group was intraperitoneally injected with 50 mg/kg[13,25], the DDP group with 2 mg/kg[26], and the control group was given normal saline. $V = (L \times W^2)/2$ was used to calculate tumor volumes (V, volume; W, width; L, length). After 14 d of continuous administration, all nude mice were killed by CO_2 inhalation and photographed.

TMT proteomic analysis

GC cells were treated with 18β-GRA, and differentially expressed proteins were detected and analyzed by China Gene Biotechnology Co., Ltd. All the obtained original data files were processed by Proteome Discoverer 2.2 (Thermo Fisher, United States) software. Proteins with expression ratio > 1.2 and $P < 0.05$ were considered as differentially expressed proteins.

Cellular processes, biological processes, and molecular functions of differentially expressed proteins were analyzed using Metascape (https://metascape.org/gp/index.html#/main/step1). Gene Ontology annotation, Kyoto Encyclopedia of Genes and Genomes pathway, and InterPro domain enrichment analysis were performed using Fisher accuracy test. WoLFPSOR was used to locate and predict the differentially expressed proteins. The protein expression levels are classified by Matplotlib to form hierarchical clustering heatmaps.

miRNAs transcriptome analysis



GC cells were treated with 18β-GRA at concentrations of 60 μmol/L and total RNA was extracted from it. Agarose gel electrophoresis, Nanodrop, Qubit 2.0, and Agilent 2100 were used to ensure that the quality of the collected RNA met the requirements of subsequent experiments. A small RNA Sample Pre kit was used to construct the library, and specific enzymes were used to connect the PCR primer connectors at the 3′ and 5′ ends. Then the cDNA synthesis can be completed efficiently and rapidly by reverse transcription. The single strand of DNA is combined with the primer and the PCR amplification stage begins. After PAGE electrophoresis, a cDNA library (effective concentration > 2 nM) was obtained. Qubit 2.0 and Agilent 2100 were combined with qPCR to ensure the quality of the library. The optical signal was transformed into a sequence by computer analysis. The original sequencing data was further assessed for quality with $P < 0.05$ and $|\text{Log}_2 \text{(fold change)}| > 1$ as a filter condition, with a certain number of differential expressions of miRNAs eventually selected.

Target prediction analysis

We predicted protein-protein interaction (PPI) networks from the STRING database (https://string-db.org/). The miRBase website (http://www.mirbase.org/) was used to predict the corresponding miRNAs of autophagy-related proteins and the TargetScan database (https://www.targetscan.org/) was used to predict the binding sites of miRNA and mRNA.

Dual-luciferase reporter assay

TargetScan predicted the binding sites for miR-345-5p and TGM2. The fragments, including the wild 3′UTR regions or mutant 3′UTR regions of TGM2, were inserted into GV716 with a firefly and renilla luciferase reporter gene. The overexpressed miR-345-5p plasmid was then individually transfected into AGS cells. After 48 h of transfection, the relative luciferase activity was detected using a dual-luciferase reporter assay system.

Figure 2 Effect of 18β-glycyrrhetinic acid on cell viability of GES-1, AGS and HGC-27 cells were detected by CCK-8 assay. A: Effect of 18β-glycyrrhetinic acid (18β-GRA) on cell viability of AGS cells; B: Effect of 18β-GRA on cell viability of HGC-27 cells; C: IC_{50} value of AGS and HGC-27 cells were treated with 18β-GRA for 24, 48 and 72 h; D: Effect of low, medium and high doses of 18β-GRA on cell viability of AGS cells; E: Effect of low, medium and high doses of 18β-GRA on cell viability of HGC-27 cells; F: Effect of 18β-GRA on cell viability of GES-1 cells. All data are from three independent samples. The data is represented as the mean ± SD. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$. 18β-GRA: 18β-glycyrrhetinic acid.

qRT-PCR

The cells were cultured and treated 18β-GRA at concentrations of 30, 60 and 120 μmol/L or 45, 90 and 135 μmol/L for 48 h, respectively. Total RNA was extracted using Trizol, and cDNA was synthesized using PrimeScript™ RT reagent kit. The expression level was detected with TB Green Premix Ex Taq II. The primer sequences are as follows: miR-345-5p, forward, 5′-GCTGACTCCTAGTCCAGGGCTC-3′ and reverse, 5′-GGCCAACCGCGAGAAGATG-3′; U6, forward, 5′-CTGCGCAAGGATGACACGCAAATT-3′ and reverse, 5′-GGCCAACCGCGAGAAGATG-3′. U6 as a housekeeping gene. The relative expression was calculated by the $2^{-\Delta\Delta Ct}$ method.

Western blot

The cells were cultured and treated 18β-GRA at concentrations of 60 μmol/L or 90 μmol/L for 48 h, respectively. The cells were collected and the total protein was extracted, the protein content was detected with BCA method. The protein was isolated and transferred onto a PVDF membrane, which is then sealed with 5% skim milk powder, soaked in primary antibodies and incubated overnight. The next day, the PVDF membrane was cleaned with TBST and soaked in secondary antibodies for 2 h. The protein was detected using an ECL solution, and ultimately the grey values were measured using ImageJ.

Statistical analysis

The statistical methods of this study were reviewed by Li-Qun Wang, Department of Epidemiology and Medical Statistics, Institute of Public Health and Management, Ningxia Medical University. All data were statistically analyzed using GraphPad Prism 7. All data were shown as mean ± SD, and the differences between different groups were analyzed using a one-way ANOVA or *t*-test. The significance level was set at $P < 0.05$.

RESULTS

18β-GRA reduced the GC cells viability

The results demonstrated that when the 18β-GRA concentration was 12.5 μmol/L-200 μmol/L, the inhibitory effect of 18β-GRA on AGS and HGC-27 cells viability was enhanced as the 18β-GRA dose was increased (Figures 2A and B). Next, 18β-GRA treated AGS and HGC-27 cells for 24 h, 48 h and 72 h, IC_{50} value was shown in Figure 2C. Therefore, we determined that the low, medium and high concentrations of 18β-GRA treated AGS cells for 48 h were 30, 60 and 120 μmol /L, and the low, medium and high concentrations of 18β-GRA treated HGC-27 cells for 48 h were 45, 90 and 135 μmol/L. AGS and HGC-27 cells viability was inhibited at low, medium and high doses of 18β-GRA when compared with the

control group (0 μmol/L) ($P < 0.01$) (Figures 2D and E).

18β-GRA had slight effect on normal gastric epithelial GES-1 cells

Subsequently, we investigated 18β-GRA's effect on GES-1 cells viability. The results demonstrated that GES-1 cells viability was slightly affected when 18β-GRA concentration was 12.5 μmol/L-100 μmol/L (Figure 2F). When the 18β-GRA concentration was less than 150 μmol/L, the GES-1 cells viability remained above 71% at 48 h.

18β-GRA arrested GC cells cycle

18β-GRA's effect on GC cells cycle results demonstrated that the percentage of G0/G1 phase (49.15%, 56.23% and 73.07%) in AGS cells treated with low, medium and high doses of 18β-GRA was higher than the control group (33.71%) (Figures 3A and B). The percentage of G0/G1 phase (46.58%, 51.69% and 77.11%) in HGC-27 cells treated with low, medium and high doses of 18β-GRA was higher than the control group (41.67%) (Figures 3C and D).

18β-GRA promoted GC cells apoptosis

18β-GRA's effect on GC cells apoptosis results demonstrated that the apoptosis rates of AGS cells treated with low, medium and high doses of 18β-GRA were 7.50%, 19.80% and 72. 00%, which were obviously higher than the control group (4. 80%) ($P < 0.01$) (Figures 3E and F). The apoptosis rates of HGC-27 cells treated with low, medium and high doses of 18β-GRA were 6.50%, 8.10% and 15.40%, which were obviously higher than the control group (6.40%) ($P < 0.05$) (Figures 3G-H).

18β-GRA inhibited the GC cells wound healing

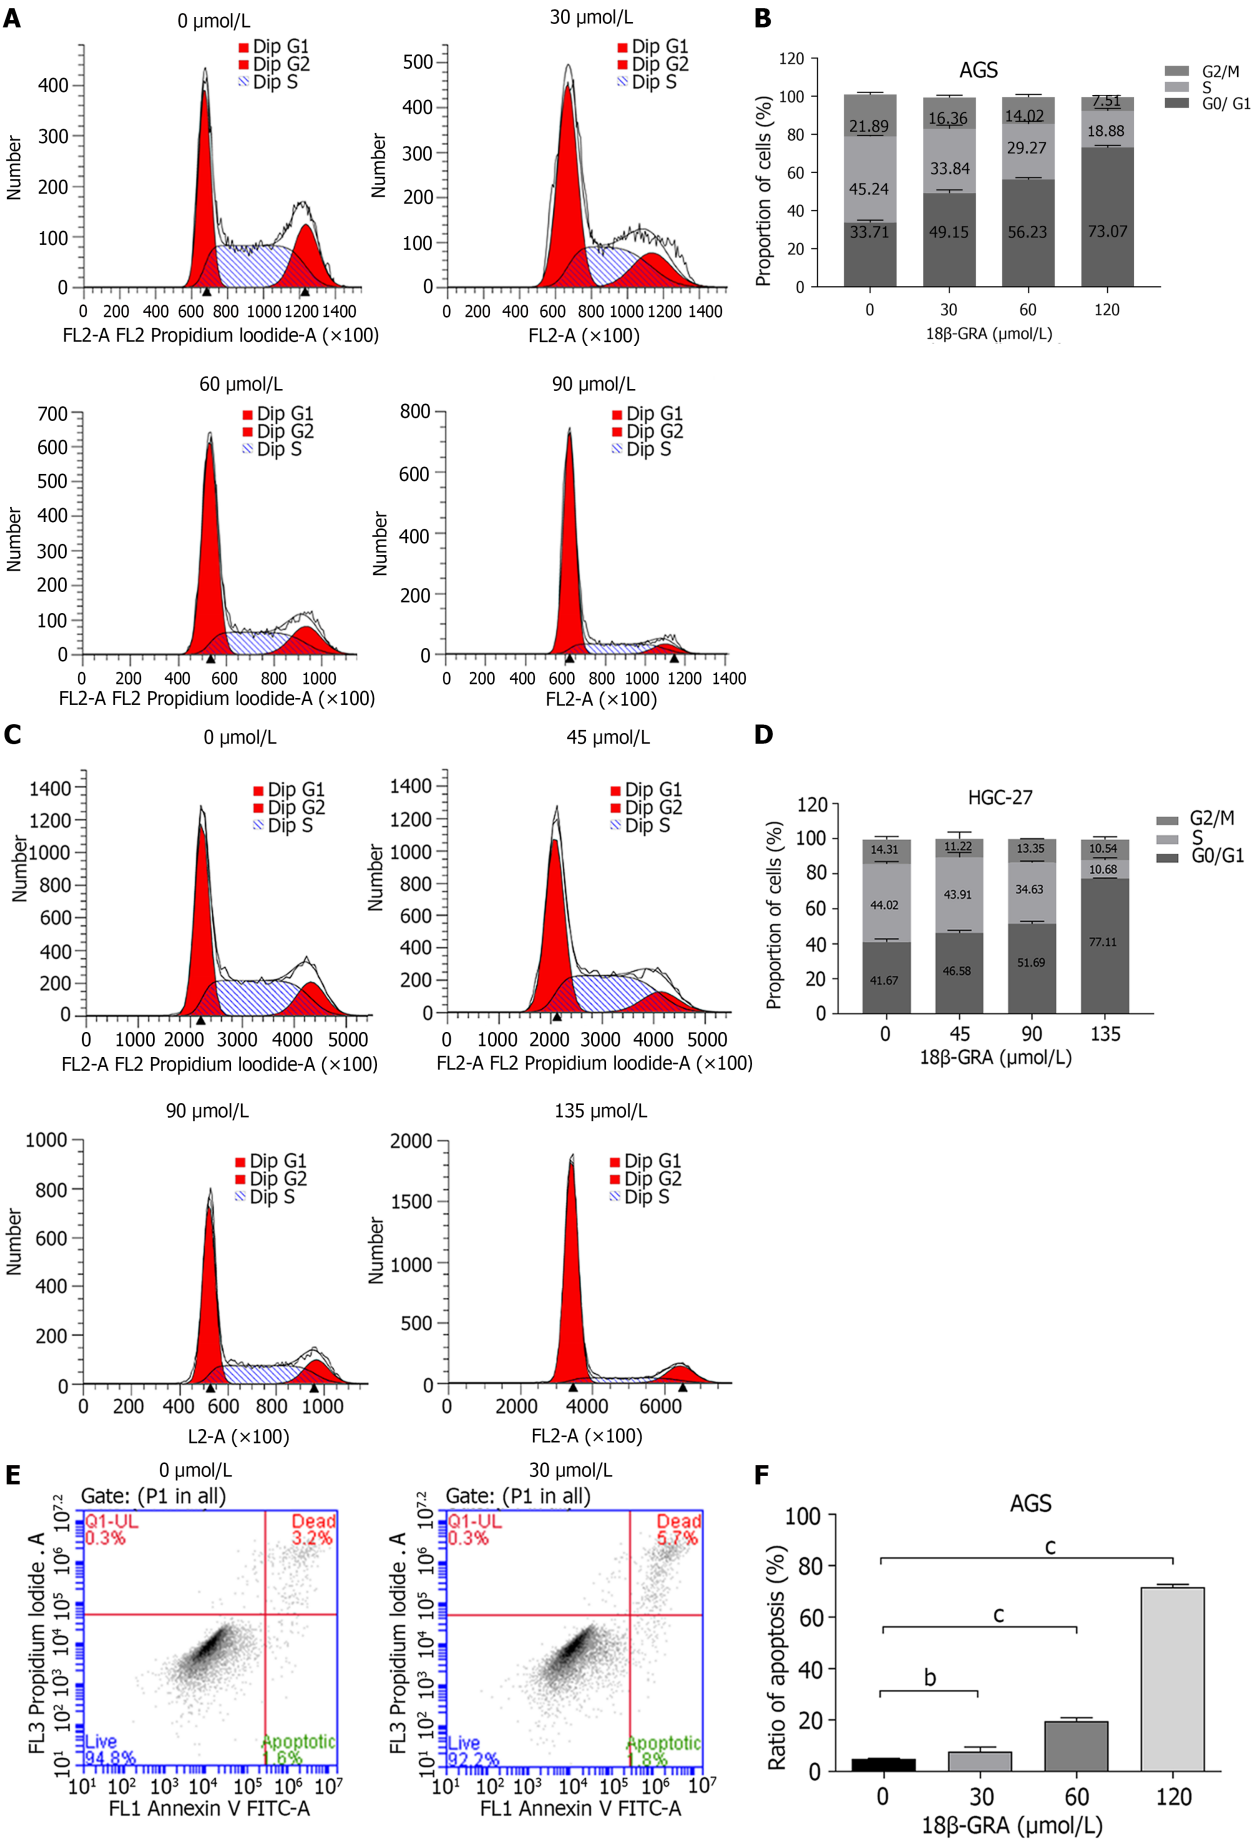
The wound healing assay revealed that both high and medium doses of 18β-GRA can inhibit AGS and HGC-27 cells' wound healing abilities ($P < 0.001$) (Figures 4A-D). The inhibitory effect of 18β-GRA on wound healing ability was gradually enhanced as the 18β-GRA dose was increased in AGS and HGC-27 cells.

18β-GRA inhibited subcutaneous tumor growth in BALB/c nude mice

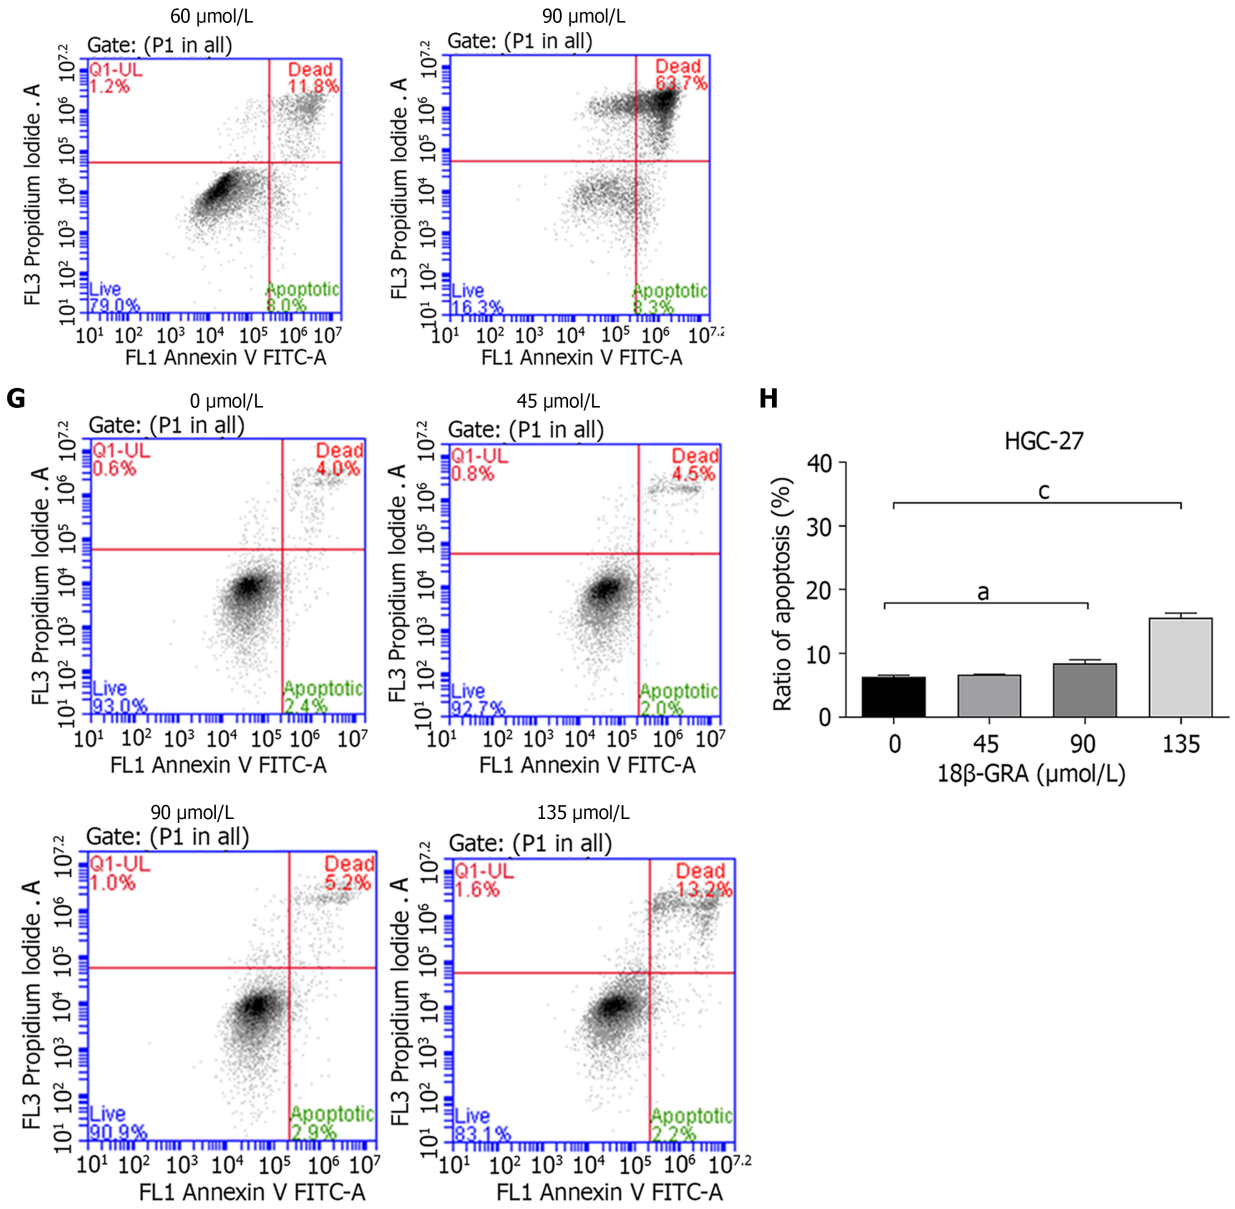
Through the subcutaneous tumor formation experiment in BALB/c nude mice, we observed that the back tumors in the control group were larger than those in the DDP and 18β-GRA groups ($P < 0.01$) (Figures 5A and B). The tumor volume was measured every 3 d and the tumor growth curve was plotted. In comparison to the control group, tumor size and growth rate were slower in the 18β-GRA and DDP groups ($P < 0.001$) (Figure 5C). Additionally, the body weight of DDP group was lower than the control and 18β-GRA groups. Diet and water intake were lower in the 18β-GRA and DDP groups when compared with the control group ($P < 0.05$) (Figures 5D-F).

Identification of autophagy-related proteins by TMT proteomic analysis and MDC staining assay

Part of the data of TMT proteomics analysis comes from the previous research of our team (Figures 6A-F)[15]. Cluster analysis was performed for differential proteins and heat map was drawn (Figure 6G), and the expression of TGM2 was down-regulated ($P = 0.01593178$). We used the STRING database to construct the PPI network, and the interaction diagram between the differentially expressed autophagy-related protein TGM2 and the autophagy marker proteins ULK1, p62 (SQSTM1), LC3I/II (MAPILC3) and AMPK (PRKAB1) was shown in Figure 6H, which indicated TGM2 was closely related to autophagy marker proteins. The results of MDC staining showed that AGS and HGC-27 cells displayed various degrees of autophagy after 18β-GRA intervention, and the number of autophagy cells increased as the dose of 18β-GRA was increased ($P < 0.05$) (Figures 6I-L).



Effect of 18β-GRA on the expression of autophagy-related proteins



Western blot analysis was used to determine 18β-GRA's influence on autophagy-related proteins in the AGS and HGC-27 cells. The findings demonstrated that, in contrast to the control group, the 18β-GRA group's protein expressions of TGM2 and p62 were lowered, whereas LC3II, ULK1 and AMPK were elevated ($P < 0.01$) (Figures 7A-E).

MiR-345-5p is a drug target of 18β-GRA

283 miRNAs were identified as differentially expressed by miRNAs transcriptome analysis, of which 163 miRNAs were down-regulated and 120 miRNAs were up-regulated, and the selection criteria for $|\text{Log}_2(\text{fold change})| > 1$, $P < 0.05$. Among them, the expression of miR-345-5p was up-regulated ($P =$ 5.68E-08) (Figure 8A). The miRBase website was used to predict the corresponding miRNAs of autophagy-related proteins, and then we intersected the miRNAs corresponding to autophagy-related proteins with the differentially expressed miRNAs screened by miRNA transcriptome. Among the obtained miRNAs, miR-345-5p was expressed most significantly.

We used qRT-PCR to determine the expression changes of miR-345-5p in AGS and HGC-27 cells treated with 18β-GRA. The outcomes demonstrated that miR-345-5p was highly up-regulated in AGS

and HGC-27 cells after 18β-GRA treatment ($P < 0.01$) (Figures B and 8C). This verified the results of miRNAs transcriptome.

MiR-345-5p could target TGM2 directly

We utilized TargetScan database to identify complementary binding sites between miR-345-5p and TGM2 (Figure 8D). According to dual-luciferase reporter analyses, overexpression of miR-345-5p reduced luciferase expression in the TGM2-wild-type reporter but not in the mutant reporter ($P < 0.05$) (Figure 8E). These results suggest that miR-345-5p can regulate the expression of TGM2.

Overexpression of miR-345-5p can inhibit TGM2

Lentivirus transfection technique caused miR-345-5p overexpression on AGS and HGC-27 cells, and the transfection rate reached about 90% after 72 h (Figure 9A). Then, qRT-PCR discovered that miR-345-5p expression in the LV-miR-345-5p group was higher compared to the LV-NC group on AGS and HGC-27 cells ($P < 0.001$) (Figure 9B). Meanwhile, overexpression of miR-345-5p inhibited the protein expression of TGM2 ($P < 0.01$) (Figures 9C and D).

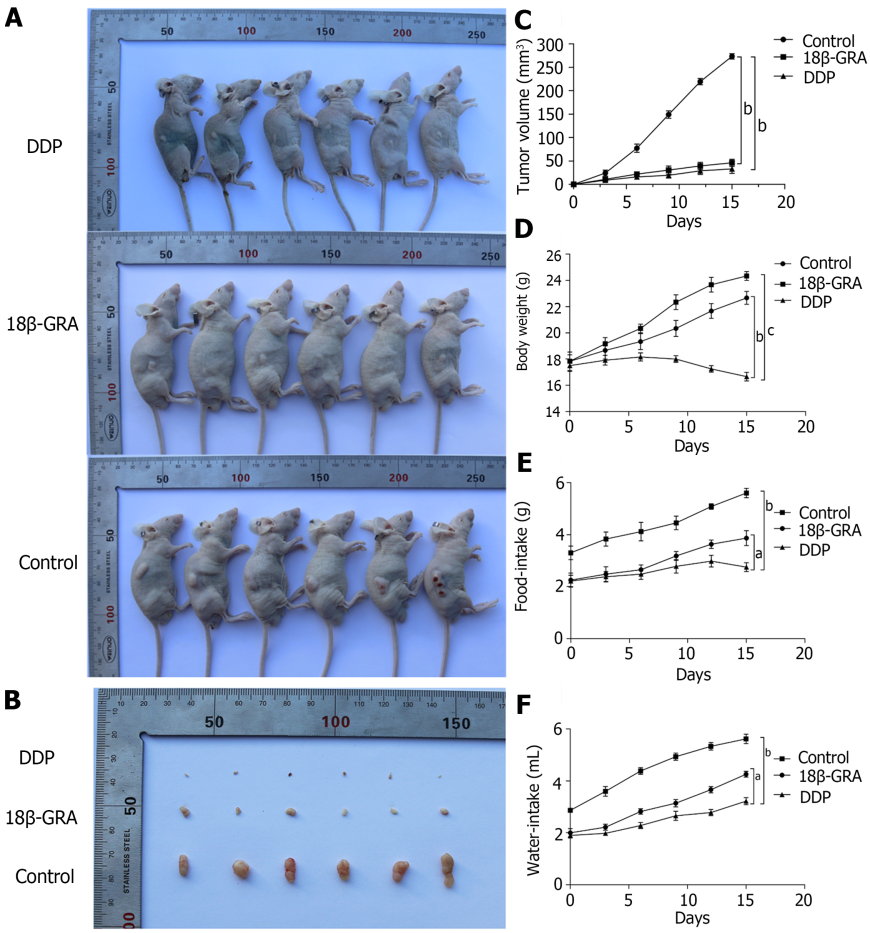
Overexpression of miR-345-5p inhibit GC cells proliferation by promoting cell apoptosis and arresting cell cycle



Some researchers found that the expression of miR-345-5p in GC tissues was significantly lower than that in para-carcinoma tissue. which was correlated with aggressive stage and grade[27]. We evaluated the impact of miR-345-5p overexpression on cell viability in GC cells through CCK-8 assay. Our findings indicated that miR-345-5p overexpression resulted in a significant inhibition of the cell viability on AGS and HGC-27 cells (P < 0.01) (Figures 10A and B).

In order to further investigate the impart of miR-345-5p overexpression on GC cells, we conducted flow cytometry analysis to examine its effect on cell apoptosis and cell cycle. Our results showed the cell apoptosis rates in the miR-345-5p overexpression group were significantly higher than that in the LV-NC group on AGS and HGC-27 cells (P < 0.001) (Figures 10C and D). Moreover, the cell cycle experiment revealed that miR-345-5p overexpression caused cell cycle arrest in the G0/G1 phase on AGS and HGC-27 cells (P < 0.001) (Figures 10E and F). These results suggested that miR-345-5p overexpression could inhibit GC cells proliferation by promoting cell apoptosis and arresting cell cycle.

DISCUSSION

In this study, 18β-GRA treated GC cells phenotypic alterations were identified *in vitro*. The findings demonstrated that 18β-GRA had a minimal effect on the survival rate of normal gastric epithelial GES-1 cells, but dramatically reduced the AGS and HGC-27 cells viability. Next, we found that 18β-GRA could block the AGS and HGC-27 cells in G0/G1 phase and promote cell apoptosis. Both DNA replication and mitosis crucially depend on the G0/G1 phase. According to studies, after drug intervention, cells can either irreversibly end the cell cycle through senescence or apoptosis[28], or they can reversibly exit the cell cycle by beginning immobilization. We looked at how 18β-GRA affected the GC cells apoptosis and verified the results of cell cycle, which led us to conclude that 18β-GRA made GC cells exit the cell cycle selectively. It has been demonstrated that cells can exit the cell cycle reversibly by initiating immobilization, or irreversibly by senescence or apoptosis. Our findings confirmed the conclusion that 18β-GRA can induce GC cells to exit the cell cycle selectively.

18β-GRA decreased the migration ability of AGS and HGC-27 cells, according to a wound healing assay. At the same time, we also performed cell invasion experiments, but the results were not statistically significant. Studies have shown that TGM2 could promote GC cells' proliferation, migration and invasion by activating extracellular signal-regulated kinase 1/2[29]. In addition, TGM2 was thought to

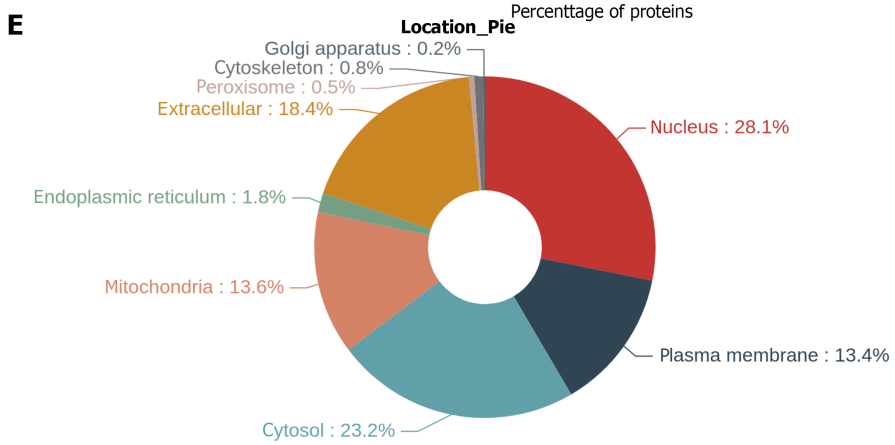
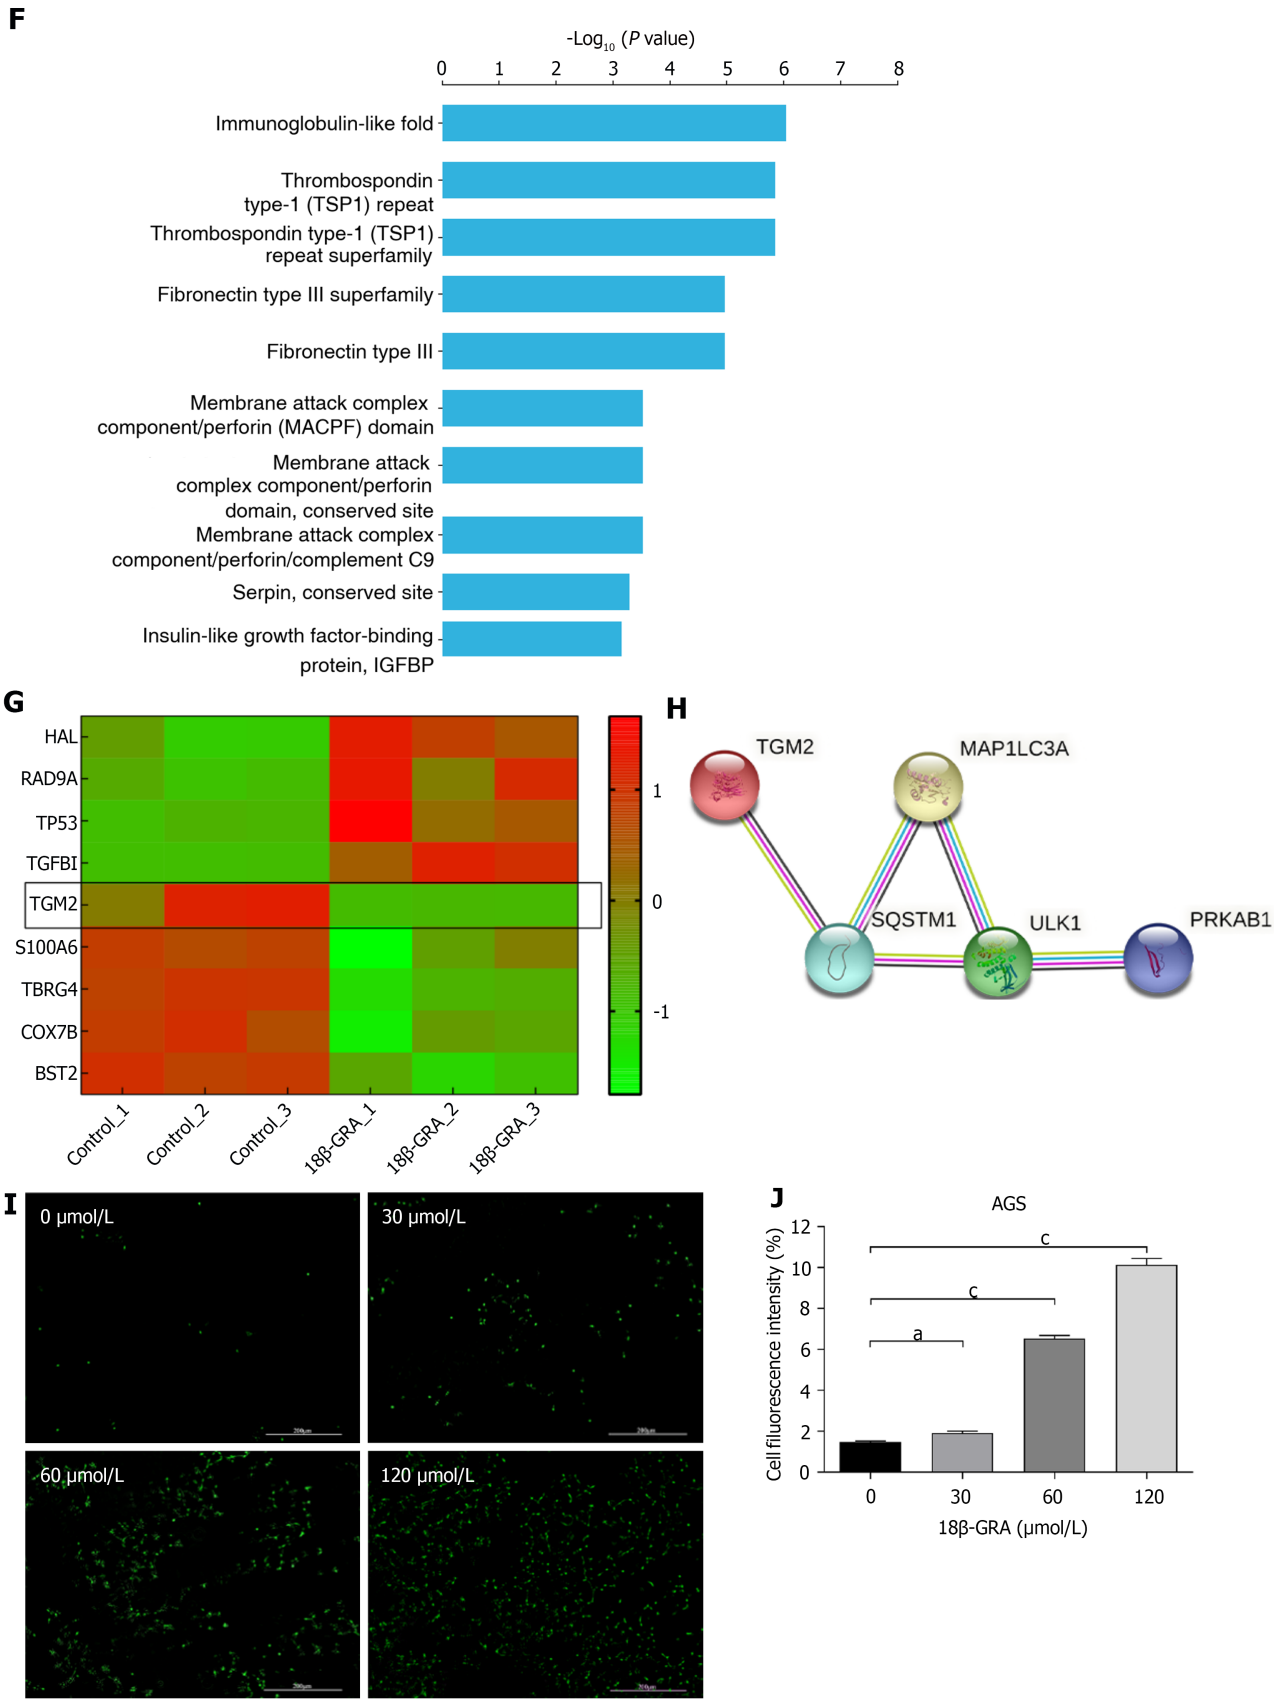
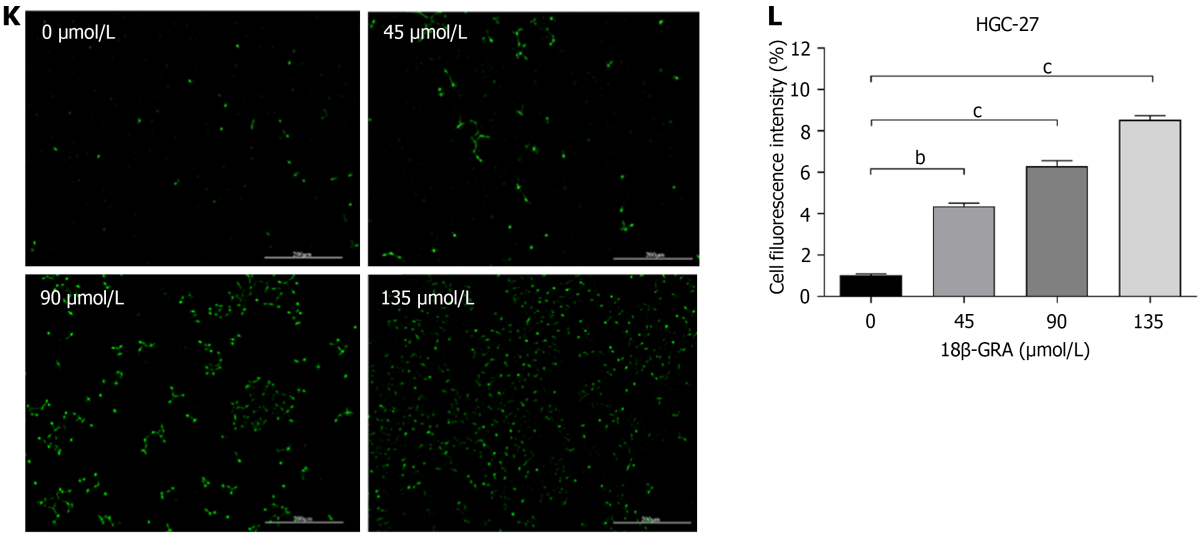
The data is represented as the mean ± SD. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$. 18β-GRA: 18β-glycyrrhetinic acid; DDP: Cisplatin.



be involved in EMT processes in breast cancer[30], colorectal cancer[31], and hepatocellular carcinoma [32], which are highly correlated with invasion phenotypes. These findings imply that TGM2 is involved in cancer cell invasion. In contrast, 18β-GRA had no impact on AGS and HGC-27 cells invasion during our studies.



In vivo tumorigenesis experiment was performed on immunodeficient nude mice. The results showed that 18β-GRA and DDP significantly inhibited the subcutaneous tumor volume in nude mice. At the same time, we monitored the body weight, diet and water intake of nude mice during the experiment. It was found that the body weight of nude mice in the DDP group was lighter than that in 18β-GRA and control groups, showing obvious adverse reactions. On the contrary, the body weight of nude mice in 18 β-GRA group was slightly higher than that in the control group and the nude mice were in good health during the experiment. In terms of diet and water intake, nude mice administered with 18β-GRA and DDP had reduced diet and water intake. Overall, the experimental results demonstrated 18β-GRA had fewer side effects.



We further investigated the mechanism of GC treatment with 18β-GRA. MDC staining results showed that 18β-GRA can promote autophagy of AGS and HGC-27 cells. TMT proteomic analysis and miRNAs transcriptome analysis revealed that TGM2 was the target of miR-345-5p, which was verified by a dual-luciferase reporter assay. The STRING database was used to build the PPI network, and it was found that TGM2 was closely related to autophagy marker proteins ULK1, p62, LC3I/II and AMPK. TGM2 induces autophagy, differentiation and inhibition of angiogenesis, and its role in cancer is very complex. In fact, it has been proven that TGM2 participates in all aspects of cancer progression by activating mTOR[33]. At the beginning phase of autophagy, AMPK promotes autophagy occurrence by directly activating ULK1 or by negatively regulating mTOR to block its inhibition of ULK1[34,35]. After the formation of pre-autophage, it enters the second stage, which is the stage of autophagy extending into nucleus. ULK1 activates p62 and promotes the binding of p62 mediated substrate proteins to autophagic bodies[36]. At the same time, the substrate protein passes through the LC3 domain of p62

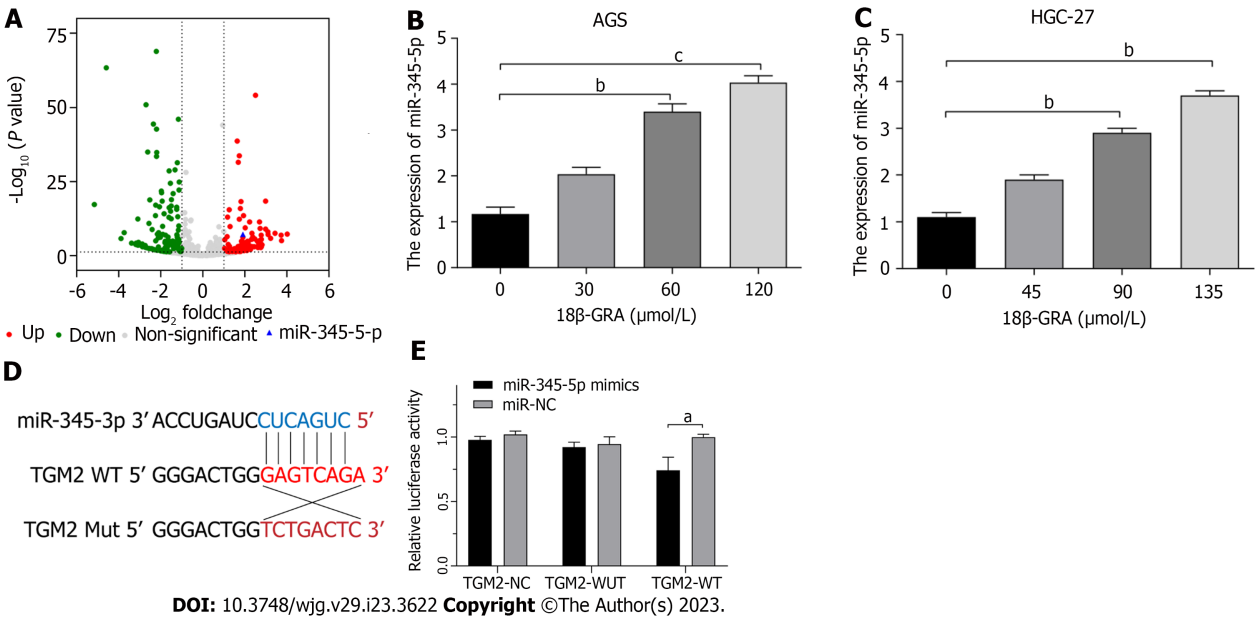
into the degradation phase of the autophagic vesicle, where it interacts with LC3, which is the third stage of autophagy. Thus, when the p62 content decreases, it indicates that autophagic lysosomal degradation is inhibited[37,38]. Therefore, when the content of p62 decreases, it indicates that autophagic lysosome degradation is inhibited. LC3I/II, one of the homologues of ATG8, is located in the cytoplasm. LC3I is formed after exposure to glycine at the carboxyl terminal, which is catalyzed to combine with phosphatidyl ethanolamine to form LC3II. The increased amount of LC3II can reflect the increased number of autophagosomes caused by enhanced autophagy activity[39] (Figure 11). Western blot results proved that TGM2 and p62 were reduced, while AMPK, ULK1, and LC3II were increased in AGS and HGC-27 cells treated with 18β-GRA. Additionally, we employed a lentiviral vector to miR-345-5p overexpress in GC cells and observed the expression of TGM2. Our findings indicate that miR-345-5p overexpression significantly reduced the protein expression of TGM2. At the same time, we also found that miR-345-5p overexpression could inhibit GC cells proliferation by promoting cell apoptosis and arresting cell cycle. Based on the aforementioned findings, we draw the conclusion that 18β-GRA may play a role in the occurrence and progression of GC *via* the miR-345-5p/TGM2 signaling pathway.



CONCLUSION

To sum up, this study proved that 18β-GRA can inhibit GC cells viability, induce cells apoptosis, block cell cycle, inhibit cell wound healing ability, and induce cell autophagy by regulating the miR-345-5p/TGM2 signaling pathway, thereby inhibiting the GC cells proliferation, which could provide theoretical basis for the research of 18β-GRA in GC treatment. However, our study has some limitations and more experiments are needed to support our future research. Hence, we will carry on exploring the relationship between 18β-GRA and GC in the future. First, GC cells were infected with RFP-GFP-LC3 double-labeled adenoviruses to research 18β-GRA's effect on the autophagic. Secondly, 18β-GRA's effect when combined with chemotherapeutic drugs on chemotherapeutic drug sensitivity will be investigated. Thirdly, the molecular mechanism of 18β-GRA treatment for GC was further studied by gene overexpression, CO-IP and other methods.

ARTICLE HIGHLIGHTS

Research background

Gastric cancer (GC) is a common gastrointestinal malignancy worldwide. Based on the cancer-related mortality, the current prevention and treatment strategies for GC still show poor clinical results. Therefore, it is important to find effective drug treatment targets.

Research motivation

At present, the treatment of GC is mainly surgery, chemotherapy and radiotherapy, and the first-line treatment drugs are harmful to side effects.

Research objectives

The purpose of this study was to explore the molecular mechanism of 18β-glycyrrhetinic acid (18β-GRA) regulating the miR-345-5p/TGM2 signaling pathway to inhibit the proliferation of GC cells.

Research methods

The effects of 18β-GRA on GC cell phenotype and tumor growth *in vivo* were studied. TMT proteomic analysis and microRNAs (miRNAs) transcriptome analysis were used to screen for targets, and targeted connections were validated using a dual-luciferase report assay. Finally, the prediction was confirmed by experiment *in vitro*.

Research results

Our experiment confirmed that 18β-GRA inhibited GC cells growth both *in vitro* and *in vivo*, and MDC staining showed that 18β-GRA promoted GC cell autophagy. By TMT proteomic analysis and miRNAs transcriptomic analysis, we found that 18β-GRA down-regulates TGM2 expression and up-regulates miR-345-5p expression in GC cells. Subsequently, TGM2 was verified as the target of miR-345-5p by a dual-luciferase report assay. In 18β-GRA treated GC cells, the expressions of autophagy-related proteins TGM2 and p62 were significantly decreased, while the expressions of LC3II, ULK1 and AMPK were significantly increased. In addition, overexpression of miR-345-5p not only inhibited TGM2 expression, but also inhibited GC cell proliferation by promoting apoptosis and blocking cell cycle.

Research conclusions

These observations indicate that 18β-GRA can promote autophagy and inhibit GC cells proliferation *via* regulating the miR-345-5p/TGM2 signaling pathway.

Research perspectives

MiR-345-5p can be used for targeted therapy of GC, and can also be used as a new biomarker for GC.

ACKNOWLEDGEMENTS

The authors would like to acknowledge Li-Qun Wang for statistical analysis assistance. Thanks to Joanna Tibenda for revising the article.

Abstract

BACKGROUND

The prognostic assessment of patients after surgical resection of gastric cancer (GC) patients is critical. However, the role of the circadian clock gene NPAS2 expression in GC remains unknown.

AIM

To explore the relationship between NPAS2 and the survival prognosis of GC

patients and clarify its role in evaluating GC prognosis.

METHODS

The tumor tissues and clinical data of 101 patients with GC were collected retrospectively. Immunohistochemical staining (IHC) was used to detect the expression of NPAS2 protein in GC and adjacent tissues. Univariate and multivariate Cox regression analysis was used to determine the independent prognostic factors of GC, and a nomogram prediction model was established. The receiver operating characteristic (ROC) curve, the ROC area under the curve, the calibration curve, and C-index were used to evaluate the predictive effectiveness of the model. Kaplan Meier analysis was used to compare the risk stratification of subgroups according to the median score in the nomogram model of each patient.

RESULTS

Microarray IHC analysis showed that the positive rate of NPAS2 protein expression in GC tissues was 65.35%, which was significantly higher than 30.69% in adjacent tissues. The high expression of NPAS2 was correlated with tumor-node-metastasis (TNM) stage ($P < 0.05$), pN stage ($P < 0.05$), metastasis ($P < 0.05$), venous invasion ($P < 0.05$), lymphatic invasion ($P < 0.05$), and lymph node positive ($P < 0.05$) of GC. Kaplan Meier survival analysis showed that the 3-year overall survival (OS) of patients with high NPAS2 expression was significantly shortened ($P < 0.0001$). Univariate and multivariate COX regression analysis showed that TNM stage ($P = 0.009$), metastasis ($P = 0.009$), and NPAS2 expression ($P = 0.020$) were independent prognostic factors of OS in GC patients for 3 years. The nomogram prediction model based on independent prognostic factors has a C-Index of 0.740 (95%CI: 0.713-0.767). Furthermore, subgroup analysis showed that the 3-year OS time of the high-risk group was significantly lower than that of the low-risk group ($P < 0.0001$).

CONCLUSION

NPAS2 is highly expressed in GC tissues and is closely related to worse OS in patients. Therefore, the evaluation of NPAS2 expression may be a potential marker for GC prognosis evaluation. Notably, the nomogram model based on NPAS2 can improve the accuracy of GC prognosis prediction and assist clinicians in postoperative patient management and decision-making.

Core Tip: The prognostic assessment of patients after surgical resection of gastric cancer (GC) is critical. However, the role of NPAS2 expression in GC remains unknown. Our study identified for the first time that high NPAS2 protein expression was associated with poor overall survival prognosis in GC patients and was an independent risk factor for patients after radical resection of GC. We constructed a nomogram prediction model by combining NPAS2 and other clinically independent risk factors, thus improving the predictive accuracy of GC prognosis.

INTRODUCTION

Gastric cancer (GC) ranks fifth and fourth in the incidence and mortality of global cancer, respectively, and is more likely to occur in men[1,2]. The etiology of GC remains unclear, involving multiple cell types and complex molecular mechanisms[3]. Despite recent improvements in the diagnosis and treatment of GC, the overall treatment outcome remains poor[4]. Notably, radical gastrectomy is the primary treatment method for GC. However, postoperative recurrence rates and mortality remain high, and their mortality rates are closely associated with peritoneal, hematologic, and lymph node metastases in GC[5]. Therefore, there is an urgent need to identify new markers to predict the malignant biological behavior and prognosis of GC to guide the treatment strategy and improve the clinical outcome of GC.

Biological rhythm is a regulatory system in almost all living things. It produces 24-h periodic rhythm changes in many essential behaviors and physiological processes[6], including the sleep-wake cycle, body temperature cycle, hormone secretion, heart rate, blood pressure, excretion, *etc.*[7,8]. The destruction of normal biological rhythm adversely affects mammalian physiology[9]. The role and mechanism of biological rhythm-related genes in tumors, and the design of tumor treatment methods targeting biological rhythm genes, are one of the hot spots in the current cancer research field[10]. NPAS2, also known as MOP4, is the largest core circadian gene found so far, with a length of about 176.68Kb, located on human chromosome 2 (2q11.2), encoding proteins belonging to the basic helix loop helix PAS domain of transcription factors[11]. NPAS2 is mainly present in the forebrain of mammals and is also expressed in some peripheral organs such as the liver and skin[12]. Additionally, it is an important part of the positive circadian rhythm feedback circuit[8]. Furthermore, Studies have confirmed that NPAS2 is associated with various rhythm-related diseases, such as cancer, diabetes, depression, sleep disorders, obesity, *etc.*[13].

Recent studies have shown that low expression of NPAS2 accelerates cell growth and tumor cell cycle progression and plays a unique and critical role in cancer progression[14]. The low expression of NPAS2 promotes the proliferation and invasion of colorectal cancer cells. Additionally, it increases the wound-healing ability of colorectal cancer cells, indicating that NPAS2 has a key tumor inhibitory effect. Additionally, its high expression is positively correlated with overall survival (OS)[15]. However, some studies have found that NPAS2, as an oncogene, promotes the proliferation of hepatocellular carcinoma (HCC) cells and participates in the critical process of hepatocellular carcinogenesis. Its high expression is related to the invasive clinical characteristics and low OS of HCC patients[16]. It promotes the survival of HCC cells by up-regulating the expression of mitotic cycle 25A and inhibiting mitochondrial-dependent intrinsic apoptosis[16]. These results have also been observed in acute myeloid leukemia [17]. In contrast, there are few studies on the expression and role of NPAS2 in GC at home and abroad, and there is a significant lack of experimental research. Therefore, the expression level of NPAS2 in GC and its role in the occurrence and development of GC in different signal pathways are controversial and need to be further studied.

This study intends to detect the expression level of NPAS2 in GC and paraneoplastic tissues by using tissue microarray immunohistochemical staining to establish a nomogram prediction model based on NPAS2 and other clinicopathologically independent risk factors. Furthermore, we aim to investigate the effect of NPAS2 on the prognosis of GC and its value in the prognosis prediction of GC patients.

MATERIALS AND METHODS

This study was approved by the Medical Ethics Committee of the Second Hospital of Lanzhou University. Informed consent was obtained from all patients, and all specimens were pseudonymous. The tumor tissues, precancerous tissues, and clinical data of 101 patients with primary GC resected by surgery from July to October 2019 in the second Hospital of Lanzhou University were collected and followed up by standard outpatient clinic and telephone. The inclusion criteria of the study were as follows: (1) Histopathological diagnosis of gastric adenocarcinoma; (2) age ≥ 18 years old; (3) patients with primary GC underwent surgical resection; (4) complete pathological, treatment, surgical and follow-up data; and (5) the patient gave written informed consent. Exclusion criteria: (1) Death before discharge; (2) preoperative radiotherapy and chemotherapy or neoadjuvant chemotherapy; (3) multiple cancers; and (4) gastric stump cancer. 10% neutral formalin fixation and routine paraffin-embedded GC and paraffin-embedded tissues were confirmed by pathology, and all pathology was independently reviewed by two pathologists. The patients were followed up every 3 mo in the first 2 years and every 6 mo in the third year. Follow-up included laboratory examination, chest X-ray examination, and abdominal computed tomography (CT) examination. The follow-up period was 36 mo, and OS was defined as from the date of the first operation to the end of follow-up or the time of death.

Construction of tissue microarray and immunohistochemical staining

One hundred one paraffin-embedded primary GC tissues and adjacent tissues were fixed with formalin and then serially sectioned on a microtome with a thickness of 4 μm. After drying, hematoxylin and eosin staining (HE) were performed. A professional pathologist selected and marked the representative positions of HE-stained pathological sections and corresponding wax blocks according to the view under the light microscope. The tissue chip wax blocks were made by a drilling mechanism and sliced with a thickness of 4μm. After being dewaxed in xylene and washed in gradient ethanol, the slices were immersed in a pressure tank containing 800 mL of 0.1% sodium citrate buffer solution (pH 6.0) and boiled for 3 min, followed by cooling. Following the manufacturer's instructions, we then conducted a streptavidin-Biotin Complex assay (Fuzhou Maxin Biotechnology Development Company). The slides were then incubated overnight with the primary antibody against NPAS2 at 4 ℃ (diluted, 1:200, rabbit anti-human NPAS2 polyclonal antibody, Biossantibodies, China). Color development, hematoxylin re-staining, differentiation, blueing, and dehydration were performed prior to sealing.

Evaluation of immunostaining

The complete immunohistochemical sections of 101 cases were observed under the microscope. NPAS2 was mainly expressed in the cytoplasm and nucleus, and the positive cells were yellow and brown granular. Two professional pathologists scored the section staining and did not know the clinicopathological factors and clinical outcome of the patient. The positive results were judged by the semi-quantitative integration method. Five high-power visual fields (400 ×) were selected for each chip on each slide under the microscope, and cells' positive rate and staining intensity were observed. (1) The score of cell positive rate: 0 indicates that the proportion of positive cells is less than 5%. The score of 5%-25% is 1, 26%-50% is 2, 51%-75% is 3, and more than 75% is 4; and (2) Staining intensity score: 0 = no coloring, 1 = light yellow, 2 = brown, 3 = brown. The immunostaining score was obtained by multiplying the positive rate of cells with the result of staining intensity. 0 was negative, 1 to 4 was weakly positive, 5 to 8 was moderately positive, and 9 to 12 was strongly positive. In this study, negative and weak positive was defined as low expression of NPAS2, while medium positive and strong positive was defined as high expression.

Statistical analysis

All data were analyzed using R software (Version 4.1.1, http://www.r-project.org) and SPSS (Version 26). Classification variables are represented by percentage (%), chi-square test, and continuity correction. Pearson's chi-squared test was used to evaluate the correlation between NPAS2 expression and clinicopathological factors. Survival analysis was performed by Kaplan-Meier curve and log-rank test. Univariate and multivariate Cox analysis determined the independent prognostic factors of OS and established the Cox proportional hazards model, and the hazard ratios (HRs) and 95% confidence intervals (CIs) were subsequently calculated. "Survival" and "surminer" R package were used for survival and Cox analysis. The "rms" package drew a nomogram model based on independent risk factors to predict OS. Furthermore, the receiver operating characteristic (ROC) curve, aera under the curve (AUC), calibration curve, and C-index were used to evaluate its prediction performance. In this study, $P < 0.05$ was considered to be statistically significant.

RESULTS

High expression of NPAS2 in human GC tissues

To explore the prognostic value of NPAS2 in GC, we performed immunohistochemical staining on 101 GC tissues collected. Strong or moderate positive immunostaining of NPAS2 protein was observed in the nucleus and cytoplasm of tumor cells in GC tissues. In contrast, weak positive or negative immunostaining was mainly detected in adjacent tissues. Representative positive staining results of NPAS2 showed that the positive rate of NPAS2 expression in GC tissues was 65.35% (66/101) (Figure 1), while the positive rate in corresponding adjacent tissues was 30.69% (31/101).

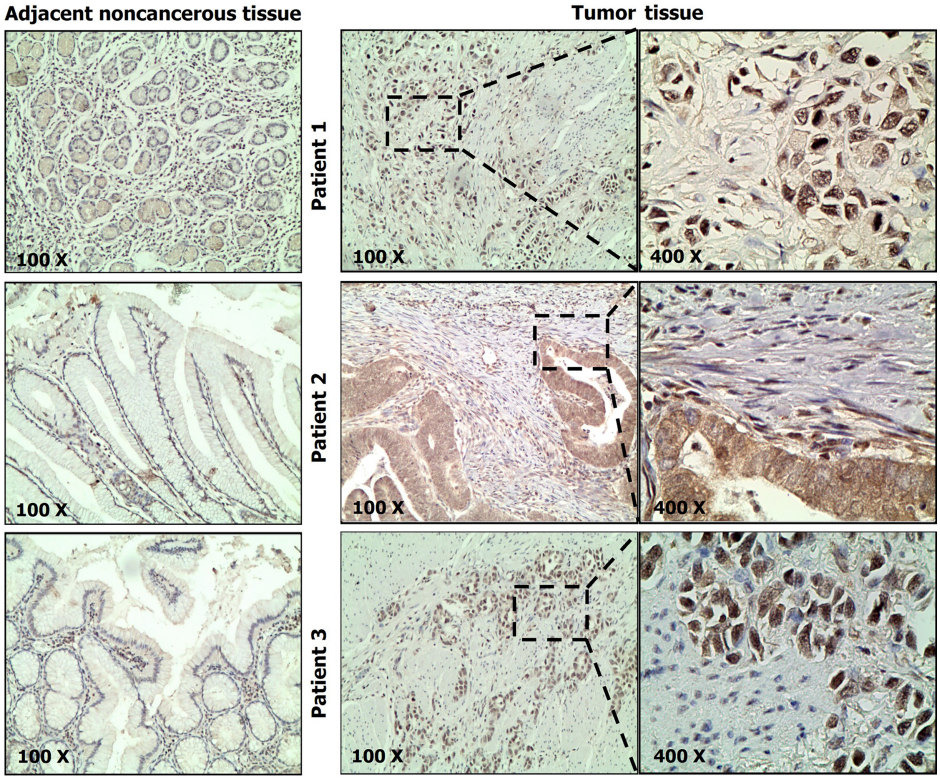
High expression of NPAS2 correlates with clinicopathological factors in GC patients

Of the 101 patients with GC, 65 (64.36%) died during follow-up. Table 1 summarizes the correlation between clinicopathological characteristics and NPAS2, showing that high expression of NPAS2 is associated with clinical progression in GC patients. The high expression of NPAS2 was significantly correlated with tumor-node-metastasis (TNM) stage ($P = 0.001$), pN stage ($P = 0.009$), metastasis ($P = 0.032$), venous invasion ($P = 0.012$), lymphatic invasion ($P = 0.001$) and lymph node positivity ($P = 0.001$).

The high expression of NPAS2 is associated with the prognosis of GC patients

The prognostic value of NPAS2 expression in GC was further investigated by Kaplan-Meier analysis and log-rank test. The results demonstrated that GC patients with high NPAS2 expression were significantly associated with shorter OS ($P < 0.001$) (Figure 2). Univariate Cox regression analysis showed that the TNM stage of GC patients (HR = 7.07, 95%CI: 3.47-14.41, $P < 0.001$), pN stage (HR = 1.72, 95%CI: 1.38-2.15, $P < 0.001$), metastasis (HR = 4.85, 95%CI: 2.24-10.46, $P < 0.001$), venous invasion (HR = 5.01, 95%CI: 1.57-15.98, $P = 0.007$), neural invasion (HR = 1.73, 95%CI: 1.03-2.9, $P = 0.037$), lymphatic invasion (HR = 3.53, 95%CI: 1.88-6.64, $P < 0.001$), lymph node positivity (HR = 3.35, 95%CI: 1.82-6.18, $P < 0.001$), and high expression of NPAS2 (HR = 5.13, 95%CI: 2.6-10.13, $P < 0.001$) were significantly correlated with OS. Multivariate Cox regression analysis showed that the TNM stage (HR = 3.61, 95%CI: 1.37-9.49, $P = 0.009$), metastasis (HR = 3.07, 95%CI: 1.33-7.1, $P = 0.009$), and high expression of NPAS2 (HR = 2.43, 95%CI: 1.15-5.13, $P = 0.020$) were independent risk factors for predicting OS (Table 2). Therefore, these collective data suggest that the expression level of NPAS2 has a good predictive value in the prognosis of GC patients.

Construction and evaluation of the prediction model



To obtain the best prediction model, TNM stage and metastasis were determined as independent

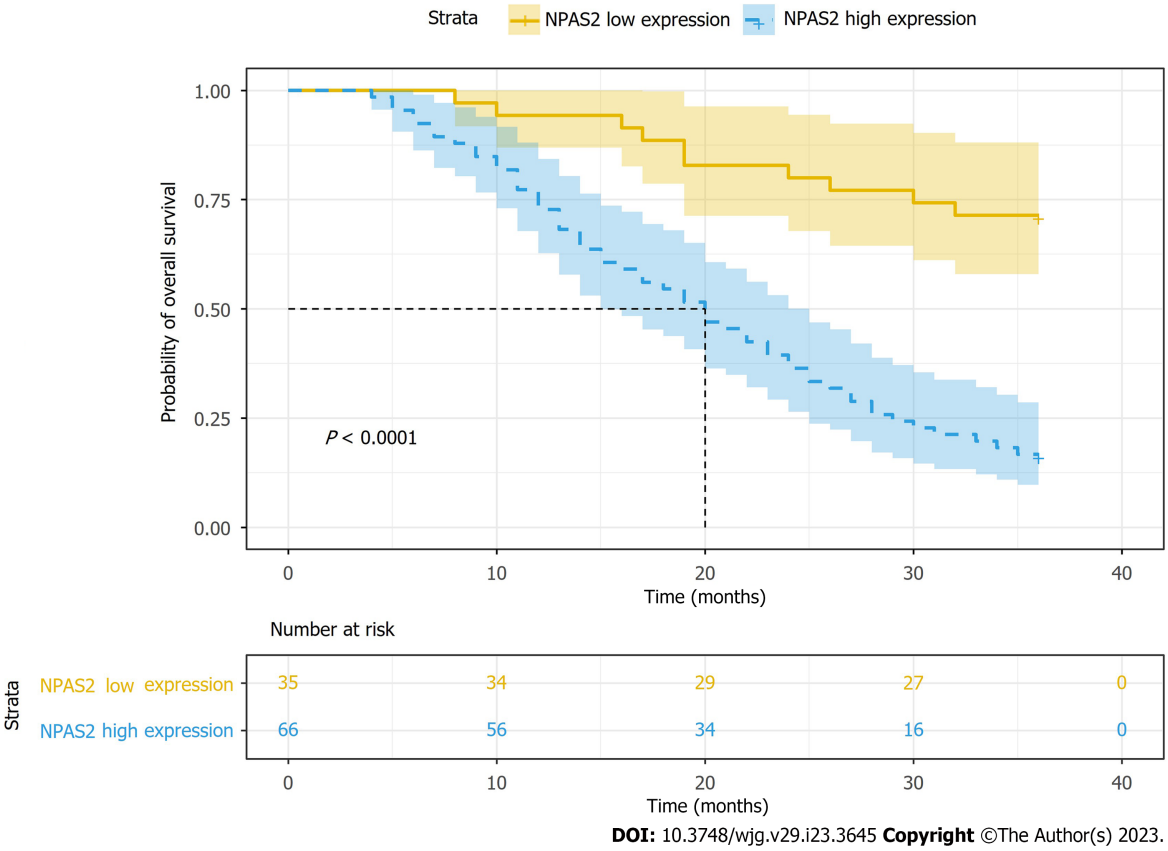
prognostic factors for GC according to multivariate Cox regression analysis and combined with NAPS2 high expression. Together, these were used as a combined prediction model for predicting OS at 1, 2, and 3 years after GC resection was constructed. The prediction model was visualized by nomogram (Figure 3). The 1-year, 2-year, and 3-year ROC curves of the Nomogram prediction model and other independent factors (Figure 4A) and the Time-dependent ROC curve were used to show the model's prediction performance (Figure 4C). The AUC of the nomogram prediction model for 1, 2, and 3 years is 0.763, 0.800, and 0.848, respectively (Figure 4B). Additionally, the C-index of each model shows the prediction performance of different models (Figure 4D), and the nomogram has the best prediction performance with a C-index of 0.740 (95%CI: 0.713-0.767). Finally, the prediction accuracy of the nomogram was verified by calibration curves, and the results showed that the combined nomogram model's 1-year, 2-year, and 3-year survival rates based on NPAS2 were in good agreement with the actual survival probability (Figure 5).

Risk stratification of OS by the nomogram model

To evaluate the positive effect of the nomogram prediction model in different subgroups, we divided all patients into a low-risk subgroup (score < 158) and a high-risk subgroup (score ≥ 158) according to the median nomogram score. Our results showed that patients in the high-risk group had significantly lower OS than those in the low-risk group ($P < 0.0001$) (Figure 6).

DISCUSSION



Epidemiological studies have shown that the disruption of normal circadian rhythm may increase the

risk of a variety of cancers[18], such as breast cancer[19], lung cancer[20], bladder cancer[21], prostate cancer[22], and liver cancer[23]. Notably, women on night shifts have a higher risk of breast cancer[19]. Likewise, breast cancer patients with irregular circadian rhythms have a worse prognosis because of changes in the expression of NPAS2 in breast cancer tissues[19]. Additionally, the disruption of biorhythm can promote the occurrence of lung cancer, which is a promising diagnostic marker for patients with lung adenocarcinoma and an independent prognostic marker for non-small cell lung cancer[24]. Notably, NPAS2 regulates the expression of several genes as markers of bladder cancer and further reduces the migration ability of bladder cancer cells[21]. The development of prostate cancer depends on androgen levels, and NPAS2 may interact with dihydrotestosterone, thus affecting the androgen receptor-dependent signaling pathway leading to prostate cancer[25]. Importantly, NPAS2 plays a role in reprogramming glucose metabolism and the progression of liver cancer, suggesting that NPAS2 may be an important therapeutic target to normalize the abnormal glucose metabolism that leads to the advancement of HCC[23]. Furthermore, NPAS2 plays different roles in different tumors, which can be understood that the expression level and function of NPAS2 are tumor-specific. The exact molecular mechanism of the change of NPAS2 expression in GC remains unclear. Moreso, there are no reports on the correlation between NPAS2 expression and clinicopathological data of GC patients.

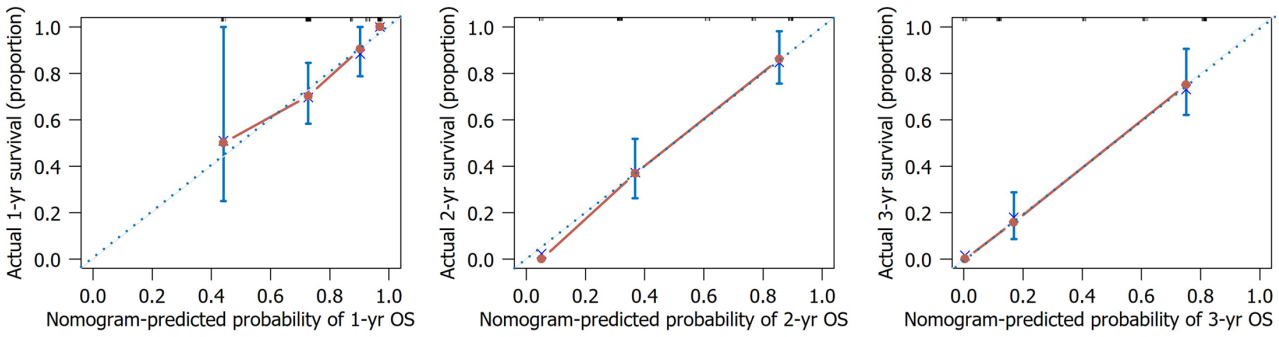
Figure 3 Nomogram prediction of 1-, 2-and 3-year overall survival rate in patients with gastric cancer. The total points is calculated by adding up the points of each factor. The total points corresponds to the 1-year, 2-year and 3-year survival probability of the patients. OS: Overall survival; TNM: Tumor-node-metastasis.

The tissue microarray results in this study showed that NPAS2 was expressed in GC and precancerous tissues and was primarily located in the nucleus and cytoplasm. The results showed that the expression was high in 65.35% of GC tissues and low in 34.65% of GC tissues. To the best of our knowledge, our experimental data demonstrate the role of NPAS2 in the diagnosis and prognosis of GC for the first time. The survival analysis showed that the high expression of NPAS2 in GC was significantly correlated with the shorter OS ($P < 0.001$). Univariate and multivariate Cox analysis also showed that the high expression of NPAS2 was an independent risk factor for GC. Furthermore, the ROC curve shows that NPAS2 is valuable in predicting the prognosis of GC. Therefore, the expression level of NPAS2 in GC tissue directly affects the OS of GC patients and may be used as a tumor-promoting factor to affect the occurrence and development of GC, which is a new prognostic biomarker. Various animal and *in vitro* studies have found that NPAS2 can regulate the expression of oncogenes (such as c-myc), tumor suppressor genes (such as P53 and P21), and transcription factors[26], thereby regulating cell cycle, apoptosis, DNA damage and repair systems, invasion, metastasis, carcinogen metabolism, and detoxification[27]. Notably, DNA repair maintains genetic stability and protects DNA from internal and external stimuli. Once human biorhythm genes are mutated (due to spontaneous mutations, prolonged late nights, or other environmental factors), it may lead to irreversible disorders and loss of DNA repair capacity[27].



The American Joint Commission on the Cancer TNM staging system is widely used to monitor the prognosis of patients with GC[28]. Our study analyzed the clinicopathological factors affecting OS in patients with GC, and our results showed that TNM stage and metastasis were independent risk factors for poor survival outcomes. Although the TNM stage and metastasis of GC patients have been widely used in the formulation of the treatment plan and the evaluation of prognosis, with the increasing number of GC patients, more studies and related factors are needed to evaluate the survival and prognosis of these patients more accurately and individually. Our study combined three independent risk factors of NPAS2 and TNM stage and metastasis to establish a Cox regression model for predicting 3-year OS in patients with GC. Compared with the TNM stage alone, it has more predictive power and can be used as a more convenient and accurate tool to predict the prognosis of patients with GC following gastrectomy. Therefore, the accurate prognosis prediction by nomogram score is of great significance for postoperative management and diagnosis and treatment of patients.

However, we can not solve the causal relationship in this study. Therefore, further basic and clinical research is needed to explore these aspects. Our advantage is that this is the first study to show that the increased expression of NPAS2 may be related to the malignant biological behavior and poor prognosis of patients with GC. Of course, our research has the following noted limitations. First, the sample size of our study is small, and there may be selection bias. Secondly, this study is a single-center retrospective study, so it is necessary to conduct a multicenter prospective study to verify it further. Finally, we used immunohistochemical staining to detect the expression of NPAS2 in the center and periphery of each

GC tissue. However, considering the heterogeneity, the expression level of NPAS2 in the sampling site may not represent whole tumor regions.

Based on these investigations, further exploration of the molecular mechanism and influence of NPAS2 in the occurrence and development of GC will help to promote its clinical application. The established nomogram prediction model provides a potential objective clinical prediction tool to assist clinicians in predicting the prognosis of GC patients and making postoperative management and clinical decisions.

CONCLUSION

In conclusion, our study found that high expression of NAPS2 is associated with poor prognosis of OS in patients with GC and is an independent risk factor for patients after radical resection of GC. We

further constructed a nomogram model by combining NAPS2 and other independent risk factors, thus improving the accuracy of predicting the prognosis of GC.

ARTICLE HIGHLIGHTS

Research background

The circadian clock gene NPAS2 expression is associated with multiple tumor prognosis, its role in gastric cancer (GC) is unknown.

Research motivation

NPAS2 can improve the accuracy of GC prognosis prediction and assist clinicians in postoperative patient management and decision-making.

Research objectives

This study aimed to explore the relationship between the circadian clock gene NPAS2 and the survival prognosis of GC patients and clarify its role in evaluating GC prognosis.

Research methods

Immunohistochemical staining was used to detect the expression of NPAS2 protein in GC and adjacent tissues. Univariate and multivariate Cox regression analysis was used to determine the independent prognostic factors of GC, and a nomogram prediction model was established. The receiver operating characteristic curve and area under the curve, the calibration curve, and C-index were used to evaluate the predictive effectiveness of the model.

Research results

The NPAS2 expression were independent prognostic factors of overall survival in GC patients for 3 years.

Research conclusions

NPAS2 is highly expressed in GC and is closely related to worse overall survival in patients. Therefore, the evaluation of NPAS2 expression may be a potential marker for GC prognosis evaluation.

Research perspectives

Based on NPAS2 expression, clinicians can predict patient prognosis and guide clinical decision making and follow up.

Abstract

BACKGROUND

The expression status of serum and glucocorticoid-induced protein kinase 3 (SGK3) in superficial esophageal squamous cell neoplasia (ESCN) remains unknown.

AIM

To evaluate the SGK3 overexpression rate in ESCN and its influence on the prognosis and outcomes of patients with endoscopic resection.

METHODS

A total of 92 patients who had undergone endoscopic resection for ESCN with more than 8 years of follow-up were enrolled. Immunohistochemistry was used to evaluate SGK3 expression.

RESULTS

SGK3 was overexpressed in 55 (59.8%) patients with ESCN. SGK3 overexpression showed a significant correlation with death (P = 0.031). Overall survival and disease-free survival rates were higher in the normal SGK3 expression group than in the SGK3 overexpression group (P = 0.013 and P = 0.004, respectively). Cox regression analysis models demonstrated that SGK3 overexpression was an independent predictor of poor prognosis in ESCN patients (hazard ratio 4.729;

95% confidence interval: 1.042-21.458).

CONCLUSION
SGK3 overexpression was detected in the majority of patients with endoscopically resected ESCN and was significantly associated with shortened survival. Thus, it might be a new prognostic factor for ESCN.

Key Words: Superficial esophageal squamous cell neoplasia; Serum and glucocorticoid-induced protein kinase; Endoscopic submucosal dissection; Immunohistochemistry; Overall survival

Core Tip: This study demonstrated that the expression status of serum and glucocorticoid-induced protein kinase 3 (SGK3) was high in the majority of patients with superficial esophageal squamous cell neoplasia (ESCN) and that high expression of SGK3 predicts a poor prognosis. These findings provide a new prognostic factor for ESCN.

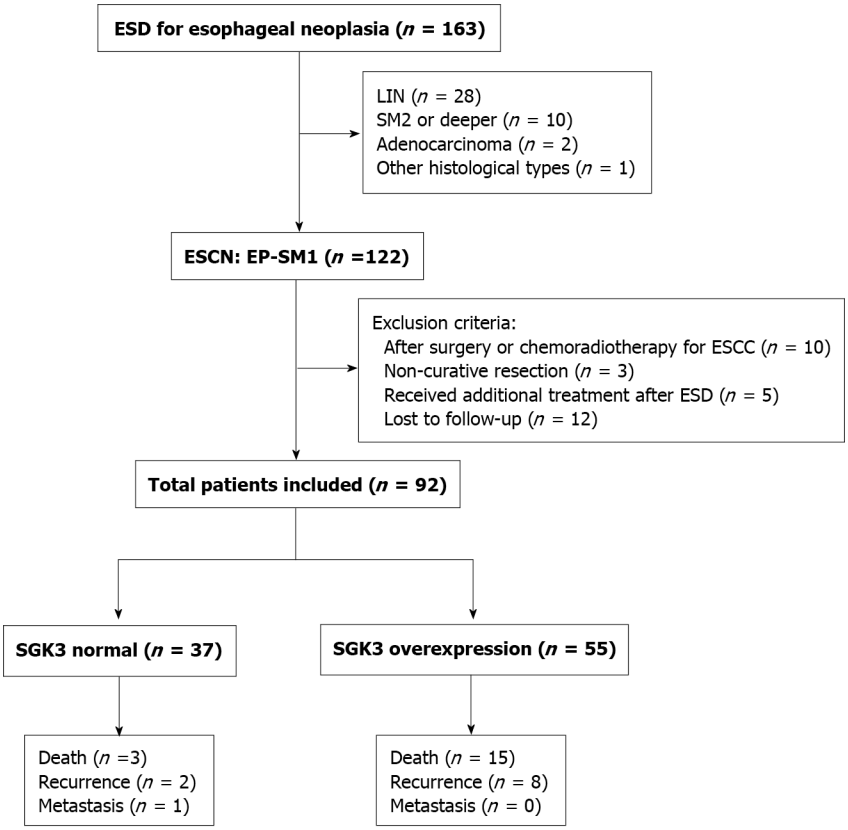
INTRODUCTION

Esophageal cancer remains a leading cause of cancer-related death, and the incidence rates of esophageal cancer worldwide are increasing[1]. Esophageal squamous cell carcinoma (ESCC) accounts for the majority of esophageal cancer cases[2]. It is usually detected at an advanced stage after the symptoms of dysphagia appear[3]. Thus, its prognosis is the worst among digestive carcinomas[4]. Early detection of the malignant epithelium at an early stage followed by endoscopic resection has become the most effective way to improve clinical outcomes[5]. However, the prognosis of patients with superficial esophageal squamous cell neoplasia (ESCN) remains poor[6,7].



The serum and glucocorticoid-induced protein kinase (SGK) family consists of three isoforms (SGK1, SGK2 and SGK3), and they regulate a range of fundamental cellular processes, such as tumor growth, metastasis, autophagy and survival[8]. SGK is a ubiquitously expressed serine/threonine kinase and plays an active role in a multitude of pathophysiological conditions[9]. It is activated by insulin and growth factors *via* phosphatidylinositol 3-kinase (PI3K) and is frequently altered in human cancers, including breast cancer and hepatocellular carcinoma[10,11]. Although SGK1, SGK2 and SGK3 share a highly similar domain, the lack of a plasma membrane-targeting domain indicates nonoverlapping functions[12].

Previous studies have shown that SGK3 is expressed in all tissues tested thus far and is especially highly expressed in the heart and spleen[13]. Encoded by chromosome 8q12.2, SGK3 is known as a downstream factor of PI3K signaling and has been reported to play a pivotal role in the development and progression of diverse cancers[14]. Therefore, it has been regarded as a potential target for cancer intervention[15]. However, a minority of studies have evaluated the impact of SGK3 expression on clinical outcomes, and the expression of SGK3 in ESCN has not been investigated[16]. Whether SGK3 is associated with the prognosis of ESCN remains unknown. Herein, we assessed the SGK3 expression levels of patients with ESCN *via* immunohistochemistry (IHC) to investigate the possible role of SGK3 as a prognostic factor.

MATERIALS AND METHODS

Patients

Patients who underwent gastrointestinal endoscopy followed by endoscopic submucosal dissection (ESD) between November 2009 and July 2011 at the First Medical Center of PLA General Hospital were included. The inclusion criteria were as follows: (1) Patients were diagnosed with primary ESCN; (2) the histological type of tumor was ESCN; and (3) the tumor penetrated the submucosal layer < 200 μm or 200 μm from the muscularis mucosa. The exclusion criteria were as follows: (1) ESCN was previously

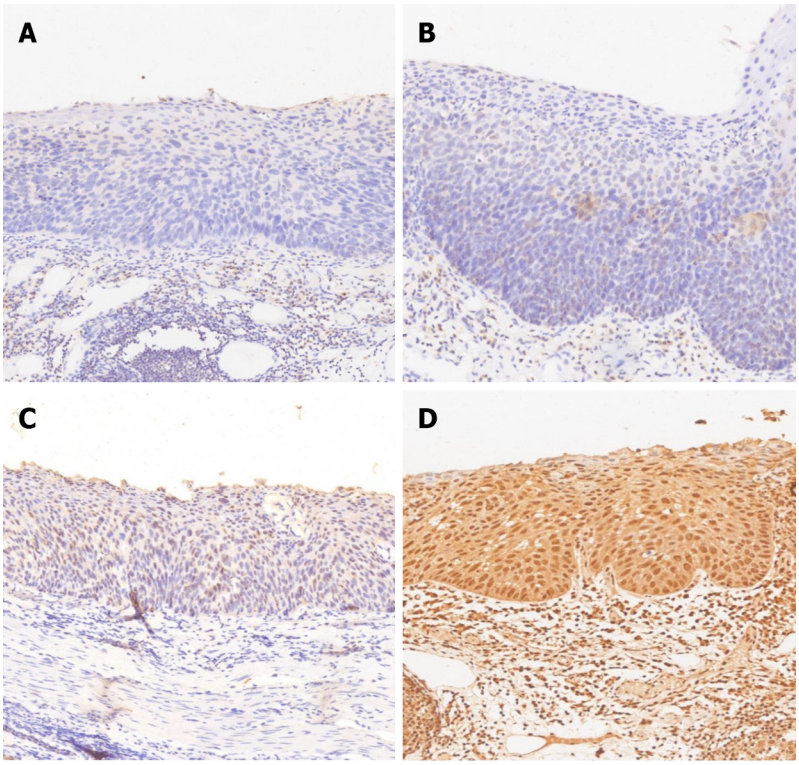
Figure 1 Study flow chart. ESD: Endoscopic submucosal dissection; LIN: Low-grade intraepithelial neoplasia; SM2: Penetration of the submucosal layer > 200 μm from the muscularis mucosa; ESCN: Esophageal squamous cell neoplasia; ESCC: Esophageal squamous cell carcinoma; EP: Epithelium; SM1: Penetration of the submucosal layer < 200 μm or 200 μm from the muscularis mucosa; SGK3: Serum and glucocorticoid-induced protein kinase 3.

treated with surgery or chemoradiotherapy ESCN; (2) pathological evaluation post-ESD indicated noncurative resection; (3) patients received additional treatment immediately after ESD; and (4) incomplete follow-up. All follow-up data were obtained at least 8 years after the first detection of the tumor. Eventually, 92 patients with complete follow-up data were included in the analysis (Figure 1). This study was approved by the Ethics Board of the First Medical Center of PLA General Hospital (approval No. S2020-251-01).

ESD procedure



All procedures were performed under general anesthesia by experienced endoscopists. A single-channel upper gastrointestinal endoscope (GIF-Q230; Olympus, Tokyo, Japan) was used during the procedure. The standard ESD is described as follows: the lesions were detected on endoscopy under white light or narrow band imaging, lesion margins were shown by iodine staining, argon plasma coagulation (ERBE Elektromedizin GmbH) was used to mark 5 mm outside the boundary of the lesion, submucosal circumferential injection was performed to lift the lesions, and submucosal dissection followed by a circumferential mucosal incision was performed to remove the lesion.

Pathological examination

Tissue specimens were fixed in formalin. All samples were subjected to histological analysis of differentiation type, depth of invasion, and lymphovascular invasion. Lymphovascular invasion was recognized as any invasion using hematoxylin and eosin staining. Curative resection was defined as complete resection of a mucosal lesion with no lymphovascular invasion, and noncurative resection implied a pathologically positive margin or clinically incomplete resection.

IHC

For IHC, we used a rabbit anti-human SGK3 antibody (Roche Diagnostics Japan. Tokyo, Japan) and 4-μm-thick sections. All sections were deparaffinized in xylene 3 times and rehydrated in a graded series of ethanol with decreasing concentrations. Then, we used Tris-buffered saline (pH 7.4) for rinsing. Heat-induced epitope retrieval was conducted by immersing the slides in Coplin jars filled with 10 mmol/L citrate buffer (pH 6.0) and microwaving the buffer for 25 min. The jars were then cooled for 20 min. The reaction products were visualized with diaminobenzidine and counterstained with hematoxylin. Two

Figure 2 Serum and glucocorticoid-induced protein kinase 3 protein expression in superficial esophageal squamous cell neoplasia (magnification: × 400). A: No serum and glucocorticoid-induced protein kinase 3 (SGK3) expression in esophageal squamous cell neoplasia (ESCN) samples (normal for SGK3 overexpression; 0); B: Weak SGK3 expression in ESCN samples (normal for SGK3 overexpression; 1+); C: Moderate SGK3 expression in ESCN samples (positive for SGK3 overexpression; 2+); D: Strong SGK3 expression in ESCN samples (positive for SGK3 overexpression; 3+).

experienced pathologists independently judged the immunostaining intensity. The staining intensity was graded based on the American Society of Clinical Oncology/College of American Pathology guidelines[17]. The criteria were as follows: 0 = no nuclear staining in tumor cells; 1+ = weak (staining in less than 10% of cells); 2+ = intense complete staining (up to 30% of tumor cells); and 3+ = uniform intense staining (more than 30% of tumor cells). The expression status of SGK3 was classified into 2 groups: normal (0 and 1+) and overexpression (2+ and 3+) (Figure 2).

Clinicopathologic parameters and definitions

In each case, clinicopathologic parameters were retrospectively obtained from the pathological results of our hospital. Basic clinical parameters included age, sex, smoking history and family history of cancer. The longest diameter of the lesion in the specimen was defined as the tumor size. Tumor location was categorized as upper thoracic, middle thoracic and lower thoracic. Based on the histological outcome, tumors were characterized into low-grade intraepithelial neoplasia, high-grade intraepithelial neoplasia, well-differentiated squamous cell carcinoma, intermediate differentiated squamous cell carcinoma, and poorly differentiated squamous cell carcinoma. The T stage of the tumor was categorized based on the 11th Japanese classification of esophageal cancer[18]. Tumors limited to the epithelium and tumors that invaded into the submucosa ≤ 200 or > 200 μm from the muscularis mucosae were classified as EP, submucosa 1 (SM1) or submucosa 2 (SM2), respectively. The two recurrence patterns, metachronous recurrence and metastatic recurrence, were both included in this study, and tumor recurrence was identified using endoscopy and histological biopsy. Tumor recurrence was defined as an ESCN or cancerous lesion detected on the esophagus during the follow-up period. Lymph node or distant metastasis was evaluated by contrast-enhanced computed tomography scan or magnetic resonance imaging and verified *via* histological examination of the biopsy.

Prognostic outcomes

The follow-up of patient survival status and cancer recurrence was completed in July 2022. Prognostic outcomes were obtained by calling patients themselves or asking the family members for the recorded death certificate of the patients. Two main variables were assessed: Overall survival (OS) and disease-free survival (DFS). OS was defined as the time that elapsed from the date of endoscopic treatment to the date of death from any cause. DFS was defined as the duration between the endoscopic treatment and any disease recurrence or any cause of death, whichever occurred first.

Statistical analysis

Continuous variables are expressed as the mean ± SD or median (interquartile range) and were compared using Student's *t* test. Categorical variables are expressed as percentages and were compared using the chi-square test or Fisher's exact test. Multivariate Cox regression was used to further analyze the relationship between SGK3 overexpression and clinical outcomes, and the covariates were screened using stepwise regression. The extended-model method was used to conduct covariate correction: Model 1 was corrected based on SGK3 expression status; Model 2 = model 1 + (age and gender); Model 3 = model 2 + (smoking history + family history of cancer); and Model 4 = model 3 + (tumor location + tumor size + T stage + differentiated types). Multicollinearity was tested using the variance inflation factor (VIF) method, and a VIF ≥ 10 was considered to indicate severe multicollinearity. Kaplan-Meier analysis was used to establish the survival curves based on each prognostic outcome. Survival curves were graphed using GraphPad Prism 8. A P value < 0.05 in the two-tailed tests was considered to indicate statistical significance. All statistical analyses were performed using SPSS 26.0 (SPSS, Inc., Chicago, IL, United States).

RESULTS

Baseline characteristics of patients with ESCN

A total of 92 patients aged 43 to 80 years were finally included in our study. Table 1 lists the baseline characteristics of the normal SGK3 expression group and the SGK3 overexpression group. The normal SGK3 expression group included 37 patients and consisted of 27 males and 10 females. There were 55 patients (36 males and 19 females) in the SGK3 overexpression group. No significant differences were observed in the baseline indicators (age, sex, tumor location, tumor size, T stage, differentiated types, smoking history, lymphovascular infiltration and family history of cancer) between the normal expression and overexpression groups.

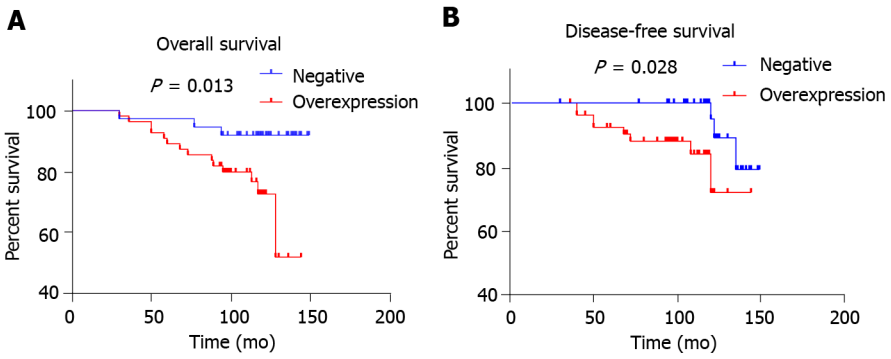
Prognostic outcomes

Table 2 summarizes the prognostic outcomes in each group. Tumor recurrence occurred in 10 patients. Of these patients, 2 (5.4%) were in the normal SGK3 expression group, and 8 (14.5%) were in the SGK3 overexpression group. Metastasis was detected in only 1 patient in the normal SGK3 expression group during the follow-up period. No significant associations were observed between SGK3 expression and tumor recurrence and metastasis. Death occurred in 3 (8.1%) patients in the normal SGK3 expression group and 15 (27.3%) patients in the SGK3 overexpression group. A significant correlation was observed between SGK3 expression status and death (P = 0.031).

SGK3 expression is related to prognostic outcomes

To evaluate the association between SGK3 overexpression and OS, a multivariate Cox regression model was performed (Table 3): Model 1 [hazard ratio (HR) 4.243; 95% confidence interval (CI): 1.219-14.773], Model 2 (HR 3.648; 95%CI: 1.030-12.917), Model 3 (HR 3.637; 95%CI: 1.028-12.866), and Model 4 (HR 4.729; 95%CI: 1.042-21.458). The P value of all four models was less than 0.05. The results of the multicollinearity test showed an average VIF of 1.525 (all VIF < 10). Figure 3 show the Kaplan-Meier curves of the relationship between SGK3 expression status and OS and DFS, respectively. The OS and DFS rates of patients were higher in the normal SGK3 expression group than in the SGK3 overexpression group during the follow-up period (P = 0.013 and P = 0.004, respectively).

DISCUSSION



The SGK family is widely dysregulated in numerous human cancers and plays a vital role in tumor development and progression[19]. Among the three members of this family, SGK1 has been well researched, and its correlation with clinical outcomes has been reported in some cancers[20]. It has been suggested that low SGK1 expression in some tumors might induce feedback inhibition by activating the AKT pathway and might result in high SGK3 expression[21]. However, due to the later detection of SGK3, its relationship with tumors or other diseases has been revealed in only a few studies[22,23]. For instance, SGK3, as a novel regulator of renal phosphate transport, is associated with autosomal dominant hypophosphatemic rickets[24,25]. Its relationship with the clinical prognosis of tumors has rarely been reported thus far.

SGK3 exhibits structural and sequence similarity to the AKT family[26]. Its activation is mediated by the PI3K pathway and requires phosphorylation at two regulatory sites, Thr-320 and Ser-486[27]. Deletion of Thr-320 of SGK3 or disruption of the SGK3 protein tertiary structure yields nonfunctional proteins. To our knowledge, the SGK3 expression status of ESCN has not been illustrated. Our analysis of the expression of SGK3 in 92 ESCN tissues identified the expression status of SGK3 in ESCN tissues. Among the 92 tissue samples, the overexpression rate of SGK3 was close to 60%, confirming its high

expression in esophageal neoplasia tissues. However, the defined functions of SGK3 in the growth or progression of ESCN have not been clarified.

ESCC is the most common pathological type of esophageal cancer and has a high incidence in some districts of China. It is difficult to detect at the early stage because its symptoms are insidious, and the majority of patients seek medical help when advanced symptoms of significant dysphagia occur. As a consequence, the traditional treatment of ESCN is mainly based on a combination of open surgery and chemotherapy/radiotherapy. Progress in imaging modalities and multidisciplinary comprehensive treatment has improved early diagnosis and clinical outcomes, respectively. However, the 5-year survival rate for ESCC is still lower than 30% because of its invasiveness and metastatic ability[28,29]. Recently, the development of endoscopy techniques has transformed the early diagnosis and treatment of diseases of the entire digestive system. In particular, the introduction of amplification techniques and narrow band imaging enables endoscopists to detect neoplasia at an early stage or in an asymptomatic period. In addition, the minimally invasive removal of lesions by ESD improves the clinical prognosis and even the quality of life. Although the 5-year survival rate of patients who undergo ESD is higher than that of patients who undergo open surgery, death caused by tumor recurrence or other reasons still occurs in some patients during the follow-up period[30]. This research focused on further exploration of ways to improve the survival rates of these patients.

The integration of small datasets in the present study demonstrated the high expression level of SGK3 in ESCN, as well as a significant relationship between its overexpression and OS. Furthermore, the 4 regression models showed that after adjusting for confounding factors, only the expression status of SGK3 was significantly associated with increased mortality. All these results indicate that the overexpression of SGK3 is correlated with the occurrence of death in ESCN patients. However, the influence of SGK3 on the occurrence and development of ESCN or cell cycle pathways has not yet been determined. Based on the results of our study, we speculate that SGK3 can be used as a prognostic indicator to assist in the outcome assessment of ESCN patients.

At present, follow-up of post-ESD patients with ESCN is generally performed *via* endoscopy as well as biopsy. The application of a standard follow-up method might aid endoscopists in identifying tumor recurrence in time, but this is only effective when endoscopists can detect the recurrence of cancerous

lesions followed by accurate biopsy sampling. Otherwise, no further action could be taken to intervene. As the overexpression of SGK3 is an independent factor in prognosis, IHC staining of SGK3 could be used to identify the population with a high mortality risk. Thus, active measures, including shortening the follow-up intervals and using moderate radiotherapy or chemotherapy, can be taken to improve survival.

However, our current study has several limitations. First, the sample size of our study was small, and all the included patients came from one hospital. Thus, these results need to be validated by expanding the sample size and performing a multicenter study. Second, this was a retrospective study. Therefore, we could not collect information without data bias. Thus, a prospective study, similar to this study, is needed in the future to verify the relationship between SGK3 overexpression and mortality.

CONCLUSION

In conclusion, SGK3 overexpression is significantly correlated with shortened survival in patients with endoscopic resection of superficial ESCN, and SGK3 might be a useful indicator for prognosis evaluation. Further studies are warranted to determine its mechanisms of action in the growth or progression of ESCN.

ARTICLE HIGHLIGHTS

Research background

Serum and glucocorticoid-induced protein kinase 3 (SGK3) regulate a range of fundamental cellular processes, such as tumor growth, metastasis, autophagy and survival, but SGK3 expression levels in patients with esophageal squamous cell neoplasia (ESCN) and their relationship with the prognosis of ESCN remain unknown.

Research motivation

SGK3 expression levels in patients with ESCN were assessed by immunohistochemistry to investigate the possible role of SGK3 as a prognostic factor.

Research objectives

Ninety-two patients who underwent gastrointestinal endoscopy followed by endoscopic submucosal dissection with complete follow-up data between November 2009 and July 2011 were included.

Research methods

A total of 92 patients who had undergone endoscopic resection for ESCN with more than 8 years of follow-up were enrolled. Immunohistochemistry was used to evaluate SGK3 expression.

Research results

Death occurred in 3 (8.1%) patients in the normal SGK3 expression group and 15 (27.3%) patients in the SGK3 overexpression group. A significant correlation was observed between SGK3 status and death (P = 0.031). The overall survival and disease-free survival rates of patients were higher in the normal SGK3 expression group than in the SGK3 overexpression group during the follow-up period.

Research conclusions

All these results indicate that the overexpression of SGK3 is correlated with the occurrence of death in ESCN patients and that SGK3 might be a useful indicator for prognosis evaluation.

Research perspectives

The sample size of this study was small, and the subjects both came from one hospital. Thus, the results need to be validated by expanding the sample size and performing a multicenter study. A prospective study, similar to this study, is needed in the future to verify the relationship between SGK3 overexpression and mortality.

Abstract

BACKGROUND

Endoscopic resection (ER) with bipolar snare, in which the electric current only passes through the tissue between the device's two electrodes, is a prominent method used to prevent perforation due to electricity potentially. ER using bipolar snare with or without submucosal injection enabled safe resection of colorectal lesions measuring 10–15 mm in an *ex vivo* porcine model. ER with bipolar snare is expected to have good treatment outcomes in 10–15 mm colorectal lesions, with high safety even without submucosal injection. However, no clinical reports have compared treatment outcomes with and without submucosal injection.

AIM

To compare the treatment outcomes of bipolar polypectomy with hot snare polypectomy (HSP) to those with endoscopic mucosal resection (EMR).

METHODS

In this single-centre retrospective study, we enrolled 10–15 mm nonpedunculated colorectal lesions (565 Lesions in 463 patients) diagnosed as type 2A based on the Japan Narrow-band Imaging Expert Team classification, resected by either HSP or EMR between January 2018 and June 2021 at the National Cancer Center Hospital East. Lesions were divided into HSP and EMR groups, and propensity score

matching was performed. In the matched cohort, *en bloc* and R0 resection rates and adverse events were compared between the two groups.

RESULTS

Of the 565 lesions in 463 patients, 117 lesions each in the HSP and EMR groups were selected after propensity score matching. In the original cohort, there was a significant difference in antithrombotic drug use ($P < 0.05$), lesion size ($P < 0.01$), location ($P < 0.01$), and macroscopic type ($P < 0.05$) between the HSP and EMR groups. In the matched cohort, the *en bloc* resection rates were comparable between both groups [93.2% (109/117) *vs* 92.3% (108/117), $P = 0.81$], and there was no significant difference in the R0 resection rate [77.8% (91/117) *vs* 80.3% (94/117), $P = 0.64$]. The incidence of delayed bleeding was similar in both groups [1.7% (2/117)]. Perforation occurred in the EMR group [0.9% (1/117)] but not in the HSP group.

CONCLUSION

Using bipolar snare, ER of nonpedunculated 10–15 mm colorectal lesions may be performed safely and effectively, even without submucosal injection.

Key Words: Adenoma; Cohort studies; Colonoscopy; Colorectal cancer; Endoscopic mucosal resection; Treatment outcome

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This study is the first to compare treatment outcomes between hot snare polypectomy (HSP) and endoscopic mucosal resection (EMR) using a bipolar snare for nonpedunculated colorectal lesions measuring 10–15 mm. First, there was no significant difference in *en bloc* and R0 resection rates between the HSP and EMR groups. Second, the incidence of adverse events was similar in both groups, but perforation occurred only in the EMR group. These results suggest that comparable treatment efficiency and safety may be obtained even without submucosal injection when resecting nonpedunculated colorectal lesions measuring 10–15 mm using a bipolar snare.

INTRODUCTION

Colorectal cancer (CRC) is the leading cause of morbidity and mortality worldwide[1]. Detection and resection of colorectal lesions *via* colonoscopy reduce CRC-related mortality[2,3]. However, complications associated with endoscopic resection (ER), such as post-procedural bleeding and perforation, are concerning[4,5]. Perforation, although infrequent, is the most serious complication that may result in hospitalization, stoma formation, and mortality[6]. Various devices and techniques related to ER have been developed to reduce the risk of complications.

ER using a bipolar snare, wherein the electric current only passes through the tissue between the two electrodes of the device, may potentially prevent perforation due to electricity. Apart from reducing electric damage to tissues, using a bipolar snare does not require a counter electrode, carries a lower risk of burns, and can be used even when a metal, such as a pacemaker, is present inside the patient's body [7]. In an *ex vivo* porcine model, using a bipolar snare for intramucosal lesions measuring 10–15 mm did not cause thermal damage to the muscularis propria. However, perforation occurred with a monopolar snare. Furthermore, thermal damage to the muscularis propria was not observed in bipolar polypectomy, regardless of whether a submucosal injection was performed before resection[8].

An ER with a bipolar snare for 10–15 mm colorectal lesions could result in favourable outcomes even without submucosal injection. However, no reports have compared bipolar polypectomy with and without submucosal injection in clinical practice. Hence, using a bipolar snare for colorectal lesions measuring 10–15 mm, this study aimed to compare the safety and efficiency of hot snare polypectomy (HSP), which involves resection without submucosal injection, to those of endoscopic mucosal resection (EMR), which involves resection with submucosal injection.

MATERIALS AND METHODS

Patients

We retrospectively enrolled 10–15-mm nonpedunculated colorectal lesions diagnosed as type 2A based on the Japan Narrow-band Imaging Expert Team (JNET) classification, resected by either HSP or EMR using a bipolar snare between January 2018 and June 2021 at the National Cancer Center Hospital East. The exclusion criteria were: (1) History of inflammatory bowel disease and familial adenomatous polyposis; (2) Pedunculated type lesions; (3) Residual lesions after previous ER; and (4) Lesions pathologically diagnosed as inflammatory or hyperplastic polyps.

HSP and EMR

Before the colonoscopy, a polyethylene glycol electrolyte solution with ascorbic acid (MobiPrep, EA Pharma, Tokyo, Japan) or magnesium citrate (Magcorol P, Horii Pharmaceutical Industries, Osaka, Japan) was administered to all patients according to the manufacturer's instructions. The examinations were performed using a magnifying endoscope (PCF-H290ZI, CF-HQ290, CF-H290ECI, CF-EZ1500DI, CF-XZ1200I colonoscope, Olympus, Tokyo, Japan; EC-L590ZP, EC-L600ZP, Fujifilm Co., Tokyo, Japan), light source, and video processor (EVIS LUCERAELITE, EVIS X1, Olympus; LASEREO, Fujifilm Co.).

All procedures were performed by either four experts (≥ 2000 colonoscopies performed) or 18 nonexperts (< 2000 colonoscopies performed) endoscopists. The treatment choice (HSP or EMR) was at the endoscopist's discretion. For EMR, a submucosal injection was performed using saline solution alone or combined with sodium hyaluronate acid. A bipolar snare (Dragonare® Xemex Co. Ltd., Tokyo, Japan) was used in both HSP and EMR. An electrosurgery generator unit (ICC200, VIO300D, VIO3; ERBE Elektromedizin GmbH Co. Ltd., Tubingen, Germany; ESG100, Olympus) was used for all ERs. The cutting mode in the forced coagulation mode was used for resection. Subsequently, resection margins were evaluated endoscopically to confirm the absence of remnants. Prophylactic clipping after resection was performed at the endoscopist's discretion. Resected lesions were retrieved by suctioning through the endoscope into a trap, using pentapod-type grasping forceps or a retrieval net. The endocopists recorded the size, location, and macroscopic type of the lesions, diagnosis according to the JNET classification, and *en bloc* or piecemeal resection. The location was recorded as right colon if the lesion was in the caecum, ascending, or transverse colon, and as left colon if it was in the descending or sigmoid colon. Once removed, the lesions were fixed in formalin, embedded in paraffin, sectioned into 2–3 mm slices, stained with hematoxylin-eosin, and evaluated by two experienced pathologists blinded to the patient's clinical information. Pathological results were described according to World Health Organization criteria[9].

Outcomes

Study outcomes were *en bloc* and R0 resection rates, and adverse events, including delayed bleeding and perforation. *En bloc* resection was defined as ER with the entire lesion resected in a single piece. Upon histological evaluation of the horizontal and vertical margins of specimens, R0 resection was defined as negative margins both horizontally and vertically; RX resection, as unclear resection margins either horizontally or vertically; and R1 resection, as positive resection margins either horizontally or vertically [10]. Delayed bleeding was defined as haemorrhage requiring endoscopic intervention within 2 wk after polypectomy. Perforation was defined as any organ or fat outside the muscularis layer visualized on endoscopy during the procedure or free air observed on computed tomography after the procedure. For subgroup analysis, the R0 resection rate according to each clinical characteristic related to lesions was assessed.

Ethical considerations

This was a single-centre retrospective study, and the protocol was approved by the Institutional Review Board of the National Cancer Center (2017-434). All data were collected from the medical records. All procedures were performed after written informed consent was obtained.

Statistical analysis

Propensity score matching was applied at a 1:1 HSP-to-EMR ratio using greedy matching with a calliper width of 0.20 of the standard deviation of the logit transformation for the estimated propensity score[11, 12]. The propensity score was estimated using the multivariate logistic regression model, which included the following: age (continuous), sex (male/female), antithrombotic drug use (no/yes), size (continuous), location (right-sided colon/Left-sided colon/rectum), macroscopic type (0-Is/0-Isp/0-IIa), and endoscopist experience (expert/nonexpert) as explanatory variables without considering outcome variables. To evaluate the balance of patient characteristics between the HSP and EMR groups, we calculated standardized differences and created histograms and box plots. The chi-square and Mann–Whitney U tests were used to compare patient characteristics between groups. For treatment outcomes, univariable analyses were performed using the χ^2 test in all enrolled lesions and the McNemar test in pair-matched lesions. All *P* values were two-sided with a significance level of 0.05. All statistical analyses were performed using EZR (Saitama Medical Center, Jichi Medical University,

Saitama, Japan) and SAS (version 9.4) graphical user interface for R 4.1.0 (R Foundation for Statistical Computing, Vienna, Austria). EZR is a modified version of R commander (version 2.7-0), designed to add statistical functions frequently used in biostatistics[13]. The statistical methods of this study were reviewed by Masashi Wakabayashi from the Biostatistics Division of Center for Research Administration and Support at National Cancer Center.

RESULTS

Background characteristics of patients

Of the 711 consecutive lesions in 602 patients, 463 patients were enrolled, and 565 Lesions in them were analysed in the present study. Of the 565 Lesions, 440 in 346 patients were resected *via* HSP; 125 in 117 patients were resected *via* EMR. A flowchart of patient enrolment is shown in Figure 1. Patient characteristics before and after propensity score matching are shown in Table 1. There was a significant difference in antithrombotic drug use ($P < 0.05$), lesion size ($P < 0.01$), location ($P < 0.01$), and macroscopic type ($P < 0.05$) between the HSP and EMR groups in the original cohort. After propensity score matching, 117/440 Lesions in the HSP group and 117/125 in the EMR group were selected. Nearly all baseline characteristics were balanced (Table 1; standardized differences < 0.1 between HSP and EMR).

En bloc and R0 resection rates

In the original cohort, the *en bloc* and R0 resection rates between the HSP and EMR groups were similar [94.8% (417/440) *vs* 92.8% (116/125), $P = 0.40$; 81.6% (359/440) *vs* 80.8% (101/125), $P = 0.84$, respectively] (Table 2). In the propensity score-matched cohort, the *en bloc* resection rate remained similar between the HSP and EMR groups [93.2% (109/117) *vs* 92.3% (108/117), $P = 0.81$]. Furthermore, there was no significant difference between the HSP and EMR groups in the R0 resection rate [77.8% (91/117) *vs* 80.3% (94/117), $P = 0.64$] (Table 2). All patients who underwent RX/R1 resection were classified as HMX/HM1, and there were no patients with VMX/VM1. There was no significant difference in the R0 resection rate between the HSP and EMR groups according to size, macroscopic type, and endoscopist experience. However, in terms of rectal location, the R0 resection rate was significantly higher in the EMR group than in the HSP group [75.0% (18/24) *vs* 100% (22/22), $P = 0.022$] (Table 3).

Adverse events

In the original cohort, there was no significant difference in the incidence of delayed bleeding between the HSP and EMR groups [1.1% (5/440) *vs* 1.7% (2/125), $P = 0.68$]. Perforation occurred in the EMR group [0.9% (1/125); $P = 0.060$] but not in the HSP group (Table 2). In the propensity score-matched cohort, the incidence of delayed bleeding was similar in both groups [1.7% (2/117)]. Perforation occurred in the EMR group [0.9% (1/117)] but not in the HSP group. One case of perforation in the EMR group occurred intraoperatively.

DISCUSSION

This study is the first to compare treatment outcomes between HSP and EMR using a bipolar snare for nonpedunculated colorectal lesions measuring 10–15 mm in clinical practice. Two important results were obtained in this study. First, there was no significant difference in *en bloc* and R0 resection rates between the HSP and EMR groups. Second, the incidence of adverse events was similar in both groups; however, perforation occurred only in the EMR group. These results suggest that comparable treatment efficiency and safety may be obtained when resecting nonpedunculated colorectal lesions measuring 10–15 mm using a bipolar snare and even without submucosal injection.

Several ER methods have been widely adopted for colorectal lesions, including cold snare polypectomy (CSP), HSP, and EMR. The European Society of Gastrointestinal Endoscopy clinical guidelines proposed selecting ER methods according to the size and macroscopic type of lesions. For nonpedunculated lesions, CSP is recommended for lesions ≤ 9 mm, HSP or EMR for lesions 10–19 mm, and EMR or piecemeal EMR for lesions ≥ 20 mm[14,15]. For HSP and EMR, electrosurgical resection with a monopolar snare is generally performed. However, there is a risk of thermal damage because high-frequency current derived from the monopolar snare flows to the patient's plate through the deep part of the patient's living tissue[7]. In fact, in treatment outcomes of ER using a monopolar snare, perforation occurs in approximately 1.3%–2.8% of cases[16,17]. Therefore, when using a monopolar snare during ER for 10–19 mm colorectal lesions, EMR is recommended instead of HSP as it can reduce the risk of deep thermal damage[14].

We recently reported on endoscopic procedures using either a monopolar or bipolar snare in an *ex vivo* porcine model[8]. When 10–15-mm lesions were resected by HSP, the muscularis propria was thermally damaged when a monopolar snare was used but not when a bipolar snare was used.

HSP: Hot snare polypectomy; EMR: Endoscopic mucosal resection; right-sided colon: Caecum to transverse colon; left-sided colon: Descending colon to sigmoid colon; SSL: Sessile serrated lesion; LGD: Low-grade dysplasia; HGD: High-grade dysplasia; T1a: Shallow submucosal invasive cancer; T1b: Deep submucosal invasive cancer; SD: Standard deviation.

Therefore, greater safety can be expected even without submucosal injection when a bipolar snare is used. However, no studies compared the safety and effectivity between HSP and EMR using a bipolar snare in clinical practice. This study revealed that HSP had a similar complication rate as EMR when a bipolar snare was used for 10–15-mm nonpedunculated colorectal lesions. Notably, perforation did not occur following HSP, suggesting a better safety profile when using a bipolar snare over a monopolar snare. The delayed bleeding rate was also reported to be 1.4%–3.1% for EMR[16,17] and 5.3% for HSP [18] when a monopolar snare was used. However, in this study, the delayed bleeding rate for both HSP and EMR when a bipolar snare was used was 1.7%, which is relatively lower than previously reported values. Saraya *et al*[19] also reported that HSP and EMR using a bipolar snare had a similar or lower risk of delayed bleeding and perforation than EMR using a monopolar snare[19]. Although the present study had a small number of cases, HSP did not cause perforation and resulted in less delayed bleeding, suggesting that HSP using a bipolar snare might be an option that results in fewer complications than EMR using a monopolar or bipolar snare.

For ER of medium-sized lesions ≥ 10 mm, determining whether *en bloc* or R0 resection is possible is important for ER method selection. Piecemeal ER and RX/R1 resection are known risk factors for local

HSP: Hot snare polypectomy; EMR: Endoscopic mucosal resection; R0: Negative margin both horizontally and vertically.

recurrence after ER[20,21]. As the lesion grows, piecemeal endoscopic and RX/R1 resection rates increase, leading to an increased risk of local recurrence. However, the R0 resection rate is equivalent between HSP and EMR using a monopolar snare for colorectal lesions measuring 10–14 mm[22]. Therefore, the *en bloc* and R0 resection rates are equivalent between HSP and EMR with a bipolar snare, although no studies have been conducted to confirm this. In this study, for nonpedunculated colorectal lesions measuring 10–15 mm, HSP resulted in *en bloc* and R0 resection rates equivalent to those of EMR with a bipolar snare. Meanwhile, the *en bloc* resection rate was as high as ≥ 90% in both groups, and the R0 resection rate was approximately 80%, lower than previously reported values[22]. This could be because resection at our hospital is performed under the coagulation mode. Also, given the characteristics of ER using a bipolar snare, it is difficult to horizontally evaluate the pathological specimen due to crushing by cauterization in lesions where the resection margin is close to the lesion edge. However,

Figure 1 Flowchart of patient enrollment. Of the 711 consecutive lesions in 602 patients, 565 lesions in 463 patients were enrolled for the analysis. Of the 565 lesions, 440 in 346 patients were resected *via* hot snare polypectomy (HSP); 125 in 117 patients were resected *via* endoscopic mucosal resection (EMR). After propensity score matching, 117 lesions in the HSP group and 117 lesions in the EMR group were selected. HSP: Hot snare polypectomy; EMR: Endoscopic mucosal resection.

resection in coagulation mode may have contributed to a lower rate of delayed bleeding than previously reported because of the ability to coagulate the vessel[16-18].

The following points contributed to this innovative study design. First, patient and lesion backgrounds were matched using property score matching. The size, location, and macroscopic type of the lesions and endoscopic experience are known factors related to *en bloc* and R0 resection, and oral intake of antithrombotic agents is related to delayed bleeding[23-26]. This is the only study to balance the many confounding factors that may affect the estimation of results by property score matching and to compare treatment outcomes between HSP and EMR with a bipolar snare.

Second, only lesions diagnosed as JNET type 2A using magnifying observation combined with narrow-band imaging were included. In the qualitative diagnosis of colorectal lesions, those diagnosed as JNET type 2A can be diagnosed as adenomas or intramucosal cancers with high accuracy[27]. On the other hand, lesions diagnosed as JNET type 2B or 3 are generally known to develop into T1 cancer more frequently, resulting in bias wherein endoscopists who perform therapeutic endoscopy more carefully select ER methods that secure lesion margins. In this study, only JNET type 2A lesions potentially avoided bias due to differences in ER methods based on the preoperative diagnosis. Therefore, although the results of this study can be applied to adenomas and intramucosal cancers, it is unclear whether ER for T1 cancers will provide similar results. Third, we analysed the R0 resection rate as a factor between HSP and EMR. There was no difference in the R0 resection rate between HSP and EMR for most of the factors. However, the R0 resection rate for lesions in the rectum was better for EMR. No study has reported a change in the R0 resection rate with or without submucosal injection for rectal lesions. However, the R0 resection rate was reportedly significantly better in EMR than in HSP for the left colon [22]. Additionally, it can be difficult to diagnose a range of lesions due to factors such as 'skirt' in the rectum compared to the colon[28]. In rectal lesions of a difficult-to-identify extent with 'skirt', EMR provides wider margins, which may lead to fewer leftovers and improved R0 resection rates.

This study had some limitations. First, this was a single-centre retrospective study. In particular, the sample size was not large enough to prove the non-inferiority of HSP to EMR for any of the outcomes. Furthermore, since the treatment choices for HSP and EMR were left to the discretion of each endoscopist, the present results may be strongly influenced by the skill of a specific endoscopist. They may have been affected by imbalanced confounding factors that were not included in the analysis between the two groups. Second, there was no clear standard for measuring lesion size. Each endoscopist judged the size of the lesion by comparing it with the size of the snare, suggesting inaccurate lesion measurements. Third, the size of the bipolar snare used for resection was not specified, and the effects on the results cannot be denied. To eliminate these biases, conducting a large-cohort, multicentre, prospective, randomized controlled trial after clarifying ER methods, size of the snare, and

lesion measurement methods is desirable.

CONCLUSION

When using a bipolar snare, HSP has comparable treatment outcomes to EMR for nonpedunculated colorectal lesions measuring 10–15 mm. This suggests that the use of a bipolar snare may replace submucosal injection and may enable a more accessible ER while maintaining efficiency and safety.

ARTICLE HIGHLIGHTS

Research background

In endoscopic resection (ER) of colorectal lesions, it is important to develop resection methods that enable efficient and safe resection. Most recently, we have reported in *ex vivo* porcine model that endoscopic resection using bipolar snare for intermediate size lesions didn't lead to thermal injury for the intrinsic muscle layer even without submucosal injection. Therefore, the bipolar ER for intermediate size colorectal lesions of 10-15 mm has the potential to provide prominent outcomes in an efficient and highly safe manner even without submucosal injection.

Research motivation

We would like to assess the treatment outcomes of the bipolar resection with and without submucosal injection.

Research objectives

The present study aims to compare the resection results of endoscopic mucosal resection (EMR), which refers to the resection following submucosal injection, and hot snare polypectomy (HSP), which refers to the resection with no submucosal injection, to evaluate the efficacy and safety of HSP with bipolar snare for 10-15 mm lesions.

Research methods

We conducted the single-centre retrospective analysis of all 10-15 mm size colorectal lesions with a diagnosis of JNET Type 2A and resected by either EMR or HSP from January 2018 to June 2021. The target lesions were divided into two groups, HSP group and EMR group, and treatment outcomes and the adverse events were compared by conducting propensity score matching analysis.

Research results

Of the 565 lesions in 463 patients, 117 lesions each in the HSP and EMR groups were selected after propensity score matching. In the original cohort, there was a significant difference in antithrombotic drug use ($P < 0.05$), lesion size ($P < 0.01$), location ($P < 0.01$), and macroscopic type ($P < 0.05$) between the HSP and EMR groups. In the matched cohort, the *en bloc* resection rates were 93.2% (109/117) in the HSP group and 92.3% (108/117) in the EMR group, in which there was no significant difference ($P = 0.81$). Moreover, no significant difference was observed in the R0 resection rate [77.8% (91/117) *vs* 80.3% (94/117), $P = 0.64$]. The rates of delayed bleeding were comparable between the groups [1.7% (2/117)]. Perforation occurred in the EMR group [0.9% (1/117)] but not in the HSP group.

Research conclusions

Using bipolar snare, ER of nonpedunculated 10–15 mm colorectal lesions may be performed safely and effectively, even without submucosal injection.

Research perspectives

A large-cohort, multicentre, prospective, randomized controlled trial is warranted to prove the non-inferiority of bipolar HSP to bipolar EMR in treatment outcomes with ER of nonpedunculated 10–15 mm colorectal lesions.

Abstract

BACKGROUND

The lymphocyte-to-white blood cell ratio (LWR) is a blood marker of the systemic inflammatory response. The prognostic value of LWR in patients with hepatitis B virus-associated acute-on-chronic liver failure (HBV-ACLF) remains unclear.

AIM

To explore whether LWR could stratify the risk of poor outcomes in HBV-ACLF patients.

METHODS

This study was conducted by recruiting 330 patients with HBV-ACLF at the Department of Gastroenterology in a large tertiary hospital. Patients were divided into survivor and non-survivor groups according to their 28-d prognosis. The independent risk factors for 28-d mortality were calculated by univariate and multivariate Cox regression analyses. Patients were divided into low- and high-LWR groups according to the cutoff values. Kaplan-Meier analysis was performed according to the level of LWR.

RESULTS

During the 28-d follow-up time, 135 patients died, and the mortality rate was 40.90%. The LWR level in non-surviving patients was significantly decreased compared to that in surviving patients. A lower LWR level was an independent risk factor for poor 28-d outcomes (hazard ratio = 0.052, 95% confidence interval: 0.005-0.535). The LWR level was significantly negatively correlated with the Child-Turcotte-Pugh, model for end-stage liver disease, and Chinese Group on the Study of Severe Hepatitis B-ACLF II scores. In addition, the 28-d mortality was higher for patients with LWR < 0.11 than for those with LWR ≥ 0.11.

CONCLUSION
LWR may serve as a simple and useful tool for stratifying the risk of poor 28-d outcomes in HBV-ACLF patients.

Key Words: Lymphocyte-to-white blood cell ratio; Hepatitis B virus; Acute-on-chronic liver failure; Child-Turcotte-Pugh score; Model for end-stage liver disease score; Chinese Group on the Study of Severe Hepatitis B-Acute-on-chronic liver failure II score

Core Tip: This manuscript introduced a simple and effective inflammatory marker, the lymphocyte-to-white blood cell ratio (LWR). Our study found that a lower LWR level was associated with poor 28-d outcomes in hepatitis B virus-associated acute-on-chronic liver failure (HBV-ACLF) patients. It may serve as a simple and useful tool for stratifying the risk of poor 28-d outcomes in HBV-ACLF patients, and it may be helpful in guiding a clinician to treatment allocation and assist in the prediction of prognosis.

INTRODUCTION

Acute-on-chronic liver failure (ACLF) is a life-threatening clinically complex syndrome characterized by high short-term mortality due to different combinations of multiorgan failures[1-3]. The main etiology of ACLF is hepatitis B virus (HBV) infection, with HBV-associated ACLF (HBV-ACLF) accounting for more than 70% of ACLF cases in most Asian countries[4]. The clinical characteristics of HBV-ACLF patients differ from those of alcoholic-related ACLF patients in Western countries, wherein coagulation and liver failure are the most common types of organ failure[5]. Early prediction of the prognosis of HBV-ACLF is important for clinical management and diminishing mortality. However, current score models are based on complicated assessments of organ failure. Therefore, it is necessary to identify an accurate and simple indicator to detect high-risk patients.

A growing body of research evidence suggests that HBV-ACLF is associated with systemic inflammation and immune paralysis[6,7]. In many recent studies, inflammation-related markers such as the platelet (PLT) to white blood cell ratio, neutrophil-to-lymphocyte ratio, and monocyte-to-lymphocyte ratio have received increasing attention in clinical settings and are used in predicting the prognosis of HBV-ACLF[8-10]. The lymphocyte-to-white blood cell ratio (LWR) is a blood marker of the systemic inflammatory response. Studies have suggested that LWR has good prognostic value for patients with cancer, infective endocarditis and COVID-19[11-13]. However, the prognostic role of LWR in HBV-ACLF patients remains unclear. Therefore, our study aims to reveal whether LWR can risk-stratify poor prognosis in HBV-ACLF patients.

MATERIALS AND METHODS

Subjects

A total of 330 patients diagnosed with HBV-ACLF were retrospectively included from May 2014 to February 2021 at the Department of Gastroenterology, the First Affiliated Hospital of Nanchang University. The inclusion criteria were as follows: (1) Age ≥ 18 years; (2) Chronic liver disease due to HBV infection; and (3) HBV-ACLF diagnosed based on the diagnostic guidelines for liver failure established in 2019[14]. The exclusion criteria were as follows: (1) Coinfection with hepatitis A/C/D/E virus; (2) Other etiologies such as drugs, autoimmunity, alcohol, or toxins that may contribute to HBV-ACLF; (3) Complicated with hepatocellular carcinoma; (4) Human immunodeficiency virus infection; and (5) Loss to follow-up. The study was approved by the Institutional Review Board of the First Affiliated Hospital of Nanchang University.

Data collection

Demographic information and clinical data were comprehensively collected by searching medical

records. Laboratory blood tests were measured in the first 24-h period on admission. LWR was computed as the lymphocyte count (× 10^9/L) divided by the white blood cell count (× 10^9/L)[12]. The Child-Turcotte-Pugh (CTP), model for end-stage liver disease (MELD) and Chinese Group on the Study of Severe Hepatitis B-ACLF II (COSSHACLFII) scores were calculated as previously described[15-17]. All patients were followed from their diagnosis until either their death or the end of the 28-d follow-up period. The survival rates at 28 d were obtained from patients' medical records or by telephone calls with the patients or their kinsfolks.

Definitions

Chronic HBV infection was defined by the presence of hepatitis B surface antigen for > 6 mo[18]. HBV-ACLF was defined according to the Asian Pacific Association for the Study of the Liver criteria in 2019: (1) Serum bilirubin ≥ 5 mg/dL; (2) International normalized ratio (INR) ≥ 1.5 or prothrombin activity < 40%; (3) Complicated within 4 wk by clinical ascites and/or encephalopathy in patients with pre-existing chronic liver diseases (diagnosed or undiagnosed); and (4) High 28-d mortality[14].

Statistical analysis

Statistical analysis was performed using the SPSS 24.0 statistical package (SPSS Inc., Chicago, IL), R software version 4.1.0 (http://www.r-project.org/), and X-tile software (Version 3.6.1, Yale University, New Haven, CT, United States). Continuous variables were compared using the *t* test or the Mann-Whitney *U* test, whereas categorical variables were compared using the chi-square test or Fisher's exact test. Univariate analysis and multivariate Cox proportional hazards models were performed to identify whether LWR was related to poor outcomes. The optimal cutoff value of LWR was determined by using X-tile. The Kaplan-Meier survival curve was generated by the "survival" and "survminer" packages in R software. All statistical tests were two-sided with a statistical significance level set at *P* values < 0.05.

RESULTS

Baseline characteristics

The baseline characteristics of the patients are summarized in Table 1. A total of 330 patients with HBV-ACLF were recruited. In the cohort, the average age of patients was 49.68 ± 12.39 years, and approximately 83.9% of patients were male. The HBV-ACLF patients were divided into survivor and non-survivor groups according to the prognosis at 28 d. At follow-up, the age, prothrombin time (PT), INR, bilirubin, CTP score (CTPs), MELD score (MELDs), and COSSHACLFII score (COSSHACLFIIs) of the non-survivors were significantly higher than those of the survivors (*P* < 0.05). However, the PLT count and LWR level of the non-survivors were significantly lower than those of the survivors (*P* < 0.05). In addition, there were no significant differences in sex, costs, hemoglobin, albumin, creatinine, blood urea nitrogen (BUN), or serum Na between the non-survivor group and survivor group (*P* > 0.05).

Low LWR as an independent risk factor for mortality in patients with HBV-ACLF

The association between the LWR level and 28-d mortality is shown in Table 2. In univariate analysis, age, PLT, PT, hemoglobin, bilirubin, BUN, and LWR were significant factors for 28-d mortality (all *P* < 0.05). In multivariable analysis, the results showed that age, PT, bilirubin, and LWR were associated with short-term mortality [hazard ratio (HR) = 1.015, 95% confidence interval (CI): 1.001-1.030; HR = 1.028, 95%CI: 1.015-1.042; HR = 1.001, 95%CI: 1.000-1.003; HR = 0.052, 95%CI: 0.005-0.535, respectively].

Correlation between LWR levels and other score models

Next, we investigated the correlation between LWR levels and other score models, including CTPs, MELDs and COSSHACLFIIs. As shown in Figures 1A-C, LWR levels were significantly correlated with the CTPs, MELDs and COSSHACLFIIs (*r* = -0.29, *P* < 0.001; *r* = -0.31, *P* < 0.001; *r* = -0.49, *P* < 0.001, respectively).

Comparison of clinical data with different LWR levels

The median LMR of HBV-ACLF patients was 0.17 (0.11-0.23), and X-tile software was used to determine the optimal cutoff values for LWR for 28-d mortality. Consequently, the threshold of 0.11 enabled us to distinguish favorable and poor outcomes that were most significant in HBV-ACLF patients (Figure 2). HBV-ACLF patients were stratified into low LWR (LWR < 0.11) and high LWR (LWR ≥ 0.11) groups according to the cutoff values. As shown in Table 3, the patients in the group with LWR < 0.11 had an older age, lower PLT count, higher PT, higher INR, lower hemoglobin, lower albumin, higher creatinine, higher BUN, higher CTPs, higher MELDs, higher COSSHACLFIIs, and significantly shorter survival rate than those in the group with LWR ≥ 0.11.

Impact of LWR on the mortality of HBV-ACLF patients

As shown above, the patients with LWR < 0.11 had higher 28-d mortality than the high LWR group (*P* <

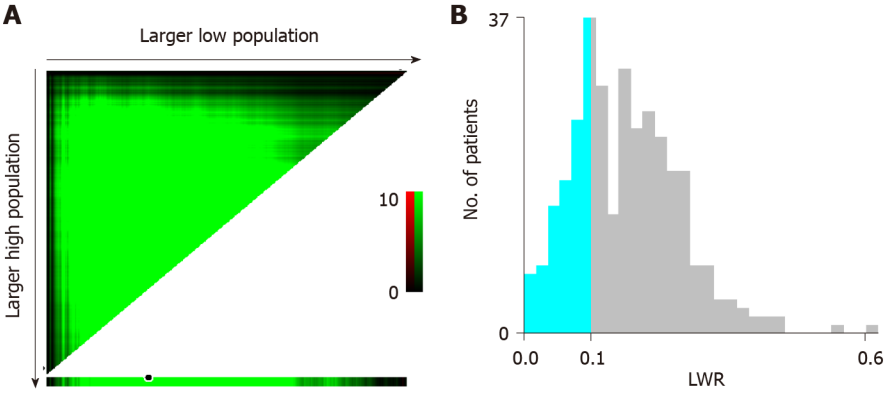
0.05). To confirm the association of the LWR level and 28-d outcomes in detail, Kaplan-Meier analysis was performed to assess LWR in HBV-ACLF patients, and patients with low LWR levels had a worse outcome than those with high LWR levels (Figure 3).

DISCUSSION

In our study, we found that a low LWR level was an independent prognostic factor related to poor 28-d outcomes in patients with HBV-ACLF. Patients with LWR < 0.11 had higher 28-d mortality than those with high LWR levels.



Systemic inflammation plays an important role in the development of HBV-ACLF[19]. The activation of inflammatory cytokines causes organ hypoperfusion and systemic circulatory dysfunction, which increase the activation of coagulation, tissue microthrombosis, and the development of organ failure [20]. Many studies have indicated that the inflammatory response can be reflected by inflammatory markers such as lymphocytes, white blood cells, PLTs, and neutrophils[21,22]. The combination of these inflammatory markers, such as the neutrophil-lymphocyte ratio (NLR), platelet-to-white blood cell ratio (PWR), and LWR, has been confirmed as a prognostic marker in a variety of liver diseases. Bernsmeier *et al*[23] reported that the NLR was an independent risk factor in patients with acute decompensation (AD) cirrhosis. Kim *et al*[22] included 1670 AD patients from a prospective cohort and found that patients with a PWR ≤ 12.1 had a higher 28-d mortality than those with a PWR > 12.1, and a lower PWR level was a prognostic factor for 28-d adverse outcomes. Overall, these inflammation-based markers could be useful for stratifying the severity of liver disease.

Our study found that LWR levels were significantly decreased in non-survivor HBV-ACLF patients, and low LWR levels were an independent risk factor for 28-d mortality in HBV-ACLF patients. The decreased LWR levels may reflect an enhanced inflammatory response and/or impaired immune

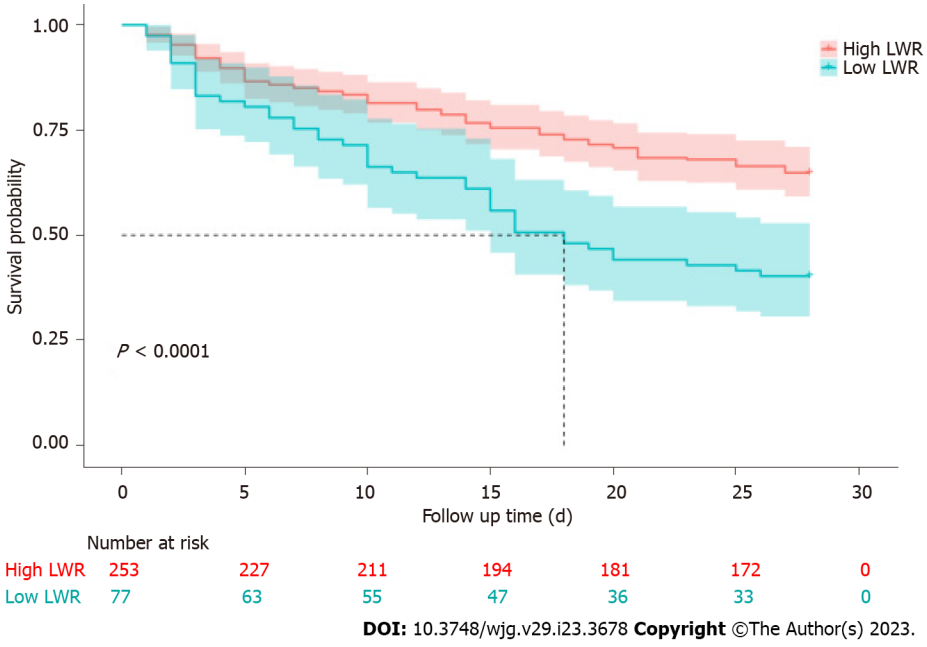

Figure 2 Analysis of lymphocyte-to-white blood cell ratio by using X-tile. A: The data on the horizontal ordinate increase from the left to the right, defined as the larger low population. The data on the vertical ordinate decrease from the top to the bottom, defined as the larger high population; B: The prognostic significance of lymphocyte-to-white blood cell ratio for hepatitis B virus-acute on chronic liver failure patients was determined by using a statistical algorithm in X-tile to calculate the most efficient cutoff point. LWR: Lymphocyte-to-white blood cell ratio.

response, which may explain the results. A previous study confirmed that lymphocytes play a critical role in the body's immune defense functions, immune response, and immune surveillance[12]. The elevated white blood cell count showed severe systemic inflammation, which was related to the prognosis of HBV-ACLF patients[24]. In addition, a recent study indicated that a low LWR level was an independent factor for poor outcomes in patients with decompensated liver cirrhosis, and the cut off value of LWR for 1 mo was 0.163. Patients with LWR < 0.163 had higher mortality than patients with LWR > 0.163[25]. Similar to this study, our research found that the cutoff value of LWR was 0.11, and

Table 2 Univariate and multivariate Cox regression analyses in hepatitis B virus-acute on chronic liver failure patients (*n* = 330)

	Univariate analysis		Multivariate analysis	
	HR (95%CI)	*P* value	HR (95%CI)	*P* value
Age	1.021 (1.007-1.035)	0.002	1.015 (1.001-1.030)	0.037
Male sex	1.202 (0.747-1.932)	0.448

Figure 3 Kaplan-Meier analysis of 28-d overall survival. The mortality rate was higher in patients with lymphocyte-to-white blood cell ratio (LWR) < 0.11 than in patients with LWR ≥ 0.11. LWR: Lymphocyte-to-white blood cell ratio.

patients with LWR < 0.11 had higher mortality than patients with LWR ≥ 0.11, and the results showed a significant negative correlation between LWR and CTPs, MELDs and COSSHACLFIIs. There are several limitations in our study. First, this is a single-center and retrospective study, which may cause selection biases. Second, lymphocytes and white blood cells were not tested dynamically during follow-up.

CONCLUSION

In conclusion, LWR is easily accessible and conveniently calculated, and it might be a good marker for

Table 3 Clinical characteristics between low and high lymphocyte-to-white blood cell ratio groups in hepatitis B virus-acute on chronic liver failure patients

identifying the risk of poor outcomes in HBV-ACLF patients. Therefore, our findings can help clinicians intervene in high-risk patients as early as possible.

ARTICLE HIGHLIGHTS

Research background

The lymphocyte-to-white blood cell ratio (LWR) is a blood marker that reflects the systemic inflammatory response. The prognostic value of the LWR remains unclear in hepatitis B virus-associated acute-on-chronic liver failure (HBV-ACLF) patients.

Research motivation

It is necessary to find an easy and effective marker that can reflect the prognosis in HBV-ACLF patients, so we explored whether LWR can risk-stratify poor prognosis in HBV-ACLF patients.

Research objectives

This study aimed to investigate whether LWR could be an easy and useful marker that can identify the risk of poor outcomes in HBV-ACLF patients.

Research methods

A total of 330 HBV-ACLF patients were included in this study, and patients were divided into survivor and non-survivor groups according to 28-d outcome. Univariate and multivariate Cox regression analyses were performed to select independent risk factors for 28-d mortality. The correlation test was

performed to evaluate the correlation between LWR and Child-Turcotte-Pugh score (CTPs), model for end-stage liver disease score (MELDs), and Chinese Group on the Study of Severe Hepatitis B-ACLF II score (COSSHACLFIIs). The cutoff value of LWR was calculated by X-tile software, and Kaplan-Meier analysis was performed to assess the association of the LWR level and 28-d outcomes in HBV-ACLF patients.

Research results

Low LWR was an independent risk factor for 28-d mortality in patients with HBV-ACLF (hazard ratio = 0.052, 95% confidence interval: 0.005-0.535), and LWR levels were significantly negatively correlated with CTPs, MELDs and COSSHACLFIIs. Moreover, the patients with low LWR levels had a higher 28-d mortality than those with high LWR levels.

Research conclusions

LWR is a simple, useful, and effective marker that could stratify the risk of 28-d adverse outcomes in HBV-ACLF patients.

Research perspectives

Further large-sample and multicenter prospective studies should be conducted to verify and confirm the prognostic value of the LWR.

Abstract

BACKGROUND

Geographical (geospatial) clusters have been observed in inflammatory bowel disease (IBD) incidence and linked to environmental determinants of disease, but pediatric spatial patterns in North America are unknown. We hypothesized that we would identify geospatial clusters in the pediatric IBD (PIBD) population of British Columbia (BC), Canada and associate incidence with ethnicity and environmental exposures.

AIM

To identify PIBD clusters and model how spatial patterns are associated with population ethnicity and environmental exposures.

METHODS

One thousand one hundred eighty-three patients were included from a BC Children's Hospital clinical registry who met the criteria of diagnosis with IBD ≤

age 16.9 from 2001–2016 with a valid postal code on file. A spatial cluster detection routine was used to identify areas with similar incidence. An ecological analysis employed Poisson rate models of IBD, Crohn's disease (CD), and ulcerative colitis (UC) cases as functions of areal population ethnicity, rurality, average family size and income, average population exposure to green space, air pollution, and vitamin-D weighted ultraviolet light from the Canadian Environmental Health Research Consortium, and pesticide applications.

RESULTS

Hot spots (high incidence) were identified in Metro Vancouver (IBD, CD, UC), southern Okanagan regions (IBD, CD), and Vancouver Island (CD). Cold spots (low incidence) were identified in Southeastern BC (IBD, CD, UC), Northern BC (IBD, CD), and on BC's coast (UC). No high incidence hot spots were detected in the densest urban areas. Modeling results were represented as incidence rate ratios (IRR) with 95%CI. Novel risk factors for PIBD included fine particulate matter ($PM_{2.5}$) pollution (IRR = 1.294, CI = 1.113-1.507, $P < 0.001$) and agricultural application of petroleum oil to orchards and grapes (IRR = 1.135, CI = 1.007-1.270, $P = 0.033$). South Asian population (IRR = 1.020, CI = 1.011-1.028, $P < 0.001$) was a risk factor and Indigenous population (IRR = 0.956, CI = 0.941-0.971, $P < 0.001$), family size (IRR = 0.467, CI = 0.268-0.816, $P = 0.007$), and summer ultraviolet (IBD = 0.9993, CI = 0.9990–0.9996, $P < 0.001$) were protective factors as previously established. Novel risk factors for CD, as for PIBD, included: $PM_{2.5}$ air pollution (IRR = 1.230, CI = 1 .056-1.435, $P = 0.008$) and agricultural petroleum oil (IRR = 1.159, CI = 1.002-1.326, $P = 0.038$). Indigenous population (IRR = 0.923, CI = 0.895–0.951, $P < 0.001$), as previously established, was a protective factor. For UC, rural population (UC IRR = 0.990, CI = 0.983-0.996, $P = 0.004$) was a protective factor and South Asian population (IRR = 1.054, CI = 1.030–1.079, $P < 0.001$) a risk factor as previously established.

CONCLUSION

PIBD spatial clusters were identified and associated with known and novel environmental determinants. The identification of agricultural pesticides and $PM_{2.5}$ air pollution needs further study to validate these observations.

Core Tip: Utilizing spatial mapping methodology, high and low incidence clusters of pediatric inflammatory bowel disease (IBD) were identified in British Columbia, Canada. Associating geographical location with IBD, rurality was negatively associated with ulcerative colitis. Notably, no high incidence hot spots were detected in the densest urban areas, suggesting unexplored urban protective factors. Novel risk factors for PIBD and specifically Crohn's disease included fine particulate matter pollution and agricultural applications of petroleum oil to orchards and grapes. Spatial distribution was partially explained by rurality, population ethnicity, family size, pesticide applications, air pollution, ultraviolet exposure, and residential greenness.

INTRODUCTION

Canada has one of the world's highest rates of pediatric inflammatory bowel disease (IBD), which includes Crohn's disease (CD) and ulcerative colitis (UC)[1]. Incidence within countries can be quite varied, but local patterns of IBD incidence are unknown for most countries[1]. Results from studies in Finland, Norway, Northern France, and Manitoba, Canada suggest that IBD may have a clustered spatial distribution, but more research is necessary for understanding local spatial patterns[2-5]. To date, no study has focused on empirically detecting and evaluating disease clusters in Canadian or North American pediatric IBD (PIBD) populations. Notably, detecting local spatial clusters of IBD would allow for a better understanding of clinical populations and identify areas where services are needed.

Moreover, spatial epidemiology can be used to identify novel environmental risk and protective factors. Although it is evident that environmental factors are important determinants for disease development, additional study is necessary.

A variety of population and environmental factors are thought to influence IBD risk. High incidence has been observed in Canadian populations of Jewish ethnicity and South Asian pediatric populations in British Columbia (BC), and low incidence has been reported in Canadian Indigenous communities[4,6,7]. Higher socioeconomic status has been associated with IBD[4,8]. A variety of environmental exposures, including rural residence, green space, ultraviolet (UV) radiation, and air pollution have also been studied[9-13]. No study known to us has examined pesticides as a potential determinant of PIBD. Pesticides can be present in food and the environment, and a variety of pesticides have been linked with changes to the gut microbiota which could have implications for IBD development[14]. Based on Canadian immigration and rural residence studies of IBD, exposures during early life appear to be important[9,15].

The aims of this exploratory study were (1) To determine spatial patterning of PIBD and identify location of disease hot and cold spots in the Canadian province of BC; and (2) to model the association between IBD case counts and population-level ethnicity, average income, rural residence, and known as well as novel environmental determinants. We hypothesized that we would identify IBD clusters that would be associated with ethnicity and environmental exposures. Modeling potential population risk factors provided context to the spatial analysis and helped identify areas where additional novel environmental risk or protective factors might have meaningfully affected disease incidence.

MATERIALS AND METHODS

Study area

BC is Canada's westernmost province. It is divided into five Regional Health Authorities, which can be further subdivided into 89 Local Health Areas (LHAs) (see Figure 1 and Supplementary Figure 1). The majority of BC's population live in urban areas located in the Vancouver Coastal and Fraser Health Authorities near the United States border[16]. Northern, Interior, and Vancouver Island Health serve largely more rural populations.

Participants

Patients for this study were selected from a clinical registry of IBD patients maintained by the BC Children's Hospital (BCCH) Division of Gastroenterology, Hepatology and Nutrition who were diagnosed with or received care for IBD at BCCH in Vancouver[17]. Author Jacobson K is data steward for this registry. As BCCH is the only tertiary care pediatric institution with academic pediatric gastroenterologists in the province, it is where most children with IBD are diagnosed. Our recent study comparing PIBD incidence derived from the BCCH registry with incidence derived from population-wide provincial health administrative data between 1996 and 2008 found similar overall rates, particularly from 2001 onwards, reaffirming the validity of the registry as a reflection of population-based cases[18]. Notably, a small number of cases are diagnosed in the community, use health services from a different province or, in the case of older patients (> 16.9 years), are diagnosed by adult gastroenterology physicians. Registry patients were excluded from the study if they were diagnosed outside the study period (2001 to 2016) or over age 16.9 years, did not have a valid postal code on file, or had a postal code associated with BCCH as this was likely not their permanent address. Postal codes were cleaned to provide consistent formatting. See Table 1 for BC pediatric incidence, and Supplementary Table 1 for incidence by patient age. Patient six-digit postal code point location at diagnosis was associated with latitude and longitude coordinates from DMTI Spatial Inc. obtained from the Canadian Urban Environmental Health Research Consortium (CANUE)[19]. Incidence was pooled for the full study period to maximize the number of cases in each analysis.

This study was approved by the University of British Columbia Children's and Women's Research Ethics Board, No. H19-00739.

Methods

Guidelines from the REporting of studies Conducted using Observational Routinely-collected health Data statement were adapted for this ecological study. The statistical methods of this study were reviewed by biostatistician Jeffrey Bone from the BCCH Research Institute. Data is summarized in Table 2, with additional details on environmental exposures presented in the Supplementary materials. Ethnicity and family size (married or common-law spouses, single parents, and at least one child) data from the Canadian census were obtained at the Dissemination Area level and resampled to LHAs by population-weighted overlay[16,20,21]. Average family income for 2005 and 2015 was available for LHAs[22]. To approximate average environmental exposures for each LHA, census population age 0-19 was used to population-weight postal code exposure data in a process that captured 92.6% of BC's youth population (excluded population resided in areas not covered by single link postal codes). Environmental data provided by CANUE for six digit postal codes included Normalized Difference

Table 1 British Columbia average pediatric incidence for inflammatory bowel disease, Crohn's disease, ulcerative colitis, and inflammatory bowel disease-unclassified from 2001–2016

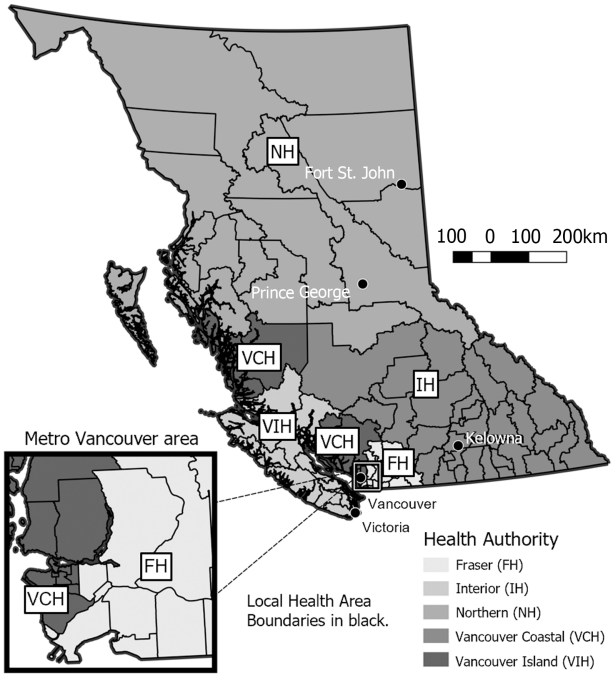
Vegetation Index (NDVI)[19,23-26] greenness[27,28], vitamin D UV[19,29,30], nitrogen dioxide (NO_2)[19,31,32], ozone (O_3)[33-37], and fine particulate matter ($PM_{2.5}$)[19,38]. Data on metam, petroleum oil, and glyphosate pesticides was resampled from Global Pesticide Grids[39,40]. The least populous LHA was excluded from regression modeling due to missing data.

Spatial cluster analysis

Standardized incidence ratios (SIRs) for each of BC's LHAs were calculated from incident registry cases using BC incidence as the reference rate[41]. DataBC provided geographic data[42]. To reduce the instability in disease rates caused by low case counts and populations, rates were averaged for the study period. In addition, spatial linear empirical Bayes estimation was used to smooth SIRs in areas with average pediatric populations under 10000[43]. The smoothing process calculated averages between a LHA's SIR and the average SIR value of adjacent LHAs. Spatial relationships for smoothing and clustering were defined by direct adjacency (queen contiguity) to approximately model geographic connectivity.

Two forms of spatial analysis were used to identify spatial patterns in PIBD. The Global Moran's I statistic measured the degree to which spatial patterning of IBD, CD, and UC in BC was clustered, dispersed, or had no detectable spatial pattern. The Local Moran's I statistic was used as a Local Indicator of Spatial Association (LISA) to identify the location of hot spots (clusters of comparatively high SIRs) and cold spots (clusters of comparatively low SIRs) among LHAs[44]. To approximate the likelihood that a cluster would arise by chance, we used 999 Monte Carlo simulations to compute a pseudo-*P* value[44], which was then adjusted with a Holm correction for multiple comparisons. We

Table 2 Data used in environmental exposure modeling



Variable	Description	Data source and database
Income	Mean of 2005 (adjusted to 2015 dollars) and 2015 census average family income for Local Health Areas	Statistics Canada, BC Community Health Atlas
Ethnicity	Census percent of the population of South Asian, Indigenous, Chinese, Jewish, and Non-Jewish European ethnic origin	Statistics Canada, University of Toronto Computing in the Humanities and Social Sciences Data Centre
Family size	Census average family size	Statistics Canada, University of Toronto Computing in the Humanities and Social Sciences Data Centre
Rurality	Percent of residents in each Local Health Area who lived outside a census metropolitan area or census agglomeration	Statistics Canada
NDVI greenness	Green vegetation cover calculated from land satellite imagery of surface reflection. Maximum and average growing season (May – August) NDVI within 250 m from postal code location. Multiplied by 100 so changes could be assessed as percentages	United States Geological Survey, Canadian Urban Environmental Health Research Consortium
UV vitamin D	Long-term stable monthly mean daily vitamin D dose from solar UV radiation adjusted for postal code elevation (J/m^{-2}) which was averaged for winter (December through February) and summer (June through August)	Environment Canada and Cancer Care Ontario, Canadian Urban Environmental Health Research Consortium
NO_2 air pollution	Annual average NO_2 concentration in parts per billion	Canadian Urban Environmental Health Research Consortium
O_3 air pollution	Average of O_3 taken from the highest rolling 8-hour daily average concentration (parts per billion)	Environment and Climate Change Canada, Canadian Urban Environmental Health Research Consortium
$PM_{2.5}$ air pollution	Annual average surface $PM_{2.5}$ ($\mu g/m^3$) concentration	Atmospheric Composition Analysis Group, Canadian Urban Environmental Health Research Consortium
Metam pesticide	2015 metam pesticide applied to fruits and vegetables (kg/ha/yr)	Global Pesticide Grids, Version 1.01, based on the United States Geological Survey's Pesticide National Synthesis Project and the Food and Agriculture Organization Corporate Statistical Database pesticide databases
Petroleum oil pesticide	2015 petroleum oil employed for grapes and orchards (kg/ha/yr)	Global Pesticide Grids, Version 1.01, based on the United States Geological Survey's Pesticide National Synthesis Project and the Food and Agriculture Organization Corporate Statistical Database pesticide databases
Glyphosate pesticide	2015 total glyphosate employed in major crops (wheat, corn, alfalfa, and others) in (kg/ha/yr)	Global Pesticide Grids, Version 1.01, based on the United States Geological Survey's Pesticide National Synthesis Project and the Food and Agriculture Organization Corporate Statistical Database pesticide databases
Population age 0-16.9	Yearly estimates of population age 0-16.9 for Local Health Areas averaged for 2001–2016	Statistics Canada, BC Stats

BC: British Columbia; NDVI: Normalized difference vegetation index; NO_2: Nitrogen dioxide; O_3: Ozone; $PM_{2.5}$: Fine particulate matter; UV: Ultraviolet.

chose LISA statistics over spatial and spatiotemporal SCAN methods given the irregular nature of the spatial areal units under analysis and the relative rarity of the disease, conditions under which LISA statistics have offered high sensitivity and specificity in cluster detection[45,46]. Data was aggregated over time (*i.e.* no spatio-temporal cluster analyses) given the aforementioned relative rarity of PIBD cases in BC.

Count regression modeling

Poisson Rate generalized linear models (PR-GLM) were used in an ecological analysis of LHAs to quantify the impact of population ethnicity, income, family size, rurality, air pollution, greenness, UV, and pesticide exposure on raw (unsmoothed) IBD, CD, and UC case counts. These models adjust for the population of each LHA and have an equal mean and variance. Model selection was based on the minimization of the Akaike Information Criterion using a stepwise algorithm combining backward elimination and forward addition[47]. PR-GLMs performed better than Negative Binomial, zero-inflated Poisson, and hurdle Poisson models. Considerations for reducing collinearity, conducting model selection, testing spatial independence of residuals, examining best model diagnostics, and considerations around the mapping of Incidence Rate Ratios (IRRs) are presented in the Supplementary materials. Multivariate models and high-quality Canadian census and exposure data were used to minimize sources of potential bias.

Figure 1 British Columbia's five Health Authorities and 89 Local Health Areas (black boundaries).

RESULTS

Spatial clustering results

The registry consisted of 1232 eligible patients diagnosed at or before age 16.9. Of these, 49 were associated with invalid or BCCH postal codes. In the spatial cluster modeling of the remaining 1183 PIBD patients, we observed a statistically significant (pseudo-$P < 0.05$) clustered distribution with a Moran's I statistic of 0.65 ($P = 0.001$). For the 780 CD patients we observed a Moran's I of 0.56 ($P = 0.001$) and for the 288 UC patients a Moran's I of 0.28 ($P = 0.001$). See Figure 2 for local cluster locations. Hot spots were observed in the lower mainland, the main urban centre of BC, for IBD ($P \leq 0.031$), CD ($P \leq 0.031$), and UC ($P \leq 0.007$), in the Okanagan region for IBD ($P \leq 0.029$) and CD ($P = 0.030$), and on Vancouver Island for CD ($P = 0.034$). A cold spot cluster was detected in southeastern BC for IBD (P values < 0.001), CD ($P \leq 0.0499$), and UC ($P \leq 0.040$), in Northern BC for IBD ($P = 0.026$) and CD ($P = 0.038$), and on BC's coast for UC ($P = 0.036$). We observed no LHA which had a significantly different trend in incidence than neighboring LHAs (spatial outliers) for IBD, CD, or UC.

Environmental modeling results

Summary statistics for variables are presented in Table 3 for BC and Supplementary Table 2 by Health Authority (see Figure 1 for reference and Table 1 for incidence). Variables (Table 3) were modeled individually and combined in a multivariate model. Lack of spatial clustering observed in the residuals indicates that the model assumption of spatial independence was met, and suggests that within the parameters of the analysis there were either no important missing variables with spatial patterning or that the existing predictors capture similar spatial variability of important unmeasured variables. The final models included variables shown in Table 4 and logged average population as an offset variable.

For the whole PIBD population, Indigenous ethnic origin, average family size, summer UV radiation, and metam pesticide application were identified as significant protective factors. In contrast, South Asian origin, greenness, $PM_{2.5}$, and petroleum oil application were significant risk factors. When broken down by disease subtype, Indigenous ethnic origin, NO_2, and O_3 were statistically significantly negatively correlated with CD, while maximum growing season greenness, $PM_{2.5}$, and petroleum oil application were significant risk factors. Rurality, and alfalfa and corn glyphosate were statistically significant protective factors for UC, while significant risk factors included South Asian origin, mean growing season greenness, O_3 pollution, and wheat glyphosate.

A 1% increase in the Indigenous population of a LHA was associated with a 4.4% decrease in the number of IBD cases (IRR = 0.956, $P < 0.001$) and a 7.7% decrease in CD (IRR = 0.923, $P < 0.001$), while a 20% increase in Indigenous population was associated with a 59% decrease in IBD. Each additional family member added to family size was associated with a 53.3% decrease in IBD cases (IRR = 0.467, $P = 0.007$). An increase of 1 J/m^{-2} in summer UV was associated with 0.001% decrease in IBD cases (IRR = 0.999, $P < 0.001$) while an increase of 500 J/m^{-2} was associated with a 29.4% decrease. A 1% increase in

LHA: Local Health Area; NDVI: Normalized difference vegetation index; UV: Ultraviolet; NO_2: Nitrogen dioxide; O_3: Ozone; $PM_{2.5}$: Fine particulate matter.

rural population was associated with a 1% decrease in UC (IRR = 0.990, P = 0.004). Each unit increase of metam pesticide was associated with a 6.9% decrease in IBD cases (IRR = 0.931, P = 0.001 for 1 kg/ha). Each ppb increase in O_3 was associated with a 9.5% increase in UC (IRR = 1.095, P = 0.001) and a 5.3% decrease in CD (IRR = 9.47, P = 0.010). Each ppb increase in NO_2 was associated with a 4.8% decrease in CD cases (IRR = 0.952, P = 0.006). Each unit increase of glyphosate applied to wheat was associated with an increase in UC (IRR = 121.196, P = 0.019 for 1 kg/ha), while the same pesticide applied to corn (IRR = 0.828, P = 0.021 for 1 kg/ha) and alfalfa (IRR = 0.001, P = 0.024 for 1 kg/ha) was a significant protective factor. It is important to note that glyphosate applications to corn (range 0.00–6.06, mean 0.49 kg/ha) were much higher than those to alfalfa (range 0.00–0.17, mean 0.02 kg/ha) and wheat (range 0.00–0.21, mean 0.02 kg/ha), and the extremely high and low IRRs for glyphosate are more reflective of the small data values than actual effect size.

A 1% increase in the percent of South Asian residents was associated with a 2% increase in IBD (IRR = 1.020, P < 0.001) and a 5.4% increase in UC (IRR = 1.054, P < 0.001), while a 20% increase in South Asian residents was associated with a 47.5% increase in IBD. A 1% increase in maximum growing season greenness was associated with a 6% increase in IBD and a 3.8% increase in CD (IRR = 1.060, P < 0.001, and IRR = 1.038, P = 0.002, respectively). A 1% increase in mean growing season greenness was associated with a 4.3% increase in UC (IRR = 1.043, P = 0.006). Each 1 μg/m^3 concentration increase in $PM_{2.5}$ air pollution was associated with a 29.4% increase in IBD cases (IRR = 1.294, P = 0.001) and a 23% increase in CD cases (IRR = 1.230, P = 0.008). Finally, a 1 kg/ha increase in the application of petroleum oil in grapes and orchards was associated with a 13.5% increase in IBD (IRR = 1.135, P = 0.033) and a 15.9% increase in CD (IRR = 1.159, P = 0.038).

DISCUSSION

Based on our exploratory analysis describing spatial patterning of PIBD in BC, incidence varied substantially across the province in both rural and urban areas, likely reflective of BC's diverse population and environments. The spatial distribution of IBD, CD, and UC was significantly clustered during the period of 2001 to 2016, with substantial overlap between cluster locations for each of the three. The lower mainland hotspot and southeastern BC cold spot were consistent across the study period in the IBD population. As previously reported in PIBD, UC represented a lower percentage of IBD cases than CD and in addition, displayed a less clustered distribution with fewer shared clusters. It is unlikely that these observed clusters resulted from chance. Notably, patients living near the eastern border (Alberta) may receive care in that province, potentially explaining the cold spot in southeastern BC.

In our modeling of the association between IBD case counts and population and environment variables, higher proportions of South Asians tended to be associated with higher IBD and UC case counts. In Ontario, Canada, similar incidence of IBD has been observed for children of immigrants of South Asian origin born in Canada and children of non-immigrants[15]. However, higher rates of IBD have been documented in South Asian populations in BC, the United States, the United Kingdom, New Zealand, and Singapore and Malaysia[7,48-51]. Our observation of lower IBD and CD cases associated with higher proportions of Indigenous residents is consistent with previous Canadian studies[4,52]. When interpreting modeling results, locations where IBD rates were well predicted by population ethnicity should still be considered places where environmental risk or protective factors were also present. Larger family size has been associated with a protective effect on CD, which is consistent with our results for IBD but not CD[6]. Higher socioeconomic status is an established risk factor[4,8], but average income quantile was not a significant predictor in any model (though it improved CD model

fit). While several identified hot spots were located in the highest income areas of BC and cold spots in the lowest income areas, there were also hot spots with low income and cold spots with high income. It may be that average household income is less relevant than other socioeconomic indicators in BC, or that an effect was not observable for aggregated populations.

Our results suggest that at the LHA level, residential environmental exposures at diagnosis may also be significant potential determinants. Links with vitamin D and sunlight have been inconsistent, due in part to variability in study design and exposure assessment[12]. Our findings indicate that summer vitamin D UV radiation may confer a protective effect on IBD development. An individual unit of UV (1 J/m^{-2}) is quite small which resulted in a low measured IRR. Mean UV in BC is significantly higher in summer (6053.15 J/m^{-2}) than winter (274.98 J/m^{-2}) and varies within the province (summer maximum of 7272.52 and minimum of 4488.80 J/m^{-2}). An increase in UV of 500 J/m^{-2}, which is more representative of actual geographic and seasonal UV variation, was associated with a 29.4% decrease in IBD cases. In the analysis stratified by disease type, summer and winter UV vitamin D were nonsignificant protective factors that improved model fit for CD and UC, respectively. Smaller sample size in stratified analysis may have contributed to nonsignificant results. Low winter UV across BC could be particularly relevant for people of South Asian descent who have a higher level of skin melanin and require substantially more UV exposure to synthesize sufficient vitamin D[30]. $PM_{2.5}$ air pollution was a significant risk factor for PIBD and CD. Italian (IBD) and Chinese (UC but not CD) studies of middle and older aged adults have identified $PM_{2.5}$ as a risk factor for incident cases as well as IBD and UC hospitalizations in China [53-55]. In contrast, an Ontario pediatric study found no association and a European adult study found a negative association with $PM_{2.5}$[13,56]. Though population exposure for most LHAs met 2020 national and provincial air quality objectives, BC experiences seasonal wildfire events which can cause short-term high $PM_{2.5}$ concentrations that would be obscured in the yearly average values used in this study [57]. Regular high exposure events should be investigated further, especially as climate change is projected to increase wildfire potential[58]. O_3 air pollution was a significant risk factor for UC which is consistent with a Chinese study which measured an association between O_3 and IBD and UC hospital visits[54]. We observed statistically significant negative associations with CD for NO_2 and O_3. This is in contrast to the lack of association observed for IBD in Ontario and Europe, a United Kingdom study which found a positive association between NO_2 pollution and CD onset before age 23, and a Chinese study which found a positive association between NO_2 and UC incidence in middle and older aged adults[13,55,56,59]. Differential effects on CD and UC have been observed for environmental exposures such as smoking and appendectomy[60].

BC had few areas of low residential greenness and high incidence (Supplementary Figures 3–5), and we observed statistically significant positive associations between IBD, CD, UC, and greenness. Our findings contrast with a pediatric cohort study in Ontario, which found a protective effect for maximum growing season NDVI at 250 m[11]. This inconsistency could be due to methodological differences between the two studies. NDVI is a measure of vegetation greenness only and may not capture other elements of green spaces, such as vegetation composition, environmental microbiome, or pesticide and herbicide applications, which may differ in BC. Measures of greenness in BC are highly dependent on specific indicators, as a Metro Vancouver study comparing green space metrics found that NDVI at 250 m from postal codes diverged significantly from other measures such as street tree density, total percentage of green space, and park quality[61].

A previous Canadian study found a protective effect of rurality on pediatric CD and UC, while our study only observed an effect for UC[9]. BC may have more diverse environments than other provinces; for example, the largely rural Interior Health Authority had many of the highest average $PM_{2.5}$ and O_3 exposures while the majority-urban lower mainland region included significant sections of Agricultural Land Reserve. A hot spot near Vancouver included mostly suburban LHAs rather than the main urban center, which is similar to results observed in Oslo, Norway[62]. Perhaps some suburban and rural areas lack protective effects conferred by other rural regions while also missing potential health-promoting features of dense urban areas (*e.g.* public transportation, public parks, and access to amenities). Some rural and peri-urban areas can also be associated with potential risk factors such as petroleum pesticides.

A novel result in this study is the measured associations between pesticides and PIBD. Petroleum oil applied to grapes and orchards was a significant risk factor for IBD and CD. Indeed, exposure to agricultural petroleum oil has been previously associated with systemic autoimmunity (measured with antinuclear antibodies) and rhinitis in a prospective cohort of pesticide applicators in the United States, suggesting that petroleum pesticide products may have inflammatory properties[63,64]. As numerous other pesticides have been linked with dysbiosis, and petroleum is used as a fungicide, agricultural applications of petroleum oil should be investigated for potential impacts on the gut microbiome which could induce CD[14,39]. Interestingly, glyphosate application appeared to have a different effect on UC depending on which crop it was applied to. Wheat crop glyphosate was a significant risk factor, while alfalfa and corn crop glyphosate were significant protective factors. Differences in agricultural practices between alfalfa, corn, and wheat may be responsible for the negative or both associations observed for UC. The unexpected negative association between IBD and metam pesticide also warrants further investigation. This association could have resulted from an unmeasured confounder such as diet. For example, proximity to fruit and vegetable crops where metam is applied could be correlated with access to these food groups which are known to lower IBD risk[65].

A key strength of this study is the use of high resolution national environmental exposure metrics which increased the quality of the study and will facilitate comparisons between our results and future research. In addition, the clinical registry only contained patients with a confirmed IBD diagnosis, confirmed diagnosis of CD or UC, and accurate date of diagnosis which minimizes risk of misclassification. Moreover, we have demonstrated that our registry data is representative of the BC IBD population[18]. The use of aggregate case counts and reliable population data in both analyses and areal geographic analysis combined with spatial smoothing in the cluster analysis reduced the instability of disease rates caused by low cases numbers. The use of Monte Carlo simulation and a multiple comparison correction for statistical significance increased confidence in the spatial results. Finally, future healthcare service planning in BC would be implemented for health administrative units such as LHAs, so our scale of analysis would allow this research to be directly integrated into planning and intervention efforts.

Despite these strengths, there are several limitations which warrant discussion. Some patients were excluded due to missing data and it is possible that cases were missing from our clinical registry, either of which may have altered spatial clustering or biased modeling results. However, the registry likely included the vast majority of PIBD patients diagnosed in BC during the study period[18]. Patient data was not initially collected for research purposes, which may have affected available variables and may have contributed to missing data. Small numbers of cases could have produced large variation in incidence in sparsely populated areas. In addition, missing early environmental exposure data for several LHAs may have impacted the results, though all but one of the modeled LHAs included environment data from the majority of the study period. An important unmeasured variable in this analysis is diet, and missing potential confounding variables may have biased the results. This was not a birth cohort study, so there is uncertainty about exposures at gestation or early life. However, specific critical periods for many environmental exposures have not been established; consequently, further prospective studies are required. Previous environmental studies have used average childhood exposure[11,13] or did not have a standardized lookback period dating from diagnosis[56,59]. Accordingly, we used broad metrics of average population-level exposure during the study period. This was an ecological analysis and our findings should not be used to make claims about individual risk.

CONCLUSION

To our knowledge, this is the first spatial hot spot analysis focused on PIBD in North America and the first study identifying an association with pesticides. Spatial cluster detection was a valuable method for exploring patterns of IBD, and we identified $PM_{2.5}$ air pollution, petroleum oil, glyphosate, and metam pesticides as novel determinants of PIBD. Given the inconsistency of IBD incidence in urban areas and relatively high incidence in some suburban and rural areas, future research should move beyond binary urban-rural classifications and use specific characteristics such as built environment and pollutant exposures to characterize environments. Expanded regional and global studies are needed to validate these results and to determine the relationship between timing of exposure and clinical onset of disease. Furthermore, the inclusion of other immune-mediated inflammatory diseases will likely uncover potential shared disease clusters and environmental determinants.

ARTICLE HIGHLIGHTS

Research background

Geospatial patterning has been observed in inflammatory bowel disease (IBD) incidence and linked to environmental determinants of disease. However, knowledge of North American IBD spatial patterns is limited, and unknown in pediatric IBD (PIBD). A further understanding of geospatial patterns of IBD will help guide distribution of healthcare services and aid in identifying potential environmental risk and protective factors and populations at risk.

Research motivation

There is a lack of knowledge of the spatial distribution and environmental exposures relevant to PIBD in Canada and specifically in the Canadian province of British Columbia (BC).

Research objectives

The main objectives of this study were (1) To determine spatial patterning of PIBD and identify location of disease hot and cold spots in the Canadian province of BC during the period of 2001–2016; and (2) to model the association between IBD case counts and population-level ethnicity, average income, rural residence, and known as well as novel environmental determinants. Both objectives were addressed using the methods described below.

Research methods

The Moran's I statistic was used as a Local Indicator of Spatial Association to measure the degree, location, and type of geographic clustering of PIBD incidence, a method which improves on visual analysis of mapped incidence by empirically quantifying clustering. Statistical significance of observed clusters was approximated using Monte Carlo simulation. Case counts of IBD, Crohn's disease (CD), and ulcerative colitis (UC) were modeled in Poisson rate models as a function of average population characteristics and average population environmental exposures to assess associations between IBD and rurality, ethnicity, income, family size, and air pollution, green space, ultraviolet (UV) light, and pesticide exposures. Data sources included a BCCH clinical registry of patients diagnosed with IBD ≤ age 16.9, high-quality national environmental exposure datasets developed for health research, and Canadian census data.

Research results

No high incidence hot spots were detected in the densest urban areas, suggesting unexplored urban protective factors. Rurality was negatively associated with UC. Novel risk factors for PIBD and specifically CD included fine particulate matter ($PM_{2.5}$) pollution and agricultural applications of petroleum oil to orchards and grapes. Spatial distribution was partially explained by rurality, population ethnicity, family size, pesticide applications, air pollution, UV exposure, and residential greenness.

Research conclusions

Pesticide and $PM_{2.5}$ exposure are linked to the development of PIBD. Suburban and low-density urban areas of BC appear to lack protective exposures conferred by rural and dense urban areas.

Research perspectives

Exploring geographic patterns of PIBD facilitated the identification of novel environmental determinants, which has prompted followup studies of environmental exposures and IBD onset.

Abstract

BACKGROUND

Shear wave speed (SWS), shear wave dispersion (SWD), and attenuation imaging (ATI) are new diagnostic parameters for non-alcoholic fatty liver disease. To differentiate between non-alcoholic steatohepatitis (NASH) and non-alcoholic fatty liver (NAFL), we developed a clinical index we refer to as the "NASH pentagon" consisting of the 3 abovementioned parameters, body mass index (BMI), and Fib-4 index.

AIM

To investigate whether the area of the NASH pentagon we propose is useful in discriminating between NASH and NAFL.

METHODS

This non-invasive, prospective, observational study included patients diagnosed with fatty liver by abdominal ultrasound between September 2021 and August 2022 in whom shear wave elastography, SWD, and ATI were measured. Histological diagnosis based on liver biopsy was performed in 31 patients. The large pentagon group (LP group) and the small pentagon group (SP group), using an area of 100 as the cutoff, were compared; the NASH diagnosis rate was also investigated. In patients with a histologically confirmed diagnosis, receiver-operating characteristic (ROC) curve analyses were performed.

RESULTS

One hundred-seven patients (61 men, 46 women; mean age 55.1 years; mean BMI 26.8 kg/m^2) were assessed. The LP group was significantly older (mean age: 60.8 ± 15.2 years *vs* 46.4 ± 13.2 years; $P < 0.0001$). Twenty-five patients who underwent liver biopsies were diagnosed with NASH, and 6 were diagnosed with NAFL. On ROC curve analyses, the areas under the ROC curves for SWS, dispersion slope, ATI value, BMI, Fib-4 index, and the area of the NASH pentagon were 0.88000,

0.82000, 0.58730, 0.63000, 0.59333, and 0.93651, respectively; the largest was that for the area of the NASH pentagon.

CONCLUSION

The NASH pentagon area appears useful for discriminating between patients with NASH and those with NAFL.

Key Words: Non-alcoholic fatty liver disease; Non-alcoholic steatohepatitis; Attenuation imaging; Shear wave elastography; Shear wave dispersion; Diagnosis

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The non-alcoholic steatohepatitis (NASH) pentagon is a novel clinical index consisting of the five parameters of shear wave speed, dispersion slope, attenuation imaging value, Fib-4 index, and body mass index. It is simple and the calculation of its area is easy. The area of the NASH pentagon is useful for discriminating between patients with NASH and those with non-alcoholic fatty liver.

INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) is a global public health problem[1,2]. It is a grouping of diseases consisting of either non-alcoholic fatty liver (NAFL) or non-alcoholic steatohepatitis (NASH) [3]. If NASH progresses, it can lead to liver cirrhosis and hepatocellular carcinoma; thus, a clinical index needs to be developed that can efficiently discriminate NASH patients from NAFL patients[4,5]. Assessments based on multiple parameters using ultrasound, including shear wave elastography (SWE), are reported to be useful in stratifying the risk of advanced NASH[6].

SWE measures the speed of shear waves (shear wave speed; SWS) generated by push pulses. SWS is slow in soft objects and fast in hard objects. Measurements of SWS by SWE are considered useful in assessing liver fibrosis in viral hepatitis and NAFLD[7-11].

The shear wave dispersion (SWD) developed in recent years obtains the "frequency dependence" (dispersion slope; DS), which is the extent of the changes in the speed of shear waves, from changes in their frequency. Some preliminary evidence has been reported that DS measurements with SWD are an index of necroinflammation of the liver[12,13].

Attenuation imaging (ATI) was developed as a new testing method for evaluation of hepatic steatosis with ultrasound technology. ATI is a technique that uses the principle of attenuation due to phenomena such as absorption and diffusion of ultrasonic pulses emitted within the body when they pass through body tissue, and it produces a value referred to as the attenuation coefficient. Magnetic resonance imaging (MRI)-determined proton density fat fraction (PDFF) values have been reportedly used for assessing histological hepatic steatosis grades[14], and Tada *et al*[15] reported a good correlation between ATI values and MRI-determined PDFF values.

On the other hand, it is important to have parameters that do not require special equipment to measure. The prevalence of NAFLD in Japanese non-obese patients is 15%[16]. In other words, 85% of NAFLD patients are obese. Therefore, the body mass index (BMI), which can be easily used to determine obesity, is one such parameter of importance.

Similarly, the scoring system for liver fibrosis by the biochemical examination of blood is also relevant. The Fib-4 index, calculated by aspartate aminotransferase (AST), alanine aminotransferase (ALT), platelets (Plts), and age, is simple and easy to use[17].

In this study, a pentagon consisting of five parameters was prepared with the addition of the BMI and the Fib-4 index to the three parameters of SWS, SWD, and ATI. Whether the area of this pentagon is useful in discriminating NASH from NAFL was then investigated.

MATERIALS AND METHODS

Patients

This was a non-invasive, prospective, observational study that conformed with the ethical guidelines of the Declaration of Helsinki in its 2008 revision and was approved by the ethics review board of the hospital with which the authors are affiliated (No. 21057). The study was conducted after complete information disclosure on the website of the authors' hospital.

Of the patients diagnosed with fatty liver by abdominal ultrasound between September 2021 and August 2022, the subjects were patients in whom SWE, SWD, and ATI were measured. Patients with a history of alcohol intake of ethanol ≥ 20 g/d, who had hepatitis B, hepatitis C, or autoimmune liver disease, and patients with concurrent drug-induced liver injury or cholangitis were excluded.

Diagnosis of fatty liver with ultrasonography

The ultrasound scanner used was an Aplio i800 from Canon Medical Systems Corp. (Otawara, Tochigi, Japan). Fatty liver was diagnosed if the following were seen on B-mode ultrasound examination: (1) Bright liver[18]; (2) Positive hepatorenal echo contrast[19]; (3) Deep ultrasound attenuation in the liver [20]; and (4) Vascular blurring in the liver[21]. Specialists with ten or more years of ultrasonographic experience (Suda T and Tamano M) performed the B-mode ultrasound examination and measured SWE, SWD, and ATI.

Measurements of shear wave elastography and SWD

All SWE measurements were done following B-mode scans, using the same diagnostic equipment and transducers. The measurement results are shown as SWS (m/s). A 1-cm-diameter, circular region of interest was placed on the sample box.

SWD was measured at the same time as SWE. Simultaneous measurements could be taken by switching to quad view mode including a SWS map and a SWD slope map. This test was also performed using five or more measurement values, and the measurement results are shown as DS [(m/s)/KHz].

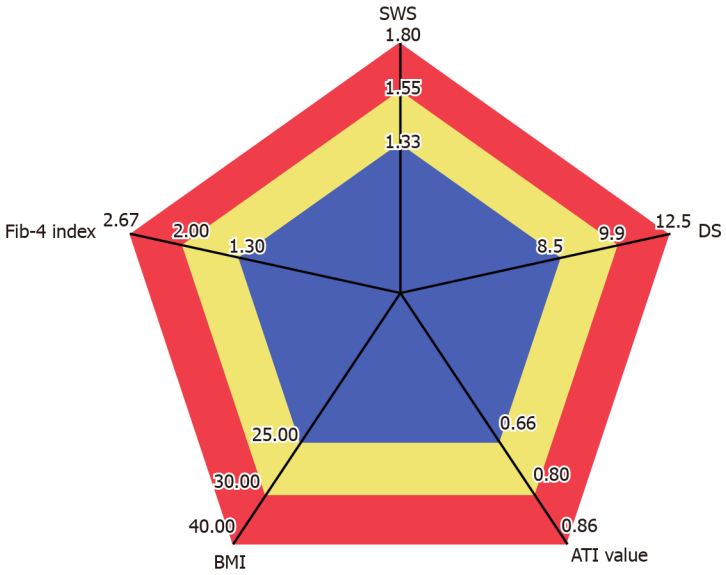
Measurements of attenuation imaging

After SWE and SWD were measured, the same physician performed the ATI test. The measurement result is shown as the ATI value [(dB/cm)/MHz]. A sample box with the default settings was used to acquire the data, set at least 1.5 cm below the liver capsule to avoid reverberation artifacts. The reliability of the results is displayed with R^2 values, categorized as poor ($R^2 < 0.80$), good ($R^2 = 0.81$-0.89), or excellent ($R^2 > 0.90$). According to information provided by the manufacturer, measurements are considered to be valid when $R^2 \geq 0.80$. Attenuation imaging examinations were performed until five valid measurements were obtained, and the mean value of the five measurements was used in the analysis.

Structure of the NASH pentagon

AST, ALT, and Plts were measured on the same day as the abdominal ultrasound. The Fib-4 index was calculated from these values and age. The BMI was calculated from height and weight on the day on which abdominal ultrasound was performed.

A pentagon consisting of these five parameters (SWS, DS, ATI value, BMI, and Fib-4 index) was created. This was defined as the NASH pentagon. The area of the NASH pentagon was calculated automatically by inputting a calculation formula into an Aplio i800 work station.



The standard value for each item was set according to previous studies as follows. The standard value of SWS was set as 1.33 m/s (cutoff value of fibrosis stage 1), that of DS was set to 8.5 (m/s)/KHz (cutoff value of lobular inflammation grade 1)[22]. Similarly, the standard value of ATI was set to 0.66 (dB/cm)/MHz, defining steatosis grade 1[16,22]. The standard value for BMI was set at 25.0 kg/m^2 based on the index of the Japanese Society for the Study of Obesity[1]. The standard value for the Fib-4 index was set to 1.30, which is the low cutoff value for advanced fibrosis (stage 3-4), based on a report by Shah *et al*[24] The investigation was done taking the area of this pentagon as 100 (Figure 1).

Diagnosis of NASH

Histological diagnosis based on liver biopsy was performed within three months from SWE measurement in those patients who provided consent. NASH diagnosis was made by an experienced pathologist certified by the Japanese Society of Pathology, based on comprehensive findings including macrovesicular steatosis, ballooning degeneration of hepatocytes, scattered inflammation and apoptotic bodies in the lobules, Mallory-Denk bodies, and fibrosis[25-27]. In this study, all patients without liver biopsy were judged to have NAFL, even if NASH was suspected clinically.

Comparison of two groups classified by the area of the NASH pentagon

Patient characteristics and individual parameters were compared between a large pentagon group (LP group), in which the area of the NASH pentagon was 100 or greater, and a small pentagon group (SP

DOI: 10.3748/wjg.v29.i23.3703 **Copyright** ©The Author(s) 2023.

Figure 1 Non-alcoholic steatohepatitis pentagon. The non-alcoholic steatohepatitis pentagon consists of the five parameters of shear wave speed (SWS), dispersion slope (DS), attenuation imaging value (ATI value), Fib-4 index, and the body mass index (BMI). Based on past reports, the reference values were set as SWS 1.33 m/s, DS 8.5 (m/s)/KHz, ATI value 0.66 (dB/cm)/MHz, BMI 25.0 kg/m^2, and Fib-4 index 1.3. SWS: Shear wave speed; DS: Dispersion slope; BMI: Body mass index; ATI: Attenuation imaging.

group), in which the area was less than 100. In addition, the NASH diagnosis rate was investigated when the NASH pentagon area of 100 was taken as the reference.

Diagnostic accuracy for NASH using the area of the NASH pentagon

In patients for whom liver biopsies were performed during the study period and a histologically confirm-ed diagnosis was made, a receiver-operating characteristic (ROC) curve was drawn for SWS, DS, ATI value, BMI, Fib-4 index, and area of the NASH pentagon.

Statistical analysis

Continuous data for SWS, DS, ATI value, and other clinical parameters are expressed as mean ± SD. A Spearman rank-order correlation coefficient test was used to test the independency of these clinical parameters. A non-paired Wilcoxon test was used in comparisons of each parameter between the two groups divided by NASH pentagon area, with $P < 0.05$ taken to indicate a significant difference.

The NASH diagnostic performance of SWS, DS, ATI value, BMI, Fib-4 index, and the area of the pentagon was investigated using the ROC curve. The area under the ROC curve (AUROC) was used to evaluate NASH diagnostic performance.

RESULTS

Patients' characteristics

The number of patients who were diagnosed with fatty liver based on abdominal ultrasound and in whom SWE, SWD, and ATI were measured was 126. After excluding 7 patients with an alcohol intake history of ≥ 20 g ethanol/d, 10 patients with concurrent hepatitis B, hepatitis C, or autoimmune liver injury, and 2 patients for other reasons, the investigation was conducted with the remaining 107 patients (Figure 2).

The characteristics for these 107 patients are shown in Table 1. There were 61 men and 46 women, with a mean age of 55.1 years. The mean BMI was 26.8 kg/m^2. Of the 107 patients, diabetes mellitus was seen in 25, dyslipidemia in 35, and hypertension in 37. Mean AST, ALT, and γ-glutamyltransferase concentrations were all mildly elevated at 44.9 U/L, 70.6 U/L, and 99.6 U/L, respectively. The mean Fib-4 index was 1.53. Twenty-five of the 107 patients were diagnosed with NASH, and the remaining 82 were diagnosed with NAFL.

The Spearman rank correlation coefficient between SWS and the Fib-4 index was 0.3486; no strong correlation was found. Similarly, the rank correlation coefficient between ATI and BMI was 0.1955, showing no correlation.

Table 1 Patients' characteristics

Patients' characteristics	*n* = 107
M/F	61/46
Age (yr)	55.1 ± 15.9
BMI (kg/m^2)	26.8 ± 4.1
Metabolic diseases	
Diabetes mellitus (yes/no)	25/82
Dyslipidemia (yes/no)	35/72
Hypertension (yes/no)	37/70
Concomitant drugs	
SGLT2 inhibitor	12
DPP-4 inhibitor	13
Thiazolidinedione	2
GLP-1 agonist	2
Statin	19
Bezafibrate	0

Hb (g/dL)	14.7 ± 1.3
Plts (10^4/μL)	23.9 ± 7.6
Fib-4 index	1.53 ± 1.90

M: Male; F: Female; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; GGT: γ-glutamyltransferase; T-Bil: Total bilirubin; Alb: Albumin; eGFR: Estimated glomerular filtration rate; HbA1c: Glycated hemoglobin A1c; T-chol: Total cholesterol; TG: Triglycerides; WBC: White blood cells; Hb: Hemoglobin; Plts: Platelets.

Comparison of two groups classified by the area of the NASH pentagon

The LP group with a NASH pentagon area ≥ 100 had 64 patients, and the SP group with an area < 100 had 43 patients. A comparison of the two groups is shown in Table 2.

There was no difference in sex between the two groups, but mean age was 60.8 ± 15.2 years in the LP group and 46.4 ± 13.2 years in the SP group, with the LP group significantly older ($P < 0.0001$).

Concurrent diabetes mellitus was seen in 18/64 patients (28.1%) in the LP group and 6/43 patients (13.9%) in the SP group. While this represents a higher tendency in the LP group, no significant difference was seen ($P = 0.0849$). Concurrent dyslipidemia was seen in 27/64 patients (42.2%) in the LP group and 8/43 patients (18.6%) in the SP group, and concurrent hypertension was seen in 29/64 patients (45.3%) and 7/43 patients (16.3%), respectively; both were significantly higher in the LP group ($P = 0.0108$, $P = 0.0183$).

Table 2 Comparison of the two groups classified by area of non-alcoholic steatohepatitis pentagon

	Large pentagon group (*n* = 64)	Small pentagon group (*n* = 43)	*P* value

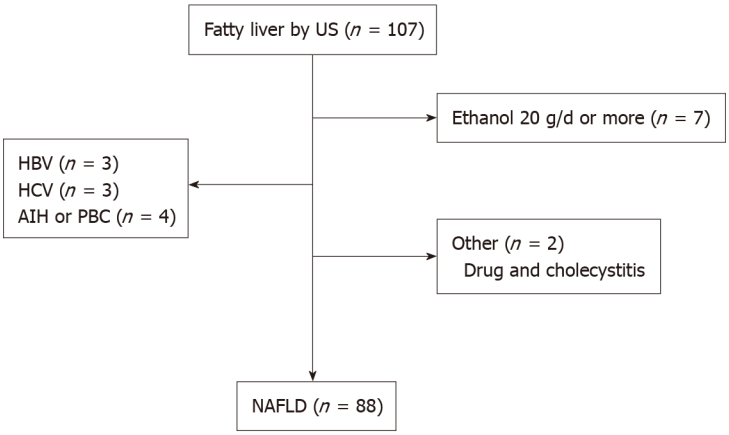
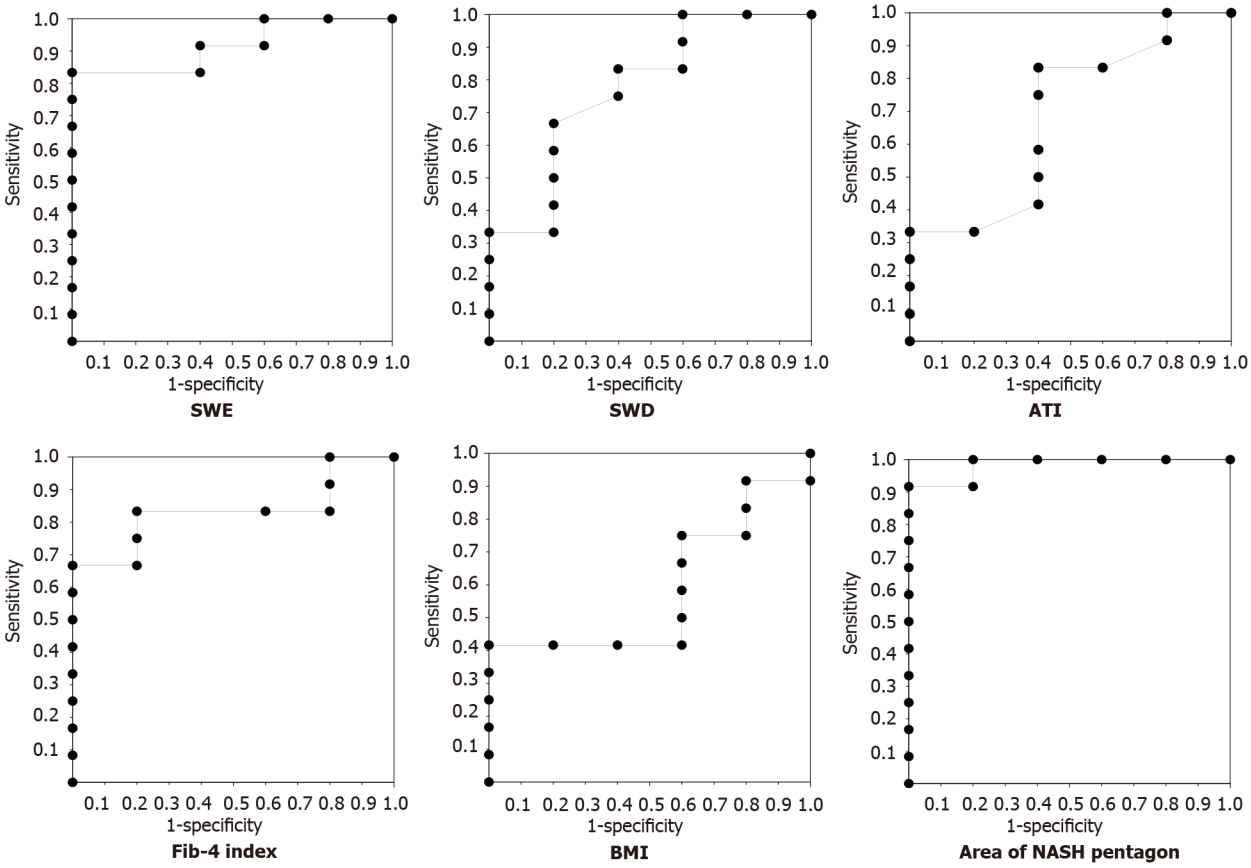
M: Male; F: Female; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; GGT: γ-glutamyltransferase; T-chol: Total cholesterol; TG: Triglycerides; WBC: White blood cells; Hb: Hemoglobin; Plts: Platelets; SWS: Shear wave speed; DS: Dispersion slope; ATI value: Attenuation imaging value; BMI: Body mass index; Alb: Albumin; eGFR: Estimated glomerular filtration rate; NASH: Non-alcoholic steatohepatitis; NAFL: Non-alcoholic fatty liver.



On blood biochemistry tests, total bilirubin was significantly higher in the LP group (P = 0.0044), whereas total cholesterol, white blood cells, and Plts were significantly lower in the LP group (P = 0.0080, P = 0.0080, P < 0.0001). There were no significant differences between the two groups in any of the other test results.

Comparisons of the five parameters that make up the NASH pentagon showed no significant difference between the groups in the ATI value (P = 0.1407), and significantly higher values in the LP group for SWS, DS, Fib-4 index, and BMI (P < 0.0001, P = 0.0004, P < 0.0001, P = 0.0249).

The number of patients diagnosed with NASH was 22 (34.3%) of 64 in the LP group and 3 (7.0%) of 43 in the SP group. The LP group had a significantly higher percentage of NASH patients (P = 0.0042).



Diagnostic accuracy of histological NAFLD using the area of the NASH pentagon

Liver biopsy was performed during the period of this study in 31 patients. Twenty-five of these 31 patients were diagnosed with NASH, and six were diagnosed with NAFL. The ROC curves indicating the NASH diagnostic performance in these 31 patients are shown in Figure 3. The AUROCs for SWS, DS, ATI value, BMI, Fib-4 index, and the area of the NASH pentagon were 0.88000, 0.82000, 0.58730, 0.63000, 0.59333, and 0.93651, respectively. Of these six items, the largest AUROC was that for the area of the NASH pentagon.

Figure 2 Flowchart of the study. A total of 126 patients who were diagnosed with fatty liver based on abdominal ultrasound and in whom shear wave elastography, shear wave dispersion, and attenuation imaging were measured during the period of this study were entered in the study. Of them, 7 patients with an alcohol intake history of 20 g ethanol/d or more, 3 with hepatitis B, 3 with hepatitis C, and 4 with autoimmune hepatitis or primary biliary cholangitis were excluded. In addition, 1 patient with drug-induced liver injury and 1 patient with cholangitis were excluded, bringing the final number of subjects in this investigation to 107. HBV: Hepatitis B virus; HCV: Hepatitis C virus; AIH: Autoimmune hepatitis; PBC: Primary biliary cholangitis; NAFLD: Non-alcoholic fatty liver disease.

Figure 3 Receiver-operating characteristic curve for each parameter. This shows the receiver-operating characteristic (ROC) curve of the 17 patients who underwent liver biopsy during the period of this study. The areas under the ROC curves (AUROCs) of shear wave speed, dispersion slope, attenuation imaging value, body mass index, Fib-4 index, and the area of the non-alcoholic steatohepatitis (NASH) pentagon are 0.88000, 0.82000, 0.58730, 0.63000, 0.59333, and 0.93651, respectively. Of these six parameters, the largest AUROC is that for the area of the NASH pentagon. SWE: Shear wave elastography; SWD: Shear wave dispersion; ATI: Attenuation imaging; BMI: Body mass index; NASH: Non-alcoholic steatohepatitis.

DISCUSSION

Ultrasound elastography has been used to evaluate fibrosis noninvasively. SWE, one type of ultrasound

elastography, includes transient elastography, point SWE, and other techniques[28-30]. The Aplio i800 used in the present study can measure SWE, SWD, and ATI with the same transducer. This machine is also equipped with a function that automatically creates radar charts from these measured values. The radar charts are created using five parameters. The three parameters of SWS, DS, and ATI value are set in the initial settings, and the remaining two can be freely set by the user. In the present study, these two were set as BMI and Fib-4 index, and it was thought that the area of this pentagon (NASH pentagon) may be useful for the diagnosis of NASH.

There are various reports about the cutoff values of SWE and DS[31]. In the present study, the cutoff values of SWE and DS were set from the report of Sugimoto *et al*[22] based on 120 liver biopsies. The cutoff values for steatosis grade 1 of ATI are reported to be 0.62-0.79[32-34]. In the present study, it was set to 0.66 from the report of Tada *et al*[35] based on 148 liver biopsies.

Obesity is the most important factor in the development of NAFLD. In NASH patients, there is a positive correlation between visceral fat and the amount of fat in hepatocytes[36]. Thus, obesity can lead to a diagnosis of NASH. In the present study, the reference value for BMI was set at 25.0 kg/m^2 based on the index of the Japanese Society for the Study of Obesity and a WHO recommendation[23,37].

The Fib-4 index calculated from age, AST, ALT, and platelet count is regularly used as a noninvasive parameter of hepatic fibrosis[38]. In this study, a value of 1.30, which is the low cutoff value for advanced fibrosis (stage 3-4), based on a report by Shah *et al*[24], was set as the reference value.

SWE and the Fib-4 index are indices of liver fibrosis. However, SWE makes use of ultrasound technology and predicts fibrosis. The Fib-4 index is calculated from biochemical evaluation and age. The correlation of the factors was examined, and no strong correlation was found. ATI is an index of hepatic steatosis assessed using ultrasound technology. BMI is an index of obesity of patients calculated from height and weight. In the present statistical analysis, there was no correlation between these two factors. Due to the above-mentioned reasons, the Fib-4 index and BMI were adopted as constituent factors of the NASH pentagon.

In a comparison of the LP group with a NASH pentagon area of 100 or more and the SP group with an area of less than 100, the LP group was older and had a lower platelet count. This is thought to be a result of the strong involvement of the Fib-4 index among the constituent elements of the pentagon. In fact, a very large difference was seen in the Fib-4 index between the groups, which was 2.2 in the LP group and 0.7 in the SP group ($P < 0.0001$).

The mean BMI, on the other hand, was 27.8 kg/m^2 in the LP group and 25.6 kg/m^2 in the SP group, tending to be higher in the SP group. Obesity is an important element of NAFLD, but as NAFL progresses to NASH, there is a tendency for weight loss. Moreover, even in the SP group, the mean BMI of 25.6 kg/m^2 was only slightly above the reference of 25.0 kg/m^2. This result is also consistent with reports that nonobese NAFLD is more common in Asia than in western countries[39,40].

The onset and progression of NAFLD/NASH are related to metabolic syndrome, and they have an especially strong relationship with diabetes mellitus[41]. In the present study, no difference was seen in concurrent diabetes mellitus by differences in the NASH pentagon area, but concurrent dyslipidemia and hypertension were significantly higher in the LP group.

The NASH pentagon consists of five parameters: Fibrosis based on SWS, inflammation as assessed by DS, steatosis as assessed by ATI value, obesity assessed by BMI, and the level of serological and clinical progression based on the Fib-4 index. Once this pentagon is programmed in the ultrasound machine, it can be automatically created and its area subsequently calculated, making it very simple to use. We thus consider it to be a useful method for identifying NASH among NAFLD patients.

In fact, when ROC curves were made for the six parameters of SWS, DS, ATI value, BMI, Fib-4 index, and the area of the NASH pentagon in 31 patients who underwent liver biopsy during the study period, the largest AUROC was the one for the area of the NASH pentagon.

In the early stage of NASH, liver fibrosis is mild, and in these patients, SWS is expected to be either normal or only mildly elevated. In young patients, the Fib-4 index also tends to be low. Even in these patients, however, DS, ATI value, and BMI are expected to be high, so it may be possible to identify them using the NASH pentagon.

Conversely, BMI tends to decrease when NASH progresses to cirrhosis, and even histologically, a state is present in which reduced fat deposition is seen (so-called "burned-out NASH")[42,43]. Such patients are expected to have low BMI and ATI values in conjunction with high SWS and Fib-4 index values. DS may have different values depending on the individual case, but the NASH pentagon is thought to be useful even in these patients.

Limitations

This was a prospective study, but only 107 patients were included, and only 31 underwent liver biopsy during the study period. These numbers are too small to obtain sufficient results. Additional studies with a larger number of patients will be needed to confirm our results. It may also be necessary to conduct a more detailed pathological investigation and a review of the reference values for the five parameters.

CONCLUSION

The preparation of a NASH pentagon consisting of five parameters, SWS, DS, ATI value, Fib-4 index, and BMI, is simple and the calculation of its area is easy. The authors believe that this multi-parametric index will be useful for identifying NASH patients among NAFLD patients.

ARTICLE HIGHLIGHTS

Research background

Non-alcoholic fatty liver disease (NAFLD) is a major problem throughout the world. If non-alcoholic steatohepatitis (NASH) progresses, it can lead to hepatocellular carcinoma. Novel clinical index needs to be developed that can efficiently discriminate NASH patients from non-alcoholic fatty liver (NAFL) patients.

Research motivation

Shear wave speed (SWS), shear wave dispersion (SWD), and attenuation imaging (ATI) are new ultrasound diagnostic parameters for NAFLD. We developed a novel clinical index as the "NASH pentagon" consisting of the 3 abovementioned parameters, body mass index (BMI), and Fib-4 index.

Research objectives

Objective of this study is to prove the utility of NASH pentagon area in the differentiation of NASH and NAFL.

Research methods

Patients diagnosed with fatty liver by abdominal ultrasound between September 2021 and August 2022 were enrolled. Histological diagnosis based on liver biopsy was performed in 31 patients. The large pentagon group (LP group) and the small pentagon group (SP group), using an area of 100 as the cutoff, were compared; the NASH diagnosis rate was also investigated. In patients with a histologically confirmed diagnosis, receiver-operating characteristic curve analyses were performed.

Research results

The preparation of a NASH pentagon consisting of five parameters, SWS, DS, ATI value, Fib-4 index, and BMI, is simple and the calculation of its area is easy. The LP group with a NASH pentagon area ≥ 100 had 64 patients, and the SP group with an area < 100 had 43 patients. The number of patients diagnosed with NASH was 22 (34.3%) of 64 in the LP group and 3 (7.0%) of 43 in the SP group. The LP group had a significantly higher percentage of NASH patients (P = 0.0042).

Research conclusions

The NASH pentagon is a novel multi-parametric index, and will be useful for identifying NASH patients among NAFLD patients.

Research perspectives

NASH pentagon should be tried in more patients. Besides, the area of NASH pentagon and the details of the histologic diagnosis should be considered.

ACKNOWLEDGEMENTS

The authors would like to thank the institutions that participated in the working group and everyone who helped collect clinical data.

FOOTNOTES

Author contributions: Funada K, Kusano Y, Gyotoku Y and Shirahashi R conceptualized and designed the study, collected data, carried out the initial analysis, and drafted the initial manuscript; Suda T and Tamano M coordinated and supervised data collection and critically reviewed the manuscript for important intellectual content; and all authors approved the final manuscript as submitted and agree to be accountable for all aspects of the work.

Institutional review board statement: The study was reviewed and approved by the Dokkyo Medical University Saitama Medical Center Institutional Review Board (approval No. 21057).

Clinical trial registration statement: This study is registered at clinical research support office, Dokkyo Medical University Saitama Medical Center. The registration identification number is 21057.

Informed consent statement: Patients were not required to give informed consent for participation in the present study because the analysis used anonymous clinical data that were obtained after each patient gave informed consent to treatment. For full disclosure, the details of this prospective, observational study were published on the home page of the medical center.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.

Data sharing statement: No additional data are available.

CONSORT 2010 statement: The authors have read the CONSORT 2010 statement, and the manuscript was prepared and revised according to the CONSORT 2010 statement.

Abstract

BACKGROUND

Robotic surgery is a cutting-edge minimally invasive technique that overcomes many shortcomings of laparoscopic techniques, yet few studies have evaluated the use of robotic surgery to treat Hirschsprung's disease (HSCR).

AIM

To analyze the feasibility and medium-term outcomes of robotic-assisted proctosigmoidectomy (RAPS) with sphincter- and nerve-sparing surgery in HSCR patients.

METHODS

From July 2015 to January 2022, 156 rectosigmoid HSCR patients were enrolled in this multicenter prospective study. Their sphincters and nerves were spared by dissecting the rectum completely from the pelvic cavity outside the longitudinal muscle of the rectum and then performing transanal Soave pull-through procedures. Surgical outcomes and continence function were analyzed.

RESULTS

No conversions or intraoperative complications occurred. The median age at surgery was 9.50 months, and the length of the removed bowel was 15.50 ± 5.23 cm. The total operation time, console time, and anal traction time were 155.22 ± 16.77, 58.01 ± 7.71, and 45.28 ± 8.15 min. There were 25 complications within 30 d and 48 post-30-d complications. For children aged ≥ 4 years, the bowel function score (BFS) was 17.32 ± 2.63, and 90.91% of patients showed moderate-to-good bowel function. The postoperative fecal continence (POFC) score was 10.95 ± 1.04 at 4 years of age, 11.48 ± 0.72 at 5 years of age, and 11.94 ± 0.81 at 6 years of age, showing a promising annual trend. There were no significant differences in postoperative complications, BFS, and POFC scores related to age at surgery being ≤ 3 mo or > 3 mo.

CONCLUSION

RAPS is a safe and effective alternative for treating HSCR in children of all ages; it offers the advantage of further minimizing damage to sphincters and perirectal nerves and thus providing better continence function.

Key Words: Robotic-assisted; Hirschsprung's disease; Continence function; Sphincter; Nerve

Core Tip: We present the largest series of patients with Hirschsprung's disease treated with robotic-assisted proctosigmoidectomy (RAPS). RAPS is a safe and effective alternative for treating Hirschsprung's disease in children of all ages. It offers the advantage of further minimizing damage to sphincters and perirectal nerves and thus providing better fecal function.

INTRODUCTION

Although beneficial for children with Hirschsprung's disease (HSCR), laparoscopic operation is more challenging than open operation, especially in newborns and infants. To address the drawbacks of laparoscopic surgery, a robotic system may be considered. Robotic-assisted surgery is utilized in various areas due to its numerous advantages, particularly in complex operations, such as anorectal malformations in children[1] and prostate and rectal cancer in adults[2,3].

Recently, laparoscopic techniques have developed into an effective treatment for HSCR. As previously shown, these minimally invasive surgical techniques result in better early postoperative outcomes than the open procedure[4,5], and the long-term results are similar between laparoscopic and open procedures[6]. Nevertheless, laparoscopic surgery for HSCR is still considered to be one of the most difficult operations in anorectal surgery. With the introduction and application of robotic surgical platforms, this technology is gradually being adopted for the treatment of HSCR. However, the safety and efficacy of the technology in treating pediatric HSCR patients have been evaluated in only a few studies.

In this paper, we present our initial experience with robotic-assisted proctosigmoidectomy (RAPS) with sphincter- and nerve-sparing surgery (SNS) for treating HSCR. To our knowledge, this represents the largest series of SNS-RAPS in children reported to date. The SNS-RAPS procedure is thoroughly detailed.

MATERIALS AND METHODS

Study design

From July 2015 to January 2022, a multicenter prospective study of consecutive children with rectosigmoid HSCR who underwent uniform SNS-RAPS was carried out at three centers (Union Hospital, Tongji Medical College, Huazhong University of Science and Technology; Guangzhou Women and Children's Medical Center, Guangzhou Medical University; Wuhan Children's Hospital, Tongji Medical College, Huazhong University of Science and Technology). A total of 156 patients were

enrolled, and all operations were performed by experienced surgical teams from three centers. Since the time the da Vinci Surgical System Si (Intuitive Surgical, Sunnyvale, CA) was introduced at the three centers to treat HSCR, all HSCR cases have been recorded in a prospectively designed database. Patient demographics, surgical parameters, and postoperative data were recorded.

This study was approved by the ethics committee at each participating center and registered in the Chinese Clinical Trial Registry (Registration ID: ChiCTR2000035220). Written informed consent was obtained from the legal guardians of each patient. The study has been reported in accordance with the Declaration of Helsinki.

Patients

Patients diagnosed with rectosigmoid HSCR preoperatively were candidates for SNS-RAPS. The diagnosis was based on clinical symptoms and signs, barium enema results, rectal aspiration biopsy, anorectal manometry, and intraoperative biopsy. Patients with trisomy 21, total colonic aganglionosis, long-segment HSCR, HSCR combined with preoperative enterostomy, and surgical contraindications were excluded. The patient selection process is detailed in Figure 1. All patients received a unified preoperative preparation and postoperative treatment plan at all centers.

Colonic irrigation with warm saline (100-200 mL/kg) was used to prepare the colon for 3-7 d. Metronidazole (25 mg/kg, bid) was given orally for 3 d (1-2 d for neonates) preoperatively, and one dose of cefoperazone was provided during anesthesia induction.

Operative procedure

Under general anesthesia, the patient was placed in the supine position, and three trocars were placed. The CO_2 insufflation pressure was set at 8-10 mmHg, and the flow rate at 2.5-4.5 L/min. The operation was performed using three ports, including a straight-cut umbilical trocar accommodating a 12 mm 30° telescope and two working trocars with 8 mm robotic devices on either side (Figure 2). The robotic arms were oriented from the caudal direction. The aganglionic segment range was assessed by seromuscular biopsy using robotic monopolar scissors and interrupted 5-0 sutures were placed in cases of bleeding or mucosal rupture. The needle and suction were alternately inserted for operation through the 8 mm port on one side, which required the process of removing and reinserting the operative instrument. A Maryland dissector and a robotic hook were used to perform the dissection. After creating a window on the sigmoid mesentery, we clipped and divided the sigmoid artery trunk and then mobilized the mesentery up to the level of the inferior mesenteric artery. SNS robotic endorectal dissection was performed circumferentially down to the pelvis, which was the most unique and crucial part of the operation. Dissection was begun circumferentially at 1.0 cm above the peritoneal reflection. The rectum was mobilized outside the longitudinal muscle layer (that is, under its serosa or proper rectal fascia extended serous layer below the peritoneal reflection), with the anatomical plane farther away from Denonvillier's fascia and the nerve plexus anterior or lateral to the rectum (Figure 3A). When we pulled the rectum cranially, intestinal wall muscle layers provided greater tensile strength than the mucosa, allowing the pelvis to be shallower (Figure 4) and avoiding intraoperative intestinal mucosal tearing with peritoneal contamination. Since the robotic platform allowed for dissection in a narrow field, we were able to dissect the rectum to a lower level, nearly up to the dentate line. The mobilization of the rectum reached 4-7 cm into the pelvis (Figure 3B).

After the robot was unlocked, a circular incision was made 0.5-1 cm from the dentate line (Figure 5A), dividing the mucosa upward by 0.2-0.4 cm, breaking through the muscular cuff, and exposing the robotic dissection plane in the pelvis. The diseased colon was then gently pulled out through the anus. The posterior wall was partially resected in a V-shape, and the pointed end of the "V" reached the level of the dentate line to release internal anal sphincter achalasia. To avoid residual dysfunctional bowel, we uniformly excised the dilated and thickened bowel; we then performed Soave's anastomosis with interrupted 5-0 or 4-0 absorbable sutures above the biopsy site. After the diseased bowel was removed, the specimen was measured for its overall length and the pelvic dissection length (Figure 5B).

Postoperative management

Intravenous antibiotics (cefoperazone, 50 mg/kg, bid) were given for the first 3 d, and a urinary catheter was left for 24-48 h after surgery. No nasogastric tube or drains were left in place, but a rectal tube was left for 5 d postoperatively to help the passage of intestinal contents and gas through the anus. Instead of sutures, we used butterfly shaped tape to fixate the tube and reduce postoperative discomfort. The patient was discharged after being confirmed to be clinically stable and tolerant of a full oral diet. A routine digital rectal examination was performed postoperatively at 2 wk, and an anal dilatation plan was formulated.

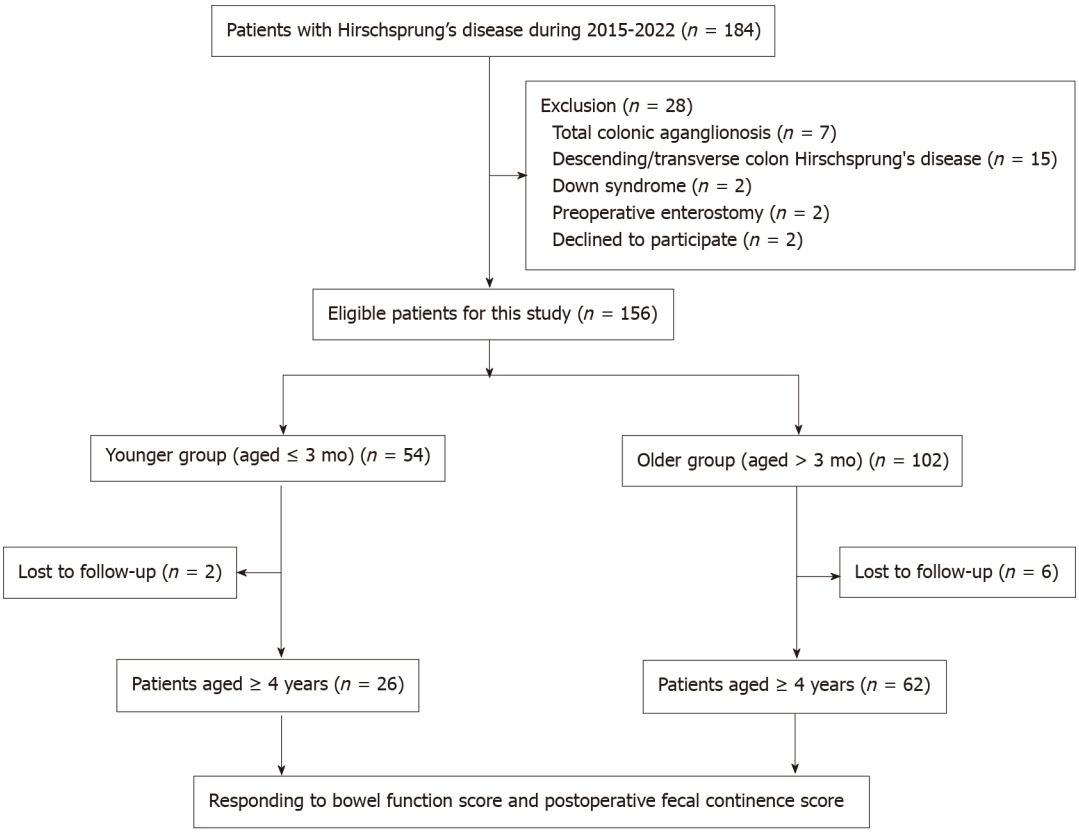
Postoperative variables and definitions

The bowel function score (BFS) was used to evaluate overall bowel function[7], while the postoperative fecal continence (POFC) score focused on SNS-related incontinence[8]. Children aged ≥ 4 years were assessed twice for each score as shown in Tables 1 and 2. A BFS ≥ 17 was represented as the lower limit of good/normal functional outcomes as more than 90% of people aged ≥ 4 years in the normal

Table 1 Scale for bowel function score

Evaluation on fecal continence	Score
Feels the urge to defecate	
Always	3
Most of the time	2
Uncertain	1
Absent	0
Ability to hold back defecation	
Always	3
Problems less than once a week	2
Weekly problems	1
No voluntary control	0
Frequency of defecation	
Every other day-twice a day	2
More often	1
Less often	1
Soiling	
Never	3
Staining less than once a week, no change of underwear required	2
Frequent staining/soiling, change of underwear required	1
Daily soiling, requires protective aids	0
Accidents	
Never	3
Less than once a week	2
Weekly accidents, often requires protective aids	1
Daily, protective aids required day and night	0
Constipation	
No constipation	3
Manageable with diet	2
Manageable with laxatives	1
Manageable with enemas	0
Social problems	
No social problems	3
Sometimes (fouls odors)	2
Problems causing restrictions in social life	1
Major social/psychosocial problems	0

population met this criterion[9]. Soiling referred to the actual presence of feces in the underwear without the patient's awareness, while fecal marks on the underwear were regarded as staining. We briefly defined the normal stool frequency as 1-3 times daily or once every 1-3 d. The diagnosis of HSCR-associated enterocolitis was based on the definitions by Teitelbaum and Coran[10]. Post-30-d complications were defined as complications occurring 30 d to 1 year after surgery.



Statistical analysis

Categorical variables are presented as counts and percentages, while continuous variables are presented as the mean ± SD or median (range). The Kolmogorov–Smirnov test was used to assess the normality

Table 2 Scale for postoperative fecal continence score

Evaluation on the POFC scores	0	1	2
Frequency of motions (/day)	≥ 6	3-5	1-2
Severity of staining/soiling	Soiling	Staining	None
Severity of perianal erosion	Often	Occasionally	Nil
Anal shape	Prolapse needing surgery	Mucosa visible	Normal
Requirement for medications	Antidiarrheals	Laxatives/enemas	Nil
Sensation of rectal fullness	Not at all[1]	Occasionally	Always[2]
Ability to distinguish flatus from stool	Not at all[1]	Occasionally	Always[2]

[1]Full awareness or ability to distinguish less than once a week.
[2]Full awareness or ability to distinguish at least 4 out of 5 times (more than 80%).
POFC: postoperative fecal continence.

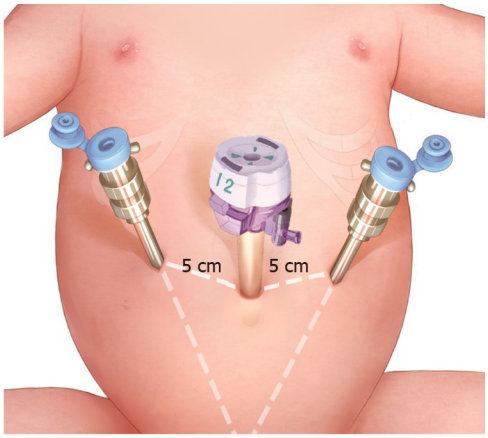

Figure 1 Flowchart of patient selection.

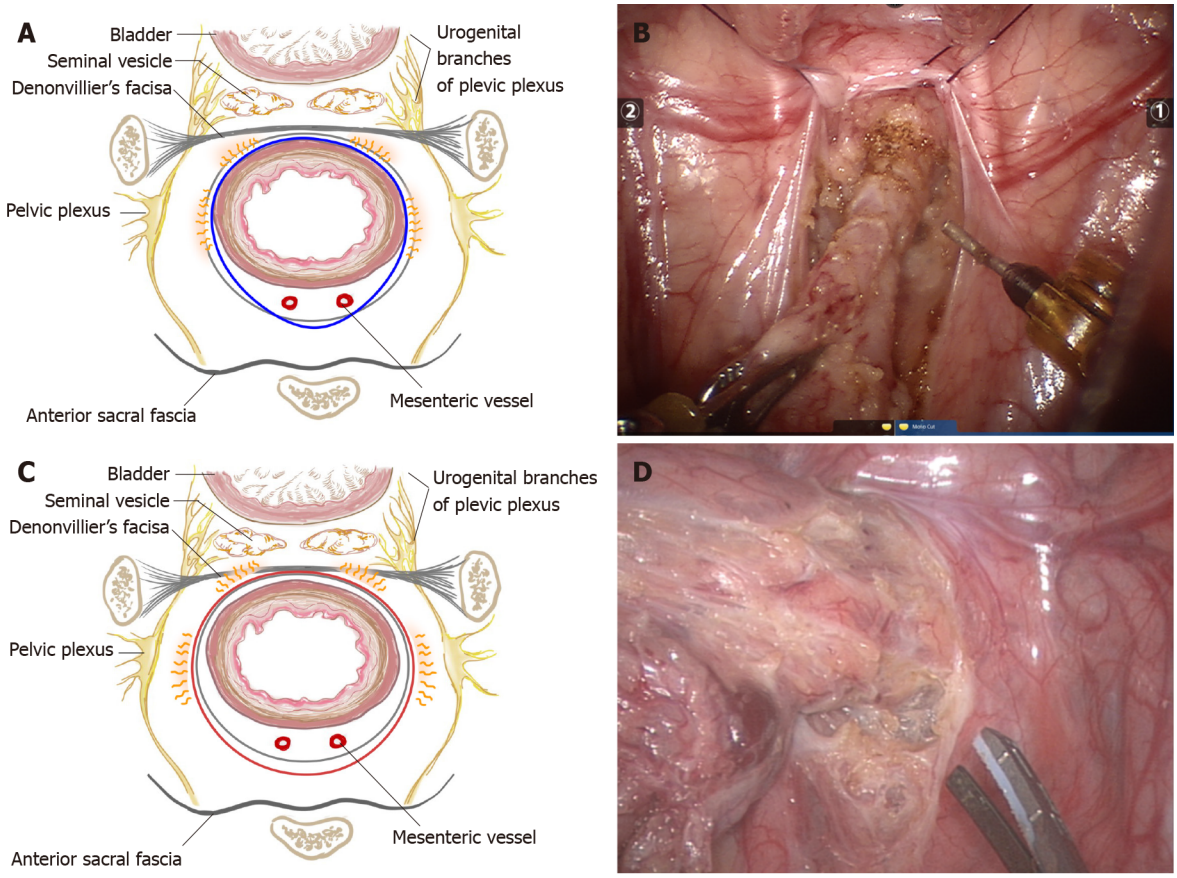
distribution of the data. To evaluate the differences between groups, the chi-square test or Fisher exact test was used to analyze categorical variables, and the Mann-Whitney U test was used to compare continuous variables because the data did not meet the normal distribution criteria. IBM SPSS Statistics version 26.0 was used for statistical analysis. A P value of < 0.05 was considered indicative of statistical significance.

RESULTS



Patient demographics and operative data

A total of 184 participants were assessed for eligibility, and 156 patients were finally enrolled in this multicenter prospective study (Figure 1). The demographics and operative outcomes are shown in

Figure 3 Diagram of pelvic dissection planes and intraoperative images of pelvic dissection. A: Pelvic dissection plane of robotic-assisted proctosigmoidectomy is under the serosa of the rectum or proper rectal fascia extended serous layer below the peritoneal reflection; B: Pelvic dissection under robotic endoscopy; C: Pelvic dissection plane of conventional laparoscopic Soave surgery is performed tightly around the rectal wall; D: Pelvic dissection under laparoscopy.

Table 3. No conversions or intraoperative complications occurred. The median age at surgery was 9.50 (range: 0.60-132.00) mo, and the weight was 9.09 ± 3.68 kg. The total operative time was 155.22 ± 16.77 min, and the robotic console time was 58.01 ± 7.71 min. The anal traction time was 45.28 ± 8.15 min, which included 15.21 ± 2.67 min for transanal dissection and 30.01 ± 5.82 min for anastomosis. The length of the removed bowel was 15.50 ± 5.23 cm, and the pelvic dissection depth under endoscopy was 4.50 ± 0.47 cm. The intraoperative estimated blood loss was 5.01 ± 1.81 mL.

Figure 4 The pelvic depth in robotic vision before and after pulling the rectum cranially; the depth becomes shallower after pulling. A: Before pulling; B: After pulling.

Postoperative outcomes

Postoperative outcomes are detailed in Table 4. The hospital stay was 7.25 ± 1.67 d, and the median follow-up duration was 44.00 (range: 6.00-78.00) mo. Eight patients were lost to follow-up one year after surgery. Postoperative complications were assessed in accordance with the Classification of Surgical Complications[11]. The postoperative 30-d complications included Clavien–Dindo grade II complications in two patients with wound infections, two patients with lung infections, six patients with enterocolitis, and thirteen patients with perianal dermatitis, all of whom were corrected by conservative treatment. One patient exhibited a Clavien–Dindo grade IIIa complication (anastomotic leakage treated

Table 4 Postoperative outcomes of patients

Enterocolitis	16 (10.26%)
Soiling	7 (4.49%)
Staining	18 (11.54%)
Constipation	4 (2.56%)
Perianal dermatitis	1 (0.64%)

by resuturing with presacral drainage[12]), and one patient had a Clavien–Dindo grade IIIb complication (omental hernia requiring surgical correction). There was no uroschesis, urinary incontinence, or cuff abscess. Post-30-d complications included Clavien–Dindo grade I complications, namely, seven soilings (received bowel habit training) and eighteen stainings (no change of underwear required) as well as Clavien–Dindo grade II complications, namely, two cases of anastomotic strictures (underwent anal dilation treatment without anesthesia), sixteen cases of enterocolitis (received rectal decompression, irrigation, and broad-spectrum antibiotics), four cases of constipation (received a laxative and enema) and one case of perianal dermatitis (received topical medication).

Normal stool frequency and enterocolitis at 1-6 years after surgery

As listed in Table 5, we divided follow-up into four phases: ≤ 1 year, 1 < years ≤ 2, 2 < years ≤ 4, and 4 < years ≤ 6, with further analysis of short- to medium-term stool frequency and enterocolitis. The incidence of normal stool frequency increased steadily while the enterocolitis rate decreased gradually over time; the overall normal stool frequency rate increased from 55.13% to 89.06% under diet control (younger group: 53.70% to 86.36%, older group: 55.88% to 90.48%) (Figure 6A) and the overall enterocolitis rate declined from 10.26% to 4.69% (younger group: 11.11% to 4.55%, older group: 9.8% to 4.76%) (Figure 6B).

BFS and POFC score in the assessment of medium-term functional outcomes

The BFS and POFC score are shown in Table 6. Eighty-eight patients aged ≥ 4 years were evaluated with two scoring systems during follow-up. The bowel functional result was good (BFS ≥ 17) in 66 patients (75.00%), moderate (12 ≤ BFS ≤ 16) in 14 patients (15.91%), and poor (BFS < 12) in 8 patients (9.09%). The total BFS was 17.32 ± 2.63, with satisfactory scores for each item. The POFC score at 4, 5 and 6 years of age postoperatively demonstrated a promising trend annually, with values of 10.95 ± 1.04, 11.48 ± 0.72, and 11.94 ± 0.81, respectively (Figure 6C).

Comparison of efficacy between patients aged ≤ 3 mo and aged > 3 mo at surgery

The outcomes comparing normal stool frequency and enterocolitis are shown in Table 5. The comparison results of postoperative complications are detailed in Table 7, while the comparison results

of BFS and POFC scores are shown in Table 8. Due to the small number of neonates in this series, we carried out a subgroup analysis to assess defecation function in younger infants, grouping the patients by age into ≤ 3 mo (younger group, n = 54) and > 3 mo (older group, n = 102). There was no significant difference in postoperative complication rates, BFSs (younger group: 17.19 ± 2.87, older group: 17.37 ± 2.54) or POFC scores at 4, 5 and 6 years of age postoperatively (younger group: 10.70 ± 0.99, 11.38 ± 0.62, 11.71 ± 0.76; older group: 11.07 ± 1.05, 11.52 ± 0.76, 12.00 ± 0.83) between the two groups (Figure 6C).

DISCUSSION

Robotic procedures are rapidly replacing open or laparoscopic procedures for the adult population in challenging procedures, such as operations for rectal and prostate cancer[2,3]. Nevertheless, the adoption of robots in pediatric surgery is low. Robotic surgery failed to show substantial benefits in studies comparing it to laparoscopic surgery because the procedures were initially used for less complex operations, such as the Nissen fundoplication[13]. In technically demanding situations, the application of robots for abdominal surgeries in children is relatively limited. Furthermore, only a few studies have revealed the feasibility of robotic-assisted surgery for HSCR, and the patient numbers were too small to generalize the application of robotic surgery in this field[14-17]. There is still a lack of studies involving large samples and long follow-up on functional outcomes. To our knowledge, 156 consecutive HSCR children who received RAPS represent the largest series in the literature. Long-segmental HSCR, total colonic aganglionosis, and trisomy 21 have been demonstrated to negatively affect the prognosis of HSCR patients[18-20]. Aiming to focus on the effect of surgical techniques on the postoperative outcomes of HSCR, we excluded these influencing factors and performed RAPS only on children with rectosigmoid HSCR.

The core of the original Soave procedure is pelvic endorectal dissection under the mucosa, but the mucosa is easily ruptured, resulting in pelvic contamination or mucosal residue. This explains the high rate of muscular sleeve infection following surgery in that era[4]. Pelvic endorectal dissection is a determining step in minimally invasive surgery for HSCR. Laparoscopic surgery facilitates tissue dissection in narrow spaces, and the technique still follows the concept of the original Soave procedure for nerve sparing. However, stiff laparoscopic instruments and unstable vision make submucosal rectal dissection more challenging, resulting in a higher mucosa rupture rate. Instead, extrarectal dissection is performed tightly around the rectal wall to 1-2 cm below the peritoneal reflection, and then a long-

distance submucosal dissection is conducted through the anus as in Georgeson's technique (Figure 3C and D) [21]. For selected patients, a totally transanal endorectal technique with submucosal dissection can even be performed as in Torre's technique[22]. These procedures have been demonstrated to provide better short-term outcomes than open surgery, with similar long-term outcomes[6,23,24]. Nonetheless, some studies have found that minimally invasive surgery, particularly totally transanal surgery that requires more anal dissection, results in poorer long-term defecation function than open surgery, especially in neonates[7,25,26]. This is probably a result of the technique's increased risk of anal sphincter traction/injury[27]. Therefore, we hypothesized that RAPS could reduce these risks to support better long-term bowel function for patients.

Herein, the primary strength of our robotic-assisted technique is that a new endorectal dissection layer (outside the longitudinal muscle) can be established. This potential gap between anatomical structures exists objectively[28]. The new layer is farther away from the urinal nerves on both sides of the rectum and the sexual nerves ahead of the Denonvillier's fascia[29]. A diagram of the pelvic dissection layer is shown in Figure 3A. The robotic system provides a magnified 3D image, stable maneuverability, and articulated movement in the narrow area *via* small incisions. Another major advantage is the image stability from robotic arm support as minor camera movements can cause image shifting. These merits facilitate ideal identification of the subserosa and precise rectum dissection, thus guaranteeing nerve-sparing. In addition, the rectum with intact longitudinal and circular muscles can be pulled strongly and is less prone to rupture; thus, the surgeon is able to pull the rectum cranially to make the pelvis shallower (Figure 4), allowing the dissection to nearly reach the dentate line (Figure 3B). Extensive intra-abdominal endorectal dissection would result in less need for transanal dissection and

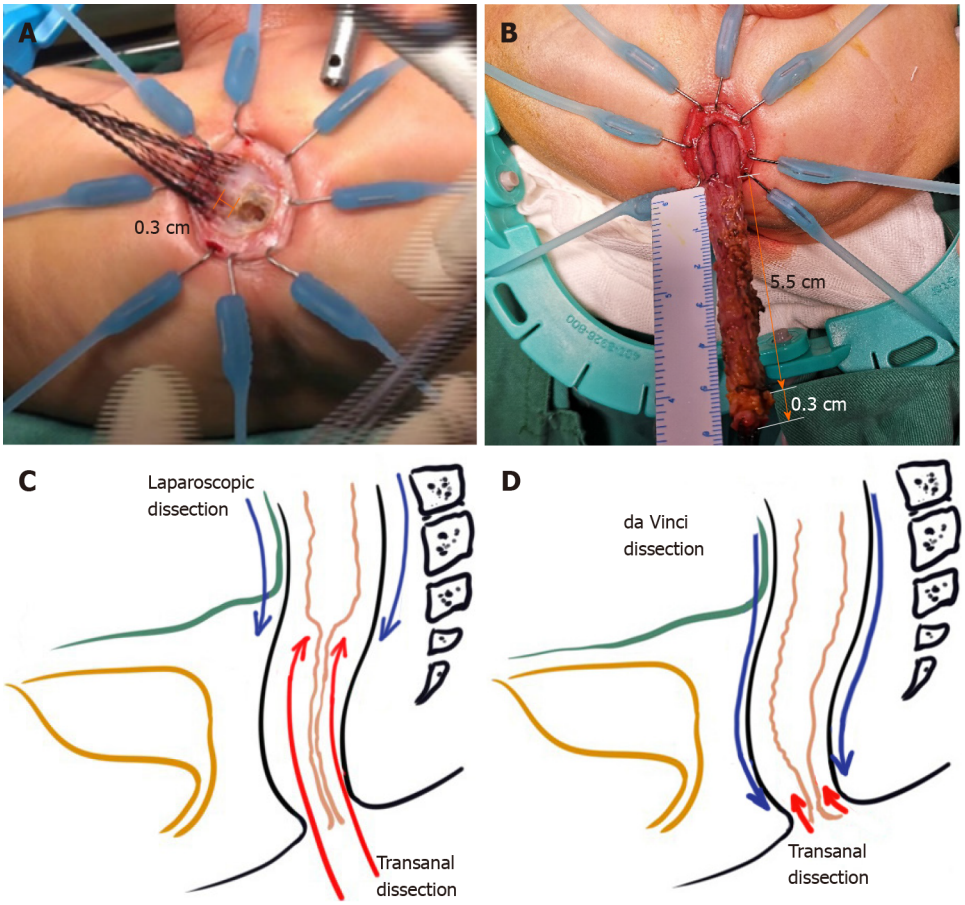

Table 8 Bowel function scores and postoperative fecal incontinence scores among patients aged 4 years or older between the younger group and the older group

Parameters	Younger group (*n* = 26)	Older group (*n* = 62)	*P* value

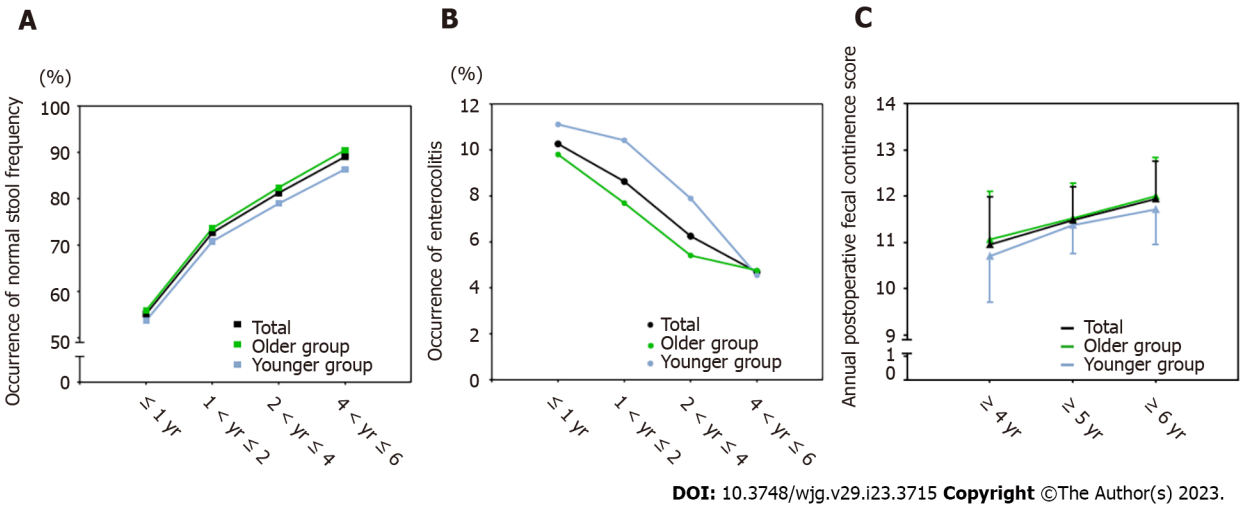
Postoperative fecal incontinence scores (Mean score ± SD)			
Aged ≥ 4 yr	10.70 ± 0.99	11.07 ± 1.05	0.16
Aged ≥ 5 yr	11.38 ± 0.62	11.52 ± 0.76	0.46
Aged ≥ 6 yr	11.71 ± 0.76	12.00 ± 0.83	0.35

simpler transanal procedures, thus permitting minor or no sphincter damage. Figure 5C and D show a comparison of the length of endorectal dissection and transanal dissection between two minimally invasive approaches. As our results show, the pelvic dissection could reach a depth of 4.50 ± 0.47 cm, so the length of the rectum dissected transanally was greatly shortened to 0.20-0.40 cm (Figure 5B). This reduces the time and intensity of sphincter traction. As reported, prolonged transanal dissection is prone to sphincter traction/injury[18,30]. Hence, robotic practice in pelvic rectal dissection may offer an excellent surgical tool.



Due to the additional docking and setting time of the robotic arms, the total operation time of robotic procedures is generally longer than that of open or laparoscopic procedures[15,31]. In our series, however, the operative time was 155.22 ± 16.77 min and was comparable to that of laparoscopic surgery, which varied from 94.00 to 294.00 min in previous large-sample studies[6,18,32-36]. Moreover, our results revealed that postoperative complication rates were similar or even lower than those of transanal or laparoscopic approaches[18,32-34]. There were no cuff abscesses in our series. This is related to precise and complete dissection of the rectum outside the longitudinal muscle up to the dentate line, preventing mucosal tube injury and ensuring no residual rectal mucosa. Previous studies have shown that the incidence of urinary incontinence in HSCR patients postoperatively ranges from 2.70%-22.00% [37-41], and urine retention ranges from 1.04%-6.67%[42-44]. Urinary complications following pelvic procedures may be caused by direct damage or indirect thermal radiation injury to the nerve endings controlling voiding. No uroschesis or urinary incontinence occurred after removal of the urinary catheter 24-48 h after surgery in any of the patients. This highlights the most obvious advantage of SNS-RAPS, which is the precise safeguarding of the urinal nerve around the rectum. Following this logic, good short-term bladder nerve protection after RAPS could indirectly predict better long-term defecation and sexual nerve function.

Postoperative bowel function and continence are the most important criteria for evaluating the effectiveness of SNS-RAPS. BFS was used for a comprehensive assessment of defecation, soiling, constipation, and social problems. Previous studies evaluating long-term outcomes (follow-up ranged from 9.5 to 28 years) after open, laparoscopic or transanal approaches have shown that 88.00% to 89.00% of HSCR patients obtained moderate-to-good bowel function (good: BFS ≥ 17, 52.00%-63.00%; moderate: 12 ≤ BFS ≤ 16, 26.00%-36.00%)[7,45], with an overall score of 15.00 to 17.10[7,9,18,45-47]. One clinical trial even found that neonates with HSCR achieved a BFS of 17.44 for long -segment HSCR and 19.06 for short-segment HSCR after a transanal procedure (follow-up for more than 8 years)[48]. Our medium-term findings showed an overall BFS of 17.32 ± 2.63 and that 90.91% of patients achieved moderate-to-good bowel function (good: 75.00%; moderate: 15.91%), which was comparable to or better than the long-term results of previous studies. As studies have shown, postoperative bowel function improves with age[8, 46], so we predict that our series of patients will have better long-term bowel function. Furthermore, we used the POFC score to analyze fecal incontinence, reflecting the role of SNS-RAPS in nerve and sphincter protection[8]. The total POFC score gradually improved and was satisfactory in patients at 4, 5 and 6 years of age following surgery (10.95 ± 1.04, 11.48 ± 0.72 and 11.94 ± 0.81), representing a result similar to or superior to that of laparoscopic operation (8.60-11.30)[8,49]. Postoperative functional results are strongly related to long-term quality of life (QoL)[9,46,47]. Satisfactory BFS and POFC scores in this

Figure 6 Short- to medium-term outcomes of robotic-assisted proctosigmoidectomy. A: Occurrence of normal stool frequency at 1-6 years after surgery; B: Occurrence of enterocolitis at 1-6 years after surgery; C: Annual postoperative fecal continence score analysis among patients aged 4 years or more.

series suggested that patients will achieve good long-term QoL.

Researchers in previous studies have mixed opinions on the efficacy in younger infants, especially neonates, compared with that in older children[49,50]. Although its appropriateness for younger infants with HSCR is debatable, robotic surgery could be successfully utilized for other diseases in the neonatal period[51]. We have gained experience in robotic surgery for these disorders and successfully applied

robotic surgery for neonates and infants with HSCR. As younger infants have a narrower pelvis and more compact structures than older children, the distance between the rectum and the surrounding structures is smaller. Moreover, younger age is associated with more fragile tissue that is vulnerable to operative injury[52]. These features increase the risk of injuring perirectal neurovascular tissues and sphincters during laparoscopic procedures, but the robotic system supplies a stable magnified 3D surgical field and precise rectal dissection to avoid the risk of disruption to the perirectal tissues. We found that HSCR patients in the younger group (aged ≤ 3 mo) and older group (aged > 3 mo) exhibited comparable complication rates, BFS and POFC scores. These data demonstrated that SNS-RAPS is feasible for HSCR patients aged ≤ 3 mo, and its efficacy was comparable to that in the older group. This also indicated that SNS-RAPS has better efficacy than previously reported open and laparoscopic procedures when considered from another perspective. Although totally transanal surgery was an option for 22.73% of patients with lower rectum HSCR in this study, our RAPS could reduce the time and intensity of sphincter traction and provide better outcomes. Taken together, our findings further support the view that the protection afforded by RAPS to the anal sphincter and perirectal nerves is no worse than other approaches and that RAPS is a preferred option for HSCR.

Although our study demonstrated favorable outcomes for RAPS, the limitations include only short- to medium-term outcomes and the absence of comparative data with other approaches. Therefore, a long-term follow-up and comparative trial should be performed to evaluate the effect of SNS-RAPS on HSCR. Currently, assessing long-term outcomes is not an option because SNS-RAPS has been used for less than 10 years. We intend to perform this clinical trial in the next several years. Moreover, the currently documented drawbacks of robotic surgery are longer operative time, expensive costs and oversized robotic devices for infants and neonates, creating economic and technical constraints. With the further advancement of pediatric robot devices, the reduction in surgical costs, and the improvement in surgeons' skills, the application of robots in pediatric surgery will mature. If surgery is to provide less pain and more effective therapy, then minimally invasive procedures achieved *via* robots that share the advantages of open or laparoscopic procedures may offer the answer.

CONCLUSION

SNS-RAPS is a safe and effective option for children of all ages with HSCR. The robotic platform can be utilized to further minimize surgical damage to the perirectal neurovascular tissue and anal sphincter, contributing to better bowel and urination function.

ARTICLE HIGHLIGHTS

Research background

Robotic-assisted surgery has been gradually introduced and applied to treat children with Hirschsprung's disease (HSCR). However, few studies have been conducted to evaluate its safety and efficacy for HSCR treatment.

Research motivation

We aimed to investigate the medium-term outcomes of robotic-assisted surgery for treating HSCR.

Research objectives

We aimed to analyze the feasibility and efficacy of robotic-assisted proctosigmoidectomy (RAPS) with sphincter- and nerve-sparing surgery (SNS) in the treatment of HSCR.

Research methods

We conducted a multicenter prospective study of 156 infants with rectosigmoid HSCR who underwent SNS-RAPS and divided them by age into a younger group (aged ≤ 3 mo) and an older group (aged > 3 mo) for comparison. Intraoperative data, postoperative complications, and medium-term outcomes were recorded and analyzed. In patients aged ≥ 4 years, the bowel function score (BFS) was used to assess overall bowel function, and the postoperative fecal continence (POFC) score was used to evaluate SNS-related incontinence.

Research results

A total of 156 patients underwent successful SNS-RAPS, with 25 complications within 30 d and 48 post-30-d complications after surgery. For children aged ≥ 4 years, the overall BFS was 17.32 ± 2.63 and 90.91% of patients showed moderate-to-good bowel function, while the POFC score increased annually from 4 to 6 years old (4 years old: 10.95 ± 1.04, 5 years old: 11.48 ± 0.72, 6 years old: 11.94 ± 0.81). There were no significant differences between the younger and older groups in postoperative complications

and POFC score.

Research conclusions

SNS-RAPS is a safe and effective alternative treatment for children of all ages with HSCR. It provides the advantage of further minimizing damage to sphincters and perirectal nerves, thus providing better continence function.

Research perspectives

Robotic-assisted surgery is beneficial for treating HSCR in infants and young children.

ACKNOWLEDGEMENTS

Abstract

BACKGROUND

Autoimmune gastritis (AIG) is a progressive, chronic, immune-mediated inflammatory disease characterized by the destruction of gastric parietal cells leading to hypo/anacidity and loss of intrinsic factor. Gastrointestinal symptoms such as dyspepsia and early satiety are very common, being second in terms of frequency only to anemia, which is the most typical feature of AIG.

AIM

To address both well-established and more innovative information and knowledge about this challenging disorder.

METHODS

An extensive bibliographical search was performed in PubMed to identify guidelines and primary literature (retrospective and prospective studies, systematic reviews, case series) published in the last 10 years.

RESULTS
A total of 125 records were reviewed and 80 were defined as fulfilling the criteria.

CONCLUSION
AIG can cause a range of clinical manifestations, including dyspepsia. The pathophysiology of dyspepsia in AIG is complex and involves changes in acid secretion, gastric motility, hormone signaling, and gut microbiota, among other factors. Managing dyspeptic symptoms of AIG is challenging and there are no specific therapies targeting dyspepsia in AIG. While proton pump inhibitors are commonly used to treat dyspepsia and gastroesophageal reflux disease, they may not be appropriate for AIG. Prokinetic agents, antidepressant drugs, and non-pharmacological treatments may be of help, even if not adequately evidence-based supported. A multidisciplinary approach for the management of dyspepsia in AIG is recommended, and further research is needed to develop and validate more effective therapies for dyspepsia.

Key Words: Dyspepsia; Dyspeptic symptoms; Gastro-intestinal symptoms; Autoimmune gastritis; Chronic autoimmune atrophic gastritis; Treatment

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The management of dyspepsia in patients with autoimmune gastritis (AIG), a chronic, immune-mediated disease, remains a challenge, as it can overlap with functional dyspepsia and gastroesophageal reflux disease. Currently, there are no specific therapies. A tailored treatment approach based on a better understanding of putative pathogenic mechanisms underlying symptoms is needed. Prokinetic agents, antidepressant drugs, and non-pharmacological treatments may be helpful, although not adequately evidence-based supported. As a future perspective, targeting dyspepsia in AIG based on changes in the microbiota and advanced endoscopic techniques to treat severe dyspeptic symptoms might be an area of ongoing research.

INTRODUCTION

Autoimmune gastritis (AIG) is an immune-mediated disease targeting the H+/K+ ATPase proton pump in the parietal cells, which are responsible for the secretion of gastric acid and intrinsic factor[1]. The pathogenesis of AIG involves the activation of both T and B lymphocytes, which infiltrate the gastric mucosa and destroy the parietal cells[1-5], leading to hypochloridria and vitamin B12 deficiency.

Symptoms of AIG can be nonspecific, with patients presenting with no or vague symptoms, including postprandial fullness, early satiation, abdominal pain, bloating[6], as well as epigastric pain. Therefore, the diagnosis of AIG can be challenging, as many of these symptoms overlap with other digestive disorders, mainly functional dyspepsia (FD) and gastroesophageal reflux disease (GERD). This overlap in clinical symptoms and characteristics can pose diagnostic challenges between AIG and FD, which share some common characteristics, including clinical symptoms, as well as a higher prevalence among women. Moreover, some patients may present with atypical symptoms, such as fatigue, joint pain, or skin rashes, which can further overlap with functional symptoms. Distinguishing between AIG and GERD can be even more challenging. While the pathophysiological mechanisms underlying GERD and AIG are different, they can present with similar abdominal symptoms, such as epigastric pain, heartburn, and nausea, which may pose diagnostic challenges, particularly in patients with atypical symptoms.

The pathophysiological mechanisms underlying clinical symptoms in AIG are poorly understood.

Appropriate evaluation, including endoscopy, is therefore required to differentiate these entities; indeed, based on the Rome Global Epidemiology Study, the diagnosis of FD requires the absence of organic, systemic, or metabolic disease upon routine investigation, including endoscopy[7,8].

It is therefore important to understand the different pathogenesis of symptoms in AIG, GERD, and FD, as the management of these conditions can be very different. This is particularly important when prescribing empirically proton pump inhibitors (PPIs) based therapies, which are often considered to be

the first-line therapy for GERD and are often used to manage symptoms of FD. Conversely, in AIG, a condition of hypochlorhydria, PPI therapy could further reduce acid secretion, stimulate gastrin hypersecretion, and further induce enterochromaffin-like (ECL) cell hyperplasia. As a result, the use of PPIs in patients with AIG is generally not indicated.

Therefore, accurate diagnosis and differentiation between these conditions are crucial to avoid inappropriate or potentially harmful management strategies. Understanding the pathophysiology of each condition can also guide the choice of appropriate treatments, including lifestyle modifications, dietary changes, and medication management.

In this review, we will discuss the putative pathogenic mechanisms underlying symptom generation in AIG, their clinical implications, and the current management strategies for this complex and multifaceted disease.

MATERIALS AND METHODS

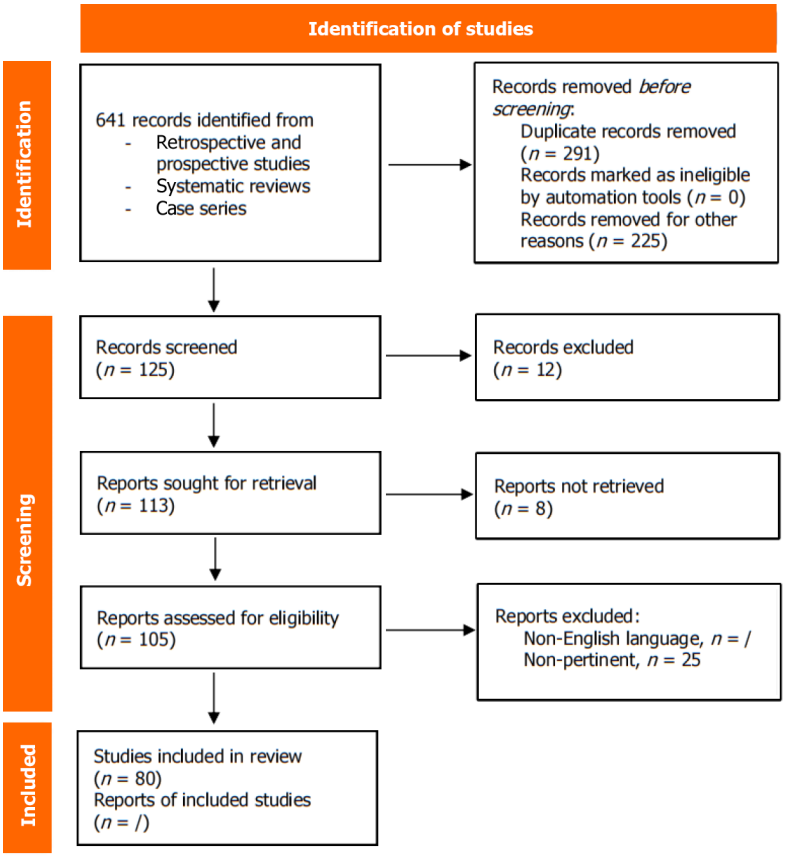
An extensive bibliographical search was performed in PubMed to identify guidelines and primary literature (retrospective and prospective studies, systematic reviews, case series) published in the last 10 years, using both medical subject heading terms and free-language keywords: Dyspepsia; dyspeptic symptoms; gastro-intestinal symptoms; chronic autoimmune atrophic gastritis; diagnosis; treatment. The reference lists from the studies returned by the electronic search were manually searched to identify further relevant reports. The reference lists from all available review articles, primary studies, and proceedings of major meetings were also considered. Articles published as abstracts were included, whereas non-English language papers were excluded.

RESULTS

A total of 125 records were reviewed and 80 were defined as fulfilling the criteria for final consideration. Figure 1 presents the flow chart showing the process of study selection.

DISCUSSION

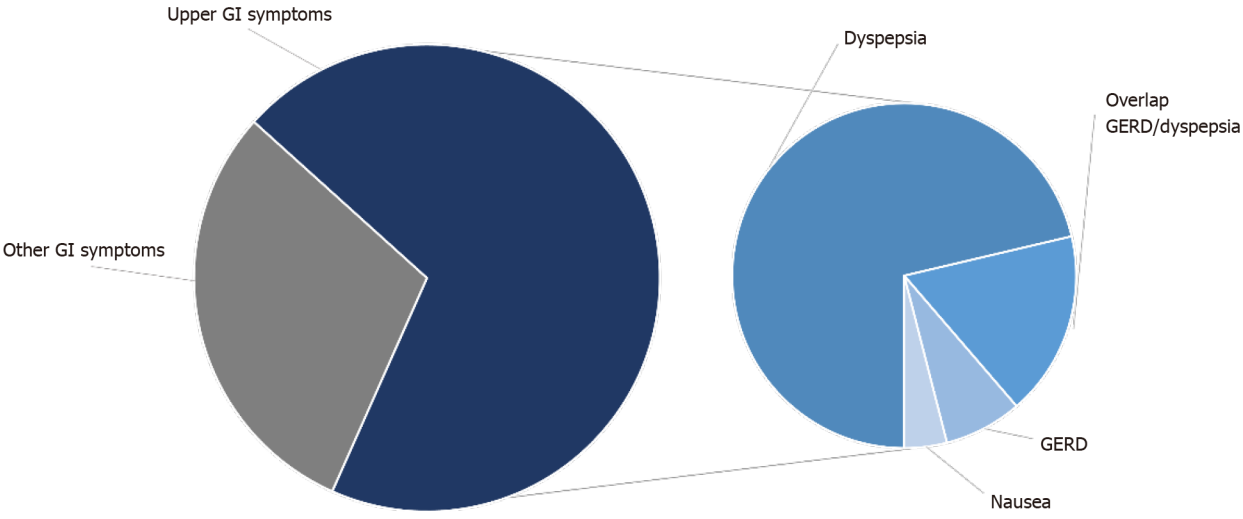
Dyspepsia in autoimmune gastritis: clinical manifestations and pathophysiological mechanisms



The spectrum of clinical manifestations in AIG is wide but often nonspecific[9,10]. Classical manifestations of AIG include pernicious anemia due to vitamin B12 deficiency, which can cause fatigue, weakness, and shortness of breath. Other hematological anomalies comprise micro/normocytic anemia due to the coexistence of iron deficiency anemia[9,11]. Neurological symptoms such as tingling, numbness, or weakness in the limbs, are due to vitamin B12 deficiency and are characterized by neuronal damage with peripheral neuropathy, myelopathy, and autonomic dysfunction[12,13]. Furthermore, psychiatric alterations have been reported such as depression, cognitive impairment, and psychosis[14,15]. As AIG is often associated with other autoimmune conditions, patients may also present with symptoms related to those conditions, such as joint pain, skin rashes, or thyroid dysfunction[16]. Also, the impaired absorption of other vitamins, such as 25-OH-vitamin D, or micronutrients, such as calcium, due to gastric hypo- or achlorhydria, has been hypothesized to be a predisposing factor also for the development of osteoporosis which can be a possible further extra gastrointestinal (GI) manifestation in AIG patients[17-19].

However, these manifestations usually characterize severe or long-standing disease.

In the early stages of AIG, patients may not present with these specific symptoms, and the patients may begin to experience non-specific GI symptoms such as upper abdominal discomfort, bloating, and nausea[11]. Focusing on GI symptoms, even if AIG is generally regarded as a silent disease, some recent studies highlight a not negligible percentage of patients who report upper GI discomfort mainly characterized by dyspeptic and/or GERD symptoms[20] and as in FD, dyspeptic symptoms may manifest as postprandial distress syndrome (PDS) with early satiation and/or postprandial fullness or as epigastric pain syndrome (EPS).



Indeed, according to both data from literature and real-life clinical practice, dyspepsia is frequently reported by AIG patients, which represents a challenge for their proper management.

In the cross-sectional study by Carabotti *et al*[21], more than half of the patients affected by AIG (56.7%, 215 out of 397) reported GI symptoms with a prevalence of upper GI symptoms (69.8%) including dyspepsia (71.2%), described as postprandial fullness, early satiety and/or epigastric pain, GERD related symptoms (7.2%) such as heartburn and/or regurgitation, overlap dyspepsia-GERD symptoms (17.2%) and nausea and vomiting (3.8%). Moreover, 15.8% of the patients enrolled in this study also reported lower irritable bowel syndrome (IBS) -like GI symptoms with overlapping of upper and lower GI symptoms in 14.4% of the patients (Figure 2).

Figure 2 More common gastrointestinal symptoms seen in patients with autoimmune gastritis. GERD: Gastroesophageal reflux disease; GI: Gastrointestinal.

Dyspepsia, meant either as EPS or PDS, together with GERD symptoms such as acid regurgitation and heartburn, are reported as the most frequent symptoms also in the paper by Miceli *et al*[22] with a prevalence of 52.4% and 36.3%, respectively in the study population of 99 AIG patients. Contextually, weight loss and nausea are referred to approximately a quarter of patients (28.3% and 22.2%, respectively), while vomiting and dysphagia are in a lower percentage (9.1% and 3%, respectively).

According to another study[23], including a cohort of 54 patients with AIG, 70% were symptomatic for one or more upper GI symptoms, particularly a quarter of patients referred at least one typical GERD symptom such as regurgitation (18.5%) or heartburn (9%), while a major percentage complained

of atypical GERD symptoms including cough (29.6%), non-cardiac chest pain (22.2%) and dysphagia (14.8%).

As far as GERD symptom is concerned, in the prospective observational study published by Tenca *et al*[24], the prevalence of GERD has been investigated in a cohort of 41 AIG patients, 28 of whom with upper GI symptoms (53% GERD-related, 47% dyspepsia-like). The authors found that 24% of patients had GERD at multichannel intraluminal impedance-pH (MII-pH) monitoring mostly defined as non-acidic reflux, hypothesizing that non-acidic reflux could play a key role in the pathogenesis of the upper GI clinical manifestations. Consistent with the data above, those from the observational prospective study by Pilotto *et al*[25] confirm that among the group of AIG patients complaining of reflux symptoms (38/172, 22%) only 2 patients had documented GERD while 9 patients (24.7%) had reflux hypersensitivity predominantly related to non-acid-reflux (6/9 patients). The remaining 27 patients didn't have alterations at MII-pH but six of them had a major motility disorder. Therefore, the presence of upper GI symptoms appears to be paradoxical as AIG is typically characterized by gastric mucosal atrophy with resulting hypochlorhydria and alkaline gastric pH.

The pathophysiological mechanisms underlying GI symptoms in AIG are poorly understood. Several mechanisms have been hypothesized. The hypochlorhydria resulting from gastric oxyntic atrophy may contribute to dyspeptic symptoms[5], even if other mechanisms may be responsible, such as delayed gastric emptying[26,27], visceral hypersensitivity, and hormonal effects. Delayed gastric emptying may occur due to reduced acid secretion, which can lead to incomplete homogenization of gastric contents with macroscopic residues of undigested food and altered peristalsis, giving feelings of fullness, bloating, and discomfort after eating.

However, in patients with AIG, delayed gastric emptying has been described with elevated circulating gastrin levels and increase in parallel with the degree of the atrophy of the gastric mucosa, affecting gastric emptying T ½ time[27]. Visceral hypersensitivity is an important candidate pathogenic mechanism for several disorders characterized by dyspepsia, even if only a few studies are available for AIG patients[26]. Moreover, some gut hormones such as motilin and ghrelin levels were significantly decreased in AIG subjects with delayed gastric emptying and deranged autonomic function[26], suggesting their potential role in the delayed gastric emptying observed in these subjects. Additionally, the loss of intrinsic factor may result in impaired absorption of nutrients such as iron and vitamin B12, which can contribute to fatigue and other symptoms. Also, low-grade chronic inflammation associated with AIG could contribute to the development of dyspepsia, in parallel to what is described for low-grade bowel inflammation with increased numbers of submucosal mast cells and lymphocytes reported in IBS[28]. Finally, chronic inflammation associated with AIG together with impaired gastric acid secretion may cause changes in the gut microbiota, and this may contribute to the development of dyspeptic symptoms; however, further research is needed to better understand the pathophysiological mechanisms underlying dyspeptic symptoms in AIG and to develop more effective treatments for this condition. It is also important to remember that abnormal thyroid function, which is quite commonly associated with AIG, has been blamed for gastric dysmotility and dyspeptic symptoms[29], which is another possible cause of dyspepsia in AIG patients. However, it is difficult to understand whether the dyspepsia observed in AIG patients is the direct result of abnormal thyroid function or is caused by AIG itself or by a combination of these two autoimmune diseases. Table 1 summarizes the most frequent upper GI symptoms reported by AIG patients together with the underlying pathophysiological mechanisms.

Diagnostic work-up of dyspepsia in AIG

According to recent guidelines on the management of dyspepsia[30-32], upper GI endoscopy [esophagogastroduodenoscopy (EGDs)] is a key test to identify any organic disease of the upper digestive tract (*i.e.*, peptic ulcer, neoplasm), which may explain dyspeptic symptoms. Since EGDs is an invasive and expensive test and most patients with dyspepsia have FD[32], the American and British guidelines suggest limiting the use of EGDs to patients with suspected organic disease. Both the American and the British guidelines[30,32] as well as a recent evidence-based revision of the existing guidelines[31] suggest screening patients for past medical history and family history, medications, previous examinations, presence of *Helicobacter pylori* (*H. pylori*) infection, age, alarm symptoms and signs (*i.e.* anemia or bleeding, weight loss, age > 55 years, recurrent vomiting, dysphagia or odynophagia, fever). When one of the aforementioned alarm symptoms or signs is present, EGDs is mandatory to exclude or confirm an organic disease. If EGDs is negative for esophago-gastric diseases, an abdominal computed tomography -scan is suggested in order to exclude pancreatic, liver, or biliary tract cancers[32]. Distinguishing between AIG and FD in patients with dyspeptic symptoms may result difficult, as the two conditions can produce similar symptoms[20,21]. However, certain factors such as a medical history of autoimmune disease, anemia (including microcytic and macrocytic), vitamin B12 deficiency, and positivity for anti-parietal cells antibodies should raise clinical suspicion of AIG. In such cases, it is important to perform an EGDs to confirm the diagnosis, stage the disease, and evaluate for possible pre-cancerous lesions[33]. According to international guidelines[33], gastric biopsies should be picked up according to Sidney protocol. The protocol requires 5 gastric biopsies, which should be placed in separately labeled jars: 2 from the antrum along the lesser and greater curvature, within 2-3 cm of the pylorus; 2 from the gastric corpus (including 1 from the lesser curvature at 4 cm proximal to the incisura angularis and the

Table 1 Reported upper gastrointestinal symptoms and the underlying pathophysiological mechanisms in patients with autoimmune atrophic gastritis

Clinical manifestation	Pathophysiological mechanisms
Dyspeptic symptoms	
Postprandial fullness; Early satiety; Epigastric pain	Hypochlorhydria. Delayed gastric emptying due to: Hormonal effects (ghrelin, motilin); Reduced acid secretion. Visceral hypersensitivity. Low-grade chronic inflammation. Changes in the gut microbiota
Typical GER like symptoms	
Heartburn; Regurgitation	Non-acid reflux; Delayed gastric emptying; Visceral hypersensitivity; Changes in the gut microbiota
Atypical GERD-like symptoms	
Cough; Non-cardiac chest pain; Dysphagia	Delayed gastric emptying; Visceral hypersensitivity
Overlap dyspepsia-GER like symptoms	As above
Vomiting	Delayed gastric emptying; Visceral hypersensitivity
Nausea	Delayed gastric emptying
Fatigue	Impaired absorption of iron and vitamin B12

GER: Gastro-esophageal reflux; GERD: Gastroesophageal reflux disease.

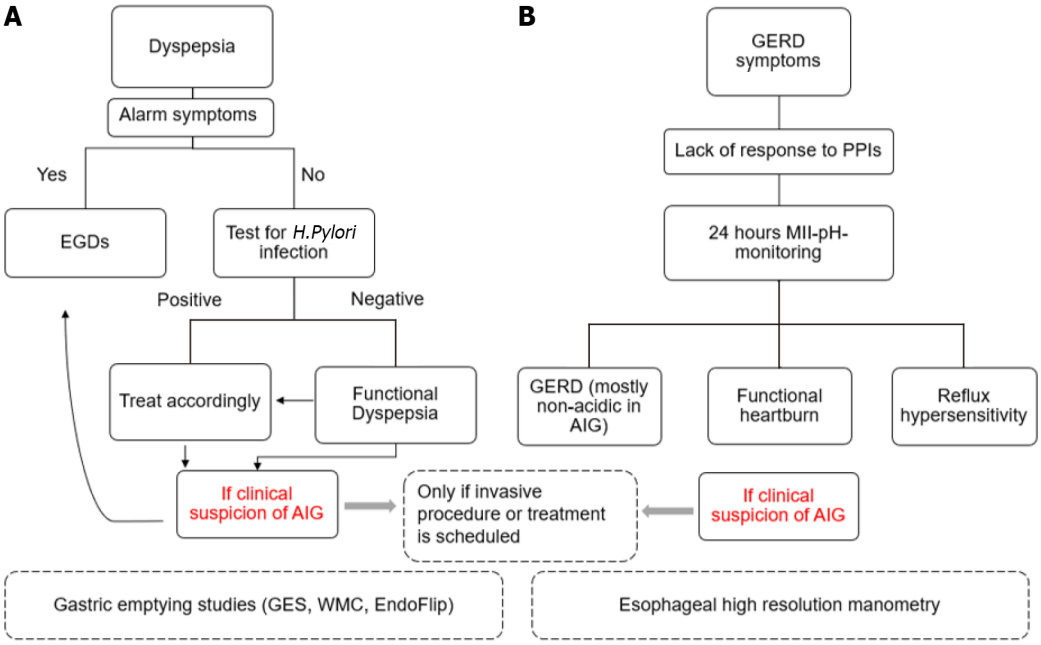
other from the middle portion of the greater curvature of the gastric body at 8 cm from the cardia), and 1 from the incisura angularis[34]. Severity and topographic distribution of atrophic lesions should be reported according to Operative Link for Gastritis Assessment (OLGA)[35] and Operative Link for Gastric Intestinal Metaplasia Assessment (OLGIM)[36]. By following this protocol, it is less likely to miss the diagnosis of AIG. Moreover, OLGA e OLGIM scores are then used to determine whether endoscopic surveillance is needed and its frequency. Conversely, if there is no suspicion of organic disease, FD could be diagnosed. However, even in these cases, both the American and British guidelines[30,32] suggest testing dyspeptic patients for *H. pylori* with non-invasive tests (*i.e.* fecal antigen or carbon-urea breath testing) and treating the infected ones accordingly, as *H. pylori* infection is considered to be an etiologic factor of dyspepsia in 5% of dyspeptic patients[37].

In case of PDS, with dyspeptic symptoms that recall altered gastric emptying, gastric emptying scintigraphy (GES) is a useful tool to explore impaired (rapid or delayed) gastric dysmotility. Briefly, the test consists of a standard meal, which is marked with Technetium (Tc)-99m; after food ingestion, imaging is performed in the anterior and posterior projections at only four-time points (0, 1, 2, and 4 h). Delayed gastric emptying is determined to be > 90% at 1 h, > 60% at 2 h, and > 10% gastric retention at 4 h. Conversely, rapid gastric emptying is determined to be < 30% at 1 h[38]. While GES performs well in diagnosing gastroparesis[39], it is not reliable for the diagnosis of FD, which is supposed to be a lighter spectrum of the same gastric disorders[40], and no specific studies exist for AIG, therefore further studies are needed to clarify this item[39]. However, this technique can be time-consuming, as the test requires imaging at set intervals over several hours, it involves radiation exposure from the radioactive material in the meal and, as for FD, also in the case of AIG, it may not be reliable, as there is only a milder form of a gastric motility disorder. Moreover, it appears to have limited therapeutic implications, as it may suggest treating the patient with prokinetic drugs at most, which can also be done ex adjuvantibus**.** Recently, the wireless motility capsule (WMC) has been introduced, in order to simultaneously assess both regional and whole gut transit[41,42]. Ingestion of this non-digestible capsule that simultaneously measures luminal temperature, pH, and pressure facilitates the measurement of the gastric, small bowel, and colonic transit times. Approved by the United States Food and Drug Administration for the evaluation of gastroparesis and slow colonic transit, WMC should be considered in suspected GI motility disorders as it provides a single study capable of simultaneously assessing for regional, multi-regional, or generalized motility disorders[43]. Triadafilopoulos *et al*[43] suggested a potential WMC role in AIG diagnosis since it is able to register intragastric pH (usually > 6) and eventually associated dysmotility[43]. However, as for GES, even for WMC at present, considering the limited availability of prokinetic drugs, therapeutic implications are limited. Finally, a recent physiologic tool has been proposed to assess the functionality of the pyloric sphincter. The functional luminal imaging probe known as EndoFlip® is a 240-cm catheter with impedance electrodes at its distal end[44,45], that is used to assess the functionality of the pyloric sphincter. The device is placed in the pylorus either through the endoscope, under endoscopic visualization[45], or either by fluoroscopy guidance[46]. After positioning the device, the balloon is filled to set volumes of 10, 20, 30, 40, and 50 mL using a stepwise protocol, and the cross-sectional area (CSA), bag pressure, and distensibility index are recorded. The pyloric distensibility index (P-DI) is calculated in the zone with the narrowest CSA

with the corresponding intra-bag pressure[46]. A decreased P-DI has been observed in patients with gastroparesis[47], and also in patients with chronic nausea and vomiting without delayed gastric emptying, suggesting that pyloric dysfunction could explain "gastroparesis-like" symptoms in this group of patients[48]. However, normal and pathological values still need to be confirmed.

As mentioned above, GERD symptoms are frequently reported by AIG patients[24,25]. According to recent guidelines[49] and Lyon consensus[50], GERD is usually a clinical diagnosis, based on patients' symptoms (typical GERD symptoms, pyrosis, and acidic regurgitation) and empiric proton pump inhibitors (PPIs) treatment response (*i.e.* single dose for 4-8 wk).

Since AIG patients are supposed to have a higher intragastric pH (registered in one study, being median intragastric pH of 6.2 (4.6-7.0)[24], due to parietal cells atrophy, it may be surprising that AIG patients complain of GERD symptoms. A previous paper by Tenca *et al*[24] registered that 15 out of 41 AIG patients had GERD symptoms. Among them, acidic reflux, recorded by MII-pH monitoring, had a minor role, being present in one patient only. This could be explained by the residual production of acid from partially atrophic mucosa. Non-acidic reflux was instead more frequent, being present in 22% of the AIG population studied. It is common knowledge that non-acidic reflux can give rise to typical or atypical GERD symptoms[51-53].



Moreover, it could be useful to study these patients with MII-pH-monitoring, which is able to identify acidic, weakly acidic, and non-acidic reflux events. The observation of a role of GERD in these patients' symptoms independently of acid is clinically relevant because it can guide their management. These patients may benefit from drugs that lower their visceral sensitivity (*i.e.*, tricyclic antidepressants and selective serotonin reuptake inhibitors)[7,54]. Furthermore, for those with severe drug-unresponsive symptoms anti-reflux surgery is an option[55,56]. Another study by Pilotto *et al*[25] characterizes AIG patients according to their GERD symptoms and MII-pH-monitoring results. Similarly, Tenca *et al*[24] found pathologic esophageal acid exposure in two out of 38 patients reporting GERD symptoms. On the contrary, a great part of them (30 out of 38 patients) had an increased number of non-acidic reflux episodes. Combining symptoms and MII-pH-monitoring results, the Authors classified AIG patients as having GERD (5%), functional heartburn (50%), and reflux hypersensitivity (24%). Interestingly, the Authors studied AIG patients with high-resolution esophageal manometry (HRM) and found that 37% of AIG patients had various motility disorders, including 8 minor disorders (n = 7 weak peristalsis and n = 1 hypertensive peristalsis), and 6 major disorders (n = 6 EGJ outflow obstruction) according to Chicago classification v 3.0[57]. Whether these manometric findings correlate with AIG is still debated. Similarly, the role of HRM in the diagnostic work-up of these patients remains unclear. MII-pH-monitoring could also have a role in the diagnosis of dyspepsia. It is known from the literature that epigastric pain is often more frequent in patients with pathologic MII-pH-monitoring[58]. In the population studied by Tenca *et al*[24], two dyspeptic patients showed a positive correlation between epigastric pain and non-acidic reflux. A possible diagnostic algorithm is represented in Figure 3.

In summary, dyspeptic symptoms and GERD are common in AIG patients; the diagnostic algorithm provides an EGDs study as the first diagnostic test to exclude organic disease and to confirm AIG diagnosis. If GERD symptoms are present, MII-pH-monitoring is useful to measure the entity of reflux and to classify patients (GERD, functional heartburn, hypersensitive esophagus) and treat them accordingly. Moreover, it could be useful in dyspepsia diagnosis. Esophageal motility tests, as well as gastric emptying tests, could have a role in AIG patients but further studies are needed to clarify these items.

Treatment

Dyspepsia is a common symptom in AIG and its management can be challenging, as the pathophysiology underlying dyspeptic symptoms in AIG is multifactorial. However, this issue is still understudied, and more research is needed to better understand the mechanisms of dyspepsia in AIG and to develop effective treatments tailored to the individual patient's symptoms and underlying pathophysiology. Indeed, although the primary goal of AIG treatment is to address vitamin deficiencies and prevent and monitor for gastric neoplasms, effectively managing common and difficult-to-treat symptoms like dyspepsia is crucial for improving patients' quality of life.

As a matter of fact, according to available guidelines[10], there is poor evidence regarding the best treatment options for dyspeptic symptoms in patients with AIG, also considering that PPIs are not indicated in this subset of patients who are typically hypochlorhydric. Despite this, several AIG patients referring dyspeptic symptoms are often prescribed PPIs by General Practitioners or gastroenterologists with no or low knowledge of this disease. The use of PPIs in this subgroup of patients should be discouraged for two main reasons. Firstly, AIG is characterized by a suppressed gastric acid secretion and consequent hypochlorhydria, thus treatment with antisecretory drugs is generally ineffective as already reported[24,59] taking into account that these patients refer reflux-like symptoms whose nature is non-acid. Secondly, and far more important, the long-term use of PPIs has been reported to be associated with the development or progression of gastric pre-malignant lesions. Of note, as already reported[60], the long-term treatment with PPIs which is responsible for increased levels of serum gastrin seems to be linked to a higher risk of progression of ECL-cell hyperplasia which precedes the development of gastric type 1 neuroendocrine neoplasm[61]; however, no clear-cut evidence was found between PPI therapy and increased progression of AIG or intestinal metaplasia[60].

Figure 3 Possible diagnostic algorithm for dyspepsia or gastroesophageal reflux disease -like symptoms in autoimmune atrophic gastritis. A: Dyspeptic symptoms; B: Gastroesophageal reflux disease symptoms. AIG: Autoimmune gastritis; EGDs: Esophagogastroduodenoscopy; GERD: Gastroesophageal reflux disease; GI: Gastrointestinal; *H. pylori*: *Helicobacter pylori*; PPIs: Proton pump inhibitors.

Initial management of dyspepsia in AIG may involve dietary modifications, such as avoiding trigger foods or eating smaller, more frequent meals. Patients may also benefit from lifestyle modifications, such as weight loss or stress reduction techniques, even if these procedures are not evidence-supported.

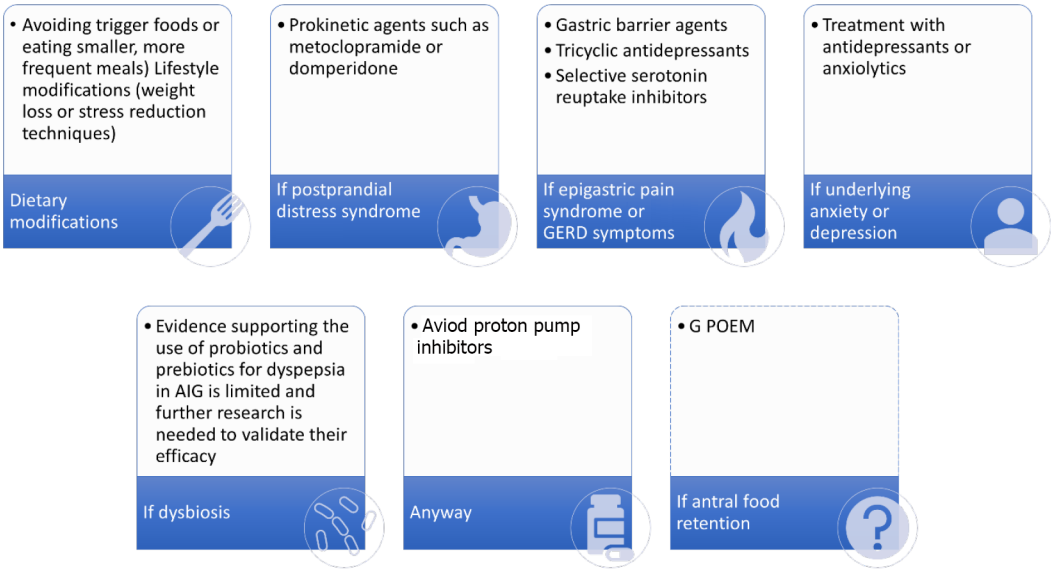
It is important to highlight that patients with AIG often have evidence of current or prior *H. pylori* infection[62]. Therefore, it is important to test these patients for *H. pylori* and, if positive, to eradicate it according to guidelines that suggested the "Test and treat" strategy[63]. Of note, *H. pylori* eradication appears to reduce the risk of gastric cancer[64]. In the specific setting of AIG, according to a randomized double-blinded placebo-controlled trial[65], that compared triple eradication therapy for *H. pylori* with placebo in histologically diagnosed AIG patients, at 3-years follow-up dyspeptic symptoms scores improved significantly in the patients in whom *H. pylori* had been eradicated. Similar findings were reported by another recent study[66], which showed that the beneficial effect of *H. pylori* eradication treatment on dyspeptic symptoms lasted until one year after treatment, being associated with a higher pretreatment symptom score and age inferior to 70 years old. Obviously, the benefit of *H. pylori* eradication in AIG patients is further increased by the fact that *H. pylori* more that autoimmunity per se, is linked to the risk of evolution towards dysplasia and gastric cancer in AIG, as recently described[1].

In addition to *H. pylori* eradication, several treatment options[67] have been investigated for their efficacy in managing dyspeptic symptoms in AIG. These treatments include prokinetic agents, neuromodulators, and herbal agents, as well as non-pharmacological treatments such as acupuncture, cognitive-behavioral therapy, and hypnotherapy. However, the evidence regarding their effectiveness is conflicting also taken into account the lack of dedicated prospective studies exploring the efficacy of prokinetics and neuromodulators in this specific setting of patients, making the management of AIG patients experiencing dyspeptic symptoms very challenging. Medications such as prokinetic agents including metoclopramide or domperidone may be used to improve gastric motility and reduce symptoms of bloating and nausea in patients with predominantly PDS symptoms. For patients presenting with EPS symptoms, a rational approach could therefore be to guide therapy based on the altered pathophysiological mechanism. As mentioned before, 24-h MII-pH-monitoring may be a useful tool to classify AIG patients having GERD symptoms. If MII-pH-monitoring found true acidic GERD, PPIs treatment could have a role. Being this an extremely rare condition, there are no clear-cut recommendations on treatment dosage and duration. Conversely, if MII-pH-impedance diagnoses a non-acidic reflux disease, as well as functional heartburn and reflux hypersensitivity, these patients may benefit from drugs that lower their visceral sensitivity (*i.e.* tricyclic antidepressants and selective serotonin reuptake inhibitors)[7,54]. Moreover, patients who did not respond to medical treatment as well as patients with a high burden of non-acidic reflux, may benefit from anti-reflux surgery[55,56].

In cases where dyspepsia is associated with underlying anxiety or depression, treatment with antidepressants or anxiolytics may be warranted[7,54]. However, future research is needed to identify more effective treatments for dyspepsia in AIG and to better understand the underlying mechanisms that drive dyspeptic symptoms in this condition.

Furthermore, a known consequence of atrophic gastritis-related hypochlorhydria and/or achlorhydria is a change in the gastric microbiome composition. However, there are currently no specific therapies targeting dyspepsia in AIG based on changes in the microbiota, even if an abnormally elevated presence of endoluminal bacteria which produce acetaldehyde from glucose metabolism has been described[68]. Again, according to some authors[69,70], L-cysteine, a non-essential amino acid, can modify the microenvironment of the achlorhydric stomach by both inactivating acetaldehyde and promoting recovery of gastric function[71,72]; furthermore, there is some anecdotal evidence that L-cysteine might improve functional symptoms often associated with atrophic gastritis. Based on these observations, Di Mario *et al*[73] recently conducted a study including a total of 330 patients with atrophic gastritis (both autoimmune or *H. pylori*-related), who were divided into two groups, treated with long-term L-cysteine and no specific treatment, respectively, and reported a significant improvement in the symptom scores of patients treated with L-cysteine when compared to the non-treated group. Of note, symptom improvement lasted all the two years of the follow-up. One limitation of this study is the inclusion of different etiologies from atrophic gastritis, which might be responsible for a certain grade of heterogeneity. While research into the gut microbiota and its role in AIG is ongoing[74,75], some studies suggest that probiotics and prebiotics may have a role in modulating the gut microbiota and reducing symptoms in patients with dyspepsia, including those with AIG[76,77]. Overall, while the potential for microbiota-based therapies in managing dyspepsia in AIG is promising, further research is needed to develop and validate such approaches.

Finally, further treatment may be available in the near future. Gastric per-oral endoscopic myotomy (G POEM) is a novel endoscopic procedure that has shown promising results in the management of refractory gastroparesis[78]. This technique has received increasing attention and emerged as a promising treatment for refractory gastroparesis, targeting the pylorus[79], as a result of the use of new tools to identify pyloric dysfunction in routine care, including functional luminal impedance planimetry (FLIP). The procedure involves creating a myotomy or an incision in the inner lining of the stomach, thereby allowing for better gastric emptying. Since AIG patients with PDS may have the same functional dysfunction of patients affected by gastroparesis, both from a pathophysiological and clinical point of view, G POEM may represent a feasible treatment for AIG patients with severe dyspeptic symptoms, which did not respond to medical treatment. Even if it is considered a safe procedure, a potential concern associated with G POEM is the risk of complications, such as bleeding, perforation, and infection[80]. Additionally, the long-term outcomes of G POEM are still unclear, and more studies are needed to assess its durability and impact on patient quality of life. Recently, Mandarino *et al*[81] found that a lower Intragastric Meal Distribution at pre-intervention gastric emptying study, which indicates antral food retention, could be associated with post-procedural functional success, defined as a decrease of more than 30% 2-h retention. However, further data are needed to establish long-term efficacy of endoscopic pyloromyotomy, especially in the management of dyspeptic AIG patients.



CONCLUSION

AIG can cause a range of clinical manifestations, including dyspepsia. Accurate diagnosis and appropriate management of dyspepsia in AIG are important to improve the patient's quality of life, as well as to prevent and monitor for potential complications such as vitamin deficiencies and gastric neoplasms. The pathophysiology of dyspepsia in AIG is complex and involves changes in acid secretion, gastric motility, hormone signaling, and gut microbiota, among other factors. Specifically, investigating the role of visceral hypersensitivity, impaired gastric accommodation, and impaired gastric motility in AIG-related dyspepsia may help to identify new targets for treatment.

Managing dyspeptic symptoms of AIG is challenging and there are no specific therapies targeting dyspepsia in AIG. While PPIs are commonly used to treat dyspepsia and GERD, they may not be appropriate for AIG, as the condition is already characterized by hypochlorhydria. Instead, prokinetic agents, antidepressant drugs, and non-pharmacological treatments may be of help, even if not adequately evidence-based supported.

Targeting dyspepsia in AIG based on changes in the microbiota is an area of ongoing research and some studies suggest that probiotics and prebiotics may have a role in reducing symptoms. G POEM may represent a feasible treatment for AIG patients with severe dyspeptic symptoms, even if more research is needed to establish its safety and efficacy in this specific setting of patients. Figure 4 summarizes the possible therapeutic approaches for dyspeptic or with GERD-like symptoms in patients with AIG.

Overall, a multidisciplinary approach for the management of dyspepsia in AIG is recommended, and further research is needed to develop and validate more effective therapies for dyspepsia in AIG, as well as to better understand the underlying pathophysiology of the disease; GERD: Gastroesophageal reflux disease.

ARTICLE HIGHLIGHTS

Research background

Gastrointestinal symptoms such as dyspepsia and early satiety are very common in autoimmune gastritis (AIG), being second in terms of frequency only to anemia, which is the most typical feature of AIG. Understanding the pathophysiology of each condition can also guide the choice of appropriate treatments, including lifestyle modifications, dietary changes, and medication management.

Research motivation

The management of dyspepsia in patients with AIG, a chronic, immune-mediated disease, remains a challenge, as it can overlap with functional dyspepsia and gastroesophageal reflux disease. Currently, there are no specific therapies. A tailored treatment approach based on a better understanding of putative pathogenic mechanisms underlying symptoms is needed.

Research objectives

In this review, we will discuss the putative pathogenic mechanisms underlying symptom generation in AIG, their clinical implications, and the current management strategies for this complex and multi-faceted disease.

Research methods

An extensive bibliographical search was performed in PubMed to identify guidelines and primary literature (retrospective and prospective studies, systematic reviews, case series) published in the last 10 years, using both medical subject heading terms and free-language keywords: Dyspepsia; dyspeptic symptoms; gastro-intestinal symptoms; chronic autoimmune atrophic gastritis; diagnosis; treatment.

Research results

A total of 125 records were reviewed and 80 were defined as fulfilling the criteria.

Research conclusions

AIG can cause a range of clinical manifestations, including dyspepsia. The pathophysiology of dyspepsia in AIG is complex and involves changes in acid secretion, gastric motility, hormone signaling, and gut microbiota, among other factors. Managing dyspeptic symptoms of AIG is challenging and currently, there are no specific therapies. A tailored treatment approach based on a better understanding of putative pathogenic mechanisms underlying symptoms is needed. While proton pump inhibitors are commonly used to treat dyspepsia and GERD, they may not be appropriate for AIG. Prokinetic agents, antidepressant drugs, and non-pharmacological treatments may be of help, even if not adequately evidence-based supported. A multidisciplinary approach for the management of dyspepsia in AIG is recommended, and further research is needed to develop and validate more effective therapies for dyspepsia.

Research perspectives

As a future perspective, targeting dyspepsia in AIG based on changes in the microbiota and advanced endoscopic techniques to treat severe dyspeptic symptoms might be an area of ongoing research.

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

Partial hepatectomy (PH) can lead to severe complications, including liver failure, due to the low regenerative capacity of the remaining liver, especially after extensive hepatectomy. Liver sinusoidal endothelial cells (LSECs), whose proliferation occurs more slowly and later than hepatocytes after PH, compose the lining of the hepatic sinusoids, which are the smallest blood vessels in the liver. Vascular endothelial growth factor (VEGF), secreted by hepatocytes, promotes LSEC proliferation. Supplementation of exogenous VEGF after hepatectomy also increases the number of LSECs in the remaining liver, thus promoting the reestablishment of the hepatic sinusoids and accelerating liver regeneration. At present, some shortcomings exist in the methods of supplementing exogenous VEGF, such as a low drug concentration in the liver and the reaching of other organs. Moreover, VEGF should be administered multiple times and in large doses because of its short half-life. This review summarized the most recent findings on liver regeneration and new strategies for the localized delivery VEGF in the liver.

Key Words: Liver regeneration; Vascular endothelial growth factor; Nano materials; Liver resection

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Low regenerative ability of the liver remaining after partial hepatectomy may lead to serious complications including liver failure. The proliferation of liver sinusoidal endothelial cells (LSECs) is slower and occurs later compared to that of hepatocytes, leading to a delayed recovery of the hepatic sinusoids and impaired liver regeneration. Hepatocytes secrete vascular endothelial growth factor (VEGF) that promotes the proliferation of LSECs, and supplementation of exogenous VEGF after hepatectomy also increases the number of LSECs in the remaining liver, thus promoting the reestablishment of the hepatic sinusoids and accelerating liver regeneration. This review summarized the most recent findings on liver regeneration and new strategies for the localized delivery in the liver.

INTRODUCTION

Approximately 300 million people in China are suffering from liver diseases[1]. Liver cancer originates from hepatitis B in 80% of patients, and the incidence and mortality of liver cancer account for more than 50% of worldwide, making liver cancer the second leading cause of death in China[2]. Surgery remains the primary treatment option for liver cancer, but only 15% of patients can undergo this procedure[3]. Insufficient residual liver volume is the primary reason why about 30% of patients are ineligible for surgery[4], thus, becoming the main factor limiting the safe implementation of major liver resection. Therefore, there is an urgent need to improve the regenerative capacity of the liver and promote liver function after partial hepatectomy (PH).

SCHEMATIC DESCRIPTION OF LIVER REGENERATION AFTER PH

The proliferation time of each cell type in the liver after PH is different[5]. Hepatocytes begin to proliferate within a few hours after PH and reach a peak at 24 h. The proliferation of liver sinusoidal endothelial cells (LSECs) is slower and later compared to that of hepatocytes. Indeed, they start to proliferate at 36 h after PH and reach the peak at 96 h[6]. In the first 72 h after PH, the hepatic plate becomes wider, the proportion of LSECs decreased due to the rapid proliferation of hepatocytes, and the density of the liver sinusoid is temporarily reduced. This leads to hypoxia in some areas of the liver, inducing the secretion of vascular endothelial growth factor (VEGF) by the hepatocyte. VEGF is a vital regulator inducing the proliferation, mobilization, engraftment and differentiation of bone marrow progenitor cells of LSECs (BM SPCs), which is the main of renew LSECs[7]. BM SPCs have a high expression of hepatocyte growth factor (HGF) that promotes hepatocyte proliferation. The different proliferation time of the different cell types in the liver leads to their interaction to complete liver regeneration[7-9].

The regeneration of the liver after PH is a complex process that involves various types of cells and signaling pathways. Hepatocytes highly expressing VEGF are mainly located around the portal vein, and LSECs have the highest proliferation ability also around the portal vein after PH. Inhibition of VEGF significantly impairs the proliferation of hepatocytes and LSECs, while exogenous VEGF significantly promotes their proliferation, suggesting that VEGF promotes the proliferation of hepatocytes by acting on LSECs[10]. Moreover, LSECs regulate the expression of stromal cell-derived factor 1 (SDF-1) after PH, which leads to the recruitment and mobilization of chemokine receptor 7^+ ($CXCR7^+$) BM SPCs into the circulation. Furthermore, CXCR7+ BM SPCs are recruited to the liver and eventually differentiated into mature LSECs, being involved in the reconstruction of the hepatic sinusoids and the promotion of liver regeneration[11]. *In vitro* and *in vivo* studies demonstrated that the expression of CXCR7 receptor and downstream paracrine factor HGF in the microenvironment is regulated by a unique transcriptional regulator called inhibitor of DNA binding 1 (Id1)[12]. The regeneration and repair response in the liver when injured is regulated by the activation of the intrahepatic CXCR7-Id1-HGF/Wnt2 pathway[13]. Therefore, our hypothesis is that VEGF changes the guiding microenvironment through the SDF-1/CXCR7 pathway, activates Id-1 in LSECs, and up-regulates the expression of HGF and Wnt2 to reprogram the microenvironment during liver regeneration (Figure 1).

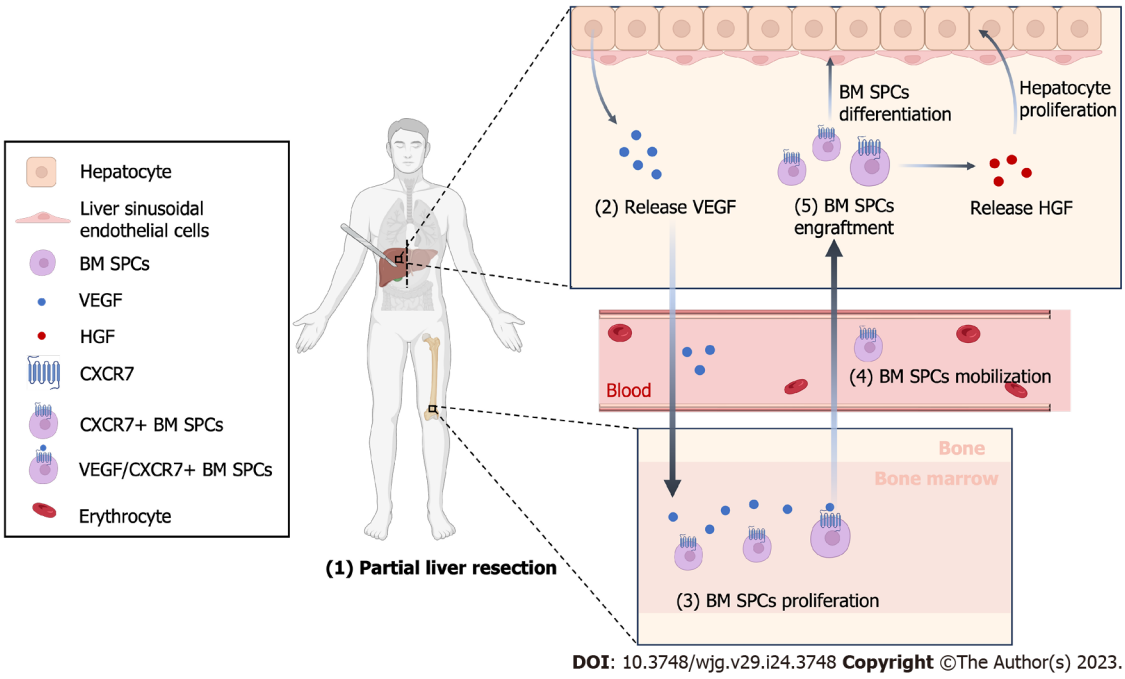

Figure 1 Schematic Illustration of liver after partial hepatectomy. After partial hepatectomy, hepatocytes begin to proliferate and release vascular endothelial growth factor, which promotes the proliferation of bone marrow-derived progenitor cells (BM SPCs) and reconstruction of hepatic sinusoids. BM SPCs secrete hepatocyte growth factor, which provides positive feedback and promotes hepatocytes proliferation. This figure was created with BioRender (BioRender.com). VEGF: Vascular endothelial growth factor; HGF: Hepatocyte growth factor; BM SPCs: Bone marrow-derived progenitor cells.

IMMUNITY AND LIVER REGENERATION

Liver regeneration is a complex process that involves multiple factors closely related to the immune response, which plays a critical role in tissue regeneration[14,15]. Following liver resection or injury, hypoxia occurs in certain liver areas, leading to hepatocyte apoptosis and release of apoptotic extracellular vesicles (aEVs). These aEVs are mainly cleared and phagocytosed by immune cells, while the main factor performing phagocytosis is still controversial. Some studies suggest that these aEVs are phagocytosed by Kupffer cells (KCs). KCs, the resident macrophages in the liver, are necessary for the emergence of liver progenitor-like cells (LPLCs), which are a source of newly regenerated hepatocytes under injury, as demonstrated by a mouse model of macrophage specific knockout[16]. KCs secrete inflammatory cytokines such as interleukin (IL)-6 and tumor necrosis factor (TNF)-α, which are crucial early signals to start regeneration[17]. While other studies demonstrated that hepatocytes are reborn from pre-existing hepatocytes[18], aEVs in the liver are mainly cleared and phagocytosed by circulating neutrophils rather than by phagocytes such as KCs[8,19]. Massive cell apoptosis after PH inhibits the phagocytic activity of immune cells resident in the liver[14]. At this time, circulating neutrophils are recruited and responsible for the phagocytosis and clearance of aEVs. Neutrophils phagocytose aEVs secreted by apoptotic hepatic cells and then, they released multiple growth factors including HGF and VEGF to regulate the proliferation of hepatic cells. Liver regeneration decreases under the specific condition of neutrophil exhaustion, and liver function recovery is also delayed[8]. Liver regeneration and immunity are closely related, and further studies should focus more on them, including the role of efferocytosis and metabolism.

RELATIONSHIP BETWEEN VEGF AND LIVER REGENERATION

VEGF belongs to a class of peptides with heparin-binding activity connected by a disulfide bond through a cysteine residue[20]. It is a potent mitogen for endothelial cells by directly acting on their specific surface receptors to exert its biological effects. The asynchronous proliferation of hepatocytes and LSECs delays the regeneration of new liver sinusoids, causing an insufficient liver regeneration in the early postoperative period (within 72 h)[21,22]. Therefore, this early period after PH is the most important period in which VEGF promotes liver regeneration. Endothelial cells under the action of VEGF migrate, proliferate and form tubular protrusions, eventually forming a network structure of arteries and veins, also increasing vascular permeability[23].

Exogenous VEGF promotes LSEC proliferation, but only in a dose-dependent manner, meaning that only above a certain dose of VEGF the proliferation of LSECs is promoted[24]. *In vitro* studies

demonstrated that the addition of VEGF to the culture medium of primary cultured LSECs promotes cell proliferation, while the group without VEGF showed a significantly less number of LSECs at 48 h than that at 16 h, and no significant difference was observed before and after the addition of 10 ng/mL VEGF. However, the number of LSECs at 48 h after the addition of 100 ng/mL VEGF is significantly higher than that at 16 h. Scanning electron microscopy showed that the window structure of LSECs gradually decreases with the increasing of time in the group without VEGF. LSECs in the liver are typically characterized by the presence of pores (fenestrae). These pores in the group with 10 ng/mL VEGF treatment are basically stable, and the number and size of this pores are significantly increased compared with those in the previous two groups. This indicated that VEGF promotes the proliferation of LSECs in a dose-dependent manner, with only a certain dose of VEGF promoting cell proliferation and exerting its function[24].

INTRAVENOUS INJECTION OF EXOGENOUS VEGF

Intravenous (IV) injection of exogenous VEGF is an proven method to induce the regeneration of the liver[25]. Indeed, it promotes the postoperative regeneration of the remaining liver after the detection of the PCNA index of hepatocytes in mice. The results showed that exogenous VEGF intervention significantly stimulates the proliferation of the remaining hepatocytes and promotes postoperative liver regeneration[26]. Another study also used tail vein injection of exogenous VEGF and *in vivo* microscopy to demonstrate that VEGF is involved in the regeneration after the removal of two-thirds of the liver [27]. The results showed that exogenous VEGF increases the hepatic vascular density, vascular diameter, and liver weight ratio as well as it enhances the proliferation of hepatocyte. Nevertheless, abnormal liver function and inhibition of hepatocyte proliferation are observed when endogenous VEGF is antagonized. However, the treatment with exogenous VEGF is not effective on liver regeneration when 90% of the liver is resected, as demonstrated by a rat resection model, suggesting that proliferation is also related to the degree of liver resection[28]. Although the administration of drugs through IV injection allows a certain degree of liver regeneration, the effective concentration of VEGF in the liver is insufficient due to its short half-life, uptake by other organs and tissues, and abundant hepatic blood flow[29]. Therefore, other efficient and safe liver-targeted drug delivery systems should be designed to overcome these shortcomings.

VEGF RELEASE BY NANOFIBERS

Electrospun nanofibers

The IV delivery of exogenous VEGF increases the content of VEGF only transiently, and long-term high concentrations in the liver cannot be achieved due to the abundant blood flow in the liver. Moreover, the short half-life of VEGF *in vivo* makes it difficult to achieve a constant effective concentration with a single injection, necessitating repeated injections that increase the complexity of treatment. Therefore, a controllable release nano-matrix membrane loaded with exogenous VEGF was designed and prepared to overcome the shortcomings, which was implanted into the residual liver wound after surgery to realize a targeted delivery of drugs by a local controlled release of VEGF.

The electrospinning technology is a universal and effective method for preparing nanoscale polymer fibers, and its principle is as follows: A polymer solution is connected with a high-voltage power supply through a wire, a receiving plate is grounded, and static electricity exists between the polymer solution and the receiving plate. The continuous increase of the voltage, the polymer solution gradually overcomes the surface tension and is ejected through a nozzle when the electrostatic action is greater than the cohesive force of the polymer flow, and the polymer is split into a fine polymer flow before reaching the collecting plate. The nanoscale polymer fibers in the form of a nonwoven fabric are thus obtained on the receiving sheet[30]. Nano-sized polymer fibers become a hot research topic in polymer material science in recent years due to their rapid preparation and their application in medical field is increasing and becoming mature.

Our research group previously developed a novel electrospun nanofiber loaded with VEGF, and thin layers of collagen were used as support to wrap the nanofiber between two layers of collagen to make a membrane-like structure. Collagen improves the stiffness of the fiber and confers a hemostatic function, which is beneficial to the fixation of the material at the implantation site. After the surgery, the fiber is directly covered on the liver wound surface, and the exogenous VEGF in the nanofiber in the local liver is continuously and efficiently controlled to form a microenvironment with effective VEGF concentration. This approach allows the proliferation of LSECs early after surgery, with an early promotion of liver regeneration[31]. The biodegradable biocompatible polymer and collagen used to make the nanofiber is approved by FDA of the United States and has a long-term traceable biological safety. The results showed that this new method of controlled release of VEGF through nanofibers significantly promotes the proliferation of the remaining hepatocytes at 48 and 72 h after surgery. The expression of

endogenous VEGF in the liver is also higher than that in the control group without nanofibers. The above results confirmed that biodegradable nanofibers represent a convenient and effective method for the release of VEGF specifically in the postoperative residual liver to effectively promote liver regeneration[31].

Hydrogel nanofiber technology

Electrospun nanofibers have some limitations in loading growth factors due to the high shear rate (10^5 to 10^6 s-1) of the polymer solution and the use of organic solvents. Moreover, the electrospinning of water-soluble polymers is difficult. These limitations make difficult the maintenance of an efficient activity of growth factors during the manufacturing process. Therefore, our research group prepared polymer composite hydrogel fibers by stretching the water-soluble polymer solution under the combined action of an electric field force and mechanical force[32]. The diameter and composition of the hydrogel fiber is realized by adjusting the components, concentration and stretching conditions of the polymer aqueous solution[33]. An important feature of this method is that the molecular chains in the fiber bundles are oriented using an electric field and a unidirectional mechanical tension. natural or synthetic polymer aqueous solutions were originally used to spin various hydrogel fibers, including alginate, collagen, fibrin, and hyaluronic acid. More importantly, this method without the use of organic solvents allows the formation of multilayered (core-shell) fibers that encapsulate growth factors in hydrogel fibers with a small impact on their bioactivity (Figure 2)[32]. In addition, the release rate of growth factors is controlled by adjusting the fiber composition and the degree of crosslinking, as well as the properties of the composite. The treatment with VEGF loaded with hydrogels accelerates the recovery of liver function after surgery in a rat model of 70% PH, and the peak value of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) was 12 h earlier than that in the control group without hydrogels. Hepatocyte proliferation was also increased[34].

Retrograde intrabiliary infusion of VEGF nanoparticles

All parenchymal cells in the remaining liver after PH develop a proliferative potential, not just an exophytic growth from the wound site. Although the strategy of releasing VEGF from nanofiber results in the local release of growth factors onto the wound surface, the concentration of VEGF inside the liver decreases when the VEGF penetrate into the liver from the liver wound surface, so that the stimulation of VEGF on the cells in the liver is not uniform. Therefore, all cells in the residual liver should be stimulated by VEFG to effectively accelerate the regeneration of the residual liver and the recovery of liver function. Hence, it is necessary to design a new strategy to obtain a wide distribution of growth factors in the liver, allow their efficient uptake by intrahepatic cells, and realize high activity and low clearance rate in the liver.

The ultrastructural surface area of the hepatic biliary system is enormous, and the biliary system provides a surface in direct contact with almost all hepatocytes[35]. In addition, there are no KCs in the intrahepatic biliary system, thus, the non-specific phagocytosis of exogenous molecules by KCs is avoided and the immune inflammatory response of the body is reduced. The large volume of the intrahepatic bile duct makes the intrahepatic biliary system more distensible and able to tolerate the retrograde injection of a certain volume of fluid. Therefore, retrograde intrabiliary infusion (RII) has become a new way to perform a targeted delivery of drugs into the liver[36-38].

Administration of the VEGF gene has some advantages compared with the administration of the VEGF protein: Gene administration induces the transient expression of growth factor in hepatocytes, which is the ideal manner to realize an administration in the full residual liver. Although the conventional transgenic viral vectors effectively transfer the target gene into the parenchymal cells of liver, the side effects and immune responses induced by viruses limit their clinical application. Non-viral gene vectors have the advantages of diverse design, simple synthesis, storage stability, flexibility of the transgene length, low toxicity, and low immune response. In addition, the transfection of a non-viral gene vector is suitable for the transient expression of growth factors in liver regeneration.

At present, researchers have successfully prepared a variety of biodegradable nanoparticle systems for gene delivery[39-41]. Chitosan is a natural polysaccharide with good biodegradability, biocompatibility, anti-inflammatory effects, and its polycation structure confers many excellent properties in drug and gene delivery. Furthermore, the cationic structure of chitosan allows higher entrapment efficiency and loading of drugs, especially negatively charged genes. Finally, positively charged chitosan nanoparticles enhance the cellular uptake thanks to their slightly negatively charged cell membrane surface[42-44]. Ultra-pure, narrow molecular weight fully characterized chitosan is now available, and therefore, it is almost reaching the approval as a vector material than other gene vectors.

Previous studies demonstrated that chitosan-DNA nanoparticles (150-300 nm) achieve high transfection efficiency *in vivo* in rat hepatocytes after RII. The expression of transgenic proteins began at 12 h, peaks at 3 d after injection, and gradually declines after 14 d. Liver function analysis and histopathological examination show that the approach of using RII of nanoparticles does not produce significant toxic reactions and damage to the liver and bile ducts[45-47]. The expression of transgenic proteins in the kidney, lung, spleen and heart is almost negligible compared with their expression in the liver, which proves that this method results in a local high-efficiency and specific expression of the introduced gene in the liver. Therefore, RII is the best approach for gene delivery in the liver.

Polycation-DNA nanoparticles are prepared by routine method, which consists of a mechanical mix polycations and plasmid DNA, but this assembly process is subjected to a variety of interference by kinetic factors during the preparation (about tens of milliseconds), easily leading to low homogeneity and unstable properties of nanoparticles. Therefore, our co-investigators developed a rapid nanocomposite method called flash nano-complexation to solve this technical problem, protecting plasmid DNA and working at very high flow rates inside a confined impact jet reactor. The polycationic solution reduces the mixing time of the two substances to approximately 10 milliseconds, avoiding significant folding denaturation of the plasmid DNA[48]. Uniform size, homogeneous properties and controllable oral plasmid DNA nanoparticles are prepared by this innovative method, and successfully used in the treatment of diabetes (Figure 3)[49]. Our group prepared VEGF-chitosan-DNA nanoparticles for RII in rats subjected to 70% hepatectomy and acute liver injury induced by acetaminophen. The preliminary results show that these nanoparticles promote the recovery of liver function and liver regeneration after PH.

LIMITATION AND FUTURE OUTLOOK

A precise spatio-temporal regulation of VEGF level is necessary for the proper functioning of the vascular system. VEGF plays a pivotal role in angiogenesis during embryonic development, tissue regeneration, and wound healing. However, VEGF is also a key mediator of angiogenesis in tumors. It can upregulate the expression of VEGF under various conditions, such as oncogene expression, multiple growth factors, and hypoxia, thereby promoting angiogenesis, which is essential for the development and growth of tumor[50]. In most solid tumors, VEGF is overexpressed. The abnormal expression of

VEGF leads to the formation of a new vascular system in and around the tumor. These tumor vessels, formed under the action of VEGF, are structurally and functionally abnormal, thus promoting tumor growth. Given the central role of VEGF in tumor angiogenesis, it represents a rational target for anti-tumor therapy[51]. Therefore, by downregulating the VEGF signal in the tumor, the vascular system returns to a "normal" state. This "normalized" vascular system increases tumor oxygenation and improves drug permeability, leading to a better therapeutic response[52]. Therefore, in the future, we need to more accurately evaluate the VEGF of the recipient tissue and balance between promoting regeneration and inhibiting tumor.

CONCLUSION

VEGF is an important growth factor promoting angiogenesis and tissue regeneration, but it also promotes tumor growth depending on its expression. This contradiction reflects the complex role of VEGF in regulating cell growth and apoptosis[53]. Therefore, more studies are needed to better control VEGF expression to avoid the promotion of tumor growth and to promote tissue regeneration[54].

In the future, the administration of exogenous VEGF might become a potential treatment to promote liver regeneration after liver injury. However, the current intervention methods to administer exogenous VEGF are still limited, and the efficiency needs to be improved. Locally controlled-release VEGF by nanofibers and retrograde injection of VEGF-DNA-chitosan nanoparticles through bile ducts can promote residual liver regeneration, providing an alternative drug delivery mode in clinical practice.

ACKNOWLEDGEMENTS

The authors would like to thank Prof. Mao HQ (Johns Hopkins University), Dr. He ZY (Ocean University of China) and Dr. Nie TQ (Sun Yat-sen University) for the valuable supports.

Abstract

Incidence rates for esophagogastric junction cancer are rising rapidly worldwide possibly due to the economic development and demographic changes. Therefore, increased attention has been paid to the prevention, diagnosis, and the treatment of esophagogastric junction cancer. Although there are discrepancies in the treatment strategy between Asian and Western countries, surgery remains the mainstay of treatment for esophagogastric junction cancer. Recent developments of perioperative multidisciplinary treatment may lead to better therapeutic effect, higher complete resection rate, and better control of the residual diseases, thus result in prolonged prognosis. In this review, we will focus on the treatment of locally advanced resectable esophagogastric junction cancer, and discuss the current status and future perspectives of the perioperative treatment including chemotherapy, radiation therapy, and immunotherapy, as well as the surgical strategy. Better understanding of the latest treatment strategy and future overlook may enable to standardize and individualize the treatment for esophagogastric junction cancer, thus leading to better prognosis for those patients.

Key Words: Esophagogastric junction cancer; Perioperative therapy; Neoadjuvant therapy; Surgery; Multidisciplinary treatment

INTRODUCTION

Incidence rates for esophagogastric junction (EGJ) cancer, especially EGJ adenocarcinoma (EGJAC) are rising rapidly worldwide possibly due to increased excess body weight, increasing gastroesophageal reflux disease, and decreasing levels of chronic infection with *Helicobacter pylori*[1,2]. These trends are predicted to continue, thus leading to increased incidence of EGJAC[1]. Treatment strategy for resectable locally advanced EGJAC differ from country to country, where perioperative therapy combined with surgery has been the standard of care for locally advanced EGJAC in the western countries[3,4], whereas surgery with or without adjuvant chemotherapy has been widely accepted in Japan since the significance of preoperative therapy has not yet been established[5]. Nevertheless, surgery remain the mainstay of treatment for locally advanced EGJAC, and therefore, there is an emerging need for the development of surgical approach, as well as other treatment modalities including chemotherapy, radiation therapy, and immunotherapy in order to improve patient outcomes.

Due to its unique anatomical location, optimal surgical strategy for EGJAC have long been questioned, and different opinions have been proposed between gastrointestinal and thoracic surgeons. Siewert type I tumors, which the tumor epicenter is located between 1cm to 5 cm above the EGJ, have usually been treated as esophageal cancer, whereas Siewert type III tumors, which is located between 2 cm to 5 cm below the EGJ, have generally been treated as gastric cardia cancer. Surgical procedure for Siewert type II tumors (1 cm above to 2 cm below EGJ) have been selected by individual surgeons or institutional preferences. Recent retrospective and prospective studies have unveiled the lymphatic flow for EGJ cancers[6,7], and thereby a standardized surgical strategy have been proposed. Another critical surgical issue during EGJ cancer treatment is the reconstruction method, which have long been related to high anastomotic complication rates[8]. Recent inventions and improvement of anastomotic methods [9-11] have enabled a safe esophagogastric anastomosis with less incidence of anastomotic leakage and gastroesophageal reflux.

Researchers have focused on the development of more intensive perioperative therapy to overcome the poor prognosis of advanced EGJ cancers. Preoperative chemotherapy or chemoradiotherapy have been utilized in the western countries[3,4], however, question remains whether which is the best treatment option. In recent years, immunotherapy has received particular attention in the treatment of EGJ cancers. Adjuvant checkpoint inhibitor immunotherapy is now the standard of care for EGJ cancer patients who received neoadjuvant chemoradiotherapy and had residual pathological disease after curative resection[12]. Recent studies have unveiled the efficacy of immunochemotherapy in neoadjuvant settings[13,14].

In this review, we will focus on locally advanced resectable EGJAC, and discuss the current clinical practice, ongoing clinical trials, and future perspectives of multidisciplinary treatment options for EGJAC.

STANDARDIZING THE SURGICAL PROCEDURE FOR EGJAC

Mediastinal lymph node dissection

The initial study to demonstrate the frequency of lymph node (LN) metastasis for EGJAC was reported by Rüdiger Siewert *et al*[15] in 2000. In this retrospective single-center study, 1002 patients with EGJAC underwent either transthoracic esophagectomy or transhiatal extended gastrectomy depending on the tumor location. Among the 271 patients with carcinoma of the cardia arising immediately at the esophagogastric junction (defined as Type II in the literature), 29 (15.6%) patients had lower mediastinal

lymph node metastasis. In another single center study by Pedrazzani *et al*[16], nodal involvement of 143 patients with locally advanced EGJAC were analyzed. In this study, middle/Lower mediastinal LN dissection was performed in 70%-85% of the patients with Siewert type I tumor, whereas the dissection rate was only 3.3%-35.5% for the patients with Siewert type III tumor. Middle and/or lower mediastinal LN metastasis was observed in 46.2%, 29.5%, and 9.3% for Siewert type I, II, and III tumors, respectively.

In 2017, Yamashita *et al*[6] conducted a questionnaire-based national retrospective study in Japan to define the optimal extent of LN dissection for EGJ cancers[6]. In this study, EGJ cancer was defined as having its tumor epicenter within 2 cm above or below EGJ according to the definition promulgated by the Japanese Gastric Cancer Association[17] and the Japanese Esophageal Society[18], and patients with tumors ≤ 4 cm were considered eligible. In total, 1560 patients with Siewert Type I/II EGJAC were enrolled. The estimated survival benefit by LN dissection was high for the abdominal LN along the lesser curvature, right and left cardia, and the left gastric artery, however, optimal extent of the mediastinal LN dissection could not be determined due to the low rate of upper/middle mediastinal LN dissection, which was below 20%. To further determine the value of mediastinal LN dissection in EGJ cancers, Kurokawa *et al*[7] reported the results of a prospective multicenter study in 2021[7], in which cT2-T4 cancers located within 2 cm of the EGJ were enrolled. Upper mediastinal LN dissection was performed for patients with esophageal invasion > 3 cm, whereas patients with esophageal invasion ≤ 3 cm underwent lower mediastinal LN dissection only. Within the 98 patients who had esophageal invasion > 3 cm (67 EGJAC and 31 esophageal squamous cell carcinomas, ESCC), rate of right recurrent laryngeal nerve LN metastasis was 10.7% (3/28) when the length of esophageal invasion exceeded 4 cm. As a result, surgical algorithm for EGJ cancers was proposed, and upper mediastinal LN dissection was recommended for advanced EGJ cancer patients with esophageal invasion > 4 cm and clinically positive LN in the upper/middle mediastinal field[19].

One of the unique features of these Japanese studies is that squamous cell carcinomas located within 2 cm of the EGJ are included, and are analyzed along with EGJAC. In Japan, regardless of histological type, tumors within 2 cm of the EGJ are classified as "EGJ cancers" according to the Nishi classification [17], possibly due to the high incidence of ESCC, whereas only adenocarcinomas have been regarded as EGJ cancers in the western countries. The difference in the definition of EGJ cancer have caused the difference in the treatment, including surgery and chemo (radio)therapy for tumors of the EGJ between countries. In the former study[7], rate of upper-mediastinal LN metastasis was similar between adenocarcinomas and squamous cell carcinomas for tumors within 2 cm of the EGJ, suggesting that similar surgical strategy may be applied regardless of histological type. Although further studies are needed to determine the optimal extent of LN dissection for tumors with greater esophageal invasion.

Some issues remain unsolved. First, is the difficulty to accurately measure the distance from the EGJ to the tumor proximal margin in patients with large tumors, circumferential tumors, and hiatal hernia. Therefore, extent of mediastinal LN dissection may not be determined preoperatively for such patients. Second, as mentioned above, EGJ tumors with long esophageal invasion, usually classified as Siewert type I, were excluded in recent studies. In our institute, 35 patients with Siewert type I EGJAC underwent curative resection including upper-mediastinal LN dissection between 2007 to 2022 (Tables 1 and 2). The rate for upper/middle/Lower mediastinal LN metastasis for the patients were 31.4%/29.4%/34.4%, respectively, suggesting the high incidence of mediastinal LN metastasis, and the importance of mediastinal LN dissection for those patients. However, survival benefit for mediastinal LN dissection for EGJAC remain unclear. In 2020, CARDIA-trial, a multinational, multicenter, randomized clinical trial which aimed to show the superiority of transthoracic esophagectomy with mediastinal LN dissection against transhiatal extended gastrectomy regarding overall survival (OS) was proposed, and is now undergoing[20]. To determine the value of mediastinal LN dissection, the results of this study and the survival analysis of the recent prospective study[7] is awaited.

Minimal-required proximal margin length

Negative surgical margin, as well as an adequate LN dissection, is essential to achieve curative resection in the surgical treatment for EGJAC. Although, especially during transhiatal approach, excessive proximal margin may lead to severe difficulty in anastomosis, thus result in higher complication rate. In 2013, Mine *et al*[21] reported the results of a single-center retrospective study which analyzed the proximal margin length of the 140 patients who underwent surgery for Siewert type II and III EGJAC. Patients with gross proximal margins greater than 20 mm had better survival outcomes than those shorter than 20 mm, and further, gross proximal margin ≤ 20 mm (hazard ratio (HR), 3.56; 95%CI: 1.39-9.14; P = 0.008) as well as pathological node status (HR, 1.76; 95%CI: 1.08-2.86; P = 0.024) were independent prognostic factors by multivariable analysis. Another recent study[22] retrospectively analyzed the proximal margin length in resected specimens for 289 EGJ/gastric cancer with gross esophageal invasion. Maximum length of discrepancy between the gross and pathological proximal boundary of the tumor was 15 mm for superficial growth type and 20 mm for expansive growth type tumors, respectively. These two studies indicate that 20 mm may be a sufficient proximal margin for advanced EGJAC, however, since proximal margins were measured in resected specimens in both studies, preoperative measures to decide the resection line remain unclear. Further, optima proximal margin for cases after preoperative therapy needs to be further studied.

Table 1 Patients with Siewert type I esophagogastric junction adenocarcinoma who underwent surgery at our institute

n	35
Male	34 (97.1%)
Age (yr)	67 (42-79)
Field of LN dissection 2/3	2/33
Open/MIE/Robot assisted	6/24/5
Preoperative chemotherapy	4 (11.4%)
Tumor size (mm)	35.3 (9-110)
Esophageal invasion length (mm)	30 (18-110)
pT 1a/1b/2/3/4a/4b[1]	4/10/3/18/0/0

Pleura	1
Pancreas	1

[1]Classified by the 8th edition of the Union for International Cancer Control (UICC)-Tumor Node Metastasis (TNM) classification.
[2]Including overlapped cases.
EGJAC: Esophagogastric adenocarcinoma; LN: Lymph node; MIE: Minimally invasive esophagectomy.

Reconstruction to prevent anastomotic complications

As a result of Japanese nationwide retrospective and prospective studies[6,7], LN along the distal portion of the stomach were much less often metastatic compared to LN along the right and left cardia, lesser curvature, and the left gastric artery for Siewert type II EGJAC. Therefore, the distal portion of the stomach does not need to be necessarily removed for Siewert type II EGJAC smaller than 4 cm, and proximal gastrectomy or total gastrectomy combined with distal esophagectomy is selected according to oncological status, patient condition, or institutional preference. According to a meta-analysis which compared proximal *vs* total gastrectomy for proximal early gastric cancer[23], proximal gastrectomy was superior to total gastrectomy in terms of operation time, intraoperative blood loss, and long-term nutritional status. Although, proximal gastrectomy followed by esophagogastrostomy was associated with a higher incidence of anastomotic complications such as stenosis and reflux esophagitis, as have been reported elsewhere[24,25]. In a prospective nationwide multicenter study in Japan[8], anastomotic leakage was observed in 12.2% of the 225 patients after transhiatal esophagectomy, and further, six patients suffered Clavien-Dindo (CD) grade IV or above anastomotic leakage where none of the patients after transthoracic esophagectomy hade leakage ≥ CD grade IV. Recently, novel surgical techniques, such as double-flap technique[11,26] and side overlap esophagogastrostomy[9,10] have been developed during gastric cancer surgery, and been introduced to EGJ cancers in order to overcome these anastomotic complications. Researchers have reported favorable results regarding anastomotic complications; however, these techniques require a more complex intracorporeal suturing technique and longer duration of surgery especially when performed for EGJ cancers which often requires intrathoracic anastomosis. Further investigation may be required for a higher level of evidence.

Table 2 Details of the mediastinal lymph node metastasis for the patients in Table 1

LN location		Metastasis rate (%)	
Upper mediastinum	Upper thoracic paraesophageal LN	8.5	(3/35)
	Left recurrent nerve LN	15.2	(5/33)
	Right recurrent nerve LN	20.6	(7/34)
	Left trachebronchial LN	17.4	(4/23)
Meddle mediastinum	Subcranial LN	18.2	(6/33)
	Middle thoracic paraesophageal LN	20.0	(7/35)
	Left main bronchus LN	12.9	(4/31)
	Right main bronchus LN	16.2	(5/31)
Lower mediastinum	Lower thoracic paraesophageal LN	17.1	(6/35)
	Supradiaphragmatic LN	13.3	(4/30)
	Posterior mediastinal LN	17.2	(5/29)

Number of patients with metastasis/number of patients who underwent lymph node dissection is indicated in each parenthesis. LN: Lymph node.

Minimally invasive surgery for EGJ cancers

Although none of the clinical trials specifically focusing on EGJ cancers have been conducted, several studies have demonstrated the safety and efficacy of minimally invasive surgery for esophageal/gastric cancer, which may also be applied to EGJ cancers. In 2012, Biere *et al*[27] reported the results of a multicenter, open-label, randomized control trial which aimed to demonstrate the safety of minimally invasive esophagectomy (MIE) verses open esophagectomy (OE) for patients with esophageal/EGJ cancers[27]. Patients in the study received preoperative therapy consisting of paclitaxel plus carboplatin plus concurrent radiotherapy of 41.4 Gy, followed by esophagectomy with two-field LN dissection, 6-8 wk after preoperative therapy. Within the 56 and 59 patients who were assigned to OE and MIE, respectively, OE group had more in-hospital pulmonary infection compared to MIE group (relative risk, 0.35; 95%CI: 0.16-0.78, P = 0.005), demonstrating the short-term benefits of MIE. Favorable short-term results regarding cardiopulmonary complications, postoperative pain, quality of life, and postoperative functional recovery were also reported in a single-center randomized trial comparing robot-assisted minimally invasive esophagectomy (MIE) *vs* OE for intrathoracic esophageal cancer (ROBOT trial)[28]. In the follow up study of ROBOT trial[29], long-term outcomes of the 112 patients including 40 EGJ cancer patients were analyzed. Comparable 5-year OS (41% *vs* 40%, P = 0.827) and disease-free survival (DFS, 42% *vs* 43%, P = 0.749) rates were observed for patients after RAMIE *vs* OE, respectively.

Regarding gastrectomy, the short-term surgical outcomes of a single-center non-inferiority randomized trial for laparoscopic *vs* open gastrectomy was reported in 2018[30]. In this study, 328 patients with cT2-3N0-3M0 gastric cancer, including 70 upper-third gastric cancer underwent open or laparoscopic total (33.5%), proximal (5.6%), and distal (60.9%) gastrectomy with D2 LN dissection depending on the tumor location. Overall complication rate was similar (laparoscopic, 11.7%; open, 14.4%; P = 0.512) between the groups, suggesting the feasibility of laparoscopic gastrectomy for advanced cancers.

Although evidence is lacking, especially for the oncological safety of minimally invasive transhiatal lower esophagectomy, minimally invasive surgery for EGJ cancer have been performed worldwide and is expanding rapidly. Surgeons must carefully decide the indication of minimally invasive surgery according to each patients general and oncological condition. In order to determine the superiority of robot-assisted over laparoscopic/thoracoscopic surgeries, results of ongoing studies[31] are awaited.

OPTIMAL PERIOPERATIVE TREATMENT FOR EGJAC

Neoadjuvant chemotherapy or chemoradiotherapy, which is the best choice?

Due to the poor survival outcome, researchers have focused on the development of more intensive preoperative treatment for advanced EGJAC. However, development and research for new therapeutic strategy has yet to be unified between Western and Asian countries. In addition, since EGJAC has been recognized as esophageal or gastric cancer until recently, various theories abound, and the optimal treatment option remain unclear.

In the Western countries, pre- and postoperative combination of docetaxel, oxaliplatin, leucovorin, and fluorouracil (FLOT) is now regarded as the standard treatment for locally advanced gastric cancer and EGJAC as a result of the FLOT4 trial[3]. For the 716 patients with cT2-4 cN+ gastric or EGJ cancer, median OS was 50 mo (95%CI: 38.33 to not reached), and pathological complete response (pCR) rate was 16% (95%CI: 10%-23%) after FLOT therapy[32], which were both significantly increased compared to conventional ECF/ECX therapy in this study. Subgroup analysis revealed that the effect of FLOT was similar between gastric and EGJ cancers. Another standard preoperative therapy for EGJ cancers in the Western countries is chemoradiotherapy as a result of the CROSS trial[4,33]. In this study, 368 patients with cT1N1 or cT2-3N0-1 esophageal or EGJ caner were either enrolled to surgery alone or neoadjuvant chemoradiotherapy followed by surgery. The chemoradiotherapy consisted of carboplatin, paclitaxel, and concurrent radiotherapy of 41.4 Gy. Within the 368 patients, results of the 366 patients were analyzed, and 88 (24%) of those patients had EGJAC. Median OS for the neoadjuvant therapy group was 48.6 (95%CI: 32.1-65.1) months, which was significantly longer than the surgery alone group. A pCR was achieved in 47 of the 161 patients (29%) who underwent resection after chemoradiotherapy.

In Korea, a phase III PRODIGY study[34] was designed to demonstrate the superiority of neoadjuvant docetaxel, oxaliplatin, and S-1 triplet therapy (DOS) followed by surgery and adjuvant S-1, *vs* conventional adjuvant S-1 after surgery in patients with gastric cancer and EGJAC. Neoadjuvant therapy was administered for 238 patients with cT2-3N+ and cT4 patients. Three-year progression-free survival (PFS) rate was 66.3% *vs* 60.2% (HR, 0.70; 95%CI: 0.52–0.95; P = 0.023) in the neoadjuvant group compared to surgery-first group. Neoadjuvant therapy led to pCR rate of 10.4%. As a result, preoperative DOS therapy is now considered as one of the standard treatment options in selected countries, however, OS was not significantly different between the two groups possibly because of the study setting, and the standard therapy for EGJAC is still questioned due to the relatively small population of EGJAC in this study (Table 3).

Thus far, several trials compared the therapeutic effect of preoperative chemoradiotherapy *vs* chemotherapy for EGJ cancers. In the NeoRes trial[35,36], patients with cT1N+ or cT2-3 esophageal or EGJ cancer were either randomized to neoadjuvant chemotherapy consisting of cisplatin plus fluorouracil, or the same chemotherapeutic regimen plus concurrent radiation therapy of 40 Gy. In this study, neoadjuvant chemoradiotherapy have achieved higher pCR rate (24% *vs* 8%) and R0 resection rate (76% *vs* 64%) when compared to neoadjuvant chemotherapy, however, three-year OS rates were equivalent between the groups (HR, 1.09; 95%CI: 0.73–1.64; P = 0.77). In another prospective randomized phase III trial[37], patients with cT3-4 EGJAC received either three courses of neoadjuvant triplet therapy (cisplatin, fluorouracil, and leucovorin, PLF) or two courses of PLF plus combined chemoradiotherapy consisting of cisplatin, etoposide, and concurrent radiation of 30 Gy. Within the evaluated 119 patients, high in-hospital mortality rate after neoadjuvant chemoradiotherapy (10.2%) compared to chemotherapy (3.8%) was observed, however, three-year OS rates were relatively higher in the neoadjuvant chemoradiotherapy group (47.4% *vs* 27.7%, HR, 0.67; 95%CI: 0.41–1.07; P = 0.07, Table 4). In 2021, preliminary results of a phase III study, which aimed to compare CROSS *vs* FLOT or MAGIC (epirubicin, cisplatin/oxaliplatin, and 5-fuluorouracil/capecitabine) regimen in terms of OS for esophagus and EGJ cancer were reported (Neo-AEGIS trial)[38]. Within the 362 evaluable patients, at a median follow up of 24.5 (1-92) mo, the 3-year estimated survival probability was equivalent between CROSS and MAGIC/FLOT arm (HR, 1.02; 95%CI: 0.74-1.42).

As shown, accumulated evidence has shown that neoadjuvant therapy may improve survival for patients with EGJAC, however, various issues remain unclear. First, is the ideal chemotherapeutic regimen for neoadjuvant treatment. The Japan Clinical Oncology Group (JCOG) is now planning a nationwide prospective study directly comparing DOS *vs* FLOT regimen as neoadjuvant treatment in EGJAC. Second, is the efficacy by the addition of radiotherapy to chemotherapy, since none of the previous studies used the current standard chemotherapeutic regimen for the chemoradiotherapy arm. Although the superiority of chemoradiotherapy have not yet been demonstrated, neoadjuvant chemoradiotherapy may be of utility in cases such as borderline resectable EGJAC because of the relatively high pCR rate. Finally, the safety of radiation therapy is a critical issue, and needs to be further discussed. Currently, a randomized phase III RACE[39] trial, which aimed to compare perioperative chemotherapy *vs* chemoradiotherapy (FLOT *vs* FLOT based chemoradiotherapy including concurrent radiation of 45 Gy) in terms of PFS in undergoing, and the results are awaited.

Immune checkpoint inhibitor immunotherapy, a paradigm shift in cancer treatment

Recent advances of immunotherapeutic agents, especially immune checkpoint inhibitors (ICI), have dramatically improved the treatment outcomes in several cancer types. In esophageal, gastric, and EGJ cancers, anti-PD-1 antibody (nivolumab/pembrolizumab) and anti-CTLA-4 antibody (ipilimumab) have already been regarded as one of the standard treatment options for unresectable/recurrent tumors[40-43]. In a recent phase II trial[13], the neoadjuvant combination of ICI and chemotherapy was investigated in locally advanced gastric and EGJ cancers. Thirty-six patients with cT3-4N+ diseases including 19 patients with EGJAC received capecitabine and simultaneous radiotherapy for 5 wk, sandwiched by a 21-d cycle of oxaliplatin plus capecitabine twice daily (days 1-14) followed by surgery. Anti-PD-1 antibody camrelizumab (day 1) was given for 5 cycles since initiating chemotherapy. The primary endpoint pCR rate was 33.3% (95%CI: 18.6-51.0), and patients with < 10% residual tumor cells/R0

Table 3 Clinical trials of neoadjuvant therapy for esophagogastric junction cancer included in this review

Study name	FLOT4[3,32]	CROSS[4,33]	PRODIGY[34]
Ref.	Al-Batran *et al*[3,32]	Shapiro *et al*[33], van Hagen *et al*[4]	Kang *et al*[34]
Year	2016/2019	2012/2015	2021
Study design	Phase II/III	Phase III	Phase III
Eligible patients	cT2-4 and/or cN+, cM0	cT1N+ or cT2-3, cM0	cT2-3N+ or cT4, cM0
	Gastric or EGJ cancer	Esophageal or EGJ cancer	Gastric or EGJ cancer
Experimental arm	FLOT	CBDCA + PTX + RT	DOS + adjuvant S1
Control arm	ECF/ECX	Surgery alone	Adjuvant S1
Total number of patients	716	366	484
EGJ cancer patients	56%	24%	6%
Primary outcome	OS	OS	Progression free survival
OS	50 *vs* 35 mo	48.6 *vs* 24.0 mo	NA
pCR rate	16% *vs* 6%	29%	10.40%
R0 resection rate	85% *vs* 78%	92% *vs* 69%	89% *vs* 84%
Special notes	Effective for EGJ cancer		Progression free survival, 66.3 months *vs* 60.2 months. Equivalent OS. Small population of EGJ cancer patients (27 patients)

EGJ: Esophagogastric junction; pCR: Pathological complete response; FLOT: 5-fluorouracil + leucovorin + oxaliplatin + docetaxel; ECF: Epirubicin + cisplatin + 5-fluorouracil; ECX: Epirubicin + cisplatin + capecitabine; CBDCA: Carboplatin; PTX: Paclitaxel; RT: Radiation therapy; DOS: Docetaxel + oxaliplatin + S-1; NA: Not available; OS: Overall survival.

resection rates were 44.4%/91.7%, respectively. Two-year PFS and OS rates were 66.9% and 76.1%, respectively in this study. In another phase II study[14], neoadjuvant nivolumab once every two weeks, 6 cycles, and ipilimumab once every six weeks, 2 cycles, followed by surgery and adjuvant nivolumab once every four weeks (nine injections) were administered in 32 patients with locally advanced resectable, deficient mismatch repair (dMMR)/microsatellite instability-high (MSI-H), cT2-4 gastric (16 patients) and GEJ cancer (16 patients). Twenty-nine patients who received surgery all had an R0 resection, and 17 (58.6%; 90%CI, 41.8-74.1) had pCR. Of those 29 patients with surgery, 23 received adjuvant nivolumab. At database lock (median follow-up, 14.9 mo), no patient had relapse and one died without relapse. Combination of ICI and chemotherapy with or without concurrent radiotherapy may exhibit promising pathological response with tolerable toxicity in patients with locally advanced EGJAC, and future phase III trials to demonstrate the safety and efficacy are awaited (Table 5).

Future of targeted therapy

In 2022, the results of the NRG Oncology/RTOG 1010 study[44], a multicenter randomized phase III trial which aimed to demonstrate the impact of monoclonal anti-HER2 (ERBB2) antibody trastuzumab with trimodality treatment for esophageal adenocarcinoma with HER2 expression was reported. In this study, patients with HER2 positive cT1N1-2 or cT2-3N0-2 diseases were either assigned to weekly intravenous paclitaxel and carboplatin for 6 wk with radiotherapy of 50.4 Gy followed by surgery, with or without intravenous trastuzumab for 5 wk during chemoradiotherapy, once preoperatively, and every 3 wk for 13 treatments starting 21-56 d after surgery. In total, 203 patients were included, and the median DFS (primary endpoint) was 19.6 mo and 14.2 mo for chemoradiotherapy with trastuzumab and chemoradiotherapy alone, respectively (HR, 0·99; 95%CI: 0.71-1.39; P = 0.97) (Table 5). Although addition of trastuzumab did not lead to increased toxicities, the study failed to demonstrate survival benefits, suggesting that combination with other chemotherapeutic agents or other drugs targeting HER2 may be necessary for the treatment of HER2 positive EGJAC. Currently, the treatment effect of an antibody-drug conjugate trastuzumab deruxtecan (T-DXd) against HER2 positive gastric and EGJ adenocarcinoma is tested under a phase II study in Japan (EPOC2003 study)[45]. In a recent analysis utilizing the Cancer Genome Atlas (TGCA)[46], EGJAC was classified into esophageal adenocarcinoma like and gastric adenocarcinoma like EGJAC according to the 400-gene classifier. Esophageal adenocarcinoma like EGJAC have shown significantly higher copy number amplification of ERBB2, as well as an increased protein expression of ERBB2 and EGFR, suggesting that the molecular characterization of EGJAC may enable to select patients who will benefit by ERBB2/EGFR blockade. Agents targeting vascular endothelial growth factor (VEGF) might also be future candidates for neoadjuvant therapy[47],

Study name	NeoRes[35,36]	POET[37]	Neo-AEGIS[38]
Ref.	Klevebro *et al*[35,36]	Stahl *et al*[37]	John *et al*[38]
Year	2015/2016	2009	2021
Study design	Randomized phase II	Phase III	Phase III
Eligible patients	cT1N+ or cT2-3, M0	cT3-4, M0	cT2-3N0-3M0
	Esophageal or EGJ cancer	EGJ cancer	Esophageal or EGJ cancer
Experimental arm	CF + RT	PLF + RT	CROSS
Control arm	CF	PLF	MAGIC/FLOT
Total number of patients	181	119	377
EGJ cancer patients	17%	100%	NA
Primary outcome	pCR	OS	OS
OS	NA	33 *vs* 21 mo	NA
pCR rate	24% *vs* 8%	15.6% *vs* 2.0%	NA
R0 resection rate	76% *vs* 64%	69.5% *vs* 71.5%	NA
Special notes	Equivalent 3-year OS	Study closed early due to low accrual, high in-hospital mortality after chemoradiotherapy	Equivalent 3-year estimated survival probability

EGJ: Esophagogastric junction; pCR: Pathological complete response; CF: Cisplatin + 5-fluorouracil; RT: Radiation therapy; PLF: Paclitaxel + leucovorin + 5-fluorouracil; CROSS: Carboplatin + paclitaxel + radiation therapy; MAGIC: Epirubicin + cisplatin (oxaliplatin) + 5-fluorouracil; FLOT: 5-fluorouracil + leucovorin + oxaliplatin + docetaxel; NA: Not available; OS: Overall survival.

Table 5 Clinical trials of neoadjuvant immunotherapy/targeted therapy for esophagogastric junction cancer included in this review

Study name	Neo-PLANET[13]	NEONIPIGA[14]	NRG Oncology/RTOG 1010[44]
Ref.	Tang *et al*[13]	Andre *et al*[14]	Safran *et al*[44]
Yr	2022	2023	2022
Study design	Phase II	Phase II	Phase III
Eligible patients	cT3-4N+, M0	cT2-4, M0, dMMR/MSI-H	cT1N1-2 or cT2-3N0-2 HER2 positive
	Gastric or EGJ cancer	Gastric or EGJ cancer	Esophageal adenocarcinoma
Experimental arm	Camrelizumab plus chemoradiotherapy	Nivolumab plus ipilimumab	Trastuzumab plus chemoradiotherapy
Control arm	NA	NA	Chemoradiotherapy
Total number of patients	36	29	203
EGJ cancer patients	53.80%	50.00%	NA
Primary endpoint	pCR	pCR	Disease-free survival
OS	NA	NA	38.5 *vs* 38.9 mo
pCR rate	33.30%	58.60%	27% *vs* 29%
R0 resection rate	91.70%	100%	98% *vs* 100%
Special notes	Two-year OS, 76.2%		Disease-free survival, 19.6 *vs* 14.2 mo

EGJ: Esophagogastric junction; pCR: Pathological complete response; NA: Not available; OS: Overall survival.

and should be further discussed.

Is adjuvant therapy needed?

In Japan, EGJAC has usually been treated as gastric cancer, and the same agents have been administered

as adjuvant therapy for both cancer types. In the CLASSIC trial[48,49] which investigated the effect of adjuvant capecitabine plus oxaliplatin for pStage II-III gastric or EGJ adenocarcinoma, a trend toward improving OS was shown in the small subset of patients with EGJAC (24 patients, HR, 0.63; 95%CI: 0.09–4.45). In another randomized controlled phase III trial JACCRO CG-07[50,51], the effect of S-1 plus DOS over S-1 alone was demonstrated for pStage III gastric cancer, however, the study included only eight EGJAC patients. Although sufficient analysis for EGJAC alone could not be performed due to the small sample size, with the results against gastric adenocarcinomas, capecitabine plus oxaliplatin, S-1 plus DOS, or S-1 monotherapy[52] have been regarded as the standard adjuvant therapy for EGJAC.

In the recent CheckMate 577 study[12], the value of adjuvant ICI (nivolumab) was evaluated in patients with ypStage II-III esophageal or EGJ cancers after neoadjuvant chemoradiotherapy. A total of 794 patients, which included 319 (40.2%) EGJAC, after curative resection were either postoperatively randomized to receive nivolumab adjuvant therapy or placebo. Median DFS was 22.4 and 11.0 mo for nivolumab group and placebo group, respectively (HR, 0.69; 95%CI: 0.56–0.86; $P < 0.001$), which demonstrated the impact of adjuvant ICI. However, in the subgroup analysis, adjuvant nivolumab could not show prognostic advantages during EGJAC (HR, 0.87; 95%CI: 0.63–1.21). Value of adjuvant therapy for EGJAC, especially for patients after neoadjuvant chemotherapy, remain unclear. The ideal regimen, and further, whether adjuvant treatment is needed, should be further investigated.

CONCLUSION

Recent development of the perioperative treatment has improved therapeutic effect for EGJAC, and further, novel immunochemotherapeutic strategies have high expectations to further improve survival outcomes for the patients. Previous studies have enabled to standardize the surgical procedure for EGJAC, and novel surgical techniques have improved the safety of operation. Since the incidence of EGJAC are rising rapidly worldwide, there is an urgent need to accumulate new evidence and to unify the treatment strategy globally. Although multiple issues remain unclear, ongoing clinical trials included in this review may further contribute to improving outcomes for patients with EGJAC.

Abstract

BACKGROUND

As a novel endogenous anti-angiogenic molecule, vasohibin 1 (VASH1) is not only expressed in tumor stroma, but also in tumor tissue. Moreover, studies have shown that VASH1 may be a prognostic marker in colorectal cancer (CRC). Knockdown of VASH1 enhanced transforming growth factor-β1 (TGF-β1)/Smad3 pathway activity and type I/III collagen production. Our previous findings suggest that ELL-associated factor 2 (EAF2) may play a tumor suppressor and protective role in the development and progression of CRC by regulating signal transducer and activator of transcription 3 (STAT3)/TGF-β1 signaling pathway. However, the functional role and mechanism of VASH1-mediated TGF-β1 related pathway in CRC has not been elucidated.

AIM

To investigate the expression of VASH1 in CRC and its correlation with the expression of EAF2. Furthermore, we studied the functional role and mechanism of VASH1 involved in the regulation and protection of EAF2 in CRC cells *in vitro*.

METHODS

We collected colorectal adenocarcinoma and corresponding adjacent tissues to investigate the clinical expression of EAF2 protein and VASH1 protein in patients with advanced CRC. Following, we investigated the effect and mechanism of EAF2 and VASH1 on the invasion, migration and angiogenesis of CRC cells *in vitro* using plasmid transfection.

RESULTS

Our findings indicated that EAF2 was down-regulated and VASH1 was up-regulated in advanced CRC tissue compared to normal colorectal tissue. Kaplan-Meier survival analysis showed that the higher EAF2 Level group and the lower VASH1 Level group had a higher survival rate. Overexpression of EAF2 might

inhibit the activity of STAT3/TGF-β1 pathway by up-regulating the expression of VASH1, and then weaken the invasion, migration and angiogenesis of CRC cells.

CONCLUSION

This study suggests that EAF2 and VASH1 may serve as new diagnostic and prognostic markers for CRC, and provide a clinical basis for exploring new biomarkers for CRC. This study complements the mechanism of EAF2 in CRC cells, enriches the role and mechanism of CRC cell-derived VASH1, and provides a new possible subtype of CRC as a therapeutic target of STAT3/TGF-β1 pathway.

Key Words: ELL-associated factor 2; Vasohibin 1; Transforming growth factor-β1; Signal transducer and activator of transcription 3; Colorectal cancer; Angiogenesis

Core Tip: Endothelial cell-derived vasohibin 1 (VASH1) can regulate tumor angiogenesis and lymphangiogenesis, and tumor cell-derived VASH1 also has a potential functional role in inhibiting cancer cell proliferation and invasion. Knockdown of VASH1 enhanced transforming growth factor beta 1 (TGF-β) /Smad3 pathway activity and type I/III collagen production. Our previous findings suggest that ELL-associated factor 2 (EAF2) may play a tumor suppressor and protective role in the development and progression of colorectal cancer (CRC) by regulating signal transducer and activator of transcription 3 (STAT3)/TGF-β1 signaling pathway. In this study, we found that EAF2 was down-regulated and VASH1 was up-regulated in advanced CRC tissue compared to normal colorectal tissue by immunohistochemistry and Western blot. And the expression levels of EAF2 and VASH1 were positively correlated in advanced CRC tissue. Furthermore, *in vitro* cellular mechanism studies suggest that overexpression of EAF2 may inhibit the activity of STAT3/TGF-β1 pathway by up-regulating the expression of VASH1, thereby attenuating the invasion, migration and angiogenesis of CRC cells. This study provides new ideas and theoretical basis for the development of new diagnostic markers for CRC and the exploration of the mechanism of targeted therapy.

INTRODUCTION

The diagnosis and treatment of colorectal cancer (CRC) have greatly improved in recent years, and its incidence and mortality have steadily decreased by about 1.7% and 3.2% per year respectively[1]. This has benefited from the continuous in-depth research on the pathogenesis of CRC, especially the application of protein molecular markers and targeted therapy. However, the pathogenesis of CRC has not been fully elucidated, and its diagnosis and treatment remain a major challenge in clinical work. Malignant tumor metastasis is one of the main factors leading to poor survival of patients with CRC[2]. Therefore, there is an urgent need to clarify the potential mechanisms of invasion and metastasis of CRC and explore new therapeutic targets.

Current studies have shown that not only the proliferation, invasion, and metastasis of cancer cells themselves contribute to the growth, progression, and distant metastasis of CRC, but tumor microenvironmental factors such as tumor angiogenesis also play a crucial role. As a novel endogenous anti-angiogenic molecule, vasohibin 1 (VASH1) increased ΔY-tubulin level to attenuate endocytosis of vascular endothelial growth factor (VEGF) receptor 2 and fibroblast growth factor (FGF) receptor 1, resulting in suppressing pro-angiogenic factor-induced endothelial cells migration[3]. Several studies have shown that the expression of VASH1 in tumor tissue and stroma can be used as a new molecular marker for tumor prognosis. In addition, cancer cell-derived VASH1 regulates tumor growth and metastasis both *in vitro* and *in vitro*[4-6]. And studies have shown that VASH1 may be a marker for the prognosis of CRC[7-9]. It has been suggested that stroma VASH1 Level is negatively correlated with tumor size, clinical stage, and distant metastasis in colon cancer patients[8]. Whereas, other studies have suggested that the overall survival (OS) of patients with high VASH1 expression in CRC tissue are significantly lower than those with low VASH1 expression[9]. To date, the expression of VASH1 in CRC

cancer tissue and cancer cells remains controversial, the effect and mechanism of cancer cell-derived VASH1 have not been clarified.

Ingenuity Pathway Analysis showed that transforming growth factor (TGF)-β/SMAD signaling pathway was one of the most common mutated pathways in CRC metastasis[10]. Knockdown of VASH1 enhanced Smad3 phosphorylation and type I/III collagen production in renal fibroblasts stimulated by TGF-β[11]. What's more, inhibition of VASH1 in islet β cells can activate GF-β1 pathway and promote insulin resistance in gestational diabetes mellitus patients[12]. TGF-β1 is abundantly expressed in the tumor microenvironment of a variety of human tumors, which is an important molecular pathway connecting tumor cells with the surrounding microenvironment and leading to resistance to checkpoint blockade therapy[13]. More notably, blockade of TGF-β1 signaling is a strategic approach to treat CRC tumor metastasis[14]. Nevertheless, whether CRC cell-derived VASH1 regulates TGF-β1 related pathways in tumor development has not been investigated.

Androgen-responsive protein ELL-associated factor 2 (EAF2) has been shown to inhibit the growth of tumor size in prostate cancer models *in vivo*[15], and inhibit the proliferation and migration of prostate cancer cells *in vitro*[16]. Recent studies have found that EAF2 acts as a tumor suppressor in a variety of malignant tumors, such as renal cancer cells, human liver cancer cells and breast cancer cells[17,18]. In-depth mechanistic studies showed that EAF2 was involved in the regulation of cancer cell function by attenuating TGF-β1-induced G1 phase cell cycle arrest and cell migration[18]. In addition, silencing of EAF2 expression could modulate the cytotoxic response to statins in HCT-116 cells[19]. Our previous findings suggested that EAF2 may play a tumor suppressor and protective role in the development and progression of CRC by regulating STAT3/TGF-β1 signaling pathway[20]. Therefore, we ventured to speculate whether the mechanism of VASH1 in CRC was related to the EAF2-mediated TGF-β1 pathway.

In this study, we aimed to investigate the expression of VASH1 in CRC and its correlation with the expression of EAF2. To further explore the functional role and mechanism of VASH1-mediated TGF-β1 related pathway in CRC cells. To investigate whether VASH1 is involved in the regulation and protection of EAF2 in CRC cells by regulating STAT3/TGF-β1 signaling pathway. It provides a clinical basis for discovering new clinical diagnostic and prognostic markers of CRC, and a theoretical basis for elucidating its development mechanism and exploring new molecular targeted therapy.

MATERIALS AND METHODS

CRC patients and tissue samples

A total of 120 cases of colorectal adenocarcinoma and corresponding adjacent tissues were collected at the First Hospital of China Medical University from 2012 to 2017. Patients who received preoperative radiotherapy or chemotherapy were excluded. The American Joint Committee on Cancer/Union for International Cancer Control 8th edition TNM staging system was used for tumor staging. The study was approved by the institutional review board of the First Affiliated Hospital of China Medical University (registration number 2021-68-2, informed consent waived).

Cell culture

We cultured NCM460 and CRC cell lines (SW480, RKO, HCT116, HT29, and LoVo) (Chinese Academy of Sciences, Shanghai, China) with PMIS 1640 medium (Gibco, Grand Island, NY, United States) containing 10% fetal bovine serum (FBS; Gibco, Grand Island, NY, United States) in a humidified incubator at 37 °C with 5% CO_2. And we treated CRC cells with 5 ng/mL recombinant human TGF-β1 protein (100-21, PeproTech, United States) for 24 h. Human Umbilical Vein Endothelial Cells (HUVECs, Chinese Academy of Sciences, Shanghai, China) were cultured with DMEM medium (Gibco, Grand Island, NY, United States) containing 10% FBS (Gibco, Grand Island, NY, United States) in a humidified incubator at 37 °C and 5% CO_2.

Cell transfection

Gene transfection plasmids designed and synthesized by GeneChem (Shanghai, China) were used to treat CRC cells, including overexpressing human EAF2 plasmid (GenBank No. NM_018456), overexpressing human VASH1 plasmid (GenBank No. NM_014909), silencing human STAT3 plasmids (GenBank registration No. NM_139276) and silencing VASH1 plasmids (GenBank No. NM_014909). Table 1 Lists three gene-silencing plasmids targeting human STAT3 plasmids and three targeting human VASH1 plasmids. Lipofectamine 2000 Kit (Invitrogen, Carlsbad, CA, United States) was used to transfect plasmids into CRC cells for cell transfection.

Immunohistochemistry

Tissue blocks were fixed and serially sectioned. Antigen repair was performed with citric acid or repair solution, and endogenous peroxidase was blocked with hydrogen peroxide (3%). Rabbit anti-EAF2 monoclonal antibody (1:200 dilution, ab237753) (Abcam, United Kingdom) and rabbit anti-VASH1

STAT3: Signal transducer and activator of transcription 3; VASH1: Vasohibin 1.

polyclonal antibody (5 μg/mL) (Abcam, United Kingdom) were then incubated overnight at 4 °C. Subsequently, secondary antibodies were incubated at 37 °C for 40 min. The stains were stained with diamine benzidine and counterstained with hematoxylin. Finally, the slices are air-dried, dehydrated and installed.

Slides were read in a double-blind manner by two experienced pathologists. The final staining score is the proportion score multiplied by the intensity score. Five 200 × high-power fields were randomly selected for each section, and the intensity of immunostaining was classified into four categories: 0 (negative immunostaining), 1 (weak immunostaining), 2 (moderate immunostaining), and 3 (strong immunostaining). The percentage of positive cells was also counted: 0 (positive cells < 5%); 1 (5%-25% positive cells), 2 (26%-50% positive cells), 3 (51%-75% positive cells), and 4 (> 75% positive cells).

Western blot assay

Tissues and cells were lysed with RIPA lysates containing PMSF protease inhibitors. Protein was extracted and assayed by BCA kit (Beyotime Institute of Biotechnology, China). Equal amounts of proteins (50 μg per sample) were separated by 10% sodium dodecyl sulfate/polyacrylamide gel electrophoresis (SDS/PAGE) at 80 V and then transferred to polyvinylidene difluoride (PVDF) membranes at a constant current of 200 mA. PVDF membranes were incubated with primary antibodies overnight at 4 °C. Primary antibodies to EAF2 (ab151692), VASH1 (ab176114) (Abcam, United Kingdom), TGF-β1 (#3709), phospho-STAT3 (Tyr705) (#9145), and STAT3 (#30835) (Cell Signaling, Danvers, MA, United States) were used at a 1:1000 dilution ratio and normalized to a 1:1000 dilution ratio for GAPDH (FL-335) (Santa Cruz, CA, United States). The PVDF membranes were further incubated with secondary antibody (1:5000) for 2 h at 37 °C. The immunoreactive bands were washed with PBS and detected by the Microchemi 4.2 bioimaging system using ECL-Plus chemiluminescence detection HRP reagent (Beyotime Institute of Biotechnology, China). ImageJ software was used to analyze the gray value of the Western blot results. The experiment was repeated at least 3 times under the same experimental conditions (Supplementary Figure 1).

Transwell invasion and migration assay

Matrigel (BD Biosciences, San Diego, CA, United States) was diluted in serum-free medium at 1:8 and spread in an 8-μM transwell chamber (3422, Corning, NY, United States) at 37 °C for 6 h. After the matrix gel for invasion assay was successfully prepared, 4 × 10^4 cells/well were diluted with 200 μL serum-free medium and inoculated into the upper chamber of 8-μM transwell chamber (3422), and 600 μL medium containing 20% FBS was added to the lower chamber.

In the transwell migration experiment, 2 × 10^5 cells/well diluted with 200 μL serum-free medium were inoculated into the upper chamber of Matrigel-free transwell chamber (3422) with a diameter of 8 μM, and 600 μL culture medium containing 10% FBS was injected into the lower chamber.

The chambers were collected after incubation for 72 h at 37 °C under constant temperature regulation. The chamber filters were fixed with methanol after removing the cells that were not invaded or migrated on the inner surface of the chamber filters. Cells that had been invaded or migrated on the fixed filter membrane were further stained with 0.1% crystal violet. The filter membrane was then

removed from the chamber and fixed. Finally, the invasive and metastatic cells were counted in 5 randomly selected fields under a light microscope (200 ×). Repeat the experiment at least 3 times under the same experimental conditions.

Wound healing assay

Cells were seeded in 6-well plates at 2 × 10^5 cells/well. When the cell confluence reached 90%, a 200 μL pipette tip was used to scratch the wound. Incubation was continued with medium containing 2% serum after gentle washing. The scratch wounds of five regions were selected and photographed (40 ×) at 0 h, 6 h, 12 h, 24 h, 48 h, and 72 h, respectively. The ImageJ software was used to measure the wound area. Repeat the experiment at least 3 times under the same experimental conditions.

Tube formation assay

Undiluted Matrigel (BD Biosciences) was plated in 96-well plates and incubated at 37 °C for 1 h in preparation for tube formation experiments. RKO cells were treated with TGF-β1 recombinant protein or EAF2 overexpression plasmid or VASH1 overexpression plasmid, and then conditioned medium was collected for later use. HUVECs were suspended with the collected conditioned medium and seeded in Matrigel coated 96-well plates at a density of 1.0 × 10^4 cells/well, and then incubated at 37 °C in an incubator containing 5% CO_2. After 6 h, the best tube formation was observed under inverted microscope (100 ×). Finally, the images were analyzed using the angiogenesis analyzer developed by Image J software to evaluate branch points. The experiment was repeated at least 3 times under the same experimental conditions.

HUVEC transwell migration assay

A total of 1 × 10^5 HUVECs were diluted with 200 μL serum-free medium and seeded into the upper chamber of Matrigel-free transwell chamber (3422) with a diameter of 8 μM. Conditioned medium was collected from RKO cells treated with TGF-β1 recombinant protein or EAF2 overexpression plasmid or VASH1 overexpression plasmid and placed in the lower chamber.

The chambers were collected after incubation for 6 h at 37 °C under constant temperature regulation. The chamber filters were fixed with methanol after removing the cells that were not invaded or migrated on the inner surface of the chamber filters. Cells that had been invaded or migrated on the fixed filter membrane were further stained with 0.1% crystal violet. The filter membrane was then removed from the chamber and fixed. Finally, the invasive and metastatic cells were counted in 5 randomly selected fields under a light microscope (200 ×). Repeat the experiment at least 3 times under the same experimental conditions.

HUVEC scratch assay

A total of 2 × 10^5 HUVECs/well was seeded in 6-well plates. When the cells reached about 90% confluence, a 200 μL tip was used for scratch. The cells were then washed three times with PBS and the incubation was continued with 2 mL of conditioned medium collected from RKO cells treated with TGF-β1 recombinant protein or EAF2 overexpression plasmid or VASH1 overexpression plasmid. Five areas (40 ×) were selected and photographed under a microscope at 0 h, 12 h, and 24 h time points. The ImageJ software was used to measure the wound area. The experiment was repeated at least 3 times under the same experimental conditions.

Statistical analysis

SPSS software (Version 26) was used for statistical analysis of the result data. Wilcoxon signed-rank test and Spearman rank correlation analysis were used to evaluate the expression of EAF2 and VASH1 and their correlation. Pearson's chi-square test was used to evaluate the correlation between proteins expression in tissues and clinicopathological parameters. All data were expressed as mean ± SD. Kaplan-Meier method and Log-rank tests were used for survival analysis. Student's t test was used for comparison between two groups, and one-way analysis of variance was used for comparison between three or more groups. One-way analysis of variance and Bonferroni test were used for statistical analysis. All P values were two-sided. A value of $P < 0.05$ was considered statistically significant.

RESULTS

Protein expression of EAF2 and VASH1 in CRC tissue

Immunohistochemical analysis was performed on paired adenocarcinoma and paracancerous tissues. The results of semi-quantitative analysis showed that the median score of EAF2 was 4.0 points in adenocarcinoma tissue and 7.2 points in paired paracancer tissue, with a median difference of -2.0 points. Wilcoxon signed-rank test showed that the expression level of EAF2 protein in adenocarcinoma tissue was significantly lower than that in paracancerous tissue ($Z = -5.843$, $P < 0.001$). Meanwhile, the median score of VASH1 was 12.0 points in adenocarcinoma tissue and 5.0 points in paired non-cancer

tissue, with a median difference of 6.0 points. The results of Wilcoxon signed-rank test showed that the expression of VASH1 protein in adenocarcinoma tissue was significantly higher than that in paracancerous tissue (Z = -8.594, P < 0.001). In addition, Spearman's rank correlation analysis showed that the expression of EAF2 and VASH1 protein in colorectal adenocarcinoma tissue was significantly positively correlated (r = 0.208, P = 0.022). Besides, localization analysis showed that EAF2 and VASH1 proteins were mainly located in the cytoplasm of colon epithelial cells (Figure 1A).

Not only that, Western blot was used to detect the protein expression of EAF2 and VASH1 in 8 paired fresh colorectal adenocarcinoma tissue and adjacent normal tissue. Compared with adjacent normal tissue, EAF2 protein expression was significantly lower (P = 0.023), while VASH1 protein expression was significantly higher (P < 0.001) in colorectal adenocarcinoma tissues (Figure 1B).

Association of EAF2 and VASH1 expression with clinicopathological parameters and the survival analysis in advanced CRC patients

The semi-quantitative immunohistochemical results of EAF2 and VASH1 in CRC patients were analyzed by ROC curve and the Youden index was determined. The results suggested that the cut-off value delimiting high and low expression of EAF2 (dependent variable is non-cancer) was 6.2 points (P < 0.001), and the cut-off value delimiting high and low expression of VASH1 (dependent variable is cancer, P < 0.01 indicated that it was significant for the diagnosis of tumor) was 8.5 points (P < 0.001). In this study, 100 of 120 CRC tissues were found to have EAF2 Low-expression and 84 were found to have VASH1 high-expression.

After defining the high and low expression of EAF2 and VASH1 proteins in colorectal adenocarcinoma tissues, the relationship between them and major clinicopathological features was further analyzed. We found that EAF2 protein was negatively correlated with angiolymphatic and/or perineural invasion (r = -0.180, P = 0.049), tumor stage (r = -0.194, P = 0.034), distant metastasis (r = -0.244, P = 0.007), and CEA (r = -0.211, P = 0.021), as well as positively correlated with the degree of differentiation (r = 0.225, P = 0.013) (Table 2). VASH1 protein was positively correlated with degree of differentiation (r = 0.186, P = 0.042), angiolymphatic and/or perineural invasion (r = 0.249, P = 0.006), distant metastasis (r = 0.190, P = 0.037), but not with other clinical characteristics (Table 2).

Furthermore, Kaplan-Meier survival analysis and Log-rank test showed that the survival rate of EAF2High group was higher than that of EAF2Low group (P = 0.016), and the survival rate of VASH1Low group was higher than that of VASH1High group (P = 0.047) (Figure 2).

Cox proportional-hazards model was used to analyze the influencing factors of OS in patients with advanced CRC. By univariate analysis, we found angiolymphatic and/or perineural invasion (P < 0.001), tumor stage (P < 0.001), tumor invasion depth (P < 0.001), lymph node status (P < 0.001), distant metastasis (P < 0.001) and EAF2 protein expression level (P = 0.024), p53 protein expression level (P = 0.048) were significantly associated with OS (Table 3). Confounding factors were further adjusted to evaluate the independent prognostic factors of OS in patients with advanced CRC. The clinicopathological features with P < 0.300 in the univariate analysis were included in the multivariate analysis, and the results suggested that, angiolymphatic and/or perineural invasion (P = 0.033), distal metastasis (P < 0.001), CEA protein expression (P = 0.004), p53 protein expression level (P = 0.048) were independent prognostic factors for OS (Table 3).

VASH1 overexpression inhibited STAT3/TGF-β1 pathway activity in RKO

Normal colorectal epithelial cells (NCM460) and a variety of human CRC cell lines (SW480, RKO, HCT116, HT29, and LoVo) were cultured *in vitro*. Western blot assay showed that, compared with NCM460 cells, VASH1 protein levels were increased to varying degrees in human CRC cell lines (Figure 3), and the expression was upregulated 2.336-fold in RKO cells (P = 0.002).

In addition, the expression level of phosphorylated STAT3 (Tyr705) (P < 0.001) and TGF-β1 protein (P < 0.001) in RKO were significantly higher than those in normal colorectal epithelial cells (NCM460). And then we suppressed STAT3 phosphorylation by transfecting RKO cells with silencing plasmid. In this study, RKO cells were transfected with three different STAT3 siRNAs (STAT3-si1, STAT3-si2, and STAT3-si3) targeting the STAT3 gene (Figure 4A). When compared to the control group (RKO-C), transfection with the three different STAT3-siRNAs decreased phosphorylated STAT3 expression. Additionally, STAT3-si2 was the most efficient, with a reduction of 61.8% in phosphorylated STAT3 expression (P < 0.001) (Figure 4A). Further study showed that when STAT3-si2 was transfected to silence STAT3, the expression of TGF-β1 protein in RKO was significantly lower than that in the normal control group (Figure 4B).

We used gene transfection technique to overexpress or silence the VASH1 gene in RKO cells and determined the activity and expression of STAT3/TGF-β1 signaling pathway. The results showed that overexpression of VASH1 (with 1.906-fold higher, P < 0.001, Figure 5B) significantly inhibited STAT3 phosphorylation (Tyr705) as well as TGF-β1 protein expression (Figure 5B). What's more, we transfected RKO cells with three different VASH1 siRNAs (VASH1-si1, VASH1-si2, and VASH1-si3) targeting the VASH1 gene (Figure 5A). When compared to the control group (RKO-C), transfection with the three different VASH1-siRNAs decreased VASH1 protein expression. Additionally, VASH1-si1 was the most efficient, with a reduction of 64.02% in VASH1 protein expression (P < 0.001) (Figure 5A). As a result,

transfection with VASH1 siRNA significantly promoted STAT3 phosphorylation (Figure 5B, $P < 0.001$). However, when RKO cells were transfected with STAT3 siRNA, the expression level of VASH1 protein was not significantly different from that of RKO control group (Figure 4B). Treatment of RKO cells with exogenous TGF-β1 recombinant protein did not affect the expression of VASH1 protein (Figure 4B).

EAF2 overexpression inhibited STAT3/TGF-β1 pathway activity in RKO

Meanwhile, Western blot results also showed that the expression levels of EAF2 protein in human CRC cell lines (SW480, RKO, HCT116, HT29, and LoVo) were decreased to varying degree compared with NCM460 cells (Figure 3), and the decrease was 82.7% in RKO cells ($P < 0.001$). Therefore, we transfected RKO cells with EAF2 overexpression plasmid *in vitro* to investigate the potential function and molecular mechanism of EAF2 in CRC cells.

Transfecting RKO cells with EAF2 overexpression plasmids significantly upregulated the expression of EAF2 protein (with 2.1-fold higher, $P < 0.001$, Figure 5B). At the same time, we also found that the levels of phosphorylated STAT3 (Tyr705) protein and TGF-β1 protein were significantly decreased in RKO cells transfected with EAF2 overexpression plasmids compared with RKO control group.

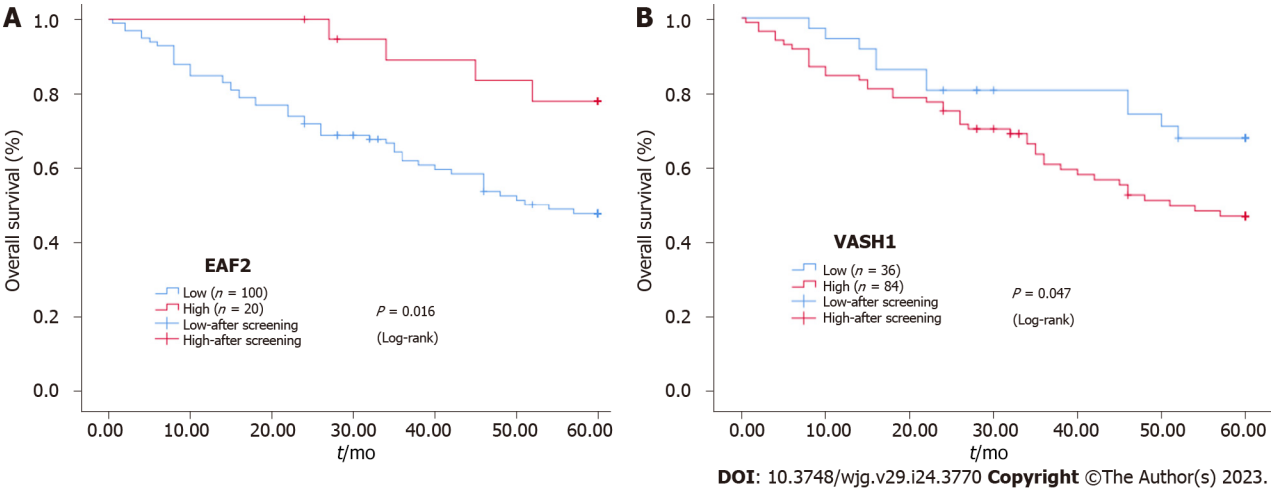

Figure 1 Expression of ELL-associated factor 2 and Vasohibin 1 proteins in tissues of patients with advanced colorectal cancer. A: Representative immunohistochemical staining of ELL-associated factor 2 (EAF2) and vasohibin 1 (VASH1) in colorectal adenocarcinoma tissue and the adjacent non-cancerous tissue (magnification 200 ×); B: The protein bands of EAF2 and VASH1 in 8-matched pairs of colorectal adenocarcinoma tissue and adjacent tissue were detected by Western blot assay. EAF2: ELL-associated factor 2; VASH1: Vasohibin 1; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase; T: Colorectal adenocarcinoma tissue; N: Adjacent non-tumor tissue.

However, silencing STAT3 gene or exogenous TGF-β1 recombinant protein did not affect EAF2 protein expression in RKO cells (Figure 4B).

EAF2 overexpression or VASH1 overexpression inhibited biological function of RKO through STAT3/TGF-β1 pathway

Subsequently, we preliminarily explored the regulatory effects of EAF2 and VASH1 proteins on the biological function of RKO cells through the STAT3/TGF-β1 pathway *in vitro*, in an attempt to provide a scientific basis for exploring the role of EAF2 and VASH1 in CRC.

Transwell invasion assay of matrigel envelope showed that the invasion ability of RKO cells was significantly weakened after transfection of EAF2 overexpression plasmids (Figure 6A, $P < 0.001$). In transwell migration assay, RKO cells transfected with EAF2 overexpressing plasmids showed a

Figure 2 Kaplan-Meier survival curves. A and B: Kaplan-Meier survival curves for the protein expression of ELL-associated factor 2 and vasohibin 1 in colorectal cancer tissue. EAF2: ELL-associated factor 2; VASH1: Vasohibin 1.

significantly reduced migration ability compared with the control group (Figure 6A, $P < 0.001$). Consistent with this, overexpression of EAF2 also significantly reduced the scratch healing ability of RKO cells (Figure 6B, $P < 0.001$). Our treatment of RKO cells with exogenous TGF-β1 recombinant protein significantly promoted the transwell invasion, transwell migration, and scratch healing abilities of RKO cells (Figure 6). More importantly, when the RKO cells transfected with EAF2 overexpression plasmids were treated with TGF-β1 recombinant protein for 24 h, it was found that the transwell invasion, transwell migration and scratch healing abilities of the RKO cells inhibited by EAF2 overexpression were reversed by TGF-β1 recombinant protein (Figure 6).

Furthermore, the RKO cells were transfected with VASH1 overexpression plasmids for transwell invasion assay, transwell migration assay and wound healing assay. Combining the results of Matrigel-coated transwell invasion assay, transwell migration assay and wound healing assay, it was found that compared with RKO control group, RKO cells overexpressing VASH1 protein showed lower transwell invasion, transwell migration, and scratch healing abilities (Figure 7, $P < 0.001$). It was also of concern to us that the transwell invasion, transwell migration, and scratch healing of RKO cells transfected with VASH1 overexpression plasmids could be reversed after 24 h treatment with TGF-β1 recombinant protein (Figure 7, $P < 0.001$).

EAF2 overexpression or VASH1 overexpression inhibited CRC angiogenesis through STAT3/TGF-β1 pathway

Conditioned medium from RKO cells treated with TGF-β1 recombinant protein, EAF2-overexpressed plasmids, or VASH1-overexpressed plasmids was collected to treat HUVECs, respectively. Following, we further examined the tube formation and migration ability of HUVECs. In this study, the potential effects and mechanisms of EAF2 and VASH1 on CRC angiogenesis were investigated *in vitro*.

Tube formation assay showed that the tubular ability of HUVECs treated with the conditioned medium from RKO cells transfected with EAF2-overexpressed plasmids (EAF2-OV group) was significantly lower than that in the control group (RKO-C group), in which HUVECs were treated by conditioned medium from RKO cells grown in medium containing 10% serum. From the results of transwell migration assay and scratch assay, we also found that the migration ability of HUVECs in EAF2-OV group was significantly lower than that in RKO-C group (Figure 8, $P < 0.001$). In addition, the tube formation and invasion ability of HUVECs in the RKO + T group cultured with conditioned medium collected from RKO cells treated with exogenous TGF-β1 recombinant protein were significantly increased compared with those in the RKO-C group (Figure 8, $P < 0.001$). HUVECs were further cultured with conditioned medium from RKO cells in the EAF2-OV + T group, which were transfected with EAF2-overexpressed plasmids and treated with TGF-β1 recombinant protein for 24 h. The results of tube formation assay, transwell migration assay and scratch assay showed that TGF-β1 recombinant protein could reverse the inhibitory effect of EAF2 overexpression in RKO cells on tube formation and migration of HUVECs (Figure 8, $P < 0.001$).

At the same time, we treated HUVECs for 24 h with conditioned medium from RKO cells in the VASH1-OV group, which were transfected with VASH1-overexpressed plasmids, to investigate the role and mechanism of CRC cell-derived VASH1 in CRC angiogenesis. Then, the tube formation assay showed that the tubular ability of HUVECs in the VASH1-OV group was significantly lower than that in the control group (RKO-C group) (Figure 9, $P < 0.001$). The results of migration experiment and scratch experiment showed that the migration ability of HUVECs in VASH1-OV group was significantly lower than that in RKO-C group (Figure 9, $P < 0.001$). After treating RKO cells transfected with VASH1

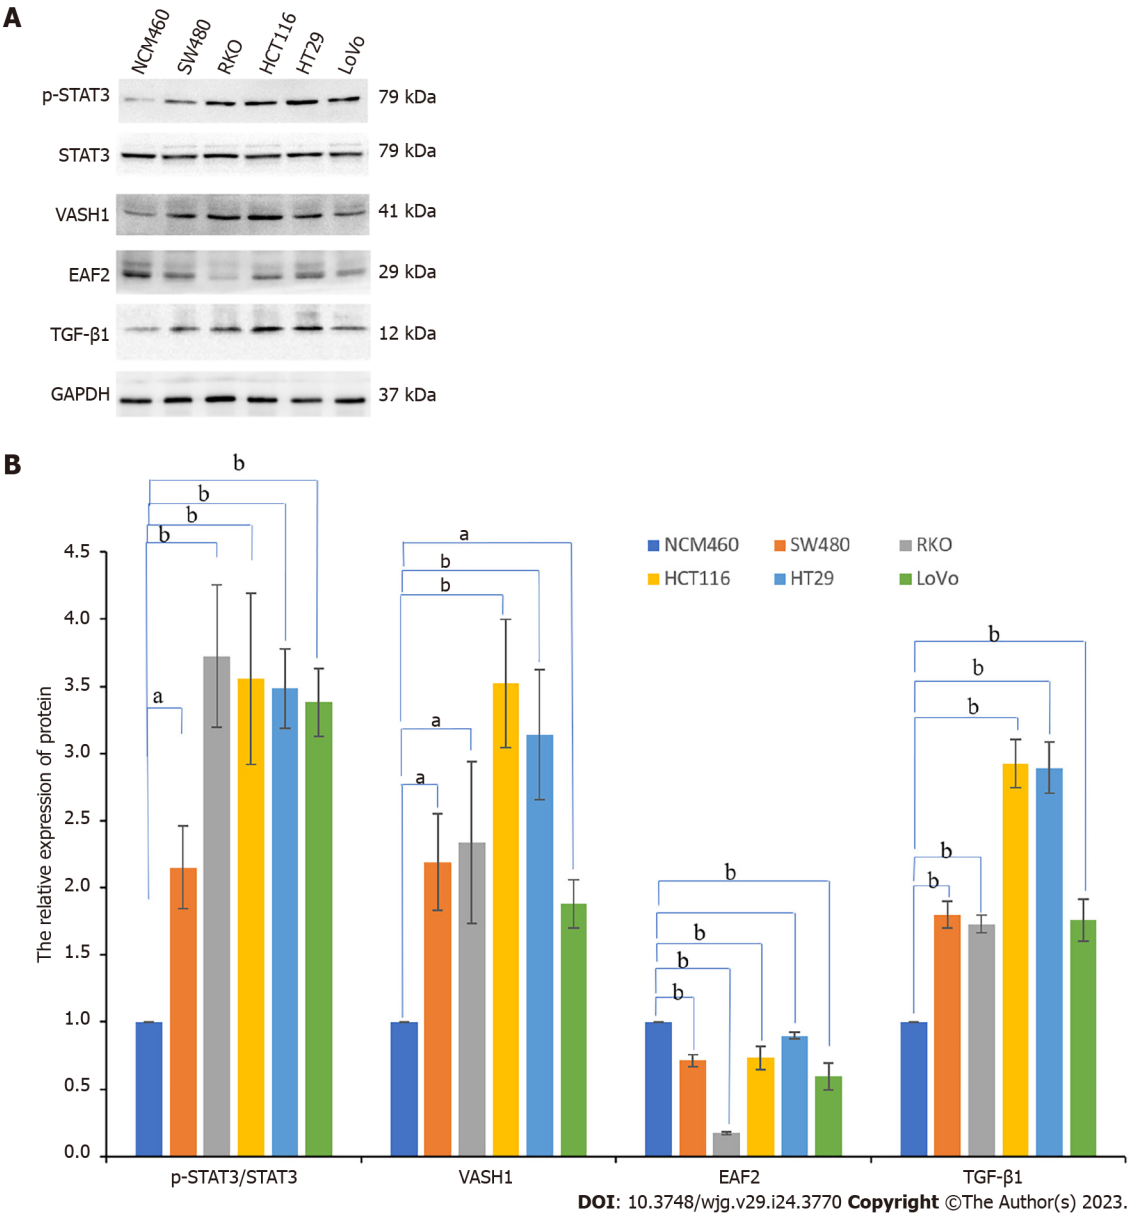

Figure 3 Protein expression of pathway-related factors in a variety of human colorectal cancer cells and colorectal epithelial cells. A and B: The protein bands of ELL-associated factor 2, vasohibin 1, phosphorylated-signal transducer and activator of transcription 3, and transforming growth factor-β1 in colorectal cancer cell lines (SW480, RKO, HCT116, HT29, and LoVo) and normal colorectal epithelial cells (NCM460) by Western blot assay and the corresponding data. $^{a}P < 0.05$, $^{b}P < 0.001$. overexpression plasmid with TGF-β1 recombinant protein (VASH1-OV + T group), it was observed that the tube forming ability and migration ability of HUVECs were significantly increased (Figure 9, $P < 0.001$).

Overexpression of EAF2 up-regulated VASH1 to inhibit the activity of STAT3/TGF-β1 pathway

The previous results suggest that the expression levels of EAF2 and VASH1 proteins are positively correlated in CRC tissues. Therefore, it is of great significance to investigate whether there is a mutual regulatory effect between EAF2 and VASH1 in CRC cells.

Compared with RKO control group, transfection of the EAF2 overexpression plasmid significantly increased VASH1 protein expression in RKO cells (Figure 5B, $P = 0.001$). However, transfection of RKO cells with VASH1 overexpression plasmid or VASH1 siRNA did not significantly modulate the expression level of EAF2 protein (Figure 5B).

In the following experiments, we transfected the RKO cells with VASH1 siRNA to further determine whether VASH1 was involved in the activation of STAT3/TGF-β1 crosstalk pathway by overexpression of EAF2. The results showed that silencing VASH1 reversed the STAT3/TGF-β1 signaling pathway inhibited by EAF2 overexpression (Figure 10).

DISCUSSION

CRC metastasis is a dynamic process that undergoes detachment of the primary cancer, infiltration into adjacent tissues and blood/lymph circulation, and metastasis to distant CRC colony formation. The mechanism is complex and affected by many factors. Angiogenesis is an important link in the process of tumor occurrence, invasion and metastasis, which can meet the oxygen and nutrients needed for the survival and growth of tumor cells[21]. The revolution of targeted agents has brought new hope for the treatment of patients with advanced tumors. Checkpoint inhibitors can significantly inhibit tumors and even may cure them, but currently only 3.8% of metastatic CRC are available[22]. The identification of predictive biomarkers and the exploration of new molecular targets contribute to the improvement of clinical diagnosis and the development of new drugs for advanced CRC.

The androgen response gene EAF2, a member of the EAF family, has tumor suppressive properties in multiple organs, including liver, lung and prostate[15]. EAF2 protein is under-expressed in prostate cancer tissues, and knocking down EAF2 in prostate cancer cell lines can enhance proliferation, migration, and invasion. Prostatic luminal epithelial cells have the potential to develop prostatic intraepithelial neoplasia in the EAF2 knockout mouse model[23]. In addition, the high expression of EAF2 also indicates a better prognosis of skin cutaneous melanoma patients[24]. Recent studies have identified EAF2 inactivation in MSI-H CRC, and not only that, but also intratumor heterogeneity (ITH) of EAF2 frameshift mutations in CRC[25]. Our previous determination of EAF2 expression levels in CRC tissues suggested that EAF2 expression was significantly lower in cancer tissues than in adjacent normal tissues[20]. In addition, the level of EAF2 protein in CRC tissues was negatively correlated with distant metastasis and CEA expression level in patients with advanced CRC[20]. In the present study, we further expanded the clinical sample size and similarly found that EAF2 protein level was significantly lower in CRC tissue than in non-cancer tissue. Further correlation analysis showed that advanced CRC tissue with low EAF2 protein expression had poor angiolymphatic and/or perineural

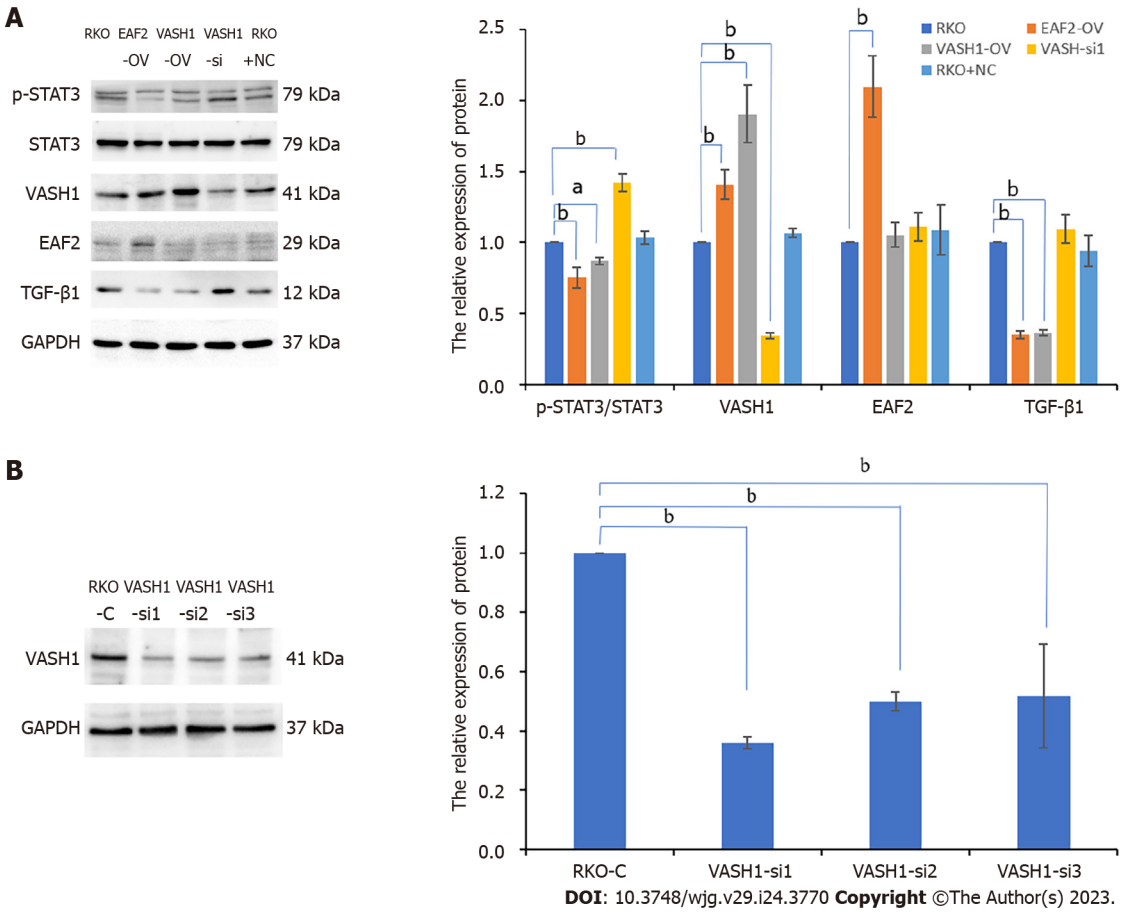

Figure 5 Overexpressing vasohibin 1 inhibits signal transducer and activator of transcription 3 phosphorylation (Tyr705) as well as transforming growth factor-β1 protein expression in RKO cells. invasion, poor TNM stage, poor distant metastasis, and high CEA protein expression compared with high EAF2. Meanwhile, advanced CRC tissue with high EAF2 protein expression had poor degree of differentiation compared with low EAF2. Therefore, by expanding the sample size, we still found that the expression level of EAF2 protein was lower in advanced CRC tissue. The results of Kaplan-Meier survival analysis were also consistent with previous studies[20], suggesting that the survival rate of the group with EAF2 high expression was higher than that of the group with EAF2 Low expression. These results further suggest that EAF2 protein expression in CRC tissues is closely related to tumor invasion and metastasis. EAF2 protein may be a new diagnostic and prognostic marker for CRC, and its low expression may be associated with poor prognosis of patients with advanced CRC. All these suggest that EAF2 may play a role in the occurrence and development of CRC, especially in the process of invasion and metastasis.

Vasohibin was originally identified and isolated as a novel angiogenesis inhibitor by microarray analysis of transcripts induced by VEGF in endothelial cells[26]. In addition, transfecting Lewis lung carcinoma (LLC) cells with vasohibin cDNA effectively inhibited tumor angiogenesis and tumor growth, indicating that vasohibin can act on endothelial cells from the outside[26]. VASH1, one of vasohibin family, is not only selectively expressed in endothelial cells under the induction of angiogenic growth factors (VEGF and FGF-2), which inhibits the migration, proliferation and tube formation of endothelial cells[26], but also expressed in tumor cells and tumor stroma, participating in the inhibition of tumor angiogenesis and prevention of tumor growth and metastasis[27,28]. Although previous studies have focused more on how endothelial cell-derived VASH1 regulates tumor angiogenesis and lymphangiogenesis[29], preliminary studies have also confirmed the potential functional role of tumor cell-derived VASH1 in inhibiting cancer cell proliferation and invasion[30,31]. It has also been shown that overexpression of VASH1 inhibits tumorigenesis and metastasis in a human colon cancer model [32]. However, the expression and function of VASH1 in CRC tissues and cells remain controversial,

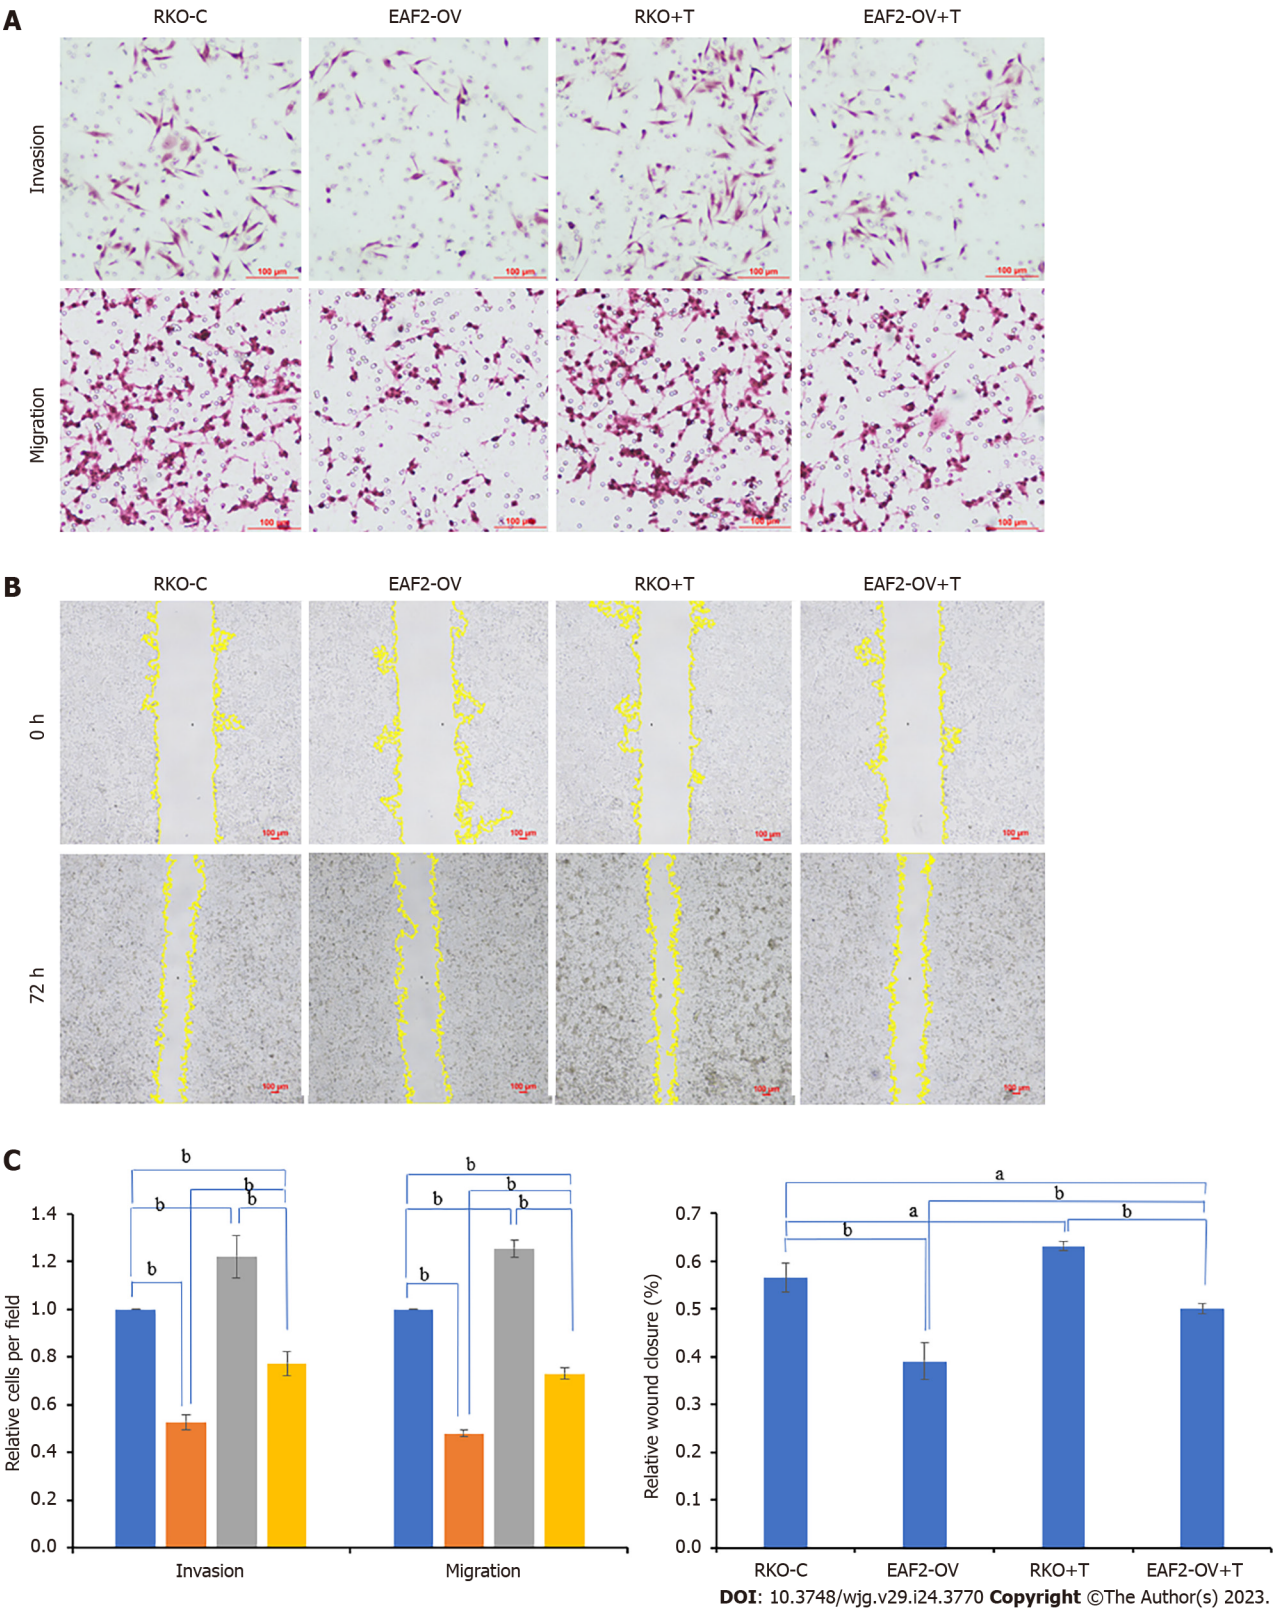

Figure 6 Overexpressing ELL-associated factor 2 inhibits the invasion and migration of RKO cells by suppressing transforming growth factor-β1 related pathway. tissues compared with adjacent normal tissues. However, through Western blot detection, Yan *et al*[9] found that the expression level of VASH1 protein in CRC tissue was significantly higher than that in adjacent normal tissues. Immunohistochemical analysis also indicated that 88.64% (117/132) of CRC tissue expressed VASH1 protein. Moreover, the expression of VASH1 protein and mRNA in colon cancer cell lines was significantly higher than that in normal colon mucosa cell lines. In this study, we also used immunohistochemistry and Western blot to detect the expression of VASH1 protein in advanced CRC tissue, and the results showed that the level of VASH1 protein in colorectal adenocar-

cinoma tissue was significantly higher than that in paracancer tissues. In addition, our results found that advanced CRC tissue with high VASH1 protein expression had poor degree of differentiation, poor angiolymphatic and/or perineural invasion, poor distant metastasis compared with those with low VASH1. Kaplan-Meier survival analysis showed that the survival rate of patients with low VASH1 expression was higher than that of patients with high VASH1 expression. It is consistent with the findings of Yan *et al*[9], who showed that high VASH1 protein expression is an independent risk factor for worse OS and PFS. It is of great significance to further explore the function and mechanism of VASH1 protein in the occurrence and development of CRC, especially in the process of invasion and metastasis.

Univariate analysis showed that vascular lymphatic and/or neural invasion, tumor stage, depth of tumor invasion, lymph node status, distant metastasis, EAF2 protein expression level and p53 protein expression level were prognostic factors for the survival of patients with advanced CRC. However, multivariate analysis did not show that EAF2 or VASH1 expression levels were an independent prognostic factor for survival in patients with advanced CRC. More cases and more comprehensive clinical studies are needed to clarify the clinical significance of EAF2 and VASH1 proteins in CRC. In addition, this study is the first to investigate the correlation between the expression of the tumor suppressor EAF2 and the anti-angiogenic factor VASH1 in CRC tissues. The expressions of EAF2 and VASH1 proteins in advanced CRC tissue are positively correlated. Immunohistochemical localization showed that EAF2 and VASH1 proteins were mainly expressed in the cytoplasm of CRC epithelial cells. Therefore, we also ventured to speculate whether EAF2 and VASH1 interact in the development of CRC.

And then, we conducted *in vitro* cell studies to investigate the role and potential mechanism of CRC cell-derived EAF2 and VASH1 protein. Western blot assay showed that EAF2 protein expression was down-regulated and VASH1 protein expression was up-regulated in RKO cells compared with normal colon epithelial cells *in vitro*. In addition, RKO cells overexpressing EAF2 protein expressed higher levels of VASH1 protein. These results suggest that EAF2 overexpression can up-regulate the expression of VASH1 protein in RKO cells. Further investigation of the potential mechanism of EAF2 and VASH1 in CRC cells may provide a research direction for exploring the role of EAF2 and VASH1 in CRC.

In parallel, our results also found that phospho-STAT3 (Tyr705) and TGF-β1 protein levels were significantly increased in RKO cells. TGF-β signaling participates in and promotes the development of metastatic CRC through multiple mechanisms[33,34]. TGF-β1 expression is also significantly increased in CRC tissue and in distant metastases of CRC[35]. Targeting TGF-β signaling is emerging as a new therapy for CRC metastasis[36]. Not only that, increased TGF-β expression specifically promotes endothelial cell angiogenesis induced by the human CRC cell line HT-29 by upregulating VEGF secretion[37]. STAT3 is also one of the main factors closely related to the occurrence and development of CRC, and is involved in tumor angiogenesis and lymphangiogenesis to promote the early occurrence of advanced CRC. Immunohistochemical evaluation of pSTAT3 in a study containing 724 CRC patients showed that pSTAT3 expression was significantly associated with high mortality and increased peritumoral lymphoid reaction[38]. What's more, TGF-β1 promotes CRC invasion by inducing EMT *via* Src/Annexin A2 (ANXA2)/STAT3 pathway[39]. We also found *in vitro* that silencing STAT3 phosphorylation significantly downregulated TGF-β1 protein expression in RKO cells. Therefore, exploring the regulatory proteins of STAT3/TGF-β1 pathway is helpful to find new therapeutic targets for CRC.

EAF2 has been shown to be a repressor of STAT3 signaling pathway in prostate cancer[40]. Down-regulation of EAF2 protein in human prostate cancer specimens correlated with the immunostaining of phosphorylated STAT3 (Tyr705), and knockdown of EAF2 gene induced STAT3 phosphorylation (Tyr705) in prostate cancer both *in vivo* and *in vitro*. Besides, EAF2 attenuates TGF-β1-induced G1 phase cell cycle arrest and cell migration in a variety of tumor cells[18]. Encouragingly, when we overexpressed EAF2 protein, the activity of STAT3/TGF-β1 pathway was inhibited in RKO cells. Furthermore, *in vitro* functional studies in CRC cells showed that overexpression of EAF2 inhibited not only the invasion and migration of RKO cells, but also the angiogenesis induced by RKO cells. However, the inhibitory effect of EAF2 overexpression on RKO cell function was reversed by recombinant TGF-β1 protein.

In this study we also found that overexpressing VASH1 protein in RKO cells significantly inhibited the activity of the STAT3/TGF-β1 pathway. More meaningfully, the silencing of VAH1 gene with variable activity in the STAT3/TGF-β1 pathway was reversed by overexpression of EAF2. It is suggested that CRC-derived VASH1 protein is involved in the EAF2-mediated STAT3/TGF-β1 pathway in CRC cells. Overexpression of VASH1 protein in colon cancer cells not only inhibited cancer cell growth and colony formation *in vitro*, but also inhibited tumor growth *in vivo*[8]. This is consistent with the results of our study, which revealed that overexpressing VASH1 protein inhibited RKO cell invasion, migration and angiogenesis. What's more, this effect was reversed by TGF-β1 recombinant protein. Similarly, VASH1 siRNA significantly increased the mobility of gastric cancer cell and endothelium cells vessel formation in Matrigel[41]. Hence, CRC cell-derived VASH1 may inhibit the invasion, migration and angiogenesis ability of RKO cells by inhibiting STAT3/TGF-β1 pathway. In

Figure 11 Schematic depiction of ELL-associated factor 2 and vasohibin 1 regulating the signal transducer and activator of transcription 3/ transforming growth factor-β1 signaling pathway in this study. Overexpression of ELL-associated factor 2 may inhibit the activity of signal transducer and activator of transcription 3/transforming growth factor-β1 pathway by up-regulating the expression of vasohibin 1, thereby inhibiting cell invasion, migration and angiogenesis. EAF2: ELL-associated factor 2; TGF-β1: Transforming growth factor-β1; STAT3: Signal transducer and activator of transcription 3; CRC: Colorectal cancer; HUVECs: Human umbilical vein endothelial cells; VASH1: Vasohibin 1.

addition, overexpression of EAF2 may inhibit the activity of STAT3/TGF-β1 pathway by up-regulating the expression of VASH1.

However, further studies are needed to clarify whether there is a direct effect of EAF2 on regulating VASH1 protein in CRC cells and the mechanism by which EAF2 and VASH1 regulate STAT3/TGF-β1 pathway. In addition, more objective and scientific experimental methods should be combined *in vivo* and *in vitro* to further comprehensively discuss and evaluate the functional effects of EAF2 and VASH1 on CRC, so as to make up for the limitations and one-sidedness of this study which only conducted *in vitro* invasion, migration and angiogenesis studies.

Moreover, in-depth study on the mechanism and methods of overexpressing EAF2 and VASH1 may provide new targets and ideas for the treatment of CRC. Deletion of EAF2 and Von Hippel-Lindau (VHL) produced a synergistic effect on angiogenesis in male fractional liver and prostate, accompanied by an increase in the expression of VHL target proteins hypoxia-inducible factor 1α and VEGF[42]. Further study on the effect and mechanism of EAF2-mediated VASH1 on endothelial cells in tumor microenvironment may help to elucidate the pathogenesis of CRC. Inhibition of cytotoxic T lymphocyte protein 4 can reactivate immune cells, especially T cells, in patients with CRC, thereby enhancing the ability of immune cells to fight tumors[43]. Regulatory T cells (Tregs) in tumor microenvironment can mediate mechanisms such as immune escape, and may also participate in the regulation of ovarian cancer angiogenesis through VEGFA and VASH1[44]. The synergistic effect of VASH1-related pathway anti-angiogenesis therapy and immunotherapy may become a new idea for CRC treatment.

CONCLUSION

In conclusion, our study found that EAF2 was down-regulated and VASH1 was up-regulated in advanced CRC tissue. Kaplan-Meier survival analysis showed that the high EAF2 Level group and the low VASH1 Level group had a higher survival rate. This study suggests that EAF2 and VASH1 may serve as new diagnostic and prognostic markers for CRC. What's more, overexpression of EAF2 protein or VASH1 protein in CRC cells inhibited STAT3/TGF-β1 pathway, and further inhibited invasion, migration and angiogenesis of CRC cells. Overexpression of EAF2 may provide tumor inhibition and protection against CRC by up-regulating VASH1 expression and inhibiting the activity of downstream STAT3/TGF-β1 pathway (Figure 11). This study provides new ideas and theoretical basis for the development of new diagnostic markers for CRC and the exploration of the mechanism of targeted therapy.

ARTICLE HIGHLIGHTS

Research background

More and more studies have suggested that the anti-angiogenic factor vasohibin 1 (VASH1) is not only expressed in the stroma of tumor cells, but also expressed in tumor cells. It also plays a certain role in the regulation of tumor growth, invasion and tumor microenvironment. Recent studies have found that ELL-associated factor 2 (EAF2) can mediate signal transducer and activator of transcription 3 (STAT3)/

transforming growth factor-β1 (TGF-β1) pathway to act on colorectal cancer (CRC). Knockdown of VASH1 enhanced TGF-β1/Smad3 pathway activity and type I/III collagen production.

Research perspectives

Further study on the effect and mechanism of EAF2-mediated VASH1 on endothelial cells in tumor microenvironment may help to elucidate the pathogenesis of CRC. The synergistic effect of VASH1-related pathway anti-angiogenesis therapy and immunotherapy may become a new idea for CRC treatment.

Research conclusions

This study suggests that EAF2 and VASH1 may serve as new diagnostic and prognostic markers for CRC. It complements the mechanism of EAF2 in CRC cells, enriches the role and mechanism of CRC cell-derived VASH1, and provides a new possible subtype of CRC as a therapeutic target of STAT3/TGF-β1 pathway.

Research results

Our findings indicated that EAF2 was down-regulated and VASH1 was up-regulated in advanced CRC tissue compared to normal colorectal tissue. Overexpression of EAF2 might inhibit the activity of STAT3/TGF-β1 pathway by up-regulating the expression of VASH1, thereby attenuating the invasion, migration and angiogenesis of CRC cells.

Research methods

We collected colorectal adenocarcinoma and corresponding adjacent tissues in patients with advanced CRC. Following, we investigated the effect and mechanism of EAF2 and VASH1 on the invasion, migration and angiogenesis of CRC cells *in vitro* using plasmid transfection.

Research objectives

To investigate the expression of VASH1 in CRC and its correlation with the expression of EAF2. Furthermore, we explored the functional role and mechanism of EAF2 and VASH1-mediated TGF-β1 related pathway in CRC cells.

Research motivation

Detection of EAF2 and VASH1 protein expression in CRC tissues may help to explore new diagnostic and prognostic markers for CRC. The study of the potential mechanism of EAF2 and VASH1 can provide new ideas for the treatment of CRC.

Abstract

BACKGROUND

Formyl peptide receptor 2 (Fpr2) is an important receptor in host resistance to bacterial infections. In previous studies, we found that the liver of $Fpr2^{-/-}$ mice is the most severely damaged target organ in bloodstream infections, although the reason for this is unclear.

AIM

To investigate the role of Fpr2 in liver homeostasis and host resistance to bacterial infections.

METHODS

Transcriptome sequencing was performed on the livers of $Fpr2^{-/-}$ and wild-type (WT) mice. Differentially expressed genes (DEGs) were identified in the $Fpr2^{-/-}$ and WT mice, and the biological functions of DEGs were analyzed by Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) enrichment analysis. Quantitative real time-polymerase chain reaction (qRT-PCR) and western blot (WB) analyses were used to further validate the expression levels of differential genes. Cell counting kit-8 assay was employed to investigate cell survival. The cell cycle detection kit was used to measure the distribution of

cell cycles. The Luminex assay was used to analyze cytokine levels in the liver. The serum biochemical indices and the number of neutrophils in the liver were measured, and hepatic histopathological analysis was performed.

RESULTS

Compared with the WT group, 445 DEGs, including 325 upregulated genes and 120 downregulated genes, were identified in the liver of Fpr2$^{-/-}$ mice. The enrichment analysis using GO and KEGG showed that these DEGs were mainly related to cell cycle. The qRT-PCR analysis confirmed that several key genes (*CycA*, *CycB1*, *Cdc20*, *Cdc25c*, and *Cdk1*) involved in the cell cycle had significant changes. The WB analysis confirmed a decrease in the expression of CDK1 protein. WRW4 (an antagonist of Fpr2) could inhibit the proliferation of HepG2 cells in a concentration dependent manner, with an increase in the number of cells in the G0/G1 phase, and a decrease in the number of cells in the S phase. Serum alanine aminotransferase levels increased in Fpr2$^{-/-}$ mice. The Luminex assay measurements showed that interleukin (IL)-10 and chemokine (C-X-C motif) ligand (CXCL)-1 levels were significantly reduced in the liver of Fpr2$^{-/-}$ mice. There was no difference in the number of neutrophils, serum C-reactive protein levels, and liver pathology between WT and Fpr2$^{-/-}$ mice.

CONCLUSION

Fpr2 participates in the regulation of cell cycle and cell proliferation, and affects the expression of IL-10 and CXCL-1, thus playing an important protective role in maintaining liver homeostasis.

Key Words: Cell cycle; Cell proliferation; Cdk1; Differentially expressed genes; Formyl peptide receptor 2; RNA-sequencing

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Formyl peptide receptor 2 (Fpr2) is an important receptor in host resistance to bacterial infection. After Fpr2 deletion, the pathways involved in the cell cycle are affected, the expression of Cdk1 is downregulated, the proliferation activity of HepG2 cells is reduced, and the distribution of cell cycle is abnormal. After Fpr2 deletion, the permeability of the hepatocyte membrane increases, and the expression of interleukin-10 and Chemokine (C-X-C motif) ligand-1 decreases. These changes reflect the important protective effect of Fpr2 in maintaining liver homeostasis.

INTRODUCTION

The liver plays an important role in human metabolism and immune homeostasis. Liver dysfunction and liver failure can directly lead to the progression of sepsis and death of patients. Pre-existing liver dysfunction is a risk factor for the progression of infection to sepsis[1]. The liver is an important organ that collects blood from the intestine *via* the portal vein. Once the intestinal barrier becomes dysfunctional, the liver is the first organ to encounter bacteria. The liver collects blood through the hepatic artery, so it is also an important organ involved in the removal of bacteria from the bloodstream in systemic infection[2,3].

As an organ mainly responsible for blood detoxification, the liver plays a key role in removing bacteria and toxins during sepsis. After intravenous injection, the liver captures 65% of bacteria in 10 min and over 80% in 6 h[4]. Two methods of liver clearance have been identified: Rapid and slow. The rapid clearance mainly relies on Kupffer cells to remove bacteria and does not depend on complement-mediated opsonophagocytosis or platelet combinations. The slow clearance ensures that the host not only removes a sufficient number of bacteria to prevent infection and damage but also maintains sufficient bacteria to induce host adaptive immunity. In addition to mesenteric lymph nodes, the liver is another important firewall against bacterial infections in the body[2,5,6].

Formyl peptide receptors (FPRs) are G-protein-coupled receptors that play an important role in host defense and inflammation. The most important biological activity of FPRs is the induction of leukocyte

chemotaxis in infected or injured areas. In addition to chemotaxis, FPRs also mediate phagocytosis, production of reactive oxygen species, and production of various cytokines/chemokines. According to sequence similarity, FPRs are divided into three family members: FPR1, ALX/FPR2, and FPR3. Based on the ability of FPRs to recognize bacterial formylated peptides, they are considered to play an important role in host defense against microbial invasion.

Initially, research on FPRs mainly focused on regulating inflammation, but increasing evidence demonstrated that FPRs can also regulate the host's defense process, including regulating the activation of neutrophils and dendritic cells and participating in host resistance to bacterial infection, tissue damage, and wound healing[7]. Liu *et al*[8] reported that during *Listeria monocytogenes* (*Listeria*) infection, FPRs can quickly recruit the first wave of neutrophils into the infected liver, followed by the second wave of neutrophil accumulation mediated by CXCR2. This discovery challenges the previously reported pattern of host defense against *Listeria*, that is, the receptor toll-like receptor 2 on the host cell is activated by bacterial lipoprotein, and then CXCR2 ligand is produced to induce neutrophil accumulation[9]. In sepsis, the biased expression of chemokine receptors CC chemokine receptor 5 (CCR5) and FPR2 in human and mouse neutrophils leads to the movement of neutrophils guided by CCR5 to aseptic tissue sites, whereas polymorphonuclear neutrophils guided by FPR2 to bacterial infection sites are significantly reduced[10]. Thus, inflammatory but non-functional neutrophils may increase the host's morbidity and mortality, which may be related to infectious injury[11]. The above findings emphasize the importance of FPRs in the host defense against microorganisms.

Our previous research revealed that in group B streptococcus infection, Fpr2 activated the downstream key signal molecules and produced chemokine (C-X-C motif) ligand (CXCL)1/2 to attract neutrophils, indicating that Fpr2, as a chemotactic receptor, could not only attract neutrophils directly, but also indirectly control neutrophil chemotaxis by regulating the production of chemokines to resist infection[12]. The liver is the most important organ in the removal of bacteria, and Fpr2 is an important receptor involved in resisting bacterial infection. However, the effect of Fpr2 on the liver homeostasis remains unclear. In the present study, we evaluated the liver of Fpr2 knockout and wild-type (WT) mice in terms of transcriptome sequencing, histology, immunity, and biochemistry to understand the reason for the antibacterial activity of Fpr2.

MATERIALS AND METHODS

Mice

$Fpr2^{-/-}$ (Fpr2 knockout) mice were purchased from Cyagen Biosciences (Guangzhou, China), who created this model according to previously reported methods[12]. The WT C57BL/6 mice (6-8 wk, 18-20 g body weight) were purchased from Charles River (Beijing, China). These mice were bred in the animal center of the Academy of Military Medical Sciences under specific pathogen free conditions. The animals were acclimatized to laboratory conditions (23 °C, 12 h/12 h light/dark, 50% humidity, and ad libitum access to food and water) for 2 wk, prior to experimentation. All animals were euthanized by isoflurane inhalation for tissue collection. The animal protocol was designed to minimize pain or discomfort to the animals. This research was conducted in compliance with the guidelines for laboratory animal care approved in China. All experimental procedures were approved by the Animal Ethics Committee of the Academy of Military Medical Sciences.

Cell culture

The HepG2 cell line was cultured in a high-glucose DMEM medium (Gibco, Rockville, MD, United States) supplemented with 10% fetal bovine serum (Gibco, Rockville, MD, United States). Cell counting kit-8 (CCK8; APExBIO, United States) assay was employed to investigate cell survival following the manufacturer's instructions. In brief, HepG2 cells were plated in 96-well plates at a density of 3×10^3 cells/well. On the second day, cells were treated with different concentrations of WRW4 [Sangon Biotech (Shanghai) Co., Ltd. China] for 24 h. Then, 10 μL CCK-8 was added to each well and cells were incubated at 37 °C for 2 h. Absorbance was measured at 450 nm using a microplate spectrophotometer (Molecular Devices LLC, Sunnyvale, CA, United States).

The cell cycle detection kit (KeyGEN BioTECH, Nanjing, China) was used to measure the distribution of cell cycles. HepG2 cells were plated in 6-well plates and treated with WRW4 (1 μM) for 24 h. Dimethyl sulfoxide used as a control to dissolve WRW4. Next, cells were collected, washed, and fixed overnight at 4 °C in 70% ethanol. The samples were then incubated with RNase A and propidium in the dark for 30 min and cell cycle distribution was analyzed using flow cytometry.

Total RNA isolation and cDNA library construction

The mice were sacrificed after anesthesia, and the liver was taken for subsequent RNA sequencing. RNA extraction, library preparation, DNA sequencing, and result analysis were conducted by Nevogene Co., Ltd (Beijing, China). Briefly, total RNA was extracted using TRIzol reagent (Invitrogen, Shanghai, China). RNA integrity was assessed using the RNA Nano 6000 Assay Kit on a Bioanalyzer 2100 system (Agilent Technologies, CA, United States).

To select cDNA fragments of 370-420 bp, the library fragments were purified with the AMPure XP system (Beckman Coulter, Beverly, United States). Polymerase chain reaction (PCR) was performed using Phusion High-Fidelity DNA polymerase, Universal PCR primers, and Index (X) Primer. Finally, PCR products were purified (AMPure XP system), and library quality was assessed on the Agilent Bioanalyzer 2100 system. Clustering of the index-coded samples was performed on a cBot Cluster Generation System using TruSeq PE Cluster Kit v3-cBot-HS (Illumina). The library preparations were sequenced on an Illumina Novaseq platform, and 150 bp paired-end reads were generated.

Sequence read quality control, mapping, and counting

After data cleaning (to obtain clean reads with high quality), reads were mapped to the reference genome. Reference genome and gene model annotation files were downloaded from the genome website directly. The index of the reference genome was built using Hisat2 v2.0.5, and paired-end clean reads were aligned to the reference genome using Hisat2 v2.0.5. FeatureCounts v1.5.0-p3 was used to count the number of reads mapped to each gene. Fragments per kilobase millions of each gene were calculated based on the length of the gene and the read counts were mapped to the respective genes.

Differential expression analysis and quantitative real time-PCR validation

Differential expression analysis of the two groups (four biological replicates per group) was performed using the DESeq2 R package (1.20.0). Genes with an adjusted $P < 0.05$ found by DESeq2 were assigned as differentially expressed. Quantitative real time-PCR (qRT-PCR) analysis further validated gene expression patterns. The primers used for qRT-PCR analysis were listed in Table 1.

Enrichment analysis of differentially expressed genes

Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) enrichment analysis of differentially expressed genes (DEGs) were implemented using the ClusterProfiler R package, in which gene length bias was corrected. GO terms with a corrected $P < 0.05$ were considered significantly enriched by DEGs. The ClusterProfiler R package was used to test the statistical significance of DEGs in KEGG enrichment pathways.

Western blotting

The liver tissues were taken and washed three times with phosphate buffer solution, then stored at -80 °C. Total proteins were extracted from the liver using RIPA buffer (Beyotime, Nantong, China), and the concentrations were estimated using the bicinchoninic acid protein assay kit (Pierce, Rockford, IL, United States). Next, 30 μg of protein was separated by sodium dodecyl-sulfate polyacrylamide gel electrophoresis on a 10% gel and transferred to PVDF membranes. The membranes were blocked in 3% nonfat dry milk and then probed with anti-CDK1 antibody (1:2000 dilution; ab32094; Abcam, Cambridge, MA, United States), and anti-beta actin antibody (1:3000; ab8227; Abcam, Cambridge, MA, United States) overnight at 4 °C. On the next day, membranes were incubated with appropriate secondary antibody for 1 h at room temperature. The protein bands were visualized using Amersham Hyperfilm™ ECL reagent (Thermo Fisher Scientific, MA, United States).

Cytokine measurements by the Luminex assay

Fresh liver tissues from the mice were weighed and homogenized. Concentrations of cytokines in the supernatants of the liver were measured by multiplexed Luminex xMAP assay (Cytokine & Chemokine 36-Plex Mouse ProcartaPlex™ Panel 1A; Thermo Fisher Scientific, MA, United States), according to the manufacturer's instructions.

Flow cytometry

The liver tissue was digested into single-cell suspension using type IV collagenase (Sigma-Aldrich, United States). The number of leukocytes in the liver were determined using a BD TruCount system (BD Biosciences, United States). The cells were stained with FITC-anti-mouse Ly6G (Biolegend, San Diego, CA, United States), PerCP-anti-mouse CD45 (Biolegend, San Diego, CA, United States), and PE-anti-mouse CD11b (Biolegend, San Diego, CA, United States) antibodies. All of the above-stained cells were assayed using a BD FACSVerse flow cytometer and data were analyzed using FlowJo software.

Determination of serum biochemical indexes

The blood from mice was collected, and serum was separated by centrifugation (4 °C, 3000 rpm, 10 min). A total of 200 μL serum was obtained and sent to the experimental animal center of the Academy of Military Medical Sciences for the determination of liver biochemical indexes.

Liver histopathology

The liver tissue of mice was fixed with 4% formaldehyde, paraffin sections were prepared, stained with hematoxylin and eosin, and observed and photographed with an Olympus camera system. The image magnifications were 200 × and 400 ×.

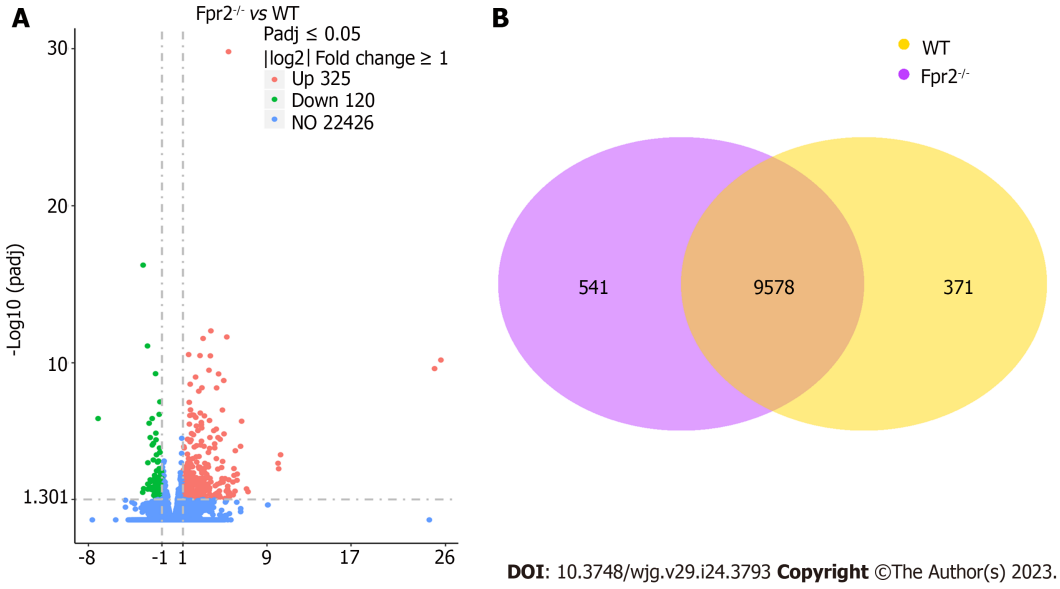
Statistical analysis

All data were analyzed using GraphPad Prism (version 8.0; GraphPad Software, La Jolla, CA, United States). Differences between the groups were calculated using an unpaired *t*-test and a log-rank test. Data were shown as mean ± SD. Differences were considered statistically significant at $P < 0.05$.

RESULTS

Identification of DEGs and their GO and KEGG pathway analysis



We used RNA-sequencing to analyze the liver transcriptome of $Fpr2^{-/-}$ mice and compared it with that of WT mice to determine DEGs. Taking $|\log2(\text{fold change})| \geq 1$ and padj ≤ 0.05 as criteria, compared with the WT group, 445 DEGs, including 325 upregulated genes and 120 downregulated genes, were identified in $Fpr2^{-/-}$ mice (Figure 1A). Venn diagram analysis showed that 9578 genes showed identical expression between $Fpr2^{-/-}$ and WT mice. On the other hand, 541 and 371 specific genes were expressed in $Fpr2^{-/-}$ and WT mice, respectively (Figure 1B).

According to the results of the enrichment analysis, 179 GO terms were obtained, including 136 biological processes (BPs), 25 cell component (CC), and 18 molecular function (MF) terms. The results showed that the DEGs were mainly annotated to the cell cycle (Figure 2A). Further GO enrichment analysis of upregulated DEGs showed that a total of 156 GO terms were obtained, including 121 BPs, 25 CC, and 10 MF terms. The BP terms were significantly enriched in mitotic sister chromatid segregation, chromosome segregation, sister chromatid segregation, and nuclear chromosome segregation. The CC terms were significantly enriched in chromosomes, centromeric regions, spindles, mitotic spindles, kinetochores, condensed chromosomes, centromeric regions, and chromosomal regions. The MF terms were significantly enriched in microtubule binding, tubulin binding, and microtubule motor activity (Figure 2B). The results of the GO analysis suggest that the upregulated DEGs are significantly enriched in many phases of cell division. In addition, GO analysis of downregulated DEGs revealed that BP terms were significantly enriched in many BPs related to liver function, such as organic hydroxy compound metabolic process, organic hydroxy compound biosynthetic process, steroid metabolic process, positive regulation of alcohol biosynthetic process, cellular hormone metabolic process, G-protein coupled receptor signaling pathway, and coupled to cyclic nucleotide second messenger (Figure 2C).

Four pathways with significant differences obtained based on KEGG analysis are listed in Table 2. These pathways included cell cycle, neuroactive ligand-receptor interaction, oocyte meiosis, and progesterone-mediated oocyte maturation (Figure 3). Both GO function analysis and KEGG pathway enrichment analysis showed that core DEGs mainly regulated the cell cycle of the liver tissue in Fpr2-deficient mice, which revealed that Fpr2 deficiency may cause cell division cycle disorder to some extent.

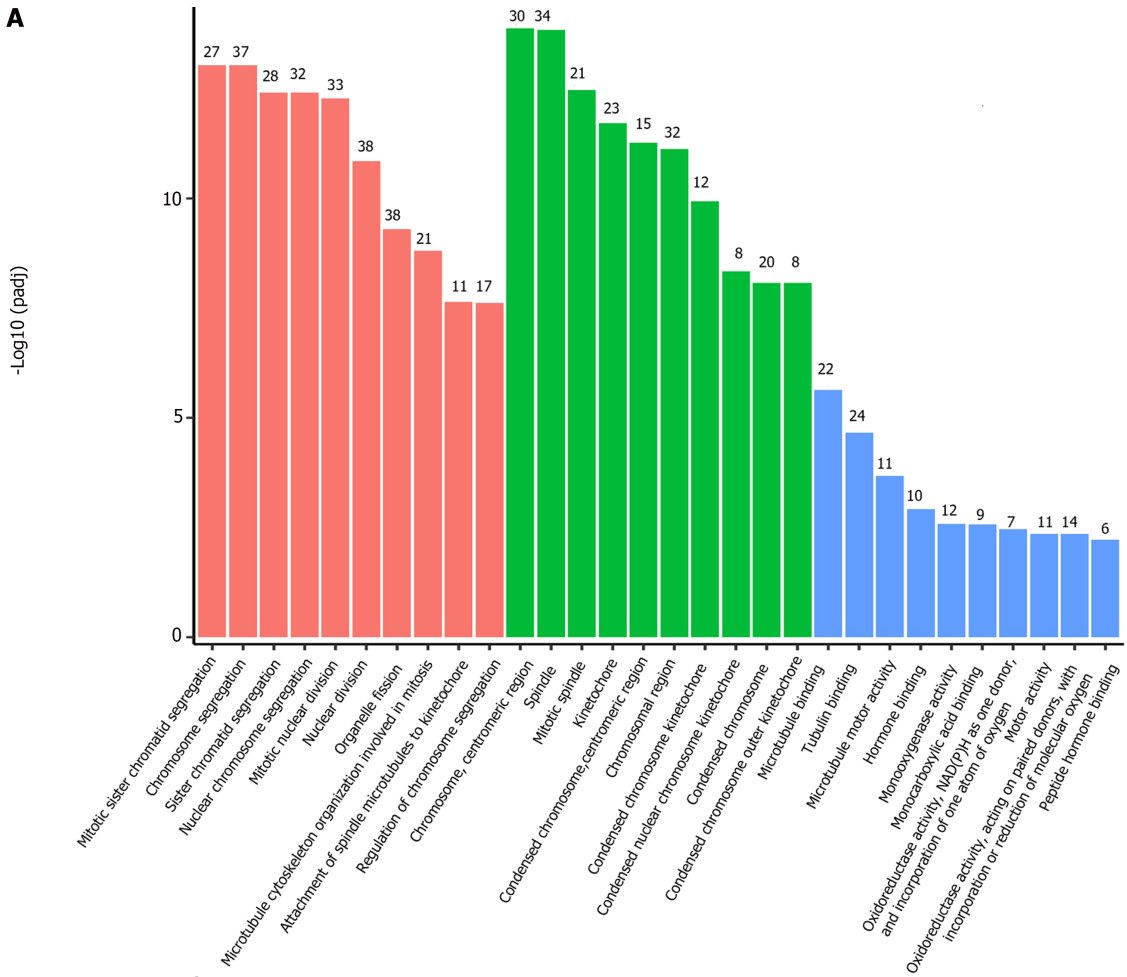

Figure 1 RNA-sequencing analysis of distributions of all differentially expressed genes. A: Volcano map of the distributions of all differentially expressed genes in formyl peptide receptor 2 (Fpr2)$^{-/-}$ and wild-type (WT) mice (n = 4). Red, green, and blue colors respectively represent upregulated genes, downregulated genes, and genes with no difference in expression; B: Venn diagram of gene counts expressed in the Fpr2$^{-/-}$ and WT mice (n = 4). 9578 genes show identical expression between Fpr2$^{-/-}$ and WT mice. 541 and 371 specific genes are expressed in Fpr2$^{-/-}$ and WT mice, respectively. Fpr2: Formyl peptide receptor 2; WT: Wild-type.

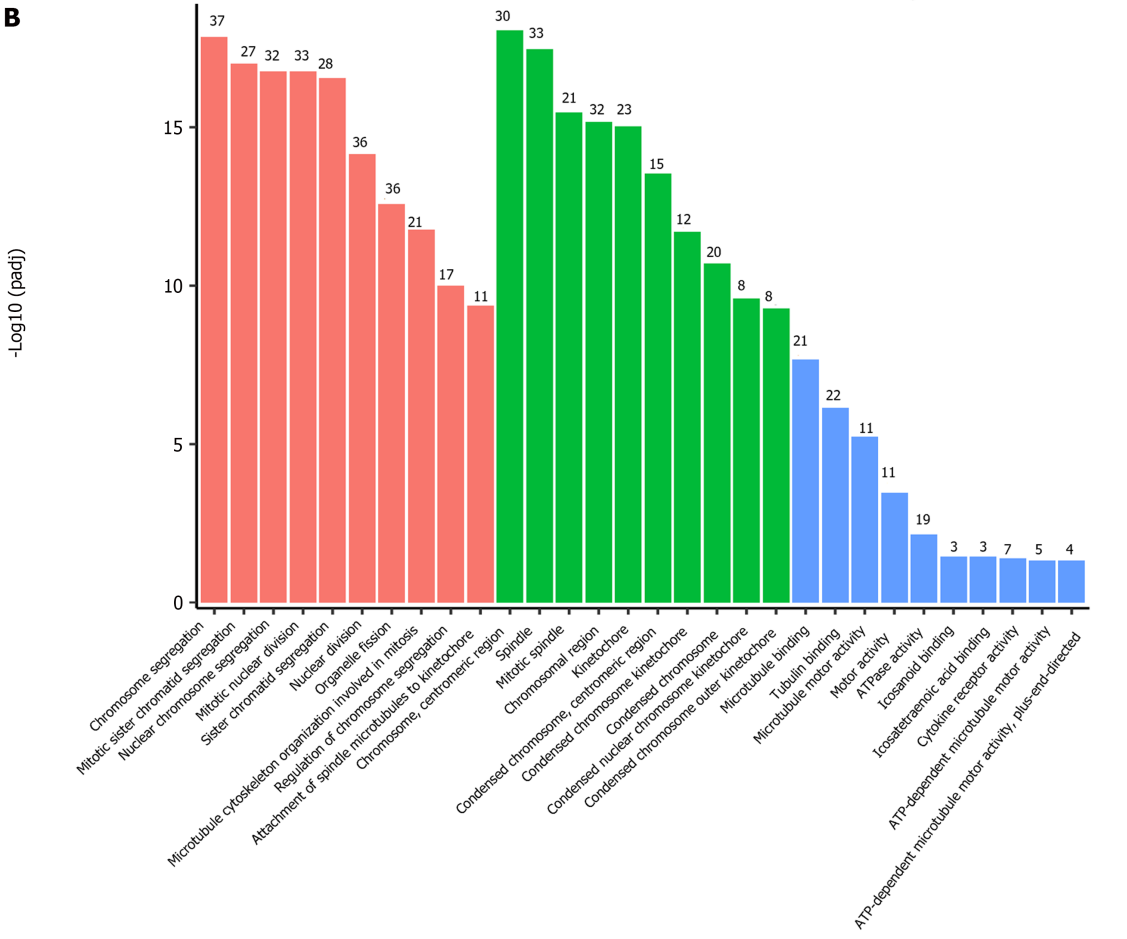
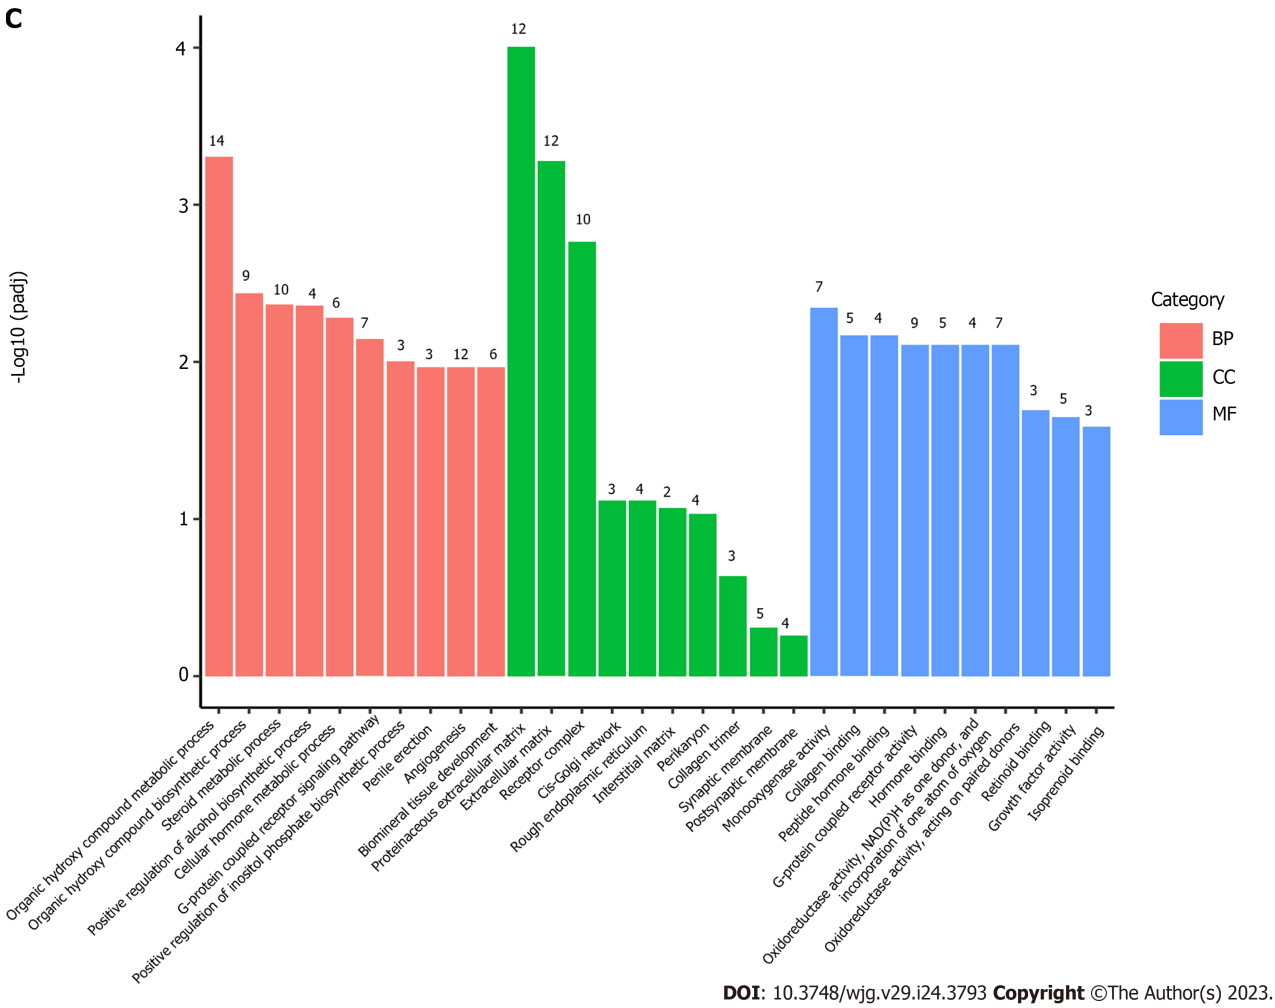


Fpr2 participated in the regulation of cell cycle



To further validate the results of RNA-sequencing, we selected several key genes *CycA*, *CycB1*, *Cdc20*, *Cdc25c*, *Mps1*, and *Cdk1*, which are closely related to the cell cycle, for qRT-PCR analysis. The results showed that the expression of *CycA*, *CycB1*, *Cdc20*, and *Cdc25c* was upregulated (Figure 4A), while the expression of *Cdk1* was downregulated in the Fpr2$^{-/-}$ mice (Figure 4B). There was no significant difference in the expression of *Mps1* between Fpr2$^{-/-}$ and WT mice (Figure 4A). The WB analysis further confirmed a decrease in CDK1 expression (Figure 4B). To clarify the impact of Fpr2 deficiency on liver cell proliferation, WRW4, an antagonist of Fpr2, was used to inhibit Fpr2 in the liver cells. CCK-8 further clarified the effect of different concentrations of WRW4 on the proliferation of HepG2 cells. Figure 4C indicates that WRW4 at all concentrations (0.125 μM, 0.25 μM, 0.5 μM, 1.0 μM, and 2.0 μM) inhibited the proliferation of HepG2 cells in a concentration dependent manner. WRW4 at 1 μM was used to analyze the distribution of cell cycles. Flow cytometry analysis showed that the number of cells in G0/G1 phase increased, and the number of cells in S phase decreased (Figure 4D). From the above analysis, it can be surmised that when Fpr2 is absent, some genes involved in cell cycle regulation are affected and these may inhibit cell proliferation by blocking the cell cycle.

Fpr2 maintained the stability of liver cell membrane

Considering that the lack of Fpr2 can lead to disruption of the liver cell cycle, we tested biochemical indicators that reflect liver function. Biochemical indicators related to liver function include determination of the levels of alanine transaminase (ALT), aspartate transaminase (AST), alkaline phosphatase (ALP), lactate dehydrogenase (LDH) and albumin (ALB). In Fpr2$^{-/-}$ mice, we detected higher levels of serum ALT and LDH compared to those in the WT mice, with no significant changes in AST, ALP, and

BP: Biological process; CC: Cellular component; MF: Molecular function.

ALB in both mice (Figure 5). When the permeability of the liver cell membrane changes, ALT overflows from the cells into the bloodstream. Therefore, the increase of serum ALT in Fpr2$^{-/-}$ mice suggest that the stability of liver cell membrane is affected.

Fpr2 regulated the expression of interleukin-10 and CXCL-1

In the GO analysis, in addition to cell cycle, ERK1 and ERK2 cascade, myeloid leukocyte activation, and positive regulation of myeloid leukocyte differentiation were also significantly enriched in BP terms, and G-protein coupled receptor activity was significantly enriched in MF terms. These results prompted us to consider whether disruptions in the cell cycle and cell membrane stability may cause inflammation. The Luminex assay was performed to measure the cytokine levels in the liver. The results indicated that in addition to the increased levels of interferon gamma, the levels of interleukin (IL)-4, IL-6, IL-9, IL-12, IL-17A, IL-22, IL-23, IL-27, monocyte chemoattractant protein (MCP)-1, MCP-3, macrophage inflammatory protein (MIP)-1α, MIP-1β, MIP-2, CXCL10, Eotaxin, and tumor necrosis factor-α were decreased at different degrees in the Fpr2$^{-/-}$ mice (Figure 6). The decreases in IL-10, IL-18, and CXCL-1 levels were statistically significant.

Based on the above results, the inflammatory status of the liver was further evaluated. We measured the C-reactive protein (CRP) levels in the peripheral blood and the number of neutrophils in the liver and performed histopathological analysis of the liver. The results showed that there was no significant difference in the CRP levels and the number of neutrophils in the liver between WT and Fpr2 $^{-/-}$ mice (Figures 7A and B), and there was no inflammatory cell infiltration in the histopathology of the liver (Figure 7C). The above results indicate that although the absence of Fpr2 can affect the cell cycle and membrane stability, it does not cause significant inflammation in the liver.

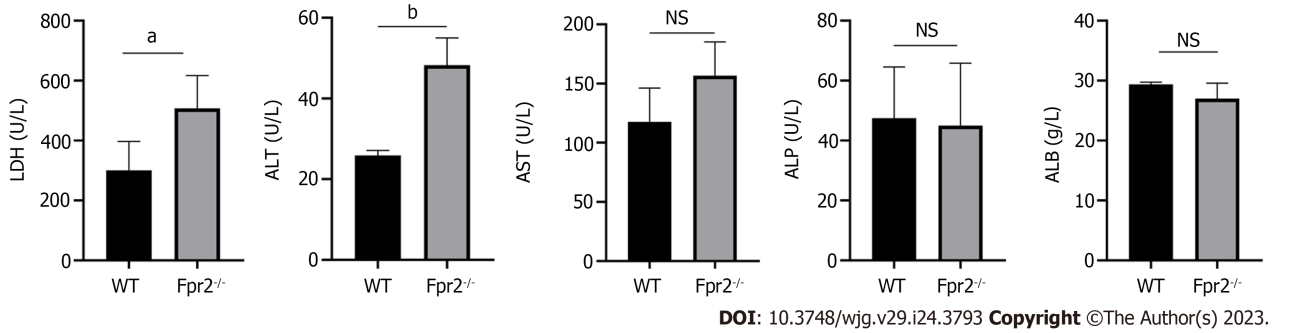
DISCUSSION

In this study, we focused on the effects of Fpr2 on liver homeostasis in mice. According to the results of RNA-sequencing, the deletion of Fpr2 mainly affects the cell cycle of the liver, which is clearly manifested by the significant changes in the expression of several key genes during cell division and enrichment of several related pathways of the cell cycle. The influence of Fpr2 deletion on the cell cycle may be multifaceted. From the perspective of function, DEGs contain many key genes in each stage of the cell cycle (*CycA*, *CycB*, *Cdk1*) and important cell cycle regulatory genes (*Cdc25*, *Cdc20*). In terms of distribution, DEGs are distributed in processes related to spindles, chromatin, and kinetochores. Cdk1 is essential for G1/S and G2/M phase transitions of eukaryotic cell cycle[13]. In $Fpr2^{-/-}$ mice, the expression level of Cdk1 is decreased. When FPR2 of HepG2 cells is blocked by WRW4, the cell proliferation activity decreased, the number of cells in G0/G1 phase increased, and the number of cells in S phase decreased, which indicates that FPR2 can affect cell proliferation by blocking cell cycle.



Most research on FPR2 has focused on its role in the regulation of immune cells in inflammation. Recently, it has also been reported that FPR2 is involved in regulating the migration and proliferation of many types of stem cells. Han *et al*[14] found that the proliferation of hair follicle stem cells and dermal papilla cells in $Fpr2^{-/-}$ mice was significantly reduced, which induced hair loss. Chen *et al*[15] found that $Fpr2^{-/-}$ mice displayed shortened colonic crypts and reduced acute inflammatory responses. This is because intestinal commensal bacteria mediate the proliferation and renewal of epithelial cells through Fpr2. In the present study, we found that the absence of this receptor in liver cells caused abnormal cell cycle. These findings provide evidence for the new function of Fpr2.

Although we found that Fpr2 deficiency can lead to abnormal liver cell cycle and membrane permeability, the infiltration of inflammatory cells in the liver was not observed when probed further. This is consistent with the fact that mice can still grow and reproduce normally with Fpr2 deficiency and do not die due to infection. Therefore, we speculate that these abnormal manifestations after Fpr2 deficiency may be offset by certain protective factors in the body. However, based on our previous research[12], the ability of $Fpr2^{-/-}$ mice to control infection was significantly lower than that of WT mice in the event of bacterial infections, with the liver becoming a severely damaged target organ. Therefore, our current findings may provide an explanation that the imbalance of cellular homeostasis caused by Fpr2 deficiency leads to insufficient defense function of the liver when encountering bacterial infections, making it a target organ for infection damage.

Data are expressed as mean ± SD. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$ *vs* the wild-type group; NS: No significant; CXCL: Chemokine (C-X-C motif) ligand; IFN-γ: Interferon gamma; IL: Interleukin; MCP: Monocyte chemoattractant protein; MIP: Macrophage inflammatory protein; TNF: Tumor necrosis factor; Fpr2: Formyl peptide receptor 2; WT: Wild-type.

homeostatic mechanism that controls the degree and duration of inflammation. IL-10 is an important factor in maintaining immunological tolerance in the liver[16]. IL-10 also plays an important role in liver regeneration and repair[17]. In addition, various cells, such as hepatocytes, endothelial cells, Kupffer cells, and hepatic stellate cells, are involved in the production of IL-10[18]. CXCL-1 is an important chemokine in neutrophils. Our previous research found that the loss of Fpr2 leads to a decrease in the recruitment of neutrophils and weakening of the host's early immune response when resisting infection with *Streptococcus lactis*[12]. Therefore, the decline in repair ability and the decrease in chemotaxis to neutrophils may be another reason why Fpr2$^{-/-}$ mice are seriously injured when infected by bacteria. IL-18 was first discovered in Kupffer cells as a pro-inflammatory factor[19,20]. In Fpr2$^{-/-}$ mice, we observed a decrease in the levels of anti-inflammatory factor IL-10 and pro-inflammatory factor IL-18, and also observed varying degrees of decreases in the levels of other interleukin members, tumor necrosis factors, and chemokines. Considering the cell cycle disruption caused by Fpr2 deficiency, we postulate that the impact of Fpr2 deficiency on cell cycle may interfere with cytokine synthesis, although further validation is needed to test this hypothesis. In short, Fpr2 plays an important role in maintaining liver

homeostasis, which may help the body resist bacterial infections.

Some limitations of this study should be noted. First, we used an immortal liver cell line for our study. Recent studies have reported that mature liver cells located in the middle region of liver lobules are the main contributors to the production of new cells in the entire liver[21,22]. Therefore, it is necessary to further evaluate the regulatory effect of Fpr2 on cell cycle using primary liver cells. Second, further research is required to establish whether Fpr2 regulates cell cycle directly or indirectly.

CONCLUSION

Fpr2 plays an important role in maintaining liver homeostasis by participating in cell cycle regulation. Fpr2 may play a positive role in liver tissue repair and neutrophil chemotaxis by regulating the expression of IL-10 and CXCL-1. Our results provide a basis and novel perspective for further understanding the functional diversity of Fpr2.

ARTICLE HIGHLIGHTS

Research background

Formyl peptide receptor 2 (Fpr2) plays an important role in host's defense and inflammatory response, as it can help the body control bacterial infections. Studies have found that in Fpr2$^{-/-}$ mice, the liver is the most severely damaged target organ in bloodstream infections. However, the reason for this is unclear.

Research motivation

To verify the role of Fpr2 in liver homeostasis, to provide new clues for the decreased ability of the liver to clear bacteria after Fpr2 deficiency, and to provide new ideas for future drug research and development.

Research objectives

To investigate the role of Fpr2 in liver homeostasis.

Research methods

The differentially expressed genes (DEGs) in Fpr2$^{-/-}$ and wild-type (WT) mice were determined by transcriptome sequencing, and the biological functions of DEGs were analyzed by Gene Ontology (GO)

and Kyoto Encyclopedia of Genes and Genomes (KEGG) enrichment analysis. Quantitative real-time polymerase chain reaction (qRT PCR) and western blot (WB) were used to further validate the expression levels of differential genes. The Cell Counting Kit-8 assay was used to study cell proliferation. A cell cycle detection kit was used to measure the distribution of cell cycles. Luminex assay was used to analyze cytokine levels in the liver. A fully automated biochemical analyzer was used to detect the levels of serum biochemical indicators and C-reactive protein in WT and Fpr2$^{-/-}$ mice. The number of neutrophils in the liver was detected by flow cytometry. The histopathology of the liver was analyzed by hematoxylin-eosin staining.

Research results

Transcriptome sequencing showed that, compared with WT group, 445 genes in the liver of Fpr2$^{-/-}$ mice had significant changes in the expression level, including 325 upregulated genes and 120 downregulated genes. The functional enrichment analysis of GO and KEGG indicated that these DEGs were mainly related to cell cycle. qRT-PCR validated that after Fpr2 deletion, the expression levels of *CycA*, *CycB1*, *Cdc20*, and *Cdc25c* genes were upregulated. Both qRT-PCR and WB confirmed a decrease in the expression of CDK1. WRW4 (an antagonist of Fpr2) could inhibit the proliferation of HepG2 cells in a concentration dependent manner. The levels of serum alanine aminotransferase levels increased in Fpr2$^{-/-}$ mice with statistical significance. Luminex assay measurements showed that the expression levels of interleukin (IL)-10, IL-18, and CXCL-1 were significantly reduced in the liver of Fpr2$^{-/-}$ mice.

Research conclusions

Fpr2 may exert a protective effect on the liver by participating in the regulation of cell cycle and proliferation, as well as affecting the expression of IL-10 and CXCL-1.

Research perspectives

Fpr2 plays an important role in maintaining liver homeostasis, and its agonist may be a potential drug against bacterial infection.

Abstract

BACKGROUND

Signet-ring cell carcinoma (SRCC) was previously thought to have a worse prognosis than other differentiated gastric cancer (GC), however, recent studies have shown that the prognosis of SRCC is related to pathological type. We hypothesize that patients with SRCC and with different SRCC pathological components have different probability of lymph node metastasis (LNM).

AIM

To establish models to predict LNM in early GC (EGC), including early gastric SRCC.

METHODS

Clinical data from EGC patients who had undergone gastrectomy at the First Affiliated Hospital of Nanjing Medical University from January 2012 to March 2022 were reviewed. The patients were divided into three groups based on type: Pure SRCC, mixed SRCC, and non-signet ring cell carcinoma (NSRC). The risk factors were identified through statistical tests using SPSS 23.0, R, and EmpowerStats software.

RESULTS

A total of 1922 subjects with EGC were enrolled in this study, and included 249 SRCC patients and 1673 NSRC patients, while 278 of the patients (14.46%) presented with LNM. Multivariable analysis showed that gender, tumor size,

depth of invasion, lymphovascular invasion, ulceration, and histological subtype were independent risk factors for LNM in EGC. Establishment and analysis using prediction models of EGC showed that the artificial neural network model was better than the logistic regression model in terms of sensitivity and accuracy (98.0% *vs* 58.1%, $P = 0.034$; 88.4% *vs* 86.8%, $P < 0.001$, respectively). Among the 249 SRCC patients, LNM was more common in mixed (35.06%) rather than in pure SRCC (8.42%, $P < 0.001$). The area under the ROC curve of the logistic regression model for LNM in SRCC was 0.760 (95%CI: 0.682-0.843), while the area under the operating characteristic curve of the internal validation set was 0.734 (95%CI: 0.643-0.826). The subgroups analysis of pure types showed that LNM was more common in patients with a tumor size > 2 cm (OR = 5.422, $P = 0.038$).

CONCLUSION

A validated prediction model was developed to recognize the risk of LNM in EGC and early gastric SRCC, which can aid in pre-surgical decision making of the best method of treatment for patients.

Core Tip: By establishing and comparing prediction models of lymph node metastasis (LNM) in early gastric cancer, we found that artificial neural network model was better than logistic regression model in sensitivity and accuracy. Among 249 signet-ring cell carcinoma (SRCC) patients, LNM was more common in mixed than in pure SRCC. A validated prediction model was also developed to recognize the risk for LNM in early gastric SRCC, which can be used to help make decisions regarding treatment of patients before performing surgery.

INTRODUCTION

According to the latest global cancer statistics, gastric cancer is considered to be the fifth leading type of cancer and the fourth leading cause of cancer-related deaths worldwide[1]. However, the progression of diagnostic methods has led to early gastric cancer (EGC) being more easily detectable[2]. Our previous study revealed that the rate of EGC diagnosis was 10.0%, while the rate of lymph node metastasis (LNM) in EGC was 12.3%[3]. EGC can be treated using surgical therapy with a 5-year survival rate of 80%-100%[4], and can also be resected *via* endoscopic resection, which is recommended as an effective method of treatment for EGC. Endoscopic submucosal dissection (ESD) can effectively improve the prognosis of patients[5]. Clinical decision of endoscopic *vs* surgical resection for EGC relies on the accurate assessment of the risk of LNM[6]. LNM mainly depends on tumor size, depth of invasion, and histological type[7].

Signet ring cell carcinoma (SRCC) is a common histological type with dismal prognosis[8] that predominantly consists of cells with poor cohesiveness with the predominance of cells in the signet ring. Among gastric cancer cases, the incidence of SRCC has increased and is reported to vary from 8.7% to 23.4%[9-11], while the behavior of SRCC in gastric cancer is controversial. In advanced gastric cancer, SRCC is considered to be a more severe invasive type with a higher level of peritoneal dissemination and a similar or worse prognosis than non-signet ring cell carcinoma (NSRC)[5,12,13]. However, it has been reported that the behavior of early SRCC may be equivalent to, or more favorable than other types of EGC due to its lower probability of LNM[14,15], suggesting that less invasive surgery is suitable. In addition, only few reports have been published on risk factors for LNM in early SRCC and the clinicopathological differences between pure and mixed SRCC.

Therefore, the objectives of this research study were to: (1) To identify the factors that can predict LNM in EGC to establish suitable models; and (2) to investigate the differences between pure and mixed SRCC to identify factors that can predict LNM in EGC with a signet-ring cell histology.

MATERIALS AND METHODS

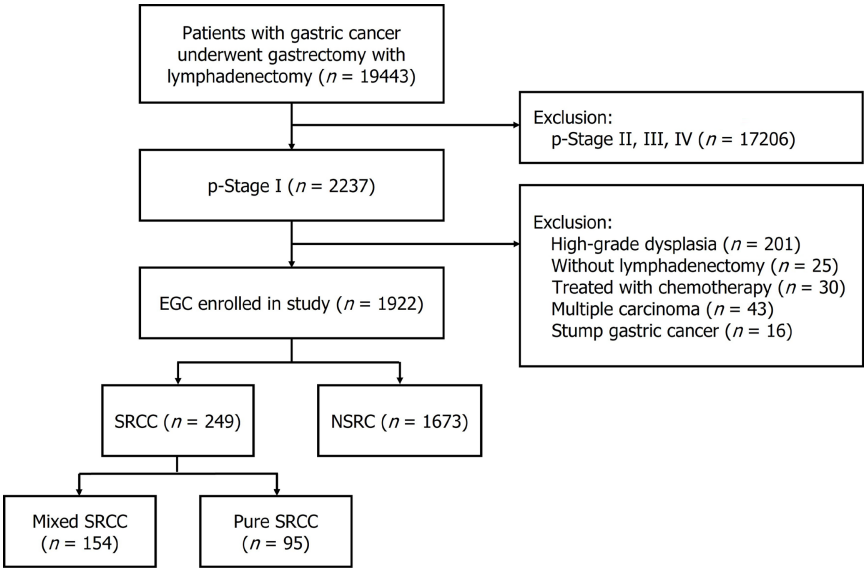
Patients

We examined the retrospective clinical information of patients who had undergone surgery at the First Affiliated Hospital of Nanjing Medical University, Nanjing, China, from January 2012 to March 2022. A total of 1922 patients were enrolled. The eligibility criteria used is illustrated in the flow diagram shown in Figure 1. Standard gastrectomy was the principal surgical procedure performed with a curative intent. Only patients who did not receive preoperative therapy were included in the study. The exclusion criteria were as follows: (1) pT2-4 gastric cancer identified using histopathological examination after radical gastrectomy; (2) high-grade dysplasia of the gastric mucosa; (3) a lack of lymphadenectomy; (4) cancer treated using neoadjuvant chemotherapy, (5) multiple gastric cancers; and (6) stump gastric cancer.

Gross and histopathological evaluation

All resected tumors samples made into 2-mm-thick slices, stained with hematoxylin and eosin (H&E) and immunohistochemical staining, and assessed by qualified pathologists at the institution using World Health Organization (WHO) diagnostic criteria. Based on this, the patients were divided into 3 groups: (1) Pure SRCC (p-SRCC), which is defined as having a predominant component (> 50%) isolated carcinoma cells containing intracytoplasmic mucin16; (2) mixed SRCC (m-SRCC), which is defined as adenocarcinoma with a minor component (10-50%) of isolated carcinoma cells containing intracytoplasmic mucin; and (3) NSRC. Identification of risk factors associated with LNM in patients with EGC were conducted by comparing the clinicopathological characteristics of the patients and the gross findings of cancer lesions, including the age and gender, tumor size, location and macroscopic type, lymphovascular invasion (LVI), LNM, depth of invasion, perineural invasion, histological type, and ulceration during surgery. The patients were also divided into 5 macroscopic type groups: Protruded (I), elevate (IIa), flat (IIb), depressed (IIc), and excavated (III). As for the location of lesion, we divided the stomach into five sections: cardia, fundus, body, antrum, and angle.

LNM was determined based on the indications for ESD recommended by the Japanese Gastric Cancer Association. Based on the guidelines for ESD and endoscopic mucosal resection for EGC (2nd edition) [16], the absolute indications for endoscopic treatment are as follows: (1) Differentiated intramucosal carcinoma with a maximum diameter of ≤ 2 cm and without ulcerative lesions; (2) differentiated intramucosal carcinoma with a maximum diameter of > 2 cm and without ulcerative lesions; (3) cT1a with a diameter of ≤ 3 cm and ulceration [UL (+)]; and (4) undifferentiated intramucosal carcinoma with a maximum diameter of ≤ 2 cm and without ulcerative lesions. The terminology used in this study is based on the Japanese classification of gastric carcinoma.



Development of a predictive model for LNM

Variables that are significantly associated with LNM ($P < 0.05$) were identified as candidate variables for the artificial neural network (ANN) model and multivariate logistic regression (LR). A random sample of 75% of all EGC patients were assigned to the training set, while the remaining 25% were used as internal validation of the LR model. The cut-off value was determined using ROC curves, which were then used to evaluate the discriminatory ability of the model. Then, a backward step-down selection process, with a maximum threshold of $P < 0.05$, was used for the final LR model selection of the nomogram. Bootstrapping using 2000 replications was conducted for internal validation.

In the ANN model, a total of 13 neural nodes were used as input layers. There were five neural nodes in the hidden layer, while the hyperbolic tangent transfer function was adopted. Two of the neural nodes in the output layer were LNM or not. The softmax transfer function was used as the transfer function. All samples were randomly assigned to the training group and the verification group at a ratio of 7:3. The training group was used to train the neural network. The verification group was used to evaluate the final neural network, and to construct the topological hierarchical structure of the neural network model. The final neural network fitting results were represented using the normalized importance percentage graph and a bar diagram was drawn. Finally, the area under the operating characteristic curve (AUC) of the recipients of the two models were calculated to compare and evaluate diagnostic accuracy using the chi-square test.

Statistical analysis

Continuous variables were converted to binary variables, and the cut-off point of age was determined by maximizing the sum of sensitivity and specificity after spline smoothing, which was found to be 65 years. Categorical variables are displayed as a percentage. Univariable analysis was performed to identify risk factors associated with LNM using various statistical tests, including the student *t*-test, Chi-square test, or the Fisher exact test. Multivariable analysis only included variables with a $P < 0.05$ in the univariate analysis. The results are shown as an odds ratio (OR), 95% confidence interval (CI), and a *P* value. The multivariate LR model was used to identify independent factors associated with LNM. Calibration of the model was assessed using the Hosmer-Lemeshow nomogram and ROC curve goodness-of-fit test. R (http://www.R-project.org) and EmpowerStats software (www.em-

powerstats.com, X&Y solutions, Inc. Boston, MA, United States) was used to determine the nomogram and ROC curve. The ANN model and further statistical analyses were performed using IBM SPSS Statistics for Windows v.23.0 software. A P value of < 0.05 was used to indicate statistical significance.

RESULTS

Clinicopathological features of patients with EGC

Among the 1922 patients enrolled, 249 patients were with SRCC and 1673 patients were with NSRC, and their outcomes are reported in Figure 1. The clinicopathological characteristics of SRCC and NSRC are described in Table 1. For patients with SRCC, the mean age was 53.14 ± 10.03, the male-to-female ratio was 1.15:1 (133/116), and the mean lesion size was 2.14 ± 1.43 cm. For patients with NSRC, the mean age was 57.01 ± 11.78, the male-to-female ratio was 2.85:1 (1238/435), and the mean lesion size was 1.89 ± 1.22 cm. When the patients were divided into five groups based on location, a majority of the EGCs were found to be in the gastric antrum and angle (n = 1189, 61.86%). There was a significant difference in SRCC and NSRC (P < 0.001) based on location. Most tumors were depressed (IIc), followed by flat (IIb) and elevated (IIa), protruded and excavated, which were in the minority, but no statistical significance was found based on macroscopic type between SRCC and NSRC (P = 0.105). Mucosa invasion occurred in 59.84% of (n = 149) SRCC, while submucosa invasion was observed more often in NSRC (n = 865, 51.70%). LVI was identified in 136 patients, among which 18 were diagnosed with SRCC and 118 were NSRC. LNM was identified in 278 patients, in which 62 were SRCC patients and 216 were NSRC patients. A total of 22 EGCs occurred with perineural invasion, of which 7 were SRCC and 15 were NSRC. Ulceration was identified in 701 patients, in which 74 (29.72%) were diagnosed with SRCC and 627 (37.48%) with NSRC. Overall, these results showed significant differences in age, gender, tumor size, LNM, depth of invasion, perineural invasion, tumor location, and ulceration between SRCC and NSRC.

Risk factors of LNM in EGC as shown through the univariate and multivariate analyses

In the univariate analysis, LNM was significantly associated with age (P = 0.015), gender (P < 0.001), tumor size (P < 0.001), macroscopic type (P = 0.008), depth of invasion (P < 0.001), LVI (P < 0.001), perineural invasion (P < 0.001), tumor location (P = 0.001), ulceration (P < 0.001) and histological subtype (P < 0.001). The multivariable analysis showed that being female (OR = 1.912, P < 0.001), tumor size (> 2 cm) (OR = 1.875, P = 0.001), submucosal invasion (OR = 3.340, P < 0.001), LVI (OR = 6.682, P < 0.001), the presence of ulcers (OR = 1.695, P = 0.001), and the pathological pattern of mixed SRCC (OR = 4.595, P < 0.001) were independent predictors of LNM in EGC (Table 2).

Comparison of clinical models of LNM in EGC

The LR model nomogram revealed that LVI had the greatest impact on scoring, followed by histological subtype and depth of invasion. The effects of gender, tumor size, and ulceration on model performance

SRCC: Signet-ring cell carcinoma; NSRC: Non-signet ring cell carcinoma; M: Mucosal; SM: Submucosal; LVI: Lymphovascular invasion; LNM: Lymph

node metastasis; UL (-): Ulcer or ulcer scar is absent; UL (+): Ulcer or ulcer scar is present.

were also significant. Each level of the variable was summed using the total score based on the point scale and was positioned on the total score scale to determine the corresponding LNM probability for each patient (Figure 2). This predictive model demonstrated that the AUC was 0.797 with 95%CI: 0.776-0.818. Following 2000 bootstrap repetitions, the AUC of the internal validation in the training set was 0.816 (95%CI: 0.794-0.839).

We also established an ANN model and assessed its ability by comparing it with a traditional LR model to predict the risk of LNM in EGC patients (Figure 3) presents the structure of the established ANN model and was influenced by 6 significant predictors: Gender, tumor size, submucosal invasion, LVI, histological type and ulceration, and histological type revealed the greatest impact on scoring, followed by the depth of invasion and LVI, while ulceration accounted for the least but still exerted a significant effect. The predictive model demonstrated an AUC of 0.878 with a 95%CI of 0.862-0.893.

In addition, differences between ANN and the multivariate LR model were further compared based on sensitivity, specificity, positive predictive value, negative predictive value, accuracy, and AUC according to the actual rate of LNM confirmed pathologically. Table 3 shows the classification distribution of the two models. The sensitivity and accuracy of the ANN model (96.4% *vs* 58.3%, $P = 0.034$, 88.2% *vs* 86.7%, $P < 0.001$) and the AUC (0.878 *vs* 0.797, $P < 0.001$; 0.899 *vs* 0.816, $P < 0.001$; respectively) were better than that of the multivariate LR model in the training and validation sets (Figure 4). The specificity (88.0% *vs* 88.8%, $P < 0.001$) and positive predictive value (19.4% *vs* 27.7%, $P < 0.001$) was inferior to that of the multivariate LR model. There was no difference in the negative predictive value between the two groups (99.9% *vs* 96.7%, $P = 0.202$). The comparisons of the diagnostic assessment are listed in Table 4.

Comparison of the clinicopathological features of pure SRCC and mixed SRCC

As shown in Table 5, differences in the clinicopathological characteristics between pure SRCC (p-SRCC) and mixed SRCC (m-SRCC) patients were significant based on the following factors: (1) Age was younger in the p-SRCC (73.68%) patients than in the m-SRCC (59.09%) group ($P = 0.037$); (2) m-SRCC patients were more likely to show invasion into the SM layer, compared with p-SRCC (49.35% *vs* 25.26%, $P < 0.001$); (3) LVI resulted in a significantly higher proportion of cases in the m-SRCC (11.69% *vs* 0.00%, $P = 0.002$) group; (4) LNM was much more frequent in the m-SRCC group (35.06% *vs* 8.42%, $P < 0.001$) than in the p-SRCC group. We also found that ulcers were more likely to be present in the m-SRCC group than in the p-SRCC group, although the difference was no statistically significant. There were no significant differences in the other characteristics between the p-SRCC and m-SRCC groups.

Risk factors for LNM in early SRCC as shown by the univariate and multivariate analyses

The univariate analyses demonstrated that the depth of invasion (M and SM), histological type and LVI differed significantly between patients with and without LNM in early SRCC patients. More frequent ulceration was observed in LNM positive SRCC patients, although the difference was not statistically significant. Based on the stepwise multivariate analysis, the significant independent risk factors for LNM in early SRCC were SM invasion (OR = 2.615, $P = 0.008$), LVI (OR = 14.903, $P = 0.001$), and a pathological pattern of mixed SRCC (OR = 1.982, $P = 0.043$). The independent risk factors are listed in Table 6. In addition, we also performed a risk analysis for LNM in SRCC limited to the mucosa and in SRCC with different histological types (p-SRCC and m-SRCC). In SRCC limited to the mucosa (Table 7), histological type ($P = 0.010$) and LVI ($P = 0.016$) were significantly different between patients with and without LNM, and the multivariate analysis showed that the pathological pattern of mixed SRCC (OR = 4.557, $P = 0.023$) was an independent predictor of LNM. In m-SRCC (Table 8), the univariate analyses showed that depth of invasion (M and SM) ($P = 0.004$) and LVI ($P < 0.001$) were risk factors for LNM, and that LVI (OR = 16.173, $P = 0.001$) was a significant independent risk factor for LNM. In p-SRCC, the analyses showed that patients with a tumor size that exceeded 2 cm ($P = 0.014$) and submucosal infiltration ($P=0.045$) were at a greater risk of LNM, indicating that tumor size > 2 cm (OR = 5.422, $P = 0.038$) is a significant independent risk factor for LNM (Table 8).

Clinical model of LNM in early SRCC

A preoperative predictive nomogram containing important risk factors related to early gastric SRCC LNM was constructed based on the LR model. All parameters of the clinicopathological risk factors of LNM in early gastric SRCC in the univariate analysis were included in the multivariable analysis. The nomogram revealed that LVI had the greatest impact on scoring, followed by invasion depth, and histological subtype (Figure 5). The equation stepwise selected prediction model from observed data included total risk points of LNM = -3.24513 + 0.93264*DEPTH + 2.86614*LVI + 0.42064* HISTOLOGICAL. This predictive model demonstrated an area under the curve (AUC) of 0.760 with a 95%CI of 0.682-0.843 (Figure 6A), while the AUC of internal validation was 0.734 (95%CI: 0.643-0.826) (Figure 6B). In the calibration plots, the bias-corrected line was calculated using 2000 bootstrapping

The factors of histological type, gender, tumor size, ulceration, depth of invasion and lymphovascular invasion were included in the model. p-SRCC: Pure signet-ring cell carcinoma; NSRC: Non-signet ring cell carcinoma; m-SRCC: Mixed signet-ring cell carcinoma; M: Mucosal; SM: Submucosal; LVI: Lymphovascular invasion; LNM: Lymph node metastasis.

iterations were indistinguishable and nearly approached the ideal line, while the 95%CI of the prediction model was also relatively accurate (Figure 6C). Therefore, the predictive power of the model was found to be good.

The black and the red curve represent the development data of the artificial neural network and logistic regression model, respectively. A: Comparison of receiver-operating characteristic (ROC) plot in the training set, the area under the curve (AUC) was 0.878 *vs* 0.797, $P < 0.001$; B: Comparison of ROC plot in the validation set, the AUC was 0.899 *vs* 0.816, $P < 0.001$. ROC: Receiver-operating characteristic; AUC: Area under the curve; ANN: Artificial neural network; LR: Logistic regression.

Positive LNM results in early SRCC based on the indications for ESD

In the p-SRCC group, the LNM rate of patients with an expanded indication was 2.44% (1/41), and that of patients out of indication was 12.96% (7/54). In the m-SRCC group, the LNM rate in patients with an expanded indication was 16.13% (5/31), and in patients out of indication was 36.59% (45/123). The LNM rate between the expanded indication and out of indication patients in the m-SRCC group was statistically significantly different ($P = 0.048$), while there was no statistical difference in the p-SRCC group ($P = 0.132$). Among all 228 patients, the LNM rate between the expanded indication (6/72, 8.33%) and the out of indication (52/177, 29.38%) patients was statistically significantly different ($P = 0.001$) (Table 9).

DISCUSSION

As the fifth most common type of cancer worldwide, gastric cancer is a significant threat to human

health. Recently, its incidence (mainly of the intestinal type) has declined in Asia, which may be associated with an increase in focus on and treatment using Helicobacter pylori in Asia. However, the incidence of SRCC is rising and needs more attention. The biological behavior of a case is very important when assessing whether ESD is feasible or not. However, the characteristics of early gastric SRCC, including LNM, clinicopathological features and prognosis, are still disputable[9,10,12].

Figure 5 Nomogram for predicting lymph node metastasis in early signet-ring cell carcinoma patients. The factors of histological type, depth of invasion and lymphovascular invasion were included in the model. M: Mucosal; SM: Submucosal; LVI: Lymphovascular invasion; p-SRCC: Pure signet-ring cell carcinoma; m-SRCC: Mixed signet-ring cell carcinoma; LNM: Lymph node metastasis.

Numerous reports have identified SRCC as an independent predictor of poor prognosis due to its specific characteristics, such as the high incidence of LNM, as well as the high rate of peritoneal carcinomatosis[17,18], and low sensitivity to chemotherapy[19], especially as the vast majority of these tumors are diagnosed at an advanced stage. Several studies have reported that tumors with a diameter > 2 cm, submucous infiltration, and lymphatic vascular infiltration are risk factors and independent risk factors for LNM in early gastric SRCC[19]. Huh *et al*[11] and Japanese Gastric Cancer Association[20] showed that the LNM rate was higher in early mixed SRCC than in early pure SRCC, and that mixed SRCC was more aggressive than pure SRCC. To reach an agreement on the treatment options for EGC and early gastric SRCC, these aspects need to be further explored.

A previous study found that being male, age, depressed type, submucosal invasion, LVI, and tumor location were independent risk factors for LNM in EGC[3]. Oh *et al*[21] demonstrated that in patients with EGC without LVI, a tumor size of > 3 cm, submucosal invasion, and undifferentiated histological type were significant risk factors for LNM. In our research study, the incidence of LNM was 14.46%, which is similar to that of previous studies[9,10,13,22-24], and we found that patients of EGC in younger (≤ 60), female, tumor size >2cm, with elevated macroscopic type, submucosal invasion, LVI, perineural invasion, tumor located in the gastric antrum and angle, ulceration, and a pathological pattern of mixed SRCC are more likely to have LNM, and all factors were statistically different. In the multivariate

Figure 6 Assessment of the nomogram for predicting lymph node metastasis in the training set and validation set. A: Receiver-operating characteristic receiver-operating characteristic (ROC) plot in the training set. The area under the curve (AUC) of the ROC was 0.760 (95%CI: 0.682-0.843); B: ROC plot in the validation set. The AUC of the ROC was 0.734 (95%CI: 0.643-0.826); C: Calibration plot in the training set. After 2000 repetitions, the bootstrap-corrected calibration curve (black line) lay close to the ideal reference line (red line), which demonstrated a perfect agreement between the predicted and actual outcomes (mean absolute error 0.012).

analysis, being female, tumor size of > 2 cm, with submucosal invasion, LVI, ulceration, and mixed SRCC were independent predictors of LNM in EGC.

Since SRCC shows different clinicopathological and biological characteristics, compared to NSRC, there are only a few studies that have previously reported on it. Therefore, we analyzed the clinicopathological and biological characteristics of SRCC, including pure-SRCC, mixed-SRCC, and SRCC limited to the mucosa in our research. By comparing the clinicopathological features of patients with NSRC and SRCC, we observed that patients with SRCC were of a younger age, were usually female, and showed fewer lesions in the upper section of the stomach with remarkable statistics differences. With respect to the risk factors for LNM in SRCC, our findings demonstrated that patients with a mixed type, submucosal invasion, and higher LVI are more likely to experience LNM. At the same time, we found that the mixed type was the only independent risk factor for LNM in patients with SRCC limited to the mucosa, which is consistent with the multivariable analysis of LNM in patients with mixed SRCC. In addition, the LNM rate in m-SRCC patients with an expanded ESD indication had a higher LNM rate than p-SRCC patients, and the difference was statistically significant. Therefore, for early gastric m-SRCC patients, caution should be exercised when selecting ESD treatment when the lesion exceeds the mucosal layer. For early gastric m-SRCC patients, a tumor size of > 2 cm was independent risk factor for LNM.

At present the predictive probability of LNM has not been clearly defined, and the clinical diagnosis of gastric LNM in EGC is still challenging. Quantitative predictive models are beneficial for both clinicians and patients in making more objective decisions regarding treatment options. The optimal threshold depends on the extent to which the patient or clinician rejects the risk. It is widely known that LR is a simple machine learning algorithm used for binary classification tasks. Neural networks are similar to a LR and can be referred to as a generalized LR. The neural network has advantages over LR models: the hidden layers facilitate the discovery of more complex and non-linear associations of variables. In our research study, we established two models: the ANN and LR model (nomogram) of LNM in EGC, and the LR model (nomogram) of LNM in early gastric SRCC patients. The ANN model and LR model both showed satisfactory performance through internal cross-validation. The methods of assessing diagnostic test accuracy were further used for model comparison. Then, we found that the ANN model of LNM in EGC performed better than the LR model with a significantly higher level of sensitivity, accuracy, and AUC. There were also some differences in the proportion of each risk factor in these two models of EGC. In the nomogram, LVI was dominant, and it was assigned 100 points; while in the ANN, the histological subtype was the most important risk factor, and it was assigned 100%. In addition, we established a nomogram of LNM in early gastric SRCC. In the nomogram, LVI was assigned 100 points; while, submucosal invasion was assigned 32.5 points, and mixed type SRCC was assigned 15 points. The potential of LNM gradually increased along with point accumulation. Our nomogram could predict the potential of LNM in every individual patient, which may help clinicians make informed and customized decisions that guide clinical treatment. Since only a few independent risk factors of LNM were obtained from the multivariate analysis, the ANN model cannot be further established in SRCC patients.

Our ANN and nomogram may serve as effective tools for predicting the incidence of LNM in Chinese patients with EGC, including early gastric SRCC, which may lead to improved selection of appropriate treatments methods. However, there are still several limitations in our study. Firstly, we utilized single-center, retrospective data to build and validate the predictive model. Secondly, we confirmed the

predictability of the model only using internal validation. However, it is necessary to conduct external validation to demonstrate the accuracy of these models. Thirdly, only a limited number of participants were included in this study, which may lead to a statistical analysis bias. Finally, we did not develop a specific cut-off value for LNM for each of the different methods of treatment available for patients with EGC or early gastric SRCC. Hence, further multicenter, large-sample clinical studies that can help establish additional risk factors for LNM in EGC or early gastric SRCC are still necessary.

CONCLUSION

In conclusion, we constructed an ANN model and a nomogram to predict the probability of LNM in patients with EGC. The ANN model was better than the LR model nomogram in terms of sensitivity and accuracy. We constructed a nomogram for LNM in SRCC as well. These models can be used not only for preoperative evaluation to determine whether standard radical gastrectomy is needed for patients with EGC or early gastric SRCC patients at a high risk of LNM, but also for intraoperative evaluation to determine whether radical lymphadenectomy is necessary.

ARTICLE HIGHLIGHTS

Research background

Signet-ring cell carcinoma (SRCC) has shown discriminative biological characteristics compared with adenocarcinoma, and the behavior of SRCC in gastric cancer is controversial. In this study, we recognize the risk of lymph node metastasis (LNM) in early gastric SRCC, which can aid in pre-surgical decision making of the best method of treatment for patients.

Research motivation

At present the predictive probability of LNM has not been clearly defined, and the clinical diagnosis of gastric LNM in early gastric cancer (EGC) and early gastric SRCC is still challenging. Quantitative predictive models are beneficial for both clinicians and patients in making more objective decisions regarding treatment options.

Research objectives

We aimed to establish models to predict LNM in EGC, including early gastric SRCC, which can aid in pre-surgical decision making of the best method of treatment for patients.

Research methods

We examined the retrospective large-sample clinical information of patients who had undergone surgery, by comparing the clinicopathological features of patients with non-signet ring cell carcinoma and SRCC. Variables that are significantly associated with LNM were identified as candidate variables for the artificial neural network (ANN) model and multivariate logistic regression.

Research results

Our ANN and nomogram may serve as effective tools for predicting the incidence of LNM in Chinese patients with EGC, including early gastric SRCC, which may lead to improved selection of appropriate treatments methods.

Research conclusions

With respect to the risk factors for LNM in SRCC, our findings demonstrated that patients with a mixed type, submucosal invasion, and higher LVI are more likely to experience LNM. At the same time, we found that the mixed type was the only independent risk factor for LNM in patients with SRCC limited to the mucosa, which is consistent with the multivariable analysis of LNM in patients with mixed SRCC.

Research perspectives

Further multicenter, large-sample clinical and randomized controlled studies that can help establish additional risk factors for LNM in EGC or early gastric SRCC are still necessary.

Abstract

BACKGROUND

Incidence of cholangiocarcinoma (CCA) is rising, with overall prognosis remaining very poor. Reasons for the high mortality of CCA include its late presentation in most patients, when curative options are no longer feasible, and poor response to systemic therapies for advanced disease. Late presentation presents a large barrier to improving outcomes and is often associated with diagnosis *via* mergency presentation (EP). Earlier diagnoses may be made by Two Week Wait (TWW) referrals through General practitioner (GP). We hypothesise that TWW referrals and EP routes to diagnosis differ across regions in England.

AIM

To investigate routes to diagnosis of CCA over time, regional variation and influencing factors.

METHODS

We linked patient records from the National Cancer Registration Dataset to Hospital Episode Statistics, Cancer Waiting Times and Cancer Screening Programme datasets to define routes to diagnosis and certain patient character-

istics for patients diagnosed 2006-2017 in England. We used linear probability models to investigate geographic variation by assessing the proportions of patients diagnosed *via* TWW referral or EP across Cancer Alliances in England, adjusting for potential confounders. Correlation between the proportion of people diagnosed by TWW referral and EP was investigated with Spearman's correlation coefficient.

RESULTS

Of 23632 patients diagnosed between 2006-2017 in England, the most common route to diagnosis was EP (49.6%). Non-TWW GP referrals accounted for 20.5% of diagnosis routes, 13.8% were diagnosed by TWW referral, and the remainder 16.2% were diagnosed *via* an 'other' or Unknown route. The proportion diagnosed *via* a TWW referral doubled between 2006-2017 rising from 9.9% to 19.8%, conversely EP diagnosis route declined, falling from 51.3% to 46.0%. Statistically significant variation in both the TWW referral and EP proportions was found across Cancer Alliances. Age, presence of comorbidity and underlying liver disease were independently associated with both a lower proportion of patients diagnosed *via* TWW referral, and a higher proportion diagnosed by EP after adjusting for other potential confounders.

CONCLUSION

There is significant geographic and socio-demographic variation in routes to diagnosis of CCA in England. Knowledge sharing of best practice may improve diagnostic pathways and reduce unwarranted variation.

Key Words: Cholangiocarcinoma; Route to diagnosis; Two Week Wait; Emergency presentation; Regional variation

Core Tip: We investigated changes to routes to diagnosis for cholangiocarcinoma patients across England's 21 regional Cancer Alliances over a 12-year period, and factors associated with differences. We found almost half (49.6%) of 23632 patients in the study were diagnosed *via* emergency presentation, a route associated with late presentation, advanced disease and poorer outcomes. Those diagnosed by Two Week Wait referral through a primary care doctor, where earlier diagnoses are possible, increased from 9.8-19.8% from 2006-2017, still considered low. Significant regional variation was found, alongside the discovery that age, comorbidities and underlying liver disease had independent associations with their routes to diagnosis.

INTRODUCTION

Cholangiocarcinoma (CCA) comprise a group of malignancies arising from the epithelium of the biliary tree within or outside the hepatic parenchyma. Globally CCA are the commonest biliary malignancy, and those arising within the liver parenchyma are the second most common primary hepatic malignancy[1]. CCA are sub-classified depending on their anatomical location within the biliary tree. Intrahepatic CCA (iCCA) arise within the hepatic parenchyma itself, anatomically above the second-order bile ducts. Extrahepatic CCA (eCCA) arise more distally and are further sub-divided into perihilar CCA and distal CCA, with the latter originating between the cystic duct and ampulla of Vater[1,2].

Studies over the past few decades have consistently reported an increasing incidence in CCA globally. These studies have utilised both international and national datasets, including data collections available through the World Health Organisation, United States cancer registries, and European cancer registries[3-6]. These studies indicate a long-running increase in the global incidence of CCA, together with a general trend of rising iCCA mortality rates but stable or decreasing eCCA mortality. The reasons for these trends remain unclear. The overall prognosis for all CCA is poor, with a 5-year overall survival of less than 10%[1]. Reasons for the high mortality of CCA include its late presentation in most patients, when the only curative option, surgery, is no longer feasible, and poor response to systemic therapies

for advanced disease[2]. Late presentation therefore presents a large barrier to preserving effective/curative treatment options and improving outcomes. Overcoming late presentation is difficult due to: The disease's largely sporadic nature, wherein most patients have no known pre-existing risk factors; a lack of effective diagnostic screening tools and an asymptomatic early disease phase. Late presentation is therefore often associated with diagnosis *via* an emergency route. It is well recognised the cancers with high rates of emergency presentation (EP) are associated with poorer outcomes[7]. This is one of the reasons behind the creation of the United Kingdom's National Health Service Urgent Two Week Waitreferral system (TWW), whereby a primary care doctor (General practitioner, GP) can ask the hospital for an urgent appointment to investigate for the presence of cancer, depending on specified symptom and laboratory test criteria. However the role of the TWW referral system toward achieving earlier diagnosis and therefore better outcomes may be limited for cancers such as CCA that are characterised by vague and non-specific symptoms that fall outside of specified referral criteria, which has led to the recent roll out of rapid diagnostic centres to provide a way for GPs to directly request diagnostic investigations of such symptoms[8,9]. Variation in the rates of TWW referrals and EP has been shown across English regions for all cancers[10]. We hypothesise that TWW referrals and EP for CCA differ across regions in England. To our knowledge there are no published studies analysing the pattern of routes to diagnosis for CCA. The aims of this study were to examine routes to diagnosis for CCA at a national level in England, to ascertain if these have changed over time and if regional variations exist and to determine which factors might influence any variation.

MATERIALS AND METHODS

Data used were obtained from the National Cancer Registration Dataset (NCRD) [AV2018][11]. Linked patient records from Hospital Episode Statistics (HES), Cancer Waiting Times and Cancer Screening Programme datasets were used to define Routes to Diagnosis and certain patient characteristics[12]. A CCA cohort was defined based upon the topographical and histological International Classification of Disease (ICD) codes to define the following tumours: Intrahepatic iCCA ICD10 C22.1; eCCA ICD10 C24.0; other CCA ICD10 C220, C222, C223, C224, C227, C229 with ICD-O2 8160 and ICD10 C248-249 (Table 1). Malignant neoplasm of liver and intrahepatic bile ducts ICD10 C220, C222, C223, C224, C227, C229 with an ICD-O2 8160 morphology were included in the study to capture CCA tumours which may have been miscoded. Patients were selected if residents in England and diagnosed between 2006 and 2017. For patients with multiple CCA diagnoses during this period, the first registered tumour was selected. Further inclusion criteria recorded were male or female gender, and age at diagnosis between 0 and 200 years following the National Cancer Registration and Analysis Service's Standard Operating Procedure[13].

Geographic variation in routes to diagnosis was analysed at the Cancer Alliance level according to 21 regions defined in 2020 for England[14]. The Cancer Alliance for each patient was assigned according to the main residence of the patient on the date of diagnosis. Patient characteristics identified a priori as possible confounding variables were: Gender (male/female); age at diagnosis (0-44/45-54/55-64/65-74/75-84/85+ years); income deprivation (quintiles)[15]; year of diagnosis; tumour sub-type (iCCA/eCCA/other); tumour morphology (adenocarcinoma/other); Charlson Comorbidity Index (CCI) (score 0/1/2/ > 2)[16]; underlying liver disease (yes/no)[17]. Underlying liver disease was identified by searching diagnostic codes in HES Admitted Patient Care (APC) episodes from 5 years before to 1 year after diagnosis indictive of chronic hepatitis C or B virus, primary biliary cholangitis, autoimmune hepatitis, haemochromatosis, alcoholic liver disease, or non-alcoholic liver disease (NAFLD). NAFLD was defined as Fatty (change of) liver, not elsewhere classified, or by the presence of cirrhosis (defined using a published algorithm[17]) combined with obesity or diabetes without the presence of any other underlying liver disease.

Routes to diagnosis were defined based on an established algorithm[12] and categorised as follows: Urgent GP TWW referral for suspected cancer; Other GP referral; EP; Other (includes Outpatient, Inpatient and Death Certificate Only routes); Unknown. The proportion of people diagnosed *via* TWW referral and EP were the outcomes of interest for the main analyses.

Statistical Analyses

The proportion of people diagnosed *via* each of five routes to diagnosis was described for all *a priori* patient and tumour characteristics. χ^2 tests were used to assess the statistical significance of any unadjusted variation in proportions diagnosed *via* TWW referral (vs any other route) or EP (vs any other route).

Linear probability models were then performed to assess the proportions of patients diagnosed *via* TWW referral or EP after adjustment for potential confounders. For these, two binary outcome variables were created (TWW referral *vs* other diagnosis routes; EP *vs* other diagnosis routes) and three models run on each with increasing levels of covariate adjustment:

Model 1 (unadjusted): A model that included only Cancer Alliance as the independent variable.

Table 1 Definition of cholangiocarcinoma: World Health Organization International Classification of Diseases codes included

Sub-type	ICD10 topography code	ICDO2 histology code
Intrahepatic (iCCA)	C221 (Intrahepatic bile duct carcinoma)	All
Extrahepatic (eCCA)	C240 (Extrahepatic bile duct carcinoma)	All
CCA other	C248 (Overlapping lesion of biliary tract), C249 (Biliary tract, unspecified)	All
	C220, C222, C223, C224, C227, C229	8160

iCCA: Intrahepatic cholangiocarcinoma; eCCA: Extrahepatic cholangiocarcinoma; CCA: Cholangiocarcinoma; ICD: International Classification of Disease; ICDO2: International Classification of Disease second edition.

Model 2 (demographic-adjusted): A model that included Cancer Alliance as well as patient age, gender and income deprivation quintile.

Model 3 (maximally-adjusted): A model that additionally included all patient and tumour characteristics.

Weighted effect coding was applied to the estimates generated by each linear probability model so that they became interpretable as percentage-point deviations from the sample mean[18]. Results from the linear probability models are presented as funnel plots with significance threshold lines denoting two and three SD from the sample mean, being approximately equivalent to 95.0% and 99.7% confidence intervals, respectively. The correlation between the proportion of people diagnosed by TWW referral and EP was investigated with Spearman's correlation coefficient on the results from Model 3.

A sensitivity analysis was also run on both binary outcome variables, equal to Model 3 with additional adjustment for the stage at diagnosis. This analysis was applied to a subgroup of the cohort who were diagnosed between 2014-2017 (covering the year from which staging data completeness improved in the NCRD) and had a known stage at diagnosis. The stage at diagnosis was not included in the main analysis due to the high proportion of missing data (72.1%) for this variable. Model 3 was repeated in this subgroup to determine how reducing the cohort impacted on model estimates before the stage was additionally adjusted for in this group.

RESULTS

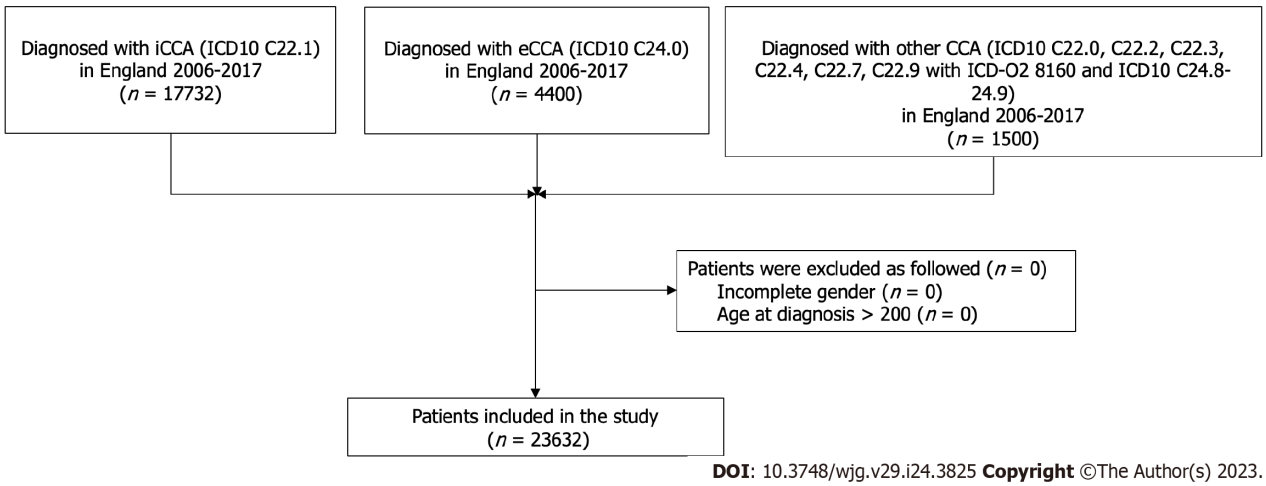
There were 23632 people diagnosed with CCA in England between 2006 and 2017 (Figure 1). Of these, 22.2% were aged under 65 years at diagnosis (Figure 2) and 51.5% were women. The majority were diagnosed with an iCCA (75.0%). Over a quarter (26.0%) had at least one comorbidity on the CCI and 7% were classified as having underlying liver disease. The largest proportion of diagnoses was situated in the West Midlands Cancer Alliance (10.9%), with the smallest in North Central London Cancer Alliance (1.7%) (Table 2).

The most common route to diagnosis was EP (49.6%). Non-TWW GP referrals accounted for 20.5% of diagnosis routes, 13.8% were diagnosed by TWW referral, and the remainder 16.2% were diagnosed *via* an 'other' or Unknown route. The proportion of people diagnosed *via* a TWW referral doubled between 2006 and 2017, rising from 9.9% to 19.8% (Figure 3). Conversely, the proportion of people diagnosed *via* EP declined, falling from 51.3% to 46.0%, as did the proportion diagnosed *via* 'other' routes, from 17.0% to 10.9%.

Geographic Variation in TWW referral

Variation in unadjusted proportions of patients diagnosed *via* a TWW referral was observed across the Cancer Alliances ranging from 8.4% to 18.9% (Supplementary Table 1; $P < 0.001$, Figure 4). In a linear probability model that included only Cancer Alliance, the proportion diagnosed *via* TWW referral was more than two SD higher than the sample mean in three Cancer Alliances (equating to statistically significant variation at the 5% significance level), but more than two SD lower than average for six Cancer Alliances (Table 3; Model 1 and Figure 5A). This finding remained present after adjustment for demographic factors (Table 3; Model 2) and adjustment for all patient and tumour characteristics being considered (Table 3; Model 3 and Figure 5B).

Geographic Variation in EP



Variation in unadjusted proportions of patients diagnosed *via* EP was observed across the Cancer Alliances, ranging from 38.1% to 58.9% (Supplementary Table 1; $P < 0.001$, Figure 4). There was wider variation in the proportion diagnosed by EP across the nation than was observed for TWW referral route in Figure 4, with a larger number of Cancer Alliances showing statistically significant variation

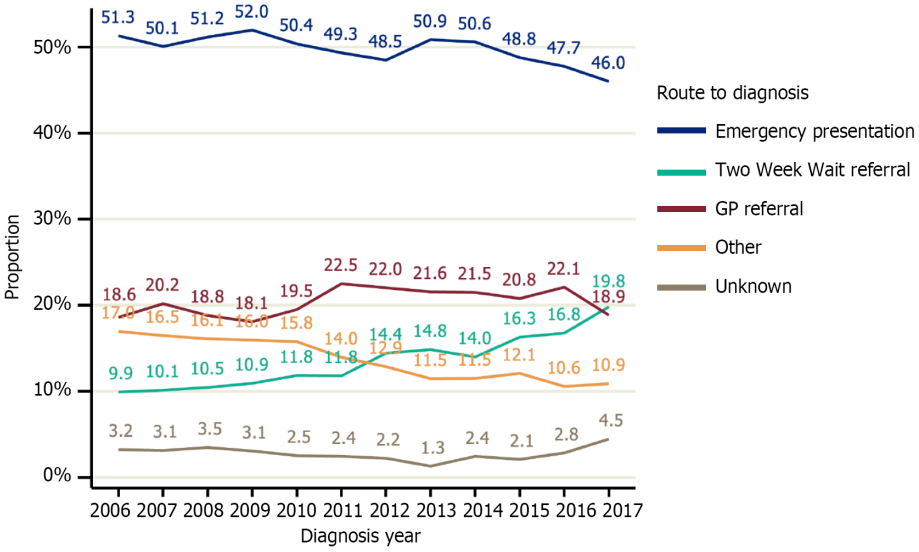
Figure 2 Age at diagnosis for cholangiocarcinoma cohort diagnosed in England 2006-2017.



significantly from the sample mean in unadjusted analyses were no longer outliers. However, one further Cancer Alliance became an outlier from the sample mean after this adjustment. Further adjustment for patient and tumour characteristics had no apparent effect on the variation observed relative to the demographic-adjusted model (Table 4; Model 3 and Figure 6B). Five Cancer Alliances had a proportion of EP that was more than two SD higher than the sample mean and three had a proportion of EP that was more than two SD lower.

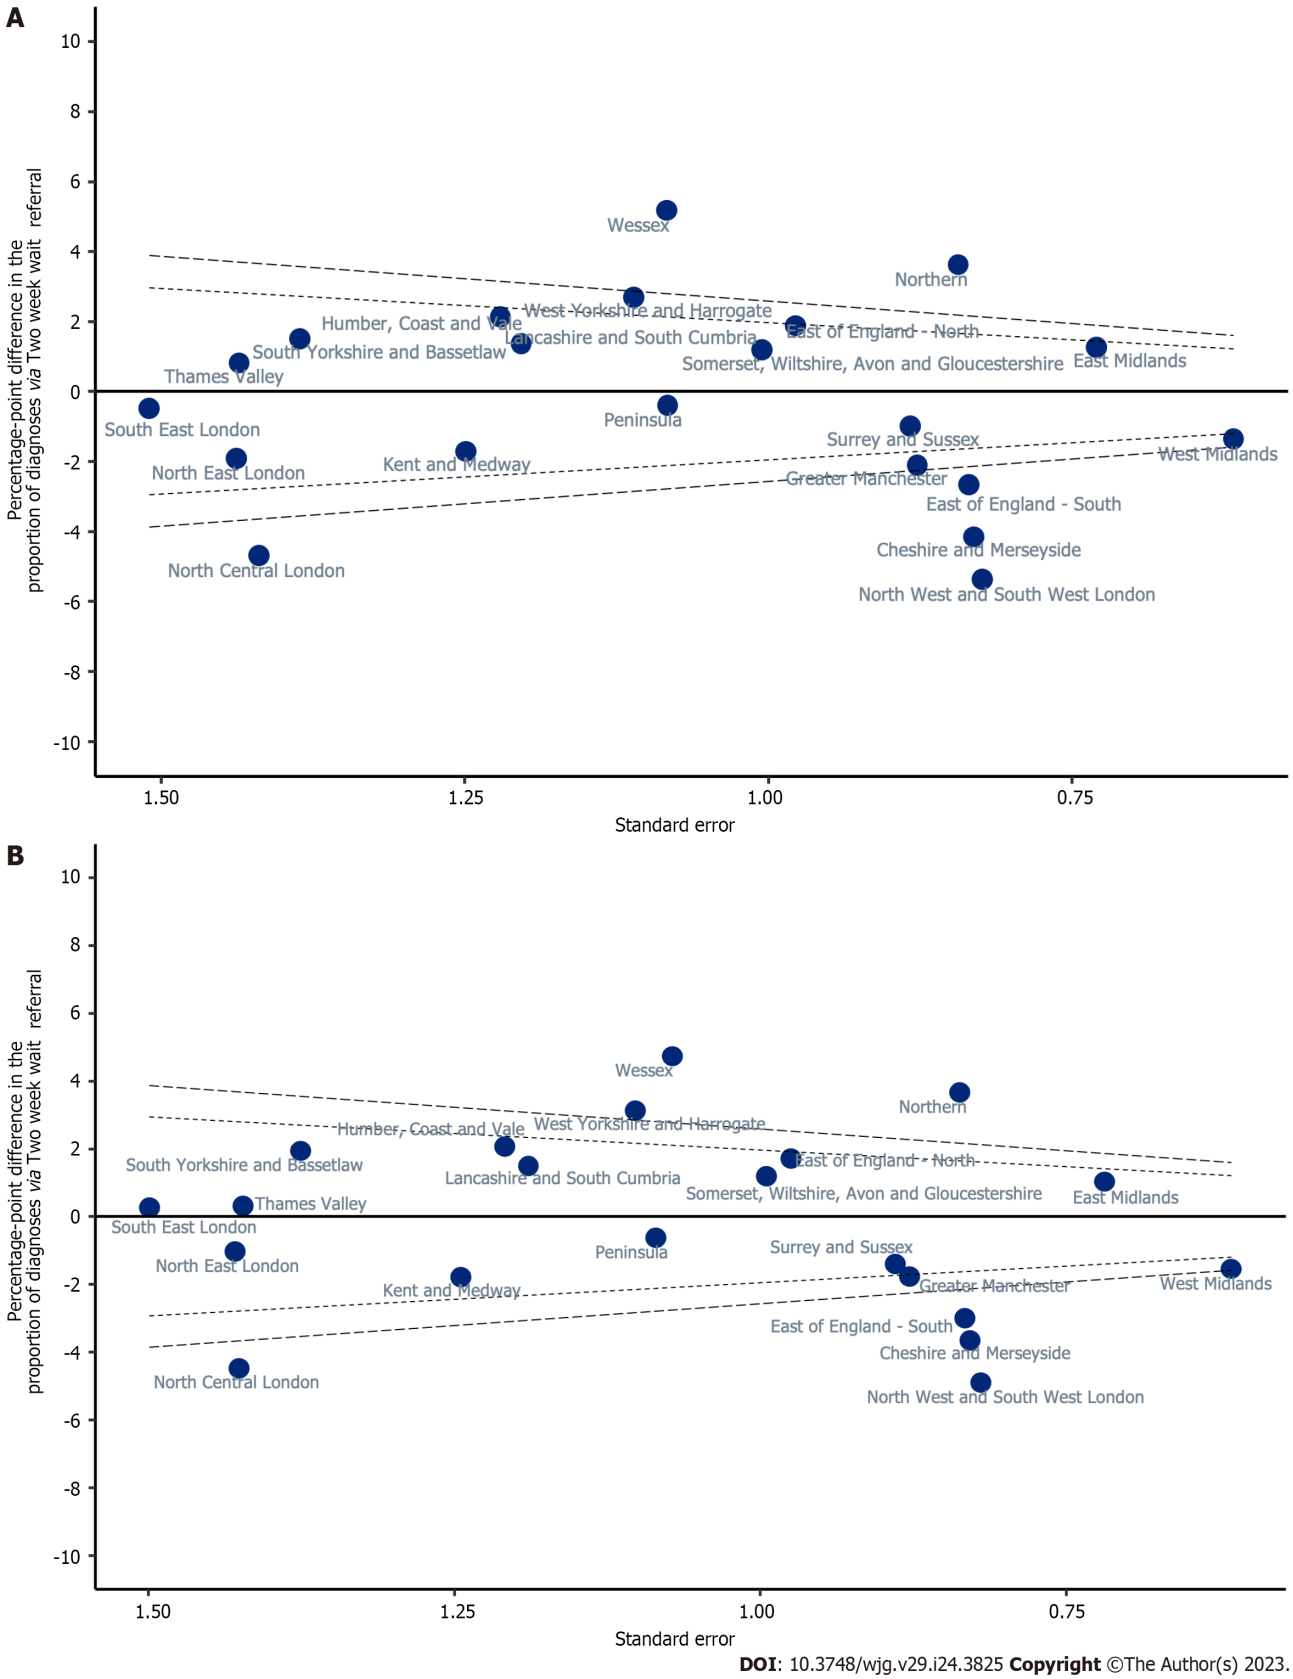
Figure 4 Routes to diagnosis according to Cancer Alliance of residence at diagnosis. GP: General practitioner.

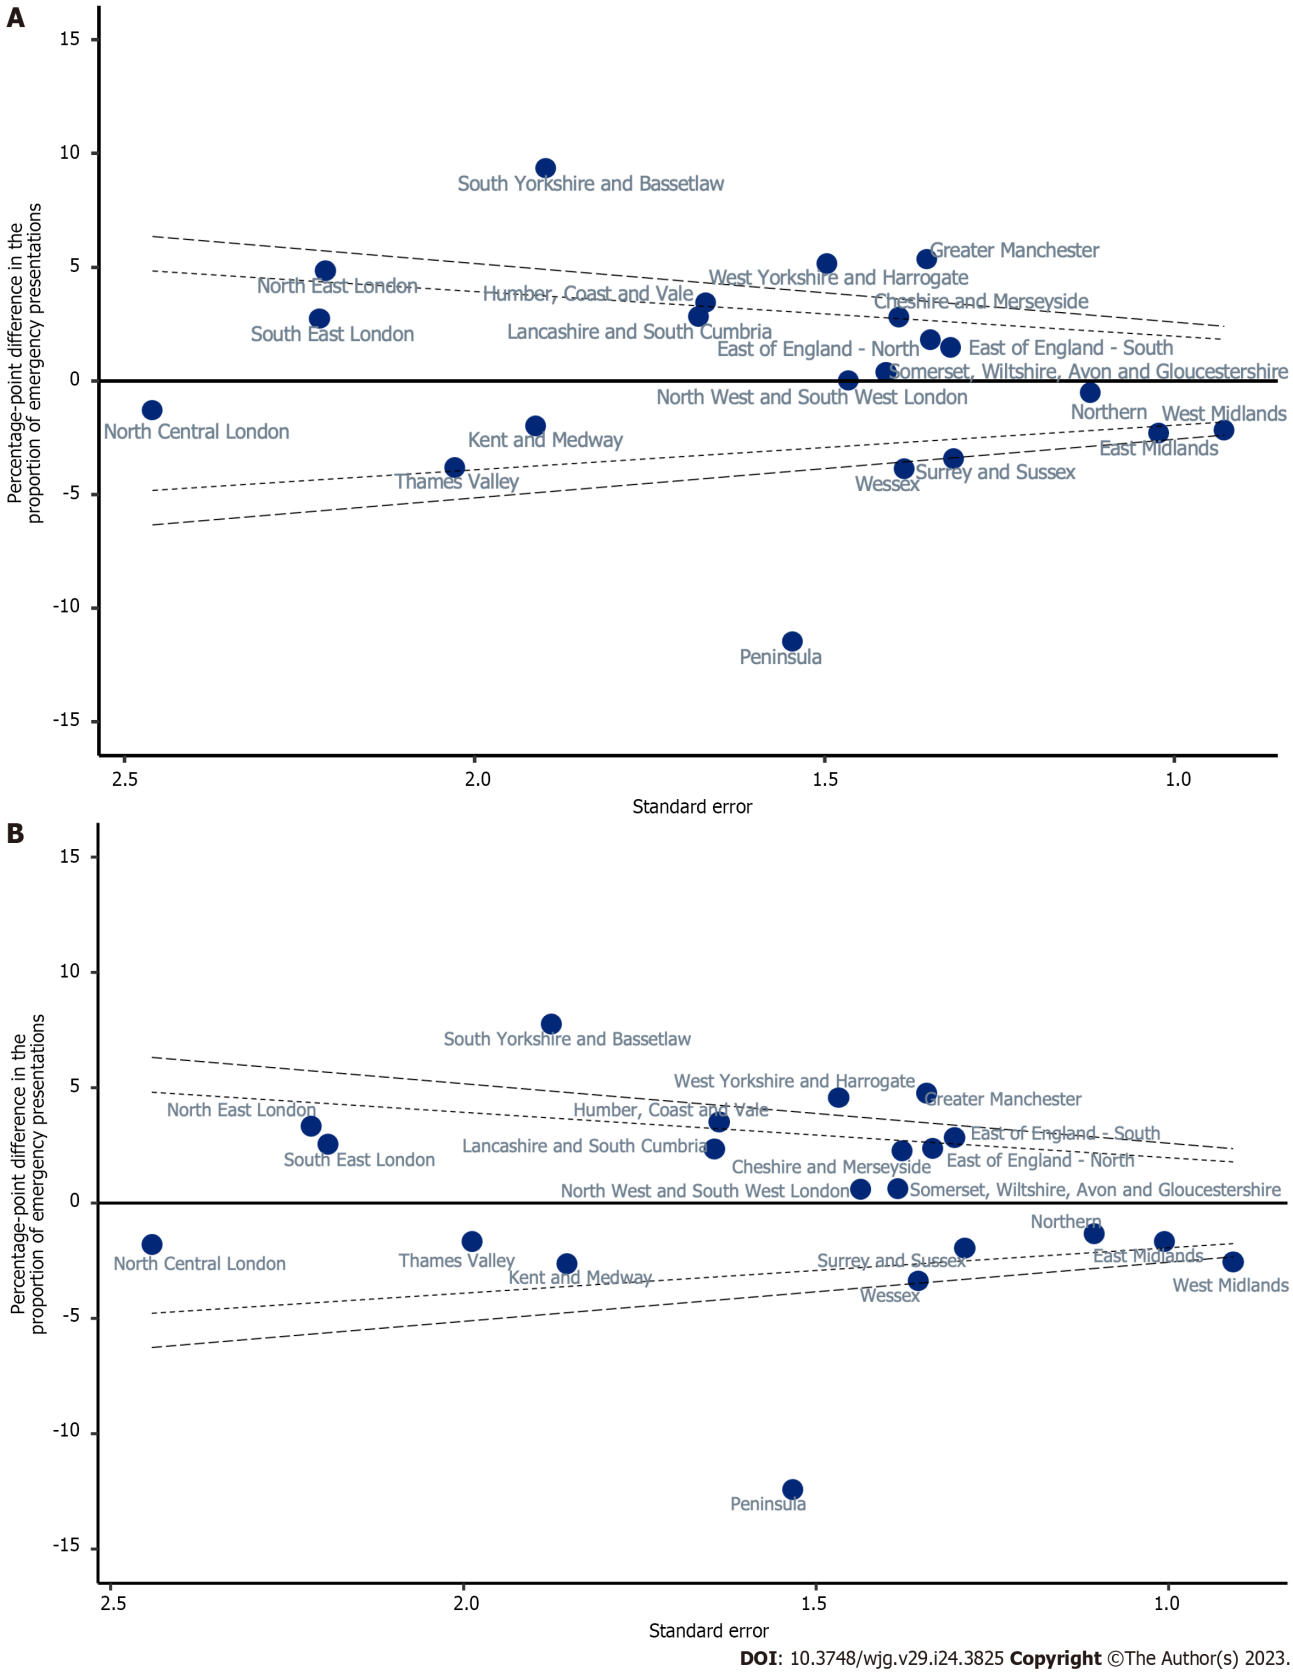
There was no strong correlation (P = 0.2) between the proportion of people diagnosed *via* TWW referral and the proportion of EP across the Cancer Alliances; only one of three Cancer Alliances with a higher than average proportion of TWW referral routes had a lower than average proportion of EP. Two of six Cancer Alliances with a lower than average proportion of TWW referral routes had a higher than average proportion of EP.



Associations with patient and tumour characteristics

A summary of all univariable associations between the route to diagnosis and patient and tumour characteristics is provided in Supplementary Table 1, with estimated proportions diagnosed *via* TWW referrals and EP in Tables 3 and 4. The lowest proportion diagnosed by TWW referral was observed in the 0-44 years age group [5.3%; unadjusted percentage point difference from average (pp) = -8.44 (95%CI: -10.44 to -6.43)], but the relationship with age was an inverted u-shape, with those aged over 84 years also having a lower proportion of TWW referral routes than average [unadjusted pp = -3.62 (95%CI: -4.44 to -2.80)]. Age remained associated with the proportion diagnosed *via* TWW referral in a model that included all other cofactors of interest (Model 3; Table 3). Likewise, the presence of comorbidity on the CCI and the presence of underlying liver disease were each independently associated with a lower proportion of people being diagnosed *via* a TWW referral (Model 3; Table 3).

A greater-than-average proportion of EP diagnosis routes was observed for females, those aged over 84 years, those who were more deprived, those with more comorbidities, intrahepatic tumour types and non-adenocarcinoma morphology (Supplementary Table 1; all P < 0.001). These associations remained present in an analysis that adjusted for all other factors of interest (Table 4; Model 3). Age above 84 [pp = 14.28 (95%CI: 12.98 to 15.57)] years and a CCI of 3 or more [pp = -7.98 (95%CI: -9.19 to -6.77)] showed the largest effect on the proportion of EP. Underlying liver disease was only associated with a higher proportion of EP after adjustment for other patients and tumour characteristics (Table 4).



Sensitivity Analysis

A subgroup of 8872 people were diagnosed with CCA between 2014 and 2017, of whom 4832 (54.5%) had a known stage at diagnosis and were included in the sensitivity analysis. The proportion of people staged varied by Cancer Alliance, from 36.7% to 74.7% (P < 0.001). Those with unknown stage at diagnosis were more likely to be older, diagnosed in an earlier year of the study period, have a high comorbidity score and an 'other' tumour subtype or morphology (all P < 0.001). For both diagnosis routes, fewer Cancer Alliances showed significant variation from the sample mean than in the main results following adjustment to all a priori confounders (Tables 3 and 4; Model 3). Upon further adjustment for stage at diagnosis, the variation observed across the Cancer Alliances was not attenuated (results not shown).

DISCUSSION

This study examined changes to routes to diagnosis for CCA across all of England's 21 regional Cancer Alliances over a 12-year period. We found significant variation in the proportion of patients diagnosed by EP and *via* TWW referral across regions. Exploration of factors contributing to regional differences revealed associations between diagnosis route and gender, the burden of comorbidity, deprivation, age at diagnosis and CCA sub-type. It is worth noting that although CCA is often deemed a cancer of the elderly, 22% of cases during the period under study were under 65 years old. The majority of CCA cases were recorded as intrahepatic, but due to the lack of historic codes specifically for peri-hilar CCA, there remains some controversy regarding the true proportional breakdown with nationally recorded numbers of the three anatomical variants of CCA[1,2]. The most common route to diagnosis was EP, in keeping with the typically late presentation of patients with CCA due to the lack of obvious early symptoms, a targetable screening population and accurate diagnostic screening tests.

The significant variation by Cancer Alliance in the proportions diagnosed *via* TWW referral and EP was found after controlling for a range of patient and tumour characteristics. This indicates there are marked differences in the routes that lead individuals to a diagnosis of CCA between Cancer Alliances in England, beyond what would be expected due to chance. The regional variation we found does not appear to be explained by case-mix, in so far as we could adjust for it. Although this variation is unlikely to be random, residual confounding could remain. For example, it was not possible to account for symptoms present prior to diagnosis or health seeking behaviour which might determine how and where people will present for care. Regions found to have higher than average EP or lower than average TWW may want to investigate why. It is possible that this reflects genuine differences in established diagnostic pathways from primary care to secondary care across regions, or different levels of expertise and knowledge of biliary tract cancers in primary care. There was more geographic variation in the proportion of EP routes for extrahepatic than for intrahepatic tumours. Possible reasons for why there might be more variation in diagnostic pathways could relate to symptom profile or other factors. It was not always the case that Cancer Alliances with significantly higher proportion of TWW have a lower proportion of EP. This suggests that for some areas 'additional' TWWs above average are in people who would otherwise have been diagnosed *via* other routes as well as *via* EP. Increases over time in the proportion of TWW were also not matched by decreases in EP alone, but also by decreases in the proportion diagnosed *via* 'other' routes. A lack of direct relationship between TWW and EP may suggest that a significant proportion of people who present as an emergency either would not meet the criteria for a TWW referral or do not interact with their GP at all prior to their diagnosis, limiting the potential for this diagnostic pathway to prevent EPs. The overall proportion of diagnoses *via* the TWW pathway did double from 9.8% to 19.8% during the study period, but this still remains low. Whilst consistent and high-quality implementation of the TWW pathway across all regions is vital to avoid disparities in care, there may also be a need to look to other techniques, particularly at primary care level, in order to further improve the early diagnosis rate specific for CCA in the UK. For example, there may be benefits for screening in patients known to be at high risk of CCA, such as patients with primary sclerosing cholangitis[19]; and the development and validation of novel diagnostic biomarkers remains an active and important area of CCA research[20].

As deprivation increased, so did the proportion diagnosed by EP, corresponding with a reduction in diagnoses by TWW referral. The association between deprivation and primary care services is complex and multi-factorial, relating both to levels of engagement with healthcare services and the availability and quality of primary care services in deprived areas[21-24]. CCA cases were also more likely to present *via* EP if they were female and the reasons for this are difficult to ascertain. That being female, deprived or elderly was associated with a higher risk of EP requires further exploration to ensure groups are not disadvantaged due to their inherent characteristics, which may not necessarily be specific to CCA.

As age at diagnosis increased, so did the proportion diagnosed by EP. Patients who are older may be more likely to excuse vague or non-specific symptoms of CCA as being down to ageing and be less likely to seek healthcare. Another possibility is that they may be less able to seek it. Similarly, CCA patients were less likely to present *via* the TWW pathway if they were over 84 years old, and had co-morbidities and/or underlying liver disease.

CCA cases were more likely to present *via* EP if the CCA was intrahepatic. This may be explained by the fact that iCCA more often presents with non-specific symptoms than eCCA, which can cause obstructive jaundice[1]. People with more specific symptoms may be more likely to seek healthcare sooner, potentially resulting in fewer diagnosed *via* EP.

Although a more limited cohort with staging data available was analysed (diagnosed 2014-2017), adjusting for stage at diagnosis did not explain geographic variation observed after controlling for other patient and tumour characteristics. The 2014-2017 cohort with complete staging data was shown to differ from the full 2006-2017 cohort, with a lower proportion diagnosed by EP, and a higher proportion diagnosed by TWW referral, which could suggest slightly better-managed diagnostic pathways in patients with complete staging data.

It is important to note that a large proportion of stage (72.1%) and performance status (89.4%) data is missing for CCA patients in the NCRD from 2006-2017, which is a limitation of this study. It is unknown if the stage of diagnosis is not known, not recorded, or missing only from the data feeds and submissions used to form the NCRD. Performance status was added to the Cancer Outcomes and Services data collection in 2013, so is only available for patients diagnosed after this. Missingness of performance status remains high (77.5%) even when restricting the cohort to 2013-2017. The completeness of CCA staging information was also variable across Cancer Alliances. Though stage completeness improved in more recent years (from 44% in 2014 to 64% in 2017), these are higher proportions of missing data compared to other tumour types. For example, 89% of colon cancers diagnosed in 2017 were staged, as were 81% of pancreas cancers[25]. Where stage at diagnosis was known, a high proportion were at an advanced disease stage. This reveals a need to publicise the value of this data and encourage the completion of these fields across all providers within Cancer Alliances, so future CCA research can monitor and adjust for these key prognostic factors for treatment options and patient outcomes.

Strengths of the study include that this was a population level analysis, and to our knowledge is the first study analysing routes to diagnosis for CCA across geographic regions and factors associated with this.

Our study does have some inherent limitations. Some of the observed geographic differences may be attributable to residual confounding that cannot be fully accounted for in the current analysis, rather than disparities in clinical practice. For example, it is not known what symptoms patients experienced leading up to their diagnosis of cancer. There is likely a significant role of patient health-seeking behaviour in these outcomes of interest particularly. It is not known from the data available whether individuals presented to their GP to seek advice prior to their diagnosis.

The study only included CCA patients diagnosed in England and therefore, without further research, it is unknown if our findings can be applied to other countries.

Regarding the identification of underlying liver disease, HES APC episodes from 5 years before to 1 year after diagnosis were searched for relevant diagnostic codes. The patient must therefore have had an inpatient episode where their underlying liver disease was documented. Patients may only spend time in the hospital towards the end of their disease and could be treated in outpatient or primary care prior to that. Therefore, the study is likely to have identified more serious cases of underlying liver disease only and may underestimate the burden by missing diagnoses or treatment exclusively documented in outpatient or primary care settings.

CONCLUSION

In conclusion, it would be preferable to reduce the amount of CCA presentations diagnosed by emergency and promote better managed diagnosis pathways earlier in the disease to improve outcomes. Whilst it is possible that the geographic variation observed may be explained by factors that we are unable to account for in the present analysis, these findings provide a signal that further research is necessary to identify and address the complex and multifactorial nature of the observed geographic differences, including potential differences in clinical practice, healthcare access, and socioeconomic factors across different regions in England. It is possible that variation in routes to the diagnosis of CCA by patient demographic factors could reflect genuine differences in practice and recognition of relevant cancer symptoms in a primary care setting, and that certain groups are disadvantaged when it comes to CCA diagnosis. Where variation exists, there may be opportunities for knowledge sharing of good practice to improve diagnostic pathways, such as education or awareness campaigns to increase public and clinician understanding of the common symptoms of CCA and increase diagnoses made by TWW urgent GP referrals. However, this may only improve things so far in a disease that often has no or non-specific symptoms, in which case there may also be a role for screening strategies and non-specific symptom diagnosis clinics.

ARTICLE HIGHLIGHTS

Research background

Cholangiocarcinoma (CCA), a cancer with rising incidence and poor survival, is often diagnosed late. Treatment options are limited for late stage patients. The only curative treatment for CCA is surgery, which is not feasible in patients with advanced disease, and response to systemic therapies at later stage is poor.

Research motivation

Late stage diagnosis presents a large barrier to improving outcomes for patients with CCA. Being diagnosed *via* an emergency presentation (EP) route is associated with later stage diagnoses, whereas

earlier diagnoses may be made *via* the Two Week Wait (TWW) referral route through primary care clinicians. Geographic variation in the proportion of patients diagnosed *via* these routes is important to understand and explore, as some regions may be diagnosing patients *via* better managed and less urgent routes at an earlier stage. Reasoning and learning behind such variation could be shared to improve CCA patients' prognoses.

Research objectives

We aimed to investigate routes to diagnosis of CCA over time, regional variation across England and influencing factors to understand if TWW referrals and EP routes to diagnosis differ across regions in England as we hypothesised.

Research methods

We conducted a retrospective cohort study including patients diagnosed with CCA from 2006-2017 in England. We linked electronic patient records to define routes to diagnosis and patient and tumour characteristics. We used linear probability models to investigate geographic variation in the proportions of patients diagnosed *via* TWW referral or EP across regions in England, adjusting for potential confounders.

Research results

Almost half of CCA patients in England from 2006-2017 were diagnosed *via* EP (49.6%), with just 13.8% diagnosed *via* TWW referrals. The proportion diagnosed *via* TWW referral doubled between 2006-2017 rising from 9.9% to 19.8%. Statistically significant variation in both the proportions diagnosed *via* a TWW referral and EP route was found across regions in England. Age, presence of comorbidities and underlying liver disease were independently associated with lower proportions of patients diagnosed *via* TWW referral and a higher proportion diagnosed *via* EP.

Research conclusions

We found significant geographic and socio-demographic variation in routes to diagnosis of CCA in England.

Research perspectives

There may be opportunities for knowledge sharing of good practice to improve diagnostic pathways where variation exists, such as education or awareness campaigns to increase public and clinician understanding of the common symptoms of CCA and increase diagnoses made by TWW urgent GP referrals. Further research is also warranted to identify and address the complex and multifactorial nature of the observed geographic differences, alongside exploring screening strategies and non-specific symptom diagnosis clinics as CCA often has no or non-specific symptoms.

ACKNOWLEDGEMENTS

This work uses data that has been provided by patients and collected by the NHS as part of their care and support. The data are collated, maintained and quality assured by the National Disease Registration Service, which is part of NHS England. Abstract

BACKGROUND

Research exploring the influence of healthier lifestyle modification (LSM) on the risk of hepatocellular carcinoma (HCC) in patients with chronic hepatitis B (CHB) is limited.

AIM

To emulate a target trial to determine the effect of LSM on HCC incidence and mortality among patients with CHB by large-scale population-based observational data.

METHODS

Among the patients with CHB enrolled in the Korean National Health Insurance Service between January 1, 2009, and December 31, 2017, those aged ≥ 20 years who drank alcohol, smoked cigarettes, and were sedentary were analyzed. Exposure included at least one LSM, including alcohol abstinence, smoking

cessation, and regular exercise. The primary outcome was HCC development, and the secondary outcome was liver-related mortality. We used 2:1 propensity score matching to account for covariates.

RESULTS

With 48766 patients in the LSM group and 103560 in the control group, the adjusted hazard ratio (HR) for incident HCC and liver-related mortality was 0.92 [95% confidence interval (CI): 0.87-0.96] and 0.92 (95%CI: 0.86-0.99) in the LSM group, respectively, compared with the control group. Among the LSM group, the adjusted HR (95%CI) for incident HCC was 0.84 (0.76-0.94), 0.87 (0.81-0.94), and 1.08 (1.00-1.16) for alcohol abstinence, smoking cessation, and regular exercise, respectively. The adjusted HR (95%CI) for liver-related mortality was 0.92 (0.80-1.06), 0.81 (0.72-0.91), and 1.15 (1.04-1.27) for alcohol abstinence, smoking cessation, and regular exercise, respectively.

CONCLUSION

LSM lowered the risk of HCC and mortality in patients with CHB. Thus, active LSM, particularly alcohol abstinence and smoking cessation, should be encouraged in patients with CHB.

Core Tip: Unhealthy behaviors, including smoking, sedentary lifestyle, or alcohol drinking, are known to have adverse effect on the outcome among chronic hepatitis B (CHB) patients. However, there are limited data on the effect of healthier lifestyle modification (LSM), including quitting smoking, regular exercise, and quitting drinking, on the risk of hepatocellular carcinoma (HCC) in CHB patients. In this first hypothetical randomized trial, we demonstrated that the LSM lowers the risk of developing HCC by using the nationwide database. The findings of this study highlight the necessity for active counseling and therapeutic intervention for LSM in CHB patients.

INTRODUCTION

Chronic hepatitis B virus (HBV) infection is the leading cause of hepatocellular carcinoma (HCC) and accounts for 56% of all cases[1,2]. Despite the introduction of neonatal immunization to prevent vertical transmission and antiviral medications with high genetic barrier, the risk of HCC remains high[3]. Thus, ongoing efforts are being made to further decrease the global health burden of chronic hepatitis B (CHB) with modifiable risk factors.

Mounting evidence indicates that not only viral factors but also host factors, such as alcohol consumption, smoking, and obesity, and diet influence the prognosis of patients with CHB[4-7]. Alcohol drinking was associated with increased risk of HCC[8] and mortality[9]. A meta-analysis reported that smoking elevated the risk of HCC by 1.44 times through an additive interaction[10], and a recent prospective cohort study on patients with diabetes and CHB showed pack per year dose responsiveness [7]. Insulin resistance[11] and central obesity[12] increase the incidence of liver cancer in patients with CHB. In contrast, increased physical activity can lower the incidence of liver cancer[13]. Correspondingly, few studies have evaluated whether the modification on behavioral risk factors reduces the incidence of HCC, although studies have demonstrated that the risk of developing HCC increases with unhealthy behavior[14]. A meta-analysis attempted to confirm whether alcohol abstinence prevents HCC; however, reliable results were not obtained owing to the lack of quality studies[14]. Evidence from observational studies and meta-analyses suggests that coffee consumption can reduce the incidence of HCC including in patients with CHB[15,16]. Furthermore, several studies have demonstrated that food-derived components may have a positive impact on the progression of liver fibrosis[17,18] and the treatment of HCC[19-21]. Randomized controlled trials (RCTs) are required to confirm the benefits of modifying behavioral risk factors for HCC in patients with CHB. However, no RCT on patients with CHB has evaluated the impact of lifestyle modifications (LSM) on the incidence of

HCC. This might be because RCTs require enormous resources and time, including medical care, patient participation, human resources, and time to observe events.

An emulated target trial using observational data can help avoid methodological pitfalls in observational studies[22]. It can yield the same estimated effects as that of an RCT if the emulation is successful [23]. HBV infection is the most common cause of HCC in South Korea[24]. South Korea has government-mandated universal health insurance coverage for the entire population[25]. The Korean National Health Insurance Service (K-NHIS) claims database includes information on disease and treatment, as well as health behaviors. Thus, we conducted an emulation trial to determine the effect of LSM on HCC incidence and mortality among patients with CHB using nationwide registry data.

MATERIALS AND METHODS

Data sources and study population

We performed a sequential trial emulation study using the K-NHIS database. The K-NHIS database represents the entire South Korean population. The K-NHIS claims database contains information on demographics, medical treatment, procedures, prescription drugs, diagnostic codes, and hospital use. Diagnoses in the K-NHIS database were based on the International Classification of Diseases, 10th revision (ICD-10). In addition, the K-NHIS claims database includes data from the National Health Screening Examination (NHSE), which is a standardized health screening program provided to all insured persons every 2 years[26]. The NHSE includes a self-administered questionnaire on medical history and health behaviors; including smoking, drinking, and physical activity; anthropometric measurements; and laboratory tests. The participation rate of the NHSE in the target population is approximately 76%. The use of the K-NHIS database was approved by the NHIS Review Committee (protocol number: NHIS-2021-1-575). All patients received an anonymous identification code in the K-NHIS data to protect the patients' information and identity.

This study included participants aged ≥ 20 years with CHB, which was defined as the presence of HBV (B18.0, B18.1, B18.10, B18.18, or Z22.5) codes in any claim or presented in a death certificate during the study period. We restricted participants to those who were drinking, smoking, and did not exercise regularly during the health screening exam between January 1, 2009, and December 31, 2017, as our study aimed to evaluate the benefits of LSM. We then selected participants who had at least one additional health screening examination to evaluate changes in lifestyle (baseline). We excluded participants with a history of cancer, human immunodeficiency virus (HIV) infection (ICD-10 codes: B20, B21, B22, and B24), hepatitis C virus (HCV) infection (ICD 10 code: B18.2), liver cirrhosis (ICD-10 codes: K70.2, K70.3, K71.7, K76.1, and K74), jaundice (ICD-10 code: R17), ascites (ICD-10 code: R18), and hepatic failure (ICD-10 code: K720). Furthermore, we excluded participants who developed cancer or died within the first month of follow-up to minimize potential reverse causality. We also excluded those with missing data for matching variables. The Institutional Review Board of Samsung Medical Center approved the study and waived the requirement for informed consent because the K-NHIS data were de-identified.

Measurements

The main exposure was LSM including alcohol abstinence, smoking cessation, and regular exercise. The NHSE used standardized questionnaires to obtain information on alcohol drinking, smoking, and exercise. For the information on smoking status, participants were asked if they had ever smoked at least 100 cigarettes in their lifetime, based on the World Health Organization definition. Ever smokers were then asked regarding the duration of smoking and the mean number of cigarettes smoked per day. For drinking, participants were asked for the frequency (number of days per week) and quantity (amount of standard unit per occasion) of alcohol consumption. A standard unit was defined as a specialized cup for each type of alcohol such as beer, wine, Korean traditional alcohol (soju), or whisky. One standard unit contains roughly 8 g of ethanol in Korea, although different drinks can have very different alcohol content. The weekly amount of alcohol consumption was calculated by multiplying these two values. Alcohol intake was categorized into none, moderate (< 40 g/d in women and < 60 g/d in men), and heavy (≥ 40 g/d in women and ≥ 60 g/d in men). The exercise questionnaire used a 7-d recall method. The questionnaire was similar to the International Physical Activity Questionnaire (IPAQ)-Short form, which was modified by the Korean NHIS (see Supplementary Figure 1). The questionnaire consisted of the following three questions: (1) How many days in the past week did you engage in vigorous activities that made you breathe much harder than normal for at least 20 min per day (*e.g.*, running, aerobics, fast biking, climbing, *etc.*)? (2) How many days in the past week did you engage in moderate activities that made you breathe somewhat harder than normal for at least 30 min per day (*e.g.*, fast walking, doubles tennis, riding a bicycle at a normal speed, mopping, *etc.*)? and (3) How many days in the past week did you engage in light activities, such as walking for at least 30 min per day, adding up to a total of at least 30 min per day (*e.g.*, walking to and from work or for leisure, light household chores, *etc.*)? This questionnaire has been widely used in previous studies. The main exposure was regular physical activity, which was defined as vigorous physical activity for ≥ 3 d per

week (at least 60 min per week) or moderate physical activity for ≥ 5 d per week (at least 150 min per week).

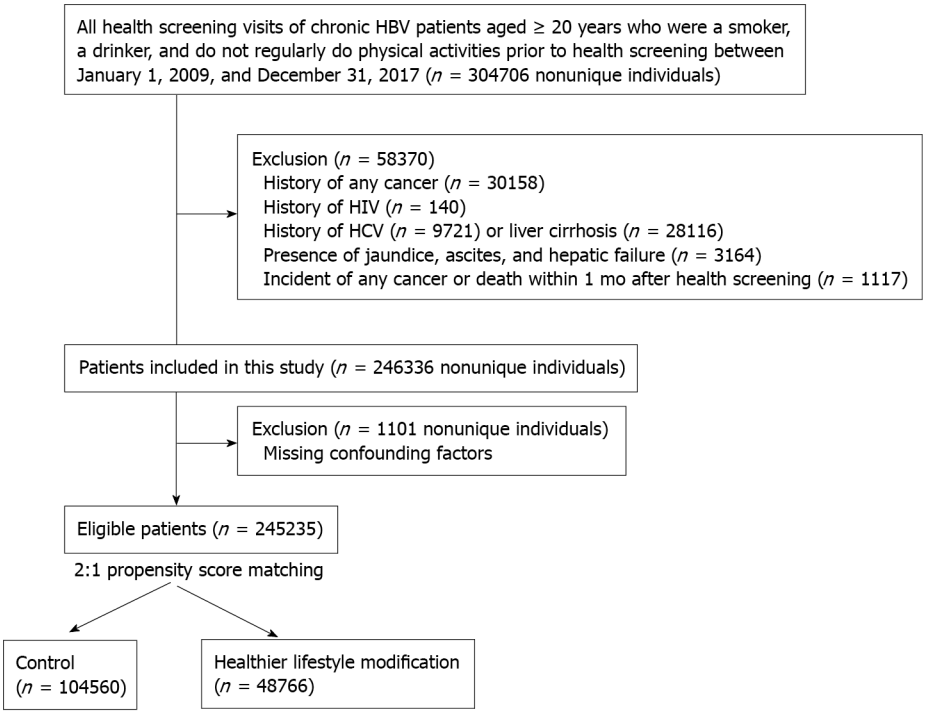
The primary endpoint was the development of HCC. HCC was defined as the presence of a cancer-specific insurance claim code (V193 code) with the C22.0 code, which is ICD-10 code for HCC. The secondary endpoint was liver-related mortality. Vital status and cause of death were obtained from death certificates collected by the Statistics Korea at the Ministry of Strategy and Finance of South Korea [27]. We considered it a liver-related death if the patients had liver cancer (C22) or liver disease (B15–B19, K70–K75) codes for the cause of death. We also included the development of all types of cancer, extrahepatic cancer, and all-cause mortality as the endpoints.

We included age, sex, body mass index (BMI), liver enzymes [aspartate aminotransferase (AST), alanine aminotransferase (ALT), and γ-glutamyl transferase (GGT)], comorbidities, and antiviral medications at baseline as covariates. Daily alcohol consumption, drinking status, smoking status, and level of physical activity at the time of inclusion were also analyzed.

Assigned groups and follow-up

We emulated a pragmatic sequence of trials by aligning the eligibility window, group assignment, and start of follow-up between study arms[28]. We identified patients with CHB who met the eligibility criteria on the day of health-screening visits to emulate a trial of the effectiveness of LSM on clinical outcomes in patients with CHB. We repeated the enrollment process for all available health screening visits. Each participant could contribute as an eligible individual to as many trials as possible. The emulation of sequential trials is a valid and efficient procedure if participants meet the eligibility criteria at several time points[29]. The participants were then reclassified into two groups according to LSM at the visit. In all trials, participants were followed from baseline until the development of HCC, death, or December 2019, whichever occurred first.

Furthermore, propensity score (PS) matching was performed to minimize the potential impact of confounders on outcomes. We conducted multivariable logistic regression using the following covariates: Age, BMI, AST, ALT, GGT, presence of hypertension, diabetes, myocardial infarction, congestive heart failure, cerebrovascular accident, whether the participant took antiviral medications at the current health screening visit, drinking status (moderate or heavy), smoking status, daily alcohol consumption, and physical activity status (not at all or a little) at the previous health screening visit to estimate the PS for the LSM group. Furthermore, if a patient had health screenings at different time points, we followed them from the date of their first screening, and then the time since the previous exam was included in the matching variables. Matching was performed using a greedy algorithm (caliper = 0.1). The control group was matched 2:1 with the LSM group in each trial. The covariate variables were updated at the start of each trial in the analysis. The covariates were updated over time following the sequential target emulate trial methods. This methodological strategy aligned the assessment of eligibility criteria, treatment assignment, and starting of follow-up, thus removing any immortal-time bias related to the delay between the health screening visit and adoption of healthy behaviors on clinical outcomes. We pooled data from all trials into a single model and included the day of the trial's baseline in the analysis.



Statistical analysis

The primary analysis was intention-to-treat analysis. Cumulative incidence of each outcome was estimated using the Kaplan-Meier method, and log rank tests were used to evaluate differences between the groups. We calculated hazard ratios (HR) with 95% confidence intervals (CI) for incidence of clinical outcome using a Cox regression model. Covariates with SMD > 0.1, which can provide evidence of an imbalance between matched groups, were adjusted for survival analysis.

We examined the proportional hazards assumption using plots of the log(-log) survival function and Schoenfeld residuals. All *P* values were two-sided, and a *P* value < 0.05 was considered as significant. Analyses were performed using of SAS® Visual Analytics (SAS Institute Inc., United States) and R 4.1.2 (R Foundation for Statistical Computing, Vienna, Austria).

RESULTS

Of the 304706 potential person-trials, we excluded participants with a history of any cancer (*n* = 30158), HIV (*n* = 140), HCV (*n* = 9721) infection, or liver cirrhosis (*n* = 28116). We also excluded participants who had jaundice, ascites, or hepatic failure (*n* = 3164) and 1117 participants who developed cancer or died within the first month of follow-up. Thus, 246336 person-trials met the eligibility criteria; however, 1101 person-trials were excluded because of missing data on confounding factors. Therefore, the final sample size included 245235 person-trials. Among them, we selected two person-trials for the control group per LSM person-trial. Thus, we obtained a control group of 104560 person-trials matched with 48766 person-trials from the LSM group (Figure 1). In the LSM group, 33.7%, 29.6%, and 16.9% of participants belonged to the quitting smoking (QS), regular exercise (RE), and quitting drinking (QD) groups, respectively. In addition, 1.5% of the participants belonged to the QD + QS + RE group.

Figure 1 Flow chart of study participants. HBV: Hepatitis B virus; HIV: Human immunodeficiency virus; HCV: Hepatitis C virus.

The mean age of the study participants was 50 years, and 95% of them were men (Table 1). All SMDs of the difference between the control and LSM groups were less than 0.1, except for age and sex (Figure 2). The LSM group was more likely to be older and female compared with the control group.

During follow-up, 14401 participants developed cancer, and 50.8% of the incident cancers were HCC. The fully adjusted HR for incident HCC comparing LSM group to the control group was 0.92 (95%CI: 0.87-0.96). The association between LSM and HCC was consistent in all subgroups analyzed, except for sex (Table 2). The QD (HR = 0.84, 95%CI: 0.76-0.94) and QS groups (HR = 0.87, 95%CI: 0.81-0.94) showed a beneficial effect on reducing incident HCC compared with the control group when we subcategorized LSM. The fully adjusted HR for incident all cancer and extrahepatic cancer comparing the LSM group to the control group was 0.93 (95%CI: 0.90-0.97) and 0.96 (95%CI: 0.91-1.01), respectively (Table 2).

During the follow-up period, 6833 participants died, and 52.8% were liver-related death. The LSM group had a significantly lower risk of liver-related death compared with the control group over the entire period. The fully adjusted HR for all-cause mortality, when comparing the LSM group with the control group, was 0.94 (95%CI: 0.90-0.99) (Table 3). The fully adjusted HR for liver-related mortality, when comparing the LSM group with the control group, was 0.92 (95%CI: 0.86-0.99) (Table 3).

DISCUSSION

This study demonstrated that LSM is associated with a reduced incidence of HCC and liver-related mortality in patients with CHB. Specifically, alcohol abstinence and smoking cessation were associated with a reduced incidence of HCC, while smoking cessation was associated with reduced liver-related and all-cause mortality.

We included patients with CHB who drank, smoked, and did not exercise regularly. As the risk of developing HCC increases with the presence of more behavioral risk factors[30], the participants of this study are expected to have the poorest prognosis. We found that the risk of HCC was reduced by 8% with the adoption of one LSM. Specifically, the risk was reduced by 16%, 13%, and -8% with alcohol abstinence, smoking cessation, and regular exercise, respectively. Risk was reduced by 21% when all LSM components were adopted. These findings strongly suggest that patients with CHB should be encouraged to adopt healthier lifestyles, particularly alcohol abstinence and smoking cessation.

To date, little is known regarding the effects of LSM on HCC and liver-related mortality in patients with CHB. Alcohol consumption increases the incidence of HCC[31,32]. A meta-analysis on the effect of alcohol abstinence in patients with CHB predicted that limiting alcohol consumption would have a protective effect against the development of HCC even though quality research has not been conducted [14]. Abstinence is believed to counteract some effects of alcohol. Drinking upregulates cytochrome P450 2E1 (CYP2E1), which promotes the generation of reactive oxygen species and electrolyte leakage in the

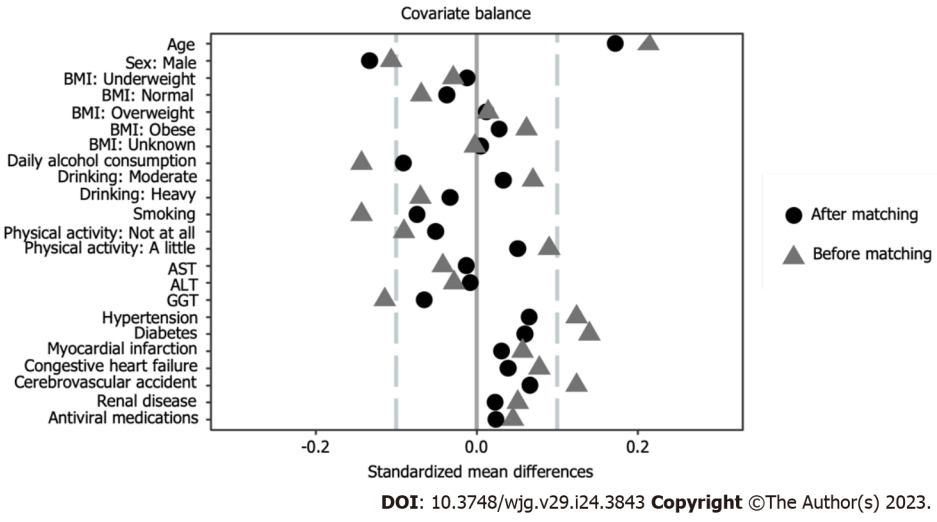
mitochondrial respiratory chain[33]. After 3 d of abstinence, the levels of CYP2E1 have been shown to decrease rapidly, corroborating our findings[34].



Smoking is another important risk factor for HCC development from the host side. In 2010, the Surgeon General's report expanded the list of smoking-related cancers to include HCC[35]. Few studies have demonstrated the effects of smoking cessation, although smoking is widely acknowledged as a risk factor for HCC. Two prospective observational studies examined the incidence of HCC, ALT elevation, and fibrosis score; however, no statistically significant results were obtained whether smoking cessation had a positive effect on the liver[36,37]. Conversely, a retrospective pooled cohort study of patients with CHB found that as the number of years of smoking cessation increased in ex-smokers, the rate of ALT elevation decreased. This effect is particularly potent after > 10 years of smoking cessation[38]. Previous research has provided an explanation on why smoking cessation reduces HCC. The ability of natural killer cells to stop HBV replication is known to be decreased by smoking, and notably, this effect is restored 1 mo after quitting smoking[39].

Some findings regarding the effect of exercise on HCC in patients with CHB are inconsistent, although the preventive effect of exercise on liver-related outcomes in patients with non-alcoholic fatty liver is well established. A study of patients with CHB revealed that exercise reduces the risk of HCC overall, whereas physical activity of ≥ 1500 MET-min/week increases the risk of HCC in patients with

liver cirrhosis[13]. In addition, in a multinational cohort study, the effect of exercise on HCC prevention was not statistically significant in the sub-analysis of patients with CHB[40]. In our study, unlike alcohol abstinence and smoking cessation, regular exercise did not have a beneficial effect on HCC prevention or mortality. However, in this study, we had no detailed information on exercise, such as intensity or reason for exercise. Future studies are required to determine the effect of exercise and its type on HCC and the dose relationship in patients with CHB.

This study had several limitations. First, because this was a retrospective study, inevitable problems were encountered. Exclusion criteria were established to identify individuals who were expected to sustain their health status for an extended length of time at baseline. Nonetheless, the issue of reverse causation may remain. The K-NHIS does not provide information on the reasons for changing health behaviors. Consequently, sick quitter bias may arise in which people abstain from drinking or smoking because their health deteriorates to the point that they no longer find drinking or smoking enjoyable [41]. We further excluded participants who developed cancer or died within the first month of follow-up from baseline to minimize potential reverse causality. Second, our study used a self-report questionnaire to assess health behaviors. People might overreport or underreport health behaviors that would affect the results[42,43]. However, the NHSE uses a standardized questionnaire to assess health behaviors. Third, quantitative guidance for HCC risk and mortality reduction could not be offered because the dose- and time-effect linkages of LSM were not determined in this study. In addition, patients' assigned groups during the study might have changes, which could potentially underestimate the association between LSM and outcomes. However, additional biases in the analysis could have been introduced as some patients did not participate in the next health screening visit. Therefore, we performed target trial emulation to reduce selection bias and provide more robust estimates of treatment effects. Specifically, we were able to allocate the two groups at the "beginning" of induction, before subsequently emulating the randomization process using coarsened exact matching, through simultaneous determination of eligibility and assigning two arms. Fourth, we lacked several important variables for the outcome of CHB, for example, the degree of liver fibrosis and hepatitis B viral load. However, the administration of antiviral agents in Korea is subject to a reimbursement policy based on the presence of liver cirrhosis, elevated AST or ALT levels, and DNA levels. In this study, we attempted to partially account for liver fibrosis and DNA levels *via* adjusting for whether or not the patient received antiviral treatment. We were able to allocate the two groups at the "beginning" of induction, before subsequently emulating the randomization process using coarsened exact matching, through simultaneous determination of eligibility and assigning two arms.

CONCLUSION

In conclusion, LSM, particularly alcohol abstinence and smoking cessation, was associated with a reduced incidence of HCC in patients with CHB. Smoking cessation is also associated with reduced liver-related and all-cause mortality. Thus, active LSM should be encouraged in patients with CHB. A prospective study is required to confirm the results of this study and establish the dose and time effects of LSM in this population.

ARTICLE HIGHLIGHTS

Research background

Despite various efforts to reduce the incidence of hepatocellular carcinoma (HCC) in patients with chronic hepatitis B (CHB), it remains a persistent issue. Reports suggest that host factors such as alcohol consumption, smoking, and obesity, in addition to viral factors, contribute to the development of HCC.

Research motivation

Few studies have investigated the impact of lifestyle modifications (LSM) on reducing the incidence of HCC and liver-related mortality in patients with CHB.

Research objectives

This study used a nationwide database in Korea to investigate whether improvements in at least one of the following lifestyle factors - drinking, smoking, and sedentary behavior - were associated with reductions in HCC incidence and liver-related mortality in patients with CHB.

Research methods

We analyzed patients with CHB who participated in the Korean National Health Insurance Service and who drank alcohol, smoked cigarettes, and were sedentary. Target trial emulation was used and covariates were adjusted through 2:1 propensity score matching.

Research results

With 48766 patients in the LSM group and 103560 in the control group, the LSM group had a lower adjusted hazard ratio for incident HCC and liver-related mortality compared to the control group. Within the LSM group, alcohol abstinence and smoking cessation were associated with lower adjusted hazard ratios for both outcomes.

Research conclusions

LSM, specifically alcohol abstinence and smoking cessation, were associated with a decreased risk of HCC in patients with CHB.

Research perspectives

The findings of this study suggest a need for active counseling for LSM in CHB patients, particularly alcohol abstinence and smoking cessation. Further investigation through a well-designed prospective cohort study is necessary to confirm these results.

Abstract

BACKGROUND

Thalidomide is an effective treatment for refractory Crohn's disease (CD). However, thalidomide-induced peripheral neuropathy (TiPN), which has a large individual variation, is a major cause of treatment failure. TiPN is rarely predictable and recognized, especially in CD. It is necessary to develop a risk model to predict TiPN occurrence.

AIM

To develop and compare a predictive model of TiPN using machine learning based on comprehensive clinical and genetic variables.

METHODS

A retrospective cohort of 164 CD patients from January 2016 to June 2022 was used to establish the model. The National Cancer Institute Common Toxicity Criteria Sensory Scale (version 4.0) was used to assess TiPN. With 18 clinical features and 150 genetic variables, five predictive models were established and

evaluated by the confusion matrix receiver operating characteristic curve (AUROC), area under the precision-recall curve (AUPRC), specificity, sensitivity (recall rate), precision, accuracy, and F1 score.

RESULTS

The top-ranking five risk variables associated with TiPN were interleukin-12 rs1353248 [P = 0.0004, odds ratio (OR): 8.983, 95% confidence interval (CI): 2.497-30.90], dose (mg/d, P = 0.002), brain-derived neurotrophic factor (BDNF) rs2030324 (P = 0.001, OR: 3.164, 95%CI: 1.561-6.434), BDNF rs6265 (P = 0.001, OR: 3.150, 95%CI: 1.546-6.073) and BDNF rs11030104 (P = 0.001, OR: 3.091, 95%CI: 1.525-5.960). In the training set, gradient boosting decision tree (GBDT), extremely random trees (ET), random forest, logistic regression and extreme gradient boosting (XGBoost) obtained AUROC values > 0.90 and AUPRC > 0.87. Among these models, XGBoost and GBDT obtained the first two highest AUROC (0.90 and 1), AUPRC (0.98 and 1), accuracy (0.96 and 0.98), precision (0.90 and 0.95), F1 score (0.95 and 0.98), specificity (0.94 and 0.97), and sensitivity (1). In the validation set, XGBoost algorithm exhibited the best predictive performance with the highest specificity (0.857), accuracy (0.818), AUPRC (0.86) and AUROC (0.89). ET and GBDT obtained the highest sensitivity (1) and F1 score (0.8). Overall, compared with other state-of-the-art classifiers such as ET, GBDT and RF, XGBoost algorithm not only showed a more stable performance, but also yielded higher ROC-AUC and PRC-AUC scores, demonstrating its high accuracy in prediction of TiPN occurrence.

CONCLUSION

The powerful XGBoost algorithm accurately predicts TiPN using 18 clinical features and 14 genetic variables. With the ability to identify high-risk patients using single nucleotide polymorphisms, it offers a feasible option for improving thalidomide efficacy in CD patients.

Key Words: Thalidomide-induced peripheral neuropathy; Refractory Crohn's disease; Neurotoxicity prediction models; Machine learning; Gene polymorphisms

Core Tip: Thalidomide-induced peripheral neuropathy (TiPN) is a life-threatening condition in Crohn's disease and has a high incidence in Asia. However, there are no effective medical interventions for TiPN. Here, we established a predictive model using machine learning and identified genes closely related to TiPN occurrence. We have found that extreme gradient boosting algorithm can sensitively identify patients who are prone to TiPN, which is useful for doctors to adjust the thalidomide therapy.

INTRODUCTION

Thalidomide is widely used in refractory Crohn's disease (CD) patients, with a remission rate of 40%-70%[1,2]. However, the clinical application of thalidomide is limited by its side effects, especially peripheral neuropathy. A large individual difference (20%-75%) was found in the incidence of peripheral nerve lesions[3]. If neurotoxicity occurs during the treatment, reduction or cessation is needed to avoid further neurotoxicity. This may lead to treatment failure[4]. The nerve lesions after withdrawal may worsen for several months, recovery can be slow and incomplete, and the resulting neurotoxicity profoundly affects quality of life[5]. Hence, developing a predictive model for thalidomide-induced peripheral neuropathy (TiPN) and identifying related factors that can accurately predict peripheral neuropathy are important.

Thalidomide is a small molecule with immunomodulatory activity[4]. Numerous clinical studies have confirmed that thalidomide is effective for treatment of CD, especially in patients with hormone intolerance, lack of efficacy of azathioprine/6-mercaptopurine, and biological treatment failure[6,7], It brings hope to patients with refractory CD, which can reduce economic and healthcare costs because of its low price from the perspective of pharmacoeconomics. A retrospective multicenter observational

study showed that the proportion of adults with refractory CD from whom thalidomide was withdrawn because of toxicity alone was up to 46% at 2 years[7], which affected maintenance of remission in nearly half of patients treated with thalidomide. TiPN may appear primarily as sensory peripheral nerve lesions and may differ in symptoms, including paralysis, sensory disturbance, sensory abnormalities, hyperalgesia and severe pain[8]. The empiric identification of agents and interventions to mitigate TiPN has been disappointing, and presently there is no intervention available for prevention except dose management. Although electrophysiological monitoring has been used in patients prescribed thalidomide, it provides no clear benefit for the occurrence of neuropathy compared to clinical assessment[3,9].

Few researchers have studied risk factors related to TiPN[10,11], and most studies have been conducted in chemotherapy patients. Szudy-Szczyrek *et al*[12] used serum brain-derived neurotrophic factor (BDNF) concentration as an indicator of polyneuropathy, which did not accurately reflect nerve damage and the results could not be generalized due to small number of patients. Only a limited number of molecular genetic studies in TiPN have been conducted, but none has discussed the association between genetic factors and TiPN in patients with CD. TiPN is thought to be a dose-limiting toxicity[13], and the therapeutic dose of thalidomide between chemotherapy and CD patients can differ by up to 10 times[14]. Thus, the existing findings are probably not fully representative of patients with CD.

The neurotoxic mechanism of thalidomide is still unclear[15]. Some hypotheses and treatment directions for TiPN have appeared. Thalidomide exhibits an antiangiogenic effect, which is considered to cause secondary ischemia and hypoxia of nerve fibers, which may lead to ischemia-related neuropathy. Vascular endothelial growth factor gene therapy in animals with TiPN led to obvious improvement in vascular recovery[16,17]. In addition, neuronal susceptibility can be increased by the dysregulation of neurotrophic factors through immunomodulatory mechanisms[18]. Tonello *et al*[19] analyzed dorsal root ganglion tissues from their animal experiments. Matrix metalloproteinase (MMP)9 monoclonal antibody significantly decreased oxidative stress and affected the expression of neuroinflammatory mediators, suggesting that MMP9 acts on peripheral nerve lesions. Thalidomide metabolites are considered to cause neuronal damage through reactive oxidative species causing damage to DNA[20]. BDNF is the only neurotrophic factor expressed during most peripheral damaged sensory neurons. It has been proven to be an effective regulator of regeneration-related gene expression in the peripheral and central nervous systems[21,22]. Additionally, Navia-Pelaez *et al*[23] observed the induction of mouse neuralgia by ATP binding cassette transporter (ABC)A1/ATP binding cassette transporter (ABC)G1 knockdown, which prevented apolipoprotein A-I binding protein from reversing peripheral neuropathy allodynia[23]. Johnson *et al*[9] reported that gene polymorphisms of ABCA1 had a significant association with thalidomide-related neuropathy[9]. Interleukin (IL)-12 was upregulated in MPTP-intoxicated mice[24]. In the patients who received CTL019, IL-2 level in those with neurotoxicity was higher than in those without neurotoxicity[25]. Zhang *et al*[26] supported IL-12 cytokine profiles as indicators of neurotoxicity[26]. Few studies have demonstrated a relationship between cumulative dose and TiPN[27,28]. The gene polymorphisms of transcriptional regulators, inflammatory cytokines and transporters may have an important impact on individual differences in TiPN. These genetic factors may adequately explain the neurotoxicity with clinical variables.

Therefore, an accurate model for identifying TiPN with comprehensive clinical and genetic variables is required in patients with CD. In recent years, powerful data mining and computing have encouraged a growing use of machine learning in the medical field, including diagnosis, treatment, prognostic data classification, and regression[29-31]. Tao *et al*[32] generated a predictive model for clinical response in patients with rheumatoid arthritis using a multiomics approach and machine learning, with a predictive accuracy > 85%[32]. Mo *et al*[33] developed a Tacrolimus nephrotoxicity predictive model in nephrotic syndrome using machine learning algorithms with clinical and genetic variables, and 78% were accurately identified[33]. To date, there is no predictive model for CD patients generated by machine learning.

The aim of this study was to develop a sensitive and accurate TiPN predictive model based on clinical and genetic variables, which is beneficial for the treatment of thalidomide.

MATERIALS AND METHODS

Study population

A total of 164 CD patients diagnosed according to the criteria of Lennard-Jones were randomly recruited from the Sixth Affiliated Hospital of Sun Yat-sen University from January 2016 to June 2022. The patients treated with thalidomide at any course of their disease were considered eligible for the study. The inclusion criteria were: (1) Diagnosis of CD; (2) CD activity index > 150 points, with endoscopically active lesions; and (3) refractory or intolerant to immunosuppressive drugs or biological agents which are used in current treatment. The exclusion criteria were: (1) fiber stenosis caused by gastrointestinal obstruction symptoms; (2) fistula, excluding anal fistula; (3) pregnancy or lactation; (4) fertility program during the study; (5) less than eight weeks of biologic treatment after last IFX; (6) central or peripheral

nervous disease; (7) abnormal liver and renal function; (8) heart dysfunction; (9) malignant tumor; and (10) active tuberculosis.

Ethical approval was obtained by the Ethics Committee of the Sixth Affiliated Hospital of Sun Yat-Sen University, Guangzhou, China. This study was registered at the Clinical Trial Registry (Registration Number: NCT02956538). Written informed consent was obtained from all participants. Blood samples were collected from all recruited patients.

Assessment of neurotoxicity

For the neurophysiological assessment, the same methods were used throughout the whole process of observation to minimize any potential bias. For the clinical assessment, the National Cancer Institute Common Toxicity Criteria Sensory Scale (version 4.0, 2009) was used. Details of thalidomide administered to each patient were acquired directly from the medical records of the patients. Meanwhile, patients without blood samples or intact clinical data were excluded.

Clinical variables

In order to adjust the influence of clinical variables on TiPN, 18 types of baseline clinical variables were collected, including demographic data (weight, age, *etc.*), inflammatory indexes (C-reactive protein, erythrocyte sedimentation rate, *etc.*), hepatic function (alanine aminotransferase, aspartate aminotransferase, *etc.*), and routine blood examination. Supplementary Table 1 shows the full names and local abbreviations of clinical characteristics.

Single nucleotide polymorphism selection and genotyping

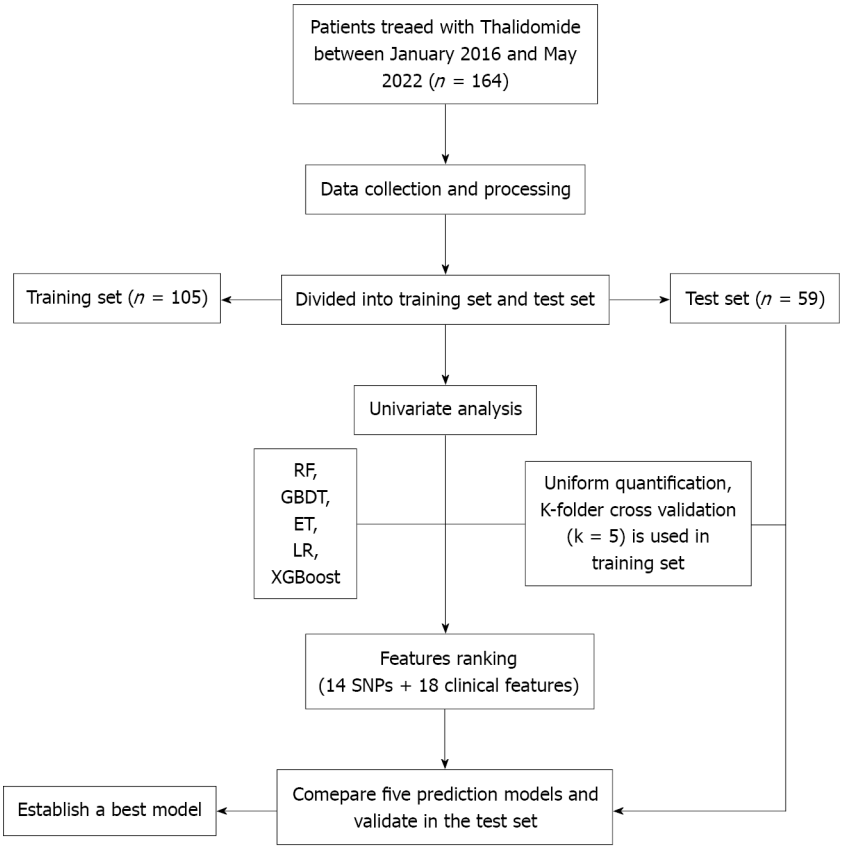
We performed comprehensive detection of genetic variables (single nucleotide polymorphisms; SNPs), including genes related to thalidomide pharmacokinetic/pharmacodynamic pathways, metabolic enzymes, transcriptional regulators, nerve growth factors, inflammatory cytokines, *etc.* Details of the selection steps of these genes (SNPs) were as follows. (1) The physical position of these genes was obtained through the human Ensembl GRCh37 database (http://asia.ensembl.org/Homo_sapiens/Info/Index). In the VCF to PED Converter window (http://grch37.ensembl.org/Homo_sapiens/Tools/VcftoPed), positions of genes were entered, the Chinese Han population in Beijing was selected, and then, PED and info file for the SNPs of these genes were download; and (2) Haploview software for entry criterion was set (minor allele frequency > 5%, $r^2 < 0.8$, min genotype > 75%, and Hardy–Weinberg equilibrium > 0.05) to obtain the tag-SNP. Ultimately, 150 genetic variables met the above standards. DNA analysis was performed by collecting 5-mL peripheral blood samples. DNA extraction from whole blood was performed using Genomic Blood DNA Extraction Kit (DP304, Tiangen, Beijing, China). Nanodrop 2000C (Thermo Scientific, Fitchburg, WI, United States) was used for the detection of DNA concentration.

The published polymerase chain reaction-restriction fragment length polymorphism method was used for the detection of all SNPs[34,35], and 150 SNPs were detected by Agena Bioscience MassARRAY (Agena Bioscience, San Diego, CA, United States).

Machine learning

Single-sample Kolmogorov-Smirnov tests were carried out to test the distribution of continuous variables. Data were shown as median (range) or mean ± SD, according to the data type.

Based on clinical and genetic variables, a predictive model for TiPN in CD patients was developed using a series of machine learning methods. We implement machine learning as a three-step process, data preprocessing, feature selection, and model generation and verification. To evaluate the performance of the model generation, a fivefold cross-verification was performed. The evaluation indicators used included confusion matrix, receiver operating characteristic (ROC) curve, precision recall (PR) curve, specificity, sensitivity, precision, accuracy and F1 core. Figure 1 shows the workflow for machine learning.



The *t*-test and nonparametric Mann–Whitney *U* test were used to analyze continuous variables while categorical variables were analyzed by χ^2 test. Machine learning techniques were performed in Python 3.7.13. GraphPad Prism version 8 (GraphPad, San Diego, CA, United States) was used for graphic analysis. $P < 0.05$ was considered to be a statistically significant difference.

Data preprocessing

Features with missing rates > 30% were removed after the collection of variables was finished. The missing value of a continuous variable was filled with an average value, and the classification variable was processed by removing the missing value. The continuous variables were uniform quantized by minimum-maximum normalization, and the categorical variables were represented using dummy variables. The range of each clinical data set is shown in Supplementary Table 1.

Feature selection

Univariate analysis was used to evaluate the relationship between each variable and TiPN. SNPs with weak effects ($P > 0.1$) were eliminated. In order to reduce the model complexity, clinical variables were

Figure 1 Flow chart display. Flow chart showing the process of model generation validation of the model. RF: Random forest; GBDT: Gradient boosting decision tree; ET: Extremely randomized trees; LR: Logistic regression; XGBoost: Extreme gradient boosting.

uniformly quantified into 11 categorical variables [0, 0.1, 0.2, ..., 1], since the dataset included both categorical variables (*e.g.* gender, polymorphisms and outcomes) and continuous variables (*e.g.* drug dose, age and clinical tests). To improve robustness and accuracy of the prediction of our approach, the dataset was reiterated 1000 times, resulting in different test sets, which were used to select model hyperparameters. Five models were established to predict TiPN development, named extreme gradient boosting (XGBoost), gradient boosting decision tree (GBDT), extremely random tree (ET), random forest (RF) and logistic regression (LR) model. The paramount variables of all these models are ranked by information gain[36].

Model development and validation

One hundred and sixty-four patients were randomly divided into training (80%) and testing (20%) data sets[37,38]. The Synthetic Minority Oversampling Technique (SMOTE) algorithm was combined in the training set and the test set to deal with the data imbalance. The five predictive models were trained using k folder cross-validation (k = 5). Through implementation and comparison, we avoided merging plans and improved the generalization performance of these models.

XGBoost, ET, GBDT, RF and LR algorithms were used to analyze the feature set and to generate neurotoxicity prediction models. To guarantee the robust stability of these computational models, the dataset was randomly divided 1000 times to obtain different training sets to test the hyperparameter for each group. Taking XGBoost as an example, the main hyperparameter included learning rate, maximum depth, estimators, and eta. The performance of the tested classification algorithm was evaluated and compared based on the area under the ROC curve, area under the PR curve, specificity, sensitivity (recall), precision, accuracy, and F1 score.

Bioinformatics analysis

The effects of expression quantitative trait loci (eQTLs) on the top-four gene expressions were examined with the Genotype-Tissue Expression (GTEx) database. https://www.gtexportal.org/home/.

RESULTS

Patient characteristics

A total of 164 patients with CD were collected in this study, including 119 men and 45 women. The average age of the patients was 34.3 ± 12.7 years. Median dose of thalidomide was 1.5 mg/kg/d (range 0.3-2.9). TiPN was observed in 59 patients (36%) during follow-up. Median duration of thalidomide treatment was 17.2 mo (range 1-60). We collected 18 baseline variables and 150 genetic variables (Supplementary Table 2) of the patients. Table 1 shows the baseline characteristics of the patients. The genotype coincided with Hardy Weinberg equilibrium.

Feature selection

In the univariate analysis, variables that had a significant impact on TiPN included *IL-12* rs1353248 (P = 0.0004), *BDNF* rs2030324 (P = 0.001), *BDNF* rs6265 (P = 0.001), and dose (P = 0.002), *ABCA1* rs10991419 (P = 0.002). After removing genetic variables with low correlation (P > 0.1), 14 SNPs and 18 clinical variables were included in the following analysis (Table 2 and Supplementary Table 1).

Identification of appropriate biomarkers that distinguished the neurotoxic symptom group from the well-tolerated group was deemed important, which helped in exploring disease biomarkers and understanding pathogenesis. After the data transformation, models were generated using ET, GBDT, RF, XGBoost and LR, and the feature importance scores were used to rank all the features. The higher the information gain value, the more significant the variable became (Figure 2). By ranking each feature, the top five ranked features were *IL-12* rs1353248, dose (mg/d), *BDNF* rs6265, *BDNF* rs2030324 and *BDNF* rs11030104. *IL-12* rs1353248 was found to have the highest predictive variable importance for TiPN, followed by thalidomide daily dose, rs6265, rs2030324 and rs11030104. Figure 3 shows the four genetic variables and the occurrence of TiPN. Patients with *BDNF* rs2030324_AG, *BDNF* rs6265_CT, *BDNF* rs11030104_AG, and *IL-12* rs1353248_TT genotypes were more likely to have TiPN; patients with BDNF rs2030324_AG genotype had more neurotoxicity than patients with AA+GG; CT genotype carriers of *BDNF* rs6265 had higher neurotoxicity than CC+TT carriers; neurotoxicity in carriers of *BDNF* rs11030104_AG was more than in patients with AA+GG genotype; and patients with *IL-12* rs1353248_TT genotype had more neurotoxicity than those who carried CT+CC. Additionally, we noticed that there were three SNPs derived from the same gene, which suggested that BDNF played a significant role in neurotoxicity.

Functional consequences of the top four SNPs

The GTEx eQTL database was used to examine the functional consequences of the top four SNPs. The results suggested that four variants, rs1353248 (chr3_159905770, $P = 8.52 \times 10^{-4}$), rs6265 (chr11_27658369, $P = 1.07 \times 10^{-4}$), rs2030324 (chr11_27705368, $P = 9.2 \times 10^{-11}$), rs11030104 (chr11_27662970, $P = 2.76 \times 10^{-5}$) could affect IL-12 and BDNF gene expression on human nerve tibial tissue (Figure 4). The expression levels of the BDNF gene were reduced in rs6265CT and rs11030104AG, with a significant reduction in the rs6265CT genotype. Additionally, the expression levels of the *IL-12* gene were significantly decreased in the rs1353248TT. The results showed a similar trend, indicating that these four loci may play an important biological role in peripheral neurotoxicity and have potential for the prediction of TiPN (Figure 3). Further investigation into their biological functions is warranted.

Comparison of five algorithms in the training set

Using k-fold cross-validation (k = 5) in the training set, we identified all possible parameter combinations identified by random grid search. The evaluation indicators used included confusion matrix, ROC curve, PR curve, specificity, sensitivity, precision, accuracy and F1 core. The average ROC curve, PR curve and 95% confidence interval (CI) are shown in Figure 5. Here, the ROC curves of four models were > 0.90, the PR curve of the LR model was 0.874, and the remainder were > 0.97. In addition, these models exhibited different performances (Table 3). The ET model obtained the highest ROC curve (0.999) but had the lowest specificity rate of 0.471. The RF model obtained a high ROC curve (0.996) and a common precision (0.769) compared with XGBoost and GBDT. The results indicated that XGBoost and GBDT had superior performance, and the precision, specificity, accuracy and F1 scores were above 0.90, 0.82, 0.88 and 0.87, respectively.

To evaluate the importance of genetic variables or clinical features in five models, we used 14 SNPs, 18 clinical features, and three top five ranked features included in five models of the other three round workouts with similar analytic approach. The results indicated that by including 18 clinical features, ROC curves were 0.759–0.999, and PRC curves were 0.602–0.998 (Supplementary Figure 1). The ET model showed the best sensitivity (1.0) but had the lowest precision (0.431) and specificity rate (0.262). The precision, specificity, accuracy, and F1 were low for LR and RF models (Supplementary Table 3). Additionally, with only input of the 14 SNPs, the models achieved better performance than the clinical features. The ROC curve and PR curve of XGBoost, ET, GBDT, and RF models were > 0.90 (Supplementary Figure 2); the precision, sensitivity, specificity, accuracy and F1 score of XGBoost and GBDT were > 0.90 (Supplementary Table 4). These results indicated that genetic variables were more important in predicting TiPN than clinical features.

Table 1 Patients characteristics

Characteristics	Values (*n* = 164)
Male/Female	119/45
Age (yr)	34.3 ± 12.7
Thalidomide dosage mg/kg/d	1.5 (0.3-2.9)
White blood cell (10^9/L)	6.2 ± 2.7
Peripheral neuropathy	59 (36%)
Duration of thalidomide treatment (m)	17.2 (1-60)

Data are presented as median with range, mean ± SD or amount.

CI: Confidence interval; OR: Odds ratio; TiPN: Thalidomide-induced peripheral neuropathy; BDNF: Brain-derived neurotrophic factor; IL: Interleukin; SNP: Single nucleotide polymorphisms.

Table 3 Performance of the models for training set (all features)

Model	Precision	Sensitivity	Specificity	Accuracy	AUROC	F1 score
XGBoost	0.904	1	0.94	0.962	0.988	0.949
ET	0.526	1	0.471	0.667	0.999	0.69
GBDT	0.952	1	0.971	0.981	1	0.976
LR	0.613	0.95	0.647	0.759	0.907	0.745
RF	0.769	1	0.824	0.889	0.996	0.87

AUROC: Area under the receiver operating characteristic; XGBoost: Extreme gradient boosting; ET: Extremely random trees; GBDT: Gradient boosting decision tree; LR: Logistic regression; RF: Random forest.

When including the top five ranked features, the ROC curve for the four models was > 0.82, The LR model only achieved a low value (0.72). The PRC curve of the LR model was 0.578, and the remainders were > 0.72. The XGBoost showed the highest PR curve (0.803, 95%CI: 0.697–0.871) and accuracy (0.718).

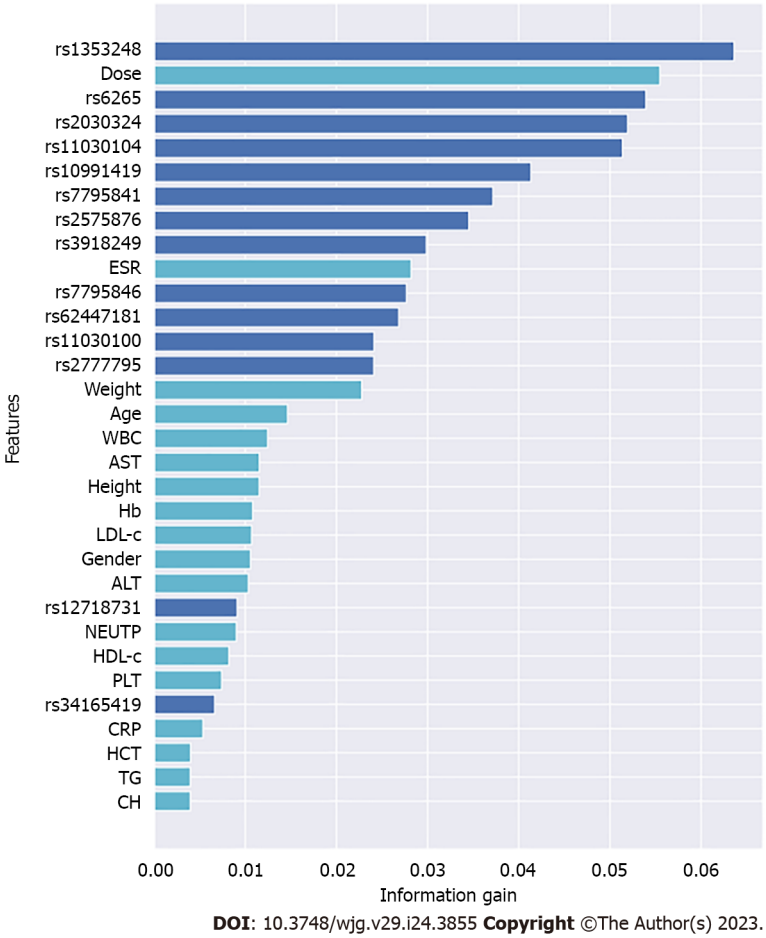

Figure 2 Information gain values of the features. The higher the information gain value, the more important the variable. Therefore, these five variables (rs1353248, dose, rs6265, rs2030324, rs11030104) are the optimal feature set.

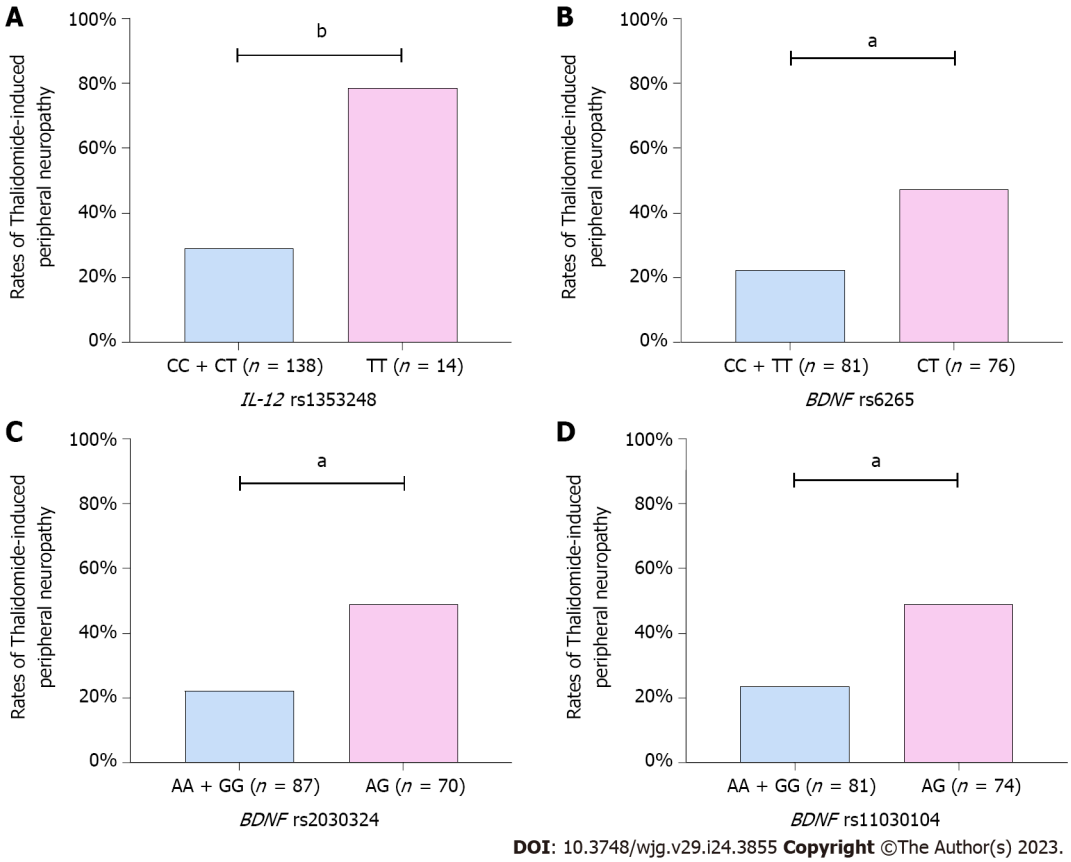
The GBDT obtained the highest ROC curve (0.88, 95%CI: 0.804-0.956). However, F1 score was < 0.70 for all models (Supplementary Figure 3 and Supplementary Table 5). The findings indicated that integration with genetic features and clinical data may be refining the performance of prediction models.

Validation of the five algorithms in the test set

Five algorithms in the test set were verified based on training results. The performance of five prediction models based on the 18 clinical features and 14 SNPs were: Precision 0.625-0.8, sensitivity 0.667-1.0, specificity 0.667-0.889, accuracy 0.733-0.818, and F1 score 0.714-0.8 (Table 4). The average area of the ROC and PR curves was 0.741-0.907 and 0.718-0.864, respectively (Figure 6). The models generated by the XGBoost algorithm had the best overall predictive power and the highest specificity (0.857), accuracy (0.818) and PR curve (0.864, 95%CI: 0.828-1.011); the ROC curve was (0.889, 95%CI: 0.757-1.021), and the remaining values for precision, sensitivity and F1 score were > 0.75. The RF acquired the highest ROC curve (0.907, 95%CI: 0.731-1.084), and the ET and GBDT achieved the best F1 score, but all three had the lowest specificity (0.667).

We validated only 14 genetic variables, 18 clinical variables and the top five ranked features in five models. All these models behaved poorly with the 18 clinical features (Supplementary Table 6), while the sensitivity score was > 0.83 for four models (XGBoost, ET, GBDT and RF). The performance of the overall value of the ROC curve (0.528-0.718) was higher than the PR curve (0.359-0.556) (Supplementary Figure 4).



When only 14 SNPs were considered, the ROC curve of XGBoost and RF were up to 0.802 and 0.907; the PRC curve was > 0.70 for the four models (XGBoost, ET, GBDT and RF) (Supplementary Figure 5), with accuracy, precision, sensitivity, specificity and F1 score above 0.73, 0.66, 0.66, 0.77 and 0.66, respectively (Supplementary Table 7). The LR had the lowest ROC curve (0.722) and PR curve (0.601).

Considering only the top five ranked features, the ROC and PR curves were > 0.79 and > 0.73 for all these models, respectively (Supplementary Figure 6). XGBoost had the best overall predictive power and highest specificity (0.857), sensitivity (0.833), accuracy (0.848) and F1 score (0.8). The LR had the lowest accuracy (0.552), specificity (0.316) and precision (0.435) (Supplementary Table 8).

Table 4 Performance of the models for testing set (all features)

Model	Precision	Sensitivity	Specificity	Accuracy	AUROC	F1 score
XGBoost	0.75	0.75	0.857	0.818	0.889	0.75
ET	0.667	1	0.667	0.8	0.833	0.8
GBDT	0.667	1	0.667	0.8	0.87	0.8
LR	0.8	0.667	0.889	0.8	0.741	0.727
RF	0.625	0.833	0.667	0.733	0.907	0.714

AUROC: Area under the receiver operating characteristic; XGBoost: Extreme gradient boosting; ET: Extremely random trees; GBDT: Gradient boosting decision tree; LR: Logistic regression; RF: Random forest.

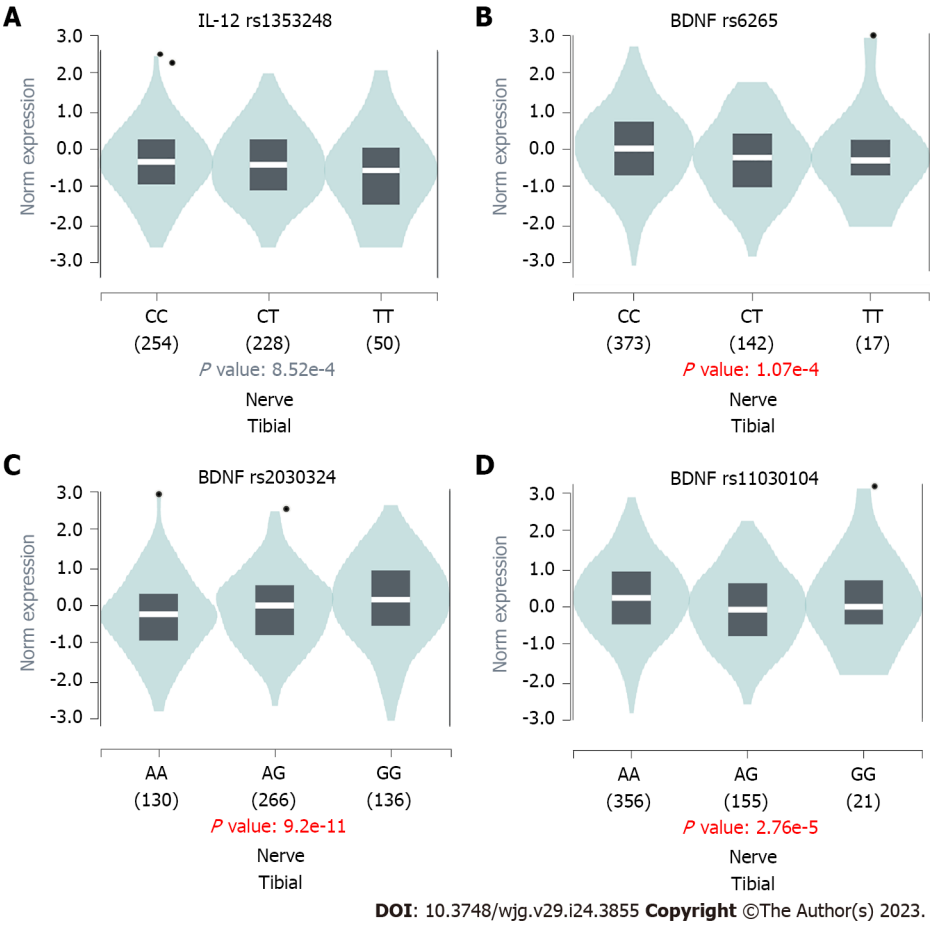

Figure 3 The correlation between the optimal variables and thalidomide-induced peripheral neuropathy. Illustrate patients with interleukin-12 rs1353248_TT, brain-derived neurotrophic factor (BDNF) rs2030324_AG, BDNF rs6265_CT, and BDNF rs11030104_AG, genotypes are more likely to have thalidomide-induced peripheral neuropathy than non-carriers. A: IL-12; B-D: BDNF. [a]$P < 0.01$, [b]$P < 0.001$. BDNF: Brain-derived neurotrophic factor; IL: Interleukin.

DISCUSSION

Thalidomide leads to well-documented adverse effects in some patients, and drug discontinuation derived from neurotoxicity alone was up to 46%[2,36]. However, it is still unclear to predict TiPN risk in Chinese people by combining genetic polymorphism and clinical factors.

So far, there have been few studies on the risk factors of TiPN in patients with CD. As far as we know, only Bramuzzo *et al*[28] developed a model to identify genetic variables using LR to predict the occurrence of TiPN in children. They found that polymorphisms in *ICAM1* and *SERPINB2* were protective factors. However, genetic tests were used only in a few patients and the survey variables were not sufficient. The LR method also reduced the predictive performance of the model[28].

In comparison with traditional statistical methods, based on the previous studies, machine learning can generate models of higher predicted performance by handling more complex data, which may achieve higher accuracy and improved generalization[37,38]. With the rapid increase in artificial intelligence, machine learning methods are widely applied in the field of disease diagnosis and

DOI: 10.3748/wjg.v29.i24.3855 **Copyright** ©The Author(s) 2023.

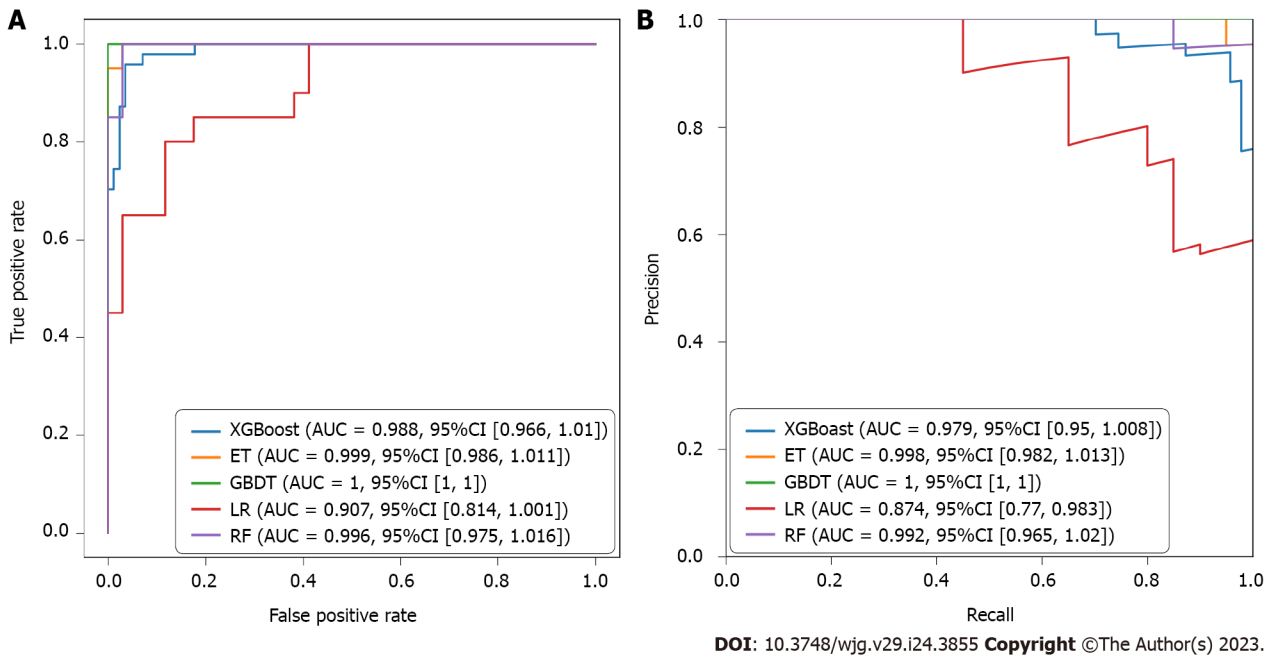

Figure 4 Examination of consequences between the top four single nucleotide polymorphisms and gene expression in nerve tibial tissue. Patients with interleukin (IL)-12 rs1353248_TT (chr3_159905770, $P = 8.52 \times 10^{-4}$), brain-derived neurotrophic factor (BDNF) rs6265_CT (chr11_27658369, $P = 1.07 \times 10^{-4}$) BDNF rs2030324_AG (chr11_27705368, $P = 9.2 \times 10^{-11}$), and BDNF rs11030104_AG (chr11_27662970, $P = 2.76 \times 10^{-5}$). A: IL-12; B-D: BDNF. The expression levels of the BDNF gene were reduced in rs6265CT and rs11030104AG. Additionally, the expression levels of the IL-12 gene were significantly decreased in the rs1353248TT. BDNF: Brain-derived neurotrophic factor; IL: Interleukin.

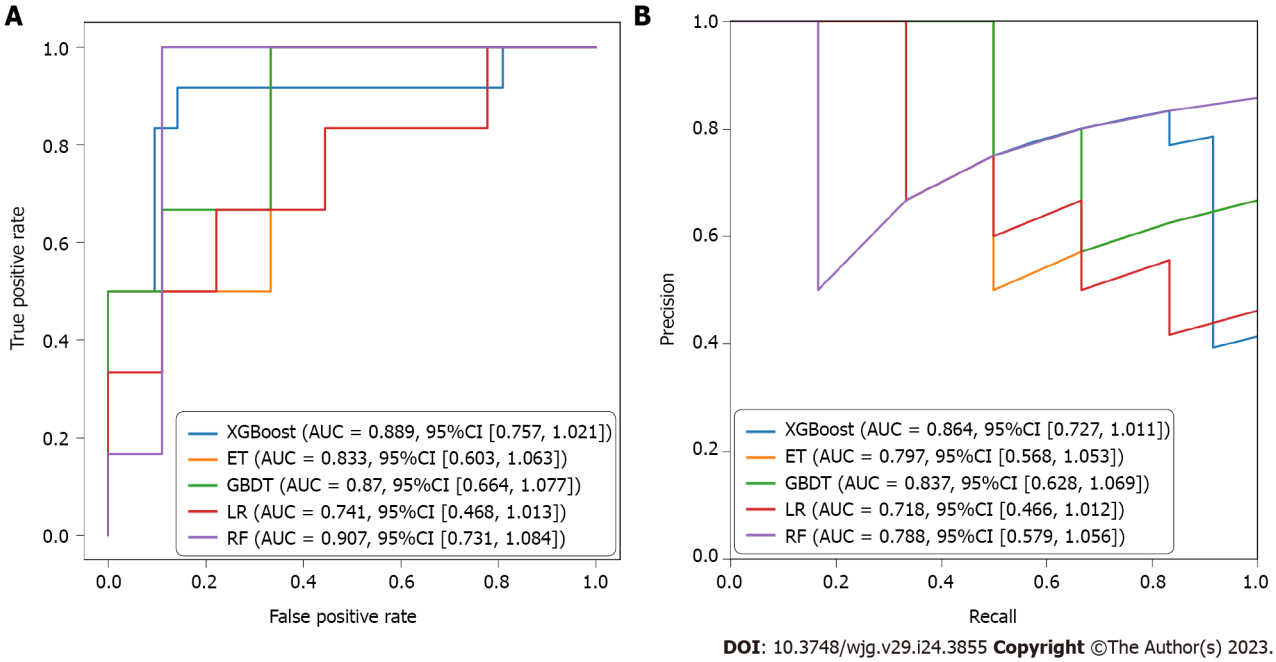
prediction[39-41]. Not only this, the method based on machine learning no longer requires strong assumptions about basic mechanisms such as image classification[40] and speech recognition[42], which have achieved cutting-edge predictive capabilities.

We developed a model for predicting TiPN in Chinese people using machine learning (XGBoost, ET, GBDT, RF and LR) based on genetic and clinical variables for the first time. As a result of the comprehensive evaluation, the model generated by the XGBoost algorithm reached the optimum prediction ability, which could accurately distinguish 88.9% of patients (Table 4), this was consistent with the results of other relevant studies[43,44]. By ranking each feature, rs1353248, rs6265, rs2030324 and rs11030104, and drug dose had the top five effects on TiPN. We showed that machine learning methods were superior to traditional statistical methods, and compared with two recently published studies on other diseases[45,46], our XGBoost model yielded higher ROC-AUC and PRC-AUC scores. Furthermore, the significant aspect of the XGBoost model is that TiPN can be identified at a high probability early in the disease course and may significantly improve the treatment outcome.



We applied an additional analysis by inputting SNPs, clinical variables, and the top five ranked features investigate whether there was any impact on model performance. As a result, all the models performed well when including SNPs and the top five features, near the level of all features combining 18 clinical variables and 14 SNPs in the models. Taken together with the ROC and PR curves, these results showed that genetic variables had a more important role than clinical variables in predicting TiPN occurrence, while in combination with clinical data, they markedly improved the model, suggesting that integration with genetic features and clinical data refined the predictive models.

Among the four SNPs, we focused mainly on *BDNF* and *IL-12* according to the ranked results. So far, the relationship between SNPs of the *IL-12* gene and the risk of TiPN has not been studied. To our knowledge, only one genome-wide association study has reported that *IL-12* rs1353248 had strong relevance to celiac disease[47]. In our study, *IL-12* rs1353248 had distinct relevance to TiPN, indicating a new and genetically relevant connection between genetic determinants of IL-12 and TiPN risk.

BDNF plays a significant role in neuronal differentiation, survival, and synaptic plasticity. BDNF protein levels in fibromyalgia patients are significantly elevated. Similar to our research, Park *et al*[48] found that *BDNF* rs11030104_GG had a protective effect against fibromyalgia compared with *BDNF* rs11030104_AG in a multicenter prospective study of the Korean population[46]. In addition, *BDNF* rs6265 SNP has been widely studied for its role in the regulation of neuronal survival, differentiation, and plasticity[49-52]. Xie *et al*[53] revealed that rs2030324_CT and rs6265_AG were associated with

amnestic mild cognitive impairment[53]. The effects of *BDNF* rs6265 polymorphism have been widely studied in animal models. In adult male mice, the *BDNF* Val66Met polymorphism impaired sports training-induced synaptic plasticity and beneficial behavior[54]. We reported similar findings, with *BDNF* rs6265_CT and *BDNF* rs2030324_AG being risk factors for TiPN. We suggest that heterozygotes for this gene impair neuronal activity, which is potentially involved in the perception of neuropathy symptoms. It can be speculated that mutation of the T allele of rs6265, G allele of rs2030324 and rs11030104 has a major impact on the expression levels of this gene according to the GTEx databases, and the mechanism of action merits further, in-depth investigation. In the Israeli population with lymphoma and myeloma, the severity and persistence of chemotherapy-induced peripheral neuropathy were markedly higher in the carriers of the Val/Val genotype than in patients with the Val/Met and Met/Met genotypes[50], which is different from our results. This difference may be due to the fact that the two research results are inherently different and difficult to compare directly. However, it suggests that the risk of neurotoxicity differs in different human populations according to the National Center for Biotechnology Information (NCBI, https://www.ncbi.nlm.nih.gov/) and China Metabolic Analytics Project (http://www.mbiobank.com/). It is noteworthy that the mutation rate of rs6265 and rs11030104 in Asian populations is as high as 49%, while in European and American populations, the mutation rate of these loci does not exceed 22%. This indicates that a higher number of individuals in Asian populations may be susceptible to TiPN, and these two loci are of predictive significance in Asian populations.

In addition to SNP-based correlation analysis, we considered 18 clinical features that may be related to the development of TiPN. In the training set, five models (LR, RF, ET, GBDT and XGBoost) were constructed to predict the TiPN risk including 14 SNPs and 18 clinical features. Considered collectively, the XGBoost model obtained the optimum performance in all functional training and test sets. As a result of predicting the characteristic importance using the XGBoost model, the dose was found to be the second most important factor. This finding was in line with previous reports[13,55]. In addition, the prospective study on 135 patients with skin disease showed that the incidence rate of TiPN was 11% (4/35) with a dose of 25-50 mg/d, 29% (11/38) with 50-75 mg/d, and 48% (19/40) with 75-100 mg/d. The incidence of neurotoxicity was three times higher in patients taking higher doses than in those taking lower doses. Similar trends were found in this study, the incidence rate of TiPN was 18% (9/49) with 25-50 mg/d, 33% (14/43) with 50-75 mg/d, and 49% with > 75 mg/d.

There were some limitations to our study. First, the sample size was small because it was a single-center trial. To improve the generalization and robustness of our predictive model, we reiterated this random procedure 1000 times. Second, clinical measures like peripheral nerve injury severity, presence of current therapy, duration and cumulative dose were not specified by the initial protocol design. Third, a limited number of SNPs and genes were selected for examination because of cost constraints, and more SNPs remain to be found.

Interventions may be a key adjunct to reducing the incidence of TiPN in future treatment. This is the first study to use cutting-edge machine learning to establish and validate a TiPN predictive model using comprehensive genetic and clinical variables. Genes encoding inflammatory cytokines, growth of nerve fibers, and enzymes involved in ubiquitination were also screened out. These SNPs are closely related to the occurrence and development of TiPN. The results suggest that SNPs are important to fully predict TiPN. Through the prediction of this model, physicians can assess the possibility of TiPN in CD patients, which contributes to the rational use, timely intervention after administration, and avoidance of peripheral nerve damage. These findings are important for the management of CD patients with thalidomide.

CONCLUSION

In this study, the XGBoost algorithm exhibited a high degree of accuracy in predicting TiPN by utilizing 18 clinical features and 14 genetic variables. Furthermore, it can identify high-risk patients through SNPs. This suggests that XGBoost may offer a feasible option for improving thalidomide efficacy in CD patients.

ARTICLE HIGHLIGHTS

Research background

Thalidomide-induced peripheral neuropathy (TiPN), a life-threatening condition in Crohn's disease (CD), has a high incidence in Asia. However, there are no effective medical interventions for TiPN.

Research motivation

Can we develop a predictive model of TiPN combining genetic and clinical variables? Which variable affects TiPN more?

Research objectives

To establish an optimal model using clinical variables and genotypes to predict TiPN and improve the safety for the thalidomide treatment.

Research methods

A total of 164 patients diagnosed with CD at the Sixth Affiliated Hospital of the Sun Yat-Sen University were included in this study. Peripheral blood was collected from the patients to detect the genotypes at School of Pharmaceutical Sciences, Sun Yat-Sen University. The X^2 method or Single-sample Kolmogorov–Smirnov test was used to determine the association of TiPN with 18 clinical features and 150 genetic variables. Five predictive models were established and evaluated by the confusion matrix receiver operating characteristic curve (AUROC), area under the precision-recall curve (AUPRC), specificity, sensitivity (recall rate), precision, accuracy, and F1 score.

Research results

TiPN was observed in 59 individuals. Among the five models, extreme gradient boosting (XGBoost) algorithm exhibited the best predictive performance with the highest specificity (0.857), accuracy (0.818), AUPRC (0.86) and AUROC (0.89) after evaluation. The top-ranking five risk variables associated with TiPN were interleukin-12 rs1353248 [P = 0.0004, odds ratio (OR): 8.983, 95% confidence interval (CI): 2.497-30.90), dose (mg/d, P = 0.002), brain-derived neurotrophic factor (BDNF) rs2030324 (P = 0.001, OR: 3.164, 95%CI: 1.561-6.434), BDNF rs6265 (P = 0.001, OR: 3.150, 95%CI: 1.546-6.073) and BDNF rs11030104 (P = 0.001, OR: 3.091, 95%CI: 1.525-5.960).

Research conclusions

The XGBoost algorithm accurately predicts TiPN using 18 clinical features and 14 genetic variables. It is able to identify high-risk patients using single nucleotide polymorphisms.

Research perspectives

Applying the machine learning to adjust thalidomide therapies based on these specific genotypes is recommended before the thalidomide treatment.

ACKNOWLEDGEMENTS

We thank the physicians and nurses from department of gastroenterology for their cooperation in this study.

FOOTNOTES

Author contributions: Mao J, Chao K, Zhu X, and Wang XD designed the study; Mao J and Zhou BJ performed the experiments; Chao K, Gao X, Yang T and Li P enrolled the patients and collected the clinical data; Mao J and Ye XP performed the machine learning analyses; Huang M and Hu PJ supervised the study; Mao J and Wang XD wrote the manuscript.

Abstract

BACKGROUND

Stereotactic body radiotherapy (SBRT) and programmed cell death 1 inhibitors have shown potential in treating hepatocellular carcinoma (HCC) in retrospective studies.

AIM

To evaluate the efficacy of combining SBRT with sintilimab for patients with recurrent or oligometastatic HCC.

METHODS

This trial involved patients with recurrent or oligometastatic HCC intravenously treated with SBRT plus sintilimab every 3 wk for 12 mo or until disease progression. The primary endpoint was progression-free survival (PFS).

RESULTS

Twenty-five patients were enrolled from August 14, 2019, to August 23, 2021. The median treatment duration was 10.2 (range, 0.7-14.6) months. SBRT was delivered at a median dose of 54 (range, 48-60) Gy in 6 (range, 6-10) fractions. The median follow-up time was 21.9 (range, 10.3-39.7) mo, and 32 targeted lesions among 25 patients were evaluated for treatment response according to the Response

Evaluation Criteria in Solid Tumors version 1.1. The median PFS was 19.7 mo [95% confidence interval (CI): 16.9-NA], with PFS rates of 68% (95%CI: 52-89) and 45.3% (95%CI: 28-73.4) at 12 and 24 mo, respectively. The median overall survival (OS) was not reached, with OS rates of 91.5% (95%CI: 80.8-100.0) and 83.2% (95%CI: 66.5-100.0) at 12 and 24 mo, respectively. The 1- and 2-year local control rate were 100% and 90.9% (95%CI: 75.4%-100.0%), respectively. The confirmed objective response rate and disease control rate was 96%, and 96%, respectively. Most adverse events were graded as 1 or 2, and grade 3 adverse events were observed in three patients.

CONCLUSION

SBRT plus sintilimab is an effective, well-tolerated treatment regimen for patients with recurrent or oligometastatic HCC.

Key Words: Stereotactic body radiotherapy; Programmed cell death 1; Sintilimab; Hepatocellular carcinoma; Efficacy and safety

Core Tip: In this single-arm phase II trial, stereotactic body radiotherapy (SBRT) plus sintilimab showed outstanding progression-free survival and objective response rate in the treatment of recurrent or oligometastatic hepatocellular carcinoma. Moreover, the combined use of SBRT and sintilimab is safe and tolerable. Patients can recover rapidly from radiotherapy-induced decreases in lymphocyte counts. This result suggests that SBRT combined with sintilimab may be a new treatment option for patients with recurrent or oligometastatic hepatocellular carcinoma.

INTRODUCTION

Liver cancer is the sixth most prevalent cancer, with the fourth highest mortality rate. China accounts for nearly half of all hepatocellular carcinoma (HCC) cases globally[1,2]. Surgery is an important curative therapy for HCC. The 5-year recurrence rate of HCC has reached 60%-70% after surgical resection and active postoperative management[3-5]. In addition to intrahepatic recurrence, the most common sites of metastasis are the lung, lymph node, and bone[6]. Oligometastasis is defined as a transition point between localized disease and widespread metastasis and has been applied to several solid tumors[7]. Although systemic treatment is the standard of care for patients with HCC presenting with extrahepatic metastases, effective treatments for oligometastatic HCC remain unknown[8]. Studies have demonstrated the efficacy of stereotactic body radiotherapy (SBRT) for HCC, with a high local control rate and acceptable toxicity[9-11]. However, the treatment effect of SBRT is determined by lesions in the irradiated field. Therefore, the development of additional treatment regimens to further reduce the recurrence out of the radiation volume and improve the prognosis of HCC is urgently required.

The combination of programmed cell death 1 (PD-1) inhibitors and targeted antiangiogenic treatment is considered the standard first-line treatment regimen for advanced HCC[12,13]. Immunotherapy, as a systematic treatment, has a long tail effect. It can provide a lasting survival benefit by generating memory T cells and exercise better control of tumor cells throughout the body[14]. The upregulation of programmed death ligand-1 (PD-L1) is associated with radioresistance in patients with HCC after radiotherapy, and the use of PD-1/PD-L1 inhibitors can kill tumor cells through the immune response effect. Thus, the recurrence rate can be further reduced owing to the potential synergistic effect of combined radiotherapy and PD-1 inhibitors[15,16].

Sintilimab is a highly selective, fully human immunoglobulin G4 monoclonal antibody against PD-1, and the combined use of sintilimab and bevacizumab is the first-line treatment for advanced HCC in China[13]. A retrospective cohort study included 76 patients with intermediate-stage HCC who presented with trans-arterial chemoembolization (TACE) refractoriness and found that progression-free survival (PFS) and overall survival (OS) were improved after the use of SBRT combined with a PD-1 inhibitor[17], but these results were not verified in clinical trials. Thus, the current phase II trial aimed to

assess the efficacy and safety of SBRT plus sintilimab in patients with recurrent or oligometastatic HCC.

MATERIALS AND METHODS

Study design and participants

This was a single-arm, open-label, single-center, phase II trial registered with ClinicalTrials.gov (NCT03857815). This study enrolled adult patients (aged between 18 and 75 years) with diagnostic criteria for HCC between August 14, 2019, and August 23, 2021, at Zhongshan Hospital, Fudan University. Patients with Child–Pugh A and an Eastern Cooperative Oncology Group performance status (ECOG PS) of 0–1 were eligible for this study. Other main inclusion criteria were as follows: (1) Patients with the number of lesions between one and five, which is suitable for SBRT; (2) patients without a history of radiotherapy; and (3) patients with adequate hematological and organ functions. Patients presenting with fibrolamellar HCC, sarcomatoid HCC, and cholangiocarcinoma and with a history of liver transplantation and other acute or chronic conditions were ineligible. The eligibility criteria are detailed in the study protocol and are shown in the supplementary file.

The Medical Ethics Committee of Zhongshan Hospital, Fudan University, approved this study (B2019-010R), which was conducted in accordance with the standards of Good Clinical Practice and the Declaration of Helsinki and Istanbul. All patients consented to participate after being informed of the study's purpose.

All authors had access to the study data and reviewed and approved the final manuscript.

Treatment and assessments

After enrollment, all patients underwent SBRT combined with sintilimab for 12 mo or until disease progression. For SBRT, the gross tumor volume (GTV) was defined as computed tomography (CT), magnetic resonance imaging (MRI), or CT/MRI/positron emission tomography fusion images, and all lesions were included. The internal target volume (ITV) was constructed based on four-dimensional CT to delineate the GTV of each time phase and was generated. The planning target volume was defined as the ITV plus a margin of 3 mm. The patients underwent daily on-board megavoltage CT for imaging guidance. The patients received a total dose of 48–60 Gy in 5–10 fractions 5 times per week. Patients received 200 mg sintilimab intravenously once every 3 wk for 12 mo or until disease progression. Tumor imaging assessments were performed every 6 wk (± 7 d) from the first day of sintilimab treatment and every 12 wk (± 7 d) after 48 wk. After the initial evaluation of imaging progression by the investigator, if the participant was clinically stable, medication was continued, and imaging was repeated 4-6 wk later to confirm disease progression, or treatment was continued if no progression was confirmed.

Endpoints

The primary endpoint was PFS, which was defined as the time from the start of treatment to the date of progressive disease or death, whichever occurred first. The secondary endpoints included OS (the time from receipt of the study drug to death), local control rate, objective response rate [ORR, the proportion of patients who achieved complete response (CR) or partial response (PR) as their best overall response (BOR)], disease control rate (DCR, the proportion of patients who achieved CR, PR, or stable disease as their BOR), and adverse events. All outcomes were assessed by blinded independent central reviewers and investigators according to the Response Evaluation Criteria in Solid Tumors (RECIST) version 1.1. The details of the adverse event assessment are shown in the study protocol.

Statistical analysis

With reference to historical controls[18], patients with HCC with oligometastases or recurrence were treated with SBRT, with a median PFS period of approximately 8 mo. Assuming a median PFS period of 14.8 mo with SBRT plus sintilimab, a sample size of 25 patients would be required to provide a power of 80% with a one-sided alpha level of 0.05, assuming a drop rate of 10%. The Kaplan-Meier method was used for survival analysis. Descriptive summaries were provided for all other efficacy and safety endpoints. Unpaired T Test was used to explore the differences in the counts of biomarkers between groups. The *P* values for biomarkers between groups were two-sided, with $P < 0.05$ being considered statistically significant. Statistical analyses were performed using R 4.0.5.

RESULTS

Patient characteristics of treatment

The baseline characteristics of the enrolled patients are shown in Table 1. Twenty-five patients were enrolled in this study. Twenty-four (96%) patients were infected with hepatitis B. The liver function of all patients was Child-Pugh class A. Nineteen (76%) patients had intrahepatic recurrence, 6 (24%) patients showed extrahepatic recurrence, and 2 patients showed both intra- and extrahepatic

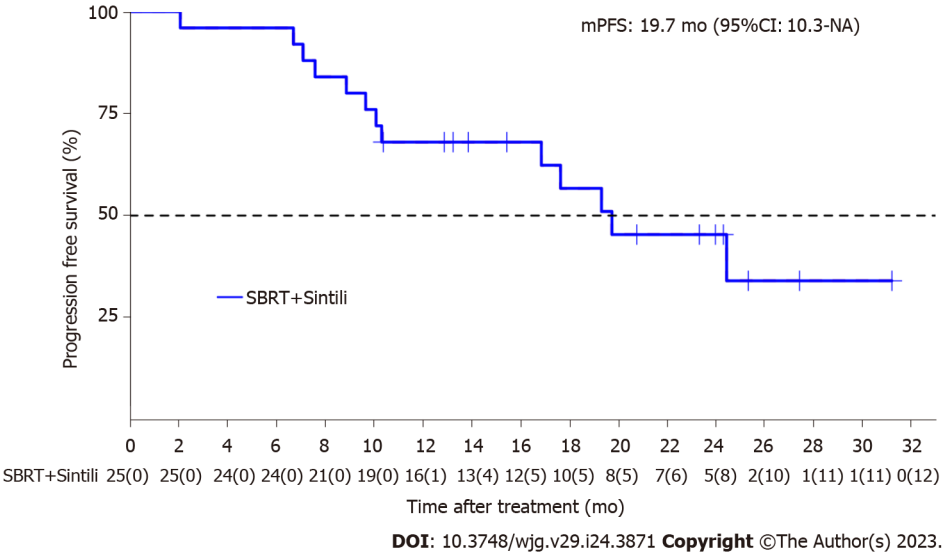
recurrences. Tumors 1, 2, and 3 were reported in 19, 5, and 1 patient(s), respectively. All the patients underwent surgery, ablation, or TACE previously. The median treatment duration was 10.2 (range, 0.7-14.6) months, and SBRT was delivered at a median dose of 54 (range, 48–60) Gy in 6 (range, 6–10) fractions.



Efficacy

The median follow-up time was 21.9 (range, 10.3–39.7) months, and 32 lesions in 25 patients were evaluated for treatment response according to RECIST version 1.1. The median PFS period was 19.7 [95% confidence interval (CI): 16.9-NA; Figure 1] mo, and the PFS rates at 12 and 24 mo were 68% (95%CI: 52-89) and 45.3% (95%CI: 28-73.4), respectively.

The median OS was not reached, and three events of death were observed, with 91.5% (95%CI: 80.8-100.0) and 83.2% (95%CI: 66.5-100.0) OS rates at 12 and 24 mo, respectively. Moreover, the 1- and 2-year local control rates were 100% and 90.9% (95%CI: 75.4%-100.0%), respectively (Table 2). The ORR was 96% (24/25) according to RECIST version 1.1, with 17 achieving CR and 7 achieving PR after sintilimab plus SBRT therapy. After one cycle of treatment, all target liver lesions disappeared, although new lesions appeared in the lungs of one patient, which was judged as PD. The best change in the target tumor size is shown in Figure 2A. One patient achieved PR after two cycles of sintilimab plus SBRT therapy. However, the patient underwent a self-determined liver transplant (protocol violation reported) and died 5 mo after surgery due to liver failure caused by liver transplantation (Figure 2B). Similarly, the DCR for patients with HCC treated with SBRT combined with sintilimab was 96% (Table 2). The median time to response was 2.1 (range, 0.9-6.6) months for the 24 responders, whereas the median duration of response was 16.9 mo (95%CI: 8.18-NA).

Safety

All the patients received at least one dose of the study treatment and were included in the safety analysis. The details of the adverse events in patients with HCC treated with SBRT combined with sintilimab are shown in Table 3. In total, 22 (88.0%) patients reported treatment-related adverse events (TRAEs), and grade 1 and 2 adverse events were observed in 17 (68%) and 14 (56%) patients, respectively. The most common TRAE was decreased lymphocyte count (probably caused by radiotherapy). The lymphocyte count decreased significantly after the second treatment (Supplementary Figure 1). However, the lymphocyte counts gradually returned to baseline after the third treatment session. Grade 3 TRAEs, including increased gamma-glutamyl transpeptidase level, decreased platelet count, and myositis, were observed in 3 (12%) patients. No grade 4 or 5 TRAEs were observed.

Four patients presented with serious adverse events. One patient had grade 1 myocarditis, possibly due to immunotherapy; one had grade 2 immune pneumonia; and one patient had viral hepatitis, which was evaluated to be independent of the treatment regimen. One patient experienced upper gastrointestinal bleeding owing to cirrhosis of liver. All four patients recovered after medical treatment. The study treatment was interrupted due to emergent adverse events in 3 (12%) of the 25 patients, including 1 patient with myocarditis, 1 with upper gastrointestinal bleeding, and 1 with arthritis. Patients should continue treatment after recovery from adverse reactions; however, all three patients refused to resume use. Permanent discontinuation due to adverse events occurred in three patients, including one patient with pneumonia (grade 2), one with elevated bilirubin level (grade 3), and one with ascites (grade 2).

Exploration of biomarkers

This study also explored biomarkers that could be used to predict efficacy. In this study, blood samples from patients after each treatment were collected and analyzed for lymphocyte counts and their subset populations [CD19+ B cells, CD3+, CD4+, CD8+ T cells, and CD15+CD56+ natural killer (NK) cells] by flow cytometry. The median PFS period (19.7 mo) was applied as a cutoff value, and there were no significant differences between PFS ≥ 19.7 and PFS < 19.7 mo for lymphocyte count, CD19+ B, CD3+, CD4+, CD8+ T, and CD15+CD56+ NK cells at baseline. PFS period ≥ 19.7 mo was associated with higher lymphocyte counts and CD3+, CD4+, CD8+ T, and CD15+CD56+ NK cells compared to PFS period < 19.7 mo after three treatments. These significant differences persisted after the four treatments, except for CD8+ T cells. Furthermore, the difference between PFS ≥ 19.7 and PFS < 19.7 mo after five treatments disappeared for most biomarkers, whereas significant differences remained for lymphocyte count and CD19+ B cells. Finally, PFS ≥ 19.7 mo persisted and was associated with elevated number of CD19+ B cells (Figure 3).

DISCUSSION

To the best of our knowledge, this is the first prospective study of SBRT in combination with PD-1 inhibitor for recurrent or oligometastatic HCC. This study demonstrated that SBRT delivered at a median dose of 54 Gy in 6 fractions plus sintilimab achieved a remarkable PFS period of 19.7 mo and an outstanding ORR of 96% in such patients. Although the median OS was not reached, the OS rates at 12 and 24 mo were 91.5% and 83.2%, respectively. Moreover, the local control rates at 12 and 24 mo were 100% and 90.9%, respectively, whereas the DCR after treatment was 96%. Furthermore, TRAEs in most patients were mild and well tolerated.

The enrolled patients in our study were diagnosed with recurrent or oligometastatic HCC and belonged to the advanced-stage HCC population. Currently, the standard systemic treatment for advanced HCC is PD-1/PD-L1 inhibitors in combination with bevacizumab, such as sintilimab plus bevacizumab and atezolizumab plus bevacizumab. The median PFS period of the experimental groups in Orient-32 and Imbrave150 were 4.6 and 6.8 mo, respectively[13,19]. In our study, 19.7 mo of median

PFS (mPFS) period showed a beneficial tendency with SBRT and sintilimab. Notably, the population characteristics of our study were different from these two phase-III studies. The proportion of patients with vessel invasion or extrahepatic metastasis was > 60% in both Orient-32 and Imbrave150. Moreover, patients accounted for approximately 40% of the total population with both ECOG PS of 1 andα-fetoprotein (AFP) ≥ 400 ng/mL. However, patients with few metastases or relapses were enrolled in our study, and the median number of metastases was 1. Additionally, most of them had ECOG PS 0 (76%), and patients with AFP ≥ 400 ng/mL only accounted for 12%. Given the above, the high proportion of patients with good physical condition and the low proportion of patients with AFP ≥ 400 ng/mL could be explained by the remarkable mPFS period in this study. Moreover, it can also be considered the main possible reason that patients with recurrent or oligometastatic HCC (tumor lesions ≤ 5) benefit from combination therapy of SBRT plus immunotherapy.

Oligometastasis was defined as ≤ 5 metastatic lesions, and SBRT was recommended for patients with oligometastasis and many other cancers. However, no prospective clinical studies have reported the treatment strategies for patients with recurrent or oligometastatic HCC. Several retrospective clinical studies on patients with recurrent or oligometastatic HCC demonstrated that after SBRT, the 1-year OS and local control rates were 55%-84% and 77%-94%, respectively[5,20-23]. In the current study, the 1-year OS and local control rates were 91.5% and 100%, respectively. Although comparisons between studies need to be made cautiously, in terms of benefit trends, it seems that SBRT plus sintilimab has more survival benefits. This encouraging therapeutic effect can be interpreted as radiation activating the immune system by inducing tumor cell death, which can promote cytokine release and damage-associated molecular patterns. The tumor-specific T lymphocytes are then primed and trafficked into the tumor microenvironment, which can enhance the efficacy of PD-1 inhibitors[24]. Another retrospective study of SBRT plus PD-1 inhibitors for patients with Barcelona Clinic Liver Cancer intermediate-stage HCC with a median PFS period of up to 19.6 mo also verified the combination efficacy[17]. It should be emphasized that this retrospective study included patients with intermediate-stage HCC, which theoret-

ically represent a better prognosis.

In addition, our study reported that the ORR after sintilimab and SBRT was 96%, and only one patient had liver lesions that disappeared with pulmonary metastasis. In previous retrospective studies on HCC with recurrence or oligometastases, the ORR of SBRT in this subset was 59%-85%. The authors clearly stated that out-of-field recurrence was the major cause of disease progression[5,20-23]. Sintilimab, as a systemic immunotherapy, can inhibit tumor cell escape and reactivate T cells, thereby reducing out-field recurrence.

In terms of safety, the combination of sintilimab and SBRT was well tolerated. Most TRAEs were of grades 1-2. Grade 3 TRAEs were observed in only 12% of the patients. A decreased lymphocyte count a common AE associated with radiotherapy. The results of monitoring changes in lymphocyte counts showed that decreased lymphocyte counts gradually recovered, and previous reports indicated that recovery from reduced lymphocyte count is faster in patients with HCC treated with SBRT than in those treated with conventional RT.

Biomarker-related analyses have mainly explored the relevance of lymphocytes and their subsets to efficacy. The results showed that patients with a longer PFS had higher lymphocyte counts and CD19+ B, CD3+, CD4+, CD8+ T, and CD15+CD56+ NK cells after four to five prior therapies. This is consistent with the result of a previous biomarker explorative study on SBRT for lung cancer, suggesting that lymphocyte counts and subsets can be potential biomarkers for predicting efficacy[25]. The significant difference gradually disappeared after the fifth to sixth treatments, which is likely related to the reduced sample size due to the increasing number of patients with disease progression and loss of follow-up. This needs to be confirmed in further studies with larger sample sizes.

This study has some limitations. The current study was designed as a phase II trial with no parallel control group. Moreover, the sample size was small, and stratified analyses according to patient characteristics were not performed. Finally, the history of prior therapy varied across the enrolled patients, which could have affected the prognosis of HCC.

CONCLUSION

In this single-arm phase II trial, SBRT plus sintilimab showed outstanding PFS and ORR in the treatment of recurrent or oligometastatic HCC. Moreover, the combined use of SBRT and sintilimab is safe and tolerable. Patients can recover rapidly from radiotherapy-induced decreases in lymphocyte counts. Considering mostly included patients (96%) infected with hepatitis B, this result suggests that SBRT combined with sintilimab may be a new treatment option for patients with recurrent or oligometastatic HCC and infected with hepatitis B. Further large-scale, parallel-control randomized controlled trials should be conducted to compare the effects of SBRT plus sintilimab with other

treatments, including SBRT without immunotherapy or radioembolization delivers doses to the tumor greater than 100 Gy.

ARTICLE HIGHLIGHTS

Research background

Hepatocellular carcinoma (HCC) accounts for the third-leading cause of cancer-related deaths, and only 30%-40% of patients were diagnosed at early stages. The oligometastatic HCC indicated the metastasis of HCC was not widespread, and some patients may obtain benefits for curative treatments.

Research motivation

Stereotactic body radiotherapy (SBRT) and programmed cell death 1 (PD-1) inhibitors are widely used for HCC, whether the use of SBRT combined with a PD-1 inhibitor could offer superior benefits for oligometastatic HCC remained unclear.

Research objectives

To assess the efficacy and safety of combining SBRT with sintilimab for patients with recurrent or oligometastatic HCC.

Research methods

Patients with recurrent or oligometastatic HCC were involved and treated with combining SBRT with sintilimab for 12 mo or disease progression. The primary endpoint was progression-free survival (PFS), while the secondary endpoints included overall survival (OS), local control rate, objective response rate (ORR), disease control rate (DCR), and adverse events.

Research results

The median PFS was 19.7 mo [95% confidence interval (CI): 16.9-NA], while the median OS was not reached. Moreover, the 1- and 2-year local control rate were 100% and 90.9% (95%CI: 75.4%-100.0%), while the ORR and DCR were 96%, and 96%, respectively. Only 3 patients reported grade 3 adverse events, including increased gamma-glutamyl transpeptidase level, decreased platelet count, and myositis.

Research conclusions

SBRT plus sintilimab can serve as an effective, well-tolerated treatment regimen for patients with recurrent or oligometastatic HCC.

Research perspectives

Further large-scale, parallel-control randomized controlled trials should be performed to verify the therapeutic effects of SBRT plus sintilimab for patients with recurrent or oligometastatic HCC.

FOOTNOTES

Author contributions: Zeng ZC, Liu TS, Chen YX, Du SS, and Yu YY contributed to the conception and study design; Chen YX, Yang P, Zhuang Y, Huang C, Hu Y, and Zhu WC contributed to the investigation and data curation; Chen YX, Zeng ZC, and Liu TS performed the data analysis and interpretation; Chen YX wrote the original draft; Zeng ZC, Liu TS, Chen YX, and Du SS wrote the review and editing; Liu TS and Zeng ZC contributed equally to this work. All authors reviewed and approved the final draft of the manuscript.

Abstract

BACKGROUND

Laparoscopic and endoscopic cooperative surgery is a safe, organ-sparing surgery that achieves full-thickness resection with adequate margins. Recent studies have demonstrated the safety and efficacy of these procedures. However, these techniques are limited by the exposure of the tumor and mucosa to the peritoneal cavity, which could lead to viable cancer cell seeding and the spillage of gastric juice or enteric liquids into the peritoneal cavity. Non-exposed endoscopic wall-inversion surgery (NEWS) is highly accurate in determining the resection margins to prevent intraperitoneal contamination because the tumor is inverted into the visceral lumen instead of the peritoneal cavity. Accurate intraoperative asse-

ssment of the nodal status could allow stratification of the extent of resection. One-step nucleic acid amplification (OSNA) can provide a rapid method of evaluating nodal tissue, whilst near-infrared laparoscopy together with indocyanine green can identify relevant nodal tissue intraoperatively.

AIM

To determine the safety and feasibility of NEWS in early gastric and colon cancers and of adding rapid intraoperative lymph node (LN) assessment with OSNA.

METHODS

The patient-based experiential portion of our investigations was conducted at the General and Oncological Surgery Unit of the St. Giuseppe Moscati Hospital (Avellino, Italy). Patients with early-stage gastric or colon cancer (diagnosed *via* endoscopy, endoscopic ultrasound, and computed tomography) were included. All lesions were treated by NEWS procedure with intraoperative OSNA assay between January 2022 and October 2022. LNs were examined intraoperatively with OSNA and postoperatively with conventional histology. We analyzed patient demographics, lesion features, histopathological diagnoses, R0 resection (negative margins) status, adverse events, and follow-up results. Data were collected prospectively and analyzed retrospectively.

RESULTS

A total of 10 patients (5 males and 5 females) with an average age of 70.4 ± 4.5 years (range: 62-78 years) were enrolled in this study. Five patients were diagnosed with gastric cancer. The remaining 5 patients were diagnosed with early-stage colon cancer. The mean tumor diameter was 23.8 ± 11.6 mm (range: 15-36 mm). The NEWS procedure was successful in all cases. The mean procedure time was 111.5 ± 10.7 min (range: 80-145 min). The OSNA assay revealed no LN metastases in any patients. Histologically complete resection (R0) was achieved in 9 patients (90.0%). There was no recurrence during the follow-up period.

CONCLUSION

NEWS combined with sentinel LN biopsy and OSNA assay is an effective and safe technique for the removal of selected early gastric and colon cancers in which it is not possible to adopt conventional endoscopic resection techniques. This procedure allows clinicians to acquire additional information on the LN status intraoperatively.

Key Words: Laparoscopic and endoscopic cooperative surgery; Non-exposed endoscopic wall inversion surgery; Early gastric cancer; Early colorectal cancer; Sentinel lymph node; One-step nucleic acid amplification; Endoscopic full-thickness resection

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The treatment efficacy of non-exposed endoscopic wall-inversion surgery combined with sentinel lymph node (LN) biopsy and intraoperative one-step nucleic acid amplification assay remains to be fully evaluated in early gastric and colon cancers. The patients included in the experiential portion of our investigations were diagnosed with early gastric and colon cancers that were not amenable to conventional endoscopic resection techniques. We found that this approach provides essential details on LN status intraoperatively and we discuss the related literature to help guide future research studies and clinical care.

INTRODUCTION

The most effective treatment for patients with resectable gastrointestinal submucosal tumors (SMTs), including gastrointestinal stromal tumors[1-4] and early gastrointestinal cancer[5], is complete surgical

resection. Segmental resection is acceptable based on oncologic principles[6-8]. Endoscopic submucosal dissection (ESD) is a well-studied treatment for adenomas and early cancer of the gastrointestinal tract [9]. In some cases, it has low rates of microscopic resections with a negative margin (R0). ESD in lesions involving the muscularis propria remains controversial due to the increased risk of perforation[10-13]. Adverse events have also been described in lesions located in anatomical positions that are difficult to access.

Previous studies reported that laparoscopic wedge resection for gastric submucosal tumors (SMTs) was oncologically feasible and safe with a decrease in blood loss and length of hospital stay[14-16] compared to other classic gastric resections. Using the conventional laparoscopic approach, it is difficult to establish the exact line of resection for intraluminally developing gastrointestinal tumors. With limited or overabundant resections, there is a risk of having postoperative functional problems or infiltrated resection margins with postoperative recurrence[17,18]. Endoscopic control of the resection margin is essential for safe local resection in early gastrointestinal cancers[19]. Narrow-band imaging (NBI) is a digital optical method of image-enhanced endoscopy that enhances the vessel and surface structure of colorectal lesions using 415 nm and 540 nm wavelength filters[20-22]. Several NBI classifications for colorectal lesions have been proposed. These classifications were unified as the NBI International Colorectal Endoscopic (NICE) classification for non-magnifying endoscopy in 2009 and the Japan NBI Expert Team (JNET) classification for magnifying endoscopy in 2014[20,23-27].

NICE was divided into three groups based on histology: Hyperplastic or sessile serrated polyp (type 1), adenoma (type 2), and deep submucosal invasive cancer (type 3). There are also three criteria: Surface pattern, vase pattern and colour[26,27]. The Japanese endoscopists separated the type 2 NICE category into type 2A (low-grade adenoma) and type 2B (high-grade adenoma and submucosal cancer) using magnifying endoscopy. They developed the JNET classification as an advanced version of the NICE classification. When magnifying endoscopy is available, the JNET classification is better at selecting the correct therapeutic strategy based on precise diagnosis[20].

To overcome the limitations of endoscopic resections and wedge resections, Hiki *et al*[28] combined the ESD technique to properly determine the resection margin with laparoscopic full-thickness excision, developing a hybrid technique of laparoscopic endoscopic cooperative surgery (LECS). The LECS allows to preserve the vascularization, the innervation of the wall, and the organs' functionality with a better postoperative quality of life for the patient.

To expand the indication of LECS, some modified LECS procedures were developed, such as non-exposed endoscopic wall-inversion surgery (NEWS)[29-36]. Currently, the LECS, already widely studied for stomach lesions, is also used for lesions of other organs, such as the duodenum[37], the rectum and the colon[38,39]. This technique allows the lesion to be approached simultaneously from the inside endoscopically and externally laparoscopically, allowing a limited resection that respects oncological principles[40-44].

Diagnostic imaging assessment of lymphadenopathy in gastric and colorectal cancers (CRCs) is challenging. Individual imaging modalities face specific intrinsic limitations, which negatively impact detection and it does not allow a correct evaluation of important lymph node (LN) details. Therefore we only have the size criterion available to determine lymphadenopathies[45]. A new semi-automated diagnostic method called one-step nucleic acid amplification (OSNA) has been developed to detect LN metastases. OSNA is based on reverse transcription–loop-mediated isothermal amplification[46,47] to amplify cytokeratin 19 (*CK19*) mRNA. The OSNA test has been used successfully in numerous malignancies[48]. Yaguchi *et al*[49] defined the CK19 mRNA cutoff to identify LN metastases with OSNA assay in gastric cancer[49-52]. Kumagai *et al*[50] showed that OSNA could be advantageously used to diagnose LN metastases in advanced gastric cancer.

CK19 is an epithelial marker. When it is identified in LNs from patients with CRC, it is highly suggestive of LN metastases[53-55]. The OSNA assay can assess LN metastasis in various cancers expressing CK19, including sentinel LNs in breast cancer and other cancers[56-59].

In this study, we determined the safety and feasibility of NEWS in early gastric and colon cancers and adding rapid intraoperative LN assessment with OSNA.

MATERIALS AND METHODS

A cohort study approach was taken, relying on data from a prospectively maintained database of consecutive patients undergoing elective NEWS for early gastric and colon cancers at St. Giuseppe Moscati Hospital of Avellino, Italy. The database included preoperative, intraoperative and postoperative data. Inclusion criteria were: (1) Adult age; (2) diagnosis with early gastric or colon cancer; and (3) eligibility for the NEWS procedure. Exclusion criterion was: Allergy to indocyanine green (ICG). In total, 10 patients were included in this study.

This study was carried out in continuity with our previous study[59] and conducted according to the ethical principles of the Institution following the Declaration of Helsinki and with approval by the Institutional Review Board of the St. Giuseppe Moscati Hospital (Approval No. 201801). Written informed consent was granted by study participants for the publication of this article.

Surgical-endoscopic technique and histopathological evaluation

Immediately after access to the abdominal cavity by laparotomy or laparoscopy, a flexible endoscope was passed to the tumor site (Figure 1) to allow a 0.5 mL submucosal injection of ICG (2.5–5.0 mg/mL) at four points around the tumor (Figure 2). The nodal basin was then examined under near-infrared (NIR) illumination (Karl Storz SE & Co., Tuttlingen, Germany). In the case of the stomach, we proceeded to the exeresis of identifiable nodes at one or two nodal basins (Figure 3). In contrast, in the case of the colon, any identifiable sentinel LNs were excised and submitted immediately to the pathology department. LNs harvested in this way were cleaned of fat. LNs weighing between 0.05 g and 0.60 g or with a cross diameter of less than 8 mm were exclusively processed using the OSNA technique. LNs weighing more than 0.60 g or with diameter over 8 mm were dissected and analyzed using the OSNA technique and hematoxylin and eosin (H&E). In the latter case, LNs were divided at 2-mm intervals, and nonadjacent blocks were alternatively subjected to definitive histopathological examination with H&E or OSNA. Our technique for preparation of materials for OSNA and interpretation of results has already been described in our previous study[59] (Figure 4). The patient's total tumor load (TTL) resulted from the sum of all *CK19* mRNA tumor copies/μL of each LN.

OSNA results with *CK19* mRNA above 250 copies/μL were designated positive, and those with fewer than 250 copies/μL were considered negative[59]. The result of the sentinel LN analysis was intraoperatively communicated to the surgeon. All patients underwent the NEWS procedure.

In this procedure, mucosal markings are placed around the tumor followed by serosal markings *via* laparoscope under endoscopic navigation. A longitudinal seromuscular incision is performed laparoscopically around the serosal markings, taking special care not to create a full-thickness opening in the wall. The pending vessels of the submucosa are coagulated laparoscopically. The seromuscular layers are sutured transversely (Figure 5) to avoid postoperative strictures, particularly in patients with colon cancer, and the lesion is inserted into the inside of the lumen. Finally, circumferential mucosal and submucosal tissue incisions are made endoscopically around the inverted tumor (Figure 6). The resected tumor is retrieved, and the mucosal defect is sutured with several endoscopic clips.

Patients with early gastric cancer and early colon cancer were encouraged to begin drinking and eating on postoperative day 1 after the NEWS procedure. If the postoperative course was uneventful, then patients could be discharged on postoperative day 1 or 2.

Subsequently, the records of each patient were discussed in a multidisciplinary conference with surgeons, pathologists, and oncologists, considering the definitive examination of the surgical specimen and the result of the sentinel LN analysis. The final histology of the surgical specimen and harvested LNs were always concluded based on the H&E analysis.

RESULTS

A total of 10 patients (5 males and 5 females) with an average age of 70.4 ± 4.5 years (range: 62-78 years) were observed in this study. Five patients were diagnosed with early-stage gastric cancer, and five patients were diagnosed with early-stage colon cancer. The mean tumor diameter was 23.8 ± 11.6 mm (range: 15-36 mm). The patient characteristics are shown in Table 1.

The NEWS procedure was successful in all cases. The mean procedure time was 111.5 ± 10.7 min (range: 80-145 min). The OSNA assay revealed no LN metastases in any patient. The diagnostic accuracy in predicting the LN status based on the sentinel LN concept by OSNA compared with the postoperative histological examination was 100%. Complete histological resection (R0) was achieved in 9 (90.0%) patients. The average post-procedure length of hospitalization was 3.1 ± 4.8 d (range: 1-8 d). There was no recurrence during the follow-up. The mean follow-up was 6.3 ± 4.2 mo.

There was only 1 patient who experienced a complication. In the gastric cancer group, 1 patient was treated conservatively for intrabdominal fluid collection (Table 2). One patient who underwent the removal of a lesion affecting the proximal transverse colon presented positive focal margins after histological examination. Therefore, he underwent a right hemicolectomy. The definitive histological examination showed no residual tumor foci or LN metastases (Table 3).

The average LN count was 2.5 ± 2.2, ranging from 1 to 5 nodes per patient. Five patients had early gastric cancer, and five had early CRC confirmed by final histology.

DISCUSSION

In this article, we investigated the possibility of adding to the NEWS (for early gastrointestinal cancers) an intraoperative study of LNs using fluorescence and ICG to identify the LN basin of the tumor and OSNA for the analysis of the excised LNs. We also performed a literature review on the use of NEWS in early gastrointestinal cancers, on sentinel LN and LN basin studies in gastric and colonic cancers, and on the intraoperative use of OSNA.

NEWS in early gastrointestinal cancers

NEWS has been reported as a novel full-thickness resection technique without wall perforation. It is primarily used to treat early gastrointestinal cancer[30,32-34,60,61]. An advantage of NEWS is that all the gastric or intestinal layers can be resected precisely under direct visualization by laparoscopy and endoscopy. As a result, wall resection is limited and oncological principles are respected. The size of the tumor is one of the main limitations of NEWS. Lesion size should be 30 mm or less as the resected specimen is retrieved perorally or transanally. The LECS concept initially adopted for gastric lesions can also be applied to colorectal tumors[38]. The appropriate indications of LECS for colorectal tumors are: (1) Intramucosal carcinoma (Tis) and adenoma with high-grade atypia accompanied by a severe degree of fibrosis in the submucosal layer (tumor recurrence after endoscopic or surgical resection); (2) Tis and adenoma with high-grade atypia involving the appendix or diverticulum; or (3) intraluminal or intramural growth-type SMTs. LECS for the colon is a safe and feasible procedure[62,63]. LECS for colorectal tumors has a 0% rate for either residual or local recurrence.

Currently, modified LECS procedures can be applied to cases of early gastrointestinal cancer (within the indication for endoscopic mucosal resection/ESD) that would be technically difficult to treat with endoscopic mucosal resection/ESD. Innovative organ-preserving procedures such as transanal minimally invasive surgery, LECS, and modified LECS allow adequate resection of early-stage tumors without extensive interventions[64].

Sentinel LN and nodal basin

The LN stage remains crucial for oncological treatments. Identifying LN metastases in gastric or CRC is still unsatisfactory despite improvements in imaging techniques[65-67]. Sentinel LN biopsy for early gastric cancer is reportedly helpful when deciding whether to perform LN dissection, and LECS combined with sentinel LN dissection has been attempted for early gastric cancer as well[31,68-70]. The sentinel LN is the first LN that receives lymphatic drainage from the primary tumor and is a predictor of the pathological status of all other LNs. Miwa[71] studied lymphatic basin dissection in gastric cancer as a method of sentinel LN biopsy. The specific lymphatic system for gastric cancer is stained by a dye tracer injected near the gastric lesion and drained into the lymphatic system. The lymphatic system is then dissected en bloc, and the sentinel LN analysis is performed.

Multiple reports have investigated lymphatic basin dissection as a specific sentinel LN biopsy in stomach cancer[72-75]. The lymphatic basin identified by dye mapping is excised en bloc, and sentinel LNs are analyzed ex vivo after dissection of the basin and sent for rapid intraoperative diagnosis. If, after sentinel LN biopsy, a positive LN is found, D2 gastrectomy is added. If LNs are negative for metastases, further dissection is avoided, gastric vasculature outside the basin is preserved, and the gastric resection area is minimized[76-79].

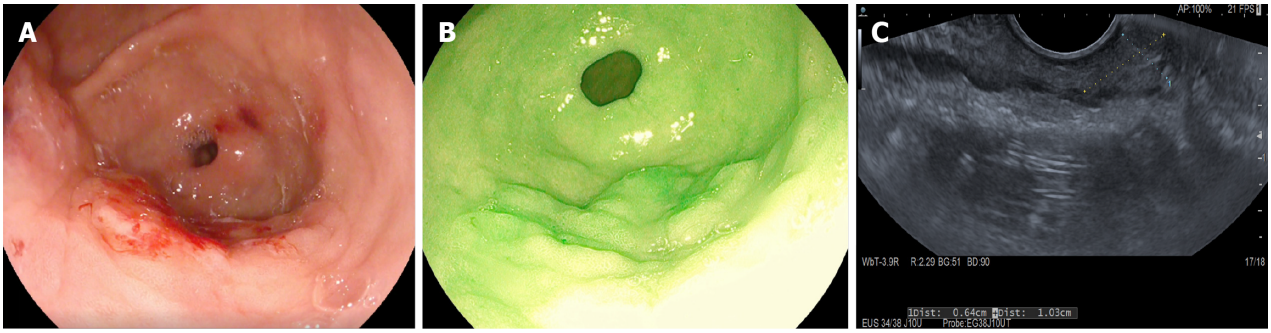
In recent years, a number of clinical trials in Japan and South Korea have shown that the safety and therapeutic effect of sentinel LN navigation surgery in early gastric cancer are acceptable[74,80-84]. A multicenter study in Japan showed that the detection rate of sentinel LNs in early gastric cancer reached 97.5%, with 93% sensitivity and 99% accuracy[75]. A multicenter randomized controlled trial (SENORITA) conducted in South Korea showed that the sentinel LN biopsy group did not have non-inferiority to the radical gastrectomy group for 3-year disease-free survival. However, the 3-year disease-free survival and 3-year overall survival rates did not differ after rescue surgery in recurrence/metachronous gastric cancer cases. The sentinel LN biopsy group had a better long-term quality of life and nutrition than the radical gastrectomy group[76,77].

Goto *et al*[34] reported the use of NEWS for early gastric cancer in combination with sentinel LN navigation surgery (SNNS). The lymphatic basin is an essential concept in SNNS.

OSNA in gastric cancer and CRC

Recent developments in the OSNA test allow for rapidly identifying metastases over the entire LN. The OSNA assay, already extensively studied in breast cancer[56], is under evaluation as an alternative diagnostic test for identifying secondary localizations of sentinel LNs in gastric cancer[65]. In the study by Yaguchi *et al*[49], the agreement rate between the OSNA test and H&E stain was 94.4%, and the sensitivity and specificity were 88.9 and 96.8%, respectively, when the CK19 mRNA cutoff value is 250 copies/μL. The multicenter study by Kumagai *et al*[50] showed that the OSNA test has the same precision as the 2 mm interval histological examination in detecting LN metastases in the case of stomach cancer. Shoji *et al*[85] showed that single-tracer sentinel LN mapping by ICG fluorescence imaging with intraoperative diagnosis by OSNA assay is feasible and safe.

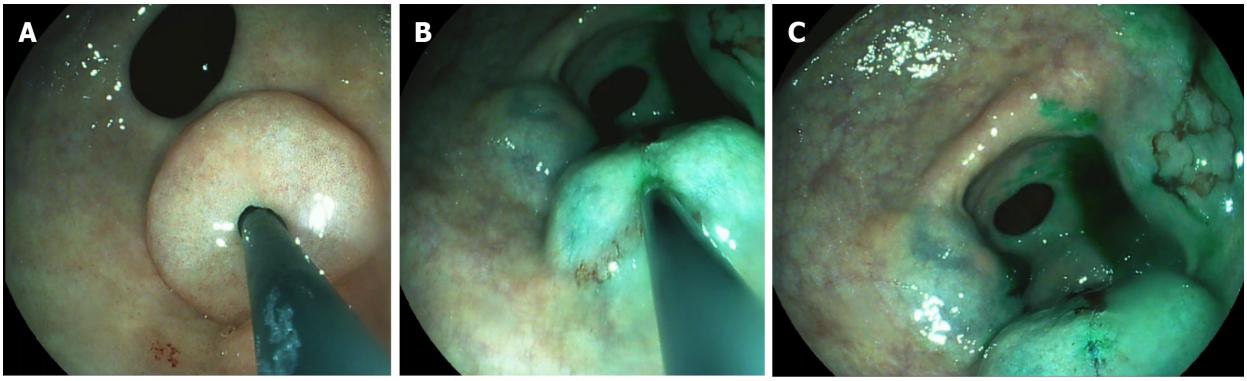
Joosten *et al*[86] in 1999 introduced the concept of sentinel LN in the CRC to reduce false negative results and study the importance of LN involvement. The main advantage of sentinel LN mapping in CRC is identifying nodes with an increased risk of metastasis so that they undergo further testing.



The OSNA test can also detect colorectal metastases in LNs based on *CK19* levels within 20 min of removal[87-89]. Until recently, it was predominantly used to evaluate the entire LN basin, but its rapidity could make it a functional intraoperative test to guide decision-making.

Vogelaar *et al*[90] compared OSNA with a single H&E stain and multilevel fine pathology (immunohistochemistry with pan-cytokeratin antibody staining) to identify metastases in the sentinel LN of

Table 3 Tumor size, number of retrieved lymph nodes, and clinical and anatomical parameters of the colonic lesions



Variables	Results

colon cancer patients. OSNA and fine pathological examination were superior to a single H&E stain. Additionally, combining the two methods observed a 46.5% upstaging rate. The study by Yamamoto *et al*[91] shows that if the sum of CK19 mRNA is higher, the number of histologically positive LNs increases. The median CK19 mRNA value was significantly lower if there were fewer than three metastatic regional LNs than in patients with more than four positive LNs.

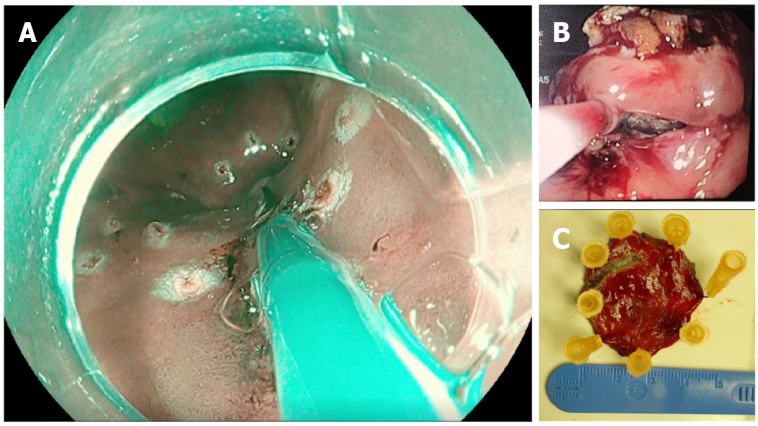
Figure 4 One-step nucleic acid amplification assay. A-F: Lymph nodes were prepared and placed in homogenized lysis buffer (Lynorhag; Sysmex) and then centrifuged. *CK19* mRNA was extracted from the lysate and analyzed by reverse transcription-loop-mediated isothermal amplification in the RD-100i system (Sysmex) using the Lynoamp (Sysmex) reagent kit[59].



The median TTL values of pN0, pN1 (1-3 LN positive), and pN2 (4 or more LN positive) were 1550 copies/μL (300-320000 copies/μL), 24050 copies/μL (250-890000 copies/μL) and 90600 copies/μL (7700-1635100 copies/μL), respectively. The TTL increases with the advancing LN stage. In the study by Aldecoa *et al*[92], TTL correlated with pT stage ($P = 0.01$) and tumor size ($P < 0.01$) in low-grade tumors. In this study, classic high-risk factors correlated with TTL in patients with stage I-II colon cancer. These results showed that the sum of CK19 mRNA obtained by the OSNA method is comparable with the current pathology diagnosis system. These studies pave the way for a new molecular staging using OSNA based on the amount of CK19mRNA rather than the number of LN metastases. Furthermore, TTL has been suggested to be related to a poor prognosis, worse disease-free survival, and other CRC risk factors[45,93,94], such as pN, pT, tumor grade, male sex, tumor size, and lymph vascular invasion.

In the literature, the association between the use of fluorescence to search for colorectal LNs and the use of OSNA to provide an accurate and rapid assessment of the oncological status of these specific LNs has been shown, which can give information on the entire LN basin. In the study by Shimada *et al*[58], there is a high agreement between OSNA and histopathology. For this reason, the OSNA test can be considered a convenient, objective and valuable alternative to the current pathological method for detecting LN metastases.

Some studies have used intraoperative OSNA testing to evaluate its diagnostic accuracy and elapsed time between surgery and postoperative adjuvant chemotherapy[59,95,96]. A rapid intraoperative test, such as OSNA (which takes approximately 40 min[95]), to obtain information on the status of LNs in the tumor drainage basin can overcome the limitations of preoperative imaging in clinically LN-negative patients. The OSNA test, thanks to its intraoperative diagnostic accuracy and rapidity, may be indispensable for safely performing minimal resections in patients with early-stage gastrointestinal cancer. With more experience using this technology and further refinement of the technique, ICG analysis could be used in conjunction with OSNA intraoperatively to identify LN metastases, which would influence surgical decision-making.

In our previous study[37] we described the advantages and limitations of the OSNA technique. Some authors have proposed that positive *CK19* on immunohistochemistry in primary tumors should be a prerequisite for OSNA use[37,73].

To our knowledge, this is the first study investigating the utility of intraoperative OSNA testing in the assessment of sentinel LN in patients with early-stage gastrointestinal cancer undergoing the NEWS procedure.

Study limitations

This article included a single-center pilot study. As such, the number of patients collected was small and

the selected patients did not have LN metastases. Therefore, it was not possible to validate the sentinel LN technique.

At present, two methods are predominantly used in the detection of sentinel LNs; it involves injecting a radioisotope with a gamma probe or a dye. Hot LNs are identified by radioisotope uptake, and sentinel LNs are colored blue or green by dye after injection around the tumor with a radioisotope colloid or dye. The currently established double-tracer method (dye and radioisotope tracers) described in several studies[97-99] appears to increase the sensitivity of identifying true sentinel LNs. We used only one tracer method in this study. ICG has hypoallergenic potential, deep detection depth, high sensitivity, and stable signal. Furthermore, tight regulation and costs of radioactive substances limit the widespread use of the probe-guided method.

The SNNS concept has been established in early gastric cancer but is still controversial in CRC. Colorectal sentinel LN basins are still not well defined. The usefulness of sentinel LN basin dissection for curative resection needs to be investigated. In this situation, the effectiveness of SNNS combined with OSNA could not be determined in CRC.

CONCLUSION

NEWS is a feasible and safe technique for organ-sparing surgery in selected patients in centers with a high experience in endoscopy, laparoscopy, and robotic surgery. ICG-NIR lymphangiography in combination with sentinel LN OSNA analysis is feasible and may allow intraoperative prediction of LN status in patients with early colon or gastric cancer treated with the NEWS procedure. Furthermore, its implementation allows more precise staging. ICG-NIR lymphangiography and OSNA could be used to plan personalized surgery and lymphadenectomy in patients with early-stage cancers. Prospective multicenter studies with large populations of patient cohorts are needed to provide definitive conclusions.

ARTICLE HIGHLIGHTS

Research background

There are more and more studies in the literature concerning endoscopic and surgical resections for organ preservation in early gastrointestinal neoplasms, respecting oncological principles. Lymph node (LN) study with one-step nucleic acid amplification (OSNA) is also the subject of numerous studies.

Research motivation

Organ-sparing endoscopic and imaging techniques do not currently allow for an accurate LN study. Using LN biopsy with rapid intraoperative results during the laparoscopic and endoscopic cooperative approach can add important information.

Research objectives

This article aims to stimulate studies that can add further information on LN status in patients with early gastrointestinal cancer, which, if treated only with endoscopic technique or with modified Laparoscopic and endoscopic cooperative surgery, would have no additional information on LN status beyond radiological ones. However, our study is the first to evaluate the utility of intraoperative OSNA assay in assessing SN in patients with early-stage gastrointestinal cancer undergoing the Non-exposed endoscopic wall-inversion surgery (NEWS).

Research methods

This pilot study with a literature review is based on data collected prospectively from a database of patients undergoing elective NEWS for early gastrointestinal cancer at St. Giuseppe Moscati Hospital of Avellino, Italy. The database included preoperative, operative, and postoperative data. Inclusion criteria included adult patients with early gastric and colonic cancer eligible for the NEWS procedure. Exclusion criteria included participants with an allergy to any indocyanine green (ICG).

Research results

A total of 10 patients were enrolled in this study, which included 5 gastric and 5 colonic early-stage cancers. The NEWS procedure was successful in all cases. The OSNA assay revealed no LN metastasis in all patients. The diagnostic accuracy in predicting the LN status based on the SN concept by OSNA compared with the postoperative histological examination was 100%. Histologically complete resection (R0) was achieved in 9 (90.0%) patients. There was no recurrence during the follow-up. An intrabdominal fluid collection treated conservatively was observed in 1 (10.0%) patient of the gastric group. One patient who underwent the removal of a lesion affecting the proximal transverse colon presented

positive focal margins on a definitive histological examination. Therefore he subsequently underwent a right hemicolectomy. The definitive histological examination showed no residual tumour foci or LN metastases.The mean follow-up was 6.3 ± 4.2 mo. There was no recurrence during the follow-up period. Ours is a single-centre pilot study. The number of patients collected is small. The selected patients were all patients without LN metastasis; therefore, it is not possible to validate the sentinel node technique.

Research conclusions

Our study is the first to analyze the utility of intraoperative OSNA assay in sentinel node and nodal basin assessment in patients with early-stage gastrointestinal cancer undergoing the NEWS procedure. NEWS is a feasible and safe technique for organ-sparing surgery in selected patients. Additionally, implementing the NEWS association with the intraoperative study with OSNA will allow for more precise staging.

Research perspectives

OSNA and ICG near-infrared lymphangiography could be used to develop customized surgery and lymphadenectomy in patients with early cancers. Prospective multicenter studies with large populations of patient cohorts are needed to provide definitive conclusions.

ACKNOWLEDGEMENTS

We thank the colleagues of the Department of Surgery and Histopathology of the "San Giuseppe Moscati" Hospital of National Importance and High Specialty for carefully reading and revising the manuscript.

Abstract

BACKGROUND

Cirrhosis results from persistent liver injury that leads to liver fibrosis. Immunological factors play important regulatory roles in the development and progression of cirrhosis. Bibliometrics is one of the most commonly used methods for systematic evaluation of a field of study. To date, there are no bibliometric studies on the role of immunological factors in cirrhosis.

AIM

To provide a comprehensive overview of the knowledge structure and research hotspots of immunological factors in cirrhosis.

METHODS

We retrieved publications related to immunological factors in cirrhosis between 2003 to 2022 from the Web of Science Core Collection database on December 7, 2022. The search strategy was TS = ((Liver Cirrhosis OR hepatic cirrhosis OR liver fibrosis) AND (Immunologic* Factor* OR Immune Factor* OR Immunomodulator* OR Biological Response Modifier* OR Biomodulator*)). Only original articles and reviews were included. A total of 2873 publications were analyzed using indicators of publication and citation metrics, countries, institutes, authors, journals, references, and keywords by CiteSpace and VOSviewer.

RESULTS

A total of 5104 authors from 1173 institutions across 51 countries published 2873 papers on cirrhosis and immunological factors in 281 journals. In the past 20 years, the increasing number of related annual publications and citations indicates that research on immunological factors in cirrhosis has become the focus of attention and has entered a period of accelerated development. The United States (781/27.18%), China (538/18.73%), and Germany (300/10.44%) were the leading

countries in this field. Most of the top 10 authors were from the United States (4) and Germany (3), with Gershwin ME contributing the most related articles (42). *World Journal of Gastroenterology* was the most productive journal, whereas *Hepatology* was the most co-cited journal. Current research hotspots regarding immunological factors in cirrhosis include fibrosis, cirrhosis, inflammation, liver fibrosis, expression, hepatocellular carcinoma, activation, primary biliary cirrhosis, disease, and hepatic stellate cells. Burst keywords (*e.g.*, epidemiology, gut microbiota, and pathways) represent research frontiers that have attracted the interest of researchers in recent years.

CONCLUSION

This bibliometric study comprehensively summarizes the research developments and directions of immunological factors in cirrhosis, providing new ideas for promoting scientific research and clinical applications.

Key Words: Immunological factors; Cirrhosis; CiteSpace; VOSviewer; Bibliometrics; Visualization

Core Tip: Over the last 20 years, 5104 authors from 1173 institutions in 51 countries have published 2873 papers on cirrhosis and immunological factors in 281 journals. Immune dysfunction, gut microbiota, epidemiology, mouse model, pathway, obesity, extracellular vesicles, bile acids, and the extracellular matrix are currently at the frontiers of research on immunological factors in cirrhosis. It is notable that in addition to focusing on basic research, we should also pay attention to the translation and application of the research results.

INTRODUCTION

Hepatic cirrhosis is defined as extensive fibrosis, pseudolobules, and distortion of the hepatic vascular architecture due to various chronic liver diseases[1]. Patients with compensated cirrhosis are asymptomatic, whereas severely impaired liver function and portal hypertension are common in the decompensated stage. Patients with decompensated cirrhosis often have complications such as ascites, bleeding esophageal varices, hepatic encephalopathy, and hepatorenal syndrome, which may eventually progress to multi-organ failure and death. Cirrhosis has a diverse etiology and can be caused by chronic liver injury, progressing to inflammation and liver fibrosis with fibrous septa and regenerative nodules[2]. Subsequently, the liver structures may collapse, resulting in distortion of the liver parenchyma and vascular structures. Progressive fibrosis and cirrhosis subsequently lead to a decrease in the metabolic and synthetic functions of the liver, causing elevated bilirubin levels, decreased production of coagulation factors and thrombopoietins, splenic platelet retention, elevated portal vein pressure, and the development of ascites and esophageal varices[3]. Viral hepatitis [hepatitis B virus (HBV) infection and HCV infection], alcoholic and non-alcoholic fatty liver diseases are the most common identifiable causes[4].

Liver inflammation and immune responses are the key factors in the pathogenesis of cirrhosis. The immune system triggers inflammation during hepatic fibrosis and is involved in wound healing and tissue repair. Various cells in the liver, such as sinusoidal endothelial cells, intravascular liver-resident macrophages (Kupffer cells), and dendritic cells (DCs), are capable of antigen presentation and produce cytokines and chemokines[5]. Following liver injury, infiltrating immune cells promote the liver fibrosis cascade by secreting pro-inflammatory cytokines such as tumor necrosis factor alpha (TNF-α), interleukin-6 (IL-6), and chemokine 4 (CCL4). These cytoplasmic factors mediate interactions between immune cells and hepatic stellate cells (HSC), leading to HSC activation and fibroblast transdifferentiation. Immune-related genes are vitally important in immune infiltration and response[6]. These results indicate that immunological factors play a complex and important role in cirrhosis, and analysis of the results obtained in this area can help us estimate the trends of cirrhosis-related immunological factors and guide experimental strategies and funding decisions.

Bibliometrics, which applies mathematical and statistical methods to the study of books and other media, is one of the most commonly used methods for the systematic evaluation of a field of study. It can be used not only for qualitative and quantitative analysis in research on countries, regions,

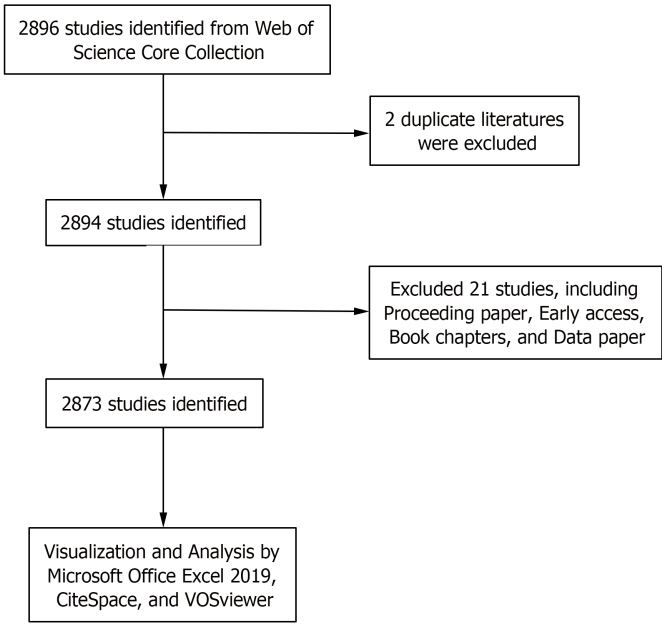
institutions, authors, co-cited authors, journals, references, and keywords, but also to describe and predict research hotspots and trends in specific fields[7]. Over the years, many scholars have applied bibliometric analyses to various fields of medicine, including cardiovascular diseases[8], respiratory diseases[9], obstetrical and gynecological diseases[10], psychiatric diseases[11], dermatological diseases [12], and biologic signaling[13]. To the best of our knowledge, bibliometric analyses of immunological factors in non-small cell lung cancer[14], cardiovascular diseases[15], and cancer[16] have been conducted by related scholars. Recent studies have shown that immunomodulators are a promising treatment option for cirrhosis. Therefore, we performed a bibliometric study of immunological factors in cirrhosis based on published data using CiteSpace and VOSviewer, two commonly used scientometric software packages, to create knowledge maps and explore the evolution and development trends of hotspots in this field. Microsoft Office Excel 2019 was used to perform a quantitative analysis of the publications and citations.

MATERIALS AND METHODS

Data source and retrieval strategy

We used the Web of Science Core Collection (WoSCC) developed by Thomson Scientific to extract relevant literature on cirrhosis and immunological factors published between January 2003 and November 2022. To avoid citation fluctuations due to rapid updates, literature searches were conducted within 1 d (December 7, 2022). The search strategy was TS = ((Liver Cirrhosis OR hepatic cirrhosis OR liver fibrosis) AND (Immunologic* Factor* OR Immune Factor* OR Immunomodulator* OR Biological Response Modifier* OR Biomodulator*)). A total of 2896 publications was obtained. Among various publication types, only original articles and reviews were included. Finally, only 2873 publications that met the inclusion criteria were included in the bibliometric analyses. The detailed screening process is illustrated in Figure 1.

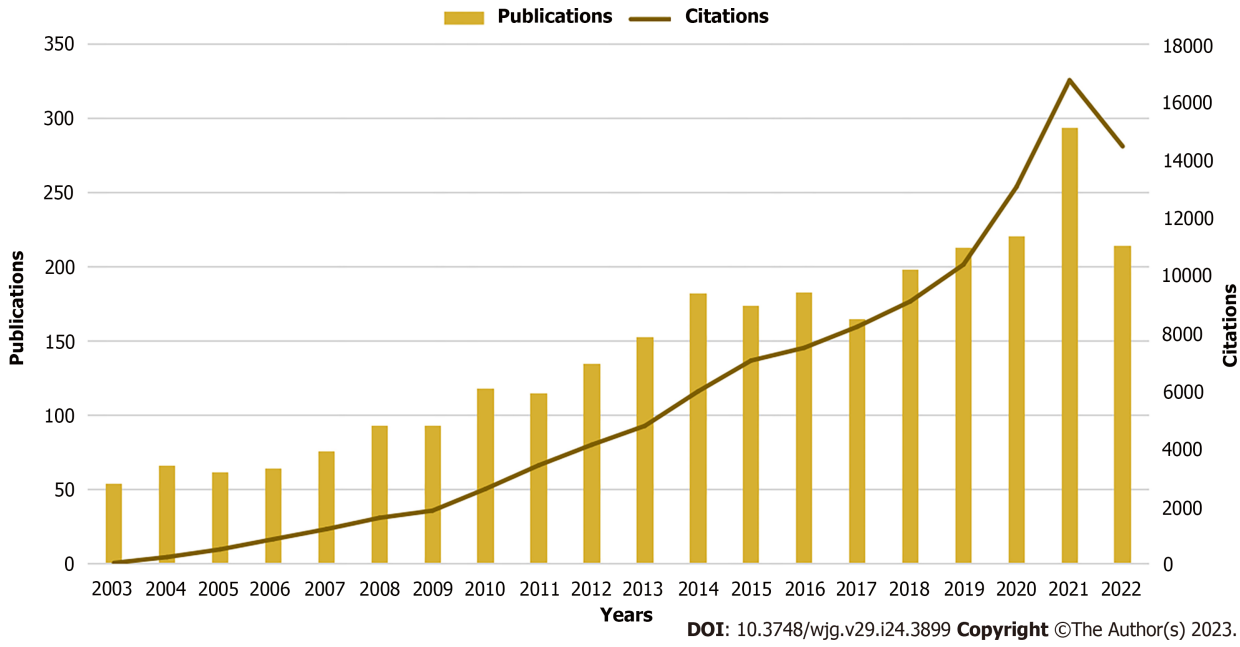
Data analysis and visualization



CiteSpace software was developed by Professor Chaomei Chen for bibliometric and visual analyses. Specifically, it explores collaborations, structures, hotspots, and frontiers in a research field and presents trends in a discipline or field of knowledge over time in a visual and intuitive form. Nodes with high centrality, highlighted by purple rings, are often considered hotspots or turning points in a research field. The thickness of the purple ring indicates the strength of its centrality; the thicker it is, the stronger its centrality[17]. Cluster analysis of keywords can be used to identify important regions of research on immunological factors in cirrhosis by classifying keywords. In addition, the variant word indicates a sudden growth of hotspots in the field and also shows the future trend of the topic[18]. A high mutation value indicated a large variation in size. Keywords and reference mutations can be used to identify new research trends in immunological factors associated with liver cirrhosis. Therefore, we used CiteSpace (version 6.1. R3) for the collaborative network analysis (country/region, institution, author, and journal), co-citation analysis (author, journal, and reference), dual mapping, and citation burst detection of references and keywords.

We constructed bibliometric maps using the VOSviewer software developed by Leiden University to obtain more comprehensive information about the results based on co-citation and co-occurrence. VOSviewer excels in map creation and presents bibliometric maps in different ways, including network, overlay, and density maps, each focusing on various aspects. The color of the nodes represents different times or clusters, the size of the nodes indicates the number of publications, and the thickness of the lines represents the strength of the relationship[19]. In our study, VOSviewer (version 1.6.18) performed the following analyses: Country and institution, authors, co-cited authors, and keywords.

RESULTS



Temporal distribution map of publications and citations

From 2003 to 2022, publications on immunological factors in cirrhosis included 1906 original articles and 967 reviews, showing a constantly increasing trend (Figure 2). From 2003 to 2014, the number of annual publications in this field steadily increased. Annual publications started with over 100 and 182 articles published in 2010 (n = 118) and 2014, respectively. Annual publications fluctuated slightly between 2014 and 2017 and gradually increased from 2018 to 2021. Subsequently, it increased significantly and peaked in 2021 (n = 294). The number of citations increased rapidly annually and exhibited a continuously rising trend. The upward trend in annual publications and citations indicates that research on immunological factors in cirrhosis has become a focus of attention and has entered a period of accelerated development.

Figure 2 Temporal distribution map of publications and citations.

Publications were from 51 countries and 1173 institutions. As shown in Tables 1 and 2, we ranked the 10 high-productivity countries/regions and institutions. The United States (781/27.18%), China (538/18.73%), and Germany (300/10.44%) published the most articles, accounting for more than half of the total number of studies reported, indicating a high interest in studying immunological factors in cirrhosis. This was followed by Italy (259/9.01%) and Japan (192/6.68%). Subsequently, we constructed collaborative networks based on the publications and relationships in each country (Figure 3). It is noteworthy that there are many active collaborations among different countries (Figure 3A). For example, the United States has actively cooperated with China, Italy, Germany, England, Japan, France, and Australia; China has collaborated closely with the United States, Japan, Germany, Italy, England, Canada, and Australia; and Germany has collaborated with the United States, Switzerland, France, the Netherlands, Australia, China, and Spain. The top 10 institutions are distributed across five countries, with half in the United States. The University of California, Davis (65, 2.26%) led the publications, followed by the Mayo Medical Center (47, 1.64%) and Zhejiang University (44, 1.53%). We also observed

Table 1 Publications in the 10 most productive countries/regions

Rank	Country/region	Year	Count (%)	Centrality
1	United States	2003	781 (27.18%)	0.36
2	China	2003	538 (18.73%)	0.06
3	Germany	2003	300 (10.44%)	0.17
4	Italy	2003	259 (9.01%)	0.19
5	Japan	2003	192 (6.68%)	0.03
6	England	2003	186 (6.47%)	0.20
7	Spain	2003	157 (5.46%)	0.09
8	France	2003	132 (4.59%)	0.17
9	Australia	2004	85 (2.96%)	0.12
10	Canada	2003	84 (2.92%)	0.12

Table 2 Publications in the 10 most productive institutions

Rank	Institution	Year	Count (%)	Centrality
1	Univ Calif Davis (United States)	2004	65 (2.26%)	0.12
2	Mayo Clin (United States)	2007	47 (1.64%)	0.02
3	Zhejiang Univ (China)	2011	44 (1.53%)	0.01
4	Univ Birmingham (England)	2009	38 (1.32%)	0.04
5	Univ Calif San Diego (United States)	2009	28 (0.97%)	0.07
6	Yale Univ (United States)	2007	26 (0.90%)	0.06
7	Inst Salud Carlos III (Spain)	2008	25 (0.87%)	0.06
8	Univ Milan (Italy)	2004	24 (0.84%)	0.06
9	Univ Barcelona (Spain)	2003	23 (0.80%)	0.03
10	Emory Univ (United States)	2006	23 (0.80%)	0.05

a network diagram of institutional collaboration in research on immunological factors in cirrhosis (Figure 4A). The figure shows a very close cooperation among the University of California, Davis, University of Milan, Monash University, Emory University, and Mayo Clinic, and a more active collaboration between Zhejiang University, Emory University, and the University of Science and Technology of China. In addition, several countries and affiliations, including the United States (0.36), England (0.20), Italy (0.19), Germany (0.17), France (0.17), Canada (0.12), Australia (0.12), Egypt (0.11), and the University of California, Davis (0.12) showed high centrality, circled in purple in Figure 3B and Figure 4B, respectively. An article with high centrality could be a transformative discovery. These findings suggest that these countries and institutions play key roles in the study of immunological factors associated with cirrhosis. Notably, despite their high volume of publications, China and Japan might not provide scientists with the same level of novel insights compared to countries with high centrality.

Analysis of authors and co-cited authors

A total of 5104 authors participated in the study on the immunological factors associated with cirrhosis. The top 10 high-producing authors are listed in Table 3. As shown in Figure 5A, a larger font size and higher yellow opacity indicate more publications. Gershwin ME from the University of California Davis was the most productive author, with 42 publications, followed by Tacke *et al*[20] (n = 27) and Trautwein *et al*[21] (n = 20) from the University Hospital Aachen. Most of the top 10 authors were from the United States (4), and Germany (3). As shown in Figure 5B, there are collaborations between different authors; however, it is noteworthy that the centrality is low (≤ 0.02), which means that various authors have little influence on each other's research. All the top 10 co-cited authors had more than 100 co-citations (Table 3). As shown in Figure 6A, a larger font size and a higher yellow opacity imply a higher citation frequency. Friedman, from the Icahn School of Medicine, had the highest number of co-citations (n = 337). The next most cited were Bataller (n = 235) from Pittsburgh Liver Research and Seki (

Table 3 Top 10 authors and co-cited authors

Rank	Author	Count (%)	Centrality	Co-cited author	Co-citation	Centrality
1	Gershwin M Eric (United States)	42 (1.46%)	0.02	Friedman Scott L (United States)	337	0.05
2	Tacke Frank (Germany)	27 (0.94%)	0.01	Bataller Ramon (United States)	235	0.06
3	Trautwein Christian (Germany)	20 (0.70%)	0.01	Seki Ekihiro (United States)	204	0.05
4	Weiskirchen Ralf (Germany)	13 (0.45%)	0	Tilg Herbert (Austria)	141	0.07
5	Hirschfield Gideon M (Canada)	11 (0.38%)	0.01	Wynn Tomas A (United States)	140	0.02
6	Friedman Scott L (United States)	9 (0.31%)	0	Albillos Agustín (Spain)	128	0.01
7	Such Jose (Spain)	9 (0.31%)	0	Szabo Gyongyi (United States)	126	0.04

9	Invernizzi Pietro (Italy)	8 (0.28%)	0	Hirschfield Gideon M (Canada)	120	0.09
10	Czaja Albert J (United States)	8 (0.28%)	0	Li J (China)	116	0.02

n = 204) from the Cedars-Sinai Medical Center. More than half (*n* = 6) of the top 10 co-cited authors were from the United States. As shown in Figure 6B, there was active cooperation between the different authors.

Analysis of journals and co-cited journals

The most influential journals on research on immunological factors in cirrhosis are listed in Table 4. A total of 2873 articles were published in 281 journals. The *World Journal of Gastroenterology* was the most frequently published journal (*n* = 113), followed by *Hepatology* (*n* = 109) and *Frontiers in Immunology* (*n* = 73). Among the top 10 journals, six belonged to *Journal Citation Reports* (JCR) Q1, and eight had impact factors (*IF*) of > 5. Among the co-cited journals, 12 had > 1000 citations. *Hepatology* was ranked first with 2409 citations, followed by the *Journal of Hepatology* (2124 citations) and *Gastroenterology* (1988 citations). Eight of the top 10 co-cited journals belonged to JCR Q1, and eight journals had *IF* > 10, including two journals with *IF* above 100. We analyzed the published and co-cited journals using a journal dual-map overlay, as shown in Figure 7. The cited and co-cited journals are located on the left and right sides of the graph, respectively. Different colored paths indicate the cited relationships. We identified two orange and green citation paths. Studies published in the Molecular/Biology/Clinics and Health/Nursing/Medicine journals were mainly cited in the Molecular/Biology/Immunology and Medicine/Medical/Clinical journals.

Analysis of co-cited references and reference bursts

The top 10 co-cited references are listed in Table 5, all of which were co-cited at least 31 times. A reference co-citation network was mapped (Figure 8A). The link between two nodes implies that they are cited in a publication. The node size indicates the co-citations of the references. A node with a purple ring represents a higher centrality. The article with the most co-citations was by Tsuchida *et al*[22], which revealed that HSC activation is regulated by multiple mechanisms, including autophagy, endoplasmic reticulum stress, oxidative stress, retinol and cholesterol metabolism, epigenetic and receptor-mediated signaling, and extracellular signals from resident and inflammatory cells, which play an essential role in the development of liver fibrosis. The second study, published by Albillos *et al*[23] in 2014, revealed that immunodeficiency in cirrhosis is induced by local immune surveillance, functional impairment of the liver, reduction of pattern recognition receptors, and damage at the systemic level of immune response cell function. The third article[24] published in the *Journal of Hepatology* by the European Association for the Study of the Liver, provided validated recommendations for the optimal management of HBV infection. Among the top 10 articles, research by Heymann *et al*[5] possessed a high centrality (0.14), indicating that the article is influential. It illustrated that the liver can rapidly activate immunity, and the final outcome of the intrahepatic immune response depends on the functional versatility of macrophages and DCs and the balance between the pro- and anti-inflammatory T cell populations. CiteSpace provides citation bursts that imply significant changes in reference citations over time. References with citation bursts have frequently been cited by researchers in recent years to represent emerging topics in specific research field[25]. Figure 8B shows the 25 most cited references with the strongest bursts. The most-cited study was by Albillos *et al*[23], with a strength of 18.92. Tsuchida *et al*[22] also reported a large burst. These are representative articles on the immunological factors involved in cirrhosis.

Analysis of research hotspots and frontiers

As shown in Table 6, the most frequently cited keywords for immunological factors in cirrhosis in the

last 20 years were fibrosis (428), cirrhosis (423), inflammation (384), liver fibrosis (381), expression (340), hepatocellular carcinoma (HCC) (309), activation (234), primary biliary cirrhosis (PBC) (232), disease (231), and HSC (228). These keywords reflect the research hotspots in this field. Among the 10689 keywords, the minimum number of repetitions was set to 20 and 288 eligible keywords were selected for VOSviewer visualization and analysis (Figure 9). The keyword clusters describe the internal knowledge structure of the research field[7]. The immunological factors associated with cirrhosis were divided into five clusters (Figure 9A). Cluster 1 (red) focused on the progression and treatment strategies for cirrhosis. Cluster 2 (green) includes the mechanisms and primary immune cells involved

Table 6 Top 20 keywords on research of immunological factors in cirrhosis

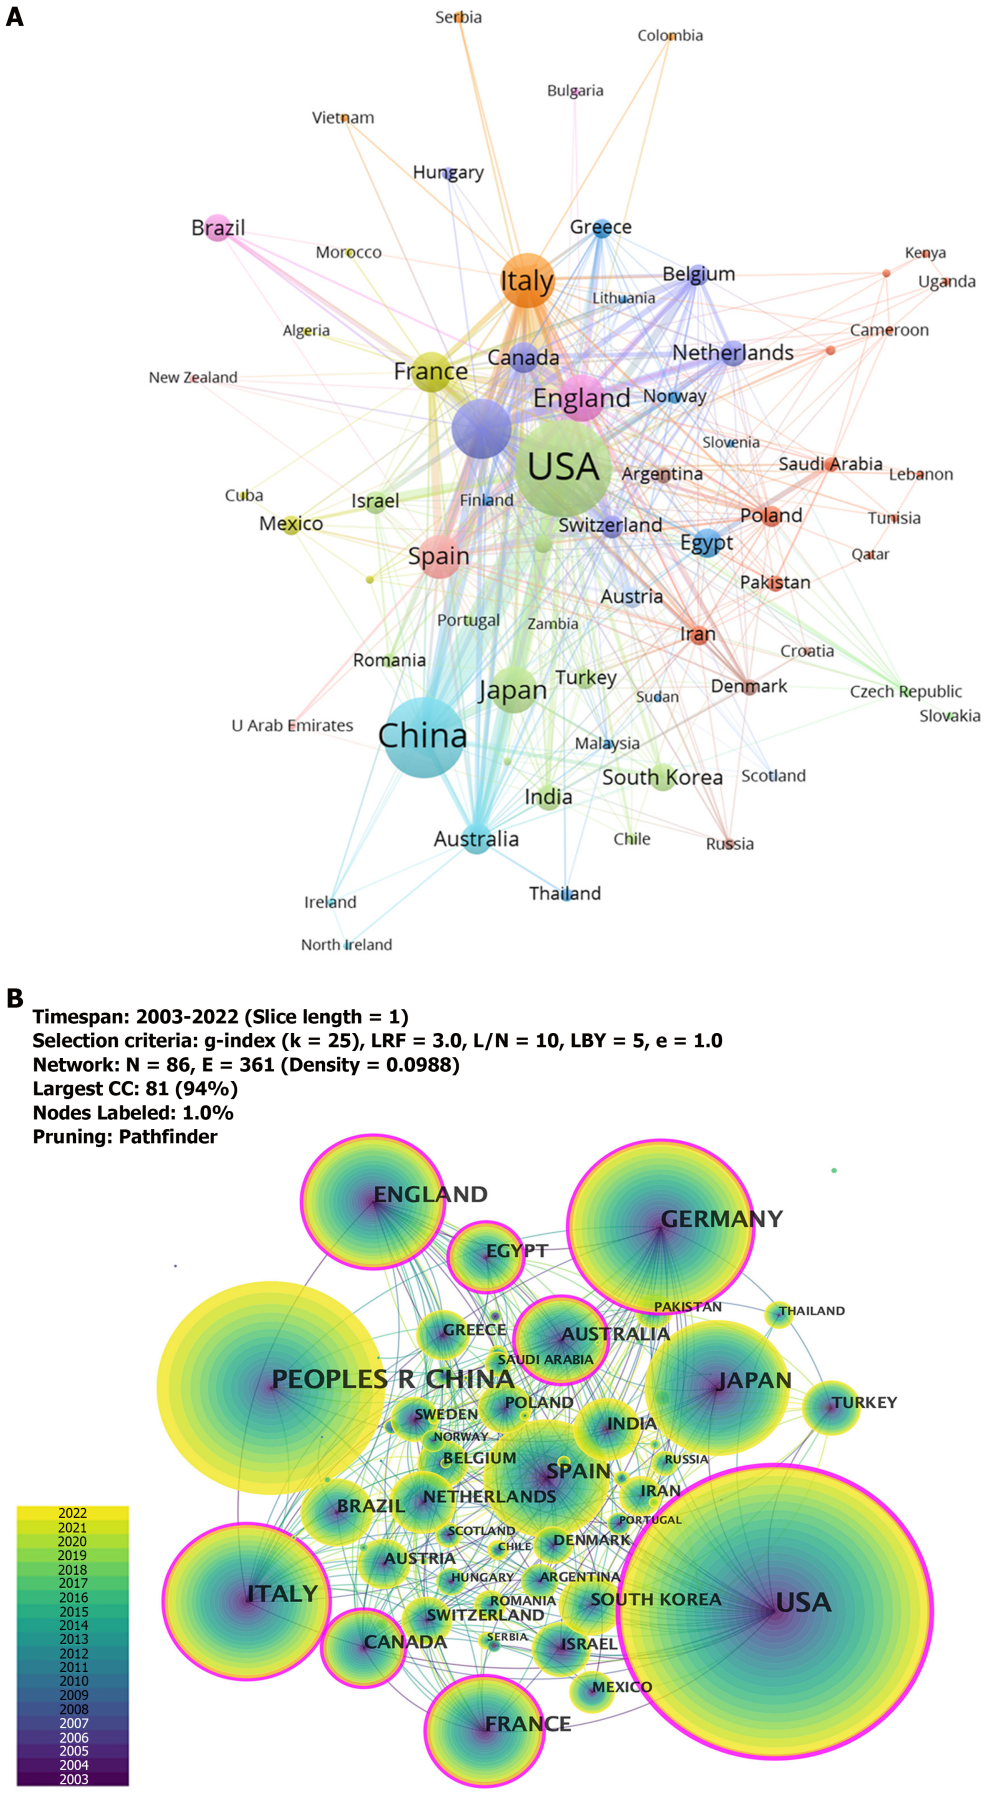
in cirrhosis. Cluster 3 (blue) mainly focused on the diagnosis and prognosis of cirrhosis. Cluster 4 (yellow) centered on the pathological mechanisms of immune inflammation. Cluster 5 (purple) mainly consisted of various chronic liver diseases that cause liver injury. Figure 9B shows the co-occurrence of keywords by the average publication year (APY). Circles in different colors indicate the APY of the study, and those closer to yellow represent more recent years. Therefore, changes in research hotspots during a given period can be observed directly. The most recent keywords were extracellular vesicles (EVs) (cluster 2, APY: 2019.55), followed by tumor microenvironment (cluster 2, APY: 2019.43), PBC (cluster 5, APY: 2019.33), nafld (cluster 4, APY: 2019.19), and gut microbiota (cluster 4, APY: 2019.17). This indicates that EVs, the tumor microenvironment, PBC, nonalcoholic fatty liver disease, and gut microbiota have interested researchers. Additionally, we used CiteSpace for keyword–citation burst detection. There are 25 keywords had strong bursts, as shown in Figure 9C. Human immunodeficiency virus ranked first, with the strongest burst (strength = 11.59). Immune dysfunction, gut microbiota, epidemiology, mouse models, pathways, obesity, EVs, bile acids, and the extracellular matrix (ECM) are the current research frontiers of immunological factors in cirrhosis and have been in an explosive period.

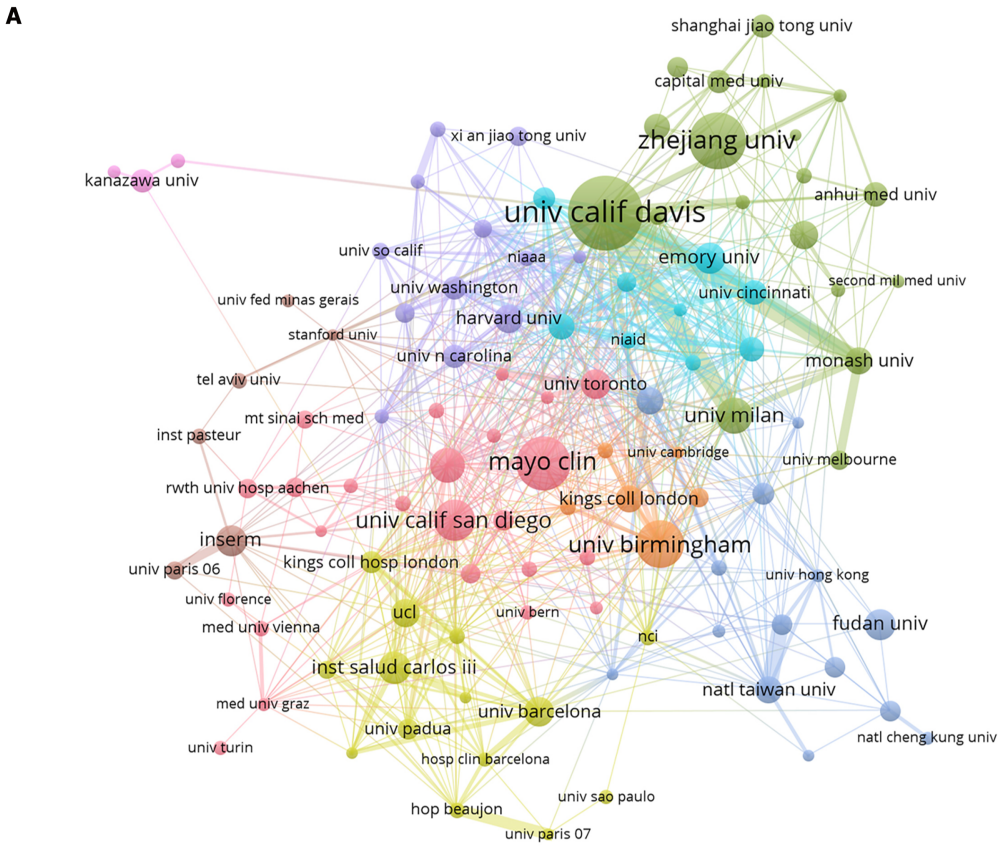


DISCUSSION

General information

According to the WoSCC database, as of December 7, 2022, 5104 authors from 1173 institutions in 51 countries have published 2873 papers on cirrhosis and immunological factors in 281 journals. Our study analyzed the literature on immunological factors in cirrhosis using CiteSpace and VOSviewer to review research results and progress. Basic information, including annual publications, countries, institutions, authors, journals, references, and keywords, was quantitatively analyzed. There is a gradual increase in publications and citations on the immunological factors of cirrhosis. More citations of a paper indicate higher quality and greater impact. The number of citations in the field has increased annually, with an accelerating trend in the later half of the period reflecting the speed and progress of the research field. This indicates that research in this field has been in an explosive period, with increasing attention from scholars.

The United States, China, and Germany are the main countries that have studied the immunological factors associated with cirrhosis. Japan, Australia, France, and United States have relatively well-researched studies on immunological factors in cirrhosis. Of the top 10 institutions, five are in the United States, two in Spain, and one each in China, England, and Italy. Davis University of California has the most publications in this field. Close collaboration between countries and institutions helps to overcome scientific difficulties and promote research on immunological factors in cirrhosis.



Gershwin ME from the United States published the most articles (42, 1.46%), followed by Tacke *et al* [20] (27, 0.94%) and Trautwein *et al*[21] (20, 0.70%) from Germany. These three authors have made outstanding contributions to the field of immunological factors in cirrhosis. Gershwin explained the immune response mechanisms in the liver[26] and elucidated the regulatory mechanisms of liver fibrosis from an immunological perspective[27,28]. They then explored the relationship between the gut microbiota and autoimmune liver disease and concluded that the gut-liver axis involves multiple inflammatory cell types, cytokines, chemokines, and other molecules that lead to the disruption of normal liver structure[29]. Tacke *et al*[20] researched the role of macrophages in liver fibrosis, the polarization and function of which can be further determined by specific environmental signals,

presenting with tissue recovery following liver injury or infection, or the progression of liver disease, conversely[30]. They found that infiltrating Ly-6C$^+$ MoMFs are associated with chronic inflammation and fibrosis[20]. They considered hepatic macrophages to be effective therapeutic targets and searched for new treatments[31]. Two study elaborated on the importance of chemokines in liver diseases and

highlighted their potential to intervene in inflammation and fibrosis[32,33]. They proposed that canicriviroc treatment significantly reduced hepatic Ly-6C$^+$ MoMF recruitment, confirming its therapeutic potential in patients with nonalcoholic steatohepatitis (NASH)[34]. They also found that

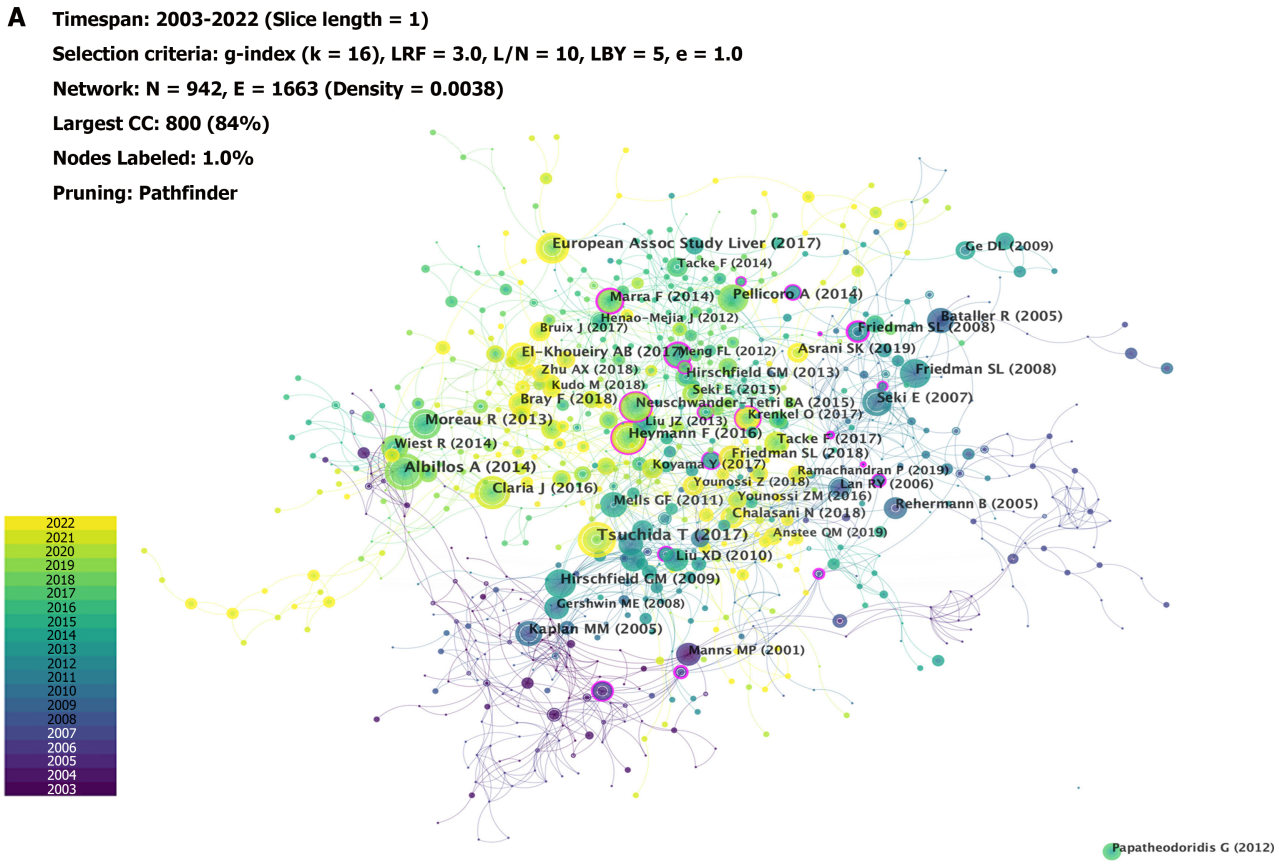
Figure 7 The dual-map overlay of journals in immunological factors in cirrhosis.

NOD-like receptor protein 3 activation was relevant to disease activity in patients with PBC[35].



Of the top 10 journals, six were in the Q1 JCR division and eight in the *IF* > 5. Most studies on immunological factors in cirrhosis were published in the *World Journal of Gastroenterology* (113, *IF* = 5.374, Q2), followed by *Hepatology* (109, *IF* = 17.298, Q1), and *Frontiers in Immunology* (73, *IF* = 8.786, Q1). These journals are the most popular in this research field. Eight of the top 10 co-cited journals were located in the Q1 JCR division, and eight had IF above 10, including two journals with IF above 100. The top three co-cited journals were *Hepatology* (2409, *IF* = 17.298, Q1), *Journal of Hepatology* (2124, *IF* = 30.083, Q1), and *Gastroenterology* (1988, *IF* = 33.883, Q1). These findings indicate that many high-quality and influential journals are interested in studying cirrhosis and its immunological factors. Figure 7 reveals that papers published in molecular, biology, clinical, health, nursing, and medicine journals are mainly cited in Molecular, Biology, Immunology, and Medicine, Medical, Clinical journals. This implies that current research on cirrhosis and immunological factors is mainly focused on basic research and translational medicine.

Knowledge base

We can observe the research base in the field of immunological factors in liver cirrhosis by analyzing the co-cited references. The most co-cited was "Mechanisms of hepatic stellate cell activation" published in *Nature Reviews Gastroenterology & Hepatology* by Tsuchida *et al*[22] in 2017, followed by "Cirrhosis-associated immune dysfunction: Distinctive features and clinical relevance" by Albillos *et al*[23], and "EASL 2017 Clinical Practice Guidelines on the management of HBV infection" by European Association for the Study of the Liver. The top 10 co-cited references were all cited 30 times at least, mainly involving the immunoinflammatory mechanisms of cirrhosis and liver fibrosis. Liver fibrosis is a dynamic process caused by chronic liver injury. The inflammatory response in the liver is initiated by danger-associated molecular patterns, Toll-like receptors (TLRs) signaling, or inflammatory vesicle activation[5]. HSC activation is the central driver of liver fibrosis[22]. The activation of hepatic macrophages (Kupffer cells) and resident mast cells promotes tissue injury by producing pro-inflammatory and vascular-permeable mediators, which induce the accumulation of neutrophils, lymphocytes, eosinophils, and monocytes in the liver[36]. Systemic inflammation, the main driver of acute-on-chronic liver failure (ACLF), affects the function of somatic tissues and alters the clinical manifestations of cirrhosis[37]. The immune response pattern changes from a proinflammatory phenotype in patients with stable decompensated cirrhosis to an immunodeficient phenotype in patients with severely decompensated cirrhosis and extrahepatic organ failure[23].

Hotspots and frontiers

In the study of immunological factors in cirrhosis, high-frequency keywords were mainly fibrosis (428), cirrhosis (423), inflammation (384), liver fibrosis (381), expression (340), HCC (309), activation (234), PBC (232), disease (231), and HSC (228), which are the hot topics of research in this field. Systemic inflammation is a crucial mechanism in the progression of cirrhosis to the decompensated stage and is a common pathophysiological mechanism underlying the clinical features of acutely decompensated cirrhosis, such as ascites, encephalopathy, gastrointestinal bleeding, bacterial infection, and extrahepatic

organ failure[38]. IL-6, TNF-α, and transforming growth factor beta (TGF-β) are key pro-inflammatory and pro-fibrotic cytokines that drive liver fibrosis[39]. A recent study found that under pathological conditions, TGF-β overexpression leads to epithelial mesenchymal-mesenchymal transition, ECM deposition, and cancer-associated fibroblast formation, resulting in fibrotic disease and cancer[40].

Figure 9 Analysis of Keywords in immunological factors in cirrhosis. A: The cluster of keywords; B: Keyword co-occurrence network. Keywords in yellow appeared later than that in blue; C: Top 25 keywords with the strongest citation bursts.

Toxins such as alcohol, steatosis, or viral infection can trigger inflammation, and the inflammatory cytokine IL-17 drives HSC and Kupffer cells to produce pro-fibrotic IL-6, TNF-α, and TGF-β[41]. A previous study[42] demonstrated that albumin binds and activates many inflammatory promoters in decompensated cirrhosis and that high doses of albumin have significant immunomodulatory effects. However, the anti-inflammatory effects of albumin in cirrhosis require further investigation. This evidence suggests the potential value of anti-inflammatory agents in the treatment of cirrhosis. Approximately 90% of HCC cases occur in a cirrhotic setting, but less than 5% of patients progress to HCC each year[43]. Cancer-associated fibroblasts, which may originate from HSC, are critical for hepatocarcinogenesis. After being activated to become myofibroblasts producing the ECM, they can interact with cancer cells, contributing to the growth and invasion of HCC[44]. PBC is characterized by a loss of immune tolerance in biliary epithelial cells, and the interdependence of biliary tract injury, cholestasis, and progressive hepatic fibrosis has become a major disease worldwide[45]. PBC is considered an autoimmune disease with a specific autoantibody, antimitochondrial antibody, and the establishment of ursodeoxycholic acid as a first-line therapeutic agent has significantly reduced disease progression in cirrhosis[46]. In patients with PBC who did not respond adequately to ursodeoxycholic acid alone, besides ursodeoxycholic acid, we also treated them with bezafibrate; however, its effect on liver transplantation and death needs to be clarified by further studies[47]. Liver fibrosis is an advanced stage of chronic liver disease that develops from a variety of diseases, such as chronic hepatitis virus infection (HBV and HCV), NASH, PBC, primary sclerosing vasculitis, autoimmune hepatitis, Wilson's disease, and hemochromatosis[48]. Researches on the pathogenesis and targeted agent of PBC have excited particular concern in recent years[49,50]. The crucial role and activation mechanisms of HSC in cirrhosis have been extensively elaborated in detail[22,51,52]. Paracrine signals from damaged epithelial cells, fibrotic microenvironment, dysregulation of immune and systemic metabolism, dysregulated intestinal microecology, and hepatitis virus products can directly or indirectly activate HSC[51]. The clearance of HSC, including apoptosis, senescence, and return to an inactivated state, has been fully elucidated[22].

In conclusion, these findings reveal the remarkable complexity and plasticity of HSC activation. The modulation of HSC provides vital value for developing therapeutic strategies for cirrhosis.

The keywords that have exploded in recent years are immune dysfunction, gut microbiota, epidemiology, mouse models, pathways, obesity, EVs, bile acid, and ECM, representing the current frontiers of research on immunological factors in cirrhosis. In hepatic fibrosis, the immune system is involved in wound healing and tissue repair by triggering inflammation. Immune cells regulate the progression and regression of liver fibrosis. Various immune cells participate in the regulation of liver fibrosis, including innate immune cells (monocytes, macrophages, and DCs), adaptive immune cells (T cells and B cells), and various cytokines. Following liver injury, infiltrating immune cells are recruited to the site of the injured hepatocytes and participate in the liver fibrosis cascade by secreting proinflammatory cytokines such as TNF-α, IL-6, and CCL4[39]. As the first line of defense against pathogens, Kupffer cells are activated by LPS, the complement system, and other pathogen-associated molecular patterns *via* the expression of TLRs, including TLR2, TLR3, and TLR4, to recognize microbial antigens and signals from damaged hepatocytes. Cytoplasmic division generated by Kupffer cells in response to TLR signaling subsequently recruits and activates neutrophils[6]. DCs present antigens, control subsequent T cell differentiation, and regulate T cell responses[53]. Systemic inflammation and immunodeficiency have been identified as two critical factors in cirrhosis-associated immune dysfunction, with the most severe immune changes being more common in ACLF[54]. The pathophysiology of ACLF involves persistent inflammation, immune dysregulation, systemic inflammatory response syndrome, and subsequent sepsis due to immune paralysis[55,56]. Two main types of systemic immune alterations are typical in cirrhosis: On the one hand, cirrhosis-associated immune dysfunction results in immunodeficiency; on the other hand, persistent under-stimulation of immune cells leads to systemic inflammation[53]. Immunodeficiency in cirrhosis results from the structural distortion of the liver parenchyma and functional impairment of circulating immune cells. It can increase the risk of bacterial infection at any stage of liver disease and may lead to acute decompensation and acute or chronic liver failure, which are associated with high short-term mortality [36,37]. Inflammatory factors play an essential role in immune regulation. Further regulation of relevant immune cells and cytokines to control inflammation and block critical targets of the immune-inflammatory response can delay and inhibit the onset and progression of cirrhosis. Gut microbiota is involved in maintaining the balance of the immune system and preventing autoimmunity[57]. In chronic liver disease, the adhesion of pathogenic bacteria to mucosal surfaces and barrier damage are central to the initiation of mucosal immunity[58]. Microbial products (especially LPSs), as pathogen-associated molecular patterns, can be transferred from the gut to the liver, bind to TLR, activate Kupffer cells, stimulate immune responses, and produce inflammatory cytokines (*e.g.*, IL-1β and TNF) and reactive oxygen species[57,59]. The gut microbiota can lead to systemic inflammation either directly through translocation or indirectly through its metabolic pathways, resulting in the progression of decompensated cirrhosis and ACLF[60]. Thus, regulation of the gut microbiome contributes to the development of cirrhosis[57]. Summarizing the epidemiological features of cirrhosis will be beneficial for providing clinical guidance and assistance. Globally, approximately 1 million people die annually from cirrhosis, the 11th most common cause of death, which is widely prevalent in low-, middle-, and high-income countries and is associated with high morbidity and mortality[1]. In 2019, an estimated 25% of global deaths from cirrhosis were alcohol-related[61]. Epidemiology-related recognition remains a hot topic and a frontier for future research. Various mouse models of liver fibrosis are often used in cirrhosis research, and the most commonly used are the toxic, biliary, and metabolic liver fibrosis models[62,63]. Recent studies on the mechanisms and pathways involved in hepatic fibrosis and cirrhosis have yielded promising results. The study of related pathways may shed light on the regulation of liver fibrosis and potential targets for therapy. For example, TGF-βpromotes liver fibrosis by activating Sma- and Mad-associated protein 3, intracellular IL-37 downregulates liver inflammation and fibrosis by interacting with Smad3[64], and curcumin inhibits liver fibrosis by activating autophagy to suppress TGF-β/Smad signaling, thereby inhibiting epithelial-mesenchymal transition and ECM production[65]. A study by Kong *et al*[66] showed that ferritin phagocytosis-mediated iron sagging in HSC is responsible for the antifibrotic effect induced by artesunate, which provides new clues for further pharmacological studies of artesunate. Zhang *et al*[67] found that melanoma differentiation-associated gene 5 effectively inhibits hepatic lipid accumulation and metabolic disorders by blocking the N-terminal dimerization of apoptosis signal-regulating kinase 1. Regardless of the etiology of the disease, obesity is an independent risk factor for hepatic decompensation[68]. Statistically, 20% of patients with NASH progress to cirrhosis and have an increased risk of developing HCC[69]. Dyslipidemia significantly contributes to cardiovascular-related mortality and morbidity in patients with NASH. Efluxifermin has been shown to remarkably reduce hepatic lipids and is usually safe and tolerated in patients with NASH (F1-F3) fibrosis, suggesting that efluxifermin may alter the progression of NASH[70]. However, further studies are required to investigate the specific mechanisms and effects. Numerous studies have been conducted on the potential role of EVs as biomarkers of liver diseases. EVs are significantly involved in intercellular communication by delivering different cargo and acting as vital cell-derived particles in the progression of liver injury and fibrosis, helping predict complications and mortality, detect early HCC, and predict the outcome of acute liver failure[71]. In the treatment of cirrhosis, EVs play a crucial role in anti-inflammatory mechanisms. For example, lipotoxic EVs mediate

the adhesion of monocytes to liver sinusoidal endothelial cells mainly through an ITGβ1-dependent mechanism, and ITGβ1 exhibits an inflammatory inhibitory effect in a mouse model of NASH; however, further studies are needed to determine whether a similar therapeutic effect exists in human patients [62]. Gao *et al*[72] demonstrated that Src-homology 2 domain protein phosphatase 2 in HSC promotes the release of fibrotic EVs by inhibiting autophagy and Rho-associated protein kinase 1, and activating the mammalian target of the rapamycin pathway, which provides a new idea for a new target for liver fibrosis treatment. However, the exact mechanism of action of the autophagy-dependent EVs requires further investigation. A previous study[73] found that EVs released from a stem cell-like population derived from the human adult liver demonstrated antifibrotic and anti-inflammatory effects in an immunocompromised NASH mouse model, providing new clues for the treatment of cirrhosis. The role of bile acids in hepatic cirrhosis is receiving increasing attention. Bile acids can alter the microbiome and liver regeneration, and chronic cholestasis in PBC caused by the bile acid-affected microbiome can reversely lead to liver injury, creating a vicious cycle of chronic liver injury[46]. It was reported that cholesterol ameliorates bile acid toxicity in mouse models of NASH and fibrosis by inducing Nrf-2 and HIF-1α-dependent hepatocyte proliferation and liver regeneration[63]. One study[74] found that antagonizing TGR5 or inhibiting ERK1/2 and p38MAPK signaling may contribute to the prevention or reversal of liver fibrosis by reducing the hepatic concentrations of conjugated 12α-OH-bile acids. Salhab *et al*[75] found that the sodium+/taurocholate co-transporting polypeptide is a membrane transporter protein that affects the enterohepatic circulation of bile acids and that sodium+/taurocholate co-transporting polypeptide blockers can prevent the development of hepatic fibrosis. These findings provide further directions for specific targeted therapies for cirrhosis. The role of bile acids in the pathogenesis of cirrhosis is extremely complex and influenced by many mechanisms of interaction. Substantial research is required to determine their specific roles. ECM has also been one of the keywords of the outbreak in recent years. Liver fibrosis and cirrhosis are characterized by the abnormal deposition of ECM proteins. Alterations in ECM composition are critical for tissue repair, remodeling, and cellular responses to fibrosis[76]. A previous study[77] reported that surface-active vesicle-based ECM therapeutics can also treat liver fibrosis. Studying the interactions between fibroblasts, ECM, and inflammation may provide new avenues for identifying new therapeutic targets for cirrhosis[78]. To date, it is not fully understood how the ECM is dynamically remodeled during the development of cirrhosis, and whether ECM signaling has a predictive value for the prognosis of early cirrhosis still needs to be studied on a large scale[79].

Advantages and shortcomings

Based on bibliometric analysis and literature visualization, the hotspots, evolutionary processes, and developmental trends of research on immunological factors in cirrhosis are presented visually, providing further insight into the current status and future perspectives compared to traditional reviews. Meanwhile, VOSviewer and CiteSpace have been used extensively for bibliometric analyses; therefore, our data analysis process was relatively objective and reliable. However, this study had some limitations. First, we retrieved publications and data from WoSCC; despite our efforts to obtain the most comprehensive literature, some articles were not included in the analysis, which may have led to bias. Second, owing to the time lag, some newly published high-quality papers did not receive sufficient citations and therefore could not be included in the analysis.

CONCLUSION

Immunological factors associated with cirrhosis have important research and application prospects. With the rapid increase in the number of studies, the study of immunological factors in cirrhosis has attracted great interest from researchers worldwide. The United States and China are the leading countries, and there is close cooperation between various countries and institutions. Current research hotspots regarding immunological factors in cirrhosis include fibrosis, cirrhosis, inflammation, liver fibrosis, expression, HCC, activation, PBC, disease, and HSCs. Immune dysfunction, gut microbiota, epidemiology, mouse model, pathway, obesity, EVs, bile acids, and the ECM are currently at the frontier of research on immunological factors in cirrhosis. It is notable that in addition to focusing on basic research, we should also pay attention to the translation and application of the research results.

ARTICLE HIGHLIGHTS

Research background

Cirrhosis is deemed a systemic disease associated with the immune system resulting from a persistent liver injury leading to liver fibrosis. Immunological factors play important regulatory roles in the development and progression of cirrhosis.

Research motivation

Bibliometrics is one of the most used methods for the systematic evaluation of a field of study. To date, no bibliometric studies have been conducted on the role of immunological factors in cirrhosis. A statistical analysis conducted by a bibliometric method may provide a more comprehensive understanding and assessment of the hot spots and trends in research on immunological factors in cirrhosis disease.

Research objectives

To provide a comprehensive overview of the knowledge structure and research hotspots of immunological factors in cirrhosis, which can help scholars quickly understand the research status and provide new ideas and directions for studying immunological factors in cirrhosis.

Research methods

We retrieved publications related to immunological factors in cirrhosis between 2003 to 2022 from the Web of Science Core Collection (WoSCC) database on December 7, 2022. The search strategy was TS = ((Liver Cirrhosis OR hepatic cirrhosis OR liver fibrosis) AND (Immunologic* Factor* OR Immune Factor* OR Immunomodulator* OR Biological Response Modifier* OR Biomodulator*)). Only original articles and reviews were included. A total of 2873 publications were analyzed using indicators of publication and citation metrics, countries, institutes, authors, journals, references, and keywords by CiteSpace and VOSviewer.

Research results

A total of 5104 authors from 1173 institutions across 51 countries published 2873 papers on cirrhosis and immunological factors in 281 journals. In this article, we explored and analyzed research in this field according to country, journal, author, and other relevant factors. Current research hotspots in this field include fibrosis, cirrhosis, inflammation, liver fibrosis, expression, hepatocellular carcinoma, activation, primary biliary cirrhosis, disease, and hepatic stellate cells. Burst keywords (*e.g.*, epidemiology, gut microbiota, and pathways) represent research frontiers that have attracted the interest of researchers in recent years.

Research conclusions

We used bibliometrics, a relatively new literature research method, to analyze the knowledge structure and hotspots of research in the field, providing new ideas for promoting scientific research and clinical applications.

Research perspectives

Burst keywords, including immune dysfunction, gut microbiota, epidemiology, mouse models, pathways, obesity, extracellular vesicles, bile acids, and the extracellular matrix, represent the current frontiers of research on immunological factors in cirrhosis.

Abstract

BACKGROUND

Splenic vein thrombosis is a known complication of pancreatitis. It can lead to increased blood flow through mesenteric collaterals. This segmental hypertension may result in the development of colonic varices (CV) with a high risk of severe gastrointestinal bleeding. While clear guidelines for treatment are lacking, splenectomy or splenic artery embolization are often used to treat bleeding. Splenic vein stenting has been shown to be a safe option.

CASE SUMMARY

A 45-year-old female patient was admitted due to recurrent gastrointestinal bleeding. She was anemic with a hemoglobin of 8.0 g/dL. As a source of bleeding, CV were identified. Computed tomography scans revealed thrombotic occlusion of the splenic vein, presumably as a result of a severe acute pancreatitis 8 years prior. In a selective angiography, a dilated mesenterial collateral leading from the spleen to enlarged vessels in the right colonic flexure and draining into the superior mesenteric vein could be confirmed. The hepatic venous pressure gradient was within normal range. In an interdisciplinary board, transhepatic recanalization of the splenic vein *via* balloon dilatation and consecutive stenting, as well as coiling of the aberrant veins was discussed and successfully performed. Consecutive evaluation revealed complete regression of CV and splenomegaly as well as normalization of the red blood cell count during follow-up.

CONCLUSION

Recanalization and stenting of splenic vein thrombosis might be considered in

patients with gastrointestinal bleeding due to CV. However, a multidisciplinary approach with a thorough workup and discussion of individualized therapeutic strategies is crucial in these difficult to treat patients.

Key Words: Pancreatitis-induced splenic vein thrombosis; Gastrointestinal hemorrhage; Colonic varices; Splenic vein stenting; Segmental/sinistral hypertension; Case report

Core Tip: Splenic vein thrombosis (SVT) is a complication of pancreatitis and can lead to development of varices with a high risk of gastrointestinal bleeding. While clear guidelines are lacking, splenectomy or splenic artery embolization are often employed. We present a rare case of recurrently bleeding colonic varices (CV) due to pancreatitis-induced (PI) SVT. In an interdisciplinary board, transhepatic recanalization of the splenic vein and consecutive stenting, as well as coiling of aberrant veins was decided and successfully performed. Follow-up revealed complete regression of varices. According to our knowledge, there is no case report in English literature describing stenting of PISVT in a patient with CV.

INTRODUCTION

Gastrointestinal bleeding due to colonic varices (CV) is rare but can be severe[1,2]. CV may be caused by thrombosis of the splenic vein. In our patient this was due to an episode of acute pancreatitis. Moreover, treatment is challenging, and a multidisciplinary individualized approach is warranted in these patients. Cases are rare and clear guidelines for management are lacking, as the available data is heterogenous and case numbers for interventional recanalization are low. Therefore, we present a patient with CV due to pancreatitis-induced splenic vein thrombosis (PISVT) and summarize the clinical features, treatment options and available data in the current literature.

SVT

The splenic vein is located at the posterior surface of the pancreas and is fed by tributaries from the spleen, the inferior mesenteric vein, the short gastric veins, the left gastroepiploic vein and pancreatic veins[2]. Isolated obstruction can occur as a result of external compression due to malignancy, retroperitoneal disease or splenic artery aneurysms[2,3]. In addition, SVT can be associated with a variety of diseases shown in Table 1[2,4,5].

PISVT

The predominant cause in approximately 50%-60% of isolated SVT is acute or chronic pancreatitis[5,6]. While Butler *et al*[7] yielded an overall incidence of PISVT of 14.1% in patients with pancreatitis (22.6% in acute and 12.4% in chronic pancreatitis), a meta-analysis including over 10000 patients reported the pooled prevalence of SVT in pancreatitis to be as high as 11.2%[7,8]. Thrombosis is a consequence of the associated inflammatory process of the pancreas, fostered by endothelial damage, the release of prothrombotic cytokines and vein compression due to edema, lymphadenopathy or pseudocysts causing stasis of blood flow[6]. However, it is still unclear if the risk of thrombosis correlates with the severity of pancreatitis[2,8]. Since PISVT is mainly diagnosed after the acute phase, recurrent indolent episodes of pancreatitis could play a major role in its development[6]. The diagnosis can be challenging as the accuracy of doppler sonography to diagnose SVT is low due to the small size, the location of the splenic vein and the presence of adjacent collaterals[6]. In addition, the incidence of compensatory splenomegaly in SVT was reported at 51.9%, rendering it unreliable for diagnosis[8]. Additionally, D-dimer levels can be elevated in SVT, but are also unspecific[4]. The diagnostic test of choice to assess the presence of SVT is late-phase celiac angiography [computed tomography (CT) or magnetic resonance imaging][6]. Ultimately, the gold standard to confirm SVT is selective angiography of the splenic artery with lacking drainage *via* the splenic vein[6]. Clinical symptoms of SVT are nonspecific and include abdominal pain and nausea[4]. Historically, patients with SVT were commonly described to present with acute bleeding, thereby overestimating the risk for hemorrhage, which has since been thought to

be about 4%-17%[9,10]. Due to a broader availability and improvement of imaging, at present the majority of cases are diagnosed at an asymptomatic state[8].

Segmental Hypertension

PISVT can lead to increased blood flow through splenoportal, gastroepiploic or mesenteric collaterals creating a localized form of venous hypertension referred to as "segmental", "sinistral" or "linear hypertension"[8]. This results in the development of varices in the area decompressing the corresponding segment and entails an increased risk of severe hemorrhage[2]. Frequently, the short gastric veins collateralize through portosystemic esophageal veins to the azygos system leading to esophageal varices[11]. Other pathways decompress the short gastric veins *via* the coronary vein into the portal vein or *via* the gastroepiploic arcade into the vena mesenterica superior creating gastric varices[11]. Another path runs along the left gastroepiploic vein to the left colic and inferior mesenteric vein[11]. Furthermore, collateral channels along intercostal and diaphragmatic veins draining into the vena cava inferior and a pathway *via* the adrenal vein into the renal vein have been described[11]. Segmental hypertension occurred in 12.5% in acute pancreatitis and in 2.7% in chronic pancreatitis[10,12]. Identified risk factors for the development of PISVT in pancreatitis were smoking, alcohol consumption, hypertriglyceridemia, diabetes, recurrent acute pancreatitis, infection of necrosis and pseudocysts[10,12]. Gastrointestinal varices are found in 53% of PISVT and are gastric in the majority (77.3%) of cases [8]. This is especially relevant as the rate of bleeding in patients with PISVT was reported to be 12.3% [8]. In case of varices the bleeding rate was at 19.1% and seemed to be higher in alcoholic than in non-alcoholic pancreatitis[12,13].

CV

CV associated with PISVT are very rare, data is scarce and only a few case reports exist[1,14-17]. In these cases, splenectomy was performed to manage bleeding and decompress the varices. The incidence rate of CV in general is estimated at 0.07%[3,18]. Causes of CV include liver cirrhosis (as the most frequent etiology), congestive heart failure, porto-mesenteric thrombosis, post-operative adhesions, inherited vascular anomalies (*e.g.*, Klippel-Trenaunay-Weber syndrome) and idiopathic varices[18,19]. Diagnosis

is primarily established *via* colonoscopy, although selective mesenteric angiography is the gold standard, as varices can be missed when flattened with insufflation and in hypotensive patients, especially if active bleeding is present[3]. Ectopic varices are reported to be more prone to bleeding and can have a mortality rate as high as 40%[20]. CV are rarer than small bowel and rectal varices; in one recent study only 3.5% of ectopic varices were situated in the colon[18,21].

CASE PRESENTATION

Chief complaints

We present a 45-year-old female who was admitted to the hospital due to recurrent hematochezia.

History of present illness

She denied abdominal pain, weight loss, fever or night sweats and there was no history of malignancy or inflammatory bowel disease.

History of past illness

Patient history included alcohol misuse, bipolar disorder, arterial hypertension, cholecystolithiasis, pancreatic insufficiency and an episode of severe acute pancreatitis 8 years prior, which required intensive care treatment.

Personal and family history

Family history for gastrointestinal disease, tumor or bleeding was negative.

Physical examination

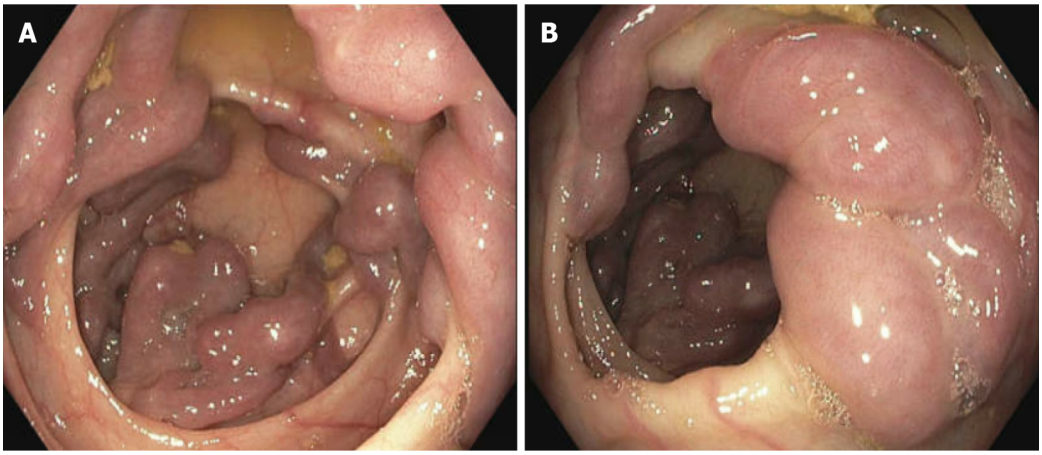
On presentation, abdominal examination was unremarkable and vital signs were stable.

Laboratory examinations

Blood work showed anemia with a hemoglobin of 8 g/dL (12-15.4 g/dL), a mean corpuscular volume of 70 fL (80-99 fL) and a mean corpuscular hemoglobin of 22 pg (27-33.5 pg) while coagulation parameters were within normal range.

Imaging examinations

Gastroscopy revealed reflux esophagitis of grade A and a mild duodenitis. There was no evidence for varices or ulcers. During colonoscopy, largely dilated and tortuous varices spreading from the right transverse colon to just underneath the right colonic flexure were diagnosed (Figure 1). There was no active bleeding. A CT angiography confirmed an extensive venous convolute at the right colonic flexure and evidenced an aberrant mesenteric collateral coming from the splenic hilum as its feeding vein (Figure 2). The varices' draining vein could be identified and lead to the superior mesenteric vein. In addition, splenomegaly (15 cm) and thrombotic occlusion of the splenic vein were diagnosed, while the portal vein and superior mesenteric vein were perfused regularly.



Selective angiography of the spleen *via* the femoral artery observed a long-segment occlusion of the splenic vein up to the confluence of the portal vein. It confirmed the findings of the CT angiography and noted that almost the entire venous drainage of the spleen occurred *via* mesenteric collaterals (Figure 2). Simultaneously, an arterio-portal fistula was ruled out. There was no evidence of liver cirrhosis or portal hypertension. Laboratory investigations showed transaminases, albumin and coagulation parameters within normal range. Platelets were slightly decreased due to splenomegaly. Transient elastography showed a value of 7.5 kPa and the hepatic venous pressure gradient was normal (3 mmHg).

FINAL DIAGNOSIS

Presumably, the splenic vein thrombosis was a result of the reported acute severe pancreatitis 8 years prior. Consequently, we postulated that PISVT prompted the formation of collaterals which lead to CV and gastrointestinal bleeding.

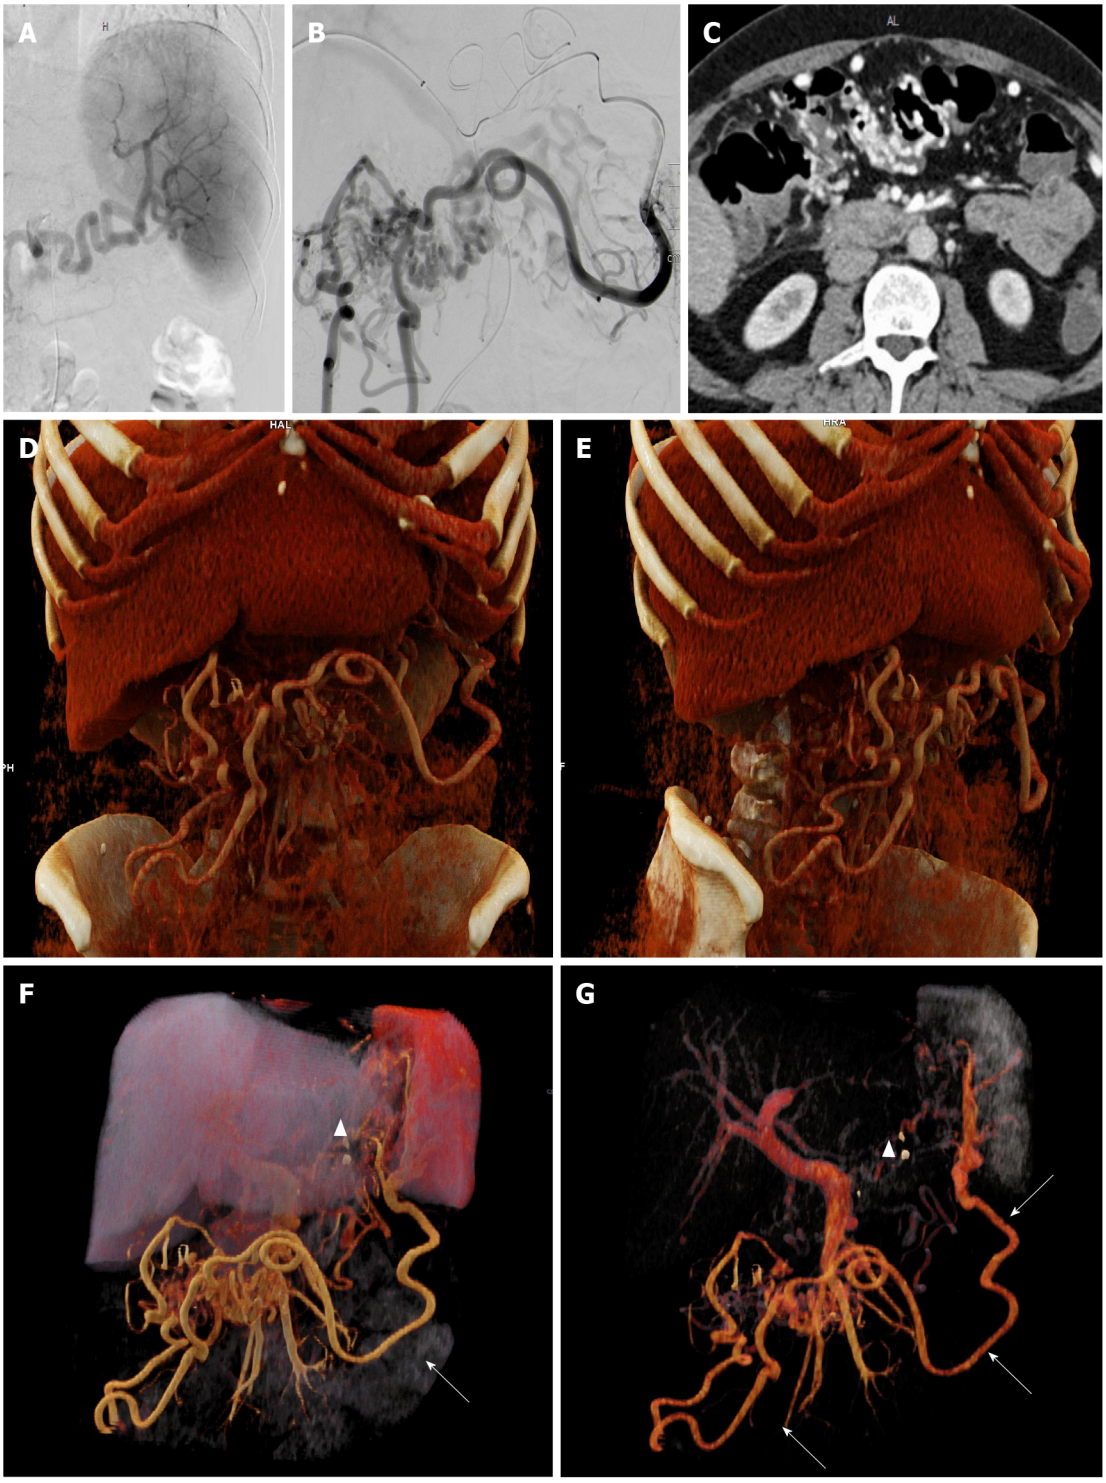
TREATMENT

In an interdisciplinary board, interventional transhepatic recanalization of the splenic vein *via* balloon dilatation and consecutive stenting, as well as coiling of the aberrant mesenteric veins under general anesthesia was planned. The splenic artery was cannulated *via* the femoral artery and a microcatheter was used to reach the splenic hilus and monitor venous drainage during the procedure (Figure 3A).

DOI: 10.3748/wjg.v29.i24.3922 **Copyright** ©The Author(s) 2023.

Figure 1 Dilated and tortuous colonic varices on endoscopy without active bleeding. A: Right transverse colon; B: Right colonic flexure.

Subsequently, right portal vein access was obtained transhepatically, a 6-French vascular sheath (Biotronik®, Berlin, Germany) was placed and a contrast venogram showed the expected occlusion of the splenic vein measuring 8 cm (Figure 3B and C). The aberrant vein feeding the varices was contrasted (Figure 3D). The obstructed vein was successfully cannulated using a 5-MP catheter and a Progreat-microcatheter (Terumo Interventional Systems, Somerset, NJ, United States). After crossing the occlusion, balloon angioplasty with a 3 mm × 12 mm and a 5 mm × 40 mm percutaneous transluminal angioplasty balloon was performed and was followed by deployment of two overlapping stentgrafts (8 mm × 57mm and 8 mm × 37 mm, BeGraft, Bentley), achieving successful recanalization of the splenic vein (Figure 3E and F). A follow-up venography confirmed restoration of antegrade flow. Afterwards, the dilated mesenteric collateral vein leading from the splenic hilum to the colon was cannulated *via* stentgrafts and a distal and proximal embolization by the deployment of multiple coils (Boston Scientific Interlock®; Marlborough, MA, United States) was performed (Figure 3G). A small gastral aberrant vein was also coiled. Follow-up angiography demonstrated patent stentgrafts allowing complete drainage of the spleen through the splenic vein (Figure 3H). The transhepatic access tract was occluded by means of gelfoam slurry (EmboCubes®; Merit Medical, South Jordan, UT, United States) and the femoral access using AngioSeal® (Terumo Interventional Systems).

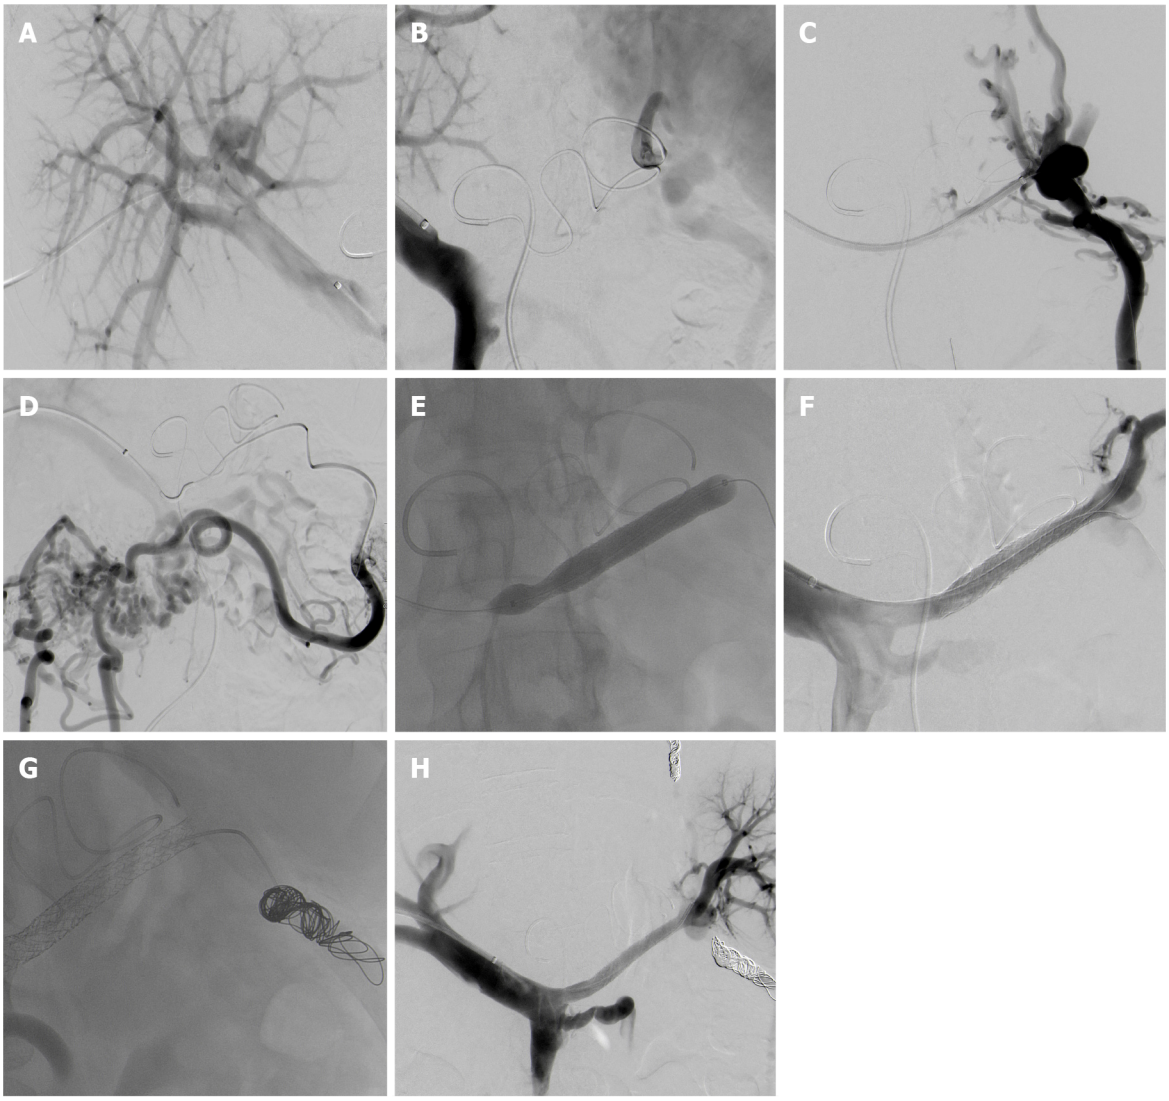


OUTCOME AND FOLLOW-UP

A consecutive Doppler examination revealed antegrade perfusion of the splenic vein and regression of splenomegaly (1 d post-recanalization 15 cm, after 4 d 13 cm). At follow-up 2 mo later, lab results found a normalization of red blood cell count (hemoglobin 12.1 g/dL) and a colonoscopy confirmed drastic regression of CV with few residual veins in the right colonic flexure (Figure 4A). One year post-intervention, hemoglobin was at 13.2 g/dL, the spleen measured 11.5 cm, the splenic vein stent was patent with orthograde perfusion on duplex sonography and residual veins had completely disappeared (Figure 4B).

DISCUSSION

Gastrointestinal bleeding due to CV caused by PISVT is rare and difficult to treat[1,14-17]. Time from the onset of pancreatitis to the detection of SVT is highly variable ranging between 10 d and 9 years[10]. In our patient, there was an 8 year gap between the episode of pancreatitis and diagnosis of PISVT.



Due to limited data, clear guidelines for the treatment of CV are lacking. The use of non-selective beta-blockers for bleeding prophylaxis has been recommended with a low quality of evidence[22,23]. Conservative treatment also includes iron supplements and avoiding constipation[24]. The use of anticoagulation (AC) in chronic SVT with collaterals is controversial and dependent on etiology, risk of recurrence, progression and hemorrhage[5]. Considering the low rate of recanalization as well as the substantial bleeding risk if varices are present, an individualized risk assessment is necessary[4,5,10]. In our case, AC was not viable due to ongoing intermittent bleeding. However, our patient had suffered from acute pancreatitis previously and AC might be beneficial in acute pancreatitis to avoid SVT[25]. In acute pancreatitis and PISVT, data on AC are conflicting regarding recanalization and bleeding rate[10,26-28].

Endoscopic therapies such as variceal ligation, injection of cyanoacrylate or sclerotherapy may be performed for bleeding control in localized varices, but success depends on the location and expansion of the varices[2,18,23]. In addition, these techniques do not treat the underlying cause, thereby resulting in high re-bleeding rates[2,23]. In the setting of portal hypertension, transjugular intrahepatic portosystemic shunt (TIPS) is an option and achieved 100% initial hemostasis in ectopic variceal bleeding, with a subsequent re-bleeding rate of 21%[29]. Nevertheless, TIPS is not expedient in segmental hypertension when portal pressure and hepatic function are normal[2,23]. Another option to manage CV is embolization of the feeding veins[23,29]. Complications are rare and include post-embolization syndrome, infection, vessel injury and thromboembolism[30]. Embolization represents

another short-term therapy with a high rate of successful bleeding control, but does not influence portal pressure, thus entailing high re-bleeding rates[23].

Surgical treatment, as for example, colon resection, can be required in cases of uncontrolled bleeding or when extensive varices are present[24]. Surgical devascularization, shunt procedures or other local therapy depending on the underlying etiology have been reported[23,29]. Historically, the surgical treatment of choice for PISVT is splenectomy, which eliminates the collateral outflow[6,31]. In patients with hemorrhage unresponsive to conservative management or a history of bleeding, it is still the treatment of choice[2]. However, considering the reported lack of progression and rarity of hemorrhage in patients with asymptomatic varices, as well as operative risk, risk of postoperative infection and portal vein thrombosis, "prophylactic splenectomy" in patients without evidence of bleeding remains controversial[2,6,11,31]. Splenic artery embolization (SAE) resulting in splenic infarction represents an option, although the risk of splenic abscess and intervention associated morbidity is considerable[2,6].

Reports on splenic vein recanalization and thereby minimizing blood flow to collaterals in segmental hypertension are scarce[11]. A retrospective study of endovascular splenic vein recanalization in patients with SVT by a transjugular approach achieved success in 8 of 11 cases[32]. Another study reported effective splenic vein stenting in 3 patients using a transhepatic approach[33]. Recently, Liu *et al*[34] compared 9 patients with splenic vein stenting, 12 cases of splenectomy and 12 patients with conservative treatment in PISVT and there were no recurrent bleeding or major complications in the interventional group[34]. Stent patency was 100% and PISVT receded significantly[34]. Furthermore, a retrospective analysis comparing splenic vein stenting and SAE in SVT related bleeding found significantly less re-bleeding in the recanalization group[35].

Figure 4 Follow-up colonoscopy. A: Right colonic flexure 2 mo after intervention; B: Transverse colon 1 year after intervention.

In our patient, endoscopic treatment and TIPS were not viable options due to the localization, size and extension of the varices and absence of portal hypertension. Embolization alone, balloon-occluded retrograde transvenous obliteration (commonly referred to as BRTO) or segmental colonic resection were considered as short-term options, but were unlikely to prevent future bleeding because of potential collateral development. Moreover, splenectomy to alleviate the segmental hypertension was discussed, but as the patient was stable and preferred a less invasive alternative, we opted to perform transhepatic recanalization of the splenic vein and consecutive stenting, as well as coiling of the feeding veins. Splenic vein stenting has been shown to be a safe option[32,33]. According to our knowledge, there is no case report in the English literature describing recanalization and stenting of PISVT in a patient with CV. We found two case reports using recanalization and stenting in superior mesenteric vein thrombosis – one in hepatitis with CV and one in PISVT and associated duodenal varices with excellent results[18,36]. Also, there is a case report of successful splenic vein stenting in PISVT with gastric varices[11]. In the current case, we describe a successful transhepatic endovascular recanalization and stenting of a fully occluded splenic vein and embolization of aberrant veins in the setting of PISVT and CV with gastrointestinal bleeding. It can be argued, that coiling of the dilated aberrant veins leads to faster recompensation but may increase risk of splenic rupture in acute stent failure[35].

CONCLUSION

In summary, splenic vein recanalization seems to be an effective and safe procedure to resolve variceal complications in PISVT. An interdisciplinary discussion of potential therapeutic options is crucial as the available experience is important and an individualized approach to these patients is mandatory.
