ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Mohamad Amin Pourhoseingholi, PhD, Associate Professor, Gastroenterology and Liver Diseases Research Center, Research Institute for Gastroenterology and Liver Diseases, Shahid Beheshti University of Medical Sciences, Tehran 19835, Iran. aminphg@gmail.com

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

Gastric cancer (GC) remains a leading cause of cancer-related death worldwide. Less than half of GC cases are diagnosed at an advanced stage due to its lack of early symptoms. GC is a heterogeneous disease associated with a number of genetic and somatic mutations. Early detection and effective monitoring of tumor progression are essential for reducing GC disease burden and mortality. The current widespread use of semi-invasive endoscopic methods and radiologic approaches has increased the number of treatable cancers: However, these approaches are invasive, costly, and time-consuming. Thus, novel molecular noninvasive tests that detect GC alterations seem to be more sensitive and specific compared to the current methods. Recent technological advances have enabled the detection of blood-based biomarkers that could be used as diagnostic indicators and for monitoring postsurgical minimal residual disease. These biomarkers include circulating DNA, RNA, extracellular vesicles, and proteins, and their clinical applications are currently being investigated. The identification of ideal diagnostic markers for GC that have high sensitivity and specificity would improve survival rates and contribute to the advancement of precision medicine. This review provides an overview of current topics regarding the novel, recently developed diagnostic markers for GC.

Key Words: Gastric cancer; Diagnostic biomarkers; Early detection; Liquid biopsy

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Gastric cancer (GC) is a major unsolved clinical problem. It is the fifth most diagnosed cancer in the world, and the fourth most frequent cause of cancer-related deaths worldwide. The outcome of advanced GC remains tremendously poor despite the use of surgery and adjuvant therapy. Therefore, the detection new biomarkers for early diagnosis will be potential therapeutic strategies for improving survival of GC patients. The aim of this review is to summarizes the current status and approaches for novel biomarkers, which could be useful for early diagnosis.

INTRODUCTION

Gastric cancer (GC) is the fifth most common cancer and the fourth most common cause of cancer-related death worldwide[1]. The overall survival rate of individuals with GC remains poor, because it is often diagnosed at an advanced stage or even as metastasis. One strategy for lowering the burden of GC is early screening and diagnosis. Even though upper gastrointestinal endoscopy has been well established as the standard for GC screening, capturing a concealed tumor in the stomach requires higher sensitivity and specificity. Upper gastrointestinal endoscopies also involve high costs with regard to cost and human resources, requiring experienced endoscopists and patient understanding.

To achieve large-scale GC screening among healthy individuals in the future, a more general and cost-effective approach is needed. Cancer biomarkers (tumor markers) are molecules indicative of the presence and progression of cancer; as such, they play a crucial role in cancer diagnoses and treatment selection[2]. Their applications are rapidly expanding owning to advances in genetic analysis technology and molecular targeting. There are at present no biomarkers with sufficient sensitivity and specificity for the diagnosis of GC that could be applied in clinical settings. Biomarkers are needed for every stage of GC to improve its clinical course. The emergence of liquid biopsy technology, which enables the detection of specific molecular information of solid tumors from body fluids, has provided major changes in cancer diagnosis and treatment[3]. There are many studies on biomarkers for GC screening. However, many of these candidate biomarkers identified thus far are preferentially expressed at advanced stages, and thus unsuitable for early detection. Moreover, a comprehensive review focusing on early detection of GC is still lacking. Herein, we review novel candidates of biomarkers focusing on early detection of GC comprehensively, from the laboratory to the clinical prevalence and the future prospects. This information will contribute to further research on GC biomarkers and their clinical applications.

METHODS

A non-systematic review was performed based on an electronic search through the medical literature using PubMed and Google Scholar. The keywords "biomarker", "gastric cancer", "early detection", "diagnostics", "liquid biopsy" were used. Review articles and guidelines investigating the values of biomarker for early detection of GC from gastroenterology, oncology and genetics were included in this review. When more than one guideline concerning the same subject was available, the most up-to-date one was selected. Only full articles in the English language published in the last ten years were considered for further review. Great importance was also given to "Clinical study" and "Review" articles dealing with the topic. The exclusion criteria comprised duplicated articles, studies absent of diagnostic outcomes. Case reports, correspondences, letters, and non-human research were not included.

LIQUID BIOPSY

Various diverse molecules in blood (serum/plasma) have been said to be correlated with GC carcinogenesis. Among them, DNA, proteins, and noncoding RNA (ncRNA) molecules have been focused. These molecules allow the dependable finding of new noninvasive biomarkers for GC in plasma/serum. Liquid biopsy has shown good potential in detecting circulating tumor cells (CTCs) from any bodily fluid, including peripheral blood, urine and cerebrospinal fluid, ascites, pleural effusion, *etc*., and includes a genomic, proteomic and metabolite assessment. It is a quick, easy and inexpensive method

with minimal invasiveness, making it widely accepted by patients, without major side effects[4]. Liquid biopsy (using mainly peripheral blood) can be used as a screening method to detect early GC (EGC) and minimal residual disease (MRD) after surgery and can create an appropriate treatment plan in GC patients.

CTCs/circulating tumor DNA

CTCs defined as tumor cells that have been detached from the primary tumor or metastases and shed in patient's bloodstream, characterize an easily attainable sample of cancer specimens. As a liquid biopsy, emerging technologies for CTC isolation have enabled the research on the pathology of CTCs and have prompted the clinical uses of CTCs in the diagnosis of malignancies[5]. Although many researchers have come to the same conclusion that CTCs positivity was associated with prognosis, few researches were found for the early diagnosis, especially in the last several years.

Circulating cell-free DNA (cfDNA) consists of fragments of extracellular DNA that can be found in the blood[6]. cfDNA changes across different pathological states have been successfully exploited as noninvasive biomarkers for liquid biopsies. Particularly, the cfDNA that is identified from tumors and shows tumor-specific mutations is named circulating tumor DNA (ctDNA)[7]. The analysis of ctDNA has been predominantly of interest over a decade as its remarkable stability in body fluids. Besides, accumulating evidences showed that ctDNA is useful for early incidence during disease progress after surgical procedure. Further improvement of the ctDNA detection system is progressing. The cfDNA-based liquid biopsy for early diagnosis is mostly restrained by the low signals shed from early-stage cancer, which directly influence the sensitivity of sequencing analyses.

Recent paper has described that the circulating biomarkers, such as cfDNA was highly expressed in stage I GC patients compared with those in benign gastric disease patients and health controls, suggesting the potential for their use for the early detection of GC[8,9]. The human epidermal growth factor receptor 2 (HER2) gene copy number detected in ctDNA was higher in GC patients compared to healthy control. Elucidation of HER2 copy number variation could distinguish healthy individuals and patients with GCs with 58% sensitivity and 98% specificity [area under curve (AUC) = 0.707, 95% confidence interval (CI): 0.593-0.821][10]. ctDNA sequencing identifies fibroblast growth factor receptor 2 (FGFR2) amplification missed by tissue testing in patients with advanced GC, and these patients may respond to FGFR inhibition. ctDNA can detect plasma *FGFR2* alterations, occasionally at a higher frequency than tissue testing, identify patients and these patients may respond to FGFR inhibition[11].

Current cancer biomarkers can be categorized into two groups: (1) Biomarkers generally used for the detection of specific cancer types; and (2) Biomarkers to be aimed to decide personalized medicine, such as companion diagnostics. Even when surgical procedure is successfully carried out, detecting MRD after surgery is still challenging for doctors, and it is difficult to detect MRD in time using radiologic imaging or tissue biopsy. Recent studies presented that ctDNA-based testing were able to detect MRD several weeks earlier than imaging[12]. Another study monitoring ctDNA in postoperative blood has verified that, the median duration from positive ctDNA detection to relapse was 4.05 mo[13]. Moreover, the postoperative positive ctDNA was significantly correlated with tumor recurrence within 12 mo after surgery, suggesting that postoperative ctDNA monitoring possess clinical application value in the prediction of postoperative GC recurrence[13]. In a similar, ctDNA positivity preceded radiographic recurrence by a median of 6 mo, suggesting that, ctDNA is a sensitive and specific biomarker for finding patients at high risk for relapse after curative treatment[14]. ctDNA-positive patients were at higher risk of relapse and exhibited worse outcome compared to the ctDNA-negative group, implying that ctDNA monitoring in the post-treatment setting is predicted to offer knowledge about necessity for further therapy[15]. The clinical usefulness of ctDNA as biomarker for longitudinal disease monitoring and identification of MRD in GC was assessed by ultra-deep sequencing methods. The occurrence of relapse was 100% (7 of 7), 100% (5 of 5), and 94% (16 of 17), respectively in patients with measurable ctDNA at the post-operative, post-adjuvant chemotherapy, and consequent longitudinal time spots. To date, novel high throughput sequencing techniques such as next-generation sequencing (NGS) or whole exosome sequence can identify mutations in multiple genetic regions[16]. Recent study conducted surveillance for recurrent disease after curative surgical resection analyzed by whole genome sequence. For 1630 patients with GC and esophageal adenocarcinomas, detection of MRD after successful surgical procedure is intensely correlated with an enhanced risk of relapse by utilizing a Guardant 360, ctDNA-NGS assay[17]. These studies elucidate that risk stratification of patients for adjuvant chemotherapy escalation/de-escalation could be predicted by incorporation of ctDNA. ctDNA-guided treatment strategy in post-surgery surveillance for patients with GC is a novel emerging strategy that will likely replace the current treatment decision, as outlined in Figure 1.

NC RNA

Diverse ncRNAs, such as microRNA (miRNA), circular RNA (circRNA), and long ncRNA (lncRNA), are implicated in GC carcinogenesis[18]. MiRNAs are small ncRNA molecules of approximately 18-22 nucleotides that regulate cell differentiation, proliferation, apoptosis and gene regulation[19]. Currently, due to the stability and specificity of expression in circulation, accumulating evidences suggest that miRNAs can serve as novel biomarkers with a prospective clinical significance tool for patient with GC. MiRNAs are very stable in blood and can be identified by various assays such as reverse transcription

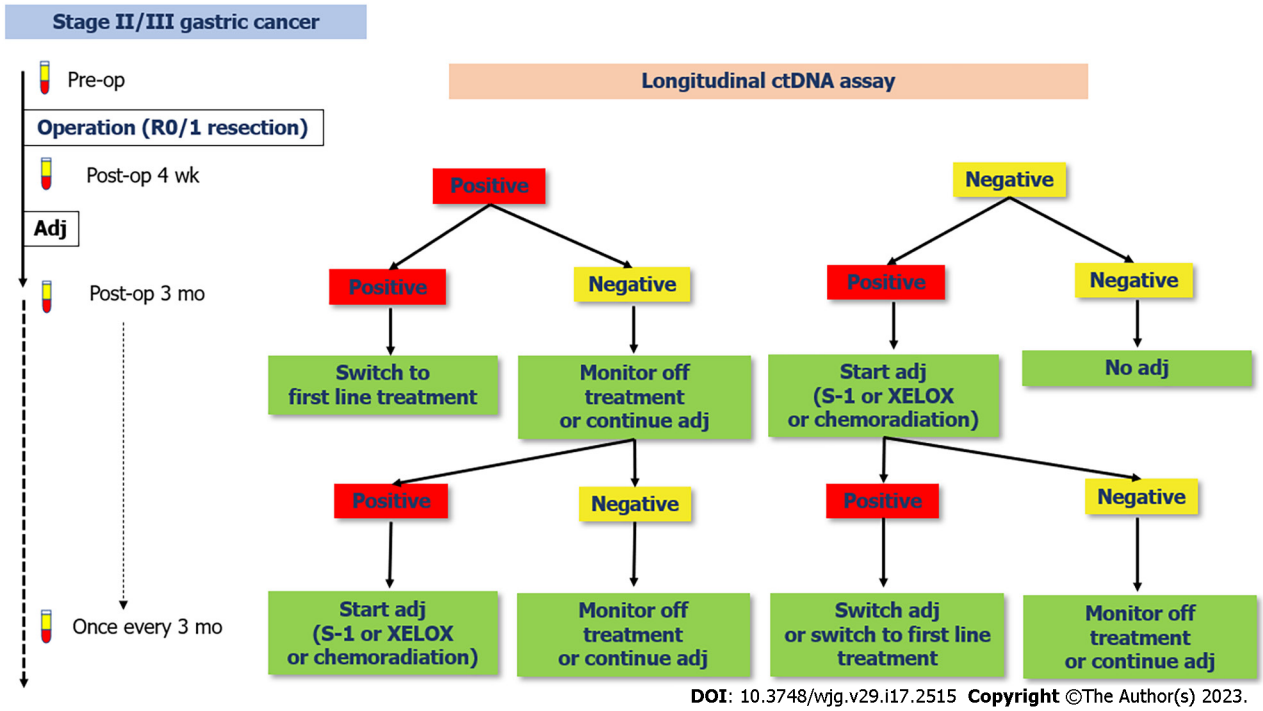

Figure 1 Proposed design of circulating tumor DNA-guided treatment strategy in gastric cancer. Schematic presentation of proposed circulating tumor DNA (ctDNA) guided treatment strategy in gastric cancer evaluating tailored treatment based on ctDNA detection. ctDNA positivity was determined by accessing the presence of plasma mutations, which indicates the existence of minimal residual disease. Adapted from Chakrabarti *et al*[100], and Kasi *et al*[101]. ctDNA: Circulating tumor DNA; Op: Operative; Adj: Ajuvant chemotherapy.

quantitative real-time polymerase chain reaction, and NGS. Recent studies challenged to verify the importance of various miRNAs in human plasma/serum as diagnostic markers for early-stage GC, including miR-17, miR-25, and miR-133b[20], miR-425-5p, miR-1180-3p, miR-122-5p, miR-24-3p, and miR-4632-5p[21]. A recent distinctive expression study of miRNA profiles utilizing two datasets from plasma samples identified hsa-miR-320a, hsa-miR-1260b, and hsa-miR-6515.5p as potential biomarkers for primary diagnosis of GC, with an AUC higher than 0.95 in all cases. Furthermore, hsa-miR-320a and hsa-miR-1260b was more stable in all the discovery and validation datasets[22]. Similarly, a recent study developed an EGC index to differentiate EGC from non-cancer controls based on the serum levels of four miRNAs (miR-4257, miR-6785-5p, miR-187-5p, and miR-5739). This index provided a sensitivity of 0.996 and a specificity of 0.953, with an AUC of 0.998 for the detection of EGC in a large sample size study (n = 1417)[23]. These results suggest that miRNAs could act as promising biomarkers for the early detection of GC. Nevertheless, further research is needed to optimize their detection methods and reproducibility of accrued results to meet the rigorous requirements for clinical setting.

LncRNAs are the transcripts of more than 200 nucleotides that have been found to participate widely in various pathological processes of organisms[24]. In colon cancer, LncRNA small nucleolar RNA host gene 11 has been presented as a promising biomarker for early detection of this malignancy[25]. Meanwhile, hepatocellular carcinoma upregulated lncRNA and ZNFX1 antisense RNA 1 have been shown to distinguish GC patients from healthy subjects and proposed as novel diagnostic biomarkers of GC[26]. LncRNAs promoter of CDKN1A antisense DNA damage activated RNA, FOXD2 adjacent opposite strand RNA 1, and SWI/SN F related, matrix associated, actin dependent regulator of chromatin subfamily c member 2 in plasma may serve as novel biomarkers for early detection of GC. The combined these three lncRNAs offer a high sufficient diagnostic sensitivity[27]. LncRNA B3GALT5 antisense RNA 1 was shown to be better than carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA19-9) and may serve as a diagnostic biomarker of GC[28]. Distinct levels of serum C5orf66 antisense RNA 1 (C5orf66-AS1) were shown between patients with GC and gastritis. A risk of gastric dysplasia and GC negatively associated with serum expression of C5orf66-AS1, implying that C5orf66-AS1 a potential biomarker for predicting EGC[29]. Combined lncRNAs have been displayed to improve biomarker values for early detection of GC. LncRNA HLA Complex P5 (HCP5) is a kind of RNA gene without protein-coding. The AUC of serum lncRNA HCP5 was 0.818 (95%CI: 0.757-0.880, 80% sensitivity, and 70% specificity) in distinguishing between GC and healthy controls. Besides, the highest AUC of 0.870 (95%CI: 0.819-0.921) with 81% sensitivity and 79% specificity were revealed by the combination of three diagnoses, HCP5, CEA, and CA19-9[30]. Thus, the results above indicate that lncRNAs possess the diagnostic potential for early diagnosis of GC.

CircRNAs are also generally categorized as a ncRNA and physically vigorous nucleic acid molecules that construct closed loop RNA and require polyadenylated tails unlike messenger RNAs[31]. CircRNAs are more stable in tissues, have a superior life period and are more resistant to Ribonuclease R compared with linear RNAs[32]. In a recent, the rapid development of high-throughput sequencing has promoted the detection of circRNAs and their roles in physiological and pathological processes, including GC carcinogenesis, have been evaluated. A recent study found circRNA Has_circ_0000745 was downregulated in GC tissues and in plasma from patients with GC. Therefore, the use of these circRNAs has great potential as a new biomarker for diagnosis of GC[33]. The expression of hsa_circ_0001789 in 24 paired of cancerous and paracancerous plasma specimens were examined. A down-regulated expression of hsa_circ_0001789 was detected in GC plasma samples in comparison to the healthy controls, indicating that hsa_circ_0001789 has the potential to be a novel GC diagnostic biomarker[34]. CircPTPN22 is an outstanding diagnostic marker for GC. Utilizing receiver operator characteristic (ROC) analysis of circPTPN22 expression in GC patients, gastritis patients, and healthy controls, showed that its AUC was higher than that of traditional tumor markers CEA and CA19-9, and the AUC reached 0.892 after combined use[35]. 8-circRNA biomarker panel (hsa_circ_0001013, hsa_circ_0052001, hsa_circ_0034398, circ_0006089, hsa_circ_0002019, hsa_circ_0007380, hsa_circ_0008768, hsa_circ_0045602) discriminated patients with GC from normal control tissues, with an AUC value of 0.87 (95%CI: 0.82-0.93, sensitivity 78.3%, specificity 78.3%). Interestingly, 7 of 8 circRNA markers significantly lower expressed in serum specimens after surgery. Furthermore, 8-circRNA panel showed a greater specificity for the identification of patients with GC *vs* all other gastrointestinal cancers, such as colorectal cancer, pancreatic cancer, esophageal cancer, and hepatocellular carcinoma[36]. Studies using ncRNAs in screening/diagnostics of GC in the past 5 years are collected in Table 1.

Exosome

Exosomes are lipid bilayer-enclosed extracellular vehicles (EVs) approximately 30-150 nm in size, consist of a lipid bilayer interspersed with various membrane proteins, and which contain a variety of nucleic acids, proteins, and lipids[37]. Exosomes are secreted continuously by all cells and offer distinct prospects for clinically relevant diagnostic content, including DNA, RNA, and proteins[37]. Exosomes have been said to be associated with driving key features of cancer activity, including facilitation of tumor cell proliferation, suppression of the immune response, stimulation of tumor cell migration, initiation of angiogenesis, and formation of metastases[38]. Recently, growing evidences have established the latent diagnostic value of EVs or circulating exosomes for early diagnosis of GC. Due to the easiness to isolate exosomes compared with CTCs and cfDNA in malignant tumors, an growing number of studies will be highlighted on exosomes in the diagnosis of EGC in the next several decades. Exosomal lncUEGC1 exhibited an AUC of 0.8760 and 0.8406 in distinguishing EGC patients from normal subjects and those with atrophic gastritis, respectively, implying that exosomal lncUEGC1 had higher diagnostic reliability compared with CEA[39]. Circulating exosomal lncRNA proprotein convertase subtilisin/kexin type 2-2:1, G protein subunit alpha q-6:1 and GC-associated lncRNA1 (lncRNA-GC1) have been reported as better biomarkers for distinguishing GC patients from healthy people, compared with CEA, CA19-9, and CA72-4[40-42]. Similarly, serum four exosoms, miR-92b-3p, miR-146b-5p, miR-9-5p, and miR-let-7g-5p have been shown to be latent biomarkers for early detection of GC[43]. Likewise, the ROC showed that serum exosomal miR-590-5p showed a good classifier with an AUC of 0.810 (95%CI: 0.751-0.860) with a sensitivity of 63.7% and specificity of 86.0%, suggesting that serum exosomal miR-590-5p expression may be a noninvasive diagnostic biomarker of GC[44]. MiR-195-5p and miR-211-5p in GC patients' plasma exosomes have shown to be upregulated compared to healthy controls. The AUC values of plasma exosomal 2-miRNAs signature was 0.820, which was more meaningful to discriminate the GC patients from the healthy samples, compared to the AUC values obtained for combined CEA, CA19-9[45]. circ_0065149 levels in plasma exosomes from EGC patients were significantly lower than those from healthy individuals. Thus, circ_0065149 revealed distinguished diagnostic accuracy, with an AUC of 0.64, sensitivity of 48.7%, and specificity of 90.2%[46]. Piwi-interacting RNAs (piRNAs) are another class of small ncRNAs that are 26-31 nucleotides in length, and quite comparable in size to miRNAs. PiRNAs are distinctly different from miRNA counterparts because they lack the sequence conservation present in miRNAs. As a source for liquid biopsy, piRNAs have similar properties to miRNAs and stabile in the blood flow and resistant to ribonuclease mediated degradation. Therefore, piRNAs can be used as effective biomarkers for the early detection of GC. Serum exosomal piR-019308, piR-004918 and piR-018569 can be utilized for the diagnosis of GC with the AUC value of 0.820, 0.754 and 0.732, respectively. Diagnostic value of these piRNAs were much better than that of CEA, CA19-9 and alpha-fetoprotein[47]. Collectively, circulating exosome has clinical potentials in the early diagnosis of GC, which may lead to the identification of cancer subtypes. Exosome investigated as potential diagnostic GC markers are listed in Table 2.

Collectively, this section highlights the developments in the ncRNAs as a source for the development of non-invasive diagnostic biomarkers for GC patients. NcRNAs appear to have a crucial potential to be implemented into biomarker development for early detection of GC. On the other hand, a variety of circulating biomarkers have been reported in different research team. The clinical value of all these factors is not still defined. Some discrepancies among different studies can be caused by the hetero-

geneity of GC. Thus, a more precise patient inclusion criteria or enlarging of the cohort size could overcome the differences in ncRNAs expression caused by the intrinsic heterogeneity of the disease. More multicenter, greater, longer-term studies are warranted to apply liquid biopsies in clinical settings, in terms of early diagnosis of GC. We systematically summarized the ncRNAs as biomarker for early detection of GC in Figure 2.

DNA METHYLATION

DNA methylation is an epigenetic mechanism which lead to oncogenesis in GC through activation of oncogenes and silencing of tumor-suppressor genes[48]. In a recent, a variety of studies demonstrated that aberrant epigenetic regulations, such as DNA methylation, histone posttranslational modifications,

Figure 2 The summary of non-coding RNAs as biomarker for early detection of gastric cancer. Schematic of the non-coding RNAs composition. Liquid biopsy obtained from peripheral blood is composed of different tumoral components such as micro-RNA, long non-coding RNAs, and circular RNAs. miRNA: MicroRNA; lncRNA: Long non-coding RNA; circRNA: Circular RNA; piRNA: Piwi-interacting RNAs.

ncRNAs and chromatin remodeling, have a pivotal influence on the pathogenesis of GC. DNA methylation is well-investigated epigenetic change among the epigenetic modifications[49]. Nowadays, the importance of aberrant DNA methylation is identified by liquid biopsy, including plasma/serum and gastric juice. Tumor suppressor genes methylation in peripheral blood has been examined most broadly. Aberrant gene methylation identified in body fluids could be a useful biomarker for the early detection of GC, likewise SEPT9 in CRC. Numerous methylated gene promoters detected in ctDNA have been proposed for GC detection as a latent diagnostic marker[50]. Among them, aberrant methylation of Reprimo, RUNX3, RASSF1A, SFRP2, PCDH10, H19, and MALAT1 show high sensitivity and specificity, suggesting that they have superiority in the early detection of GC[51-55]. A recent study elucidated the association of aberrant DNA methylation with the risk of GC. Hypermethylation of SOCS3 promoter in blood extensively facilitated GC risk[56]. Genome-wide hypomethylation commonly occurs in repeated components that are normally hypermethylated to keep genomic stability. Long interspersed nucleotide element 1, Alu repetitive elements and human endogenous retroviruses are the main components of scattered repeated sequences[57]. Although a number of studies examined the perspective of DNA methylation as a biomarker in GC, the methylation levels in those studies were mainly shown from the tissues. Thus, novel aberrantly methylated genes whose roles in GC should be investigated, especially those detected by non-invasive methods.

DNA methylation is major epigenetic changes when pathogens invade to gastric mucosa, which allows the infection to persist and promotes the development of GC[58]. *Helicobacter pylori* (*H. pylori*) is one of the most important pathogens for GC. Previous studies have demonstrated that Alu and Satα hypomethylation was significantly correlated with *H. pylori* infection in patients with GC[59]. Although numerous studies were examined to elucidate the mechanism of epigenetic changes induced by *H. pylori* infection, useful biomarker for early detection in GC is still not applied in clinical setting. Most recent report demonstrated that FGFR4 activation was interacted with signal transducer and activator of transcription 3 thorough steroid receptor coactivator in response to *H. pylori* infection, suggesting that FGFR4 could be a candidate of biomarker for early detection of GC[60].

NOVEL BIOMAKER IDENTIFIED FROM MULTI-OMICS DATA

Previous classifications of GC have quite restricted achievement in advocating the advancement of subtype-specific treatment applies due to the heterogeneity of GC and their incapacity to detect latent molecular targets. With NGS, omics technologies have offered beneficial tools to examine the molecular basis of GC. Multiple omics-based studies have been used to evaluate the biofluids of GC patients,

which resulted in numerous novel biomarkers due to rapid progress in machine learning approaches [61]. A number of mutations, gene alteration, protein abundance differences, epigenetic mutations, and metabolite concentrations which is linked to GC heterogeneity and staging, leading to improve our understanding of GC, have been successfully identified. NGS has high throughput and can screen unknown variants. A variety of methods are applying NGS to target panel, namely Tagged-Amplicon deep sequencing, Safe-Sequencing System, and Cancer Personalized Profiling by deep sequencing. The developments of NGS enable many applications in both DNA and RNA sequencing (RNA-seq), such as whole-genome, whole-exome, and targeted sequencing of DNA, and total RNA, mRNA, and small RNA [62].

Proteins contribute to determine the identity of a cell[63]. Cell function can be affected by aberrant protein expression, or altered post-translational arrangements. Proteomic signatures can afford complementary information for patient stratification to genetic signature. Besides, proteins can be a useful tool as a biomarker for malignances[63]. The development of proteomics technologies, such as mass-spectrometry (MS), has made it easier to identify protein biomarkers applied to tumor diagnosis. Liquid chromatography-MS (LC-MS) of digested proteins conducted with high-resolution instruments enable to quantitate thousands of proteins from complex biological specimens. Study using LC-MS/MS combined with TMT labeling, found that 11 proteins differentially expressed in plasma from EGC patients and healthy controls identified from the total of 2040 proteins. This model presented that the altered proteins found by plasma proteomics could provide a resource of potential biomarkers for diagnosis of EGC[64]. Isobaric tags for relative and absolute quantification (iTRAQ) are said to be the most widely used method for high-throughput protein quantification. The study using iTRAQ-labeled quantitative proteomics revealed that NAD(P)-dependent steroid dehydrogenase-like (NSDHL) and neutral cholesterol ester hydrolase 1 (NCEH1), key enzymes in cholesterol metabolism, were aberrantly expressed in patients with GC. Moreover, the combined analysis of NSDHL and NCEH1 showed high sensitivity compared with a single marker in detecting GC, indicating that NSDHL and NCEH1 may be adequate for novel biomarkers in the screening[65]. Identically, thioredoxin reductase 1 was aberrantly expressed in GC by using Itraq-labelling and/or LC-MS, supporting that these proteins are an important target for early determining and follow-up monitoring for GC[66]. Integration of phosphoproteome data with other types of omics data from young diffuse-type GC patients provided links of somatic mutations to phosphorylation changes in signaling pathways, association of mRNA-protein abundance correlations with survivals, and four subtypes of young diffuse-type GC patients characterized by genomic and proteomic signatures, which may contribute to have a deep insight into diffuse-type GCs[67]. More recent study using proteomics methods of serum based on high-resolution MS with ion mobility separation followed by multivariate statistics and network analysis presented that a 29-protein marker panel containing, integrin β6 and glutathione peroxidase, and ten serum markers specific for GC (ITIH1, FZD6, DPP10, SERPINA4, AKAP12, S100A9, POTEF, CACNB1, CRP KIAA1328), which were independent of *H. pylori* infection[68]. Multi-omic analysis characterizing the intricate relationships between the intragastric microbiome and gastric mucosal gene expression revealed higher abundances in several bacterial taxa (*Pasteurellaceae*, *Enterococcaceae*, *Helicobacteraceae*, *Gemellales* and *Neisseriaceae*) and genes (*SOCS3* and *ITM2A*) were shown in GC patients. In turn, *Lachnospiraceae* was closely associated with the expression of *Ubiquitin D*, which regulates mitosis and cell cycle time in GC [69]. Besides, lower abundances of B cell signatures in GC compared to gastritis may suggest a previously unidentified immune evasion process in gastric carcinogenesis. These results suggest that a combined analysis of microbiome and gene expression may help to devise a diagnostic kit that screens for high-risk patients of GC who require surveillance endoscopy.

STOMACH SPECIFIC BIOMARKER

The measurement of a biomarker in a gastric juice sample should be specific for early-stage GC than the same biomarker measured in plasma/serum because it is obtained directly from the area of the lesion, which would lead to avoid dilution of the biomarkers and their lack of specificity[70]. Because DNA is easily degraded due to gastric juice acidity, the main part of biomarkers identified in gastric juice are ncRNAs and some proteins. A significantly increased miR-135b-3p and miR-199a-3p, and a decreased miR-451a levels in gastric juice-derived EVs from GC patients was shown compared to non-cancer individuals[71]. LncRNAs in gastric juice and urine have also been reported as biomarkers of GC and urinary system cancer, respectively[72]. On the other hand, a recent study revealed that the levels of SNCG in gastric juice detected by enzyme-linked immunosorbent assay were significantly higher in the GC group compared with the control group[73]. Analysis using gastric juice-derived exosomal DNA samples presented that BARHL2 methylation had an area under the curve of 0.923 with 90% sensitivity and 100% specificity which suggested the feasibility of the application of BARHL2 methylation for screening for GC biomarker[74]. Although a number of studies elucidating the value of gastric juice as a biomarker for early detection of GC were carried out, the limitation is the tolerance of the patients as a usual examination due to the discomfort of gastroscopy.

Serological examinations, which are noninvasive and relatively convenient. can offer efficient indicators of gastrointestinal diseases. Markers of gastric function such as pepsinogen (PG)-I, PG-II, PG-I/PG-II ratio, gastrin 17, anti-*H. pylori* antibodies are used to cooperatively diagnose chronic atrophic gastritis (CAG)[75]. A recent meta-analysis has presented the use of serum pepsinogens revealed significant diagnostic accuracy for the early detection of gastric CAG or GC[76]. Among the various cut-off values investigation, PG rate ≤ 3 and PG-I ≤ 70 ng/mL have been proposed for CAG and GC prediction. Although there are numerous studies for evaluating PG as biomarker for early detection of GC, the potential use of pepsinogens in GC prevention is still not well-established.

DISCUSSION AND FUTURE PERSPECTIVE

Biomarkers are biological molecules implicated in the initiation and progression of cancer, and determination of their levels can clarify abnormal molecular changes in patients[77]. Morphological detection of diseased gastric epithelial cells using upper gastrointestinal endoscopy has always been the standard method for diagnosis of GC. However, the false-positive rates for endoscopic screening in the first round are said to be 14.9%. Notably, endoscopy is easily missed during screening, even when it is performed by qualified endoscopists. In this review, we describe the comprehensive and systematic search for and development of blood-based biomarkers for early detection of GC. Identification of highly sensitive biomarkers for GC screening might render upper gastrointestinal endoscopy unnecessary. Biomarker has assisted in the advancement of new DNA, RNA, and protein-based cancer biomarkers that can be detected from noninvasive, sensitive, specific, and cost-effective body fluids. These include the OncoBEAM™ RAS CRC liquid biopsy assay approved by the European Commission as an *in vitro* diagnostic tool for colorectal cancer therapy, and this has led to the early detection of emergent resistance to anti-epidermal growth factor receptor treatment and the assessment of genomic profile during treatment in clinical settings[78]. Such assays may also enable us to abandon approved but useless treatments for patients resistant to molecular targeted agents or immunosuppressants. For instance, with this technology the future patients with stage II or III GC with a low risk of postoperative recurrence may be simply monitored under active surveillance without adjuvant chemotherapy and possibly be started to treat from when MRD is detected (Figure 1). Although ctDNA for detection of MRD can be an emerging clinical biomarker for disease monitoring in GC, applications of ctDNA in clinical practice require more comprehensive examination in prospective trials.

However, several technical factors are hindering the use of liquid biopsy biomarkers in clinical use. A major challenge is the very low levels of peripheral DNA/RNA[79]. In 2022, ESMO published recommendations on the use of ctDNA in genomic testing and clinical practice. Based on its review of the different aspects of ctDNA, the ESMO Precision Medicine Working Group provides some outlook on the future of ctDNA examination. Considering deficient sensitivity in clinical practice for gene fusions and copy number variations and advancing tests to discriminate accurate results for more progressive genotyping are included in their recommendations[80]. To overcome these issues, several upgraded liquid biopsy approaches for cancer diagnosis are under development. It is likely that precancerous and cancerous lesions can be detected by combinations of biomarkers with superior sensitivity and specificity, fulfilling an unmet need in clinical practice. Combining biomarkers, such as ncRNAs, can enhance the sensitivity and specificity for detecting EGC. However, it would be difficult to identify the ideal combination of other biomarkers that can enhance the overall detection performance. Correlations between different types of biomarkers like the association pattern to guide the choice of panels can be effectively identified using biostatistical approaches. For example, a serum biomarker miRNA panel consisting of 12 miRNAs was developed for risk assessment in patients with GC. With the use of a multitarget miRNA assay in more than 5000 individuals in Singapore and Korea, this panel showed an AUC of 0.848 and 87% sensitivity and 68.4% specificity values to distinguish GC patients from healthy controls. Moreover, upgrading of the AUC to 0.884 and specificity to 69.4% for GC detection were achieved by the combination of this 12-miRNA panel with patient age, *H. pylori* serology, and the plasminogen I:II ratio[81]. Combinations of ctDNA mutations with other biomarkers, such as protein or methylation have been examined toward the goal of improving the overall sensitivity. It has been demonstrated that the combination of ctDNA and protein biomarkers can markedly increase the sensitivity[82]. Genome-wide methylation and protein marker profiles have been validated for a combination of *mSEPT9*, *mRNF180* and CA724 for the detection of GC, and the combination of all three markers detected 68.6% of GC cases[83].

Another important strategy for improving the sensitivity and specificity of GC detection is the use of innovative bioinformatic algorithms. Machine learning involves various computational techniques that are used to simplify large numbers of measurements into lower-dimensional outputs that are more explainable[84]. In the case of GC, a combination of artificial intelligence (AI)-based endoscopy and miR148a methylation has been evaluated for the diagnosis of gastric indefinite dysplasia[85]. Interestingly, a recent study using the microbial compositions of the Cancer Genome Atlas (TCGA) of 18116 human blood samples across 33 cancer types and stochastic gradient-boosting machine learning models effectively discriminated cancer-free individuals, patients with cancer, and patients with

multiple types of cancer[86]. A new concept of cfDNA is also expected to be applied to cancer diagnoses in the near future.

Unfortunately, there is a lack of standardized technique for isolation, amplification and detection in the use liquid biopsies for early diagnoses in clinical settings. One of the most meaningful accomplishments regarding biomarkers for early cancer detection is the emergence of high-throughput technological platforms such as NGS, which allows comprehensive quantification of whole genome or transcriptome. The cost of NGS has greatly declined over the past several decades, which has allowed the sequencing of a larger number of clinical biospecimens, as well as the ability to generate datasets with higher depth of coverage. The opportunity to generate higher resolution data for low expressing transcripts improves the ability to detect rare cancer-derived transcripts in circulation. A study aiming to found the latent miRNA for predicting GC by AI in the Gene Expression Omnibus (GEO) datasets, particularly with several states of the machine learning methods and the Boruta algorithm, demonstrated that the use of hsa-miR-1343-3p could predict GC with the AUC of 100% (sensitivity 100%, specificity 100%, ROC 100%)[87]. In a recent study using high-throughput RNA-seq, the expression profiles of circRNAs in serum EV between GC patients and healthy individuals were examined. The results demonstrated that the circRNA, Chr10q11, Chr1p11, and Chr7q11 were upregulated in GC; the AUC of the three combined circRNAs was 0.839 (95%CI: 0.772-0.893) with 73.2% sensitivity and 84.1% specificity. The construction of a circRNA-miRNA-mRNA network predicted that the three identified circRNAs interact with 13 miRNAs and 91 mRNAs. These findings suggest that panels of EV circRNAs may provide new insights into the early diagnosis of GC[88]. With the use of publicly available gene expression profiles from the TCGA and GEO datasets, a recent study explored the circRNA-miRNA-mRNA interaction axis by constructing a competing endogenous (ce)RNA network. On the basis of the hub RNAs included in ceRNA, the screening of the model for predicting the mRNA signature and miRNA signature by LASSO regression analysis found that both five mRNA-based signatures (CTF1, FKBP5, RNF128, GSTM2 and ADAMTS1) and five miRNA-based signatures (miR-145-5p, miR-615-3p, miR-6507-5p, miR-937-3p and miR-99a-3p) had superior capacity to predict the diagnosis of GC patients with the AUC of 0.9975[89]. Similarly, a study using regulatory networks for circRNA-miRNA-immune-related mRNA validated in the new GEO and TCGA datasets identified various ceRNA (circRNA-miRNA-immune-related mRNA) regulatory networks in GC constructed by hsa_circ_0050102–hsa-miR-4537-NRAS-Tgd cells, hsa_circ_0001013-hsa-miR-485-3p-MAP2K1-Tgd cells, hsa_circ_0003763-hsa-miR-145-5p-FGF10-StromaScore, hsa_circ_0001789-hsa-miR-1269b-MET-adipocytes, hsa_circ_0040573-hsa-miR-3686-RAC1-Tgd cells, and hsa_circ_0006089-hsa-miR-5584-3p-LYN-neurons, among which FGF10, MET, NRAS, RAC1, MAP2K1, and LYN showed promising diagnostic significance for GC patients[90]. In a study based solely on bioinformatics models constructed a circRNA-miRNA-mRNA network based on three circRNAs, 43 miRNAs, and 119 mRNAs, and upregulations of hsa_circ_0001013, hsa_circ_0007376, and hsa_circ_0043947 were observed, which may offer a new pathway for mechanical examinations and provide possible biomarkers for early detection of GC[91]. Likewise, in a bioinformatics circRNA-miRNA-gene interaction network analysis, two circRNAs (CircCEACAM5 and CircCOL1A1) cooperated with GC correlated miRNAs and their host genes were suggested as the pivotal diagnostic biomarker for GC[92]. The emergence of single-cell sequencing technologies has markedly improved the resolution of low-input sequencing. The recent introduction of single-cell DNA/RNA-seq provides an opportunity to detect cell types and cell status. For example, a single-cell expression atlas of gastric premalignant gastric lesions and EGC identified the expression signatures of multiple cell types across different lesions, as well as a panel of six high-confidence markers that could serve as specific biomarkers for early diagnosis of GC[93]. A weighted gene co-expression network analysis (WGCNA) aims to: (1) Identify co-expressed modules in multiple biological samples based on correlations between different gene expression profiles; and (2) Explore the relationship between gene networks and phenotypes of interest, as well as the hub genes in the network[94]. Performing a WGCNA can prevent the false-negative and false-positive results of previous biological methods. WGCNA data from the GEO database revealed hub genes involved in GC and identified four functional genes (*ITGAX*, *CCL14*, *ADHFE1*, and *HOXB13*) that were differentially expressed in tumor and normal gastric samples. Another study applying a WGCNA to screen potential biomarkers for EGC using RNA-seq and clinical data from the TCGA database identified five hub genes, *MS4A1*, *THBS2*, *VCAN*, *PDGFRB*, and *KCNA3*[94]. These technological developments will allow more researchers to conduct comprehensive assessment of molecular profiles in the human circulatory system.

Systematic studies applying the molecular profiling of ncRNAs for cancer biomarker have been developed. Several investigations have used tissue profiling data to identify ncRNA as a potential biomarker, leading to the evaluation of these cancer-associated ncRNA signatures in blood cohorts. Multiple tissue sequencing datasets were recently used to identify highly overexpressed miRNAs in GC tissues. Risk probabilities using quantitative reverse transcriptase polymerase chain reaction data for three miRNAs (miR-18a, miR-181b, and miR-335) were validated and showed much better diagnostic performance than the conventional tumor markers CEA and CA19-9 currently in use. Moreover, the three-miRNA signature discriminated between patients with stage I GC and cancer-free individuals. More importantly, using the miRNA signature was significantly more cost-effective relative to the current clinical practice of endoscopic screening, suggesting the robustness of a GC associated miRNA signature in multiple cohorts[95].

Table 3 Clinical trials of blood-based biofluid biomarkers for gastric cancer detection

Clinical trials	Type of trial	Phase	Results	Participants (estimated)	Assay	Comments
ctDNA						
NCT05027347	Cohort	NA	Recruiting	200	Ultradeep massive parallel sequencing assay	Development of a protocol for detection of ctDNA in plasma of patients with early stages of GC
NCT04511559	Cohort	NA	Not yet recruiting	540	ctDNA methylation sequencing	The correlation between the plasma ctDNA methylation status and the diagnosis of patients with early GC
NCT05208372	Case-control	NA	Recruiting	200	CTC and ctDNA test	Investigation of the value of CTCs and ctDNA in the diagnosis of metastasis of GC in peritoneal flushing fluid and blood
NCT04665687	Cohort	NA	Recruiting	1730	Illumina HiSeq2000/2500-based, MiSeq NGS targeted sequencing	Identification whether tumor's molecular profiling based on blood could be used for diagnosis of EGC and precancerous gastric adenoma
NCT05029869	Cohort	NA	Recruiting	100	NGS technologies	Study aims to evaluate the use of NGS to detect ctDNA in GC patients after gastrectomy
NCT05224596	Case-control	NA	Recruiting	498	Blood draw and blood-based biomarkers analyses	Multi-omics 498 study aimed at detecting GC by combined assays for serum protein markers, deep sequencing of cfDNA, ctDNA mutation and RNA
miRNAs						
NCT04329299	Cohort	NA	Completed	6862	Blood-based biomarkers analyses	Validation of the predictive value of various blood biomarkers, such as miRNA
lncRNAs						
NCT05397548	Cohort	NA	Recruiting	700	RT-PCR	Study to investigate the predictive value of circulating exosomal lncRNA-GC1 for early-detection and monitoring progression of GC
Methylation						
NCT04511559	Cohort	NA	Not yet recruiting	540	ctDNA methylation sequencing	Methylation analysis of ct DNA in early diagnosis in patients with GC
NCT03076567	Observational	NA	Completed	440	NA	Discovery and validation of plasma DNA methylation biomarker for detection of GC
NCT05336058	Cohort	NA	Recruiting	1240	Multi-target PCR	Exploration of the clinical performance of polygene methylation in the adjunctive diagnosis of GC
NCT04253106	Non-randomized	NA	Recruiting	10	NGS	Activating methylation profiles identified by liquid biopsies could identify CDH1 and CTNNA1 pathogenic variants carriers with DGC
Multi-omics						
NCT04947995	Case-control	NA	Recruiting	450	ctDNA multi-omics test	Exploration of a blood-based multi-omics assay and computational model for early detection of GC
NCT05347524	Observational	NA	Recruiting	384	Blood draw and blood-based biomarkers analyses	Detection of peritoneal metastasis of GC by combined assays for methylation of cfDNA and other blood-based biomarkers

GC: Gastric cancer; NGS: Next generation sequencing; PCR: Polymerase chain reaction; DGC: Diffuse gastric cancer; ctDNA: Circulating tumor DNA; cfDNA: Cell-free DNA; miRNA: MicroRNA; lncRNA: Long non-coding RNA; NA: Not applicable; lncRNA-GC1: Gastric cancer-associated lncRNA1.

More multicenter studies and prospective evaluations in large clinical trials are necessary for the integrations of such biomarkers into GC screening platforms supporting the daily clinical treatments of GC patients. Several clinical trials have explored the use of a liquid biopsy for early diagnosis of setting for patients with GC (Table 3). However, all of the trials were either observational, case-control, or cohort trials; no randomized control trial assessing liquid biopsy have been conducted to date. Hence, incorporating liquid biopsies into clinical practice for GC may be difficult.

Regarding the development of a circulating non-invasive biomarkers for early detection of GC, specificity for stomach would provide an additional confidence and suggested robustness of GC biomarkers. Biomarkers that are highly specific to GC will reduce the false positive rates, and thus are helpful in clinical practice. The detection of dysregulated genes that are highly expressed specifically in distinct organ could make it easier to find the locations of cancer. For example, KRAS mutations are rarely identified in healthy individuals, which makes these mutations highly cancer-specific. Nevertheless, detecting KRAS mutations in the circulation does not help identify the location of cancer as KRAS mutations can occur in multiple cancer types. Using candidates for GC specific driver genes, such as CDH1 and RhoA, may be possible to increase the specificity as diagnostic biomarkers of GC [96]. Growing evidences suggest that some EVs released from specific organs retain tissue-specific molecular features. It was recently reported that tumor cell-specific molecules, *i.e.*, circulating exosome-derived lncRNA-GC1 can be used as a biomarker to detect EGC and monitor disease progression[42]. Interestingly, a clinical study (ClinicalTrials.gov identifier NCT05397548) investigated whether circulating exosomal lncRNA-GC1 could support the early-detection and progression monitoring of GC. It is thus possible to measure ncRNA content of cancer-specific exosomes to further increase cancer specificity as biomarkers for GC diagnosis. The status of acquired DNA methylation can be tissue-specific and maintained during carcinogenesis, and examination of this status could allow the discovery of the tumor of origin[97], suggesting that biomarkers based on DNA methylation could have the additional potential to provide key information to guide follow-up clinical decision making. Multiple cancer types have been identified *via* high-depth, targeted bisulfite sequencing analysis of a large panel of methylation sites that have signals specific to certain organs; these panels include DEEPGEN™, CancerSEEK, PanSEER, cfMeDIP-se,q GRAIL, IvyGene®, and stMCEDs. Using these panels, excellent rates of detection in individuals with cancer were obtained[98]. However, the specificity of GC in individuals with early disease have been limited. A cost-effective experimental assay, called cell-free DNA Methylome Sequencing (cfMethyl-Seq) profiles the genome-wide methylation of cfDNA, offering > 12 × enrichment over whole-genome bisulfite sequencing in CpG islands[99]. By integrating four marker types, namely cancer-specific hypermethylation markers, tissue hypermethylation markers, cancer-specific hypomethylation markers types, and tissue hypomethylation markers, a cfMethyl-Seq model showed an AUR of 0.974 (95%CI: 0.926-0.998), yielding a sensitivity of 80.7% (95%CI: 68.6%-90.7%) at 97.9% specificity in multiple organs, including those with GC.

Collectively, the combination of multiple parameters and multiple analytes obtained by emerging machine learning methods will help address the challenges of EGC detection. Overcoming the limitation of cancer biomarker translation into clinical practice will require the development of high throughput, multiplexing techniques that can be easily incorporated into clinical settings as well as large-scale prospective research and interventional clinical trials with standardized specimen processing and data collection procedures.

CONCLUSION

Increased understanding of the molecular genetics and epigenetics of GC has led to the progress of molecular marker assays for GC screening. Liquid biopsy is emerging as a promising future screening technique for clinical testing owing to the use of a single sample and ease of specimen collection. The advancement of new technologies with improved sensitivity, such as methylation sequencing and multi-omics analysis, and rapid, global detection capacities that allowed the identification of novel potential biomarkers for early detection of GC.

Abstract

In the world, nonalcoholic fatty liver disease (NAFLD) accounts for majority of diffuse hepatic diseases. Notably, substantial liver fat accumulation can trigger and accelerate hepatic fibrosis, thus contributing to disease progression. Moreover, the presence of NAFLD not only puts adverse influences for liver but is also associated with an increased risk of type 2 diabetes and cardiovascular diseases. Therefore, early detection and quantified measurement of hepatic fat content are of great importance. Liver biopsy is currently the most accurate method for the evaluation of hepatic steatosis. However, liver biopsy has several limitations, namely, its invasiveness, sampling error, high cost and moderate intraobserver and interobserver reproducibility. Recently, various quantitative imaging techniques have been developed for the diagnosis and quantified measurement of hepatic fat content, including ultrasound- or magnetic resonance-based methods. These quantitative imaging techniques can provide objective continuous metrics associated with liver fat content and be recorded for comparison when patients receive check-ups to evaluate changes in liver fat content, which is useful for longitudinal follow-up. In this review, we introduce several imaging techniques and describe their diagnostic performance for the diagnosis and quantified measurement of hepatic fat content.

Key Words: Non-alcoholic fatty liver disease; Hepatic steatosis; Imaging techniques; Quantitative evaluation; Ultrasound; Quantitative ultrasound

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Accurate evaluation of the hepatic steatosis is important. The conventional gray scale ultrasound has the limitation of low diagnostic accuracy for mild hepatic steatosis and inability to make quantification evaluations. Quantification imaging techniques including ultrasound-based techniques and magnetic resonance imaging-based techniques can provide objective continuous numbers associated with liver fat content and past records can be found when patients receiving check-ups to evaluate change of liver fat content, which is useful for the longitudinal follow-up to monitor the impact of clinical interventions.

INTRODUCTION

There are several types of chronic liver diseases, but nonalcoholic fatty liver disease (NAFLD) is the broadest state[1,2]. NAFLD represents a wide range of liver abnormalities[3]. Over 25% of general population is influenced by NAFLD, while affected proportion of type 2 diabetes population is 55%-80% [1]. Simple fatty liver may progress to non-alcoholic steatohepatitis (NASH), which is a severe form of fatty liver characterized by inflammation of hepatocyte. This form may result in cirrhosis with portal hypertension or liver dysfunction or even to hepatocellular carcinoma (HCC)[4]. Notably, there is an annual incidence of 0.4 cases of HCC per 1000 population-years among patients with NAFLD, making it the third most common cause of HCC in the United States[5]. A diagnosis of NAFLD is associated with not only adverse effects on the liver, but also an increased risk of type 2 diabetes and cardiovascular disease[6,7]. A study suggested that there was a significant increase in mortality associated with liver-specific diseases or cardiovascular diseases in patients with NAFLD compared to controls[8]. For patients who received hepatectomy, hepatic steatosis can increase incidence of postoperative complications and death[9]. The risk of graft failure for patients undergoing liver transplantation increases when hepatic steatosis exceeds 30%[10].

As NAFLD poses substantial risks of HCC, liver-associated complications and other adverse events to patients, it is of great importance to diagnose and quantify hepatic fat content early[4]. NAFLD is likely to be reversible in its early stage even with simple treatments, for example, lifestyle changes[11]. In addition, the main factor contributing to disease progression in patients with NAFLD is liver fibrosis[1, 3]. Abundant liver fat accumulation can trigger and accelerate hepatic fibrosis, thus contributing to disease progression[12,13]. Therefore, in patients with NAFLD, quantitative measurements of liver steatosis could be useful for prognostic assessment and treatment[4]. Although high level of liver fat can lead to fibrosis progression, it is of note that the level of liver fat is not always parallel to the grade of fibrosis. It has been suggested that patients without fibrosis or in the early stages of fibrosis may demonstrate obvious disease progression with high level of liver fat content; however, the fat content decreases when disease progresses to advanced fibrosis or cirrhosis[14-16]. Therefore, when evaluating the value of measuring hepatic steatosis for assessing disease progression and prognosis, the fibrosis status should first be taken into account[17].

When it comes to diagnosing diffuse hepatic disease, liver histopathologic examination is the most precise method. With liver biopsy, quantification of the liver fat level is classified into four grades (grade 0, < 5%; grade 1, 5%-33%; grade 2, 33%-66%; grade 3, > 66%)[18]. Although the use of liver biopsy correctly evaluates liver steatosis, its limitations include its invasiveness, sampling error, which make biopsy impractical for patients who have only simple steatosis[19,20]. Therefore, noninvasive methods to diagnose the presence of steatosis and to monitor changes in hepatic steatosis are needed (Table 1). Conventional gray-scale ultrasound can be applied to diagnose liver steatosis. However, its inability to provide accurate quantification of liver fat has limited its use in the diagnostic pathway of liver steatosis[21]. At present, a number of imaging techniques for the evaluation of hepatic fat content, including MR- and ultrasound-based methods, have been developed. In this review, we summarize the available imaging methods for the quantified measurement of hepatic fat content. In addition, we briefly discuss the clinical performance of these methods.

ULTRASOUND-BASED METHODS TO DIAGNOSE AND QUANTIFY HEPATIC STEATOSIS

Table 2 summarizes published diagnostic utility metrics and optimal cutoff values of quantitative ultrasound methods for quantified measurement of hepatic fat content.

Table 1 Characteristics of imaging techniques for hepatic steatosis evaluation

Techniques	Clinical characteristics	Limitations
CAP	Low cost; High availability; Time-saving	High measurement failure rate
	Allows simultaneous evaluation of steatosis and fibrosis	Measurement without B-mode ultrasound image
	Moderate to high diagnostic accuracy for detecting and grading steatosis	The cutoff value for diagnosing steatosis is poorly standardized
	Moderate to high repeatability and reproducibility	
	Well validated	
ATI, ATT and UGAP	Outperform or have comparable diagnostic accuracy compared with CAP	The measurement may be influenced by liver fibrosis
	High repeatability and reproducibility	Fairly small number of studies
	Strong correlation with liver histology or MRI-PDFF	
	Low measurement failure rate	
	Measured on B-mode ultrasound images	
Att. PLUS	Measurement is obtained at the same time as the sound speed measurement	Fairly small number of studies
	Comparable diagnostic accuracy with CAP	No study comparing this technique with liver histology or MRI-PDFF
TAI and TSI	High diagnostic accuracy for detecting and grading steatosis	Fairly small number of studies
	Strong correlation with MRI-PDFF	
	High repeatability and reproducibility	
BSC	Uses a reference phantom to reduce sources of variability due to ultrasound systems or operators	Fairly small number of studies
	High diagnostic accuracy for detecting and grading steatosis	
	Strong correlation with liver histology or MRI-PDFF	
	High repeatability and reproducibility	
UDFF	Is a combination of both attenuation coefficient and backscatter coefficient	Fairly small number of studies
	UDFF approximates MRI-PDFF	
ASQ and NLV	Moderate to high diagnostic accuracy for detecting and grading steatosis	Weak correlation with liver histology
	Strong correlation with CAP	The correlation with MR-based techniques is controversial
		The influence of fibrosis on measurement is controversial
		Fairly small number of studies
SS	Moderate to high diagnostic accuracy for detecting and grading steatosis	Fairly small number of studies
	Strong correlation with CAP	
MRS and MRI-PDFF	High diagnostic accuracy for detecting and grading steatosis	High cost; low availability
	Considered as the reference standard	Time-consuming

CAP: Controlled attenuation parameter; ATI: Attenuation imaging; ATT: Attenuation measurement function; UGAP: Ultrasound-guided attenuation parameter; Att. PLUS: Attenuation plane-wave ultrasound; TAI: Tissue attenuation imaging; TSI: Tissue scatter distribution imaging; BSC: Backscatter coefficient; UDFF: Ultrasound-derived fat fraction; ASQ: Acoustic structure quantification; NLV: Normalized local variance; SS: Speed of sound; MRS: Magnetic resonance spectroscopy; MRI-PDFF: Magnetic resonance imaging-proton density fat fraction.

Conventional gray scale ultrasound

Due to its low price and availability, gray scale ultrasound is a traditional diagnostic method for diagnosing and monitoring liver steatosis[22]. When using this method, fatty infiltration is indicated by the following signs: Hyperechogenicity of the liver parenchyma, liver-to-kidney comparison, ultrasound beam attenuation, and impaired visualization of the intrahepatic structures[23]. However, it is difficult for operators to grade liver steatosis solely based on the gray scale ultrasound[24]. Degree of liver fat content can be classified into 4 grades (normal, mild, moderate, and severe)[22]. For moderate to severe hepatic steatosis, gray scale ultrasound has a high diagnostic accuracy. A meta-analysis enrolling a total of 2815 patients and using hepatic histopathologic results as the golden standard demonstrated that the overall sensitivity and specificity of gray scale ultrasound to distinguish normal liver and moderate steatosis were 85% and 93%[25]. However, gray scale ultrasound has restricted diagnostic performance for mild steatosis[24]. Another limitation is that gray scale ultrasound is based on qualitative visual features, and the intraobserver and interobserver reproducibility vary with different operators[26,27].

Hepatorenal index

To improve the diagnostic performance of using gray scale ultrasound for the measurement of liver content, hepatorenal index (HRI) was developed[28] (Figure 1). This metric calculates the rate of parenchymal echo of the liver and the renal cortex[28]. Previous studies found that HRI had a significant correlation with histologic steatosis[29-31]. Marshall *et al*[32] reported a sensitivity, confirmed by liver biopsy, of 100% with an HRI cutoff of 1.27 for detecting more than 5% steatosis. Borges *et al*[33] reported for diagnosing fatty liver, the cutoff value of 1.24 revealed 93% sensitivity and specificity, but this study only used healthy volunteers as the control group. Stahlschmidt *et al*[34] suggested in livers with advanced fibrosis, HRI should not be used to measure steatosis because fibrosis replaces fat as NAFLD progresses. Similarly, patients suffering from chronic kidney disease may present increased echo of the renal cortex, which makes the HRI unreliable for grading steatosis[35]. Furthermore, Kjaergaard *et al*[36] found that HRI presented a higher incidence of failure (12%) compared to controlled attenuation parameter (CAP, 2%). In addition, it can be challenging to diagnose mild steatosis by HRI[33].

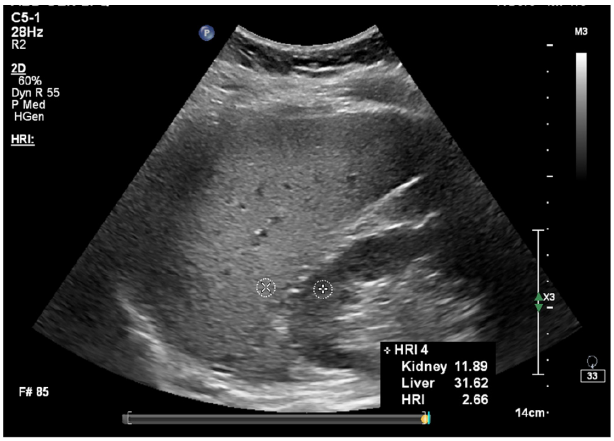
Quantitative ultrasound techniques

Mechanism of quantitative ultrasound techniques: Conventional gray scale ultrasound and HRI cannot provide quantitative information about liver fat content. Essentially, quantitative methods are used to model the relationship between physical properties of hepatic tissue and the echo signals that are scattered by it. The impedance difference of fat vesicles in hepatocytes causes increased scattering magnitudes and signal attenuation. A frequency-dependent analysis of signal attenuation and backscatter is performed on signals returned by tissue[37].

The quantitative ultrasound techniques used for the measurement of hepatic fat quantification included the spectral-based techniques and the techniques based on envelope statistics. Estimation of either attenuation coefficient (AC) or the backscatter coefficient (BSC) is used for spectral based techniques. The AC measures energy loss as ultrasound wave passes through tissue and the BSC measures the returned ultrasound energy when ultrasound wave strikes the microstructure of tissue. Techniques based on the envelope statistics of the backscattered ultrasound include the acoustic structure quantification (ASQ), normalized local variance (NLV), and estimation of sound speed[38]. Techniques according to envelope statistics are relatively novel. Microstructural characteristics of tissues can be determined by the shape and attributes of backscattered ultrasound[38].

Current commercial techniques and their mechanism of hepatic steatosis quantification are presented in Table 3.

CAP: CAP was the initial available technique for quantified measurement of hepatic fat content. Attenuation of the ultrasound beam is applied to generate the CAP amount[39,40]. Typically, two types of probes, the medium probe and the extra-large probe, can be utilized. The choice of optimal probe is automatically controlled according to skin-to-liver capsule distance (SCD). When the SCD exceeds 2.5 cm, the extra-large probe is more effective than the M probe. The CAP is presented in units of decibels per meter (dB/m)[41].



More than 160 studies have discussed the efficacy of CAP as a metric for quantified measurement of liver fat content, and acceptable accuracy was found. The general diagnostic accuracy evaluated by the area under the receiver operating curve (AUROC) of CAP for detecting presence of steatosis has been displayed to range from 0.64 to 0.97[42-44]. A meta-analysis including 19 studies found that CAP had good diagnostic performance with AUROCs of 0.823 for distinguishing steatosis grade > S0, 0.865 for distinguishing steatosis grade > S1, 0.882 for distinguishing steatosis grade > S2. The corresponding optimal cutoff values for > S0, > S1, > S2 were 248, 268 and 280 dB/m. Moreover, they found that there was a potential link between NAFLD, diabetes mellitus, and body mass index with the CAP value[45]. Although the diagnostic utility of CAP for differentiating patients with and without hepatic steatosis has been fully validated, the optimal cutoff value to determine the presence of steatosis varies significantly between studies[17]. A meta-analysis of 2346 participants with different diffused hepatic diseases demonstrated that CAP cutoffs varied according to the etiology of the hepatic diseases,

Table 2 Summary of studies using ultrasound methods to evaluate hepatic steatosis

Figure 1 Hepatorenal index. In this case, the result was 2.66, indicating severe hepatic steatosis.

including NAFLD, chronic viral hepatitis, alcoholic liver disease[46].

The CAP value demonstrated a moderate to strong correlation with magnetic resonance (MR)-based techniques for liver steatosis quantification[47,48]. However, compared with MR-based methods, the CAP has inferior diagnostic ability in grading liver steatosis. Diagnostic effectiveness of MR spectroscopy (MRS) over CAP for diagnosing S1 was significantly higher (AUROC, 0.77 *vs* 0.99)[49]. Imajo *et al*[50] demonstrated suboptimal diagnostic performance of CAP compared to MRI-proton density fat fraction (MRI-PDFF) in grading liver steatosis.

However, CAP has the limitation of failure rate up to 7.7%. According to previous reports, an association was found between measurement failure and sex, body mass index, and metabolic syndrome[51]. Use of the extra-large probe can reduce the failure rate because it is designed for patients

Table 3 Summary of techniques for liver fat quantification and their mechanisms

Technique	Mechanism for liver fat quantification	Principle of the techniques
CAP	Spectral based technique (AC)	CAP measures the attenuation of or reduction in the amplitude of the ultrasound waves on their way through the liver
ATI	Spectral based technique (AC)	ATI quantifies the degree of the ultrasound beam attenuation. The attenuation of the ultrasound beam is calculated by analyzing echo signals received by the transducer
ATT	Spectral based technique (AC)	Two ultrasonic waves of different frequencies (F0, F1; F0 < F1) are transmitted to the same beamline and the received signal is obtained. ATT estimates the attenuation coefficient it by calculating the slope of the received signal ratio (F0/F1)
UGAP	Spectral based technique (AC)	UGAP compares the measured liver signal and the referential signal (measured on the reference phantom with known attenuation and backscatter coefficients)
Att. PLUS	Spectral based technique (AC)	Att. PLUS measures the decrease in amplitude of ultrasound waves as they propagate throughout the tissue
TAI	Spectral based technique (AC)	TAI is determined based on the attenuation properties of different frequency components in the tissue, and the spectrum of radiofrequency signals provides a downshift of the center frequency according to depth. The TAI parameter indicates the slope of the ultrasound center frequency downshift
BSC	Spectral based technique (BSC)	BSC measures the ultrasound energy returned from the tissue
UDFF	Spectral based technique (BSC)	UDFF is obtained by combining both AC and BSC and the result is presented as the percentage of hepatic steatosis. Reference phantom data is integrated into the ultrasound system and fixed-acquisition region of interest is applied
TSI	Envelope Statistic based technique	The TSI is based on the shape parameter of the Nakagami distribution which reflects the local concentration and arrangement of ultrasound scatterers
ASQ	Envelope Statistic based technique	ASQ measures the FD ratio, which is based on the difference between theoretical and real echo amplitude distributions
NLV	Envelope Statistic based technique	NLV parameter was derived from ASQ, which analyzed ultrasound amplitudes sampled from gray-scale ultrasound images
SS	Envelope Statistic based technique	SS calculates the speed of sound through the liver
SSp.PLUS	Envelope Statistic based technique	SSp.PLUS is a novel technique that allows quantification of the intrahepatic speed of sound which is correlated with the liver fat content

with obesity[4].

Quantification of attenuation using ultrasound imaging: Several techniques aiming to evaluate the attenuation coefficient applying ultrasound guidance have been exploited, including attenuation imaging (ATI), attenuation measurement function (ATT), and ultrasound guided attenuation parameter (UGAP). CAP has a disadvantage that it lacks the guidance of gray scale ultrasound images in choosing the area for measurement. In contrast, the ATI, ATT, and UGAP techniques are characterized by evaluating liver steatosis on gray scale ultrasonography images with accurate placement of region of interest[17]. When using these techniques, conventional gray scale ultrasound images can be evaluated simultaneously, and the exact region of interest can be placed to avoid the vessels, bile duct, masses or cysts. Therefore, the technical success rate using these methods is high[52-55]. Another advantage of ATI, ATT, and UGAP is that these techniques have high intraobserver and interobserver agreement. A range of 0.81 to 0.98 is found for the intraobserver agreement of ATI, and a range of 0.79 to 0.92 is found for the interobserver agreement. Although there are few studies investigating the topic, the intraobserver and interobserver agreement of UGAP is reported to be 0.86 and 0.84, respectively. In addition, ATI measurements among different operators demonstrated high agreement (intraclass correlation coefficients: 0.91)[17,44,56].

ATI is a kind of two-dimensional attenuation imaging technique (Figure 2)[57,58]. ATI assesses the attenuation of ultrasound beams in a region of interest using color-coded maps in real time. dB/cm/MHz is the unit of measurement for the attenuation coefficient[35]. In addition, to ensure a high technique success rate, the ATI is equipped with a reliability index (R^2), and an R^2 value ≥ 0.80 is considered a reliable measurement[59-61]. In the reported measurements, the cutoff values ranged from 0.63 to 0.69 dB/cm/MHz for detecting ≥ S1, 0.66-0.72 dB/cm/MHz for detecting ≥ S2, and 0.68-0.86 dB/

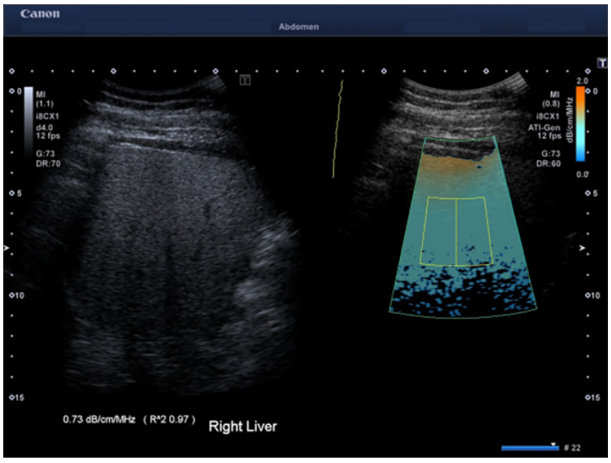

Figure 2 Attenuation imaging technique by Canon with reliability indicator (R^2)[40]. The Gray scale image and the corresponding attenuation imaging image are shown side by side. The attenuation coefficient measurement of the images shown here is 0.73 dB/cm/MHz with an R^2 of 0.97, indicating a valid measurement. Citation: Seneviratne N, Fang C, Sidhu PS. Ultrasound-based hepatic fat quantification: current status and future directions. *Clin Radiol* 2023; 78: 187-200. Copyright© The Author(s) 2023. Published by Elsevier Ltd. The authors have obtained the permission for figure using (Supplementary material).

cm/MHz for detecting = S3. The reported AUROCs were 0.80-0.97 for detecting ≥ S1, 0.86-0.99 for detecting ≥ S2, and 0.79-0.99 for detecting = S3[59-70]. It has been found that ATI measurements have a significant correlation with histological steatosis grade determined by liver biopsy[59,60,67]. Additionally, in case where MRI-PDFF was applied as the gold standard, the ATI demonstrated positive correlation with it (r = 0.70-0.83)[57,65,66]. The ATI also outperformed the CAP in evaluating the grades of hepatic steatosis. A study including 72 consecutive adult patients found that the AUROC for detecting S0 *vs* S1-S3 of CAP was lower than that of ATI (0.85 *vs* 0.92, respectively)[66].

ATT is a technique developed by Fujifilm Health Care company (previously Hitachi Medical Systems, Japan) (Figure 3). In ATT, a beamline is connected to an ultrasonic transmitter with two ultrasonic waves of different frequencies (F0, F1) at once. The received signal is obtained, and attenuation coefficients are determined by the slope of the received signal ratio (F0/F1). The results are presented in units of dB/cm/MHz[54,55,71-73]. A study enrolled 351 patients and biopsy specimens were examined quantitatively for fat content. In terms of fat area, ATT had a significant correlation (r = 0.50, P < 0.001). The cutoff values were 0.62 dB/cm/MHz for S ≥ 1, 0.67 dB/cm/MHz for S ≥ 2 and 0.73 dB/cm/MHz for S ≥ 3 and corresponding AUROCs were 0.79, 0.87 and 0.96[54]. An analysis of 94 patients who received both ATT and CAP examinations when undergoing liver histopathologic examination revealed that ATT exhibited diagnostic accuracy equivalent to that of CAP for grading histological steatosis[73].

With known attenuation and BSC, an ultrasound system uses a phantom method to calculate attenuation coefficients measurement implemented in UGAP (Figure 4). Using this method, the US system's transmitting and receiving beamforming characteristics can be compensated. The result is presented in units of dB/cm/MHz[4,74-76]. Several studies reported good diagnostic efficacy of UGAP for liver fat content quantification applying hepatic histological results as the gold standard, and a positive association was found between UGAP and steatosis percentage (correlation coefficient: 0.78-0.81). The reported AUROCs were 0.89-0.92 for detecting steatosis grade ≥ S1, 0.90–0.95 for detecting steatosis grade ≥ S2, and 0.88-0.96 for detecting steatosis grade = S3[75,77-79]. Several other studies compared UGAP with MR-based methods, and a significant correlation between MR-based methods and attenuation coefficient values by UGAP was found (correlation coefficient: 0.72-0.77)[76,80]. Imajo *et al*[76] conducted a multicentric study with 1010 patients and reported that UGAP had good diagnostic efficacy for making quantified measurement of liver fat content. In their study, the AUROCs were 0.910 for detecting MRI-PDFF ≥ 5.2%, 0.912 for MRI-PDFF ≥ 11.3%, and 0.894 for MRI-PDFF ≥17.1%[76]. Fujiwara *et al*[75] reported that as compared to CAP, UGAP achieved significantly higher AUROCs for identifying ≥ S2 (0.950 *vs* 0.841) and ≥ S3 (0.959 *vs* 0.817). In addition, they also reported 5.2% of CAP patients had measurement failures, while no UGAP patients did. Tada *et al*[81] reported that there was no effect of liver stiffness on UGAP attenuation coefficient values.

Attenuation plane-wave ultrasound: Attenuation Plane-Wave Ultrasound (Att. PLUS) presents information on ultraphonic beam attenuation through a region of interest. The ultrasound beam attenuation is calculated in a region of interest at a constant depth. The attenuation coefficient results are displayed in units of dB/cm/MHz[56]. The Att. PLUS measurement is combined with the sound speed measurement for each acquisition. It is the median of five measurements taken consecutively that determines the final result[35]. Only one published study regarding this method was found. Popa *et al*[82] carried out a study aiming to assess the clinical value of Att. PLUS of noninvasive measurement of fatty liver with the CAP value considered as control. They reported that the cutoff value to detect S2-S3

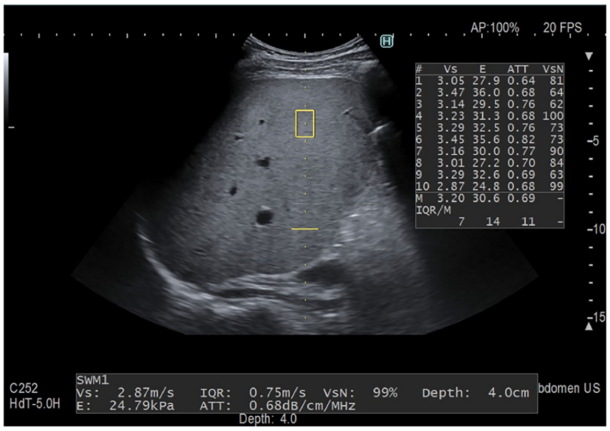

Figure 3 The attenuation measurement function technique was developed by Fujifilm Health Care company[4]. The attenuation coefficient (0.68 dB/cm/MHz) is measured in a fixed area (yellow box) along the same axis as the liver stiffness measurement. Ten acquisitions are performed, and the median value is utilized as the final metric. was 0.5 dB/cm/MHz (sensitivity 53.1%, specificity 82.0%), and the AUROC was 0.72.

Tissue attenuation imaging and tissue scatter distribution imaging: Tissue attenuation imaging (TAI) parameter indicates slope of the ultrasound central frequency downshift along depth, which is able to be utilized to calculate acoustic attenuation. The tissue scatter distribution imaging (TSI) parameter is a measurement of the Nakagami parameters in the region of interest, which reflects the concentration of ultrasound scatterers and their arrangement locally[35,83].

We found three studies comparing TAI and TSI with MRI-PDFF, and these studies revealed that both TAI and TSI revealed correlation with MRI-PDFF[84-86]. Jeon *et al*[86] enrolled 120 patients to assess feasibility of TAI and TSI for hepatic steatosis quantification utilizing MRI-PDFF as the reference. According to MRI-PDFF, the participants were classified into three groups (≤ 5%, 5%-10%, and ≥ 10%). They found that both methods had excellent utility for diagnosing and evaluating the degree of hepatic steatosis. For diagnosing fatty quantification of ≥ 5% and ≥ 10%, the AUROCs of TAI were 0.861 and 0.835, and those of TSI were 0.964 and 0.935, respectively[86]. Rónaszéki *et al*[84] compared TAI with TSI utilizing MRI-PDFF as gold standard enrolling 101 participants and found that TAI provided better diagnostic performance than TSI for diagnosing ≥ 5% MRI-PDFF (AUROC: 0.89 *vs* 0.87) and ≥ 10% (AUROC: 0.93 *vs* 0.86). TAI and TSI revealed good intra- and interobserver agreement. In TAI, the intra- and interobserver ICCs were reported at 0.994 and 0.975, respectively, while in TSI, they were reported at 0.991 and 0.947[87].

Techniques based on ultrasound BSC: Using the BSC, we can determine amount of ultrasound energy reflected by the tissue. Applying computer algorithm and a reference phantom, the BSC can be

estimated with less changeability resulted from ultrasound systems and operators. The right liver lobe was used to obtain gray scale images, and in the same liver region, a continuous series of 10 frames of transducer signals was captured. Then, in the tissue-imitating reference phantom, which mimics the acoustic properties of human hepatic tissue, consecutive frames were noted without changing scanner settings[35,88-90].

The diagnostic accuracy of the BSC has been evaluated by Lin *et al*[91] by analyzing 204 participants. They found that BSC was positively correlated with MRI-PDFF (Spearman's $\rho = 0.80$; $P < 0.0001$). BSC had an AUROC of 0.98 with a cutoff value of 0.00381/cm-steradian for detecting patients with hepatic steatosis. In addition, when using the optimal BSC cutoff value, in the training group, hepatic steatosis was detected with 93% sensitivity and 97% specificity, while in the validation group, it was detected with 87% sensitivity and 91% specificity[91].

Han *et al*[89,90,92,93] published several studies focusing on the use of the BSC. In a study including 102 participants, they revealed moderate correlation of the BSC with MRI-PDFF (Pearson's $r = 0.58$, $P < 0.001$)[93]. In addition, they enrolled 41 participants to study the repeatability and reproducibility of BSC and found that ICC were 0.87-0.95 for BSC acquired without participant repositioning and 0.69-0.82 with participant repositioning, suggesting that BSC measurement is repeatable and reproducible in patients with NAFLD[89].

Ultrasound-derived fat fraction

The ultrasound-derived fat fraction (UDFF) technique is a coalition of attenuation coefficient and BSC, and a percentage of liver fat content is reported as the result. Data from reference phantoms is integrated into the ultrasound system, and a fixed-acquisition region of interest is utilized[4] (Figure 5). Labyed and Milkowski[37] designed the UDFF method and conducted a study including 101 participants. They found that the UDFF was positively correlated with the MRI-PDFF (Pearson's $r = 0.87$). Using the histology results as the gold standard, the AUROCs of UDFF were 0.94 for detecting S ≥ 1, 0.88 for S ≥ 2 and 0.83 for S = 3. When using MRI-PDFF to be the gold standard, AUROCs of UDFF were 0.97 for diagnosing MRI-PDFF higher than 5%, 0.95 for diagnosing MRI-PDFF higher than 10% [37]. Similarly, Dillman *et al*[94] reported that liver fat content quantification applying UDFF showed a significant correlation with MRI-PDFF (Spearman's $\rho = 0.82$; $P < 0.001$).

ASQ: Quantifying the acoustic structure of an environment by comparing theoretical and real echo amplitude distributions is referred to as ASQ. In order to compute the theoretical echo amplitude distribution of the hepatic section imaged, the Rayleigh distribution function, assuming that solely ultrasound beam interference from small scattering objects generates the speckle pattern, is applied. However, actual echo amplitude distribution of the liver parenchyma does not follow the Rayleigh distribution. Because ultrasound beams are scattered by small structures, for example the walls of hepatic vessels, resulting in heterogeneity in echo amplitudes[95,96]. However, when diffuse liver diseases cause changes in parenchymal echotexture, ASQ can provide quantitative information by comparing theoretical echo amplitude distribution to a real distribution[97]. Kuroda *et al*[98] tested the ASQ-derived focal disturbance ratio (FD ratio) with 9 Leptin-deficient mice in comparison with histopathological results and found that the FD ratio had significant negative correlations with the fat droplet area (Spearman $r = -0.72$, $P = 0.0017$) and fat droplet size (Spearman $r = -0.98$, $P = 0.0052$), suggesting that the FD ratio can be used to quantify steatosis grade in an animal model and may be a quantitative metric of hepatic steatosis[98]. Karlas *et al*[95] conducted a cohort study to compare ASQ with MRS, and negative correlation was found between FD ratio and MRS (Spearman $r = -0.43$, $P = 0.004$). Similarly, in a prospective study including 36 patients with suspected fatty liver disease, the FD ratio showed a strong, negative correlation with the MRS in 36 patients[99]. Son *et al*[100] also reported FD ratio is comparable to hepatic fat fraction by MRS to make quantified measurement of liver fat content and diagnose liver fat content more than 10% in donor liver patients. Keller *et al*[96] found significant negative correlation between ASQ and steatosis level obtained by histological examination ($r = -0.55$, $P < 0.0001$). Nevertheless, they found no correlation between histologically determined fibrosis stage and any measurements of ASQ.

NLV: The NLV is derived from ASQ and analyzes ultrasound amplitudes sampled from grayscale ultrasound images[4,101]. Bae *et al*[102] assessed the clinical value of the NLV in the measurement of liver fat content in comparison with MRS in 40 male mice using histopathology as the golden standard and found that the AUROCs for diagnosing mild, moderate, and severe hepatic steatosis were 0.953, 0.896, and 0.735, and the NLV value performed similarly to MRS in detecting mild or moderate hepatic steatosis. The same authors also conducted a study with 194 patients to assess the diagnostic efficacy of the NLV for diagnosing and grading liver fat content using liver histopathology as the reference standard. They demonstrated the NLV had excellent diagnostic efficacy in detecting and grading fatty liver with AUROCs of 0.911 for ≥ steatosis grade 1, 0.974 for ≥ steatosis grade 2, and 0.954 ≥ steatosis grade 3[103].

Speed of sound: A speed of sound (SS) estimation is based on the fact that sound speed varies with fat content in soft tissues, and that the relationship between sound speed and liver fat percentage can be

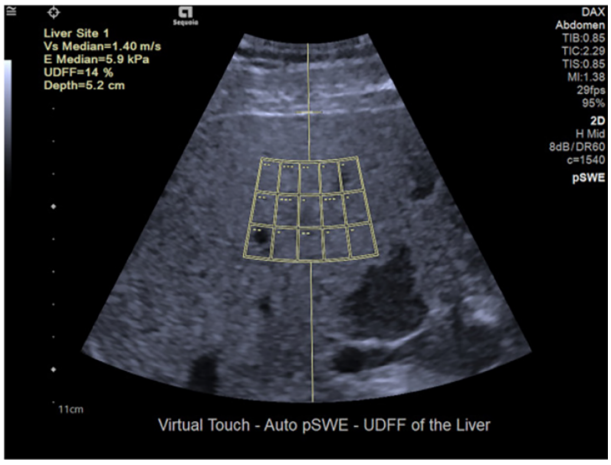

Figure 5 Ultrasound-derived fat fraction method[40]. The ultrasound-derived fat fraction method approximates the magnetic resonance imaging-derived proton density fat fraction and is based on the combination of the attenuation and backscatter coefficient. The method provides both liver stiffness measurement (5.9 kPa in this case) and the percentage of fat accumulation (14% in this case). Citation: Seneviratne N, Fang C, Sidhu PS. Ultrasound-based hepatic fat quantification: current status and future directions. *Clin Radiol* 2023; 78: 187-200. Copyright© The Author(s) 2023. Published by Elsevier Ltd. The authors have obtained the permission for figure using (Supplementary material).

identified[104]. Dioguardi Burgio *et al*[104] carried out a study aiming to explore the value of SS for detecting and quantifying liver steatosis and included 100 patients who underwent both SS and abdominal MR. They found that, in the training cohort, a cut-off value of less than 1.537mm/s led to 87% sensitivity and 95.7% specificity for diagnosing any steatosis with an AUROC of 0.882%. Based on an SS cut-off value of 1.511mm/s, the sensitivity was 100% and specificity was 95.6% for detecting moderate to severe steatosis and the AUROC was 0.989[104].

Sound speed plane-wave ultrasound (SSp.PLUS) is a novel technique for measuring intrahepatic sound speed which is correlated with the liver fat content. The measurement of SSp.PLUS is expressed in m/s[82]. Popa *et al*[82] performed a study with 215 patients to test the value of SSp.PLUS in detecting and grading hepatic fat level applying the CAP value as the gold standard. As a first finding, SSp.PLUS is more closely correlated with CAP values than Att.PLUS: (r = -0.74) *vs* (r = 0.45). Furthermore, the SSp.PLUS cut-off of less than 1516 m/s indicated 98.36% specificity and 58.74% sensitivity for predicting the presence of significant steatosis (S2-S3)[82].

CONCLUSION

Quantification ultrasound techniques can provide objective continuous number associated with liver fat content and past records can be found when patients receiving check-ups to evaluate change of degree of fatty liver, which is useful for follow-up to monitor the impact of any clinical interventions. Besides, as hepatic steatosis may pose adverse effects to prognosis of patients, quantification of liver fat holds clinical significance. For example, substantial hepatic fat accumulation may contribute to rapid disease progression toward NASH or liver fibrosis[105]. Patients with liver resections are more likely to suffer postoperative complications and die due to liver fat accumulation. Compared with patients without steatosis, those with ≤ 30% steatosis have a significantly increased risk of postoperative complications and patients with > 30% steatosis have an increased risk of postoperative death[9,106,107]. It is worth to be mentioned that simple steatosis may lead to poor prognosis. A study carried out in a nationwide Swedish cohort from 1966 to 2017 including 10568 patients found that simple steatosis, non-fibrotic NASH, non-cirrhotic fibrosis, and cirrhosis were associated with significant higher hazard ratio for mortality risk compared with controls. The all-cause mortalities of cohorts with simple steatosis, non-fibrotic NASH, non-cirrhotic fibrosis, and cirrhosis were 2.52% person-years, 3.03% person-years, 3.53% person-years, and 7.05% person-years respectively whereas the mortality of population comparators was 1.69% person-years[108]. Association between imaging quantification method and clinical prognosis is another issue. In patients with chronic hepatitis C, CAP value ≤ 221 dB/m is associated with higher risk of HCC and in patients with NAFLD, CAP value ≤ 265 dB/m is associated with higher risk of HCC[109]. Similarly, in another cross-sectional study including 130 patients (HCC) and 54 patients (chronic hepatitis C), the authors reported that CAP value of chronic hepatitis C group was significantly higher than that of HCC group (259.96 dB/m *vs* 209.57 dB/m, P < 0.001)[110].

While serving as the conventional reference standard, liver histopathologic test has the limitations of invasiveness, sampling error, and high cost. Issues including availability, cost, accuracy and reliability should be taken into consideration when choosing the optimal noninvasive methods. The further

application of noninvasive methods is desirable for detecting and grading hepatic steatosis at the initial diagnosis and monitoring changes in liver fat content during follow-up after receiving clinical therapies.

MRS and MRI-PDFF are reported to be the most accurate imaging modalities for quantified measurement of liver fat content. However, their low accessibility and high cost make it impossible to use MR-based techniques as repeatable methods to monitor the process of liver steatosis. Therefore, ultrasound-based techniques are more desirable with the advantages of portability and cost-effectiveness. CAP is the first method based on attenuation of the ultrasound beam, and its performance has been validated in several studies. However, the limitations of CAP are nonnegligible in that due to its blindness, it has a high rate of measurement failures because it cannot determine the exact location of the region of interest. UGAP, ATT and ATI have been developed to improve this situation, and these metrics can be used to evaluate degree of fatty liver on gray scale ultrasonography in real-time with a correct region of interest. The CAP measurement also showed suboptimal performance in quantifying liver fat content especially in mild steatosis, which limited its use as a golden standard to evaluate the efficacy of novel imaging methods for liver fat content quantification. In addition, techniques derived from other principles, such as ASQ, TSI and UDFF, have been developed. These techniques are reported to have nice clinical efficacy for liver fat quantification. Nevertheless, studies exploring value of such techniques enrolled a small number of participants. Therefore, future studies enrolling more participants are needed to test the utility of such techniques. Besides, imaging-based techniques may have some limitations. For example, CAP, ATI and MRI-PDFF may be unable to differentiate grade 2 with grade 3 liver steatosis.

Several hepatic steatosis quantification tools are launched by commercial platforms. Larger clinical studies are needed to compare the efficacy among different products. For patients with NAFLD, except for steatosis, inflammation and fibrosis are also significant features which are associated with prognosis. The steatosis measurement is able to be obtained together with the stiffness value by some tools. In this way, comprehensive evaluation of patients with NAFLD can be made. Except for elastography tools, ASQ has also been studied to evaluate liver stiffness. Hepatic steatosis measurement and stiffness measurement, in conjunction with other ultrasound methods, are promising tools for patients with diffuse liver disease to supervise curative effect and disease progression. Developing such a multiparametric ultrasound modality will require future studies.

Abstract

Alcohol-related hepatitis (ARH) is a unique type of alcohol-associated liver disease characterized by acute liver inflammation caused by significant alcohol use. It ranges in severity from mild to severe and carries significant morbidity and mortality. The refinement of scoring systems has enhanced prognostication and guidance of clinical decision-making in the treatment of this complex disease. Although treatment focuses on supportive care, steroids have shown benefit in select circumstances. There has been a recent interest in this disease process, as coronavirus disease 2019 pandemic led to substantial rise in cases. Although much is known regarding the pathogenesis, prognosis remains grim due to limited treatment options. This article summarizes the epidemiology, genetics, pathogenesis, diagnosis and treatment of ARH.

Key Words: Alcohol; Hepatitis; Epidemiology; Prevalence; Treatment; Clinical trials

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The aim of this article is to review alcohol-related hepatitis (ARH). Despite the increased understanding of the pathogenesis of this disease process, treatment options remain limited. Our review article focuses on epidemiology, genetics, pathogenesis, diagnosis and treatment. We also discuss complications of ARH along with their optimal management and ongoing clinical trials. Further research evaluating therapeutic targets for its management are warranted.

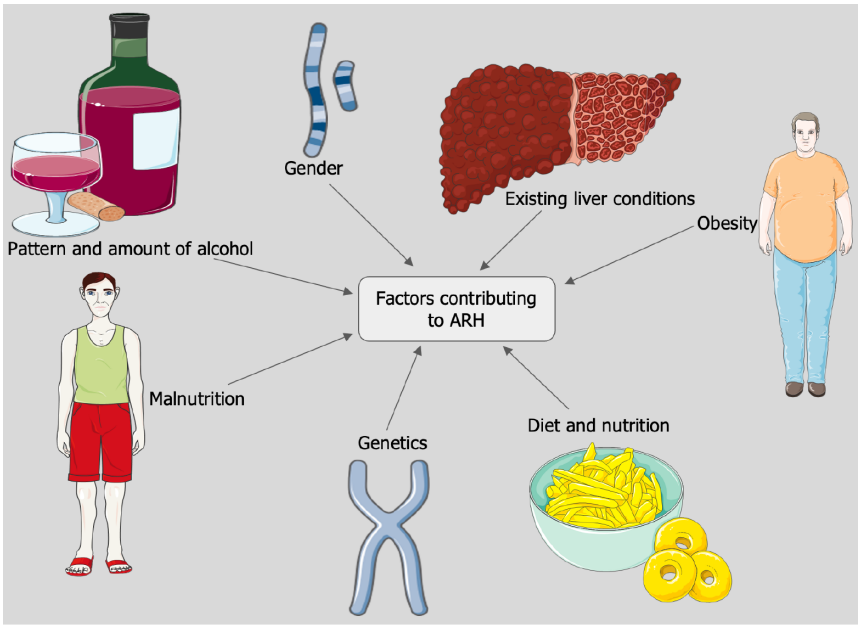
INTRODUCTION

The burden of alcohol-associated liver disease continues to grow with rising cases during and even after the coronavirus disease 2019 (COVID-19) pandemic[1-2]. Some experts believe that the rise in cases during the COVID-19 pandemic will have long lasting effects on society and healthcare. Alcohol is an integral part of American culture and its widespread use cuts across socioeconomic and racial lines. Alcohol-related liver disease (ALD) can range from hepatic steatosis to end-stage liver disease. Alcohol-related hepatitis (ARH), a form of ALD, is an acute inflammatory syndrome of jaundice and liver injury occurring in patients with significant alcohol use. The severity can range from subclinical to acute severe illness, which is associated with high mortality. The recent trends in ARH hospitalizations in the United States suggest its importance in the current realm of clinical practice[1-4].

The prevalence of ARH has been on a rise even prior to COVID-19 pandemic[4]. Studies have shown a 53% increase in ARH from 2019 to 2020 with a 64% increase in the latter phase of the pandemic[2]. Multiple other studies have shown that the societal disruptions associated with the pandemic have further intensified the rise in cases of ARH. ARH can resolve with abstinence and supportive therapy; however, these measures do not guarantee recovery in all patients. Acute-on-chronic liver failure (ACLF) and development of cirrhosis are the most feared complications of ARH and is associated with significant morbidity and mortality. Thus, identifying patients early during the course of the disease is critical.

PREVALENCE

The true prevalence of ARH is difficult to assess as patients can be asymptomatic and remain undiagnosed. A study by Jinjuvadia *et al*[5] evaluating the temporal trends in ARH hospitalizations reported an increase in patients with ARH from 249884 in 2002 to 326403 in 2010. Their study included hospitalizations with a primary and secondary diagnosis of ARH. To estimate true prevalence, Ali *et al* [4] included patients only with a primary diagnosis of ARH and reported an increase in the total hospitalizations from 67070 in 2009 to 125540 in 2019. They also reported an increase in inpatient mortality from 2.48% in 2009 to 3.78% in 2019. The increase in the cases of ARH has been further intensified during the COVID-19 pandemic, especially in younger patients and in women.



ARH is also associated with a significant risk of mortality. Mortality has been estimated to be around 15% at 30 d and 39% at 1 year and has been linked to the severity of the disease[5]. Patients with mild liver injury have a 20% mortality, while patients with severe liver injury have an overall 40% mortality [6]. Mortality in patients with higher Maddrey's discriminant function (MDF) score (> 30), a surrogate marker of severity, is estimated to be between 30%-50%[7-8].

In previous years, there has also been an increase in the healthcare burden of ARH hospitalizations. An increase was noted in the mean inpatient cost for ARH hospitalizations from $31189 in 2009 to $62229 in 2019[4]. A study by Thompson *et al*[9], using commercial insurance claims, examined hospitalized patients between 2006-2013 and reported the average cost per patient is $145000 in their cohort of 15546 patients. They also reported the cost surrounding death of ARH was 200%-300% higher than the average cost surrounding death.

EPIDEMIOLOGY

Alcohol intake: The amount of alcohol consumption that places patients at risk of ARH is largely unknown. The estimates of the amount of alcohol consumed by patients may not be accurate as they are based on interviewing patients and family members[9]. The majority of patients with ARH consume more than 100 g/d of alcohol[10]. American Association for the Study of Liver Disease (AASLD) practice guidelines recommend suspecting ARH in women who consume > 40 g of alcohol and in men who consume > 60 g/d for ≥ 6 mo[11-12]. It is also pertinent to note that not all patients who drink heavily develop ALD. In a study by Friedman *et al*[13], 35% of the patients developed steatohepatitis and ARH, while only 10% of the patient's developed cirrhosis.

The pattern of drinking as well as the type of alcohol consumed also contributes to the risk of developing ARH. Drinking spirits or beer, binge drinking as well as drinking outside of the typical mealtimes has been associated with a higher risk of developing ALD[13-15] (Figure 1).

DOI: 10.3748/wjg.v29.i17.2551 **Copyright** ©The Author(s) 2023.

Figure 1 Risk factors of alcohol-related hepatitis. ARH: Alcohol-related hepatitis.

Gender: There are significant differences based on gender. Women are at a higher risk of developing ARH at a lower threshold compared to men. This is attributed to differences in the variability of alcohol dehydrogenase activity, sex hormones, body fat distribution and liver volume between the two genders [16-18]. There has been an increase in the cases of ARH in women in recent years. A study conducted between 2009-2019 showed an increase in the proportion of women being admitted with ARH from 29.1% to 34.1%[4].

Malnutrition: Patients who consume alcohol excessively are often malnourished and can suffer from vitamin deficiencies[19]. Mortality has been closely related to the severity of protein-energy malnutrition. Patients with severe malnutrition and ARH have an estimated mortality of 80%[20]. Additionally, depletion of hepatic vitamin A and vitamin E can aggravate liver disease[21]. Zinc deficiency in patients with excessive alcohol can lead to disruption of mucosal permeability which may play a role in the pathogenesis of ARH.

Concurrent liver disease: It is well established that the combination of alcohol misuse and chronic hepatitis C (HCV) increases the incidence of cirrhosis and hepatocellular carcinoma (HCC) and is associated with reduced survival compared to patients with either HCV or alcohol use alone[22]. Consuming upward of 50 g/d of alcohol increases the relative risk of liver disease compared to patients with HCV who do not consume alcohol[23]. Patients with chronic HCV have been noted to have worse outcomes and higher in-hospital mortality when admitted with ARH[24].

While the literature clearly demonstrated worse outcomes in patients with concomitant alcohol misuse and chronic HCV, the data regarding the effect of alcohol use on patients with chronic hepatitis B (HBV) remains understudied. A study by Iida-Ueno *et al*[25] revealed that patients with light to moderate alcohol consumption had a 1.5-fold increase of chronic HBV infection while patients with heavy alcohol consumption had significantly accelerated progression to cirrhosis and HCC with 1.3 to 8.4-fold increased risk. Although the mechanism by which alcohol enhances disease progression is less studied in patients with chronic HBV in comparison to patients with HCV, patients with either chronic HCV and HBV should be counseled to avoid alcohol consumption to minimize chances of liver disease progression.

Obesity, diabetes mellitus and metabolic syndrome-underlying non-alcoholic fatty liver disease, a hepatic manifestation of metabolic syndrome, can be additive to the damage sustained through alcohol misuse and lead to worse outcomes. A study by Siddiqui *et al*[26] reported obesity to be an independent predictor of mortality in ARH.

Seasonality: Studies have shown that there might be a seasonal trend to admissions with alcohol use. We have previously reported that in the United States, ARH was highest in the summer months, as compared to the common opinion that ARH hospitalizations are higher in the winter season[27].

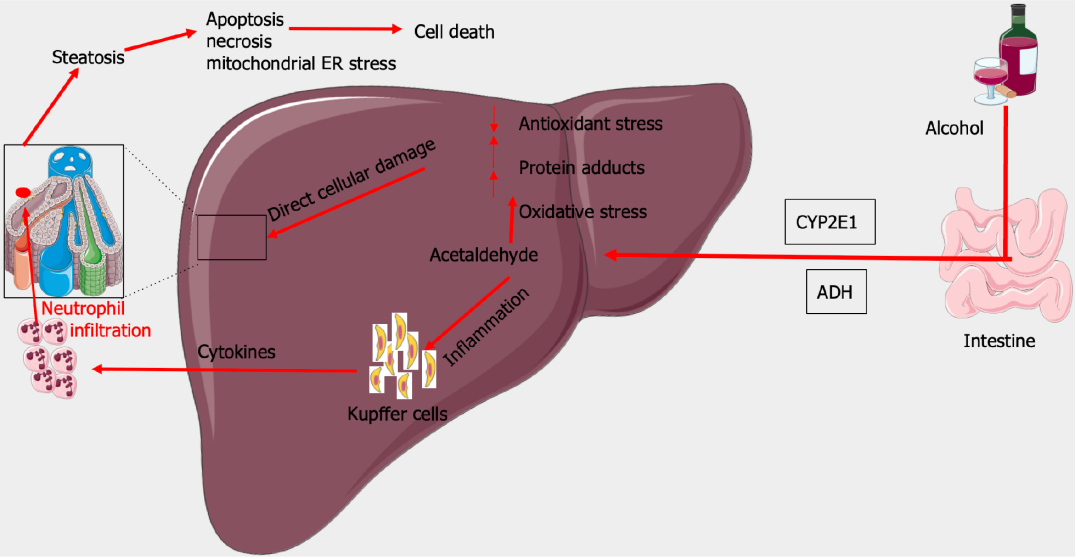
GENETICS

Significant variability has been noted among patients in regard to the susceptibility of developing ARH as well as the severity of symptoms. This variability has prompted several studies exploring a possible genetic basis for individual response to ARH. Studies have found an alteration in the expression of claudins, osteopontin, CD209, selenoprotein, and bile duct proliferation genes in patients with ARH compared to patients with alcoholic steatosis and healthy controls without liver disease[28]. Colmenero *et al*[29] identified several genes that were upregulated in ARH including extracellular matrix proteins, fibrogenesis mediators, inflammatory cytokines, and apoptosis regulators. Cytochrome p450 2E1 and angiotensinogen were found to be downregulated. Additionally, certain genes were found to be correlated with the severity of disease features including tissue inhibitors of metalloproteinases-1 and growth-related oncogene α. Epigenetic studies have also shown that a liver affected by ARH has significant alterations in HNF4α-dependent genes, which play a role in impairing metabolic and synthetic function[30]. A cohort study by Beaudoin *et al*[31] demonstrated an increased risk for developing ARH with a higher total bilirubin in patients with variants in the patatin-like phospholipase domain-containing protein 3 (*PNPLA3*) and the haptoglobin genes as compared to other genetic variants associated with chronic liver disease states[32].

The *PNPLA3* gene in particular has been identified to play a significant role in the pathogenesis of several liver diseases, as it belongs to a group of lipid-metabolizing enzymes. The I148M variant, a single-nucleotide polymorphism of the gene, is associated with an increased risk for developing hepatic steatosis, non-alcoholic steatohepatitis (NASH), ALD, cirrhosis, and HCC[33]. Despite these correlations, the precise function of the *PNPLA3* gene is yet to be fully understood. Palmer *et al*[33] demonstrated that variants in the *PNPLA3* gene in Hispanic-American and African-American patients is significantly associated with the development of hepatic steatosis, and other studies have shown that these groups suffer from higher mortality rates due to ALD. Levy *et al*[34] reported that patients of Hispanic ancestry presented with ALD at a significantly earlier age than patients of Caucasian or African-American background, though the mechanisms remain unclear and may be related to the gene variants described by Palmer *et al*[33] as well as health care disparities. Future studies can help to elucidate the underlying mechanisms of these discrepancies and the potential of gene-targeted therapy in the management of ARH.

PATHOGENESIS

The pathogenesis of ARH involves acute inflammation superimposed on chronic ALD. Initial hepatic injury results from the metabolism of ethanol into acetaldehyde by alcohol dehydrogenase and cytochrome P450 2E1 (CYP2E1). As ethanol builds up as a result of increased consumption, acetaldehyde also accumulates in the liver and begins to exert toxic effects[35]. Acetaldehyde leads to the formation of adducts, in the form of bonds with proteins, lipids, and DNA. This in turn impairs the normal function of the affected proteins and lipids and leads to DNA damage. CYP2E1 further contributes to liver injury by the production of reactive oxygen species which leads to hepatocyte injury [36]. This is thought to occur as a result of lipid peroxidation and interaction with proteins and nucleic acids, leading to hepatocyte necrosis[37] (Figure 2).



The oxidation of ethanol and acetaldehyde leads to an increase in the levels of nicotinamide adenine dinucleotide, which enhances lipogenesis in the liver[38]. Fatty infiltration of the liver is also a result of increased gut permeability due to alcohol ingestion, leading to higher levels of lipopolysaccharides present in the portal circulation[39]. Endotoxin, a lipopolysaccharide present in cell walls of gut microbiota, forms a protein complex and binds to the CD14 receptor on Kupffer cells in the liver[40]. The activation of Kupffer cells leads to the release of tumor necrosis factor-α (TNF-α), a pro-inflammatory cytokine[41]. TNF-α exerts its hepatotoxic effects by causing hepatocyte apoptosis and stimulating the release of other cytokines[42]. Higher levels of TNF-α are correlated with increased severity of ARH, demonstrating the significance of the cytokine in the pathogenesis of ARH[43].

The stimulation of Kupffer cells also lead to an increase in polymorphonuclear leukocyte infiltrate in the liver, as a result of chemotactic factors such as interleukin-8[44]. The multifactorial process of inflammation superimposed on alcohol-induced hepatic damage leads to the impairment of liver function observed as systemic illness and laboratory abnormalities in ARH. A thorough understanding of the pathogenesis of ARH can aid in its treatment, and further studies elucidating the precise mechanisms involved may improve treatment modalities and outcomes.

DIAGNOSIS

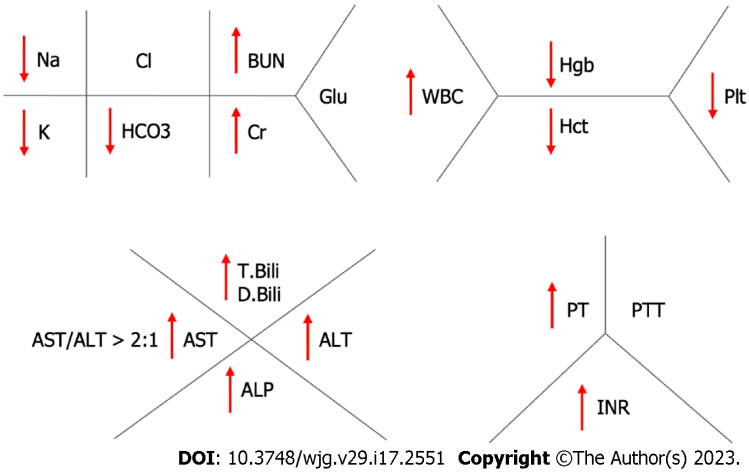
Physical Examination

Physical examination can range from benign to profoundly abnormal[45]. Patients may have signs of

DOI: 10.3748/wjg.v29.i17.2551 **Copyright** ©The Author(s) 2023.

Figure 2 Pathogenesis of alcohol-related hepatitis. ADH: Alcohol dehydrogenase.

malnutrition/sarcopenia manifested as temporal or thenar muscle wasting. Jaundice and scleral icterus may be apparent in patients with more severe disease while subtle signs of jaundice can be noted sublingually or in the tympanic membranes in patients with less severe disease. The presence of spider angiomas, gynecomastia in men and caput medusa is uncommon in patients with ARH in the absence of cirrhosis. Right upper quadrant tenderness to palpation along the enlarged hepatic border is common, with the liver edge extending into the pelvis and crossing the midline in severe cases. Some studies have reported a bruit over the liver as a feature of severe ARH in > 50% of patients[46]. Splenomegaly can often be appreciated as well even in the absence of cirrhosis. Fluid wave, shifting dullness and frank abdominal distention signifying large-volume ascites can be seen in severe cases. Lower extremity swelling progressing to anasarca can also be seen in severe cases. Finally, asterixis can be seen in patients with significant hepatic dysfunction.



Laboratory findings

Patients with suspected ARH should undergo a broad laboratory workup including comprehensive metabolic panel, complete blood count, international normalized ratio (INR), and gamma glutamyl transferase (GGT). Serologies for HAV, HBV and HCV should also be obtained to rule out alternative/concomitant infectious causes. Typical laboratory findings in ARH consist of elevated white blood cell count, thrombocytopenia, low sodium, potassium and magnesium. Other findings include total bilirubin > 3 mg/dL, elevated alanine transaminase (ALT) and aspartate transaminase (AST) with levels usually < 400 U/L, AST:ALT ratio > 2, GGT > 100 U/mL, INR > 1.5, and albumin < 3.0 g/L[47]. Other sequelae of chronic alcohol use such as macrocytic anemia can also be seen (Figure 3).

It is pertinent to rule out alternative/concomitant causes of liver disease such as Wilson's disease, autoimmune liver diseases and iron overload syndromes. This is especially important in patients with severe disease who may be considered for liver transplantation, as these diagnoses will have significant implications on patient's ability to qualify for an urgent transplant as well as pre-and post-transplant management. Making these diagnoses can be challenging as patients with ARH may have multiple metabolic derangements. For example, patients with ARH may have decreased ceruloplasmin levels in the setting of hepatic dysfunction leading to suspicion of Wlison's disease. If there is a significant clinical concern for Wilson's disease, patients should undergo a slit lamp examination for Kayser-Fleischer rings as well as a 24-h urine copper collection. Ferritin levels as well as iron saturations in patients with ARH can be markedly elevated in ARH therefore genetic testing for *HFE* gene mutation should be considered[48]. A clinical suspicion of autoimmune liver disease, especially in the setting of elevated autoimmune markers [antinuclear antibody (ANA), anti-smooth muscle antibody (SMA), antimitochondrial antibody, anti-liver kidney microsomal antibody], should prompt consideration of liver biopsy. Alpha-1-antitrypsin levels can be artificially elevated in the setting of acute illness; genetic testing should be considered if clinical suspicion is sufficiently high.

Imaging

Abdominal imaging can be effective in the initial evaluation of suspected ARH however, it cannot serve as the sole basis for the diagnosis. Abdominal ultrasound (US) computed tomography scan and/or magnetic resonance imaging will likely reveal and enlarged liver with smooth contours and decreased

attenuation, and in more severe cases, an enlarged spleen, ascites and other sequelae of portal hypertension. The presence of smooth hepatic borders, as opposed to the nodular contour, can help to differentiate ARH from cirrhosis[49] (Figure 4).

BIOPSY

The European Association for the Study of the Liver clinical practice guideline in 2014 stated that the "presence of acute steatohepatitis can be suspected on the clinical and biochemical grounds, but a definitive diagnosis of acute steatohepatitis requires liver biopsy"[50]. AASLD practice guidelines in 2019 recommend performing biopsy for confirmation if there are potential confounding factors such as [11]: (1) Ischemic hepatitis (*e.g.* severe upper GI bleed, cocaine use within 7 d or hypotension); (2) Suspected drug-induced liver disease; (3) Uncertain alcohol use assessment; and (4) Atypical laboratory tests (AST < 50 or > 400 IU/L, AST/ALT < 1.5), ANA > 1:160 or SMA > 1:80. Liver biopsy is controversial, especially in patients with coagulopathy and ascites. Percutaneous biopsy may be performed in most patients, but transjugular biopsy is preferred in patients with severe thrombocytopenia and prolonged INR. Liver biopsy is also recommended in patients suspected of having additional etiology for ACLF.

HISTOLOGY

Histology in patients with ALD can range from steatosis to steatofibrosis[51-52]. Steatofibrosis is defined as steatosis with fibrosis, with or without hepatitis. Histological features include steatosis, hepatocyte ballooning, neutrophil-rich inflammation in the lobular parenchyma, necrosis, apoptosis and Mallory-Denk bodies (MDB)[53]. The predominant mode of hepatocyte injury is *via* ballooning degeneration, followed by lytic necrosis and apoptosis. The hepatocytes become swollen, with clumping of intermediate filaments and loss of cytokeratin 8 and 18[51]. The swelling in hepatocytes can be attributed to severe ATP depletion and an increase in intra-cellular calcium, resulting in loss of plasma membrane volume control, oncotic necrosis and disruption of the intermediate filament network. The majority of changes in ALD are seen in the centrilobular region of hepatic lobe as they contain enzymes such as alcohol dehydrogenase, which are critical in alcohol metabolism[54].

It is pertinent to note there are histological similarities between NASH and ARH[53]. The differentiation is based on clinical information regarding alcohol intake; however some features are seen more commonly in ARH as compared to NASH (Table 1).

Apoptosis can be triggered by oxidative stress. Apoptotic hepatocytes, also known as councilman bodies or acidophil bodies, are visualized as shrunken cells, chromatin condensation and cellular fragmentation[55]. MDB contain eosinophilic material, located primarily in the perinuclear location in the cytoplasm of hepatocytes[56]. They are formed due to the misfolding of aggregated keratin filaments. MDB demonstrate immunoreactivity with antibodies to keratin 8, 18 and p62. Portal inflammation is milder as compared to other etiologies of liver disease. Portal inflammation, when present, is accompanied by ductular reaction and periportal inflammation[57]. Other features of this disease

Table 1 Histological differences between non-alcoholic steatohepatitis and alcohol-related hepatitis

Histological features	NASH	ARH

Figure 4 Computerized tomography showing enlarged liver with smooth contour.

include glycogenated nuclei, megamitochondria, cholestasis and hemosiderin deposits[58]. Iron deposition can also occur in patients with ALD[59-60]. Based on the index of suspicion, concomitant hereditary hemochromatosis should be ruled out.

As the disease progresses, fibrosis begins in perivenular region (Zone 3) and extends to the perisinusoidal region in patients giving classic "chicken-wire fibrosis". Trichrome stain visualizes the fibrosis. If the injury continues, fibrosis progresses resulting in nodule formation and finally cirrhosis. An orcein stain, can be beneficial in later stages to differentiate broad bands of fibrosis from areas of collapse, which can occur in superimposed ARH[54].

A histological severity score including cytokeratin 8 and 18, has shown good accuracy in predicting 90-d survival[61]. Alcoholic hepatitis histologic score was created using parameters such as degree of fibrosis, degree of neutrophil inflammation, type of bilirubin stasis, and presence of mitochondria[62]. This score has been shown to be predictive of 90-d mortality. Trépo *et al*[63] combined the expression patterns of 123 genes with the model for end-stage liver disease (MELD) score to create gene-signature

plus MELD scoring system. This helped in discriminating patients with poor and good 90-d survival with an area under the curve of 0.86. This score outperformed other models including MELD plus Lille. This is not yet commercially available for use, however, may hold promise for the future.

COMPLICATIONS

Complications of ARH include infection, kidney injury, gastrointestinal bleeding, and acute liver failure amongst others (Figure 5).

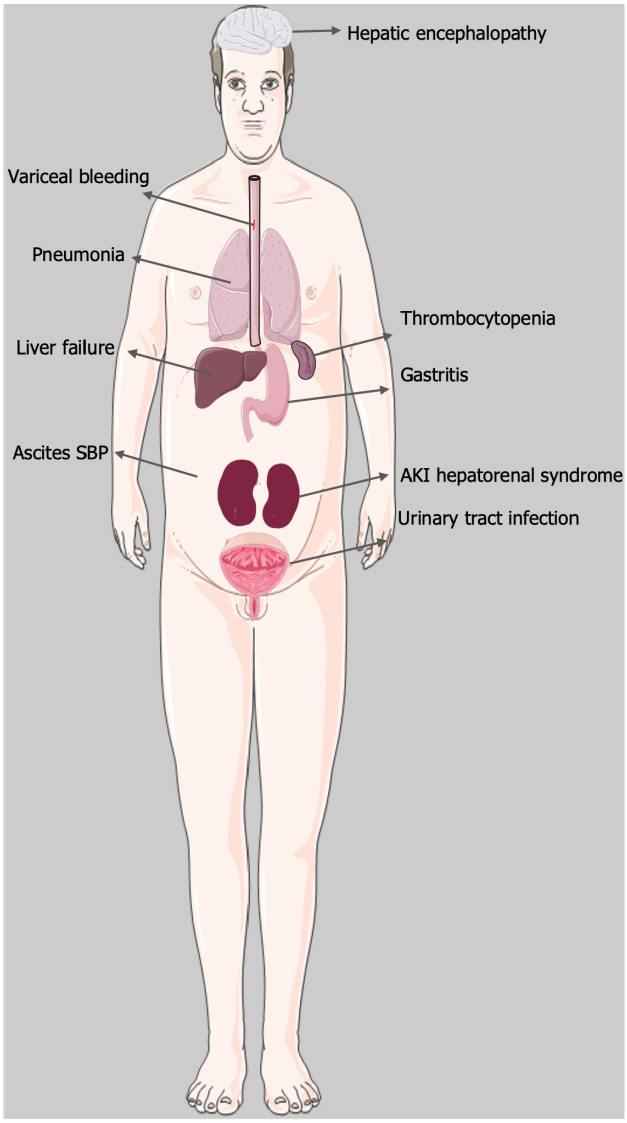
Infection

Patients with ascites are at risk for developing spontaneous bacterial peritonitis (SBP), a life-threatening infection of the peritoneal cavity. SBP is almost exclusively seen in patients with ascites and is a result of bacterial translocation of enteric microflora into the ascitic fluid with concurrent failure of liver-related defensive mechanisms due to cirrhosis[64]. Additionally, patients with ARH are often treated with corticosteroids, further suppressing the immune response and increasing the risk of serious infection. Treatment of SBP is usually with a third-generation cephalosporin, such as ceftriaxone, which can also be used prophylactically in patients with decompensated cirrhosis or known patient with cirrhosis who presents with gastrointestinal bleeding.

Despite the well-known association of SBP with ALD, several studies demonstrate that infection due to pneumonia and urinary tract infection (UTI) is more common in severe ARH than SBP[65]. Infection overall is a major cause of mortality in severe ARH, with the majority being bacterial in nature[66-67]. A recent meta-analysis[68] found pneumonia to be the most common infection in severe ARH at 23%, followed by UTI at 10%. In comparison, SBP accounted for only 7% of infections. Patients with acute severe ARH have also been shown to have a greater level of immunosuppression compared to patients with cirrhosis, as they were found to have reduced T-lymphocyte and neutrophil activity[69]. Furthermore, obesity has been associated with increased susceptibility to infection in patients with ARH [70]. A high index of suspicion is needed in monitoring infectious signs and symptoms in patients with ARH as these patients often lack typical signs of infection such as fever or abdominal pain and may present instead with progressive hepatic decompensation. A low threshold for initiation of antibiotic therapy is advised and can be initiated empirically while infectious work-up is in progress.

Acute kidney injury

Acute kidney injury (AKI) is a common complication in hospitalized patients with ARH and can be due to pre-renal, intrinsic renal and post-renal causes. Pre-renal AKI continues to be the most common etiology, while the most feared etiology is hepatorenal syndrome (HRS). These entities can be differentiated *via* volume expansion challenge (25% albumin 1 g/kg for 48 h). Renal US can be used to rule out post-renal causes. Diuretics should be discontinued in patients with AKI.



Another etiology that should be considered in patients with ARH is acute tubular necrosis (ATN) secondary to cholemic nephrosis, or bile salt nephropathy and should be suspected in patients with prolonged severe cholestasis. Hyperbilirubinemia can also lead to formation of tubular casts, which can lead to ATN[71]. Evaluation of fractional excretion of sodium/urea as well as urine microscopy is beneficial to identify the etiology of kidney disease. Workup for AKI in patients with ARH is presented in Figure 6.

The most feared complication, HRS, results from renal artery vasoconstriction secondary to splanchnic vasodilation seen in liver disease[72]. Patients with ARH and other ALD often develop dilation of the splanchnic vasculature in response to increased hepatic resistance, which in turn leads to activation of the renin-angiotensin-aldosterone system, sympathetic nervous system, and arginine vasopressin system. The activation of these vasoconstrictor systems leads to constriction of the renal arteries and subsequent AKI due to decreased renal blood flow often in the setting of decreased cardiac output[73]. The development of AKI in patients with ARH is associated with a significantly higher mortality rate compared to patients without AKI, 65% *vs* 7% ($P < 0.0001$) respectively[74].

Treatment of HRS is complex, with most studies supporting the use of vasoconstrictors in combination with albumin administration. Terlipressin, a vasopressin analogue, has shown promising results in the treatment of HRS as it was found to be superior to both placebo and octreotide[75]. It has recently been approved in the United States by the Food and Drug Administration for the management of HRS. Liver transplantation (LT) is the treatment of choice in patients with HRS as renal dysfunction is potentially reversible with the correction of hepatic failure[76]. Interestingly, obesity has been found to be associated with decreased survival in acute ARH, and this is thought to be due to an increased risk of developing renal failure[77].

Acute on chronic liver failure

Severe ARH can lead to ACLF, a condition that is associated with increased mortality in patients with ARH and is commonly seen during the course of the disease[78]. ACLF manifests as worsening jaundice and coagulopathy and is usually triggered by a precipitating event. Current literature shows that ARH

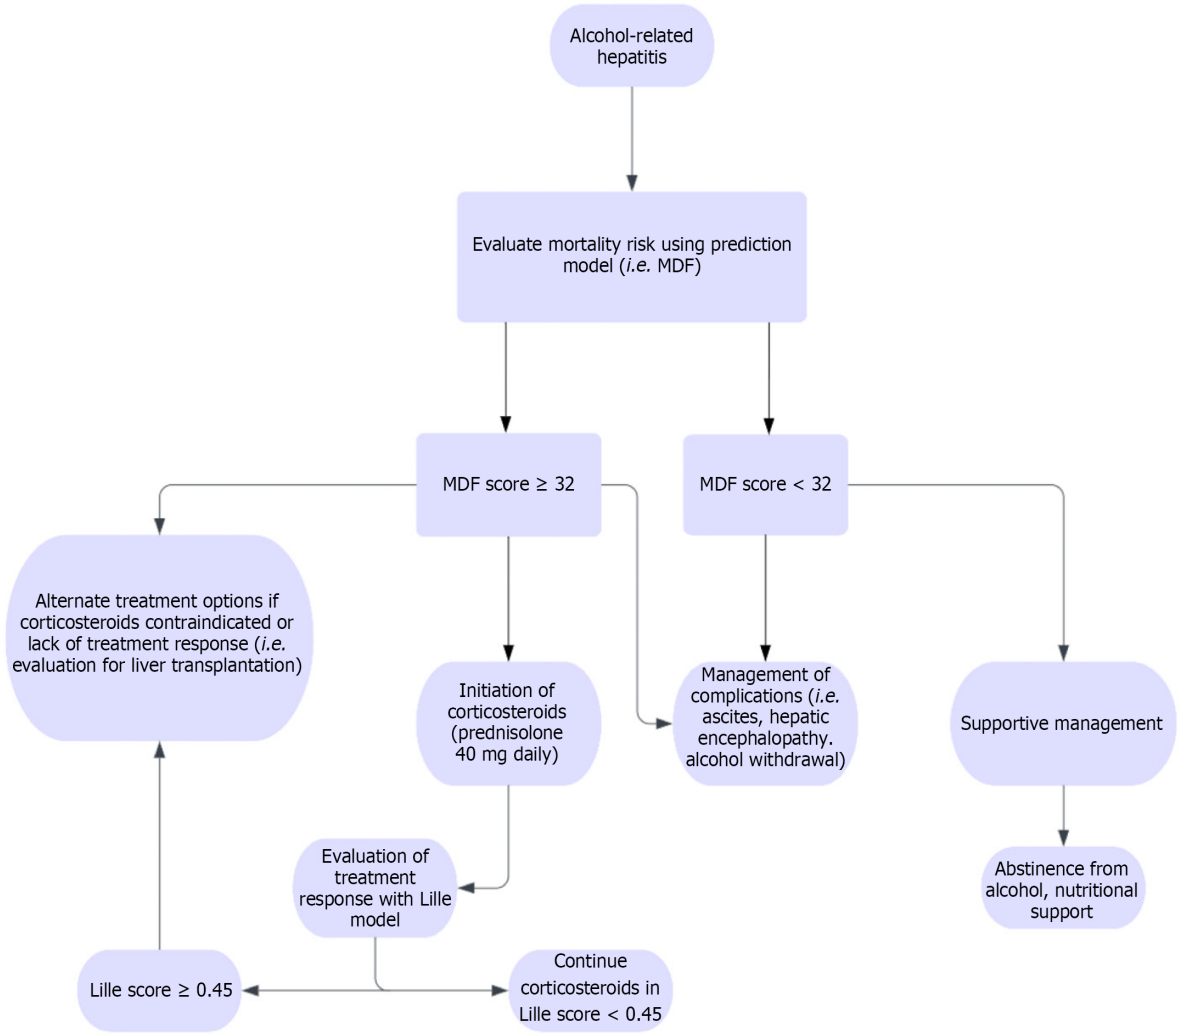

Figure 5 Complications and clinical features in patients with alcohol-related hepatitis. SBP: Spontaneous bacterial peritonitis; AKI: Acute kidney injury.

serves as a common precipitating event for the development of ACLF[76]. Studies have demonstrated that 65% of patients with severe ARH had ACLF at the time of diagnosis or within a 6-mo follow-up period[77]. Given the poor prognosis of ACLF, early liver transplantation is becoming more commonplace in the treatment of severe ARH, with recent literature supporting its use with stringent patient selection criteria[79-80].

Portal hypertension and cirrhosis

Many patients with ARH also have portal hypertension or will develop portal hypertension at some point during their disease course potentially leading to variceal hemorrhage. Overall one-month mortality in moderate to severe ARH is 23%, with the most common causes of death being liver failure, gastrointestinal bleeding, and infection[81] The one-month mortality in non-severe ARH is 6%, however the rate increases to 13% after one year[82].

Long-term follow-up in patients with ARH over 4 years revealed the probability of developing cirrhosis to be 10%-20% per year and up to 70% of patients will ultimately develop cirrhosis[83]. In another study, about 40% of the patients were diagnosed with cirrhosis on biopsy, 5 years after the episode of ARH[84]. The probability of developing cirrhosis is associated with continued alcohol use, as Rehm *et al*[85] demonstrated in a meta-analysis that there is a close dose-dependent relationship between ongoing alcohol use and the risk of progression of ALD to liver cirrhosis. Parés *et al*[86] found an 18% risk of progression to cirrhosis in patients who abstained from alcohol after 20 mo compared to 23% in patients with continued alcohol consumption.

PREDICTION MODELS

MDF is a commonly used prognostic indicator in the management of ARH as it is specific for ARH and has shown to be relatively accurate in predicting short-term outcomes[87]. The MDF score incorporates two of the major indices of liver function, prothrombin time (PT) and total bilirubin with the formula 4.6 × (prolongation of PT in seconds) + bilirubin (μmol/L)/17. MDF score of < 32 signifies mild to moderate ARH with 30-d survival estimated at 80%-100%. MDF score ≥ 32 is considered to be severe ARH with a 30-d survival of only 50%, and these patients warrant corticosteroid administration for treatment of their disease[87] (Table 2).

Lille Model is used to evaluate treatment response to corticosteroids and includes age, initial serum albumin, change in total serum bilirubin at day 7 of treatment, renal insufficiency, and initial MDF score [88]. Patients with a Lille score of < 0.45 had an average 6-mo survival rate of 85%, compared to just 25% in patients who scored ≥ 0.45 after 7 d of treatment (P < 0.0001). The Lille model is primarily used in conjunction with the MDF to guide treatment of ARH. Patients who score ≥ 0.45 after receiving corticosteroid therapy for 7 d are considered for discontinuation of steroids and initiation of alternative treatment modalities, as continuation of steroids is of little benefit in these patients.

MELD was initially created to assess the mortality risk in patients with portal hypertension undergoing transjugular intrahepatic portosystemic shunts procedure however, it has now become a validated tool in assessing patients with a variety of liver pathologies[89]. MELD differs from MDF in that it incorporates serum creatinine and uses INR rather than PT. The formula for MELD is 9.57 × loge (creatinine) + 3.78 × loge (total bilirubin) + 11.2 × loge (INR) + 6.43. In comparison to the MDF, the MELD has been shown to be superior in predicting outcomes of patients with ARH. Several studies have demonstrated this effect, further supporting the use of MELD in patients with ARH[90-94]. Patients with a MELD score ≤ 11 have mild disease associated with a very low mortality rate. Patients who score > 21 are considered to have severe ARH.

Table 2 Prediction models for alcohol-related hepatitis

Score	Variables	Mortality rate
MDF	PT, total bilirubin	50% at 30 d for score ≥ 32
Lille model	Age, albumin, change in total bilirubin, renal insufficiency, MDF score	75% at 6 mo for score ≥ 0.45
Model for end-stage liver disease	Creatinine, total bilirubin, INR	20% at 90 d for score > 21
Glasgow alcoholic hepatitis score	Age, white blood cell count, BUN, total bilirubin, PT	48% at 28 d for score ≥ 9
ABIC score	Age, total bilirubin, creatinine, INR	75% at 90 d for score > 9

PT: Prothrombin time; BUN: Blood urea nitrogen; INR: International normalized ratio; ABIC: Age, serum bilirubin, international normalized ratio, serum creatinine; MDF: Maddrey discriminant function.

Glasgow alcoholic hepatitis score (GAHS) was developed in order to present a model with increased specificity than MDF and a more accurate cutoff score than MELD. The GAHS incorporates many of the same parameters as the MDF and MELD, but differs in its inclusion of the peripheral white blood cell count[95]. The inclusion of an inflammatory component is thought to provide a more accurate predictor of mortality in ARH and has been shown to be superior to MDF in predicting 28-d and 84-d mortality. The cutoff point delineating severe ARH from non-severe is a GAHS score of ≥ 9.

Age, serum bilirubin, INR, serum creatinine (ABIC) score is another scoring system that was developed to predict mortality in patients with ARH[96]. The ABIC score includes liver function as well as kidney function and has a formula of (age × 0.1) + (serum bilirubin × 0.08) + (serum creatinine × 0.3) + (INR × 0.8). This model is validated for predicting 3-mo survival rates in ARH based on stratification of the severity of disease. Patients are classified based on their ABIC score into low (< 6.71), intermediate (6.71-8.99), and high (> 9.0) mortality risk. These classes correspond to a 90-d mortality of 0%, 30%, and 75%, respectively. Despite its efficacy in death risk stratification, the ABIC score does not play a major role in treatment or in determining whether corticosteroid administration is indicated.

TREATMENT

The management of ARH involves reducing hepatic inflammation by targeting pro-inflammatory and immunologic substances acutely and reversing alcohol-induced hepatotoxicity in the long term. The mainstay of treatment in ALD is abstinence from alcohol. A retrospective study by Lackner *et al*[97] demonstrated a 5-year mortality rate of 13% in early ALD and 43% in decompensated ALD. Abstaining from alcohol showed an improvement in survival in patients with both early and decompensated ALD. A meta-analysis by Xie *et al*[98] determined that patients with ALD see an improvement in survival rates after approximately 1.5 years of abstinence. However, studies have also shown that histological improvements in ALD can be observed in patients as soon as 2 wk after discontinuation of alcohol consumption[99].

Many of the traditional pharmacologic agents used to promote abstinence from alcohol such as disulfiram, naltrexone, acamprosate, and topiramate are of limited use in ALD as they may be hepatotoxic and lack data supporting their usage[100]. Baclofen, a selective gamma-aminobutyric acid B receptor agonist, has been studied as a potential agent of choice in patients with ALD as it has minimal hepatic clearance. A recent multi-site randomized control trial[101] of patients with and without ALD demonstrated that low-medium dose baclofen at 30-75 mg daily led to a significant improvement in alcohol abstinence.

Nutritional supplementation is a vital component in the treatment of ALD. Malnutrition is common in patients with ALD, and the severity of malnourishment is correlated with the severity of liver disease [102]. The AASLD recommends a diet of at least 2000 kcal/d with at least 1.5 g protein/kg/d in patients with ALD[103]. These patients suffer from nutritional deficiencies and appropriate nutritional supplementation should be provided as nutritional deficiencies have been shown to be associated with worse outcomes[104].

Treatment of mild to moderate ARH, as defined by an MDF score < 32, consists mainly of supportive care and management of complications such as ascites, hepatic encephalopathy, and acute alcohol withdrawal syndrome[105]. Ascites is managed primarily through sodium restriction and diuresis. Patients with ascites generally have decreased sodium excretion, warranting a daily sodium restriction of 2-4 g/d. AASLD guidelines recommend that for the first episode of ascites, aldosterone antagonists alone can generate an adequate response with few side effects[106]. On the contrary, if the patient has long-standing ascites, anasarca or hepatic hydrothorax, the recommended regimen is a combination of an aldosterone antagonist and loop diuretic.

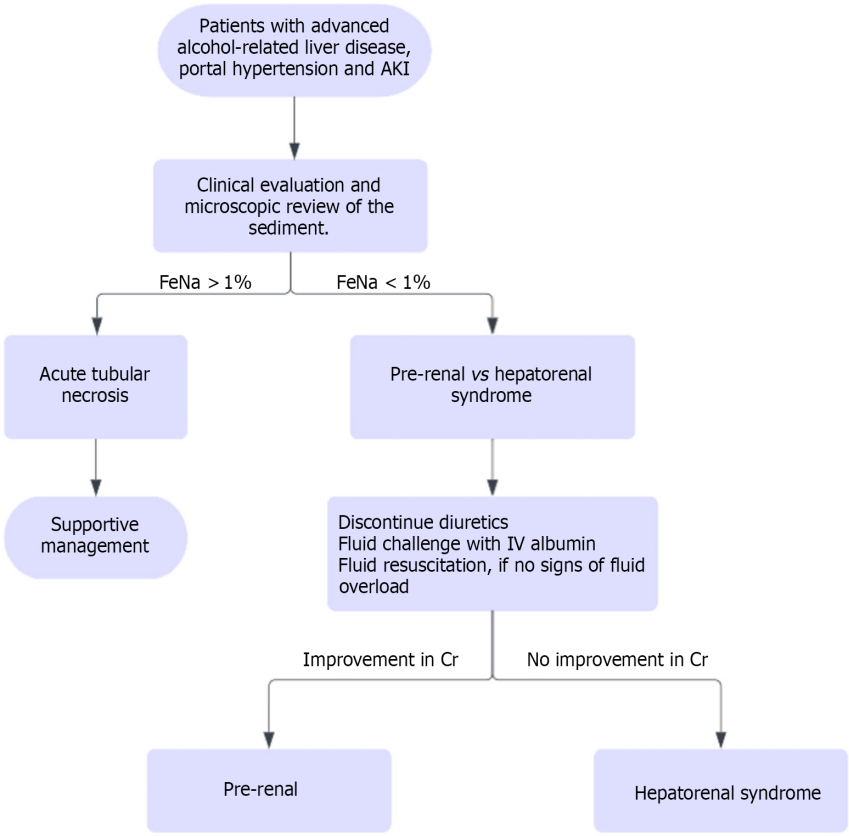
Hepatic encephalopathy is managed primarily with lactulose and rifaximin in order to promote the excretion of toxic metabolites *via* stool and improve the biodiversity of gut flora. Acute alcohol withdrawal is treated with benzodiazepines such as lorazepam on a scheduled regimen or symptom-triggered dose in accordance with protocols such as the Clinical Institute Withdrawal Assessment. Lorazepam has been shown to be the safest agent in its class in patients with liver disease due to minimal hepatotoxicity and is therefore the drug of choice[107]. Use of long-acting benzodiazepines, such as chlordiazepoxide, should be avoided in patients with significant hepatic dysfunction due to decreased rate of hepatic metabolism and potential for rapid accumulation leading to progressive decline in mental status[108].

The most well-studied treatment modality in severe ARH, classified as an MDF score ≥ 32, is the use of corticosteroids. Its use was validated in the "Steroids or pentoxifylline for alcoholic hepatitis" (STOPAH)[109] trial, which included 1053 subjects with ARH. There was a 28-d mortality benefit in patients treated with prednisolone. On the contrary, no mortality benefit was observed in the prednisolone group after 90 d or 1 year, adding further evidence that the positive effects of steroids in severe ARH are limited to short-term (Figure 7).

A meta-analysis of 5 randomized control trials[110] revealed a significant improvement in 28-d survival among patients with severe ARH treated with corticosteroids (79.97% ± 2.8% *vs* 65.7% ± 3.4%, $P = 0.0005$). A more recent meta-analysis[111] of 11 randomized control trials found similar results in short-term mortality benefit, however also demonstrated that corticosteroid treatment did not decrease mortality rate after 6 mo. The primary mechanism by which corticosteroids exert their effect in severe ARH is by blunting the immune response and inflammation that contributes to mortality[112]. The standard regimen for treatment of severe ARH is administration of prednisolone 40 mg daily[113]. Contraindications to steroid administration include active infection, gastrointestinal bleeding, acute pancreatitis, and renal failure, as steroids can acutely exacerbate these conditions[114].

STOPAH109 trial reported that incidence of serious infections occurred in 13% of patients in the prednisolone group compared to 7% in patients who were not treated with prednisolone ($P = 0.002$). However, a recent meta-analysis[115] found that corticosteroid administration in severe ARH reduced 28-d mortality from liver-related death with no significant change in mortality from bacterial infection or gastrointestinal bleeding. The study also found a higher incidence of fungal infection in steroid-treated patients. Pentoxifylline was previously used in the management of ARH. Its use has been limited based on the results of STOPAH trial, in which use of pentoxifylline was not associated with mortality benefit.

LT has been controversial in the treatment of ARH, as patients with ALD have historically been considered poor candidates for transplantation due to concern for continued alcohol use after transplantation. However, recent trends have shown an opportunity for LT to gain a larger role in the treatment of ARH with strict selection criteria for candidates, as demonstrated in several studies[116]. A prospective trial by Mathurin *et al*[117] showed a significantly improved 6-mo survival rate in patients with severe ARH (MDF > 32, Lillie > 0.45) who received LT compared to controls without LT (77% and 23% respectively, $P < 0.001$). However, selection criteria were remarkably strict, as only patients with no prior episodes of hepatic decompensation, strong family support, complete commitment to abstinence, and consensus among all care providers were accepted for LT, which was less than 2% of all patients admitted with ARH during the study period. A more recent trial by Weeks *et al*[118] demonstrated a 97% 1-year survival rate in patients who received LT for severe ARH, however had an alcohol use relapse rate at 17% due to less strict inclusion requirements (including patients with recent hepatic decompensation). A recent large multi-center retrospective analysis (ACCELERATE-AH)[119] found a 94% 1-year survival rate and 84% 3-year survival rate with a 11% relapse rate. Of note, median MELD score was 39 and median Lille score was 0.82 for patients who received LT.



In summary, LT should be considered for patients with life-threatening ARH who have failed medical therapy and who have a low likelihood of alcohol relapse based on predetermined medical and social criteria. The proportion of candidates meeting these criteria may be relatively low, however stringent patient selection can aid in avoiding improper use of donor organs while dramatically improving survival rates. A study reported that the rates of relapse-free survival and hazardous relapse-free survival did not differ between the patients who received early transplantation compared to those who were transplanted after 6 mo of abstinence[120].

THERAPIES/CLINICAL TRIALS UNDER INVESTIGATION

Multiple therapies are currently under clinical trial for the management of ARH. While the discussion regarding all the therapies under investigation is beyond the scope of this article, information regarding the various mechanisms and clinical trials currently targeting this disease is presented in Table 3 below.

Table 3 Clinical trials under investigation

Drugs	Mechanisms	Clinical trials
Anakinra and Canakinumab	Reduce hepatic inflammation	NCT01809132[121], NCT04072822[122], NCT03775109[123]
N-acetyl cysteine, S-adenosyl methionine (SAM-E)	Reduce oxidative stress	NCT03069300[124], NCT00851981[125], NCT02024295[126]
DUR-928	Epigenetic modulation of lipid homeostasis, inflammation, cell survival, tissue regeneration	NCT03432260[127], NCT03917407[128]
Granulocyte colony stimulating growth factors, interleukin-22 and obeticholic acid	Boosts liver regeneration	NCT02442180[129], NCT03703674[130], NCT04066179[131], NCT02655510[132], NCT01918462[133], NCT02039219[134]
Rifaximin, zinc supplementation, bovine colostrum, probiotics, and fecal microbiota transplant	Targets the gut-liver axis	NCT02116556[135], NCT02485106[136], NCT01968382[137], NCT02473341[138], NCT01922895[139], NCT02335632[140], NCT02458079[141], NCT03091010[142], NCT03827772[143]

Figure 7 Treatment algorithm for alcohol-related hepatitis. AKI: Acute kidney injury.

CONCLUSION

ARH remains a disease process with high morbidity and mortality. Despite research advances in pathogenesis of this disease process, limited progress has been made in management of this condition. Abstinence remains critical in maximizing the chances of hepatic recovery; corticosteroids continue to play a role in select populations. Given the grim prognosis and increasing prevalence of ARH, research efforts are aiming at inhibiting inflammatory cytokine pathways that lead to progressive hepatic damage. In the meantime, many centers around the world are resorting to liver transplantation as salvage therapy. The COVID-19 pandemic exacerbated the pre-existing trend of rising cases of ARH. Urgent societal and government interventions are needed to prevent the ongoing rise in ARH cases in addition to intensifying research efforts in identifying and testing therapeutic targets for this complex disease process.

Abstract

Hepatocellular carcinoma (HCC) is one of the most lethal malignant tumours worldwide. The mortality-to-incidence ratio is up to 91.6% in many countries, representing the third leading cause of cancer-related deaths. Systemic drugs, including the multikinase inhibitors sorafenib and lenvatinib, are first-line drugs used in HCC treatment. Unfortunately, these therapies are ineffective in most cases due to late diagnosis and the development of tumour resistance. Thus, novel pharmacological alternatives are urgently needed. For instance, immune checkpoint inhibitors have provided new approaches targeting cells of the immune system. Furthermore, monoclonal antibodies against programmed cell death-1 have shown benefits in HCC patients. In addition, drug combinations, including first-line treatment and immunotherapy, as well as drug repurposing, are promising novel therapeutic alternatives. Here, we review the current and novel pharmacological approaches to fight HCC. Preclinical studies, as well as approved and ongoing clinical trials for liver cancer treatment, are discussed. The pharmacological opportunities analysed here should lead to significant improvement in HCC therapy.

Key Words: Liver cancer; Systemic therapy; Immunotherapy; Drug repurposing; Drug combinations; Hepatocellular carcinoma

Core Tip: Hepatocellular carcinoma (HCC) is one of the most lethal malignant tumours worldwide. Unfortunately, most HCC cases are diagnosed at an advanced stage, and "curative" options are not suggested for these patients. The best option is to start with drug therapy, with sorafenib and lenvatinib as the first-choice drugs. However, most patients do not respond to these treatments; therefore, new therapeutic strategies are urgently needed. Here, we review current potential and novel pharmacological approaches, including immunotherapy, drug combination, and drug repositioning, that should help to improve the prognosis of HCC patients.

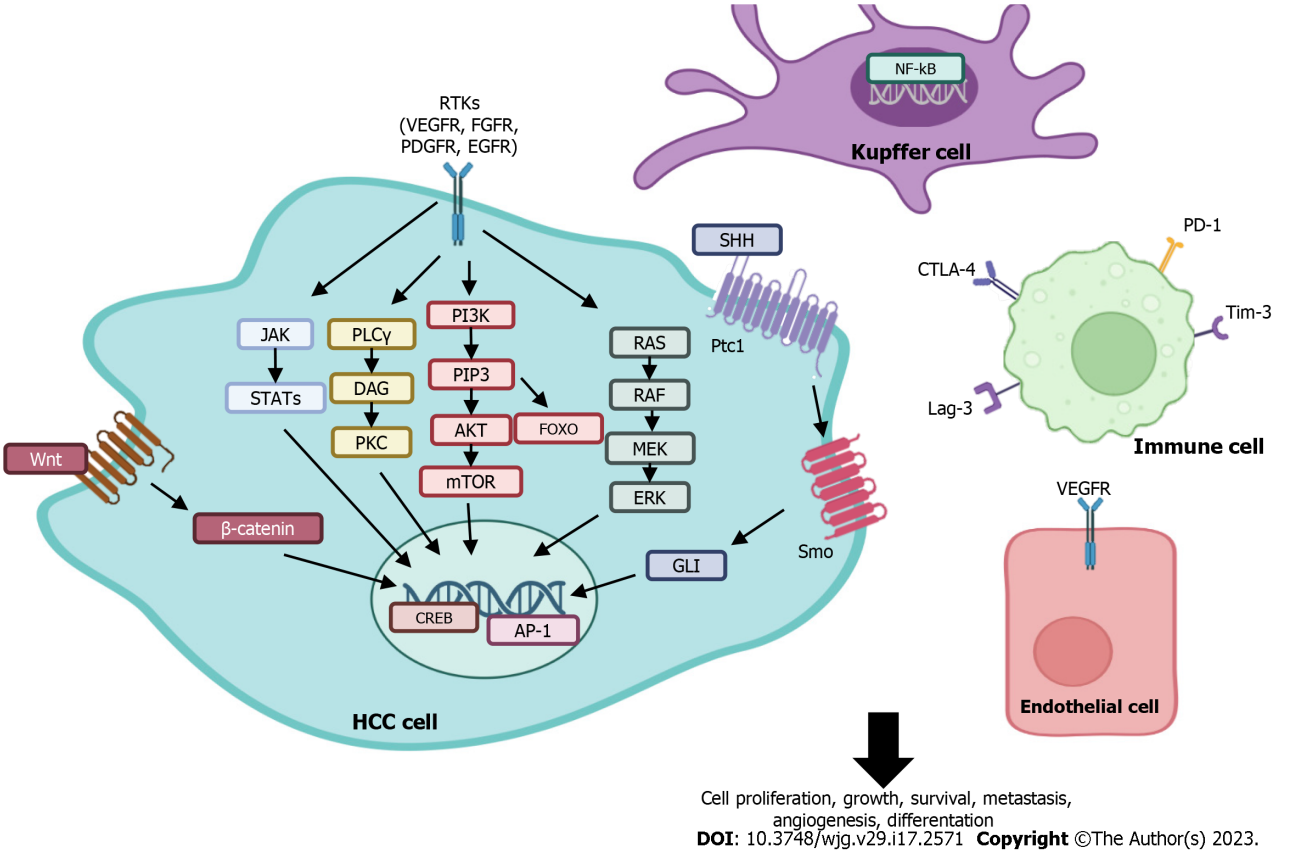
INTRODUCTION

Liver cancer ranks seventh in incidence and fourth in mortality worldwide. It is one of the malignancies with the highest mortality-to-incidence ratio, reaching up to 91.6%, according to the World Health Organization[1]. This cancer frequently occurs in association with chronic liver disease and is classified according to the cells of origin of the tumour. Hepatocellular carcinoma (HCC) is the most common, originating in hepatocytes and accounting for 75%-85% of all cases[2].

The main risk factors for developing HCC are chronic liver disease, such as non-alcoholic fatty liver disease and non-alcoholic steatohepatitis, as well as hepatitis B (HBV) and C virus (HCV) infections[3]. In addition, some habits, including excessive alcohol consumption and smoking, are also considered major risk factors for developing HCC[2].

The most appropriate management in clinical practice depends on the stage of the disease. At an early or even intermediate stage, the treatment options currently available are surgical methods (liver resection and transplantation), locoregional therapy (radiofrequency ablation), and transarterial chemoembolization therapy[4]. The 5-year survival rate for patients at these stages is 14%, and only 30% can be subjected to curative treatment. Unfortunately, most diagnoses are made when HCC is at an advanced stage, and treatment options are no longer viable[5,6]; pharmacological therapy is suggested in these cases. Chemotherapy is a potential treatment for these patients, but the main disadvantage is that such agents target both cancer and healthy cells, leading to unwanted events that can even endanger the life of the patient. The use of chemotherapeutic agents in monotherapy is ineffective; therefore, more effective and directed drugs are urgently needed. A new generation of treatments called “targeted therapy” (also known as “systemic therapy”) aims to specifically target some molecular features that provide malignant advantages to cancer cells while having low toxicity to non-cancerous cells[7,8]. Table 1 summarizes the recommended HCC management based on the Barcelona Clinic Liver Cancer strategy (BCLC), the most widely used liver cancer staging system. This system has five stages depending on disease extension, liver function, and performance status (Table 1)[9-11].

Systemic therapy is the standard treatment for advanced-stage disease (BCLC stage C). This type of treatment is classified into first- and second-line therapies, and its use in clinical practice depends on the individual patient characteristics. To date, many potential drug targets for the treatment of HCC have been investigated; the most critical targets are listed below and represented in Figure 1[8].



Growth factors and their receptors include vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), epidermal growth factor (EGF), mesenchymal-epithelial transition factor (c-Met), insulin-like growth factor, and transforming growth factor α (TGF-α).

Intracellular signalling pathways include phosphoinositide 3-kinase (PI3K)/Akt/mechanistic target of rapamycin (mTOR), RAS/RAF/MEK/ERK, Janus kinase (JAK)/signal transducer and activator of transcription (STAT), and Wnt/β-catenin and the Hedgehog pathway. There are also cell cycle regulators such as CDKs. Transcription factors include nuclear factor kB (NF-kB), activating protein-1 and cyclic AMP response element binding (CREB).

Table 1 Barcelona Clinic Liver Cancer staging system and treatment strategy

Stage	Very early stage (0)	Early stage (A)	Intermediate stage (B)	Advanced stage (C)	Terminal stage (D)
Characteristics	Single nodule < 2 cm, preserved liver function, ECOG PS 0	Single or 2-3 nodules < 3 cm, preserved liver function, ECOG PS 0	Multinodular, unresectable, preserved liver function, ECOG PS 0	Portal invasion/extrahepatic spread, preserved liver function, ECOG PS 1-2	Not transplantable HCC, end-stage liver function, ECOG PS 3-4
Treatment	Ablation, resection, transplant		Chemoembolization	Systemic therapy	Best supportive care
Survival	> 5 yr		> 2.5 yr	> 2 yr	3 mo

ECOG PS: Eastern Cooperative Oncology Group performance status; HCC: Hepatocellular carcinoma.

Figure 1 Critical signalling pathways involved in hepatocellular carcinoma progression. Systemic therapy primarily targets signalling pathways triggered by tyrosine kinase receptors expressed on tumour cells, which are known to play an essential role in liver carcinogenesis. However, Wnt/B-catenin and Smo (hedgehog pathway) signalling are also important components in liver cancer development. Furthermore, Kupffer cells, immune cells, and endothelial cells are part of the tumour microenvironment, and activation of critical signalling pathways in these cells may also contribute to cancer development. Indeed, the expression of immune checkpoint molecules (cytotoxic T-lymphocyte-associated protein 4, programmed cell death protein 1, Lag-3, Tim-3) on the surface of immune cells play an essential role in the development of hepatocellular carcinoma (discussed in the main text). RTK: Receptor tyrosine kinase; VEGFR: Vascular endothelial growth factor receptor; FGFR: Fibroblast growth factor receptor; PDGFR: Platelet-derived growth factor receptors; EGFR: Endothelial growth factor receptor; JAK: Janus kinase; STAT: Signal transducer and activator of transcription; PLCγ: Phospholipase C-γ; DAG: Diacylglycerol; PKC: Protein kinase C; PI3K: Phosphoinositide 3-kinase; PIP3: phosphatidylinositol 3,4,5-trisphosphate; mTOR: Mechanistic target of rapamycin; FOXO: Forkhead box O; AP-1: Activating protein-1; CREB: Cyclic AMP response element binding; NF-kB: Nuclear factor kB; CTLA-4: Cytotoxic T-lymphocyte-associated protein 4; PD-1: Programmed cell death protein 1.

Next, first- and second-line systemic therapies approved for advanced HCC, as well as those drugs and targets under investigation for treating the disease, are described and discussed in detail and summarized in Table 2.

Table 2 Summary of first and second-line drugs approved for the treatment of advanced hepatocellular carcinoma

Drug	Pharmacological target	Trial (NCT)	Treatment arm	Control arm
First-line				
Systemic therapy				
Sorafenib	VEGF 1-3, PDGF, KIT, FLT3, BRAF, RAF	SHARP (NCT00105443)	Sorafenib (400 mg twice daily)	Placebo
Lenvatinib	VEGFR1-3, FGFR 1-4, PDGR, RET and KIT	REFLECT (NCT01761266)	Lenvatinib (12 mg/day for bodyweight ≥ 60 kg or 8 mg/day for bodyweight < 60 kg)	Sorafenib (400 mg twice-daily in 28-d cycles)
Immunotherapy				
Atezolizumab plus bevacizumab	PD-L1, vEGF	IMbrave150 (NCT03434379)	1200 mg of atezolizumab plus 15 mg per kilogram of body weight of bevacizumab intravenously every 3 wk	Sorafenib (400 mg orally twice daily)
Tremelimumab plus durvalumab	CTLA-4, PD-L1	HIMALAYA (NCT03298451)	STRIDE: Tremelimumab plus durvalumab or durvalumab alone (300 mg, one dose of tremelimumab plus 1500 mg every 4 wk for durvalumab)	Sorafenib (400 mg orally twice daily)
Second-line[1]				
Systemic therapy				
Regorafenib	VEGFR 1-3, PDGFR, FGFR 1-2, RET, RAF	RESORCE (NCT01774344)	Regorafenib (160 mg once daily during weeks 1-3 of each 4-wk cycle)	Placebo
Cabozantinib	VEGFR 1-3, MET and AXL	CELESTIAL (NCT01908426)	Cabozantinib (60 mg once daily)	Placebo
Ramucirumab	VEGFR	REACH-2 (NCT02435433)	Ramucirumab 8 mg/kg intravenous ramucirumab every 2 wk	Placebo
Immunotherapy				
Nivolumab	PD-1	CheckMate-459 (NCT02576509)	Nivolumab (240 mg intravenously every 2 wk)	Sorafenib(400 mg orally twice daily)
Nivolumab plus ipilimumab	PD-1, CTLA-4	CheckMate-040 (NCT01658878)	Nivolumab 1 mg/kg plus ipilimumab 3 mg/kg, administered every 3 wk (4 doses), followed by nivolumab 240 mg every 2 wk (arm A); nivolumab 3 mg/kg plus ipilimumab 1 mg/kg, administered every 3 wk (4 doses), followed by nivolumab 240 mg every 2 wk (arm B); or nivolumab 3 mg/kg every 2 wk plus ipilimumab 1 mg/kg every 6 wk (arm C)	Placebo
Pembrolizumab	PD-1	KEYNOTE-240 (NCT02702401)	Pembrolizumab (200 mg intravenously every 3 wk for at least 35 cycles during approximately 2 yr)	Placebo

[1]Eligible patients who had received previous treatment with sorafenib.

CTLA-4: Cytotoxic T-lymphocyte-associated protein 4; PD-1: Programmed cell death protein 1; VEGFR: Vascular endothelial growth factor receptor; FGFR: Fibroblast growth factor receptor; PDGFR: Platelet-derived growth factor receptors; OS: Overall survival; PFS: Progression-free survival; PD-L1: Programmed death ligand-1.

FIRST-LINE SYSTEMIC THERAPIES

Sorafenib

The need for new and better treatments for patients in advanced stages has led researchers to develop molecules to specifically target components of the carcinogenesis process. Sorafenib was the first oral multikinase inhibitor drug approved by the Food and Drug Administration (FDA) in 2007 to treat advanced HCC. *In vitro* experiments found that this drug inhibited HCC cell line growth and angiogenesis by inhibiting the RAF/MEK/ERK signalling pathway, as well as tyrosine and serine/threonine kinase receptors, including those for VEGF, PDGF, c-KIT, FLT3 and BRAF[12]. This drug is indicated in patients with preserved liver function who are not candidates for surgical or locoregional therapies and those with advanced tumours according to the BCLC classification and the Child-Pugh scale[9].

Sorafenib was the first drug to significantly improve the survival of patients with advanced HCC in the Asia-Pacific region. The median overall survival (OS) was 6.5 mo [95% confidence interval (CI): 5.56-7.56] in patients treated with sorafenib compared to 4.2 mo (3.75-5.46) in patients treated with placebo [13]. Similar results in terms of improved survival were observed in the SHARP clinical trial (ClinicalTrials.gov identifier: NCT00105443), a phase III, double-blind, placebo-controlled study that evaluated the effect of sorafenib on OS and time to symptomatic progression in patients diagnosed with advanced HCC. Here, the median OS was 10.7 mo in the sorafenib group and 7.9 mo in the placebo group. The most frequent adverse events in the sorafenib group were weight loss, diarrhoea, hypophosphataemia, and hand-foot skin reactions. Based on these trials, sorafenib became the first targeted therapy drug to be approved for the treatment of advanced HCC and has been the first-choice drug since its approval. Currently, the treatment of patients with sorafenib until significant radiographic progression and simultaneous treatment with regorafenib (discussed below) are recommended[9]. Unfortunately, only 30% of sorafenib users benefit, and within a short period of time, resistance to sorafenib often develops, rendering further use ineffective[14].

Lenvatinib

Following the approval of sorafenib, research led to the recognition of lenvatinib as another drug targeting important receptors and pathways in HCC. Lenvatinib is an oral receptor tyrosine kinase inhibitor and was approved in 2018 by the FDA as a first-line treatment for unresectable HCC[15]. VEGF receptor (VEGFR), FGF receptor (FGFR), PDGRα, RET, and KIT[16,17] are among its therapeutic targets. In preclinical models, lenvatinib was shown to selectively inhibit the proliferation of human HCC cell lines and *in vivo* tumour growth in xenograft models[18]. The approval of this molecule was based on the REFLECT clinical trial (ClinicalTrials.gov identifier: NCT01761266), a phase III, multicentre, open-label, non-inferiority trial that evaluated the OS of patients diagnosed with advanced HCC treated with lenvatinib *vs* patients treated with sorafenib. Lenvatinib met non-inferiority criteria against sorafenib, as the median survival for lenvatinib was 13.6 mo (95%CI: 12.1-14.9) *vs* 12.3 mo for the sorafenib group [12.3 mo, 10.4-13.9; hazard ratio (HR): 0.92, 95%CI: 0.79-1.06][19]. The most common adverse events in the lenvatinib group in this study were diarrhoea, loss of appetite, and weight loss.

Atezolizumab plus bevacizumab

Atezolizumab is a monoclonal antibody that selectively targets programmed death ligand-1 (PD-L1) to reverse the suppression of T-cell activity[20]. Its activity was assessed through an assay that determined predictive correlates of response to this antibody in cancer patients. According to Herbst *et al*[20], who studied various types of cancer, responses were observed in patients with tumours expressing high levels of PD-L1, mainly when it was expressed on tumour-infiltrating immune cells[20].

Conversely, the monoclonal antibody bevacizumab interferes with angiogenesis and tumour growth by inhibiting VEGF activity[21]. Finn *et al*[22] demonstrated the potential of bevacizumab as a promising anti-VEGF treatment for liver cancer in preclinical trials. They evaluated the effect of this humanized antibody in an orthotopic mouse model of HCC using the Hep3B cell line and found that bevacizumab treatment significantly reduced tumour microvessel density and alpha-fetoprotein (AFP) levels and prolonged time to progression compared to the control group[22].

The combination of atezolizumab and bevacizumab is a therapeutic strategy aiming to simultaneously inhibit PD-L1 (atezolizumab) and VEGF (bevacizumab) signalling in patients with advanced HCC. This combination was evaluated in the Imbrave150 clinical trial (ClinicalTrials.gov identifier: NCT03434379), a global, open-label, phase III study that evaluated the effect of the combination of these two antibodies in patients with unresectable HCC against the effect of sorafenib as a single drug, resulting in improved OS and progression-free survival (PFS) for the combination group [67. 2% (95%CI: 61.3-73.1) and 54.6% for the sorafenib group (95%CI: 45.2-64.0)][23]. A few years later, a longer follow-up of these patients was performed, reporting that the combination maintained the improvement in patients over the effect of sorafenib[24]. Accordingly, atezolizumab plus bevacizumab combination therapy was very recently approved by the FDA (2020) as the initial treatment for advanced HCC, adding a targeted drug combination to the first-line treatment strategies for these patients[25].

Tremelimumab plus durvalumab

In October 2022, the FDA approved the combination of tremelimumab plus durvalumab for treating

patients with unresectable HCC, which could form part of the first-line treatment for this cancer[26].

Tremelimumab is a fully human immunoglobulin G (IgG)2 monoclonal antibody against cytotoxic T-lymphocyte-associated protein 4 (CTLA-4), a receptor that inhibits T-cell activity[27]. Duffy *et al*[28] subjected patients diagnosed with HCC to a study evaluating the efficacy of treatment with tremelimumab plus an ablative procedure performed during week 6 (ClinicalTrials.gov identifier: NCT01853618). The authors observed that such a combination led to the accumulation of intratumoural CD8+ T-cells and suggested it as a potential new treatment for patients with advanced HCC[28]. In contrast, dirvalumab is another human monoclonal antibody that binds to the PD-L1 protein and has been shown to be effective in liver cancer and in small-cell lung cancer, especially when used in combination with another therapeutic agent[29,30].

A phase I/II clinical trial (ClinicalTrials.gov identifier: NCT02519348) evaluated the safety and efficacy of monotherapy and combination treatment of tremelimumab plus durvalumab (300 mg and 1500 mg, respectively) in patients with HCC who had progressed on, were intolerant to, or refused sorafenib. The objective response rates (ORRs) were 24.0% (95%CI: 14.9-35.3) for the combination, 10.6% for durvalumab (5.4-18.1), and 7.2% (2.4-16.1) for tremelimumab, while the median OS was 18.7 (10.8-27.3), 13.6 (8.7-17.6), and 15.1 (11.3-20.5) months, respectively[31]. However, the clinical study that led to the approval of this combination was HIMALAYA (ClinicalTrials.gov identifier: NCT03298451), a phase III and global study with a heterogeneous population representative of HCC patients and no previous systemic treatment, which also evaluated the effect of durvalumab monotherapy and compared it to sorafenib. Here, the median OS was 16.43 mo for the combination (95%CI: 14.16-19.58), 16.56 mo (95%CI: 14.06-19.12) with durvalumab, and 13.77 mo (95%CI: 12.25-16.13) with sorafenib. The combination significantly improved OS over sorafenib, and durvalumab was not inferior to sorafenib in these patients, suggesting that it could be used as a first-line treatment[32].

SECOND-LINE SYSTEMIC THERAPIES AND IMMUNOTHERAPY

Although approximately 30% of patients receiving sorafenib show improvement, resistance to treatment can develop after prolonged use (approximately 6 mo), rendering it ineffective after this period[14]. Therefore, second-line treatments are indicated for patients who either have progressed on previous sorafenib or do not respond to it. Notably, to date, no clinical trials have evaluated second-line therapy after lenvatinib[33].

Regorafenib

Regorafenib is another oral multikinase inhibitor that primarily targets VEGFR, PDGF receptors, FGFR, RET, and RAF and, in preclinical trials, was shown to significantly inhibit liver tumour development [34]. In addition, it activates proteins involved in MAPK signalling, apoptosis, and autophagy[35]. The FDA approved this drug as a second-line treatment for patients who have already been treated with sorafenib. The safety and efficacy of this drug in humans were tested in a multinational, randomized, double-blind, placebo-controlled, phase III clinical trial (RESORCE, ClinicalTrials.gov identifier: NCT01774344), in which the median OS was 10.6 mo (95%CI: 9.1-12.1) for the regorafenib group *vs* 7.8 mo (6.3-8.8) in the placebo group[36]. The most common adverse events reported in this study were hypertension, hand-foot skin reactions, fatigue, and diarrhoea. Thus, because of the survival benefit of regorafenib in HCC patients unresponsive to sorafenib, it was approved by health agencies in several countries, including the United States, Japan, and China.

Cabozantinib

Cabozantinib is a multikinase inhibitor suppressor of tumour growth, metastasis, and angiogenesis that primarily targets VEGFR but also targets MET and AXL, which in addition to being implicated in HCC progression are involved in sorafenib resistance[37]. Initially, this drug showed clinical activity in a phase II study in previously untreated HCC patients and those with progression or no response to sorafenib, resulting in a median OS of 5.5 mo with no significant radiographic responses[38]. However, its approval was based on the results of the CELESTIAL clinical trial (ClinicalTrials.gov identifier: NCT01908426), a randomized, double-blind, phase III trial evaluating cabozantinib *vs* placebo in patients diagnosed with advanced HCC, in which cabozantinib demonstrated significant benefit over placebo in OS and tumour PFS. The median OS was 10.2 mo with cabozantinib and 8.0 mo with placebo (95%CI: 0.63-0.92). The median PFS was 5.2 mo with cabozantinib and 1.9 mo with placebo (95%CI: 0.36-0.52)[39]. In 2019, the FDA approved cabozantinib for treating patients with advanced HCC who were previously treated with sorafenib[40].

Interestingly, this drug is involved in tyrosine kinase inhibition and has also been reported to be an immunomodulator since some of its targets are involved in the immune response. Indeed, in combination with anti-programmed cell death protein 1 (PD-1) therapy, cabozantinib showed a greater antitumour effects than monotherapy or placebo in animal models of HCC. On its own, cabozantinib significantly increased neutrophil infiltration and reduced intratumoural CD8+ PD-1+ T-cell ratios, while the combination further stimulated this effect[41].

Ramucirumab

Ramucirumab is an antiangiogenic anti-VEGFR2 monoclonal antibody[42,43]. The efficacy of this drug was tested in the REACH clinical trial, a randomized, placebo-controlled, double-blind, multicentre, phase III trial (ClinicalTrials.gov identifier: NCT01140347). Here, ramucirumab was tested against placebo in patients diagnosed with advanced HCC who were previously treated with sorafenib and who experienced either progression or intolerance. The median OS for the ramucirumab group was 9.2 mo (95%CI: 8.0-10.6) *vs* 7.6 mo (6.0-9.3) for the placebo group (HR: 0.87; 95%CI: 0.72-1.05; $P = 0.14$). Consistent with these results, second-line treatment with ramucirumab did not significantly improve survival over placebo in patients with advanced HCC[44]. A follow-up trial, REACH-2, was a randomized, double-blind, placebo-controlled, phase III trial comparing ramucirumab *vs* placebo at a 2:1 ratio in the same population, but this time for a preselected population with AFP concentrations ≥ 400 ng/mL. The median OS was 8.5 mo (95%CI: 7.0-10.6) *vs* 7.3 mo (5.4-9.1); HR: 0.71 (95%CI: 0.53-0.95; $P = 0.0199$) and PFS [2.8 mo (2.8-4.1) *vs* 1.6 mo (1.5-2.7); 0.452 (0.33-0.60); $P < 0.0001$] were significantly improved in the ramucirumab group compared with the placebo group. This trial showed improved OS with ramucirumab compared to placebo in patients with HCC and AFP concentrations of at least 400 ng/mL who had previously received sorafenib[45].

Very recently, the clinical relevance of rechallenge treatment with previously administered drugs was evaluated, with five consecutive patients with advanced HCC who received rechallenge treatment with lenvatinib and with failure after treatment with ramucirumab. Here, the radiological findings using the modified Response Evaluation Criteria in Solid Tumours showed stable disease in four patients and a partial response in one. This trial demonstrated that re-exposure to lenvatinib treatment after ramucirumab might be effective for treating advanced HCC[46].

IMMUNOTHERAPY

Unfortunately, cancer cells can develop resistance to systemic therapies. Thus, more and better drug treatments must be devised for these patients. Potential strategies include combination approaches and immunological therapy. In fact, immunotherapy has now been postulated as a possible therapeutic strategy to treat different types of cancer.

Cancer cells can escape the defence mechanisms of immune cells in the tumour microenvironment, thus avoiding detection and elimination by host lymphocytes by downregulating stimulatory immunoreceptors and stimulating inhibitory immunoreceptors. For example, in the case of T cells, tumour cells can modulate stimulatory activity by downregulating MHC-I on the surface. Conversely, inhibitory activity can be modulated by these cells through upregulation of PD-L1 on the surface[47-49]. Such molecules are known as immune checkpoints, which act as modulators of immune responses. These molecules can be used as pharmacological targets to generate various monoclonal antibodies that modulate their activity. Among the most studied immune receptors are PD-1, CTLA-4, LAG3, TIM3, TIGIT, and BTLA[49].

Immunotherapy has been shown to have significant efficacy in the treatment of different types of cancer, including HCC[50], making it an excellent option for patients with cancer progression or for whom systemic therapy with sorafenib was ineffective. Several immune checkpoint inhibitors that primarily target CTLA-4, PD-1, and its ligand PD-L1 have been tested to date. Some ICIs have also been approved by the FDA for the treatment of HCC. PD-L1, also called B7-H1 or CD274, is expressed in many cancer and immune cells and plays an essential role in blocking the "cancer immunity cycle" by binding to PD-1 and B7.1 (CD80), both of which are negative regulators of T-cell activation[51,52].

Antibody-based therapy is the main strategy designed to modulate the tumour immune response, but other cancer immunotherapeutic strategies, such as adoptive cell therapy, chimeric antigen receptor-modified immune cells, engineered cytokines, and therapeutic cancer vaccines, are still under development[53,54].

Nivolumab

Nivolumab is a human IgG4 monoclonal antibody that binds to the PD-1 receptor, inhibiting its interaction with PD-L1 and PD-L2 and restoring T-cell activity[55]. Nivolumab has been shown to be effective in several malignancies, including melanoma, renal Hodgki''s lymphoma, lung cancer, and gastric cancer[56-60].

Nivolumab was evaluated in HCC patients in a study called CheckMate-040 (ClinicalTrials.gov identifier: NCT01658878), a phase I/II, open-label, non-comparative, multicentre trial that included patients with advanced HCC who either had also reported progression after treatment with sorafenib or were sorafenib naive. Patients received intravenous nivolumab 240 mg every 2 wk until unacceptable toxicity or disease progression occurred. In this study, nivolumab showed favourable clinical activity and safety with manageable toxicities, suggesting that it could be suitable for patients with advanced HCC[61].

Subsequently, the activity of nivolumab (240 mg intravenously every 2 wk) was compared to that of sorafenib (400 mg orally twice daily) in a randomized, open-label, phase III trial (CheckMate 459, ClinicalTrials.gov identifier: NCT02576509) until disease progression or unacceptable toxicity. OS was improved from 14.7 mo for sorafenib to 16.4 mo with nivolumab but did not reach statistical significance (P = 0.0752). In addition, there was no significant difference in PFS (3.7 *vs* 3.8 mo). The ORRs for nivolumab and sorafenib were 15% and 7%, respectively. Nivolumab showed relevant clinical activity and a favourable safety profile for patients with advanced HCC. However, nivolumab administered for the first time in these patients was not significantly better than sorafenib in terms of OS[62]. Thus, in September 2017, nivolumab was approved by the FDA as a second-line treatment for patients with advanced HCC. It is worth mentioning that this antibody has only been approved by this institution[63].

Recently, the effect of the combination of nivolumab plus ipilimumab, a fully human IgG1 monoclonal antibody that binds to CTLA-4 on T cells[64], was evaluated. The efficacy of this combination was tested in the CheckMate 040 study (ClinicalTrials.gov identifier: NCT01658878), a multicentre, open-label, multicohort, phase I/II study in which it was shown that the combination of nivolumab plus ipilimumab led to high OS rates and had a manageable safety profile[65]. Based on the results of this trial, in March 2020, the FDA approved the combination of nivolumab plus ipilimumab as a second-line treatment for patients with HCC who had been previously treated with sorafenib[66].

Pembrolizumab

Pembrolizumab is an anti-PD-1 monoclonal antibody that demonstrated clinical efficacy in patients with advanced HCC. This antibody was evaluated in a non-randomized, multicentre, open-label, phase II study in patients with BCLC B-C HCC pre-treated with sorafenib (ClinicalTrials.gov identifier: NCT02702414), and it showed antineoplastic activity with an ORR of 17% and a manageable safety profile[67]. Based on these results, in November 2018, the FDA granted accelerated approval to pembrolizumab for patients with HCC who had been previously treated with sorafenib[68]. A subsequent study was then conducted evaluating pembrolizumab in a randomized, double-blind, phase III study in patients with advanced HCC previously treated with sorafenib (KEYNOTE-240, ClinicalTrials.gov identifier: NCT02702401). Here, the median OS was 13.9 mo (95%CI: 11.6-16.0 mo) for pembrolizumab *vs* 10.6 mo (95%CI: 8.3-13.5 mo) for placebo (HR: 0.781; 95%CI: 0.611-0.998; P = 0.0238). The median PFS for pembrolizumab was 3.0 mo (95%CI: 2.8-4.1 mo) *vs* 2.8 mo (95%CI: 1.6 to 3.0 mo) for placebo[69].

Additionally, the KEYNOTE-394 trial (ClinicalTrials.gov identifier: NCT03062358), a randomized, double-blind, phase III study, evaluated the efficacy of pembrolizumab plus best supportive care *vs* placebo in Asian HCC patients as second-line therapy. Overall, the results were consistent with those seen in previous trials, further supporting the use of pembrolizumab in patients with advanced HCC. Here, the median OS was 14.6 mo (12.6-18.0) for pembrolizumab and 13.0 mo (10.5-15.1) for placebo (95%CI); furthermore, pembrolizumab showed significant improvement of PFS (HR: 0.74, 95%CI: 0.60-0.92, P = 0.0032)[70].

INNOVATIVE STRATEGIES FOR HCC TREATMENT

Drug combination and repurposing

Currently, monotherapies are ineffective in fighting cancer mainly due to the development of resistance of cancer cells to available drugs[71], and preclinical findings may not be replicated in patients. For instance, the monoclonal antibody bortezomib demonstrated promising antineoplastic activity in preclinical assays, but in humans, it did not show notable single-agent activity compared to sorafenib [72]. Thus, more and better treatment options are needed for these patients, and drug combinations are promising options. This strategy consists of simultaneously administering two or more drugs aimed at different cancer-specific drug targets and has shown significant benefits compared to monotherapy[73]. However, combining drugs must become a rational strategy that guarantees significant pharmacological responses, especially for those patients who either did not respond to current therapy or developed resistance.

Several tools have been developed for the identification of potentially useful drug combinations; these tools include dose-response matrices, RNA interference technology, and the wide adaptation of clustered regularly interspaced short palindromic repeats (CRISPR) systems, as well as more novel techniques such as patient-derived xenograft (PDX) models and *ex vivo* primary cell and organoid models[74]. For instance, Lim *et al*[75] used PDXs of HCC, PDX-derived organoids and a hybrid experimental-computational approach–namely, the quadratic phenotypic optimization platform–and found that the combination of the second-generation proteasome inhibitor ixazomib and the CDK inhibitor dinaciclib (Dina), which they tested *in vitro* and *in vivo*, is effective against HCC[75]. Another example of the usefulness of these strategies is CRISPR-Cas9 combinatorial screening, a technique that accelerated the discovery of combination treatment with the approved drug ifenprodil (an NMDA receptor antagonist) and sorafenib as a new therapeutic alternative for advanced HCC[76].

Therefore, implementing the abovementioned strategies should aid the discovery of potentially useful drug combinations. In this manner, medical staff may have different choices and establish a selection order more suitable for each HCC patient in a personalized manner[77,78].

Conversely, it is well known that the discovery of new molecules with pharmacological activity is a process with two main disadvantages: Time and cost. It takes at least 10 years to bring a new drug to the market, and the approximate cost ranges from $314 million to $2.8 billion[79]. Furthermore, in emergency situations such as cancer, the demand for effective treatments is extremely high, and additional strategies are required to obtain novel therapies in an expedited manner. Thanks to advances in pharmacology and genomics, several non-cancer drugs have been shown to have great potential for use in treating multiple cancers. Drug repurposing is a strategy that involves the discovery of already known drugs initially used to treat other diseases but with the potential to treat various malignancies. The main advantage of this approach is that it allows an accelerated and less costly process to identify new cancer treatments since it focuses on the selection of drugs already approved by relevant health institutions[80,81]. Some non-cancer drugs showing antineoplastic activity against HCC and with high repurposing potential are described below and summarized in Table 3.

One of the differences between repositioned drugs and existing drugs approved to treat HCC is that the latter target relatively few signalling pathways; in contrast, repositioned drugs have the enormous advantage of targeting a surprisingly wide variety of signalling pathways involved in liver carcinogenesis (Table 3). For instance, Nair *et al*[82] identified CDC20 as a marker of poor prognosis during the development of early and advanced HCC. Through molecular docking studies, it was determined that labetalol, a beta blocker, binds with high affinity to CDC20[82], suggesting that the effect of labetalol against the development of HCC should be tested. The same research group further investigated this possibility by *in vitro* cytotoxicity studies, in which labetalol significantly inhibited the growth of the HepG2 cell line[83]. Subsequent application of bioinformatics analysis tools to repositioned drugs provides an incredible advantage for the identification of unknown drug targets and signalling pathways potentially involved in liver carcinogenesis.

Antihistamines

Histamine exerts a variety of physiological activities *via* its G protein-coupled receptors, the activation of which has been associated with the progression of different types of cancer[84,85]. It is well known that histamine favours the development of different types of cancer, including liver cancer[86]. Accordingly, overexpression of the histamine H1 receptor (H1HR) is associated with HCC cell proliferation and metastasis by inducing cell cycle progression, lamellipodia production, matrix metalloprotease 2 (MMP2) production and inhibition of apoptosis. Furthermore, suppressing H1HR activity significantly inhibited tumour growth and metastasis in mouse xenograft models[86]. Interestingly, very recently, it was shown that antihistamine consumption is associated with a significant decrease in the developing of liver cancer in patients diagnosed with HBV, HCV or both viruses[87].

Astemizole

Ellegaard *et al*[88] analysed cohort studies and reported that the use of cationic amphiphilic antihistamines, including astemizole (an H1-antihistamine), was associated with a significant reduction in mortality in lung cancer patients[88]. It is worth mentioning that astemizole might affect cancer cell proliferation *via* different molecular mechanisms, including ion channels.

The ether à-go-go-1 (Eag1) potassium channel has been reported to play an important role in the development of several types of cancer, such as liver, cervical, breast, lung and colon cancer[89-93], suggesting that this channel is a potential early biomarker and drug target for these tumours[94]. Eag1 overexpression has been implicated in cell cycle progression and cancer cell proliferation[95], and inhibition of this channel has reduced tumour progression in both *in vitro* and *in vivo* assays in leukaemia and gastric cancer[86-97]. De Guadalupe Chávez-López *et al*[98] found that astemizole inhibited cell proliferation and induced apoptosis in human HCC cell lines[98]. In the same study using an HCC model induced by diethylnitrosamine (DEN) in mice, they found that astemizole inhibited tumour development and decreased Eag1 mRNA and protein levels[98].

Cytochrome P450 2J2 (CYP2J2) is implicated in the development of different types of cancer. In HCC, CYP2J2 is overexpressed, and its activity promotes cell proliferation[99-101]. Interestingly, astemizole and loratadine inhibit CYP2J2 activity[102]. Ellegaard *et al*[88] proposed the possibility that this drug targets this protein, which would partially explain the effect of reduced mortality in lung cancer patients [88].

TRPV2 is a calcium channel expressed in and associated with several types of cancer, including HCC progression. Both mRNA and protein levels of this channel are increased in well-differentiated HCC tumour tissue compared to undifferentiated tissue. There is a strong association between its expression and portal vein invasion. Van den Eynde *et al*[103] reported that TRPV2 is related to endometrial cancer progression and identified astemizole, loratadine, and clemizole as TRPV2 blockers, with loratadine being the most potent antagonist, leading to inhibition of cell proliferation and migration in *in vitro* assays in HEK293 cells[103].

Table 3 Identified drugs and their targets for drug repurposing in hepatocellular carcinoma

Drug	Original therapeutic indication	Molecular targets in HCC	Ref.
Antihistamines	Allergy	H1R-H4R, Eag1, CYP2J2, TRPV2, AP-1, NF-B	[88,91,96,98,102,103,105,109,111,113,115,116]
Raloxifene, bazedoxifene	Breast cancer (raloxifene), osteoporosis	ER-, ER-, GPER, IL-6R, aHR, NF-B, STAT3, PI3K/AKT, MAPK	[135-137,141,142]
Disulfiram	Alcoholism	NF-B, TGF-β, ROS-JNK	[149-151,157]
Clofazimine	Antimycobacterial used to treat leprosy	Wnt/-catenin pathway	[166-178]
Albendazole	Anthelmintic	Tubulin, ERK1/2-HIF-1α-p300/CREB	[175]
Pimozide	Antipsychotic used to manage Tourette's Disorder	STAT3, Wnt/-catenin	[185,188]
Natamycin	Macrolide antifungal	PRDX1	[191]
Metformin	Glycemic control in type 2 diabetes mellitus	PI3K-mTOR pathway, AMPK	[200-202,206,207]
Valproate	Anticonvulsant	HDAC, Notch-1, MAPK pathway, -catenin pathway	[220,221,223]
Atorvastatin	Lower lipid levels and reduce the risk of cardiovascular disease	Mevalonate pathway	[231]
Celebrex	NSAID	COX-2, PNO1	[237,243]
Hydroxychloroquine	Antimalarial	Autophagy inhibition, TLR9 pathway	[247]

NSAID: Non-steroidal anti-inflammatory drug; mTOR: Mechanistic target of rapamycin; HCC: Hepatocellular carcinoma; NF-kB: Nuclear factor kB; AP-1: Activating protein-1; CYP2J2: Cytochrome P450 2J2; ER: Oestrogen receptor; IL-6R: Interleukin-6R; STAT3: Signal transducer and activator of transcription 3; PI3K: Phosphoinositide 3-kinase; TGF-β: Transforming growth factor-β; PRDX1: Peroxiredoxin 1; HDAC: Histone deacetylase; aHR: Adjusted hazard ratio.

Loratadine

Loratadine is a second-generation antihistamine indicated for the treatment of allergic rhinitis and urticaria. It is a selective H1HR receptor antagonist[104]. Fritz *et al*[105,106] evaluated the effect of loratadine through retrospective studies in patients diagnosed with breast cancer and melanoma and found that loratadine use was associated with improved OS[105,106]. In patients diagnosed with lung cancer, a cohort study found that the use of loratadine or its metabolite desloratadine was associated with a significant reduction in mortality; the authors proposed that cancer-related changes in lysosomal membranes could favour the entry of these antihistamines[88,107]. To date, there has been scarce evidence studying the effect of loratadine in HCC. In a thesis from a few years ago, the cytotoxic effect of the combination of loratadine and cisplatin in HCC cell lines was evaluated; loratadine alone had a concentration-dependent cytotoxic effect on liver cancer cell lines, and the combination of loratadine with cisplatin had a synergistic effect[108]. The same thesis showed that loratadine alone and in combination also induced apoptosis and cell cycle arrest in the G2/M phase. Loratadine targets proteins that have been suggested to be involved in the development of HCC. As in the case of astemizole, loratadine might exert antineoplastic effects through H1HR antagonism, lysosomal membrane sensitization, TRPV2 calcium channel blockade and inhibition of CYP2J2 activity[86,88,102,103]. Furthermore, it has been reported that loratadine could exert anti-inflammatory activity by inhibiting the inflammatory response triggered by NF-kB signalling[109], an effect that reduces the levels of proinflammatory components, including interleukin (IL)-6 and tumour necrosis factor (TNF)-α. The effect of loratadine on HCC and its potential mechanisms of action deserve further investigation.

Deptropine

Deptropine is a first-generation H1HR antihistamine indicated to treat asthma[110]. This drug has activity against cancer cells. For example, *in vitro* assays in human liver cancer cells showed that, compared to the activity of other first- and second-generation antihistamines, deptropine was more potent in inhibiting cell proliferation and inducing autophagosome formation by significantly increasing the expression of light chain 3B-II. In mouse xenograft models, deptropine potently inhibited the tumour effect[111].

Cyproheptadine

This antihistamine is a potential anti-HCC agent. Feng *et al*[112] evaluated the activity of cyproheptadine in liver cancer cell viability and found that this drug had a potent inhibitory effect on cell proliferation through cell cycle arrest. Interestingly, a minimal cytotoxic effect was observed in healthy

hepatocytes[112]. Subsequently, a cohort study in Taiwanese patients at different stages of HCC compared patients who received cyproheptadine treatment and those who did not. The adjusted HR (aHR) of all-cause mortality significantly decreased in all stages in the patients who received palliative treatments with cyproheptadine use compared with those who received palliative treatments without cyproheptadine use (all $P < 0.0001$ and aHR = 0.76, 0.80, 0.66, and 0.66 for stages I, II, III, and IV, respectively). The authors suggested that cyproheptadine could improve survival in patients with HCC at any stage[113]. The same research group conducted a case report documenting that a 62-year-old woman with suspected advanced HCC and bone metastases showed disease remission after cyproheptadine monotherapy[114]. A dose of 4 mg of this drug three times daily for 17 mo reduced serum AFP concentrations from 17697.62 ng/mL to 4.3 ng/mL in only 3 mo. A liver biopsy performed two months after starting cyproheptadine treatment showed no malignancy. This outcome was previously observed in another case report in which two patients with HCC and lung metastases were treated with a combination of cyproheptadine plus thalidomide (it should be noted that the cyproheptadine prescription was indicated for skin itching). Computed tomography imaging showed complete remission of HCC in both patients after 6 mo and 6 wk of treatment[115].

A cohort study evaluated the efficacy of the combination of cyproheptadine with sorafenib compared to sorafenib alone in patients with advanced HCC. The median OS was 11 mo in the combination group (95%CI: 6.8-15.1 mo) and 4.8 mo in the sorafenib group (95%CI: 3.1-6.6 mo), while the median PFS time was 7.5 mo (95%CI: 5.1-10.0 mo) in the combination group compared with 1.7 mo (95%CI: 1.4-2.1 mo) in the sorafenib group[116].

Roles of other histamine receptors and antihistamines in HCC

Histamine 2 receptor: Histamine receptor 2 (H2HR) activation has an inhibitory effect on tumour progression in colorectal cancer; gene expression profiling studies in tumour samples from colorectal cancer patients described the elevated expression of this receptor, associated with improved OS outcomes[117]. In human liver cancer cells, H2HR activation leads to the inhibition of IL-6 expression and signalling, arresting cell proliferation[118]. In contrast, there is evidence that H2HR activation in HCC favours the expression of β-catenin and survivin, leading to cell survival[119]. Cimetidine, an H2 antihistamine, decreases intracellular cAMP concentrations, as well as EGF-induced cell proliferation and migration, and it has been suggested as an HCC chemopreventive agent[120]. Additionally, cimetidine treatment was shown to inhibit liver carcinogenesis in rats with DEN-induced HCC[121]. Recently, Crouchet *et al*[122] developed a system in human liver cells that models a clinical prognostic liver signature predicting long-term liver disease progression to HCC, and they identified nizatidine, an H2HR antihistamine, for the treatment of advanced liver disease and prevention of HCC[122].

Histamine 3 receptor: The H3HR receptor has been described to participate in the carcinogenesis of different types of cancer, including colorectal and pancreatic cancer[123,124]. In tumour tissues from HCC patients, H3HR was overexpressed and associated with poor prognosis, and its activation promoted the growth and metastasis of HCC cell lines by inducing lamellipodia formation[125,126]. Zhang *et al*[126] reported that H3HR activation favours HCC progression through an acceleration of the G1-S phase transition, inhibition of apoptosis, and activation of the AMPc/PKA/CREB signalling pathway to downregulate the expression of CDKN1A, a cyclin-dependent kinase inhibitor that has anti-oncogene activity[126]. Thus, the oncogenic role of H3HR might be antagonized as a potential therapy in HCC.

Histamine 4 receptor: Analysis of cancer genomic data from The Cancer Genome Atlas showed that the histamine H4 receptor (H4HR) is slightly but significantly overexpressed in human HCC tumour tissues compared to healthy tissue[84]. Furthermore, patients with increased H4HR protein expression in tumour cells also had increased tumour sizes and more metastasis compared to those with lower receptor expression, suggesting that H4HR levels could be used as a prognostic marker for liver cancer [127]. However, to date, there have been insufficient studies demonstrating the role of H4HR in HCC and its clinical relevance, so it is crucial to investigate its association with this cancer.

ESTROGEN RECEPTOR MODULATORS

According to the Global Cancer Observatory, liver cancer ranks fifth in incidence in men, while in women, it ranks ninth[1]. This fact has attracted the attention of researchers, who have argued that oestrogens explain this difference. Accordingly, oestrogens play a protective role against liver damage and prevent the development of HCC[128-130]. Epidemiological data have indicated that oestrogen deficiency in peri- and postmenopausal women increases the risk of developing liver damage and increases HCC incidence in postmenopausal women; in concordance, oestrogen treatment suppresses this phenomenon[131,132].

Both isoforms of the nuclear oestrogen receptor (ER), ER-α and ER-β, are involved in the development of liver cancer; however, the functions of ER-β have not yet been fully described. Both ER-α and ER-β are expressed in the liver under normal conditions, but their expression is modified during inflammatory

processes. Both are decreased in HCC patients compared to healthy tissue samples[133] and are believed to lose their function during disease progression; indeed, the ER-α isoform might even be considered a predictor of poor prognosis in HCC[128,134]. Conversely, Matsushima *et al*[135] reported that the selective oestrogen receptor modulators (SERMs) raloxifene and bazedoxifene inhibited HCC progression through their specific interaction with ER-β. They proposed that both drugs could activate the ER-β receptor in the liver, which through downstream signal transduction suppresses TGF-induced HCC cell migration *via* inhibition of Akt[135].

Raloxifene is indicated for the treatment of osteoporosis and is used for the treatment and prevention of breast cancer[136]. Raloxifene is a potent inhibitor of the IL-6/GP130 signalling pathway, which is involved in the process of oncogenesis of various cancers, including HCC[137]. This research group observed that raloxifene inhibited cell viability in human liver cancer cell lines. Furthermore, using an *in vivo* model, they also demonstrated that it could inhibit tumour growth.

Because liver cancer frequently develops in the context of chronic inflammatory liver disease, proinflammatory cytokines and immune cells play important roles in carcinogenesis. One of the most relevant cytokines in the development of HCC is IL-6; when overproduced, it has a strong effect on liver carcinogenesis, and its high expression is related to a high rate of metastasis and poor prognosis in HCC [138-140]. Naugler *et al*[141] reported in an animal model that oestrogen administration inhibited IL-6 secretion and significantly reduced DEN-induced injury in males[141]. When IL-6 binds to its receptor, it recruits JAK, leading to activation of STAT3, a transcription factor that favours proliferative processes, angiogenesis, invasion, *etc*[142]. In addition, ER-α could interact directly with NF-kB and inhibit IL-6 secretion, and raloxifene could interact with ER-α and inhibit IL-6 secretion and thus tumour progression[142].

OTHER DRUGS

Disulfiram

Disulfiram is an FDA-approved drug from several years ago and has been extensively used in the treatment of alcoholism[143]. This drug has potential anticancer activity in different types of cancer, including lymphoma[144], breast cancer[145,146], and pancreatic cancer[147]. A phase II, multicentre, randomized, double-blind trial (ClinicalTrials.gov identifier: NCT00312819) evaluated the safety and efficacy of the combination of disulfiram with cisplatin and vinorelbine in patients diagnosed with lung cancer. Interestingly, a significant increase in survival was observed in patients given this combined treatment[148]. Intracellular copper (Cu) levels are significantly elevated in HCC cells and are associated with poor patient prognoses[149,150]. Surprisingly, the increase in Cu concentration might be harnessed for therapeutic use since disulfiram has Cu-dependent anticancer properties. Li *et al*[151] found that disulfiram inhibited the proliferation, migration, and invasion of liver cancer cells; interestingly, Cu enhanced this activity when combined with disulfiram; however, Cu alone did not [151]. In this regard, a phase I clinical trial determined the maximum tolerated dose of Cu administered with disulfiram in patients with liver cancer and found that 250 mg of daily Cu gluconate were well tolerated by these patients[152]. In the same study, temporary disease stabilization was observed in some patients, but there were no objective responses. Disulfiram can penetrate cancer cells and chelate intracellular Cu because Cu levels are elevated in many cancers. This action provides the advantage of specificity for cancer cells compared to healthy cells. Disulfiram might work as a Cu ionophore that induces oxidative stress by promoting reactive oxygen species (ROS) production, resulting in the inhibition of NF-kB[151], a transcription factor involved in the regulation of inflammatory processes and the development of liver injury, as well as HCC progression[153,154]. Blocking NF-kB signalling leads to an increase in ROS-induced toxicity and consequent cell apoptosis[155]. Furthermore, Thiery[156] found that inhibition of NF-kB signalling also resulted in inhibition of liver cancer cell metastasis by reversing the epithelial-to-mesenchymal transition (EMT), an important process in cancer metastasis in which NF-kB and TGF-β are important components[156]. Indeed, in this same study, disulfiram was found to inhibit TGF-kβ signalling. Interestingly, disulfiram plus Cu reversed EMT more effectively than disulfiram alone[151].

Most recently, Zhang *et al*[157] reported that disulfiram plus copper in combination with sorafenib resulted in increased anticancer activity against HCC under *in vitro* and *in vivo* conditions. Moreover, this combination synergistically inhibited the proliferation of human HCC cell lines and significantly increased autophagy and apoptosis compared to sorafenib alone. In addition, in a mouse orthotopic HCC xenograft model, the combination effectively inhibited tumour growth compared to the effect of sorafenib alone[157].

Clofazimine

The canonical Wnt/β-catenin signalling pathway is a crucial component during embryonic development and normal adult homeostasis because it participates in processes such as cell differentiation, polarity, migration, and apoptosis[158]. However, abnormal activation of this pathway (especially of the transcription factor β-catenin) has been linked to cellular malignant transformation

and promotion of carcinogenesis, and it is present in many types of cancer, including HCC[159-161]. Notably, mutations in the *CTNNB1* gene, which codes for β-catenin, are the most frequent mutations during HCC[162,163]. Interestingly, clofazimine, an anti-leprosy agent, could be useful for treating Wnt-dependent cancers. For instance, it has been shown to be effective against triple-negative breast cancer, both *in vitro* and *in vivo*, through inhibition of Wnt/β-catenin signalling[164,165]. Furthermore, Xu *et al* [166] demonstrated that clofazimine could effectively suppress HCC cell growth, inhibiting Wnt/β-catenin canonical signalling[166]. This drug has been evaluated for some years, and the results have suggested that it might work successfully as an antitumour agent. For example, Van Rensburg *et al*[167] found that it inhibited HCC cell line proliferation *in vitro*[167]. In addition, in a phase II clinical trial in patients with unresectable or metastatic liver cancer, 600 mg of this drug were administered daily for two weeks, followed by a dose reduction to 400 mg until progression or death. In this trial, 13 of 30 treated patients had disease stability for up to 20 mo, and the median OS was 13 wk[168]. Furthermore, a phase II clinical trial evaluated the combination of clofazimine plus doxorubicin in patients diagnosed with HCC. Although no patients showed complete or partial response, this combination showed only mild toxic effects, and the authors recommended further studies involving this antileprosy agent[169]. Overall, these trials provided strong evidence to suggest that clofazimine might be useful in treating HCC.

Albendazole

Albendazole is an antiparasitic agent used to treat parenchymal neurocysticercosis and other helminth infections by blocking parasite microtubules, leading to the inhibition of glucose uptake and transport and, ultimately, cell death[170]. Interestingly, this drug has been reported to possess antitumour activity and has been studied in different malignancies, including liver, lung, breast, prostate, and colorectal cancers and melanoma[171-175]. Pourgholami *et al*[176] evaluated the effect of this drug in several liver cancer cell lines and in mouse xenograft models (human SKHEP-1 tumour growth in nude mice), reporting that the drug induced dose-dependent inhibition of [^{3}H] thymidine incorporation in all the cell lines studied and a significant decrease in the number of SKHEP-1 cells significantly inhibiting tumour growth[176].

Pimozide

Pimozide is a dopamine receptor antagonist neuroleptic drug[177] that was approved by the FDA for the treatment of Tourette's syndrome and schizophrenia[178] and it has shown efficacy for the treatment of different types of cancer, such as breast cancer[179,180], prostate cancer[181], brain tumours[182], colorectal cancer[183], and chronic myelogenous leukaemia[184]. In liver cancer, pimozide effectively inhibited cell proliferation of HCC cell lines through disruption of Wnt/β-catenin signalling and reduction of epithelial cell adhesion molecule expression, a marker of both liver stem cells[185] and HCC tumour-initiating cells[186,187]. Furthermore, Chen *et al*[188] found that pimozide was able to inhibit cell proliferation, migration, colony formation, and sphere formation *in vitro* in HCC cell lines and stem-like cells by suppressing STAT3 activity. Additionally, pimozide reduced the tumour burden in a xenograft model in nude mice[188]. Moreover, the same research group found that the antiproliferative effects of pimozide on HCC cell lines were reversible and in line with the involvement of cell quiescence and ROS production. Interestingly, pimozide combined with sorafenib synergistically inhibited HCC cell proliferation *in vitro*[188].

Natamycin

Natamycin is a natural polyene amphoteric macrolide antibiotic with antifungal properties[189]. It has been reported to significantly inhibit the proliferation of prostate cancer cells[190]. Conversely, An *et al* [191] found that natamycin induced apoptosis and inhibited the proliferation of HCC cells by triggering excessive ROS production through the downregulation of peroxiredoxin 1 (PRDX-1). Additionally, they found that the combination of natamycin plus sorafenib exerted a synergistic effect on cell growth suppression compared to the effect of monotherapy[191].

Dysregulation of cellular redox systems is a critical feature of many types of cancer. Increased ROS play a fundamental role in the tumour microenvironment, activating important signalling pathways in carcinogenesis, such as MAPK/ERK, JNK, and PI3K/AKT, and in turn activating NF-kB, MMPs, and VEGF, consequently affecting angiogenesis, metastasis and cell survival in many types of cancer[192-194]. However, at significantly elevated ROS concentrations, cancer cells are able to develop antioxidant defence systems to maintain redox homeostasis and survive[195]. An example of this situation is the participation of the peroxiredoxin family, which consists of peroxidases that break down hydrogen peroxide, protecting the cancer cell from oxidative stress and consequently providing a survival advantage; thus, this family of enzymes are potential targets for tumour growth arrest and cancer therapy[196,197]. It is worth mentioning that the PRDX-1 isoform is the most abundant and positively regulated protein in different types of cancer, and its expression is associated with poor prognosis[198].

Valproic acid

Valproic acid is a drug that possesses anticonvulsant activity and is primarily indicated for the

treatment of epilepsy. However, it is also useful for treating migraine, bipolar disorder, anxiety, and psychiatric disorders[199]. The interest in testing the activity of this drug as an antineoplastic agent came from findings in human neuroblastoma models. This molecule was able to inhibit proliferation and induce differentiation of primitive neuroectodermal tumour cells *in vivo*, providing evidence for using valproic acid as a treatment for neuroblastoma patients[200]. Machado *et al*[201] reported the effect of this drug on human liver cancer cells both *in vitro* and *in vivo*. Valproic acid significantly inhibited cell proliferation in a dose-dependent manner, while in mouse xenograft models, it reduced tumour growth, in addition to negatively regulating Notch-1 mRNA levels[201]. Very recently, Bai *et al*[202] evaluated the effect of valproate in animal models of HCC in rats treated with DEN and found that this drug significantly reduced liver nodules and AFP levels, as well as other important liver enzymes, compared to rats treated with DEN alone. Additionally, valproate reduced inflammatory cytokines, such as TNF-α, IL-6, IL-1β, NF-kB and TGF-β1, in liver tissue[202].

Lee *et al*[203] took advantage of the benefits of combination therapy to evaluate the effects of cytokine-induced killer (CIK) cells with valproic acid. CIK cells are *ex vivo* expanded T lymphocytes expressing natural killer and T-cell markers that are used as adjuvant therapy to reduce HCC recurrence, yet CIK cell monotherapy is insufficient to treat advanced HCC[203-205]. Therefore, this research group determined whether treatment with CIK cells and valproic acid synergized to inhibit tumour growth in mouse models of HCC. After seven days of the combined treatment, there was a synergistic effect on relative tumour volume in the animals since the relative tumour volume in control animals was significantly increased[206].

Additionally, Yu *et al*[207] implemented a therapeutic strategy in HCC cells *in vitro* and *in vivo* that consisted of testing the combined effect of valproic acid with proton and photon irradiation. Histone deacetylase (HDAC) inhibitors, including valproic acid, have shown promising results in the treatment of different cancers[208-210]. However, their use as monotherapy has not been satisfactory, so using them in combination with another therapy is an appealing strategy. HDAC inhibitors can sensitize human cancer cells to ionizing radiation[211], which is a therapeutic strategy for cancer[212]. In a study by Yu *et al*[207], valproic acid prolonged DNA damage and increased proton-induced apoptosis and ROS formation while suppressing the expression of nuclear factor erythroid 2–related factor 2, a transcription factor involved in cellular antioxidant regulation. In tumour xenograft models, valproic acid significantly enhanced tumour growth retardation[207]. In addition, An *et al*[213] reported that valproic acid could induce cellular senescence in HCC cells through its role as an HDAC inhibitor[213].

ONGOING CLINICAL TRIALS USING ONCOLOGY AND NON-ONCOLOGY DRUGS

Table 4 summarizes the ongoing clinical trials for HCC patients. Immunotherapy is currently positioned as the most innovative pharmacological strategy to treat different types of cancer, including liver cancer. In addition, it is interesting to note that most of the ongoing HCC clinical trials are evaluating the effects of combination therapy and that drug repurposing is gaining tremendous interest, as non-oncology molecules are now being tested. Next, the non-oncology drugs used in ongoing clinical trials (Tables 3 and 4) are discussed.

Metformin

This drug is commonly used for the treatment of type 2 diabetes and was approved by the FDA in 1994. Metformin lowers glucose levels and improves insulin sensitivity[214]. Surprisingly, metformin has been shown to have antineoplastic activity in different types of cancer[83,215]. It is one of the most successful non-cancer drugs used in oncology. Several clinical trials are currently investigating the therapeutic potential of this drug in various cancers, including breast, prostate, endometrial, and colorectal cancer[216-219]. In the case of liver cancer, metformin has gained interest as an antineoplastic agent, given the increased risk of developing liver cancer in diabetic patients. Meta-analyses have reported that metformin has a beneficial effect on the incidence and/or survival of patients with liver cancer. For example, Ma *et al*[220] reported the association between metformin use and improved survival in diabetic patients with liver cancer[220]. Afterwards, the same research group reported a meta-analysis of 19 studies in diabetic subjects and suggested that metformin use reduced the proportion of liver cancer by 48% compared to non-users[221]. At the molecular level, metformin reduces insulin levels, activating the PI3K-mTOR signalling pathway and inhibiting cell proliferation in cancers expressing the insulin receptor[222]. Other mechanisms include negative regulation of mTOR *via* AMPK activation[223].

Ongoing clinical trials in HCC patients are evaluating the use of metformin in combination with other molecules, such as vitamin C (ClinicalTrials.gov identifier: NCT04033107), statins (ClinicalTrials.gov identifier: NCT02819869) and Celebrex (ClinicalTrials.gov identifier: NCT03184493).

Statins (atorvastatin)

Statins are agents that decrease the level of low-density lipoprotein cholesterol in the blood. They are specific inhibitors of the mevalonate pathway through inhibition of the conversion of 3-hydroxy-3-

Table 4 Ongoing clinical trials involving monotherapy, drug combination and non-oncology drugs

Study title	NTC number	Study design	Drugs	Status
Monotherapy				
Study of Pembrolizumab (MK-3475) as Monotherapy in Participants With Advanced Hepatocellular Carcinoma (MK-3475-224/KEYNOTE-224)	NCT02702414	Phase II, non-randomized, parallel assignment, open label	Pembrolizumab	Active, not recruiting
An Investigational Immuno-therapy Study of Nivolumab Compared to Sorafenib as a First Treatment in Patients With Advanced Hepatocellular Carcinoma	NCT02576509	Phase III, randomized, parallel assignment, open label	Nivolumab. Sorafenib	Active, not recruiting
Exploratory Study on Combined Conversion Immuno-therapy for Liver Metastasis of MSS Type Initial Unresectable Colorectal Cancer Based on Gene Status	NCT05409417	Phase II, III, single group assignment, open label	Experimental drug	Recruiting
First-in-Human Safety, Tolerability and Antitumour Activity Study of MTL-CEBPA in Patients With Advanced Liver Cancer	NCT02716012	Phase I, non-randomized, parallel assignment, open label	MLT-CEBPA. Sorafenib (200 mg)	Active, not recruiting
Drug combination				
A Phase III, Open-Label, Randomized Study of Atezol-izumab in Combination With Bevacizumab Compared With Sorafenib in Patients With Untreated Locally Advanced or Metastatic Hepatocellular Carcinoma (IMbrave150)	NCT03434379	Phase III, randomized, parallel assignment, open label	Atezolizumab. Bevacizumab. Sorafenib	Active, not recruiting
A Trial of Lenvatinib Plus Pembrolizumab in Participants With Hepatocellular Carcinoma	NCT03006926	Phase I, single group, open label	Lenvatinib. Pembrol-izumab (200 mg)	Active, not recruiting
A Study of Durvalumab or Tremelimumab Monotherapy, or Durvalumab in Combination With Tremelimumab or Bevacizumab in Advanced Hepatocellular Carcinoma	NCT02519348	Phase II, randomized, parallel assignment, open label	Tremelimumab. Durvalumab. Bevacizumab	Active, not recruiting
Pembrolizumab With or Without Elbasvir/Grazoprevir and Ribavirin in Treating Patients With Advanced Refractory Liver Cancer	NCT02940496	Phase II, non-randomized, parallel assignment, open label	Elbasvir/Grazoprevir. Pembrolizumab. Ribavirin	Active, not recruiting
Clinical Recruitment of Patients With First-line Targeted Drug Resistance or Intolerance to Hepatocellular Cancer With PD-1 Inhibitor (Toripalimab, JS001) Detected on the NGS Platform Combined With Anlotinib	NCT05453383	Phase II, single group assignment, open label	Anlotinib. Toripalimab	Recruiting
TACE Combined With Camrelizumab and Apatinib in the Treatment of Advanced Liver Cancer	NCT05550025	Phase II, single group assignment, open label	Camrelizumab. Apatinib	Recruiting
IBR900 Cell Injection Combined With Lenvatinib or Bevacizumab in the Treatment of Advanced Primary Liver Cancer	NCT05411757	Phase I, single group assignment, open label	IBR900. Lenvatinib. Bevacizumab	Not recruiting yet
Trial to Evaluate the Safety of Talimogene Laherparepvec Injected Into Tumors Alone and in Combination With Systemic Pembrolizumab MK-3475-611/Keynote-611	NCT02509507	Phase I, II, non-randomized, sequential assignment, open label	Talimogene. Laherparepvec. Pembrol-izumab	Active, not recruiting
HAIC Sequential TAE Combined With Lenvatinib and Tislelizumab in Unresectable HCC	NCT05532319	Phase II, single group assignment, open label	HAIC sequential TAE. Lenvatinib. Tislelizumab	Not recruiting yet
A Study of E7386 in Combination With Other Anticancer Drug in Participants With Solid Tumor	NCT04008797	Phase I, non-randomized, sequential assignment, open label	E7386. Lenvatinib	Recruiting
An Immuno-therapy Study to Evaluate the Effectiveness, Safety and Tolerability of Nivolumab or Nivolumab in Combination With Other Agents in Patients With Advanced Liver Cancer	NCT01658878	Phase I, II, parallel assignment, open label	Nivolumab. Sorafenib. Ipilimumab. Cabozantinib	Active, not recruiting
A Phase I Clinical Study of Recombinant Humanized Anti-BTLA Monoclonal Antibody (JS004) Injection Combined With Toripalimab Injection in Patients With Advanced Solid Tumors	NCT05427396	Phase I, single group assignment, open label	JS004. Toripalimab	Recruiting
mFOLFOX7 Plus Camrelizumab and Apatinib for Advanced HCC	NCT05412589	Phase II, single group assignment, open label	mFOLFOX7. Camrel-izumab. Apatinib	Recruiting
Trial of PXS-5505 Combined With First Line Atezolizumab Plus Bevacizumab For Treating Patients With Unresectable Hepatocellular Carcinoma	NCT05109052	Phase II, III, single group assignment, open label	PXS-5505. Atezolizumab. Bevacizumab	Not recruiting yet

Combination of Regorafenib and Nivolumab in Unresectable Hepatocellular Carcinoma	NCT04310709	Phase II, single group assignment, open label	Regorafenib. Nivolumab	Recruiting
Phase Ib Trial of Infigratinib In Combination With Atezolizumab And Bevacizumab for The Second-Line Treatment of Advanced Cholangiocarcinoma With FGFR2 Fusion/Amplification	NCT05510427	Phase I, randomized, single group assignment, open label	Infigratinib. Atezolizumab. Bevacizumab	Recruiting
A Study of TAK-500 With or Without Pembrolizumab in Adults With Select Locally Advanced or Metastatic Solid Tumors	NCT05070247	Phase I, non-randomized, parallel assignment, open label	TAK-500. Pembrolizumab	Recruiting
A Study of Nivolumab and Relatlimab in Combination With Bevacizumab in Advanced Liver Cancer	NCT05337137	Phase I, II, randomized, parallel assignment, quadruple (participant care, provider, investigator, outcomes assessor)	Relatlimab. Nivolumab. Bevacizumab	Recruiting
Drug repurposing				
High Dose Vitamin C Combined With Metformin in the Treatment of Malignant Tumors	NCT04033107	Phase II, single group assignment, open label	Vitamin C. Metformin	Recruiting
Statin Combination Therapy in Patients Receiving Sorafenib for Advanced Hepatocellular Carcinoma	NCT03275376	Phase II, randomized, parallel assignment, Quadruple (Participant, Care Provider, Investigator, Outcomes Assessor)	Atorvastatin	Terminated
The Combination Effect of Statin Plus Metformin on Relapse-free	NCT02819869	Phase II, randomized, parallel assignment	Statin. Metfotmin	Terminated
Statin for Preventing Hepatocellular Carcinoma Recurrence After Curative Treatment	NCT03024684	Phase IV, randomized, parallel assignment, triple masking (Participant, Care Provider, Investigator)	Atorvastatin	Recruiting
Meclizine for Hepatocellular Carcinoma	NCT03253289	Phase I, single group assignment, open label	Meclizine	Recruiting
Celebrex and Metformin for Postoperative Hepatocellular Carcinoma	NCT03184493	Phase III, non- randomized, parallel assignment	Celebrex plus metformin	Recruiting
Sorafenib Induced Autophagy Using Hydroxychloroquine in Hepatocellular Cancer	NCT03037437	Phase II, non-randomized, parallel assignment, open label	Sorafenib. Hydroxychloroquine	Recruiting

PD-1: Programmed cell death protein 1; HCC: Hepatocellular carcinoma.

methylglutaryl coenzyme A into mevalonate, which is responsible for cholesterol synthesis[224]. Interestingly, mevalonate signalling is deregulated in several types of cancer and is also involved in the process of tumorigenesis[225,226], making it a potentially useful target for cancer treatment. Preclinical trials have demonstrated that statins can be used as antitumour agents in colorectal cancer[227-229]. It was suggested that statins might reduce the risk of developing HCC[230]. Kim *et al*[231] reported that atorvastatin inhibited the activation of YAP (*via* the mevalonate pathway) and AKT (*via* stabilization of the truncated retinoid X receptor alpha pathway), which are involved in cancer development[231].

Ongoing clinical trials are evaluating the effects of statins in patients with advanced HCC, such as a trial evaluating atorvastatin in patients receiving treatment with sorafenib (ClinicalTrials.gov identifier: NCT03275376) and a clinical trial studying two non-oncology drugs-statins and metformin-either alone or in combination (ClinicalTrials.gov identifier: NCT03024684).

Celebrex

Celebrex (celecoxib) is a cyclooxygenase-2 (COX-2) selective non-steroidal anti-inflammatory drug indicated for the treatment of pain and inflammation caused by osteoarthritis, rheumatoid arthritis, and ankylosing spondylitis[232]. Interestingly, celecoxib anticancer activity is presumed to occur by inhibiting COX-2[233-235] because this cyclooxygenase isoform is frequently expressed in many types of cancer and promotes carcinogenesis and resistance of cancer cells to chemotherapy[236]. Dai *et al*[237] found that celecoxib also targets the RNA-binding protein ""partner of NOB1"" (PNO1) and exerts antitumour activity through the AKT/mTOR pathway[237]. In addition, PNO1 has been reported to participate in the progression of lung, oesophageal, breast, bladder, and colorectal cancer[238-242]. Targeting PNO1 (which is overexpressed in HCC tissues) can inhibit cell apoptosis by promoting autophagy through the ERK/MAPK signalling pathway[243].

A clinical trial is currently ongoing to compare the effect of Celebrex alone, metformin alone, and the combination of both drugs in preventing HCC recurrence after hepatic resection (ClinicalTrials.gov identifier: NCT03184493). In preclinical trials, it was shown that the combination of the two *in vitro* and

in vivo inhibited HCC proliferation more effectively than the effect of each drug alone[244].

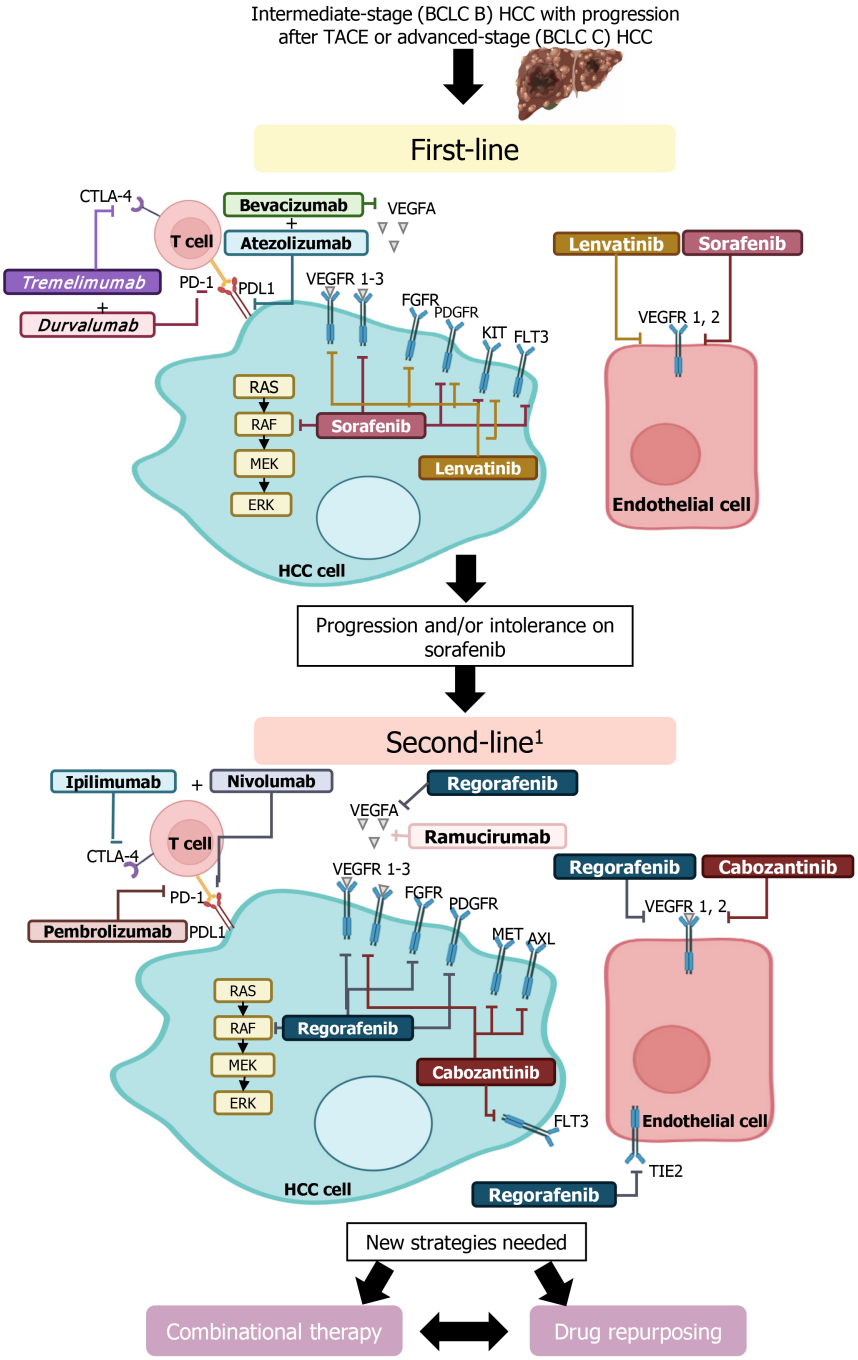
Hydroxychloroquine

Hydroxychloroquine is an antimalarial drug that has been evaluated as an antitumour agent in HCC and has even been used for the treatment of other cancers, either alone or in combination with other therapeutic agents[215,245]. This drug targets cancer cells and the tumour microenvironment; among its molecular mechanisms of action, it inhibits autophagosome-lysosome fusion and Toll-like receptor 9 (TLR9) signalling, along with TLR7, which are overexpressed in HCC and are involved in cell proliferation and inhibition of apoptosis[246]. Furthermore, Chen *et al*[247] reported that hydroxychloroquine and miRNA (hsa-miR-30a-5p) target and resensitize sorafenib-resistant HCC cells to sorafenib through impairment of autophagy and DNA damage by oxidative stress *via* the TLR9/SOD1/hsa-miR-30a-5p/Beclin-1 pathway[247]. Since one of the mechanisms of sorafenib resistance is the induction of autophagy, a prospective, phase II clinical trial is currently under way to evaluate the efficacy of sorafenib and hydroxychloroquine treatment in patients with advanced HCC (ClinicalTrials.gov identifier: NCT03037437).

PERSPECTIVES

The high mortality caused by liver cancer remains an important concern in oncology. Therefore, there is an urgent need to implement new therapeutic strategies to provide significant benefits in patients with advanced HCC.

Immunotherapy is a tool that has shown great promise in treating HCC. Nevertheless, it is necessary to continue developing immunotherapy agents, which increase understanding of the role of the immune response in the tumour and take advantage of this process.



In contrast, the use of combination therapy has shown very favourable results compared to the effect of monotherapy, reflected by the diversity of current clinical trials evaluating the impact of the combination of two or more agents in HCC. Drug combinations simultaneously targeting relevant signalling pathways in liver carcinogenesis provide at least four potential advantages: (1) Anticancer synergistic effects; (2) minimization of treatment resistance; (3) reduction of individual drug doses; and (4) the occurrence of minimal adverse events. These advantages should facilitate HCC treatment, making it extremely important to consider possible future drug combinations to achieve greater benefits for HCC patients.

Furthermore, growing evidence has supported that non-cancer drugs possess antineoplastic activity. In emergency situations such as cancer, drug repurposing can be a very useful strategy. Compared to the traditional process of developing new drugs, drug repurposing allows for the rapid and less costly discovery of new treatments, increasing the likelihood of success with the advantage that safety issues in humans have already been described. It is crucial to mention that drug repurposing does not replace the traditional process; both are extremely important. However, repurposing non-oncology drugs is an attractive strategy to obtain more treatment options for advanced HCC.

Simultaneously, implementing non-oncology drug repurposing and proposing combinations of non-oncology drugs with systemic therapy or immunotherapy are very attractive strategies to generate significant benefits in patients with unresectable HCC. In addition, new relevant signalling pathways, critical drug targets, and biomarkers of this cancer might be identified along the way, providing significant advantages for understanding liver carcinogenesis.

CONCLUSION

Currently, approved drug options for treating advanced HCC are limited, and the likelihood of generating resistance is high, making the use of novel pharmacological approaches urgent (Figure 2). Compared to monotherapy, this review demonstrated that combining therapies has resulted in more significant benefits for HCC patients. Furthermore, evidence has been provided indicating that several non-oncology drugs are potentially useful for the treatment of this cancer. In addition, immunotherapy has significant effects in some cases compared to current systemic therapy, making this approach, along with repositioning and combination therapy, promising for the pharmacological treatment of advanced liver cancer.

Figure 2 Pharmacological strategies for the treatment of advanced hepatocellular carcinoma. When a patient is diagnosed with hepatocellular carcinoma either intermediate (BCLC B) or advanced (BCLC C) stage, surgical and locoregional therapeutic options are no longer indicated. In these cases, the most appropriate treatment option is systemic therapy with first-line treatments with sorafenib and lenvatinib as the initial drugs. However, if the patient develops resistance to sorafenib or disease progression after therapy, treatment with second-line drugs indicated in the schedule is initiated. It is important to note that immunotherapy using monoclonal antibodies is already part of the current and approved drug options. Because current drug treatments are limited and monotherapy is ineffective, the implementation of combination and drug repositioning are two therapeutic strategies to achieve more and better treatments. [1]All agents require prior sorafenib use. BCLC: Barcelona Clinic Liver Cancer; TACE: Transarterial chemoembolization; CTLA-4: Cytotoxic T-lymphocyte-associated protein 4; PD-1: Programmed cell death protein 1; VEGFR: Vascular endothelial growth factor receptor; FGFR: Fibroblast growth factor receptor; PDGFR: Platelet-derived growth factor receptors; HCC: Hepatocellular carcinoma.

Abstract

Colonoscopy has been shown to be an effective modality to prevent colorectal cancer (CRC) development. CRC reduction is achieved by detecting and removing adenomas, which are precursors of CRC. Most colorectal polyps are small and do not pose a significant challenge for trained and skilled endoscopists. However, up to 15% of polyps are considered "difficult", potentially causing life-threatening complications. A difficult polyp is defined as any polyp that is challenging for the endoscopist to remove owing to its size, shape, or location. Advanced polypectomy techniques and skills are required to resect difficult colorectal polyps. There were various polypectomy techniques for difficult polyps such as endoscopic mucosal resection (EMR), underwater EMR, Tip-in EMR, endoscopic submucosal dissection (ESD), or endoscopic full-thickness resection. The selection of the appropriate modality depends on the morphology and endoscopic diagnosis. Several technologies have been developed to aid endoscopists in performing safe and effective polypectomies, especially complex procedures such as ESD. These advances include video endoscopy system, equipment assisting in advanced polypectomy, and closure devices/techniques for complication management. Endoscopists should know how to use these devices and their availability in practice to enhance polypectomy performance. This review describes several useful strategies and tips for managing difficult colorectal polyps. We also propose the stepwise approach for difficult colorectal polyps.

Key Words: Adenoma; Colonic polyps; Colonoscopy; Endoscopic mucosal resection; Endoscopic submucosal dissection; Polypectomy

Core Tip: Most colorectal polyps are small and do not pose a significant challenge to resection. However, up to 15% of polyps are considered "difficult" because of their size, shape, or location. Advanced polypectomy techniques and skills are required for the resection of difficult colorectal polyps. Recent advancements in techniques and devices for endoscopic mucosal resection, endoscopic submucosal dissection, and endoscopic full-thickness resection allow curative therapy of these difficult polyps and avoid unnecessary surgery that carries the risk of morbidity and mortality. However, the proper selection of adjunct endoscopic devices/techniques and stepwise training for skill improvement are critical for successful advanced polypectomy.

INTRODUCTION

In 2020, colorectal cancer (CRC) was the fourth most common malignancy worldwide, with 1.9 million new cases recorded[1]. Colonoscopy has been shown to be an effective modality to prevent CRC development. Previous studies have shown a 60%-90% reduction in CRC incidence after screening colonoscopy[2,3]. CRC reduction is achieved by detecting and removing adenomas, which are precursors of CRC. Most colorectal polyps detected during colonoscopy are small, benign, and easily resected by skilled endoscopists. However, 10%-15% of colorectal polyps are classified as "difficult" colorectal polyps[4,5]. Generally, difficult colorectal polyps are defined as any polyps that are technically challenging for endoscopic resection because of their size (> 20 mm), morphology (pedunculated polyp with a thick stalk, laterally spreading tumor), or location (ileocecal valve, appendiceal orifice, dentate line)[5,6].

Endoscopic resection of difficult polyps is associated with an increased risk of incomplete resection and serious adverse events, including intra-procedural massive bleeding and perforation. Therefore, difficult polypectomy should be performed or supervised by an experienced endoscopist. This review describes helpful strategies and tips for dealing with difficult colorectal polyps.

THE STEPWISE APPROACH FOR DIFFICULT COLORECTAL POLYPS

Lesion assessment

The first step in managing colorectal polyps is lesion assessment. Dye-based chromoendoscopy and image-enhanced endoscopy (IEE) with magnifying observation should be used to distinguish benign lesions, adenomas, and adenocarcinomas. Dye-based chromoendoscopy with indigo carmine and crystal violet enables pit pattern diagnosis based on Kudo's classification[7]. However, IEE techniques such as narrow-band imaging (NBI) and blue laser imaging are more common than chromoendoscopy in clinical practice outside Japan. IEE can diagnose lesions by visualizing surface patterns and microvessels based on the NBI International Colorectal Endoscopic (NICE) and Japan NBI Expert Team (JNET) classification[8,9] (Table 1). The accuracy of discriminating non-neoplastic from neoplastic lesions was 95% for magnifying observation with IEE and 96%-98% for pit pattern observation with chromoendoscopy, while the accuracy for discriminating adenomas from adenocarcinomas was 70%-90% for both IEE and chromoendoscopy[10].

Colorectal cancers with submucosal invasion have a 7%-14% risk of lymph node metastasis[11-14]. For submucosal cancers, it is crucial to differentiate between superficial (< 1000 μm) and deep submucosal invasive (≥ 1000 μm) cancer. Current evidence strongly supports the theory that superficial cancer with submucosal invasion < 1000 μm without lymphovascular invasion, grade 2/3 tumor budding, or poorly differentiated component have no risk of lymph node metastasis[15,16]. A Japanese study suggested that magnifying chromoendoscopy with crystal violet is the best modality for estimating the invasion depth in early colorectal lesions. Matsuda *et al*[17] found that the diagnostic accuracy of the invasive pattern in magnifying chromoendoscopy with crystal violet to differentiate superficial (< 1000 μm) and deep submucosal invasive (≥ 1000 μm) cancers was 98.8%. Patients with submucosal invasive cancer should undergo radical colectomy considering the risk of nodal metastasis, whereas patients with adenoma or cancer with submucosal superficial invasion are candidates for endoscopic resection. It should be noted that experienced examiners performed magnifying chromoendoscopy in this study; therefore, the effectiveness of magnifying chromoendoscopy should be revalidated in general endoscopists. Togashi *et al*[18] reported a minimum experience of observing 200

Table 1 The Japan Narrow-band Imaging Expert Team classification[8]

	Type 1	Type 2A	Type 2B	Type 3
Vessel pattern	Invisible	Regular caliber, regular distribution (meshed/spiral pattern)	Variable caliber, irregular distribution	Loose vessel areas, interruption of thick vessels
Surface pattern	Regular dark or white spots, similar to surrounding normal mucosa	Regular (tubular/branched/papillary)	Irregular or obscure	Amorphous areas
Suspected pathology	Hyperplastic polyp/sessile serrated polyp	Low grade intramucosal neoplasia	High grade intramucosal neoplasia/shallow submucosal invasive cancer	Deep submucosal invasive cancer

lesions with magnifying chromoendoscopy is needed to understand pit pattern diagnosis. Moreover, the limited availability of crystal violet outside Japan makes this approach difficult to apply in clinical practice.

Identification of the causes of difficult polypectomy

Table 2 shows the causes of difficult polypectomy. The difficulty might arise from the size, location, morphology, or other specific conditions. Possible solutions for each complex polyp character or situation are described in the following subsections.

The Size, Morphology, Site, Access (SMSA) classification system has been proposed by Gupta *et al*[19] for stratifying lesion complexity (Table 3). This stratifies polyps into 4 levels of difficulty, with level 1 being the easiest to resect by all endoscopists and level 4 being very difficult to resect. Longcroft-Wheaton *et al*[20] validated the SMSA system in a prospective study of 220 lesions ≥ 20 mm in diameter. They found that lesions with SMSA level 4 had higher complication rates (8.6% *vs* 0%, $P = 0.007$) and lower complete resection rates (87.5% *vs* 97.5%, $P = 0.009$) than the lesions with SMSA level 2 and 3. European Society of Gastrointestinal Endoscopy guideline for colorectal polypectomy and endoscopic mucosal resection (EMR) recommends using the SMSA system to assess large and complex polyps. If the lesions have SMSA level 4, they should be resected by experts at a high-volume tertiary care center [21].

Basic techniques of colorectal polypectomy

Endoscopists should have the appropriate basic skills to conduct a colorectal polypectomy. First, looping on the colonoscope should be unwound by shortening before performing polypectomy; otherwise, colonoscope manipulation would be paradoxical and troublesome. Second, endoscopists should position the polyp at 5-6 o'clock on the monitor because the instrument exits the colonoscope channel at 5 o'clock (Figure 1A). Finally, the base of the polyp, particularly that of a pedunculated polyp, should lie opposite to gravity. Polyp stretching by gravity improves the visualization of the polyp base, and this maneuver prevents blood pooling at the resected site (Figure 1B and C).

Selection of therapeutic modality for large colorectal polyps

The selection of the appropriate modality from various polypectomy techniques depends on the morphology and endoscopic diagnosis. Large pedunculated polyps are mainly resected by polypectomy with a prophylactic strategy against bleeding. The selection of a therapeutic modality for large non-pedunculated polyps, mostly laterally spreading tumors (LSTs), is highly debated. LST is defined as a lesion ≥ 10 mm in diameter, extending laterally with a low vertical axis[22]. The comparison between EMR and endoscopic submucosal dissection (ESD) is an important issue for large LSTs. ESD has higher *en bloc* resection and lower recurrence rates than EMR because the snare EMR method tends to result in piecemeal resection for large lesions[23,24]. Moreover, ESD allows accurate histopathologic diagnosis regarding the depth of invasion without segmentation of the carcinomatous part, which compromises the pathological diagnosis[25]. Nevertheless, colorectal ESD is one of the most challenging endoscopic procedures with high complications. The learning curve of colorectal ESD is steep, with approximately 80 procedures required to gain proficiency in large polyp resection[26]. Recently, Tip-in EMR was proposed as a promising modified EMR technique for the resection of large nonpedunculated polyps [27,28]. After the submucosal injection, the snare tip with a cut current was used to make a spot-shaped mucosal incision at the proximal side of the tumor. The small incision helps fix the snare tip in the submucosal layer during the snare placement; therefore, endoscopists could place the snare flexibly and repeatedly in the appropriate position. Takada *et al*[29] compared Tip-in EMR with ESD for the resection of 20- to 30-mm nonpedunculated polyp using propensity score matching. They found that Tip-in EMR had a lower *en bloc* resection (85% *vs* 99%, $P < 0.001$) and R0 resection rates (63% *vs* 91%, $P < 0.001$) than ESD; however, Tip-in had a shorter procedural time (8 min *vs* 60 min, $P < 0.001$) and comparable local recurrence rate (2% *vs* 0%, $P = 0.386$). They concluded that Tip-in EMR could be a feasible alternative to ESD for 20- to 30-mm nonpedunculated polyps.

Table 2 Characteristics of the difficult colorectal polyps

Size	> 20 mm
Location	Near or involving the appendiceal orifice
	Ileocecal valve
	Anorectal junction
	Behind the fold
	Angulated segment
Morphology	Pedunculated polyp with thick stalk and large head
	Laterally spreading tumor
	Submucosal fibrosis or positive non-lifting sign
Special situation	Recurrent lesion
	Strong colonic peristalsis

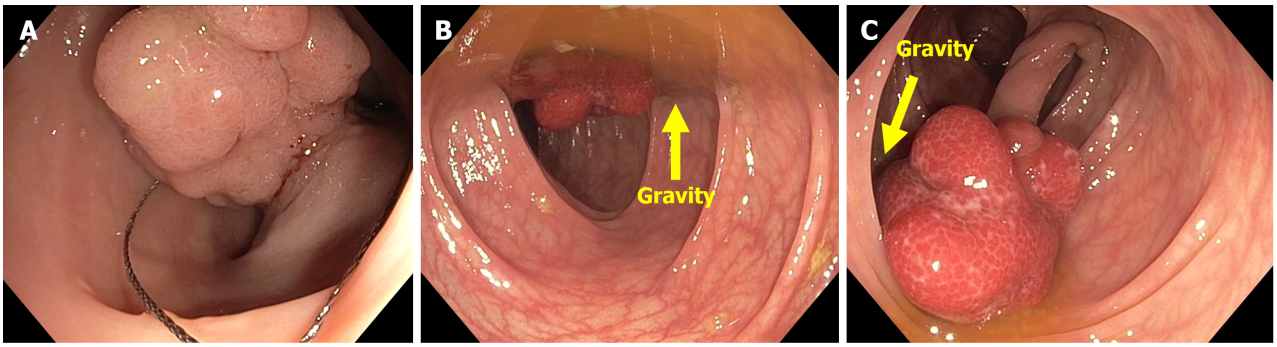
Table 3 Size/Morphology/Site/Access scoring system[19]

Parameter	Range	Score
Size	< 1 cm	1
	1.0-1.9 cm	3
	2.0-2.9 cm	5
	3.0-3.9 cm	7
	> 4 cm	9
Morphology	Pedunculated	1
	Sessile	2
	Flat	3
Site	Left	1
	Right	2
Access	Easy	1
	Difficult	3

Size/Morphology/Site/Access (SMSA) level 1: 4-5 points, level 2: 6-8 points, level 3: 9-12 points, level 4: > 12 points.

LST is classified as granular type (LST-G), which has a nodular surface, or non-granular type (LST-NG), which has a smooth surface. These two types have different patterns of submucosal invasion. In a large retrospective cohort study by Yamada *et al*[30], 19% of the LST-G cases had submucosal invasion; the invasion site was the large nodule in 56%, the depression area in 28%, and multifocal in 16%. LST-NG showed 39% submucosal invasion, and the invasion site was 10% at submucosal mass-like elevation, 45% at depression, or 45% multifocal. Because of the substantial risk of multifocal submucosal invasion, ESD is warranted for LST-NG, and *en bloc* resection is required for large LST-G nodules. Table 4 shows the indications for colorectal ESD suggested by the 2020 Japan Gastroenterological Endoscopy Society (JGES) guidelines for colorectal ESD and EMR[10].

APPROACHES TO DIFFICULT POLYPECTOMY IN SPECIFIC SITUATIONS



Pedunculated polyp with thick stalk and large head

The risk of bleeding after polypectomy of large pedunculated polyps with thick stalk increases due to the possibility of large blood vessels in the stalk. A prospective study found that pedunculated polyps with stalk diameter > 5 mm and polyp size > 17 mm are risk factors for post-polypectomy bleeding[31]. Therefore, prophylactic strategies against bleeding should be implemented prior to polypectomy.

Table 4 Indications for colorectal endoscopic submucosal dissection[10]

	Lesions requiring *en bloc* resection
1	Lesions which *en bloc* resection with EMR is difficult
	LST-NG, particularly LST-NG with pseudo-depressed type
	Lesions with V_I-type pit pattern
	Carcinoma with shallow T1 invasion
	Large depressed-type tumor
	Large protruded-type lesions suspected to be carcinoma
2	Mucosal tumors with submucosal fibrosis
3	Sporadic tumors in conditions of chronic inflammation such as ulcerative colitis
4	Local residual or recurrent early carcinomas after endoscopic resection

EMR: Endoscopic mucosal resection; LST-NG: Laterally spreading tumor non-granular type.

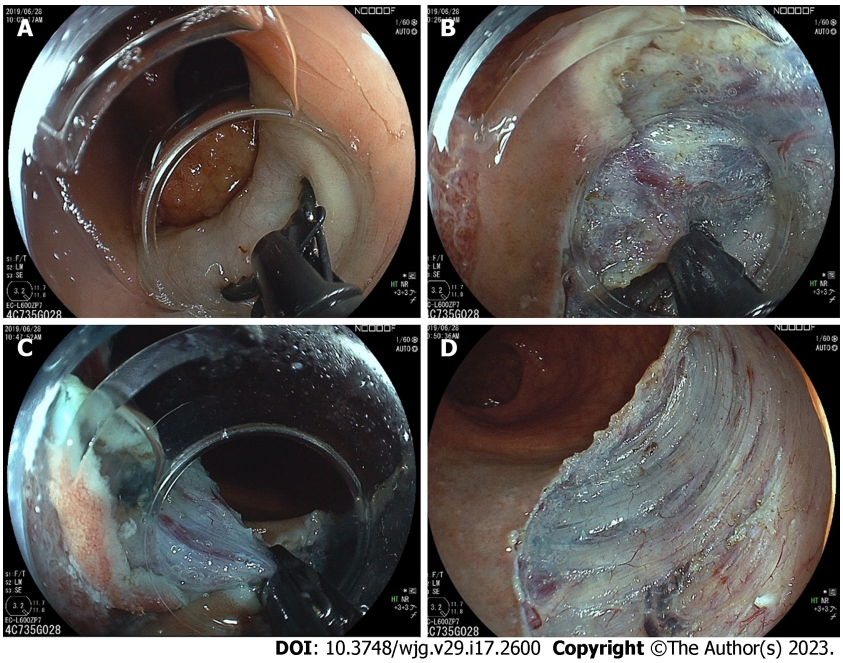
Figure 1 Basic maneuvers of polypectomy. A: Positioning the polyp at 5-6 o'clock on the monitor before polypectomy; B: The polyp's base lying on gravity, this leads to poor visualization of the resection area; therefore, the patient's position should be altered; C: The polyp's base lying opposite to gravity after changing the patient's position. This position change allows polyp stretching and avoids blood pooling on the resected site.

A randomized controlled trial (RCT) by Dobrowolski *et al*[32] found that colorectal polyps ≥ 1 cm that underwent prophylactic adrenaline injection at the stalk before polypectomy had a lower immediate bleeding rate than conventional polypectomy (2% *vs* 16%, $P < 0.05$). In contrast, another RCT by Lee *et al*[33] revealed no statistical difference in immediate and delayed post-polypectomy bleeding rates between the prophylactic adrenaline injection and control groups.



A detachable snare (endoloop) was developed by Hachisu to prevent post-polypectomy bleeding from large pedunculated polyps[34]. A nylon-thread loop is tightened around the polyp stalk to ensure hemostasis before polypectomy (Figure 2). Three RCTs confirmed that a detachable snare effectively prevents post-polypectomy bleeding in large colorectal polyps[35-37]. However, endoloop placement might not be possible for all polyps, especially those with a large head or a short stalk. A previous study reported an 8.3% failure rate in endoloop placement[37]. Although the largest available endoloop has an opening diameter of 30 mm, it is floppy and challenging to place at the stalk of large polyps. Moreover, the polyp stalk will be shortened after endoloop tightening; therefore, endoloop-assisted polypectomy might not be suitable for polyps with short stalks due to the possibility of incomplete resection. A case series reported successful ESD for large pedunculated polyps with failed endoloop placement using a scissor-type knife[38], which allows precise dissection with targeted hemostasis. With a scissor-type knife, the tissue and vessels could be grasped between two blades and pre-coagulated before cutting (Figure 3). In addition, a case report described successful ESD with a scissor-type knife for a large pedunculated polyp with a short, thick stalk[39].

Prophylactic clip application at the thick stalk before polypectomy may prevent post-polypectomy bleeding (Figure 4). Soh *et al*[40] conducted an RCT of 137 pedunculated polyps ≥ 1 cm in 116 patients and found that prophylactic clip application before polypectomy significantly decreased immediate bleeding compared with conventional polypectomy [odds ratio (OR): 0.22; 95% confidence interval (95%CI): 0.08-0.57]. The delayed bleeding rate did not differ between the two groups. However, this technique is difficult to apply to polyps with a short thick stalk due to the risk of incomplete resection, and endoscopists should be aware of transmural burns from electrical current conducted by the

endoscopic clip.

A meta-analysis of 15 RCTs involving 3,462 patients found that both prophylactic adrenaline injection and mechanical therapy reduced the risk of early post-polypectomy bleeding [injection therapy, risk ratio (RR): 0.32; 95%CI: 0.11-0.67; mechanical therapy: RR: 0.13; 95%CI: 0.03-0.37], although no prophylactic therapy decreased the risk of delayed bleeding[41]. In conclusion, prophylactic therapy, including adrenaline injection, detachable snare, or clipping, should be performed before the resection of a pedunculated polyp with a thick stalk or large head. However, detachable snare placement or prophylactic clipping may not be possible for polyps with a short, thick stalk, which may be suitably resected using ESD.

Polyps involving the appendiceal orifice

Endoscopic resection of polyps involving the appendiceal orifice is technically challenging because of the poor-lifting nature of submucosal fibrosis, thin cecal wall, and inability to access the lesion extending deep into the appendiceal orifice. Traditionally, these polyps have been managed surgically. However, recent advances have allowed endoscopists to perform a safe endoscopic resection for these polyps.

A Japanese retrospective study revealed the safety and effectiveness of ESD for the treatment of polyps involving the appendiceal orifice. For a total of 76 lesions, the authors reported a 95.0% *en bloc*

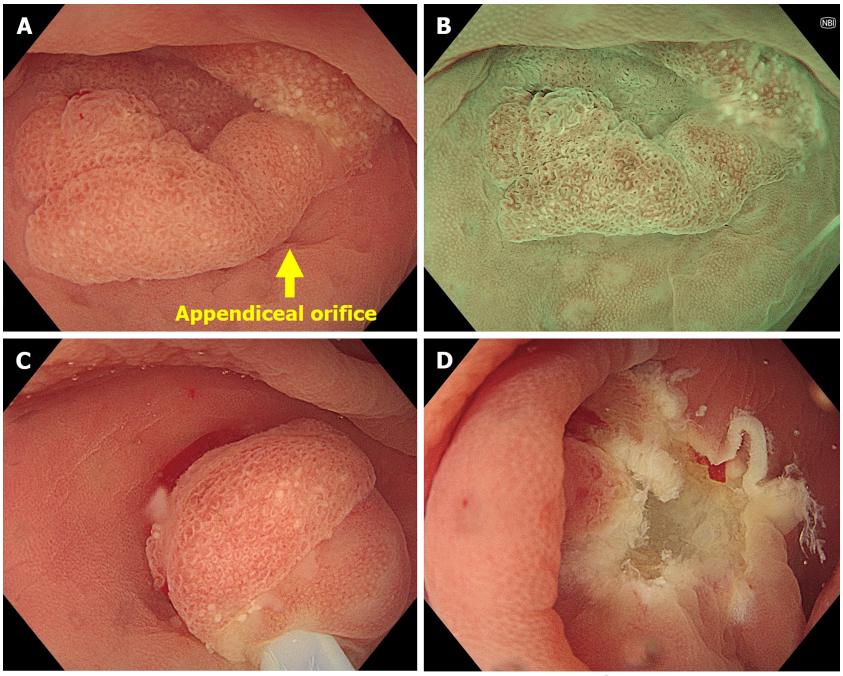
Figure 4 Prophylactic clip application at the stalk before polypectomy. A: A pedunculated polyp with a thick stalk and large head. There were failed attempts placing the endoloop due to the large polyp head; B: Clip application before snaring; C: No bleeding evidence after the resection.

resection rate, 1.3% perforation, and 2.6% post-ESD appendicitis rate. However, they excluded patients with lesions deeply involving the orifice and without a history of appendectomy. The authors emphasized that ESD should be performed by experienced and skilled endoscopists in this situation[42].

Binmoeller *et al*[43] suggested the usefulness of underwater endoscopic mucosal resection (UEMR) without submucosal injection for polyps involving the appendiceal orifice. With a water-filled lumen, the floating effect facilitated snare capture (Figure 5). They reported an 89% success ratio for UEMR in 27 polyps involving the appendiceal orifice (rim, 5 patients; extending deep inside, 22 patients). There was no perforation or post-resection appendicitis; however, 7% of the patients had post-polypectomy syndrome. During surveillance, 10% of the patients had residual adenomas that could be treated endoscopically.



Endoscopic full-thickness resection (EFTR) has recently been employed for difficult polyps and is another suitable modality for polyps involving the appendiceal orifice. In a multicenter retrospective study, Schmidbaur *et al*[44] found that EFTR achieved R0 resection in 64% of 50 lesions involving the appendiceal orifice. However, 14% of patients developed acute appendicitis, and 42% of those with appendicitis required appendectomy. Similarly, a multicenter retrospective study by Ichkhanian *et al*[45], including 66 appendiceal orifice lesions (61% polyps extending deep into the appendiceal lumen) with a mean size of 14.5 mm, found that EFTR achieved an 89% technical success ratio and 93% R0 resection of the neoplastic lesions. Post-resection appendicitis occurred in 17% of patients without a prior history of appendectomy, and 60% (six patients) required appendectomy. Even with the promising outcomes of EFTR, the authors of both studies emphasized that patients must be counseled about the risk of post-resection appendicitis.

In summary, ESD is a viable option for polyps involving the rim of the appendiceal orifice for experienced endoscopists. However, ESD may not be feasible for lesions with a deep extension into the appendiceal orifice. UEMR is also a decent modality that is less technically demanding and has a high success rate. For lesions with deep extension into the appendiceal orifice, EFTR is the suitable option due to the high R0 resection rate. However, patients must be counseled regarding the risk of post-resection appendicitis.

Polyps on the ileocecal valve

Polyps on the ileocecal valve are technically challenging for endoscopic resection because the valve shape and orifice make it difficult to approach the lesions. Moreover, lesions may extend from the valve orifice to the terminal ileum. Therefore, resection is extremely difficult and associated with a high risk of recurrence[46]. A large retrospective study revealed a high complete resection rate (76.3%) of piecemeal EMR for polyps on the ileocecal valve, and the rate increased to 93.0% in the most recent eight years. Delayed bleeding and perforation occurred in 3.3% and 0% of the patients, and residual polyps were found in 16.5% and 18.6% during the first and second surveillance, respectively. They suggested four EMR keys for polyps on the ileocecal valve: (1) Use of a high-definition colonoscope; (2) use of a cap on the distal end of the scope; (3) inclusion of a dye in the injection fluid; and (4) initiating injection at the margin of the polyp with the valve orifice[47].

ESD for polyps on the ileocecal valve may be necessary for lesions suspected to be early carcinomas. However, ESD in this area is technically challenging because of the valve anatomy and composition. The ileocecal valve has abundant submucosal fatty tissue; consequently, the colonoscope lens often becomes cloudy during dissection. Yoshizaki *et al*[48] found no difference in the *en bloc* resection and perforation rates between ESD of lesions involving the ileocecal valve and lesions that did not involve it. Lesions involving the ileocecal valve were reported to have a 97% *en bloc* resection rate without perforation. The authors highlighted the critical steps for successful ESD. The mucosal incision should be started on the ileal side of the tumor to prevent the tumor from prolapsing into the terminal ileum.

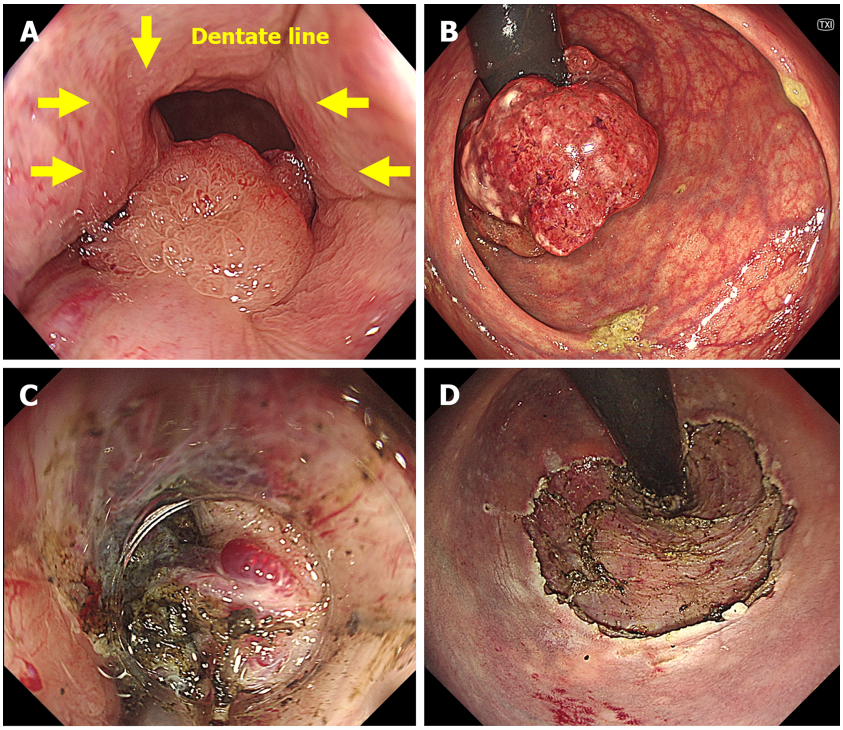
Figure 5 Underwater endoscopic mucosal resection for a polyp involving appendiceal orifice. A: Endoscopic image showing a 15-mm sessile polyp involving the appendiceal orifice; B: Magnifying narrow-band image showing a type 1 polyp of the Japan Narrow-band Imaging Expert Team classification with open pit pattern. The most likely diagnosis was sessile serrated lesion; C: Underwater snaring without submucosal injection; D: Mucosal defect after completed underwater endoscopic mucosal resection.



For areas with abundant submucosal fatty tissue, the electrical setting should be changed from the forced coagulation mode to the endocut or swift coagulation mode to enhance tissue cutting. Recently, Tanaka *et al*[49] conducted a study to evaluate the outcomes of ESD for polyps of the ileocecal valve with extension into the terminal ileum. They found that ESD of lesions with or without extension into the terminal ileum showed no difference in the *en bloc* resection rate (95% *vs* 94%, $P = 0.79$), R0 resection rate (90% *vs* 89%, $P = 0.89$), postoperative bleeding (5% *vs* 3%, $P = 0.79$), intraoperative perforation (0% *vs* 4%, $P = 0.34$), or delayed perforation (0% *vs* 0%, respectively). Therefore, ESD for polyps involving the ileocecal valve with extension into the terminal ileum is safe and effective in expert hands.

Polyps at the anorectal junction

Polyps close to the dentate line can be challenging to resect because of the risk of bleeding from the hemorrhoids. Polypectomy in this area is painful due to the sensory nerves in the squamous epithelium below the dentate line. Moreover, the anatomy of the anal sphincter makes it difficult to maintain good visualization[50]. For polyps at the anorectal junction that are indicated for ESD, Imai *et al*[51] proposed the following strategies: (1) Using a cap on the distal end of the scope to maintain good visualization in the narrow space of the anal canal; (2) addition of 1% lidocaine to the submucosal injection solution to prevent pain; (3) employing a horizontal approach with an endoscopic knife to minimize thermal damage to the muscular layer; and (4) performing preventive hemostasis when thick hemorrhoidal vessels are observed. With these strategies, they reported an *en bloc* resection rate of 95.6% and an R0 resection rate of 53.3%. The low R0 resection rate was due to burning artifacts on the anal side of the specimens. They reported a 4.4% perforation and a 2.2% postoperative bleeding rate. Tamaru *et al*[52] investigated the outcomes of ESD for polyps at the anorectal junction in patients with and without hemorrhoids. They found no differences in *en bloc* resection (93% *vs* 95%) or postoperative bleeding (16% *vs* 11%) rates between patients with and without hemorrhoids. Therefore, ESD is safe and effective for patients with lesions near the anorectal junction and hemorrhoids. Similarly, several studies have shown the safety and effectiveness of ESD for polyps at the anorectal junction[53-55]. In conclusion, ESD for polyps at the anorectal junction is safe even in the presence of hemorrhoids, and special strategies to prevent bleeding and pain should be implemented (Figure 6).

Locally recurrent colorectal polyps

Locally recurrent polyps mostly result from incomplete resections. A systematic review and meta-analysis found that local recurrence after EMR of non-pedunculated polyps occurred in 3% of *en bloc* resections and 20% of piecemeal resections, and 90% of recurrences were detected within 6 mo after EMR[56]. Locally recurrent polyps without risk factors for lymph node metastasis and positive vertical margins can be resected endoscopically[57]. However, endoscopic resection of locally recurrent polyps

DOI: 10.3748/wjg.v29.i17.2600 **Copyright** ©The Author(s) 2023.

Figure 6 Endoscopic submucosal dissection for a polyp involving the anorectal junction. A: Endoscopic image showing a 6-cm laterally spreading tumor involving the dentate line; B: Retroflexed view of the same polyp; C: Hemorrhoidal plexus at the anus makes the endoscopic submucosal dissection (ESD) challenging with the bleeding risk; D: Mucosal defect after completed ESD.

is extraordinarily challenging because it is associated with poor lifting with submucosal injection from submucosal fibrosis[58].

The 2020 JGES guidelines for colorectal ESD and EMR suggest that local recurrence of early carcinoma after endoscopic resection is an indication of ESD[10]. A Japanese retrospective study revealed that ESD had a higher *en bloc* resection rate than EMR for locally recurrent lesions (56% *vs* 39%, respectively), although the lesions in the ESD group were significantly larger than those in the EMR group (mean size; 25.3 mm *vs* 7.8 mm, $P = 0.001$)[59]. Perforations were not observed in the ESD group. However, this study was conducted at a single center with expertise in ESD. ESD for locally recurrent lesions is technically demanding and requires high operator skills. It is noted that the *en bloc* resection rate of locally recurrent polyps was much lower than their previous report of colorectal ESD (168/200 patients, 84%)[60]. Ide *et al*[61] conducted a retrospective study comparing ESD with the pocket-creation method using a traction device and conventional ESD for locally recurrent lesions. They found that ESD using the pocket-creation method with a traction device had higher *en bloc* resection and R0 resection rates than conventional ESD (100% *vs* 78%, $P = 0.008$, and 97% *vs* 66%, $P=0.001$, respectively). Therefore, the combination of the pocket creation method and traction device is a promising strategy for the resection of locally recurrent polyps.

UEMR without submucosal injection has been reported as a promising technique for the salvage treatment of recurrent adenomas. Fibrosis prevents elevation of the recurrent lesion after submucosal injection, while the surrounding normal mucosa still elevates around the non-lifting lesion after the injection. This makes snare capture difficult. The floating effect after UEMR facilitates snare capture with minimal risk of perforation because the colonic muscularis propria remains circular with a water-filling lumen. Kim *et al*[62] conducted a retrospective, cross-sectional study involving patients with recurrent adenomas after piecemeal resection of colorectal LSTs. They found that the *en bloc* resection and complete resection rates were higher in the UEMR group than in the EMR group (47.2% *vs* 15.9%, $P = 0.002$, and 88.9% *vs* 31.8%, $P < 0.001$, respectively). The recurrence rate on surveillance colonoscopy was lower in the UEMR group than in the EMR group (10.0% *vs* 39.4%, $P = 0.020$). In this study, UEMR was an independent predictor of *en bloc* resection and complete removal.

In summary, ESD and UEMR are the appropriate modalities for treating locally recurrent colorectal polyps. Previous studies have shown a higher *en bloc* resection rate with ESD than with UEMR and ESD using the pocket-creation method and a traction device is a promising strategy for locally recurrent polyps. However, ESD for locally recurrent lesions is only suitable for centers with high ESD expertise because it is technically difficult, even with advances in ESD devices and techniques. In extremely difficult cases, endoscopists may consider surgery if the anticipated risk of complications is too high.

Polypectomy in patients with strong colonic peristalsis

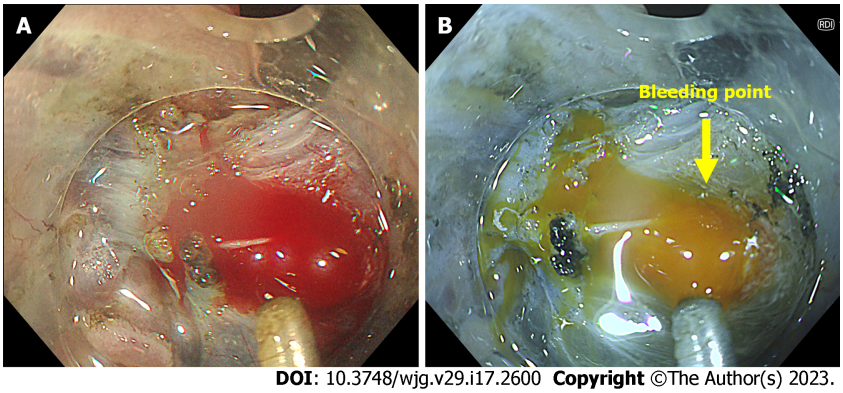
Strong colonic spasm is a common obstacle during colorectal polypectomy, limiting visualization and scope manipulation. In this situation, endoscopists generally use antispasmodic drugs. Hyoscine butylbromide is the most common antispasmodic agent in practice, and the recommended dose is 20 mg *via* intravenous injection. Hyoscine butylbromide exerts an antimuscarinic anticholinergic effect that reduces the smooth muscle tone at multiple sites in the gastrointestinal tract. Contraindications of hyoscine butylbromide include cardiovascular disease, glaucoma, myasthenia gravis, and hypersensitivity to the drug[63]. In patients with these contraindications, other antispasmodic agents, including glucagon or peppermint oil, should be administered. The dose of glucagon is 1 mg *via* intravenous injection, which is contraindicated in patients with pheochromocytoma[64]. Peppermint oil was administered *via* intraluminal application of 20 mL of 1.6% L-menthol solution without contraindications[65]. Topical lidocaine, a local anesthetic, also functions as an antispasmodic agent by blocking the Na^+ channels. It was administered *via* the intraluminal application of 30 mL of 2% lidocaine hydrochloride. An RCT found no difference in the inhibitory duration between topical lidocaine and peppermint oil; however, topical lidocaine significantly decreased rebound spasm[66].

In specific situations with intense colonic spasms, even with the administration of antispasmodic drugs, UEMR may be a decent modality. Another advantage of the water-filled lumen in UEMR is the stabilized visualization of the lumen. Pattarajierapan *et al*[67] reported successful UEMR for rectal adenoma in the non-distensible rectum due to severe fecal incontinence and intense colonic peristalsis. Therefore, UEMR may be a suitable option for patients with intense colonic spasms who have failed medication.

RECENT ADVANCES IN POLYPECTOMY DEVICES AND TECHNIQUES

Several technologies have been developed to aid endoscopists in performing safe and effective polypectomies, especially complex procedures such as ESD. These advances include video endoscopy system, equipment assisting in advanced polypectomy, and closure devices/techniques for complication management. Endoscopists should know how to use these devices and their availability in practice to enhance polypectomy performance, particularly in challenging cases.

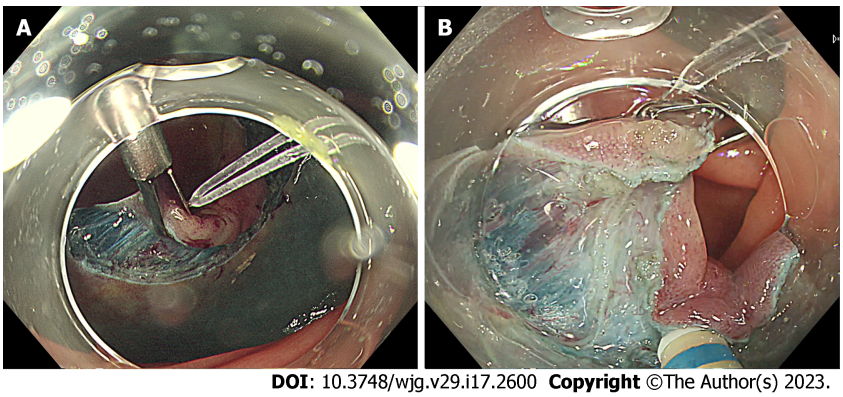
Video endoscopy system



Red dichromatic imaging (RDI) was recently installed in the latest Olympus endoscopy system EVIS X1. RDI utilizes two long-wavelength lights (600 nm and 630 nm), which improve the visibility of thick blood vessels in deep tissues[68,69]. Therefore, easier identification of bleeding sources during polypectomy is expected in the RDI mode (Figure 7). Fujimoto *et al*[69] conducted an RCT comparing hemostatic procedures using RDI and white-light imaging (WLI). Although they found that RDI did not shorten the hemostatic time, it significantly reduced psychological stress compared to WLI. They concluded that it is safe and reasonable to use the RDI during hemostatic procedures to reduce the psychological stress experienced by endoscopists.

Equipment assisting advanced polypectomy

Although ESD has been widely accepted as a standard procedure for colorectal polyps that require *en bloc* resection, a limited number of endoscopists outside East Asia are competent owing to the difficulty of the method[70]. Colorectal ESD is more technically demanding than gastric or esophageal ESD because of its thin colonic wall and narrow colonic lumen, as well as peristalsis and respiratory movement. In addition to good training with experienced endoscopists, the recent development of traction devices and techniques may facilitate the procedure. The lack of traction during dissection contributes to the technical difficulty of ESD; therefore, various traction devices and techniques have been proposed (Figure 8). These devices include the clip-line method[71], S-O clip[72], double clips and rubber band traction[73], and traction wire[74]. To date, there have been no head-to-head comparisons of these traction devices, and the traction method has been selected based on tumor location and preference[75]. The clip-line method is helpful for rectal lesions but may not be feasible for colon lesions. For colonic ESD, endoscopists can use an S-O clip, double clips and rubber band traction, or traction wire. Without traction devices, ESD using the pocket creation method is a special technique that maintains a stable scope position inside the pocket while sustaining good traction[76,77]. This technique starts with an initial small mucosal incision, the creation of a submucosal pocket under most of the tumor, and then the completion of opening the pocket in a step-by-step manner.



Closure devices and techniques for complication management

Perforation is the most feared complication of polypectomy. With advances in closure devices, most perforations after polypectomy can be closed endoscopically, thereby eliminating the need for surgery, which is associated with morbidity and mortality[78]. Endoscopic closure devices can be classified into through-the-scope clips (TTSC), over-the-scope clips (OTSC), and suturing devices. Useful modified

Figure 7 Bleeding during endoscopic submucosal dissection. A: Endoscopic image in white light imaging showing the bleeding from the large vessels of the polyp; B: Identification of bleeding sources during polypectomy is easier in the Red Dichromatic Imaging (RDI) mode. RDI mode also reduces the endoscopists' psychological stress by turning the blood color yellow.

techniques in TTSC include the hold-and-drag closure technique using reopenable clips[78], mucosal incision method[79], endoloop-assisted clip closure[80], over-the-line clip method[80], and dual-action clip closure[81]. To date, no RCT has compared these closure techniques after colorectal polypectomy. Modified techniques in TTSC help close defects larger than the width of the clips. Therefore, endoscopists should learn these modified techniques, which are feasible for their centers because they may occasionally be necessary.

The OTSC system is a super-elastic nitinol clip that must be mounted at the end of an endoscope before deployment. This results in full-thickness closure of the teeth arranged in a bear-trap shape[78]. The reported successful closure rate for iatrogenic colon perforation for OTSC is 89%-100%[82-85]. However, the limitations of OTSC include lower success rates in the right colon compared with the left side and limited availability.

Endoscopic suturing is a promising method for defect closure with a 100% success rate in a report of 16 patients[86]. The endoscopic suturing device consists of a curved needle placed on the endoscope tip, a catheter-based suture anchor, and an operating handle attached to the neck of the instrument channel of the endoscope[87]. Limitations to the suturing device include the requirement of a double-channel endoscope and special training in endoscopic suturing to become competent in this technique. In addition, endoscopic suturing devices are expensive and limited in availability.

CONCLUSION

Recent advancements in EMR, ESD, and EFTR techniques and devices allow curative therapy of difficult colorectal polyps and prevent unnecessary surgery that carries the risk of morbidity and mortality. Moreover, these advancements also help endoscopists cope with feared complications, such as massive intra-procedural bleeding and perforation. However, proper selection of adjunct endoscopic devices/techniques according to polyp characteristics and step-by-step training for skill improvement are critical for successful advanced polypectomies. Based on current evidence, we summarize the stepwise

Figure 9 Stepwise approach for difficult colorectal polyps.

approach (Figure 9) that might help endoscopists make better decisions for the treatment of difficult colorectal polyps.

Abstract

BACKGROUND

Cryptotanshinone (CPT) has wide biological functions, including anti-oxidative, antifibrosis, and anti-inflammatory properties. However, the effect of CPT on hepatic fibrosis is unknown.

AIM

To investigate the effects of CPT treatment on hepatic fibrosis and its underlying mechanism of action.

METHODS

Hepatic stellate cells (HSCs) and normal hepatocytes were treated with different concentrations of CPT and salubrinal. The CCK-8 assay was used to determine cell viability. Flow cytometry was used to measure apoptosis and cell cycle arrest. Reverse transcription polymerase chain reaction (RT-PCR) and Western blot analyses were used to measure mRNA levels and protein expression of endoplasmic reticulum stress (ERS) signaling pathway related molecules, respectively. Carbon tetrachloride (CCL_4) was used to induce *in vivo* hepatic fibrosis in mice. Mice were treated with CPT and salubrinal, and blood and liver samples were collected for histopathological examination.

RESULTS

We found that CPT treatment significantly reduced fibrogenesis by modulating

the synthesis and degradation of the extracellular matrix *in vitro*. CPT inhibited cell proliferation and induced cell cycle arrest at the G2/M phase in cultured HSCs. Furthermore, we found that CPT promoted apoptosis of activated HSCs by upregulating expression of ERS markers (CHOP and GRP78) and activating ERS pathway molecules (PERK, IRE1α, and ATF4), which were inhibited by salubrinal. Inhibition of ERS by salubrinal partially eliminated the therapeutic effect of CPT in our CCL_4-induced hepatic fibrosis mouse model.

CONCLUSION
CPT can promote apoptosis of HSCs and alleviate hepatic fibrosis through modulating the ERS pathway, which represents a promising strategy for treating hepatic fibrosis.

Key Words: Hepatic fibrosis; Endoplasmic reticulum stress; Cryptotanshinone; Hepatic stellate cells; Apoptosis

Core Tip: Hepatic fibrosis is a necessary stage of liver cirrhosis, and there is currently no effective treatment. Cryptotanshinone (CPT), one of the extracts of Chinese herbal medicine Radix Salviae Miltiorrhizae, has a good anti-fibrosis effect. Through this study, we found that CPT can treat hepatic fibrosis by activating endoplasmic reticulum stress and leading to apoptosis of hepatic stellate cells, which provides a new method for the treatment of hepatic fibrosis.

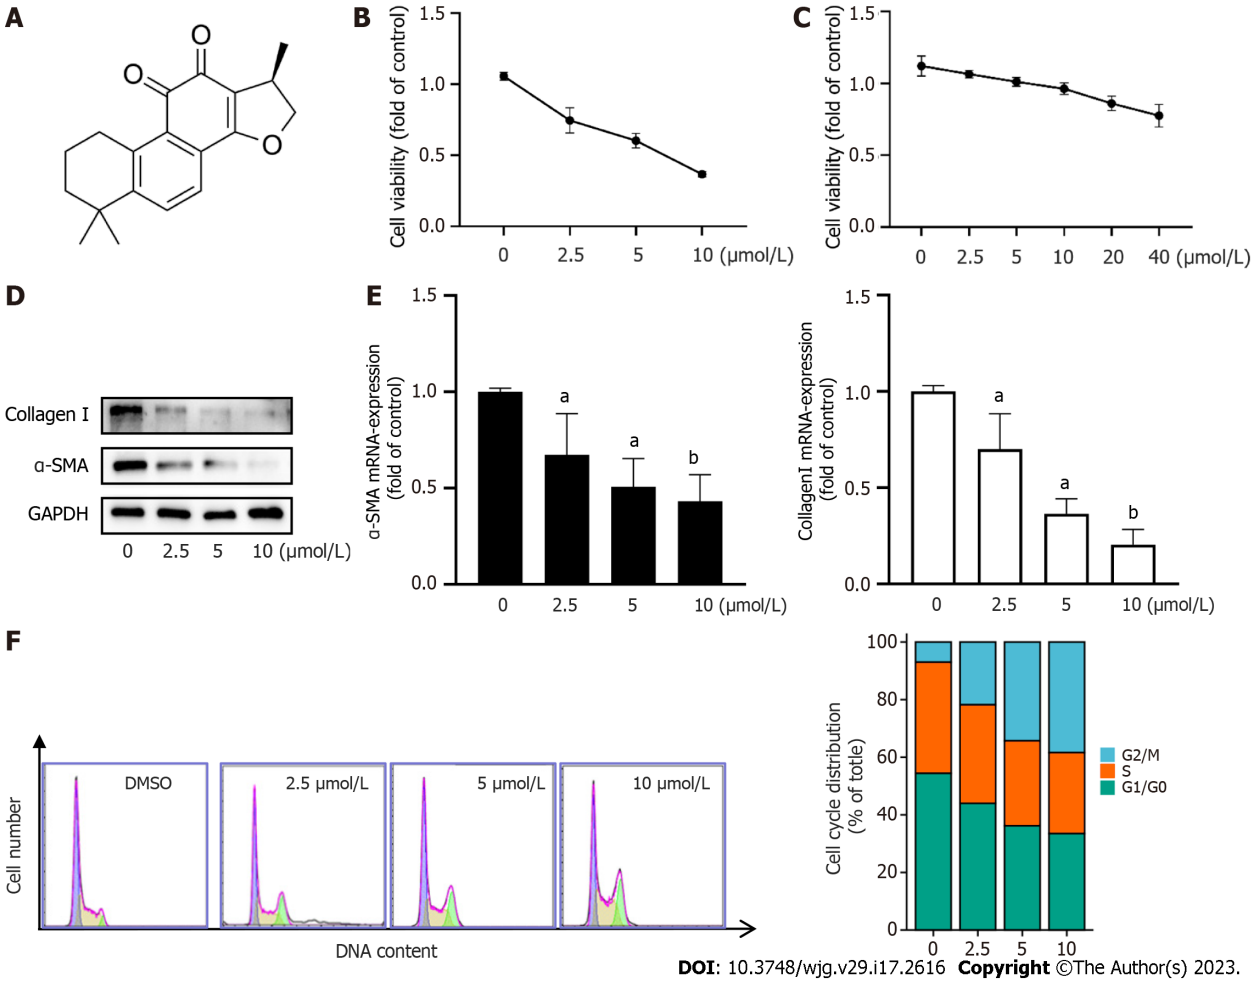
INTRODUCTION



Hepatic fibrosis is a reversible liver injury that occurs in response to viruses, drugs, inflammation, fat deposition, and other causes. The underlying pathological mechanism of hepatic fibrosis involves the deposition of extracellular matrix (ECM), which leads to the replacement of functional liver parenchyma by scar tissue, proliferation and activation of hepatic stellate cells (HSCs), and increased production of collagen and unfolded proteins[1-3]. The endoplasmic reticulum (ER) is an important organelle in eukaryotic cells that is involved in a variety of biological processes, including protein synthesis, processing, modification, folding, and transport, lipid and carbohydrate metabolism, and Ca^{2+} maintenance, among others[4-6]. In some cases, when the physiological function of the ER is disturbed, ER stress (ERS) will be activated to promote cell survival. However, persistent ERS can lead to apoptosis [7,8], which can either promote the occurrence and development of hepatic fibrosis or lead to the activation of HSCs, which can reverse the transformation of hepatic fibrosis[2,9-11].

Cryptotanshinone (CPT) is a diterpene quinone compound that is isolated from Salvia miltiorrhiza. CPT has been shown to have anti-oxidant, anti-inflammatory, and antibacterial properties[12]. Studies have also reported that CPT antifibrotic effects on cardiac and renal tissues[13-15]. These findings suggest that CPT plays a protective role in fibrotic disease. Therefore, we hypothesized that CPT might also protect against hepatic fibrosis. In this study, we treated LX2 cells with different concentrations of CPT and found that cell viability decreased and apoptosis increased in a dose-dependent manner. We also found that expression of proteins related to ERS increased, and inhibiting ERS decreased the apoptosis rate. Based on our findings, we speculate that CPT promotes apoptosis of HSCs through modulating the ERS pathway.

MATERIALS AND METHODS

Reagents and antibodies

CPT (purity ≥ 98% purity by HPLC, Cat No. HY-N0174), were purchased from Med Chem Express LLC (Shanghai, China) (Figure 1A). Primary antibodies for α-SMA, Collagen I, eIF2α, p-eIF2α, p-PERK, PERK, IRE1-α, BAX, BCL2, CHOP, and GRP78/BIP and all secondary antibodies were purchased from Proteintech (China). ATF4, and XBP1 were purchased from Sigma (United States). The primers used in

quantitative reverse transcription polymerase chain reaction (qRT-PCR) were purchased from Qingke Co. Ltd. (China) (Table 1).

Animals and experimental procedures

All experiments were approved by institutional and local committees. All mice were provided humane care according to the National Institutes of Health (NIH, United States) guidelines[16]. Male C57BL/6 mice (20-25 g) were randomly divided into five groups (n = 8 per group). Group 1 (vehicle control) did not receive carbon tetrachloride (CCL_4) or CPT treatment. Group 2 (model group) received CCL_4. Group 3 received intraperitoneal injections of salubrinal (1 mg/kg). Group 4 received CCL_4 followed by intraperitoneal injections of CPT (40 mg/kg). Group 5 received simultaneous intraperitoneal injections of salubrinal and CPT. Groups 2, 3, 4, and 5 were administered CCL_4 twice a week for 8 wk to induce hepatic fibrosis. Groups 3, 4, and 5 were intraperitoneally injected with CPT or salubrinal every day from 5 wk to 8 wk. CPT and salubrinal were dissolved in physiological saline. After 8 wk of treatment, blood samples and livers were collected. Livers were fixed in 4% buffered paraformaldehyde for histological (hematoxylin and eosin) and Western blot analyses.

Cell culture

The HSC LX2 cell line was donated by Professor Wenting Li. Cells were cultured in high-sugar DMEM medium with 10% fetal bovine serum (FBS) in an incubator at 37 °C[17].

qRT-PCR analysis

RNA was extracted from the LX2 cells using an RNA extraction kit (Biyuntian, China) according to the kit's instructions. The Stepone system was used for qRT-PCR, and the experiment was repeated three times to calculate the mRNA levels of the target genes.

Western blot analysis

RIPA buffer containing protease and phosphatase inhibitors was used to lyse cells and tissues on ice. Proteins were electrophoresed and transferred to PVDF membranes (Millipore, United States), which were blocked with 5% bovine serum albumin for 2 h. Subsequently, the membranes were incubated with primary antibodies at 4 °C overnight, followed by incubation with second antibodies at room temperature for 2 h. Finally, the PVDF membranes were washed using 1% TBST and detected by the Bio-Rad ChemiDoc Touch Imaging System.

Enzyme-linked immunosorbent assay

Serum levels of interleukin (IL)-6 and IL-10 were determined using enzyme-linked immunosorbent assay (ELISA) kits (LinkTech Biotechnology, China) according to the manufacturer's instructions. The absorbance was observed at 450 nm using a full-wavelength microplate reader.

Transmission electron microscopy

LX2 cells were treated with CPT for 24 h, gently scraped with a cell scraper, washed with PBS three times, precipitated, centrifuged, and fixed overnight with an electron microscopy fixative. The fixed cells were imaged using a transmission electron microscope (Tokyo, Japan).

Biochemical analysis

Serum levels of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) were measured using a liver function analysis kit (Nanjing Chengjian Institute of Bioengineering, China) according to the kit's instructions. The absorbance was measured using an enzyme-labeled instrument.

Cell proliferation assay

The Cell Counting Kit 8 (CCK-8) kit (Biyuntian, China) was used to assay cell proliferation. LX2 cells were inoculated into a 96-well plate at 3000 cells per well and cultured overnight at 37 °C. After 24 h cells were treated with CPT at different concentrations, and 10 μL of the CCK-8 solution was added to each well. The cells were cultured at 37 °C for 2 h. The absorbance of each well was measured at 450 nm using a microplate reader.

TUNEL staining

LX2 cells were inoculated into a 24-well plate. After the cells attached, DMSO, CPT, or salubrinal was added for 24 h. A TUNEL staining kit (Biyuntian, China) was used to detect apoptotic cells according to the kit's instructions. Cell apoptosis was observed with a fluorescent microscope (Nikon).

Flow cytometry analysis of cell cycle and apoptosis

LX2 cells were inoculated into a 6-well plate at a density of 2×10^4 cells/well. On the following day, the cells were treated with CPT at different concentrations for 24 h. Cell cycle was measured using a cell cycle kit (KeyGen Biotech). Cell apoptosis was determined using Annexin V and propidium iodide double staining with fluorescein isothiocyanate. The percentage of apoptotic cells was determined using flow cytometry (FACS Calibur)[17].

Statistical analysis

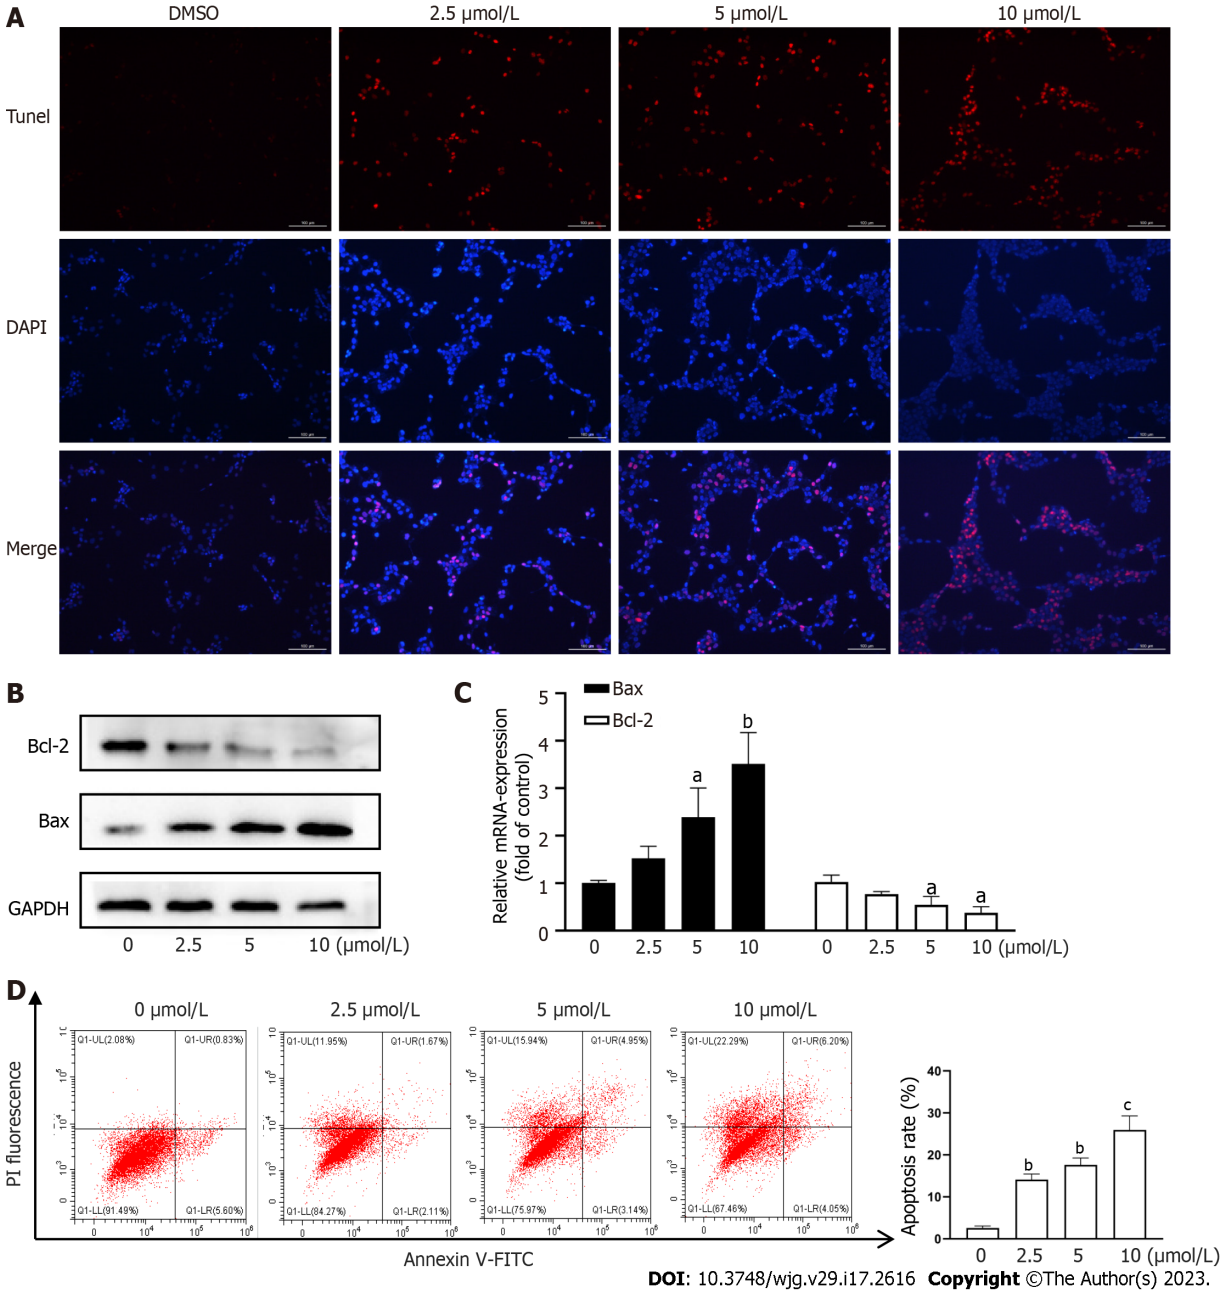
Experimental data were graphed using Prism 9.0 and statistically analyzed using SPSS26.0. Statistical significance of differences was determined using one-way analysis of variance with the post-hoc Dunnett's test. A P value of <0.05 was considered statistically significant.

RESULTS

CPT inhibits the proliferation of LX2 cells

Hepatic fibrosis is characterized by progressive and excess accumulation of ECM, leading to disruption of normal liver structure and function. HSC activation is a key cellular event in the pathogenesis of hepatic fibrosis[18,19]. In this study, we sought to determine the effects of CPT on hepatic fibrosis. To do so we first investigated the effect of CPT on cell viability. We treated LX2 cells with varying concentrations of CPT (0, 2.5, 5, 10, and 20 μmol/L) for 24 h and assessed cell proliferation using the CCK-8 assay. The results showed that CPT significantly reduced cell viability in a dose-dependent manner (Figure 1B). We also observed that CPT inhibited the vitality of normal hepatocytes (L02) at 40 μm (Figure 1C), which was far in excess of the concentration that affected HSC viability. To further observe the inhibitory effect of CPT on activated LX2 cells *in vitro*, we examined ECM accumulation under different concentrations of CPT. We found that CPT reduced ECM deposition (Figure 1D and E). To further investigate the inhibitory effect of CPT on cell growth, we measured cell cycle distribution using flow cytometry. Cell cycle analysis showed that the number of cells in the G2/M phase significantly increased while those in the G1 phase significantly decreased with higher concentrations of CPT (Figure 1F). Collectively, these findings suggest that CPT can induce HSC growth.

CPT stimulates apoptosis of activated HSCs



Apoptosis of activated HSCs has been shown to reduce the degree of hepatic fibrosis[2,3]. We assessed HSC apoptosis using TUNEL staining and found that CPT induced activated HSC apoptosis in a dose-dependent manner (Figure 2A). We next explored the pathway underlying CPT-induced HSC apoptosis. We observed that CPT dose-dependently reduced Bcl-2/Bax expression in HSCs (Figure 2B and C). We quantitatively evaluated the apoptotic rate using flow cytometry, which demonstrated that CPT dose-dependently increased the apoptotic rate in activated HSCs (Figure 2D). These data indicate that CPT activates HSC apoptosis.

CPT activates the ERS pathway

ERS is a signaling response pathway intended to protect against cell death. However, if the stress response is very strong or prolonged, it can cause cellular damage[20]. We investigated the underlying mechanism of CPT-induced HSC apoptosis by detecting ERS-related mediators. We found that CPT significantly upregulated the mRNA levels and protein expression of GFR78 and CHOP in LX2 cells, resepectively (Figure 3A and B). Subsequently, we examined the expression of GFR78 and CHOP in L02 cells and found that their expression was not significantly altered (Figure 3C and D). These results suggest that CPT promotes ERS in activated HSCs without triggering ERS in normal liver cells. Western blot analysis revealed that CPT significantly upregulated protein expression of ERS regulatory molecules (Figure 3E and F). We also observed the expansion and swelling of the ER lumen in CPT-treated HSCs using electron microscopy. More specifically, we observed a disappearance of the normal sheet-like folded structure and the formation of numerous vacuoles within the ER (Figure 3G).

CPT-induced apoptosis of HSCs requires ERS activation

Salubrinal, an inhibitor of ERS, can protect HSCs from ERS-induced apoptosis[20]. Based on the above experimental results, we next investigated if activation of ERS by CPT leads to apoptosis of LX2 cells. To test this hypothesis, we treated LX2 cells with both CPT and salubrinal and found that CPT did not significantly upregulate the mRNA and Western blot levels of GFR78 and CHOP (Figure 4A and B). We also measured the expression of ECM components at the mRNA and protein levels. Interestingly, The

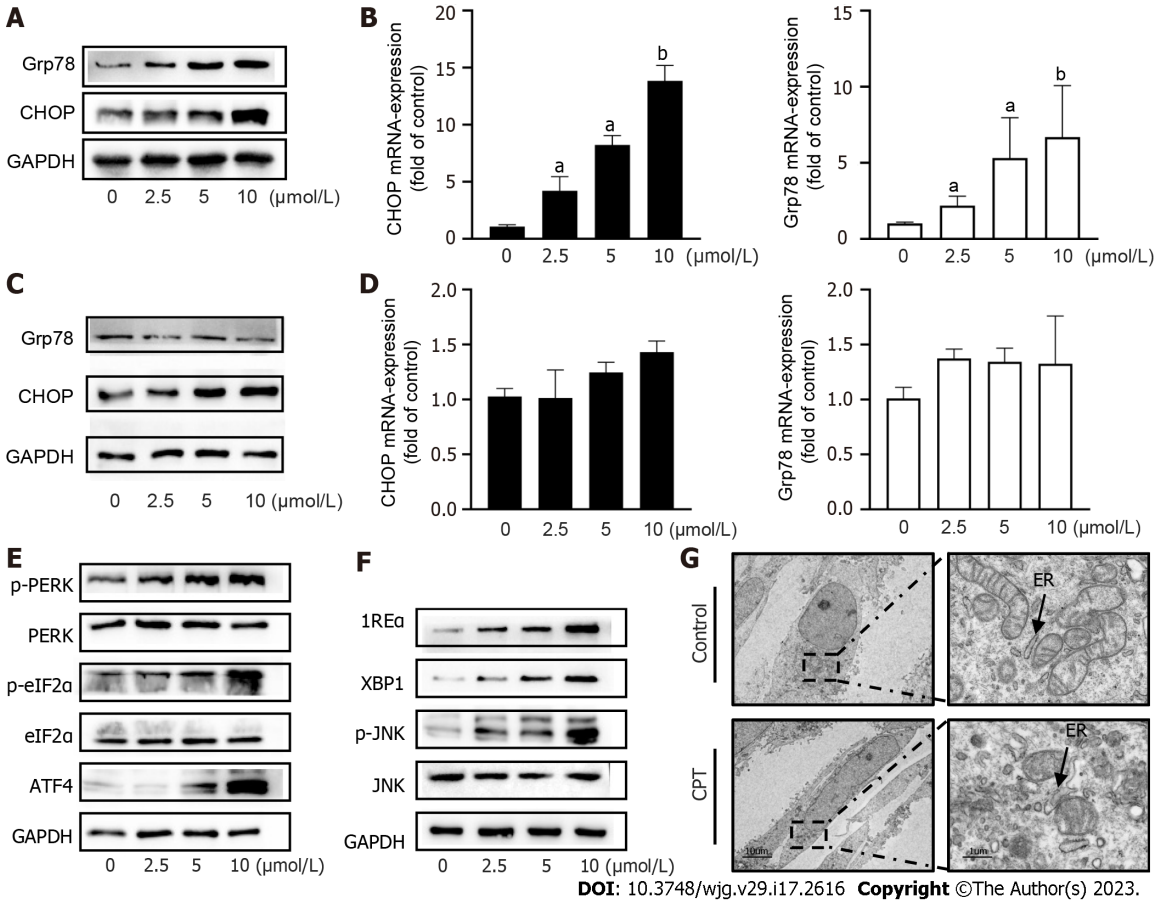
Figure 2 Cryptotanshinone induces apoptosis of activated hepatic stellate cells. A: TUNEL staining to assess LX2 apoptosis. Red fluorescence indicates apoptotic cells. Scale baes: 100μm; B: Western blot analysis of Bcl-2 and Bax protein expression in LX2 cells; C: Reverse transcription polymerase chain reaction analysis of Bcl-2 and Bax mRNA levels in LX2 cells; D: Flow cytometric analysis of LX2 cell apoptosis using fluorescein isothiocyanate-labeled Annexin-V/propidium iodide staining. Cells located in the right two quadrants of each figure were considered apoptotic cells. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$ versus control.

decrease of ECM accumulation following CPT treatment was prevented by salubrinal (Figure 4C and D). These results suggest that CPT can activate ERS, leading to apoptosis of LX2 cells, which may be a mechanism to promote HSC clearance. We found that the apoptotic effect of CPT on activated LX2 cells could be reversed by salubrinal (Figure 4E-H). Taken together, these findings suggest that CPT can induce apoptosis of HSCs through modulating ERS, which may be a mechanism for promoting HSCs clearance.

CPT protects mice from CCL_4-induced hepatic fibrosis

CCl_4-induced hepatic fibrosis is a well-established model to investigate hepatic fibrosis *in vivo*. We used this model to confirm the protective effect of CPT in mice(Figure 5A). To this end, we measured protein expression of major markers of hepatic fibrosis including α-SMA and collagen I. CPT effectively diminished expression of these proteins in the CCL_4-induced model of hepatic fibrosis (Figure 5B). In addition, we analyzed biochemical markers of liver injury after 8 wk of CCL_4 treatment. Levels of AST and ALT increased in the model group but were reduced in the CPT groups (Figure 5C and D). During chronic liver disease, hepatic fibrogenesis is commonly accompanied by inflammation. As demonstrated



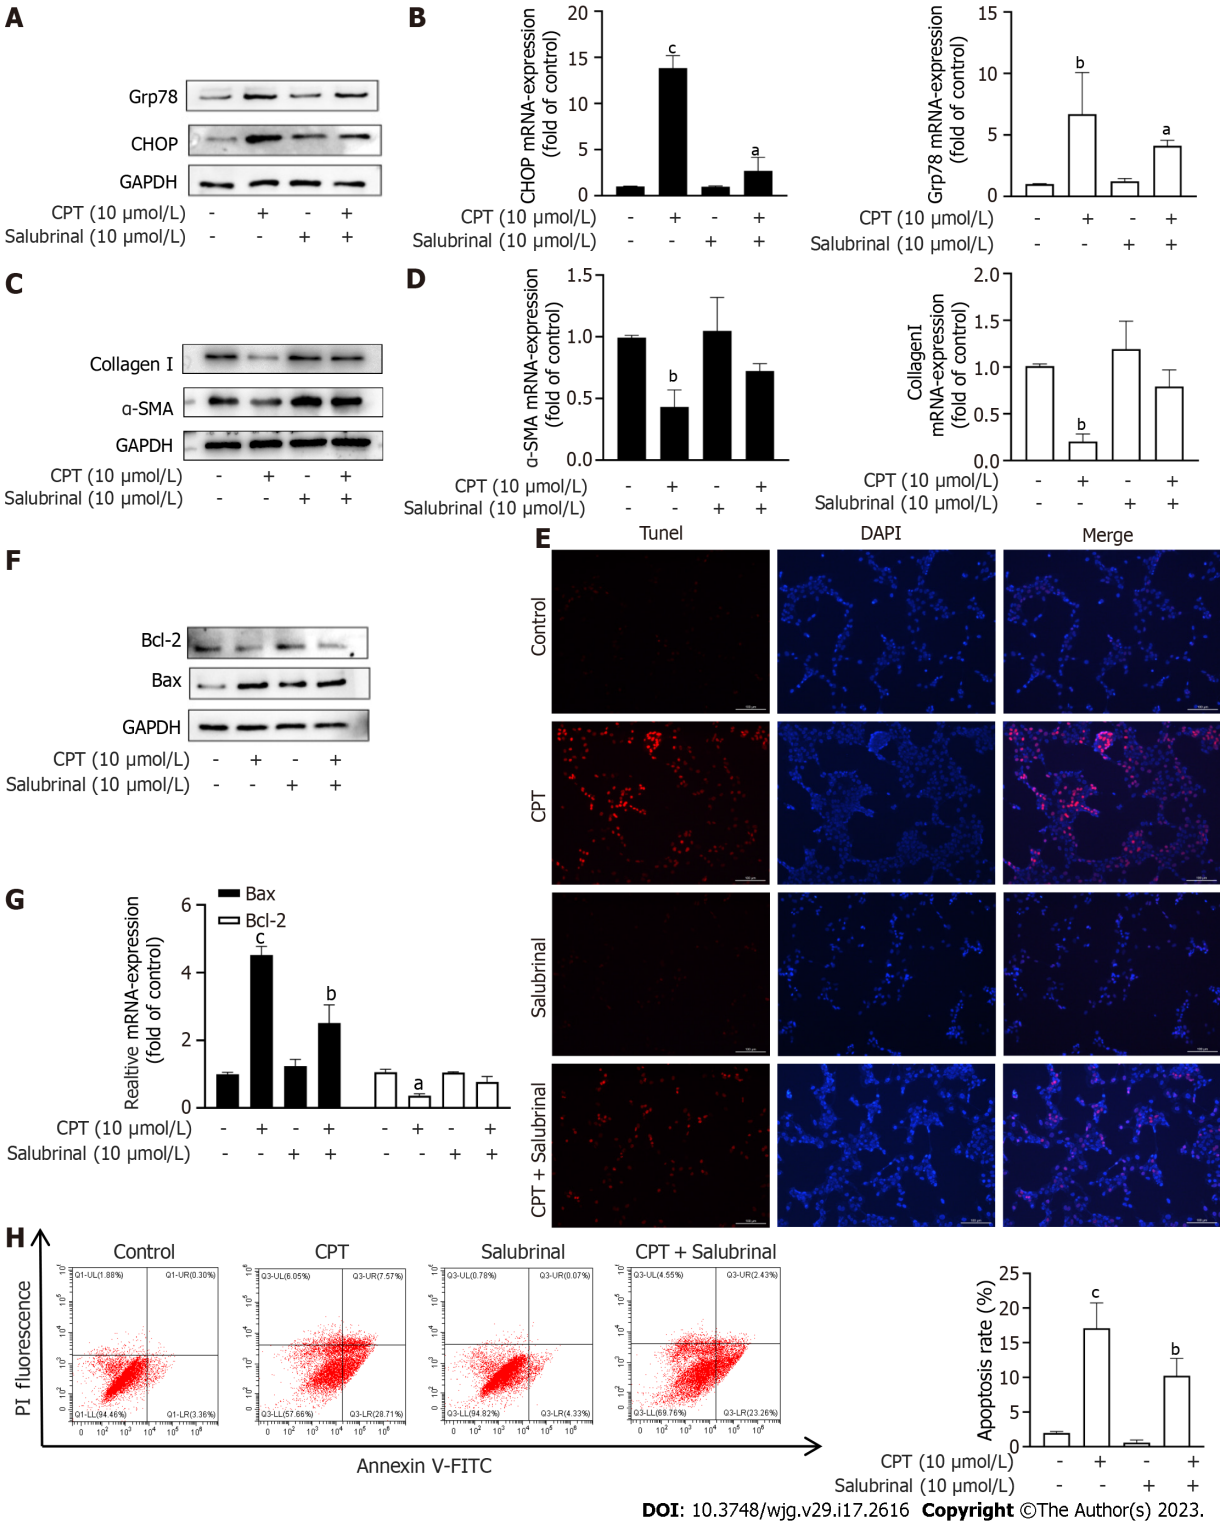


Figure 3 Cryptotanshinone activates the endoplasmic reticulum stress pathway in activated LX2 cells. A: Western blot analysis of endoplasmic reticulum stress (ERS)-related protein expression in LX2 cells; B: Reverse transcription polymerase chain reaction (RT-PCR) analysis of Grp78 and CHOP mRNA levels in LX2 cells; C: Western blot analysis of ERS-related protein expression in LO2 cells; D: RT-PCR analysis of Grp78 and CHOP mRNA levels in LO2 cells; E and F: Western blot analyses of ATF4, PERK, and IRE1 signaling pathways in hepatic stellate cells; G: Transmission electron microscopy showing that CPT caused ER swelling and destruction of the mitochondrial membrane integrity. Data are presented as mean ± SD. $^{a}P < 0.05$, $^{b}P < 0.01$ versus control. ER: Endoplasmic reticulum.

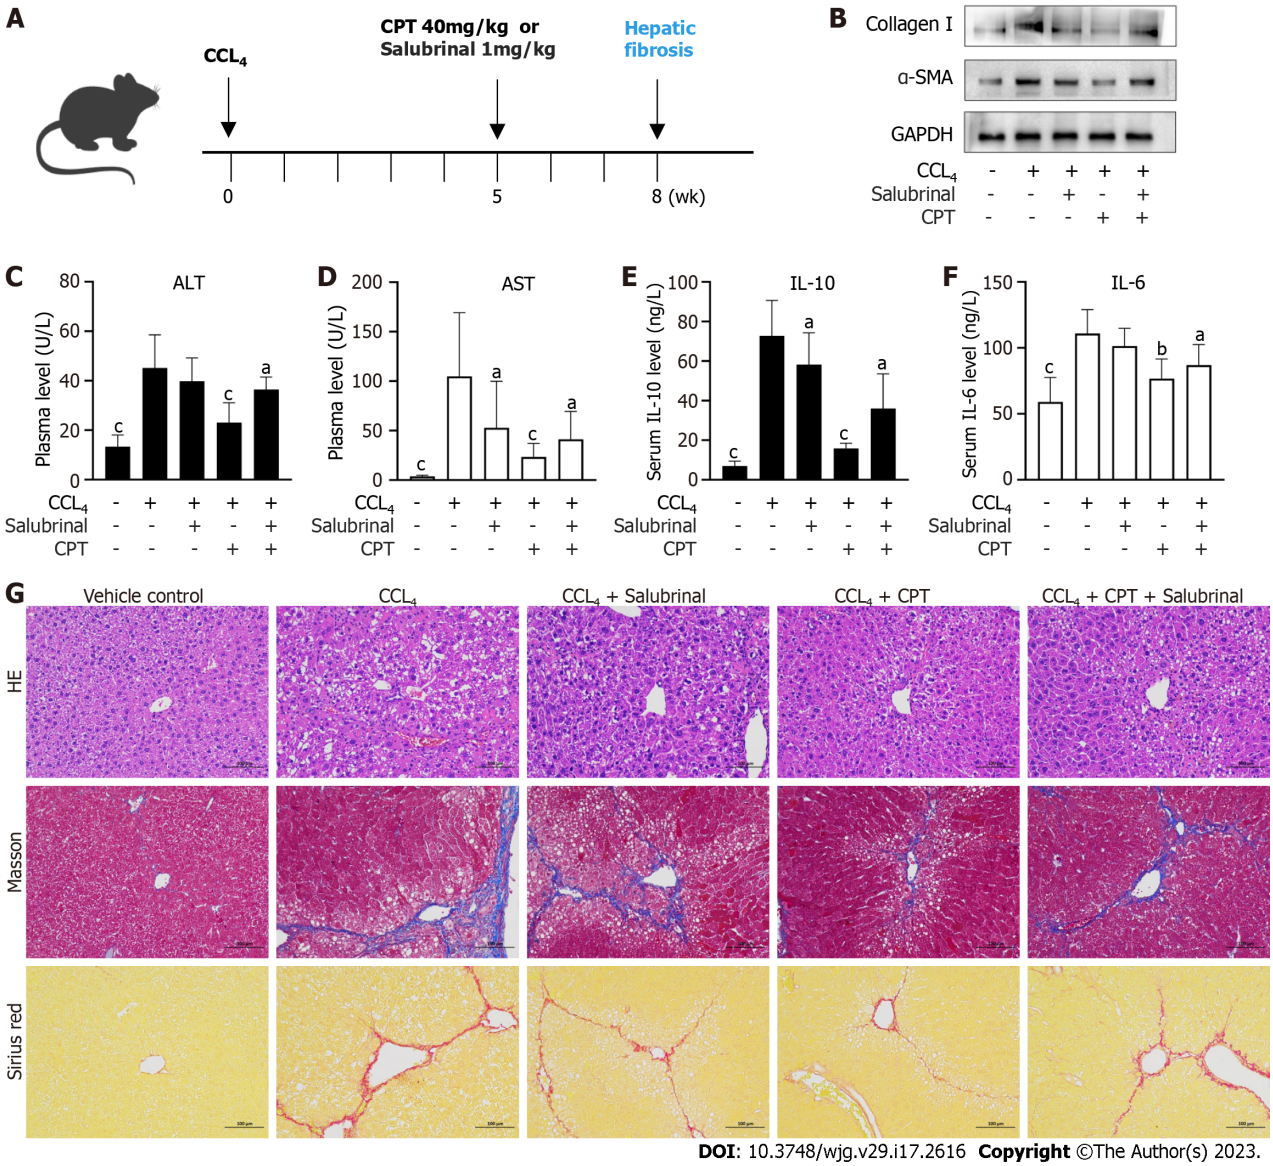
by ELISA, CPT decreased serum levels of IL-6 and IL-10 (Figure 5E and F). Furthermore, the inhibitory effect of CPT on the secretion of pro-inflammatory cytokines was diminished by salubrinal. Thus, we propose that CPT protects against CCL_4-induced liver injury by suppressing inflammation. Next, we analyzed the pathological changes in the liver tissue after CPT treatment. Histological staining showed that treatment with CPT significantly improved morphological changes in liver tissue (Figure 5G). As fibrogenesis is accompanied by accumulation of collagen, liver tissue sections were stained with Masson's reagent and Sirius red to detect collagen deposition. The results showed that collagen was markedly deposited in the CCL_4-injured livers but reduced in the livers of mice in the CPT-treated groups, which was further suppressed by salubrinal (Figure 5G). Taken together, these data provide *in vivo* evidence that activation of ERS signaling can result in reduced collagen accumulation and attenuation of fibrotic damage in a hepatic fibrosis mouse model.

DISCUSSION

Due to their diverse sources and high safety profiles, there has recently been a widespread increase in the use of natural bioactive components from plants for the prevention and treatment of diseases. Salvia miltiorrhiza is a traditional Chinese medicine that has been used to treat many diseases. CPT is one of the main tanshinones extracted from Salvia miltiorrhiza Bunge and is considered an important compound with various pharmacological properties. Specifically, recent studies have shown that CPT has antifibrotic properties in the heart, lung, and kidney[14,15]. However, the relationship between CPT and hepatic fibrosis remains unclear.



Hepatic fibrosis involves inflammatory responses caused by various acute and chronic liver injuries. If left untreated, hepatic fibrosis can progress to liver cirrhosis or even liver cancer. The production of ECM by activated HSCs plays an important role in hepatic fibrosis and cirrhosis[21]. Hepatic fibrosis might be prevented or even reversed by inducing apoptosis of activated HSCs. In this study, we

Figure 4 The endoplasmic reticulum stress signaling pathway leads to LX2 cell apoptosis and reduces collagen deposition induced by cryptotanshinone. A: Protein expression of Grp78 and CHOP was determined using Western blot analysis; B: mRNA levels of Grp78 and CHOP were determined using reverse transcription polymerase chain reaction (RT-PCR); C: Protein expression of collagen type I and α-SMA was determined using Western blot analysis; D: mRNA levels of α-SMA and collagen I were determined using RT-PCR; E: TUNEL staining was used to assess LX2 cell apoptosis. Red fluorescence indicates apoptotic cells. Scale bars: 100 μm; F: Protein expression of Bax and Bcl2 was determined using Western blot analysis; G: mRNA levels of Bax and Bcl2 were determined using RT-PCR; H: Flow cytometry data are presented as mean ± SD. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$ versus control. CPT: Cryptotanshinone; FITC: Fluorescein isothiocyanate.

established that CPT induces apoptosis through ERS in activated HSCs, which may offer a new strategy for the treatment of hepatic fibrosis. We discovered that CPT decreased both mRNA levels and protein expression of α-SMA and type I collagen in activated HSCs, which resulted in reduced ECM deposition. Furthermore, flow cytometry revealed that CPT dose-dependently induced apoptosis of activated LX2

Figure 5 Cryptotanshinone protects the liver against carbon tetrachloride-induced injury and inflammation. Cryptotanshinone (CPT) alleviates hepatic fibrotic injury in mice. Mice were injected with carbon tetrachloride (CCL_4) for 8 wk to induce liver fibrosis. During weeks 5 through 8, mice in the treatment groups were given CPT (40 mg/kg) or salubrinal (1 mg/kg). A: CPT treatment protocol in the CCL_4-induced hepatic fibrosis mouse model; B: Western blot analysis of α-SMA and collagen I in the liver tissue; C: Determination of serum alanine aminotransferase levels; D: Determination of serum aspartate aminotransferase levels; E: Enzyme-linked immunosorbent assay (ELISA) measurement of IL-6 levels in the serum; F: ELISA measurement of IL-10 levels in the serum; G: Liver sections were stained with hematoxylin and eosin, Masson reagents, and Sirius red. Scale baes: 100 μm. $^aP < 0.05$, $^bP < 0.01$, $^cP < 0.001$ compared with the CCL_4 group. CPT: Cryptotanshinone; CCL_4: Carbon tetrachloride.

cells. Bax is considered an apoptotic factor, while Bcl2 is an anti-apoptotic molecule that inhibits the release of cytochrome C from the mitochondria and inhibits HSC apoptosis[22]. We found that CPT upregulated the expression of the pro-apoptotic protein Bax and downregulated the expression of the anti-apoptotic protein Bcl2 in activated HSCs, increased the Bax/Bcl ratio, and promoted HSC apoptosis. Interestingly, the pro-apoptotic effect of CPT was more specific for activated HSCs than for normal hepatocytes, which did not undergo apoptosis. This finding is important because it indicates that CPT does not affect normal liver cell activity. Thus, we found that CPT is an effective drug that can induce apoptosis of activated HSCs but have no effect on normal hepatocytes during the treatment of hepatic fibrosis.

Our results demonstrated that CPT upregulated expression of ER-resident chaperone proteins, such as CHOP and GRP78, which are significant markers of ERS[23,24]. In addition, the PERK, IRE1, and ATF6 signaling pathways were activated, all of which can phosphorylate the downstream molecules eIF2α, ATF4, and JNK, modulating the ERS response[25,26]. We also observed ultrastructure changes using electron microscopy. The results showed that the ER cavity of the HSCs was swollen, and the integrity of the mitochondrial membrane was damaged after CPT treatment. The ER and mitochondria are important organelles that cooperate to complete a variety of biological functions through their

interactions with various proteins. In the early stage of ERS, GRP78 is translocated to the mitochondria, and the subsequent damage to the integrity of the mitochondrial membrane becomes an early feature of apoptosis[27,28]. Our results indicate that CPT could promote ERS in HSCs to promote apoptosis. Salubrinal is an ERS inhibitor that selectively induces eIF2α phosphorylation and inhibits its dephosphorylation, ultimately protecting cells from ERS-induced apoptosis[29]. To better understand if CPT-induced HSC apoptosis is regulated by activating the ERS pathway, we incubated HSCs with salubrinal to protect cells from ERS-induced apoptosis. In activated HSCs, salubrinal effectively attenuated CPT-induced apoptosis, reducing secretion of apoptotic proteins. Therefore, these results confirm that targeting ERS can trigger HSCs apoptosis.

To further verify the therapeutic effect of CPT on hepatic fibrosis, we conducted *in vivo* experiments using a CCL_4-induced mouse model of hepatic fibrosis. We found that intraperitoneal injection of CPT reversed the development of hepatic fibrosis in mice, and the therapeutic effect of CPT was reduced after by salubrinal. Interestingly, CCL_4 also induces experimental hepatocarcinoma, which shares common features with hepatic fibrosis, such as increased expression of matricellular proteins (SPARC, BM-40, and osteonectin)[30-32]. However, whether or not CPT also has a significant effect on the treatment of liver cancer requires further investigation.

CONCLUSION

In summary, we found that CPT limited HSC activation through an ERS-dependent pathway *in vivo* and *in vitro*, suggesting that CPT should be further investigated as a prospective therapeutic agent for hepatic fibrosis.

ARTICLE HIGHLIGHTS

Research background

Cryptotanshinone (CPT) has been accepted to be an anti-inflammatory molecule.

Research motivation

Hepatic stellate cell (HSC) activation plays an indispensable role in hepatic fibrosis. Inducing apoptosis of activated HSCs can attenuate or reverse fibrogenesis.

Research objectives

This study investigated the effects of CPT treatment on hepatic fibrosis and its underlying mechanism of action.

Research methods

In vitro, we used reverse transcription polymerase chain reaction, Western blot, TUNEL staining and flow cytometry, which demonstrated that CPT can induce HSC apoptosis through the ERS pathway. *In vivo*, we used liver function kit, enzyme-linked immunosorbent assay, pathological section staining a few columns of technical means to prove that CPT has a certain therapeutic effect on hepatic fibrosis.

Research results

In vitro, CPT was considered to activate HSC apoptosis by promoting endoplasmic reticulum stress (ERS) detrimental response to a certain extent. Main molecules came down to the unfolded protein response signaling pathway. *In vivo*, We found CPT protected the Carbon tetrachloride (CCL_4)-induced hepatic fibrosis. Furthermore, CPT inhibited the levels of the downstream inflammatory cytokines, which were triggered by CCL_4-induced hepatic fibrosis.

Research conclusions

CPT can promote apoptosis of HSCs and alleviate hepatic fibrosis through modulating the ERS pathway, which represents a promising strategy for treating hepatic fibrosis.

Research perspectives

Hepatic fibrosis, cirrhosis and liver cancer are typical "trilogy of liver diseases", which seriously endanger human health. Hepatic fibrosis is reversible in the early stage, but it is difficult to reverse in the late stage of liver cirrhosis. Early treatment is therefore essential. CPT is a diterpene quinone compound that is isolated from Salvia miltiorrhiza. CPT has been shown to have anti-oxidant. In this study, we found that CPT could induce apoptosis of activated HSCs and had good prospects for the treatment of hepatic fibrosis.

Abstract

BACKGROUND

Inflammatory bowel diseases (IBD) are a worldwide health problem and mainly affect young people, consequently affecting the workforce. Available treatments are often associated with side effects, and new therapeutic options are needed. For centuries, plants have represented important substrates in the field of drug development. *Lafoensia pacari* (*L. pacari*) is a plant whose pharmaceutical potential has been described, and may have biological activity relevant to the treatment of IBD symptoms.

AIM

To investigate the activity of keto-alcoholic extracts of *L. pacari* with respect to ameliorating the inflammatory and nociceptive symptoms of acute experimental colitis in mice.

METHODS

Keto-alcoholic extracts of *L. pacari* leaves and bark were administered to male and

female Swiss mice weighing 25 g to 30 g (n = 8 male mice and n = 8 female mice). The effect of these extracts was observed in an acetic acid-induced acute experimental model of colitis with regard to antinociception/analgesia and inflammatory tissue damage. Recorded macroscopic indices included the Wallace score and the colon weight obtained using a precision scale. Mechanical hyperalgesia was determined using an electronic analgesimeter. Behavior related to overt pain was determined by quantifying the number of writhing instances within 20 min of administration of acetic acid. Molecular docking was performed using human and murine cyclooxygenase-2 (COX-2) with 3 flavonoids (ellagic acid, kaempferol, and quercetin) on the AutoDock Vina software. Analysis of variance followed by Tukey's posttest was used with $P < 0.05$ indicating significance.

RESULTS

In this murine model of colitis, administration of extracts from *L. pacari* ameliorated acetic acid-induced writhing and colitis-associated inflammatory pain. These improvements may be attributable to the reduction in edema, inflammation (*e.g.*, ulcers, hyperemia, and bowel wall damage), and the intensity of abdominal hyperalgesia. The keto-alcoholic extracts of *L. pacari* leaves and bark administered at a dose of either 100 mg/kg or 300 mg/kg significantly reduced the number of writhing events when compared to the negative control ($P < 0.05$). Additionally, extracts of *L. pacari* bark also performed better than Dipyrone. Leaf extracts administered at 10 mg/kg, 30 mg/kg, and 100 mg/kg and bark extracts administered at 30 mg/kg significantly reduced or prevented the development of edema in the colon of treated mice, while mesalazine did not. Moreover, using molecular docking, we observed that the flavonoids present in *L. pacari* extracts bind to COX-2, an event not unique to ellagic acid.

CONCLUSION

The results of this study demonstrate a potential novel application of *L. pacari* extracts for the reduction of inflammation and promotion of antinociception/analgesia as demonstrated by our findings in a murine model of colitis. These findings were also corroborated by *in silico* analyses, and suggest that *L. pacari* extracts may be a promising therapeutic agent in the treatment of IBD.

Key Words: Antinociceptive activity; Anti-inflammatory activity; Cyclooxygenase-2; Flavonoids; Inflammatory bowel disease; *Lafoensia pacari*

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Keto-alcoholic extracts derived from the leaves and bark of *Lafoensia pacari* (*L. pacari*) demonstrate significant analgesic/antinociceptive activity in a murine acetic acid-induced pain model of colitis. These results can likely be extrapolated to humans, as the identities and structures of mouse and human cyclooxygenase-2 (COX-2) are similar. Furthermore, mouse and human COX-2 interacted in a similar fashion with *L. pacari* extract flavonoids when tested *in silico*. Extracts from both the leaves and bark of *L. pacari* were found to improve inflammation and pain symptoms in mice with acetic acid-induced acute colitis.

INTRODUCTION

Inflammatory bowel diseases (IBD) represent a wide spectrum of pathologies that manifest with chronic inflammation of the digestive tract and in many cases may not have a defined etiology[1]. The major diseases under the umbrella of IBD are Crohn's disease and ulcerative colitis, which are both characterized by the presence of an inappropriate immune response against gastrointestinal microbiota and other antigens in the digestive tract lumen[2]. Individual genetic susceptibility and other external factors are also important in the pathogenesis of IBD[3].

IBD occurs worldwide and represents a serious health problem, as it affects young people, frequently relapses, and can often be clinically severe. As such, IBD commonly negatively impacts patient quality of life[4,5].

Conventional pharmacological treatment for IBD is associated with many adverse effects[6] and is often associated with long-term resistance[7]. These phenomena are observed with aminosalicylates, corticosteroids, immunosuppressants, immunomodulators, and antibiotics, all of which are commonly used for induction of remission and are also used for disease maintenance as these drugs reduce inflammatory lesions[8]. Therefore, the search for new drugs to treat IBD is critical. Research on medicinal plants could lead to the discovery of bioactives with anti-inflammatory properties that are capable of curbing the symptoms of IBD with the benefit of avoiding adverse reactions associated with current drugs. *Lafoensia pacari* (*L. pacari*) (Lythraceae), a tree from the Brazilian Cerrado popularly known as dedaleiro, mangava-brava, or pacari, is a fever reducer and promoter of healing according to folk knowledge, and is a candidate for an alternative IBD treatment. Pharmacological trials using extracts derived from the leaves and bark of this plant have demonstrated its antifungal, antimicrobial, and anti-free radical properties. *L. pacari* has also been used in the treatment of gastric ulcers and inflammation [9].

Preclinical models of intestinal inflammation are important tools in the study of bioactives, and can assist in the identification of compounds with therapeutic potential, including drugs used in the treatment of IBD such as mesalazine and sulfasalazine[10].

The most common IBD symptom is abdominal pain, and is even reported in individuals in remission. Yet, IBD-associated abdominal pain is undertreated and there is a scarcity of research on this common issue[11]. Therefore, a drug with antinociceptive (reducing pain *via* modulation of nociceptive pathways [12]) and anti-inflammatory activities would be ideal for IBD therapy.

In view of the colloquial sense of the effects of *L. pacari*, it is possible that its components may be able to help improve the symptomatology of IBD through its antinociceptive and anti-inflammatory actions. Here, we tested this hypothesis using an *in vivo* preclinical mouse model and *in silico* analysis of molecular docking to elucidate the bioactive potential of keto-alcoholic extracts of *L. pacari* leaves and bark.

MATERIALS AND METHODS

Keto-alcoholic extracts of L. pacari

Leaves and bark of *L. pacari* were collected in the cerrado of Presidente Olegário, Minas Gerais, Brazil (coordinates 18°24'56" S; 46°25'17" W) in November 2021. The samples were analyzed by a biologist from the Centro Universitário de Patos de Minas (Minas Gerais, Brazil). The material was processed according to a previously published protocol[13] with some modifications. Leaves and bark of *L. pacari* were sanitized, disinfected, washed, dried at 40 ºC for 72 h, and finally ground.

The keto-alcoholic extracts were prepared according to another previously published protocol[14] with modifications. The ground material was mixed in a 1:1 acetone/methanol solution in a 1:10 plant/solution ratio, sonicated (5 cycles of 5 min on/5 min off), incubated at room temperature for 24 h, filtered, and evaporated. The entire extraction process was carried out in the dark. For the *in vivo* experiments, the extracts were solubilized in dimethyl sulfoxide (DMSO) 2% (v/v) in saline [NaCl 0.9% (w/v)].

Determination of total flavonoid content

Keto-alcoholic extracts were submitted for total flavonoid content determination by spectrophotometry using a methanol solution of $AlCl_3$ 5% (w/v). Quercetin was used as the standard with results expressed as quercetin equivalents[15].

Experimental animals

This study was approved by the Ethics Committee for Animal Use of the Setor de Ciências Biológicas at the Universidade Federal do Paraná, Paraná, Brazil (CEUA no. R.O. 07/2022). Male and female Swiss mice weighing 25 g to 30 g were used in the experiments. The animals were kept in the animal house of the Universidade Federal do Paraná - Toledo Campus in polypropylene boxes (41 cm × 33 cm × 16 cm) with pine shavings. Animals had access to rodent food and chlorinated drinking water *ad libitum* and were kept at a controlled temperature (22 ºC ± 2.0 ºC), in a 12 h light/dark cycle.

Writhing test

Female Swiss mice weighing 25 g to 30 g were used (n = 8 per group). The induction of nociceptive response was achieved by intraperitoneal administration of acetic acid [0.8% (v/v)] in saline (10 mL/kg). The noxious stimulus was given 30 min after administration *via* gavage of keto-alcoholic extracts of *L. pacari* leaves and bark (10 mg/kg, 30 mg/kg, 100 mg/kg, or 300 mg/kg), saline (negative control), dipyrone monohydrate 100 mg/kg (positive control), DMSO 2% (v/v), or ellagic acid (a flavonoid found in *L. pacari)* in DMSO 2% (v/v) in saline (1.6 mg/kg)[16]. The mice were individually housed in

glass cylinders and writhing and paw extension events were recorded over a span of 20 min. The intensity of the contortional response was expressed by the cumulative number of contortions over this 20 min period[17,18].

Induction of experimental acute colitis

The following experiment lasted for 14 h. After 24 h of solid fasting, male Swiss mice weighing 25 g to 30 g (*n* = 8 per group) were anesthetized with isoflurane (1.5% in 100% oxygen). At hour 0 and hour 6, the mice were pretreated with keto-alcoholic extracts of *L. pacari* leaves and bark (10 mg/kg, 30 mg/kg, 100 mg/kg, or 300 mg/kg), mesalazine 200 mg/kg (positive control), or saline (negative control). Mice in which colitis was not induced were used as controls. At hour 9, saline enema was performed on all animals. At hour 10, induction of experimental acute colitis was achieved with 7.5% (v/v) acetic acid administered rectally.

The intracolonic injection was performed with a polyethylene cannula measuring 3 cm in length[19]. At hour 12, treatment was administered using the same protocol as for pretreatment. At hour 13, the animals were subjected to mechanical hyperstimulation (Von Frey nociception test). At hour 14, the animals were euthanized by overdose of isoflurane followed by cervical dislocation.

The distal colon of each animal was collected and washed with saline to remove fecal debris. Macroscopic evaluation of each specimen was performed and the severity of lesions was rated using a numerical score (from 0 to 6)[20]. The presence of edema was also evaluated[19,21] by weighing a 2 cm colonic segment using a precision digital scale.

Von Frey test

Visceral mechanical hyperalgesia was assessed using the electronic Von Frey test[22]. Mice were allocated to a box in a temperature-controlled room for at least 45 min prior to testing. Withdrawal reflexes were elicited with a portable force transducer (Digital Algesimeter EFF 310; Insight Ltda, São Paulo, Brazil) fitted to a 0.7 mm^2 polypropylene tip. This apparatus was applied to the lower abdomen up to the mid-abdomen of each animal. After tip removal, the pressure intensity was automatically recorded (recording values from the average of 3 measurements).

Statistical analysis

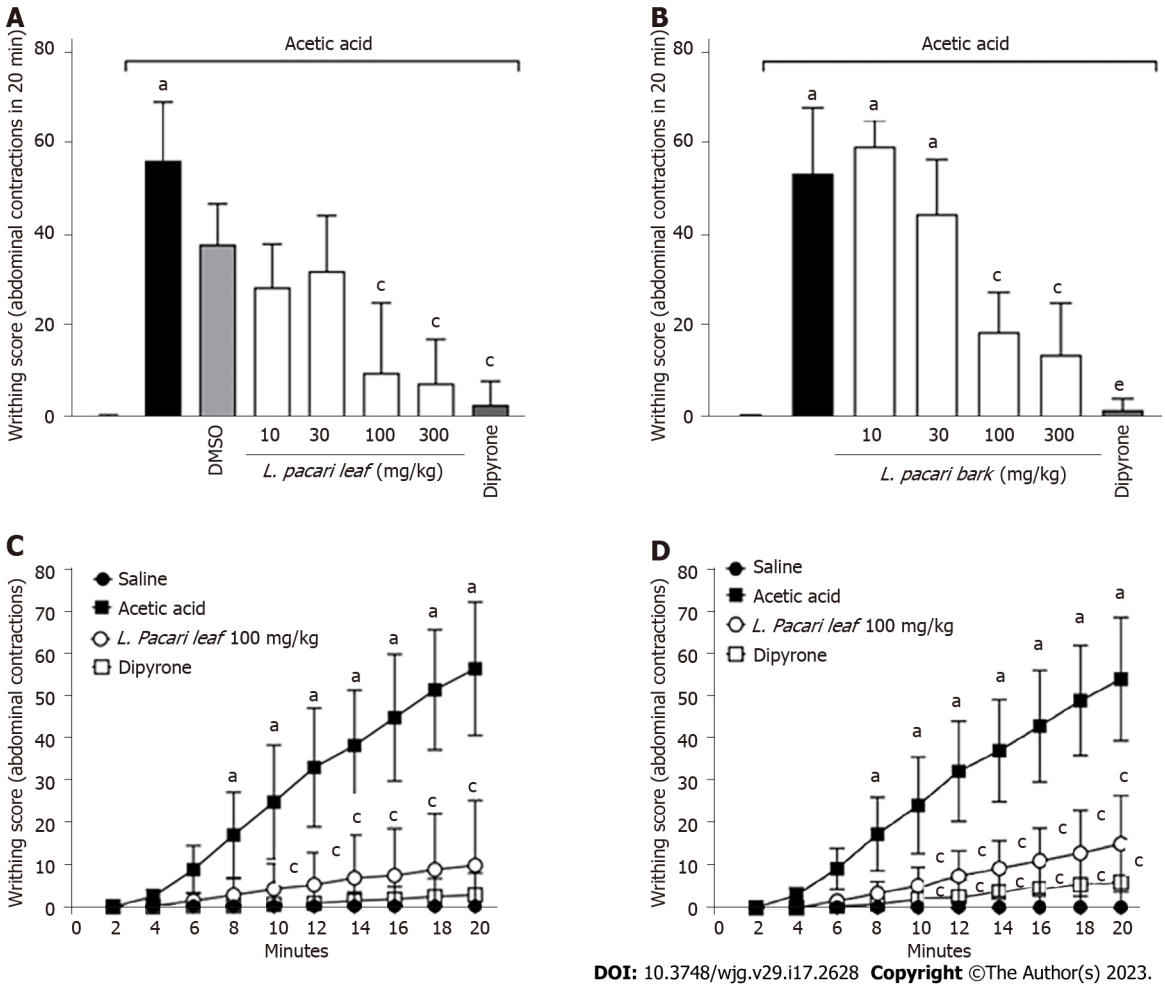
The means of the values obtained for each group in each experiment were calculated and analyzed using Prism 9.0.1 software. One-way analysis of variance was used to compare groups according to treatment dose followed by Tukey's test. Significance was set at $P < 0.05$.

Bioinformatic analysis by molecular docking

In order to better understand the results of the *in vivo* antinociceptive testing, an *in silico* molecular docking technique was used to evaluate the activity of flavonoids present in *L. pacari*[23] with respect to murine cyclooxygenase-2 (COX-2). The same simulations were performed with human COX-2 for extrapolation of the murine data. Primary sequences of both murine and human COX-2 were analyzed by global alignment using ClustalX 2.1 software[24] for obtaining identity data.

The structure files of the flavonoids (ligands) were obtained from the ZINC database (zinc.docking.org). The 2-dimensional ".sdf" files were converted into 3-dimensional ".pdb" files using the ViewerLite 5.0 software (Accelrys Inc., San Diego, CA, United States). The 3-dimensional structure of murine COX-2 (receptor) was obtained from the Protein Data Bank (PDB) (rcsb.org).

Molecular docking was performed using flexible ligandrigid receptor methodology[25]. For the execution of molecular docking, the AutoDock Tools 4[26] and AutoDock Vina v.1.2.0[27] programs were used. Preparation of molecules was performed, which included the detection of torsion points and calculation of the torsion angles of the ligands, besides the delimitation of the region where the docking was performed (Grid box).



RESULTS

Total flavonoids from L. pacari leaves and bark

The determination of total flavonoid content indicated 97.38 ± 0.0091 (97.38%) and 47.95 ± 0.0035 (47.95%) quercetin/g dry mass equivalents in *L. pacari* leaves or bark, respectively (*i.e.* 97.38 g and 47.95 mg of total flavonoids/g dry mass of leaves or bark, respectively).

Antinociceptive activity of keto-alcoholic extract of L. pacari leaves and bark

The writhing test revealed that DMSO 2% (v/v) did not influence the number of painful contortions when compared to the acetic acid noxious stimulus. A statistically significant decrease in the number of writhing events was observed in mice treated with dipyrone when compared to negative controls (Figure 1).

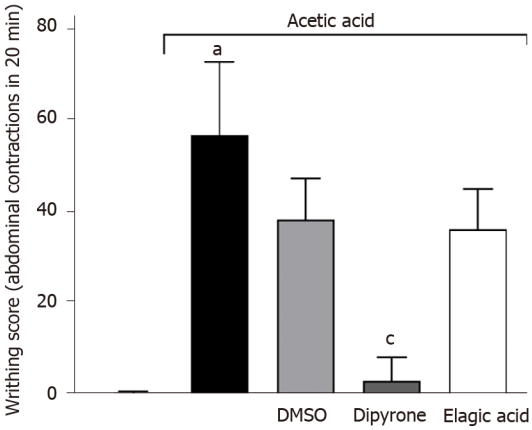
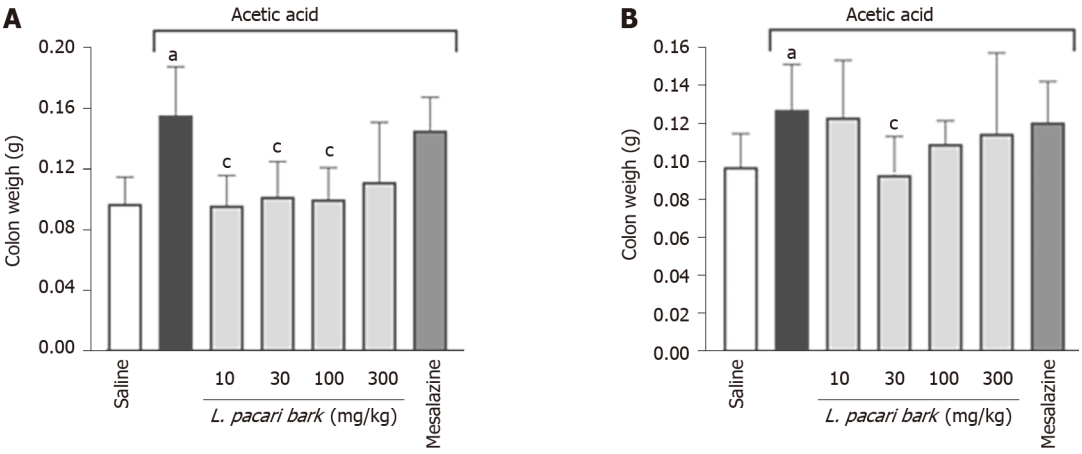
Figure 1 Antinociceptive activity of keto-alcoholic extracts of *Lafoensia pacari*. A: Keto-alcoholic extracts of leaves; B: Keto-alcoholic extracts of bark; C: Time-dependent action of the keto-alcoholic extract of *Lafoensia pacari* (*L. pacari*) leaves at 100 mg/kg; D: Time-dependent action of the keto-alcoholic extract of *L. pacari* bark at 100 mg/kg. Results presented ± representative error of 8 animals per group. $^{a}P < 0.05$ *vs* saline group; $^{c}P < 0.05$ *vs* DMSO 2% (v/v), acetic acid; $^{e}P < 0.05$ *vs* all groups except the saline group. One-way analysis of variance followed by Tukey's *t*-test. Error bar: Standard error of the mean; *L. pacari*: *Lafoensia pacari*.



With respect to the keto-alcoholic extracts of *L. pacari* leaves, doses of 100 mg/kg and 300 mg/kg reduced the number of acetic acid-induced writhing events significantly as compared to negative controls, but positive controls (dipyrone-treated; Figure 1A). The keto-alcoholic extracts of *L. pacari* bark at 100 mg/kg and 300 mg/kg significantly reduced the number of acetic-acid induced writhing events as compared to negative controls and also when compared to dipyrone (Figure 1B).

No statistically significant difference was observed between the antinociceptive potential of the low and high *L. pacari* leaves or bark extract doses (100 mg/kg and 300 mg/kg, respectively). The lower dose (100 mg/kg) was found to act in a time-dependent manner, exhibiting effects 10 min after administration (Figure 1C and D). Ellagic acid alone, administered at 1.6 mg/kg, did not significantly reduce the number of contortions (Figure 2).

Activity of keto-alcoholic extracts of L. pacari leaves and bark in acute colitis



Colitis-induced edema was observed and quantified by weighing the removed colonic segment. Colon segment weight of colitis mice was higher than that of healthy mice with no colitis induction. Keto-alcoholic extracts of *L. pacari* leaves administered at doses of 10 mg/kg, 30 mg/kg, and 100 mg/kg significantly reduced or prevented the development of colonic edema in treated mice (Figure 3A); similar results were observed in mice treated with the keto-alcoholic extracts of *L. pacari* bark administered at 30 mg/kg (Figure 3B), as evidenced by the weight of colonic segments of these animals being similar to that of healthy mice. Treatment with mesalazine did not improve edema.

Numerical lesional severity scores as assigned by gross assessment of colonic segments ranged from 0 to 2 (0 = no lesion; 1 = hyperemia without ulceration; 2 = ulceration without intestinal wall hypertrophy). No control mice were found to have lesions (score 0), and untreated mice with induced colitis demonstrated scores of 1 or 2 (Figure 4). Gross assessment of colonic segments of mice treated with keto-alcoholic extracts of *L. pacari* bark at 30 mg/kg, 100 mg/kg, and 300 mg/kg had fewer lesions

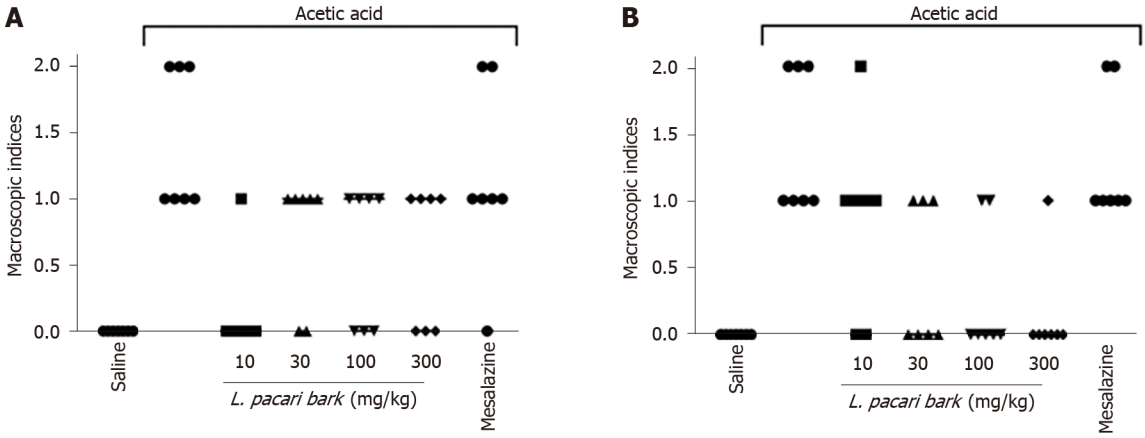
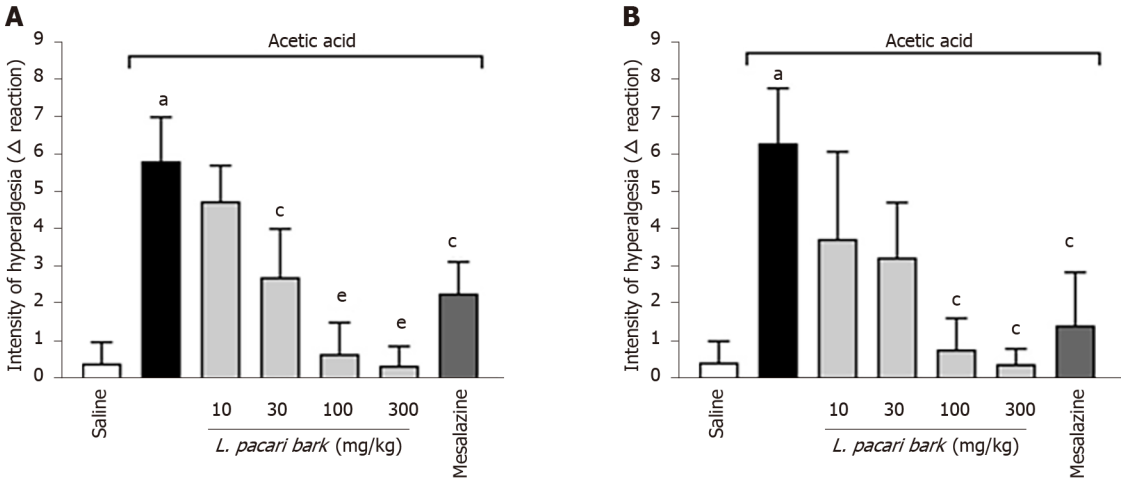
than untreated mice (Figure 4B); similar results were observed in mice treated with keto-alcoholic extracts of *L. pacari* leaves at 10 mg/kg (scores = 0 or 1; Figure 4A). In general, the keto-alcoholic extracts of *L. pacari* showed anti-inflammatory activity in the colon of animals with acute colitis. Mice treated with mesalazine showed intestinal lesions with scores of 1 or 2, suggesting poorer performance of this drug when compared to keto-alcoholic extracts of *L. pacari* leaves or bark.



Activity of keto-alcoholic extracts of L. pacari leaves and bark in hyperalgesia

Results of the Von Frey test were expressed as the difference between the intensity required to elicit a positive response before and after the induction of acute colitis by acetic acid. Mice treated with the keto-alcoholic extract of *L. pacari* leaves at 30 mg/kg, 100 mg/kg, or 300 mg/kg or mesalazine showed greater analgesic effect when compared to untreated mice. The keto-alcoholic extract of the leaves administered at 100 mg/kg or 300 mg/kg performed better than the extract administered at 30 mg/kg or mesalazine (Figure 5A).

With respect to the keto-alcoholic extract of *L. pacari* bark, mice treated with 100 mg/kg or 300 mg/kg or mesalazine required a higher intensity of stimulus to elicit a positive response when compared to negative controls. No significant difference was observed among these 3 treatments, although both 100 mg/kg and 300 mg/kg doses of the extract trended toward higher analgesic activity when compared to mesalazine (Figure 5B).



In silico analysis

The 3-dimensional structures of murine COX-2 (PDB: 3LN0) and human COX-2 (PDB: 5 LKQ) were selected from PDB; these were originally complexed to compound 5c-S and meclofenamic acid,

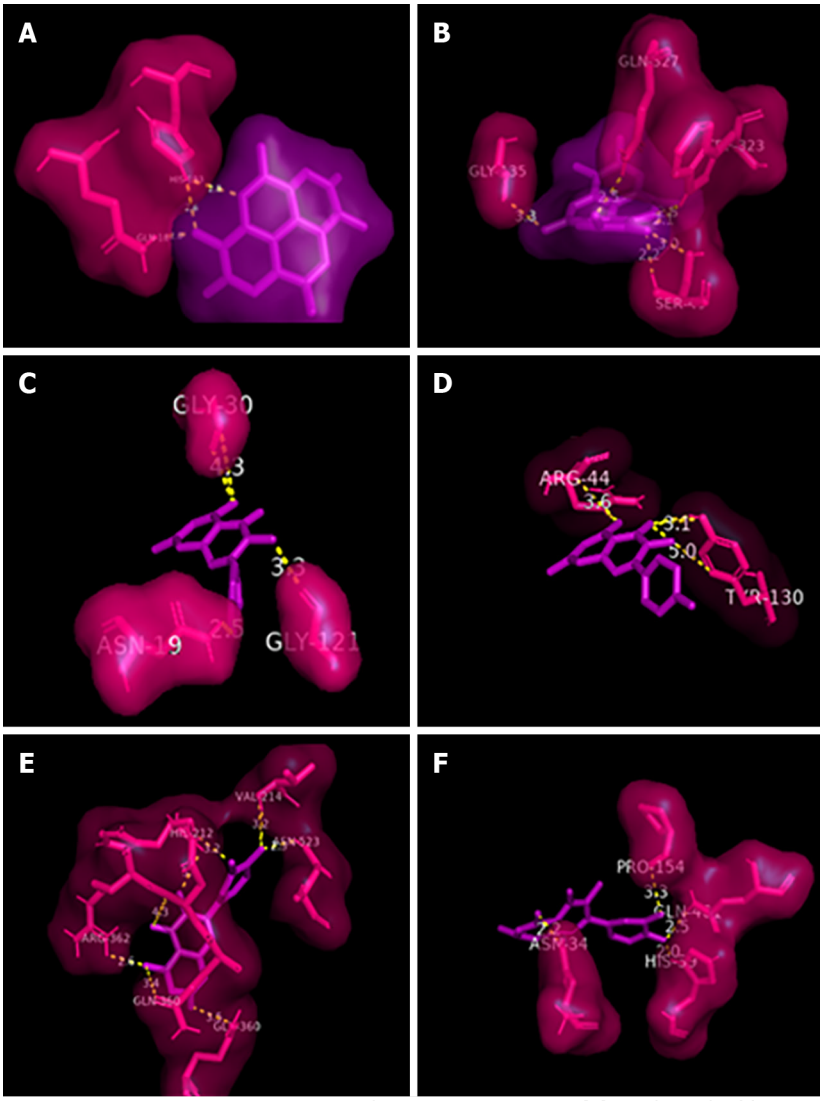
DOI: 10.3748/wjg.v29.i17.2628 **Copyright** ©The Author(s) 2023.

Figure 4 Macroscopic indices of colonic segments from mice with induced colitis post-treatment. Scores: 0 = no lesion; 1 = hyperemia without ulceration; 2 = ulceration without hypertrophy of the intestinal wall, according to Wallace *et al*[20]. Error bar: Standard error of the mean; *L. pacari*: *Lafoensia pacari*.

DOI: 10.3748/wjg.v29.i17.2628 **Copyright** ©The Author(s) 2023.

Figure 5 Antinociceptive activity of the keto-alcoholic extract of *Lafoensia pacari* in the acute colitis model. A: Keto-alcoholic extract of *Lafoensia pacari* (*L. pacari*) leaves; B: Keto-alcoholic extract of *L. pacari* bark. Results presented ± representative error of 8 animals per group. $^{a}P < 0.05$ *vs* saline group; $^{c}P < 0.05$ *vs* acetic acid; $^{e}P < 0.05$ *vs* mesalazine. One-way analysis of variance followed by Tukey's *t*-test. Error bar: Standard error of the mean; *L. pacari*: *Lafoensia pacari*.

respectively. These compounds were removed for analysis in this study. Human and murine COX-2 are homologous and have similar structures. The number of total residues in the primary sequence of both is 604, and the number of residues resolved by X-ray diffraction of human COX-2 and murine COX-2 is 551 and 587, respectively. After global alignment analysis, it was observed that these enzymes have 86.6% primary sequence identity.



Molecular docking simulations with COX-2 were performed with 3 flavonoids: ellagic acid (ZINC000003872446), kaempferol (ZINC000003869768) and quercetin (ZINC000003869685). It was observed that all flavonoids bind to chain A, the catalytic monomer of COX-2, with significant affinity (Table 1) and possibly, under physiological conditions, the interaction is stable and negatively affects enzyme activity.

Ellagic acid was bound to 2 amino acid residues of murine COX-2 (3 bonds; 2.0-2.8 Å) and to 4 residues of human COX-2 (5 bonds; 2.1-3.3 Å; Figure 6A and B). Kaempferol bound to 3 residues of murine COX-2 (3 bonds; 2.5-4.3 Å) and 2 residues of human COX-2 (3 bonds; 3.1-5.0 Å; Figure 6C and D), and quercetin bound to 6 residues of murine COX-2 (8 bonds; 2.3-4.3 Å) and 4 residues of human COX-2 (4 bonds; 2.0-3.3 Å; Figure 6E and F). None of the flavonoids were bound to the prosthetic group (heme group) of COX-2. The values of the affinity energies are similar to each other, the most significant interactions were between ellagic acid and murine COX-2 and between quercetin and human COX-2.

Table 1 Energy of affinity of cyclooxygenase-2/flavonoid complexes

Flavonoid	Energy of affinity in kcal/mol	
	Human COX-2	Murine COX-2
Ellagic acid	-9.7	-9.9
Kaempferol	-9.9	-8.8
Quercetin	-10.1	-9.5

COX-2: Cyclooxygenase-2.

The name of the amino acid is represented by the three-letter code followed by their number in the primary sequence. The numbers next to the dashed lines are the bond lengths in Angstrom.

DISCUSSION

Using extraction in acetone/methanol solution, 97.38 ± 0.0091 mg total flavonoids/g dry mass of the leaves and 47.95 ± 0.0035 mg total flavonoids/g dry mass of the bark of *L. pacari* were obtained; in crude hydroalcoholic and methanolic extracts of leaves, 15.7 ± 0.02 and 14.4 ± 0.04 equivalents of quercetin were obtained, respectively[28]. In another study[29] 13.61% ± 0.72 equivalents of quercetin was obtained from an aqueous extraction of the bark of *L. pacari*. Comparatively, the keto-alcoholic

extraction was more efficient in obtaining total flavonoids from both leaves and bark of *L. pacari*.

The antinociceptive effect of the keto-alcoholic extracts of *L. pacari* leaves and bark was demonstrated by the writhing test, an assay of nociception using injection of a noxious agent[30]. When tissues and cells are exposed to a noxious stimulus, chemical mediators are released, which in turn stimulate C-type nerve fibers causing local pain. Acetic acid has properties that can cause pain, in addition to stimulating the release of cytokines (IL-1β, TNF- and IL-8) by macrophages and basophils present in the abdominal cavity[31]. The writhing test is considered a model for studying visceral pain[32]; keto-alcoholic extracts of *L. pacari* leaves and bark decreased the number of writhing events in this test, suggesting the efficacy of these extracts in treating this type of pain.

The extracts of *L. pacari* leaves and bark administered at 100 mg/kg and 300 mg/kg, reduced the number of painful contortions in the murine colitis model; however, there was no significant difference between these dosages in terms of analgesic effect. However, the extract administered at 300 mg/kg (the highest concentration used in this study) did not exert such a potent antinociceptive effect when compared to the positive control group (dipyrone-treated).

The aqueous extract of *L. pacari* bark administered at 0.5 g/kg and 1.0 g/kg had previously shown an antinociceptive effect in the writhing test[33]. In a study using the ethanolic extract of *L. pacari* leaves administered at 1.0 g/kg, the extract reduced the number of writhing events, especially when it was administered subcutaneously; however, this dose caused toxicity and death in treated animals[31]. Therefore, although the dose of 300 mg/kg is still below the accepted toxic value[31], in order to avoid undesirable adverse effects, the 100 mg/kg dose of keto-alcoholic *L. pacari* extract may be more appropriate.

The choice of oral administration of the extracts was based on the better viability and ease of administration considering future drug development from the plant's bioactive compounds. As we observed analgesic activity when extracts were administered orally, it seems that this route of administration is sufficient for absorption of the active compound at a therapeutic level.

In comparison, one study evaluated the analgesic and anti-inflammatory activity of total flavonoids from the leaves of *Juniperus sabina*, a plant commonly known as sabina native to Europe and Asia. This study indicated significant dose-dependent analgesic activity in the acetic acid-induced writhing test, with the highest dose (500 mg total flavonoids/kg animal mass) showing the greatest inhibition of writhing (22.02%)[34]. In the present study, the most effective inhibitory dose was 100 mg/kg of dry mass of *L. pacari* leaves and bark, which is equivalent to 9.738 mg/kg and 4.795 mg/kg total flavonoids, respectively.

Other studies have investigated the ethanolic extract of white willow as an anti-inflammatory and antinociceptive, with results similar to ours in which the plant extract was effective in an animal model, but the positive control treatment was more effective, even at lower concentrations[35]. Another study aimed to elucidate the effects of an ethanolic extract of *L. pacari* on acute peritonitis in mice[9], and demonstrated significant anti-inflammatory activity of this extract. This finding may be akin to the antinociceptive effect of the keto-alcoholic *L. pacari* extracts demonstrated in the present study.

Although this study does not present the rate of inhibition of writhing, the difference in concentration of total flavonoids used per body mass in each study suggests that flavonoids from *L. pacari* are more effective, as analgesia was observed at lower doses. One possible explanation for this observation may be the types of flavonoids present in each plant species analyzed, and those of *L. pacari* may act more synergistically to produce an analgesic effect.

Fractionation of the *L. pacari* bark extract leads to the isolation of ellagic acid as the main flavonoid compound, suggesting that this compound is responsible for the anti-inflammatory and anti-edema activity of the extract observed in mouse models of asthma. Ellagic acid was also identified in *L. pacari* leaves by high performance liquid chromatography[31]. Recently, evidence regarding the efficacy of ellagic acid in the treatment of acute visceral pain has been growing; its analgesic effects are attributed to the inhibition of COX, which synthesizes prostaglandins at sites of peripheral cell damage[36].

Ellagic acid is reported to have several benefits, such as anti-inflammatory, anticancer, and hepatoprotective actions, and is also a promising agent for the treatment of chronic diseases such as ulcerative colitis, Crohn's disease, Alzheimer's disease, and diabetes[37]. However, according to the results obtained in this study, ellagic acid was not the only phenolic compound present in the extract of the *L. pacari* that may be responsible for the observed analgesic effect. In a statistical comparison, its effect resembles that of the 30 mg/kg dosage of leaf extract in the twitch test. The relatively low efficiency of ellagic acid compared to other doses of extract indicates that this flavonoid likely acts synergistically with other compounds present in the plant to confer a more robust analgesic pharmacological effect.

Regarding acute experimental colitis, the keto-alcoholic extracts of *L. pacari* leaves administered at 10 mg/kg, 30 mg/kg, or 100 mg/kg significantly reduced or prevented the development of colonic in treated mice. The same was observed in mice treated with the keto-alcoholic extract of *L. pacari* bark administered at 30 mg/kg as evidenced by similar colonic segment weights between treated and health mice.

Gross evaluation of colonic segments of mice revealed lower lesional severity scores in mice receiving keto-alcoholic extracts of *L. pacari* leaves and bark, with further reduction in the groups that received a higher dose. The mice that received mesalazine had similar lesional severity scores compared to the saline-treated group; this may be due to the fact that mesalazine typically used in the treatment of

chronic inflammatory bowel disease[38,39], and we used an acute colitis model.

The macroscopic findings suggest that the keto-alcoholic extracts of *L. pacari* leaves and bark have an anti-inflammatory effect on the mucosa of the gastrointestinal tract and reduce tissue destruction in this model of acute colitis. In agreement with these findings, one study showed that a methanolic extract of the bark of *L. pacari* had a potent gastroprotective effect against ethanol-, indomethacin-, and stress-induced ulcers[40].

Another study showed that an ethanolic extract of *L. pacari* possesses healing properties when applied to skin wounds, accelerating healing when compared to controls. This is attributed to the inhibition of the proliferation and inflammation phases of the healing process, corroborating the findings in our acute colitis induction experiments, which showed reduced colonic tissue damage in mice treated with *L. pacari* extracts. These data suggest a negative modulation of tissue inflammatory processes[23].

The anti-inflammatory effects of extracts derived from *L. pacari* leaves have also been demonstrated in a murine model of asthma. One study showed a significant reduction in lung inflammation and tissue damage in animals that received the extract as evidenced by gross tissue damage score analysis[41]. These data corroborate the results of the present study, which also demonstrated the anti-inflammatory effects of keto-alcoholic extracts of *L. pacari* leaves and bark in reducing macroscopic damage to colonic tissue.

Both the Von Frey monofilament and the electronic Von Frey tests are used as quantitative sensory assays to explore mechanical hyperalgesia[42]. In this study, pain stimuli were administered to mice using the electronic Von Frey test, and the keto-alcoholic extracts of *L. pacari* leaves administered at 30 mg/kg, 100 mg/kg, or 300 mg/kg or mezalazine showed greater analgesic effect when compared to untreated mice. Among the treatments, the keto-alcoholic extract administered at 100 mg/kg or 300 mg/kg performed better than the extract at 30 mg/kg or mesalazine.

Regarding the keto-alcoholic extract of *L. pacari* bark, mice treated with the doses 100 mg/kg or 300 mg/kg or mesalazine required a higher intensity stimulus to induce a positive response when compared to the negative controls. No significant difference was observed among these 3 treatments, although the keto-alcoholic extract at 100 mg/kg or 300 mg/kg had greater analgesic effect as compared to mesalazine. It is important to emphasize that, since this is a study based on a model of acute colitis, the findings regarding mesalazine are consistent with what is expected, since this drug has a better effect with long-term use[43]. The Von Frey test was one of the first evoked stimulus tests to be developed and continues to be widely used today[44]. This test is an excellent tool for evaluating hyperalgesia, visceral pain, and inflammation[45].

Molecular docking is an important method to complement and help better understand results obtained by *in vivo* testing. In humans, despite being structurally a homodimer, COX-2 functions as a conformational heterodimer, with 1 monomer being catalytic and the other allosteric[46]. In our experiments, the catalytic monomer, composed of the A chain, was the interaction target of ellagic acid, kaempferol, and quercetin in both human and murine COX-2.

We observed that the evaluated flavonoids bind to COX-2, but also that the interactions are strong. Binding affinity is measured by the affinity energy, which when lower than -6.0 kcal/mol indicates interaction in a biological environment[47]. Although the values are expressive, they are all within a narrow range (-8.8 1 kcal/mol to 10.1 kcal/mol). Our data suggest that COX-2 inhibition after interaction with any of the flavonoids tested should not trigger events other than the expected inhibition of prostaglandin production and consequent decrease in pain sensation.

Our findings also demonstrate that ellagic acid is not the only compound of interest with respect to analgesia found in the keto-alcoholic extracts of *L. pacari* leaves and bark. The affinity energy evaluated by molecular docking represents the strength of interaction between 2 or more interacting molecules. The strength of interaction is favorable when it is negative, and the receptor/ligand interaction is greater when the energy is lower.

Corroborating our study, another demonstrated that quercetin is also effective in inhibiting hyperalgesia[48]. This flavonoid showed an analgesic effect in animal models of inflammatory pain, inhibiting hyperalgesia induced by mechanical or thermal stimuli, and reduced the pain behaviors of studied animals. In addition, it also inhibited the development of inflammation-related edema, cytokine production, myeloperoxidase activity, and cell migration[49].

Nonsteroidal anti-inflammatory agents (NSAIDs) are part of a heterogeneous group of compounds from different chemical classes, and have 3 main actions: Anti-inflammation, analgesia, and fever reduction. NSAIDs are the most commonly used therapeutic agents[50]. Although they are effective, their long-term use is limited in most patients, as they are associated with adverse gastrointestinal effects such as abdominal pain, ulcers, bleeding, and even gastric or duodenal perforation. These effects have been attributed to the low specificity of these compounds for COX-2[51]. Acetylsalicylic acid (ASA) promotes the irreversible inhibition of human COX activity by covalent binding to a serine residue within the active site.

In COX-1, ASA acetylates serine 530, preventing the binding of arachidonic acid to the enzyme's active site, thus suppressing the production of prostaglandins. In COX-2, ASA acetylates serine 516, blocking the activity of this isoform[50,51]. In our study, *in silico* analysis showed that these amino acid residues, which are key to the action of some analgesics, showed no direct interaction with the evaluated flavonoids, demonstrating that in this model there are other residues involved in COX-2

inhibition.

CONCLUSION

We demonstrated the anti-inflammatory effects of keto-alcoholic extracts of *L. pacari* leaves and bark in a murine acetic acid-induced colitis model. Both extracts inhibited colitis-induced tissue damage as assessed using the Wallace score and the development of colonic edema; this effect seems to be COX-2-dependent. The flavonoid content of *L. pacari* extracts has been used to treat many diseases, and shows anti-inflammatory, analgesic, and antioxidant properties. However, the effects of this plant on symptoms related to colitis have not been described. Using molecular docking, we showed a strong interaction between ellagic acid, kaempferol or quercetin with both human and murine COX-2; however, the inflammatory and antinociceptive effects of *L. pacari* are not solely attributable to ellagic acid. Taken together, these results suggest the potential of oral *L. pacari* extract administration in the treatment of inflammatory diseases such as colitis.

ARTICLE HIGHLIGHTS

Research background

Therapeutic activities of *Lafoensia pacari* (*L. pacari*) have been reported in folk medicine, and this plant has been used as an antifungal, an anti-ulcer, an antibacterial, an anti-inflammatory, a fever reducer, in the treatment of pneumonia, and in the treatment of stomach pain. Despite the common use of this plant, the mechanisms by which it achieves medicinal effects have not been elucidated.

Research motivation

L. pacari is a tree found in Brazil thought to have beneficial pharmacological properties, with its main bioactive compounds belonging to the flavonoid class. One of the most studied flavonoids found in this plant is ellagic acid, which has been reported to have anti-inflammatory activity. However, *L. pacari* contains numerous flavonoids, and these compounds may also have similar activity to or act synergistically with ellagic acid.

Research objectives

We aimed to evaluate the activity of keto-alcoholic extracts of *L. pacari* leaves and bark, which contain a significant amount of flavonoids, with respect to the improvement of symptoms related to inflammatory bowel diseases (*e.g.*, inflammation of the intestinal mucosa, edema, and abdominal pain).

Research methods

The methodology used in this study was based on protocols already well established in the scientific literature, and, when necessary, some modifications were made. All experiments were performed with a number of mice that allowed for statistical analysis of the data and were performed in duplicate or triplicate depending on statistical requirements.

Research results

Our results corroborated those described by other studies with respect to the beneficial effects of *L. pacari* extracts; however, to our knowledge, we are the first to evaluate the therapeutic potential of these extracts in a murine model of acute colitis. Antinociception/analgesia in this murine model were observed with respect to treatment with extracts derived from *L. pacari* leaves and bark.

Research conclusions

Our findings suggest that keto-alcoholic extracts of *L. pacari* leaves and bark are beneficial for the reduction of symptoms related to inflammatory bowel disease. These effects are attributed to the decrease or inhibition of inflammation in the intestinal mucosa. Regarding pain, bioinformatics techniques indicated that ellagic acid alone is not responsible for these effects, since other flavonoids interact and inhibit with significant affinity cyclooxygenase-2, an enzyme that produces pain mediators.

Research perspectives

This study is part of a larger research project; follow-up experiments are planned using a rat model of chronic colitis, other antinociception tests. Future experiments will also investigate the histology of intestinal segments after induction and treatment of chronic colitis with *L. pacari* extracts.

Abstract

BACKGROUND

An in-depth study of the pathogenesis and biological characteristics of ampullary carcinoma is necessary to identify appropriate treatment strategies. To date, only eight ampullary cancer cell lines have been reported, and a mixed-type ampullary carcinoma cell line has not yet been reported.

AIM

To establish a stable mixed-type ampullary carcinoma cell line originating from Chinese.

METHODS

Fresh ampullary cancer tissue samples were used for primary culture and subculture. The cell line was evaluated by cell proliferation assays, clonal formation assays, karyotype analysis, short tandem repeat (STR) analysis and transmission electron microscopy. Drug resistances against oxaliplatin, paclitaxel, gemcitabine and 5-FU were evaluated by cell counting kit-8 assay. Subcutaneous injection 1 × 10^6 cells to three BALB/c nude mice for xenograft studies. The hematoxylin-eosin staining was used to detect the pathological status of the cell line. The expression of biomarkers cytokeratin 7 (CK7), cytokeratin 20 (CK20), cytokeratin low molecular weight (CKL), Ki67 and carcinoembryonic antigen

(CEA) were determined by immunocytochemistry assay.

RESULTS

DPC-X1 was continuously cultivated for over a year and stably passaged for more than 80 generations; its population doubling time was 48 h. STR analysis demonstrated that the characteristics of DPC-X1 were highly consistent with those of the patient's primary tumor. Furthermore, karyotype analysis revealed its abnormal sub-tetraploid karyotype. DPC-X1 could efficiently form organoids in suspension culture. Under the transmission electron microscope, microvilli and pseudopods were observed on the cell surface, and desmosomes were visible between the cells. DPC-X1 cells inoculated into BALB/C nude mice quickly formed transplanted tumors, with a tumor formation rate of 100%. Their pathological characteristics were similar to those of the primary tumor. Moreover, DPC-X1 was sensitive to oxaliplatin and paclitaxel and resistant to gemcitabine and 5-FU. Immunohistochemistry showed that the DPC-X1 cells were strongly positive for CK7, CK20, and CKL; the Ki67 was 50%, and CEA was focally expressed.

CONCLUSION

Here, we have constructed a mixed-type ampullary carcinoma cell line that can be used as an effective model for studying the pathogenesis of ampullary carcinoma and drug development.

Key Words: Ampullary carcinoma; Cell line; Xenograft; Drug resistance

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: A new ampullary carcinoma cell line has been established, making up for the shortage of Chinese ampullary carcinoma cell lines. And this is the the first study to report a mixed-type ampullary carcinoma cell line. The cell line inoculated into BALB/c nude mice can quickly form xenograft tumors. It is an excellent model for studying the mechanisms of invasion, metastasis and other mechanisms of ampullary carcinoma. The cell line is sensitive to oxaliplatin and paclitaxel but is naturally resistant to gemcitabine and fluorouracil, which can be used for drug resistance mechanism research and new drug development.

INTRODUCTION

Ampullary carcinoma is a relatively rare tumor, accounting for 0.2% of gastrointestinal cancers but 20% of all periampullary cancers[1,2]. Recently, the incidence rate of ampullary cancer has gradually increased[3,4]. Ampullary carcinoma can occur at any age; however, it is more common between 60 and 65 years of age, and the sex ratio is approximately 3:2[1,2]. As biliary obstruction symptoms appear early, the surgical resection rate of ampullary carcinoma is higher than that of other periampullary malignant tumors, and approximately 50% of patients are eligible for surgery on diagnosis[1,5,6]. Its operation amount is over one-third of the total operation amount of pancreatoduodenectomy. The prognosis is good, and the 5-year survival rate exceeds 52.8%[7]. Despite a high potential curative resection rate, most patients with ampullary cancer eventually succumb to tumor recurrence[8,9].

In 1994, Kimura *et al*[10] first classified ampullary carcinoma into intestinal and pancreaticobiliary types according to their histological characteristics. The prevalence of the pancreaticobiliary type was 72%, which is much higher than that of the intestinal type[10]. In 2010, according to the morphological and immunohistochemical characteristics, WHO revised the pathological diagnosis criteria of ampullary carcinoma into three different histopathological subtypes: Intestinal-, pancreaticobiliary-, and mixed-type ampullary carcinoma[11,12].

To date, only eight ampullary cancer cell lines have been included in the official databases of ATCC, JCRB, RIKEN, and DSMZ. One is American, one is Italian, two are Korean, and four are Japanese (three of them are from different lesions of the same patient)[13-17] (Table 1). Among them, SNU-869 is an intestinal-type cell line, whereas the remaining are pancreaticobiliary-type cell lines[18]. No mixed-type ampullary carcinoma cell line has yet been reported.

No randomized clinical trial for adjuvant chemotherapy of ampullary carcinoma currently exists, and the data based on which doctors choose treatment methods are limited. Presently, adjuvant therapy for ampullary carcinoma is being tailored according to the histological subtypes. Pancreatic biliary ampullary carcinoma is typically treated similarly to pancreatic adenocarcinoma or biliary tract carcinoma. In contrast, patients with intestinal ampulla receive the usual protocol for colorectal cancer. Based on these premises, the optimal treatment plan for ampullary carcinoma in adjuvant therapy and chemotherapy for advanced patients remains to be determined[19,20].

Based on the aforementioned factors, establishing an ampullary carcinoma cell line, conducting in-depth research on the pathogenesis and biological characteristics of ampullary carcinoma, and then investigating therapeutic targets to formulate effective treatment strategies for patients with ampullary carcinoma are currently required.

In this study, we establish a stable mixed-type ampullary carcinoma cell line named DPC-X1 from the tumor tissue of a patient with ampullary carcinoma. Our study findings underscore the effectiveness of DPC-X1 as an experimental model that can be used to explore the molecular mechanism of ampullary carcinoma and develop therapeutic schemes for disease control.

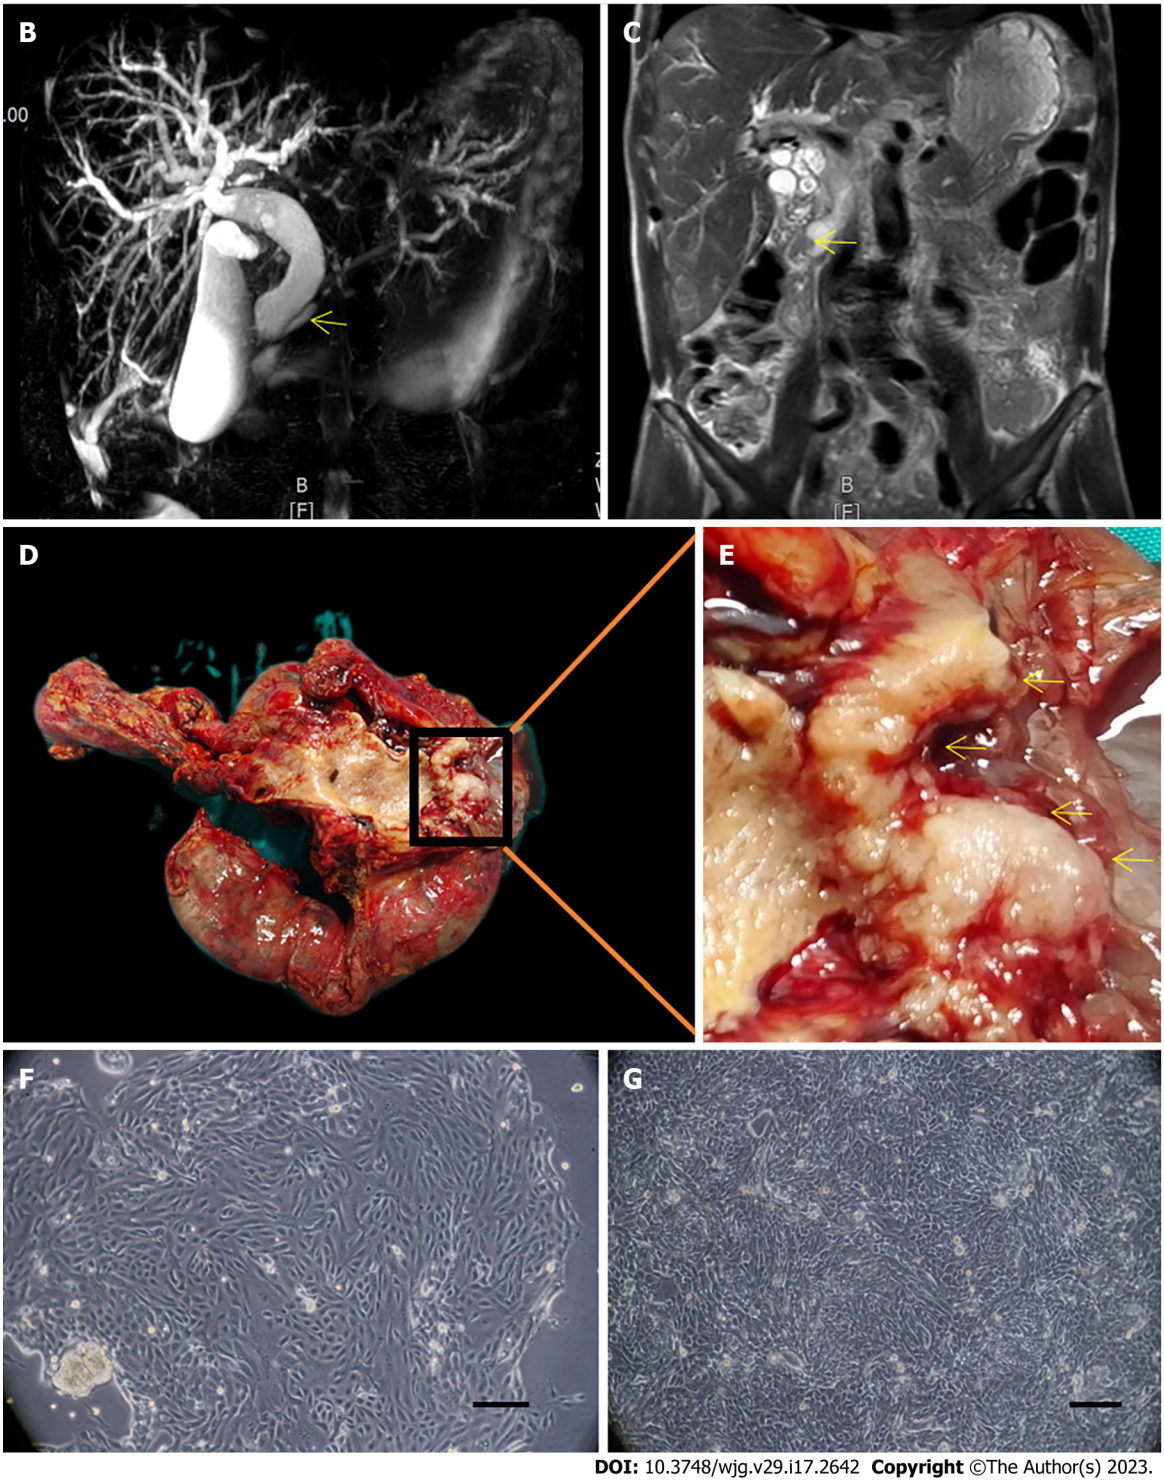
MATERIALS AND METHODS

Tissue source

The tissue samples were collected from a patient with ampullary cancer who was admitted to the First Hospital of Lanzhou University on November 17, 2021, for pancreatoduodenectomy. The patient was a 60-year-old man who presented with jaundice, had a long history of smoking and drinking, and had no history of carrying hepatitis B or C. His carbohydrate antigen 199 levels exceeded 1000 U/mL (reference range: 0–35 U/mL; Figure 1A), and preoperative magnetic resonance imaging + magnetic resonance cholangiopancreatography indicated ampullary carcinoma (Figure 1B and C). The new organisms growing around the ampulla were grayish-white and were taken from the primary focus for primary culture and subculture (Figure 1D and E).

This study was approved by the Medical Ethics Committee of the First Hospital of Lanzhou University (LDYYLL-2022-487), and signed informed consent was obtained from the patient.

Drugs



Gemcitabine was obtained from Jiangsu Haosen Pharmaceutical Group Co., Ltd., oxaliplatin from Jiangsu Hengrui Pharmaceutical Co., Ltd., 5-FU from Tianjin Jinyao Pharmaceutical Co., Ltd., and paclitaxel from Jiangsu Aosaikang Pharmaceutical Co., Ltd.

Nude mice

In this study, experiments were conducted on 4–6-week-old BALB/c nude female mice, weighing 16–20 g. They were obtained from Changzhou Kavens Experimental Animal Co., Ltd. and raised in the SPF laboratory of the Animal Experiment Center of Lanzhou University. The animal protocol was designed to minimize pain or discomfort to the animals. The animals were acclimatized to laboratory conditions (23 °C, 12 h/12 h light/dark, 50% humidity, ad libitum access to food and water) for 2 wk prior to experimentation. All animals were euthanized by barbiturate overdose (intravenous injection, 150 mg/

kg pentobarbital sodium) for tissue collection.

All animal experiments were reviewed and approved by the Medical Animal Experiment Ethics Committee of the First Hospital of Lanzhou University (LDYYLL-2022-487). The methods followed in this study were similar or identical to those employed in previous studies[21-23].

Establishment of the cell line

The tumor tissue samples were immersed in sterile phosphate buffered saline (PBS) (Gibco) 3–5 times and sectioned into small pieces. The small woven pieces were mixed with type II collagenase (Gibco) and neutral protease (Invitrogen) and digested in a shaking table at 37 ℃. On digestion of half the tissue block, the supernatant was absorbed, filtered with a 100 mesh filter screen, and centrifuged at 300 × *g* for 3 min. Thereafter, the supernatant was discarded; the sample was resuspended in PBS and centrifugated at 300 × *g* for 3 min. The precipitate was added to a complete medium [RPMI-1640 + 10% fetal bovine serum (FBS) + 1% penicillin–streptomycin, Biological industries (BI)] and uniformly inoculated on a six-well plate (NEST). The medium was refreshed after 48 h. The mixed fibroblasts in the primary culture were removed using differential digestion with 0.25% trypsin. When the cells reached 70% confluency, they were digested and passed on. The cell growth was regularly observed under a light microscope. From the fifth generation, the cells were subcultured in a ratio of 1:2 and frozen with Serum-free rapid cell cryopreservation solution (Mei5 Biotechnology Co., Ltd.).

Cell growth curve

The cell density of DPC-X1 cells in the logarithmic growth phase (P20) was adjusted to 1×10^4/mL after trypsin digestion. After mixing, 0.1 mL of sample was inoculated in each hole in a 96-hole plate cell counting kit-8 (CCK-8) reagent (Dojindo) was added at the same time for 4 consecutive days after inoculation and allowed to react for 2 h. The UV absorbance value at 450 nm wavelength was measured with a microplate reader. The cell doubling time was calculated using the following formula: Td = t × Lg2/Lg (N1/N0). The cell growth curve was plotted with time as the horizontal axis and absorbance value as the vertical axis.

Analysis of short tandem repeats

DPC-X1 cells in the logarithmic growth stage (P10) were collected after trypsin digestion. Together with the primary tumor tissue, they were sent to Suzhou Jianda Biotechnology Company for short tandem repeat (STR) analysis to determine the correlation between the cells and primary tumor tissue.

Karyotype analysis

DPC-X1 cells in the logarithmic growth phase (P40) were treated with 0.25 μg/mL colchicine for 6 h overnight at 37 ℃. The metaphase cells were collected and fixed with methanol glacial acetic acid (3:1). After trypsin digestion, the specimens were stained using Giemsa dye and observed under a microscope. The mitotic phase cells with good dispersion and moderate staining were selected for karyotype analysis.

Organoid culture

DPC-X1 cells in the logarithmic growth phase (P35) were digested, centrifuged, washed twice with PBS, resuspended in a complete culture medium (RPMI-1640 + 10% FBS + 1% penicillin–streptomycin, BI), and inoculated on an ultra-low adsorption cell culture plate (Corning). A thousand cells were added to each well, and 2 mL of culture medium was added for 14 d. The state and number of organ-like cultures were observed under a light microscope.

Transmission electron microscopy

DPC-X1 cells in the logarithmic growth phase (P45) were digested, centrifuged, fixed with an electron microscope fixative, and stored and transported at 4 ℃. Embedding, ultrathin sectioning, and dyeing were performed at Wuhan Servicebio Co., Ltd. Finally, the images were observed under the transmission electron microscope.

Drug sensitivity test

The logarithmically grown DPC-X1 cells (P50) were digested using trypsin to prepare a single-cell suspension. We inoculated 10000 cells/100 μL per well into 96-well plates, and 6 wells in each group were repeated. After the cells adhered to the wall, different concentrations of anti-tumor drugs were added. After 72 h of drug action, 100% X containing 10% (v/v) CCK-8 μL serum-free medium was used to replace the complete medium. The optical density value was measured after 2 h at 450 nm.

Xenograft tumor in nude mice

The cell density of cells in the logarithmic growth phase (P45) was adjusted to 1 × 10^7/mL after trypsin digestion. Thereafter, three BALB/c nude mice each were inoculated with 0.1 mL of this sample. We observed and recorded the tumor growth of the nude mice every alternate day. The mice carrying the tumor were killed after four weeks, and the tumor tissue was excised and fixed with 10% formalin. The surgery was performed under sodium pentobarbital anesthesia, and all efforts were made to minimize suffering. Thereafter, routine histopathological and immunohistochemical examinations were performed.

Immunohistochemical staining

Cells of the 40th generation were digested and inoculated onto sterile slides. After 48 h, the slides were washed with PBS, fixed with 4% paraformaldehyde for 15 min, dried, and treated with 0.5% Triton X-100 for 20 min.

The paraffin sections of primary tumors, transplanted tumors, and organ-like tissues were prepared and incubated at 60 ℃ overnight. The dewaxing, gradient alcohol hydration, and antigen repair processes were completed using Dako's Autostainer Link 48 instrument. Subsequently, 3% hydrogen peroxide solution was incubated at 37 ℃ for 15 min to block the activity of peroxidase; 100 μL of normal goat serum was dripped and then kept sealed at 37 ℃ for 15 min. The first antibody was incubated at 37 ℃ for 1 h with Fuzhou Maxin ready-to-use antibodies [cytokeratin 7 (CK7), cytokeratin 20 (CK20), cytokeratin low molecular weight (CKL), Ki67, and carcinoembryonic antigen (CEA)]. The DAB dye kit (Dako) was used for color development, followed by rinsing with running water for 5 min. Dehydration and xylene transparency were carried out after hematoxylin counterstaining, and the samples were observed under the microscope after neutral resin sealing.

Statistical analyses

All statistical analyses were performed using the SPSS 22.0 software. The data are presented as mean ± SD. Student's *t*-tests and ANOVA were used for group comparisons. Statistical significance was set at $P < 0.05$.

RESULTS

Establishment of the DPC-X1 cell line

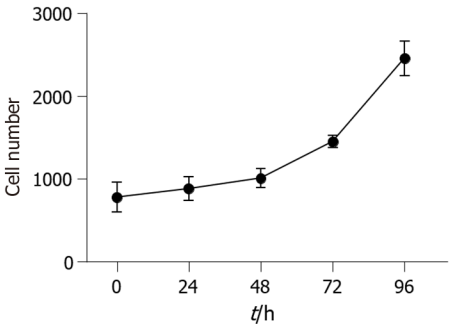
Through primary culture and subculture of primary tumor tissue of ampullary carcinoma, an ampullary carcinoma cell line, named DPC-X1, was successfully established. Using light microscopy, we found that DPC-X1 cells adhered to the wall and grew like typical epithelial cells. The cells were mainly short spindle-shaped, with large nuclei and visible nucleoli. The polykaryocytes and megakaryocytes were visible. Loss of contact inhibition between cells likely led to accumulation growth as the cells were closely adherent and grew in clumps and sheets (Figure 1F and Video). The cell morphology and growth mode remained unaltered even though it passed to the 80th generation (Figure 1G).

Cell growth curve

DPC-X1 cells proliferated vigorously and grew stably in RPMI-1640 medium with 10% FBS. Through the CCK-8 method, the doubling time of the DPC-X1 cell population was found to be 48 h using the CCK-8 method. The cell growth curve was plotted using culture time as the abscissa and absorbance values as the ordinate (Figure 2A).

Analysis of STRs

The DNA typing results demonstrated that the two submitted samples were from the same individual with a likelihood ratio = 4.1867 × 10^{20} (Figure 2B and Supplementary material). The results indicate that DPC-X1 is a new human ampullary carcinoma cell line with the same origin as that of the primary tumor tissue and is not contaminated by the existing cell line.



Karyotype analysis

Karyotype analysis showed that DPC-X1 cells were mainly sub-tetraploid, with large differences in chromosome number and morphology. The representative karyotype was 80, XX del (2) (q32) del (5) (p12) del (6) (q24) inv (9) del (10) p (13) del (17) p (12) (Figure 2C).

Organoid culture

After inoculating the DPC-X1 cells on the ultra-low attachment culture plate, the cells were observed to proliferate well and gradually form spherical or cystic organs (Figure 2D). With time, the number of organoid organs gradually increased and appeared spore-like or branch-like (Figure 2E).

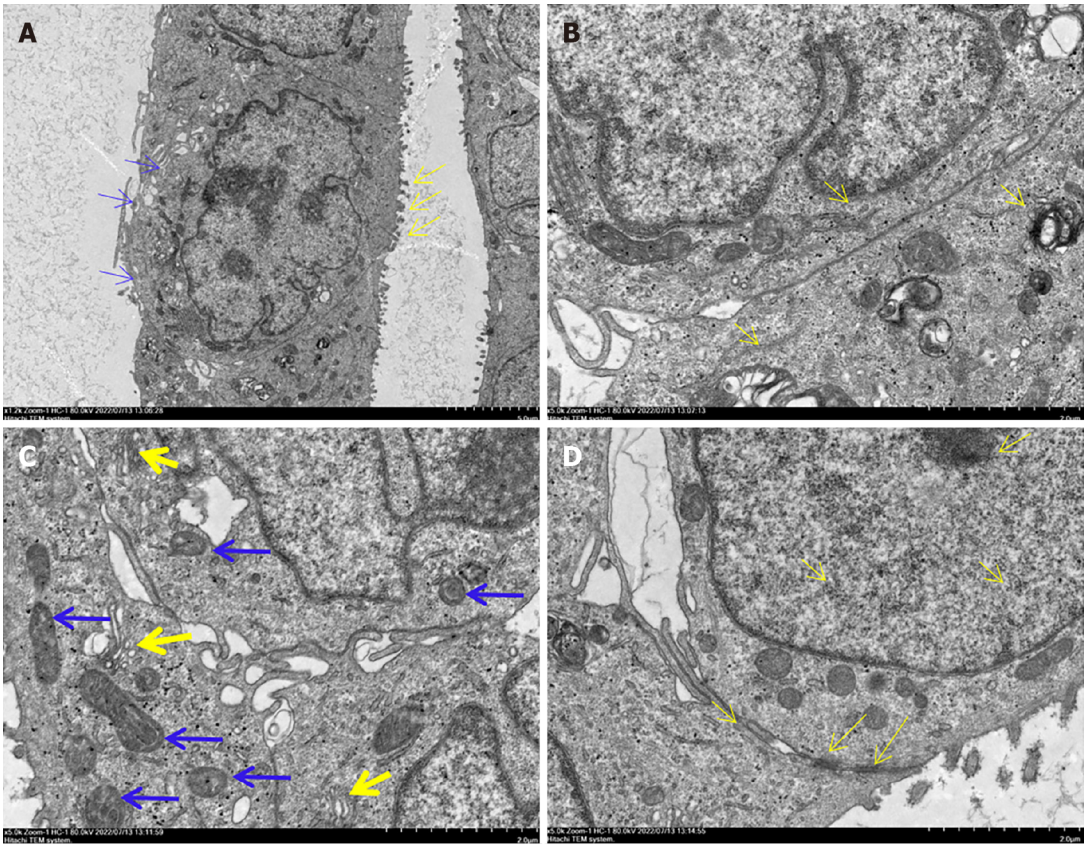

Figure 2 DPC-X1 population doubling time, short tandem repeat detection, karyotype analysis and Organoid culture. A: DPC-X1 growth curve; cell doubling time is 48 h; B: The likelihood ratio between the short tandem repeat results of DPC-X1 and the primary tumor tissue is 4.1867 × 1020. The cells are not contaminated by other cell lines; C: Karyotype analysis shows that DPC-X1 cells are mainly sub-tetraploid, with large differences in chromosome number and morphology. The representative karyotype is 80, XX del (2) (q32) del (5) (p12) del (6) (q24) inv (9) del (10) p (13) del (17) p (12); D: Morphology of DPC-X1organoids after one week. The organoids are spherical or cystic in shape; E: Morphology of DPC-X1 organoids after two weeks. The organoids are spore-like or branch-like in shape. Scale bars: 100 μm.

Transmission electron microscopy

Under the transmission electron microscope, the DPC-X1 nucleus appeared large and deformed, and its number was increased. The nucleolus was clustered in the nuclear membrane, and the cytoplasm was less. Microvilli and pseudopodia were visible on the cell surface (Figure 3A). The endoplasmic reticulum and ribosome were abundantly present in the cells (Figure 3B). Furthermore, the Golgi apparatus was developed, and the mitochondria differed in size and shape (Figure 3C). The desmosome structure was observed between the cells (Figure 3D).

Drug sensitivity test

The chemotherapy drugs gemcitabine and paclitaxel are commonly used for biliary and pancreatic tumors, whereas 5-FU and oxaliplatin are commonly used for gastrointestinal tumors. Our drug

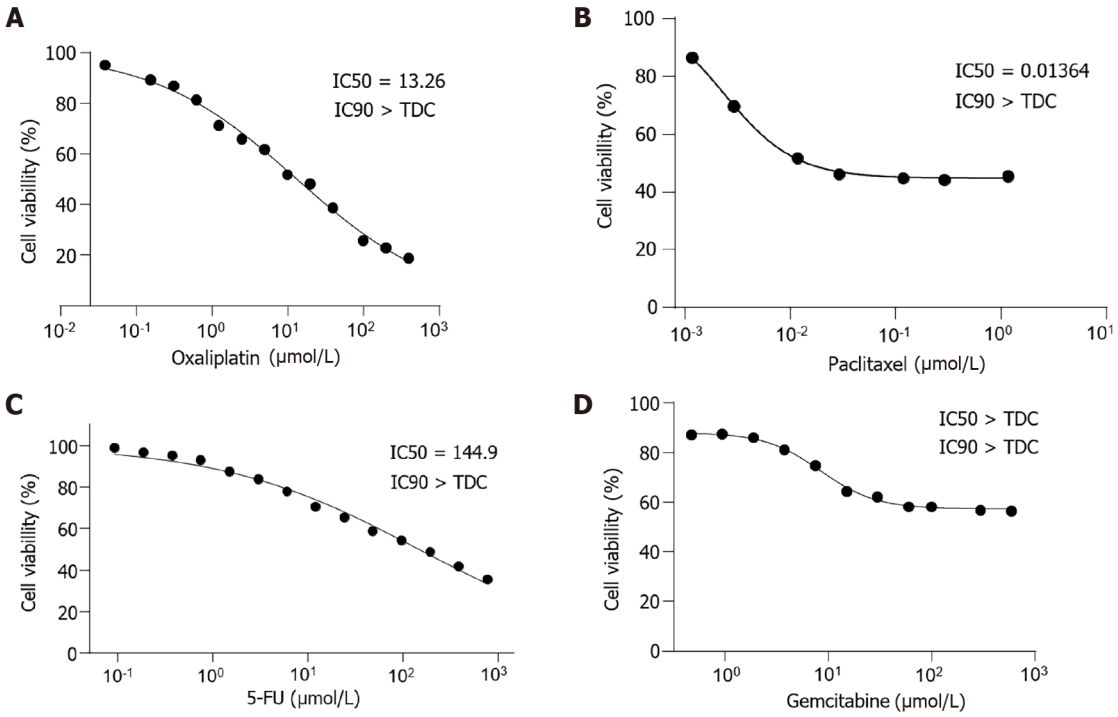
DOI: 10.3748/wjg.v29.i17.2642 **Copyright** ©The Author(s) 2023.

Figure 3 Ultrastructure of DPC-X1 under a transmission electron microscope. A: DPC-X1 has a large and deformed nucleus; it is increased in number. The nucleolus is clustered in the nuclear membrane. There are fewer cytoplasm. Microvilli (yellow arrow) and pseudopodia (blue arrow) were visible on the cell surface; B: DPC-X1 cells are rich in the endoplasmic reticulum (yellow arrow) and ribosome; C: DPC-X1 cells have well-developed Golgi apparatus (yellow arrow), and the size and shape of the mitochondria are different (blue arrow); D: DPC-X1 desmosome structure can be seen between the cells (arrow).

sensitivity test revealed that DPC-X1 was sensitive to oxaliplatin [half maximal inhibitory concentration (IC50) = 13.26 μmol/L; Figure 4A] and paclitaxel (IC50 = 0.014 μmol/L; Figure 4B) and resistant to fluorouracil (IC50 = 144.9 μmol/L; Figure 4C) and gemcitabine (IC50 > 600 μmol/L; Figure 4D).

Xenograft tumor formation experiment

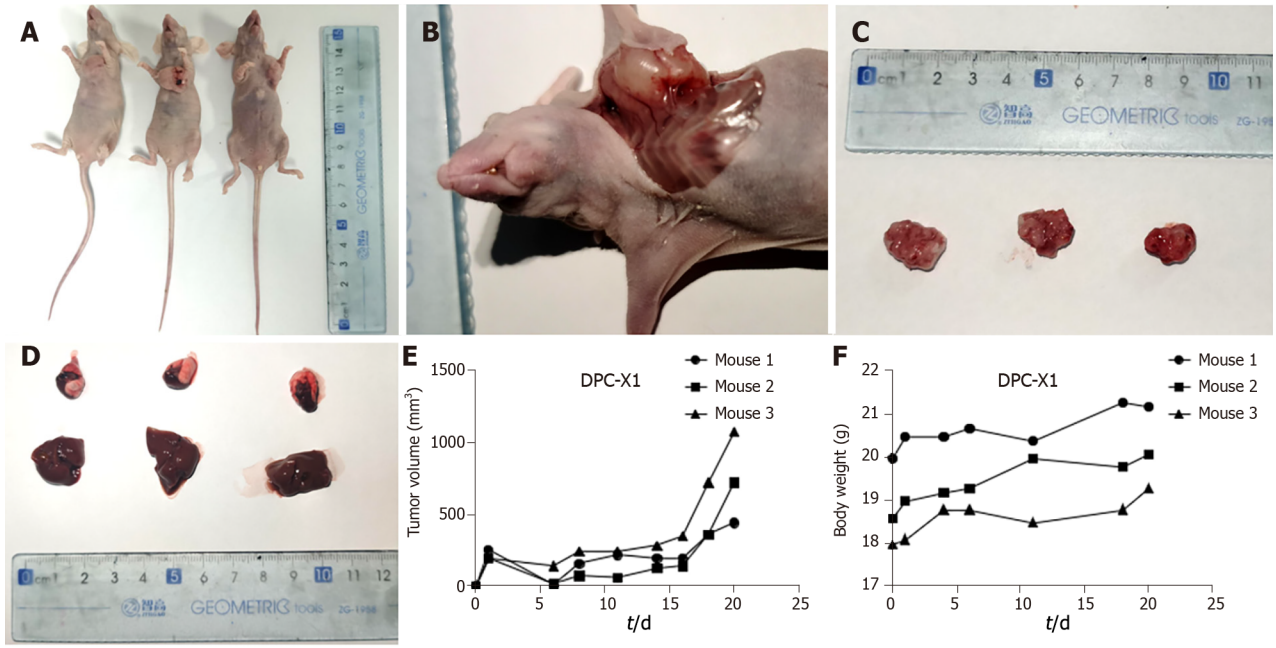
To verify the ability of DPC-X1 to form xenograft tumors *in vivo*, 1 × 10^6 DPC-X1 cells were inoculated subcutaneously in three BALB/c nude mice. The results showed that DPC-X1 was able to rapidly form xenograft tumors under the skin of nude mice, and the tumor formation rate was 100% (Figure 5A). The xenograft tumor grew rapidly and showed invasive growth. New blood vessels were visible on the surface of the xenograft tumor (Figure 5B). At four weeks, the diameter of the tumor body exceeded 1 cm (Figure 5C). No metastatic lesions were found in the liver and lungs of the dissected mice (Figure 5D). Tumor growth curve and mouse weight curve are shown in the figure (Figure 5E and F).



Hematoxylin and eosin and immunohistochemical staining

Hematoxylin-eosin staining showed that DPC-X1 cells were of different shapes, primarily short fusiform, with enlarged nuclei, apparent nucleoli, and less cytoplasm. The polykaryocytes and megakaryocytes were visible, exhibiting typical malignant tumor characteristics (Figure 6A).

The DPC-X1 organoids were observed to form irregular gland-like structures; the cells were closely connected, with a gland cavity-like structure inside. The cells in the organoid organs were highly heterotypic and varied in size (Figure 6B), which is highly similar to the histomorphology of the primary tumor tissue.



The xenograft tumor formed an irregular gland-like structure, and its histological morphology was similar to that of the primary tumor. The nucleus of the tumor was large and hyperchromatic, and the megakaryocytes were visible. The mitotic images depicted the vigorous proliferation of the DPC-X1 cells (Figure 6C); this observation is consistent with the characteristics of malignant tumors.

The postoperative pathological diagnosis of the patient's primary tumor showed moderately to poorly differentiated, and the tumor cells were arranged in irregular glandular tubes, strips, and nests (Figure 6D).

Figure 5 Xenograft tumor formation experiment. A: In four weeks, DPC-X1 quickly formed xenograft tumors under the skin of BALB/c nude mice. The tumor formation rate is 100%; B: Anatomically, the xenograft tumor and muscle tissue of the mouse shows invasive growth, and new blood vessels can be seen on the surface of the tumor; C: General view of the xenograft tumor; D: No metastatic lesions were found in the lungs and liver of BALB/c nude mice within four weeks; E: Growth curve of DPC-X1 transplanted tumor; F: Body weight curve of BALB/c nude mice.

Immunohistochemical examination of DPC-X1 cells, organoids, xenograft tumor, and primary tumor showed that CK7 (Figure 6E–H), CK20 (Figure 6I–L), and CKL (Figure 6M–P) were strongly expressed among the four groups, indicating that they had the same origin. Moreover, DPC-X1 cells were found to exhibit both intestinal and pancreaticobiliary characteristics; thus, they were a mixed ampullary carcinoma cell line. Ki67 (Figure 6Q–T) was highly expressed, consistent with the rapid proliferation of

Figure 6 Hematoxylin and eosin and immunohistochemical staining of DPC-X1 cells, organoid, xenograft tumor, and primary tumor. A-D: Hematoxylin and eosin staining of DPC-X1 cells, organoids, xenograft tumor, and primary tumor; E-H: Strong cytokeratin (CK)7 positive staining of DPC-X1 cells, organoids, xenograft tumor, and primary tumor; I-L: Strong CK20 positive staining of DPC-X1 cells, organoids, xenograft tumor, and primary tumor; M-P: Strong cytokeratin low molecular weight positive staining of DPC-X1 cells, organoids, xenograft tumor, and primary tumor; Q-T: Ki67 staining of DPC-X1 cells, organoids, xenograft tumor, and primary tumor; U-X: Carcinoembryonic antigen focal staining of DPC-X1 cells, organoids, xenograft tumor, and primary tumor. Scale bars: 100 μm. H&E: Hematoxylin and eosin; CK7: Cytokeratin 7; CK20: Cytokeratin 20; CKL: Cytokeratin low molecular weight; CEA: Carcinoembryonic antigen.

the tumor, and CEA (Figure 6U–X) showed focal expression. These observations are consistent with the characteristics of malignant tumors.

DISCUSSION

In recent years, with development in endoscopy, imaging equipment, and technological progress, an increasing number of ampullary cancer cases have been diagnosed[24-26]. Owing to the lack of cell lines and related research models of ampullary carcinoma, research on the pathogenesis and biological characteristics of ampullary carcinoma remains limited.

In this study, we successfully established a novel ampullary carcinoma cell line named DPC-X1 from the primary tumor tissue of patients with ampullary carcinoma through primary culture and subculture. This cell line was continuously cultured for more than a year and stably passaged for over 80 generations. DPC-X1 cells adhered to the wall and grew like typical epithelial cells. The cells were chiefly short spindle-shaped, with large nuclei and visible nucleoli, and multinucleated cells and megakaryocytes were visible. The cells were closely adherent and grew in clumps and sheets. The characteristics of DPC-X1 were highly consistent with those of the patient's primary tumor, and it was not contaminated by other cell lines and microorganisms. DPC-X1 could efficiently form organoids in suspension culture. The Ki67 of DPC-X1 was 50%, indicating that DPC-X1 has a vigorous proliferation, which is consistent with its population doubling time of 48 h.

CK7 is typically used as a tumor marker of biliary and pancreatic origin, whereas CK20 and villin are used as tumor markers of gastrointestinal origin[18,20,24,27,28]. In this study, DPC-X1 immunohistochemistry showed that CK7, CK20, and CKL were strongly positive, indicating that DPC-X1 was a mixed ampullary carcinoma cell line. To the best of our knowledge, this is the first study to report a mixed-type ampullary carcinoma cell line. Thus, DPC-X1 may provide a useful model for studying mixed-type ampullary carcinoma.

Chromosome instability and chromosomal aneuploidy are common in human cancers and are important characteristics of tumor cells[29-32]. Aneuploid karyotype of tumor cells is closely related to poor prognosis of patients[33,34]. Triploid karyotype may be related to endogenous drug resistance of tumors, whereas tetraploidy of tumors is associated with acquired drug resistance[35]. Spontaneous chromosomal missegregation events in aneuploid cells promote chromosomal instability, thereby increasing the risk of tumor recurrence[36]. Karyotype analysis showed that DPC-X1 cells had a subtetraploid abnormal karyotype, and the representative karyotype was 80, XX del (2) (q32) del (5) (p12) del (6) (q24) inv (9) del (10) p (13) del (17) p (12). The results of drug sensitivity showed that DPC-X1 was sensitive to oxaliplatin and paclitaxel but was naturally resistant to gemcitabine and fluorouracil. The patient underwent four cycles of chemotherapy with the XELOX regimen and two cycles with the AG regimen after surgery; however, he succumbed to tumor recurrence one year after surgery. Our results are highly consistent with that of earlier studies.

Desmosomes are intercellular junction complexes that anchor the intermediate filaments of adjacent cells and provide them with strong cell adhesion; thus, they are essential in maintaining the organizational structure and structural integrity[37]. Much evidence has substantiated the importance of desmosomes and their components in cancer. Desmosome expression is downregulated in poorly differentiated head and neck transitional and squamous cell carcinoma. In these tissues, desmosomes may have the function of inhibiting invasion and metastasis. In colon cancer, no downregulation has been found[38,39]. The change in desmosome component expression may promote tumor progression by altering the intracellular signal transduction pathway or leading to reduced cell adhesion. The loss of desmosome function is a prerequisite for epithelial-mesenchymal transformation, which is related to the transformation of early tumors to invasive cancer[40-44]. When DPC-X1 cells were subcultured, most of them grew in clumps and sheets, and digesting them into single cells in conventional digestion time was difficult, indicating the strong adhesion between the cells. The presence of intercellular desmosomes under transmission electron microscopy provides some ultrastructural evidence for the aforementioned phenomenon. DPC-X1 cells can be used to further study the relationship between tumors and desmosomes.

Animal models are an intermediate step between cell experiments and human clinical trials. They are a powerful tool for studying canceration and tumor progression and for testing the efficacy and toxicity of therapeutic compounds[45]. Suitable animal models not only help to explore the mechanism of ampullary carcinoma occurrence and development but also provide a good platform for exploring new strategies for early clinical diagnosis and precise treatment[46]. DPC-X1 cells inoculated into BALB/C nude mice could quickly form transplanted tumors, with a tumor formation rate of 100%, and the histology of the xenografts resembled that of the original tumor.

CONCLUSION

In summary, we report a novel human mixed-type ampullary carcinoma cell line DPC-X1 developed from a Chinese patient's tumor. This cell line provides a new experimental model for studying the biological and molecular mechanisms of ampullary carcinoma and developing new therapeutic drugs.

ARTICLE HIGHLIGHTS

Research background

To date, only eight ampullary cancer cell lines have been reported, and a mixed-type ampullary carcinoma cell line has not yet been reported.

Research motivation

There is no ampullary cancer cell line of Chinese origin, and there is no report of mixed ampullary cancer cell line.

Research objectives

To establish a stable mixed-type ampullary carcinoma cell line originating from Chinese.

Research methods

Establish cell lines through primary culture and subculture, and identify their biological characteristics.

Research results

In this study, we successfully established and characterized of a mixed-type ampullary carcinoma cell line, DPC-X1, from the primary tumor of a patient with ampullary carcinoma.

Research conclusions

DPC-X1 can be used as an effective model for studying the pathogenesis of ampullary carcinoma and drug development.

Research perspectives

The establishment of ampullary carcinoma cell lines provides suitable experimental models for further study of ampullary carcinoma.

Abstract

BACKGROUND

Mucosal patterns (MPs) observed on blue laser imaging in patients with atrophic gastritis can be classified as spotty, cracked, and mottled. Furthermore, we hypothesized that the spotty pattern may change to the cracked pattern after *Helicobacter pylori* (*H. pylori*) eradication.

AIM

To further substantiate and comprehensively investigate MP changes after *H. pylori* eradication in a larger number of patients.

METHODS

We included 768 patients who were diagnosed with atrophic gastritis with evaluable MP using upper gastrointestinal endoscopy at the Nishikawa Gas-

trointestinal Clinic, Japan. Among them, 325 patients were *H. pylori*-positive, and of them, 101 patients who underwent upper gastrointestinal endoscopy before and after *H. pylori* eradication were evaluated for post-eradication MP changes. The patients' MPs were interpreted by three experienced endoscopists who were blinded to their clinical features.

RESULTS

Among 76 patients with the spotty pattern before or after *H. pylori* eradication, the pattern disappeared or decreased in 67 patients [88.2%, 95% confidence interval (CI): 79.0%-93.6%), appeared or increased in 8 patients (10.5%, 95%CI: 5.4%-19.4%), and showed no change in 1 patient (1.3%, 95%CI: 0.2%-7.1%). In 90 patients with the cracked pattern before or after *H. pylori* eradication, the pattern disappeared or decreased in 7 patients (7.8%, 95%CI: 3.8%-15.2%), appeared or increased in 79 patients (87.8%, 95%CI: 79.4%-93.0%), and showed no change in 4 patients (4.4%, 95%CI: 1.7%-10.9%). In 70 patients with the mottled pattern before or after *H. pylori* eradication, the pattern disappeared or decreased in 28 patients (40.0%, 95%CI: 29.3%-51.7%), appeared or increased in 35 patients (50.0%, 95%CI: 38.6%-61.4%), and showed no change in 7 patients (10.0%, 95%CI: 4.9%-19.2%).

CONCLUSION

After *H. pylori* eradication, MPs changed from spotty to cracked in most patients, which may help endoscopists easily and precisely evaluate *H. pylori*-related gastritis status.

Key Words: Atrophic gastritis; *Helicobacter pylori*; Gastrointestinal endoscopy; Image enhancement; Classification

Core Tip: We investigated whether the mucosal patterns on blue laser imaging may change from spotty to cracked after *Helicobacter pylori* (*H. pylori*) eradication. The spotty pattern disappeared or decreased in 88.2% of patients, while the cracked pattern appeared or increased in 87.8% of patients. These suggest that the spotty pattern observed in *H. pylori*-positive patients is likely to disappear after eradication and may be replaced by the cracked pattern. These observations may help endoscopists easily and precisely evaluate *H. pylori*-related gastritis status.

INTRODUCTION

Helicobacter pylori (*H. pylori*) infection and related atrophic gastritis is closely associated with the development of gastric cancer[1]. Therefore, it is critical to observe the gastric mucosa to precisely judge the infection status as "current," "previous," or "none." Recently, various types of image-enhanced endoscopy have been used to ensure the accurate evaluation of *H. pylori* infection[2-6].

In our previous study[7], we classified mucosal patterns (MPs) into three types (spotty, cracked, and mottled) using blue laser imaging (BLI)[8,9] in patients with *H. pylori*-related gastritis. We found that the spotty pattern indicated the possibility of *H. pylori* infection, the cracked pattern indicated a post-inflammatory change after *H. pylori* eradication, and the mottled pattern indicated an intestinal metaplasia resulting from the progression of *H. pylori*-related gastritis. Thus, we hypothesized that the spotty pattern would disappear or decrease and the cracked pattern would newly appear or increase after *H. pylori* eradication.

To further explore these changes, we quantitatively analyzed the changes to determine whether each pattern would increase, decrease, or remain unchanged. Since little is known concerning the pattern changes after *H. pylori* eradication, clarification of these changes may help endoscopists diagnose the existing pattern as being pre- or post-eradication and understand the MP changes more precisely. Thus, this study aimed to clarify the significance and diagnostic viability of each MP using BLI.

Representative images of the spotty pattern shown as white spots of 1-2 mm in diameter in the gastric antrum of 6 patients infected with *Helicobacter pylori* (*H. pylori*) observed using blue laser imaging-bright mode. A: 45-year-old female, *H. pylori*-positive; B: 51-year-old female, *H. pylori*-positive; C: 27-year-old female, *H. pylori*-positive; D: 59-year-old female, *H. pylori*-positive, nodular gastritis; E: 49-year-old male, *H. pylori*-positive; F: 66-year-old female, *H. pylori*-positive.

MATERIALS AND METHODS

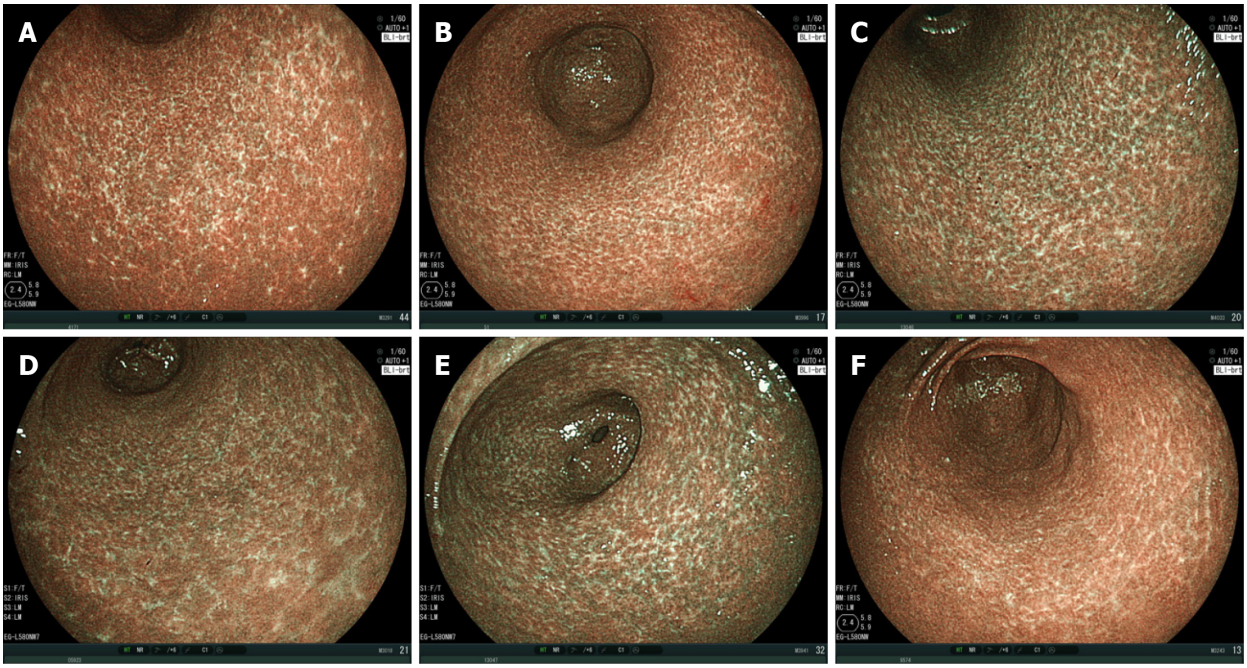
Patients and methods

A total of 2242 patients underwent upper gastrointestinal (GI) endoscopy at the Nishikawa Gastrointestinal Clinic, Ehime, Japan from April 1, 2015 to March 31, 2017. Of these, 768 patients were endoscopically diagnosed with atrophic gastritis. The presence or absence of *H. pylori* infection was confirmed. Among them, 325 patients were *H. pylori*-positive, and of them, 101 patients who underwent *H. pylori* eradication and subsequent endoscopy were examined for MP changes.

An EG-L580NW nasal upper GI endoscope (FUJIFILM Medical Co. Ltd., Tokyo, Japan) was used orally or nasally. The BLI bright mode was used to evaluate MPs in the intermediate or distant views.

This study was approved by the Ethics Committee of Ehime University Hospital (No: 1605010; August 22, 2016). Prior to receiving an endoscopic examination, all patients agreed that the data obtained in this study might be published in academic papers.

Classification of MPs



The MPs were classified into three types: The spotty pattern, which consists of 1-2 mm diameter spots (Figure 1); the cracked pattern, which consists of net-like cracks (Figure 2); and the mottled pattern, which has a mottled appearance (Figure 3)[7].

Evaluation of the MP changes after H. pylori eradication

The MP patterns were evaluated as follows: (1) Three expert GI endoscopists, with at least 25 years of experience, evaluated the mucosal changes after *H. pylori* eradication; (2) They were blinded to the patients' endoscopic data, including the patterns obtained before and/or after *H. pylori* eradication; (3) They compared two randomly listed endoscopic image groups and evaluated which image group was dominant, less dominant, equal, or absent for the spotty, cracked, and mottled patterns; (4) When two or all endoscopists agreed on a particular pattern, that pattern was adopted for analysis. When they had conflicting pattern determinations, the final determination was reached through a joint discussion; and (5) *H. pylori* infection was diagnosed using the anti-*H. pylori* IgG antibody serology tests[10,11], urea breath tests[12-15], and biopsies.

Statistical analysis

Student's *t*-test was used for the analysis of age, and the χ^2 test was used for the analyses of other variables. Statistical significance was set at $P < 0.05$. A 95% confidence interval (CI) was calculated to determine the uncertainty of the sample estimates. All statistical analyses were performed using

Figure 2 Cracked pattern. Representative images of the cracked pattern as white net-like cracks consisting of lines in the gastric antrum of 6 patients after *Helicobacter pylori* (*H. pylori*) eradication observed using blue laser imaging-bright mode. A: 69-year-old female, *H. pylori*-negative, 2 years, 11 mo after eradication; B: 75-year-old female, *H. pylori*-negative, 6 years, 0 mo after eradication; C: 63-year-old female, *H. pylori*-negative, 1 year, 2 mo after eradication; D: 72-year-old female, *H. pylori*-negative, 1 year, 0 mo after eradication; E: 63-year-old female, *H. pylori*-negative, 1 year, 2 mo after eradication; F: 52-year-old male, *H. pylori*-negative, 2 years, 1 mo after eradication.

Microsoft Excel 2016, version 1907, Build 11901.20176 (Microsoft Corporation, Redmond, WA, United States), and the statistical methods of this study were reviewed by Dr. Natsumi Yamashita from Clinical Research Center, National Hospital Organization Shikoku Cancer Center.

RESULTS

Patient characteristics

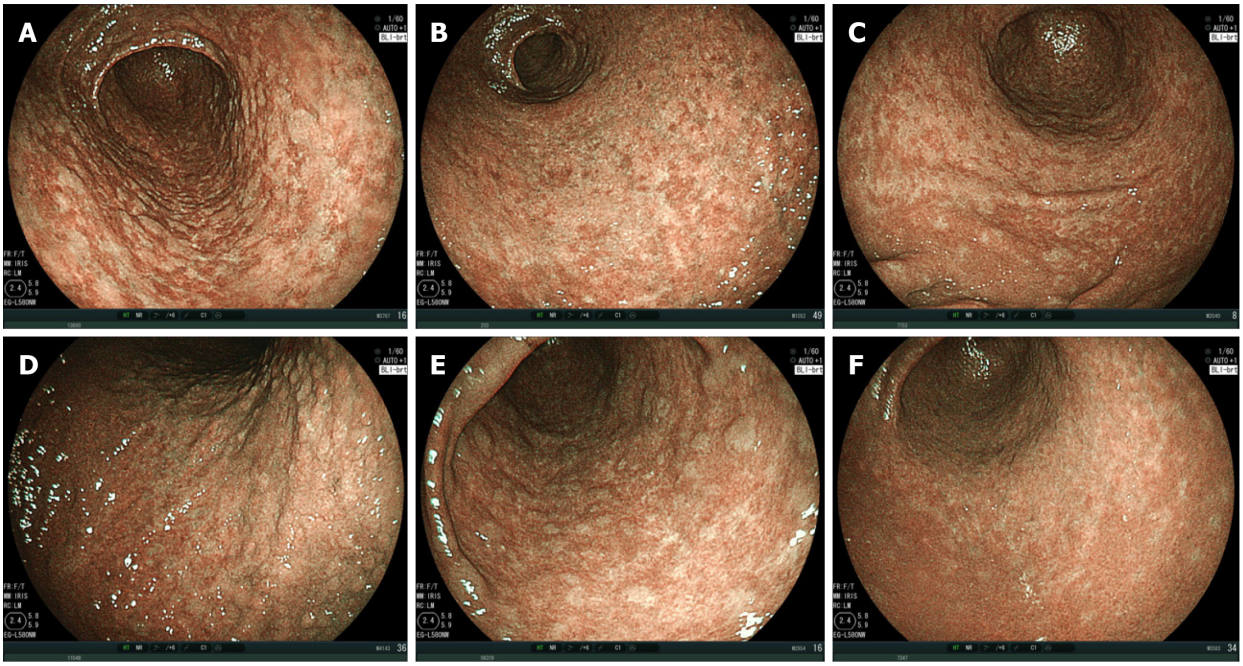
The number of patients evaluated was 768 (480 females and 288 males) with a mean age of 65.8 ± 12.9 (standard deviation) years. The numbers of patients with and without *H. pylori* infection were 325 (204 females and 121 males) and 443 (276 females and 167 males), respectively.

The mean ages of patients with and without *H. pylori* infection were 61.6 ± 14.3 years and 68.9 ± 10.7 years, respectively, with significant differences among them ($P < 0.001$). No significant difference was observed between the proportions of female and male patients with and without *H. pylori* infection ($P = 0.895$; Table 1).

Changes in MPs after H. pylori eradication

Upper GI endoscopy was performed for 101 patients (females: 75; males: 26; mean age: 57.5 ± 14.1 years) who successfully underwent *H. pylori* eradication, and the endoscopic mucosal changes were evaluated. Patients in whom evaluation was difficult because there were no comparable images of the specific parts were excluded from the analysis. The mean interval between *H. pylori* eradication and post-eradication endoscopy was 27.1 ± 13.1 mo.

In our study, multiple patterns commonly coexisted in many patients, with some patients having all three patterns. Of the 101 patients, 38 patients showed all three patterns (spotty, cracked, and mottled), 59 had two patterns (spotty and cracked, 28; spotty and mottled, 7; and cracked and mottled, 24), and 4 patients presented with only one pattern (spotty, 3; cracked, 0; and mottled, 1) either before or after eradication.



In 76 patients with a spotty pattern before or after *H. pylori* eradication, the pattern disappeared or decreased in 67 patients (88.2%, 95%CI: 79.0%-93.6%) and appeared or increased in 8 patients (10.5%, 95%CI: 5.4%-19.4%). In 1 patient (1.3%, 95%CI: 0.2%-7.1%), no change was observed after *H. pylori* eradication.

In 90 patients with a cracked pattern before or after *H. pylori* eradication, the pattern disappeared or decreased in 7 patients (7.8%, 95%CI: 3.8%-15.2%) and appeared or increased in 79 patients (87.8%,

Table 1 Patient characteristics

Item	Patients with atrophic gastritis	Patients with *H. pylori* infection	Patients underwent both *H. pylori* eradication and follow up endoscopy
No. of patients	768	325	101
Age, mean ± SD	65.8 ± 12.9	61.6 ± 14.3	57.5 ± 14.1
Female	480	204	75
Male	288	121	26

SD: Standard deviation; *H. pylori: Helicobacter pylori*.

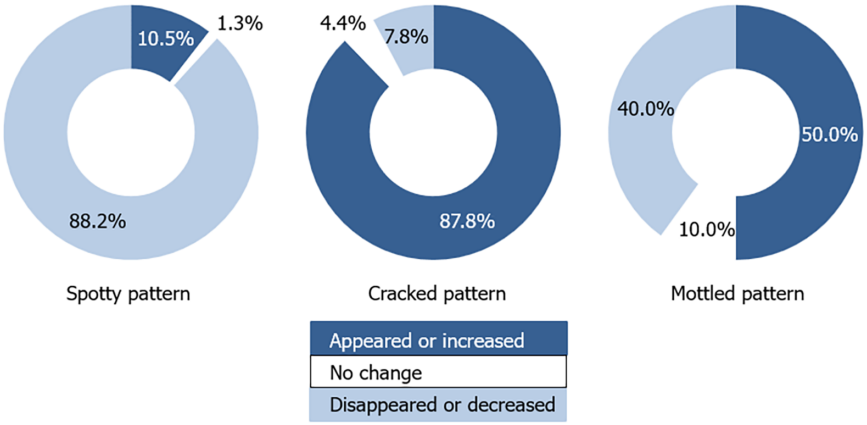

Figure 3 Mottled pattern. Representative images of the mottled pattern observed using blue laser imaging-bright mode in the gastric antrum of 6 patients. The whitish-colored mottled areas varied from small to large. Only panel A shows the pattern of a patient infected with *Helicobacter pylori* (*H. pylori*). A: 67-year-old male, *H. pylori*-positive, before eradication; B: 74-year-old male, *H. pylori*-negative, no eradication; C: 73-year-old female, *H. pylori*-negative, 2 years, 11 mo after eradication; D: 87-year-old male, *H. pylori*-negative, no eradication; E: 83-year-old male, *H. pylori*-negative, 5 years, 2 mo after eradication; F: 60-year-old female, *H. pylori*-negative, 2 years, 2 mo after eradication.

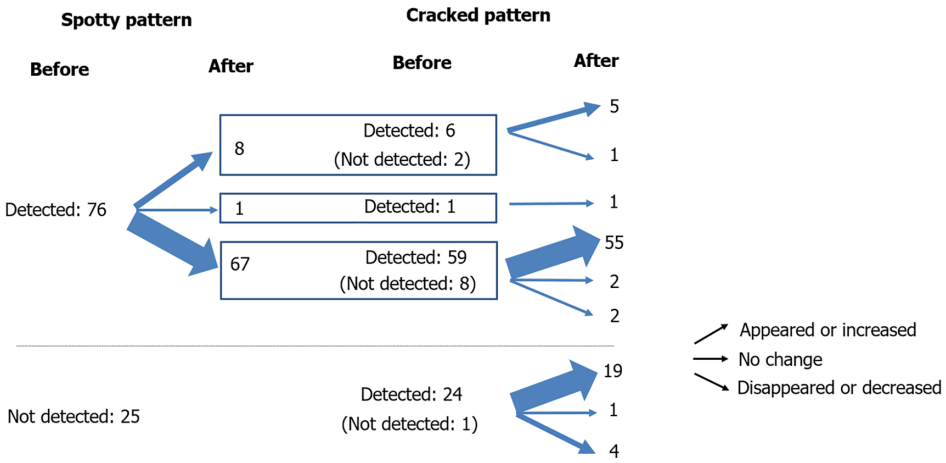
95%CI: 79.4%-93.0%). In 4 patients (4.4%, 95%CI: 1.7%-10.9%), no change was observed after *H. pylori* eradication.

In 70 patients with a mottled pattern before or after *H. pylori* eradication, the pattern disappeared or decreased in 28 patients (40.0%, 95%CI: 29.3%-51.7%) and appeared or increased in 35 patients (50.0%, 95%CI: 38.6%-61.4%). In 7 patients (10.0%, 95%CI: 4.9%-19.2%), no change was observed after *H. pylori* eradication (Figure 4).



We investigated the relationship between the spotty and cracked patterns before and after eradication. The spotty pattern disappeared or decreased in 67 out of the 76 patients who had a spotty pattern before or after eradication. Of the 67 patients, the cracked pattern appeared or increased in 55 patients. Among the 8 patients with spotty patterns that appeared or increased after eradication, the cracked pattern appeared or increased in 5 patients. The cracked pattern appeared or increased in most of the 25 patients who did not have a spotty pattern before or after eradication (Figure 5).

We further investigated the difference in MP changes due to *H. pylori* eradication between the short-term (8-24 mo) and long-term (25-60 mo) observation groups. The spotty pattern disappeared or decreased in 88.6% and 87.8% (short-term *vs* long-term) of the patients. The cracked pattern newly appeared or increased in 88.9% and 86.7% (short-term *vs* long-term) of the patients. No significant differences were observed between the patients under short-term and long-term observations.

Figure 5 Relationship between the spotty and cracked patterns before and after *Helicobacter pylori* eradication.

DISCUSSION

We investigated the use of BLI, an image-enhanced endoscopy, for the diagnosis of *H. pylori*-related gastritis, with a focus on the MP changes after *H. pylori* eradication. The Kyoto Classification of Gastritis was established in 2014 for the endoscopic diagnosis of *H. pylori*-related gastritis[16,17]. The classification of MPs observed on BLI in this study is simpler and easier to use in endoscopic assessment than the Kyoto classification and thus has the potential to become a new standard method with the addition of new diagnostic information to the Kyoto classification. We previously reported the efficacy of MPs on BLI in an intermediate-to-distant view evaluation of *H. pylori* infection and had the benefits of easy detection of atrophic gastritis and easy diagnosis of infection status (current, previous, or no infection) [7].

The results obtained in the current study indicate that the disappearance of the spotty pattern is evidence of *H. pylori* clearance, while newly-appearing cracked pattern is evidence of post-gastritis healing. The mottled pattern may reflect "intestinal metaplasia," as identified in our previous study using biopsies.

Knowledge of the endoscopic changes after *H. pylori* eradication is helpful in clarifying the meaning of each MP. The spotty pattern disappeared or decreased in 88.2% of patients, whereas the cracked pattern appeared or increased in 87.8% of patients after *H. pylori* eradication. The mottled pattern exhibited no specific tendency. As indicated in Figure 5, the spotty pattern observed in *H. pylori*-positive patients before eradication may disappear and may be replaced by the cracked pattern. Based on these observations, we can diagnose the *H. pylori* infection status as current, previous, or no infection. No difference was detected between the short-term and long-term observations of MP changes after *H. pylori* eradication, suggesting that the changes in MP would occur relatively quickly after eradication. The primary tendency of MP changes after *H. pylori* eradication have been clarified in this study. Irregular pattern changes (those other than spotty to cracked pattern) were observed after eradication in

a limited number of patients. Further verification is necessary.

CONCLUSION

In conclusion, the spotty pattern may indicate *H. pylori* infection, the cracked pattern may indicate post-inflammatory changes after *H. pylori* eradication, and the mottled pattern may indicate intestinal metaplasia resulting from the progression of *H. pylori*-related gastritis. We verified that MPs on BLI may change from a spotty to a cracked pattern after *H. pylori* eradication. These observations may help endoscopists easily and precisely evaluate the status of *H. pylori*-related gastritis. We hope that MP changes on BLI will be routinely used to confirm the diagnosis of *H. pylori*-related gastritis in the future.

ARTICLE HIGHLIGHTS

Research background

Determination of the presence or absence of *Helicobacter pylori* (*H. pylori*) infection is important in the diagnosis of atrophic gastritis. Various studies have been conducted to distinguish these two conditions.

Research motivation

In our previous study, we reported that *H. pylori* eradication may lead to the disappearance of the spotty pattern and the appearance of the cracked pattern.

Research objectives

To further substantiate and comprehensively investigate mucosal pattern changes after *H. pylori* eradication in a larger number of patients.

Research methods

Among the patients with atrophic gastritis in whom *H. pylori* positivity was confirmed, we investigated 101 patients who underwent both *H. pylori* eradication and follow-up endoscopy and evaluated the change of patterns before and after eradication.

Research results

The spotty pattern tended to disappear or decrease, and the cracked pattern tended to appear or increase after *H. pylori* eradication, while the mottled pattern exhibited no specific tendency.

Research conclusions

The spotty pattern likely changes to the cracked pattern after *H. pylori* eradication.

Research perspectives

In future studies, it will be necessary to examine the morphological and histological changes of each mucosal pattern, compare these pattern changes with the Kyoto classification, examine the relationship with other classifications of atrophic gastritis, and clarify the meaning of the mucosal pattern changes.

Abstract

BACKGROUND

Fecal microbial transplantation (FMT) is a promising new method for treating active ulcerative colitis (UC), but knowledge regarding FMT for quiescent UC is scarce.

AIM

To investigate FMT for the maintenance of remission in UC patients.

METHODS

Forty-eight UC patients were randomized to receive a single-dose FMT or autologous transplant *via* colonoscopy. The primary endpoint was set to the maintenance of remission, a fecal calprotectin level below 200 μg/g, and a clinical Mayo score below three throughout the 12-mo follow-up. As secondary end-points, we recorded the patient's quality of life, fecal calprotectin, blood chemistry, and endoscopic findings at 12 mo.

RESULTS

The main endpoint was achieved by 13 out of 24 (54%) patients in the FMT group and by 10 out of 24 (41%) patients in the placebo group (log-rank test, P = 0.660). Four months after FMT, the quality-of-life scores decreased in the FMT group compared to the placebo group (P = 0.017). In addition, the disease-specific quality of life measure was higher in the placebo group than in the FMT group at the same time point (P = 0.003). There were no differences in blood chemistry, fecal calprotectin, or endoscopic findings among the study groups at 12 mo. The adverse events were infrequent, mild, and distributed equally between the groups.

CONCLUSION

There were no differences in the number of relapses between the study groups at the 12-mo follow-up. Thus, our results do not support the use of a single-dose FMT for the maintenance of remission in UC.

Key Words: Fecal microbial transplantation; Ulcerative colitis; Quality of life; Maintenance of remission; Inflammatory bowel disease; Fecal calprotectin

Core Tip: This randomized controlled trial compared the efficacy of fecal microbial transplantation *via* colonoscopy and autologous placebo containing patients' own feces for the maintenance of remission in 48 patients with ulcerative colitis. The colitis activity was measured with the clinical Mayo score and fecal calprotectin. There was no significant difference in relapses between the groups at the 12-mo follow-up. Remission remained in 54% of the patients in the fecal microbial transplantation group compared to 41% in the placebo group. There was no difference in the adverse events between the groups.

INTRODUCTION

Ulcerative colitis (UC) is a chronic inflammatory disease with an uncertain etiology. The symptoms of UC include bloody diarrhea and abdominal cramps. The pathophysiology is thought to involve an altered and exaggerated inflammatory response to commensal bacteria in genetically predisposed individuals[1]. An increasing proportion of the population is affected by UC, and the prevalence is highest in North America and Northern Europe. For example, in Finland, the yearly incidence is over 25/100000 and is growing[2]. The lifelong risk of colectomy remains elevated despite new immune response-targeting treatment options[3]. Patients with UC show a reduced quality of life compared to the general population even if the disease is quiescent[4].

UC is associated with decreased gut microbial diversity and stability as well as altered microbiota composition and function[5]. In conditions such as *Clostridioides difficile* infection (CDI) and irritable bowel syndrome (IBS), fecal microbial transplantation (FMT) has been shown to alter the patients' gut microbiota in the long term to resemble that of healthy donors[6-8]. During the last decade, FMT has become a recommended treatment option for recurrent *Clostridioides difficile* infection (rCDI)[9]. The efficacy of FMT for rCDI exceeds 90% using an optimal protocol[10,11]. On this basis, it is worthwhile to investigate FMT in UC patients.

FMT has shown promising efficacy for active UC in placebo-controlled trials, although the methodology has varied between studies[12-15]. Repetitious FMTs have been the most frequently applied approach among these studies, while the applied treatment protocols have been otherwise diverse. Some studies have applied a multidonor approach and prepared each transplant from the feces of multiple donors[14,15]. Anaerobic conditions for manufacturing the fecal transplant have been investigated and shown to yield good results[15], as has the administration of a transplant to each patient as many as 40 times[14]. One study showed a clear difference in efficacy between donors, as transplants from one donor were more effective than transplants from the other five donors[13].

A recent randomized placebo-controlled trial from India investigated the efficacy of FMT in the maintenance of UC remission[16]. In this study, FMT prevented relapses through the administration of transplants during bimonthly colonoscopies, making the implementation of the applied protocol very

laborious in clinical practice. Additionally, the study population consisted of primary responders to FMT treatment; thus, the patients in the trial were a highly selective group.

Given that a single FMT alters the gut microbiota for the long term in rCDI[6] as well as in IBS[8] patients, we aimed to investigate the efficacy of a single FMT *via* colonoscopy to maintain remission in UC patients. Additionally, we aimed to investigate the potential differences in quality of life, fecal calprotectin, blood chemistry [blood count, liver enzymes, creatinine, and C-reactive protein (CRP)], and endoscopic findings during the 12-mo follow-up period.

MATERIALS AND METHODS

Study design

We randomized patients with UC in remission into two groups in a 1:1 ratio to receive either FMT from a healthy donor ("FMT group") or an autologous transplant made from the patient's own feces ("placebo group"). To ensure blinding, all participants donated their stool for the preparation of the placebo transplant, and the FMT group samples were discarded. Bowel lavage was performed using a macrogol solution prior to colonoscopy. The transplant was administered into the cecum of the patient during colonoscopy at baseline.

After the baseline intervention, the patients were followed until a colonoscopy 12 mo later. During the follow-up period, the participants were contacted at 2 mo, 4 mo, and 8 mo after the intervention, at which times the clinical Mayo score[17] was recorded and blood samples were obtained. The quality of life was assessed at baseline as well as at 4 mo and 12 mo[4]. Fecal calprotectin samples were obtained at seven timepoints (baseline and at 2 mo, 4 mo, 6 mo, 8 mo, 10 mo, and 12 mo).

The primary endpoint was sustained remission through the 12-mo follow-up time. Remission was defined as a clinical Mayo score below three and a fecal calprotectin level below 200 μg/g. Additionally, an overt relapse between the measurement points leading to a course of steroids or escalation of maintenance therapy was considered a failure.

This randomized placebo-controlled study was conducted in Finland in the Gastroenterology Departments of Helsinki University Hospital, Helsinki and Päijät-Häme Central Hospital, Lahti. The ethical review board of Helsinki University Hospital approved the study (29/13/03/01/2014). The principles of the Declaration of Helsinki were followed. The trial was registered at ClinicalTrials.gov (NCT03561532).

Participants

Forty-eight patients (21-70-years-old) diagnosed with UC were recruited for the study. The inclusion criteria stated that the patients had to be in remission, and the eligibility criteria included fecal calprotectin levels below 100 μg/g and a clinical Mayo score < 3 at the time of screening. The exclusion criteria included the use of antibiotics within 3 mo prior to study entry, a history of tumor necrosis factor-α blockers or other biologics, the use of a high dose of corticosteroids (prednisolone ≥ 20 mg/d), and pregnancy. The patients were recruited from primary and secondary health care centers of the Helsinki and Lahti regions. At baseline, the majority of the patients were on mesalazine.

After the screening visit and before the start of the trial, some patients experienced minor activation of the disease; 8 patients, 4 in each group, had a clinical Mayo score ≥ 3, and 10 patients, 3 in the FMT group and 7 in the placebo group, had fecal calprotectin levels ≥ 200 μg/g. At baseline, none of these patients experienced significant symptoms, and they did not require escalation of medication. Participants with fecal calprotectin ≥ 200 μg/g or a clinical Mayo score ≥ 3 were analyzed separately as "subgroup B" (n = 15), and the participants without these signs of disease activity at baseline were included in "subgroup A" (n = 33). Among all the recruited patients, 16 patients had minor endoscopic colitis activity with an endoscopic Mayo score of 1 at baseline, while the rest of the patients had an endoscopic Mayo score of 0 at baseline.

Participant recruitment started in October 2014. At the beginning of the study, the inclusion criteria required a diagnosis of UC within 6 mo. However, due to very slowly proceeding recruitment, an amendment to the study protocol was made and approved by the ethical board in October 2016 (HUS/1652/2016). Thereafter, patients with any disease duration were eligible. Recruitment remained slow even after the amendment. The study proceeded using fewer than the desired 80 participants due to time constraints. The follow-up of the last included patient was completed in May 2020 (CONSORT flow diagram in Supplementary Figure 1).

Donors

Transplants from three healthy donors were used in this study. The donors had normal body weights and were healthy without any diagnosed long-term illnesses or medications. All donors had a healthy lifestyle and a diet that included animal products but was rich in vegetables. They were screened according to the best practice at the time[10]; however, the donor screening guidelines have evolved since the start of the trial[9]. The laboratory tests for donor screening are collectively presented in Supplementary Table 1. We applied transplants from a female in her forties ("Donor 1") and a young

adult male ("Donor 2"), both of whom had previously served as donors in our studies[6,8] and in routine clinical practice of FMT to treat rCDI. A male in his fifties ("Donor 3") was a new donor recruited for this study.

Intervention

Half of the participants, 24 out of 48, received FMT *via* colonoscopy into the cecum as described previously[10]. The fecal transplants were produced from 30 g of feces from a healthy donor. We used three universal donors, and the fecal suspensions were prepared as previously described and stored at -80 °C[10].

Briefly, feces were suspended in sterile saline and mixed with glycerol (final concentration of 10%) in a 250 mL screw cap container by using a spatula. The suspension was frozen at -80 °C immediately after preparation and within 2 h of defecation to minimize the time of exposure to oxygen. For FMT application, the suspension was thawed at 37 °C or room temperature, mixed briefly and loaded into syringes to avoid clogging by unsuspended particles. If necessary, the suspension was passed through a presterilized, stainless steel tea strainer to remove particles before loading the syringes. The remaining 24 participants in the placebo group were treated in an otherwise similar manner, but the fecal suspension was made using the participants' own freshly donated stool. Autologous placebo was prepared from fresh feces for practical reasons to prevent an extra visit and minimize inconvenience to the patients.

Power calculation and estimated sample size

The relapse rates during the 12-mo follow-up period were estimated to be 50% in the placebo group and 15% in the FMT group. Previous studies of FMT for maintenance of remission of UC were not published at the time of study design. Due to the lack of available studies, the estimation of outcomes was based on knowledge concerning the maintenance of remission using mesalazine[18] and extrapolating from FMT studies for rCDI[11], in which over 90% efficacy had been achieved.

The calculated sample size using the z-test (95% confidence interval, $\alpha = 0.05$ and $\beta = 0.1$, 90% power) to find a significant treatment effect was 33 patients in each group, and to cover possible dropouts, we aimed for a sample size of 40 participants per group, 80 participants in total[19].

Randomization and blinding

The participants were randomized 1:1 to receive FMT or placebo. The randomization was executed in blocks of 6 patients by a study nurse not involved in the treatment of the patients. The participants and the treating personnel were blinded to the type of feces transplanted. The randomization was decoded only after all the patients had completed the 12-mo follow-up.

Outcomes

The primary outcome was the maintenance of remission through the 12-mo follow-up period. A relapse of colitis was considered a failure to achieve the primary outcome. The patients were followed until the time of the recorded relapse, after which they were dropped from the follow-up. The patients who remained in remission were followed until the study endpoint of 12 mo after baseline.

The secondary endpoints were quality of life, endoscopic and histologic findings at 12 mo, fecal calprotectin, and blood chemistry. General quality of life was assessed with the 15 dimensions (15D) questionnaire, and disease-specific quality of life was assessed with the Inflammatory Bowel Disease Quality of Life Questionnaire (IBDQ) (McMaster University, Hamilton, Canada, license No. IBDQ22-081)[4]. The histologic activity was graded in four categories: histological remission; mild activity (lamina propria or intraepithelial neutrophils); moderate activity (presence of crypt abscess); and strong activity (presence of erosion or ulcer)[20].

The participants donated stool samples every 2nd mo (months 0, 2, 4, 6, 8, 10, and 12) for the detection of fecal calprotectin. Blood samples were obtained at baseline as well as at months 4, 8, and 12. The blood tests included complete blood counts, liver enzymes, creatinine, and CRP. Fecal calprotectin values below 50 μg/g and CRP values below ten were not reported by the laboratory and were coded as null accordingly.

Statistical methods

Descriptive statistics are presented as the means with standard deviations (SDs) for continuous variables and as frequencies and percentages for qualitative variables. Differences between the study groups in the maintenance of remission during the follow-up were assessed using the Kaplan-Meier method. Associations of baseline characteristics with the maintenance of remission were analyzed with univariate Cox regression models. In addition, 15D scores were presented using profile plots, and differences between groups were assessed by *t* tests. Differences in endoscopic and histological colitis activity between the study groups were analyzed with the χ^2 test. *P* values < 0.05 were considered statistically significant for all analyses. SPSS version 27 (IBM Corp. Released 2020. IBM SPSS Statistics for Windows, Version 27.0. Armonk, NY, United States) was used for the statistical analysis.

RESULTS

Baseline characteristics

Forty-nine patients were recruited for this study. After the screening visit and before randomization, 1 patient had overt activation of colitis and was excluded. This left 48 patients to be randomized, with 24 in each group. The patient flow of the study is presented in Supplementary Figure 1, and the baseline characteristics of the patients are presented in Table 1. The placebo group had a longer duration of disease than the FMT group (114 mo *vs* 39 mo, $P = 0.006$). At baseline, the mean fecal calprotectin level was 115.8 (SD: 184.7) in the placebo group and 66.4 (SD: 108.6) in the FMT group ($P = 0.261$). The majority of the patients were on mesalazine: 21 out of 24 patients in the FMT group and 22 out of 24 in the placebo group. Four patients in the placebo group were on thiopurine, but none were in the FMT group. At the study baseline, 2 patients in both groups were still on lower doses of tapering corticosteroid therapy. There were no statistically significant differences between the randomization groups within subgroups A and B, in which the patients had fecal calprotectin < 200 μg/g and a clinical Mayo score < 3 or fecal calprotectin ≥ 200 μg/g and a clinical Mayo score ≥ 3 at baseline, respectively (Table 1).

The primary endpoint-maintenance of remission

The primary endpoint of the study was the maintenance of remission through the 12-mo follow-up, which was achieved by 13 out of 24 (54%) patients in the FMT group and by 10 out of 24 (41%) patients in the placebo group. The difference between the groups was not statistically significant (log-rank test $P = 0.660$). A Kaplan-Meier survival curve of relapses in the FMT and placebo groups is presented in Figure 1A.

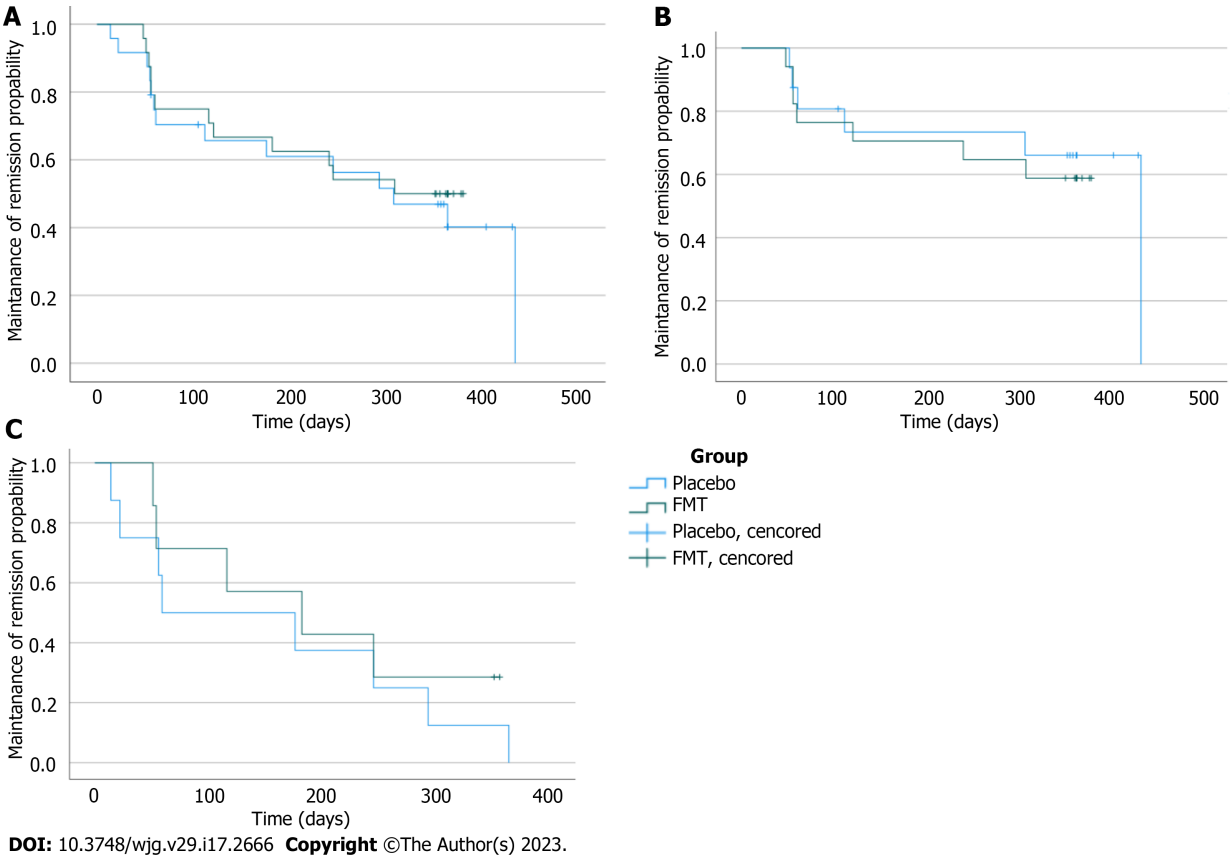
A similar result was obtained when the patients were divided into subgroups according to the clinical Mayo score and fecal calprotectin level at baseline. In subgroup A, 6 out of 16 patients relapsed in the placebo group, and 7 out of 17 patients relapsed in the FMT group ($P = 0.703$, Figure 1B). Similarly, subgroup B showed no difference between the placebo and FMT groups ($P = 0.556$) in the number of relapses; all 8 patients in the placebo group and 5 out of 7 patients in the FMT group relapsed (Figure 1C).

To study the possible effect of a specific donor on the patient's outcome, we divided the patients into three groups according to the donor and compared these to the placebo. There were no statistically significant differences in the number of relapses between the different donors (log-rank, $P = 0.517$). At the 12-mo follow-up, 41.7% (10/24) of the patients in the placebo group remained in remission compared to 33.3% (2/6) from Donor 1, 50.0% (5/10) from Donor 2, and 62.5% (5/8) from Donor 3.

We also analyzed the effect of essential baseline characteristics on the maintenance of remission between these donor groups, which included the duration of disease status, fecal calprotectin, clinical Mayo score, total 15D score, and total IBDQ score (Supplementary Table 2). The mean duration of disease was 114 mo in the placebo group, 5 mo in the Donor 1 group, 52 mo in the Donor 2 group, and 49 mo in the Donor 3 group. The disease duration did not have a statistically significant effect on the maintenance of remission in any of the donor groups. There were some statistically significant relationships between baseline characteristics and maintenance of remission. In the placebo group, lower maintenance of remission time was associated with higher baseline fecal calprotectin [Cox regression, hazard ratio (HR): 1.003; 95% confidence interval (CI): 1.001-1.005; $P = 0.010$) and a higher baseline clinical Mayo score (Cox regression, HR: 1.498; 95%CI: 1.067-2.102; $P = 0.020$). In the Donor 2 group, a lower mean 15D total score at baseline was associated with lower maintenance of remission (Cox regression, HR: 0.000; CI: 0.000-0.374; $P = 0.033$). All other analyzed associations were statistically insignificant (Supplementary Table 2).

Secondary endpoint–changes in patient quality of life

We investigated the impact of FMT on patient quality of life as measured with the 15D questionnaire and disease-specific quality of life as measured with the IBDQ questionnaire.



The 15D total score was similar between the placebo and FMT groups at baseline (*t* test, $P = 0.335$) (Figure 2A) and at the 12-mo follow-up after FMT treatment ($P = 0.905$) (Figure 2B). However, there was a significant difference in the 15D total score between the FMT and placebo groups ($P = 0.017$) 4 mo after treatment (Figure 2C). The mean change in the 15D total score from baseline to 4 mo was -0.032 (slightly worse) in the FMT group and -0.009 (no change) in the placebo group. The estimation of the importance of change was performed as presented previously[21]. The mean change in the 15D total score from baseline to 12 mo was -0.008 (no change) in the FMT group and -0.015 (slightly worse) in the placebo group. Additionally, of the 15D, there were statistically significant differences in breathing ($P = 0.049$), usual activities ($P = 0.042$), and vitality ($P = 0.006$), all favoring the placebo group.

The disease-specific quality of life as measured with the IBDQ[22] was also similar between the placebo and FMT groups at baseline ($P = 0.519$) and at 12 mo ($P = 0.868$), but at 4 mo, there was a difference in the IBDQ total score favoring the placebo group ($P = 0.003$). Of the four IBDQ subcategories, there were statistically significant differences in the emotions ($P = 0.008$) and systemic ($P = 0.010$) subcategories.

Table 1 The baseline demographics of patients included in the analysis

Baseline variable	All patients (*n* = 48)		*P* value	Subgroup A (*n* = 33)		*P* value	Subgroup B (*n* = 15)		*P* value
	FMT	Placebo		FMT	Placebo		FMT	Placebo	
Sex as M/F	14/10	12/12	0.562	8/9	8/8	0.866	4/4	5/2	0.608
Age	43.0 (12.9)	43.1 (12.1)	0.982	43.6 (13.0)	44.8 (12.0)	0.781	41.7 (13.6)	39.8 (12.5)	0.775
Disease duration in mo	39.2 (51.0)	114.0 (117.6)	0.006	41.0 (56.2)	125.4 (121.7)	0.015	34.9 (38.7)	91.3 (113.2)	0.233
Fecal calprotectin	66.0 (108.6)	115.8 (184.7)	0.261	34.7 (46.3)	18.9 (44.9)	0.330	142.3 (172.9)	309.6 (208.3)	0.117
15D	0.903 (0.095)	0.928 (0.072)	0.335	0.899 (0.106)	0.939 (0.070)	0.221	0.915 (0.070)	0.907 (0.078)	0.830
IBDQ	169.4 (28.8)	162.7 (39.8)	0.519	166.9 (28.6)	171.4 (32.0)	0.688	175.0 (30.5)	147.4 (49.3)	0.223

Subgroup A included patients with fecal calprotectin < 200 μg/g and a clinical Mayo score < 3 at baseline, and subgroup B included patients with fecal calprotectin ≥ 200 ug/g or a clinical Mayo score ≥ 3 at baseline. Figure 1 Kaplan-Meier survival curve demonstrating the maintenance of remission defined as fecal calprotectin < 200 μg/g and the clinical Mayo score < 3 or an overt relapse in between the measurement points. A: All patients included in analysis (log rank test *P* = 0.660); B: Subgroup A, *i.e.* the patients with fecal calprotectin < 200 μg/g and clinical Mayo score < 3 at the baseline (*P* = 0.703); C: Subgroup B, *i.e.* the patients with fecal calprotectin ≥ 200 μg/g or the clinical Mayo score ≥ 3 at the baseline (*P* = 0.556). Censored means the end of follow-up without a relapse. FMT: Fecal microbiota transplantation.

Secondary endpoint-blood chemistry and fecal calprotectin

The blood chemistry, complete blood count, liver enzymes, and creatinine and CRP levels were analyzed at four different timepoints. Fecal calprotectin was measured every 2nd mo at six different timepoints. There were no clinically significant changes in any of the blood tests compared to the baseline. All laboratory tests at each timepoint showed no statistically significant differences between the FMT and placebo groups ($P > 0.05$). The blood chemistry and fecal calprotectin values are collectively presented in Supplementary Table 3.

[a]$P \leq 0.05$ and [b]$P \leq 0.01$. FMT: Fecal microbiota transplantation; 15D: The total score of the 15 dimensions quality of life questionnaire.

Endoscopic and histologic colitis activity at 12 mo

A colonoscopy was performed at the end of the trial, and pinch biopsies were obtained from all 23 patients who reached the primary endpoint and remained in clinical remission throughout the follow-up period. Endoscopic colitis activity was detected in 2 out of 13 patients in the FMT group and in 2 out of 10 patients in the placebo group. Likewise, mild histological colitis activity was detected in the colon pinch biopsies in 2 out of 13 patients in the FMT group and 2 out of 10 patients in the placebo group, indicating chronic inflammation. Thus, the number of patients who were in endoscopic and histologic remission in the follow-up colonoscopy was 11 out of 13 in the FMT group and 8 out of 10 in the placebo group (χ^2, $P = 0.772$).

Adverse events

A similar number of patients experienced UC activation in the FMT and placebo groups (Figure 1). In addition to colitis activation, other adverse events were recorded in 4 patients in the FMT group and 6 patients in the placebo group.

In the FMT group, the adverse events included fatigue through the follow-up period, gastroenteritis at 8 mo after FMT, constipation at 3 wk after FMT and a diagnosis of primary sclerosing cholangitis. In addition, 1 patient reported fatigue and episodes of atrial fibrillation at the 4-mo timepoint, for which he underwent ablation treatment. This patient subsequently developed pneumonia.

In the placebo group, 1 patient with fibromyalgia reported back pain and colitis symptoms simultaneously. Another patient visited the emergency room 6 mo after the procedure and was diagnosed with mitral valve insufficiency. One patient with spondylarthritis experienced arthralgia during the follow-up. One patient experienced an escalation of bloating after the procedure, and 2 patients experienced a prolonged mild respiratory infection. Possible hospitalizations were monitored in all the participants for 12 mo, but none were attributable to FMT.

DISCUSSION

In this placebo-controlled trial, we examined the effect of a single FMT *via* colonoscopy on the maintenance of remission in UC patients. The primary endpoint was sustained remission over a 12-mo follow-up period. A relapse of UC was regarded as a failure to achieve the primary endpoint. We set the cutoff values to differentiate between remission and relapse to a clinically significant level; thus, a clinical Mayo score above three and fecal calprotectin levels above 200 μg/g were considered to indicate colitis activation. There was no statistically significant difference in the number of patients with a relapse of UC during the follow-up period in the FMT and placebo groups. According to the results, a single FMT *via* colonoscopy was ineffective for maintaining UC in remission.

Previously, the impact of the donor on the outcome of FMT was demonstrated in patients with active UC[13]. Including more than one donor in FMT trials enables comparison between the donors. In this trial, we used three donors. Sustainable remission through the follow-up was achieved by 33.3% of the patients who received FMT from Donor 1, whereas the same was achieved by 62.5% of the patients treated with FMT from Donor 3. However, the number of patients in each group was small, and the differences did not reach statistical significance. Furthermore, the Donor 1 treatment was applied at the beginning of the trial when the inclusion criteria were different, requiring new-onset disease, and consequently the baseline activity markers, fecal calprotectin and clinical Mayo score were higher in the patients of Donor 1 than in the patients of Donor 3. For these reasons, the existence or magnitude of the donor effect could not be proven or disproven.

Studies evaluating FMT for active as well as quiescent UC have been encouraging[13,16], but the present data are not sufficient to justify treating UC patients with FMT in clinical practice. Our goal was to investigate whether manipulation of the gut microbiota with FMT early after UC diagnosis would help in the maintenance of remission and the effect on the course of the disease. When planning this study, we aimed to recruit patients whose UC was diagnosed within 6 mo prior to the study baseline. However, due to slow recruitment, we made a change in the study protocol and started including patients with any duration of the disease. Additionally, another center, Päijät-Häme Central Hospital, joined the study in addition to Helsinki University Hospital. Nevertheless, the recruitment remained slow, and we were only able to recruit 48 of the originally planned 80 patients within a reasonable time.

As a result of the change in the protocol, 31% of the patients fulfilled the initial inclusion criteria and had been diagnosed within the previous 6 mo, of whom 6 patients were in the FMT group and 9 patients were in the placebo group. Coincidentally, the patients with the longest duration of the disease were also randomized into the placebo group, resulting in a statistically significant difference in the duration of disease status between the randomization groups. The groups were similar to each other in all other parameters (Table 1). Patients with biologics were not included in the trial; thus, the participants did not have a history of severe and difficult-to-treat disease.

Previously published randomized, placebo-controlled FMT trials investigating patients with UC have included patients with active colitis or patients who have reached clinical remission after several FMT sessions[15,16,23]. The patients in our study had UC in clinical remission but had not previously received FMT therapy. Between the recruitment and the study baseline, a portion of the patients had elevated calprotectin and clinical Mayo score values without overt colitis symptoms and were included in a subgroup analysis (Table 1). Overall, the population of our study represented UC patients in real-world clinical practice.

As a secondary endpoint, we aimed to investigate the effect of FMT on patient quality of life. We evaluated this outcome with the disease-specific IBDQ questionnaire and with the 15D questionnaire, which measures general health-related quality of life. Both questionnaires measure the quality of life in IBD patients with equal reliability[4]. Interestingly, the placebo group presented higher quality-of-life scores 4 mo after the treatment. This may refer to the extraintestinal influence of the gut microbiota, although the difference between the groups may partly be explained by the longer duration of disease in the placebo group and consequently better adaptation to the fluctuating symptoms of the disease. Indeed, the statistically significant differences concerned vitality, usual activities, and breathing in the 15D questionnaire, while intestinal symptoms did not differ between the groups. Additionally, in the IBDQ questionnaire, the subcategories of emotions and systemic symptoms were statistically significantly better in the placebo group at the 4-mo timepoint. We found disease duration and adaptation to be the most plausible explanation for the observed differences since the subscores of the FMT group increased and the differences between treatment groups disappeared at 12 mo. However, changes in microbiota composition and activity extrapolating to extraintestinal effects should also be addressed in future investigations. Previously, we observed a possible link between microbiota, general mental health, and depression in our FMT studies on IBS and rCDI[8,24].

In line with our previous placebo-controlled FMT trial[8], the reported adverse events in this trial were evenly distributed between groups. There were no severe adverse events attributable to FMT, replicating previous reports stating that FMT was safe when performed with high standards[25]. Even as FMT appears safe in randomized controlled trials[8,13,15] and evidence of long-term safety appears encouraging[24], we find it highly important to continue gathering safety data on FMT from randomized trials as well as collecting registry data from clinical practice. The interindividual variability of donors is high concerning microbiota profiles as well as other characteristics, and therefore the

scientific community and clinicians performing FMT for CDI need to stay alert for infectious complications and for possible rare short-term and long-term adverse effects of FMT[26].

Our study had some limitations. First, the number of studied patients remained rather low, with only 48 patients in total due to slow recruitment. Second, after patients experienced a relapse of UC, further data were not recorded. This decreased the amount of obtained data and complicated the comparison of secondary endpoints between the groups, as there were fewer cases left for the analysis with each successive time point. However, after a relapse, some of the patients were given corticosteroids or the medication was changed, which would have misrepresented the true effects of FMT or placebo. Another drawback was that the patients in the placebo group had UC for a longer duration than those in the FMT group and were likely in a more stable phase of the disease. This may have impacted the results of the primary endpoint as well as secondary endpoints; however, there were no statistically significant correlations between the duration of disease and the time to relapse or quality of life in either study group.

Our study also had clear advantages. Its blinded placebo-controlled design is a definite strength. We applied an autologous placebo, which assures very reliable blinding, and the same method has yielded valid results in FMT trials for rCDI[27] and in other conditions such as IBS[8] and Crohn's disease[28]. However, it must be noted that the composition of the fecal microbiota may change when it is exposed to oxygen, and in the case of patient samples, the duration of oxygen exposure could not be carefully controlled, unlike for the donor samples, which were prepared and frozen within 2 h of defecation. The advantage of applying an autologous placebo is that it assures very reliable blinding. Other forms of placebo may be more easily detected by the patient or treating personnel. Another advantage of our study is the sufficiently long follow-up time, which enabled the treatment effect durability to be monitored.

Unlike in rCDI, clinical efficacy may not be achieved in UC by just a single FMT, possibly due to difficulties in modulating the microbiota in the longer term by only one FMT dose. Repeated FMT treatments could possibly enhance efficacy, as shown by Sood *et al*[16] where repeated FMT treatments were associated with maintenance of remission. In that trial, the study population was selected from responders to FMT given for induction of remission, and bimonthly colonoscopic FMTs for 1 year maintained UC in remission better than placebo. Thus, the positive effects of FMT may be maintained by repeated treatments. Repeated FMT treatments have also shown promising results in the induction of remission of active UC[13-15]. Engraftment of the transplanted microbes may be more difficult in an active colitis environment than in a state of remission. From this perspective, repeated FMT can be more justified in active disease.

Moreover, FMT may also exert its efficacy *via* host-derived biomolecules that exert immunoregulatory action or induce transcriptional changes in the affected intestinal epithelium. Action by nonpersisting biomolecules could also explain why multiple FMTs are needed for the induction of remission. On the other hand, if microbiota modulation is considered critical, a single FMT by colonoscopy with our protocol (applying 30 g of donor feces) can induce prolonged microbial engraftment in rCDI patients as well as in IBS patients[6,8].

To our knowledge, our trial is the first controlled trial to investigate a single FMT for the maintenance of remission in UC patients. In future FMT studies on the maintenance of UC remission, repeated treatments seem reasonable. However, other methods to enhance and prolong the effects should also be considered. For example, combining a dietary intervention may improve results and prolong remission [29]. In one recent trial, a dietary intervention resulted in a superior effect on the induction of remission in UC patients compared to FMT[30].

The optimization of donor selection could possibly improve outcomes even with a single FMT given in remission. Additionally, conditions for the engraftment and functioning of beneficial microbiota may be important, particularly when FMT is given to patients in remission. Diet has a great impact on gut microbiota and is likely an important factor affecting the survival and function of transplanted microbes [31]. We suggest prompt documenting of the diet in future FMT studies. Additionally, the combination of FMT with dietary modulation should be addressed in future studies[29,30].

There are many open questions to be answered before we can determine whether FMT may be applied for the maintenance of remission in UC. More research is needed to define the optimal donor characteristics, patient population, and timing for FMT. Additionally, the best route of FMT administration remains undefined. While the colonoscopic route has shown promise[16], FMT with capsules may be considered when high numbers of patients need to be treated[23]. Finally, we do not yet know which stool components are responsible for the positive effects of FMT, and there is much room for future innovative research.

CONCLUSION

In conclusion, there were no statistically significant differences in the number of UC relapses after a single FMT or placebo treatment; therefore, the main outcome of our study was negative. Our results do not support applying a single FMT for the maintenance of UC remission. However, these results must

be interpreted with caution due to the small sample size, and larger studies are warranted.

ARTICLE HIGHLIGHTS

Research background

Ulcerative colitis (UC) is associated with altered gut microbiota. The pathophysiology of UC is thought to involve an altered and exaggerated inflammatory response to commensal bacteria. Fecal microbiota transplantation has yielded good results in the induction of UC remission.

Research motivation

Despite the development in medications for UC, some patients do not respond sufficiently to current treatment options and new treatment modalities are needed. Modulation of gut microbiota *via* fecal microbial transplantation (FMT) is a potential new treatment option for UC patients.

Research objectives

The goal of this trial was to gather information of the role of gut microbiota in maintenance of remission in UC patients, and the aim was to investigate FMT for the maintenance of UC remission.

Research methods

Forty-eight patients with quiescent UC were randomized 1:1 to receive a single FMT *via* colonoscopy or a placebo made from the patient's own stool. The patients were followed for 12 mo, and colitis symptoms were measured as well as fecal calprotectin. As secondary endpoints, quality of life, blood chemistry, and endoscopic findings at 12 mo were measured.

Research results

UC remission was maintained by 13 out of 24 (54%) patients in the FMT group and by 10 out of 24 (41%) patients in the placebo group (log-rank test, $P = 0.660$). The quality of life was lower in the FMT group at 4 mo after FMT as compared to the placebo group ($P = 0.017$). There were no differences in blood chemistry, fecal calprotectin, or endoscopic findings at 12 mo between the groups.

Research conclusions

There were no significant differences in the maintenance of remission between the groups during the 12-mo follow-up. Thus, our results do not support the use of a single-dose FMT for the maintenance of remission in UC patients.

Research perspectives

Many open questions need to be answered before we can determine whether FMT may be applied for the maintenance of remission in UC. We do not yet know which stool components distribute the positive effects of FMT. More research is needed to define the optimal donor characteristics, patient population, and the optimal number and timing of FMT treatments.

ACKNOWLEDGEMENTS

Study nurses Pirkko Tuukkala (Helsinki University Hospital) and Virve Liukkonen (Päijät-Häme Central Hospital) are acknowledged for their contribution to the study with a high level of expertise and commitment.

Abstract

BACKGROUND

Multiple studies investigating the relationship between intake of different types of fruit and colorectal cancer (CRC) risk have yielded inconsistent results.

AIM

To perform a meta-analysis of existing studies to assess the association between the intake of different kinds of fruit and the incidence of CRC.

METHODS

We searched online literature databases including PubMed, Embase, WOS, and Cochrane Library for relevant articles available up to August 2022. With data extracted from observational studies, odds ratios (ORs) with 95% confidence intervals (CIs) were assessed using random-effects models. A funnel plot and Egger's test were used to determine publication bias. Furthermore, subgroup analysis and dose-response analysis were performed. All analyses were conducted using R (version 4.1.3).

RESULTS

Twenty-four eligible studies involving 1068158 participants were included in this review. The meta-analysis showed that compared to a low intake, a higher intake of citrus, apples, watermelon, and kiwi reduced the risk of CRC by 9% [OR (95%CI) = 0.91 (0.85-0.97)], 25% [OR (95%CI) = 0.75 (0.66-0.85)], 26% [OR (95%CI) = 0.74 (0.58-0.94)], 13% [OR (95%CI) = 0.87 (0.78-0.96)], respectively. No significant association was observed between the intake of other types of fruit and the risk of CRC. In the dose-response analysis, a nonlinear association was found [R (95%CI) = -0.0031 (-0.0047 to -0.0014)] between citrus intake and CRC risk (P < 0.001), with the risk minimized around 120 g/d (OR = 0.85), while no significant dose-response correlation was observed after continued increase in intake.

CONCLUSION

We found that a higher intake of citrus, apples, watermelon, and kiwi was

negatively associated with the risk of CRC, while the intake of other types of fruits were not significantly associated with CRC. Citrus intake showed a non-linear dose-response relationship with the risk of CRC. This meta-analysis provides further evidence that a higher intake of specific types of fruit is effective in preventing the occurrence of CRC.

Core Tip: In this study, we summarized and analyzed existing studies on the association between the intake of different types of fruit and the risk of colorectal cancer (CRC). Some specific types of fruit, such as citrus and apples, were found to reduce the incidence of CRC. We also found a nonlinear association between citrus intake and CRC risk in the dose-response analysis. Finally, this study proposed that people should change their diets to lower the risk of CRC, thereby easing the heavy economic burden of cancer worldwide.

INTRODUCTION

As the third most common cancer, colorectal cancer (CRC) is the third leading cause of cancer death in both men and women, as well as the second leading cause of cancer death in the United States. when men and women are added together[1]. From 2000-2002 to 2014-2016, the incidence of CRC increased by nearly 15% among adults aged 40 to 49 years[2]. The prognosis of CRC varies which mainly depends on the cancer stage, with a 5-year survival rate of about 90% for stage I patients and only 0%-10% for stage IV patients, making the prevention of cancer of great potential and value.

Important risk factors for early-onset CRC include hyperlipidemia, obesity, alcohol consumption and a history of CRC in first-degree relatives[3], of which dietary habits are modifiable. Up to now, various phytochemicals with the potential to prevent cancer have been found in fruits, such as polysaccharides (modified apple polysaccharides, MAP), resveratrol, and flavonoids[4]. MAP inhibits the binding of galectin-3 to its ligand, which is considered to be the promoter of the inflammatory response[5-7], and this may be part of the mechanism by which MAP promotes apoptosis and prevents tumorigenesis[8]. As suggested by Liu *et al*[9], resveratrol regulates PTEN/PI3K/Akt and Wnt/β-catenin signaling pathways, respectively, and thus exhibits growth inhibitory effects in human colon cancer cells. Anticancer properties of flavonoids include modification or inactivation of enzymes that activate or detoxify carcinogens, free radical scavenging, inhibition of transcription factor induction (*e.g.*, activator protein-1 activity), and induction of apoptosis[10]. Epidemiological studies have also highlighted the protective effect of chemicals present in plants and fruits on the risk of CRC[11-14]. For example, data from Jordan and Italy have shown that high intake of flavonoids can reduce CRC risk. Moreover, a considerable number of studies have demonstrated the association between higher intake of fruits and vegetables and lower mortality[15]. However, results from prospective cohorts began to show nonexistent or weak associations[16,17], and a pooled analysis of 14 studies[18] also showed a weak association. Wang *et al*[19] concluded that mortality was not further reduced in those who consumed five servings of fruits and vegetables daily. A meta-analysis showed that increased intake of vegetables, but not fruits, reduced the risk of liver cancer[20]. This finding was also questioned by a large prospective study[21]. Certain types of fruit may be more strongly associated with cancer risk compared with others due to their particular chemical composition and underlying molecular mechanisms, which may be hidden in epidemiological studies. Here, we systematically reviewed the existing evidence and explored potential sources of heterogeneity between study results and whether study results differ by gender, region, and tumor location in order to elucidate the association between intake of different types of fruits and CRC risk.

MATERIALS AND METHODS

The effect of different types of fruit intake on the risk of CRC was reported in this study according to the

Preferred Reporting Items for Systematic Reviews and meta-analyses (PRISMA) statement[22], and it was previously registered with Prospero (study number: CRD42022354620).

Search strategy

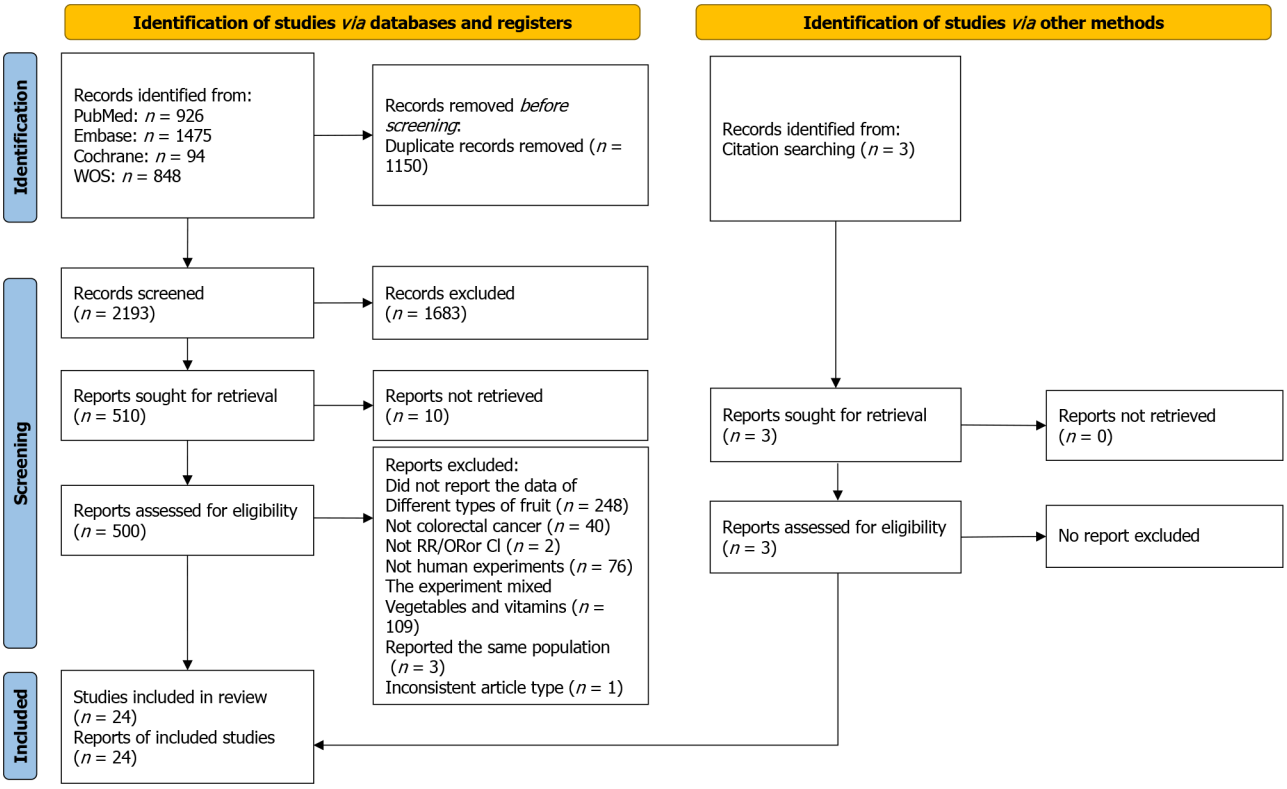
Two researchers (Zhen-Ying Wu and Jia-Li Chen) independently conducted a computerized literature search of PubMed, Cochrane, EMBASE, and Web of Science databases until August 2022 for literature on the association of different types of fruit consumption with CRC risk. Studies were identified with the following medical subject heading (MeSH) terms or keywords: (1) Fruit, berry, and plant; (2) cancer, neoplasm, colorectal tumor, CRC, and colorectal neoplasm; and (3) case-control, cohort, and prospective. Titles, abstracts and citations were exported to Endnote 20. The database search strategy is presented in Supplementary Table 1.

Study selection

Two authors (Zhen-Ying Wu and Jia-Li Chen) independently evaluated the titles and abstracts of potentially eligible studies based on the following inclusion criteria: (1) Original articles; (2) human participants; (3) case-control or cohort design; and (4) studies examining the association between intake of different types of fruit and CRC risk. All full-text articles meeting the inclusion criteria were collected. The following exclusion criteria were applied: (1) Articles with confounding of fruits or other food sources; (2) no specific indication of fruit type; (3) no corresponding 95% confidence interval (95%CI) for the relative risk (RR), odds ratio (OR), or hazard ratio (HR) for estimating the highest to lowest levels of fruit consumption; and (4) systematic reviews, meta-analyses, and reviews. Differences between reviewers were resolved through discussion.

Data extraction

For each included potential study, selection evaluation, data extraction and quality assessment were performed independently by two researchers. We extracted the following data from the included studies: The surname of the first author, study area and design, year of publication, sample size (number of cases and controls; cohort size and incident cases), age, follow-up time of the cohort studies, dietary assessment methods, comparison of exposure levels, OR/RR/HR estimates corresponding to fruit intake, and 95%CIs for the highest and lowest fruit intake. We extracted the estimation models that adjusted the most for confounding factors when multiple estimates were reported in the article. If there were independent risk estimates for men and women in a study, or risk estimates for cancers at different sites such as the colon and rectum, we treated them as separate studies.



The number of cases and person-years or non-cases for each category of data are required to calculate the slope of the dose-response curve[23]. With citrus intake in each study divided into at least three groups, we took the mean or median consumption under each category and assigned it to the corresponding RR. The midpoint of the upper and lower boundaries was used as the dose for the corresponding category if the study only reported interval ranges for citrus consumption[24]. When the range of intake was unlimited, we assumed the same level as the adjacent category[25]. For instance, the median for the lowest group was 0, while the median for the highest group was 1.5 times the lower limit for that group. For most studies in the meta-analysis, we used 80 g/serving to calculate intake if the study reported intake in servings[26]. Discrepancies between researchers on included studies were resolved through discussion or consultation with the third author.

Assessment of study quality

We assessed the quality of included studies and their potential risk of bias using the Risk of Bias In Non-randomized Studies of Interventions (ROBINS-I) tool[27]. This assessment tool contains seven domains covering pre-intervention (Bias due to confounding, Bias due to selection of participants), at intervention (Bias in classification of interventions) and post-intervention (Bias due to deviations from intended interventions, Bias due to missing data, Bias in measurement of outcomes and Bias in selection of the reported result). The categories for risk of bias judgements are "low risk", "moderate risk", "serious risk", "critical risk", and "no information". The risk of bias was determined independently by two reviewers, and their disagreements were resolved by mutual consensus.

Statistical methods

The meta-analysis was conducted by comparing the risk of CRC reported in the highest and lowest fruit intake groups. Considering a risk of less than 10% for CRC and a small OR, the RR/HR we calculated was approximately equal to the OR[28]. For the overall estimation, the meta-analysis was performed according to the case where all types of rates were OR. The heterogeneity of the results across studies was evaluated with the I^2 test. Since observational study results are inevitably affected by various sources of heterogeneity such as statistical heterogeneity and conceptual heterogeneity in the real world, we followed the Cochrane Handbook for Systematic Reviews of Interventions and used combined results from random-effects models. The effect of individual studies on risk estimates was investigated through sensitivity analyses by omitting each study in turn. We also conducted sensitivity analyses based on quality assessment to improve the reliability of the results. When an outcome indicator was

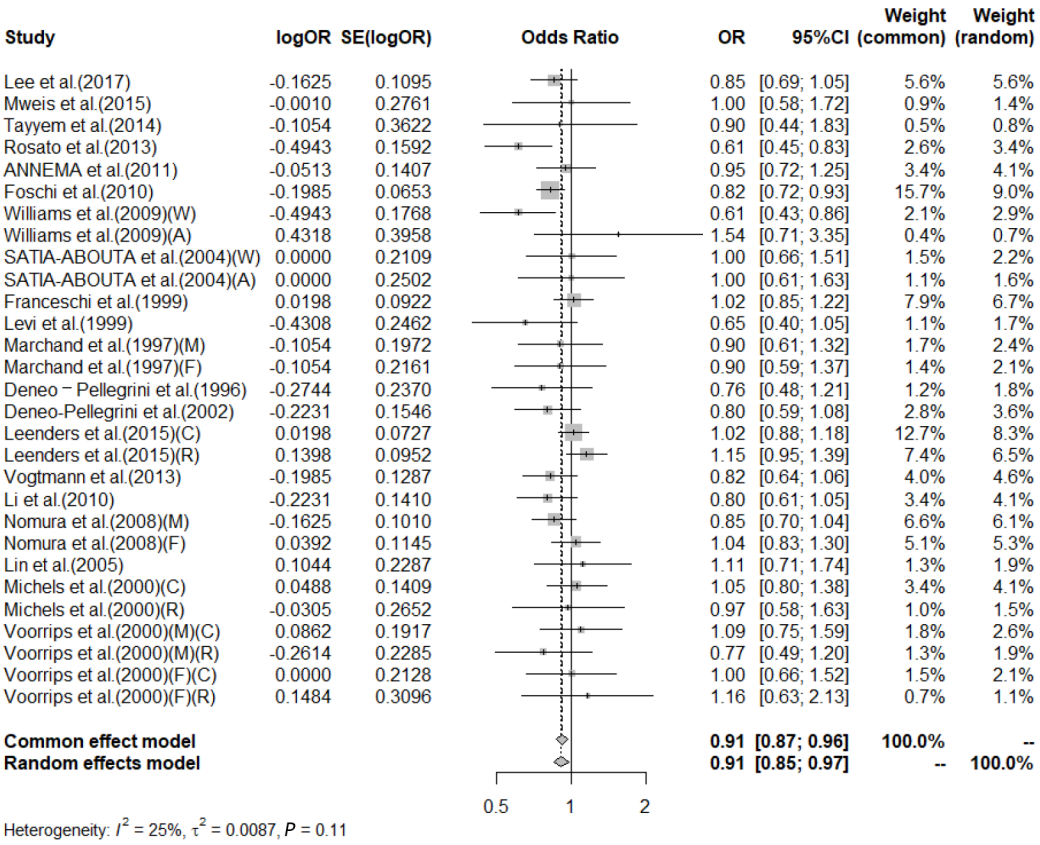
Figure 1 PRISMA flow chart of literature search and selection. RR: Relative risk; OR: Odds ratio; CI: Confidence intervals.

reported in more than 10 included studies, publication bias analysis was conducted using Egger's linear regression test and funnel plots. Significant publication bias was considered to exist if the intercept of the Egger's regression line deviated from zero and the *P* value < 0.05. In the present study, we performed pre-specified subgroup analyses based on study design type, location of CRC occurrence, geographic region, and gender. To check for possible non-linear relationships, we also carried out pre-specified dose-response analyses by calculating restrictive three-times sample bars for each study for three or more exposure categories[25]. All analyses were performed by R (version 4.1.3), with two-tailed *P* < 0.05 considered statistically significant.



RESULTS

Included studies

A total of 3343 articles were obtained by the initial literature screening, and after removing 1150 duplicate articles, we identified 2193 articles that were potentially eligible for review. Then 1683 irrelevant entries were eliminated by screening titles and abstracts. Of the remaining 510 articles, 486 were eliminated according to the exclusion criteria. In particular, three studies[29-31] were all from the same study, so only the one with the most complete data was included[29]. Another two studies[32,33] were also from the same study, and similarly the one with the most complete data was included[32]. The results of Tuyns *et al*[34] and Tajima *et al*[35] were removed due to lack of OR and corresponding 95%CI for citrus intake and CRC risk. Three additional[36-38] studies that met the inclusion criteria were identified by manually searching the reference list. The 24 articles were ultimately included in the current meta-analysis[29,32,36-57]. The flow chart for study selection is presented in Figure 1.

Characteristics of the studies

Detailed characteristics of the studies investigating the intake of different types of fruit and CRC risk are shown in Table 1. The final analysis included 16 case-control studies[29,32,37-39,41-49,56,57] and 8 cohort studies[36,40,50-55]. The articles were published between 1996 and 2017, with a total of 1068158 participants aged under 80 years. One study involved only men[50] and one study involved only women[55]. Seven articles distinguished between tumor locations such as rectum and colon (even into proximal and distal colon cancer)[29,38,39,44,50,53,54]. Five articles conducted the research with the classification of gender[36,38,39,52,56]. As for the regional distribution of the study population, nine studies were conducted in Europe[29,32,37,40,43,45,47,49,53], two studies in South America[38,57],

Figure 2 Meta-analysis of the risk of colorectal cancer in the highest *vs* lowest category of Citrus intake. F: Female, M: Male; W: Whites, A: African-Americans; C: Colon cancer, R: Rectal cancer. OR: Odds ratio; CI: Confidence intervals.

seven studies in North America[36,46,48,52,54-56], five studies in Asia[39,41,42,50,51], and one study in Australia[44]. Most studies matched or adjusted for age and energy intake; several studies adjusted for BMI (body mass index), smoking status, alcohol use, history of disease associated with CRC, and physical activity; other adjusting factors included gender, education level, and red meat intake (Table 2). Based on the ROBINS-I tool, we identified all studies as having moderate risk of bias. Most of the problems found were regarding confounding and missing data. There was a moderate bias in the classification of interventions in five studies and a moderate bias in the selection of participants in five studies. Among all observational studies, Bias due to deviations from intended interventions, outcomes measurement bias and selection of reported results were considered low. Risk of bias assessment results are summarized in Table 3.

Heterogeneity and pooled results

High *vs* low analysis: Citrus: For 20 included articles[29,38-46,48-57], the overall outcome analysis found that higher citrus intake was related to a lower risk of CRC [I^2 = 25%, P = 0.11, REM; OR (95%CI) = 0.91 (0.85-0.97), P < 0.01] (Figure 2). Further subgroup analysis based on study design showed that citrus intake may reduce the risk of CRC by 15% in case-control studies [I^2 = 17%, P = 0.26, REM; OR (95%CI) = 0.85 (0.78-0.93)], whereas a similar association was not found in cohort studies [I^2 = 0%, P = 0.48, REM; OR (95%CI) = 0.98 (0.90-1.06)] (Figure 3). We also performed a subgroup analysis of 7 included articles based on the specific location of tumorigenesis, which were divided into a total of four locations, namely distal colon, proximal colon, colon, and rectum, but the results suggested no significant association between citrus intake and proximal colon [I^2 = 0%, P = 0.64, REM; OR (95%CI) = 0.93 (0.65-1.32)], distal colon [I^2 = 0%, P = 0.89, REM; OR (95%CI) = 0.80 (0.57-1.12)], colon [I^2 = 0%, P = 0.60, REM; OR (95%CI) = 0.97 (0.91-1.05)], and rectum [I^2 = 55%, P = 0.03, REM; OR (95%CI) = 0.90 (0.78-1.05)] (Figure 4). In the analysis stratified by region, an association between citrus consumption and lower CRC risk was demonstrated only in studies conducted in Asia [I^2 = 0%, P = 0.96, REM; OR (95%CI) = 0.84 (0.73-0.96)], whereas no association was found in studies conducted in North/South America [I^2 = 1%, P = 0.43, REM; OR (95%CI) = 0.91 (0.83-1.01)] and Europe [I^2 = 60%, P < 0.01, REM; OR (95%CI) = 0.92 (0.81-1.05)] (Figure 5). Finally, our stratified analysis of gender in 6 included articles found the protective effect of citrus was only present in men [I^2 = 30%, P = 0.22, REM; OR (95%CI) = 0.84 (0.75-0.96)] but not in women [I^2 = 47%, P = 0.11, REM; OR (95%CI) = 0.98 (0.78-1.25)] (Figure 6).

Figure 3 Subgroup analysis of the risk of colorectal cancer in the highest *vs* lowest category of Citrus intake by study type. F: Female; M: Male; W: Whites; A: African-Americans; C: Colon cancer; R: Rectal cancer; OR: Odds ratio; CI: Confidence intervals.

Apple: The analysis of the results in 9 included articles[29,32,36,37,41,42,44,47,57] showed that greater intake of apples led to a significant 25% reduction in CRC risk [I^2 = 49%, P = 0.04, REM; OR (95%CI) = 0.75 (0.66-0.85), P < 0.01] (Figure 7). When studies were stratified by region, a significant association was found between apple intake and reduced risk of CRC in the European population [I^2 = 62%, P = 0.03, REM; OR (95%CI) = 0.77 (0.67-0.90)], while no association was observed in the Asian population [I^2 = 0%, P = 0.69, REM; OR (95%CI) = 0.87 (0.55-1.38)] and the North/South American population [I^2 = 76%, P = 0.04, REM; OR (95%CI) = 0.56 (0.30-1.03)] (Supplementary Figure 1).

Banana: The analysis results of six included articles[29,38,41,42,56,57] demonstrated that consuming more bananas did not contribute to reduced risk of CRC [I^2 = 79%, P < 0.01, REM; OR (95%CI) = 0.74 (0.55-1.00), P = 0.05] (Supplementary Figure 2). When stratified by region, banana intake was found to be related to a lower risk of CRC in North/South American populations [I^2 = 58%, P = 0.07, REM; OR (95%CI) = 0.54 (0.39-0.76)], whereas no association was revealed in European populations [I^2 = 0%, P = 1.00, REM; OR (95%CI) = 1.00 (0.92-1.09)] and Asian populations [I^2 = 0%, P = 0.95, REM; OR (95%CI) = 1.16 (0.70-1.92)] (Supplementary Figure 3). When stratified by gender, we found a protective effect of Bananas for both men [I^2 = 0%, P = 0.59, REM; OR (95%CI) = 0.65 (0.49-0.86)] and women [I^2 = 0%, P = 1.00, REM; OR (95%CI) = 0.60 (0.43-0.83)] (Supplementary Figure 4). In a stratified analysis of tumor sites, high banana intake did not show the association with the risk of malignancy in either the colon [I^2 = 86%, P < 0.01, REM; OR (95%CI) = 0.90 (0.72-1.12)] or the rectum [I^2 = 0%, P = 0.36, REM; OR (95%CI) = 0.95 (0.85-1.06)] (Supplementary Figure 5).

Peach: For the four included articles[29,40,42,57], the total analysis results showed that consuming more peaches did not reduce the risk of CRC [I^2 = 62%, P = 0.02, REM; OR (95%CI) = 0.95 (0.83-1.09), P = 0.50]

Figure 4 Subgroup analysis of the risk of colorectal cancer in the highest *vs* lowest category of Citrus intake by region of cancer. PC: Proximal colon cancer; DC: Distal colon cancer; C: Colon cancer; R: Rectal cancer; F: Female; M: Male; OR: Odds ratio; CI: Confidence intervals.

(Supplementary Figure 6). When stratified by study type, both case-control studies [I^2 = 86%, P = 0.03, REM; OR (95%CI) = 0.90 (0.75-1.07)] and cohort studies [I^2 = 47%, P = 0.17, REM; OR (95%CI) = 1.06 (0.87-1.29)] indicated that peach intake was not related to CRC risk (Supplementary Figure 7). The subgroup analysis based on tumor sites revealed that greater peach intake was not associated with the risk of malignancy in the colon [I^2 = 0%, P = 0.77, REM; OR (95%CI) = 0.99 (0.91-1.08)] and rectum [I^2 = 88%, P < 0.01, REM; OR (95%CI) = 0.96 (0.65-1.42)] (Supplementary Figure 8).

Strawberry: With three articles included in the analysis[29,40,42], overall results demonstrated no reduction in CRC risk even with higher intake of strawberries [I^2 = 58%, P = 0.05, REM; OR (95%CI) = 0.97 (0.90-1.05)], P = 0.42] (Supplementary Figure 9). In the stratified analysis of tumor sites, strawberry intake was not related to cancer risk in either the rectum [I^2 = 34%, P = 0.22, REM; OR (95%CI) = 0.93 (0.83-1.04)] or colon [I^2 = 0%, P = 0.67, REM; OR (95%CI) = 1.00 (0.95-1.06)] (Supplementary Figure 10). In the stratified analysis by study type, case-control studies [I^2 = 75%, P = 0.02, REM; OR (95%CI) = 0.95 (0.86-1.05)] and cohort studies [I^2 = 0%, P = 1.00, REM; OR (95%CI) = 1.04 (0.91-1.19)] showed that strawberry consumption was not associated with CRC risk (Supplementary Figure 11).

Grape: With four articles included[29,40,42,57], overall analysis results indicated that the intake of large amounts of grapes was not related to a reduced risk of CRC [I^2 = 51%, P = 0.07, REM; OR (95%CI) = 1.00 (0.91-1.10), P = 0.97] (Supplementary Figure 12). Subgroup analysis by tumor site showed that grape intake was not significantly associated with malignancy in both the rectum [I^2 = 0%, P = 0.52, REM; OR (95%CI) = 0.91 (0.83-1.01)] and colon [I^2 = 57%, P = 0.13, REM; OR (95%CI) = 1.05 (0.92-1.19)] (Supplementary Figure 13). Stratified by study type, case-control studies [I^2 = 59%, P = 0.06, REM; OR

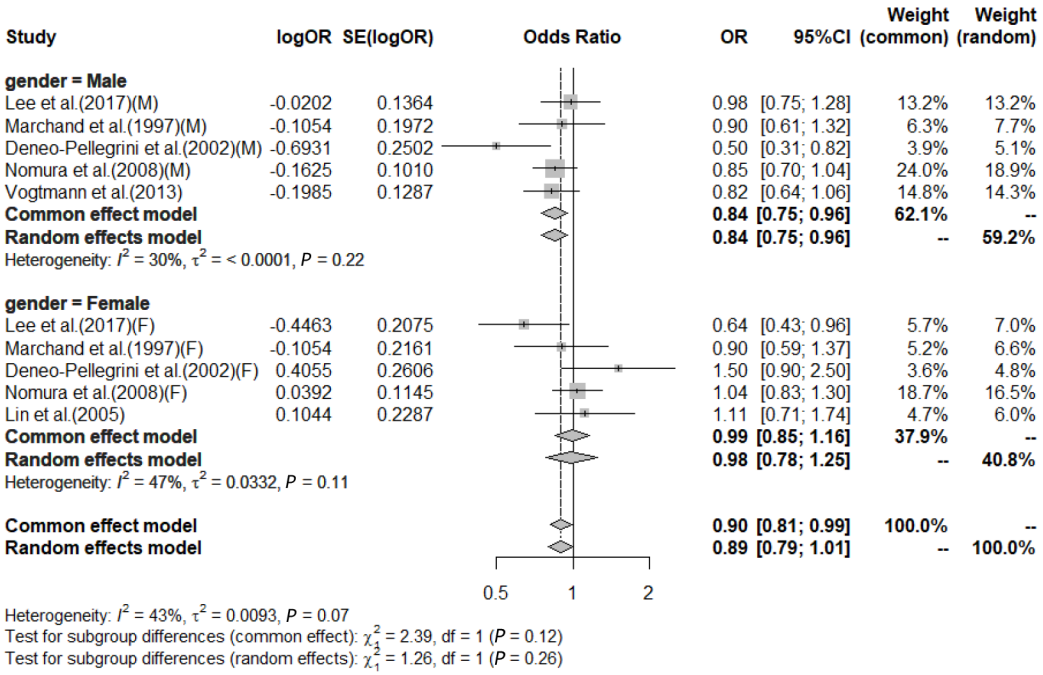

Figure 5 Subgroup analysis of the risk of colorectal cancer in the highest *vs* lowest category of Citrus intake by location. F: Female; M: Male; W: Whites; A: African-Americans; C: Colon cancer; R: Rectal cancer; OR: Odds ratio; CI: Confidence intervals.

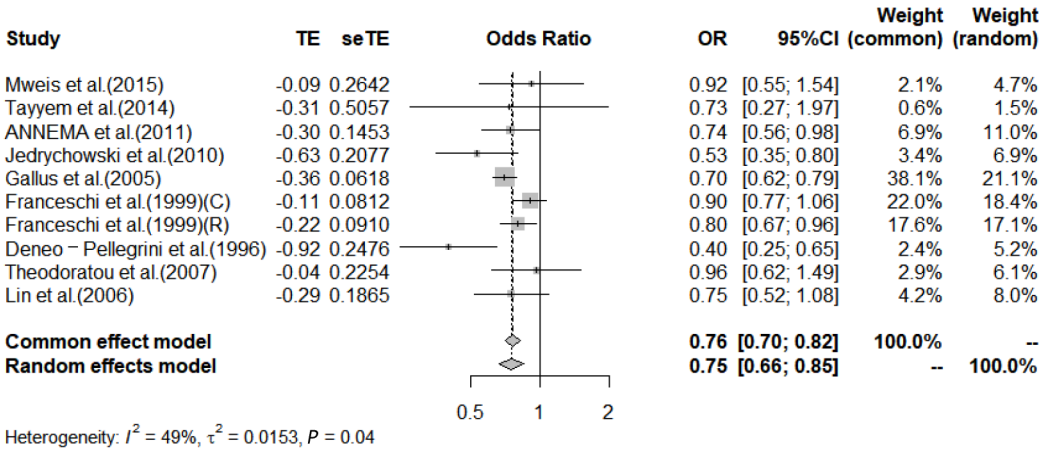
(95%CI) = 0.97 (0.87-1.08)] and cohort studies [I^2 = 13%, P = 0.28, REM; OR (95%CI) = 1.08 (0.93-1.26)] revealed no reduction in the risk of CRC with grape consumption (Supplementary Figure 14).

Other fresh Fruits: Watermelon[42,50] [I^2 = 0%, P = 0.37, REM; OR (95%CI) = 0.74 (0.58-0.94), P = 0.02] (Supplementary Figure 15) and kiwi[29,42] [I^2 = 0%, P = 0.51, REM; OR (95%CI) = 0.87 (0.78-0.96), P < 0.01] (Supplementary Figure 16) were related to a reduced risk of CRC. Pears[42,57] [I^2 = 0%, P = 0.88, REM; OR (95%CI) = 1.08 (0.72-1.62), P = 0.70] (Supplementary Figure 17), melons[29,42] [I^2 = 34%, P = 0.22, REM; OR (95%CI) = 0.96 (0.87-1.06), P = 0.39] (Supplementary Figure 18), and figs[42,57] [I^2 = 80%, P = 0.03, REM; OR (95%CI) = 0.83 (0.32-2.17), P = 0.70] (Supplementary Figure 19) were not associated with a reduced risk of CRC.



Dose-response meta-analysis

The dose-response analysis of citrus intake included seven articles[39,42,44-46,51,54] (Figure 8). A nonlinear relationship was observed between citrus intake and CRC risk [R (95%CI) = -0.0031 (-0.0047 to -0.0014), P < 0.001]. Based on the above meta-analyses results, a citrus intake of (0 g/d) was used as a reference group and the risk was minimized around 120 g/d (OR = 0.85), whereas no significant dose-response correlation was observed after continuing to increase intake, with correlations only assessed in the range of 0-248 g/d. Dose-response relationships between intake and CRC risk could not be calculated for other types of fruits due to the paucity of available data.

Sensitivity analysis and publication bias

A sensitivity analysis was conducted for all outcome indicators with more than 50% heterogeneity and P < 0.05, and the results showed that the combined results were stable for heterogeneity. A sensitivity analysis based on quality assessment was also conducted. After articles with relatively low quality of evidence (three domains were graded as moderate risk) were excluded, the remaining data were pooled and analyzed again, and the outcome showed that our combined results were robust (Supplementary Figures 20 and 21). No potential publication bias was found. For the analysis of high and low fruit intake, the P value of the citrus Egger's test was 0.8467 (Figure 9A), and the P value for the apple Egger's test was 0.6068 (Figure 9B). Other types of fruits were not tested for publication bias as the number of articles was less than 10.

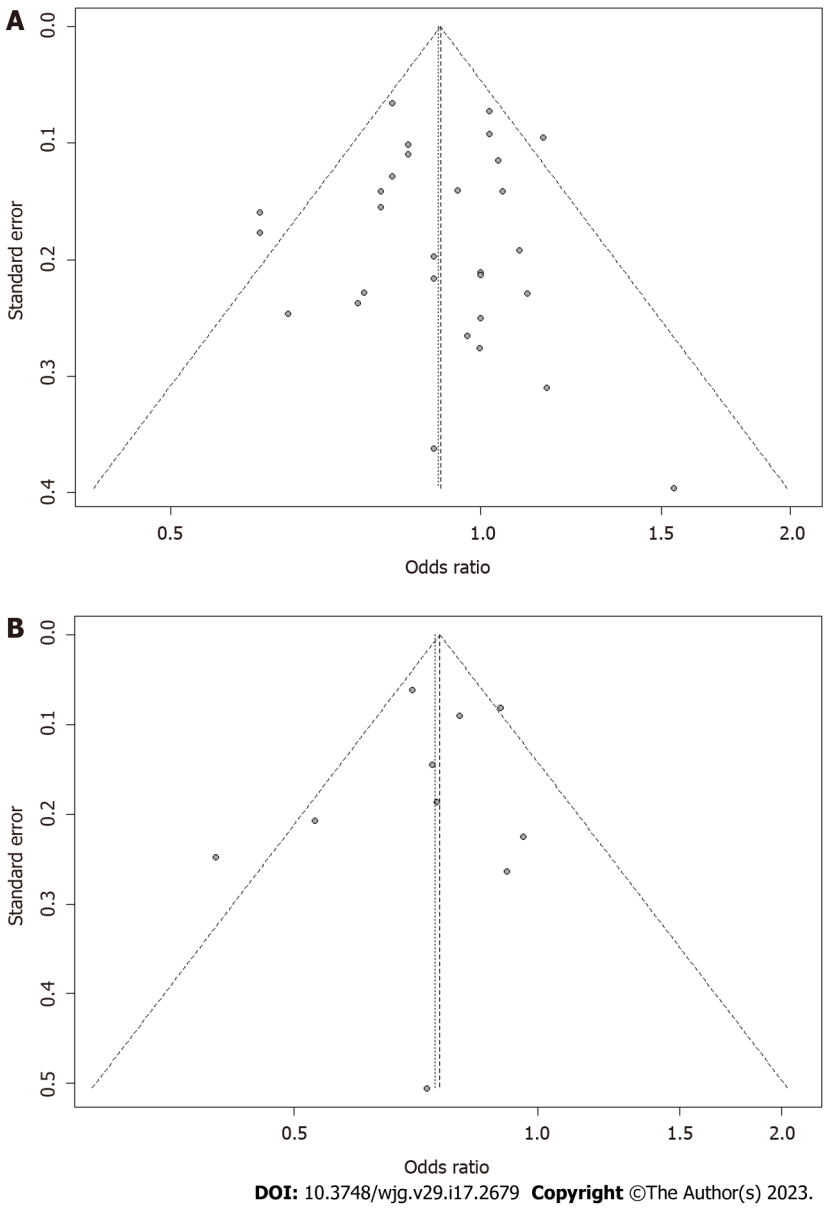

Figure 8 Nonlinear relation between Citrus fruit intake and the risk of colorectal cancer.

DISCUSSION

The main findings of this meta-analysis demonstrated that compared to low intakes, higher intakes of citrus, apples, watermelon, and kiwi reduced the risk of CRC by 9%, 25%, 26%, and 13%, respectively, while bananas, grapes, strawberries, peaches, pears, figs, and other melons did not exhibit an association with CRC risk. A nonlinear dose-response relationship was observed between citrus and CRC risk in the present study. To our knowledge, this study is the first meta-analysis to investigate the association between different fruit intake and CRC risk, and the first to perform a dose-response analysis between citrus intake and CRC risk.

The results of this meta-analysis are supported by relevant biological theories. Citrus has many chemopreventive effects on CRC[58]. Nobiletin, a compound extracted from citrus, blocks the cell cycle, inhibits cell proliferation, induces apoptosis, prevents tumor formation, reduces inflammatory effects and limits angiogenesis[59]. Naringenin, which is rich in citrus, inhibits the proliferation of HT-29 colon cancer cells[60] and also reduces the severity of colorectal adenomas and colitis by inhibiting pro-inflammatory mediators GM-CSF/M-CSF, bone marrow-derived suppressor cells, IL-6 and TNF-α, and NF-κB/IL-6/STAT3 cascade in colorectal tissues[61]. Neohesperidin, derived from citrus fruits, has also been confirmed to prevent colorectal tumors by altering the intestinal microbiota[62]. Moreover, APs contained in apples have been verified to prevent AOM/dss-induced colitis-associated CRC (CACC) in ICR mice. APs modulate intestinal flora composition, reduce infiltration of neutrophils, macrophages and T cells in the colon, and more importantly, inhibit the entry of β-catenin into the nucleus, which in turn retards the Wnt/β-catenin pathway[63]. APs also induce apoptosis in colon cancer cells through microactivating the NF-κB pathway, and inhibit CRC cell migration and invasiveness by targeting the LPS/TLR4/NF-κB pathway[64,65]. It has also been shown that apple polyphenols and apple anthocyanin Cy3Gal inhibit and reduce the appearance of precancerous markers of CRC[66] as well as tumor lesions in AOM-induced CRC mice[67]. In addition, apple polyphenols affect the initiation of apoptosis in human colon cancer cells and the activity of protein kinase C[68]. That other fruits did not show protective effects may be owing to the small number of original studies, resulting in large heterogeneity and wide confidence intervals, which masked their anticancer effects. It could also be possible that the intake was too small to show a protective effect, and more research is needed for verification.

There are many reasons contributing to inconsistent results in several subgroup analyses. In citrus, case-control studies tended to show protective factors, while cohort studies did not. In other types of fruits, no correlation was seen in the subgroup analysis of the study type. Generally speaking, case-control studies have several weaknesses, such as a control group that may not be representative of the general population or more problems with reverse causality and recall bias. On the other side, dietary assessment questionnaires used in a prospective study setting may not be as accurate as those used in a retrospective case-control setting. Meanwhile, it is difficult for individuals to accurately report their fruit intake, and this low correlation has been confirmed in some studies (Spearman's correlation coefficient of 0.6 for fruit consumption[69,70]), which may have weakened the estimates of the associated risk. Thus, the true association may be stronger than what we observed, reinforcing the conclusion of protective effect. In another subgroup analysis of studies' geographic location, a negative association between citrus intake and CRC risk was observed in Asia but not in North/South America or Europe,

Figure 9 Funnel plot. A: Funnel plot of studies evaluating for the association between Citrus fruit intake and risk of colorectal cancer. Dotted lines on both sides indicate 95% pseudo-confidence intervals; B: Funnel plot of studies evaluating for the association between Apple intake and risk of colorectal cancer. OR: Odds ratio; CI: Confidence intervals.

and a negative association for bananas only in North/South America and apples in Europe. These results may be attributed to the varied consumption patterns of fruits and vegetables among countries, leading to errors in the measurement of dietary intake[71]. According to our pooled results, the specific sites of tumor occurrence, such as the distal colon, proximal colon, and rectum, were not significantly associated with the risk and benefit of fruit intake, indicating that fruits improve the function of the entire intestine or regulate the microbial flora of the entire digestive tract, but do not target specific sites, so there is no correlation with the specific location of tumors. No significant risk benefit was seen for men or women in the gender-based subgroup analysis either, possibly due to an insufficient number of included original studies or dietary measurement errors. From the dose-response analysis, the risk of CRC was found to be minimized at a citrus intake of 120 g/d, while the risk of CRC did not decrease further after continuing to increase intake. The underlying mechanism may be related to the availability and digestibility of nutrients from citrus fruits[72,73]. However, further studies are needed to validate our results.

Surgery, chemoradiotherapy and targeted drugs currently used to treat CRC are not only expensive but also highly toxic. Through this Meta-analysis, we can prioritize fruits with proven protective effects to prevent CRC. If cancer prevention can be achieved by changing dietary habits such as fruit supplementation, it will certainly reduce the huge economic burden and mortality of cancer in the world. As for future research directions, we hope to find the key components of anti-cancer through research and make element-specific nutritional preparations to help people better prevent cancer. More prospective

Table 1 Characteristic of eligible studies included in the meta-analysis assessing the relationship between different types of fruit intake and the risk of colorectal cancers

Ref.	Country	No. of cases/controls (age)	Dietary assessment	Comparison of exposure level	Category, OR/RR (95%CI)	Confounding factors
Lee *et al*[39], 2017	-	923 (625 males, 298 females)/1846 (1250 males, 596 females)	SQFFQ, 106 food items	Orange/yellow fruits (g/d); males: T3 (≥ 47.9) *vs* T1 (< 15.9); females: T3 (≥ 90.6) *vs* T1 (< 32.5); proximal colon/distal colon/rectum: T3 (≥ 90.6) *vs* T1 (< 32.5)	Males: 0.98 (0.75-1.28); females: 0.64 (0.43-0.97); total: 0.85 (0.69-1.06); proximal colon: 0.79 (0.37-1.70); distal colon: 0.77 (0.44-1.35); rectum: 0.44 (0.25-0.80)	Age, education, alcohol consumption, BMI, regular exercise, red meat, processed meat, total EI
Leenders *et al* [40], 2015	Ten European countries (Denmark, France, Germany, Greece, Italy, The Netherlands, Norway, Spain, Sweden, and United Kingdom	442961 cohort; 3082 incident cases (2128 colon cancer (954 proximal, 965 distal), 1242 rectal cancer cases); 51.2 (38.3-63.0) years; follow-up 8 years	Center-specific dietary questionnaire	Medians of consumption per quartiles; berries: 21 g/d *vs* 1 g/d; citrus fruits: 110 g/d *vs* 7 g/d; grapes: 32 g/d *vs* 1 g/d; hard fruits: 153 g/d *vs* 10 g/d; stone fruits: 83 g/d *vs* 2 g/d	Colon cancer; berries: 1.04 (0.88-1.24); citrus fruits: 1.02 (0.88-1.17); grapes: 1.15 (0.97-1.37); stone fruits: 0.97 (0.81-1.15); rectal cancer: Berries: 1.04 (0.83-1.30); citrus fruits: 1.15 (0.95-1.38); grapes: 0.98 (0.78-1.25); stone fruits: 1.19 (0.94-1.50)	All other fruit and vegetable consumption, height, weight, dietary calcium consumption, dietary alcohol consumption, dietary cereal fiber consumption, smoking status, time since stopped smoking, duration of smoking, number of cigarettes smoked per day and PA
Abu Mweis *et al*[41], 2015	Jordan	167/240, NA	FFQ, 109 food items	≥ 3 times/wk (high) *vs* ≥ 2 times/wk (low)	Apples: 0.915 (0.545-1.535); bananas: 1.167 (0.670-2.033); oranges: 0.999 (0.581-1.715)	Age, sex, total EI, metabolic equivalent, smoking, education level, marital status, work, income, and family history of CRC
Tayyem *et al* [42], 2014	Jordan	220/281 (248 males, 253 females); males: mean age 55.27 years; females: mean age 48.67 years	NA; 42 food items	Daily (high) *vs* ≤ rarely (low)	Apple: 0.73 (0.27-1.96); banana: 1.12 (0.34-3.67); orange: 0.90 (0.44-1.82); pear: 1.13 (0.56-2.29); peach: 0.64 (0.32-1.25); grape: 0.62 (0.27-1.40); melon: 0.82 (0.38-1.78); watermelon: 0.54 (0.26-1.11); strawberry: 0.75 (0.26-2.13); fig: 0.51 (0.28-0.92); kiwi: 1.14 (0.25-5.06); dried Fruit: 1.42 (0.55-3.67)	Age, sex, total EI, MET minutes/week, tobacco use, education level, marital status, work, income, PA, marital status, family history of CRC
Rosato *et al* [43], 2013	Italia and Swiss	329/1361, median age 40 yr	FFQ; 78 food items	High *vs* Low	Citrus fruit: 0.61 (0.45-0.84)	Age, sex, center, study, year of interview, education, family history, alcohol consumption, EI
Vogtmann *et al*[50], 2013	China	61274 male's cohort (40-74 years); 398 incident cases (236 colon, 162 rectal); follow-up 2002-2006 to 2010	Validated FFQ; 46 food items	Citrus fruit intake g/day: ≥ 12.61 (high) *vs* < 2.70 (low); watermelon intake g/day: ≥ 93.33 (high) *vs* < 33.33 (low)	Citrus fruit: Colorectal cancer: 0.82 (0.64-1.06); colon cancer: 0.86 (0.62-1.19); rectal cancer: 0.76 (0.51-1.14); watermelon: Colorectal cancer: 0.77 (0.59-0.99); colon cancer: 0.76 (0.55-1.06); rectal cancer 0.77 (0.51-1.15)	Age, total EI, red meat intake, total meat intake, education, income, occupation, smoking status, alcohol consumption, BMI, MET hours of exercise participation, history of diabetes mellitus, family history of CRC
Annema *et al* [44], 2011	Western Australia	834 (64.9 yr ± 8.9 yr)/939 (64.6 yr ± 9.4 yr)	FFQ; 74 food items	Servings/d) ≥ 0.50 (high) *vs* < 0.07 (low)	Total: Citrus fruit: 0.95 (0.72-1.25); apples: 0.74 (0.56-0.99); fruit juice: 1.38 (1.08-1.75); citrus fruit: Proximal Colon: 0.97 (0.65-1.45); distal Colon: 0.81 (0.53-1.24); rectum: 1.03 (0.71-1.49); apples: Proximal Colon: 1.13 (0.72-1.77); distal colon: 0.51 (0.34-0.77); rectum: 0.73 (0.49-1.08); fruit	Sex, age, BMI at age 20 yr, EI, multiv-itamin use, alcohol consumption, PA, smoking, diabetes, socioeconomic status

Foschi *et al* [45], 2010	Italy and Switzerland	3634 (median age 62 yr)/6804 (median age 57 yr)	Validated FFQ; 78 food items	Citrus fruit or citrus fruit juice intake: ≥ 4 portions/wk *vs* < 1 portion/wk	Citrus: 0.82 (0.72-0.93)	Age, sex, study center, tobacco smoking, alcohol, education, BMI, PA, EI
Li *et al*[51], 2010	Japan	42470 cohort (40-79 yr) (20222 males, 22248 females); 665 incident cases; follow-up 9 years	FFQ; 40 food items	Citrus consumption daily *vs* ≤ 2 times/wk	Citrus: 0.80 (0.61-1.06)	Age, sex, job status, years of education, BMI, time engaging in sports or exercise, time spent walking, cigarette smoking, alcohol drinking, history of hypertension, diabetes mellitus and gastric ulcer, family history of cancer, daily total EI, consumption of rice/miso soup/soybean products/total meat/total fish/dairy products/other fruits/total vegetables/oolong tea/black tea/coffee /green tea
Jedrychowski *et al*[32], 2010	Poland	592/765; NA	EPIC-FFQ148 food items	Apples, servings/d: > 1.50 (Q5; high) *vs* < 0.18 (Q1; low)	Apples: 0.53 (0.35-0.79)	Age, gender, place of residency, marital status, tobacco smoking, total EI, intake of vegetables, fruits excluding apples
Williams *et al* [46], 2009	North Carolina	945/959; 40-79 yr; whites (n = 1520); African-Americans (n = 384)	Diet history questionnaire; 124 food items	Citrus fruit (servings/wk): White: 16.4 Q4 (high) *vs* 1.89 Q1 (low); African-Americans: 21.7 Q4 (high) *vs* 2.3 Q1 (low)	Whites: 0.61 (0.43-0.86); African-Americans: 1.54 (0.71-3.35)	Age, sex, education, income, BMI 1 yr ago, PA, family history, nonsteroidal anti-inflammatory drug use, total EI
Nomura *et al* [52], 2008	Hawaii and Los Angeles	191011 cohort (85903 males, 105108 females); 2110 incident cases (1138 males, 972 females) (1571 of the colon, 515 of the rectum, 24 cases both sites) (45-75 yr); follow-up 7.3 years	Self-administered quantitative FFQ (QFFQ); 180 food items	Citrus fruit were quantified as g × 1000 kcal-1 × d-1; Q5 (high) *vs* Q1 (low)	Citrus fruit: Male: 0.85 (0.70-1.04); female: 1.04 (0.83-1.30)	Ethnicity, age, family history of CRC, history of colorectal polyp, pack-years of cigarette smoking, BMI, hours of vigorous activity, aspirin use, multivitamin use, replacement hormone use (women), log EI, alcohol, red meat, folate, vitamin D, calcium
Gallus *et al* [47], 2005	Italy	1953 (1225 of the colon, 728 of the rectum)/4154	Validated FFQ 78 food items	Average consumption of apples per day ≥ 1 (high) *vs* < 1 (low)	Apples: 0.70 (0.62-0.79)	Age, sex, study center, education, BMI, tobacco smoking, alcohol drinking, total EI, vegetable consumption, PA, other fruit
Lin *et al*[55], 2005	United States	39876 female cohort (mean age 45 years); 240 incident cases; follow-up 10 years	FFQ; 131 food items	Citrus fruit (serving/day) Median intake; 1.6 (Q5) high *vs* 0.1 (Q1) low	Citrus fruit: 1.11 (0.71-1.74)	Age, randomized treatment assignment, BMI, family history of CRC in a first-degree relative, history of

						colon polyps, PA, smoking status, baseline aspirin use, red meat intake, alcohol consumption, total EI, menopausal status and baseline post-menopausal HT use, folate intake, multivitamin use
Satia-Abouta *et al*[48], 2004	United States	613 (337 Caucasians, 276 African-Americans)/996(596 Caucasians, 400 African-Americans) (40-80 years)	Validated FFQ; 100 food items	Citrus fruits and juices: Median g/d: Caucasians: 4th quartile (high) 168 g *vs* 1st quartile 0 g (low); African-Americans: 4th quartile (high) 173 g *vs* 1st quartile 0 g (low)	Caucasians: 1.0 (0.7-1.6); African-Americans: 1.0 (0.6-1.6)	Age, gender, total EI, education, BMI, smoking history, PA, family history of colon cancer, NSAID use, fat, carbohydrates, dietary fiber, vitamin C, vitamin E, beta-carotene, calcium, folate, fruits, vegetables
Voorrips *et al* [53], 2000	Netherlands	4087 cohort; 620 colon cancer cases (332 males, 288 females), 344 rectal cancer cases (217 males, 127 females); follow-up 6.3 years	Validated FFQ; 150 food items	Citrus fruit Median intake (g/d); male: Q5 (167 g/dk) (high) *vs* Q1 (0g/dk) (low); female: Q5 (187 g/dk) (high) *vs* Q1 (8 g/dk) (low)	Male: Colon cancer: 1.09 (0.75-1.59) Rectal cancer: 0.77 (0.49-1.20); female: Colon cancer: 1.00 (0.66-1.52); rectal cancer: 1.16 (0.63-2.12)	Age, family history of CRC, category of alcohol intake
Michels *et al* [54], 2000	United States	136089 cohort (88764 females (30-55 years), 47325 males (40-75years); 1181 incident cases (937 colon cancer, 244 rectal cancer); follow-up 16 years	Validated FFQs; 61 food items	Citrus fruit: Frequencies of intake ≥ 2 servings/d *vs* 1 serving/wk or fewer	Colon cancer: 1.05 (0.80-1.39); rectal cancer: 0.97 (0.58-1.64)	Age, family history of CRC, sigmoidoscopy, height, BMI, pack-years of smoking, alcohol intake, PA, menopausal status, postmenopausal hormone use, aspirin use, vitamin supplement intake, total caloric intake, red meat consumption
Franceschi *et al*[29], 1998	Italy	1953 (1225 colon cancer, 728 rectal cancer)/4154 (2073 males, 2081 females)	Validated FFQ; 78 food items	Mean weekly servings: Citrus fruit Q5 7.5 (high)/Q1 1.0 (low); apples/pears: Q5 15.0 (high)/Q1 3.0 (low); bananas: Q5 3.0 (high)/Q1 0.5 (low); kiwi: Q5 4.0 (high)/Q1 0.5 (low); peaches/apricots/prunes: Q5 5.0 (high)/Q1 0.8 (low); melon: Q5 0.5 (high)/Q1 0.1 (low); grapes: Q5 1.0 (high)/Q1 0.2 (low); Strawberries/cherries: Q5 0.4 (high)/Q1 0.1 (low)	Citrus: Total: 1.02 (0.85-1.22), colon: 1.0 (0.9-1.1), rectal: 0.8 (0.7-1.0); apples/pears: Colon: 0.9 (0.8-1.1) rectal: 0.8 (0.7-1.0); bananas: Colon 1.0 (0.9-1.1), rectal 1.0 (0.8-1.1); kiwi: colon 0.9 (0.8-1.0) rectal 0.8 (0.7-1.0); peaches/apricots/prunes: Colon 1.0 (0.9-1.1) rectal 0.8 (0.7-0.9); melon: Colon 1.0 (0.9-1.0) rectal 0.9 (0.8-1.0); grapes: colon 1.0 (0.9-1.0) rectal 0.9 (0.8-1.0); strawberries/cherries: Colon 1.0 (0.9-1.0) rectal 0.9 (0.9-1.0)	Age, sex, centre, education, PA, total EI
Levi *et al*[49], 1999	Swiss	223 (males 142, females 81) (119 colon cancer, 104 rectal cancer, median age 63 yr)/491 (211 males, 280 females, median age 58 yr)	FFQ; 79 food items	Citrus fruits (Servings per week): Q3 (> 3.5/wk) *vs* Q1 (1.5/wk)	Citrus fruits: 0.65 (0.40-1.05)	Age, sex, education, smoking, alcohol, BMI, PA, meat and vegetable consumption, total EI
Le Marchand *et al*[56], 1997	Hawaii	1192 (698 males, 494 females) (mean age 66 yr)/1192 (698 males, 494 females) (mean age 66 yr)	Validated FFQ; 282 food items	Bananas: Male ≥ 55 g/d (Q4 high) *vs* ≤ 9 g/d (Q1 low), female: ≥ 54 g/d (Q4 high) *vs* ≤ 11 g/d (Q1 low); citrus fruits: Male ≥ 52 g/d (Q4 high) *vs* ≤ 4 g/d (Q1 low), female: ≥ 58 g/d (Q4 high) *vs* ≤ 8 g/d (Q1 low)	Bananas: Male: 0.7 (0.5-1.1), female: 0.6 (0.4-0.9); citrus fruits: Male: 0.9 (0.6-1.3), female: 0.9 (0.6-1.4)	Age, family history of CRC, alcoholic drinks per week, pack-years of cigarette smoking, lifetime recreational activity, Quetelet index 5 years earlier, total calories, egg,

						and calcium
Deneo-Pellegrini *et al*[57], 1996	Uruguay	160 (71 rectal cancer, 89 colon cancer)/221	FFQ; 61 food items	(T3; high) *vs* (T1; low)	Orange: 0.76 (0.47-1.19); apple: 0.40 (0.25-0.66); peach: 1.05 (0.65-1.69); pear: 1.06 (0.65-1.74); grape: 1.61 (0.94-2.74); fig: 1.36 (0.73-2.54); banana: 0.28 (0.16-0.50)	Age, sex, residence, education, BMI, total EI, alcohol intake
Lin *et al*[36], 2006	United States (NHS and HPFS)	71976 female cohort; 498 incident cases (30-55 yr); 35425 male cohort; 380 incident cases (40-75 yr); follow-up 10 yr	Validated FFQ; 131 food items	Apple: ≥ 2 servings/d (Q5; high) *vs* 0-2 servings/wk (Q1; low)	Total: 0.75 (0.52-1.08); NHS females: 0.64 (0.35-1.17); HPFS males: 0.82 (0.51-1.30)	Age, BMI, PA, history of CRC, previous colorectal polyps, prior screening sigmoidoscopy or colonoscopy, smoking, multiv-itamin use, current aspirin use, alcohol, EI, red meat, total Ca, total folate, total fibre
Theodoratou *et al*[37], 2007	United Kingdom	1456 (mean 63.9 yr ± 9.6 yr) yr)/1456 (64.7 yr ± 9.5 yr)	Validated FFQ; 150 food items	Apples: Q4 (high) *vs* Q1 (low)	Apples: 0.96 (0.62-1.50)	Age, sex, residence area, family history of CRC, total EI, fibre, alcohol, NSAID, smoking, BMI, PA
Deneo-Pellegrini *et al*[38], 2002	Uruguay	484 (260 colon cancer, 224 rectal cancer)/1452	FFQ; 64 food items	Citrus fruits estimate: Q4 (high) *vs* Q1 (low); banana estimate: Q4 (high) *vs* Q1 (low)	Total: Citrus fruits: 0.8 (0.6-1.1), banana: 0.6 (0.4-0.8); citrus fruits: Male: 0.5 (0.3-0.8), female: 1.5 (0.9-2.5); colon: 0.9 (0.9-1.1); rectum: 0.9 (0.7-0.9); banana: male: 0.6 (0.4-0.9), female: 0.6 (0.3-0.9); colon: 0.8 (0.7-0.9); rectum: 0.9 (0.8-1.1)	Age, residence, urban/rural status, education, family history of colon cancer for first-degree relatives, BMI, total EI and red meat intakes

NA: Not available; EI: Energy intake; PA: Physical activity; CRC: Colorectal cancer; BMI: Body mass index; MET: Metabolic equivalentr; NSAID: Non-steroidal anti-inflammatory drugs; NHS: Nurses' Health Study; HPFS: Health professionals follow-up study.

studies are also expected to verify the anti-cancer effects of other kinds of fruits.

We observed low heterogeneity between studies. Despite moderate heterogeneity in the studies on bananas and peaches, further sensitivity analysis indicated robust primary outcome and the heterogeneity was acceptable. The funnel plots and Egger's test we adopted produced consistent results, suggesting no publication bias. Moreover, the meta-analysis involved more than 1.06 million subjects, which makes it possible to explore associations between different subgroups, such as gender, geographic location and tumor location. Besides, a significant dose-response relationship was observed between citrus intake and CRC risk, further strengthening the association.

Nevertheless, there are some limitations of our study. First, synthetic results are limited due to the lack of research data on many types of fruits (*e.g.*, grapes, pears, and figs, *etc.*). This is coupled with the fact that dietary assessments of the frequency/amount of fruit intake varies so much that the protective effect against cancer cannot be truly captured. Additional potential bias may exist due to the diversity of designs and inconsistency of adjustment factors in the studies we analyzed. Although we extracted data with the most comprehensive adjustment for confounders, a subset of studies still did not adjust for potential dietary confounding variables (*e.g.*, meat, fiber, income status, and occupation). The limited range of citrus intake in the dose-response meta-analysis may have led to incomplete results. And limited available data for other fruits and the small number of original studies and made it impossible to investigate dose-response relationships between their intake and cancer risk.

CONCLUSION

Taken together, our results support the hypothesis that citrus, apple, watermelon and kiwi intake may contribute to a reduced risk of CRC. A nonlinear dose-response relationship was also observed between citrus intake and CRC risk within a certain range. However, the relationship between other types of fruit intake and CRC risk may be obscured by the various limitations mentioned above. Therefore, future prospective studies are required to further explore the effects of measurement error and control for important confounders, and thus reveal the true relationship between fruit and CRC.

ARTICLE HIGHLIGHTS

Research background

Colorectal cancer (CRC) is the third most prevalent cancer, and the prevalence of CRC in adults aged 40-49 has increased by approximately 15% between 2000-2002 and 2014-2016. However, inconsistent findings have been reported in different studies on the association between the intake of different types of fruits and CRC. Given their different chemical compositions and underlying molecular mechanisms, some types of fruits may have a closer correlation with CRC risk than others. This meta-analysis provides more reliable evidence that a higher intake of certain fruits is more effective in CRC prevention.

Research motivation

The main topic of this study is exploring the association between intake of different types of fruits and CRC risk. The key problem to be solved is to compare the CRC risk in the highest and lowest intake groups and conduct a meta-analysis. The significance of this study is that we have found that certain types of fruits can effectively reduce CRC risk.

Research objectives

To help people improve their lifestyles and dietary habits to live a healthy life. The most important goal is to ease the CRC-related social and economic burden worldwide. In terms of goal realized, through this meta-analysis, we have found that eating more citrus, apple, watermelon and kiwi fruit can effectively reduce CRC risk. Implications of achieving the goals: Further analysis of specific types of fruit is needed to explore key anti-cancer components.

Research methods

This meta-analysis was conducted by comparing the reported CRC risk between the highest and lowest fruit intake groups. Considering that CRC is rare, the risk is less than 10%, and the OR is small, the RR/HR we have calculated is approximately equal to the OR. Heterogeneity of results across studies was assessed by the I^2 test. Publication bias was determined using funnel plots and Egger's linear regression test. A dose-response analysis of citrus fruits was also conducted to examine a possible nonlinear relationship. All analyses were performed using R (version 4.1.3). Characteristics and novelty of the research method: No research has used this method to explore this topic before. This research direction is very suitable for this research method.

Research results

Findings: High intakes of citrus, apple, watermelon, and kiwi reduced CRC risk by 9%, 25%, 26%, and 13%, respectively, compared with low intakes. However, other types of fruit did not show an association with CRC risk. A non-linear dose-response relationship was found between citrus and CRC risk. Contribution to the field: This study performed a meta-analysis of previous data in a scientific context and identified the fruit types most effective in reducing CRC risk. Unresolved issues: More prospective studies are needed in the future to further elucidate the association between fruit and CRC.

Research conclusions

The results of this study underpin the hypothesis that certain types of fruit are effective in preventing CRC. This meta-analysis is based on the reported CRC risk of the highest and lowest fruit intake groups. It convincingly demonstrates the real association between fruit and CRC.

Research perspectives

In future research, we hope to find out the key anti-cancer components of specific types of fruits, so as to help people prevent cancer more effectively.

ACKNOWLEDGEMENTS

We would like to thank the researchers and study participants for their contributions.

Abstract

Several studies have shown that the immune system is highly regulated by tryptophan metabolism, which serves as an immunomodulatory factor. The indoleamine 2,3-dioxygenase 1 (IDO1), as an intracellular enzyme that participates in metabolism of the essential amino acid tryptophan in the kynurenine pathway, is an independent prognostic marker for pancreatic cancer (PC). First, overexpression of IDO1 inhibits the maturation of dendritic cells and T-cell proliferation in the liver and spleen. Second, the high expression of kynurenine induces and activates the aryl hydrocarbon receptor, resulting in upregulated programmed cell death protein 1 expression. Third, the induction of IDO1 can lead to loss of the T helper 17 cell/regulatory T cell balance, mediated by the proximal tryptophan catabolite from IDO metabolism. In our study, we found that overexpression of IDO1 upregulated CD8+ T cells and reduced natural killer T cells in pancreatic carcinoma in mice. Hence, it may be essential to pay more attention to tryptophan metabolism in patients, especially those who are tolerant to immunotherapy for PC.

Key Words: Immunosuppression; Pancreatic cancer stroma; T cell; Tryptophan metabolism; Xxx

TO THE EDITOR

We have an interest in the recently published article by Goulart *et al*[1],which summarized the pancreatic cancer (PC) immune landscape, T-cell interactions and immune dysfunction, T-cell phenotype and functions, T-cell exhaustion, and immunotherapy in PC. In this review, Goulart *et al* stated that immune cells including CD8+ T, natural killer (NK) cells, T helper 17 cells (Th17), and regulatory T cells (Tregs) are regulated by different cytokine factors. However, several studies have shown that the immune system is highly regulated by tryptophan metabolism. Indoleamine 2,3-dioxygenase 1 (IDO1), as an intracellular enzyme that participates in the metabolism of the essential amino acid tryptophan in the kynurenine (Kyn) pathway, is an independent prognostic marker for PC. There are numerous lines of evidence for tryptophan metabolism, which serves as an immunomodulatory factor. First, IDO1 overexpression inhibits the maturation of CD11c and dendritic cells, and T-cell proliferation in the liver and spleen[2]. Second, the high expression of Kyn induces and activates the aryl hydrocarbon receptor (AhR), resulting in upregulated programmed cell death protein 1 expression. Inhibition of the Kyn-AhR pathway can enhance the efficacy of antitumor adoptive T-cell therapy and reduce the rate of migration and invasion in both tumor-bearing mice and patients with cancer[3]. In *in vivo* experiments, inactivation of the Kyn-AhR pathway showed amelioration of IDO1-mediated immunosuppression[4]. In a clinical study, high expression of the AhR transcript was correlated with reduced CD8 T-cell infiltration and worse outcomes in patients with PC[5]. Third, the induction of IDO1 can lead to loss of the Th17/Treg balance *in vivo*. Similarly, loss of the Th17/Treg balance is mediated by the proximal tryptophan catabolite from IDO metabolism[6]. In our study, we found that overexpression of IDO1 upregulated CD8+ T cells and reduced NK T cells in both hepatic cancer and PC in mice. Hence, it may be essential to pay more attention to tryptophan metabolism in patients with PC, especially those who are tolerant to immunotherapy.

ABOUT COVER

Editorial Board of *World Journal of Gastroenterology*, Octavio Caba, PhD, Professor, Senior Scientist, Department of Human Anatomy and Embriology, University of Granada, Granada 18016, Spain. ocaba@ugr.es

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

Diabetes, as a metabolic disorder, is accompanied with several gastrointestinal (GI) symptoms, like abdominal pain, gastroparesis, diarrhoea or constipation. Serious and complex enteric nervous system damage is confirmed in the background of these diabetic motility complaints. The anatomical length of the GI tract, as well as genetic, developmental, structural and functional differences between its segments contribute to the distinct, intestinal region-specific effects of hyperglycemia. These observations support and highlight the importance of a regional approach in diabetes-related enteric neuropathy. Intestinal large and microvessels are essential for the blood supply of enteric ganglia. Bidirectional morpho-functional linkage exists between enteric neurons and enteroglia, however, there is also a reciprocal communication between enteric neurons and immune cells on which intestinal microbial composition has crucial influence. From this point of view, it is more appropriate to say that enteric neurons partake in multidirectional communication and interact with these key players of the intestinal wall. These interplays may differ from segment to segment, thus, the microenvironment of enteric neurons could be considered strictly regional. The goal of this review is to summarize the main tissue components and molecular factors, such as enteric glia cells, interstitial cells of Cajal, gut vasculature, intestinal epithelium, gut microbiota, immune cells, enteroendocrine cells, pro-oxidants, antioxidant molecules and extracellular matrix, which create and determine a gut region-dependent neuronal environment in diabetes.

Key Words: Enteric neurons; Neuronal environment; Gut region specificity; Type 1 diabetes, Hyperglycemia; Microbiota-gut interactions

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Diabetes-related intestinal motility disturbances result from multifactorial damage to the enteric nervous system. However, the diversity of the neuronal environment in different gut segments basically determines the regionality of diabetic enteric neuropathy. Therefore, in this review, we highlight the role of enteric glial cells, gut circulation, intestinal epithelium, gut microbiota, immune and enteroendocrine cells, pro-oxidants, antioxidant defence and extracellular matrix, which have great impact on the formation and maintenance of a region-specific enteric neuronal environment in diabetes.

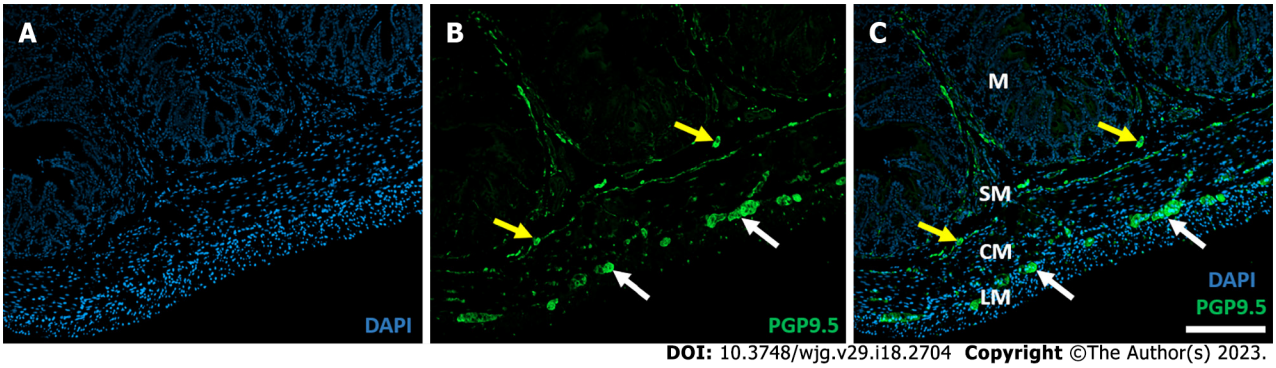
INTRODUCTION

In the middle of last century, the general belief was that the neurons within the intestinal wall are parasympathetic neurons[1]. In recent decades, it has become evident that the neurons and glia cells of the gastrointestinal (GI) tract form a third, unique division of the nervous system besides the sympathetic and parasympathetic divisions[2]. The enteric nervous system (ENS) can function independently from the rest of the nervous system and at the same time are in a close, bidirectional connection with it [2,3]. The types and the proportion of enteric neurons were characterized by their morphology, neurochemical code, function and intestinal location in different species[1,4,5]. Nowadays specialized high-throughput "omics" technologies like single cell RNA sequencing even combined with spatially barcoded RNA sequencing can confirm and supplement previous data[6,7].

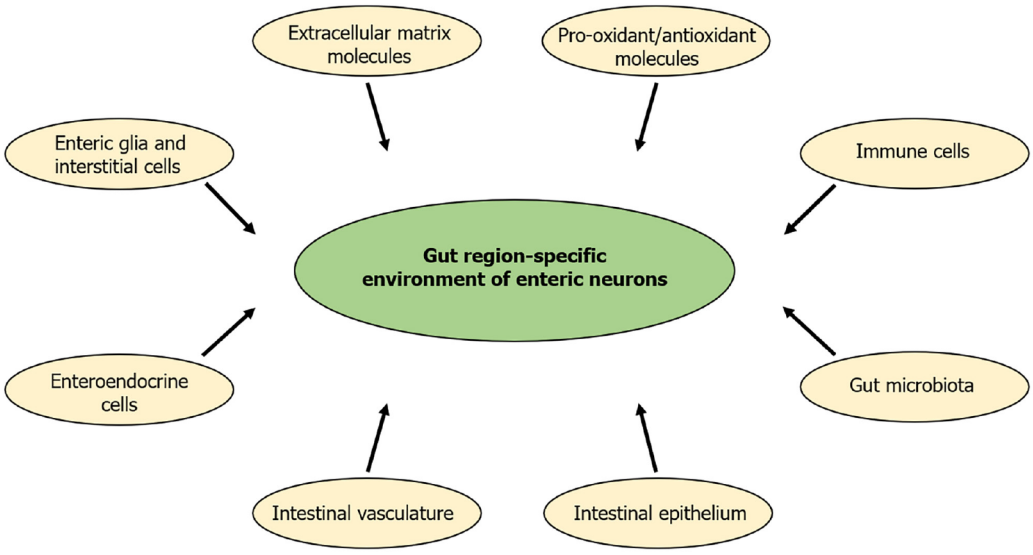
There is a large body of data on the structure and function of the ENS in physiological state, and it is clear that many pathological conditions strongly affect the enteric plexuses. Since the enteric plexuses are embedded in the histological layers of the intestinal wall (Figure 1), the projections of neurons and glia cells weave through the cross-section of the entire intestine, and because of the lack of blood-brain barrier in the periphery, the role of the environment surrounding the enteric ganglia and neuronal projections is increasingly evident in both health and diseases[2,8].



In this review, we provide a brief overview of the effects of type 1 diabetes (T1D) on the intestinal region-specific enteric neuronal environment. Unfortunately, the incidence of T1D is increasing and this incurable disease causes severe GI symptoms[8]. Chronic hyperglycemia influences the structural and functional features of the enteric neurons[9,10], it could change neurochemical code or even can cause neuronal cell death and thus lead to enteric neuropathy described by others and in our former review [11-13]. Hyperglycemia-related enteric neuropathy shows gut-region specific alterations. Therefore, the aim of this paper is to review the main environmental factors (Figure 2) in the intestinal tube from enteric glia cells (EGCs) to the luminal microbiota, which can play a crucial role in the region-specific damage of enteric neurons in the diabetic state. Some key factors like gut microbiota[14-16], GI immune [17-19] or epithelial cells[20-24] are highly emphasized in several papers, so here these are briefly summarized, while other, also critical components of the neuronal environment [*e.g.* EGCs, intestinal vasculature, pro-oxidant/antioxidant balance and extracellular matrix (ECM) molecules], are discussed in more detail.

EGCs AND INTERSTITIAL CELLS OF CAJAL

EGCs are not only supporting their neighboring neurons, but also actively regulate GI barrier function, immune homeostasis, or gut motility[25,26]. They directly interact with numerous cells in the gut wall, like enterocytes, immune cells, muscle cells, enteric neurons and vasculature, and these cross-talks influence their survival and functions in different intestinal layers and gut segments in health and disease[27].



Based on cellular morphology and location within different anatomical layers, EGC subtypes are classified into mucosal, intramuscular, submucosal and myenteric glia cells[28,29]. Glial fibrillary acidic protein (GFAP), S100ß and Sox10 are among the main glial markers, but expression patterns of different EGCs inside and outside the ganglia can be varied and reflect dynamic gene regulation[30]. In summary, the variety of EGCs, as functional heterogeneity and phenotypic plasticity, fundamentally determine the cellular microenvironment within the gut wall[31,32].

Besides gut layer-dependent diversity, intestinal regional heterogeneity of EGCs is also demonstrated among GI segments. Unique developmental patterns derived from different enteric precursors and specialized functions of EGCs are associated with different GI regions (*e.g.* esophagus, stomach or intestine) and result in local environmental properties[32,33]. Different protein expression and transcrip-

Figure 2 Main elements determining the gut region-specific neuronal microenvironment. Enteric glia cells, interstitial cells of Cajal, intestinal vasculature and epithelium, enteroendocrine cells, intestinal microbiota and immune cells, balance of pro-oxidants and antioxidants and extracellular matrix molecules create and determine a strictly regional environment of enteric neurons in diabetes.

tional profiles of myenteric glia cells have observed in mouse ileum and colon[31,34]. EGCs of myenteric ganglia displayed region-dependent responses to neuromodulators and glial regulation of gut contractility was also region- and pathway-specific in the duodenum and colon[35].

Development and function of EGCs and enteric neurons are in close interdependence[36]. Different neurotransmitters can activate EGCs and glial derived neurotrophic factors are crucial for neuronal survival and maintenance[27,37]. EGCs could also act as a critical link in the communication of enteric nervous and immune systems through the modulation of macrophages[38]. Because of the close neuron-glia relationship, it would be beneficial to investigate the involvement of EGCs in diabetes in addition to gut region-specific diabetic neuronal damage[39].

In the duodenum of type 2 diabetic mice with high-fat diet, a decline in the mucosa-associated glial network density was observed, however, neither the glial density and ultrastructure nor the expression of S100ß, Sox10 and GFAP markers were changed in the EGCs of myenteric ganglia[40]. Meanwhile, in a distal direction, an intense reduction in the number of both the enteric neurons and S100-immunoreactive glia cells was seen in diabetic rat jejunum[41]. Expression of GFAP and neurotrophins, like glia cell-derived neurotrophic factor (GDNF) and neurotrophin-3 were decreased in the colon of diabetic rats [42]. Loss of enteric neurons and progressive decrease in GDNF expression was demonstrated with the course of diabetic state both in proximal and distal colon of Sprague-Dawley diabetic rats. Moreover, reduced Akt phosphorylation also accompanied these changes[43]. Also, hyperglycemia stimulated EGC apoptosis in culture by repressing the PI3K/Akt molecular pathway[44]. The down-regulation of

the PI3K/Akt pathway, an important mediator of neuronal survival, is heavily involved in the diabetic damage of enteric neurons[45,46].

Interstitial cells of Cajal (ICCs) are pacemaker cells in GI motility that generate spontaneous and rhythmic slow waves to promote the spontaneous contractions of smooth muscles[47]. The delayed gastric emptying both in diabetic patients and diabetic animal models is associated with ICC depletion [10,48]. Furthermore, damage of ICCs contributes to impaired motility in other GI regions causing constipation[49,50].

INTESTINAL VASCULATURE

Blood vessels enmeshing the small and large intestine are important in nutrient transport and also responsible in supplying enteric cells. Macro- and microvascular anatomy of the GI tract fundamentally determine its regionality. Extramural circulation of the duodenum arises from the coeliac trunk, the jejunum and ileum are supplied by branches of superior mesenteric artery, while different parts of large intestine are supplied by the superior or inferior mesenteric arteries[51]. The impairment of large mesenteric vessels has been described in T1D[52], and substantial heterogeneity of endothelial dysfunction of different large arteries has been observed in a type 2 diabetic animal model[53]. Besides the variability of diabetic macroangiopathy, the impact of diabetes on the intestinal microvasculature can also be region-dependent[54-56].

Investigation of small capillaries in the close vicinity of myenteric ganglia revealed their different susceptibility to diabetic damage along the duodenum-ileum-colon axis[54]. Structural changes such as thickening of the endothelial basement membrane, caveolar hypertrophy and tight junction opening were confirmed in the ileum and colon, whereas only junctional alterations were visible in the duodenal capillaries. In addition, a severely impaired regulation of vascular permeability was shown in ileal and colonic capillaries, while an accelerated, but well-balanced albumin transport was indicated in the duodenum. Immediate insulin treatment prevented most of the diabetes-related changes of the capillary endothelium in the ileum, but not in the colon[54]. Increased thickening of arteriolar wall representing microangiopathy in colonic submucosal vessels was also shown in diabetic patients[56].

Naturally, distinct degrees of capillary damage in different gut segments strongly determine a segment-specific cellular environment and contribute to the diabetic fate of the cells they supply[8]. Close interaction between the capillary endothelial cells and migrating neural crest-derived cells has already been observed in intestinal neurovascular development and has an important role in creating a favorable neuronal microenvironment[57]. Therefore, the diabetes-related regional capillary impairments may greatly contribute to region-dependent enteric neuropathy in T1D[8].

However, not only the structural complications in the vascular system, but also the circulating microparticles can impair the endothelial function in diabetes[58]. Different gut segments feature their distinct microbial compositions and metabolites. Imbalance in the microbial composition accompanying diabetes results in changes of metabolites production, like short-chain fatty acids, bile acids, or tryptophan catabolites[59,60]. Enhancement of gut permeability related to dysbiosis may allow not only the release of different metabolites and endotoxin but also bacterial translocation from the gut to the venous circulation. These elements as integral mediators significantly contribute to vascular inflammation and immune activation[59-62].

INTESTINAL EPITHELIUM

The lining of the GI tract is directly exposed to an ever-changing environment. This single layer of epithelial cells is crucial for preserving gut homeostasis and functions both as barrier and channel for the crosstalk between the GI immune cells and microbiota[23,63].

Epithelial tight junctions are the key components of the physical intestinal barrier along the GI tract [20]. Altered barrier function of enterocytes and colonocytes leads to several pathologic conditions, including obesity or diabetes[20,21,23]. The chronic hyperglycemia-related breakdown of barrier integrity leads to the systemic influx of microbial products and an enhanced incidence of enteric infection[64].

The intestinal epithelium also has an immunological role, as it contains pattern recognition receptors, such as the Toll-like receptors (TLRs)[20]. Recently, several studies demonstrated the expression of TLR4 in metabolic diseases[65-67]. When sensing microbial lipopolysaccharides of Gram-negative bacteria, TLR4 can activate pro-inflammatory pathways in the GI tract[16,22], thus TLRs may play a crucial role in diabetic enteropathy[65]. TLR4 not only affects ENS function, but also modulates neuro-immune interactions by mediating the effects of the intestinal microbiota[65].

GUT MICROBIOTA

In the last two decades it has become clear that the imbalance of microbial species due to a reduction in microbial diversity, known as dysbiosis, is associated with several pathological conditions like autoimmune diseases[68], cancers[69], arteriosclerosis[70] depression[71,72], neurodegenerative diseases[73], obesity or diabetes[74-76]. Dysbiosis contribute to the formation of a proinflammatory milieu and gut leakiness[77,78].

Decreased microbiota diversity has been observed in T1D. At the phyla level, the proportion of *Firmicutes* decreased in patients compared to the healthy individual group, while *Bacteroidetes* abundance increased[16,79].

It is also obvious that the composition of microbiota and the number of microbes is different along the GI tract and each segment contains unique microorganism communities[80,81]. Unfortunately, only a very few studies performed longitudinal comparisons, but results showed that the mode and severity of dysbiosis has also been distinct in different gut segments[82-85]. Besides a longitudinal variability, a horizontal gradient also exists in the gut, with oxygen, redox and mucus gradients from the mucosal surface to the lumen[80] and these variables can contribute to the differences of luminal and mucosal microbiota both in health and disease[83,84,86].

By now, a sufficient amount of evidence has been gathered which show that probiotics have a beneficial influence on diabetes-related dysbiosis[78], and a plethora of studies investigate the effects of prebiotics, synbiotics and fecal microbiota transplantation on hyperglycemia and other diabetes-associated symptoms. Among others, *Roseburia intestinalis, Lactobacillus casei, Akkermansia muciniphila* and *Bacteroides fragilis* have been shown to ameliorate glucose metabolism and insulin sensitivity[75]. In the last 20 years, considerable progress has been made and the intestinal microbiota most certainly represents a promising target for T1D prevention and therapy; however, numerous unresolved concerns require further in-depth investigation.

GI IMMUNITY

The GI tract is the largest immune organ in vertebrates, where the intestinal homeostasis is determined by the gut microbiota, intestinal epithelium and host immunity[21,87].

The complex and enormous amount of information available about the GI immune system is summarized in other reviews[17-19], here we would like to highlight only one aspect. In earlier studies, the GI immune system has been examined as small *vs* large intestine, based on obvious differences in structure and function. Recently it has become apparent that the immunological niches of the GI tract differ between more refined functional compartments, making it necessary to study them separately to understand the consequences on intestinal immune homeostasis[88].

Based on the review of Brown and Esterházy[88], the GI tube can be divided into the following five main parts: Proximal small intestine, gut-draining lymph nodes, distal small intestine, large intestine and mesentery. Each intestinal niche is influenced by a combination of intrinsic tissue properties, extrinsic environmental signals, and immune cell composition.

It would be beneficial if therapies would take into account the regionally different susceptibility of the GI tract to infections and diseases.

ENTEROENDOCRINE CELLS

Enteroendocrine cells (EECs) not only play a role in humoral processes but also act as sensory cells in the GI mucosa next to the neurons and immune cells[89]. Therefore, microbial metabolites could stimulate or suppress hormone secretion by EECs, while endocrine and paracrine factors regulate GI functions and affect several metabolic processes in the body[90]. The diversity of EECs prompts the introduction of a new classification scheme. Earlier, EECs were classified based on producing a single hormone, but in the last decade it was shown that most EECs contain multiple hormones. Several hormones, like secretin and serotonin, are in separate storage vesicles at subcellular level[91]. The hormones produced by EECs might have a big potential in the future as novel microbiota-based therapies to alter metabolically active hormone levels, similarly to the use of the anorectic gut hormone, glucagon-like peptide 1, in the treatment of obesity and type 2 diabetes[90].

It is well established that EEC composition and proportion is different along the GI tract[92,93]. A recently published paper by Martin *et al*[93] has indicated that regional differences in nutrient sensing capability exist in mouse EECs. Colonic EECs has been shown to be more sensitive to glucose, while duodenal EECs to fructose and sucrose.

PRO-OXIDANTS AND ANTIOXIDANTS

The intestinal redox state is critical in maintaining gut homeostasis and functional regulation. The maintenance of this delicate balance in redox state is influenced by the gut microbiota, immune cells and epithelium, which can all produce and respond to redox signals[94]. Numerous genera of bacteria has been identified as biomarkers for gut redox state[95]. Reactive sulfur species-producing bacterial families enhance the host's antioxidant capacity[96], however, sulfur metabolism can be distracted by opportunistic pathogens[94]. Large differences can be observed in different GI segments regarding the quantity and composition of microbiota, intestinal pH or partial pressure of oxygen within the luminal-facing epithelium[80]. There is a richer and more diverse microbial community and deeper anaerobic state from proximal to distal parts of the gut, therefore, it is not surprising that oxidant and antioxidant mechanisms have also been linked to strict region-dependency in health and disease[97]. Foods containing numerous antioxidants, such as vitamins, carotenoids, flavonoids, polyphenols, bioactive peptides or others, however, also include a lot of pro-oxidant molecules[98-100] and all of these can modulate the composition of microbial communities[101]. Consumed and endogenously produced antioxidants have varied strategies at different levels to maintain optimal redox balance[102,103]. Still, the accumulation of reactive oxygen species and/or decrease in antioxidant defence contribute to serious imbalance of intestinal pro-oxidant/antioxidant milieu[104].

Higher mucosal vitamin E and carotenoid concentration, higher total antioxidant activity, superoxide dismutase and catalase activity, as well as glutathione level were observed in the duodenum compared to the ileum and colon of different animal species[105-107]. The presence of probiotic *Lactobacillus* species also reflects a highly beneficial cellular environment in the duodenum[108]. Moreover, in diabetic rats, an increased abundance of the genus *Lactobacillus* has been observed relative to controls [83], which can result in enhanced antioxidant capacity[109]. While no significant changes in peroxynitrite production has been observed, a robust increase of metallothionein 2 and elevated glutathione level has been found in the duodenum of diabetic rats[110], which may contribute to cell survival in this particular gut segments.

In contrast to the duodenum, diabetes increased lipid peroxidation and catalase activity, as well as the percentage of nitrotyrosine-immunoreactive myenteric neurons in the jejunum[111]. Decreased superoxide dismutase and increased myeloperoxidase enzyme concentrations were also demonstrated in the diabetic jejunum[112]. Enhanced lipid peroxidation and protein oxidation accompanied with significantly lower superoxide dismutase levels, catalase and glutathione levels were also observed in the diabetic ileum[113,114]. However, a great increase in the activity of the endogenous heme oxygenase system was shown in myenteric neurons of diabetic ileum[115], maybe as an effect of microbial changes [116]. In the colon of diabetic rats, the doubled peroxynitrite level, reduced superoxide dismutase activity and the induction of the endogenous heme oxigenase system emphasizes the observation that distal gut segments have greater susceptibility to the diabetic oxidative environment, which is in correlation with diabetic neuronal cell loss[97,110,115].

ECM

ECM structures composed of various proteins and polysaccharides are essential in the maintenance and well-regulated remodeling of tissues and have a key role in regulating different cellular events, like cell proliferation, differentiation or migration[117-119]. In the gut, numerous cells (*e.g.* epithelial, mesenchymal, stem cells) participate in the production of matrix molecules, and their precise composition is indispensable for the optimal cellular environment and normal intestinal function. Sensing the stiffness or the porosity of the ECM through specific receptors such as integrins, intestinal cells can change their intracellular state or dynamics[120,121].

Diabetes-related alterations of ECM is demonstrated in all parts of the gut, but with different extent in different regions and intestinal layers. In streptozotocin-induced diabetic rats, a significant increase in the amount of laminin-1 and fibronectin was observed in the small intestine by Western blotting and immunohistochemistry, and the strong labelling was restricted mainly to the intestinal smooth muscle and serous layers[122]. These hyperglycemia-mediated ECM accumulation was reversed by insulin treatment[122]. Additionally, in the distal colon, a marked increase of type 1 collagen was detected with no changes in type 3 and 4 collagen expression[123]. Besides of the well-marked pockets of collagen among the smooth muscle cells, formation of advanced glycation end-products was also observed in diabetic rats. Type 1 collagen deposits and glycation increase stiffness of the diabetic colon muscle, which contribute to limited colonic function[123]. There is a strict association between collagen content and mechanical properties, however, this varied in different parts of the small intestine [124]. Increased ECM deposition, as well as high levels of type 1 and 3 collagen and fibronectin mRNAs were also detected in diabetic colon mucosa[125]. The accumulation of ECM in the mucosa of the diabetic colon was associated with the deregulation of the transforming growth factor (TGF)-β1/Smad signaling pathway[125]. However, TGF-β can also influence deposition of matrix molecules by upregulating several ECM receptors[126].

Structural alterations of basement membranes as specialized ECM structures have been characterized in diabetes mellitus. Thickening of capillary basement membrane is among the first histological hallmarks of the disease. Capillaries located in gut smooth muscle in different gut segments displayed region-specific thickening of their basement membranes in T1D[54]. Additionally, significant increase in mRNA levels of different matrix scaffold proteins, like fibronectin or procollagen type 1, was observed in the aorta and mesenteric artery of type 2 diabetic Goto-Kakizaki rats[127]. Moreover, gene expression was restored in the mesenteric bed but not in the aorta using an endothelin-1 antagonist[127]. Basement membrane thickening of smooth muscle cells was also demonstrated in the small intestine[122] and colon[123]. Moreover, the basement membrane surrounding the myenteric ganglia was also thickened in diabetic rats with strict regionality in different gut segments[128].

ECM accumulation can be due to the enhanced synthesis of matrix components, but also their decreased degradation, which in turn leads to the imbalance of ECM dynamics[129]. Matrix metalloproteinases (MMPs) and their tissue specific inhibitors (TIMPs) mainly produced by macrophages, neutrophils or epithelial cells have an essential role in tissue remodeling as a response to intestinal inflammation[130,131]. Growing molecular evidence support that these proteolytic enzymes are also targets of diabetic damage. In the diabetic ileum, MMP9 expression decreased in myenteric ganglia, capillary endothelial cells and intestinal smooth muscle cells, while these values did not change in the duodenum, which is in perfect agreement with the regionally distinct thickening of the ganglionic basement membrane. However, a specific, but great induction was revealed in MMP9 and TIMP1 at the mRNA level both in duodenum and ileum homogenates of diabetics[128]. Increased early expression of MMP2 and MMP9 mRNAs and MMP1 later on was also demonstrated in the diabetic colon mucosa. On the other hand, increased TIMP1 and TIMP2 expression could be the result of decreased MMPs degrading activities here[125].

CONCLUSION

Because of its various functions, as food intake, mechanical and chemical breakdown, motility, absorption, regulation of blood flow, secretion, water reabsorption and immune functions, the GI tract has unique features. It has three detecting systems, which are more extensive than those of any other organ: (1) The ENS contains as many neurons as the spinal cord and different subpopulations of the EGCs cover all histological layers of the intestinal wall. Intrinsic primary neurons, interneurons and motoneurons can form local reflex circuits in the gut wall[1,2]; (2) There are more than 20 hormones produced by several types of EECs[89]; and (3) The GI tract is the largest immune organ with the cc. 70-80% of the body's immune cells[87,132].

In addition to the three systems listed above, other essential factors such as intestinal epithelial barrier, microcirculation of the gut wall, pro-oxidant/antioxidant milieu, ECM components and gut microbiota also play a crucial role in the formation of the enteric neuronal environment in both physiological and pathological states. Results demonstrated a clear relationship between intestinal microorganisms and the occurrence of T1D, but the correlation or causality remains an important question for several reasons. Altered gut microbiota-mediated redox imbalance and changes in cellular cross-talks may contribute to enteric neuropathy and also influence the function of gut-brain axis[15].

Considering these properties and the size of the GI tract, it is not surprising that it shows profound functional and structural differences along its length. When planning experiments, the gut should be regarded as a multiple organ, and in the case of illness, the applied therapies should take into account the intestinal segment-specific effects[88].

Abstract

There has been a rapid expansion in the knowledge of paediatric gastroenterology over the recent decade, with a fast-growing repertoire of diagnostic techniques and management strategies for a wide spectrum of childhood gastrointestinal (GI) diseases. Paediatric GI endoscopy is a core competency every paediatric gastroenterologist should possess, and represents one of the most common procedures performed in children for both diagnostic and therapeutic purposes. Yet there remains a dearth of literature on the utility and outcomes of paediatric GI endoscopy in the Asia-Pacific region. Data on the diagnostic value of paediatric GI endoscopy would be an important aspect of discussion, with the emergence of inflammatory bowel disease (IBD) and eosinophilic GI disease as increasingly common endoscopic diagnoses. Time-based trends in paediatric GI endoscopy do point towards more IBD and gastroesophageal reflux disease-related complications being diagnosed, with a declining incidence of GI bleeding. However, the real-world diagnostic value of endoscopy in Asia must be contextualised to the region-specific prevalence of paediatric GI diseases. *Helicobacter pylori* infection, particularly that of multidrug-resistant strains, remains a highly prevalent problem in specific regions. Paediatric functional GI disorders still account for the majority of childhood GI complaints in most centres, hence the diagnostic yield of endoscopy should be critically evaluated in the absence of alarm symptoms. GI therapeutic endoscopy is also occasionally required for children with ingested foreign bodies, intestinal polyposis or oesophageal strictures requiring dilation.

Endoscopic haemostasis is a potentially life-saving skill in cases of massive GI bleeding typically from varices or peptic ulcers. Advanced endoscopic techniques such as capsule endoscopy and balloon-assisted enteroscopy have found traction, particularly in East Asian centres, as invaluable diagnostic and therapeutic tools in the management of IBD, obscure GI bleeding and intestinal polyposis. State of the art endoscopic diagnostics and therapeutics, including the use of artificial intelligence-aided endoscopy algorithms, real-time confocal laser endomicroscopy and peroral endoscopic myotomy, are expected to gain more utility in paediatrics. As paediatric gastroenterology matures as a subspecialty in Asia, it is essential current paediatric endoscopists and future trainees adhere to minimum practice standards, and keep abreast of the evolving trends in the diagnostic and therapeutic value of endoscopy. This review discusses the available published literature on the utility of paediatric GI endoscopy in Asia Pacific, with the relevant clinical outcomes.

Key Words: Endoscopy; Paediatric; Asia; Children; Gastroscopy; Colonoscopy

Core Tip: Paediatric gastrointestinal (GI) endoscopy has gained traction in Asia as an invaluable tool in the diagnosis and management of chronic GI diseases of current and emerging epidemiological importance. Yet the lack of consensus guidelines and heterogeneity in clinical practice, variability in the referral patterns, healthcare access and prevalence of diseases across the Asian continent, inevitably leads to a wide variance in outcomes for different endoscopic modalities. There is a need for comprehensive and accreditable paediatric endoscopy training in Asia, so that endoscopists adhere to a minimum practice standard and are adequately trained to apply diagnostic and therapeutic endoscopic techniques appropriately and competently.

INTRODUCTION

Gastrointestinal (GI) symptoms remain a common presenting feature of various ailments in childhood, and the advent of modern GI diagnostic and therapeutic techniques have allowed centres across Asia to utilise GI endoscopy early in the evaluation of a child with suspected GI disease. There remains a lack of consensus statements and guidelines on the utility of paediatric GI endoscopy in the Asian context, leading to a lack of consistency in clinical practice and highly variable clinical outcomes between centres [1]. The epidemiological situation in Asia is unique as rapidly evolving disease trends occur amidst changing lifestyle and environmental factors: Paediatric inflammatory bowel disease (IBD) is of rapidly emerging importance[2], yet its early diagnosis is often complicated by the relatively high prevalence of GI infections such as intestinal tuberculosis[3] and other infectious diseases in certain endemic regions. *Helicobacter pylori* (*H. pylori*) has fallen in prevalence in developed regions of Asia but remains a highly prevalent pathogen in association with peptic ulcer disease and gastric cancer in other regions[4]. There is increasing awareness and knowledge of the role of the gut-brain-axis in disorders of gut-brain interaction or functional GI disorders[5], prompting interest in the actual diagnostic yield of GI endoscopy in childhood abdominal pain syndromes. While Asia remains vastly heterogeneous in socioeconomic status, access to early endoscopy and advanced endoscopy techniques has greatly improved, and has enhanced both the diagnostics and therapeutics in various chronic paediatric GI ailments such as IBD, intestinal polyposis syndromes, varices in portal hypertension and GI strictures.

DIAGNOSTIC ENDOSCOPY

Time-based trends in paediatric endoscopy in Asia: More IBD and gastroesophageal reflux disease-related complications

Improved healthcare access and the maturation of paediatric gastroenterology as a specialty has contributed to the rapid rise in endoscopies performed in children[6]. There are few paediatric

endoscopy consortiums within Asia, with most of the published experience coming from East Asian centres. Data from the Japan Paediatric Endoscopy Society demonstrated a five-fold increase in the number of paediatric endoscopies performed in the latest survey in 2011-2016 *vs* 2000-2004, an increase in advanced endoscopies such as endoscopic retrograde cholangioscopies and balloon-assisted enteroscopies, with a slight rise in adverse events (0.25% from 0.03%) inevitably so from increased procedural complexity[7]. A retrospective review of children undergoing upper GI endoscopy at the Children's Hospital of Philadelphia (CHOP) demonstrated a rapid rise of first-time endoscopes from 107 in 1985 to 1294 in 2005[8]. Interestingly this same study also showed a decline in the proportion of GI bleeding (34% to 5%), a decline in both the overall clinical severity of cases and corresponding endoscopic and histological abnormalities, and yet a rise in the proportion of upper GI endoscopies done for abdominal pain (23% to 43%)[8]. It begets the question if centres are performing more endoscopies in otherwise healthy children, hence the need to examine the diagnostic yield of paediatric GI endoscopies and the impact on clinical management.

There are very limited publications comparing trends in paediatric endoscopy within Asia, to contrast with the aforementioned North American data. In contrast to the significant fall in oesophageal histological abnormalities detected in the CHOP study, a Japanese paediatric study demonstrated a significant rise in the proportion of erosive oesophagitis (9.8% to 18.1%) or endoscopic Barrett's oesophagus (2.5% to 9.6%) between eras 2005-2012 to 2013-2019[9]. It is postulated by the authors that this trend is related to dietary changes and the decreasing prevalence of *H. pylori* amongst the Japanese population. Published adult data from Japan[10] and Malaysia[11] also clearly demonstrates the decline in peptic ulcers and associated upper GI bleeding, with rates of gastroesophageal reflux disease (GERD) increasing on the contrary.

A single centre in Beijing shows a statistically significant rise in the number of colonoscopies performed amongst the 0-3 year age group, from the era 2005-2011 to 2012-2017 (3.0% to 14.1%, $P < 0.001$) but no significant change in diagnostic yield rates between the two eras (36.3% to 38.2%)[12]. The proportions of IBD and colonic polyps detected did not differ between the two eras. A paediatric South Korean cohort study in Busan, however did show a substantial rise in colonoscopies from 2001-2005 to 2011-2015 (200 to 746)[13], with trends in indications somewhat mirroring those in the CHOP study. The number of colonoscopies performed for abdominal pain increased from 27.5% to 43.7%, while those performed for haematochezia fell from 56.0% to 42.5%. There was an actual rise in diagnostic yield with the proportion of Crohn's disease diagnosed doubling from 13.5% (2001-2005) to 26.8% (2011-2015). This is consistent with the rapid rise in paediatric IBD incidence observed in South Korea[14] and the rest of Asia[2].

Diagnostic yield varies widely according to referral indication and regional disease prevalence

Tables 1 and 2 describe the overall diagnostic yield in upper and lower endoscopies (follow-up endoscopies excluded unless stated otherwise). The positive endoscopic yield varies substantially between centres: Between 45%-93% for upper endoscopies (Table 1) and correspondingly 43%-85% (Table 2) for lower endoscopies. The large variability in the diagnostic yields is clearly multifactorial, from varying referral patterns and referral indications, regional differences in disease prevalence and healthcare resource allocation between centres. For instance, in single-centre studies out of Malaysia[15] and India[16], abdominal pain/dyspepsia were indications for just 13.4% and 17.4% of upper GI endoscopies respectively, while upper GI bleeding and variceal surveillance were more common indications. This is in contrast to other cohorts *e.g.*, the North American CHOP[8] and the South Korean cohort[17], where abdominal pain/dyspepsia were the most common indications (43%-64% of upper GI endoscopies) and upper GI bleeding being far less prevalent. These differing trends in GI bleeding rates could be attributed to varying prevalence in *H. pylori*-associated gastroduodenal ulcer disease and upper GI haemorrhage[10], variability in healthcare access, timeliness of referrals for biliary atresia and other childhood liver diseases. Resource-scarce centres also likely prioritise allocation of endoscopy resources for GI emergencies, typically acute GI bleeding, rather than uncomplicated abdominal pain.

Childhood H. pylori infection remains a highly prevalent problem in Southeast Asia and South/West Asia

It must be emphasised that the vast Asian continent is both economically and culturally heterogenous: Peptic ulcerations and *H. pylori* still remain fairly common in certain regions. Jordanian data from 2014-2020 showed *H. pylori* accounted for 66.1% of all abnormal upper GI endoscopies in children[18]; an earlier Israeli paediatric study showed 22.5% of all upper GI endoscopies had peptic ulcerations, of which 66.3% of these were *H. pylo*ri positive[19]. The global trend of increasing antimicrobial resistance in *H. pylori*[20] hinders the implementation of eradication strategies in these regions with high *H. pylori* prevalence. Vietnam has a very high *H. pylori* prevalence rate (> 75%) associated with the highest prevalence of gastric cancer in Southeast Asia[4]. A study of 237 symptomatic Vietnamese children undergoing upper GI endoscopy for suspected *H. pylori*-associated gastroduodenal disease showed 80.6% and 71.7% of *H. pylori* isolates were resistant to clarithromycin and amoxicillin respectively[21]. These figures place Vietnam as one of the regions with the highest rates of *H. pylori* antimicrobial resistance, and emphasises the added importance of upper GI endoscopy to obtain biopsies for a culture

Table 1 Diagnostic yield of oesophagogastroduodenoscopies

Country	Year	Cohort size (*n*)	Indications (top three) (%)	Findings (%)	Ref.
China	2018-2019	2268	Abdominal pain (86.2). Vomiting (31.1). Weight loss (15.1)	62.5% abnormal. Highest yield in dysphagia	[105]
Nepal	2013-2016	270	Abdominal pain (77.3). Vomiting/reflux (8.4). Failure to thrive (7.0)	92.5% abnormal. Gastroduodenitis (28.1). Antral gastritis (18.5). Erosive gastritis (15.9)	[106]
India	2013-2016	822	Variceal surveillance (19.1). Dyspepsia (17.4). Upper GI bleed (16.5)	45.8% abnormal. Duodenal ulcers/varices most common	[16]
Israel	2014	407	Suspected coeliac disease (28.2). Abdominal pain (15.0). Persistent *H. pylori* (10.3)	59.2% abnormal. Coeliac disease (28), *H. pylori* (16.5), Crohn's disease (5.4)	[107]
Jordan	2014-2020	778	Abdominal pain (45.1). Vomiting (21.1). Weight loss (10.3)	47.2% abnormal. *H. pylori* (66.1). Coeliac disease (30.4). Eosinophilic GI disease (3.6)	[18]
Malaysia	2008-2011	231 OGD. 44 OGD and Colonoscopies	Variceal surveillance (50.0). Upper GI bleed (26.0). Abdominal pain (13.4)	79.0% abnormal	[15]
South Korea	2008-2013	554	Abdominal pain (64.1). Dysphagia (9.0). Vomiting (9.0)	88.1% abnormal. Gastritis (53.1). Esophagitis (17.7)	[17]
Thailand	2000-2002	38	Recurrent abdominal pain	45% abnormal. *H. pylori* (26.3)	[108]
United States	2002-2005	454	Recurrent abdominal pain	38.1% abnormal. Reflux esophagitis (23.0). *H. pylori* (5.0). Peptic ulcers (3.0)	[37]

OGD: Oesophagogastroduodenoscopies; *H. pylori*: *Helicobacter pylori*; GI: Gastrointestinal.

and antimicrobial sensitivity-based eradication strategy. This has implications on the feasibility of healthcare access and early endoscopy, as *H. pylori* is typically most prevalent in regions of lower socioeconomic status.

Paediatric IBD: A rapid rise in prevalence with possibly many more undiagnosed cases

While IBD was once considered uncommon in Asia, an emerging number of paediatric publications have documented its meteoric rise in prevalence[2,14] as alluded to earlier. Table 2 describes IBD detection rates between 14%-40% of all abnormal paediatric colonoscopies performed in Asia, emphasising the importance of IBD as an endoscopic diagnosis. Of note, 'non-specific colitis' accounts for a substantial 8%-27% of all abnormal colonoscopic findings across most published studies. It is highly plausible that these unspecified cases may evolve into a more definite diagnosis of IBD on follow-up investigations: These published IBD rates underestimate the true burden of IBD in Asia and may just represent the tip of the iceberg. Paediatric-onset IBD typically has less classical endoscopic features and more subtle histologic findings[22] compared to adult-onset disease, often prompting a diagnosis of 'indeterminate colitis'[23] or 'IBD-unclassified'.

Intestinal tuberculosis, while often considered as an important differential to IBD, was far less common a colonoscopic diagnosis than IBD, even in regions with high tuberculosis burden. Intestinal tuberculosis accounted for 1.5% cases *vs* 14.1% IBD and 27.0% non-specific colitis in a Mainland Chinese paediatric cohort[12]; a Kuwaiti study showed Intestinal tuberculosis in 1.2% *vs* IBD in 21.3% of children undergoing colonoscopy[24]. There is a paucity of epidemiologic data from the Indian subcontinent, where the world's tuberculosis burden is the highest. An Indian publication in 1991 described a cohort of 72 Indian children undergoing colonoscopy: Tuberculous colitis was seen in 2.7%, ulcerative colitis in 5.5% and amoebic colitis in 1.3% of cases[25]. A more recent Bangladeshi study of 332 children undergoing colonoscopy showed intestinal tuberculosis in 1.5% *vs* IBD in 6% and nonspecific colitis in 13.6%[26]. It is not detailed in the aforementioned studies how intestinal tuberculosis is reliably distinguished from IBD, and this distinction remains a diagnostic challenge especially in India. A therapeutic trial of empirical anti-tuberculous therapy is still often practised in cases of diagnostic uncertainty[3].

Paediatric eosinophilic GI disease

There is little published data on the actual prevalence of eosinophilic GI diseases (EGIDs) in Asia, although it is believed the incidence of EGIDs will rise in tandem with the rise of allergic disorders[27]. Symptoms may mimic GERD especially in infants and young children, to recurrent dyspepsia, dysphagia and/or food impaction in the older child. The diagnosis of an EGID hinges greatly on histological findings of significant tissue eosinophilia (> 15 eosinophils per high power field) in the absence of other attributable causes. The increasingly widespread empirical use of proton-pump inhibitors in children[28,29] may reverse the tissue eosinophilia in a subset of patients with acid

Table 2 Diagnostic yield of ileocolonoscopies

Country	Year	Cohort size (*n*)	Indications (top three) (%)	Findings (%)	Ref.
Australia	2001-2010	999 colonoscopies (15.0% done as follow-up)	Suspected IBD (45.0). Haematochezia (20.0). Abdominal pain (5.0)	61.0% abnormal. IBD (28.2). Polyp (3.9)	[109]
China	2005-2017	326	-	62.6% abnormal. IBD (14.1). Nonspecific colitis (27.0). Polyp (12.0)	[12]
China	2013-2016	229	Abdominal pain (35.4). Haematochezia (27.9). Crissum abscess/anal fistula (17.5)	64.2% abnormal. IBD (38.8). Polyp (27.2). Nonspecific colitis (26.5)	[110]
Hong Kong	2003-2008	79	Haematochezia (58.0). Suspected IBD (29.1)	50.6% abnormal. IBD (16.5). Polyp (29.1)	[111]
Japan	2011-2016	275	Haematochezia (75.0). Diarrhoea (13.0). Abdominal pain (2.2)	77.1% abnormal. IBD (18.5). Eosinophilic GI disease (23.0). Polyp (14.0)	[33]
Japan	2007-2015	274	Haematochezia (42.7). Abdominal pain (30.7). Diarrhoea (15.3)	66.8% abnormal. IBD (43.4). Eosinophilic GI disease (2.2). Polyp (5.9). Nonspecific colitis (8.4)	[112]
Malaysia	2010-2015	121	Suspected IBD (30.0). Haematochezia (21.0). Change in bowel habits (17.0)	85.0% abnormal. IBD (42.0). Polyp (7.0). Nonspecific/infective colitis (25.0)	[113]
Saudi Arabia	1993-2002	183	-	44.0% abnormal. Nonspecific colitis or rectal ulcer (71.0). Polyp (20.0)	[114]
South Korea	2008-2013	168	Abdominal pain (37.5). Diarrhoea (28.0). Haematochezia (27.4)	43.5% abnormal. IBD (19.6). Polyp (1.8). Nonspecific inflammation (14.3)	[17]
South Korea	2011-2015	746	Abdominal pain (43.7). Haematochezia (42.5). Diarrhoea (29.1)	72.2% abnormal. IBD (33.9). Polyp (11.5)	[13]
Taiwan, China	1998-2010	192	Haematochezia (53.5). Abdominal pain (20.6). Iron deficiency anaemia (11.8)	75% abnormal. IBD (8.3). Polyp (20.4). Nonspecific colitis (23.4)	[115]

IBD: Inflammatory bowel disease; GI: Gastrointestinal.

suppression-responsive EGID[30], further complicating the diagnostic process. Nevertheless, a short finite trial of acid-suppression is still deemed reasonable, with upper GI endoscopy and/or pH-impedance testing reserved for those refractory to empirical treatment or for those who cannot be weaned off acid-suppressive therapy[31].

In a fairly large study of 910 South Korean children presenting with symptoms of oesophageal dysfunction (vomiting, dysphagia, persistent reflux), 1.5% was diagnosed with eosinophilic oesophagitis (EoE) and 1.3% with eosinophilic gastroenteritis. 30.8% of patients with EGID had normal macroscopic findings, stating the importance of performing biopsies on even normal-appearing segments. The authors commented that the incidence of EoE was similar to a previous Japanese study but much lower than 10%-15% incidence in Western cohorts[32]. A multi-centre study in Japanese children undergoing colonoscopies by Nambu *et al*[33] showed EGIDs accounted for a substantially high proportion (23.0%) of the diagnoses followed by IBD (19.0%), but the authors had included food allergies and food protein-induced proctocolitis within the spectrum of EGIDs. Future studies are required to see if the incidence of EGIDs in Asia would mimic the rising trend seen with IBD.

Low diagnostic yield of endoscopy in uncomplicated abdominal pain

While paediatric endoscopy has high value in the diagnosis and management of IBD, *H. pylori* and EGIDs, most children with GI complaints have a non-organic aetiology yet the prevalence of functional GI disorders in Asian children is largely unknown and seldom described. Functional constipation was the most common condition identified in otherwise healthy Vietnamese (5.6%) and Mainland Chinese (7.0%) children between 7-48 mo of age[34,35]. Recurrent abdominal pain and dyspepsia in children is far more likely to be of a functional aetiology than in adults, prompting one to question the necessity and cost-effectiveness of invasive investigations. El-Matary *et al*[36] evaluated a cohort of 103 British children fulfilling Apley's original criteria of recurrent abdominal pain, *via* a series of blood, stool, imaging investigations with endoscopy done as clinically indicated. Approximately 70% of these children had a non-organic aetiology to their abdominal symptoms, with irritable bowel syndrome being the most common diagnosis. This study was conducted within a hospital setting, and it is likely that the actual prevalence of paediatric functional GI disorders would be much higher if the study were to be repeated in a community setting.

The diagnostic yield of paediatric GI endoscopy in childhood abdominal pain varies widely between published cohorts (Table 1), depending on the referral indication, presence of alarm symptoms[37] and/or index of suspicion guided by abnormal biochemistry (*e.g.*, coeliac serology) or imaging pre-

endoscopy. Moreover, the definition of a 'positive diagnostic yield' can be debatable as positive endoscopic pathology does not equate causality of symptoms *e.g.*, *H. pylori* infection is often asymptomatic and may be an 'innocent bystander' in children with functional abdominal pain[38], especially in the high-prevalence areas. An Israeli study of 329 children undergoing endoscopy for various indications (abdominal pain, diarrhoea, failure to thrive, short stature and iron deficiency anaemia) showed only 36% of children with abdominal pain had a diagnostic finding on endoscopy; if the child had abdominal pain in association with an objective test *e.g.*, positive coeliac serology and/or iron deficiency, the diagnostic yield would be more than 50% while those with subjective symptoms of nausea and constipation would have a positive yield in less than 25%[39]. A Hong Kong-based cohort of 80 children, fulfilling the Rome III criteria of functional dyspepsia and undergoing upper GI endoscopy, showed only 6.3% had ulcerations or erosions. There was a strongly positive correlation between alarm features *e.g.*, nocturnal pain and endoscopic findings[40]. These findings suggest that a risk stratification strategy, combining a clinical assessment for alarm features and the use of non-invasive objective tests, would be potentially helpful in discerning those who would benefit most from diagnostic endoscopy. An example would be the stool calprotectin assay, which is now commonly used globally as a highly sensitive stool biomarker for gut inflammation, both in the diagnosis and monitoring of IBD[41,42].

Advanced paediatric GI endoscopy in Asia

Advanced endoscopy techniques such as video capsule endoscopy (VCE) and balloon-assisted enteroscopy (BAE) can enhance diagnostics especially for obscure small bowel pathology, which would otherwise be inaccessible with standard endoscopy. VCE has been approved in children as young as 2 years old since 2009[43] and remains one of the commonly used modalities to complement standard endoscopy findings or when standard endoscopy has been non-diagnostic. Much of the published Asian experience with VCE has been from large East Asian (China[44], Japan[45] and South Korea[46]) adult and paediatric cohorts. A large Mainland Chinese cohort of 825 children in a single paediatric IBD centre underwent VCE for the main indication of abdominal pain (61.2%) followed by anaemia (17.0%) [44]. The authors noted a much higher diagnostic yield (55.6%) primarily of Crohn's disease-related small bowel pathology, compared to previous studies for similar indications quoting 20%-28%[47,48]; this was ascribed to a higher referral load of suspected IBD patients, further emphasising the strong influence of referral indications on published yields. Other typical VCE findings included idiopathic small bowel ulcers, intestinal polyps, lymphangiectasia and vascular malformations.

While the experience of VCE in adult cohorts has been for obscure GI bleeding, VCE has gained increasing utility for the pan-enteric evaluation of IBD[49]. VCE can be utilised as a non-invasive first-line modality in suspected IBD cases after a patency capsule test, followed by confirmatory endoscopy. VCE may also be advantageous in detecting early mucosal healing in IBD disease monitoring. A Korean paediatric study of Crohn's disease found VCE to be more sensitive than magnetic resonance enterography in detecting mucosal healing and early therapeutic response in the first year post diagnosis[50]. Other indications for VCE include the surveillance of intestinal polyposis, particularly in Peutz-Jeghers' syndrome where small bowel polyps have been known to form a lead point for small bowel intussusception. The use of VCE facilitates the planning of BAE for definitive small bowel polyp clearance[51].

As observed with studies of VCE, much of the published Asian paediatric experience with BAE are from East Asian cohorts[52-54]. Of note, these cohorts may include a varying number of patients undergoing balloon-assisted endoscopic retrograde cholangioscopes primarily for therapy of biliary stenoses. BAE complements the diagnostic value of VCE by providing the means to obtain histological samples and provide therapeutic intervention. Hagiwara *et al*[54] described a multi-centre study of 96 BAEs (both antegrade and retrograde) in 79 paediatric patients. The main indications were for follow-up of IBD, obscure GI bleeding, abdominal pain, and therapy of hereditary polyposis syndromes. The positive diagnostic yield in obscure GI bleeding and abdominal pain was 48%. There were higher reported diagnostic yields of approximately 77% for similar indications in the mainland Chinese paediatric cohorts[53,55], but this variation can be explained by differing referral indications as aforementioned.

State of the art advanced endoscopic diagnostic techniques

While most of these techniques are not in mainstream use at most Asian-Pacific paediatric gastroenterology centres, they are worth discussing in brevity as recent publications have discussed their utility in enhancing current paediatric GI diagnostics.

Transnasal endoscopy: This technique would be useful especially in children with EoE as they commonly require multiple upper GI endoscopies for mucosal surveillance[56]. Transnasal endoscopy may be done as an unsedated office procedure with topical pharyngeal anaesthesia, and significantly save time, costs and endoscopy resources.

Mucosal impedance: This technique measures transmucosal conductivity and thus the mucosal integrity of the oesophageal mucosa, *via* a catheter containing very closely spaced impedance sensors resting close to the mucosa wall. This catheter is inserted through the working channel of a standard upper GI scope, such that the sensors rest directly on the oesophageal mucosa. This has advantages over

standard 24-h pH impedance studies, by directly measuring the barrier function of the oesophageal mucosa in a matter of seconds while the child is sedated[57]. Mucosal impedance can be used to discern between GERD, EoE and non-GERD conditions, as well as to monitor treatment response/disease activity in GERD and EoE[58,59].

Endoluminal functional lumen imaging probe: Endoluminal functional lumen imaging probe (EndoFLIP) is another adjunct technique to measure oesophageal luminal dimensions, distensibility, pressure changes and motility[60], typically while the child is sedated for standard upper GI endoscopy. It involves insertion of a sensor balloon-mounted catheter transorally, and inflating the balloons within the oesophageal and gastric lumens. While high resolution oesophageal manometry is the current gold standard in the assessment of oesophageal function, it is potentially uncomfortable and requires the child to cooperate with swallowing during the manometry. EndoFLIP has utility in the assessment of patients with GERD, EoE[61] and achalasia, as well as patients experiencing persistent symptoms post fundoplication.

Confocal laser endomicroscopy: Confocal laser endomicroscopy is an endoscopic technique that allows for high-resolution histological examination of the GI mucosa at the cellular level. Besides its obvious utility in real-time detection of neoplastic lesions in adults, the group at Sheffield Children's Hospital, United Kingdom has described its usefulness as a biopsy-free method of assessing mucosal pathology in enteropathies, EoE, ileo-colitis and polyposis[62]. This enhances the diagnostic accuracy of GI endoscopy, and reduces the time, risks and costs associated with multiple GI mucosal biopsies.

Artificial intelligence and machine learning in endoscopic diagnostics: Patel *et al*[63] recently reviewed the potential application of artificial intelligence (AI) in paediatric GI pathologies. The aim of utilising machine learning, a form of AI, is to at least semi-automate the process of macroscopic pathology and pattern recognition, which would otherwise be subject to the endoscopist's individual expertise and experience. In paediatrics, AI could potentially automate the process of accurately classifying macroscopic disease severity and extent in IBD and celiac disease, as current endoscopic scoring systems are often time-consuming and subjective. Current AI research in adults is driven by the need for accurate polyp detection: Early published data of the computer-aided detection EYE system demonstrates its AI driven algorithm detects and classifies polyps with excellent sensitivity and specificity[64]. AI would play a major role in standardising endoscopy outcomes across different endoscopists of varying experience levels, especially in units with rotating trainees.

THERAPEUTIC ENDOSCOPY

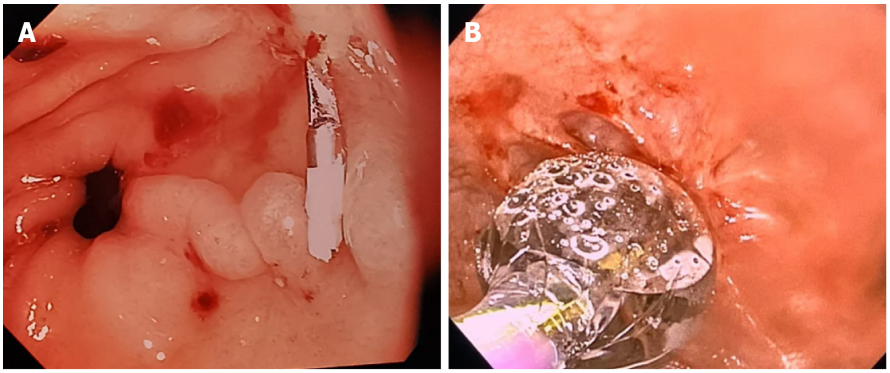
Foreign body removal

Foreign body ingestion is a common presentation in the ambulatory and emergency department settings. The exploratory behaviour and normal development of young infants and toddlers lead these kids to accidentally grasp and ingest foreign objects. The common age group usually ranges between 6 mo to 6 years[65]. The initial manifestation can range from asymptomatic to significant GI symptoms (drooling, dysphagia, vomiting, obstructive symptoms), coughing, choking, severe respiratory distress, or even death[66,67]. One of the largest cohorts from China reported 1265 children (aged 6 mo to 16 years) admitted with a history of foreign body ingestion, of which 552 (43%) children had detected foreign bodies from endoscopies. The two most common objects were coins (49%) and non-metallic sharp objects (31%)[66]. A systematic review also noted that the coin was the most frequently ingested object in the paediatric population[68]. In contrast to most reports, a medical record review in 105 Iranian children, the button battery was the most commonly found object in 41%[69]. The types of foreign body vary between different countries and geographic locations, that may be likely due to diverse sociocultural and dietary factors[70]. Another study from Khorana *et al*[67] from northern Thailand included 194 patients aged < 15 years (median age of 44 mo) found that most were symptomatic (56%), with vomiting as the commonest complaint. The most common location of impacted foreign bodies was in the oesophagus (37%), similar to most previous reports[68]. Plain radiography can usually confirm the location, size and shape of most radiopaque objects (such as coin, magnets, safety pin, *etc.*), but has little diagnostic value for radiolucent objects such as plastic toys, fishbone, or woods. Contrast studies or computed tomography scans may be needed to locate the radiolucent foreign bodies before deciding on the further management.

Timing of foreign body removal: As most of the ingested objects were coins, which were mostly considered as small and blunt objects, spontaneous passage usually occurred[67,71]. However, endoscopic intervention or even surgical exploration may be needed in some cases especially individuals with symptoms or complications. The timing of endoscopic intervention in paediatric foreign body ingestion has been proposed in various guidelines published from various scientific societies, namely the European Society for Paediatric Gastroenterology Hepatology and Nutrition

(ESPGHAN)/European Society of Gastrointestinal Endoscopy (ESGE)[71], and the North American Society of Paediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) Endoscopy Committee[72]. The proper timing of endoscopy is mainly based on 3 key factors: The type of ingested objects, the location, and the presence of symptoms. Types of common foreign bodies are button batteries, magnets, sharp objects, long objects, absorptive objects, drug packets, impacted food boluses, and coins.

Button batteries: During the past few decades, major concerns with button battery ingestion have been raised as the integrity of the strong alkali-containing battery can be degraded and cause severe caustic injury to the GI mucosa, especially the oesophagus (*i.e.*, a hollow organ with small lumen). A cohort from the United States reviewing 8648 cases of button and cylindrical battery ingestions, occurring between 1990-2008, found 73 cases with major adverse outcomes (0.8%), including prolonged compromise of feeding and/or breathing that required surgical procedures, tube feedings, tracheostomies. There were 13 deaths (0.15%) related to damage to the oesophagus, major vessels, and/or the airway[73]. Huang *et al*[74] from China reported children with inhaled/ingested button batteries and found that 13 of 116 (11%) cases had button batteries either in the oesophagus or stomach (n = 6 and 7, respectively). One child developed an oesophageal stricture and another one died from sudden cardiac arrest during the perioperative period. A recent Position Paper from ESPGHAN proposed 2 major strategies in the diagnosis and management of button battery ingestion in children. This includes: (1) Computed tomography scan to evaluate injuries to the adjacent organs and blood vessels before endoscopic removal if ingested > 12 h even in asymptomatic children; and (2) Honey (in children > 1 year of age) and sucralfate can be considered in ingestions < 12 h while waiting for endoscopic removal [75].



Endoscopic techniques of foreign body removal: Conventional flexible endoscopy is a safe and effective tool for removing most foreign bodies from the GI tract. A high success rate is found when using retrieval nets, polypectomy snares, and the rat-tooth forceps[71]. Opasanon *et al*[76] reported 34 Thai patients with upper GI tract foreign bodies and found that removal was successfully performed in all cases with either rat-tooth forceps, snare, dormia basket or tripods with no procedure-related complications.

Device-assisted enteroscopy for foreign body removal: The challenging cases in paediatric foreign body ingestion are typically the ones with objects beyond the reach of the conventional endoscope, *i.e.*, the depths of the small bowel in the jejunoileal area. Adult-based ESGE guidelines on small bowel endoscopy and device-assisted enteroscopy strongly recommend enteroscopy as an alternative to surgery for retrieving foreign bodies retained in the small bowel in patients without acute intestinal obstruction[77]. Device-assisted enteroscopy refers to any adjunct device used to assist endoscopic advancement into the small bowel (balloon, overtube, stiffening device). As with the use of BAE as an advanced diagnostic tool discussed earlier[54], age- and weight-appropriate device-assisted enteroscopy may be used for foreign body removal and other therapeutic applications within the small bowel.

Haemostasis of GI bleeding

GI bleeding can be divided into upper GI and lower GI bleeding. Upper GI bleeding is defined as bleeding from the GI tract proximal to the ligament of Treitz, while lower GI bleeding is bleeding occurring distal to the aforementioned ligament. Upper GI bleeding can also be further divided into non-variceal bleeding and variceal bleeding which may (or usually) need haemostatic intervention (Figure 1A). On the other hand, for the paediatric population, lower GI bleeding rarely needs endoscopic intervention in the colon or distal small bowel mainly because of the 3 following reasons: (1) Most of the severe GI bleeding occurs up in the upper GI tract; (2) Acute colonic bleeding in children usually stops spontaneously; and (3) Various common aetiologies such as Meckel's diverticulum, intussusception, colitis from infection, inflammation or allergy, or anal fissures rarely need endoscopic intervention to stop bleeding. One of the few exceptions being endoscopic polypectomy for juvenile (colonic) polyps which usually present in a non-urgent setting. After initial haemodynamic stabilization consisting of judicious fluid resuscitation and, if necessary, blood product replacement, endoscopic haemostatic intervention for the lesions causing GI bleeding would need to be justified based on the site and type of the lesion, patient's underlying disease and resource availability/procedural feasibility in conjunction with the potential contraindications.

Haemostasis for acute upper GI bleeding: Non-variceal and variceal bleeding: ESPGHAN/ESGE guidelines suggest early oesophago-gastroduodenoscopy within 12 h in cases presenting with acute upper GI bleeding that require ongoing circulatory support, or those presenting with large volume haematemesis or melena (weak recommendation and low quality of evidence, but a strong recommendation and moderate quality of evidence in cases with a known history of oesophageal varices) [71]. Most recommendations with regards to upper GI bleeding have been adopted from previous adult-dominated studies. An oesophago-gastroduodenoscopy should also be performed in cases with bleeding that require packed red blood cell transfusion due to a haemoglobin value below 8 g/dL and

Figure 1 Images. A: Haemostatic clip applied to a bleeding gastric antral ulcer; B: Balloon dilation in oesophagus with a mucosal tear.

an acute drop of at least 2 g/dL, or a bleeding clinical severity index score above a defined validated threshold such as the Sheffield Scoring System[78]. Furthermore, endoscopy should be performed before discharge from hospital, in children with pre-existing liver disease or portal hypertension.

Endoscopic haemostatic techniques for non-variceal lesions: Overall, lesions causing non-variceal upper GI bleeding such as bleeding ulcers or Dieulafoy lesion should use either thermal techniques such as heater probe, bipolar probe or mechanical techniques such as haemostatic clips, with/without epinephrine injection for controlling bleeding[71,79]. Yabe *et al*[80] reported 36 Japanese children with upper GI bleeding from gastroduodenal ulcers (50%) or gastritis (26%), and 14/36 (39%) underwent haemostatic intervention [clips (n = 12), hypersaline and epinephrine injection and coagulation therapy (n = 1), pure ethanol injections (n = 1)] with 100% initial success rate. Rebleeding occurred only in one patient who was initially treated with ethanol injections.

Endoscopic haemostatic techniques for variceal bleeding: For oesophageal varices, Zargar *et al*[81] demonstrated that endoscopic variceal band ligation is more effective than sclerotherapy in 49 Indian children with extrahepatic portal vein obstruction and variceal bleeding. Band ligation required fewer endoscopic sessions [3.9 (SD 1.1) *vs* 6.1 (SD 1.7) times for sclerotherapy] and had lower rates of rebleeding (4% *vs* 25%)[81]. Since then, studies comparing the efficacy of banding with sclerotherapy in children are sparse. A recent Cochrane Review was initially planned to analyse randomized controlled trials (RCTs) but was eventually unable to find any RCTs comparing band ligation *vs* sclerotherapy as primary variceal prophylaxis (*i.e.*, preventing the first variceal bleeding episode in children with oesophageal varices) in children with chronic liver disease or portal vein thrombosis[82].

Polypectomy

The technique of polypectomy is based on the location, morphology, and size. The ESPGHAN guideline suggests using cold biopsy forceps for small polyps (< 3 mm), hot or cold snaring in polyps diameter 3-8 mm, and hot snaring in the larger polyps[71]. However, hot biopsy forceps induce larger histopathological lesions, increased necrotic depth and submucosal inflammation in a pig's colon model[83], and more cytological artefacts[84]. A retrospective study in 91 Korean children, who underwent endoscopy to find polyps, found that polyp size was the one single factor associated with the presence of any polyps located proximal to the splenic flexure [odds ratio = 2.3, 95% confidence interval (CI): 1.3-4.3]. Polyps proximal to the splenic flexure and sessile morphology were associated with the presence of any adenomatous polyp. Therefore, the authors concluded that a full colonoscopy remains crucial before the occurrence of complications[85]. Another study from Thailand investigated 32 patients with symptoms of colorectal polyps such as haematochezia, rectal mass, or diarrhoea. Most (20/32, 63%) had a single polyp, 6/32 had 2-4 polyps, and a minority (6/32) was diagnosed with polyposis coli. Most had polyps in the rectosigmoid region and only 6 cases had polyps proximal to the splenic flexure. All had pathologically confirmed juvenile polyps without adenomatous changes, which demonstrated an absence of malignant potential[86].

Oesophageal dilation

Dilation of the oesophagus is indicated when symptoms of oesophageal stricture/stenosis occur. Various causes include congenital anomalies, post caustic ingestion, EoE, and GERD[87]. Symptoms of oesophageal stricture include dysphagia, odynophagia, food bolus impaction, vomiting and poor oral intake. Nowadays, the 2 main options for oesophageal dilatation in oesophageal stricture are balloon dilation and bougie dilation.

Balloon dilation (Figure 1B) can be safely performed under both the direct endoscopic and/or fluoroscopic examinations, while most of the bougie dilations are Savary-Gilliard bougies that could dilate up to 12 mm in children age < 5 years and 15 mm in older children. The "rule of 3" has been widely used as dilation to not more than 3 times the stricture diameter with a minimal period of 3 wk between dilation sessions and an average of 3 sessions in total[88,89]. Lan *et al*[90] reported 75 children from Hong Kong with oesophageal strictures [post-oesophageal atresia repair (n = 63), reflux esophagitis (n = 7), caustic ingestion (n = 3) and post-fundoplication (n = 2)], who underwent a total of 260 balloon dilations (mean number of 3.4 sessions per patient). Four oesophageal perforations (1.5%) were noted, with one child required surgical repair; all other patients were asymptomatic after the dilation sessions. Balloon dilation has been reported to be more effective and less traumatic than the bougie dilation, but a study from India reported comparable complications (perforations of 0.9%)[89], and a recent study from China reported a high perforation rate of 4.4% in children undergoing oesophageal balloon dilation[91]. The aforementioned study also reported only a 60% success rate, and found that stricture length was the main determining factor of treatment outcome. Therefore, a universally-agreed dilation choice remains controversial. Furthermore, oesophageal stent placement, intralesional mitomycin C or steroid injections have also been used in refractory oesophageal strictures in children[92].

Bowel preparation of ileocolonoscopy

Low volume bowel preparations preferred: Ileocolonoscopy is an established diagnostic and therapeutic tool in a variety of GI disorders. The optimal bowel preparation is an important key success factor in paediatric ileocolonoscopy[93]. While standardised bowel preparation protocols remain unavailable[94], more recent recommendations propose low-volume preparations using either polyethylene glycol (PEG)[95] along with ascorbate or sodium picosulfate magnesium citrate (SPMC)[71]. The preferable regimen in standard clinical practice should provide optimal colonic cleansing with small volumes of laxatives, acceptable palatability and drinkability and minimal side effects. In 2017, 15 RCTs (n = 1435) from 2124 studies with heterogeneity/bias risk compared PEG with other medications (sodium phosphate enema (n = 2 studies, relative risk = 1.27 with 95%CI: 0.66-2.44), SPMC (n = 3 studies, relative risk = 0.99 with 95%CI: 0.89-1.11), sennasoids (n = 3 studies, relative risk = 0.73 with 95%CI: 0.31-1.76) which showed no difference in the bowel preparation quality. Noninferior efficacy was also noted when comparing low volume PEG with SPMC *vs* standard volume PEG. Children who received PEG regimen also needed nasogastric tube insertions more often than those receiving the SPMC regimen (38% *vs* 1.6%)[96]. Later in 2022, four good quality RCTs (n = 390) showed higher tolerability and acceptability in the SPMC group when compared to the PEG group with comparable efficacy[97].

Split bowel preparation regimens: The newer studies also implement a 'split regimen' of the laxatives at different timepoints prior to GI endoscopy[98-100]. Sriphongphankul *et al*[98] performed an RCT in 45 children aged 2-18 years. The split dose group was given PEG in 2 split doses for 8-12 h apart and at least 6 h before the procedure, and the full single dose was given once the night before scope. Successful preparation (defined as Boston Bowel Preparation Scale ≥ 6) was superior in the split group (95% *vs* 72% in the standard high-volume PEG regimen). Willingness to repeat the same protocol was also much higher (83% *vs* 36%, P = 0.002), but nasogastric tube insertion rates were comparable (57% *vs* 68%). A later meta-analysis, including 4 paediatric studies, also found a trend of significantly higher efficacy in the split dose group (P = 0.07) but significant heterogeneity was noted among studies[99]. Therefore, further high-quality RCTs with low risk of bias are required. With regards to the recommended diet before the procedure, Jiao *et al*[101] studied 321 Chinese children and found that either 1-d or 2-d low residue diet had similar efficacy in bowel preparation but the 1-d low residue diet group had higher acceptability.

State-of-the-art interventions for therapeutic endoscopy

The endoscopic interventions for (esophageal) achalasia, a rare condition with incomplete or lack of normal lower esophageal sphincter relaxation, include pneumatic dilation and botulinum toxin injection. Recently, peroral endoscopic myotomy (POEM) has become another therapeutic intervention in both adults and children that demonstrates satisfactory success rate. The NASPGHAN Endoscopy Committee recently reviewed various aspects of POEM[102]. In brief, the myotomy is made starting from 8-10 cm above to 2-3 cm below the gastroesophageal junction along the cardia. Submucosal injection of the posterior wall is then performed to create a mucosotomy and submucosal tunnel, which would reveal the circular muscle fibers of the lower oesophagus. Complete myotomy of the circular muscle layer is made with longitudinal muscle layer underneath and the clip is finally deployed to close the mucosotomy. However, studies reporting efficacy and complications of POEM in children remain limited. Furthermore, appropriate training and adequate number of the performed procedures would also be required before implementing POEM as a standard of care in paediatric achalasia.

Future training opportunities in paediatric endoscopy in the Asia-Pacific region

ESPGHAN launched a Position Paper on paediatric endoscopy training in 2020[103]. The main content on achievement of training milestones, with regards to competency and procedural numbers including

'Train the trainers' courses, have been mentioned. Educational material such as e-learning, simulator training would also be needed to train the trainees in paediatric endoscopy.

Different scientific societies recommend varying competency thresholds for lower and upper GI endoscopies. NASPGHAN, the Joint Advisory Group in GI Endoscopy Paediatric Certification from the United Kingdom, the Conjoint Committee for Recognition of Training in Gastrointestinal Endoscopy from Australia proposed a minimum of 100-120 lower GI endoscopies with a caecal intubation rate of ≥ 90% (ranges from 15-30 min). NASPGHAN and the Joint Advisory Group from the United Kingdom proposed a minimum of 100 upper GI endoscopies and the Australian Committee proposed a minimum of 200 upper GI endoscopies (≥ 100 in children). Interestingly, ESPGHAN did not specifically define any numbers for endoscopies. The number of therapeutic endoscopies such as foreign body removal, haemostatic intervention, and polypectomy vary greatly across different societies. One of the preprocedure objective outcomes is the rate of adequate bowel preparation before ileocolonoscopy, with a minimum standard of 90% and a target of 95%.

Another important point is that the group suggests endoscopic procedures in children be performed by endoscopists trained in paediatric gastroenterology with established procedure-specific competency. Special consideration must be made to a child requiring GI endoscopy. Physicians need to consider the size of the patient, indications and contraindication of the procedure, proper equipment, bowel preparation, anaesthesia and sedation as well as the psycho-emotional factors of the children and their caregivers throughout the process[104]. Therefore, before implementing training in paediatric endoscopy in the Asia-Pacific region, aforesaid aspects should be carefully considered and implemented in the formal standardized curriculum. The Asian Pan-Pacific Society for Paediatric Gastroenterology, Hepatology and Nutrition conducted its first Paediatric Endoscopy Masterclass on June 2 to 3, 2022 in Bangkok with the purpose of addressing gaps in paediatric endoscopy training within the Asia-Pacific region. The subsequent way forward would be a regionalised set of guidelines and consensus statements, to facilitate standardisation of indications and endoscopic terminology across different paediatric GI centres.

CONCLUSION

Paediatric GI endoscopy has undoubtedly gained utility in the Asia-Pacific region as an invaluable tool in the diagnostics and management of GI diseases of current and emerging epidemiological importance. This is the first article to comprehensively review the evolving epidemiologic trends in paediatric GI endoscopy within Asia-Pacific, and delve into the future directions for paediatric endoscopy training and the advent of state of the art endoscopic techniques which are increasingly applied in the adult population. Yet the lack of consensus guidelines and heterogeneity in clinical practice, variablity in the referral patterns, healthcare access and disease prevalence across the Asian continent, inevitably leads to a wide variance in outcomes for different endoscopic modalities. While it is crucial that early endoscopy is done for a prompt diagnosis and treatment, it must be balanced with avoiding un-necessarily invasive investigations in otherwise benign functional GI conditions. The maturation of paediatric gastroenterology as a subspecialty hence necessitates comprehensive and accreditable endoscopy training, so that paediatric endoscopists in Asia adhere to a minimum practice standard and are adequately trained to apply diagnostic and therapeutic endoscopic techniques appropriately and competently. The inauguration of regular endoscopy masterclasses and workshops by the regional society Asian Pan-Pacific Society for Paediatric Gastroenterology, Hepatology and Nutrition sets the stage for more uniformity in endoscopic practices and outcomes, as well as future inter-regional collaborative efforts in paediatric endoscopic research.

Abstract

Ulcerative colitis (UC) and Crohn's disease (CD) are part of Inflammatory Bowel Diseases (IBD) and have pathophysiological processes such as bowel necrosis and enteric neurons and enteric glial cells. In addition, the main inflammatory mediator is related to the tumor necrosis factor-alpha (TNF-α). TNF-α is a mediator of the intestinal inflammatory processes, thus being one of the main cytokines involved in the pathogenesis of IBD, however, its levels, when measured, are present in the serum of patients with IBD. In addition, TNF-α plays an important role in promoting inflammation, such as the production of interleukins (IL), for instance IL-1β and IL-6. There are two receptors for TNF as following: The tumor necrosis factor 1 receptor (TNFR1); and the tumor necrosis factor 2 receptor (TNFR2). They are involved in the pathogenesis of IBD and their receptors have been detected in IBD and their expression is correlated with disease activity. The soluble TNF form binds to the TNFR1 receptor with, and its activation results in a signaling cascade effects such as apoptosis, cell proliferation and cytokine secretion. In contrast, the transmembrane TNF form can bind both to TNFR1 and TNFR2. Recent studies have suggested that TNF-α is one of the main pro-inflammatory cytokines involved in the pathogenesis of IBD, since TNF levels are present in the serum of both patients with UC and CD. Intravenous and subcutaneous biologics targeting TNF-α have revolutionized the treatment of IBD, thus becoming the best available agents to induce and maintain IBD remission. The application of antibodies aimed at neutralizing TNF-α in patients with IBD that induce a satisfactory clinical response in up to 60% of patients, and also induced long-term maintenance of disease remission in most patients. It has been suggested that anti-TNF-α agents inactivate the pro-inflammatory cytokine TNF-α

by direct neutralization, *i.e.*, resulting in suppression of inflammation. However, anti-TNF-α antibodies perform more complex functions than a simple blockade.

Key Words: Tumor necrosis factor 1 receptor; Tumor necrosis factor 2 receptor; Inflammatory bowel diseases; Enteric nervous system; tumor necrosis factor-alpha

Core Tip: This review summarizes the role of Tumor Necrosis Factor-alpha (TNF-α) in promoting inflammation. Studies have suggested that TNF-α is one of the main pro-inflammatory cytokines involved in the pathogenesis of Inflammatory Bowel Diseases (IBD). In addition, the enteric nervous system is affected by IBD. There are two receptors for TNF: The tumor necrosis factor 1 receptor; and the tumor necrosis factor 2 receptor. They are involved in the pathogenesis of IBD. The application of antibodies aimed at neutralizing TNF-α in patients with IBD induce a satisfactory clinical recovery. This review addresses the main aspects of TNF-α in IBD and anti-TNF therapies.

INTRODUCTION

Inflammatory bowel diseases (IBD) comprise ulcerative colitis (UC) and Crohn's disease (CD), which are chronical and recurrent disorders that affect the gastrointestinal (GI) tract[1-4]. The etiology of IBD is not yet fully understood, but there are reports of a complex relationship between genetic[5,6], immunological and environmental factors[7-10], as well as gut microbiota[11-15]. There is an imbalance between anti- and pro-inflammatory cytokines that cause an exacerbated and inadequate immune response.

The enteric nervous system (ENS) is composed by intrinsic neurons, their axons and enteric glial cells, which constitute a complex of structures responsible for controlling motility of the GI tract, secretion of gastric acid, regulation of fluid movement through the epithelium, local blood flow control, and interactions with the endocrine and immune systems of the gut[16-18]. The ENS is affected by IBD which causes necrosis, apoptosis, degeneration of enteric ganglia and alterations on motility patterns [19-23].

Tumor necrosis factor-alpha (TNF-α) is a mediator in intestinal inflammatory processes, thus being one of the main cytokines involved in pathogenesis of IBD, with high levels in patients with IBD[24,25]. There are two receptors for TNF-α as following: The tumor necrosis factor receptor 1 (TNFR1); and the tumor necrosis factor receptor 2 (TNFR2). After TNF-α binding to these receptors, it activates signaling pathways for cell survival, death and differentiation[26]. An increase in TNF-α expression can lead to mucosal barrier defects in patients with IBD, which increases inflammation and worsens the prognosis [10].

Due to the TNF-α relation with IBD, biological drugs have been used to treat CD and UC with neutralizing monoclonal antibodies used for TNF-α target and blockade, which reduce the development of the inflammatory process and the activation of immune system cells[27]. Anti-TNF-α agents are indicated by various guidelines for the treatment of IBD[28,29] and the use of these agents induces a satisfactory clinical response, and long-term maintenance of disease remission in most patients[24,30]. This review aims to provide the main aspects of IBD and TNF-α relationship, elucidating the role of the TNF-α receptors, anti TNF-α therapy and some perspectives related to the involvement of the ENS.

THE ENS AND IBD

The ENS is a complex of structures responsible for controlling motility of the GI tract, secretion of gastric acid, regulation of fluid movement through the epithelium, changes in local blood flow, and interactions with the endocrine and immune systems of the gut[16-18]. The ENS is located in the intestinal wall and is organized into two ganglionated plexuses: The myenteric plexus; and the submucosal plexus[16-18].

The myenteric plexus (Auerbach's plexus) is situated between the longitudinal muscle layer and the circular muscle layer throughout the entire GI tract, from the esophagus to the rectum. It has three

components as following: A primary plexus; a secondary plexus; and a tertiary plexus. The myenteric plexus is involved with reflex regulation of the contractile activities of the muscle layer[16,17]. The submucosal plexus (Meissner's plexus) is predominantly found in the small and large intestines, with a smaller ganglion and finer interconnected fibers when compared to the myenteric plexus[16,17]. It has a direct role in controlling secretion and absorption through motor neurons that regulate the secretomotor and vasomotor activity of the mucosal layer[16,17].

Enteric neurons can be classified according to their function into motor neurons, interneurons, and Intrinsic Primary Afferent Neurons[16]. Motor neurons are further divided according to their chemical code into excitatory neurons (labeled by the enzyme choline acetyltransferase or by calretinin), inhibitory neurons (labeled by the enzyme neuronal nitric oxide synthase), and secretomotor/vasodilator neurons. Excitatory and inhibitory motor neurons are observed in the myenteric plexus and are involved in motility control, while secretomotor/vasodilator neurons are observed in the submucosal plexus and are responsible for innervating the mucosa and regulating secretion, absorption, and local blood flow[16,17].

Enteric glial cells are small, consisting of numerous processes that do not synthesize myelin, and are also essential for the organization and function of the ENS[31]. These cells have a star shape with numerous branches that surround the neurons. They also exhibit a series of voltage-dependent ion channels that are connected by gap junctions, giving the impression of an intimate and complex intertwining of neurons and glial cells. In addition to their role in supporting neurons, enteric glia cells regulate synaptic transmission, release cytokines, and mediate communication with the immune system [32-34].

Enteric glial cells are identified by immunohistochemical methods such as labeling of cells expressing glial fibrillary acidic protein (GFAP) and/or calcium-binding protein S100/S100β since mature enteric glial cells express these protein types[35,36]. GFAP expression is modulated by enteric glial cell proliferation, differentiation, and inflammation[22]. S100 is a calcium-binding protein that can be found in the nucleus or cytoplasm and acts to regulate the cytoskeleton structure and function as well as the calcium homeostasis in the cytoplasm[35,37,38]. Under inflammatory conditions, enteric glial cells can acquire new functional properties, and in patients with IBD there was an increase in GFAP expression in mucosal inflammation compared to non-inflamed areas[39].

The enteric plexuses are formation of cells that spread throughout the entire GI tract, however, differences in the density and size of enteric neurons and glial cells, as well as in ganglion morphology, may occur in the same segment of the GI tract in different species, or in different experimental models such as undernourishment protein and renutrition[40,41], obesity[42,43], ischemia and reperfusion[44-47], and intestinal inflammation[23,48-52].

About IBD specifically, they are classically classified into UC and CD, disorders that chronically and recurrently affect the GI tract[1-4]. Inflammatory reactions in the intestinal mucosa cause epithelial damage that compromises the intestinal barrier[53]. Although the etiology of IBD is not yet fully understood, they are usually triggered by a complex relationship between genetic[5,6], immunological and environmental factors[7-10], and gut microbiota itself[11-15]. There is, then, an imbalance between anti- and pro-inflammatory cytokines that cause an exacerbated and inadequate immune response. It is emphasized that, in colitis, there are alterations in the neuronal density such as imbalances of contractile and secretory functions associated with diarrhea due to intestinal inflammation[20,49,50,52].

CD is characterized by a segmental and transmural disorder that can affect the entire GI tract, and it could be noted there is also involvement of T-auxiliary cells (TCD4) in the pathogenesis of the disease [54,55]. In contrast, UC is characterized by continuous inflammation of the distal colon and a modification of the cytokine profile coming from Th2 cells, involved in humoral immune response patterns[2,56]. The main clinical manifestations of IBD are abdominal pain, diarrhea, vomiting, weight loss, and the presence of blood in the stool[2,50] and, worryingly, it has been demonstrated that this occurrence has increased worldwide over the years[57-60].

The literature has shown that the ENS may be affected by the IBD, thus presenting necrosis, apoptosis and degeneration of enteric ganglia[19-23]. Similarly, alterations in neurotransmitters and neuropeptides of enteric neurons have been noted in these pathologies[19,48]. Furthermore, injuries in the ENS result in activation of enteric glial cells[61,62], and the onset and/or progression of IBD can be attributed to an immune-mediated damage of enteric glial cells[32]. This activation is pointed to as a signaling mechanism that results in subsequent neuronal death[63].

The diversity of neurotransmitters and receptors found in the ENS makes the intestine one of the main tissue choices for studies of neurotransmitter receptors in pharmacological tests. In turn, several ENS-related treatment strategies have been explored to alter gut function in an effort to improve symptoms, which include drugs targeting opioid, serotoninergic, dopaminergic, and cholinergic receptors[64].

Induced colitis models in the laboratory has been widely used to study intestinal inflammation, especially through dextran sulfate sodium and 2,4,6-trinitrobenzene sulfonic acid[65-69]. Despite this, the cell signaling mechanisms underlying neuronal and tissue damage are poorly understood[49,70], and new therapeutic approaches for IBD are emerging[71-74].

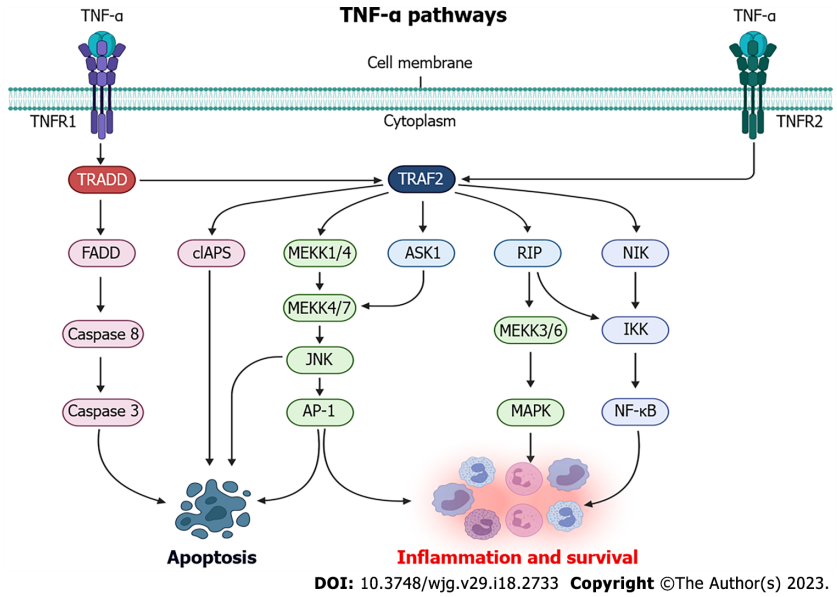
As expected, experimental animal models of colitis, enteric neuronal hyperplasia and hypoplasia may be associated with increased and reduced levels of TNFα production, respectively[75,76]. In addition,

hypertrophy and hyperplasia of enteric neurons have been reported in IBD[77]. Although, the mechanism responsible for neuronal modulation of inflammation severity is still unclear, due to modulations of neuroimmune interactions, it is speculated that enteric neurons could produce and regulate cytokines involved in IBD[76].

TNFR

Specific markers have been identified in GI tract when tissues are affected by injury or disease such as IBD. They are responsible for mucosal injury and tissue damage and consequently may trigger autoimmune disease - specific immune responses in UC[10]. The TNF-α, inducible nitric oxide synthase, heme oxygenase 1, arginase-1 or CD206 in higher levels can lead to massive tissue damage in the intestine[25,54,78].

TNF-α is a mediator in intestinal inflammatory processes, being one of the main cytokines involved in pathogenesis of IBD, since their levels, are frequently high in patients with IBD[24,25]. TNF-α was first described in 1975 by a group in Sloan-Kettering who identified TNF as a promising serum soluble activity[79]. Thus, TNF-α plays roles in promoting inflammation such as the production of interleukins (IL) such as IL-1β and IL-6[10,80]. In the central nervous system (CNS), TNF-α plays homeostatic roles by regulating crucial physiological processes, such as synaptic plasticity, learning and memory, sleep and food and water intake[81]. However, some findings demonstrated that overexpression of TNF in the CNS has negative effects on cognitive functions and TNF deficiency is related to learning processes and poor memory[82]. In addition, it may be involved in gliosis and tissue remodeling and in various processes about mechanisms subserving cognition, such as synaptic scaling, change in neurotransmitter metabolism, and the process of neurodevelopment[82,83]. This observation may pave the way for understand mechanisms of innate immunity and the pathogenesis of infectious diseases which are driven by the same cascade of pro-inflammatory cytokines[79].



TNF-α is mainly generated by macrophages and monocytes. However, other cells such as some subsets of T cells, NK cells, dendritic cells, B cells, cardiomyocytes, fibroblasts, and astrocytes are also low-level producers of this cytokine[84]. In pathological conditions, astrocytes and microglia release large amounts of TNF-α, seeing that the production of this cytokine is an important component of the neuroinflammatory response that is associated with various neurological disorders such as Alzheimer's, Parkinson's, multiple sclerosis and amyotrophic lateral sclerosis[81].

TNF-α operates significantly in the apoptotic phase increasing the expression of the TNF receptor-associated factor 2 (TRAF2)[53]. Furthermore, TNF-α activates mitogen-activated protein kinase and nuclear factor which contribute to cell differentiation and proliferation and increased expression of pro-inflammatory cytokines[10]. Two distinct forms of TNF-α were identified: 26kDa homotrimeric transmembrane precursor form (mTNF), which is cleaved by the TNF-α-converting enzyme, and matrix metalloproteinase (TACE/Adam17) to its next 17kDa TNF soluble form (sTNF) of monomers[85,86]. Both forms of TNF are biologically active and are signaled through two distinct receptors discussed below.

There are two receptors for TNF being: The 75 kDa TNFR1, ubiquitously expressed and has a cellular death domain; and the 55 kDa TNFR2 has been found in lymphocytes and endothelial cells. Interactions of TNF-α with its receptor activate signaling pathways for cell survival, death and differentiation that control immune function and disease, and various receptors pairs of ligands within TNF family molecules expressed by immune cells that play important roles in T cell Immunity[26].

When TNF-α binds to TNFR1 and TNFR2, several intracellular pathways are activated, thus mediating cell death and/or survival response (Figure 1). When TNF-α binds to TNFR1, TNF receptor associated death domain protein (TRADD) is activated which, in turn, can induce the activation of three signaling pathways. In the first one, after TNFR1 activation, TRADD binds to FAS-associated death domain protein, which recruits caspase 8 proteins, culminating in the activation and cleavage of caspase 3, as well as leading to cell death by apoptosis[87]. The second TNFR1 pathway is related to the recruitment of TRAF2 and receptor-interacting protein (RIP) kinase *via* TRADD. TRAF2, in turn, recruits the IκB kinase (IKK) protein, which will be activated by RIP and will result in the phosphorylation of nuclear factor κB (NF-κB), which will mediate the transcription of proteins involved in the inflammation response and cell survival[87,88]. The third pathway resulting from TNFR1 activation is connected with activation of mitogen-activated protein kinase (MAPK) pathways *via* TRAF2, which activate MAPK kinase kinase 1/4 (MEKK1/4) and, upon phosphorylation, MEKK4/7 leads to activation of c-Jun N-terminal kinase, which is translocated to the nucleus and activate transcription factors such as activator protein 1 (AP-1), that can converge to activate the apoptotic and survival responses[89-91].

Although the pathways behind TNFR2 activation remains poorly understood, when the TNF-α binds to TNFR2, its activation is mediated by TRAF2, and TNFR2 has been widely known as a mediator of the activation of genes related to cell survival and proliferation[91-93]. After TNF-α binds to TNFR2, TRAF2 is activated which, through common signaling pathways to TNFR1 activation, can activate NF-κB through IKK, and AP-1 *via* MEKK, which can also be activated *via* apoptosis signal-regulating kinase 1 [94]. Furthermore, activation of TRAF2 *via* TNFR2 can lead to the recruitment of cellular inhibitor of

apoptosis (cIAPS), which will partially inhibit caspase activation and, for this reason, reduce apoptosis response[95]. When both TNFR1 and TNFR2 are activated together, cIAPS recruitment is reduced and the caspase activity, mainly mediated by TNFR1, is activated[91].

These receptors are involved in the pathogenesis of IBD and their expression is correlated with disease activity[96]. The sTNf binds selectively to the TNFR1 receptor, and its activation results in a signaling cascade with effects such as apoptosis, cell proliferation and cytokine secretion[24,97]. In contrast, the mTNF can bind both to TNFR1 and TNFR2[91]. TNFR1 signaling pathways deserve attention, due to cytotoxic effects triggered by activation of TNFR1 *via* sTNF binding and it could be noted that some aspects regarding TNFR2 function are still unclear[91].

Some studies pointed to the presence of a functional cross-talk between TNFR1 and TNFR2, whichever TNFR2 would act as an complement-dependent cytotoxic effect of TNFR1, thus being responsible for the inhibition of anti-apoptotic pathways and for the increase in the cytotoxicity triggered by TNFR1 when both receptors are co-expressed and activated[91,98,99]. This finding could be seen as a distinct situation of the classic phenomenon in which the balance between apoptotic and anti-apoptotic signals triggered by TNF-α determines the accuracy in cell signaling[91].

The TNFR2 pathway does not contain death domains and its stimulation can result in proliferation, migration and production of cytokines such as IL-1 and IL-6. This receptor not only activate an intracellular signaling pathway, but can also induce reverse signaling within the cell expressing TNF-α [100].

TNFR2 is also involved in several autoimmune diseases, playing a protective role or being involved in its development. Thus, TNFR2 is known to be involved in rheumatoid arthritis, CD, erythematosus systemic lupus, UC, scleroderma, among other diseases[10]. It was recognized that the expression of TNFR2 is more limited than that in TNFR1, *i.e.*, this finding suggests that the sTNF-mediating signaling pathway *via* TNFR1 drives a predominantly pro-inflammatory program, whereas mTNF binding to TNFR2 primarily initiates immune modulation and tissue regeneration[84]. Thus, an increase in TNF-α expression can cause mucosal barrier defects in patients with IBD, exacerbating inflammation[10]. However, only a part of the role of TNF-α receptors in the pathogenesis of IBD is understood. It is known that it can be indicated the presence of TNFR2 in the CNS, *i.e.*, in neurons of the cerebral cortex [83], and no data in the literature could identify the presence of TNFR2 in enteric neurons.

ANTI-TNF-α TREATMENT

The immune response plays an important role in the initiation and maintenance of UC[101]. Cytokines play key roles in inflammatory processes, such as targeting cell signaling molecules during inflammation and UC pathogenesis through different roles, such as the production of inflammatory mediators and activation of inflammatory pathways[5,57,102,103]. They are also involved in several biological processes, such as cell activation, differentiation and central factors in the process of developing the

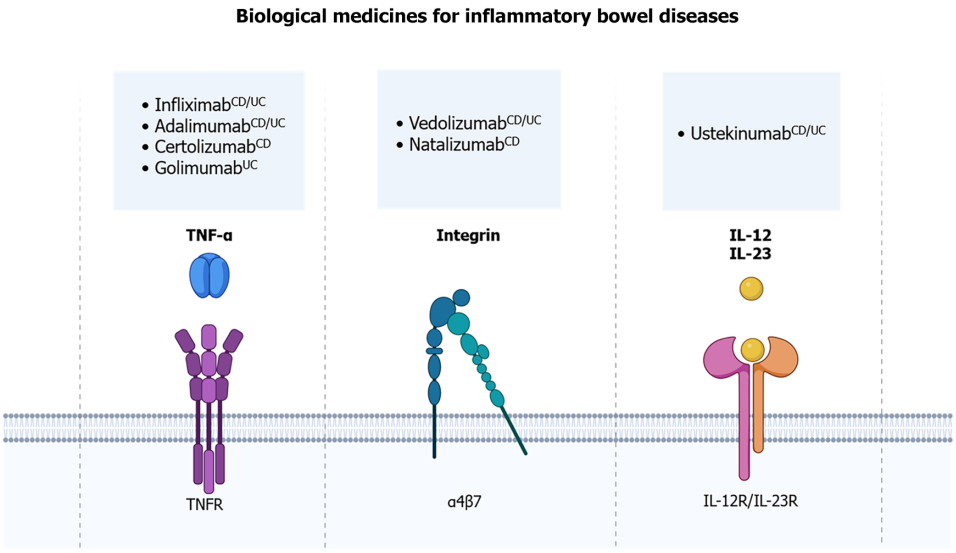
inflammatory and immune response. In addition, studies provide evidence of their involvement in epithelial injury, and consequently, intestinal barrier injury and tissue damage[5,104,105].

The treatment approach in the control of inflamed GI tissue in IBD, including clinical, laboratory conditions, endoscopic and histological remission for a prolonged period, play an important role in its evolution and possibly modifying the natural course of the disease[9,106]. Recent studies have suggested that TNF-α is one of the main pro-inflammatory cytokines involved in the pathogenesis of IBD, as higher TNF-α levels are present in the serum of both patients with UC and CD[25].

For the treatment of IBD, different classes of drugs can be used, respecting the particularities of CD and UC, with the aim of alleviating the symptomatic crisis of patients, as well as inducing and maintaining remission of the disease[107,108]. Generally, the first treatment option for mild to moderate cases of UC and CD involves aminosalicylates, or 5-ASAs, and other treatments include the use of corticosteroids, immunosuppressants, and biological drugs[109,110].

Biological drugs used to treat IBD are monoclonal antibodies that neutralize/block key targets in the development of intestinal[27]. There are biological drugs that target, for example, integrins, interleukins, and cytokines, such as TNF-α, which are related to the development of the inflammatory process and the activation of immune system cells (Figure 2)[111,112].

Currently, four anti-TNF-α agents are indicated by various guidelines for the treatment of IBD: Infliximab; adalimumab; certolizumab pegol; and golimumab[28,29]. Infliximab and adalimumab are indicated for the treatment of both UC and CD, while golimumab is indicated only for the treatment of UC and certolizumab pegol only for CD. American Gastroenterological Association (AGA) and American College of Gastroenterology (ACG) guidelines recommend the use of infliximab, adalimumab, and certolizumab pegol to induce and maintain CD remission in moderate to severe patients unresponsive to corticosteroid or methotrexate treatment, and regarding UC, it could be noted that AGA and ACG recommend the use of infliximab, adalimumab and golimumab in patients who have not responded to conventional therapy[28,29]. These anti-TNF-α antibodies bind to TNF-α, blocking its harmful effects, such as NF-κB activation and increase of pro-inflammatory cytokines, that mediate intestinal inflammation[113,114].



Intravenous and subcutaneous biologics targeting TNF-α have revolutionized the treatment of IBD, becoming the best available agents, when conventional therapy does not work, to induce and maintain IBD remission[115-117]. The application of this type of antibodies in patients with IBD induces a satisfactory clinical response in up to 60% of patients, and induced long-term maintenance of disease remission in most patients[24,30] and also reduces colorectal cancer risks[118]. Despite this, some patients do not improve after the use of these antibodies, some relapses within the first year of treatment and, one alternative used for the management of these cases has been to change the anti-TNF-α used for another one, or even to increase the dosage used[119]. Other alternative option for anti-TNF-α non responsiveness is the use other biological medicines like anti-integrin or anti-interleukin therapies.

Anti-integrin therapy, such as vedolizumab, which can be used for UC and CD treatment, block the integrin α4β7, which is expressed in B and T lymphocytes and interact with mucosal addressin-cell adhesion molecule-1 on intestinal vessels[120-122]. So, vedolizumab blocks lymphocyte trafficking only in the gut, preventing a systemic immunosuppression[123]. Otherwise, natalizumab blocks the integrin α4β7 and α1β7 and blocks lymphocyte trafficking in other organs, for example the brain, which can lead to infections such as progressive multifocal leukoencephalopathy[124]. For this reason, the use of natalizumab is very carefully, considering risk-benefits factors, and it is not available in some countries. Other biological medicine is ustekinumab, an anti-interleukin agent for subunit p40 of IL-12 and IL-23, used for CD and UC. This biological medicine attenuates the immune cell activation by these interleukins and consequently reduces inflammatory response and pro-inflammatory signaling[125-127].

Limitations of therapy with biological drugs include the high cost of adherence to therapy, differences in legislation and availability of these drugs in different countries, and the meticulous risk-benefit analysis related to the choice over treatment alternatives. However, new strategies and medicines have constantly been studied at pre-clinical and clinical instances for treatment of IBD.

ANTI-TNF-α TREATMENT AND APPROACH IN THE ENS

Although the involvement of TNF-α in the ENS is poorly described in the literature, it is reported that the ENS has TNF-α receptors and responds to the inflammatory stimulus, can lead to changes in motility patterns and fluid and electrolyte balance, a condition often found in patients with IBD[128]. When comparing the intestine, under normal conditions, and the intestine in IBD, some aspects must be considered (Figure 3). Under physiological conditions, large populations of microorganisms (bacteria, virus and fungi) inhabit the gut, which constitute the gut microbiota[129]. This microbiota establishes a symbiosis with the host[130]. The intestinal barrier, composed mainly by mucus layer and epithelial, is an intact and functional structure[131]. There is a balance between the levels of pro-inflammatory cytokines TNF-α, IL-12 and IL-23, and anti-inflammatory cytokines such as transforming growth factor-beta and IL-10 by innate immune cells, which leads to a balance between regulatory and effector T cells,

Figure 2 Biological medicines for inflammatory bowel diseases. Biological medicines used for the treatment of inflammatory bowel diseases (IBD) can be classified into anti- Tumor necrosis factor (TNF)-α, anti-integrin and anti-interleukin therapies. Anti-TNF-α binds to TNF-α and inhibits TNF receptor activation. Infliximab, adalimumab, certolizumab pegol and golimumab are examples of anti-TNF-α used in the treatment of IBD. Vedolizumab and natalizumab are anti-integrin agents, which bind to the α4β7 integrin and prevent the migration of inflammatory cells into the intestinal tissue. Ustekinumab is an anti-interleukin that blocks interleukin (IL)-12 and IL-23, which cannot bind to IL-12 receptor and IL-23 receptor on T and B lymphocytes, thus reducing the inflammatory response in the gut. ^{CD}indication only for Crohn's Disease; ^{UC}indication only for Ulcerative Colitis; $^{CD/UC}$indication both for Crohn's Disease and Ulcerative Colitis. inducing tolerance to microorganisms from the gut microbiota[130,132]. In physiological conditions, both submucosal plexus and myenteric plexus are functional and controls, respectively, fluid secretion and intestinal motility.

In IBD, there is an imbalance in the gut microbiota (dysbiosis), the intestinal barrier is compromised, with a reduction in the mucus layer, weakening of the intercellular junctions and consequently increased epithelial permeability and entry of microorganisms in the lamina propria[15,133]. Innate immune cells increase the secretion of pro-inflammatory cytokines such as TNF-α, IL-12 and IL-23, which leads to a dysregulation of the immune system, which increases the activity of effector T cells which, in turn, recruit cells for the inflammatory response[134]. Morphological findings include submucosal edema, as well as a reduction in the number of neurons in the SMP, causing changes in secretion patterns and loss of neurons in the myenteric plexus, thus changing the motility patterns[51,52,135].

Experimental UC has been shown to affect enteric neurons, causing changes in the number of enteric neurons and glia, as well as changes in intestinal motility and secretion patterns[50-52,136]. As the presence of TNFR1 and TNFR2 have been reported in the ENS, the use of anti-TNF-α agents can exert a series of beneficial effects on ENS levels, improving the inflammatory response, peristalsis and intestinal secretion patterns, relieving symptoms such as diarrhea, fecal bleeding and colic. However, despite the important approach to the ENS and its relationship with IBD, literature data on anti-TNF treatment with analysis focused on the ENS are scarce. Therefore, further studies on the role of mechanisms/signaling pathways of sTNF, mTNF, TNF-α and their receptors in enteric neurons in IBD are needed, since this approach can guide the choice of a more adequate, effective anti-TNF-α agent with lower chances of failure responsiveness.

CONCLUSION

This review provided main details about TNF-α relationship with IBD. The role of TNF receptors in the development of IBD is an issue that deserves attention and may be a key to the treatment of UC and CD. In addition, anti- TNF-α treatments have been very promising in the treatment of IBD unresponsive to conventional therapies. The relationship of the ENS with TNF-α and its response to anti- TNF-α treatment are important aspects to be addressed, as they may direct new therapies and reduce non-responsiveness to specific anti- TNF-α agents.

Figure 3 Comparison of the intestine in normal conditions and in the bowel with inflammatory bowel disease. Under normal conditions (left), the intestinal microbiota establishes a symbiotic condition with the host, the intestinal barrier is intact and functional, and there is a balance between the levels of pro-inflammatory cytokines such as tumor necrosis factor alpha (TNF-α), interleukin (IL)-12 and IL-23 and anti-inflammatory cytokines such as transforming growth factor beta and IL-10 by innate immune cells. In this way, there is a regulation of the immune response through a balance between regulatory T cells and effector T cells. Submucosal plexus (SMP) and myenteric plexus neurons are functional and controlling, respectively, fluid secretion and intestinal motility. In inflammatory bowel diseases (IBD) (right), there is an imbalance in the intestinal microbiota, the intestinal barrier is compromised, with a reduction in the mucous layer, increased epithelial permeability and consequent passage of microorganisms to the lamina propria. Innate immune cells increase the secretion of pro-inflammatory cytokines such as TNF-α, IL-12 and IL-23, which leads to a dysregulation of the immune system mediated by T cells, increasing the activity of effector T cells which, in turn, recruit cells for the inflammatory response. In IBD, submucosal edema is observed, as well as a reduction in the number of neurons in the SMP, causing changes in secretion patterns and loss of neurons in the myenteric plexus, resulting in changes in motility patterns. Abstract

Acute pancreatitis (AP) is an inflammatory disease of the pancreas, which can progress to severe AP, with a high risk of death. It is one of the most complicated and clinically challenging of all disorders affecting the abdomen. The main causes of AP are gallstone migration and alcohol abuse. Other causes are uncommon, controversial and insufficiently explained. The disease is primarily characterized by inappropriate activation of trypsinogen, infiltration of inflammatory cells, and destruction of secretory cells. According to the revised Atlanta classification, severity of the disease is categorized into three levels: Mild, moderately severe and severe, depending upon organ failure and local as well as systemic complications. Various methods have been used for predicting the severity of AP and its outcome, such as clinical evaluation, imaging evaluation and testing of various biochemical markers. However, AP is a very complex disease and despite the fact that there are of several clinical, biochemical and imaging criteria for assessment of severity of AP, it is not an easy task to predict its subsequent course. Therefore, there are existing controversies regarding diagnostic and therapeutic modalities, their effectiveness and complications in the treatment of AP. The main reason being the fact, that the pathophysiologic mechanisms of AP have not been fully elucidated and need to be studied further. In this editorial article, we discuss the efficacy of the existing diagnostic and therapeutic modalities, complications and treatment failure in the management of AP.

Key Words: Pancreatitis; Etiology and pathogenesis; Diagnostic criteria; Nutrition; Antibiotics; Management of complications

Core Tip: Acute pancreatitis (AP) is an inflammatory disease of the pancreas, with abnormal trypsinogen activation as the primary pathogenesis and varies from clinically mild to fulminant form. Severe forms of AP are a relatively common cause of death. Progress in the establishment of biochemical, imaging and clinical criteria for the severity and prognosis of the disease has markedly influenced the therapeutic approach and the outcome of the disease. This article presents the diagnostic and therapeutic modalities with regard to their effectiveness, complications and treatment failure, as well as discussing some of the controversial issues in the treatment of AP.

INTRODUCTION

Acute pancreatitis (AP) is an inflammatory pancreatic disease affecting all ages, with an annual incidence of 10-50 cases per 100000 persons[1]. The main causes of AP are gallstone migration and alcohol abuse. Among these, predominance of one cause over the other depends on socioeconomic, ethnic, and cultural differences[2-5].

Most patients with AP present with a mild and self-limited disease. Conversely, 15%-20% patients with AP develop local and/or systemic complications, frequently leading in multiple (respiratory, cardiovascular, renal, and hepatic) organ failure (MOF) and death. According to the revised Atlantic classification, the severity of AP is divided into three levels: Mild, moderately severe, and severe, based on organ failure as well as local and systemic complications[3]. However, the pathophysiologic mechanism of AP has not been fully elucidated and there are several controversies regarding the diagnostic and therapeutic modalities due to their effectiveness and complications in the treatment of the disease. These controversies primarily relate to the therapeutic treatment at the early stage of the disease, which includes fluid resuscitation, including the most appropriate type of fluid to use, as well as the time, volume, and rate of administration. Other controversies include the timing of restart and the importance of nutritional support, the role of prophylactic antibiotics, the timing of application of more aggressive methods including surgery, as well as the treatment of complications which can negatively impact the patient's prognosis and quality of life[4-6].

This editorial article presents the most important diagnostic and therapeutic modalities with respect to their efficacy, complications and treatment failure in the treatment of AP.

ETIOLOGY OF AP

There are multiple causes and pathological conditions potentially associated with AP (Table 1). It is generally accepted that gallstones and alcohol abuse are responsible for about 90% of all cases of AP. The role of gallstones is very important in the etiopathogenesis of AP and any finding indicating the presence of gallstones in the gallbladder or biliary tract in patients with AP can be classified as the cause of the disease. Therefore, all patients with AP should be screened by ultrasound for the presence of cholecystolithiasis, common bile duct stones, or diagnose signs of biliary obstruction[2,7,8]. Alcohol-induced pancreatitis is more common in young and middle-aged people in whom an idiosyncratic sensitivity to alcohol may exist at levels of alcohol exceeding 80 g/dL. Other predisposing factors may be the level of alcohol dehydrogenase activity in the gastric mucosa and the liver[2,7,8].

Hypertriglyceridemia (triglycerides > 600 mg) is well-known cause of AP. One of the predominant causes of serum triglycerides elevation is alcohol intake. Therefore, it is sometimes challenging to assess whether the cause of AP is alcohol consumption or hypertriglyceridemia[9-11].

A large variety of drugs have been related to AP. Although, some drugs such as diuretics, azathioprine, sulfonamides, drugs used in the treatment of acquired immunodeficiency syndrome such as didanosine and zalcitabine, and steroids can cause AP through a direct toxic effect, most cases of drug-related pancreatitis are probably triggered by individual sensitivity. In large epidemiological

studies, it has been proven that potentially pancreatotoxic drugs are not independent risk factors for the development of AP. The interval from the beginning of drug intake to the development of AP is highly variable and ranges from a few weeks, in a drug-induced immunologic reaction, to several months, when accumulation of toxic metabolites (*e.g.* valporic acid, pentamidine, didanosine) is required. The mechanism of AP for many of these medications is obscure[12-16].

PATHOGENESIS OF AP

AP is predominantly acute inflammatory process which involves the parenchyma of the pancreas, with involvement of other regional tissues or distant organ systems in severe forms of the disease. The pathogenic mechanism of AP is presented by inappropriate activation of trypsinogen and destruction of secretory cells followed by systemic release of cytokines and inflammatory mediators, causing the activation of inflammatory cells, fever and MOF. Calcium overload, mitochondrial dysfunction, impaired autophagy, endoplasmic reticulum stress, and exosomes are other factors in pathogenesis of the disease[16]. Edema of pancreatic and peripancreatic tissues and fat necrosis are common in all forms

of AP (mild, moderately severe and severe) however, in the severe AP (SAP), there is a possibility of hemorrhage within the pancreas[4,7,17,18].

Cellular necrosis elements (acinar cells, duct cell, and islet cells) are considerable in SAP but necrosis is usually absent in mild and moderate forms of the disease. During SAP, pancreatic necrosis (PN) develops due to impairment in pancreatic microcirculation and its complete development takes usually several (approximately 4-7) day after the beginning of the disease but, the development of PN is not strictly fixed in time and may progress during the first 2 wk[4,16-18]. During that period, PN is usual sterile and its infection is extremely rare. After the first 1-2 wk, the development of secondary infection in PN, due to translocation of intestinal flora, is associated with increased morbidity and mortality[4].

Early in the course of AP, acute pancreatic fluid collections (APFC) can occur as amylase-rich and protein-rich pancreatic juice collections and they usually resolve spontaneously. Pancreatic fluid collections, which present for more than 4 wk, are usually caused by disruption of pancreatic duct (PD) with extravasation of pancreatic juice and they are termed as pancreatic pseudocysts (PPC) or pancreatic walled-off necrosis (WON). Extra-pancreatic manifestations of SAP include systemic inflammatory response syndrome (SIRS) following by systemic MOF or exacerbation of serious pre-existing illness related to AP[4,16-18].

DIAGNOSIS OF AP

Diagnosis of AP is based on clinical presentation, laboratory tests, and imaging findings and requires two out of the following three criteria to be present: Clinical (acute pain attack in the upper abdomen spreading to the back), laboratory (serum lipase and/or amylase levels are three or more times higher than normal values) and typical imaging [computed tomography (CT), magnetic resonance imaging, ultrasonography] findings that are characteristic for AP[5].

The most common presenting symptoms of the disease are abdominal pain (80%–95%) followed by nausea and vomiting (40%–80%), rebound tenderness, breathlessness, impaired consciousness with pyrexia, distension and reduced bowel sounds[4,16].

The diagnosis of AP can be supported by serum and urinary laboratory tests to clarify its origin. They usually reflect organ dysfunction and metabolic disturbances. Amylase is traditionally the laboratory test of choice but, given its higher sensitivity and specificity, lipase (serum level greater than three times normal appears) is more valuable test for diagnosing of AP. The elevation of these enzymes in the serum occurs due to the leakage of pancreatic acinar cells into the interstitial space followed by their subsequent absorption into the circulation[19-21]. Some authors consider that the lipase/amylase ratio can be a crucial parameter in establishing alcohol as the etiology of AP. Transaminases are mostly used in differentiation biliary from other causes of AP[22]. The negative predictive value of urinary trypsinogen-2 level is 99%. Therefore, urinary trypsinogen-2 levels accurately diagnose AP and may be considered as useful markers to determine extra-pancreatic inflammation in AP[19,23,24]. Serum immunoreactive trypsin, chymotrypsin, elastase, phospholipase A2, alfa2-macroglobulin, methem-albumin, and carboxipeptides levels have been suggested in diagnosing AP. However, these tests are not in routine use and are not commercially available[25,26].

When the clinical presentation is typical but the laboratory parameters are ambiguous or inconclusive, imaging techniques are necessary. Contrast-enhanced CT (CECT) is the most performed imaging test and the modality of choice for the diagnosis of PN, the determination of its extent, and the diagnosis of local complications[4,27-29]. However, the complete development of PN takes usually several (approximately 4-7) days from the beginning of the disease and CECT cannot be applied to reliably assess the presence and extent of necrosis before that time[1,4].

Magnetic resonance imaging is a good alternative to CECT due to its superiority soft tissue contrast resolution and better evaluation of the biliary tree and PD. Also, this method can be used as a substitute for endoscopic retrograde cholangiopancreatography (ERCP) in the diagnostic evaluation of the PD[4, 30-32].

Ultrasound, endoscopic ultrasound and ERCP are adjuncts to CECT and they are used for the diagnosis of cholelithiasis, disconnected PD, evaluation of the collection contents, and follow-up imaging. Imaging examinations are usually not necessary in an emergency when the clinical presentation and laboratory tests are consistent with features of AP[1,4,28,33,34].

PREDICTION OF SEVERITY AND OUTCOME OF AP

AP varies from clinically mild to fulminating disease and has been recorded as a cause of sudden death. The outcome of acute attack depends in part on the etiology and in part on the severity of the attack. It is generally accepted that death from AP has a bimodal temporal distribution: Early mortality is the consequence of SIRS followed by MOF, while late mortality is caused by superinfection of PNs and peripancreatic fluid collections resulting in sepsis[4,7,34,35].

Advances made in establishing diagnostic criteria for the severity and prognosis of an attack have markedly influenced therapeutic approach. Several multifactorial scoring systems (Ranson, APACHE II, Glasgow-Imrie, SOFA, Balthazar, BISOP, *etc*.) have been extensively applied with the goal of predicting which patients might have a severe clinical course and which of them will recover without major complications[7,20,21,36-41].

A commonly accepted definition of SAP was not established until 1993, when the first version of the Atlanta classification for AP was published. The classification emphasizes the difference between milder interstitial form of AP from SAP related to 'local complications', but do not contain a clear definition of pancreatic and peripancreatic collections that was standardized worldwide[42]. The classification was revised in 2012[1,3], defining early and late AP which can be either edematous interstitial or necrotizing one. According to the severity of the disease, AP is divided into mild, moderately severe, and severe form, based on organ failure as well as local and systemic complications. AP collections are differentiated into APFC, PPC, acute necrotic collection, and pancreatic WON, according to the type of AP[1,3,7] (Figure 1).

However, the value of early prognostic evaluation of AP remains uncertain due to the fact that patients who have the same initial predicting scores often have very different subsequent clinical courses of the disease. Also, the relevance of the prognostic evaluation is markedly affected by the lack of widely accepted definition of severity and outcome of the disease[1,4,7].

INITIAL TREATMENT OF AP

AP is a dynamic disease process in which most attacks are mild (mild and moderately severe forms), AP is a dynamic disease process in which most attacks are mild (mild and moderately severe forms), with ongoing recovery after a few days of conservative supportive therapy. However, some patients with SAP can develop local and/or systemic complications and MOF. There are two treatment periods in AP: Early treatment of the acute attack should be applied in both mild and severe forms of AP, while late management includes treatment of SAP complications. The most important measures of intensive monitoring and supportive therapeutic procedures in AP are presented in Table 2.

In early stage of AP, all patients require appropriate conservative treatment and sufficient nutritional support. Most patients with mild or moderately SAP will recover with conservative treatment that includes correction of hypovolemia and hypoxemia, as well as pain relief. For a long time, correction of hypovolemia, even with mild AP, was carried out by early aggressive hydration with monitoring vital constants and urine output[3,5,6,42-44]. However, there is conflicting evidence regarding the fluid management strategy both in terms of fluid type, optimal volume and rate of administration, as well as severity of AP. Several recent randomized trials showed that early aggressive fluid resuscitation, in patients with AP, resulted in a higher incidence of fluid overload (with potentially increasing risk for acute kidney injury and pulmonary edema) without improvement in clinical outcomes[45-48]. Other, also randomized controlled trials, reported that early aggressive intravenous hydration hastens clinical improvement in patients with AP and that aggressive fluid strategy is beneficial especially for certain subsets of patients and some types of AP[48-51]. Most authors agree that these discrepancies are not fully elucidated and that future studies are needed to investigate which fluid management strategy is optimal for majority of the patients and which subsets of patients with AP may benefit from different management of fluid replacement[6,47].

Pain control is a very important therapeutic measure in the early stage of AP and can be provided by appropriate intravenous administration of a non-opiate analgesic. Opiates (*e.g*., meperidine) may also be given as required[52-54]. Some recent systematic reviews and meta-analysis suggest that epidural anesthesia is safe and effective in reducing pain severity, improving pancreatic perfusion, and decreasing mortality, within the first 24 h of AP onset. However, there is paucity of evidence to guide pain management in AP with small datasets per study[55,56] Hypoxemia is a rare event in mild and moderately SAP but, in severe forms of the disease, respiratory insufficiency with hypoxemia is often present as single organ failure. Hypoxemia could be avoided by ensuring airway patency and supplemental application of humidified oxygen, which would allow maintenance of arterial oxygen saturation above 95%. In case of development of respiratory insufficiency, mechanical ventilation with positive expiratory pressure is mandatory[4-6,43,44].

Conversely, patients with SAP are at high risk of developing PN, MOF, and septic complications. The most important therapeutic goals in the initial treatment of SAP are the provision of supportive therapy and the treatment of specific complications that may occur at the beginning of the disease[4].

Nutritional support

The nutritional management strategy for patients with AP has generated intense debate over the past few decades. Oral nutrition should be restarted immediately in patients with preserved gastrointestinal peristalsis, without abdominal pain, nausea, vomiting, or evidence for intestinal obstruction or ileus[5,18]. Most patients with SAP have increased basal energy needs, pronounced protein catabolism and endogenous gluconeogenesis.

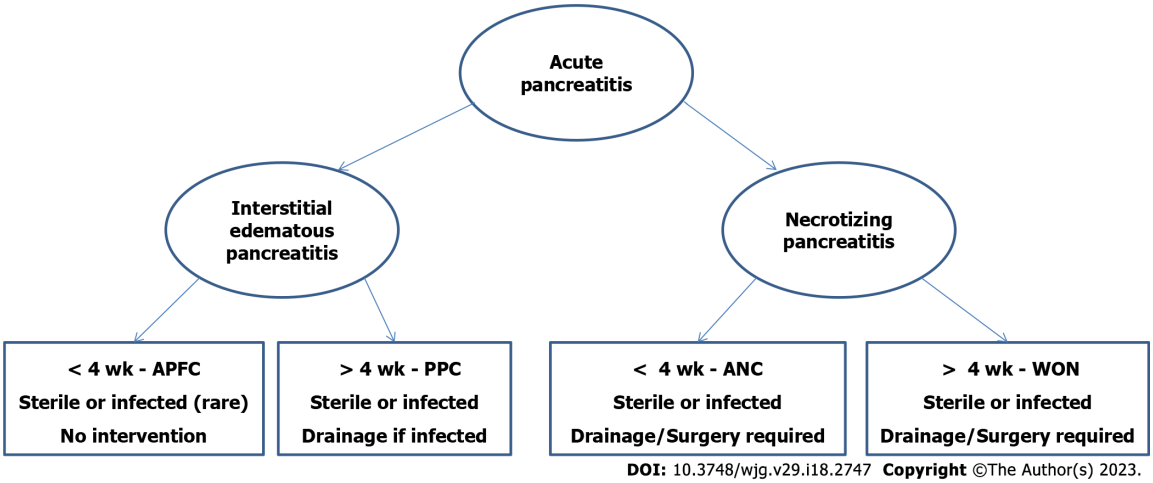

Table 2 Management of acute pancreatitis

Cornerstone treatment measures
Intensive monitoring and support of cardiac, pulmonary, renal, and hepatobiliary functions
Fluid resuscitation with monitoring of vital constants and urine output
Electrolyte solutions and Plasma expanders
Humidified oxygen administration
Catecholamine (dopamine, dobutamine) to prevent renal failure
Appropriate nutritional support
Early treatment of systemic complications
Mechanical ventilation with positive end-expiratory pressure
Catecholamine (epinephrine) if shock develops
Hemofiltration, dialysis
Insulin and calcium substitution to treat metabolic complications
Prevention of infectious complications
Biliary tract management
Management of necrotizing pancreatitis
Conservative, Imaging, Endoscopic, Surgical management
Management of late complications
Pancreatic pseudocysts
Walled-off pancreatic necrosis
Disconnected pancreatic duct syndrome/pancreatic fistula
Acute non-infectious complications in acute pancreatitis
Intra-abdominal hypertension
Pseudoaneurysm
Venous thrombosis
Bowel fistula
Management of special types of acute pancreatitis
Pediatric
Hyperparathyroidism
Hypertriglyceridemia
Post-ERCP pancreatitis
Trauma
Pregnancy
Long term complications and long-term care

ERCP: Endoscopic retrograde cholangiopancreatography.

The purpose of nutritional support is the reduction of wasting, to support the structure and function of organs, and to have a positive influence on the clinical course of the disease. Also, if patients with SAP develop paralytic ileus as a complication of the disease, keeping the pancreas at rest is necessary. Since they require nutritional support to achieve a positive nitrogen balance, parenteral nutrition should be started as soon as possible with the aim to achieve a positive nitrogen balance within the first 72 h after the onset of the disease[4].

However, SAP represents a typical model of septic syndrome due to the gastrointestinal barrier failure, which reduces gastrointestinal motility and damages mucosal integrity with subsequent increases in its permeability. This leads to an increased risk of bacterial overgrowth and their translocation from the intestinal tract to peripancreatic necrosis. Therefore, one of the main therapeutic goals in

Figure 1 The revised Atlanta Classification: Key terms diagram. APFC: Acute pancreatic fluid collection; PPC: Pancreatic pseudo cyst; ANC: Acute necrotic collection; WON: Walled-off necrosis.

SAP is to maintain intestinal integrity to prevent bacterial and endotoxin translocation and improve the immune system of the gastrointestinal tract. Administration of enteral feeding, with or without immunonutrition can maintain mucosal integrity and prevent or decrease bacterial translocation. Therefore, early nutritional support should be prioritized as soon as possible (optimally, within the first 24–72 h)[4,18,57-59].

Role of antibiotics

The presence of infected PN is the most important negative indicator and is the main cause responsible for morbidity and mortality in SAP. The infection organisms that are responsible for PN infection are mostly Gram-negative bacteria of intestinal origin, and they can reach PN through a previously damaged intestinal mucosal barrier[4,18].

Broad-spectrum antibiotics with ability to pass into PN (*e.g.*, carbapenems, quinolones, and metronidazole), should be prescribed only when infected necrosis is confirmed or strongly suspected [18]. However, the administration of antibiotic prophylaxis in order to prevent infection of sterile necrosis is controversial. Some authors advocate the use of prophylactic antibiotics in SAP considering that they can prevent the development of superinfection in necrotic tissues, which is the only measure of initial treatment of PNs, since their development are not preventable[4,18,60-65]. Some authors consider that there is a reduction in pancreatic infection in the subgroup of patients who received broad-spectrum antibiotics, concluding that more evidence is needed[60,61].

However, multiple prospective, randomized, placebo-controlled trials and most important guidelines have demonstrated that the routine use of prophylactic broad-spectrum antibiotics, in patients with SAP, has no influence on the development of infected necrosis, systemic complications, need for surgery, or mortality[18,62-65]. Besides, prolonged antibiotic therapy increases the prevalence of fungal infections[4,18,61]. Evidence supporting the prophylactic use of antifungal agents in patients with PN is lacking. Also, the use of probiotic prophylaxis is not suggested for the prevention of infectious complications in AP[18,62,63].

MANAGEMENT OF NECROTIZING PANCREATITIS

The development of extensive PN is a main cause of complications and mortality in patients with SAP. Therefore, it is very important to apply the best methods to identify patients with PN who require more aggressive interventions than those who could be treated with less aggressive measures. Different clinical entities, such as persistent pancreatic fluid collections, pancreatic fistula, persistent SIRS, obstructive jaundice, and ongoing symptoms can be detected during SAP and they can predict the severity of clinical course of the disease. Their management vary depending on the severity and the type of complication, since different complications require different treatment modalities. The revised Atlanta classification offers useful recommendations to determine the strategy for management of the SAP complications[1,3-5,18,66].

Step-up approach

The step-up approach is used, in the treatment of infected PN, as a less invasive alternative approach compared to early surgical necrosectomy. This approach is based on the statement that surgical

debridement should be delayed until demarcation of necrotic from normal tissue is established, which would reduce the risk of bleeding into the necrotic tissue during or after the surgical intervention. Several studies that have conducted long-term follow-up of clinical outcomes in patients with AP have shown that the step-up approach leads to a reduction in morbidity and mortality and should be preferred over the classic surgical approach if both methods are technically feasible[4,8,18,67-71].

However, there are still certain disagreements regarding the comparison of the endoscopic and surgical step-up approach. In a randomized trial, Bang *et al*[72], compared outcomes of the surgical *vs* endoscopic step-up approach and they reported that the endoscopic was superior to the surgical step-up approach in reducing major complications, lowered costs, and increased quality of life in patients with infected PN[72]. Dutch Pancreatitis Study Group, in the TENSION trial, reported that the endoscopic approach may be more suitable than the surgical step-up approach, in the treatment of infected PN, based on favorable short-term outcomes. However, they presented that the endoscopic was not superior to the surgical step-up approach in reducing death or major complications in patients with infected PN, while the rate of pancreatic fistulas and length of hospital stay were lower in the endoscopy group[73-75]. Most experts in the discussion of this issue point out that the endoscopic approach is the best management for patients with infected PN, but that it is necessary to develop common protocols for endoscopic approach, based on all the observations and suggestions[76-79]. Finally, it can be concluded that, some segments of the step-up approach can be changed and improved, but its basic concept (delay, drain, and debride) remains as the reference standard intervention for PN[71].

The role of abdominal paracentesis drainage in necrotizing pancreatitis

If necrotizing pancreatitis is associated with liquefied necrotic debris in the pancreatic and peripancreatic regions, with the presence of abdominal and/or pelvic fluid several authors[80-85] have advocated the concept of removing the peritoneal fluid. The rationale for removing the peritoneal fluid is to reduce inflammation and disease severity since the intra-abdominal fluid, accumulated during the disease, may contain factors that trigger and increase the severity of AP, including proinflammatory mediators and infection.

In general, abdominal paracentesis drainage (APD) has the role of a preparatory procedure before the application of PCD with the intent to achieve better result than through conventional step-up approach. Therefore, the integration of APD into a step-up approach is beneficial for patients, due to the fact that this procedure removes great number of inflammatory factors from the seroperitoneum[82].

Management of sterile necrosis and acute fluid collections

Early in the course of AP, pancreatic inflammation, manifesting as partial or total PN, causes more liquefied areas and leads to extravasations of enzyme-rich pancreatic juice into the peripancreatic regions, with the consequent development of sterile necrosis and ANC. They usually resolve spontaneously and the vast majority of patients with sterile PN can be treated conservatively and without interventional procedures (*i.e.* catheter drainage or necrosectomy). However, if unresolved spontaneously, they can lead to a poor clinical course and allow active pancreatic enzymes to initiate physiologic pathways leading to MOF and sepsis[4,17].

Therefore, PCD or endoscopic drainage may be required in symptomatic patients with sterile PN and persistent malaise characterized by abdominal pain, nausea, vomiting, and nutritional failure or with associated complications, including gastrointestinal and/or biliary obstruction, persistent SIRS, or fistulas[5]. Continuous PCD may justify this approach based on the concept that elimination of cytokines and inflammatory mediators from initially sterile pancreatic juice collections may avoid or prevent systemic complications in severe forms of AP[4,17,86-90]. Besides, in cases whereby a high output of amylase-rich fluid continues to drain through the catheter, continued prolonged drainage is necessary despite the sterility of the collection[91].

Treatment of infected PN

The development of secondary infection in PN is associated with increased morbidity and mortality (15%–20%) and there is consensus that infected necrotic tissue should be removed in order to prevent the sepsis[4,8,33,92,93]. A small proportion of patients with documented infected PN who remain clinically stable can be managed with only conservative treatment and close monitoring, without intervention[5]. The traditional method of treating patients with infected PN by laparotomy retains its role in the treatment of the disease. However, surgical intervention is performed under general anesthesia and causes significantly greater trauma compared to minimally invasive methods, with possible consequent worsening of organ dysfunction, profuse bleeding and sepsis as well as postoperative mortality[8,94,95]. Therefore, laparotomy should be delayed for as long as possible or avoided in order to decrease mortality and morbidity rates[96]. Although there is no globally accepted treatment modality and it should be tailored to each individual patient, the step-up approach starting with monitoring and conservative measures, followed by PCD or endoscopic drainage and minimally invasive VARD has been shown to produce superior outcomes to the traditional open necrosectomy in the treatment of infected PN[4,8,18,66-72,97-99].

Disconnected PD syndrome

Disconnected PD syndrome (DPDS) is anatomic condition which is usually seen in PN. Early in the course of necrotizing pancreatitis, pancreatic inflammation causes extravasation of pancreatic secretion into the pancreatic and perpancreatic tissues with the consequent development of sterile PN which may lead to the PD disruption and interruption of continuity between the duct in the left sided pancreas and the luminal gastrointestinal tract. In such clinical setting, when the PD has no continuity with the viable tissue of the pancreas, this part no longer drains its contents into the duodenum, but produces a persistent pancreatic fistula, there is a high probability of consequent peripancreatic collection formation [1,18,100-102].

There are three types of DPDS: Concurrent (there is necrosis of the neck and body, but there is perfusion of the tail of the pancreas), delayed (PPC or WON occupy the middle part of the gland but with the perfused left-sided remnant of the pancreas) and DPDS associated with chronic pancreatitis (PD is blocked by a stricture or calculus in the proximal part, leading to atrophy of the distal segment of the duct and resulting in the formation of PPC)[1,102].

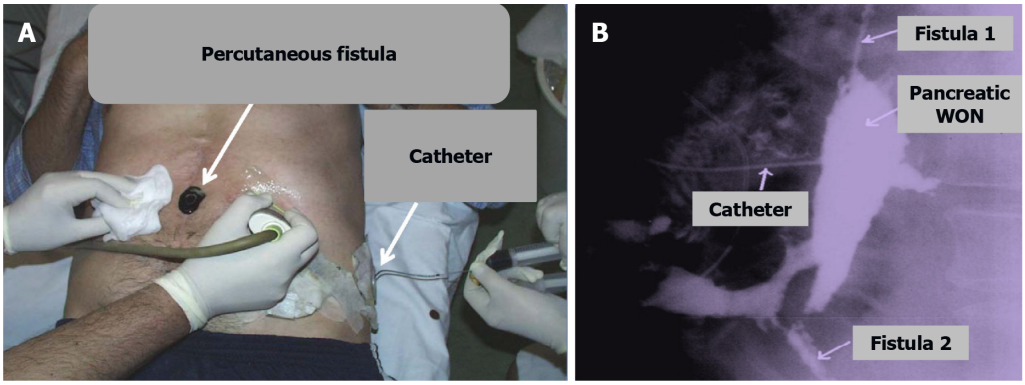
Standard treatment for DPDS is operative resection of the disconnected pancreas[103,104]. PN causing DPDS could be initially treated with percutaneous[105], endoscopic, or minimally invasive surgical techniques as temporary measures. However, elective distal pancreatectomy is mandatory in most patients as definitive treatment for DPDS[106-108].

Pancreatic fistula

Pancreatic fistulas are the consequence of pancreatic autodigestion or necrosis that results in a persistent PD disruption. Disruption of the PD secondary to PN causes the lack of continuity between PD and the viable pancreatic tissue, so that this segment of the pancreas no longer drains into the duodenum, but into the surrounding regions (usually in the pancreatic tail area) leading to its accumulation and PPC formation[1,4,18,100]. However, pancreatic secretions can also reach distant sites, causing pancreatic ascites, pleural effusion, distant PPC, or pancreatocutaneous fistula. According to that, pancreatic fistulas can be divided into two groups: (1) Internal, in which the PD communicates with the peritoneal or pleural cavity or some other hollow viscus; and (2) external, where the PD communicates with the skin[1,4,100,105,109].

Treatment of pancreatic fistulas depends on both the site of duct disruption and presence or absence of downstream ductal obstruction or DPDS. In the beginning of the disease, the management is usually conservative including total parenteral nutrition and the administration of pancreatic secretory inhibitor octreotide. However, if this management fails interventional procedures (Figure 2) and surgery are the following options. Surgical intervention, for fistula treatment, is technically challenging and could be followed with major complications[100-102,106-112].

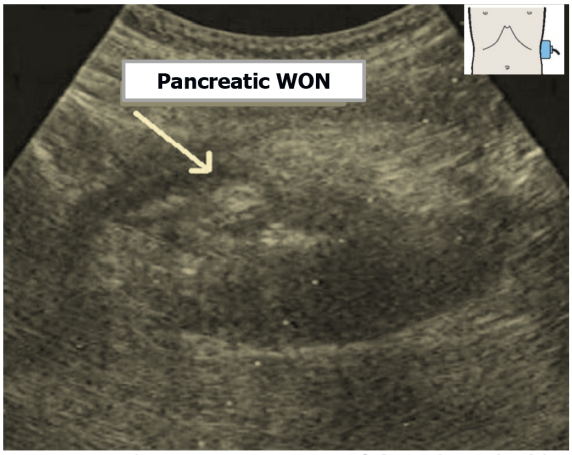
Pancreatic WON



Pancreatic WON is a located WON of pus resulting from liquefaction of necrotic areas or secondary infection of acute PPC, with or without communication with main PD. WON occurs at a relatively late stage, most commonly three to five weeks after of onset of AP. APFCs tend to be poorly walled-off and can leak into retroperitoneum, the peritoneal cavity, the mediastinum, the pleura or the soft tissues. Pancreatic WON is a heterogeneous, low-density collection in a defined cavity containing gas bubbles (Figure 3). CECT scanning is the diagnostic test of choice. Diagnosis may be confirmed by percutaneous or endoscopic aspiration[113]. Asymptomatic WON does not mandate intervention and may resolve spontaneously over a period of time[29]. Symptomatic WON generally requires intervention. The most common treatment modality is PCD (Figure 2) or endoscopic drainage. Surgical drainage is done rarely, only when percutaneous drainage is not successful[114-116].

PPC

A PPC is a fluid collection usually found near the pancreas that is formed by the secretion of pancreatic juice from the inflamed parenchyma or from a disrupted duct. The PPC wall consists of fibrous non-epithelialized tissue[42]. PPC can sometimes appear at a great distance from the pancreas (*e.g.* thorax, groin) when the fluid dissects through tissue planes. At early stage of AP, APFC are common, but majority of them regress spontaneously and need no treatment. About 5% of patients with APFC develop PPCs, which are defined by their ellipsoidal shape and well-formed wall. Treatment for PPCs varies depending on their size and the presence of symptoms. Asymptomatic PPCs, less than 50 mm in diameter, should only be monitored by ultrasound. However, some of them may persist and progress to produce complications such as pain, infection, gastric outlet, intestinal or biliary obstruction. These PPCs are symptomatic and require treatment. The most common treatment modalities for symptomatic PPCs are minimally invasive approaches, such as PCD or endoscopic drainage. Surgical drainage is done rarely, only when percutaneous drainage is not successful[4,97,105,110,115-119].



Hemorrhage

Upper gastrointestinal bleeding is common in AP and usually results from stress ulcers, peptic ulcer disease, or hemorrhagic gastroduodenitis. Massive hemorrhage occurs rare in AP, most commonly into

the gastrointestinal tract, the abdominal cavity or into the PD. Erosion of the great pancreatic or peripancreatic vessel leads to rupture or formation of a pseudoaneurysm. The splenic artery is most often affected vessel, followed by the pancreaticoduodenal and gastroduodenal arteries[42,63]. Pseudoaneurysm formation should be suspected if there are repeated episodes of gastrointestinal bleeding, an increasing pulsatile abdominal mass and in patients with bloating and increasing abdominal pain. Unfortunately, aneurysm rupture in these arteries mostly results in severe and life-threatening bleeding. The diagnosis can be made by angiography or angio-CT. Sometimes, arteriography with embolization of bleeding vessel in order to stop the bleeding can be performed as a temporary measure. Otherwise, some patients will require urgent surgery to stop the bleeding[33,63,120].

How to prevent relapses of AP?

The prevention of relapses of AP starts with the current episode treatment. Potential etiologic causes should be determined and adequately treated in order to prevent future relapses of the disease. This implies an adequate and prompt diagnostic and therapeutic approach to patients with biliary stones and sludge, as well as to patients with hyperlipidemia and hypercalcemia[1,5,7,16].

AP caused by hyperlipidemia tend to develop more severe forms of the disease and up to 50% of them develop SAP. Therefore, appropriate diet and drug management of the lipoprotein metabolic disorders as well as alcohol abstinence are crucial in preventing relapses of pancreatitis[9-11]. Morphologic abnormalities and tumors also have to be excluded.

After discharge from the hospital, patients with AP should follow a diet without alcohol and high fat food consumption, eating frequent small meals four to six times per day. A few months after the acute phase of AP, patients can try to introduce a diet with a slightly increased fat content and grilled meat. Patients should be warned that the next attack of AP could be more dangerous than the previous one, so lifestyle changes are necessary to reduce the risk of disease relapse[16,121,122].

CONCLUSION

AP is an inflammatory pancreatic disease that is characterized by inappropriate activation of trypsinogen and destruction of secretory cells which leads to activation of inflammatory cells, fever, and MOF. Diagnosis of AP is based on clinical, laboratory and imaging parameters, which are included into prognostic scoring system, developed with the aim of predicting the severity of the disease. Advances made in establishing diagnostic criteria for the severity and prognosis of AP have markedly influenced therapeutic approach and reduced the mortality rate of the disease.

There are two treatment periods in AP: Initial management remains supportive, consisting of conservative treatment which should be applied in both mild and severe forms of AP, while late management incorporates the treatment of the SAP complications. Currently, the treatment of SAP complications has shifted from early surgical approach to minimally invasive step-up strategy as the reference standard intervention. However, AP is a complex disease and despite the existence of numerous criteria, it is difficult to predict its clinical course. Additional researches, preferably randomized trials or prospective collaborative studies, are required to increase understanding of the pathophysiology of the disease and enable adequate responses to the diagnostic and therapeutic challenges, in order to improve the management of particularly severe forms of AP.

Abstract

The liver is the most common site of metastases in patients with colorectal cancer. Colorectal liver metastases (CRLMs) are the result of molecular mechanisms that involve different cells of the liver microenvironment. The aberrant activation of Wingless/It (Wnt)/β-catenin signals downstream of Wnt ligands initially drives the oncogenic transformation of the colon epithelium, but also the progression of metastatization through the epithelial-mesenchymal transition/mesenchymal-epithelial transition interactions. In liver microenvironment, metastatic cells can also survive and adapt through dormancy, which makes them less susceptible to pro-apoptotic signals and therapies. Treatment of CRLMs is challenging due to its variability and heterogeneity. Advances in surgery and oncology have been made in the last decade and a pivotal role for Wnt/β-catenin pathway has been recognized in chemoresistance. At the state of art, there is a lack of clear understanding of why and how this occurs and thus where exactly the opportunities for developing anti-CRLMs therapies may lie. In this review, current knowledge on

the involvement of Wnt signaling in the development of CRLMs was considered. In addition, an overview of useful biomarkers with a revision of surgical and non-surgical therapies currently accepted in the clinical practice for colorectal liver metastasis patients were provided.

Core Tip: The liver is the most common site of metastasis in patients with colorectal cancer. Wingless/It (Wnt)/β-catenin signals can drive progression and metastatization by epithelial-mesenchymal transition/mesenchymal-epithelial transition. In the hepatic microenvironment, metastatic cells can survive through dormancy and become refractory to therapy. Further studies are needed to elucidate involvement of Wnt signaling in the development of colorectal liver metastases and to improve current surgical and non-surgical therapeutic approaches.

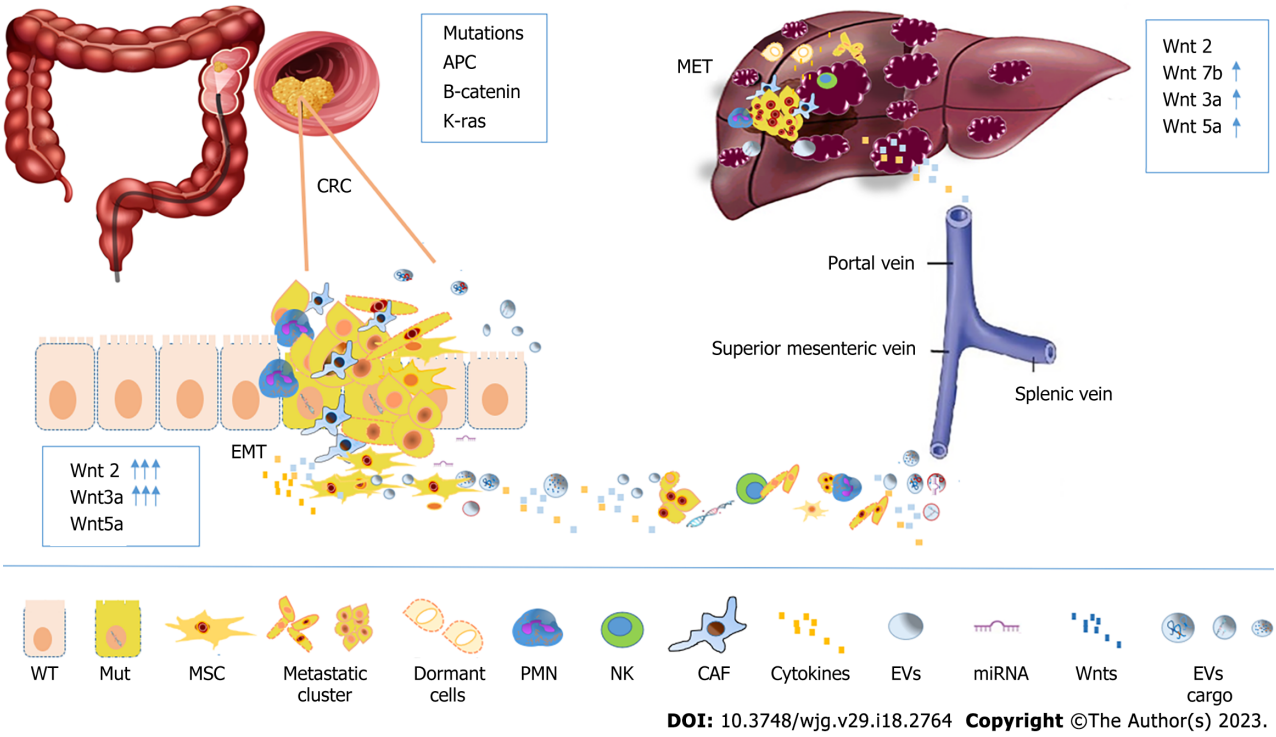
INTRODUCTION

In patients with colorectal cancer (CRC), the liver and the peritoneum are the most common sites of visceral metastases[1]. Especially in Western countries, CRC appears to be a primary cancer with a predominant ability to metastasize to the liver[2-4]. Although CRC represents the third most common cancer worldwide, it appears to be the leading cause of death in both sexes[1,5,6]. Colorectal liver metastases (CRLMs) develop in 15%-60% of CRC patients[7-9]; at the time of diagnosis, approximately 20%-34% of CRC patients have synchronous liver metastases and more than 50% develop distant metastases within 5 years of primary tumor diagnosis[2,10]. If untreated, median survival of patients with CRC and unresectable CRLM is 5-10 mo[11]. CRLMs are the consequence of sequential molecular events. CRCs are caused by an aberrant Wingless/It (Wnt)/β-catenin pathway, which in 70%-80% of cases is rooted in mutational inactivation of the tumor-suppressor gene adenomatous polyposis coli (*APC*)[12,13]. Aberrant activation of both canonical and non-canonical Wnt/β-catenin signalings, downstream of Wnt ligands, initially drives the process of colon epithelial oncogenic transformation [14]. Particularly in CRC cells, activation of the canonical pathway induces transcriptional regulation of molecules that control cell division, apoptotic evasion, and metabolic demand of the microenvironment, which favor tissue growth. In contrast, in the non-canonical pathway, β-catenin-independent signal transduction controls cytoskeleton activation and invasiveness[14]. Increased nuclear β-catenin has been documented in the invasive front of primary CRC and in the liver metastases; furthermore, this increased expression has been correlated with increased invasive capacity and synchronous CRLM formation[15-17]. Wnt signaling pathway, initially deregulated in CRC tumorigenesis, may crosstalk with RAS-extracellular signal-regulated kinase (ERK)[18], epidermal growth factor receptor (EGFR) cascade[19] and also with vascular endothelial growth factor (VEGF)[19,20]. CRLM differs in *WNT* and *EGFR* gene expression compared with normal liver tissue, showing a high degree of heterogeneity[21]. Treatment of metastatic CRC is challenging because of its variable and heterogeneous characteristics. Advances in the field of oncology have been made in the last decade, and a central role of Wnt/β-catenin pathway has been recognized in CRC chemoresistance[17]. The molecular features of intrahepatic metastatic tissue, including the mutational status of *EGFR* or *VEGF*, may be a therapeutic target to increase the efficacy of neoadjuvant chemotherapy[22]. Current treatments, including radical surgery as well as systemic and localized therapy, achieve clinical results in only a minority of patients with CRLM, who have also a high recurrence rate. Surgical resection appears to be the unique treatment that can offer long-term survival and a better chance of cure, although it applies to only one-third of the patients with CRLM[23]. Unfortunately, about 80% of patients have unresectable metastatic lesions at the time of diagnosis, and for this, 5-year overall survival is low, with a rate of around 48%[24]. For these reasons, development of new integrated treatments has to be advocated to improve CRLM patient clinical outcome. According to these concepts, it is important to remember that early CRC diagnosis remains paramount to achieve a better prognosis[25,26].



A better understanding of the mechanisms that regulate CRLM holds great potential for both adapting conventional therapies and developing new diagnostic methodologies. In this review, current knowledge on Wnt signaling in the process of CRLM was considered. In addition, an overview of valuable biomarkers with a revision of surgical and non-surgical therapies accepted in the clinical practice for CRLM patients were provided.

WNT SIGNALING: A DRIVER OF LIVER METASTASES FROM CRC

Cancer metastases result from complex selective processes depending on hepatic tissue anatomical, biological and microenvironmental factors. Evidence of metastatic propensity and organ-specific tropism of metastatic tumor cells mirror the concepts of "seed-soil", pre-niche and crosstalk between tumor cells and immune cells. These events allow tumor cells dislocated from the primary site to express their anchoring features on the tissue to be colonized as a site of implantation. Understanding of the interdependence of these biological mechanisms can provide valuable insights into treatment of CRLM[24]. During the metastatic event, tumor cells go through several stages, which include: Epithelial-mesenchymal transition (EMT) process, local tissue and vascular invasion, transition into the vascular system, extravasation process and seeding into the niche of the hepatic tissue. At the end of this multistep and dynamic model, metastatic cells finally have to be able to survive and grow by integrating into the cell community of the metastatic site[27]. Wnts are secreted glycoproteins that regulate multiple signaling pathways through both β-catenin-dependent and -independent mechanisms[28]. Aberrant activation of cellular pathways by Wnt ligands and β-catenin-dependent signaling promotes tumor progression and regulates EMT in CRC[1]. Wnt pathway somatic mutations are present in approximately 80%-90% of CRC patients. Both tumor cells and the surrounding microenvironment can express and release specific hyperactive Wnt ligands that can drive metastases even in cells with APC-inactivating mutations. However, several follow-up studies have revealed that the most aggressive subtypes of CRC do not show the highest levels of Wnt signaling[29]. RNA sequencing has shown that interference with Wnt signaling leads to up-regulation of gene programs that promote cell migration, invasion and downregulation of inflammation signatures in the tumor microenvironment (TME)[29]. Furthermore, it is believed that multiple ligands of Wnts may trigger numerous signaling pathways in addition to the β-catenin-mediated one; some of these alternative pathways have not yet been adequately studied in liver metastases[30]. Alterations in gene and protein expression allow CRC cells to make EMT/mesenchymal-epithelial transition (MET). EMT/MET program generates migrating tumor cells with intermediate phenotypic characteristics (Figure 1). CRC cells with a hybrid EMT/MET program migrate individually or in clusters through local or systemic spread[31]. Wnt signaling dysregulation activates downstream EMT by promoting emergence of migrating cancer stem cells (mCSCs) at the invasive front of the primary lesion. MCSCs invade locally through the driving force of the local TME and form distant metastases (Figure 1)[32].

Tumor progression results from interaction and cooperation between tumor and stromal cells of the hepatic microenvironment. In particular, inflammatory and metabolic signals can significantly influence rooting of metastatic cells in tissue niche, which can lead to reversion from EMT to MET and to their integrated adhesion with the new tissue site (Figure 1). The microenvironmental signals then induce EMT reversal (also called MET) to establish secondary micrometastases (colonization)[33-35].

Recent studies have revealed that cancer cells can follow an intermediate metastatic transition, with a mixture of cells showing features of either epithelial, mesenchymal phenotype or both at the molecular and morphological levels[36,37]. In intermediate stages, "quasi-mesenchymal" cells, which are mobile, more challenging to kill, and aggressive, express the *CDH1* gene (coding for E-cadherin protein) at the transcriptional level without displaying E-cadherin protein on the cell surface[38]. At this intermediate stage the cells have characteristics similar to stem cells and may co-express genes typical of both the epithelial and mesenchymal phenotype[39]. EMT/MET hybrid intermediates can promote metastatic tendency. It is unclear whether EMT/MET hybrid intermediate subpopulations may be responsible for treatment failure (immunotherapy, radiotherapy and/or chemotherapy). EMT can be regulated by different transcription factors and their gene regulatory networks that drive multiple levels of molecular changes. Some key transcription factors, such as Snail family transcriptional repressor 1 (Snail1)/Slug and zinc-finger E-box binding homeobox 1/2 (Zeb1/2), and myocyte enhancer factor 2A, promote the mesenchymal phenotype, while other transcription factors, such as ovol-like zinc finger 1/2 and grainyhead like transcription factor 2, suppress it by promoting the epithelial phenotype[40-43]. These transcription factors can act as either activator or repressor of downstream target gene expression, depending on Wnt signaling pathway activation level. One well-studied example involves the transcriptional activities of zinc finger E-box binding homeobox 1 (ZEB1) and Wnt/β-catenin signaling that mutually modulate each other, as ZEB1 potentiates transcription factor 4/β-catenin-mediated transcription, which in turn transforms ZEB1 from repressor to activator[44]. In addition to modulating its functions as either activator or repressor, Wnt/β-catenin signaling regulates ZEB1 protein expression [44].

Figure 1 Metastatic liver microenvironment in colorectal cancer. Genetic changes such as adenomatous polyposis coli, β-catenin mutations or K-RAS mutations can generate epithelial-mesenchymal transition/mesenchymal-epithelial transition; aberrant activation of Wingless/It (Wnt)2, Wnt7b, Wnt3a and Wnt5a ligands promotes local invasion of mesenchymal stem cell and cell migration from primary lesion to form distant colorectal liver metastases; tumor microenvironment, including extracellular matrix, blood vessels, extracellular vesicles, different types of cells, such as cancer and immune cells, proinflammatory cytokines, chemoattractants, and angiogenic factors, influences the metastatic cell colonization in tissue niches. EMT: Epithelial-mesenchymal transition; MET: Mesenchymal-epithelial transition; APC: Adenomatous polyposis coli; Wnt: Wingless/It; CRC: Colorectal cancer; MSC: Mesenchymal stem cell; CRLMs: Colorectal liver metastases; WT: Wild type; MUT: Mutant; PMNs: Polymorphonuclear neutrophils; CAF: Cancer-associated fibroblast; NK: Natural killer; EVs: Extracellular vesicles; miRNA: MicroRNA.

EMT regulation is also influenced by the action of microRNAs and long noncoding RNAs, as well as chromatid and post-translational modulations[43,45,46]. In the liver, Wnt/β-catenin signaling has physiological functions related to hepatocellular growth, metabolic liver zonation and regeneration[47]. Signal transduction of the canonical pathway mainly involves β-catenin and its ability to modulate T-cell factor (TCF)/lymphoid enhancer-binding factor (LEF)-dependent nuclear transcription factors, together with the activation of genes involved in cell proliferation, survival, differentiation, and migration, such as matrix metalloproteinases and c-Myc[48]. The non-canonical Wnt signals are many and involve calcium-dependent and independent pathways, as well as pathways mediated by c-Jun N-terminal kinase (JNK), protein kinase C, Ca^{2+}, Rho-type GTPases, mitogen-activated protein kinases (MAPK), and nuclear factors such as JUN/FOS and nuclear factor of activated T-cells[28]. While the canonical pathway drives tumor cells towards undifferentiation and growth, the non-canonical pathways appear to be involved in remodeling tissue architecture and mesenchymal differentiation.

Wnt family proteins transduce signals from tissue microenvironment through Frizzled (FZD) and low-density lipoprotein receptor-related protein (LRP) 5/6 receptors to the Wnt/β-catenin signaling as the canonical Wnt pathway and through FZD and/or tyrosine kinases ROR1/ROR2/RYK receptors to the Wnt/planar cell polarity cascade, while Wnt/receptor tyrosine kinase transduces Wnt signals to Wnt/Ca^{2+} signaling called non-canonical pathway[14,28].

Wnt signaling inhibits glycogen synthase kinase-3β (GSK3β) to stabilize β-catenin, which translocates into the nucleus to recruit transcription factors, LEF and TCF, and to promote the expression of SNAIL1 and SLUG, which modulate EMT. Loss of E-cadherin has long been believed to be a hallmark of EMT [49]. Its suppression is mainly attributed to the functions of SNAIL and SLUG expression, which directly bind to the E-box of the promoter region and downregulate its expression[49].

In adult tissue, renewal cell fate decisions appear to be distinct between the opposing Notch/Wnt responses. Crosstalk between Notch and Wnt allows signaling across the two pathways to be resolved into Notch-ON/Wnt-OFF[50]. Notch signaling indirectly activates β-catenin to promote and regulate EMT. Indeed, activation of Notch results in cleavage of Notch intracellular domain, which undergoes nuclear translocation of transcriptional factor, binds to SNAIL promoter, and regulates the mRNA level of SNAIL1/2 and ZEB1/2[35].

Interestingly, Wnt2 mRNA is frequently up-regulated in colorectal polyps, CRC, and CRLM[51]. Wnt2 contributes to CRC-derived cell invasive and metastatic ability by generating genetic changes in fibroblasts. This process seems to occur through extracellular vesicles (EVs) that play a key role in CRC genesis by activating Wnt signaling[17]. Wnt2 protein released from cancer-associated fibroblasts (CAFs) enhances invasion and migration of CRC cells[52]. Activation of Wnt7b may trigger EMT process through Wnt/β-catenin signaling and promote CRLM. Overexpression of the Wnt3a ligand can stimulate Wnt/β-catenin pathway in such a way as to modify cell morphology, regulate EMT and thus favor invasive capacity of tumor cells (Figure 1)[52]. In CRC, Wnt3a and Wnt5a are highly expressed at both primary and metastatic sites. In particular, Wnt3a expression increases at the primary site with a concordance rate higher than 70%. Wnt5a shows no correlation with pathological features or the expression of invasion-related proteins[13]. The expression profile suggests that Wnts might be involved initially when CRC develops and during tumor progression[13]. Recently, several Wnt/β-catenin target genes, including *S100A4*, *p16INK4a* and *BAMBI*, have been identified, showing the ability to promote cell migration *in vitro* and metastases *in vivo*[53]. Interestingly, three Wnt/β-catenin target genes, *5 BOP1* , *CKS2* and *NFIL3* have been found to be correlated with experimental metastases[53].

Increased expression of miR-92a-3p activates the Wnt/β-catenin pathway and promotes stemness, EMT, and metastases from CRC cells[52]. Nuclear β-catenin expression at the invasive front and in CRC tissue vasculature predicts metachronous liver metastases[51]. Both canonical and non-canonical Wnt signaling cascades play a key role in the development and evolution of CSCs. In addition to the classical reversible EMT/MET-driven transport pathway (hybrid-EMT), an alternative cell death process-driven transport pathway [blebbishield metastatic-witch (BMW)] involving a reversible cell death process has been identified[54]. Knowledge of EMT and BMW pathways is important for metastatic tumor therapy, as these pathways confer drug resistance and immune evasion/suppression in the context of coordinated oncogenic, metabolic, immunological, and cell biological events that drive metastases[54]. Specifically, in the tissue microenvironment, cell death signals such as apoptosis, ferroptosis, necroptosis, and neutrophil extracellular traps formation (NETosis) related to BMW or EMT pathways recruit immune cells that may despite themselves promote migration of cancer cells to distant sites to establish metastases[54]. Proinflammatory molecules of the TME may modulate CRC progression. In TME, stromal cells secrete multiple factors, such as chemokines that attract inflammatory cells producing soluble cytokines that promote tumor cell survival. Indeed, high levels of tumor necrosis factor alpha (TNF-α), interleukin (IL)-6, IL-1β and chemokines, such as CXC ligand of chemokines 1 (CXCL1), CXCL2 and CXCL12, counteract host defense mechanisms. Increased levels of IL-6 expression are associated with advanced-stage CRC, since liver metastasis formation is supported by CAFs involved with the creation of a prometastatic microenvironment through IL-6 and monocyte chemo-attractant protein-1 activation. On the other hand, IL-1β activates inflammasome and induces angiogenesis in both the primary colon cancer and metastases[55]. High expression of chemokine receptor type 4 (CXCR4) is observed in patients with liver metastases from CRC, while its ligand CXCL12 is highly expressed in the most frequent metastatic sites of CRC, such as liver, lymph nodes, and lungs, and is a chemoattractant for CXCR4-positive cancer cells[56,57]. Some of these inflammatory mediators, such as TNF-α, may also fulfil the role of tumor suppressors, reconstitute TME by increasing cytotoxic T-cell activity, mature dendritic cells and prevent neoangiogenesis[55].

Immune components of TME may modulate tumor progression and represent interesting therapeutic targets in liver metastases. Indeed, CRLM is also promoted by activating TDO2-kinurenin-AHR pathway, which facilitates programmed cell death protein-1 (PD-1)-mediated immune evasion and maintenance of stemness through Wnt signaling[58]. Recently, in a single-cell analysis on intratumor mutational diversification of CRC cells, a highly heterogeneous tumor immune microenvironment has been found to be enriched with the granulocyte component in CRLMs. Therefore, it was proposed that activation of Wnt signaling coupled with ferroptosis death may promote granulocyte migration into the tumor and metastatic microenvironment (MME)[59].

Metastatic organotropism is believed to be a process that relies on the intrinsic properties of tumor cells and their interactions with molecules and cells in the microenvironment. Even before tumor cells spread, hepatocytes secrete multiple factors to recruit or activate immune cells and stromal cells in the liver to form a favorable premetastatic niche. Liver-resident cells, including Kupffer cells, hepatic stellate cells (HSCs), and hepato-sinusoidal endothelial cells, are co-opted by recruited cells, such as myeloid-derived suppressor cells (MDSCs) and tumor-associated macrophages to establish an immunosuppressive hepatic microenvironment suitable for tumor cell colonization and growth. For these reasons, understanding of the mechanisms that regulate metastasis-prone hepatic immune microenvironment could facilitate immuno-oncology interventions for treating CRLM[27,59,60].

The spread of tumor cells and their ability to survive and grow in a secondary site require intercellular communication pathways with other cells residing in the tissue microenvironment. In recent years, several signaling cascades have been found to use EVs in tumor-stroma interaction. Indeed, modulation of Wnt signaling may also be associated with EVs formation. Tumor cell-derived EVs exert their protumorigenic effects through direct interactions among biologically active surface molecules, transfer of proteins and nucleic acids into recipient cells, or transfer of metabolites that can be used as energy source by the recipient cell; these events induce physiological and phenotypic alterations in tissue environment[61]. Secretion of Wnt proteins through endosomal compartments on

exosomes plays an evolutionarily conserved functional role in extracellular vesicular transport[62]. CRC cells promote angiogenesis through Wnt/β-catenin signaling mediated by Wnt4-enriched exosomes in endothelial cells under hypoxic conditions, which could represent a novel mechanism in the development of CRC and its progression towards CRLM[63]. Moreover, constitutively active mutant β-catenin can be transported through EVs, activate the Wnt pathway in recipient cells and promote cancer progression[64].

Accumulating evidence indicates that EVs have roles in pre-metastatic niche formation and organotropic metastasis. EVs modify the microenvironment to recruit distinct supporting stromal cells, upregulate pro-inflammatory genes, and activate an immunosuppressive state[65]. These signals may mediate the awakening of dormant niches of cancer cells. A minority of disseminated tumor cells (DTCs), surviving as latent entities may take root in the new microenvironment of the recipient organ even years after the removal of a primary CRC. Possibly, over time, the conditions of the recipient organ may change and favor awakening and engrafting of latent tumor cells into the premetastatic niche[66]. Recently, the gut microbiome has also been documented in controlling the metastatic process and premetastatic niche formation[67]. Various bacteria have been implicated in CRC progression by modulating β-catenin pathway[17]. In the liver, CRC premetastatic niche is induced by bacteria dissemination from the primary tumor[10]. Moreover, in CRC patients concomitant chronic hepatitis B virus infection significantly increases the risk of CRLM[68]. Furthermore, in some patients, the same therapeutic programs could induce macro- and micro-environmental changes in the receiving organ, to favor a greater engraftment capacity of cancer cells[69]. Autocrine inhibition of Wnt could promote metastatic latency and immune evasion by deregulating the expression of Dickkopf's Wnt signaling pathway inhibitor 1 (DKK1), in which case the cells arriving to the recipient organ would undergo a slow cell cycle state which would allow them to evade natural killer cell-mediated clearance. By expressing a stem state but actively silencing Wnt signaling, cells could enter quiescence and evade innate immunity to remain dormant for prolonged periods[70]. Finally, cancer cells can actively emit large amounts of EVs with onco-functionality in a variety of contexts such as stromal crosstalk, immune evasion, metastatic site priming and drug resistance. In other cases, tumor cells may remain as latent entities at low cycles and sometimes reactivate following changes in the microenvironment. Currently, there is a lack of clear understanding of why and how this occurs and thus, where exactly the opportunities for developing anti-CRLM therapies may lie.

DORMANT CELLS IN LIVER METASTASES

Cancer cells can enter dormancy, which is a state characterized by either a reversible arrest or a slow cycling[71]. Dormant cells arise from DTCs derived from primary lesion[72]. They acquire new features, becoming non- or slower proliferating cancer cells and resistant to chemo- or targeted therapy, while tumor progression is not clinically visible. A dormant cancer mass (indolent small clusters) includes equilibrium between cell division and apoptosis. Dormant cells can be activated to re-enter cell cycle under particular conditions[72-75]. Micrometastases of CRC can enter a dormant state for years before recurring as metastatic disease[76]. CRC is characterized by two different types of recurrence, the first of which results from reactivation of dormant tumor cells, possibly in distal organs. In contrast, the second type is a relapse after surgical remission due to micrometastatic lesions present in apparently normal tissue adjacent to the tumor. Recurrence implicates changes in TME or immune escape[77]. Indeed, a successful metastasis depends on the dynamic interactions between cancer cells and the host MME[7]. During dissemination and tumor progression, dormant cells show a reduced metabolism associated with constrained growth and can survive under hypoxia and nutritional deprivation[73]. Dormant cells reduce E-cadherin expression and up-regulate activity of the survival pathway through unfolded protein response. This results in down-regulation of major histocompatibility complex class I molecules and immune evasion through undetectability by CD8+ T lymphocytes[78-80]. E-cadherin blocks cell cycle to reduce fraction and velocity of cell proliferation, limiting the effectiveness of therapeutic agents targeting cell cycle. Dormancy-independent resistance stems from E-cadherin signaling pathway and survival kinases, such as AKT, ERK and Janus kinase (JAK)[78]. A high ratio of p38 MAPK/ERK MAPK can induce DTCs into dormancy, while a high ratio of ERK MAPK/p38 MAPK can induce dormant cell awakening and proliferation. These pathways prevent cMET activation, while their downregulation induced by hepatocytes in the MME induces E-cadherin re-expression[73]. Primary CRCs can promote the formation of hepatic pre-niches through microRNA (miRNA)-containing exosomes[24]. Moreover, proinflammatory cytokines, chemoattractants, and angiogenic factors produced by primary tumor induce pre-niche formation by the involvement of bone marrow-derived cells, and marrow-derived granulocytic MDSCs[24]. Activation of HSCs into proliferative myofibroblasts is a significant cause of recurrence of CRLM and hepatic fibrosis[78]. The liver microenvironment offers beneficial conditions for cancer cell dormancy[72].

Surgical procedures can lead to increased levels of pro-angiogenic growth factors, such as VEGF, which could activate dormancy tumor cells by altering their equilibrium through the involvement of the immune system; inhibition of angiogenesis limits tumor growth through increased cancer cell apoptosis

[71,81]. Detection of single-nucleotide polymorphisms in cellular and angiogenic dormancy-related (*NOTCH3* and *NME1*) and dormant CSC related genes (*CD44*) has been associated with treatment response, recurrence and clinical outcome in patients with resected CRLMs[82]. In human CRLMs, quiescence induced by 5-fluorouracil (5-FU) is linked to activation of Yes tyrosine kinase (YES1) and to nuclear depletion of Yes-associated protein (YAP). Moreover, *YES1* silencing decreases nuclear YAP accumulation and induces cell quiescence in 5-FU-free conditions. Increased *YES1* and *YAP* transcript levels in residual CRLMs treated with adjuvant chemotherapy are related to the risk for CRC recurrence and reduced survival[76,83].

The number of resident hepatic $CD25^{-}$ TCR^{+} cells is critical for tumor dormancy in the presence of immunosuppressant cyclosporin A in a rat model. Transformation of growth factor-beta 1 is involved with the acquisition of tumor invasiveness and metastatic spread[84]. Cancer dormancy is poorly understood in its complexity[79]. In disease recurrence and metastases, reactivation of chemotherapy-resistant quiescent cancer cells is the key mechanism that needs to be fully understood. Interestingly, itraconazole-derived subsequent inhibition on suppressor of fused activation in Wnt epithelial tumor cells prevents nuclear localization of β-catenin causing Wnt inhibition. Itraconazole perturbs dormancy by signaling effects on Wnt pathway[85]. Dormant cells are also re-activated through JAK/STAT3 pathway regulation induced by chemokine (C-C motif) ligand 7 (CCL7), which is secreted by monocytic MDSCs[75].

It is of clinical importance to effectively identify and target dormant CRC cells as potential drivers of CRLM with emphasis on Wnt/β-catenin deregulation. Induction of Wnt signaling has been involved with activation of cell cycling of quiescent cells and regulation of stem cell self-renewal[86]. Specifically, Wnt3a alters cell fate program of primitive hematopoietic stem and progenitor cells[86]. Moreover, Wnt pathway is implicated in reactivation of dormant cancer cells induced by extracellular matrix (ECM)[87]. It has been hypothesized that ECM constituents derived from metastasis-initiating cancer cells (stem cell-like properties) and stromal cells may create a suitable microenvironment that activates signaling pathways useful for metastatic cell proliferation and colonization[88]. On the other hand, inhibition of Wnt signaling by DKK1 is a mechanism used by cancer cells to enter quiescence[87]. Several markers can be used to assess CRC cell dormancy state in the liver, such as CK, E-cadherin, Sox-2 and CD133 and cell awakening state such as vimentin, cyclin-D1, Ki-67, c-Myc and VEGF[89]. Some studies have found that tumor cell quiescence can also be induced by metabolic modulation and reactive oxidative species (ROS) *via* miRNAs and peroxisome proliferator-activated receptor γ coactivator 1α, which is a pivotal factor in lipid and metabolic regulation[90,91]. It has recently been suggested that redox mechanisms can control dormant or low-activity tumor cell life cycle, including long-term dormancy and metastatic recurrence. Indeed, quiescent tumor cells overexpressing antioxidant enzymes may survive at low levels of ROS. These cells are strongly involved with cancer recurrence and are able to escape chemotherapy-induced death[92]. On the other hand, increased redox levels associated with oxidative stress may be responsible for a reprogramming process leading to reactivation of dormant cancer cells. Moreover, activation of p38 MAPK signaling is redox-mediated and has priority over ERK1/2 under oxidative stress. In this context, endoplasmic reticulum-stress signaling can induce a dormant state in DTCs[92]. Cooperation between antioxidant enzyme nuclear factor erythroid 2-related factor 2 (Nrf2) and β-catenin has been found in hepatocellular cancer. Nrf2 activation plays a role in oxidative stress as transcriptional regulator of many genes with effects on carcinogenesis suppression[93]. Under acute oxidative distress, CRC cells subjected to growth factor deprivation that mimics cell dormancy show differential gene expression in Wnt/β-catenin-dependent and independent pathways, and cytoplasmic APC modulation[94]. Furthermore, ROS regulate relationships between β-catenin and forkhead box O in JNK signaling activation and cell quiescence[95]. These findings demonstrate that Wnt pathway is a redox-dependent signaling in cancer cellular dormancy and can play an important role in CRLM development and progression.

TUMOR BIOMARKERS AND TARGET THERAPIES IN CRLM

In CRC patients, biomarkers are increasingly needed to improve tumor stratification, detection and prognosis[96]. Biomarkers are both clinical and biochemical, such as the ECOG Performance Status Scale, white blood cell count, alkaline phosphatase, lactate dehydrogenase, CRC staging according to the tumor-nodes-metastasis (TNM) system from the American Joint Committee on Cancer[97].

It is recommended that CRLM patients, especially those considered in a third-line/salvage-therapy setting, should be stratified according to whether their tumors are *RAS* wild-type or *RAS* mutant[98]. Indeed, in metastatic disease setting, the presence of activating *RAS* (*KRAS*/*NRAS*) mutations represents a negative predictive biomarker for cancer cell resistance to monoclonal antibodies directed to EGFR[99], which may detrimentally affect patient health status, specifically when combined with an oxaliplatin-based cytotoxic backbone.

As a result, the European Medicines Agency has restricted chemotherapy and EGFR-directed antibodies, such as cetuximab and panitumumab, only to patients with *RAS* wild-type metastatic CRC. In CRC tumorigenesis, the most frequent mutations are *APC* and *KRAS*[18]. Dysregulation of Wnt/β-

catenin signaling plays a pivotal role in the development and progression of several human cancers, including CRC[17]. A synergistic cooperation between Wnt/β-catenin and RAS-ERK pathways has been observed in CRC with *APC* and *KRAS* mutational status, which has led to stabilization of both β-catenin and RAS[18].

For prognostic assessment of CRLM patients, both the European Society for Medical Oncology and the National Comprehensive Cancer Network guidelines recommend assessing *RAS* and *BRAF* mutation status simultaneously[100,101]. Double mutations in *APC* and *BRAF* are associated with poorer prognosis as compared to single mutations[102]. It has been reported that two-thirds of *BRAF*-mutant primary tumors are located on the right side of the colon and associated with an increased incidence of peritoneal and distant lymph node metastases[103]. *BRAF* gene mutations (most commonly V600E substitution) are present in 8%-12% of patients with CRLM and are considered unfavorable prognostic biomarkers. Indeed, the presence of mutated BRAF correlates with a median survival of 10.4 mo as compared to 34.7 mo in wild-type BRAF[103]. Notably, $BRAF^{V600E}$ mutation, when present, is almost exclusively non-overlapping with *RAS* mutations. $BRAF^{V600E}$ mutation is a negative predictive biomarker for EGFR antibody therapy for CRLM patients, making response to panitumumab or cetuximab treatment highly unlikely. $BRAF^{V600E}$ mutations are present in nearly one-third of CRC patients with microsatellite instability (MSI). Among patients with CRLM, MSI has been documented in less than 10%[104].

Predictive data from treated patients with CRLMs have recently shown that the mismatch repair status can predict an objective response of a tumor to blockade of PD-1[105]. Thus, MSI testing in patients with CRLM has become strongly recommended for its predictive value in treating CRC patients with immune checkpoint inhibitors (with pembrolizumab or nivolumab ± ipilimumab). In terms of response to adjuvant treatment, for CRC patients with *RAS* and *BRAF* wild-type tumors, chemotherapy associated with anti-EGFR antibodies has demonstrated to be significantly more beneficial in the presence of primary left-sided tumors. In contrast, for right-sided tumors, greater survival is associated with chemotherapy combined with bevacizumab[106].

Interactions between the Wnt/β-catenin and RAS-ERK pathways have already been reported in CRC [18]. Combined anti-CSC therapy with drugs targeting both Wnt signaling and tyrosine kinases could be a useful anti-cancer rationale[107]. Tyrosine kinases are aberrantly activated in cancer cells due to genetic alterations. Tyrosine kinase inhibitors can improve CRC prognosis; however, unavoidable drug resistance and cancer relapse are serious problems in clinical practice[107].

Resistance to targeted therapies in CRLM patients exists even among patients whose tumors are wild-type in *KRAS*/*NRAS* and *BRAF* genes, underlining the need to find and better characterize additional resistance biomarkers. A list of biomarkers beyond *RAS*, *BRAF*, and MSI molecular testing is emerging, which may impact the next clinical decisions in targeted therapies. Though they are not recommended for routine patient management outside a clinical trial setting, some of the emerging biomarkers are: *ERBB2* and *MET* gene amplifications, ligands such as amphiregulin (*AREG*), epiregulin (*EREG*), alterations/mutations in phosphoinositide-3-kinase (*PI3KCA*), phosphatase and tensin homolog deleted on chromosome 10 (*PTEN*) and *HER3*.

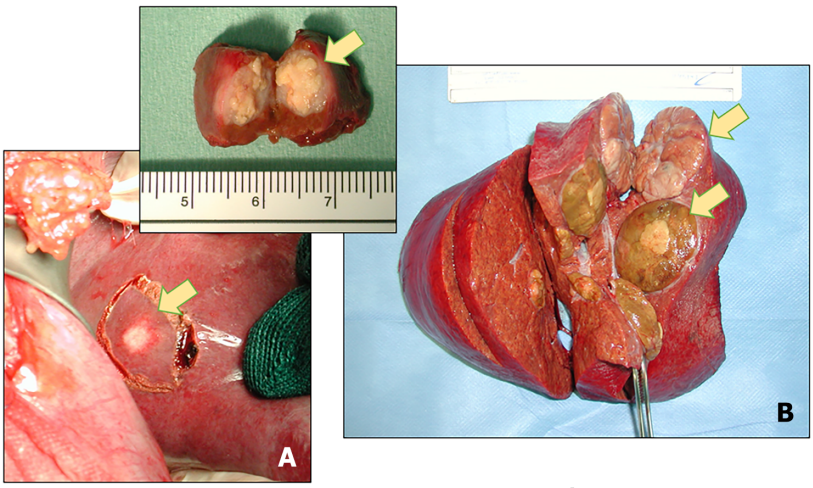
In CRLM, *MET* amplification is reported to be a potential mechanism of patient acquired resistance to anti-EGFR therapy[108]. However, multiple trials with different types of MET inhibitions have been unsuccessful in proving a predictive value for MET inhibition in CRLM patients previously treated with chemotherapy and EGFR-directed antibodies[109].

EGFR activation is involved with cell survival and proliferation through MAPK and the PI3K pathways[110]. Approximately 20% of *PIK3CA* mutations have been reported in exon 20 of its gene locus on chromosome 3q26.32. The presence of these mutations in tumor tissue has been associated with resistance to anti-EGFR therapies in chemorefractory CRC[111]. However, at the moment, there are no clinical recommendations for detecting mutations in *PIK3CA* exon 20 outside the CRC research field.

Other biomarkers associated with sensitivity to anti-EGFR therapies are gene expression status of *EREG* and *AREG*, which encode for EGFR ligands epiregulin and amphiregulin[112]. *EREG* and *AREG* are strongly regulated by methylation, and their expression is associated with CpG island methylator phenotype status and primary tumor site[113]. It is well documented that high *EREG* and *AREG* expression and left-sided primary colon tumors are associated with efficacy of anti-EGFR therapy[114]. Therefore, assessment of methylation status of *EREG* and *AREG* could be rationally used to predict resistance or susceptibility to anti-EGFR therapies in CRLM patients.

Recently, attention has been placed on the role that HER3 plays in resistance to anti-EGFR therapy. HER3 is overexpressed in several human cancers, including CRC[115]. Somatic mutations in *HER3* have been found in approximately 10% of CRC patients[116], and patients harboring CRC overexpressing HER3 display a worse clinical outcome as compared to those with low expression levels[117]. HER3-targeted therapies based on the use in clinical trials of either monoclonal antibodies, such as patritumab [118] and seribantumab[119], or bispecific monoclonal antibodies against EGFR/HER3, such as duligotuzumab[120], failed to have clinical benefits in CRLM patients.

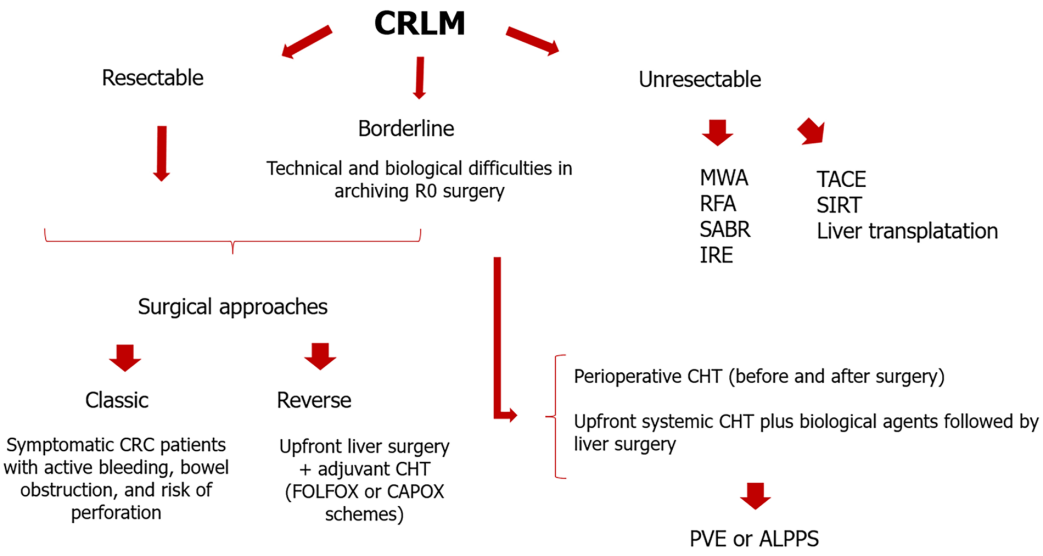
We need to establish predictive biomarkers that are reliable indicators of activated Wnt signaling. Biomarkers on Wnt activity that show diagnostic, prognostic and therapeutic importance are strongly advocated. Plasmalemma vesicle-associated protein-1, which is a marker of intestine-vascular barrier impairment, is a prognostic marker for CRC recurrence, leading to CRLM[10]. High Wnt6 expression in



CRC indicates an unfavorable prognosis for patients with CRLM after hepatectomy, suggesting that Wnt6 expression may be a valuable biomarker[51]. Loss of Wnt5a expression is correlated with recurrence reduction and decreased survival in node-negative CRC patients[121]. Serum Wnt4 level may represent a potential biomarker for CRC patients[52]. COX-2 overexpression may have prognostic/diagnostic implications regarding Wnt signaling[121]. In addition, the presence of β-catenin in the nucleus is the only irrefutable proof of Wnt pathway activation. Nuclear β-catenin expression in metastatic lymph node is associated with age, tumor differentiation, TNM stage and liver metastases. Nuclear β-catenin expression may represent a clinically useful marker in differentiating highly metastatic and less invasive CRC[16]. Developing more sensitive antibodies that detect activated (dephosphorylated) β-catenin may represent valid prognostic markers.

THERAPEUTIC STRATEGIES IN CRLMS

Recamier introduced the concept of metastatic cancer cells in 1829 and only in 1952, the first liver metastasis was removed by Lortat-Jacob[81]. The incidence of CRLM is around 12.8%-15% during five years of follow-up after primary CRC diagnosis[7,122]. About 14%-25% of patients have synchronous CRLM at diagnosis, defined as CRLM detected concurrently or before primary CRC, while 7%-40% develop metastatic lesions during the follow-up[6,9,11,122-124]. The occurrence of metachronous CRLMs is related to histopathology and serum-based biomarkers, TME and liquid biopsy[122].



Surgical approaches for CRLM patients

Unfortunately, only 20%-30% of patients are eligible for hepatectomy[9,125,126]. However, after resection, around 65% of patients develop recurrence[127,128]. For patients with only CRLM, surgical resection is still the treatment for curative intent (Figure 2)[6,8,9]. Liver resection has perioperative mortality and morbidity rates of 1%-3% and 30%, respectively[128]. Specifically, major hepatectomy for CRLM has a mortality and major morbidity of 1%-5% and 20%, respectively[9]. In resectability assessment, CRLM patients are considered "resectable", "borderline" or "unresectable" (Figure 3)[6]. The definition of borderline patients concerns technical and biological difficulties that reduce the possibility of achieving an R0 resection. Based on the European Society of Medical Oncology guidelines and multidisciplinary evaluation, three approaches are currently defined: Upfront liver surgery followed by adjuvant chemotherapy (FOLFOX or CAPOX schemes), perioperative chemotherapy (chemotherapy before and after surgery based on FOLFOX or CAPOX scheme), and upfront systemic chemotherapy plus biological agents followed by liver surgery[128]. Surgery planning is based on a "classic" approach with primary CRC resection and a "reverse" approach, where liver metastases are resected first[9,124,128]. The liver-first approach or reversed strategy is more appropriate for either asymptomatic CRC or in locally advanced CRC[6,9]. Classic and reverse surgery showed similar outcomes. In common clinical practice, patients have symptomatic primary tumors with bleeding, obstruction, and a high risk of perforation. For this population of patients, the classic procedure is more often indicated (Figure 3). The reverse approach is performed when the primary tumor is asymptomatic with the aim of reducing the risk of CRLM progression[6,128]. A better prognosis is documented in patients treated with liver resection, which includes a resection margin > 1 mm from the tumor border [128,129]. R1 resection is associated with a higher rate of intra-hepatic local recurrence. Combined colorectal and hepatic resection in one setting is reserved to patients with easy-to-resect primary cancers and limited hepatic disease[9]. Currently, no differences in surgical outcome or survival have been reported when comparing classic, synchronous and liver-first approaches[9,81]. Liver resection combined with chemotherapy offers the best chance of cure with a reported 5-year survival and 10-year survival of 33%-58% and 23%-39%, respectively[123]. Routine chemotherapy improves progression-free survival by 8% at 3 years[130]. Metastatic cancer cells can also remain dormant after obtaining R0 surgical resection[131]. In literature, the percentage of disappearing CRLM ranges from 2.7% to 37%[9]. Although disappearing CRLM cells are of great interest, no consensus on their management has been reached[132]. Disappearing CRLM should be resected whenever feasible because a conservative management of leaving disappearing hepatic lesions results in a local recurrence of 19%[9]. This is a complex topic and the incidence of disappearing CRLM is likely to increase with advances in chemotherapy. The current management of patients with CRLM is multidisciplinary. Current guidelines for major hepatectomy recommend a future liver remnant (FLR) of > 20%-25% in healthy patients, > 30% in patients treated with chemotherapy, and > 40% in cirrhotic patients[6,130]. If FLR is inadequate, a variety of techniques are indicated to induce hepatic hypertrophy, *i.e.,* portal vein embolization, two-stage hepatectomy, association of liver partition and portal vein ligation for staged hepatectomy (ALPPS). Technically, ALPPS consists in liver transection and ligation of the portal vein (first operative approach) followed by resection of metastatic liver segments[9]. Surprisingly, ALPPS causes great hepatic hypertrophy as compared to portal vein ligation with low perioperative risk and satisfactory survival in large hospitals[9]. Laparoscopy has become the gold standard for minor hepatectomies[133]. With implementation of surgical education and minimally invasive techniques, such as laparoscopy and robotic systems, major and extended hepatectomies have been progressively reported. Laparoscopic

liver resection (LLR) improves hospitalization and decreases complications as compared to open surgery[123]. LLR is commonly indicated for tumors located along the liver periphery (segment II, III, IVb, V and VI)[134]. For larger tumors located in superior or posterior hepatic segments, either robotic or hybrid approach (hand-assisted or laparoscopic-assisted open approach) has potential advantages and has overcome the limitations of laparoscopic procedures. After LLR, the reported overall survival at 1-, 3-, and 5-years is 88%, 69%, and 50%, respectively. For disease-free survival, the reported results at 1-, 3-, and 5-years are 65%, 43% and 43%, respectively[134]. Recent data confirm that simultaneous laparoscopic resection of CRC and liver metastases are safe and feasible with the same benefits in terms of oncological outcome compared with open approach[11,124]. Robotic surgery is considered one of the options for CRLM resection to ameliorate the technical limitations of LLR[135]. Robotic systems overcome the disadvantages of laparoscopic approach and facilitate complex surgical procedures such as right hepatectomy, left hepatectomy, central bisegmentectomy, and posterior sectionectomy[136]. Current evidence documents a longer operative time for robotic surgery for CRLM compared with open approach, but a significantly shorter hospital stay[137]. Robotic surgery for CRLM might achieve R0 resection with similar results in terms of overall and disease-free survival compared with open surgery. A multi-institutional analysis of ultrasound-guided robotic surgery for CRLM reported a curative resection rate of 92% in patients with a median tumor size of 2.7 cm (range 0.4-13 cm)[135]. In patients

with CRLM treated with major hepatectomy using robotic systems, 1-, 3-, and 5- year overall survival rates are 87%, 87% and 87%, while disease-free survival rates are 85%, 85% and 85%, respectively[136]. In a multi-center Italian experience, the reported 1- and 3-year disease-free survival is 83.5% and 41.9%, while the 1- and 3-year overall survival is 90.4% and 66.1%, respectively[135]. The open approach has still a role in treating CRLM, especially in patients with a previous history of abdominal open surgery, with synchronous colonic and liver disease and with large liver metastases (Figure 2). Current guidelines consider thermal ablation the gold standard to eliminate small unresectable CRLM[137]. Microwave ablation (MWA), radiofrequency ablation (RFA), irreversible electroporation (IRE) and stereotactic ablative body radiotherapy (SABR) are valid local treatment options for patients with CRLM (Figure 3)[137]. RFA uses alternating electrical current at the frequency of 400 MHz to generate thermal energy, while MWA uses electromagnetic waves with frequencies greater than 900 MHz. Ablative therapies are indicated for patients with unresectable CRLM in combination therapy with hepatectomy, and for patients with comorbidity that are unfit to undergo major surgery. Ablation procedure could be performed using open, laparoscopic or percutaneous approaches[137,138]. The final objective is to obtain complete ablation with 10 mm margins in all directions[9]. While RFA is susceptible to the heat-sink effect with its limits in treating hepatic lesions in close proximity of large vessels, MWA has demonstrated effective in reaching higher tissue temperatures with a more homogeneous tissue heating [138]. Ablative treatments are relatively safe and less invasive methods. The reported morbidity rate is 4%-9% and the mortality rate is 0%-2.0%. Common complications include postoperative bleeding, infections, pneumothorax, hepatic abscess, and biliary tract injury[138,125]. Regarding local tumor control, recurrence after RFA ranges from 4%-40%, while after MWA the reported range is from 6%-10%. Tumor size > 3 cm and ablation margin < 0.5 cm represent predictor factors of local recurrence. Patients with unresectable CRLM have shown a median disease-free survival of 6 mo and median overall survival of 24 mo after laparoscopic RFA[138]. Other studies have reported a median survival of 24-39 mo. 1-, 2-, 3-, and 5-year overall survival ranged from 73%-92%, 41%-72% and 20%-40% in patients with CRLM of 3-5 cm[125]. Median disease-free survival is around 12 mo in patients with CRLM of 4-5 cm. For CRLM > 3 cm, 1-, 2-, 3- and 5-year overall survival ranged from 74%-93%, 30%-70%, and 8%-31%. The reported median disease-free survival in CRLM > 3 cm is 12.4 mo[125]. In patients with difficult-to-reach anatomical lesions, some authors have suggested SABR as an alternative procedure to treat large and unresectable CRLMs[125]. An Italian study reported a 1-, 2-, and 3-year overall survival of 68%, 40% and 17%, respectively, in patients with CRLM > 3 cm. SABR seems to have benefits in local control of larger hepatic lesions compared with MWA. The reported pooled 1- and 2- year control rates are 67% and 59.3%, while 1- and 2-year overall survival are 67.2% and 56.5%, respectively[9,137]. Guidelines have defined SABR as a reasonable therapy for CRLM patients unsuitable for surgery or ablative therapies, but a definitive validation in a large randomized analysis is required[9]. A relatively new non-thermal ablative method for unresectable CRLM is represented by IRE[8]. It is a nonthermal ablation modality using high-voltage electric pulses that induce permanent cell membrane disruption by sparing ECM and preserving critical structures such as blood vessels and biliary ducts[8,9,137]. After IRE treatment, the reported median overall survival ranges from 19.7-32.4 mo[125]. The reported hepatic IRE efficacy varies from 45.5%-100%[8]. A phase II trial (COLDFIRE-2) has reported that IRE is an effective relatively safe treatment for CRLM of 5.0 cm or smaller, with an overall complication rate of 40% (infected biloma, portal vein thrombosis, embolic event, cardiac arrhythmias and acute myocardial infarction). Around 68% of patients are alive one year after IRE treatment, with a median overall survival of 2.7 years after first IRE, and 4.8 years after CRC resection[8]. IRE might be indicated for liver recurrence after previous percutaneous treatment. After repeated IRE, local tumor control is reached in 74% of patients[8]. IRE represents a new and attractive research field and should be considered for patients with oligometastatic CRLM of 5.0 cm or smaller, anatomically unsuitable for surgical procedure or thermal ablation. Although IRE is a promising technique, evidence of IRE in CRLM treatment is still under validation[137]. Liver transplantation is a rare procedure for CRLM patients but mounting evidence suggests survival benefits in selected instances[6]. CRLM prognosis strongly depends on node-positive primary CRC, disease-free interval from primary tumor resection and metastasis detection < 12 mo, hepatic lesion > 5 cm, carcinoembryonic antigen levels > 200 ng/mL and > 1 hepatic lesion. More than two reported prognostic determinants are related to poor prognosis[128]. Surgical resection remains the gold standard for CRLM patients. CRLM distribution, size and number may have prognostic value[6]. CRLM outcome might be improved only if a personalized treatment approach is taken into account, and this has to consider tumor biology, disease staging and patient condition[9].

Chemotherapy for CRLMs

Neoadjuvant chemotherapy has the advantage of down-staging metastatic disease to facilitate curative hepatic resection. It is indicated for patients with borderline resectable or unresectable CRLM with high surgery risk (Figure 3)[129]. First-line schemes consist in fluorouracil-based regimens containing oxaliplatin and/or irinotecan. Neoadjuvant therapy offers no survival advantage in resectable synchronous CRLM with a 5-year overall survival of 42%, which is similar to patients treated with upfront surgery[9,129]. Systemic oxaliplatin- or irinotecan-based chemotherapy constitutes the standard for CRLM patients in many countries[129,139]. Systemic treatments for CRLM consist in a combination of fluorouracil (plus leucovorin) and either irinotecan (FOLFIRI) or oxaliplatin (FOLFOX) plus

bevacizumab, or XELOX (capecitabine and oxaliplatin) and fluorouracil, leucovorin, oxaliplatin, and irinotecan (FOLFOXIRI)[7,129,140]. The choice of a primary line therapy is based on the physician choice and not on drugs, because irinotecan or oxaliplatin lead to similar results. Induction therapy with FOLFOXIRI plus bevacizumab improve CRLM outcome and increase incidence of some adverse events compared with FOLFIRI plus bevacizumab[140]. Several trials have shown that using anti-angiogenic bevacizumab in addition to systemic chemotherapy improves overall survival and progression-free survival[128]. Chemotherapy might downsize CRLM and 12%-54% of unresectable patients become resectable[7,129]. Adjuvant hepatic arterial infusion pump (HAIP) chemotherapy demonstrates promising results. In a phase II study based on the results of two high-volume centers in the Netherlands, the authors have demonstrated that adjuvant HAIP chemotherapy is safe and feasible in resectable CRLM patients[139]. Trans-arterial chemoembolization (TACE) is based on the infusion of high concentration of cytotoxic agents in liver metastases[9]. Usually, mytomycin C and cisplatin/doxorubicin are the conventional drugs for TACE[137]. This selective infusion of tumoricidal agents enhances the effect on liver tumor and minimizes the damage to normal liver. Hepatic arterial infusion chemotherapy (HAIC) represents an attractive strategy to expand resectability and tumor progression. Administration of chemotherapy into the hepatic artery is a selective procedure that allows drug delivery to the tumor with sparing of normal liver parenchyma[126,127]. Systemic side effects of HAIC are limited due to the high first-pass effect in the liver[140]. Most protocols no longer include the use of HAIC alone in favor of a combination therapy with HAIC plus systemic chemotherapy, for patients with initially unresectable CRLM[126]. Floxuridine has been the primary HAIC agent used in several studies by inserting a catheter in the gastroduodenal artery with the tip at the hepatic artery or by subcutaneous port[139]. Floxuridine improves overall survival of HAIC patients treated with concurrent systemic chemotherapy[6,139]. Floxuridine has been approved since 1971, but it is still not registered in Europe[140]. Systemic chemotherapy plus HAIC are associated with a response rate of 85% in patients with previous chemotherapy, and around 100% in chemotherapy naïve patients[6]. The combination of systemic chemotherapy and HAIC induces conversion to resectability in around 52% of patients.

Similar to TACE, selective internal radiation therapy (SIRT) is based on infusion of radiolabeled microspheres (Yttrium-90) in the branches of the hepatic artery (Figure 3)[9]. SIRT associated with systemic 5-FU prolonged progression-free survival in chemo-refractory patients[9]. Currently, data on the efficacy of Yttrium-90 radiotherapy are limited and should be interpreted with caution[137]. The use of irinotecan-loaded drug-eluting beads represents an emergent technique for administration of TACE in liver disease[129]. In addition, immunotherapy represents an alternative option to chemotherapy, for patients with CRLM derived from CRC with high MSI (MSI-H) or mismatch repair deficiency (dMMR)[129]. Pembrolizumab, a monoclonal antibody targeting PD-1 has been found of great interest in patients who had tumors with MSI-H and dMMR. Several trials are needed to evaluate the safety and efficacy of combined immune- and chemotherapy for CRLM patients with dMMR[129].

Wnt/β-catenin signaling pathway as a pharmacological target in CRLM patients

There are currently no approved drugs targeting Wnt/β-catenin pathway available for clinical use in CRLM patients, although several compounds capable of inhibiting Wnt/β-catenin signaling in advanced CRCs have been developed[52]. Inhibitory signaling molecules have been targeted towards the ability to form and secrete Wnt ligands (*e.g.*, PORCN) or towards their receptors and coreceptors (*e.g.*, FZD and LRP5/LRP6), or cytoplasmic proteins (*e.g.*, tankyrase and CK1alpha)[141].

Currently, some drugs that have an inhibitory effect on Wnt signaling are already used for CRC treatment[52]. They include indomethacin, pyrvinium, sulindac, aspirin, celecoxib and rofecoxid. Clinical trials are investigating the role of aspirin as an adjunctive drug for CRLM prevention[52,142,143]. As vitamin D deficiency is a common feature of patients with metastatic rectal cancer, its supplementation could be of great interest. Recently, a pilot study has examined the effect of vitamin D supplementation in patients with stage II-III CRC undergoing chemotherapy. Interestingly, the active form of vitamin D can promote binding of β-catenin to vitamin D receptor and increase expression of E-cadherin. The result is reduction of available β-catenin molecules that can bind to TCF/LEF transcription factors[52].

A phase I/II clinical trial has indicated that genistein combined with chemotherapy is an effective treatment for metastatic CRC. Genistein is a soy-derived isoflavone and phytoestrogen that inactivates Wnt signaling by regulating GSK3β and E-cadherin expression[52,143,144]. Other plant compounds such as curcumin and (-)-epigallocatechin-3-gallate can inhibit Wnt signaling by increasing β-catenin degradation[143,145]. A phase I trial has initially explored the efficacy and safety of curcumin in combination with 5FU in metastatic colon cancer and in combination with irinotecan for metastatic CRC patients[143].

The role of PORCN inhibitor LGK974 is under consideration in a phase II trial in a population of BRAF V600-mutated metastatic CRC patients, since in *vivo* studies have demonstrated that LGK974 inhibits tumor invasion and metastases[143,144]. Vantictumab (OMP-18R5) is a novel monoclonal antibody that interacts with FZD receptors[144]. To date, two phase I/II clinical trials are ongoing with OMP-18R5 modulating ligand/FZD-receptor interfaces, and with PRI-724 molecule interfering with β-catenin transcription[146].

OMP-18R5 inhibits CRC growth by synergizing with irinotecan[143]. OMP-54F28 is a recombinant protein that competes for binding with Fz8 receptor through sequestering Wnt ligands and inhibiting tumor growth[143,144,147,148]. Foxy-5, a Wnt5a peptide mimic, is evaluated in phase I-II clinical trials of metastatic CRC[147]. Secreted R-spondins (RSPO1-3) and their receptors RNF43/ZNRF3 are required to potentiate Wnt signaling in various conditions[144]. Rosmantuzumab (OMP-131R10), a monoclonal antibody against RSPO3 has been evaluated in phase I trial for metastatic CRC, but no results have been published[144]. Currently, phase I studies with anti-LGR5 and anti-RSPO3 therapies are under evaluation for patients with metastatic CRC. The tankyrase inhibitor IWR-1 has the potential to prevent tumor metastases by blocking Wnt/β-catenin pathway[140]. Besides developing new antagonistic molecules, pharmacological research could be directed towards repurposing non-oncology drugs, which are already active for other diseases, and evaluating natural compounds that may have an anti-inflammatory effect on TME. This theoretical concept might be valid for primary and secondary liver cancers. New drugs should be evaluated individually or in combination.

CONCLUSION

Wnt/β-catenin signaling pathway is an emerging target for cancer research and regulates liver metastasis through a complex network of interactions modulated by TME. Immune components of TME can modulate progression and metastatic capacity by promoting CRC cell survival. Proinflammatory molecules and maintenance of stemness through Wnt pathway may be considered potential therapeutic targets. Wnt signaling dysregulation activates downstream EMT by promoting cancer cell migration at the invasive front of the primary lesion. These biological mechanisms are not fully defined. Some evidence of invasive propensity and organ-specific tropism of metastatic tumor cells mirrors the concepts of "seed-soil", pre-niche and crosstalk between tumor and immune cells. Understanding the interdependence of these biological mechanisms can provide useful insight into CRLM treatment. Different cells participate to metastatization, and dormant cells show a leading role. Cancer dormancy is poorly understood in its complexity. It is of clinical importance to effectively identify and target dormant cells as potential drivers of CRLM with emphasis on Wnt/β-catenin deregulation and with the aim to reach a consensus in clinical management. Advances in the field of oncology have been made in the last decade and a central role for Wnt/β-catenin pathway has been recognized in CRC chemoresistance. At the current state of research, there is a lack of clear understanding of why and how CRC chemoresistance occurs, and thus, where exactly the opportunities for developing anti-CRLM therapies may lie. Although several compounds have been developed that inhibit Wnt/β-catenin signaling in advanced CRCs, there are currently no approved drugs targeting Wnt/β-catenin pathway and available for clinical use in CRLM patients. In this review, we considered current knowledge on clinical implication of Wnt signaling in CRLM process, provided the state of the art concerning potential biomarkers with a revision of surgical and non-surgical therapeutic guidelines for CRLM patients. Further efforts in translational medicine are needed to develop and validate novel therapies that antagonize both CRC cell metastatic capacity and their ability to be harbored in liver tissue.

Abstract

Biologic agents with various mechanisms against Crohn's disease (CD) have been released and are widely used in clinical practice. However, two anti-tumor necrosis factor (TNF) agents, infliximab (IFX) and adalimumab (ADL), are the only biologic agents approved by the Food and Drug Administration for pediatric CD currently. Therefore, in pediatric CD, the choice of biologic agents should be made more carefully to achieve the therapeutic goal. There are currently no head-to-head trials of biologic agents in pediatric or adult CD. There is a lack of accumulated data for pediatric CD, which requires the extrapolation of adult data for the positioning of biologics in pediatric CD. From a pharmacokinetic point of view, IFX is more advantageous than ADL when the inflammatory burden is high, and ADL is expected to be advantageous over IFX in sustaining remission in the maintenance phase. Additionally, we reviewed the safety profile, immunogenicity, preference, and compliance between IFX and ADL and provide practical insights into the choice of anti-TNF therapy in pediatric CD. Careful evaluation of clinical indications and disease behavior is essential when prescribing anti-TNF agents. In addition, factors such as the efficacy of induction and maintenance of remission, safety profile, immunogenicity, patient preference, and compliance play an important role in evaluating and selecting treatment options.

INTRODUCTION

Crohn's disease (CD) has become an important concern of clinicians owing to its rapidly increasing prevalence and incidence worldwide, including in emerging industrial countries[1]. Even though the incidence rate in Western countries has stabilised, most studies have revealed a statistically significant increase in the incidence of pediatric CD[2,3]. Pediatric patients with CD are more likely to have complications such as growth impairment, delayed puberty, psychosocial problems, aggressive disease course, and extensive gastrointestinal involvement than adult patients[4].

After infliximab (IFX) was approved by the Food and Drug Administration (FDA) in 1998[5], biologic agents with various mechanisms have been released and are widely used in clinical practice[6]. Among this broad spectrum of biologics, anti-tumor necrosis factor-α (TNF-α) agents have been classically used as first-line biologics for the treatment of moderate-to-severe CD refractory to conventional therapy[7]. Anti-TNF agents modulate the inflammatory response by binding to the TNF receptor on the cell membrane. IFX is a purified, recombinant DNA-derived chimeric human-mouse immunoglobulin G monoclonal antibody. Adalimumab (ADL) is a human monoclonal antibody that binds specifically to TNF-α[8,9]. Anti-TNF agents, such as IFX and ADL, are the only biologic agents that are currently approved by the FDA for pediatric patients with CD (Table 1)[10,11]. Therefore, the initial biologic agents to modify the disease course of CD and to achieve the therapeutic goal should be chosen more carefully in pediatric patients with CD.

Although head-to-head trials are the gold standard method for determining which treatment option is more effective, to date, no head-to-head trials have directly compared biologic agents. Until direct comparative studies of which biologic agents should be used first are performed, several points must be considered when selecting the initial biologic agent. In this study, we provide practical insights into the choice of anti-TNF therapy in pediatric CD. We reviewed the comparative efficacy, safety profile, immunogenicity, preference, and compliance between IFX and ADL.

MAIN STUDIES IN PEDIATRIC CD ASSESSING THE EFFICACY OF ANTI-TNFα THERAPIES

Anti-TNFα therapies have been well studied in adults and have showed efficacy in both the induction and maintenance of remission[12,13]. Targan *et al*[14] found that after a single 5 mg/kg IFX infusion, more than 80% of patients had a clinical response after four weeks. In the ACCENT-I study in which 58% of 573 patients with CD who had a response after the first dose of IFX were randomised, the IFX 5 mg/kg and 10 mg/kg groups were more effective in achieving clinical remission at week 54 than the placebo group[15].

After IFX and ADL were approved for use in the treatment of pediatric CD in 2006 and 2012, respectively, more than 20 years of data, including those from clinical trials, have been accumulated. There is evidence from randomised controlled trials (RCT) involving open-label induction and randomised dose-ranging maintenance therapies (Table 2). Four RCTs conducted on pediatric CD treated with anti-TNF agents showed the clinical remission rate in both the induction and maintenance periods[16-19].

The first RCT with IFX in pediatric patients with CD showed clinical response and remission in the induction and maintenance phases[16]. Among 112 patients, 99 patients (88.4%) responded to IFX, and 66 patients (58.9%) showed clinical remission at week 10. Patients responding to IFX were randomly assigned to receive IFX 5 mg/kg every 8 or 12 wk. By week 54, 63.5% of patients receiving IFX every eight weeks had a clinical response, and 55.8% achieved clinical remission, which is significantly higher than the clinical remission rate of 23.5% in those who received IFX every 12 wk. Ruemmele *et al*[17] also demonstrated the efficacy of IFX in pediatric patients with CD. Forty patients received IFX according to the induction regimen (weeks 0, 2, and 6) and were then randomly assigned to maintenance therapy of

Table 1 Biologic agents currently used or under study for the treatment of pediatric Crohn's disease

Class	Biologics	FDA approval for CD	Pediatric CD indications
Anti-TNF	Infliximab	Adult: 1998; Pediatric: 2006	Moderate to severe diseases refractory to conventional therapy[10]
	Adalimumab	Adult: 2007; Pediatric: 2012	First-line therapy for patients with CD who are at risk for progressive disease or for whom corticosteroids may exacerbate underlying conditions[10]; Prophylactic therapy for preventing postoperative recurrence in high-risk patients[10]
Anti-α4β7 integrin	Vedolizumab	Adult: 2014; Pediatric: N/A	Guideline recommendations for this pediatric indication are not yet available
IL-12/23 p40 inhibitor	Ustekinumab	Adult: 2016; Pediatric: N/A	Second-line biologic therapy after anti-TNF agent failure[11]

FDA: Food and Drug Administration; CD: Crohn's disease; TNF: Tumor necrosis factor; IL: Interleukin; N/A: Not applicable.

CD: Crohn's disease; RCT: Randomised controlled trial; IFX: Infliximab; PCDAI: Pediatric Crohn's disease activity index; NA: Not applicable; ADL: Adalimumab; HD: High dose; LD: Low dose; TDM: Therapeutic drug monitoring.

IFX infusion every two months or an on-demand regimen. Around 85.0% of patients achieved clinical remission during IFX induction therapy. After the induction phase, the relapse rate was significantly higher in the on-demand group (91.7%) than in the IFX-maintenance group (23.1%).

A double-blind RCT evaluating the efficacy and safety of a dose-dependent maintenance regimen with ADL following open-label, weight-adjusted induction therapy (IMAgINE-1) was conducted on both IFX-naïve patients and patients who did not respond to IFX therapy[18]. In patients who had a clinical response in the induction phase, 38.7% and 33.5% of clinical remission was observed at week 26 and week 52, respectively. In addition, there was no statistically significant difference between the high- and low-dose groups. In a recently published RCT conducted in anti-TNF-naïve pediatric patients with CD, the clinical remission rate after the induction phase was much higher than that in the IMAgINE-1 study (48%-82% *vs* 38.7%)[19]. These results are in line with findings from previous adult studies[12,13] and highlight the importance of the choice of initial biologic agents according to risk stratification.

ANTI-TNFα AND ITS INDICATIONS FOR PEDIATRIC CD

The indications for the use of biologic agents have changed over the last two decades since the introduction of anti-TNF agents for the treatment of pediatric CD. Previously, anti-TNF agents were considered when disease activity was not controlled despite conventional therapies such as immunomodulators (IMMs), the so-called step-up strategy[16]. However, the guidelines recently published by the European Society of Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) recommended early anti-TNF treatment within < 3 mo after diagnosis for the induction of remission in moderate-to-severe pediatric CD with a high risk of complications such as extensive disease, deep colonic ulcers, perianal disease, stricturing (B2), or penetrating disease (B3), growth impairment, the so-called top-down strategy[20]. The RISK study demonstrated that early induction therapy with anti-TNF agents was associated with higher corticosteroid- and surgery-free remission rated at 1 year compared to induction with exclusive enteral nutrition (EEN) and corticosteroids[21]. Kugathasan *et al*[22] also reported that early induction therapy with anti-TNF agents significantly lowered the risk of penetrating (B3) complications, however did not seems to reduce the risk of stricturing (B2) complications. In addition, even in patients with low risk of poor outcome, anti-TNF therapy should be considered in patients with severe growth impairment or who have not achieved clinical (pediatric CD activity index < 10) and biochemical remission (fecal calprotectin < 250 μg/g) despite induction therapy with EEN or corticosteroids[20].

Walters *et al*[21] reported that early anti-TNF therapy was more effective at maintaining remission than IMM monotherapy [relative risk (RR), 1.41; 95%CI: 1.14-1.75; P = 0.0017]. In addition, a prospective study in 76 pediatric patients with CD compared the step-up group and the top-down group in terms of endoscopic healing[23]. Compared with that in the step-up strategy, the rate of achieving endoscopic healing at week 54 was higher in the top-down group of pediatric patients with CD (42% *vs* 72%, P = 0.007), which means that seizing the therapeutic window of opportunity in pediatric CD should be considered earlier than generally accepted[24]. Based on these results, guidelines suggest that either IFX or ADL can be provided to pediatric patients with CD who have not previously received anti-TNF therapy, taking into account the efficacy, route of administration, and preference.

Standard dosing of IFX is weight-based at 5 mg/kg at weeks 0, 2, and 6, followed by maintenance treatment every 8 wk. In the case of ADL, patients weighing < 40 kg received 80/40 mg, and those weighing ≥ 40 kg received 160/80 mg in the first 2 wk. Thereafter, patients weighing < 40 kg were administered 20 mg, and patients weighing ≥ 40 kg were administered 40 mg every 2 wk. Dose escalation is considered in patients who lose response to standard anti-TNF treatment; adjustment of the infusion interval to 4 or 6 wk or an increment in the dose of 10 mg/kg for IFX; and adjustment of the administration interval to every week for ADL. Especially, children at risk for accelerated IFX clearance during induction [*i.e.*, patients < 30 kg, those with extensive disease, and those with low serum albumin] require dose escalation to achieve target trough levels (TLs) or their first proactive therapeutic drug monitoring (TDM) at the second or third anti-TNF infusion[25].

EFFICACY OF ANTI-TNF THERAPY IN PEDIATRIC CD

Comparative efficacy of anti-TNF agents for induction of remission in CD

Head-to-head trials, in which each drug or treatment strategy is compared formally, are the gold standard method for comparing distinct therapies[26]. However, there are currently no head-to-head trials of biologic agents in pediatric or adult CD. Owing to the absence of results, the choice of IFX or ADL relied on expert opinion, real-world data, or indirect comparison of biologic agents. Unfortunately, for pediatric patients with CD, there is a lack of accumulated data, which requires the extrapolation of adult data for the positioning of biologics in pediatric CD.

In 2018, the results of a network meta-analysis that indirectly compared the efficacy of FDA-approved biologic agents in the treatment of CD, which included IFX, ADL, vedolizumab, ustekinumab, and certolizumab pegol, were published[27,28]. When IFX and ADL were compared with respect to the efficacy of remission induction, IFX was ranked higher than ADL [surface under the cumulative ranking (SUCRA) 0.93 *vs* 0.75] for inducing clinical remission in biologic-naïve patients with moderate-to-severe CD. Additionally, IFX was predicted to be more effective in induction therapy than ADL; the rates of achieving clinical remission with induction therapy were 59.6% and 48.7% for IFX and ADL, respectively.

These findings are partly explained by differences in the pharmacokinetics or tissue penetration of IFX and ADL[29]. Drug levels of IFX and ADL show completely different patterns over time after administration. Intravenous (IV) formulations, such as IFX, show the highest concentrations with administration, and the concentrations gradually decrease over time, dropping to the lowest level just before the next administration, that is, to the TLs. In the case of subcutaneous (SC) formulations, including ADL, the concentrations at the time of administration, at the peak point, and at the lowest point are similar[30]. Because IFX has relatively large fluctuations in drug levels according to the drug infusion type, it is necessary to increase drug levels during the induction phase to maintain TLs,

whereas ADL maintains relatively constant drug concentrations.

Post-induction TLs, which can modulate inflammation in patients with high disease and inflammatory burdens, differ according to the type of anti-TNF agent used. In Figure 1A[31], we assumed the threshold of drug levels to control the inflammatory burden in the induction phase as the purple dotted line. IFX exhibits higher TLs than ADL during the induction phase, which is beneficial for maintaining post-induction TLs above the threshold required for treatment in patients with severe inflammation. Therefore, IFX might be more advantageous than ADL in patients with a high inflammatory burden owing to differences in the pharmacokinetics of the two anti-TNF agents during the induction period.

Specifically, a post-hoc analysis of the ACCENT-I study found that high IFX TLs after induction therapy were a key factor in maintaining response after one year of treatment[32]. The study revealed that more than 3.5 μg/mL of post-induction TLs of IFX was associated with a durable, sustained response to maintenance therapy. Feng *et al*[33] reported that post-induction TLs of IFX were correlated with endoscopic healing, and the median TLs in patients who achieved endoscopic healing after the induction of IFX were 7.5 μg/mL.

Similar to adult inflammatory bowel disease (IBD), higher post-induction IFX TLs were the only independent factor that predicted clinical or biochemical remission and durable sustained response during the first year of treatment in pediatric IBD[34]. Singh *et al*[35] reported that cut-off levels of > 3, > 4, > 7 μg/mL of IFX TLs had positive predictive values of 64%, 76%, and 100%, respectively, for predicting persistent remission in pediatric IBD. Recently, El-Matary *et al*[36] showed that higher post-induction IFX TLs had a strong relationship with the healing of the fistula in pediatric perianal CD. The post-induction IFX TLs in the clinical responder group were higher than those in the non-responder group (12.7 μg/mL *vs* 5.4 μg/mL, $P = 0.002$).

Likewise, post-induction TLs of ADL correlated with clinical and biochemical remission[37,38]. Zittan *et al*[37] reported that ADL TLs at week 4 were higher in the biological remission group than in the non-responder group of adult patients with CD (19.8 μg/mL *vs* 10.2 μg/mL, $P = 0.001$). After induction therapy, it was shown that similar to adult CD, there was a positive relationship between ADL TLs and clinical outcomes in pediatric CD[38]. The cut-off values of ADL TLs at weeks 4 and 8 to predict clinical and biological remission at week 24 were 22.5 μg/mL and 12.5 μg/mL, respectively.

Although the cut-off values of post-induction TLs for regulating the inflammatory burden at anti-TNF initiation are different for IFX and ADL, it is anticipated that the higher the post-induction TLs, the higher the clinical and endoscopic remission rate. Considering the pharmacokinetics of the route of administration, IFX can reach drug levels above the threshold in a shorter period of time than ADL and exhibits a rapid response of induction. Therefore, predictions based on the pharmacokinetics of anti-TNF agents and the difference in remission according to post-induction TLs show that IFX is more advantageous than ADL when the inflammatory burden is high.

Comparative efficacy of anti-TNF agents for maintenance of remission in CD

As with the selection of anti-TNF agents for the induction of remission, there are no head-to-head trials comparing the efficacy of maintenance therapy between IFX and ADL. According to a network meta-analysis study conducted in adults, ADL was superior to IFX in the maintenance phase, in contrast to the induction phase. In biologic-naïve adult patients with moderate-to-severe CD, the SUCRA of maintaining remission over one year was 0.97 and 0.68 for ADL and IFX, respectively[27,28].

These results can also be explained by the differences in the pharmacokinetics of IFX and ADL. For IV drugs, a clear distinction can be made among the peak, intermediate, and trough concentrations available for TDM. However, for SC drugs, there is no clear distinction among the peak, intermediate, and trough concentrations. In the case of SC drugs, the sampling time for TDM is less important because the TLs of SC drugs are kept relatively constant because not only is frequent administration required but also the absorption rate is relatively low[29].

Figure 1B shows the concentration changes in IFX and ADL during the maintenance phase, and the purple dotted line indicates the threshold for controlling the inflammatory burden during the maintenance phase[31]. The drug level of IFX tends to be lower than the threshold as it approaches the trough time, whereas the drug level of ADL is continuously maintained above the threshold because of the relatively constant levels of ADL. In the maintenance phase, it is important to keep the drug concentrations above the threshold to not only inhibit the formation of anti-drug antibodies (ADAs) but also to suppress the occurrence of loss of response and increase the durability of anti-TNF agents. Owing to the differences in the pharmacokinetics of the two anti-TNF agents, ADL might be more advantageous than IFX in the maintenance phase.

The association between IFX TLs in the maintenance phase and clinical outcomes has been demonstrated in many studies conducted on adults. One meta-analysis indicated that patients who achieved clinical remission had significantly higher IFX TLs than those who did not achieve remission during the maintenance phase (3.1 μg/mL *vs* 0.9 μg/mL)[39]. In addition, it has been shown in several studies that IFX TLs in the maintenance phase are an important prognostic factor in achieving endoscopic healing. Another study revealed that the only factor associated with endoscopic healing was an increase in IFX TLs > 0.5 μg/mL (likelihood ratio, 2.02; 95%CI: 1.01-4.08; $P = 0.048$) in patients with IBD[40]. Additionally, Yarur *et al*[41] demonstrated a correlation between IFX TLs and fistula healing [area under the curve (AUC), 0.82; $P < 0.0001$]. Likewise, higher maintenance IFX TLs were associated

with clinical and biochemical remission in pediatric patients with CD[42]. Recently, it has been reported that IFX TLs during maintenance treatment are important determinants of endoscopic healing as well as clinical remission in pediatric patients with CD. According to this study, IFX TLs to achieve endoscopic remission with 80% specificity were ≥ 5 μg/mL[43].

Similar to IFX, maintenance TLs of ADL were associated with clinical and laboratory responses in adult patients with CD[44]. The study showed that ADL TLs were associated with clinical remission (AUC, 0.748; $P < 0.001$), with an optimal cut-off value for predicting clinical remission of 5.85 μg/mL (sensitivity, 68%; specificity, 70.6%). In addition, Zittan *et al*[45] conducted a large, homogenous CD cohort study which revealed that patients with endoscopic healing have higher ADL TLs during the maintenance phase than those without endoscopic healing (14.7 μg/mL *vs* 3.4 μg/mL, $P < 0.001$). Similar results were found in studies conducted on pediatric patients with CD. The IMAgINE-1 study showed that patients with clinical remission at week 26 had slightly higher ADL TLs than those without remission (11.3 μg/mL *vs* 10.5 μg/mL, $P = 0.028$)[46]. Choi *et al*[47] reported that pediatric patients with endoscopic healing had significantly higher ADL TLs at week 16 than those without endoscopic healing (13.0 μg/mL *vs* 6.2 μg/mL, $P = 0.023$).

As can be inferred from the above studies, clinical remission and endoscopic healing can be achieved when the drug concentrations are sustained above the threshold despite the difference in the cut-off values for withstanding the inflammatory burden in the maintenance phase between IFX and ADL. Considering the pharmacokinetics of the maintenance phase, ADL maintains drug levels more constantly than IFX; therefore, it is expected that ADL is more advantageous in sustaining remission than IFX in the maintenance phase.

IMMUNOGENICITY OF ANTI-TNF AGENTS

Although anti-TNF agents are effective in patients with CD refractory to conventional therapy, loss of response increases over time, and approximately, half of patients among primary responders require dose escalation[48]. Among patients receiving anti-TNF agents, 60%-87% of patients show clinical remission or partial response in the induction phase, and less than 40% of patients maintain clinical remission at one year[49]. Immunogenicity due to the formation of ADAs to anti-TNF agents as the main reason for the loss of response.

Immunogenicity to anti-TNF agents develops when the immune system of patients recognises drugs as antigens and triggers the formation of ADAs. ADAs accelerate drug clearance by the reticuloendothelial system and neutralise drugs by binding to anti-TNF agents[50]. Additionally, suboptimal TLs of anti-TNF agents are associated with a more immunogenic state, which leads to lower efficacy and greater loss of response[37,51,52]. Higher body weight, the development of ADAs to anti-TNF agents, a low albumin level, and an elevated C-reactive protein level are the covariates that accelerate the clearance of anti-TNF agents[53-56].

Vermeire *et al*[57] reported that the rate of ADA formation in IBD patients receiving IFX was up to 65.3% and that in patients receiving ADL was 38.0%. Theoretically, as ADL is a humanised monoclonal antibody, it is thought that the incidence of immunogenicity in the human body is lower than that for IFX, which is a monoclonal chimeric anti-TNF antibody (partly murine, partly human). Therefore, ADL was superior to IFX in terms of immunogenicity.

ANTI-TNF AGENTS FOR GROWTH IMPROVEMENT

In Selecting Therapeutic Targets in IBD-II, restoration of normal growth was established as an intermediate target for pediatric patients[58]. Therefore, a very important goal in treatment for pediatric patients with CD is to normalise the linear growth.

To date, no study has compared the effects of IFX and ADL on the restoration of linear growth. Studies have shown that each of the two anti-TNF agents has a positive effect on the recovery of normal growth. In the case of IFX, there is a study published on the restoration of growth as well as clinical response and endoscopic healing in 195 pediatric patients with CD[59]. The effect on the recovery of linear growth was greater when IFX was administered at the Tanner 1-2 stage with growth potential than at the Tanner 4-5 stage. Another study showed that early administration of IFX within one month after diagnosis was more effective for linear growth than the conventional step-up therapy ($P = 0.026$) [60]. For Tanner stage 4-5 patients receiving IFX, there was no statistically significant difference in height z-score between patients with early IFX administration and those with the conventional step-up therapy ($P = 0.438$). However, in patients with Tanner 1-2, the restoration of growth was significantly improved in patients with early IFX administration ($P = 0.016$).

Similarly, it was reported that ADL was effective in restoring linear growth at weeks 26 and 52 compared with baseline in patients with growth impairment at diagnosis (median height z-score, baseline, -3.25; 26 wk, -0.34; 52 wk, 0.21, $P < 0.001$)[61]. Additionally, Matar *et al*[62] showed that ADL improves weight as body mass index as well as linear growth after 72 wk of treatment.

SAFETY AND ADVERSE EVENTS DURING ANTI-TNF THERAPY

From an immunological point of view, as TNFα is a cytokine responsible for macrophage activation, neutrophil recruitment, and granuloma formation, anti-TNF agents are associated with an increased risk of infection, especially granulomatous infection[63]. Dulai *et al*[64] reported that the rate of serious infectious disease in pediatric patients with IBD who were treated with anti-TNF agents was similar to that of pediatric patients who received IMMs [352/10000 *vs* 33/10000 patient-years of follow-up evaluation (PYF); 95%CI: 0.83-1.36] but significantly lower than that of adult patients (654/10000 PYF; 95%CI: 0.43-0.67). In addition, the risk of infection is higher when anti-TNF agents are administered in combination with IMMs than with anti-TNF monotherapy (RR, 1.19; 95%CI: 1.03-1.37)[65]. According to a network meta-analysis of adult studies that indirectly compared IFX and ADL, IFX had a lower risk of any infection (SUCRA, 0.83) than ADL (SUCRA, 0.22)[27].

Previous studies have shown the risk of malignancy and lymphoproliferative disorders with IBD treatment, particularly with thiopurine and anti-TNF agents. Based on a meta-analysis of 49 randomised placebo-controlled studies comprising 14590 adult patients, there was no evidence related to an increased risk of malignancy with the use of biologic agents including IFX or ADL (odds ratio, 0.90; 95%CI: 0.54-1.50)[66]. Studies with pediatric patients also showed similar results to those of adult studies. In a study conducted using the DEVELOP registry including 5776 pediatric patients with IBD treated with anti-TNF agents, malignancy occurred in 15 patients[67]. An increased risk of malignancy was found in patients treated with thiopurine when a stratified analysis of thiopurine exposure was performed regardless of biologic agents. Even though the standardised incidence of malignancy for thiopurine exposure was 2.43 when compared to the prevalence in healthy children, no significant increase in the incidence of malignancy was observed in children who were only exposed to IFX.

Recent studies showed that the most common complications in patients with IBD treated with anti-TNF agents were dermatologic complications such as psoriasis, eczema, and skin infection[68]. Similarly, the frequency of skin problems appears to be high in pediatric patients with CD on anti-TNF. When comparing patients treated with IFX and ADL, the rate was much higher in IFX-treated patients than in ADL-treated patients. In a pediatric retrospective, large cohort study comprising 409 patients, 11.5% of patients showed at least one dermatologic complication. Among them, 35 were treated with IFX and 12 with ADL. In particular, among patients who developed psoriasis, the proportion of patients treated with IFX was significantly higher than that of those treated with ADL (84.8% *vs* 15.2%, $P = 0.05$) [69]. Additionally, Hradsky *et al*[70] reported that the only predictive factor for any dermatologic complication in pediatric CD was IFX therapy (*vs* ADL, hazard ratio, 2.07; 95%CI: 1.03-4.17).

EFFECTS OF CONCOMITANT IMM TREATMENT

For patients starting on IFX, combination therapy with IMM including azathioprine (AZA) and methotrexate (MTX) is recommended. As the first RCTs regarding the comparison of combination therapy of IFX and AZA with monotherapy of IFX or AZA, the SONIC trials showed the superiority of combination therapy to monotherapy regarding clinical remission, endoscopic healing, pharmacokinetics, and immunogenicity in adult patients with CD[71]. At week 30, ADAs developed in only 0.9% of patients receiving combination therapy, whereas these were produced in 14.6% of patients receiving IFX monotherapy, leading to higher IFX TLs in the combination therapy group than in the IFX monotherapy group (3.5 μg/mL *vs* 1.6 μg/mL, $P < 0.001$). Additionally, the combination therapy group was more likely than the IFX or AZA monotherapy group to achieve corticosteroid-free clinical remission and endoscopic healing. Likewise, it was revealed that the combination of IFX plus MTX had a lower ADA development (4% *vs* 20%, $P = 0.01$) and higher IFX TLs (6.35 μg/mL *vs* 3.75 μg/mL, $P = 0.08$) than IFX monotherapy in the COMMIT trial conducted in adult[72].

No RCT has compared the effects of combination therapy with IFX and IMM and IFX monotherapy in pediatric CD. A retrospective study conducted on 229 pediatric patients with CD confirmed that combination therapy with IFX and AZA reduced the formation of ADAs and loss of response compared to IFX monotherapy[73]. Moreover, pediatric patients who were treated with IFX monotherapy had a lower probability of remaining ADA than patients with combination therapy at 12, 24, and 36 mo after induction of IFX (72.6% *vs* 93.4%, 57.7% *vs* 91.0%, and 48.1% *vs* 91.0%, respectively). Similarly, pediatric studies comparing combination of IFX plus IMM (including AZA and MTX) and IFX monotherapy reported results similar to those in adult studies[59,74,75]. Therefore, up-front anti-TNF agents in combination with IMMs should be considered in patients with high risk of poor outcomes such as perianal disease, structuring (B2) or penetrating (B3) disease behaviour or severe growth impairment.

A meta-analysis comparing the efficacy of combination therapy of ADL and IMMs and ADL monotherapy in adult CD revealed that the induction of remission rate of ADL monotherapy was lower than that of combination therapy with IMMs, although the maintenance of remission was comparable [76]. In contrast to the results of studies on adults, a post-hoc analysis of the IMAgINE-1 study found that combination therapy of ADL and IMMs is not superior to ADL monotherapy in terms of pharmacokinetics, efficacy, and safety in pediatric patients with CD[77]. Clinical response and remission rates

were comparable in patients treated with combination therapy and ADL monotherapy at weeks 4, 26, and 52. Regarding pharmacokinetics, there were no significant differences in the mean TLs between the two groups. These results are in line with the findings of other studies showing that combination therapy with ADL and IMMs was not more effective than ADL monotherapy in pediatric CD[48,78].

Therefore, the recently updated ESPGHAN guidelines for the medical treatment of CD in children and adolescents recommend combination therapy with IFX and IMMs, whereas ADL monotherapy can be an alternative to combination therapy with IMMs[20].

PREFERENCES OF PATIENTS AND PARENTS

There are several differences between IFX and ADL. However, the primary difference is the mode of administration. The IV delivery of biotherapeutics has the advantage of being able to elicit a relatively rapid induction of response and is suitable for administering a large volume of drugs. On the other hand, SC formulations have the advantage of requiring fewer frequent visits to the clinic and being less invasive than IV administration[79]. Because of these differences in the route of administration, not only the efficacy of anti-TNF agents but also the preference of patients and caregivers for the delivery of drugs should be considered.

In a study conducted on rheumatoid arthritis patients treated with anti-TNF agents, patients under the age of 61 years showed a tendency to prefer SC preparations to IV preparations owing to the convenience of administration[80]. Similarly, a study conducted on adult patients with CD in Switzerland also showed the same results. The patient's choice of a specific anti-TNF agent was influenced by the convenience of use (69%), time required for treatment (34%), frequency of drug administration (31%), scientific evidence for efficacy (19%), and fear of syringes (10%). For these reasons, most patients prefer SC rather than IV injection when choosing anti-TNF agents[81].

However, a recent study conducted on anti-TNF selection in Korea reported the opposite result. Among 189 anti-TNF naïve patients with CD, 63.5% of patients preferred IFX, and 36.5% of patients preferred ADL[82]. In contrast to Western studies, the reason for choosing the IV route of administration over the SC route was the reassurance from the presence of doctors (68.3%).

The differences in results of these studies seem to show differences between Western and Eastern countries in terms of culture and medical environments. Unlike Western countries, Asia has a cultural context in which patients have relative interdependence in the decision-making process during treatment[83]. Therefore, characteristics, daily life, preferences, and cultural differences between patients and caregivers should be considered when selecting biologic agents for the treatment of pediatric patients with CD. Clinicians should discuss the route of administration of biologic agents with patients and their caregivers before prescribing anti-TNF therapy.

ADHERENCE TO ANTI-TNF AGENTS

Low compliance and delayed administration of anti-TNF agents are highly related to the formation of ADAs, which can lead to adverse events and loss of response due to low TLs[84,85]. In the treatment of patients with CD, adherence to anti-TNF agents plays an important role in improving treatment efficacy and patient outcomes. The rate of adherence to anti-TNF agents is known to be approximately 70% in patients with CD[86]. When the adherence rates of IFX and ADL were compared, the adherence rate of IFX was 66%-85%, and that of ADL was 55[87-89], with an RR of 0.76 (95%CI: 0.64-0.91)[86].

The difference in adherence between IFX and ADL is thought to be caused by the route of administration, intervals of injection, and supervision of clinicians during the injection. Adherence could be controlled in favour of IFX because the administration of IV drugs requires patient visits to an outpatient clinic.

However, special circumstances, such as coronavirus disease 2019 (COVID-19), may lead to different results. In 2020, the Pediatric IBD Porto Group of ESPGHAN published a society paper[90]. While investigating and reporting the experience of pediatric IBD management during the COVID-19 situation in China and South Korea, it has been recommended that standard treatment be not stopped or delayed. During the COVID-19 pandemic period, anti-TNF infusion delays were reported in 28% of cases in China and 5% in Korea, and exacerbation of disease among delayers was reported in 21% and 23%, respectively. The difference in infusion delay between the two countries may have been contributed to some extent by social factors such as social distancing or lockdown. However, it can be assumed that the main reason is that self-injectable ADL is not available in China, and only IFX, which requires an outpatient visit and IV infusion, can be administered. Therefore, when contagious diseases such as COVID-19 are spreading, ADL might have an advantage in terms of adherence to IFX.

CONCLUSION

Anti-TNF agents have proven to be effective in endoscopic, clinical, and biochemical remission in pediatric patients with moderate-to-severe CD. However, careful anti-TNF therapy is required because of the limitations of biologics approved for pediatric patients. Careful evaluation of clinical indications and disease behavior is essential when prescribing anti-TNF agents. In addition, factors such as the efficacy of induction and maintenance of remission, safety profile, immunogenicity, patient preference, and compliance play an important role in evaluating and selecting treatment options (Figure 2)[20]. Larger cohorts and clinical trials comparing groups based on risk stratification are needed to provide more effective and personalised treatment strategies for pediatric patients.

Abstract

BACKGROUND

Hepatic fibrosis is a serious condition, and the development of hepatic fibrosis can lead to a series of complications. However, the pathogenesis of hepatic fibrosis remains unclear, and effective therapy options are still lacking. Our group identified hepatitis C virus nonstructural protein 3-transactivated protein 1 (NS3TP1) by suppressive subtractive hybridization and bioinformatics analysis, but its role in diseases including hepatic fibrosis remains undefined. Therefore, additional studies on the function of NS3TP1 in hepatic fibrosis are urgently needed to provide new targets for treatment.

AIM
To elucidate the mechanism of NS3TP1 in hepatic fibrosis and the regulatory effects of calcitriol on NS3TP1.

METHODS
Twenty-four male C57BL/6 mice were randomized and separated into three groups, comprising the normal, fibrosis, and calcitriol treatment groups, and liver fibrosis was modeled by carbon tetrachloride (CCl_4). To evaluate the level of hepatic fibrosis in every group, serological and pathological examinations of the liver were conducted. TGF-β1 was administered to boost the *in vitro* cultivation of LX-2 cells. NS3TP1, α-smooth muscle actin (α-SMA), collagen I, and collagen III in every group were examined using a Western blot and real-time quantitative polymerase chain reaction. The activity of the transforming growth factor beta 1 (TGFβ1)/Smad3 and NF-κB signaling pathways in each group of cells transfected with pcDNA-NS3TP1 or siRNA-NS3TP1 was detected. The statistical analysis of the data was performed using the Student's *t* test.

RESULTS
NS3TP1 promoted the activation, proliferation, and differentiation of hepatic stellate cells (HSCs) and enhanced hepatic fibrosis *via* the TGFβ1/Smad3 and NF-κB signaling pathways, as evidenced by the presence of α-SMA, collagen I, collagen III, p-smad3, and p-p65 in LX-2 cells, which were upregulated after NS3TP1 overexpression and downregulated after NS3TP1 interference. The proliferation of HSCs was lowered after NS3TP1 interference and elevated after NS3TP1 overexpression, as shown by the luciferase assay. NS3TP1 inhibited the apoptosis of HSCs. Moreover, both Smad3 and p65 could bind to NS3TP1, and p65 increased the promoter activity of NS3TP1, while NS3TP1 increased the promoter activity of TGFβ1 receptor I, as indicated by coimmunoprecipitation and luciferase assay results. Both *in vivo* and *in vitro*, treatment with calcitriol dramatically reduced the expression of NS3TP1. Calcitriol therapy-controlled HSCs activation, proliferation, and differentiation and substantially suppressed CCl_4-induced hepatic fibrosis in mice. Furthermore, calcitriol modulated the activities of the above signaling pathways *via* downregulation of NS3TP1.

CONCLUSION
Our results suggest that calcitriol may be employed as an adjuvant therapy for hepatic fibrosis and that NS3TP1 is a unique, prospective therapeutic target in hepatic fibrosis.

Core Tip: We proved that hepatitis C virus nonstructural protein 3-transactivated protein 1 (NS3TP1) promoted hepatic fibrosis *via* the transforming growth factor beta 1/Smad3 and NF-κB signaling pathways. Calcitriol attenuates liver fibrosis through NS3TP1-mediated above both signaling pathways. These novel findings profoundly expand our knowledge about the mechanisms underlying the role and function of NS3TP1 in hepatic fibrosis. The relationship between NS3TP1 and liver fibrosis was discussed for the first time and provided a foundation for research related to liver fibrosis by targeting NS3TP1. We first showed that calcitriol alleviated hepatic fibrosis through the above signaling pathways *via* NS3TP1.

INTRODUCTION

Hepatic fibrosis is a dynamic process that occurs in any type of chronic liver damage that causes a net increase in the extracellular matrix. Further development of liver fibrosis can lead to liver cirrhosis and a series of complications[1,2]. Early intervention for liver fibrosis is crucial, but currently, there is no

effective treatment. Therefore, additional studies on the mechanism of liver fibrosis are urgently needed to provide new targets for treatment.

The open reading framework region of the hepatitis C virus (HCV) genome consists of a core protein region, envelope protein region and a nonstructural protein region. The NS3 gene is located in the nonstructural protein region of the HCV genome and it has serine protease activity and RNA helicase activity. HCV NS3 is crucial for the maturation and replication of the HCV RNA protein[3]. Moreover, this gene contributes to the occurrence of hepatic fibrosis through interaction with host cell components [4]. In this study, we screened and cloned HCV nonstructural protein 3-transactivated protein 1 (NS3TP1) by suppressive subtractive hybridization and bioinformatics analysis. This protein is also referred to asparagine synthetase domain containing 1 (ASNSD1) and registered in GenBank as NBLA00058. The registration number is AY11696. This gene is located on human chromosome 2q32.2. The total length of the gene coding sequence was 1932 nucleotides, and the coding product was 643 amino acid residues. NS3TP1 is widely distributed in the human body[5-8]. NS3 regulates the occurrence of liver fibrosis by interacting with host cells. Whether NS3TP1, as a trans-activator of NS3, can also affect liver fibrosis should be further investigated. Meienberg *et al*[9] demonstrated that NS3TP1 may interact with type 3 collagen alpha 1 chain (COL3A1). In our studies, we found that the NS3TP1 protein increased the expression levels of transforming growth factor beta receptor I (TGFβRI) by gene chip technology. Moreover, TGFβRI is one of the key molecules involved in the activation of the classic transforming growth factor beta 1 (TGFβ1)/Smad3 pathway in liver fibrosis[10]. Therefore, we speculate that NS3TP1 is related to the occurrence of liver fibrosis.

Furthermore, calcitriol was shown to downregulate the expression of NS3TP1 at the mRNA level in the Comparative Toxicogenomics Database (CTD)[11]. Thus, a correlation was established between calcitriol, NS3TP1, and liver fibrosis. As a conventional drug for treating vitamin D deficiency-related rickets, calcitriol regulates biological effects by binding to the vitamin D receptor (VDR). Pop *et al*[12] discovered that VDR was substantially generated in HSCs and Kupffer cells but weakly expressed in hepatic cells. Moreover, VDR is fully functional in HSCs and Kupffer cells. The role of vitamin D in the emergence of chronic hepatic fibrosis was highlighted by the identification of VDR as a crucial endocrine checkpoint for the fibrogenic activity of HSCs[13,14]. This finding indicated that the active component of vitamin D is a vital regulator of hepatic fibrosis. The activating of VDR in HSCs inhibits liver inflammation and fibrosis through the TGFβ1/Smad3 signaling pathway[15]. Moreover, activation of VDR reduces hepatic fibrosis by alleviating inflammation[16,17]. The activation of hepatic stellate cells (HSCs) has been proven to be a main driving factor of liver fibrosis[18]. The TGFβ1/Smad3 signaling pathway is the classical pathway of liver fibrosis activation[19,20]. In addition, NF-κB regulates cell death, inflammation, and wound healing and is therefore a crucial regulator of the progression of hepatic fibrosis[21,22].

The mechanism and mutual regulation between NS3TP1 and calcitriol in liver fibrosis have not been elucidated. However, based on previous studies, it was speculated that NS3TP1 increases hepatic fibrosis by triggering the TGFβ1/Smad3 and NF-κB signaling pathways. Moreover, calcitriol can regulate NS3TP1, but further studies are necessary for verification.

MATERIALS AND METHODS

Materials

Calcitriol was purchased from MedChemExpress (United States).

Animals

Liver fibrosis was induced by carbon tetrachloride (CCl_4) solubilized in corn oil (Sigma-Aldrich, Germany). Male C57BL/6 mice aged 8 wk were bought from Beijing Weitonglihua Laboratory Corporation (China). They experienced a week in a clean animal room at 24 °C with unrestricted access to food and water prior to the trials. The average weight of mice before modeling was 23-25 g, and mice were given an intraperitoneal (*i.p.*) injection with CCl_4 three times/wk (0.5 μL/g) for 4 wk to induce fibrosis[21,23,24]. Mice with liver fibrosis were successfully established and randomly separated into calcitriol and negative control (NC) groups. Mice in the control group were administered normal saline (10 μL/g/d, 5 times/wk) intragastrically for 4 wk and injected (*i.p.*) with corn oil or CCl_4, while mice in the calcitriol group were intragastrically administered calcitriol (1 μg/kg/d, 5 times/wk) and intraperitoneally injected with CCl_4 for 4 wk. Finally, 48 h after being injected with CCl_4, the mice were sacrificed. Normal saline was used to dilute 100% avertin to a 2.5% solution, and the anesthesia dose for mice was an *i.p.* injection of 100-200 μL/10 g. The mice were euthanized by deep anesthesia, followed by cervical dislocation. The Xi'an Jiaotong University Medical Science Center's specific pathogen free Animal Laboratory Center served as the site for all investigations. The Research Ethics Council of the Xi'an Jiaotong University Medical Science Center (Xi'an, China) gave its approval to all animal trials. All animals were treated humanely, and the experimental protocols were carried out in line with the regulations of the institution.

Cell culture

LX-2 cells are hepatogenic mesenchymal human cells and were obtained from Xiang Ya Central Laboratory (Xiangya Medical College, China). The cells were transfected using jetPRIME reagent (PolyPlus Transfection SA, NY, United States) and treated with calcitriol. Recombinant human TGFβ1 (BioLegend, CA, United States) was administered to the cell cultivation medium at 2.5 ng/mL or 5.0 ng/mL for 24 h[18,25]. All procedures were executed in accordance with the manufacturer's guidelines.

Plasmids and shortinterfering RNA (siRNA) oligonucleotides

PcDNA3.1/mycHis(-)NS3TP1, pGL4.10-NS3TP1 promoter, pGL4.10-p65 promoter, and pGL4.10-TGFβ 1R promoter were constructed by Beijing Genomics Institute (BGI, China). NS3TP1-siRNA was purchased from Gene Pharma (Hong Xun, Suzhou, Jiangsu Province, China).

Real-time quantitative polymerase chain reaction

Total RNA (Total RNA Kit, Omega, United States) was extracted from LX-2 cells and reverse-transcribed into single-stranded cDNA (Prime Script RT Reagent Kit, TaKaRa, China). Real-time quantitative polymerase chain reaction (RT-qPCR) was used to amplify the genes using specific primers (Hong Xun, Suzhou, Jiangsu Province, China), and β-actin was used as the internal control gene. The level of the target gene was estimated using the ΔΔCT method and normalized to that of the control. Supplementary Table 1 includes a list of the primer sequences.

Immunoblot

Proteins were extracted from mouse livers or LX-2 cells and isolated using 10% BIS-Tris gel/MOPS (Invitrogen, NY, United States) in MOPS SDS-PAGE (Thermo Fisher, United States). Transferring the separated proteins to a membrane made of polyvinylidene fluoride (PVDF) (Millipore, United States), which was incubated with secondary antibodies for 1.5 h after being exposed to primary antibodies (Supplementary Table 2) for 12 h at 4 °C. The immunoreactive bands were created using intensified chemiluminescence (Thermo Fisher Scientific) and visualized using the ChemiDoc™ touch imaging system (Bio-Rad, Hercules, CA, United States). ImageJ was used to assess the pictures.

Coimmunoprecipitation

Ice-cold M-PERTM mammalian protein extraction reagent was used to lyse LX-2 cells, and it also contained a mixture of protease and phosphatase inhibitors. Whole cell lysates (500 μL) were incubated with 50 μL protein magnetic beads for 2 h at room temperature and centrifuged, and the supernatant was transferred to a new 1.5 mL centrifuge tube. After that, the beads were mixed for 2 h at room temperature with whole-cell lysates containing 2 μL of anti-HIS antibody and 3 μL of regular mouse IgG antibody. The beads were eluted in DTT-free Laemmli buffer and then washed three times with PBST before being subjected to western blotting analysis.

Proliferation assay

On a 96-well plate, LX-2 cells were exposed to various calcitriol concentrations for 24 h. PBS was used to wash the cells twice after the initial medium was removed. Each well received a 1:100 addition of CCK-8 (Dojindo, Kumamoto, Japan) reagent before being cultured for 1 h at 37 °C. At 450 nm, the optical density was calculated.

Flow cytometry

LX-2 cells were treated with various concentrations of calcitriol for 48 h. The original medium was washed twice with PBS. The cells were collected by flow cytometry, treated with the reagents from an Annexin V-FITC/7-AAD apoptosis detection kit (BioLegend, CA, United States), and measured by a FACSCalibur flow cytometer (Beckman Coulter, CA, United States).

Hematoxylin-eosin staining, Masson staining, Sirius red staining, and oil red O staining

Hematoxylin was obtained from Yili Reagent Company (Beijing, China). Eosin was obtained from Zhongshan Jinqiao Biotechnology Company (Beijing, China). A Masson Tricolor staining kit was bought from Bogoo Corporation (Shanghai, China). A Pico Sirius Red Staining Kit was bought from Ruisai Biologicals (Shanghai, China). Oil red dye was obtained from Sigma-Aldrich (MO, United States). The manufacturer's instructions were strictly adhered to the conduct of every experiment.

Immunohistochemistry

Liver slices underwent an overnight incubation at 4 °C with a primary antibody and a 40-minute incubation at room temperature with an enzyme-labeled anti-rabbit antibody (PV-6001, ZSGB-BIO, Beijing, China). The slices were then developed using DAB substrate (Gene Science and Technology Company, China) after 30 min at room temperature incubation with avidin-biotin complex (PK-6100, Vectastain Elite ABC Standard kit, Vector Laboratories, Burlingame, CA, United States).

Assay of luciferase activity

HepG2 cells were transiently transfected with different promoter plasmids. A renal cell luciferase vector plasmid was used as a control. Dual-luciferase reporter gene activity was evaluated using a dual-luciferase reporter gene detection kit (Promega, United States).

Statistical analysis

Statistical analyses were performed using SPSS 24.0. The Student's *t* test was used to statistically examine all data. A P value < 0.05 was regarded as statistically significant. The data is shown as the mean ± SE.

RESULTS

Upregulated expression of NS3TP1 in HSCs and CCl_4-treated mouse livers

Herein, we confirmed the *in vivo* and *in vitro* roles of NS3TP1 in hepatic fibrosis. The level of NS3TP1 was measured in mice with CCl_4-induced hepatic fibrosis and TGF β1-activated LX-2 cells. Hematoxylin-eosin staining, Masson staining, Sirius red staining, and immunohistochemical staining for α-SMA demonstrated the successful establishment of CCl_4-induced fibrosis models (Supplementary Figure 1). The levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were elevated in mouse plasma (Supplementary Figure 2), suggesting hepatocyte injury. Hepatic fibrosis scores confirmed the disease, and the Ishak score was higher in the CCl_4 group (Supplementary Figure 3).

In vivo, COL1A1, COL3A1, α-SMA, and NS3TP1 were considerably elevated at the mRNA level in CCl_4-treated mouse livers (Figure 1A). The level of α-SMA in the CCl_4-treated mouse livers was upregulated, as indicated by immunofluorescence (Figure 1B). NS3TP1 in CCl_4-handled mouse livers was upregulated, as indicated by immunohistochemistry (Figure 1C and D) and immunofluorescence (Figure 1E).

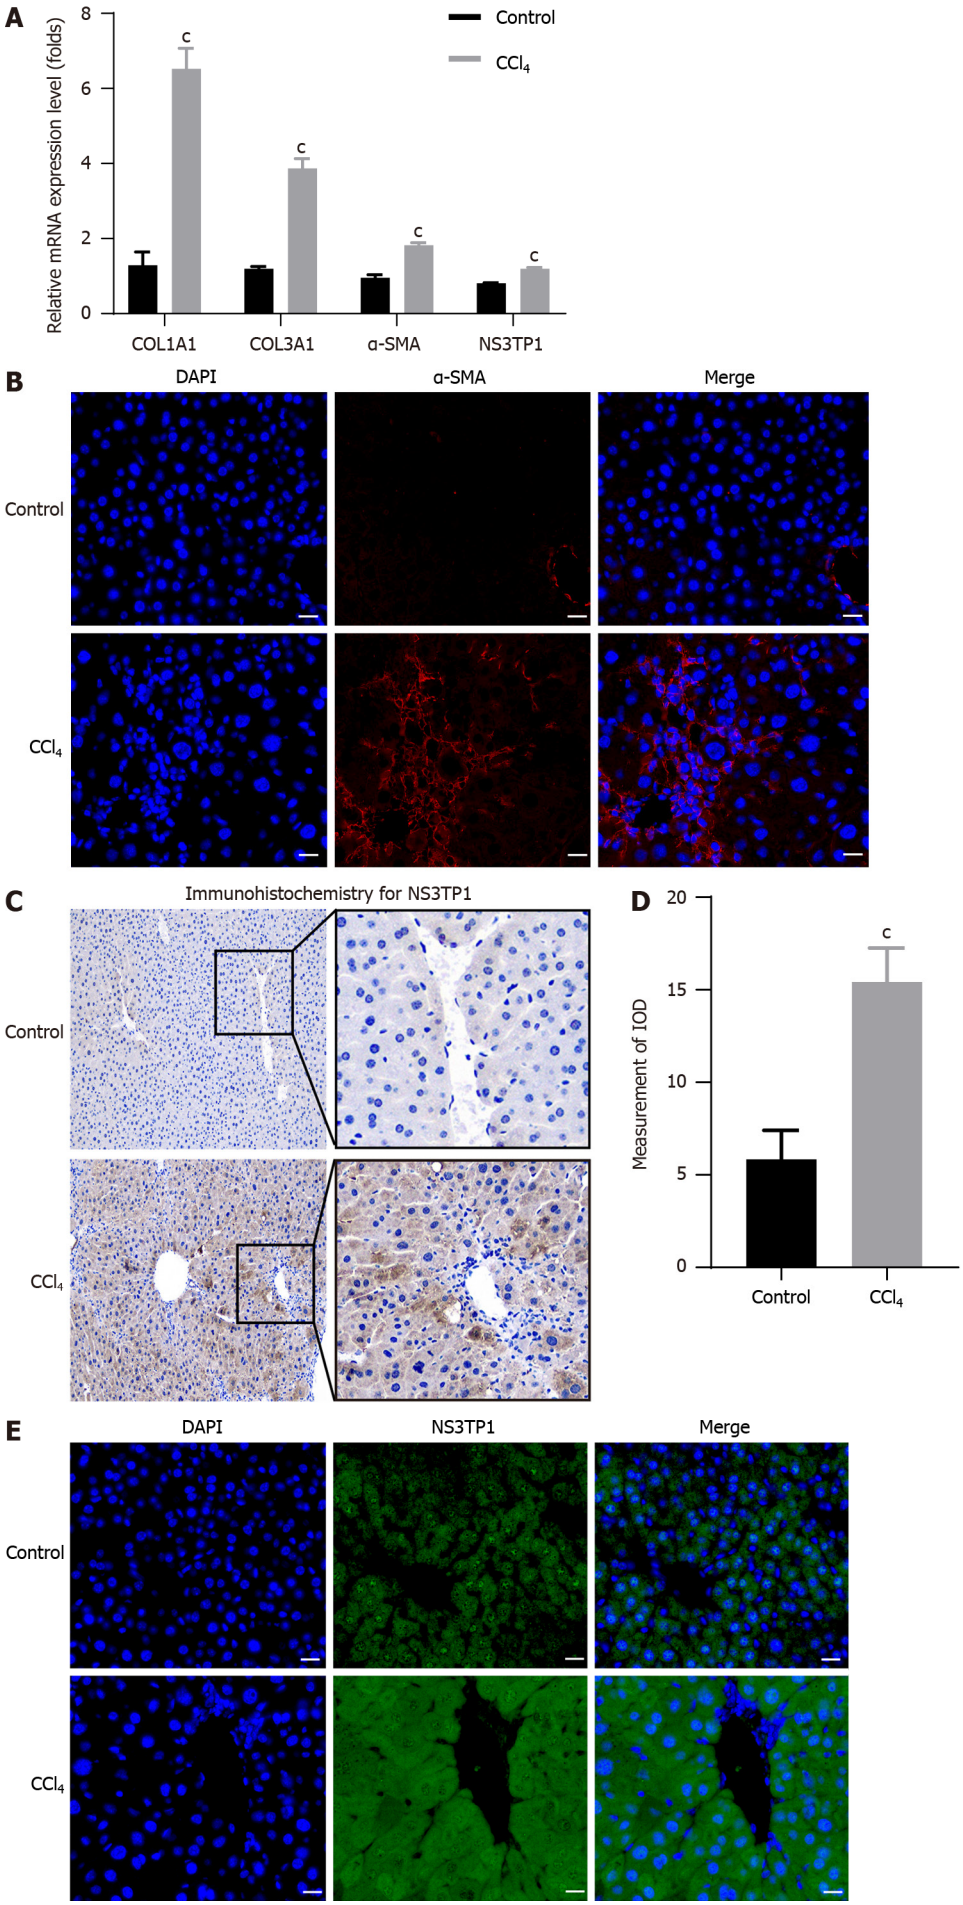
In vitro, Western blotting was performed to monitor the level of NS3TP1 in various cell lines, such as L02, LX-2, Huh7, and HepG2, and NS3TP1 was significantly raised in LX-2 cells (Figure 1F). In addition, LX-2 cells were administered with recombinant human TGFβ1 protein for 24 h. Then, α-SMA, collagen I, collagen III, and NS3TP1 were found to be significantly upregulated at the protein and mRNA levels (Figure 1G and H).

Therefore, *in vivo* and *in vitro* investigations validated the elevation of NS3TP1 in hepatic fibrosis.

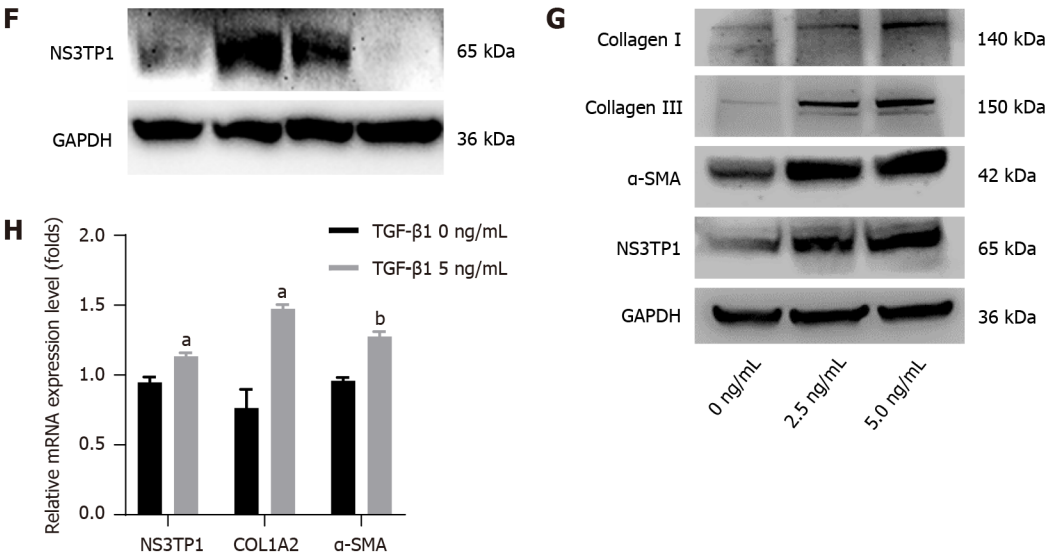
Influence of NS3TP1 overexpression or interference on the progression of hepatic fibrosis in vitro

The pcDNA-NS3TP1 plasmid was constructed and transiently transfected into LX-2 cells. The expression levels of fibrosis-related proteins were detected by Western blotting after 48 h. Compared to those in the negative control group, the levels of collagen I and α-SMA in the NS3TP1 overexpression group were increased (Figure 2A). The mRNA levels of COL1A1, COL2A1, COL3A1, COL4A2, and -SMA were monitored using RT-qPCR, and the results matched those of the Western blotting (Figure 2B). The levels of collagen I, collagen III, collagen IV, and α-SMA in NS3TP1 knockdown LX-2 cells were measured by Western blotting and RT-qPCR after 48 h. The results showed that in the NS3TP1 gene interference group, the expression of collagen I, collagen III, collagen IV, and α-SMA at the protein and mRNA levels was significantly downregulated (Figure 2C and D). This finding was the opposite of that of the NS3TP1 overexpression group.

NS3TP1 was interfered or overexpressed in LX-2 cells, the impact of NS3TP1 on HSC growth was then examined after 24 h, 48 h, and 72 h using a Cell Counting Kit-8 (CCK-8) cell proliferation and activity detection kit. Compared to the control group's results, the proliferation of HSCs in the NS3TP1 interference group decreased, while it increased after NS3TP1 overexpression, indicating that NS3TP1 increased the proliferation of HSCs (Figure 2E and F).



In LX-2 cells, after NS3TP1 was knocked down, the level of Bcl-2 was downregulated, the level of Bax was upregulated, apoptosis was enhanced, and the effects induced by overexpression were reversed. These results indicated that NS3TP1 inhibited the apoptosis of HSCs (Figure 2G and H).



Consequently, *in vitro* research supported NS3TP1's significance in fostering hepatic fibrosis.

Effect of NS3TP1 overexpression or interference on the TGFβ1/Smad3 and NF-kB signaling pathways

After transient transfection of LX-2 cells with the NS3TP1-overexpressing plasmid or siRNA-NS3TP1 for 48 h, the activity of the TGFβ1/Smad3 and NF-κB signaling pathways was evaluated. In comparison to that of the control group, the activity of both signaling pathways was elevated in the NS3TP1 overexpression group and decreased in the gene interference group. These results suggested that NS3TP1 promoted hepatic fibrosis *via* both signaling pathways (Figure 3A and B).

We applied 3 μmol/L Smad3-specific inhibitor (SIS3) and 2 μmol/L licochalcone D (LD, inhibition of the phosphorylation of NF-κB at serine 276) to inhibit the above pathways and then added TGFβ1 (5 ng/mL) or LPS (1 μg/mL). NS3TP1 and downstream collagen I, α-SMA, p-smad3, and p-p65 Levels were decreased, indicating that NS3TP1 was localized downstream of Smad3 and p65 (Figure 3C and

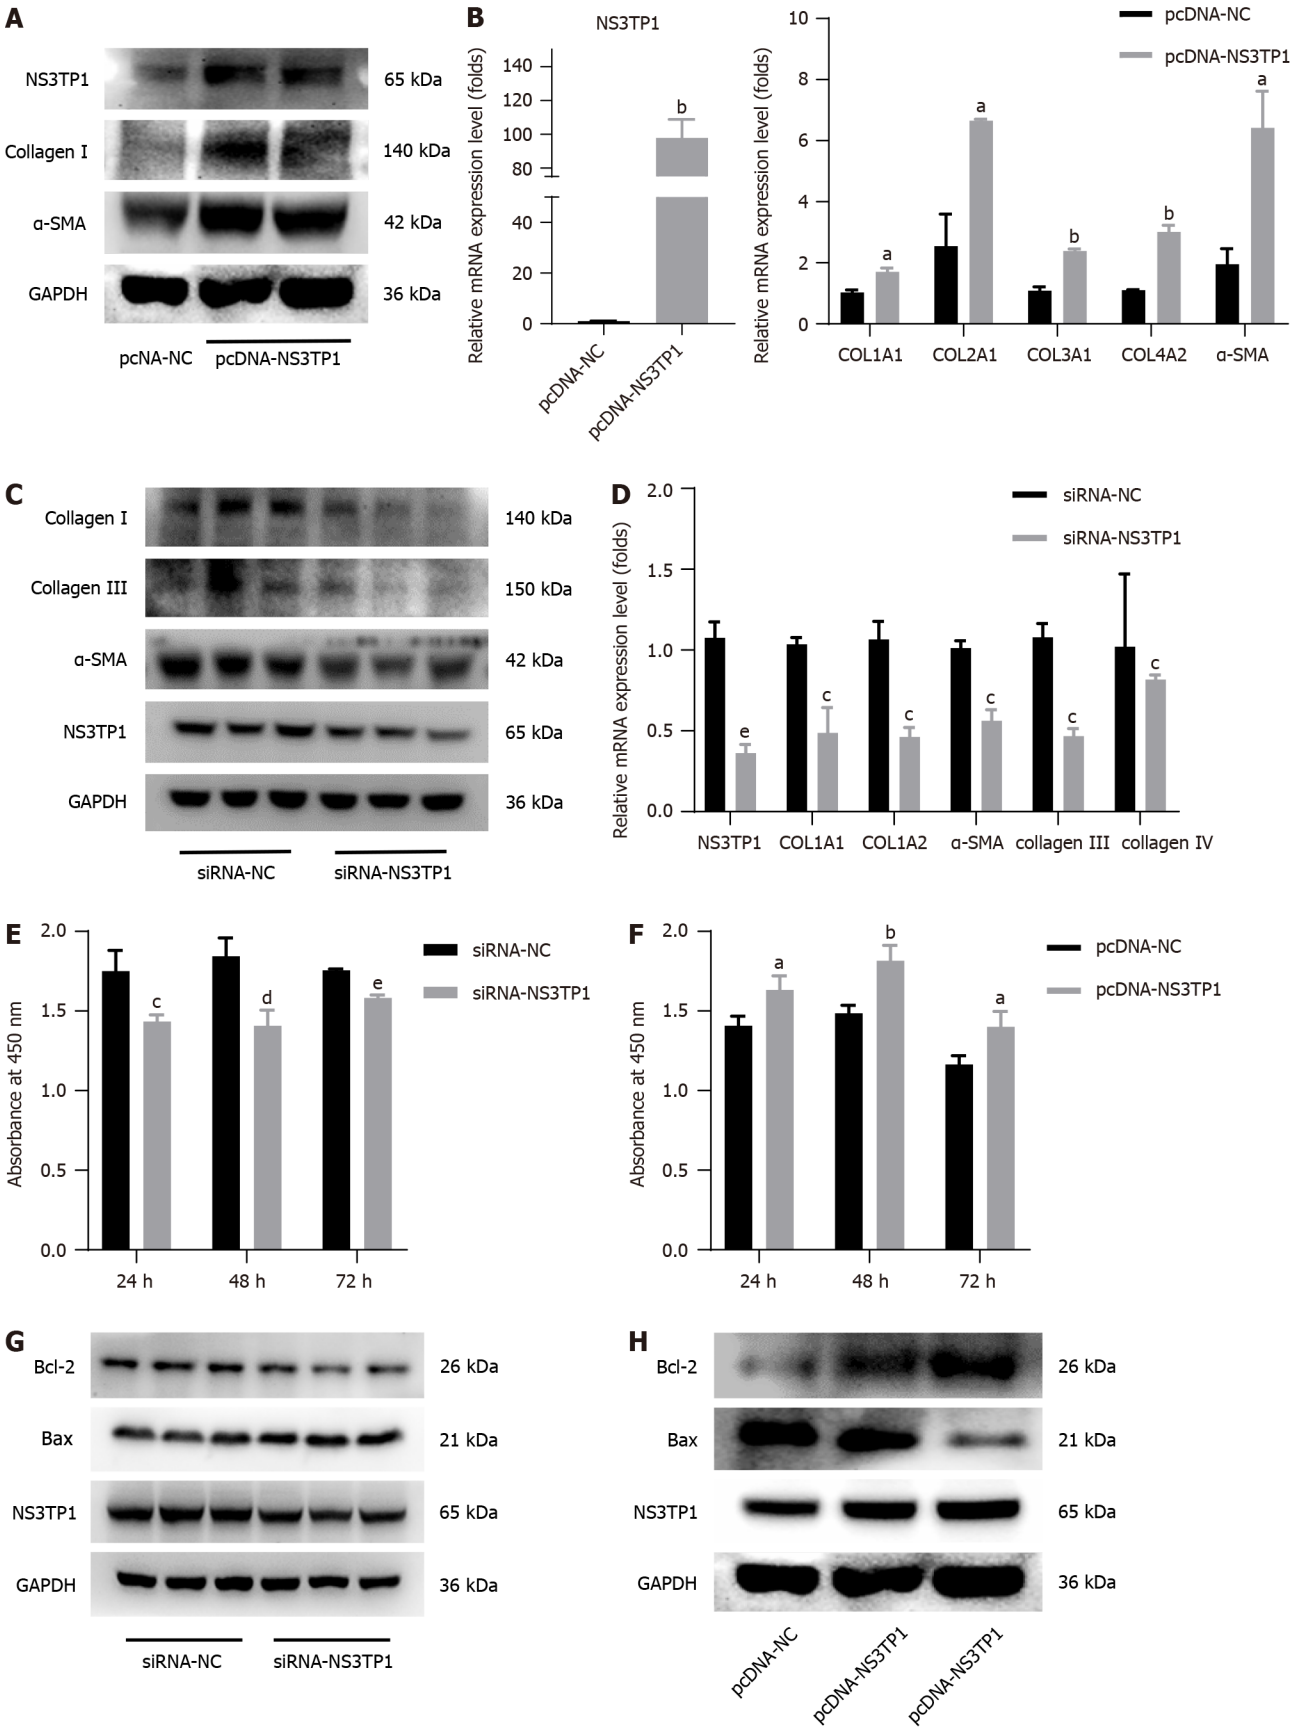
D).



Using coimmunoprecipitation (Co-IP), we found that NS3TP1 could bind to Smad3 and p65 (Figure 3E). The dual luciferase assay revealed that NS3TP1 enhanced TGFβRI promoter activity (Figure 3F), while TGFβ1 had no effect on NS3TP1 promoter activity (Figure 3G). Moreover, NS3TP1 had no effect on p65 promoter activity (Figure 3H), while p65 increased NS3TP1 promoter activity (Figure 3I). Therefore, NS3TP1 may inhibit the activity of both signaling pathways by suppressing the phosphorylation of Smad3 or p65 at the protein level. In addition, NS3TP1 may regulate the TGFβ1/Smad3 signaling pathway at the mRNA level by upregulating the TGFβRI promoter, and the regulation of the NS3TP1 and NF-κB signaling pathways at the mRNA level may be realized through the upregulation of the NS3TP1 promoter by p65.

Calcitriol alleviates liver fibrosis

The CCK-8 kit was used to detect LX-2 cells stimulated with various concentrations of calcitriol. After incubation for 48 h with the CCK-8 reagent, the absorbance value decreased with increasing calcitriol concentration, which could be attributed to calcitriol-inhibited cell proliferation (Supplementary Figure 4). Calcitriol reduced the activation of HSCs in a concentration- and time-dependent manner. The optimum concentration of calcitriol was 16 μmol/L (Figure 4A). The optimum time for calcitriol treatment was 48 h (Figure 4B). Calcitriol promoted the return of TGFβ1-activated HSCs to quiescent HSCs (qHSCs) (Figure 4C). Following calcitriol administration, a Western blot analysis revealed concentration-dependently elevated Bax and diminished Bcl-2 Levels (Figure 4D). Flow cytometry showed that LX-2 cell apoptosis increased with increasing calcitriol concentration (Figure 4E and F). Oil red O staining showed an increased number of fat droplets in LX-2 cells (Supplementary Figure 5). Calcitriol reduced the migration of activated HSCs (Figure 4G and H).

In vivo, the dose and the protocol for this study were chosen based on the results of previous studies [26-28]. The optimal dosage of calcitriol was identified as 1 μg/kg/d, 5 times/wk according to the preliminary experimental results, and subsequent experiments were carried out with this dosage.

Calcitriol treatment reduced CCl_4-induced collagen accumulation in the mouse liver, as shown by hematoxylin-eosin staining, Masson staining, Sirius red staining, immunohistochemistry for α-SMA (Figure 4I), and immunofluorescence for α-SMA (Figure 4J). Western blot results further support these conclusions (Figure 4K and L). Liver fibrosis was improved by calcitriol treatment, according to the Ishak scoring system (Figure 4M). Plasma ALT and AST levels also demonstrated that calcitriol decreased CCl_4-induced inflammation in the mouse liver (Figure 4N). These findings showed that calcitriol prevented hepatic fibrosis both *in vivo* and in a lab setting.

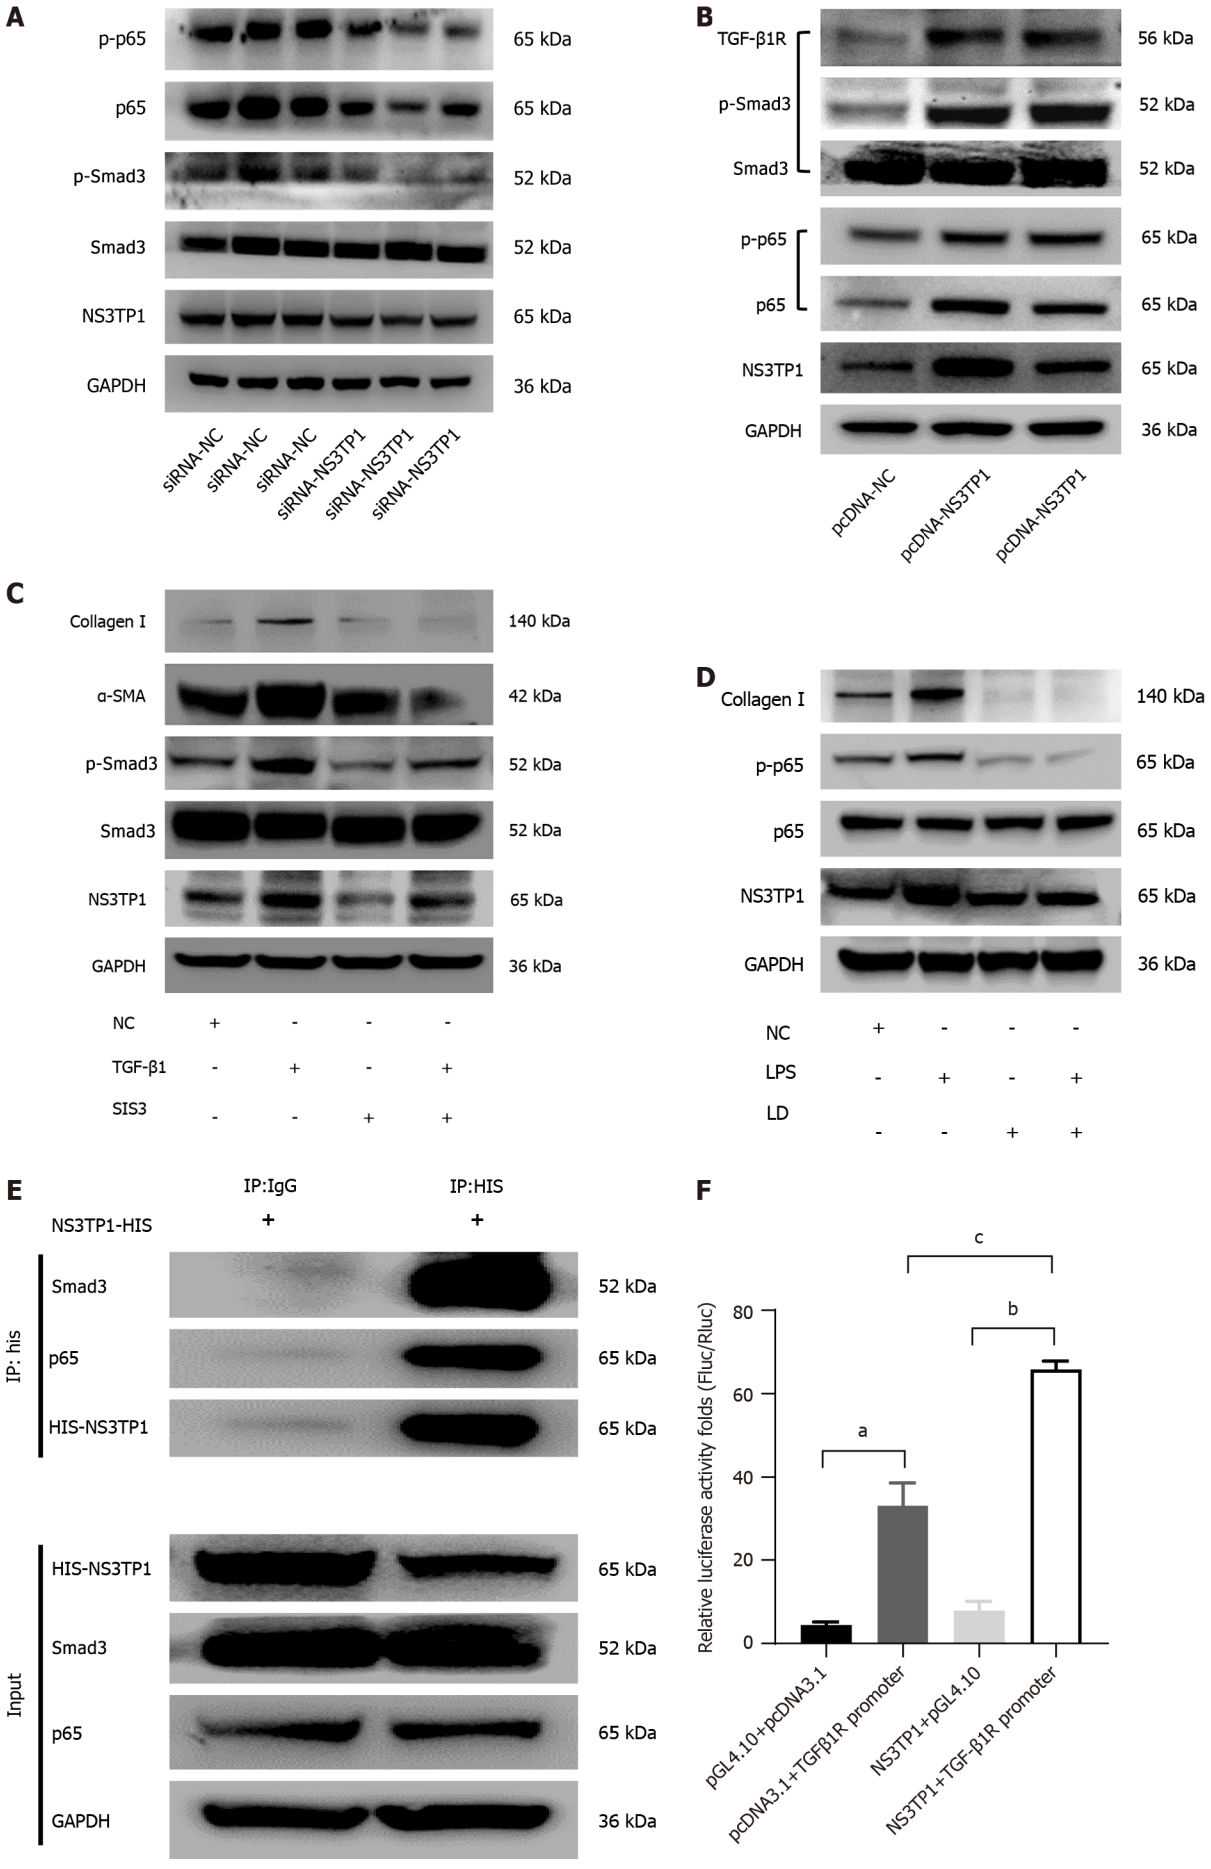
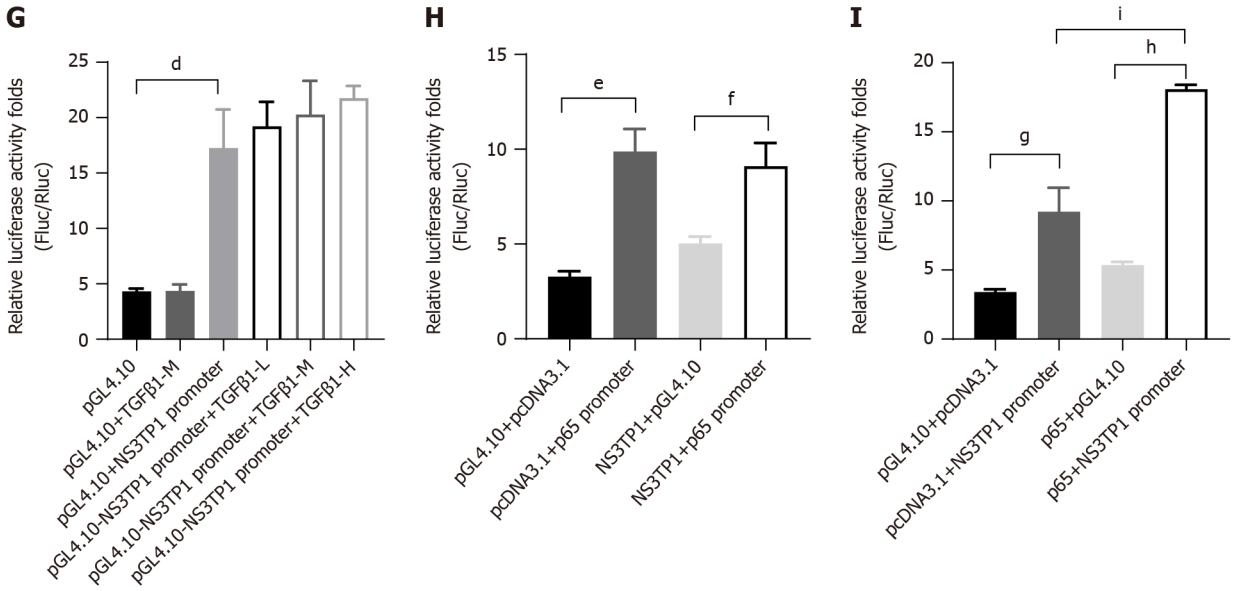
Prevention of calcitriol on liver fibrosis through the TGFβ1/Smad3 and NFkB signaling pathways via NS3TP1 in vivo and in vitro

Calcitriol prevented the expression of NS3TP1 at the mRNA level in the CCl_4-treated mouse liver, as shown by RT-qPCR (Figure 5A) and by immunohistochemistry (Figure 5B and C). Moreover, calcitriol inhibited the expression of NS3TP1 at the protein level, as shown by immunofluorescence staining for NS3TP1 (Figure 5D). In LX-2 cells, the inhibition of NS3TP1 by calcitriol at the protein level was time- and concentration dependent, with an optimal concentration of 16 μmol/L and an optimal treatment time of 48 h (Figure 5E and F). In addition, the activity of the NS3TP1 promoter was inhibited by 32 μmol/L calcitriol in HepG2 cells, as validated by dual-luciferase reporter gene assay (Figure 5G).

Both signaling pathways were inhibited in a dose- and time-dependent manner after 12 h of TGFβ1 treatment and 48 h of calcitriol treatment in LX-2 cells (Figure 5H). Calcitriol significantly inhibited the LPS-activated NF-κB signaling pathway in HSCs (Figure 5I). PcDNA 3.1/myC-His(-)-NS3TP1 was transfected into LX-2 cells for 24 h, and then the cells were stimulated with calcitriol for 48 h. Calcitriol inhibited LX-2 cell activation following NS3TP1 overexpression (Figure 5J).



In conclusion, these results confirm that calcitriol prevented hepatic fibrosis through the above signaling pathways *via* NS3TP1.



DISCUSSION

The present study first showed that NS3TP1 promoted hepatic fibrosis by enhancing the TGFβ1/Smad3 and NF-κB signaling pathways. NS3TP1 controlled HSC activation, proliferation, and differentiation. These results provide solid proof for the role of NS3TP1 contributing to hepatic fibrosis.

Both *in vivo* and *in vitro* experiments confirmed that NS3TP1 was elevated in liver fibrosis (Figure 1), which was consistent with our group's previous results. TGF-β1 activates hepatic stellate cells effectively[29], and the CCl_4-induced liver fibrosis model is one of the classical models of liver fibrosis [30]. There was an increase in NS3TP1 expression levels in the treated cells and tissues, indicating that NS3TP1 plays a role in liver fibrosis development. Moreover, NS3TP1 promoted the activation and proliferation but inhibited the apoptosis of LX-2 cells (Figure 2), Meienberg *et al*[9] demonstrated that NS3TP1 may interact with COL3A1, which further supports that NS3TP1 regulates the occurrence of hepatic fibrosis. The TGFβ1/Smad3 and NF-κB signaling pathways have been well established as two classical pathways for hepatic stellate cell activation[20,22,31]. To confirm the correlation between NS3TP1 and the activity of both signaling pathways, we overexpressed or interfered with NS3TP1 in LX-2 cells. We found that the activities of both signaling pathways were enhanced in the NS3TP1 overexpression group. However, the activities of both signaling pathways were decreased in the gene interference group, suggesting that NS3TP1 regulated hepatic fibrosis through both the above signaling pathways. To further elucidate the specific mechanisms between NS3TP1 and both signaling pathways, we used Co-IP and dual-luciferase assays. Co-IP analysis demonstrated that Smad3 and p65 could bind to NS3TP1. Therefore, NS3TP1 may decrease the activity of both signaling pathways by inhibiting the phosphorylation of Smad3 or p65. It is necessary to examine the possible colocalization of NS3TP1 and Smad3 or p65 in LX-2 cells by confocal microscopy. The dual-luciferase assay revealed that NS3TP1 increased the activity of the TGFβRI promoter and that p65 increased the activity of the NS3TP1 promoter. Altogether, NS3TP1 regulated both signaling pathways at protein and mRNA levels (Figure 3). The key targets of both signaling pathways are p-smad3 and p65 respectively, and p65 is the classic regulatory factor of the inflammatory pathway[32,33], which further supports our research.

We confirmed that calcitriol inhibited hepatic fibrosis *in vitro* and *in vivo* (Figure 4). This finding is consistent with previous research[26,34,35]. *In vivo* experiments were conducted using CCl_4-induced model mice, wherein calcitriol was found to attenuate liver fibrosis. The optimal dosage of calcitriol to treat liver fibrosis was 1 μg/kg/d, administered five times per week, which also reduced CCl_4-induced inflammation in the mouse liver. Calcitriol decreased the deposition of extracellular matrix following HSC activation, prevented the proliferation, activation, and migration of HSCs, and promoted cell apoptosis, and these *in vitro* experiments were primarily conducted using LX-2 cells. In addition, HSCs were also able to accumulate lipid droplets when exposed to calcitriol, which may be related to the dedifferentiation of activated HSCs into qHSCs, suggesting that calcitriol reversed hepatic fibrosis as described previously[25,36]. In conclusion, calcitriol inhibited liver fibrosis, however, the precise mechanism was uncertain. Therefore, we investigated the mechanisms by which calcitriol prevented hepatic fibrosis.

We demonstrated that calcitriol downregulated NS3TP1 at the mRNA level in CTD[11]. Moreover, we first proved that calcitriol inhibited NS3TP1 *in vivo* and *in vitro* (Figure 5) in a dose-dependent manner, and the increased NS3TP1 expression levels were found to be suppressed by calcitriol in mouse liver fibrotic tissues. The dual-luciferase assay showed that calcitriol blocked the promoter activity of NS3TP1, which conforms with the research of Wang *et al*[11]. Finally, we first demonstrated that calcitriol prevented hepatic fibrosis through the above signaling pathways *via* NS3TP1. Calcitriol inhibited liver fibrosis by binding to VDR, and NS3TP1 may be one of the targets. Whether other molecules that can bind to VDR can also reduce the expression of NS3TP1 will be the focus of further research. The results by Hah *et al*[15] supported this phenomenon. It was found that activating VDR in HSCs prevented liver inflammation and fibrosis through the TGFβ1/Smad3 signaling pathway. Activation of the TGFβ1 signaling pathway leads to genome-wide reallocation of VDR binding through TGFβ1-dependent chromatin remodeling in the presence of VDR ligands. By attaching to Smad3, VDR decreases Smad3 occupancy at these locations and inhibits fibrosis[15]. We proved that calcitriol decreased liver fibrosis through the NF-κB signaling pathway *via* NS3TP1. This finding is consistent with previous studies. Calcitriol suppresses the NF-κB signaling pathway, which confirms its anti-inflammatory effect, and activated HSCs are involved in inflammation[37].

Regarding the limitations of this study, animal experiments were not completed on NS3TP1-KO mice. In our research, we discovered that NS3TP1-KO mice could not give birth normally. Combined with the results of GeneCards database retrieval, we found that the NS3TP1 content in the reproductive system is quite rich. We therefore speculated that knocking down NS3TP1 would also have an impact on reproductive functions. To learn more about how the protein contributes to liver fibrosis, we will concentrate on NS3TP1 knockouts that target the liver.

CONCLUSION

In conclusion, NS3TP1 regulates TGFβ1/Smad3 and NF-κB signaling pathways to induce liver fibrosis. These results contribute to NS3TP1 as a novel, prospective therapeutic target for the treatment of

hepatic fibrosis, and calcitriol may be employed as an adjuvant therapy.

ARTICLE HIGHLIGHTS

Research background

Despite the lack of a specific therapeutic medicine, liver fibrosis still constitutes a serious hazard to human health, hence it is critical to identify novel targets for its therapy. After screening using suppressive subtractive hybridization and bioinformatics analysis, our research team discovered that hepatitis C virus nonstructural protein 3-transactivated protein 1 (NS3TP1) may be involved in the occurrence of liver fibrosis. As a result, the role of NS3TP1 in liver fibrosis was investigated to provide a new target for the treatment of liver fibrosis.

Research motivation

A potential new target for the treatment of hepatic fibrosis is provided by this work.

Research objectives

To determine whether NS3TP1 can promote liver fibrosis and whether calcitriol can inhibit the occurrence of liver fibrosis through NS3TP1.

Research methods

In vitro experiments were performed on carbon tetrachloride mouse liver, and NS3TP1 and fibrosis-related indexes were studied through serological and pathological tests. *In vivo* experiments were performed on LX-2 cells, and siRNA-NS3TP1 and pcDNA-NS3TP1 were constructed and transfected into LX-2 cells, respectively. Collagen I, collagen III, α-smooth muscle actin (α-SMA), TGFβ1/Smad3 and NF-κB signaling pathways were detected by western blot, RT-PCR, Co-imunoprecipitation and luciferase assays.

Research results

Collagen I, collagen III, α-SMA, transforming growth factor beta (TGFβ1)/Smad3, and NF-κB signaling pathways were found to be up-regulated following overexpression of NS3TP1, whereas the aforementioned indices were shown to be down-regulated after NS3TP1 interference *in vitro*. Results from Co-IP and Luciferase assays confirmed that Smad3 and p65 could both bind to NS3TP1, and that p65 boosted NS3TP1's promoter activity while NS3TP1 increased the promoter activity of TGFβ receptor I (TGFβ-RI). NS3TP1 and fibrosis-related indicators decreased after calcitriol therapy both *in vitro* and *in vivo*, and calcitriol restrained the expression of TGFβ1/Smad3 and NF-κB signaling pathways *via* NS3TP1.

Research conclusions

NS3TP1 promotes hepatic fibrosis through TGFβ1/Smad3 and NF-κB signaling pathways. Calcitriol further inhibits TGFβ1/Smad3 and NF-κB signaling pathways to reduce liver fibrosis by down-regulating NS3TP1.

Research perspectives

NS3TP1 provides a novel target for the treatment of liver fibrosis and a direction for the research of potential drug targets. Calcitriol is endowed with new functions as an adjunct therapeutic drug for liver fibrosis.

Abstract

BACKGROUND

Helicobacter pylori (*H. pylori*) is the main pathogen that causes a variety of upper digestive diseases. The drug resistance rate of *H. pylori* is increasingly higher, and the eradication rate is increasingly lower. The antimicrobial resistance of *H. pylori* is an urgent global problem. It has been confirmed that Banxia Xiexin decoction (BXXXT) demonstrates the effects of treating gastrointestinal diseases, inhibiting *H. pylori* and protecting gastric mucosa. The purpose of the present study is to further explore the therapeutic effects of BXXXT on drug-resistant *H. pylori*.

AIM

To confirm that BXXXT demonstrates therapeutical effects *in vivo* and *in vitro* on gastritis mice with drug-resistant *H. pylori* and explain its mechanism to provide an experimental basis for promoting the application of BXXXT.

METHODS

The aqueous extract of BXXXT was gained by water decocting method. The inhibitory effect of the aqueous extract on *H. pylori* was detected by dilution *in vitro*; drug-resistant *H. pylori* cells were used to build an acute gastritis model *in*

vivo. Thereafter, the model mice were treated with the aqueous extract of BXXXT. The amount of *H. pylori* colonization, the repair of gastric mucosal damage, changes of inflammatory factors, apoptosis, *etc*., were assessed. In terms of mechanism exploration, the main medicinal compositions of BXXXT aqueous extract and the synergistic bacteriostatic effects they had demonstrated were analyzed using mass spectrometry; the immune function of peripheral blood cells such as $CD3^+$ T and $CD4^+$ T of mice with gastritis before and after treatment with BXXXT aqueous extract was detected using a flow cytometry; the *H. pylori* transcriptome and proteome after treatment with BXXXT aqueous extract were detected. Differently expressed genes were screened and verification was performed thereon with knockout expression.

RESULTS

The minimum inhibitory concentration of BXXXT aqueous extract against *H. pylori* was 256-512 μg/mL. A dose of 28 mg/kg BXXXT aqueous extract treatment produced better therapeutical effects than the standard triple therapy did; the BXXXT aqueous extract have at least 11 ingredients inhibiting *H. pylori*, including berberine, quercetin, baicalin, luteolin, gallic acid, rosmarinic acid, aloe emodin, *etc*., of which berberine, aloe emodin, luteolin and gallic acid have a synergistic effect; BXXXT aqueous extract was found to stimulate the expressions of $CD3^+$ T and $CD4^+$ T and increase the number of $CD4^+$ T/$CD8^+$ T in gastritis mice; the detection of transcriptome and proteome, quantitative polymerase chain reaction, Western blotting and knockout verification revealed that the main targets of BXXXT aqueous extract are *CFAs* related to urea enzymes, and *CagA*, *VacA*, *etc*.

CONCLUSION

BXXXT aqueous extract could demonstrate good therapeutic effects on drug-resistance *H. pylori in vitro* and *in vivo* and its mechanism comes down to the synergistic or additional antibacterial effects of berberine, emodin and luteolin, the main components of the extract; the extract could activate the immune function and enhance bactericidal effects; BXXXT aqueous extract, with main targets of BXXXT aqueous extract related to urease, virulence factors, *etc*., could reduce the urease and virulence of *H. pylori*, weaken its colonization, and reduce its inflammatory damage to the gastric mucosa.

Key Words: Banxia Xiexin decoction; *Helicobacter pylori*; Drug resistance; Therapeutic effects; Mechanism

Core Tip: The failure rate of treating *Helicobacter pylori* (*H. pylori*) infectious diseases is increasing, leading to an urgent need to study and develop anti-*H. pylori* drugs. Banxia Xiexin decoction (BXXX) has a good effect on Hp infection and Hp-infection-related diseases. However, its pharmacological mechanism remains unclear, and whether it has an effect on drug-resistant *H. pylori* infection has not been confirmed by animal experiments. Our study confirms that BXXX decoction (BXXXT) has good therapeutic effects on drug-resistant *H. pylori* infection through *in vivo* and *in vitro* experiments in mice, then the composition of BXXXT and effective components, the immunomodulatory effect, the main target were verified. We preliminarily explain why BXXXT has a good effects.

INTRODUCTION

Helicobacter pylori (*H. pylori*) is the main pathogen that causes a variety of upper digestive diseases[1], such as chronic gastritis, peptic ulcer, and gastric cancer[2]. At present, the treatment options for *H. pylori* infections include standard triple therapy, bismuth-containing quadruple therapy, and sequential therapy. The drug resistance rate of *H. pylori* is increasingly higher, and the eradication rate is increasingly lower. Clarithromycin-resistant *H. pylori* has been listed as a focus for the research and development of antibiotics by the World Health Organization in 2017. The antimicrobial resistance of *H. pylori* is an urgent global problem. Multiple antibiotic resistance existed in 16847 *H. pylori* strains

isolated in Wenzhou from 2013-2020. Separate statistics on the resistance rates of *H. pylori* to the six commonly used antibiotics revealed that the resistance rates to levofloxacin, clarithromycin and metronidazole were high in the region, respectively 32.81%, 26.02%, and 95.67%. Therefore, how to avoid, overcome and eradicate *H. pylori* and *H. pylori*' s drug resistance brings challenges to the current clinical work. In China, traditional Chinese medicine could be used to treat a variety of refractory diseases, reducing drug resistance and improving the eradication rate of *H. pylori*[3]. "BXXXT" comes from Zhang Zhongjing' s Treatise on Febrile Diseases, which consists of 15 g *Pinellia ternate*, 9 g *Radix scutellariae*, 9 g *Dried ginger*, 9 g *Ginseng*, 9 g *Roasted licorice*, 3 g *Coptis chinensis*, and 4 *Jujubes*. At present, experimental studies and clinical efficacy of this prescription have been reported for gastrointestinal dysfunction, peptic ulcer, chronic gastritis, atrophic gastritis and other digestive system diseases[4-6]. There are numerous studies at home and abroad on the efficacy of this prescription[7-9], and it has been confirmed that BXXXT demonstrates the effects of treating gastrointestinal diseases, inhibiting *H. pylori* and protecting gastric mucosa[10-12]. However, whether it has the same effect on the refractory gastritis caused by drug-resistant *H. pylori* remains unreported.

Therefore, the purpose of the present study is to further explore the therapeutic effects of BXXXT on drug-resistant *H. pylori* through establishing mouse models, and to study the molecular mechanism of BXXXT applied in the treatment of the refractory gastritis caused by drug-resistant *H. pylori* through ingredient analysis, immune regulation, identification of therapeutical targets, *etc*., so as to provide an experimental basis for improving the application efficiency and of this prescription worldwide.

MATERIALS AND METHODS

Strains and culture conditions

H. pylori strains (standard 26695, G27, NSH57, and multi-drug-resistant BHKS159 all provided by Professor Bi Hongkai of Nanjing Medical University) containing the preservation solution and stored at -80 °C, clinical strains HPBS001-HPBS016 that had been isolated by Huang Yanqiang Laboratory, Youjiang Medical College for Nationalities were used. The *H. pylori* strains were cultured in a Columbia (OXOID, United Kingdom) medium with 10% serum or a BHI (OXOID, United Kingdom) medium in a microaerobic environment (85% nitrogen, 5% oxygen, and 10% carbon dioxide) at 37 °C.

Experimental animals

SPF C57BL/6 mice aged six to eight weeks were purchased from Changsha Tianqin Biological Co., Ltd.; the number of SPF animal license: SYXK Gui 2017-0004; animal experiment ethics number: No. 2019112501.

Preparation of BXXXT aqueous extract

The prescription consists of 15 g *Pinellia ternate*, 9 g *Radix scutellariae*, 9 g *Dried ginger*, 9 g *Ginseng*, 9 g *Roasted licorice*, 3 g *Coptis chinensis*, and 4 g *Jujubes*. In the first round, the medical materials used to prepare BXXXT were crashed to crude powder that was placed in a beaker with sterile distilled water at a ratio of 1:10, soaked for 4 h, treated with diluted and boiled for 0.5 h with the liquid filtered out. In the second round, the filtered powder was treated with distilled water in a ratio of 1:5 and boiled for 20 min with the filtrate filtered out; in the third round, the filtered powder was treated following the same steps described in the second round but boiled for 5 min with the liquid filtered out. The liquids prepared during the three rounds were combined, concentrated to crude drug (1 g/mL), evaporated under atmospheric pressure, sterilized, and stored for later use.

Evaluation of MIC of BXXXT against H. pylori in vitro

A medium of BXXXT aqueous extract that had been diluted two-fold was prepared as the treatment group: BXXXT aqueous extract was mixed with BHI and diluted two-fold with berberine set as the positive drug control group. *H. pylori* cells were adjusted at OD^{600} = 0.03 (equivalent to 1.0 × 10^7 CFU/mL). Bacterial solution (100 μL, equivalent to 1.0 × 10^6 CFU/mL) was inoculated into a 96-well plate that contained medicated BHI and incubated at 37 °C for 48 h to determine the results with the lowest concentration of drugs that could inhibit *H. pylori* growth being minimum inhibitory concentration (MIC).

Detection of therapeutic effects of BXXXT aqueous extract on mice with drug-resistant H. pylori gastritis in vivo

BXXXT aqueous extract, amoxicillin (Sigma-Aldrich, Germany), clarithromycin (Sigma-Aldrich, Germany) and omeprazole (Sigma-Aldrich, Germany) were all dissolved and diluted to 10 mg/mL. C57BL/6 model mice (BHKS159) were divided into four groups: The omeprazole + amoxicillin + clarithromycin group (the dose was 138.2 mg/kg of omeprazole, 28.5 mg/kg of amoxicillin, and 14.3 mg/kg of clarithromycin), the omeprazole + BXXXT aqueous extract (28 mg/kg), the omeprazole + BXXXT aqueous extract (7 mg/kg) and the phosphate-buffered saline (PBS) group, with six mice in each group.

Mice were given administration once a day for three consecutive times. Two days after drug withdrawal, the blood was collected from the eyeballs of the mice. The mice were then sacrificed through cervical dislocation with tissues taken from their stomach and broken to acquire *H. pylori* that was then isolated, cultured, and identified with the amount of colonization calculated. Part of the stomach tissues was made into paraffin sections with HE staining, TUNEL immunohistochemistry and fluorescence immunoassay performed thereon.

Main pharmacodynamic components of BXXXT aqueous extract

This analysis was performed by Beijing Bio-Tech Pack Technology Company Ltd using a TripleTOF5600 + and an AB SCIEX™ with the ion source being ESI. The chromatographic column was SHIMADZU InerSustain C18 (100.0 mm × 2.1 mm, 2 μm) with the column temperature being 35 °C and flow rate of 0.300 (mL/min). The mobile phase: (1) Equate = "acetonitrile"; and (2) equate = "0.1% CH3COOH-H2O". The chromatographic conditions were shown in Table 1. The scanning range of mass spectrometry conditions was m/z 100-1500. The scanning mode: DIA. Capillary voltage: 5000 V (positive) and 4500 V (negative). Capillary Temp: 500 °C, DP 60 V, CE 35 V, and CES 15 V.

Synergistic antimicrobial effects of main pharmacodynamic components of BXXXT aqueous extract

According to the protocols of the checkerboard method, drug A in the first row and drug B in the first column were diluted two-fold respectively. Then the transverse and longitudinal drugs were also cross-diluted two-fold and treated with 100 μL bacterial suspension, with the optimal combination effect selected to calculate the antimicrobial concentration index (FICI) after culture for 48 h. FICI= MIC of A drugs used in combination/MIC of A drugs used alone + MIC of B drugs used in combination/MIC of B drugs used alone. Criteria: synergistic effects (FICI ≤ 0.5); additive effect (0.5 < FICI ≤ 1.0); no effect (1.0 < FICI ≤ 2.0); antagonistic effects (FICI > 2.0).

Immunobactericidal effects of BXXXT aqueous extract

During the process of testing the efficacy of BXXXT aqueous extract described previously in section 1.5, the peripheral blood of mice before and after administration was collected and cells thereof were treated with anticoagulant and then with 50 μL antibody mixtures: CD3, CD4, and CD8, *etc*. After the membranes were fixed and broken, the cells were treated with 100 μL antibody mixtures: IFN and IL-4. After filtration, the expressions of immune cells and cytokines were detected using a flow cytometry.

Effect mechanism of BXXXT aqueous extract on H. pylori

BHKS159 bacteria were cultured on a Columbia plate overnight. Thereafter, the single colony was selected and diluted to 0.5 Mcfarland standard (MCF) with 2 μL taken and added to 5 mL BXXXT aqueous extract (1/2 MIC, prepared by being treated with BHI). The negative control group was induced with PBS, shaken at 37 °C and centrifuged to collect the bacteria solutions after it had been treated with the aqueous extract for 4 h and 8 h. The bacteria solutions were delivered to Nanjing Medical University where they were observed under a transmissive electron microscope. *H. pylori* cells were treated with BXXXT aqueous extract at the half inhibitory concentration that had been detected before for 8 h, after which the samples were collected and frozen in liquid nitrogen for 10 min, frozen with dry ice and delivered to Beijing Allwegene Technology Co., Ltd. for detection and analysis of transcriptome and proteome. The transcriptome analysis was performed using the Illumina PE150 sequencing strategy; the length of RNA fragments was detected using Agilent 2100; the alignment and transcript assembly analysis were performed using Boetie2 and the Rockhhoper software; quantitative protein analysis was performed using the ITRAQ labeling quantitative strategy, ITRAQ/TMT labeling performed using isoheavy isotope labeling, and the quantitative detection of target genes performed using a fluorescent polymerase chain reaction (PCR) instrument and Western blotting. Strains with low expressions of related target genes were used to verify MIC changes and mutant strains were constructed with reference to the protocols described in the previous studies[13]. The relevant mRNA amplification primers are shown in Table 2, and the relevant antibody information is displayed in Table 3.

Statistical analysis

Statistical analysis and mapping were performed using the Graphpad Prism software, version 8.0. Continuous data were expressed as mean ± SD. Differences between groups were analyzed using the one-way ANOVA. $P < 0.05$ was considered statistically significant.

RESULTS

The MIC of BXXXT aqueous extract on H. pylori detected in vitro

The MICs of BXXXT aqueous extract on three sensitive *H. pylori* strains and 11 drug-resistant *H. pylori* strains were detected by applying the solid plate method. BXXXT aqueous extract was found to have

GAPDH Ab	AF7021	Affinity Biosciences
Goat anti-rabbit IgG (H+L) HPR	S0001	Affinity Biosciences

antibacterial effects on strains, both resistant and sensitive (the MIC was 256-512 μg/mL). The antibacterial effect of BXXXT aqueous extract was compared with that of berberine (the MIC was 512-2048 μg/mL), as shown in Table 4. The results suggested that there was a two-to-four-fold difference between them and that BXXXT aqueous extract produced better antibacterial effects than 98% pure berberine. The reason might be that although berberine accounts for a small portion of the prescription, there might be other antibacterial components, or there might be synergistic or additive effects among these components.

Therapeutic effects of BXXXT aqueous extract were detected in vivo on mice with H. pylori-resistant acute gastritis

Model mice with acute gastritis caused by the drug-resistant strain BHKS159 were constructed and treated with PBS, omeprazole (OPZ) + amoxicillin clarithromycin (AC), OPZ + BXXXT (28 mg/kg) and OPZ + BXXXT (7 mg/kg), respectively. Although *H. pylori* colonization, inflammatory factors IL-1β, IL-6 and tumor necrosis factor-alpha (TNF-α), inflammatory damage, and apoptosis factors Bcl-2 and Bax were improved in OPZ + AC treatment group, there were still significant differences compared with OPZ + BXXXT (28 mg/kg) treatment group. After OPZ + BXXXT (28 mg/kg) treatment, the mice could basically recover to the normal level, implying therapeutical effects significantly better than that of the triple group (Figure 1). However, amoxicillin which does not develop drug resistance, produced therapeutical effects that contributed to the improvement in the OPZ + AC treatment group when

BXXXT: Banxia Xiexin decoction. The minimum inhibitory concentrations of the drugs for sensitive and drug-resistant strains are amoxicillin ≥ 0.5 μg/mL, clarithromycin ≥ 1.0 μg/mL, levofloxacin ≥ 2.0 μg/mL, and metronidazole ≥ 8.0 μg/mL.

combined with omeprazole. BXXXT, which did not demonstrate good effects *in vitro*, produced obvious therapeutical effects *in vivo*, which might be related to the synergistic and immunomodulatory effects of BXXXT aqueous extract.

Main pharmacodynamic components of BXXXT aqueous extract

MS-DIAL 3.70 (MS-DIAL: Data independent MS/MS deconvolution for comprehensive metabolome analysis) (Nature Methods, 12, 523-526, 2015).The original LC-MS data of BXXXT aqueous extract were imported into MS-DIAL, version 3.70 for preprocessing (MS-DIAL: Data independent MS/MS deconvolution for comprehensive metabolome analysis) (Nature Methods, 12, 523-526, 2015), including peak value extraction, noise-removal, deconvolution and peak alignment, and thereafter the three-dimensional data matrix in comma-separated values format was derived (original data matrix). The peak information extracted was compared with the database, with the full database search of MassBank, Respect and GNPS (14951 records in total). About 428 monomer components were identified, among which, as the related literature suggests, there were a total of 78 major components related to *H. pylori* resistance. Eleven species including berberine, emodin, baicalin, quercetin have been widely reported and demonstrate good antibacterial effects. Their ion additions and molecular structure are displayed in Table 5. It could be suggested that among the components of BXXXT aqueous extract, in addition to berberine, other components such as emodin also have inhibitory effects, which provides experimental basis for the better antibacterial effects *in vitro* BXXXT aqueous extract could produce compared with berberine.

Synergistic antimicrobial effects of main pharmacodynamic components of BXXXT aqueous extract

Six groups of berberine and emodin, berberine and luteolin, luteolin and gallic acid, luteolin and rosmarinic acid, catechuic acid and quercetin, catechuic acid and emodin were selected from 12 main anti-HP components of water extract of BXXXT aqueous extract for combined drug sensitivity detection. The results suggested that the six groups demonstrated additive or synergistic effects on *H. pylori* (Table 6), berberine and emodin, luteolin and gallic acid in particular producing better synergistic effects. Similar effects might also be found in other component combinations that had not been verified, which provides further experimental evidence that BXXXT aqueous extract could produce better antibacterial effects *in vitro* than berberine.

Immunobactericidal effects of BXXXT aqueous extract on mice

The *t*-test was used to analyze the proportion of $CD3^+$ T, $CD4^+$ T, and $CD8^+$ T cells in total lymphocytes

before and after administration. After administration, the proportion of $CD3^+$ T and $CD4^+$ T in total lymphocytes increased ($P1 = 0.0009$, $P2 = 0.0115$), as shown in Figure 2A-F; no significant difference was found between $CD8^+$ T cells and TH1 cells ($P3 = 0.1937$, $P4 = 0.8061$), Figure 2A, C, D, and G, and the ratio of $CD4^+$ T/$CD8^+$ T cells was increased ($P5 = 0.0280$) as displayed in Figure 2H. These results indicated that BXXXT aqueous extract could improve the ratio of lymphocytes $CD3^+$ T and $CD4^+$ T to the total number of lymphocytes and the ratio of $CD4^+$ T/$CD8^+$ T cells. However, BXXXT aqueous extract could enhance immune functions, thus helping improve the immunity and antibacterial ability of the body, which might explain why BXXXT could produce better treatment effects *in vivo*.

Mechanism of action of BXXXT aqueous extract on H. pylori

No significant changes were found at × 10000 magnification on the morphological structures of *H. pylori* after 4 h and 8 h of BXXXT treatment (Figure 3A), indicating that BXXXT did not produce antibacterial effects by directly destroying morphological structures. In the samples treated with BXXXT for 8 h, a total of 357 differentially expressed genes were detected after transcriptome analysis, among which 133 genes were up-regulated and 224 genes down-regulated (Figure 3B), mainly concentrating in five metabolic pathways including metabolic pathways, the epithelial cell signaling in *H. pylori* infection and the microbial metabolism in diverse environments (Figure 3C). The epithelial cell signaling in *H. pylori* infection pathway suggested that it is closely related to urease genes and virulence genes, as shown in Figure 3D. The proteome detection found 86 differentially expressed genes, among which 44 were up-regulated and 42 down-regulated (Figure 3E), mainly concentrating in oxidoreductases and transferases pathways (Figure 3F). Among the related genes and proteins found in transcriptome and proteome, respectively, and concentrating in the main pathways, five possible proteins of BXXXT were screened, among which four were urease-related and one was related to the virulence gene *CagA* (Table 7). The quantitative PCR (Q-PCR) and Western blot detection were performed to confirm the correlation between BXXXT action and virulence genes and urease genes. The results suggested that the mRNAs and protein expressions of *CagA* and *VacA* after BXXXT treatment were significantly decreased (Figure 4A-D), providing additional evidence for the obvious effects of BXXXT *in vivo* from the point that BXXXT could reduce virulence of *H. pylori*. The gene *CFAs* related to environmental regulation, urease and drug resistance was mutated (Figure 4E), after which the MIC of the mutant strains increased 2-4 times (Figure 4F), further proving that the urease-related gene *CFAs* might be one of the main targets of BXXXT. However, the decrease of urease could affect the adaptive regulation of stomach acid for which *H. pylori*' s ability to colonize would be significantly reduced.

DISCUSSION

There are about 4.4 billion people with *H. pylori* infections worldwide, with an average infection rate of 62.8%. Southeast Asia could be considered as high-incidence areas, mainly China, Japan, and South Korea[14,15]. The eradication of *H. pylori* has proven to prevent gastric cancer. However, the overuse of antibiotics leads to serious drug resistance. The drug resistance rate varies in different countries and regions and will change over time, indicated by those of clarithromycin, metronidazole, and levloxacin, all increasing over time. For example, the drug resistance rate of clarithromycin rose to 21% between 2012 and 2016[16-18]. Therefore, the failure rate of treating *H. pylori* infectious diseases is increasing,

MIC: Minimum inhibitory concentration.

leading to an urgent need to study and develop anti-*H. pylori* drugs. In 2018, Hu *et al*[19] from Peking University proposed that non-antibiotic drugs such as traditional Chinese medicine, mucosal protective agents and probiotics could be used to treat *H. pylori* infection. Traditional Chinese medicine, including BXXXT, has a good effect on *H. pylori* infection and *H. pylori*-infection-related diseases[20,21]. However, its pharmacological mechanism remains unclear, and whether it has an effect on drug-resistant *H. pylori* infection or not has not been confirmed by animal experiments.

This study confirms that BXXXT has good therapeutic effects on drug-resistant *H. pylori* infection through *in vivo* and *in vitro* experiments in mice, which provides an experimental basis for elaborating that BXXXT could treat refractory gastritis caused by drug-resistant bacteria. While the efficacy of BXXXT is well established, explaining its mechanism is difficult. Traditional Chinese medicine, especially compound prescriptions, has complex components and a very complex mechanism of action in the body, which might be affected by multiple factors, especially those in stomach. Besides, it produces effects that are multi-target. As the content of the main components of the prescription is not high, the effects on the target may not always appear[22-24], which makes it difficult to elaborate on the mechanism of action. In the present study, the composition of BXXXT was analyzed, the effective anti-HP components were screened out with reference to the related literature and reports, the material basis of the efficacy was identified, and the synergistic effects among some of the effective components was verified. It was found that most of the components had additive or synergistic effects, such as berberine and emodin, luteolin and gallic acid. This indicated that though only accounting for a small portion, the active components of the Chinese medicine prescription, which could produce synergistic or additive effects demonstrated better antibacterial effects. The MIC of BXXXT against *H. pylori* is 256-512 μg/mL, much worse than that of clinical antibiotics but producing better therapeutical effects *in vivo*, especially

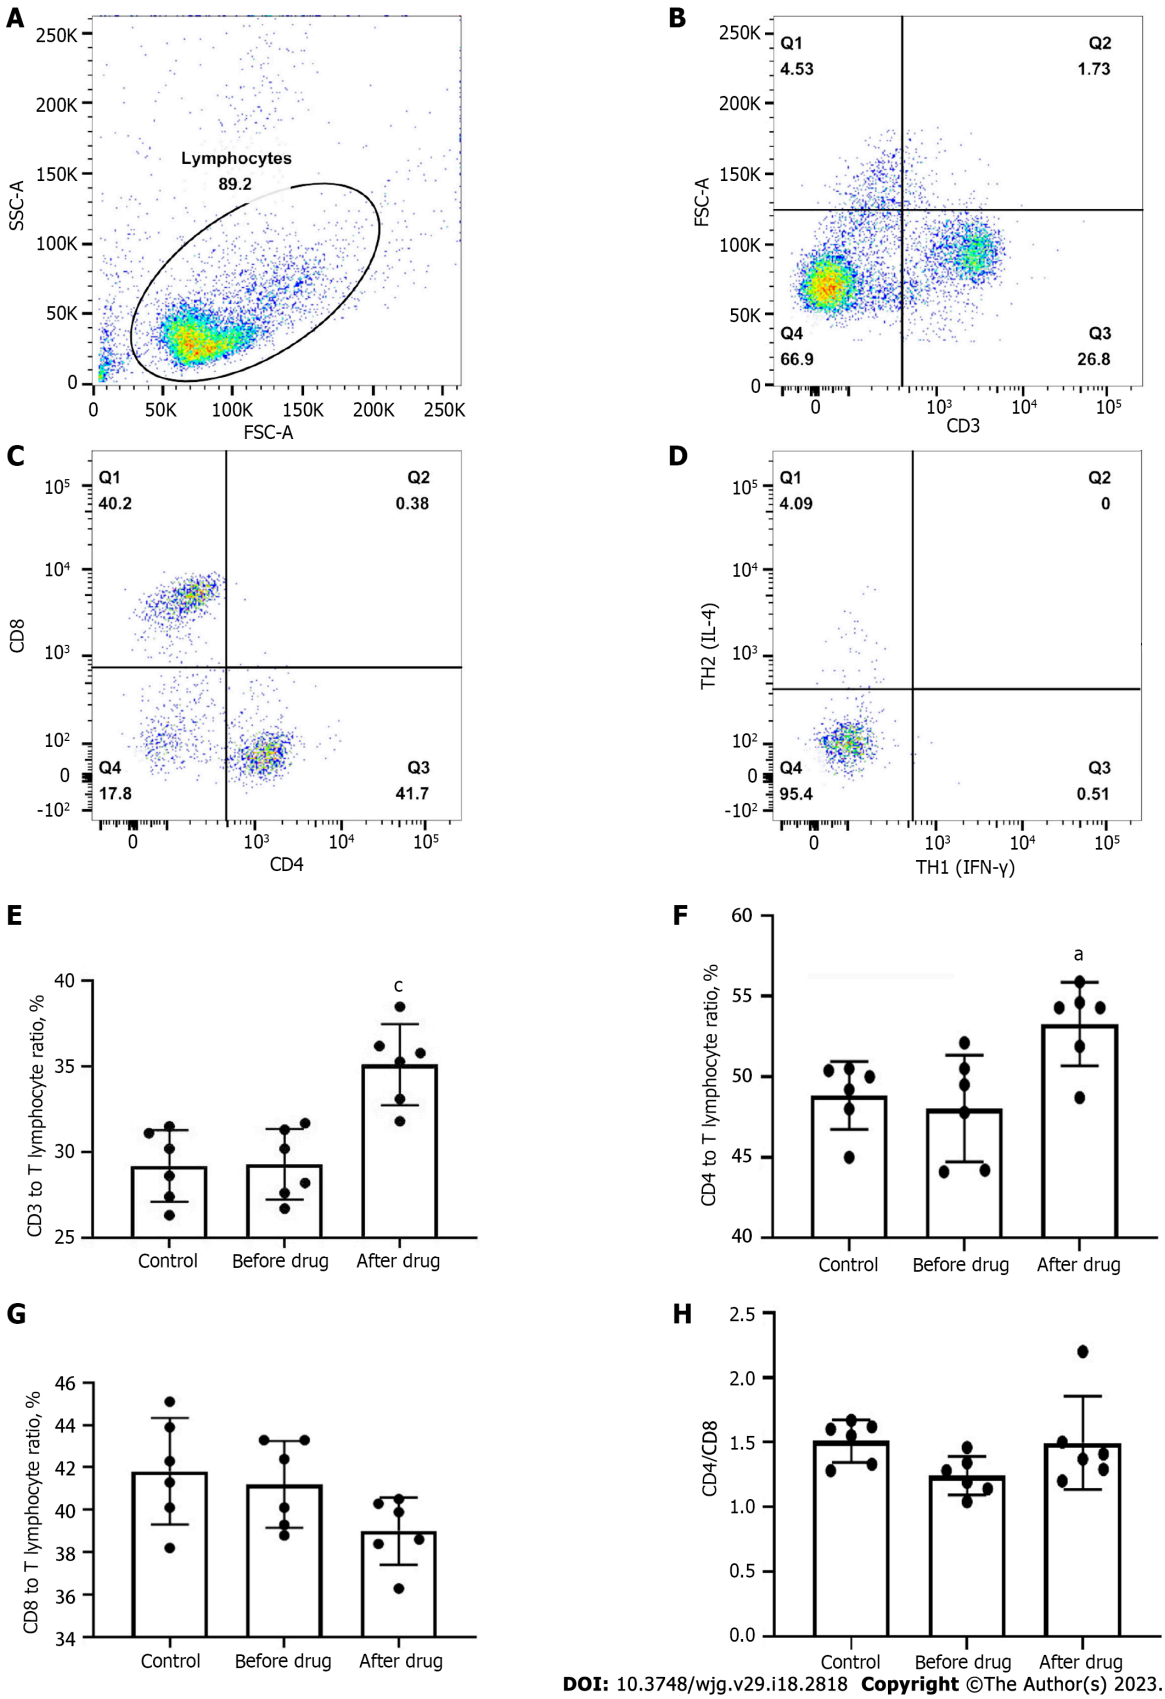
for drug-resistant *H. pylori*, why?

H. pylori can adhere to the gastrointestinal mucosa, produce virulence factors, damage gastric epithelial cells, and induce, control and regulate inflammatory responses. CagA encodes variety of proteins, including CagA and VacA, *ect*[25]. Karbalaei *et al*[26] found that *CagA* and *VacA* genes were potentially associated with resistance to clarithromycin, metronidazole, amoxicillin, tetracycline and levofloxacin. The VacA can not only destroy mitochondria[27,28], but also reduce the proliferation of T cells, B cells, and the other immune cells, and affect the immune response[29-31]. Among the components of BXXXT, Gingerol, a crude extract containing gingerol, is able to can inhibit the growth of *H. pylori* strains (MIC range is 0.78 μg/mL to 12.5 μg/mL) and has significant activity against $CagA^+$ strains[32]. Kaempferol is able to reduce the transcription of subunit protein A by the type IV secretory system, reduce the expression of pro-inflammatory cytokines (TNF-α, IL-1β) and IL-8 production in cells [33]. Urease can increase the pH value of the stomach and provide a suitable environment for *H. pylori* colonization. Palmatine in Coptis coptitis can act on sulfhydryl at the active site of urease and inhibit the conformational change of the urease molecules, and reduce urease activity[34]. Hesperidin can reduce the expression of UreA and UreB[35].



In the present paper, the immunomodulatory effect of BXXXT was analyzed, and it was found that it could up-regulate the expressions of immune factors such as $CD4^+$ T and enhance immunity and the ability of sterilization; the main target of BXXXT was urease-related gene *CFAs*, which was related to the virulence factors *CagA* and *VacA*. When urease was destroyed, *H. pylori* cells could not survive in the gastric acid environment, and its colonization ability would be significantly weakened. With low expressions of *H. pylori* virulence factors, the inflammatory damage caused by *H. pylori* to gastric mucosa would be reduced. The effects of these three aspects could preliminarily explain why BXXXT has good effects *in vivo*. However, clarifying the action mechanism of BXXXT is very complicated and difficult, for there are many components of BXXXT, among which many are anti-*H. pylori*, the

transcriptome and proteome analyses in this study also suggested that many membrane transporter genes were involved, such as ABC transporter, *etc*. Besides, we also found that berberine and other components of BXXXT could inhibit *HefA* gene to reverse drug resistance[25] and *CFAs* in this study might also be related to drug resistance[36,37]. Therefore, the action mechanism of BXXXT will be further studied.

ARTICLE HIGHLIGHTS

Research background

Helicobacter pylori (*H. pylori*)' s drug resistance brings challenges to the current clinical work. In China, traditional Chinese medicine could be used to treat a variety of refractory diseases, reducing drug-resistance, and improving the eradication rate of *H. pylori*. The study is to explore the therapeutic effects of Banxia Xiexin Decoction (BXXXT) on drug-resistant *H. pylori*.

Research motivation

H. pylori' s drug resistance brings challenges to the current clinical work. The study is to explore the therapeutic effects of BXXXT on drug-resistant *H. pylori*, avoid, overcome *H. pylori*' s drug resistance.

Research objectives

To confirm that BXXXT demonstrates therapeutical effects *in vivo* and *in vitro* on gastritis mice with drug-resistant *H. pylori* and explain its mechanism.

Research methods

The aqueous extract of BXXXT was gained by water decocting method. The inhibitory effect of the aqueous extract on *H. pylori* was detected by dilution in vitro. In terms of mechanism exploration, the main medicinal compositions of BXXXT aqueous extract and the synergistic bacteriostatic effects they had demonstrated were analyzed using mass spectrometry; the immune function of peripheral blood cells such as $CD3^+$ T and $CD4^+$ T of mice were detected using a flow cytometry; the *H. pylori* transcriptome and proteome were detected. Differently expressed genes were screened and verification was performed thereon with knockout expression.

Research results

BXXXT aqueous extract against *H. pylori* was better therapeutical effects *in vivo* and *in vitro*; BXXXT aqueous extract was found to stimulate the expressions of $CD3^+$ T and $CD4^+$ T and increase the number of $CD4^+$ T/$CD8^+$ T in gastritis mice; the detection of transcriptome and proteome, quantitative polymerase chain reaction, Western blot and knockout verification revealed that the main targets of BXXXT aqueous extract are *CFAs* related to urea enzymes, and *CagA*, *VacA*, *etc*.

Research conclusions

BXXXT aqueous extract could demonstrate good therapeutic effects on drug-resistance *H. pylori in vitro* and *in vivo* and its mechanism is related to reduce the urease and virulence of *H. pylori*, weaken its colonization, and reduce its inflammatory damage to the gastric mucosa, *etc*.

Research perspectives

BXXXT aqueous extract has good therapeutic effects on drug-resistance *H. pylori*, can overcome *H. pylori* 's drug resistance.

ACKNOWLEDGEMENTS

Thank Professor Bi Hongkai of Nanjing Medical University for the gift of *Helicobacter pylori* strain.

Abstract

BACKGROUND

Endoscopy has rapidly developed in recent years and has enabled further investigation into the origin and features of intestinal tumors. The small size and concealed position of these tumors make it difficult to distinguish them from nonneoplastic polyps and carcinoma in adenoma (CIA). The invasive depth and metastatic potential determine the operation regimen, which in turn affects the overall survival and distant prognosis. The previous studies have confirmed the malignant features and clinicopathological features of *de novo* colorectal cancer (CRC).

AIM

To provide assistance for diagnosis and treatment, but the lack of a summary of endoscopic features and assessment of risk factors that differ from the CIA prompted us to conduct this retrospective study.

METHODS

In total, 167 patients with small-sized CRCs diagnosed by endoscopy were reviewed. The patients diagnosed as advanced CRCs and other malignant cancers or chronic diseases that could affect distant outcomes were excluded. After screening, 63 cases were excluded, including 33 *de novo* and 30 CIA cases. Patient information, including their follow-up information, was obtained from an electronic His-system. The characteristics between two group and risk factors for invasion depth were analyzed with SPSS 25.0 software.

RESULTS

Nearly half of the *de novo* CRCs were smaller than 1 cm (n = 16, 48.5%) and the majority were located in the distal colon (n = 26, 78.8%). The IIc type was the most common macroscopic type of *de novo* CRC. In a Pearson analysis, the differential degree, Sano, JNET, and Kudo types, surrounding mucosa, and chicken skin

mucosa (CSM) were correlated with the invasion depth ($P < 0.001$). CSM was a significant risk factor for deep invasion and disturbed judgment of endoscopic ultrasound. A high degree of tumor budding and tumor-infiltrating lymphocytes are accompanied by malignancy. Finally, *de novo* CRCs have worse outcomes than CIA CRCs.

CONCLUSION

This is the first comprehensive study to analyze the features of *de novo* CRCs to distinguish them from nonneoplastic polyps. It is also the first study paying attention to CSM invasive depth measurement. This study emphasizes the high metastatic potential of *de novo* CRCs and highlights the need for more research on this tumor type.

Key Words: *De novo* colorectal cancer; Carcinoma in adenoma; Endoscopic features; Clinical characteristics; Pathological features

Core Tip: *De novo* colorectal cancer (CRC) is a specific tumor with a small lesion. Many different features of *de novo* CRCs exist to distinguish them from non-neoplastic polyps. Moreover, the study highlights that *de novo* CRCs have special endoscopic and pathological features that distinguish them from traditional adenocarcinomas. Different pit pattern types indicate various tumor types; for example, the III-type pit pattern often occurs in tubular adenomas. For CRCs, invasion depth evaluation is a vital issue. Computed tomography imaging and endoscopic ultrasound are used for judging invasive depth. Besides, chicken skin mucosa may also be a risk factor.

INTRODUCTION

A *de novo* colorectal cancer (CRC) is a unique CRC that represents a significant public health challenge with high morbidity and mortality globally[1,2]. At present, CRCs have four recognized pathways of development: The carcinoma in adenoma (CIA) pathway (aka chromosomal instability pathway), the *de novo* carcinoma pathway, the serrated lesion-carcinoma pathway, and the inflammatory-carcinoma pathway. In the 1950s, *de novo*-originated CRCs emerged increasingly after the definition "de novo" was proposed. In recent decades, the Japanese proposed a *de novo* carcinoma pathway[3]. Unlike other pathways, a *de novo* CRC is a tumor derived from cancer cells without progression of adenomatous changes, as shown in Figure 1, and its true pathway remains unknown. Normal I type around tumor and lack of III or IV type pits is a hallmark of *de novo* CRC under endoscopy[4-6].

For endoscopists, the endoscopic featrures occupied a key position in diagnosis and treatment. Magnified chromoendoscopy and narrow-band imaging (NBI) technology can be used to observe pit pattern and extimate depth of invasion[7-11]. Apart of pit pattern, there existed several indicators could forecast depth of invasion, such as chicken skin mucosa (CSM), mucosa pulling and converging. The CSM is an area of 0.5 mm of pale-yellow speckles adjacent to colonic neoplasms resulting from fat accumulation in the lamina propria[12]. CSM was more common in neoplastic and advanced polyps [13]. In this study, we concentrate on relationship between CSM and depth of invasion. For the whole CRCs, we should get to know three things: Get to know who they are firstly, estimate depth of invasion secondly, and predict the risk of metastasis at last.

Epithelial-mesenchymal transition (EMT) refers to a cellular reprogramming process in which epithelial cells acquire a mesenchymal phenotype[14]. EMT has an important role in development, wound healing, and malignant progression[15]. Mueller *et al*[16] have found that E-cadherin express lower in *de novo* than ex adenoma carcinomas through immunohistochemistry (IHC)[16]. We further want to know the relationship between E-cadherin proportion and distant metastsis.

Until now, there was no a complete study about *de novo* CRC, so we make this study to construct a comprehensive system for diagnosis and treatment of *de novo* CRC.

MATERIALS AND METHODS

We retrospectively reviewed patients diagnosed with CRCs between 2010 to 2020 year. We selected all *de novo* CRC and CIA-type patients on the His Electric System. All lesions were diagnosed by a senior pathologist and confirmed by two pathologists. The results from two pathologists had more than 90% similarity, and discrepant results were determined by a cheif pathologist. These patients did not have other comorbidities that could significantly impact the distant outcomes. Essential clinical information was collected, including endoscopic features and pathological results (size, endoscopic features, macroscopic type, pit pattern, clinical diagnosis, pathologic diagnosis, infiltration (IFN), immunohistology, invasive depth, tumor budding (TB), grading, lymphocyte IFN, perineural IFN, growth pattern, and lymph node metastasis). Pearson and χ^2 tests were performed using SPSS (25.0) software. The difference between each group was statistically significant ($P < 0.05$). Oral informed consent was obtained from all participants *via* telephone calls.

The degree of staining was scored according to the staining intensity (0, no staining; 1, weak; 2, moderate; 3, strong) and the proportion of positive cells (0: 0%; 1: < 25%; 2: < 50%; 3: < 75%; 4: ≥ 75%). The score of each slice was determined by the staining index (staining intensity × proportion of positive cells). A staining index > 4 was classified as high-grade expression, while an index ≤ 4 was defined as low-grade expression.

The pathological film used in the study was IHC, with the patient's consent, and the patient's information was kept confidential; therefore, ethical approval was not required.

RESULTS

Clinical features of de novo CRCs

Nearly half (n = 16, 48.5%) of the *de novo* CRCs were less than 1 cm in size and located in the distal colon (n = 26, 78.8%). In contrast, CIA CRCs were mostly 2 cm (n = 21, 70.0%) and located at the proximal colon (n = 21, 70.0%). There were no significant differences in the other risk factors between the *de novo* and CIA groups ($P > 0.05$). In addition, we focused on the choice of treatment. All submucosa *de novo* CRCs were treated surgically, and seven CIA submucosa CRCs were treated endoscopically. The results are presented in Table 1.

Table 1 The clinical information of *de novo* and carcinoma in adenoma colorectal cancers

		De novo (*n* = 33)	CIA (*n* = 30)	χ^2	*P* value
Clinical information

Endoscopic characteristics of de novo CRCs

Based on endoscopic appearance, small CRCs were classified as type I (polypoid), type IIa (slightly raised), type IIb (flat), or type IIc (depressed)[12]. Type IIa + IIc is the most common type of *de novo* CRC. Notably, 15 (45.5%) *de novo* CRCs were Is type. We showed different macroscopic types of *de novo* CRCs, as shown in Figure 2. For CIA CRCs, the Is + IIc type (polypoid with depression) was the most common presentation (n = 19, 63.3%). Another significant finding was surface changes: We found that erosion and reddened mucosa are hallmark features of *de novo* CRCs. In the CIA group, erosion was the same as ulceration. Furthermore, reddened mucosa was seldom observed in the CIA group (n = 28, 93.3%). The endoscopic results are shown in Table 2.

There was a significant difference in the Sano and pit pattern types (P < 0.05) but no significant difference in the NBI International Colorectal Endoscopic (NICE) classification and JNET types between the two groups (P > 0.05). About half of the *de novo* CRCs were IIIA type (n = 17, 51.5%) with a Vi + Vn type pit pattern (n = 19, 57.6%). The most striking difference was in the pit pattern around the edges of the lesions: I type pit patterns (small and round pits) were observed in all *de novo* CRCs (n = 33, 100%), and III + VI type pit patterns were observed in all CIA CRCs (n = 30, 100%).

We also analyzed the risk factors associated with the invasive depth (Table 3). A third (33.3%) of the *de novo* group had a CSM1 × *vs* 13.3% of the CIA group. CSM was associated with the depth of invasion [r (correlation coefficient) = -0.796, P < 0.001]. CSM1 has a high invasive potential for CRC. In addition to CSM, pulling and converging folds also appear in the mucosa surrounding CRCs. Mucosal pulling appeared more frequently in the CIA group (n = 21, 70.0%) than in the *de novo* group (n = 9, 27.3%). In contrast, the converging fold was more frequent in the *de novo* group (n = 27, 81.8%) than that in the CIA group (n = 15, 50%). After analyzing the relationship between these parameters and invasive depth, we found that mucosal pulling (r = 0.567, P < 0.001) and converging folds (r = 0.620, P < 0.001) were also significantly associated with invasive depth.

Pathological characteristics of de novo CRCs

Pathological results revealed that TB was significantly associated with invasive depth (r = 0.669, P < 0.001) (Table 4). Although there was no significant difference between the two groups, budding grade 3 (BD3) accounted for 33.3% of the *de novo* group, which is far more than that of the CIA group (n = 6,

20%). Regarding other pathological characteristics, perineural IFN, lymph node metastasis, and tumor-infiltrating lymphocytes (TIL) have also emerged in CRC tissues. There was a significant difference in perineural IFN and lymph node metastasis between the two groups ($P < 0.05$).

Another critical issue that deserves attention is IHC. In both groups, approximately 70% of the cases were MLH1 (+), MSH2 (+), MSH6 (+), PMS2 (+), CDX2 (+), Ki67 (+), and P53 (+). We extracted several sections that were stained for E-cadherin and vimentin (VIM). In the *de novo* group, the E-cadherin expression was low in the epithelial regions and VIM was high in the mesenchyma. The CIA group showed opposite results to the *de novo* group, as shown in Figure 3. We analyzed risk factors for distant metastasis in *de novo* group, the results are shown in Supplementary Table 1. Differential degree, Sano classification, expression of E-cad and VIM were correlated with distant metastasis. High expression of E-cad was negatively related with distant metastasis and VIM had an opposite result.

In addition, we explored whether the *de novo* type was correlated with relapse and survival. In the *de novo* group, 11 subjects developed neoplastic polyps again within 5 years, and 10 relapsed within 5 years. The 5-year survival rate was 93.3% for CIA and 69.7% for *de novo* CRCs. Log-rank analysis revealed no significant difference in relapse between the two groups ($\chi^2 = 0.49$, $P = 0.515$); however, there was a significant difference in the survival probability between the two groups ($\chi^2 = 7.08$, $P = 0.020$). Survival curves are shown in Figure 4.

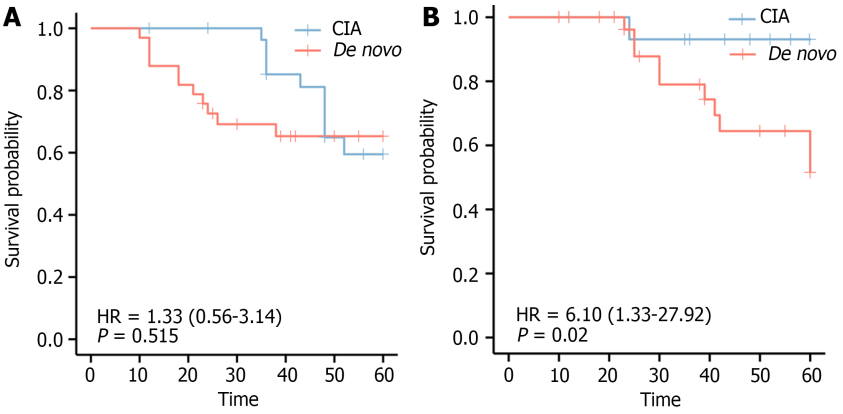
DISCUSSION



In this study, we present our novel findings pertaining to the characteristics of *de novo* CRC. The key findings included the following: (1) The incidence rate of *de novo* CRCs is considered lower than CIA CRCs, but our study showed that it is related to the classification of CRC. Although some *de novo* CRCs are limited to intramucosal cancer, they are not the same as high-grade dysplasia or cancer with high-grade intraepithelial neoplasia, which could be called advancing adenoma. An advancing adenoma is a precancerous lesion, whereas a *de novo* CRC is a type of early CRC. Some endoscopic physicians misdiagnose advanced adenomas as early CRCs; this will improve the diagnostic rate of CRC but reduce the incidence rate of *de novo* cancer. Therefore, we believe that the diagnostic bias of endoscopic physicians affects the incidence rate. One of the aims of this study was to bolster the standardized diagnostic requirements of endoscopic physicians and to understand *de novo* cancer from the molecular, pathological, and endoscopic perspectives. According to the Vienna classification, category 4 includes advanced adenoma/dysplasia and noninvasive carcinoma. The reason for the lower incidence of *de novo* CRCs in the previous study may be eliminated by comprehensively evaluating the characteristics comprehensively[17-20]; (2) In our study, 48.5% of *de novo* CRCs were < 1 cm in size. Some investigators excluded tumors > 1 cm because they thought that the adenomatous component might be obliterated by the expanding tumor mass[12]. In our study, 42.4% of the *de novo* CRC-derived tumors diagnosed by endoscopists and pathologists were ≥ 1 cm and ≤ 2 cm. In addition, there were three lesions larger than 2 cm. Therefore, warning regarding small lesions without adenomatous components should be escalated; and (3) In addition to platform lift, converging mucosa, pulling, and CSM are significant indicators of invasive depth. Fibroplasia causes surface changes during cancer cell invasion. Converging mucosa was more likely to occur in *de novo* CRCs than that in CIA group, and nearly half of the lesions (n = 16, 48.5%) had deeper invasion. Mucosal pulling may be caused by shrinkage of the mucosa or muscularis mucosa, indicating superficial layer invasion.

The cause of CSM may be fat accumulation in macrophages, which may result from the breakdown of lipids within colonocytes or adjacent tumors. These findings suggest that CSM is a valuable marker for differentiating between neoplastic and advanced polyps using conventional white colonoscopy[21]. Lee *et al*[13] divided CSM into three types based on their characteristics. Type 1 CSM was confirmed before

injection; type 2 CSM was observed after injection; and type 3 CSM was not observed. Types 1 and 2 were considered positive CSM findings. CSM is accompanied by an increased IFN of foam macrophages in the lamina propria, representing a large-scale inflammatory reaction. The appearance of CSM is also related to the increased expression of Ki-67 and COX2, which suggests that the early appearance of CSM symbolizes a high malignancy. However, whether the appearance of CSM and the IFN of macrophages in the lamina propria affect the determination of the depth of IFN by endoscopic ultrasound (EUS) is unknown. After diagnosing white light endoscopy, magnifying endoscopy, and endoscopic ultrasonography, we concluded that the lesion was a *de novo* cancer with deep invasion, which was no longer suitable for endoscopic treatment. However, after surgical resection, pathology showed that the depth of invasion only reached the M2 layer. After further analysis of the pathology, we found that many inflammatory cells infiltrated the lesion, leading to errors in determining the IFN depth.

Figure 5 The surrounding pit of *de novo* colorectal cancer and carcinoma in adenoma group. The surrounding pit around *de novo* colorectal cancer (CRC) is elongated I-type and IIIL-type around carcinoma in adenoma CRC.

Under NBI and magnifying endoscopy patterns, the surface and vascular microstructures can be clearly evaluated. The NICE classification is a method for assessing the characteristics of lesions under the NBI model, which is based on the color, vessel, and general surface pattern[22]. The NICE classification can help reduce the risk of failing to detect diminutive and small lesions, which are easily regarded as polys[23]. Nevertheless, the NICE classification had no differential ability for *de novo* CRCs and CIA CRCs. The pit pattern of CRC characteristics was categorized according to the Kudo and Tsuruta classification system. Type IIIL and IV patterns are often observed in adenomas and CIA CRCs. Type V is subclassified into Vi and Vn, and occurs in cancers. The surrounding I type pit is a landmark in the diagnosis of *de novo* CRCs. However, the normal I type often deforms and confounds with an abnormal pit due to the extrusion or invasion of cancer. The IIIs type pit was round and smaller than the I type pit, and IIIL was more irregular than the elongated I type pit. An example is shown in Figure 5.

De novo CRCs have greater metastatic potential, and all pathological indicators indicate that *de novo* carcinoma has a higher metastatic potential and worse prognosis. All *de novo* cancers were classified as microsatellite stability (MSS). In the *de novo* group, the degree of TB and lymphocyte IFN was higher than that in the CIA group and was positively correlated with the depth of invasion and poor prognosis. The IHC results also showed that the expression of E-cadherin in the *de novo* group was lower than that in the CIA group. At the same time, the interstitial-related index VIM was higher than that in the CIA group, which means that the metastatic potential of the tumor in the *de novo* group was higher than that in the CIA group. TB is defined as "a single cancer cell or a cell cluster of 5 cancer cells or less". Larger tumors are called poorly differentiated tumor cell nests. TB is closely correlated with disease recurrence and poor prognosis in SM-invasive CRCs[24-27].

In addition, the TB degree had a relationship with other pathological features. In general, tumor tissues with BD2/3 are considered for further surgery[28]. The lymphocytic reaction is another crucial part of pathological changes in CRCs, which includes Crohn's-like reaction, peritumoral reaction, intratumoral periglandular reaction, and TIL[29]. TIL are defined as lymphocytes on the top of cancer cells, which can be used to predict immunotherapy response and survival outcomes. One study reported that tumors with microsatellite instability-high and sufficient CD8+ TIL had better outcomes than those with MSS/microsatellite instability-low and lower CD8+ TIL[30]. Compared to typical pathological indicators, TIL are a better factor for overall survival[29,31,32]. TIL are related to the expression of exhaustion and senescence markers in the tumor microenvironment[33,34].

This study have several promising implications during clinical practice. Due to the highly invasive and metastatic ability of *de novo* CRC, endoscopic mucosal resection or endoscopic submucosal dissection could not be performed without exact observation when we find small protruded or depressed lesions. Observing the lesions with magnified endoscopy and chromoendoscopy is necessary to confirm the diagnosis. If we suspect the lesions may be *de novo* CRCs, it is crucial evaluating invasion depth by magnified endoscopy and chromoendoscopy, or by computed tomography imaging and EUS when necessary. Then, the treatment regimens should be chosen cautiously. In the future, we will further study the molecular biological difference between *de novo* CRC and CIA CRC to find out the molecular mechanism of invasion and metastasis of *de novo* CRCs.

However, there exists some limitations in the study. The sample size appear to be small for deficience of acknowledge of *de novo* CRCs. Moreover, this appears as a single center study, and the pathogenesis/incidence of *de novo* CRC might be different in other countries.

CONCLUSION

This review summarizes the characteristics of *de novo* CRCs and confirms the conclusions of our study.

A *de novo* CRC is a small, but malignant tumor that requires more attention during colonoscopy examination. *De novo* CRCs have special endoscopic and pathological features that distinguish them from the traditional adenocarcinomas. However, more studies are needed to determine the molecular characteristics to explain the genesis mechanism.

ARTICLE HIGHLIGHTS

Research background

The small colorectal small tumors usually be ignored during colonoscopy. However, many depressed or flat lesions have substantial invasion and metastasis. *De novo* colorectal cancer (CRC) is one type of small tumor related to poor prognosis. And some endoscopists could not distinguish *de novo* CRC during the examination.

Research motivation

Some small lesions were cut off directly in the examination without computed tomography imaging and endoscopic ultrasound. This may lead to mistreatment because endoscopists often ignore the judgment of invasion depth. The *de novo* CRC may have a deep invasion layer.

Research objectives

This study aimed to comprehensively review *de novo* CRCs and provide a reference atlas for future studies and analyze the features of *de novo* CRCs to distinguish them from non-neoplastic polyps.

Research methods

This study collected clinical and pathological information on *de novo* patients and stained E-cadherin and vimentin by immunohistochemistry. Based on this information, we analyzed the characteristic of *de novo* CRC and the relative correlation between different indicators.

Research results

This study highlights that *de novo* CRCs have special endoscopic and pathological features that distinguish them from traditional adenocarcinomas. It is also the first study paying attention to chicken skin mucosa invasive depth measurement. More importantly, this study summarized several factors relevant to invasion depth and provide tremendous help in clinical practice to increase diagnostic ability.

Research conclusions

This first study pointed out the relationship between *de novo* CRC and epithelial-mesenchymal transition related genes. And it is the first study put forward that chicken skin mucosa indicates the depth of invasion.

Research perspectives

We will further study the molecular biological difference between *de novo* CRC and carcinoma in adenoma CRC to discover the mechanism of invasion and metastasis of *de novo* CRCs.

Abstract

BACKGROUND

Advanced gastric cancer with synchronous peritoneal metastases (GC-PM) is associated with a poor prognosis. Although cytoreductive surgery with hyperthermic intraperitoneal chemotherapy (CRS-HIPEC) is a promising approach, only a limited number of Western studies exist.

AIM

To investigate the clinicopathological outcomes of patients who underwent CRS-HIPEC for GC-PM.

METHODS

A retrospective analysis of patients with GC-PM was conducted. All patients were seen at the Department of General and Visceral Surgery, Hospital Barmherzige Brüder, Regensburg, Germany between January 2011 and July 2021 and underwent CRS-HIPEC. Preoperative laboratory results, the use of neoadjuvant

trastuzumab, and the details of CRS-HIPEC, including peritoneal carcinomatosis index, completeness of cytoreduction, and surgical procedures were recorded. Disease-specific (DSS), and overall survival (OS) of patients were calculated.

RESULTS

A total of 73 patients were included in the study. Patients treated with neoadjuvant trastuzumab (n = 5) showed longer DSS (P = 0.0482). Higher white blood cell counts (DSS: P = 0.0433) and carcinoembryonic antigen levels (OS and DSS: P < 0.01), and lower hemoglobin (OS and DSS: P < 0.05) and serum total protein (OS: P = 0.0368) levels were associated with shorter survival. Longer HIPEC duration was associated with more advantageous median survival times [60-min (n = 59): 12.86 mo; 90-min (n = 14): 27.30 mo], but without statistical difference. To obtain additional data from this observation, further separation of the study population was performed. First, propensity score-matched patient pairs (n = 14 in each group) were created. Statistically different DSS was found between patient pairs (hazard ratio = 0.2843; 95% confidence interval: 0.1119-0.7222; P = 0.0082). Second, those patients who were treated with trastuzumab and/or had human epidermal growth factor receptor 2 positivity (median survival: 12.68 mo *vs* 24.02 mo), or had to undergo the procedure before 2016 (median survival: 12.68 mo *vs* 27.30 mo; P = 0.0493) were removed from the original study population.

CONCLUSION

Based on our experience, CRS-HIPEC is a safe and secure method to improve the survival of advanced GC-PM patients. Prolonged HIPEC duration may serve as a good therapy for these patients.

Key Words: Cytoreductive surgery; Hyperthermic intraperitoneal chemotherapy; Peritoneal metastasis; Stomach neoplasms; Gastric cancer

Core Tip: Advanced gastric cancer (GC) cases with peritoneal metastases are known for their poor survival rates. It has been previously reported that these patients benefit from cytoreductive surgery (CRS) with hyperthermic intraperitoneal chemotherapy (HIPEC) but available data on this treatment are scarce. In this study, we retrospectively analyzed the clinicopathological and laboratory data of 73 patients with advanced GC and synchronous peritoneal metastases. It was found that prolonged HIPEC duration after macroscopic complete CRS in the scope of multimodal treatment along with advanced perioperative chemotherapy and biologicals may serve as the best currently available therapy for these patients.

INTRODUCTION

Gastric cancer (GC) is the fifth most common cancer, with a worldwide incidence of 1,089,103 new cases and 768,793 deaths based on the 2020 GLOBOCAN results[1,2]. The majority of the new cases are diagnosed in Asia, where occurrence is 6-fold higher than in Europe; a similar distribution is observed in GC mortality[1]. In Germany, 15322 new cases and 9196 deaths were reported in 2020[1]. GC is known for its morphological diversity[3], and the most commonly used classifications are those outlined by Nakamura *et al*[4], Lauren[5], and the World Health Organization (WHO)[6]. The treatment of gastric cancer is multidisciplinary and depends on the clinical staging of the tumor. While early-stage GC (stage T1a) can be endoscopically resected[7], stage T1 with positive lymph node(s) and T2-T4a tumors regardless of lymph node status are treated by surgical resection and peri- or postoperative chemotherapy[8]. Advanced resectable GCs are typically treated with neoadjuvant chemotherapy followed by gastrectomy and adjuvant chemotherapy[9]; if not amenable to resection, then the treatment of choice is chemotherapy[8].

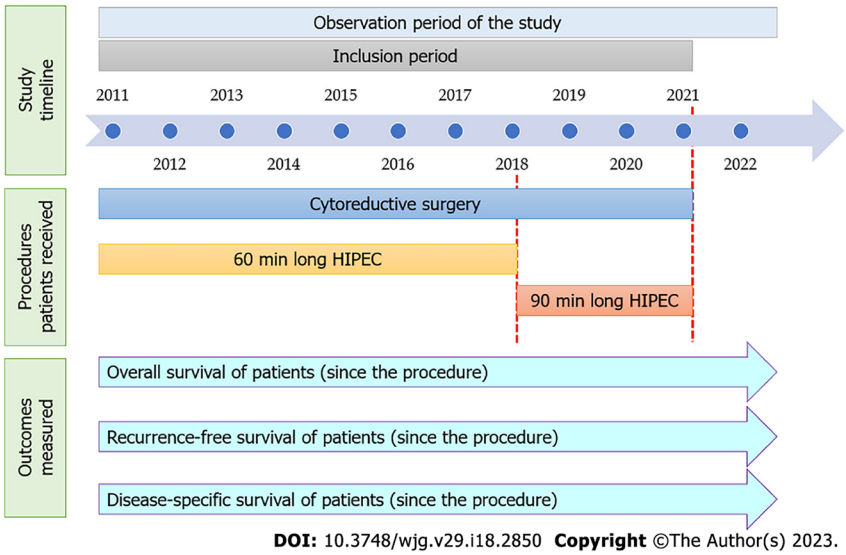
A recent analysis of 18,000 United States patients showed that advanced GC with PM has a median survival of 8.6 mo if treated with chemotherapy only[10], while studies from the United States[11], China[12] and Germany[13] have shown that advanced GCs with peritoneal carcinomatosis benefit significantly from cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC)[11-15] when complete macroscopic resection of the tumor tissue can be achieved[16]. Nevertheless, the available data regarding the use of CRS and HIPEC in advanced GC with PM is scarce, and this multimodal therapy has infrequently been recommended in any national or international guidelines. To date, the Japanese[17] and the United States[18] guidelines do not include CRS and HIPEC as therapeutic options. In France, the guidelines for treatment of advanced GC with PM[19] are yet to be defined in future randomized phase III studies. The same is true in Germany, where an expert consensus-based recommendation calls for the implementation of CRS and HIPEC in clinical studies[8]. The European Society for Medical Oncology guidelines for the treatment of gastric cancer describe CRS and HIPEC as safe procedures, but with unclear oncological outcomes[20]. Accordingly, the aim of this retrospective study was to investigate the clinical outcome after administration of this multimodal therapy in a tertiary center to treat patients with primary advanced GC with PM.

MATERIALS AND METHODS

Patients and study design

The HIPEC database of a single tertiary care center was analyzed in a retrospective manner. A total of 73 patients seen at the Department of General and Visceral Surgery, Hospital Barmherzige Brüder, Regensburg, Germany between January 2011 and July 2021 with primary GC and synchronous PM were included (Figure 1). All patients gave written and verbal informed consent to be included in the national HIPEC registry, administered by the German Society for General and Visceral Surgery (DGAV), and for the use of their anonymized data for research purposes and quality assurance prior to any study-specific procedures. All 73 patients underwent CRS + HIPEC and were treated according to national or international multidisciplinary recommendations[8,20].

Details of CRS + HIPEC



Each of the 73 cases was discussed by a multidisciplinary board of experts (oncologists, surgeons and anesthesiologists) before any treatment decision was made. Preoperatively, the extent of peritoneal dissemination was assessed using abdominal and chest computed tomography (CT) scans. The peritoneal carcinomatosis index (PCI)[21] was calculated based on diagnostic laparoscopy performed on tumors of T3 stage or higher or CT evidence of peritoneal carcinomatosis[22]. Prior to surgery, all patients were preconditioned as per the enhanced recovery after surgery (ERAS) protocol. During CRS, the completeness of cytoreduction (CC) was scored as proposed by Jacquet and Sugarbaker[21]: No residual disease, residual nodules measuring less than 2.5 mm, between 2.5 mm and 2.5 cm, or greater than 2.5 cm were defined as CC-0, CC-1, CC-2, and CC-3, respectively.

Closed HIPEC with a goal temperature of 42 °C with bidirectional HIPEC with cisplatin (75 mg/m^2) and doxorubicin (15 mg/m^2) was administered immediately after CRS for 60 min or 90 min duration (Figure 1). The duration of HIPEC was changed from 60 min to 90 min in 2018 based on the findings of van Driel's study[23]. The cytotoxic agents were added to a 3000 mL-4000 mL isotonic saline solution with a mean flow rate of 1400 mL/min-1800 mL/min. During the treatment, temperature probes for monitoring the 42 °C goal temperature were placed in the right subphrenic and pelvic areas.

Clinicopathological and laboratory data measurements

Clinicopathological and laboratory data were obtained from the DGAV HIPEC registry and the electronic medical system of Hospital Barmherzige Brüder, Regensburg, Germany. The staging of the tumors was unified using the 8th American Joint Committee on Cancer (AJCC) TNM system[24]. Histopathology types of the tumors were categorized as diffuse type adenocarcinoma (ACD), intestinal type adenocarcinoma (ACI), or signet-ring cell adenocarcinoma (SRC)[3]. Neoadjuvant chemotherapeutic treatment of patients was recorded as the latest lineage the patient received prior to CRS + HIPEC. Except for a single patient, all study participants were treated with at least docetaxel-based first-line chemotherapy (FLOT protocol: 5-fluorouracil, leucovorin, oxaliplatin, and docetaxel; or DCF protocol: docetaxel, cisplatin, and 5-fluorouracil). Chemotherapy was administered in accordance with the German guidelines on GC; when recommendation changed from EFC/ECX (Epirubicin, Cisplatin, Fluorouracil/Epirubicin, Cisplatin, Capecitabine) to FLOT after Al-Batran's FLOT-4 study in 2019[25], chemotherapy was accordingly changed. The additional use of trastuzumab (trade name: Herceptin) was also recorded.

Complete blood count, liver enzyme, lipase, creatinine, and tumor marker blood tests were performed at the Department of Laboratory Medicine, Microbiology, and Hospital Hygiene, Hospital Barmherzige Brüder, Regensburg, Germany. The Chronic Kidney Disease Epidemiology Collaboration equations were used to calculate estimated glomerular filtration rate[26]. The Clavien–Dindo Classification[27] was used to assess postoperative adverse events. Although some recent publications have

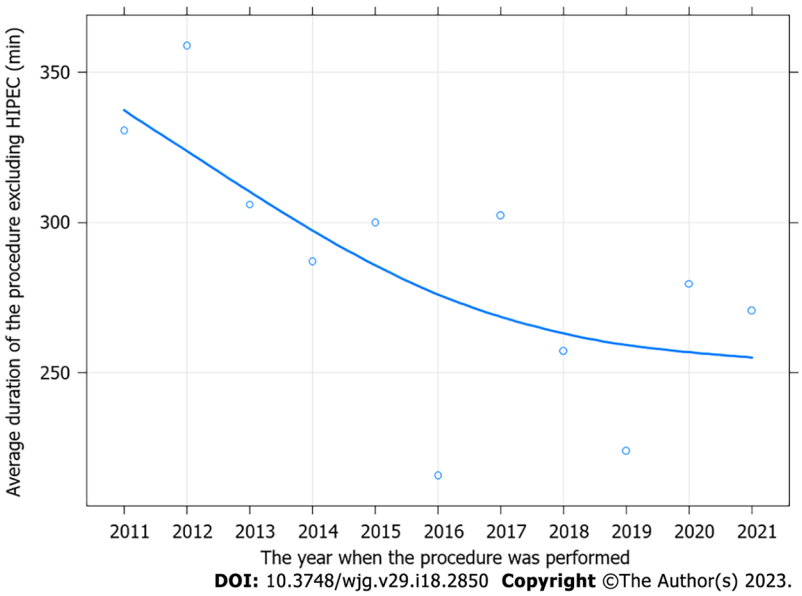
Figure 1 Timeline of the study. HIPEC: Hyperthermic intraperitoneal chemotherapy.

suggested including all patient deaths within 90 d as post-procedure deaths[28,29], HIPEC-related post-procedure deaths were defined as follows: (1) Those occurring during the observation period at the intensive care unit or at the surgical inpatient unit prior to discharge; or (2) Between discharge and adjuvant chemotherapy. If a patient had started adjuvant chemotherapy, their death was defined as GC-related. Recurrence-free (RFS), disease-specific (DSS), and overall survival (OS) were calculated from the date of surgery (CRS + HIPEC) to the date of tumor recurrence, cancer-related death, or death from any cause, respectively. The follow-up of patients was terminated on 30 September 2022 and the patients alive at this time point were right censored (Figure 1).

Statistical analysis



Statistical analyses were performed within the R for Windows version 4.2.1 environment (R Foundation for Statistical Computing, 2022, Vienna, Austria). Wilcoxon rank sum test and Fisher's exact test were used for group comparisons. Linear models were used to investigate whether there was an improvement in the duration of the procedure (learning curve). Matching of patient pairs was done *via* propensity score matching (R-package "Matching" version 4.10-8). DSS, OS, and RFS were determined using the cause-specific competing risk Cox survival model (R packages "survival" version 3.4-0 and "survminer" version 0.4.9). Parameter selection for multivariate survival models was not based on univariate P value, but on literature data and the medical/clinical importance of the given parameter. $P < 0.05$ was considered statistically significant, and P values were corrected with the Holm method[30] for the multiple-comparisons problem. Continuous, survival, and count data were expressed as the mean ± standard deviation (SD), the hazard ratio (HR) with a 95% confidence interval (95%CI), and the number of observations (percentage), respectively.

RESULTS

A total of 73 GC patients with PM were included in the study. Sixty-four cancer-related death events, 13 tumor recurrence events, and 1 death due to postoperative complications occurred. The complete list of pre-, peri- and postoperative clinicopathological characteristics of study participants are listed in Supplementary Table 1. In general, the average operating times (excluding the time for HIPEC) improved significantly over observation period ($P = 0.0097$; Figure 2).

First, it was investigated whether any of the CRS + HIPEC-related or clinicopathological features had a significant effect on patient survival. The need to remove any further organs, such as the removal of the bladder or the appendix during CRS ($n = 9$), was associated with a negative effect on DSS (HR: 2.0538; 95%CI: 1.2715-3.3179; $P = 0.0033$). Those patients who received additional trastuzumab treatment during neoadjuvant chemotherapy ($n = 5$) before the CRS + HIPEC procedure had better DSS (HR: 0.4446; 95%CI: 0.1989-0.9937; $P = 0.0482$). A trend towards longer RFS was found in patients who did not require pelvic peritonectomy (HR: 0.3382; 95%CI: 0.1099-1.0410; $P = 0.0588$). OS was significantly better in patients without pelvic peritonectomy (HR: 0.5459; 95%CI: 0.3152-0.9454; $P = 0.0307$).

Longer HIPEC duration (60 min *vs* 90 min) was associated with more advantageous median survival times: 12.86 mo (95%CI: 11.01-17.31) for the 60 min and 27.30 mo (95%CI: 16.20-NA) for the 90 min cohorts (Supplementary Table 1). However, despite the clinically different median survival times, the

Figure 2 Improvement of the operating times of cytoreductive surgery (excluding hyperthermic intraperitoneal chemotherapy) in our surgical center during the study period. HIPEC: Hyperthermic intraperitoneal chemotherapy.

survival of the groups did not differ based on the results of the statistical models with respect to DSS (HR: 0.6239; 95%CI: 0.3413-1.1410; P = 0.1250; Figure 3), OS (HR: 0.6134; 95%CI: 0.3007-1.2510; P = 0.1790), or RFS (P = 0.9650). Furthermore, the type of histology (ACD *vs* ACI *vs* SRC) did not affect DSS (P = 0.4096; Supplementary Figure 1),OS (P = 0.2422), or RFS (P = 0.2799). However, the RFS survival curves of the different histology types seemed to be visually different (Figure 4).

The effect of pre-HIPEC laboratory results on patient survival was also investigated. Higher white blood cell counts (HR: 1.1319; 95%CI: 1.0037-1.2770; P = 0.0433) and carcinoembryonic antigen (CEA) levels (HR: 1.1490; 95%CI: 1.0422-1.2667; P = 0.0053) were associated with an increased risk for shorter DSS. In contrast, higher hemoglobin (HR: 0.7897; 95%CI: 0.6562-0.9505; P = 0.0125) and serum total protein (HR: 0.6795; 95%CI: 0.4330-1.0660; P = 0.0928) levels were associated with a significant and marginally decreased risk for shorter survival, respectively. The same results were found for OS (white blood cell count: P = 0.0945; CEA: P = 0.0052; hemoglobin: P = 0.0087; serum total protein: P = 0.0368), while shorter RFS times were observed in patients with higher RDW levels (HR: 1.2190; 95%CI: 1.0030-1.4810; P = 0.0466). Moreover, similar to that observed with respect to OS and DSS, marginally advantageous RFS was justified for higher serum total protein levels (P = 0.0875).

The effect of clinicopathological and laboratory data on survival was also further investigated in a multivariate setting (Table 1). DSS was marginally affected by the duration of HIPEC [60 min (ref.) *vs* 90 min: HR: 0.5252; 95%CI: 0.2565-1.0750; P = 0.0781] and by PCI (HR: 1.0630; 95%CI: 0.9982-1.1310; P = 0.0569), and significantly by preoperative serum CEA levels (HR: 1.2220; 95%CI: 1.0880-1.3720; P = 0.0007). Similar trends were observed for OS, while worse RFS was more likely associated with lower preoperative white blood cell count (HR: 0.4616; 95%CI: 0.2270-0.9385; P = 0.0327), lower T stage (HR: 13.1182; 95%CI: 1.0285-167.3080; P = 0.0475), and higher N stage (HR: 5.6893; 95%CI: 0.7616-42.4972; P = 0.0902).

Comparison of the 60 and 90-min-long HIPEC patient groups

Further comparison was performed by creating 2 groups according to the duration of HIPEC. Fifty-nine and 14 study participants were enrolled in the 60 min and 90 min groups, respectively. Except for the above-described median survival differences (12.86 mo *vs* 27.30 mo; Figure 3), no difference was found in any clinicopathological characteristic between the two groups after P value adjustment (Supplementary Table 1).

By investigating the results without P value adjustment, several observations were made. The length of CRS trended toward being shorter in the 90 min group (299 ± 76 min *vs* 264 ± 82 min; crude P = 0.0718). Peritonectomy of the omental bursa was more frequently performed in the 60-min group (30.5% *vs* 0%; crude P = 0.0157), while lesser omentectomy was more common in the 90-min group (33.9% *vs* 71.4%; crude P = 0.0153). Fresh frozen plasma (FFP) transfusion was needed only once in the 90 min group, while in the 60-min group, FFP was administered in 32 patients (7.1% *vs* 54.2%; crude P = 0.0009). On average, the length of hospital stay was shorter in the 90 min group (crude P = 0.0134); a more detailed examination of the data revealed that hospitalization longer than 20 d was more common in the 60 min group (39.0% *vs* 7.1%; crude P = 0.0276). Moreover, abnormal serum levels of gamma-glutamyl transferase (crude P = 0.0407, Figure 5A) and serum total protein (crude P = 0.0570, Figure 5B)

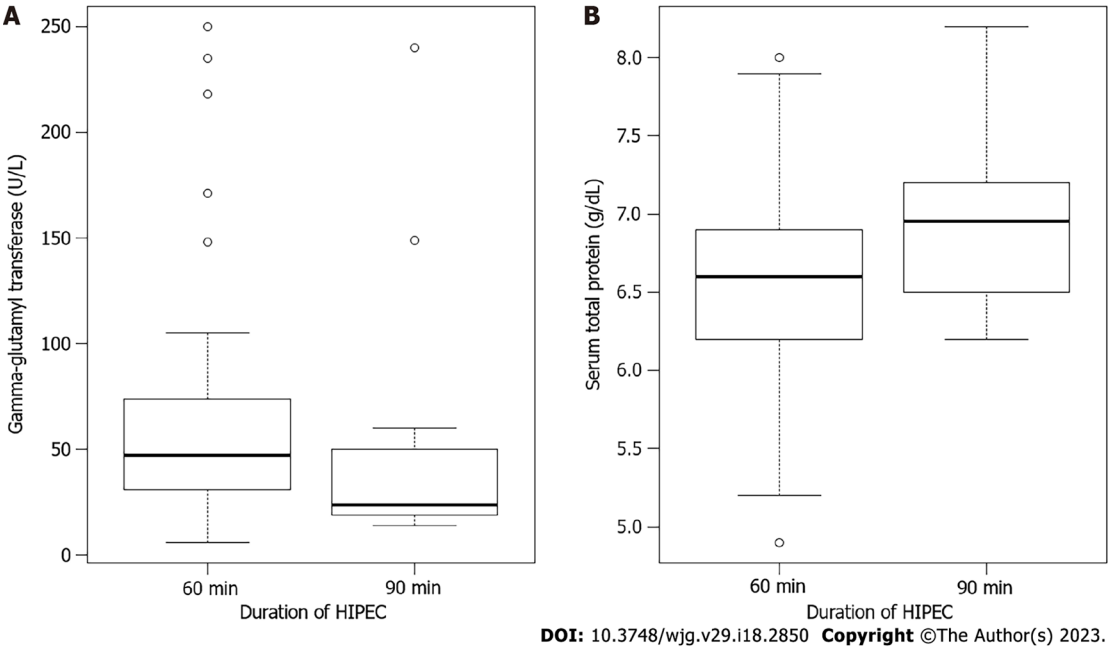
The dotted line represents median survival. CRS: Cytoreductive surgery; HIPEC: Hyperthermic intraperitoneal chemotherapy.



levels were observed more often in the 60-min group (Supplementary Table 1).

To further investigate the cause of the clinically significant difference in median survival, the following adjustments to the groups were performed with consideration of any possible confounding effects. First, propensity score-matched patient pairs (n = 14) were created in which patients were matched by age, sex, PCI score, CC score, time spent in the intensive care unit after CRS + HIPEC, duration of CRS, and the presence of lymph node metastasis (stage N = 0 *vs* stage $N \geq 1$). No differences in adjusted or in crude P values were found in any of the preoperative, perioperative, and postoperative

Figure 5 Gamma-glutamyl transferase and total protein levels in 60 min and 90 min hyperthermic intraperitoneal chemotherapy groups. Clinically abnormal serum levels of gamma-glutamyl transferase (crude $P = 0.0407$) and total protein (crude $P = 0.0570$) were observed more often in those gastric cancer patients who received hyperthermic intraperitoneal chemotherapy (HIPEC) for 60 min after the cytoreductive surgery. Thick lines and hollow circles represent the median and outliers, respectively. A: Gamma-glutamyl transferase; B: Total protein.

parameters between propensity score-matched groups. However, the seemingly different survival between the 2 groups became statistically significant [60 min (ref.) *vs* 90 min: HR = 0.2843; 95%CI: 0.1119-0.7222; $P = 0.0082$; Figure 6] with 10.91 mo (95%CI: 9.56-17.77) and 27.30 mo (95%CI: 16.20-NA) median survivals for the 60 min and 90 min groups, respectively.

We also investigated whether results changed if patients who received trastuzumab and/or had immunohistochemically positive pathological results against human epidermal growth factor receptor 2

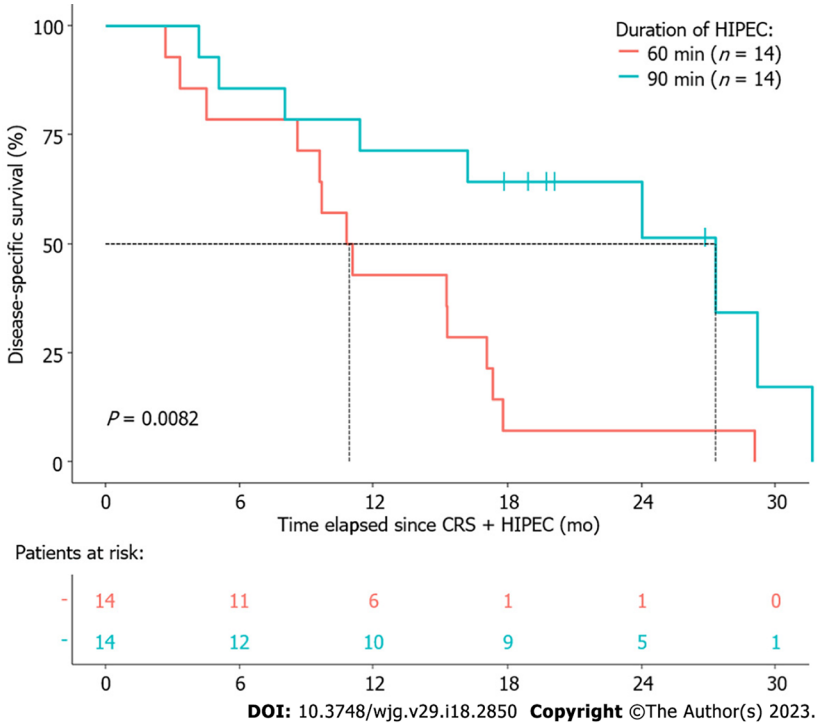

Figure 6 Differences in disease-specific survival between propensity score in matched gastric cancer patient-pairs. Patients were matched by age, sex, peritoneal carcinomatosis index score, Jacquet and Sugarbaker's completeness of cytoreduction score, time spent in the intensive care unit after cytoreductive surgery (CRS) + hyperthermic intraperitoneal chemotherapy (HIPEC), duration of CRS, and presence of lymph node metastasis (stage *N* = 0 *vs* stage *N* ≥ 1). The dotted line represents median survival.

(HER2; *n* = 7) or had the procedure before 2016 (*n* = 44) were removed from the original cohort. For the former, we obtained the same results as those for the full cohort. Median survivals of 12.68 mo and 24.02 mo were observed for the 60-min and 90-min groups, respectively, and no statistical difference was detected in the survival models (DSS: *P* = 0.1540; OS: *P* = 0.2040; Supplementary Figure 2A). However, the same difference was seen for the modified patient population that seen with propensity-matched pairs. Median survivals of 12.52 mo and 27.30 mo were found for the 60 min and 90 min groups, respectively (HR: 0.4225; 95%CI: 0.1789-0.9975; *P* = 0.0493; Supplementary Figure 2B).

DISCUSSION

There are only a few Western studies concerning the treatment of advanced GC with CRS and HIPEC. Although the positive effects of cytoreduction and HIPEC on survival have been described[11-13,31], the practical nonexistence of prospective clinical studies (except for two studies with small sample sizes [12,32]) on CRS and HIPEC highlights the need for additional primary research. Moreover, more randomized trials are required to substantiate the effect of CRS and HIPEC. For example, the results of the German phase III PREVENT study, in which the effect of HIPEC applied for prevention in lieu of FLOT-chemotherapy, is currently recruiting patients, and results are eagerly anticipated[33].

In the current retrospective study, we demonstrated prolonged survival with multimodal therapy in the treatment of primary GC patients with PM. The 27.3 mo median survival that we observed is in line with similar studies. For example, in the phase II trial by Badgwell *et al*[11], the median OS was 24.2 mo from the date of diagnosis and 16.1 mo from the date of CRS and HIPEC. Similarly, a recent Spanish multicenter study found a median survival of 21.2 mo[34], while in the German retrospective HIPEC-register study the median survival times ranged from 7.9 mo to 21.2 mo[35]. The same is true of median PCI-scores; median PCI was 2, 6, 6, and 8 in the studies of Badgwell *et al*[11], Bonnot *et al*[31], Manzanedo *et al*[34], and Rau *et al*[35], respectively; a median PCI of 3 was calculated in the current study. In addition, Rau *et al*[35] reported OS of 18 mo, 12 mo, and 5 mo for the 3 patient groups, with corresponding PCI scores of 0-6, 7-15, and 16-39, respectively; this finding suggests that significantly better outcomes are associated with higher CC. In our study, 93.2% of patients underwent complete macroscopic tumor reduction. An important conclusion of the above presented studies is that patients with small tumor burden (PCI < 6, but maximally 9) benefit the most from this multimodal therapy. Although in the current study we could not confirm the benefit of reduced PCI scores, our results were in line with the previously described observations (*i.e.* patients with higher PCI scores trended toward shorter survival). Furthermore, an interesting observation emerged during the analysis of our data over

time and with an increasing number of cases: The duration of surgery to reach complete cytoreduction became significantly shorter. These findings match with the results of a study outlining the technical aspects and learning curve of CRS/HIPEC by Vining *et al*[36], where the authors describe a steep learning curve and a correlation between CC and surgeon expertise. This observation underscores the idea that treatment of advanced GC with PM should be performed in specialized centers by expert surgeons. Recent studies have also found that sodium thiosulfate can prevent impairment of renal function following HIPEC[37,38]. In the patient population analyzed in the current study, sodium thiosulfate was not used; however, since January 2022, we have started to use it routinely in our center.

There is still no consensus regarding the ideal duration of HIPEC. In the current analysis, the median survival time was 27.30 mo in the 90 min group, which was significantly longer than that of the 60 min group (12.86 mo). Near the publication date of the van Driel *et al*[23] study for ovarian cancer and the PRODIGE-7 trial[39] for HIPEC in colorectal cancer, our institutional HIPEC protocol was changed in favor of the 90 min HIPEC perfusion. Our group has recently described the advantages of prolonged HIPEC duration have been recently described for primary peritoneal carcinoma, primary advanced epithelial carcinoma, and ovarian or fallopian tube carcinoma[40,41]. Longer HIPEC duration does not adversely affect perioperative morbidity and mortality, and a potential survival benefit could be realized by the application of prolonged HIPEC[40]. However, a recent study found that a secondary inflammatory reaction might occur after 90 min HIPEC with mitomycin C/doxorubicin or cisplatin, but not with shorter duration and oxaliplatin[41]. These and the current findings suggest that a prolonged peritoneal perfusion time may be more advantageous after complete cytoreduction; however, as the study of Roth *et al*[41] has shown, gathering additional data is essential.

Another possible reason for better survival in patients with longer HIPEC duration is enhanced cytotoxicity and anti-tumor effects of chemotherapeutic drugs in hyperthermia; the longer exposure may allow for more effective drug action[42]. The effect of cytoreductive surgery with macroscopic complete tumor reduction followed by HIPEC with effective neoadjuvant chemotherapy extends survival time of patients with advanced GC with PM, as recently shown in the CYTO-CHIP study[31]. Since 2016, the most frequently used neoadjuvant chemotherapy for advanced GC with PM is the FLOT-protocol; however, due to differences in cytochrome P450 family 2 subfamily A member 6[43], the S-1 regime (tegafur, gimeracil, and oteracil) is the standard adjuvant treatment in Asia[44,45]. The latest advancements in preoperative chemotherapy with[46] or without[25] biological agents can significantly extend the survival of GC patients. Recently, it has also been demonstrated that the 15%-20% of GC cases that overexpresses HER2 should be treated with monoclonal antibodies like trastuzumab in a neoadjuvant setting due to the positive influence of these drugs on patient survival and fewer side effects than traditional chemotherapies[47]. In the current study, the individual responses to pre- and/or postoperative chemotherapy were not known for most patients, which was one of the biasing factors affecting patient survival in our study.

SRC differentiation is described as a tumor with aggressive growth and a poorer prognosis than non-SRC carcinomas of the stomach[48]. In contrast, we found that the type of histology did not affect DSS, OS, or RFS. A similar finding was reported in an Asian study of 136 advanced GC patients, in which the authors described no difference in median survival between the histopathologic entities after R0-resection[49]. Moreover, we observed that if pelvic peritonectomy during CRS is not necessary, the OS of the patient improved. We hypothesize that the extent of the tumor may have a greater influence on patient survival than the histopathological differentiation. Improvement in patient survival may also be influenced by the experience of the surgical team; this factor may have also introduced additional bias in the current study.

We also investigated whether any preoperative laboratory result was predictive of patient survival. Strong correlations were found between patient survival and white blood cell count, hemoglobin, CEA, and serum total protein. These findings match with previously reported data of non-HIPEC-treated GC patients[50-55]. Furthermore, results of a recent German multi-center study[56] and the WHO urgent call[57] to implement blood management in surgical patients have shown that preoperative anemia is a serious threat to patient survival. Preoperative iron supplementation in preoperative anemia is also an important part of the recently published ERAS protocol for CRS and HIPEC[58]. As such, emphasis should be placed on iron supplementation and normalization of hemoglobin prior to surgery[58].

Limitations

The current study had a few limitations, including the small sample size, the retrospective nature of the study, the fact that data were available from a single center only, and the heterogeneity of the data. Also, during the study period, preoperative chemotherapy protocols changed and surgeon expertise grew. Furthermore, in this small cohort of patients with GC and PM, there were limited data regarding post-HIPEC treatment. Our follow-up data could only differentiate between alive and dead patients and tumor recurrence or no recurrence. Efforts were made to collect post-HIPEC patient data; however, we could not collect these in a timely manner, as routine oncological treatments were often performed in other hospitals. Moreover, the lack of chemotherapy-only control patients should also be mentioned as a limiting factor.

CONCLUSION

In summary, we conducted a single-center retrospective observational study to investigate what factors influence the survival of advanced GC patients with PM who underwent CRS and HIPEC. We confirmed that CRS followed by HIPEC applied over 90 min has a positive impact on DSS in comparison with CRS followed by 60 min of HIPEC. Of note, the learning curve of surgeons may confound the interpretation of this observation. Furthermore, the preparation of patients for surgery based on preoperative laboratory testing according to the current ERAS protocol might optimize the positive effect of CRS and HIPEC. To further expand upon our findings, multi-institutional and cooperative randomized group trials should be organized to further support and confirm survival and safety outcomes.

ARTICLE HIGHLIGHTS

Research background

Cytoreductive surgery (CRS) with hyperthermic intraperitoneal chemotherapy (HIPEC) is one of the last options in the treatment of advanced gastric cancer (GC) with peritoneal metastasis (PM); however, most national and international guidelines only recommend it to be performed within clinical trials. Despite this, CRS with HIPEC is a safe and effective method to treat advanced GC with PM, and recent studies have shown encouraging results with respect to increased patient survival.

Research motivation

CRS and HIPEC are safe and effective therapeutic options for the treatment of advanced GC with PM. To investigate the optimal length of HIPEC procedure, it is important to provide a basis for further research. Improving the composition of HIPEC medications could further improve the outcomes of this modern multimodal therapy. It is expected that ongoing research regarding antibody and checkpoint inhibitor therapies will strongly influence not only perioperative therapy but also the therapeutic agents used during HIPEC itself.

Research objectives

The aim of the study was to explore the effect of CRS and HIPEC in the treatment of advanced GC with PM and find parameters that could further improve patient survival.

Research methods

We conducted a retrospective observational study with the inclusion of 73 GC patients with synchronous PM. Details of CRS + HIPEC, preoperative laboratory results, and pre-, peri-, and postoperative surgical details of the patients were recorded. Overall survival (OS), disease-specific survival (DSS), and recurrence-free survival (RFS) were calculated.

Research results

In line with recently published data, we found that CRS + HIPEC had a measurable impact on the survival of advanced GC patients without significantly elevating the rate of postoperative complications. The effects of longer HIPEC duration, higher white blood cell count, lower hemoglobin and serum total protein, and higher carcinoembryonic antigen levels with respect to the survival of patients were found.

Research conclusions

In general agreement with previously published findings, we concluded that 90 min HIPEC treatment correlates with improvement in the OS and DSS of patients compared to that of 60 min HIPEC. Moreover, more complete cytoreduction also contributes to longer patient survival and better disease management.

Research perspectives

The improvement of CRS and HIPEC with respect to the duration and composition of HIPEC therapeutic agents is a controversial research topic. The current report provides evidence from a single center retrospective study that could be implemented in future randomized multicenter studies.

Author contributions: Steinhoff H, Acs M, Szasz AM and Piso P built the study design; Steinhoff H, Acs M, Blaj S and Sanchez-Velazquez P were involved in the collection of patient data; Herold Z performed the statistical analysis of data; Steinhoff H, Acs M, Herold Z, Herold M, Herzberg J, Strate T and Szasz AM interpreted the data; Steinhoff H, Blaj S, Acs M, Sanchez-Velazquez P and Piso P were involved in patient selection; Steinhoff H, Acs M and Herold Z prepared the draft of the manuscript; All authors were involved in the manuscript editing and reviewing; Dank M and Piso P supervised the study; all authors have read and agreed to the published version of the manuscript.

Institutional review board statement: The study was conducted according to the guidelines of the Declaration of Helsinki. Ethical review and approval were waived for this study due to the retrospective nature of the study. All the patients had agreed to data recording for the national HIPEC registry and to the use of their anonymized data for quality assurance and research purposes by written and verbal informed consent prior to surgery. Therefore, no institutional or further approval of a review board was necessary.

Informed consent statement: Informed consent was obtained from all subjects before cytoreductive surgery with hyperthermic intraperitoneal chemotherapy (CRS + HIPEC). All patients agreed to their data being recorded for the national HIPEC registry, administered by the German Society for General and Visceral Surgery.

Conflict-of-interest statement: All the authors report having no relevant conflicts of interest for this article.

Data sharing statement: The datasets used and/or analyzed during the current study are available from the corresponding author upon reasonable request.

Abstract

BACKGROUND

Genetic tests are increasingly performed for the management of unresectable pancreatic cancer. For genotyping aimed samples current guidelines recommend using core specimens, although based on moderate quality evidence. However, in clinical practice among the endoscopic ultrasound (EUS) guided tissue acquisition methods, fine needle aspiration (FNA) is the most widely performed.

AIM

To assess the adequacy for next generation sequencing (NGS) of the DNA yielded from EUS-FNA pancreatic adenocarcinoma (PDAC) samples.

METHODS

Between November 2018 and December 2021, 105 patients with PDAC confirmed by EUS-FNA were included in the study at our tertiary gastroenterology center. Either 22 gauge (G) or 19G FNA needles were used. One pass was dedicated to

DNA extraction. DNA concentration and purity (A260/280, A260/230) were assessed by spectrophotometry. We assessed the differences in DNA parameters according to needle size and tumor characteristics (size, location) and the adequacy of the extracted DNA for NGS (defined as A260/280 ≥ 1.7, and DNA yield: ≥ 10 ng for amplicon based NGS, ≥ 50 ng for whole exome sequencing [WES], ≥ 100 ng for whole genome sequencing [WGS]) by analysis of variance and *t*-test respectively. Moreover, we compared DNA purity parameters across the different DNA yield categories.

RESULTS

Our cohort included 49% male patients, aged 67.02 ± 8.38 years. The 22G needle was used in 71% of the cases. The DNA parameters across our samples varied as follows: DNA yield: 1289 ng (inter quartile range: 534.75-3101), A260/280 = 1.85 (1.79-1.86), A260/230 = 2.2 (1.72-2.36). DNA yield was > 10 ng in all samples and > 100 ng in 93% of them (one sample < 50 ng). There were no significant differences in the concentration and A260/280 between samples by needle size. Needle size was the only independent predictor of A260/230 which was higher in the 22G samples (P = 0.038). NGS adequacy rate was 90% for 19G samples regardless of NGS type, and for 22G samples it reached 89% for WGS adequacy and 91% for WES and amplicon based NGS. Samples with DNA yield > 100 ng had significantly higher A260/280 (1.89 ± 0.32 *vs* 1.34 ± 0.42, P = 0.013). Tumor characteristics were not corelated with the DNA parameters.

CONCLUSION

EUS-FNA PDAC samples yield DNA adequate for subsequent NGS. DNA amount was similar between 22G and 19G FNA needles. DNA purity parameters may vary indirectly with needle size.

Core Tip: Genetic testing is increasingly undertaken in pancreatic adenocarcinoma (PDAC). The main diagnostic method is endoscopic ultrasound (EUS)-guided tissue acquisition and fine needle aspiration (FNA) is most frequently performed in clinical practice. However, current guidelines recommend using core specimens for genotyping aimed samples. In our cohort analysis, we show that EUS-FNA PDAC samples yield DNA of adequate amount and purity for subsequent next-generation sequencing (NGS). DNA amount was similar between 22G and 19G FNA needles. DNA purity parameters may vary indirectly with needle size. EUS FNA PDAC samples may be used for NGS.

INTRODUCTION

Pancreatic cancer (PC) is among the most the most aggressive malignancies with a mortality rate comparable to the incidence[1,2]. In more than 80% of cases it is detected in advanced stages that require systemic treatment[3]. Moreover, there is growing evidence about the benefits of neoadjuvant treatment over upfront surgery for the management of resectable pancreatic cancer[4]. Regardless of stage, anatomopathological confirmation of the disease is mandatory prior to chemo or radiotherapy initiation [5].

Endoscopic ultrasound (EUS) guided tissue acquisition (TA) is the main sampling method for the diagnosis of pancreatic solid lesions with high sensitivity (85%-89%) and specificity (96%-99%)[6]. Among the EUS-TA methods, fine needle aspiration (FNA) is the most widely performed[5].

Despite the high diagnostic accuracy, EUS-TA samples are still associated with an inconclusive diagnosis in 10% to 15% of cases[7]. Detection for KRAS mutations in inconclusive samples could decrease with up to 50% the rates of false negative results[6].

Precision medicine has changed the paradigm in oncologic treatment and although the targeted therapies are not yet routinely used in PC, it is known that up to 25% of the tumors harbor actionable alterations[8]. Molecular testing on tumor tissue for guiding personalized treatment is recommended in the current guidelines for the management of unresectable pancreatic adenocarcinoma (PDAC) amenable for anti-cancer therapy[9].

The roles of EUS-TA in PC have therefore broadened from tumor diagnosis to obtaining adequate samples for further molecular testing that enable the use of targeted therapies and may also increase diagnostic accuracy[6,9,10]. Although according to the current guidelines in pancreatic solid masses core tissue specimens should be used in downstream applications, there is increasing evidence on the feasibility of performing comprehensive genomic profiling based on FNA samples[5,11].

In our study we evaluated the adequacy for NGS [targeted, amplicon based, whole exome sequencing (WES) and whole genome sequencing (WGS)] of the DNA extracted from fresh EUS FNA PDAC samples, in terms of quantity and purity as measured by spectrophotometry. Moreover, we assessed the influence of needle the size and tumor characteristics on the DNA parameters.

MATERIALS AND METHODS

Study design and settings

The research was conducted in Fundeni Clinical Institute-a tertiary gastroenterology referral center in Bucharest, Romania, between November 2018 and December 2021. This prospective observational study was approved by the Internal Review Board of Fundeni Clinical Institute. Patients provided informed consent for EUS-FNA and study enrolment before the procedure.

Study participants

For enrolment, we assessed the cases with pancreatic lesions referred to our department for EUS-TA. The eligibility criterion was-diagnosis of PDAC established by EUS-FNA. We only considered for inclusion in the study patients with a high suspicion of PDAC (as evaluated by clinical, biological, and imaging criteria). Patients with subsequent diagnoses other than PDAC were excluded from our analysis.

Highly experienced endosonographers performed all the procedures and all patients were under propofol sedation. A linear echoendoscope was used (EG-3870UTK, Pentax, equipped with a Hitachi Arietta v70 processor, Tokyo, Japan) and either 19 gauge (G) or 22G FNA needles (EchoTip Ultra Endoscopic Ultrasound Needle; Cook Medical, Bloomington, IN, United States). The endosonographer decided on the needle type. After obtaining the samples for the pathological diagnosis, one pass was dedicated to sample acquisition for DNA extraction. The needle stylet or air flushing were used to facilitate the specimen extrusion. The samples dedicated to diagnosis were smeared onto slides and fixed with ethanol and/or placed into 10% formalin for further paraffin fixation and cell block analysis, FNA yielded small tissue fragments (about 50% of cases). Dedicated pathologists with extensive experience in cytology techniques assessed the samples on site. The diagnosis of PDAC was confirmed if the pathology findings were positive or suspicious for malignancy[12]. The samples purposed for DNA extraction were placed directly in 1.5 mL of RNA later solution, in 2 mL Eppendorf tubes and kept at room temperature until DNA extraction that was performed within 4 h after sampling. For DNA extraction we used a commercially available silica membrane-based column DNA extraction kit (PureLink™ Genomic DNA, Invitrogen™, Waltham, MA, United States) according to the manufacturer's indications.

The purity and quantity of the extracted DNA were assessed immediately after extraction by spectrophotometry (Nanodrop, Thermo Fisher™, Waltham, MA, United States). The DNA concentration was measured in ng/μL and the purity was assessed by the absorbance ratios-A260/280 and A260/230 (the ratios between absorbances of the samples at 260 nm-which is characteristic for nucleic acids, and 280 nm and 230 nm respectively)[13]. The optimal DNA parameters for second generation high throughput sequencing were considered as follows: For DNA yield ≥ 100 ng will be sufficient for NGS of any type (whole genome-WGS, whole exome-WES or amplicon based targeted NGS), for WES at least ≥ 50 ng are required, whereas for amplicon based targeted NGS a minimum of 10 ng is necessary[14-16]. The main purity parameter assessed in terms of NGS adequacy is A260/280 and values ≥ 1.7 are considered optimal[17]. A260/230 is a secondary purity parameter with optimal values ranging between 2.0-2.2 [17]. Abnormal values of the purity parameters reflect mainly a contaminated sample with proteins, phenols, carbohydrates, salts among others[17]. To calculate the DNA yield we multiplied the measured concentration with the elution volume which was 25 μL in all cases. The DNA samples were stored at -80 °C until further analysis. We have successfully performed targeted amplicon based NGS in 20 of the collected samples, using the Illumina NextSeq500 platform.

Data sources

Two investigators, trainees in gastroenterology, collected the data using a customized form. Among the gathered information, we used in our study: Patients demographics (age, gender), tumor characteristics-

size (mm)-the maximum diameter measured during EUS) and location (coded as head/neck or body/tail respectively), if cross-sectional imaging was performed we also collected-TNM (tumor, node, metastasis) stage according to the American Joint Committee on 8th Cancer edition[18], and the vascular invasion status; information about the procedure: total number of passes, needle size (recorded either during the procedure or retrieved from the EUS registry of the department), the parameters for the extracted DNA-concentration and absorbance ratios. We included in our analysis only samples from patients with confirmed PDAC on the FNA specimens.

Outcomes

Our end-points were as follows: To evaluate the adequacy for NGS of the DNA extracted from EUS-FNA PDAC samples we generated several categorical variables based on the previously mentioned criteria: Three of them defining optimal DNA yield for the main types of NGS with the cut-offs: ≥ 100 ng for WGS, ≥ 50 ng for WES and ≥ 10 ng for amplicon based targeted NGS, and one for optimal DNA purity: A260/280 ≥ 1.7. NGS adequacy was defined as optimal parameters for both DNA yield and purity for each type of NGS (WGS, WES and amplicon based NGS adequacy respectively). The definitions of the categorical variables are detailed in Supplementary Table 1. The variables were coded as 1 if the corresponding criteria were accomplished and 0 if not. We also compared the purity parameters between the predefined categories of optimal DNA yield. Furthermore, we assessed the association between the FNA needle size and tumor characteristics (diameter and location) and the DNA parameters (DNA concentration [ng/μL], A260/280, A260/230).

Statistical analysis

Continuous variables are computed as either mean and standard deviation (mean ± SD) or median and inter quartile range. We analyzed the impact of needle size on DNA parameters by one way analysis of variance. We assessed the association between needle size and NGS adequacy using chi-square test. The impact of both needle size and tumor characteristics on the DNA parameters was evaluated by linear regression, while their impact on DNA NGS adequacy was evaluated by logistic regression respectively. The differences in purity parameters across the predefined DNA yield categories were assessed with independent sample *t*-test. Data was normalized using a two-step approach-transforming the variable into a percentile rank and subsequent inverse-normal transformation[19]. Two-tailed alpha of 0.05 defined statistical significance. Data analysis was performed with SPSS (IBM Corp. Released 2020. IBM SPSS Statistics for Windows, Version 27.0. IBM Corp, NY, Armonk, United States). The statistical review of the study was reviewed by Daniel Veres, MD, PhD who is a biomedical statistician at Center for Translational Medicine of Semmelweis University.

RESULTS

Patients characteristics

The characteristics of patients included in our analysis are summarized in Table 1. Out of the 128 patients who accepted to participate in our study, 105 were confirmed with PDAC subsequent to EUS-FNA (Figure 1). Sex distribution was almost equal and the mean age at diagnosis was 67.02 ± 8.38 years. Tumors were more frequently located in the head or neck of the pancreas than in the body or tail, and the tumor diameter was in average 43.66 ± 14.83 mm. More than half of the cases were metastatic at diagnosis. Most of the samples were acquired with 22G FNA needles-75 (71%).

Adequacy of the EUS-FNA PDAC samples for second generation high throughput analysis

In our cohort the DNA yield was in average 1289 ng (inter-quartile range: 534.75-2995). All samples resulted in more than 10 ng of DNA while 98 (93%) of them yielded more than 100 ng of DNA. All 7 samples from which less than 100 ng of DNA were extracted, were acquired with 22G needles, and only one yielded below 50 ng of DNA. In our analysis, needle size was not correlated with DNA NGS adequacy rate regardless of NGS type (Supplementary Table 2). For 19G needles, NGS adequacy rate was 90% for all types of NGS while for the 22 G needles the adequacy rate was 89% for WGS and 91% for both WES and amplicon based NGS. Tumor location and diameter did not significantly influence DNA NGS adequacy regardless of NGS type. When comparing the purity parameters across the predefined DNA yield categories (Table 2), the only significant difference we found was for the A260/280 parameter which was significantly higher in the samples with DNA yield ≥ 100 ng (1.89 ± 0.32 *vs* 1.34 ± 0.42, $P = 0.013$).

Association between FNA needle size and DNA parameters

The DNA parameters across our samples were as follows: median concentration 51.56 ng/μL (21.39-124.04), A260/280 = 1.85 (1.79-1.86), A260/230 = 2.2 (1.72-2.36). The association between FNA needle size and the extracted DNA parameters are summarized in Figure 2. Needle size did not influence the concentration of the extracted DNA nor the A260/280 ratio. The median A260/230 was significantly

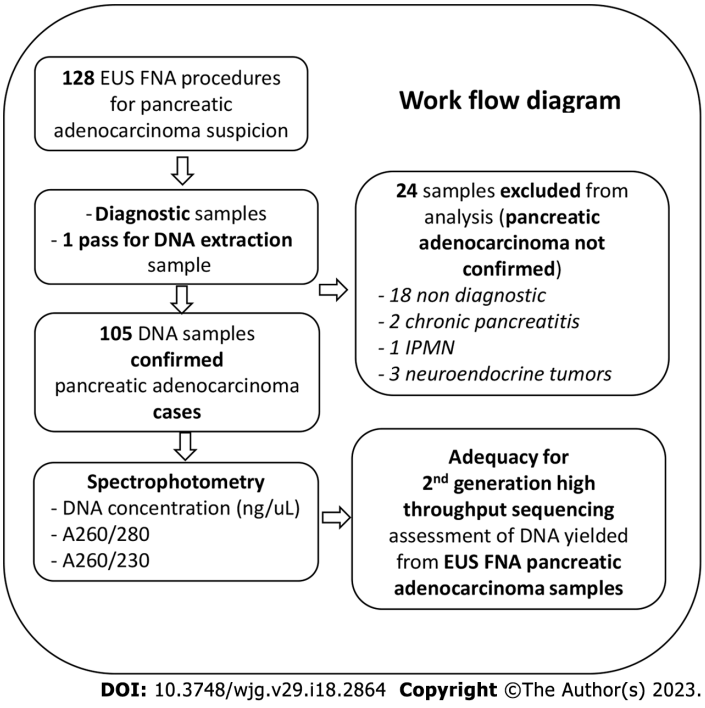
PDAC: Pancreatic adenocarcinoma; FNA: Fine needle aspiration; G: Gauge; NGS: Next generation sequencing. Data is given as: mean ± standard deviation, or median (inter quartile range).

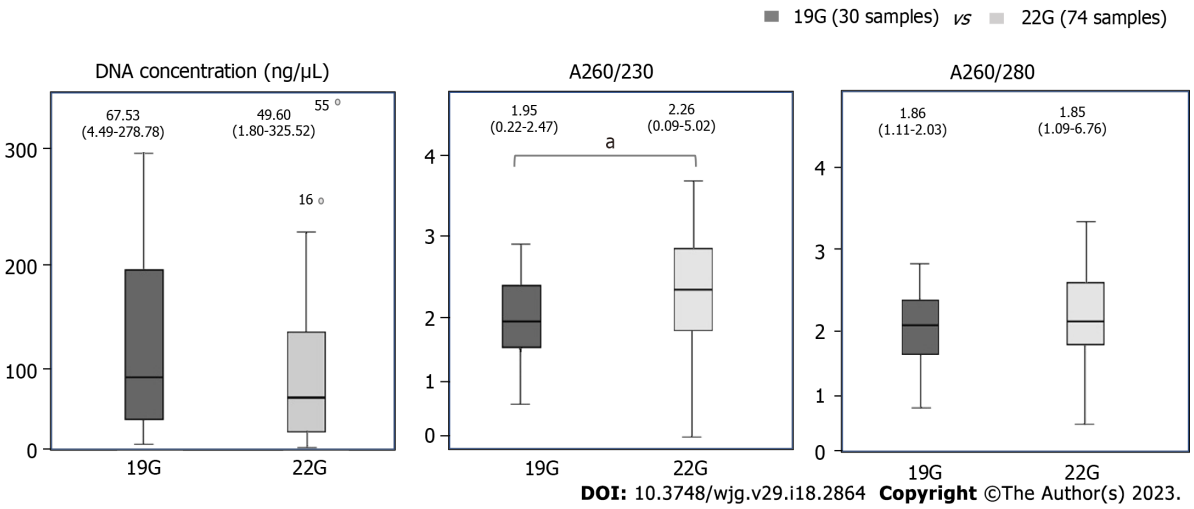
Table 2 Purity parameters across the different DNA yield categories



DNA yield	Purity parameters	
	A260/280	A260/230
≥ 100 ng	1.86 (1.80-1.89)	2.23 (1.79-2.35)
≥ 50 ng	1.85 (1.80-1.89)	2.21 (1.7-2.36)
≥ 10 ng	1.85 (1.79-1.86)	2.2 (1.72-2.36)

higher in the 22G samples than in 19G samples (P = 0.038). In multivariate analysis (on needle size, tumor location and tumor diameter) the only independent predictor of A260/230 was needle size (β = 0.36, $t(104)$ = 2.1, P = 0.038). None of the DNA parameters were significantly influenced by the tumor size or location.

DISCUSSION



The quantity and quality of the genetic material extracted from tumor samples are essential for their adequacy for downstream genetic analyses performed to further guide the individualized cancer therapy[21]. The requirements for NGS dedicated specimens vary with extraction protocols and testing method, but also with acquisition method, sample manipulation, disease type[22]. Although prior research has demonstrated the suitability of several pancreatic EUS-TA sample types for a range of comprehensive genetic testing techniques, the best sampling protocol for this use is still up for debate [23]. The current guidelines recommend the use of core samples for molecular testing in pancreatic solid lesions based on a moderate level of evidence[6,11].

Our cohort analysis revealed that FNA needle size does not influence the concentration and the primary purity parameter (A260/280) of the DNA extracted from 19G or 22G EUS-FNA PDAC samples. However, needle size was the only independent predictor of A260/230. Tumor diameter and location

Figure 2 The association between needle size and DNA parameters. G: Gauge. To complement the graphical information, the additional data is given as median (min-max). [a]*P* < 0.005.

did not influence the DNA purity and concentration parameters. Based on the purity and DNA yield thresholds there were no significant differences in NGS adequacy rates between the two FNA needle sizes. NGS adequacy rate was 90% for 19G needle samples regardless of NGS type, while for the 22G needle samples it was 89% for WGS and 91% for both WES and amplicon based NGS. Regarding purity parameters, A260/280 was significantly better in samples with DNA yield above 100 ng. We further successfully performed targeted amplicon based NGS on a subgroup of 20 samples.

Park *et al*[24] evaluated which of the EUS-TA related factors and tumor characteristics have a significant impact on the NGS success rate on a cohort of 190 PDAC confirmed cases. They used for DNA analysis the remaining material after acquiring cytologic or histologic specimens for PDAC diagnosis[24]. As needed, 19G, 22G or 25G FNA or Fine needle biopsy (FNB) needles were used[24]. While tumor location in the body or tail of the pancreas was associated with a higher NGS success rate in their cohort than head or uncinate process tumor location, in multivariate analysis the only independent predictor of NGS success was a greater needle size (19G and 22G *vs* 25G)[24]. Although we were able to evaluate only a surrogate marker of NGS success, respectively-the adequacy of the DNA parameters for high throughput analysis, did we did not find a significant impact of tumor character-

istics and neither of needle size on this outcome. Notably, we only used higher gauge needles (19G and 22G and not 25 G).

A group from Johns Hopkins evaluated the concordance of the mutational profiles assessed by targeted NGS between EUS-FNA snap frozen PDAC samples and the corresponding biopsy specimens from the primary tumors that were subsequently resected [25]. Although on a pool of 16 cases only, they detected a 100% concordance between the two sample types for KRAS mutations. They concluded that it is feasible to perform NGS on FNA samples and the results are reliable in complementing pathology results[25].

Besides the parameters of the extracted DNA, the total cellularity and the tumor cell content of the samples are also essential for the assessment of adequacy for NGS[22,26]. We did not evaluate these metrics in our cohort, since we used dedicated FNA samples, processed directly after collection, for DNA extraction. However, we must emphasize that the same needle types were used for the samples dedicated to diagnosis and we only report on confirmed PDAC cases. Moreover, more than 50% of specimens obtained by FNA yielded small tissue fragments and were subjected to cell block techniques to increase the diagnostic accuracy. The most widely used NGS platforms to date require a sample cellularity between 1000 and 5000 cells and a minimum 10% "lesional to-non-lesional cell ratio"[26-28]. A group from MD Anderson compared these parameters between concurrently acquired, percutaneous, image guided FNA and core needle biopsy samples in 24 various malignancy cases. They obtained higher cellularity and better tumor fraction in the cytologic specimens, arguing that by comparison with core biopsies, during FNA the proportion of acquired stromal cells is lower[27].

In their study Berry *et al*[21] performed molecular profiling of 66 snap frozen EUS-FNA pancreatic cancer samples. They revealed a high epithelial and tumor cell content in their specimens and a low contamination with inflammatory, gastric or duodenal cells[21]. Moreover, they compared the DNA yield between the FNA samples dedicated to molecular testing and formalin fixed paraffin embedded cell-block preparations used for PDAC diagnosis, obtaining 10 times higher amounts of DNA from the FNA samples which was in average 4.8 ± 3.7 μg[21]. This could be explained by the degrading effect of formaldehyde on nucleic acids and the cross-links formation between protein and DNA that it determines[22].

Cytologic specimens yield optimal DNA and have adequate cellularity for further NGS. The quality of nucleic acids is altered in samples previously fixed with formalin. More standardized procedures that are focused on specimen sparing and keeping costs and processing times within accessible ranges are needed for the optimization of the sample assessment in the preanalytical phase of NGS.

Implications for practice and research

Regarding the implications for practice our study has shown that both 19G and 22G fresh EUS-FNA PDAC samples yield DNA of adequate amount and purity for next generation high throughput sequencing, regardless of tumor size or location within the pancreas. Overall, the NGS adequacy rates corresponded to the diagnostic accuracy of EUS-FNA samples in PDAC in our cohort[6]. A randomized controlled trial could reliably evaluate the cause-effect relationship between EUS needle G and DNA output from pancreatic cancer samples. Since the technical requirements in various clinical scenarios may limit the feasibility of randomization, prospective cohort studies of greater sizes that allow propensity score matching could decrease the influence of confounders in analyzing this association. Besides targeted NGS, the EUS-FNA samples yielding below 100 ng of DNA could be also used in other downstream applications for genetic testing like droplet digital PCR or TaqMan assays, which, although addressing fewer targets, have the advantage of good sensitivity for samples with low DNA amount.

Strengths and limitations

Even though relatively similar analyses have been previously reported, our study included a high number of samples[21,27]. Besides measuring the yielded DNA concentration and purity ratios, we were able to successfully perform NGS on subgroup of samples, functionality in the downstream application being a reliable method of sample adequacy evaluation[26]. Nevertheless, several limitations should be pointed out: (1) Study design-one of the main limitations of our work-since lack of patients randomization precludes the evaluation of causality between needle size and samples' NGS adequacy; (2) our study was performed in a tertiary gastroenterology center and all involved personnel were experts in their fields (endosonographers, pathologists, biologists); (3) the analysis was not based on a prior sample size calculation therefore our results must be interpreted with caution especially since 71% of the procedures were performed with one EUS-FNA needle type; (4) we did not use 25G needles for our samples therefore our conclusions cannot be extrapolated to all FNA needle sizes; and (5) lack of a comparison group comprising samples obtained by EUS-FNB-another main limitation of our study; to this end however we cite the study of Razzano *et al*[29] that compared the performance for NGS between FNA, FNB and resection PDAC specimens. They obtained similar success rates for mutation and amplification analysis between FNA and FNB samples and proposed FNA material as a source for comprehensive molecular testing[29]. Moreover, the spectrophotometric methods may overestimate the quantity of amplifiable DNA by measuring not only the double stranded fragments, but also single stranded DNA, free and oligonucleotides[22].

CONCLUSION

Acquiring EUS-FNA specimens dedicated for genetic testing is associated with a high adequacy rate for NGS of the extracted DNA. Nineteen and 22G EUS-FNA PDAC samples generate similar amount of DNA. DNA purity may vary indirectly with needle size in EUS-FNA samples. Further standardization in sample handling and cellularity assessment in the pre-analytical phase of NGS will increase reliability of the results for EUS-FNA PDAC samples and hence their usability in current practice.

ARTICLE HIGHLIGHTS

Research background

Due to the opportunities for personalized treatment in pancreatic adenocarcinoma (PDAC), genetic testing is increasingly performed. Fine needle biopsy is the method recommended for endoscopic ultrasound (EUS) guided tissue acquisition to obtain samples dedicated to downstream comprehensive molecular analyses. In current practice however, fine needle aspiration (FNA) is more widely accessible.

Research motivation

We evaluated the EUS-FNA PDAC samples in terms of adequacy for next generation sequencing (NGS) of the yielded DNA to assess the possibility of using this type of samples for genetic testing.

Research objectives

To investigate the association between DNA parameters (amount and purity) measured by spectrophotometry and FNA needle size (19 gauge [G] or 22G), and also tumor characteristics.

Research methods

We performed an observational prospective study on PDAC cases diagnosed through EUS-FNA at a tertiary center of Gastroenterology in Romania. During EUS one pass acquired samples dedicated to genetic testing. NGS adequacy was a dichotomus variable defined based on DNA parameters (purity: A260/280 ≥ 1.7 and DNA amount: ≥ 100 ng for whole genome sequencing, ≥ 50 ng for whole exome sequencing or ≥ 10 ng for amplicon based targeted NGS).

Research results

Our cohort analysis comprised 105 confirmed PDAC cases. The majority of samples were acquired with 22G FNA needles-75 (71%). The DNA amount was in average 1289 ng (inter-quartile range: 534.75-2995). All samples yielded more than 10 ng of DNA while 98 (93%) of them yielded more than 100 ng of DNA. Needle size was not correlated with DNA NGS adequacy rate regardless of NGS type. Needle size did not influence the concentration or A260/280 ratio of the extracted DNA. The median A260/230 was significantly higher in the 22G samples than in 19G samples ($P = 0.038$). In multivariate analysis (on needle size, tumor location and tumor diameter) the only independent predictor of A260/230 was needle size ($\beta = 0.36$, $t(104) = 2.1$, $P = 0.038$).

Research conclusions

Both 22G an 19G EUS-FNA PDAC samples are adequate for downstream NGS. FNA needle size and tumor characteristics did not significantly influence sample NGS adequacy rate. Greater FNA needle size might be associated with decreased sample purity.

Research perspectives

PDAC FNA samples (22 and 19G) yield samples of adequate purity and amount for NGS and can be used both in current practice and for research purposes.

ACKNOWLEDGEMENTS

we would like to give special thanks to Daniel Veres, MD, PhD, for his guidance in performing the formal analysis for the project and Mihaela Topala, MD for her help with patients' enrolment.

Abstract

BACKGROUND

Skeletal muscle abnormalities, such as muscle mass depletion (sarcopenia) and fatty infiltration of the muscle (myosteatosis), are frequent complications in cirrhotic patients scheduled for transjugular intrahepatic portosystemic shunt (TIPS).

AIM

To investigate the association and predictive value of sarcopenia and myosteatosis for overt hepatic encephalopathy (HE) and mortality after TIPS.

METHODS

The records of cirrhotic patients who underwent the TIPS procedure at our hospital between January 2020 and June 2021 were retrospectively retrieved. The transversal psoas muscle thickness (TPMT) and psoas muscle attenuation (PMA) measured from the unenhanced abdominal computed tomography (CT) at the level of the third lumbar vertebrae were used to analyze the sarcopenia and myosteatosis, respectively. The area under curve (AUC) was used to evaluate the discriminative power of TPMT, PMA, and relevant clinical parameters. Fur-

thermore, log-rank test was performed to compare the incidence of overt HE and survival between the different groups, and the association of risk factors with overt HE and mortality was analyzed using Cox proportional hazards regression models.

RESULTS

A total of 108 patients were collected. Among these patients, 45.4% of patients developed overt HE after TIPS treatment. Furthermore, 32.4% and 28.7% of these patients were identified to have myosteatosis and sarcopenia, respectively. Myosteatosis (51.0% *vs* 16.9%, $P < 0.001$) and sarcopenia (40.8 *vs* 18.6%, $P = 0.011$) were found to be more frequent in patients with overt HE, when compared to patients without overt HE. The receiver operating characteristics analysis indicated that the predictive power of TPMT and PMA in overt HE (AUC = 0.713 and 0.778, respectively) was higher when compared to the neutrophil lymphocyte ratio (AUC = 0.636). The cumulative incidence of overt HE was the highest in patients with concomitant sarcopenia and myosteatosis, followed by patients with myosteatosis or sarcopenia, while this was the lowest in patients without sarcopenia and myosteatosis. In addition, sarcopenia and myosteatosis were independently associated with overt HE and mortality after adjusting for confounding factors in post-TIPS patients.

CONCLUSION

CT-based estimations for sarcopenia and myosteatosis can be used as reliable predictors for the risk of developing overt HE and mortality in cirrhotic patients after TIPS.

Key Words: Sarcopenia; Myosteatosis; Hepatic encephalopathy; Transjugular intrahepatic portosystemic shunt; Transjugular intrahepatic portosystemic shunt

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Few studies have investigated the relationship among sarcopenia, myosteatosis, and overt hepatic encephalopathy (HE) after transjugular intrahepatic portosystemic shunt (TIPS). The present study revealed that the cumulative incidence of overt HE was the highest in patients with concomitant sarcopenia and myosteatosis, followed by patients with myosteatosis or sarcopenia, and the lowest incidence was found in patients without myosteatosis and sarcopenia. Sarcopenia and myosteatosis were the independent risk factors for overt HE and mortality in patients following TIPS. Therefore, identifying strategies for improving muscle mass (sarcopenia) and muscle fatty infiltration (myosteatosis) may help to reduce the incidence of HE after TIPS.

INTRODUCTION

Transjugular intrahepatic portosystemic shunt (TIPS), which establishes an artificial shunt between the portal and hepatic vein, has been considered an effective method for treating portal hypertension, and can be used to manage refractory ascites and variceal hemorrhage in patients with liver cirrhosis[1]. However, the TIPS procedure leads to a significantly high incidence of overt hepatic encephalopathy (HE), which occurs in approximately 20%-50% of post-TIPS patients[2-4]. Previous studies have suggested that post-TIPS HE is associated with increased hospitalization rates, mortality, and poor quality of life[5]. The use of rifaximin and lactulose remains controversial in treating this pathological entity[6,7]. Thus, studies that can precisely predict post-procedure HE in cirrhotic patients would be beneficial in developing appropriate preventive measures.

More recent studies have revealed that abnormalities in the skeletal muscle, such as sarcopenia (muscle mass depletion) and myosteatosis (fatty infiltration of the muscle), are more prevalent[8,9], and that these are associated with the development of HE in cirrhotic patients[10]. Cirrhosis can lead to the excessive accumulation of ammonia in the skeletal muscle, in which a cascade of molecular alterations and metabolic disturbances may contribute to sarcopenia and myosteatosis. Consequently, both sarcopenia and myosteatosis may, in turn, further increase the circulating ammonia levels to induce

overt HE. These two skeletal muscle abnormalities can hypothetically be targeted for preventing overt HE.

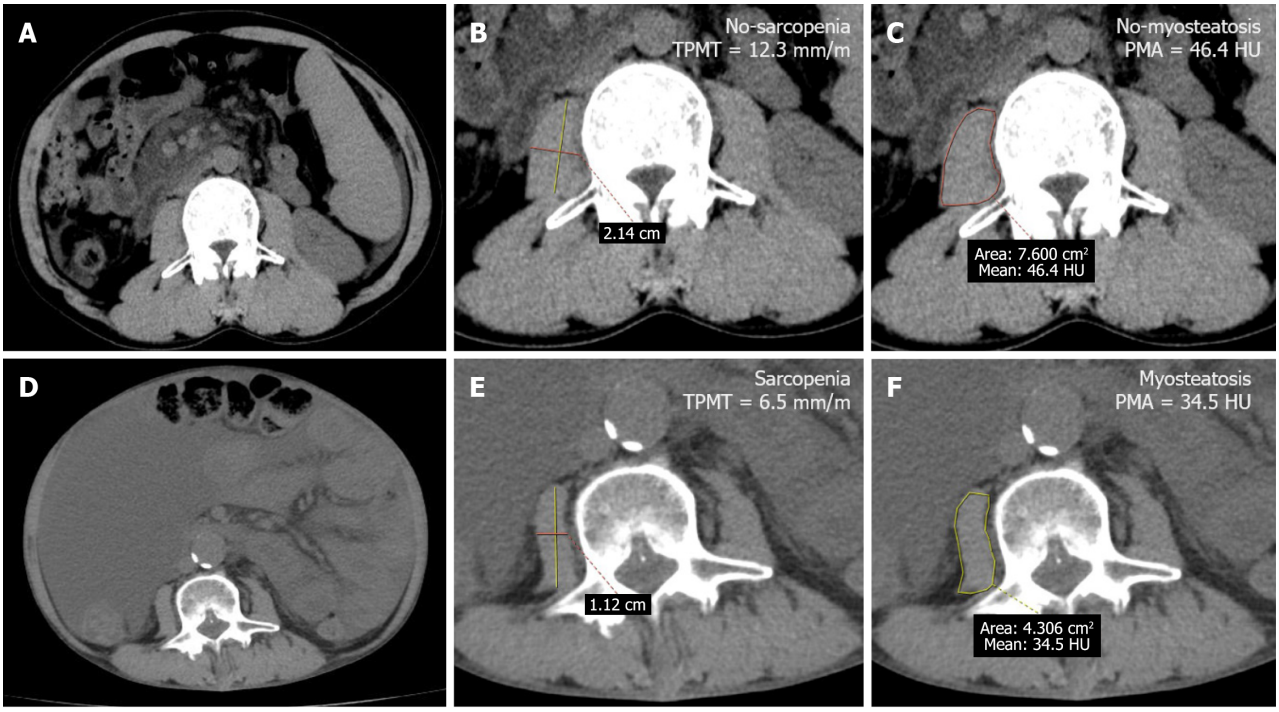
In clinic, both sarcopenia and myosteatosis can be reliably and objectively diagnosed through the computed tomography (CT) image-based measurement of body composition. Compared to the skeletal muscle index (SMI) and total psoas muscle volume, the CT-based measurement of transversal psoas muscle thickness (TPMT) has become an easy-to-use method to diagnose sarcopenia through gauging the psoas diameter, and this has become an independent risk factor for mortality in cirrhotic patients [11]. Furthermore, myosteatosis can be quantitatively graded by CT measurements, which shows that lower muscle radiodensity for designating muscle attenuation can be considered as evidence of fat infiltration in the skeletal muscle[12]. Previous studies have demonstrated that psoas muscle attenuation (PMA) is associated with postoperative complications and mortality in elderly patients[13,14]. The present study employed these CT-based methods to evaluate the association and predictive value of sarcopenia and myosteatosis for overt HE after TIPS.

MATERIALS AND METHODS

The present study retrospectively analyzed the demographic, clinical, laboratory and radiological data of cirrhotic patients who underwent TIPS at our institution between January 2020 and June 2021. A total of 108 patients were included (Supplementary Figure 1). The inclusion criteria were, as follows: (1) Patients diagnosed with cirrhotic portal hypertension; and (2) patients with at least one episode of variceal hemorrhage or refractory ascites after treatment with vasoactive drugs, endoscopic treatment, or large-volume paracentesis. The exclusion criteria were, as follows: (1) Patients < 18 years old; (2) patients with a history of overt HE (grade ≥ 2, according to the West-Haven criteria[7]) within the past six months; (3) patients with hepatocellular carcinoma or other malignancies; (4) patients with no or poor quality preoperative abdominal CT scans; (5) patients with severe medical comorbidities, such as renal failure, pulmonary insufficiency, or extensive cardiovascular and cerebrovascular disease; and (6) patients who were lost to follow-up within three months.

Our institutional ethics review board approved the present retrospective study. According to the Declaration of Helsinki, all data of the study patients remained confidential throughout the study, and the informed consent for the study was waived due to the retrospective nature of the study.

The TIPS procedure



The TIPS procedure was performed based on the following steps: (1) After successfully puncturing the internal jugular vein, a transjugular liver access set (RUPS-100; Cook Incorporated, Bloomington, IN, United States) was introduced over the guidewire into the right hepatic vein; (2) the bifurcation of the left and right branches of the portal vein was punctured from the right hepatic vein; (3) the pre-shunt portosystemic pressure gradient (PPG) was measured; (4) a balloon catheter of 6-7 mm in diameter was passed over the guidewire to dilate the puncture channel; (5) an 8-mm polytetrafluoroethylene-covered stent (Viatorr stent, W. L. Gore & Associates, Flagstaff, AZ, United States) was implanted to establish the portosystemic shunt; (6) an 8-mm balloon catheter was used to further dilate the in-place stent and ensure that the expansion of the stent reaches 8 mm; (7) after the stent insertion, portography was performed to visualize the left and right branches of the portal vein; (8) if the patient was complicated with variceal rebleeding, the esophageal and gastric varicose vessels were embolized at the same time; and (9) finally, the post-shunting PPG was measured again to determine whether the target PPG was ≤ 12 mmHg or reduced by more than 50% from baseline.

CT image analysis

The abdominal CT scans of all studied patients were retrieved from our hospital's Picture Archiving and Communication System (Carestream, Canada). Then, the PMA and TPMT were measured at the level of the third lumbar vertebrae (L3) using the ADW4.4 workstation. In order to standardize the measurement, TPMT was obtained by gauging the transversal diameters of the right psoas muscle, further normalizing these to the body height, and presenting the values in mm/m. PMA was determined as the mean muscle attenuation in Hounsfield unit (HU) of the right psoas muscle at the L3 level (Figure 1). For the present study, sarcopenia was defined as TPMT < 10.7 mm/m in males and TPMT < 7.8 mm/m in females[11], while myosteatosis was defined as PMA < 41 HU for body mass index (BMI) < 25 kg/m^2 and PMA < 33 HU for BMI ≥ 25 kg/m^2[15].

Evaluation and follow-up of overt HE

All patients were followed-up at 1, 3 and 6 mo after TIPS, and every six months thereafter, during the inpatient rounds and outpatient visits. The follow-up evaluation included the following: General clinical manifestations, physical examination, laboratory tests, shunt patency, and HE. The different stages of HE were assessed and classified based on the detailed neurological examination, and according to the clinical criteria (West-Haven criteria). Overt HE was clinically diagnosed according to the grade 2 West-Haven criteria or higher, or based on the evidence of asterixis and disorientation[5].

DOI: 10.3748/wjg.v29.i18.2875 **Copyright** ©The Author(s) 2023.

Figure 1 Abdominal computed tomography images at the level of the third lumbar vertebrae were used to measure the transversal psoas muscle thickness and psoas muscle attenuation in a 45-year-old man without sarcopenia and myosteatosis, and a 51-year-old man with sarcopenia and myosteatosis. A: The axial computed tomography (CT) scan image of a 45-year-old cirrhotic patient (height: 1.74 m, weight: 74 kg) who developed variceal rebleeding; B and C: The patient had normal transversal psoas muscle thickness (TPMT) and psoas muscle attenuation (PMA) levels: 12.3 mm/m (21.4 mm/1.74 m) and 46.4 HU, respectively; D-F: The axial CT scan image of a 51-year-old cirrhotic patient (height: 1.72 m, weight: 55 kg) who developed refractory ascites (D), and had low TPMT and PMA (6.5 mm/m [11.2 mm/1.72 m] and 34.5 HU) (E and F). TPMT: Transversal psoas muscle thickness.

Statistical analysis

The statistical analysis was performed using SPSS v26.0 (IBM, United States). The data were presented as mean ± SE, or in frequency and percentage. Before the analysis, tests were performed to verify the normal distribution of the variables. The comparison of two groups for quantitative variables was performed using Student's *t*-test or Mann-Whitney *U*-test, while the comparison of two groups with qualitative variables was analyzed using χ^2 test. Receiver operating characteristic (ROC) analysis was performed to determine the prognostic significance and precision of various relevant parameters in predicting the development of overt HE. The Kaplan-Meier survival estimates were graphed to plot the survival trends of the patients, and log-rank test was conducted to determine the cumulative rates for overt HE. Univariate and multivariate Cox proportional hazards regression models were used to assess the association of risk factors with HE and mortality, and forward regression analysis was subsequently performed to select the appropriate variables in the multivariate model. A two-sided P value of < 0.05 was considered statistically significant for all statistical tests.

RESULTS

Patient demographics

Among the 108 patients, 84 (77.8%) patients were male, with a mean age of 53.0 ± 10.8 years old. The detailed demographic data and clinical information of these 108 patients are presented in Table 1. The table shows that the most common etiology of cirrhosis was viral hepatitis (67.6%). Furthermore, 74 (68.5%) patients had ascites, and the mean Child-Pugh score, model for end-stage liver disease (MELD) score, and neutrophil-lymphocyte ratio (NLR) was 7.4 ± 1.5, 11.0 ± 4.4 and 4.4 ± 4.1, respectively. The mean levels for hepatic [total bilirubin (TBIL), 22.8 ± 12.9 umol/L; alanine aminotransferase, 27.5 ± 19.7 U/L; aspartate transaminase, 37.8 ± 28.6 U/L] and renal (creatinine, 67.8 ± 25.7 umol/L) function were within the normal range. The mean value for PMA and TPMT was 43.5 ± 6.9 HU and 11.6 ± 3.1 mm/m, respectively. In general, myosteatosis and sarcopenia were found in 35 (32.4%) and 31 (28.7%) patients, respectively, and overt HE was diagnosed in 49 (45.4%) post-TIPS patients.

Table 1 Demographic data, relevant clinical characteristics, and skeletal muscle abnormalities of patients in the study

HE: Hepatic encephalopathy; BMI: Body mass index; MELD: Model for end-stage liver disease; NLR: Neutrophil-lymphocyte ratio; TBIL: Total bilirubin; ALT: Alanine aminotransferase; AST: Aspartate transaminase; PPG: Portosystemic pressure gradient; PMA: Psoas muscle attenuation; TPMT: Transversal psoas muscle thickness; HU: Hounsfield units.

Features associated with overt HE

The comparison between patients with and without overt HE is presented in Table 1. The table shows that patients with overt HE were older, had higher TBIL, MELD, Child-Pugh scores and reduction of PPG, and had lower NLR, PMA and TPMT values, when compared to patients without overt HE ($P < 0.05$). Furthermore, both myosteatosis (51.0% *vs* 16.9%, $P < 0.001$) and sarcopenia (40.8 *vs* 18.6%, $P = 0.011$) were more common in patients with overt HE, when compared to patients without overt HE. ROC curves were further plotted to determine the area under curve (AUC) values for PMA (AUC = 0.759, 95%CI: 0.669-0.849) and TPMT (AUC = 0.7143, 95%CI: 0.615-0.811), which were similar to the MELD score (AUC = 0.737, 95%CI: 0.642-0.833), but were greater than the NLR (AUC = 0.636, 95%CI: 0.530-0.743). The diagnostic sensitivity and specificity for the combined TPMT and PMA were 81.4% and 69.4%, respectively, and the AUC value was 0.799 (95%CI: 0.715-0.884) (Figure 2). The univariate Cox proportional hazards regression analysis revealed that the following were potentially associated with overt HE: age (HR = 1.044, 95%CI: 1.016-1.071, $P = 0.001$), Child-Pugh score (HR = 1.292, 95%CI: 1.091-1.531, $P = 0.003$), MELD score (HR = 1.137, 95%CI: 1.074-1.203, $P < 0.001$), TBIL (HR = 1.033, 95%CI: 1.014-1.053, $P = 0.001$), reduction of PPG (HR = 1.039, 95%CI: 1.007-1.071, $P = 0.017$), PMA (HR = 0.901, 95%CI: 0.863-0.940; $P < 0.001$), and TPMT (HR = 0.853, 95%CI: 0.774-0.940, $P < 0.001$). The further multivariate Cox proportional hazards regression analysis identified the following as independent predictive variables for overt HE after TIPS: MELD score (HR = 1.083, 95%CI: 1.020-1.449, $P = 0.009$),

Figure 2 Receiver operating characteristic curves for the probability of transversal psoas muscle thickness, psoas muscle attenuation, and neutrophil-lymphocyte ratio in predicting overt hepatic encephalopathy. TPMT: Transversal psoas muscle thickness; PMA: Psoas muscle attenuation; NLR: Neutrophil-lymphocyte ratio.

PMA (HR = 0.930, 95%CI: 0.889-0.974, P = 0.002), and TPMT (HR = 0.895, 95%CI: 0.808-0.992, P = 0.035) (Table 2).

Incidence of overt HE

The 3-mo, 6-mo, 1-year, and 2-year cumulative incidence of overt HE after TIPS was 32.8%, 38.0%, 44.7% and 52.6%, respectively. The incidence of overt HE was significantly higher in patients with sarcopenia (log-rank P = 0.022) or myosteatosis (log-rank P < 0.001), when compared to those without either condition. Furthermore, the 108 studied patients were divided into the following groups: Concomitant sarcopenia and myosteatosis (13.9%, 15/108), myosteatosis alone (18.5%, 20/108), sarcopenia alone (13.0%, 14/108), and normal muscle (54.6%, 59/108) groups (Table 3). It was determined that the cumulative incidence of overt HE was the highest in the concomitant sarcopenia and myosteatosis group, followed by the myosteatosis alone and sarcopenia alone groups, while the incidence was the lowest in the non-myosteatosis and non-sarcopenia groups (Figure 3).

Survival analysis

The univariate Cox proportional hazards regression analysis revealed that age (HR = 1.042, 95%CI: 1.008-1.077, P = 0.016), Child-Pugh score (HR = 1.317, 95%CI: 1.064-1.630, P = 0.011), MELD score (HR = 1.089, 95%CI: 1.013-1.172, P = 0.021), albumin (HR = 0.904, 95%CI: 0.836-0.977, P = 0.011), PMA (HR = 0.887; 95%CI: 0.839-0.938, P < 0.001), and TPMT (HR = 0.851, 95%CI: 0.759-0.954, P = 0.006) were potentially associated with overall mortality. When these above parameters were reprocessed using the multivariate Cox proportional hazards regression model, merely albumin (HR = 0.903, 95%CI: 0.827-0.986, P = 0.023), PMA (HR = 0.901, 95%CI: 0.853-0.951, P < 0.001), and TPMT (HR = 0.867, 95%CI: 0.760-0.988, P = 0.032) were identified as independent predictors for overall mortality (Table 4). Based on the Kaplan-Meier survival analysis, the cumulative survival rate was significantly lower in patients with overt HE (log-rank P < 0.001), sarcopenia (log-rank P = 0.001), and myosteatosis (log-rank P = 0.002), when compared to patients without overt HE. Furthermore, the cumulative survival rate was the lowest in patients with concomitant sarcopenia and myosteatosis, followed by patients with sarcopenia alone and myosteatosis alone, while the cumulative survival rate was the highest in patients without myosteatosis and sarcopenia (Figure 4).

DISCUSSION

Skeletal muscle abnormalities are frequently observed in advanced cirrhosis and cancer, and are associated with unfavorable outcomes[16-18]. Few studies have investigated the relationship between sarcopenia and myosteatosis, and overt HE after TIPS. The present study revealed that the cumulative incidence of overt HE was the highest in patients with concomitant sarcopenia and myosteatosis, followed by patients with myosteatosis alone and sarcopenia alone, while the lowest incidence was identified in patients without myosteatosis and sarcopenia. Furthermore, both myosteatosis and

sarcopenia were identified as independent risk factors for predicting the occurrence of overt HE and mortality in cirrhotic patients following TIPS.

Overt HE is a frequent complication of decompensated cirrhosis, which is eventually induced and/or aggravated by the TIPS procedure, and this can impact the quality of life and increase the mortality of patients[19]. The present study revealed that the overall incidence of overt HE after TIPS treatment was 45.4%, which is similar to the reports of previous studies[20,21]. However, merely the MELD score (HR = 1.083, 95%CI: 1.020-1.449, $P = 0.009$), myosteatosis (HR = 0.930, 95%CI: 0.889-0.974, $P = 0.002$) and sarcopenia (HR = 0.895, 95%CI: 0.808-0.992, $P = 0.035$) were identified as independent risk factors after adjusting for confounding variables in the present study. Two retrospective studies on 279 and 284 patients with TIPS reported that a unit of increase in the MELD score would lead to a 1.69 higher odds and a 1.06-fold increase in risk of post-TIPS HE development[22,23]. At the same time, a prospective study on 46 patients who underwent the TIPS procedure also reported that the MELD score and sarcopenia were independently associated with the development of HE after TIPS placement[24]. In addition, several studies reported that age, albumin, creatinine, Child-Pugh score, previous HE, PPG, proton pump inhibitors, and shunt size (> 8 mm *vs* 8 mm) are potential risks for developing post-TIPS

HE[4,23,25-27]. Thus, correct patient selection and early intervention for TIPS based on these potential risk factors may contribute to preventing HE complications, and improving the life quality of patients.

The relationship among myosteatosis, sarcopenia and HE may have different pathophysiological mechanisms. Previous studies have suggested that sarcopenia is caused by impaired protein synthesis and reduced satellite cell function[28]. Furthermore, since the muscle has been considered as an alternative site for the detoxification of ammonia, the accumulation of ammonia may contribute to the development of sarcopenia in cirrhotic patients by interfering with the protein remodeling[29]. On the other hand, myosteatosis may reduce the detoxification of ammonia by inhibiting glutamine synthetase, and increasing inflammatory cytokines[30]. Previous systematic reviews and meta-analyses have revealed that sarcopenia and myosteatosis are highly associated with complications and poor overall survival in patients with various diseases[31,32]. In the present study, patients with sarcopenia (log-rank $P = 0.022$) or myosteatosis (log-rank $P < 0.001$) had a higher cumulative incidence of overt HE after TIPS. In addition, subgroup analysis revealed that the cumulative incidence of overt HE was the highest in patients with concomitant sarcopenia and myosteatosis, followed by patients with myosteatosis alone or sarcopenia alone, while the cumulative incidence was the lowest in patients with normal skeletal muscles. These findings are consistent with those reported by previous studies[10,33], showing that sarcopenia and myosteatosis are independent predictive factors for overt HE in patients with cirrhosis. Furthermore, the relationship between skeletal muscle abnormalities (sarcopenia and myosteatosis) and minimal HE in patients with cirrhosis was further suggested by the Firth's bias-reduced multivariate analysis[33].

Similar to the present study, Liu *et al*[34] observed that the incidence of overt HE after TIPS was higher in patients with sarcopenia, when compared to patients without sarcopenia (29% and 16%, $P = 0.04$). However, that study could only identify sarcopenia as the possible risk factor for post-TIPS HE in the univariate analysis (HR = 1.86, 95%CI: 0.99-3.46, $P = 0.004$), and its significance in the multivariate analysis could not be verified. Another study conducted by Gioia *et al*[35] revealed that the psychometric HE score, ammonia, and occurrence of minimal and overt HE significantly improved in post-TIPS patients, with an amelioration SMI of > 10%, suggesting that the reversal of sarcopenia after TIPS can reduce the risk of occurrence of minimal or overt HE.

Figure 3 Kaplan-Meier curves for the cumulative incidence of post-transjugular intrahepatic portosystemic shunt overt hepatic encephalopathy. A: For all patients; B: For patients with and without myosteatosis; C: For patients with and without sarcopenia; D: For patients with coexisting sarcopenia and myosteatosis. HE: Hepatic encephalopathy.

Furthermore, the present study revealed that patients with coexisting myosteatosis and sarcopenia had the lowest cumulative survival rate, and it was identified that hypoalbuminemia (HR = 0.903, 95%CI: 0.827-0.986, P = 0.023), sarcopenia (HR = 0.901, 95%CI: 0.853-0.951, P < 0.001) and myosteatosis (HR = 0.867, 95%CI: 0.760-0.988, P = 0.032) are independent predictors of post-TIPS morbidity. Although other relevant factors, including age, creatinine, Child-Pugh score and MELD score, were significant in the present univariate analysis, these lost its significance as independent predictors in the multivariate analysis. A possible explanation is the inherent complexity and heterogeneity of TIPS cohorts, in general, with a high number of factors potentially affecting the clinical outcomes. A retrospective cohort study on 855 patients with cirrhosis reported that myosteatosis and sarcopenia are associated with mortality after adjusting for factors, and it was even quantitatively extrapolated that one HU of increase in muscle radiodensity corresponds to a 2% decrease in mortality risk (HR = 0.98, 95%CI: 0.96-0.99, P < 0.001)[36]. Another recent retrospective study on 224 patients with TIPS also identified sarcopenia (determined by L3 SMI) as an independent risk factor for mortality after TIPS (HR = 3.0, 95%CI: 1.2-7.8), and that patients who converted from sarcopenic to non-sarcopenic had a higher cumulative survival rate, when compared to those who did not convert (96.4% *vs* 82.1%, log-rank P = 0.04)[34]. In the present study, the cumulative survival rates were significantly lower in patients with sarcopenia/myosteatosis, when compared to patients without sarcopenia/myosteatosis (log-rank P = 0.001 and log-rank P = 0.002, respectively), further confirming the predictive value of sarcopenia/myosteatosis in the unfavorable prognosis of cirrhotic patients with TIPS.

There were several limitations in the present study. First, the present study was a single-center retrospective cohort study with a limited number of patients, and the intrinsic limitation of the study design appeared to be inescapable. Second, the diagnostic values for sarcopenia and myosteatosis were heterogeneous across studies in the literature. Thus, more studies and external validation of data are needed to standardize the CT-derived diagnostic criteria for sarcopenia and myosteatosis. Third,

Figure 4 Kaplan-Meier curves for the cumulative survival rate of post-transjugular intrahepatic portosystemic shunt. A: For all patients; B: For patients with and without hepatic encephalopathy; C: For patients with and without myosteatosis; D: For patients with and without sarcopenia; E: For patients with coexisting sarcopenia and myosteatosis. HE: Hepatic encephalopathy.

sarcopenia and myosteatosis were merely evaluated through CT measurements at admission, and these were not re-evaluated through CT imaging during the post-TPS follow-up period[35]. Thus, further well-designed studies are needed to determine whether the improvement in muscle abnormalities after TIPS can reduce the risk of overt HE and variceal rebleeding in post-TIPS patients[34].

CONCLUSION

The present study revealed that patients with coexisting myosteatosis and sarcopenia had the highest incidence of overt HE, and the lowest cumulative survival rate after TIPS placement, when compared to patients with myosteatosis alone or sarcopenia alone, or patients without muscle abnormalities. Sarcopenia and myosteatosis are independent variables for the development of overt HE and mortality in post-TIPS patients.

ARTICLE HIGHLIGHTS

Research background

Skeletal muscle abnormalities, such as muscle mass depletion (sarcopenia) and fatty infiltration of the muscle (myosteatosis), are frequent complications in cirrhotic patients scheduled for a transjugular intrahepatic portosystemic shunt (TIPS) procedure, leading to an incidence of approximately 20%-50% for overt hepatic encephalopathy (HE).

Research motivation

The motivation of the study was to provide computed tomography (CT) image-based methods for predicting overt HE and mortality after TIPS, based on the sarcopenia and myosteatosis.

Research objectives

The study aims to investigate the association and predictive volubility of sarcopenia and myosteatosis for overt HE, and mortality after TIPS.

Research methods

The records of cirrhotic patients, who underwent the TIPS procedure at our hospital, were retrospectively reviewed. Transversal psoas muscle thickness and psoas muscle attenuation, which were measured by unenhanced abdominal CT at the level of the third lumbar vertebrae, were used to diagnose the sarcopenia and myosteatosis, respectively. Then, the incidence of overt HE and mortality were compared based on the sarcopenia and myosteatosis status.

Research results

A total of 108 patients were collected. Myosteatosis (51.0% *vs* 16.9%, $P < 0.001$) and sarcopenia (40.8 *vs* 18.6%, $P = 0.011$) were identified to be more frequent in patients with overt HE, when compared to patients without overt HE. The cumulative incidence of overt HE was the highest in patients with concomitant sarcopenia and myosteatosis, followed by patients with myosteatosis or sarcopenia, while this was the lowest in patients without sarcopenia and myosteatosis. In addition, sarcopenia and myosteatosis were independently associated with overt HE and mortality after adjusting for confounding factors in post-TIPS patients.

Research conclusions

The CT-based diagnostic method of sarcopenia and myosteatosis can be used as a reliable predictor for the risk of developing overt HE and mortality in cirrhotic patients after TIPS.

Research perspectives

In the future, more well-designated trials are required to standardize the CT-derived diagnostic criteria for sarcopenia and myosteatosis. In addition, more validation studies are needed to confirm the predictivities of sarcopenia and myosteatosis in post-TIPS overt HE.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, John K Triantafillidis, MD, PhD, FEBGH, Associate Professor of Medicine, Staff Physician, Iasi University of Medicine and Pharmacy, Romania, "Metropolitan General" Hospital, Holargos, Athens 15562, Greece. jktrian@gmail.com

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

The main therapeutic options for colorectal cancer are surgical resection and adjuvant chemotherapy in non-metastatic disease. However, the evaluation of the overall adjuvant chemotherapy benefit in patients with a high risk of recurrence is challenging. Radiological images can represent a source of data that can be analyzed by using automated computer-based techniques, working on numerical information coded within Digital Imaging and Communications in Medicine files: This image numerical analysis has been named "radiomics". Radiomics allows the extraction of quantitative features from radiological images, mainly invisible to the naked eye, that can be further analyzed by artificial intelligence algorithms. Radiomics is expanding in oncology to either understand tumor biology or for the development of imaging biomarkers for diagnosis, staging, and prognosis, prediction of treatment response and diseases monitoring and surveillance. Several efforts have been made to develop radiomics signatures for colorectal cancer patient using computed tomography (CT) images with different aims: The preoperative prediction of lymph node metastasis, detecting *BRAF* and *RAS* gene mutations. Moreover, the use of delta-radiomics allows the analysis of variations of the radiomics parameters extracted from CT scans performed at different timepoints. Most published studies concerning radiomics and magnetic resonance

imaging (MRI) mainly focused on the response of advanced tumors that under-went neoadjuvant therapy. Nodes status is the main determinant of adjuvant chemotherapy. Therefore, several radiomics model based on MRI, especially on T2-weighted images and ADC maps, for the preoperative prediction of nodes metastasis in rectal cancer has been developed. Current studies mostly focused on the applications of radiomics in positron emission tomogra-phy/CT for the prediction of survival after curative surgical resection and assessment of response following neoadjuvant chemoradiotherapy. Since colorectal liver metastases develop in about 25% of patients with colorectal carcinoma, the main diagnostic tasks of radiomics should be the detection of synchronous and metachronous lesions. Radiomics could be an additional tool in clinical setting, especially in identifying patients with high-risk disease. Nevertheless, radiomics has numerous shortcomings that make daily use extremely difficult. Further studies are needed to assess performance of radiomics in stratifying patients with high-risk disease.

Key Words: Colorectal cancer; Radiomics; Artificial intelligence; Liver metastases; Magnetic resonance imaging; Computed tomography; Positron emission tomography/computed tomography

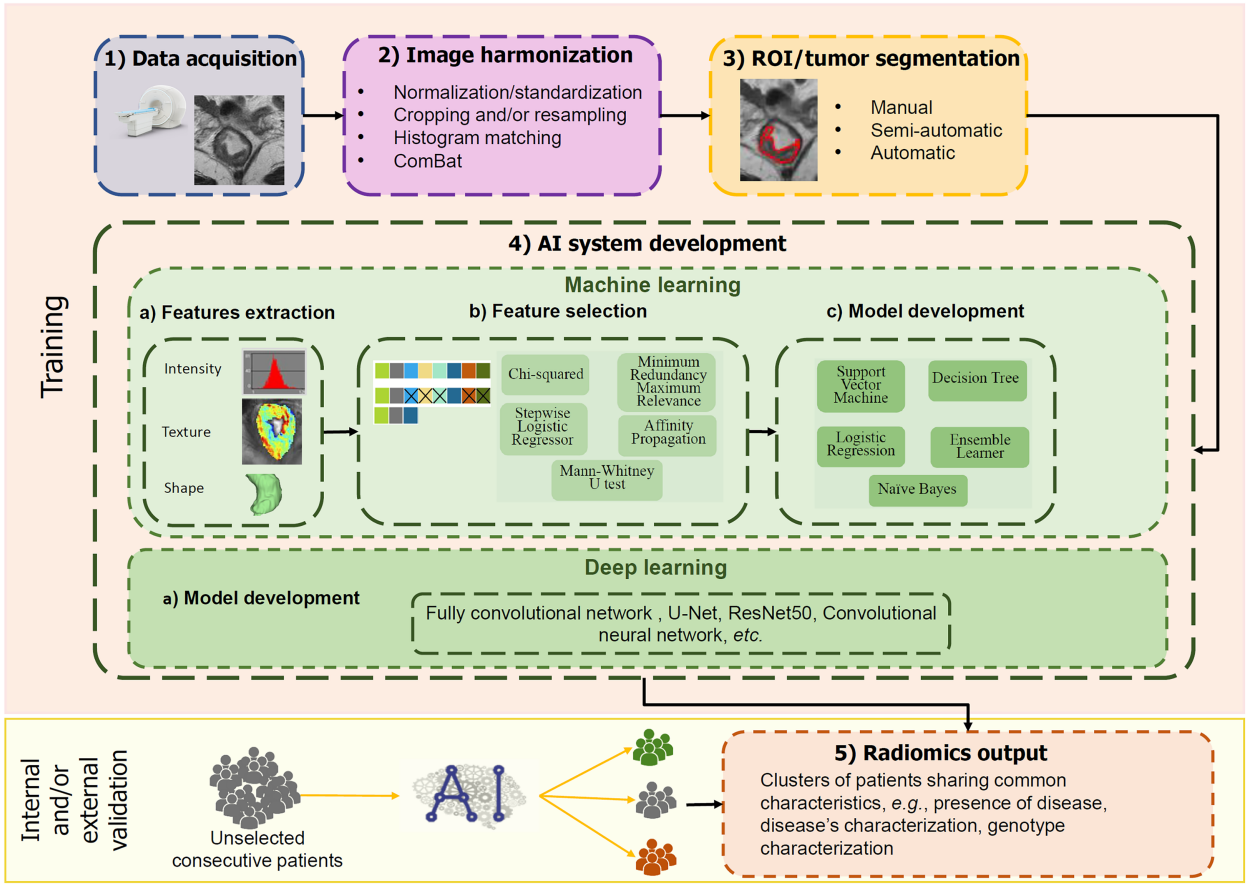
INTRODUCTION

Colorectal cancer is the fifth-most-common frequent in terms of incidence and mortality, with 1480000 new cases in 2020 worldwide[1]. The TNM staging process itself is widely based on radiological definition of boundaries of primary lesion, nodal and distant metastases. The main therapeutic options for colorectal cancer are surgical resection and adjuvant chemotherapy in non-metastatic patients; however, the evaluation of the overall adjuvant chemotherapy benefit in patients with a high risk of recurrence is a clinical challenge[2]. The decision is based on the TNM staging system[3], which represents the most important parameter: Colorectal cancer patients at stage III are globally recognized as patients who can benefit from chemotherapy, while for those at stage II with other clinical risk factors, the advantages of chemotherapy are still debated[2,4]. In presence of clinical risk factors, the final strategy is often decided by the oncologist or multidisciplinary teams.

Nowadays radiological images can represent a source of data that can be analyzed by using advanced computer-based techniques, working on numerical information coded within the Digital Imaging and Communications in Medicine files[5]: This image numerical analysis has been named "radiomics"[6]. Radiomics might be used as a non-invasive imaging biomarker and be able to provide a quantitative evaluation of medical images, with the chance to shift imaging from a qualitative to a quantitative approach[7,8]. To date, the radiomics approach has been extensively investigated in cancer patients with a specific focus on tumor diagnosis, staging, prognosis prediction, and long-term monitoring[7,9,10]. In this context, radiomics could play a pivotal role in colorectal cancer workup with the expectancy to help clinicians in identifying patients with high-risk disease.

RADIOMICS APPLIED TO CANCER-SUMMARY (PATHOLOGICAL CORRELATION, DIAGNOSIS, PROGNOSIS)



Since its advent in 2012[5], radiomics has been extensively applied in oncology studies and it has been demonstrated as a promising tool that can offer a risk-free and efficient method for diagnosis, classification, and prognosis prediction in oncology[11]. Radiomics, indeed, allows the extraction of quantitative features from radiological images, mainly invisible to the naked eye, that can be further analyzed by machine learning and artificial intelligence (AI) algorithms to produce signatures representing tumor phenotype.

The radiomics pipeline consists of different steps (Figure 1). First, multi-dimensional and multi-institutional data should be collected including high-quality medical images, clinical, and, eventually, molecular data. Once acquired, images should be pre-processed to improve image quality, harmonize raw data, and ensure generalizability across imaging protocols and patient populations, especially if multicentre datasets are acquired. This pre-processing step usually involves image co-registration, image denoising, signal intensity standardization, and/or normalization. Once the image datasets have been pre-processed, tumors should be segmented to extract regions of interest (ROIs) on which subsequent steps will be focused on. This task can be performed either manually, semi- or fully automatically. A big effort in the research field is addressed to the development of AI-based systems to automatically segment lesions and overcomes the most common limitations of manual segmentation. Afterward, from the segmented ROIs a large number of parameters (features) are extracted, including: (1) First-order features, from gray-level intensity histograms and lesion shape; (2) second-order features, related to the spatial relationship between pixels, calculated using different matrices, *e.g.*, gray-level co-occurrence, gray-level run-length, gray-level dependence, gray-level size zone, neighboring gray tone difference; and (3) transform-based features, *e.g.*, Wavelet, Gabor, Laws, Laplacian. However, since the number of extracted features could be much larger than the sample size of patients included in the algorithms' development, it is vital to reduce the number of features through a step called features selection. This step will strongly reduce the risk of overfitting[12], which occurs when the algorithm overadapts its performances based on data in the training set and consequently loses its generalizability. Besides, features selection will ensue to exclude features that are non-reproducible, redundant, and/or non-relevant for the task, and to reduce the computational cost, while improving the performance of the model[13]. Once the most performing features are selected, the radiomics signature is finally developed by using algorithms for classification, such as logistic regression[14,15], k-nearest neighbour[16], naïve Bayes classifier[17], support vector machines (SVM)[18,19], random forest (RF)[20,21], neural network [22,23] and deep learning[24,25]. In this step, is crucial to divide the image dataset into three subgroups: One for training, used to develop the algorithm, the second for testing, to fine-tune the model, and the last for validation, which aims to evaluate the performance on a different dataset. Training and testing could be performed also using a cross-validation approach, *i.e.*, in which different portions of the dataset are iteratively used to train and test the model. Conversely, the validation should be performed using patients that were never seen during the development of the algorithms. The validation step can be internal, when applied in a similar clinical setting and population to the training set, or preferably external, when applied in multiple clinical settings with varying disease prevalence[12,26].

Thanks to the vast number of images routinely used by radiologists and oncologists in their daily workload, radiomics is substantial in oncology to understand tumor biology or develop imaging biomarkers useful for diagnosis, staging, prediction of treatment response, disease monitoring and surveillance[27].

Understanding tumor biology through radiomics can be feasible because it allows the extraction of quantitative information about spatial and temporal heterogeneity in a non-invasively way and using routinely acquired images. This information can be consequently correlated with tumors' phenotype that can either reflects distinct traits (*e.g.*, internal necrosis and proliferation at the periphery) or mirrors genomic and molecular traits or be a signature or different outcomes. Moreover, texture features used in radiomics have been also demonstrated useful in reflecting key oncogenomics processes such as tumor angiogenesis[28], hypoxia[29], tumor invasion[30] and tumor proliferation[31].

The second scope of radiomics in the oncology field is to enhance precision medicine through the implementation of diagnostics and prognostic imaging biomarkers in a variety of solid tumors. Biomarkers for detection and diagnosis are those in a more advanced status since there are many studies that demonstrated their usefulness in discriminating between healthy, benign and malignant cancer in different sites[23,32-34]. However, the most promising applications in which radiomics could truly improve clinical practice are related to the prediction of treatment response and disease monitoring. Indeed, knowing, before or during therapy, which patients would respond might help choosing the best management possible. Moreover, after treatment, radiomics biomarkers may suggest more intense post-treatment surveillance due to a high risk of a tumor recurrence for a particular patient. In parallel to radiomics, it is worthwhile underling that a boost for the development of prognostic biomarkers for precision medicine could be provided by integrating radiomics features to additional layers of -omics information, *i.e.*, pathomics (features derived from digital pathological samples), and genomics. The motivation for this multi-omics approach to disease understanding is that the conventional markers

Figure 1 Radiomics pipeline. ROI: Regions of interest.

discovery which molecularly dissect the disease part by part, if the sum of knowledge of parts will explain the operation of the whole, has mostly failed to understand the causes and cures for complex diseases. On the contrary, recent evidence suggests that patterns discovered from high dimensional, multi-modal data could improve estimation of disease aggressiveness and patient outcomes compared to single modality data.

COMPUTED TOMOGRAPHY

Tumor and nodes

Several efforts have been made to develop radiomics signatures for colorectal cancer patient using computed tomography (CT) images with different aims (Table 1). Li *et al*[35] developed and validated a clinical-radiomics nomogram for the preoperative prediction of nodes metastasis. They validated their algorithm on an internal dataset of 308 patients (136 with and 172 without lymph node metastases) and showed that the model which included clinical parameters, radiomics on both tumor and peripheral nodes was the one reaching the highest accuracy in predicting nodes metastases [area under the curve (AUC) = 0.7509; 95%CI: 0.6901-0.8071; accuracy: 73.70%; sensitivity: 60.29%; specificity: 84.30%; positive predictive value (PPV): 75.23%; and negative predictive value (NPV): 72.86% in the internal validation set]. If further validated, also on an external validation set, this model could be used as an individualized preoperative non-invasive tool, assisting in clinical treatment decision making and achieving precision treatment.

From another point of view, radiomics has also been proven effective in detecting *BRAF* and *RAS* (*KRAS* and *NRAS*) gene mutations, that are genomics signatures usually associated with shorter disease-free and overall survival. These mutations are determined through genetic molecular profiling by sampling the tumor, however biopsy carries several drawbacks, including the risk of adverse events, such as bleeding, physical and psychological discomfort[36].

For these reasons, radiomics could potentially be used to non-invasively predict RAS and BRAF mutation status in patients with colorectal cancer and to further guide treatments with surgery or chemotherapy[16,37]. Shi *et al*[16] validated a combined score that tracks *RAS* (*KRAS* and *NRAS*) and

Table 1 Summary of the most important published papers regarding the usefulness of radiomics in colorectal cancer patients using computed tomography imaging

Ref.	Imaging	Main aim	Patients (*n*)	Main findings
Li *et al*[35], 2020	CT	Prediction of nodes metastases	766	Overall diagnostic values: Sensitivity = 60.3%; specificity = 84.3%; PPV = 75.2%; NPV = 72.9%; AUC = 0.750
Shi *et al*[16], 2020	CT	Detect *RAS* and *BRAF* phenotypes	159	Combined score (semantic features and radiomics) AUC = 0.950; validation cohort AUC = 0.790
Giannini *et al* [41], 2020	CT	Predict response to treatment	38 (141 lesions)	Per-lesion diagnostic values: Sensitivity = 89%; specificity = 85%; PPV = 78%; NPV = 93%
Dercle *et al* [47], 2020	CT	Tumor response to anti-EGFR therapy	667	Sensitivity to therapy: AUCs 0.800 and 0.720 for FOLFIRI and FOLFIRI + cetuximab
Dohan *et al* [48], 2020	CT	Overall survival	491	SPECTRA score > 0.02 has a lower OS; SPECTRA Score at 2 mo has the same prognostic values as RECIST at 6 mo
Giannini *et al* [41], 2020	CT	Predict response to treatment	57 (242 lesions)	Per-lesion diagnostic values: Sensitivity = 99%; specificity = 94%; PPV = 95%; NPV = 99%; the radiomic approach can predict R- wrongly classified by RECIST as R^+
Taghavi *et al* [103], 2021	CT	Prediction of synchronous liver metastases	91	The radiomics model outperformed the clinical model: AUC = 0.93 *vs* 0.64
Rao *et al*[108], 2014	CT	Prediction of synchronous liver metastases	29	The mean entropy of the liver is significantly higher in metastatic patients (P = 0.02); Liver entropy can help the differential between metastatic and non-metastatic patients (AUC = 0.73-0.78)
Li *et al*[109], 2022	CT	Prediction of synchronous liver metastases	323	A combined clinical-radiomics model has a good AUC (= 0.79) in detecting liver metastases
Ng *et al*[111], 2013	CT	Prediction of overall survival	55	Entropy, uniformity, kurtosis, skewness, and standard deviation of the pixel distribution histogram can predict survival; each parameter can be considered an independent predictor of the overall survival state
Mühlberg *et al* [112], 2021	CT	Prediction of overall survival	103	Tumor burden score can discriminate patients with at least 1-year survival (AUC = 0.70); a machine-learning model better predict survival (AUC = 0.73)
Ravanelli *et al* [116], 2019	CT	Prediction of response and prognosis after chemotherapy	43	Uniformity is lower in responders (P < 0.001); uniformity is independently correlated with radiological response (OR = 20.00), overall survival (RR = 6.94) and progression-free survival (RR = 5.05)

PPV: Positive predictive value; NPV: Negative predictive value; AUC: Area under the curve; OS: Overall survival; SPECTRA: Survival PrEdiction in patients treated by FOLFIRI and bevacizumab for mCRC using contrast-enhanced computed tomography TextuRe Analysis; CT: Computed tomography.

BRAF mutant phenotypes in colorectal cancer from multicentre CT image data AUC of 0.79 on the validation cohort.

Recently, efforts have been made to translate radiomics signatures from a patient level to a lesion level, since it has been demonstrated that heterogeneous response, caused by the onset of new resistant tumor clones in some lesions, is a predictor of poor overall survival[38-40]. Differentiating which colorectal liver metastases (CRLM) responds and which lingers and eventually will progress in the same patient could pave the way to truly personalized treatment. Giannini *et al*[41] preliminary demonstrated the feasibility of using radiomics features from baseline CT to predict response of treatment after 3 mo. They validated the signature on an independent cohort of patients obtaining encouraging results especially in identifying patients with outlier lesions, *i.e.*, that do not respond in general condition were most lesions respond. In these cases, a target biopsy on non-responder lesions could have revealed a different genetic makeup or, in absence of extrahepatic lesions, suggested the local ablation of outlier metastases. More recently, another breakthrough has been made using the use of delta-radiomics, whose aim is to assess the treatment-induced change of radiomics features over time that could provide information about prognosis[42,43]. These variations can be measured in different ways, for example as the differences between features computed on the same tumour before and after treatment[44,45] or the net-change (*i.e.*, difference of radiomics features after treatment over the value before treatment)[46]. Other than providing additional information about tumour behaviour, delta-radiomics represents a very interesting approach since it could theoretically allow to adapt and modulate the ongoing treatment approach thanks to the predictive power of this technique[42].

Delta-radiomics has been already proven effective in predicting overall survival in patients with metastatic colorectal cancer[47,48]. Dercle *et al*[47] developed and validated on a multicentre dataset a delta-radiomics associated with tumor sensitivity to anti-EGFR therapy in colorectal cancer patients (AUC = 0.80). Similarly, Dohan *et al*[48] validated a delta-radiomics signature able to predict overall survival and identify good responders better than RECIST1.1 criteria in patients with metastatic colorectal cancer treated by FOLFIRI and bevacizumab as a first-line treatment. From a per-lesion point

of view, Giannini *et al*[45] validated a delta-radiomics signature able to predict long-term response (*i.e.*, more than 8 mo) of individual CRLM with an accuracy of 86% in the validation dataset. Of note, the delta-radiomics signature was able to reliably predict non-responder liver metastases wrongly classified as responder by lesion RECIST at the first time point. This per-lesion approach could strongly impact treatment, since according to the delta-radiomics signature it would be possible to pinpoint lesions with distinct biological and molecular features, thus enabling studies toward lesion-specific personalized treatment in liver-only metastatic colorectal cancer patients.

MAGNETIC RESONANCE IMAGING

Tumor evaluation

The application of radiomics and texture analysis by using magnetic resonance imaging (MRI) images has increased interest in recent years (Table 2), with a specific focus on liver pathology, renal carcinoma, prostate cancer, and, in slight minority of published studies, rectal cancer[49]. As mentioned above, the staging of rectal cancer is mainly based on MRI; however, radiological images analyzed by dedicated software can add important data useful for the best management of patients. In this setting, it is of utmost importance to underline the potentiality of radiomics as a non-invasive biomarker for predicting histopathological data, as demonstrated for different abdominal pathological conditions, related to the liver, pancreas, and colorectal[8]. Even if for many abdominal organs it can be difficult to obtain a useful histological sample, rectal cancer pathological data are easy to collect, considering that colonoscopy or sigmoidoscopy, depending on the location of the lesion, is the reference standard technique[50]. On these bases, most published studies when this search was performed mainly focused on the response of advanced tumors that underwent neoadjuvant therapy.

Recently, Chen *et al*[51], in a single-center prospective study, enrolled 137 patients who underwent neoadjuvant chemotherapy. The Authors demonstrated that the traditional clinical model reported an AUC of 67.6% and 70.1% in the training and validation cohort, respectively, quite similar to the selective clinical model (77.5% and 59.6%, respectively). On the other hand, when combining radiomics with clinical data the AUC raised to 94.9% and 84.4% in the training and validation cohort, respectively.

Similarly, Horvat *et al*[52], by enrolling 114 patients who underwent neoadjuvant chemotherapy, demonstrated that radiomics can help the radiologist determine the pathological complete response. The Authors found that combined clinical and radiomics models increased the agreement compared with radiologist interpretation and can help the less experienced radiologist in increasing diagnostic values, in particular specificity, PPV, and NPV.

Analogously, Dinapoli *et al*[53] analyzed the radiomics data of 221 patients from three different centers and demonstrated that this tool can help the prediction of pathological complete response before starting neoadjuvant chemotherapy. Moreover, the Authors performed an external validation, to test the obtained results, with good diagnostic values.

Even if few studies are published in the literature, to test the robustness of the radiomics approach in rectal cancer patients, Shahzadi *et al*[54], demonstrated that only one study can be used for external validation, underlying the overall lack of reproducibility and the need of further standardization before considered it a useful clinical tool. In this setting, future directions should be focused on multicentre studies with standardized MR protocols to validate and test the feasibility of the radiomics approach and its potential usefulness in current everyday clinical practice.

Node's evaluation

Nodes metastases is the main metastatic site of colorectal cancer and an important cause of post-operative recurrence and death[55]. Nodes status is a key factor in the TNM staging of colorectal cancer and the main determinant of adjuvant chemotherapy[56,57].

Preoperative knowledge of NS can provide valuable information for determining the need for adjuvant therapy and the adequacy of surgical resection, thus aiding in pre-treatment decision making [58].

In clinical practice, CT is the most used preoperative imaging method to detect metastatic lesions and perform tumor staging in patients with colorectal cancer. However, the limitation of CT examination is that it cannot discriminate between benign and malignant nodes[59].

MRI has the highest contrast resolution for soft tissues, allowing the best depiction of neoplastic lesions, their anatomical relationships, the depth of the rectal wall involvement, extramural venous invasion, circumferential resection margins, and the assessment of the N stage. For these reasons, MRI examination is considered the reference standard for locoregional staging and restaging in RC according to the main international guidelines[60-62].

Advances in pattern recognition tools and the increase in data set sizes have facilitated the development of radiomics, which may potentially improve predictive accuracy in oncology[63].

Therefore, in the last decade, several papers have been published, with different imaging techniques, reporting the potential role of radiomics in diagnosis, characterization, and evaluation of the tumor response to treatments[64-67] and nodal assessment[68-70].

Table 2 Summary of the most important published papers regarding the usefulness of radiomics in colorectal cancer patients using magnetic resonance imaging

Ref.	Imaging	Main aim	Patients (*n*)	Main findings
Horvat *et al* [52], 2022	MRI	Response to chemotherapy	114	Combined radiological-radiomics model increased agreement (κ = 0.82 *vs* κ = 0.25)
Dinapoli *et al* [53], 2018	MRI	Pathological complete response	221	Significant covariates, skewness, and entropy can predict pathological complete response, with AUCs = 0.730 and 0.750 for internal and external cohorts
Shahzadi *et al* [50], 2022	MRI	Response to chemotherapy	190	Radiomics combined with the T stage better predict response
Liu *et al*[23], 2021	MRI	Prediction of nodes metastases	186	Clinical-radiomics model improves performance: AUC = 0.827
Chen *et al*[72], 2022	MRI	Tumor differentiation and nodes metastases	37 (487 nodes)	Radiomics features of the primary tumor can predict tumor differentiation: AUC = 0.798
Liu *et al*[73], 2017	MRI	Tumor differentiation	68	Skewness and entropy are lower in pT1-2 in comparison with pT3-4 (P < 0.05)
Yang *et al*[74], 2019	MRI	Prediction of T and N stage	88	Skewness, kurtosis, and energy are higher in metastatic nodes in comparison with non-metastatic ones (P < 0.001)
Ma *et al*[75], 2019	MRI	Prediction of nodes metastases and N staging	152	SVM has higher diagnostic values for T and N stages (AUC = 0.862) in comparison with MLP and RF
Zhu *et al*[76], 2019	MRI	Prediction of nodes metastases	215	Radiomic model AUC = 0.818
Zhou *et al*[77], 2020	MRI	Prediction of nodes metastases	391	The combined model predicts nodes metastases: NPV = 93.7%, AUC = 0.818
Shu *et al*[34], 2019	MRI	Prediction of synchronous liver metastases	194	The Radiomics model combined clinical risk factors and LASSO features and showed a good predictive performance: AUC = 0.921
Liu *et al*[107], 2020	MRI	Prediction of synchronous liver metastases	127	A radiomic nomogram presents an accuracy of 81.6% in predicting liver metastases (AUC = 0.918)
Granata *et al* [115], 2022	MRI	Prediction of overall survival	90	Second-order features can predict infiltrative tumor growth, tumor budding, and mucinous type; a second-order feature can predict the risk of recurrence with an accuracy of 90%
Jalil *et al*[119], 2017	MRI	Prediction of prognosis after chemotherapy	56	MPP can predict overall survival (HR = 6.9) and disease-free survival (HR = 3.36); texture analysis can predict relapse-free survival on pre- and post-treatment analyses

AUC: Area under the curve; SVM: Support vector machine; MLP: Multilayer perceptron; RF: Random forest; NPV: Negative predictive value; HR: Hazard ratio; MPP: Mean positive pixel; MRI: Magnetic resonance imaging.

MRI can provide multiparameter images different from those obtained by CT, so it is of interest whether there exists an association between NS and multiregional radiomics features of multiparametric MR images in rectal cancer patients[71].

Liu *et al*[71] aimed to develop and validate a multiregional radiomics prediction model based on MRI and combine it with clinical-semantic data for the individualized preoperative prediction of lymph node metastasis in rectal cancer patients.

Similarly, the study of Chen *et al*[72] provides two non-invasive and quantitative methods, which respectively predict the tumor differentiation and regional nodes metastases for rectal cancer preoperatively. MRI images of both the primary tumor alongside the lymph nodes and specimens were performed with a node-to-node match and labeling. A prediction model was then successfully developed, which provided AUC values of 84.6% and 73.3% in the training and test cohort, respectively.

Liu *et al*[73] performed a histogram analysis on the ADC map of the whole tumor and reported that entropy was an independent predictor of nodal involvement. Recently, Yang *et al*[74] performed the same analysis on T2-weighted imaging of the whole tumor: They found that a lower skewness was an independent risk factor for lymph node metastases.

In a recent retrospective single-center study, radiomics features were extracted from preoperative high-resolution T2-weighted imaging of different histological RC and analyzed using different algorithms. The RF analysis showed a good diagnostic performance for the N-stage with an AUC of 74.6%. The prediction model was able to differentiate N0 from N1-N2 patients with a sensitivity of 79.0% and a specificity of 72.0%[75].

Zhu *et al*[76] compared the performance of two models based, respectively, on the radiomics signature of the primary tumor and of the lymph nodes, before and after chemoradiotherapy (CRT), for the prediction of nodal involvement in advanced rectal cancer. The authors concluded that the features

from the lymph node model perform better than the tumor features for the prediction of nodal involvement[76].

Similarly, Zhou *et al*[77] evaluated a multi-parametric MRI radiomics model for nodal assessment following CRT by combining the radiomic signature with an experienced radiologist's visual evaluation: stratified analyses indicated that the combined model could predict lymph node metastasis with a NPV of 100 and 87.8% after treatment[77].

Even if current literature is focusing on the importance and applicability of radiomics in rectal cancer, no significant studies have been published in the field of colorectal cancer, mainly because MR is not still validated as imaging technique for local staging and restaging of this kind of tumor.

PET/CT

18F-fluorodeoxyglucose positron emission tomography/computed tomography (18F-FDG PET/CT) is frequently employed in the staging and post-neoadjuvant assessment of patients with rectal cancer. PET/CT provides functional information of the primary tumor, nodes and distant metastases. In patients with colorectal cancer, the combination of texture parameters with the functional information obtained with PET/CT scan can further enhance the predictive power of PET/CT imaging[78]. Current studies mostly focused on the applications of radiomics in PET/CT for the prediction of survival after curative surgical resection and assessment of response following neoadjuvant chemoradiotherapy (Table 3).

For the prediction of prognosis in patients with colorectal cancer, Kang *et al*[79] showed that radiomics score from baseline PET scans was significantly associated with progression-free survival. Similarly, Lovinfosse *et al*[80] and Hotta *et al*[81] correlated the texture features in PET/CT with both progression-free survival and overall survival. Furthermore, a recent study provided a combined clinical-radiomics model with high predictive performance (C-index of 0.780) for recurrence-free survival in 196 patients with PET/CT[82].

Several studies explored the potential of radiomics for the prediction of response and survival after neoadjuvant chemoradiotherapy[83-89]. In an initial study of 27 patients with rectal cancer treated with neoadjuvant chemoradiotherapy, Bundschuh *et al*[83] calculated texture parameters (skewness and kurtosis) on PET/CT, which provided a good performance for late response prediction but no significant predictive capability for the assessment of early response. In a retrospective study performed by Bang *et al*[84], texture parameters extracted from PET images correlated with both tumor regression grading and disease-free survival in patients with rectal cancer undergoing neoadjuvant chemoradiotherapy. Giannini *et al*[85] combined radiomics features from PET and MRI to predict pathological complete response following neoadjuvant chemoradiotherapy with high accuracy (AUC of 0.86) in patients with rectal cancer. Similarly, Schurink *et al*[86] combined pretreatment tumor features on PET/CT and MRI to predict response to chemoradiotherapy in rectal cancer, with an AUC of 0.81. Shen *et al*[87] developed a RF model to predict pathological complete response after neoadjuvant chemoradiotherapy in 169 patients with rectal cancer, which demonstrated a sensitivity of 97.3% and a specificity of 81.8% for the identifications of cancers with complete response. Nevertheless, a study by Karahan Şen *et al*[88] found no superiority of texture features compared to metabolic tumor volume in predicting response to neoadjuvant chemoradiotherapy in patients with locally advanced rectal cancer.

For the prediction of lymph node metastasis, a retrospective study published by He and colleagues [90] analyzed the radiomics score and five machine-learning models to predict metastatic lymph nodes based on the radiomics features of 199 colorectal cancers, with an AUC of 0.747-0.581 in the test set. Additionally, the performance of PET/CT radiomics features for predicting perineural invasion has been explored in a recent retrospective study[91].

Finally, few other studies explored the correlation between radiomics signature extracted from PET/CT and rectal cancer genotypes, such as microsatellite instability status[92], RAS mutational status[93, 94], TP53 and adenomatous polyposis coli mutations[94].

Despite the promising value of radiomics in PET/CT scans of rectal cancer, it should be noted that all current results are based on retrospective single-center studies with heterogeneity on the type of extracted features and analysis. Moreover, several current studies demonstrated insufficient quality according to the radiomics quality score assessment[95].

CRLM

CRLM develop in about 25% of patients with colorectal carcinoma, being more commonly synchronous (14%-17%) rather than metachronous (8%-15%)[96-99]. CT is most adopted to detect CRLM at preoperative staging due to its higher availability compared to MRI, while MRI is usually used in selected doubtful cases particularly in the challenging scenario of the "too small to characterize" hypoattenuating lesion. In addition, chemotherapy regimens may cause focal or diffuse hepatic changes at imaging that can profoundly alter visualization of hepatic metastases on CT, reducing its diagnostic accuracy and MRI proves to be helpful as problem-solving tool in some cases[100]. Therefore, the overall sensitivity, specificity and accuracy for the diagnosis of CRLM are lower for CT compared to

Table 3 Summary of the most important published papers regarding the usefulness of radiomics in colorectal cancer patients using positron emission tomography/computed tomography imaging

Ref.	Imaging	Main aim	Patients (*n*)	Main findings
Lovinfosse *et al* [80], 2018	PET/CT	Progression-free and overall survival	86	SUVmean, dissimilarity, and contrast from the neighborhood intensity-difference matrix are independently associated with overall survival
Hotta *et al*[81], 2021	PET/CT	Progression-free and overall survival	94	MTV, TLG, and GLCM entropy are associated with overall survival; SUVmax, MTV, TLG, and GLCM entropy are associated with progression-free survival
Bundschuh *et al* [83], 2014	PET/CT	Response after neoadjuvant chemotherapy	27	COV can assess histopathologic response during (sensitivity 68%, specificity 88%) and after (sensitivity 79%, specificity 88%) therapy
Bang *et al*[84], 2016	PET/CT	Response after neoadjuvant chemotherapy	74	MV is associated with 3-yr disease-free survival; Kurtosis and kurtosis gradient are associated with 3-yr disease-free survival
Giannini *et al* [85], 2019	PET/CT	Response after neoadjuvant chemotherapy	52	Second-order texture features (five from PET and one from MRI) can help distinguish responder and non-responder patients: Sensitivity = 86%; specificity = 83%; AUC = 0.860
Yuan *et al*[89], 2021	PET/CT	Response after neoadjuvant chemotherapy	66	A radiomics model can predict TRG 0 vs TRG 1-3: Sensitivity = 77.8%, specificity = 89.7%, AUC = 0.858
Schurink *et al* [86], 2021	PET/CT	Response after neoadjuvant chemotherapy	61	Combined baseline and global tumor features better predict response compared to baseline and local texture (AUC = 0.83 *vs* 0.79)
Shen *et al*[87], 2020	PET/CT	Predict pathological complete response	169	RF can predict complete response: Sensitivity = 81.8%; specificity = 97.3%; PPV = 81.8%; NPV = 97.3%; accuracy = 95.3%
He *et al*[90], 2021	PET/CT	Prediction of nodes metastases	199	Logist regression and XGBoost can accurately predict nodes metastases with AUC = 0.866 and 0.903, respectively
Ma *et al*[91], 2022	PET/CT	Prediction of perineural invasion and outcome	131	12 radiomics signatures are associated with peri-neural invasion; a radiomic score can differentiate between perineural positive and negative lesions: AUC = 0.900
Li *et al*[92], 2021	PET/CT	Prediction of microsatellite instability	173	2 radiomics features can predict microsatellite instability: Sensitivity = 83.3%; specificity = 76.3%; accuracy = 76.8%
Lovinfosse *et al* [93], 2016	PET/CT	Prediction of RAS status	151	SUVmax, SUV mean, skewness, SUV standard deviation, and SUV coefficient of variation are associated with RAF mutation (all $P < 0.001$)
Chen *et al*[94], 2019	PET/CT	Prediction of genetic mutations	74	MTV and SUV max are increased in mutated KRAS tumors (all $P < 0.001$); short-run low gray-level emphasis is associated with p53 mutations ($P = 0.001$); gray-level zone emphasis is associated with APC mutations ($P = 0.006$)

PET/CT: Positron emission tomography/computed tomography; PPV: Positive predictive value; NPV: Negative predictive value; AUC: Area under the curve; RF: Random forest; MTV: Metabolic tumor volume; TLG: Total lesion glycolysis; GLCM: Gray-level co-occurrence matrix; COV: Coefficient of variation; MV: Metabolic volume; OR: Odd ratio; MPP: Mean positive pixel.

MRI[100-102]. For this reason, at some center, abbreviated gadoxetate disodium MRI protocols are adopted rather than trusting CT only[103,104].

The adoption of radiomics has been proven successful in diagnostic, prognostic, and therapeutic stages[78].

Diagnosis and risk assessment

In term of diagnosis of synchronous classical logistic regression models (CLRM), it is relevant to highlight that even with MRI the sensitivity may be lower than 80%, particularly in patients with mucinous adenocarcinoma as primary tumor, prior local treatment in the liver or metastases smaller than 1 cm[102]. Therefore, the first main diagnostic task of radiomics should be the identification of CRLM before they can be seen by radiologist's naked eye (*i.e.*, detection of synchronous metastases). In a pilot study, Devoto *et al*[105] proved that radiomics can potentially predict the development of liver metastases on baseline liver CT, by demonstrating a higher heterogeneity of liver texture analysis in patients who developed liver metastases compared to patients who did not develop them. Other authors[34,106] investigated whether radiomics applied to T2-weighted images of the primary tumor on MRI could help in the preoperative prediction of CRLM: Shu *et al*[34] used a region of interest while Liu *et al*[107] used a volume of interest and both demonstrated that a radiomics nomogram constructed by combining radiomics and clinical data achieve AUC higher than 90% in the preoperative prediction of

CRLM.

The second main diagnostic task of radiomics should be preoperative identification of patients at risk of developing CLRM (*i.e.*, detection of metachronous metastases) based on micro-environmental changes in the apparently normal liver. Taghavi *et al*[106] and Rao *et al*[108] designed a prediction model based on liver CT radiomics for the detection of metachronous CRL, with the first study including more patients imaged at three centers and combining radiomics and clinical data achieving AUC of up to 86% in the validation cohort. Other studies tried to achieve the same goal by assessing the primary tumor on CT[109] or MRI[110]. Specifically, Li *et al*[109] obtained an AUC of 0.72 for the prediction of metachronous CLRM by combining clinical data and volumetric radiomics of the primary tumor on CT. In regard of MRI, a systematic review including 1497 patients estimated a pooled sensitivity and specificity of radiomics applied to rectal MRI of 0.76 and 0.85 respectively in predicting metachronous CLRM, and AUC of the included studies ranging from 0.83 to 0.87[110].

Prognosis

In terms of prognostic information, radiomics of CRLM has emerged as a promising tool to preoperatively predict patient survival at diagnosis and after therapy. Ng *et al*[111] suggested that tumors demonstrating less texture tumor heterogeneity using radiomic CT analysis may predict poorer survival at diagnosis[111]. Mühlberg *et al*[112] showed that CT-based geometric distribution and radiomics analysis of whole liver tumor burden from preoperative CT may help for prediction of 1-year survival. Radiomics of CRLM on CT seems also promising for differentiating desmoplastic from replacement histopathological growth patterns[113], and this differentiation may provide an earlier estimate of disease aggressiveness and prognosis as the desmoplastic histopathological growth pattern usually has longer overall survival[114]. As demonstrated by Granata *et al*[115] contrast MR-based radiomics and machine learning analysis may help in the preoperative prediction of the front of tumor growth (expansive or infiltrative), the tumor budding (absent, low grade or high grade) and tumor recurrence after surgery, all of which may affect patient outcome. Studies looking at survival after chemotherapy in patients with CRLMs obtained similar results regarding the role of texture homogeneity/heterogeneity in the prediction of prognosis[116,117]. As an example, Ravanelli *et al*[116] demonstrated that lower uniformity of CRLM on CT texture analysis was independently correlated with overall survival and progression free survival in patients treated with bevacizumab, but not in those treated with standard chemotherapy. Other radiomic features such as entropy, kurtosis, and skewness have been investigated so far on CT and MRI, all providing an additional piece of the puzzle and supporting the concept that the addition of texture analysis in the pre-treatment assessment may provide information on prognosis in patients with primary colorectal cancer and CLRM[118,119].

Treatment response

Finally, the correct assessment of response in the treatment of CLRM and the prompt prediction of early response is of utmost important in defining the success or failure of treatment interventions and in the selection of those patients requiring a change of the therapeutic regimen. Chemotherapy for CLRM in the modern era of oxaliplatin- and irinotecan-containing regimens (*e.g.*, FOLFOX, FOLFIRI, CAPOX/FOLFOXIRI, XELOX) has been implemented with the introduction of targeted biologics and immunotherapeutic agents (*e.g.*, bevacizumab, cetuximab, panitumumab, pembrolizumab), thus expanding the proportion of patients eligible for curative-intent surgery, but their use may lead to side effects or complications[120]. Prediction of tumor response before starting chemotherapy would allow to choose the best treatment, avoiding unnecessary adverse effects of the therapy. Radiomics of CLRM has been proven promising for predicting response to different chemotherapy regimens, but the predictive value of radiomics features seems to be treatment dependent[95]. As shown by two systematic reviews[95,121], most studies performed radiomics on CT rather than MRI. In patients treated with FOLFOX or FOLFIRI, low skewness and narrower standard deviation-both suggesting increased tumor homogeneity-were associated with a high response rate to chemotherapy[122]. Giannini *et al*[41] developed a radiomics signature to predict behaviour of individual CLRMs to targeted treatment in patients with HER2 amplification undergoing dual target therapy; in their model, the two most important radiomics features were difference in variance and homogeneity, thus again highlighting the role of texture analysis homogeneity of CLRM for assessing lesion diagnosis and outcome. Other studies investigated the role of radiomics in assessing tumor response after other targeted biologics and immunotherapeutic agents, such as regorafenib[117], and bevacizumab[116,48].

CONCLUSION

Nowadays much evidence has revealed that not all clinical risk features are equal, not all affect overall survival, and the decision to treat colorectal cancer with adjuvant chemotherapy should be assessed in multidisciplinary approach[123]. In this scenario, radiomics could play a pivotal role in colorectal cancer workup as an additional tool in clinical setting with the expectancy to help clinicians in identifying patients with high-risk disease. In particular, the main fields examined were the preoperative assess-

ment of the differentiation between low- and high-grade colorectal cancer, and the prediction of nodal metastases[124-131]. The results achieved good and consistent efficiency in identifying high-risk clinical factors, reinforcing the idea that radiomics could play a central role in colorectal cancer patient workup. Nevertheless, radiomics has numerous shortcomings that make daily use extremely difficult. Among these, the lack of standardization and validation, poor reproducibility, and missing prospective multicentric studies represent the main drawbacks that must be overcome to introduce the radiomics approach to the clinical routine[7]. Further studies are needed to assess the performance of radiomics in stratifying patients with high-risk disease in patients with non-metastatic colorectal cancer who could benefit from adjuvant chemotherapy.

FOOTNOTES

Author contributions: Inchingolo R, Maino C, Cannella R, Vernuccio F, Cortese F, Dezio M, Pisani AR, Giandola T, Gatti M, Giannini V, Ippolito D, and Faletti R equally contributed to this paper with conception and design of the study, literature review and analysis, drafting and critical revision and editing; and all authors gave final approval of the final version.

Abstract

Liver cirrhosis is commonly associated with nutritional alterations, reported in 20% of patients with compensated disease and over 60% of patients with decompensated cirrhosis. Nutritional disturbances are associated with a worse prognosis and increased risk of complication. Serum levels of branched-chain amino acids (BCAAs) are decreased in patients with liver cirrhosis. The imbalance of amino acids levels has been suggested to be associated with the development of complications, such as hepatic encephalopathy and sarcopenia, and to affect the clinical presentation and prognosis of these patients. Several studies investigated the efficacy of BCAAs supplementation as a therapeutic option in liver cirrhosis, but uncertainties remain about the real efficacy, the best route of administration, and dosage.

Key Words: Branched-chain amino acids; Hepatic encephalopathy; Sarcopenia; Liver cirrhosis

Core Tip: Nutritional perturbance is frequent in liver cirrhosis and has been correlated with the development of complications such as hepatic encephalopathy and sarcopenia. Branched-chain amino acids (BCAAs) have been implicated in the pathophysiology of these two complications and supplementation has been proposed as a therapeutic measure. In this review, we will examine the scientific evidence supporting the clinical use of BCAAs in cirrhotic subjects.

INTRODUCTION

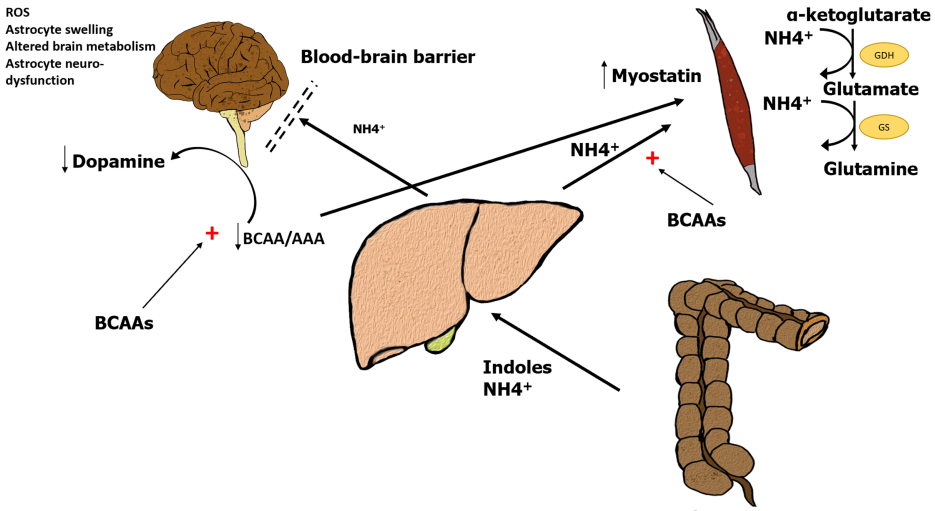
Liver cirrhosis is commonly associated with nutritional alterations, being reported in 20% of patients with compensated disease and over 60% of patients with decompensated cirrhosis[1]. In cirrhotic subjects, nutritional disturbances are associated with a worse prognosis and increased risk of complications such as hepatic encephalopathy (HE) and sarcopenia. On the other hand, serum levels of branched-chain amino acids (BCAAs) are decreased in patients with liver cirrhosis, and this has been associated with the development of complications[2]. Several studies investigated the efficacy of BCAAs supplementation in liver cirrhosis for the treatment and prevention of both HE and sarcopenia. The aim of this review is to analyze scientific evidence supporting the administration of BCAAs in patients with liver cirrhosis affected by HE and sarcopenia (Table 1).

HE

HE is one of the main complications of advanced cirrhosis. It consists of a wide spectrum of non-specific neurological or psychiatric abnormalities, ranging from subclinical alterations to coma, caused by liver failure and/or porto-systemic shunting. According to the West Haven classification HE is classified, as covert HE (CHE), including minimal HE (MHE) and grade 1 HE, and overt HE (OHE), including grade 2, grade 3, and grade 4 HE of the West Haven classification[3]. The prevalence of OHE in liver cirrhosis is 30%-40% at any time during the clinical course of the disease[4] while MHE or CHE occurs in 20%-80% of patients with cirrhosis[5]. HE is associated with a poor prognosis, and high socioeconomic costs and also carries a psychological burden on patients and families[6]. According to the American Association for the Study of Liver Diseases and the European Association for the Study of the Liver (EASL) Clinical Practice Guidelines, episodes of OHE should be actively treated[3]. The therapeutic approach encompasses the active treatment of precipitant factors (*e.g.*, infections, variceal bleeding), administration of non-absorbable disaccharides, such as lactulose, and non-absorbable antibiotics, such as rifaximin[7]. Secondary prophylaxis with oral rifaximin is recommended after an episode of OHE. In case of recurrent and intractable OHE associated with advanced liver disease, the patients should be evaluated for liver transplantation[3]. Other treatments such as metronidazole, neomycin, or intravenous administration of L-ornithine L-aspartate, have been proposed for the treatment of HE, but the evidence supporting their use is still limited or under debate[8]. According to EASL guidelines, despite their limited efficacy, the use of these medications is advocated as an additional treatment for patients -non-responsive to conventional therapies[3].

BCAAS AND HE

In recent years, growing interest in the role of BCAAs in liver cirrhosis has been observed in the scientific literature. A common feature in patients with liver cirrhosis is decreased BCAA plasmatic levels associated with the increase of aromatic amino acids (AAA), namely tyrosine and phenylalanine, thus leading to a low BCAA/AAA ratio, the so-called "Fisher ratio"[9]. This ratio is negatively correlated with the Child-Turcotte-Pugh score (CTP) and the severity of liver disease[10]. A low Fisher ratio is also associated with the development of HE and an excellent correlation has been found between this ratio and the grade of HE[11]. The role of BCAAs in the development of HE was first advocated in the "false neurotransmitters" hypothesis in the 80s[12]. Both AAA and BCAAs compete for the same transporter across blood-brain barrier. According to this hypothesis, the increased concentration of AAA in liver cirrhosis leads to an increased availability of aromatic neurotransmitters precursors, which cause a "false" dopaminergic transmission and inhibition of dopamine synthesis, resulting in neurodepression[13]. Other studies focused on the key role of increased ammonia levels in the development of HE, underling its neurotoxic role[14]. Despite this evidence, mechanisms involved in the pathogenesis of HE remain poorly understood.



The increase in blood ammonia is a consequence of impaired liver function and portosystemic shunts. Skeletal muscle is a key site of extrahepatic ammonia detoxification by the absorption of plasma ammonia and the conversion of α-ketoglutarate to glutamate, and then of glutamate to glutamine through glutamate dehydrogenase and glutamine synthetase enzymes, which remove two moles of

Table 1 Selected published studies on beneficial effects of branched chain amino acids in liver cirrhosis

Ref.	Study design	Participants	Intervention	Route	Treatment duration	Associated treatments	Outcomes	Results
Horst *et al* [16], 1984	Multicentric RCT	37 cirrhotic patients with OHE	BCAAs (20 g/d increased to 80 g/d) *vs* isonitrogenous diet (placebo)	Oral	4 wk	No	Mortality and hepatic encephalopathy assessed after 4 wk	HE recurrence (decreased). No differences in nitrogen balance
Muto *et al* [17], 2005	Multicentric RCT	646 patients with decompensated cirrhosis	BCAAs (12 g/d) *vs* standard diet (1.0-1.4 protein kg/d	Oral	2 yr	No	Mortality, development of liver cancer, rupture of esophageal varices, or progress of hepatic failure (event-free survival)	EFS (increased), health-related quality of life, mortality (decreased). No differences in improvement of HE
Les *et al*[18], 2011	Double-blind multicentric RCT	40 cirrhotic patients with previous episodes of minimal hepatic encephalopathy	BCAAs (30 g/d) *vs* isocaloric placebo (maltodextrin)	Oral	56 wk	No	Mortality and hepatic encephalopathy assessed after 56 wk	Improvement in MHE symptoms and muscle mass. No reduction of HE recurrence
Gluud *et al* [19], 2017	Meta-analysis of RCT	11 RCT; 14 RCT	BCAAs *vs* diets, antibiotics (neomycin) and non-absorbable disaccharides	Oral and IV	Variable	No	Effect on HE manifestations and prevention of HE episodes	Oral BCAAs improve HE manifestations and prevention of HE episodes. No effects for IV BCAA
Gluud *et al* [20], 2013	Systematic review with meta-analysis	8 RCT: 382 cirrhotic patients with recurrent MHE or OHE	BCAAs (0.25 g/kg body weight/day) *vs* no intervention/placebo/control supplements	Oral	Variable	No	Effect on HE manifestations, mortality, nutritionalstatus, and adverse events in patients with recurrent HE	Improvement in the recurrent HE manifestation (more evident in OHE than MHE). No differences in survival
Gluud *et al* [19], 2017	Cochrane systematic review	16 RCT: 827 cirrhotic patients with OHE or MHE	BCAAs *vs* placebo/no intervention/other (diet, lactulose, neomycicn)	Oral and IV	Variable	No	Beneficial or harmful effects of BCAA versus any control intervention in HE	Oral BCAAs improve HE manifestation (no effect *vs* lactulose or neomycicn). No effect on mortality
Park *et al* [21], 2017	Multicentric retrospective cohort study	307 cirrhotic patients with CTP 8-10	BCAAs (4.15 g/d or 8.3 g/d or 12.45 g/d) *vs* normal diet	Oral	24 wk	No	Changes in MELD score, CP score, incidence of cirrhosis-related complications and event-free survival over 2 yr	Improvement in MELD score, serum bilirubin and CTP score in 12.45/d BCAAs. No differences in HE manifestation
Tajiri *et al* [23], 2018	Retrospective observational study	53 cirrhotic patients with OHE	IV BCAAs and conventional therapies *vs* IV BCAAs and conventional therapies + IV L-carnitine	IV	Median 5 d (range 2-20 d)	L-carnitine conventional therapies (non-absorbable disaccharides and non-absorbable antibiotics)	Effect on HE manifestation, recurrence-free-survival and overall-survival	L-carnitine + BCAAS improve HE manifestation and reduce HE recurrence

BCAAs: Branched chain amino acids; RCT: Randomized control trial; OHE: Overt hepatic encephalopathy; HE: Hepatic encephalopathy; EFS: Early feeding skill; MELD: Model for end stage liver disease; CP: Child-pugh score; CTP: Child-Turcotte-Pugh score.

ammonia for each α-ketoglutarate molecule. Muscle uptake of plasma BCAAs increases with ammonia concentration in patients with liver cirrhosis, suggesting that BCAAs play an important role in ammonia detoxification in muscle and can contribute to preventing HE[13] (Figure 1).

DOI: 10.3748/wjg.v29.i19.2905 **Copyright** ©The Author(s) 2023.

Figure 1 Gut derived ammonia and other aromatic compounds pass into the systemic circulation due to reduced liver function and the presence of porto-systemic shunts. A low plasma branched chain amino acids (BCAA)/aromatic amino acids (AAA) ratio has been observed in liver cirrhosis. BCAA and AAA compete for the same transporter at blood-brain barrier. The increased availability of AAA causes an increase in aromatic neurotransmitter precursors resulting in a false dopaminergic transmission and a reduction in dopamine synthesis. At brain level, ammonia causes astrocyte metabolism changes including reactive oxygen species increase, altered glucose and protein metabolism and astrocyte swelling, resulting in altered neurotransmission. Muscle is a key site of ammonia detoxification by means of the sequential action of glutamate dehydrogenase and glutamine synthetase. Ammonia increases myostatin expression, thus resulting in reduced protein synthesis and inhibition of myogenesis. The administration of BCAAs can increase muscle ammonia uptake from blood and can interfere with amino acids pass throughout the blood brain barrier with beneficial effects on both hepatic encephalopathy and sarcopenia. BCAAs: Branched chain amino acids; AAA: Aromatic amino acids; NH4+: Ammonia; ROS: Reactive oxygen species; GDH: Glutamate dehydrogenase; GS: Glutamine synthetase.

EVIDENCE SUPPORTING THE THERAPEUTIC USE OF BCAAS IN HEPATIC ENCEPHALOPATHY

A possible therapeutic role of BCAAs supplementation in HE was first evaluated in animal models. In dogs with portocaval shunt, which developed HE, neurological manifestations induced by the simultaneous infusion of 1% tryptophan and 1% phenylalanine were prevented by the concomitant infusion of BCAAs (0.63% leucine + 0.4% isoleucine + 0.46% valine)[15]. Subsequently, several clinical studies evaluated the role of BCAAs in the treatment and prevention of HE in cirrhotic subjects. In the early 80s, a randomized study evaluated the effect of BCAAs in protein-intolerant cirrhotic. Enrolled subjects were fed with increasing amounts of either dietary protein or a BCAAs solution until they attained an intake of 80 g protein per day or until they developed stage 2 encephalopathy. Oral BCAAs supplements induced a positive nitrogen balance as an equivalent amount of dietary protein but decreased the risk of HE recurrence[16]. In 2005, a multicenter randomized controlled trial evaluated oral BCAAs (12 g/d for 2 years) compared with diet therapy with defined daily food intake (1.0-1.4 g protein kg/day) in patients with decompensated cirrhosis. The group who received BCCA showed an improvement in event-free survival and consequently, a reduction in mortality, but no statistically significant differences were found in HE[17]. Another randomized, double-blind, multicenter study evaluated subjects with cirrhosis with a previous episode of HE. The two groups of patients received a standard diet and a supplement of 30 g of BCAAs or maltodextrin over 56 wk. BCAAs supplementation was not associated with a reduction in HE recurrence but an improvement in MHE and muscle mass recovery were found in the BCAA-treated group[18]. A meta-analysis of randomized trials, performed by Gluud *et al*[19], confirmed that oral BCAAs administration has a beneficial effect on the clinical manifestation of HE, but no similar results were found for intravenous administration. Based on this evidence, the authors suggested using nonabsorbable disaccharides as the first-line treatment for HE, with a more beneficial effect through the addition of nonabsorbable antibiotics, while oral BCAAs may be considered as a second-line treatment. Another systematic review with meta-analysis evaluated the effects of oral BCAAs compared with placebo or control supplements in patients with HE. The administration of oral BCAAs was found to be associated with an improvement in HE recurrence {87 of 172 patients in the BCAAs group *vs* 56 of 210 in controls, risk ratio (RR) = 1.71 [95% confidence interval (CI): 1.17-2.51]}. The effect of oral BCAAs was higher in patients with OHE rather than in patients with MHE, but no difference in survival was found. These results strengthen the recommendation of oral BCAAs in patients who developed HE during enteral nutrition and in the case of recurrent HE. Most of the analyzed studies used the same dose of oral BCAAs (0.25 g/kg body weight/die) and no adverse events (including nausea and diarrhea) were reported[20]. A Cochrane systematic review, updated in 2017, evaluated the beneficial and harmful effects of BCAAs *vs* any control intervention for people with HE.

The study analyzed 16 randomized clinical trials, including 827 patients with OHE (12 trials) or MHE (4 trials). Control groups received placebo/no intervention in 2 trials, diets in 10 trials, lactulose in 2 trials, or neomycin in 2 trials. BCAAs were administrated orally in 8 trials and intravenous in 7 trials. No differences in mortality were found between BCAAs groups and control groups (RR = 0.88, 95%CI: 0.69-1.11). Reduced mortality was noted only when excluding trials in which control groups were treated with lactulose or neomycin (RR = 0.76, 95%CI: 0.63-0.92). The analysis also showed that BCAAs supplementation was associated with a beneficial effect on HE compared with controls (RR = 0.73, 95%CI: 0.61-0.88). Subgroup analyses showed that oral BCAAs but not intravenous BCAAs had a beneficial effect on overt encephalopathy. These differences were not found for MHE[21]. This systematic review supported the use of oral BCAAs in clinical practice but did not provide enough evidence to evaluate the benefit of BCAAs compared with other interventions. The most adequate dosage and duration of BCAAs supplementation is also a debated issue, since homeostasis of BCAAs in the body is extremely rapid, and circulating values quickly return to baseline after administration. A multicenter retrospective cohort study evaluated the effects of long-term BCAAs supplementation (at least 6 mo) compared with diet in patients with advanced liver disease (CTP 8-10) compared with no BCAAs enriched diet. Patients in the BCAAs group were divided into 3 subgroups according to the dose administrated: 4.15 g, 8.3 g, or 12.45 g/d. Statistical analysis revealed differences in the model for end-stage liver disease (MELD) score, serum albumin levels, and CTP score between the BCAAs group and control group at the baseline. Patients enrolled in the BCAAs group showed lower albumin levels and higher CTP scores, MELD scores, and HE grades (mostly grades 1-2). This was probably related to the propensity of physicians to prescribe BCAAs to patients with a worsened deterioration of hepatic function. Sub-group analysis showed a significant improvement in MELD score, serum bilirubin levels, and CTP score in patients who received the highest dose of BCAAs (12.45 g daily), whereas no significant differences were found in albumin levels. Conversely, only improvement in the serum bilirubin levels was observed in patients who received the lowest dose of BCAAs (4.15 g). This evidence provides a relationship between BCAAs dosage and its beneficial effect on prognostic scores in liver cirrhosis, suggesting high-dose BCAAs supplementation to achieve benefits. The study did not find significant differences in HE manifestations between the two groups. This was probably related to the shorter duration of BCAAs supplementation than in previous studies (about 30% of patients discontinued BCAAs within one year)[22].

A possible synergic role of L-carnitine and BCAAs on HE has been postulated. L-carnitine is a vitamin-like bio-factor that has been shown to induce ureagenesis, and improve energy metabolism leading to a reduction in blood and ammonia levels, thus protecting human astrocytes from ammonia-induced acute cytotoxicity[23]. A study on cirrhotic patients affected by OHE treated with intravenous BCAAs supplementation and conventional therapy (lactulose and non-absorbable antibiotics, showed that the addition of L-carnitine provided an improvement in blood ammonia concentration and Glasgow Coma Scale) with an improvement in HE recurrence. Despite the preliminary nature of the study, these results suggest a possible synergic role between L-carnitine and BCAAs in HE treatment [24].

SARCOPENIA IN LIVER CIRRHOSIS

Patients with chronic liver disease are at risk of malnutrition and sarcopenia[2]. The first definition of sarcopenia was proposed by Rosenberg[25], deriving from the Greek words "sarx" (muscle) and "penia" (reduction), to point out the decline in muscle mass and strength that occurs with healthy aging. The European Working Group on Sarcopenia in Older People in 2019 defined sarcopenia as a progressive and generalized skeletal muscle disorder that consists of decreased muscle quality or quantity and decreased physical function or muscle strength. Sarcopenia is distinguished as primary, or age-related in the absence of other evident specific cause, and secondary when the causal factor is a systemic, neoplastic, or inflammatory disease (*e.g.*, malignancy, inflammatory disease, or organ failure such as liver cirrhosis[26], affecting about 20%-60% of patients in the latter condition)[27]. In cirrhotic patients, the pathogenetic cascade is multifactorial: Since muscle mass is the result of protein anabolism and catabolism balance, reduced liver function, together with portosystemic shunts, causes decreased protein synthesis and ammonia detoxification, thus promoting sarcopenia and hyperammonemia. Hyperammonemia leads to increased muscle expression of the cytokine myostatin, a negative regulator of muscle growth by inhibition of myogenesis[28] (Figure 1). Other involved factors are BCAAs deficiency, which plays a key role in maintaining muscle mass and strength, and perturbation of sex hormone levels, with reduction of testosterone and concomitant increase in estrogen-to-androgen ratio. Hormonal changes suppress myoblast differentiation in skeletal muscle thus promoting sarcopenia[29]. Recently, changes in the intestinal microbiome (reduction of Methanobrevibacter, Prevotella e Akkermansia) and in the intestine-liver-muscle axis with increased bowel inflammation and bacterial translocation have been described in sarcopenic cirrhotic[30]. The role of gut microbiota is crucial for energy extraction from nutrients, in controlling low-grade systemic inflammation and bacterial infections, and has been involved in the genesis of HE, sarcopenia, and hepatocellular carcinoma (HCC) in liver cirrhosis[30-34].

BCAA IN THE TREATMENT OF SARCOPENIA

Despite growing interest in the clinical role of sarcopenia, few evidence-based therapeutic interventions are available to revert this condition in the context of liver cirrhosis. Current literature changed the old concept of protein restriction in patients with liver cirrhosis and daily recommended protein intake has been changed accordingly[35]. According to the European Society for Clinical Nutrition and Metabolism, high protein intake, variable from 1.2 g/kg/d protein in patients with compensated liver cirrhosis to 1.5 g/kg/d protein in patients with malnutrition and/or sarcopenia, is considered safe, well-tolerated, and recommended in liver cirrhosis. Another suggested dietary intervention is to shorten fasting periods by consuming three to five meals per day and taking a late evening snack. The aim of these suggestions is to reduce protein catabolism during overnight fasting and to reverse anabolic resistance and sarcopenia[1].

A nutritional interventional strategy aimed at increasing protein synthesis and preventing sarcopenia is BCAAs exogenous supplementation. BCAAs play a key role in protein synthesis and glucose metabolism. Leucine is involved in the activation of the intracellular mammalian target of rapamycin (mTOR) complex 1 pathway and inhibition of ubiquitin-proteasome signaling, thus resulting in increased protein synthesis, skeletal muscle hypertrophy, and reduced muscle turnover[36].

In experimental animal models of carbon tetrachloride-induced liver cirrhosis, muscle mass loss was described in association with decreased BCAAs and increased AAA plasma levels, while decreased α-ketoglutarate and ATP concentration in muscles was found[37]. A Japanese study evaluating cirrhotic subjects demonstrated a high prevalence of sarcopenia, low serum levels of BCAAs, and insulin-like growth factor 1. Patients with lower baseline levels of BCAAs had also a higher prevalence of CTP class B and C, lower albumin and zinc blood concentration, and lower body mass index (BMI), associated with risk of malnutrition, disease complication, and poor prognosis[38]. The presence of sarcopenia and low plasma levels of total BCAAs have also been associated with a significant reduction of survival in liver cirrhosis[39].

Several studies were performed to evaluate the effect of BCAAs administration to prevent sarcopenia and its complication in cirrhotic patients. In animal models, the administration of BCAAs reversed the metabolic alterations in skeletal muscles, promoting glucose uptake, which improves ATP production and muscle function[40,41]. In patients affected by alcoholic cirrhosis, skeletal muscle biopsy showed increased myostatin expression, dysfunctional mTOR pathway, and increased autophagic proteolysis when compared to well-matched healthy controls. These pathologic alterations were reversed after the administration of a single oral BCAAs mixture enriched with leucine. A monocentric prospective study on adult cirrhotics showed that oral BCAAs powder administration (13.5 g twice a day) for 24-wk was able to improve muscle strength with limited increase in muscle mass. It suggests that BCAAs supplementation alone could not be enough to achieve effective improvement of sarcopenia in cirrhotic patients and that aerobic and resistance exercise could also be necessary to induce protein synthesis response[42]. A prospective, randomized double-blind clinical trial in patients with liver cirrhosis and sarcopenia assessed by computed tomography (CT) scan, showed that BCAAs supplementation, in addition to a nutritional intervention and physical activity, could improve albumin levels and muscle mass. Administration of BCAAs also increased zinc levels after 12 wk of intervention[43]. Zinc is an essential nutrient for human health and its deficiency is often associated with malnutrition and chronic liver disease[44]. Improvement of hypoalbuminemia after BCAAs supplementation is correlated with improved glucose metabolism and a decrease in skeletal muscle fat infiltration, miming exercise training. In these patients, an improvement in liver-related event-free survival (including refractory pleural effusion, ascites, or both, varices rupture or treatment, and hepatocarcinogenesis) was observed and it might contribute to a better prognosis[45]. Today, in liver cirrhosis, an intervention program including physical exercise is considered useful to decelerate sarcopenia progression, but it can't completely prevent skeletal muscle atrophy[46]. The combination of BCAAs supplementation and walking exercise was found to be more effective than exercise alone in improving muscle mass and function and it should be considered a good therapeutic strategy in patients with overt sarcopenia and a prevention strategy in patients at risk of sarcopenia[47]. In a retrospective cohort study, patients with liver cirrhosis were classified into low, intermediate, and high-risk according to the presence of hypoalbuminemia and/or sarcopenia. The high-risk group, including patients with both sarcopenia ad hypoalbuminemia, had significantly lower overall survival than the low-risk group, including patients without both hypoalbuminemia and sarcopenia, regardless of HCC occurrence. The administration of BCAAs improved overall survival and prognosis in treated patients. The survival benefit of BCAAs supplementation was pronounced in the high and intermediate-risk groups[48]. Lastly, in cirrhotic patients, sarcopenia contributes to hyperammonemia due to the reduced capacity of sarcopenic muscle to detoxify circulating ammonia which increases the risk of HE. On the other hand, hyperammonemia through myostatin upregulation, mitochondrial dysfunction, and cellular stress response, induces further muscle depletion, generating a vicious circle. On these bases, nutritional interventions against sarcopenia, including BCAA supplementation, may have a beneficial effect also on HE[49,50].

β-HYDROXY-β-METHYLBUTYRATE SUPPLEMENTATION

A different strategy to counteract muscle mass loss, acting on BCAAs metabolism, is β-Hydroxy-β-methylbutyrate (HMB) supplementation. HMB is a natural derivative of the BCAA leucine, which has shown a positive effect on muscle mass and strength in malnourished subjects. Recently, the randomized, placebo-controlled, double-blind, parallel design strengthening health in the elderly through nutrition trial showed a significant improvement in weight, BMI, mid-arm circumference, and leg strength in elderly subjects receiving an HMB containing oral nutritional supplement along with dietary counseling over six months. Female treated subjects also showed a significant increase in handgrip strength and the whole population showed an improvement in nutritional parameters (including vitamin D levels, fat, protein, and carbohydrate intakes), but no significant difference was found in overall survival and hospital (re)admission rate[51].

A prospective non-randomized interventional cohort study evaluating the effectiveness of HMB supplements in the prehabilitation program of sarcopenic patients undergoing gastrointestinal surgery (HEROS trial, NCT05344313) is ongoing. The effect of HMB supplementation on muscle health and nutritional status has also been evaluated in liver cirrhosis. HMB supplementation in cirrhotic rats was able to increase plasma levels of BCAAs but showed detrimental effects on muscle and liver protein content and was associated with higher mortality and lower weight gain[52].

Despite some conflicting data in the experimental animal, recently, a small pilot randomized controlled clinical trial conducted in Italy demonstrated a significant improvement in muscle mass and performance in cirrhotic subjects receiving HMB supplements as well as dietary and lifestyle counseling. In the HMB-treated group a statistically significant improvement was found in muscle performance assessed through a six-minute walking test and chair stand test. HMB supplementation was also associated with a significant increase in muscle mass at the quadriceps level and with improvement in frailty (evaluated using liver frailty index[53])[54].

In a similar prospective randomized trial, HMB supplementation was evaluated in addition to standard BCAAs supplementation in two matched groups. Both HMB + BCAAs and BCAAs alone treatment have been associated with a significant longitudinal decrease in MELD score, an increase in BMI and fat mass but without significant changes in fat-free mass and handgrip strength. No significant differences were found between the two treated groups[55].

In both studies in cirrhotic subjects HMB supplements were well tolerated and no significant adverse events were reported. HMB supplementation represents an interesting therapeutic approach in the treatment of cirrhotic subjects with sarcopenia, but it is unclear whether it has additional positive effects compared to BCAAs supplementation. Adequately powered prospective studies are needed to assess efficacy, duration, and dose requirements.

THE ROLE OF ZINC IN HEPATIC ENCEPHALOPATHY AND SARCOPENIA

Another condition that can influence protein metabolism and nutritional status in cirrhosis, acting as a bridge between HE and sarcopenia, is zinc deficiency. Zinc is a trace element that is essential for the structure and function of various human proteins and enzymes[56]. Zinc deficiency has been described in cirrhotic subjects, resulting from multiple mechanisms including, among others, reduced dietary intake, reduced intestinal absorption, increased urinary excretion, reduced hepatic extraction, and hypoalbuminemia[57-60]. Ammonia metabolism in the liver requires urea cycle activity, which key enzyme, ornithine transcarbamylase, is a zinc enzyme. It has been reported that zinc supplementation in cirrhotic subjects results in an increase in urea cycle activity with an improvement, though not normalization, of the capacity for ammonia detoxification in the liver[61,62]. The reduction of ammonia detoxification in the liver, at least in part due to zinc deficiency, is associated with increased ammonia uptake in the muscle. In skeletal muscles, BCAAs serve as a glutamate source for glutamine-synthetase reaction to detoxify ammonia. It is therefore possible to link zinc deficiency with reduced plasma BCAAs levels in liver cirrhosis and with the above-described consequences of such condition on HE and sarcopenia [63]. Zinc deficiency has also been associated with taste alterations in elderly individuals and subjects with chronic diseases, including liver cirrhosis[64,65]. Taste alterations in cirrhosis go together with the reduction of appetite caused by abdominal distension due to ascites or osmotic laxatives and with reduced nutrient absorption due to portal hypertensive enteropathy and intestinal dysbiosis. All the described alterations contribute to the worsening of the nutritional status of patients with liver cirrhosis.

BCAAS AND LIVER FUNCTION

As reported above, some evidence exists regarding the effect of BCAA supplementation on overall liver function. Long-term BCAAs supplementation has been associated with improvement in MELD, CPT score, and bilirubin reduction in a retrospective Korean study, but no clear difference was reported in event-free survival[22]. A recent prospective study from the same research group confirmed the

improvement in prognostic scores in subjects receiving long-term BCAAs supplementation, but no differences in albumin and bilirubin levels were found. Interestingly, a significant increase in event-free survival, mainly regarding ascites and HE, was observed in the BCAAs-treated group, but no difference was noted regarding survival[66]. BCAAs supplementation has been investigated also in subjects undergoing treatment for HCC, showing some improvement in liver function after locoregional treatments. Three months of supplementation with a late evening snack enriched with a BCAAs mixture was associated with a rapid improvement in albumin and bilirubin levels and CPT score after radiofrequency ablation[67]. In subjects undergoing trans-arterial chemo-treatment for HCC, BCAAs supplementation was associated with an improvement in albumin but not in bilirubin values. Improved CPT score and survival were also observed in the BCAAs treated group but only in CPT class B patients[68].

CONCLUSION

Today it is widely accepted that low plasma levels of BCAAs levels play a key role in the development of cirrhosis complications such as sarcopenia and HE. The restoration of normal amino acid levels with BCAAs supplementation may improve the clinical course of HE and sarcopenia with few side effects. For these reasons, BCAAs administration should be considered in adult patients with advanced liver disease. BCAAs administration alone improves HE manifestation and reduces HE recurrence but has no significant improvement in mortality. Conversely, the use of BCAAs in addition to conventional therapies, such as non-absorbable disaccharides and non-absorbable antibiotics, shows benefits also in survival. In patients with sarcopenia, the administration of BCAAs improves muscle mass, muscle strength, and albumin levels with a consequent improvement in survival. All these beneficial effects are amplified when BCAAs are used in combination with physical exercise and nutritional intervention. These evidences supports the use of BCAAs supplements in clinical practice, especially in patients affected by concomitant HE and sarcopenia. BCAAs supplements should be used in combination with standard treatments. There is a need to identify patients at high risk of malnutrition and sarcopenia who could have an increased benefit from early nutritional intervention and BCAAs supplementation. According to the scientific literature, oral administration is more effective than intravenous administration and should be preferred. Early discontinuation of BCAAs administration is associated with reduced benefit so a long-term supplementation should be preferred. A minimum dose of 12 g/d of oral BCAAs is more effective than lower doses but further studies are needed to evaluate the most adequate dose and duration of BCAAs treatment.

Abstract

Delayed bleeding is a major and serious adverse event of endoscopic submucosal dissection (ESD) for early-stage gastrointestinal tumors. The rate of post-ESD bleeding for gastric cancer is higher (around 5%-8%) than that for esophagus, duodenum and colon cancer (around 2%-4%). Although investigations into the risk factors for post-ESD bleeding have identified several procedure-, lesion-, physician- and patient-related factors, use of antithrombotic drugs, especially anticoagulants [direct oral anticoagulants (DOACs) and warfarin], is thought to be the biggest risk factor for post-ESD bleeding. In fact, the post-ESD bleeding rate in patients receiving DOACs is 8.7%-20.8%, which is higher than that in patients not receiving anticoagulants. However, because clinical guidelines for management of ESD in patients receiving DOACs differ among countries, it is necessary for endoscopists to identify ways to prevent post-ESD delayed bleeding in clinical practice. Given that the pharmacokinetics (*e.g.*, plasma DOAC level at both trough and T_{max}) and pharmacodynamics (*e.g.*, anti-factor Xa activity) of DOACs are related to risk of major bleeding, plasma DOAC level and anti-FXa activity may be useful parameters for monitoring the anti-coagulate effect and identifying DOAC patients at higher risk of post-ESD bleeding.

Key Words: Direct oral anticoagulants; Gastrointestinal tumors; Endoscopic submucosal dissection; Delayed bleeding; Adverse events; Anticoagulants

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Recent international clinical guidelines for early-stage gastrointestinal tumors recommend endoscopic submucosal dissection (ESD) as the first-line treatment. Direct oral anticoagulants (DOACs) are a major risk factor for post-ESD bleeding and the pharmacokinetics and pharmacodynamics of DOACs may be related to risk of post-ESD bleeding. Therefore, one way to monitor the anticoagulant effect of DOACs in clinical practice may be to develop a system that effectively measures anti–FXa activity and plasma concentration. In the future, it may be useful to stratify risk of post-ESD delayed bleeding based on a scoring system that includes pharmacological parameters of DOACs.

INTRODUCTION

Endoscopic resection, a minimally invasive endoscopic non-surgical treatment, is now accepted as first-line management for most cases of early-stage esophageal cancer, gastric cancer and colorectal cancer or adenoma around the world[1]. Endoscopic resection mainly includes endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD). Indication for endoscopic resection for EMR and ESD is typically a local mucosal lesion with an extremely low risk of metastasis to lymph nodes (generally less than 1%), and lesions that can be resected *en-bloc*, irrespective of localization in the esophagus, stomach, duodenum or colon. Because ESD enables complete *en-bloc* resection and is associated with a lower recurrence rate than EMR[2,3], recent international clinical guidelines for early-stage gastrointestinal tumors recommend ESD as the first-line treatment over EMR and surgical resection[1,3-7]. To achieve good results and prognosis in ESD for early-stage gastrointestinal tumors, endoscopists and gastroenterologists require excellent skills and knowledge of the diagnosis, indications, actual procedures, and evaluation of curability, complications, long-term postoperative surveillance, and histopathology[3].

ESD often causes adverse events such as intra-operative and delayed bleeding from an artificial ulcer and perforation. The occurrence of such events has been linked to several procedure-, lesion-, physician- and patient-related factors[8-12]. Of the possible risk factors for post-ESD delayed bleeding, use of antithrombotic drugs, especially anticoagulants, is the biggest risk factor[13,14]. Although anticoagulants are mainly divided into warfarin and direct oral anticoagulants (DOACs), no parameters identified to date can be used to accurately monitor the anti-coagulate effect of DOACs in clinical practice or endoscopic/surgical procedures. Thus, it is important to clarify the association between post-ESD delayed bleeding for early-stage gastrointestinal tumors and DOACs, identify risk factors of post-ESD delayed bleeding in patients taking DOACs and methods to prevent bleeding in these patients.

Here, we review delayed bleeding after ESD for gastrointestinal tumors, risk factors for post-ESD bleeding, the pharmacological characteristics of DOACs, international clinical guidelines for endoscopic procedures in patients receiving DOACs, and post-ESD bleeding in patients receiving DOACs.

DELAYED BLEEDING AFTER ESD FOR GASTROINTESTINAL TUMORS

In Japan, upper and lower gastrointestinal tumors are detected in the early stages in many patients, mainly through the use of optimal screening methods, appropriate surveillance and the development of endoscopic diagnostic techniques for early detection and endoscopic equipment[15-17]. In general, evaluation of early-stage gastrointestinal tumors should be performed by expert endoscopists, using a high-definition endoscope by white-light imaging and advanced image-enhanced endoscopy[18]. The experience of the endoscopist may be related to the incidence of adverse events and effective prevention of procedure-related adverse events after ESD. Careful and appropriate coagulation for exposed blood vessels may reduce the gastrointestinal bleeding risk, especially in the stomach[7,19]. The rate of bleeding and its risk factors are known to differ among patients with esophagus, stomach, duodenum and colon cancer.

Esophageal squamous cell carcinoma

The recent development of high-vision endoscopes and techniques for endoscopic diagnosis, including narrow band imaging, has led to more frequent early detection of esophageal esophageal squamous cell carcinoma (SCC)[15,20]. Therefore, ESD is accepted as an effective procedure for detecting superficial

esophageal SCC. In Japan, the Esophageal Cancer Practice Guidelines 2017 weakly recommends endoscopic resection as first-line treatment for preoperatively diagnosed cT1a-MM/T1b-SM1 non-circumferential SCC[6]. In 2014, a meta-analysis of 15 studies with 776 patients with ESD-treated SCC reported pooled estimates of complete resection and *en bloc* resection rates of 89.4% [95%CI: 86.2%–91.9%] and 95.1% (92.6%–96.8%), respectively[21]. In addition, pooled estimates of adverse events such as post-ESD bleeding, perforation, and stenosis were 2.1% (95%CI: 1.2%–3.8%), 5.0% (3.5%–7.2%), and 11.6% (8.2%–16.2%), respectively[21].

Barrett's neoplasia and esophageal adenocarcinoma

The incidence of esophageal adenocarcinoma (EAC) located in Barrett's epithelium has been increasing, especially in Western countries, due to decreases in the *Helicobacter pylori (H. pylori)* infection rate and increases in reflux esophagitis[22]. The European Society of Gastrointestinal Endoscopy (ESGE) recommends using EMR for ≤ 20 mm visible lesions with low probability of submucosal invasion and for larger or multifocal benign dysplastic lesions. In Japan, ESD is strongly recommended over EMR for the radical treatment of superficial EAC with a low risk of metastasis[6]. A meta-analysis of 11 studies investigating the efficacy and safety of ESD for EAC (mean size: 27 mm) reported pooled estimates for *en bloc* resection and pooled R0 resection of 92.9% (95%CI: 90.3%-95.2%) and 74.5% (66.3%-81.9%), respectively[23]. Incidence of recurrence after curative resection was 0.17% (95%CI: 0%-0.3%) at a mean follow-up of 22.9 mo (17.5-28.3 mo)[23]. In adverse events, estimates for bleeding, perforation, and stricture were 1.7% (95%CI: 0.6%-3.4%), 1.5% (0.4%-3.0%) and 11.6% (0.9%-29.6%), respectively. Thus, the rate of post-ESD delayed bleeding in both esophageal SCC and EAC may not be very high (1.7%-2.1%).

Gastric cancer

In the ESGE, gastric cancers that are ≤ 30 mm, submucosal (sm1), and well-differentiated, or ≤ 20 mm, intramucosal, and poorly differentiated, and without ulcerative findings for both sets of criteria can be considered for ESD, although the decision should be individualized[4]. ESD for gastric cancer is associated with high rates of *en bloc* and R0 resection (> 90%), curative resection (75%–80%), low local recurrence (< 5%) and acceptable rates of adverse events (post-ESD bleeding 5%–10% and perforation < 3%)[24,25]. A recent meta-analysis of 22 studies in Western countries reported estimates for *en bloc* resection and R0 resection of 96% (95%CI: 93%-98%) and 84% (79%-89%), respectively[26]. Overall, adverse events occur in 9.5% of patients, including delayed bleeding (5.8%), perforation (3.4%), and stenosis (0.35%)[26]. The odds ratio (OR) indicates that there is no significant difference in risk of post-ESD bleeding between ESD and EMR (OR 1.26, 95%CI: 0.88-1.80)[27]. Another meta-analysis of 74 articles by Libânio *et al*[28] reported post-ESD bleeding rates ranging from 0.6% to 26.9% and a pooled bleeding rate of 5.1% (95%CI: 4.5%-5.7%), with significant heterogeneity across studies (I^2: 84.46, P < 0.001). However, bleeding rates were not significantly different among different study designs (5.9% in randomized clinical trials, 6.1% in prospective studies, and 4.9% in retrospective studies). The elderly Japanese population aged ≥ 85 years has increased from 1.4 to 4.8 million over the last two decades[29] and our investigation of a cohort of 10,320 patients showed that the incidence of bleeding in elderly patients aged > 80 years was 5.7% (95%CI: 4.6%-6.9%), which was significantly higher than in patients aged < 80 years (4.5%, 4.1%-5.0%)[30].

Duodenum

Because ESD for duodenal tumors is associated with high rates of post-ESD bleeding and perforation at both the early and late phases, the ESGE suggests reserving its use for selected cases and tumors in expert centers[4]. In particular, perforation rates are high, with an incidence > 10% in studies involving expert centers[31]. Further, distal location to the ampulla of Vater is a risk factor for delayed perforation [32]. A meta-analysis reported pooled rates of *en bloc* resection, need for surgical intervention, delayed bleeding, intraoperative and delayed perforation of 87%, 4%, 2%, 15% and 2%, respectively[33]. Meanwhile, a recent large retrospective Japanese study reported that the rate of post-ESD adverse events was significantly reduced in cases with complete closure of the mucosal defect compared to partial closure and no closure (1.7%, 25.0% and 15.6%, respectively, P < 0.01)[34].

Colon

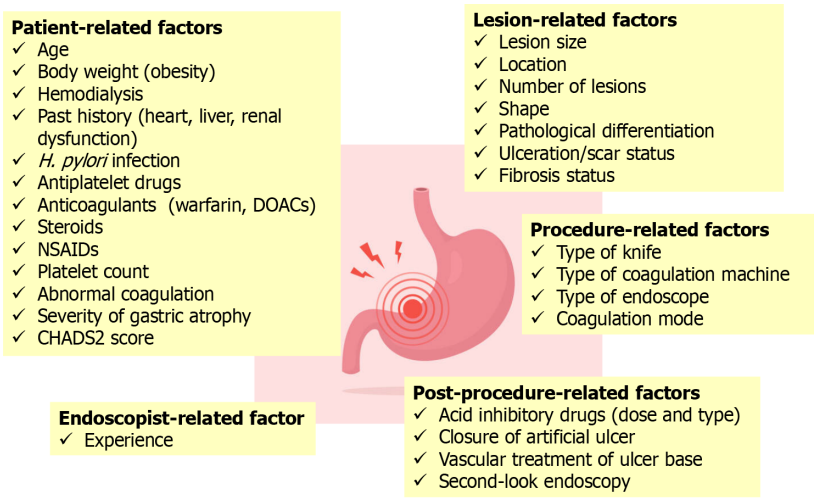
In Japan, indications for ESD for colorectal tumors are lesions for which endoscopic *en bloc* resection is required, as follows: (1) Lesions for which *en bloc* resection with snare EMR is difficult to apply; (2) Mucosal tumors with submucosal fibrosis; (3) Sporadic localized tumors in conditions of chronic inflammation such as ulcerative colitis; and (4) Post-EMR local residual or recurrent early-stage cancers[5]. A recent systematic review of 109 studies on 19484 colorectal lesions resected by ESD reported rates of *en bloc* resection of 91%, R0 resection of 82.9%, and local recurrence of 2%. The study also reported a rate of post-ESD bleeding of 2.7% and perforation of 5.2%, and that 1.1% of all patients needed surgical treatment by severe adverse events[35].

Because the rate of post-ESD bleeding may be higher for gastric cancer (5%-8%) than that at other sites (around 2%-4%) due to direct exposure of artificial ulcers to gastric acid and bile, it is necessary for

endoscopists to be aware of and develop countermeasures for gastric ESD.

RISK FACTORS FOR POST-ESD GASTROINTESTINAL DELAYED BLEEDING

Risk factors for post-ESD bleeding are expected to differ among patients with esophagus, stomach, duodenum and colon cancer. Post-ESD bleeding has been shown to be associated with procedure-related factors (*e.g.*, type of knife, coagulation machine and endoscope, and coagulation mode), lesion-related factors (*e.g.*, gastrointestinal organ, large lesion size, location, presence within the ulcerated lesion, scarring, and fibrosis), physician-related factors (*e.g.*, experience with ESD) and patient-related factors [hemodialysis, drugs (antiplatelet drugs, anticoagulants, steroids, and non-steroidal anti-inflammatory drugs), hemostasis ability, and platelet count] (Figure 1)[8-12].



Libânio *et al*[28] showed in a meta-analysis of 74 articles that male sex (OR 1.25), cardiopathy (OR 1.54), antithrombotic drugs (OR 1.63), cirrhosis (OR 1.76), chronic kidney disease (CKD) (OR 3.38), tumor size > 20 mm (OR 2.70), resected specimen size > 30 mm (OR 2.85), localization in the lesser curvature (OR 1.74), flat/depressed morphology (OR 1.43), carcinoma histology (OR 1.46), and ulceration (OR 1.64) were significant risk factors for post-ESD bleeding of gastric cancer, whereas age, hypertension, submucosal invasion, fibrosis, and location (upper, middle, or lower third of stomach) were not. In terms of procedural factors, procedure duration > 60 min (OR, 2.05) and use of histamine-2 receptor antagonists instead of proton pump inhibitors (PPIs) (OR, 2.13) were associated with post-ESD bleeding, whereas endoscopist experience was not. Recently, Hatta *et al*[36] conducted a nationwide multicenter retrospective study focusing on post-ESD bleeding for gastric cancer and used the data to develop a model that applies 10 factors [warfarin, DOAC, hemodialysis, P2Y12 receptor antagonist, aspirin, tumor size > 30 mm, tumor location in the lower third, presence of multiple tumors and interruption of each kind of antithrombotic agent] to predict post-ESD bleeding (BEST-J score). According to the BEST-J score, rates of bleeding in patients categorized as low-risk, intermediate-risk, high-risk, and very high-risk were 2.8%, 6.1%, 11.4%, and 29.7%, respectively[36]. A validation study of the BEST-J score showed that the area under the curve for the BEST-J score at multicenter trials was 0.713 (95%CI: 0.625–0.802), which suggests that the BEST-J score may be useful for predicting post-ESD bleeding in not only expert centers but also general hospitals[37]. In addition, because the healing speed of post-ESD artificial ulcers is related to the post-ESD bleeding rate, factors that affect the healing speed of ulcers, namely *H. pylori* infection status, type of acid inhibitory drug (*e.g.*, PPIs and vonoprazan) and severity of gastric atrophy, may also be risk factors for post-ESD bleeding in gastric cancer[11,12,38]. In today's aging society, the number of patients taking anti-platelet drugs and anticoagulants for the prevention of cardio- and cerebrovascular diseases has risen. That a multicenter study reported a high incidence of post-ESD bleeding in Japanese aged > 80 years, especially in patients receiving hemodialysis and taking warfarin[30], indicates that careful management of ESD is required to prevent bleeding in patients aged > 80 years compared to younger patients.

Major risk factors for post-ESD bleeding for colorectal tumors are generally larger tumor size, location in the rectum or cecum, long procedure time, number of tumors, and taking anti-thrombotic drugs. Recently, Li *et al*[39] reported that post-ESD bleeding for colorectal tumors is observed in 4.7% of patients, and that hypertension (OR 2.829, 95%CI: 1.101-7.265) and using hot biopsy forceps for wound management (OR 2.873, 95%CI: 1.013-8.147) remain significant risk factors for bleeding after multivariate analysis. In another study, Seo *et al*[40] developed a risk-scoring model to predict bleeding after colorectal ESD following identification of the tumor location in the rectosigmoid colon (OR 6.49; 95%CI: 1.96-21.42), large tumor (> 30 mm) (2.10, 1.01-4.40), and use of antiplatelet agents except for aspirin alone (4.04, 1.44-11.30) as risk factors for bleeding[40]. When use of antiplatelet agents except for aspirin alone was scored as 1 point, tumor size > 30 mm as 1 point, and location in the rectosigmoid area as 2 points, the incidence of bleeding in low-risk (score 0-2) and high-risk groups (score 3-4) was 1.5% and 6.0%, respectively.

Thus, current evidence indicates that the use of antithrombotic drugs, especially anticoagulants (DOACs and warfarin) is the biggest risk factor for post-ESD bleeding[13,14].

PHARMACOLOGICAL CHARACTERISTICS OF DOACS

DOACs are currently the first-line drug for the pharmacological prevention of systemic embolism or stroke in atrial fibrillation patients. They are categorized into two main classes: Direct thrombin inhibitors (*i.e.*, dabigatran) and activated coagulation factor X (FXa) inhibitors (*i.e.*, apixaban, edoxaban, rivaroxaban, and betrixaban). Compared with anticoagulation with vitamin K antagonists (*i.e.*, warfarin) or low-molecular-weight heparins, DOACs are new agents that demonstrate superiority or noninferiority to prior standards of care in reducing the risk of thromboembolic complications and major and minor bleeding risk, have fewer monitoring requirements and less frequent follow-up need; and have more immediate drug onset and offset effects and fewer drug and food interactions[41-44]. However, an advantage of using vitamin K antagonist therapy is that a therapeutic international

normalized ratio range of 2.0-3.0 has been established and is recommended to prevent embolic complications in non-valvular atrial fibrillation in the treatment of deep vein thrombosis and pulmonary embolism. In contrast, a disadvantage of DOACs is that their anticoagulant effects in patients are unclear because there are no Food and Drug Administration (FDA)-approved methods to measure correctly the anticoagulant effect of DOACs. Although qualitative coagulation assays (*e.g.*, thrombin time, activated partial thromboplastin time, and prothrombin time) can be selected as first-line tests, they do not accurately measure the anticoagulant effect of DOACs (Table 1). Quantitative measures for direct assessment of anticoagulant effects do exist, including anti–FXa activity, plasma drug concentration (standard method in preclinical/clinical research and the most accurate method), dilute thrombin time, and ecarin thrombin time[45,46]. In fact, plotting anti–FXa activity against plasma levels of apixaban and rivaroxaban has been confirmed to show a direct linear relationship for both compounds[47].

Pharmacokinetic characteristics such as oral bioavailability, plasma protein binding and relative involvement of renal and non-renal elimination differ substantially among DOACs (Table 2). Pharmacokinetics is influenced by the type of DOAC, dose, renal function, liver function, age, sex, body weight, drug metabolic enzyme gene polymorphisms and drug-drug interactions, but not ethnicity, geographic region, aspirin use, or clopidogrel use[48]. DOACs are relatively safe and effective in patients with moderate CKD [creatinine clearance (Ccr) 30–50 mL/min]. Rivaroxaban, dabigatran and edoxaban will require dose adjustment for renal impairment and patients with severe renal dysfunction (Ccr < 30 mL/min) are recommended to avoid their use[49]. Regulatory agencies such as the FDA and European Medicines Agency have provided guidelines for performing dose adjustments according to the DOAC dose based on Ccr and anticoagulant indications[50]. The International Society on Thrombosis and Hemostasis suggests that use of DOACs are safe in patients of body mass index ≤ 40 kg/m^2 (body weight ≤ 120 kg) at standard doses but does not recommend them for patients of body weight > 120 kg [51]. Compared to warfarin, DOACs are more effective and safer in patients with low body weight (< 50 kg)[52].

DOACs are metabolized by either cytochrome P450 (CYP) metabolic enzymes in the liver or permeability glycoprotein transporters; thus, agents that induce or inhibit CYP metabolic enzymes or glycoprotein transporters can lead to major drug-drug interactions and place the patient at undue risk for adverse events. In fact, concomitant use of apixaban, rivaroxaban, or dabigatran with clarithromycin, a potent inhibitor of CYP3A4, and ATP-binding cassette multidrug transporters increases serum levels of DOACs by 20% to 100% and prolongs coagulation time[53,54]. The pharmacokinetics of DOACs also depend on genetic variations, such as *ABCB1* (ATP-binding cassette multidrug transporters, MDR1) (1236C>T, 2677G>T/A, and 3435C>T), *ABCG2* (421C>A), and *CYP3A5* polymorphisms (6986A>G)[55]. The plasma trough C/D ratio of apixaban is significantly higher in patients with the ABCG2 421A/A genotype and CYP3A5 6986 G allele carriers than in patients with the ABCG2 421C/C genotype and CYP3A5 6986 A/A genotype[55]. Given that CYP3A5 6986A>G and ABCG2 421C>A polymorphisms have allele frequencies of 65%-85%[56] and 29%-36%[57], respectively, in Asians, ABCB1, ABCG2, and CYP3A5 genotypes play pivotal roles in the interindividual variability of apixaban concentrations in Japanese patients.

Although the pharmacodynamic parameters of DOACs differ significantly among individuals and anticoagulant effects also vary widely among patients receiving DOACs, the lack of approved methods to monitor the anticoagulant effect of DOACs makes it unclear whether the effect is adequate in patients

receiving DOAC. Compared with vitamin K antagonist therapy (therapeutic international normalized ratio range: 2.0-3.0), a disadvantage of DOACs is that the dosage of DOAC cannot be controlled according to anticoagulant effect. Therefore, the trough and time to reach maximum plasma concentration (T_{max}) and anti-FXa activity of DOAC-metabolizing enzyme polymorphisms may be useful parameters for accurately monitoring the anti-coagulate effects of DOACs and selecting patients at higher risk of major bleeding. Developing a system that easily measures the anti–FXa activity and plasma level could be an important way to monitor the anticoagulant effect of DOACs in clinical practice.

PHARMACOKINETICS OF DOACS AND MAJOR BLEEDING

Clinical trials have investigated the efficacy of dabigatran (RE-LY trial[58]), apixaban (ARISTOTLE trial [41]), edoxaban (ENGAGE AF TIMI48 trial[59]) and rivaroxaban (ROCKET AF trial[60]) for the prevention of stroke and embolism. According to these trials, adverse events of major bleeding and gastrointestinal bleeding occur at rates of 3.11% and 1.51% for dabigatran 150 mg given twice daily (bid), 2.13% and 0.76% at apixaban 5 mg bid, 2.75% and 1.51% at edoxaban 60 mg given once daily (oid) and 3.6% and 3.2% at rivaroxaban 20 mg oid (Table 3), respectively.

Because the anti-coagulate effects of DOACs are linked to plasma levels of DOAC and anti-FXa activity at trough and T_{max}[48,61,62], these pharmacokinetic and pharmacodynamic parameters are also expected to be related to risk of major bleeding, such as intracerebral and gastrointestinal bleeding. Using multiple logistic regression, Reilly *et al*[48] showed that major bleeding risk increased with dabigatran exposure ($P < 0.0001$), age ($P < 0.0001$), aspirin use ($P < 0.0003$), and diabetes ($P = 0.018$) as significant covariates. Further, patients with major bleeding had higher trough levels (55%) and post-dose levels (36%) than non-bleeding patients[48]. Reilly *et al*[48] also reported a median trough level of 116 ng/mL in 323 major bleeding patients compared with 75.3 ng/mL in 5899 no bleeding patients[48]. Additionally, a Cox regression analysis of time to first major bleeding with trough level, age, and CHADS2 score as covariates showed that, compared with the median trough level of 88 ng/mL, the rate of major bleeding doubled at a level of 210 ng/mL after adjustment for age and CHADS2 score. Moreover, Sakaguchi *et al*[63] showed that, in rivaroxaban-treated patients with major bleeding in Japan, major bleeding is independently predicted to be higher peak rivaroxaban levels and higher anti-FXa activity. Additionally, Sin *et al's* prospective study[64] of rivaroxaban-treated patients with atrial fibrillation with differing severity of CKD (Stage 1–3) showed that trough levels of rivaroxaban were higher in those with bleeding (59.9 ± 35.6 ng/mL) than in those without (41.1 ± 29.2 ng/mL; $P < 0.05$). Therefore, although plasma level and anti–FXa activity may be useful parameters for selecting patients receiving DOACs at higher risk of major bleeding, there is no evidence that patients with higher plasma levels and anti–FXa activity have higher risk of post-ESD bleeding.

A retrospective analysis of 5041 patients demonstrated that concomitant dabigatran–PPI treatment is linked to a significant reduction in bleeding risk compared with dabigatran alone without a PPI[65]. Although dabigatran is an orally administered prodrug, it is rapidly absorbed and converted to its active form, dabigatran. Thus, a potential mechanism for PPI–dabigatran interaction may be reduced dabigatran absorption and availability, which is most probably mediated *via* the effects of PPI on gastric pH, given the poor solubility of dabigatran at pH > 4[66]. Therefore, interactions between PPIs and dabigatran may lead to decreases in dabigatran levels[67].

In terms of gastrointestinal bleeding, unlike warfarin, DOACs remain in the gastrointestinal tract without being absorbed into the blood. Therefore, DOACs may directly inhibit the hemostatic

mechanism in the gastrointestinal tract, thereby aggravating bleeding[68].

CLINICAL GUIDELINES: MANAGEMENT FOR PATIENTS TAKING DOACS IN ENDOSCOPIC PROCEDURES WITH HIGHER RISK FOR BLEEDING (ESD)

During gastrointestinal endoscopy and endoscopic treatment of patients receiving antithrombotic therapy, it is necessary to balance the risk of major and minor bleeding with the risk of thromboembolism resulting from withdrawal of antithrombotic therapy. Therefore, it is important to determine a management strategy (with withdrawal or not) that is optimized for individual patients based on consultation between the endoscopist and physician prescribing the antithrombotic drugs. The risk of thromboembolism is closely related to the underlying disease requiring anticoagulants, and the absolute risk of thromboembolism increases by more than 1% when anticoagulants are withdrawn for more than 4 d[69].

In 2012 the Japan Gastroenterological Endoscopy Society published "Guidelines for gastroenterological endoscopy in patients undergoing antithrombotic treatment" concerning thromboembolism associated with antithrombotic therapy withdrawal and bleeding[70]. The guidelines were updated with a 2017 appendix on anticoagulants in 2017[71]. Although the 2012 version recommends replacing DOACs with heparin during ESD in patients with high risk for post-procedure bleeding as an adverse

event, the 2017 version recommends that patients receiving DOACs should continue to take the DOAC orally until the day before ESD and discontinue it on the morning of ESD (Table 4)[71]. Because the anticoagulant effects last 36–48 h for rivaroxaban and edoxaban given oid and 24–36 h for apixaban given bid, and the disappearance of anti-FXa activity and anticoagulant effects increase the risk of thrombosis, DOACs may be resumed the morning after ESD (up to 36 and 48 h when given bid and oid). In addition, when performing ESD, patients receiving concomitant DOAC and antiplatelet agents should be handled with care depending on the individual's condition and needs, while ESD can be performed on patients receiving antiplatelet monotherapy with aspirin or cilostazol[71].

In contrast to the Japanese guidelines, the updated guidelines by the British Society of Gastroenterology and ESGE suggest that patients receiving low-risk procedures for bleeding withdraw from the morning dose of DOAC on the morning of ESD, and recommend that the last dose of DOAC be taken 3 d before ESD for high-risk endoscopic procedures (strong recommendation and low-quality evidence) (Table 4)[72]. For patients receiving dabigatran with a Ccr 30–50 mL/min, this updated version recommends that the last dose be taken 5 d prior to the procedure (strong recommendation and low-quality evidence)[72].

The American Society for Gastrointestinal Endoscopy (ASGE) published a guideline on how to manage patients receiving antithrombotic agents for endoscopy in 2016[73]. This guideline suggests that patients undergoing low-risk procedures should continue taking DOACs (Table 4)[73] and that the resumption of DOACs after ESD be delayed until adequate hemostasis is ensured. If DOACs cannot be resumed within 12 to 24 h post-ESD, thromboprophylaxis should be considered to decrease thromboembolism risk in those with high risk for thromboembolism. However, this version of the ASGE guideline recommends that patients at high risk for thromboembolic events withdraw DOACs and receive bridge therapy to adequately manage patients taking DOACs when ESD is performed (Table 4).

Table 4 Summary of international guidelines concerning withdrawal of direct oral anticoagulants during gastroenterological endoscopy

Ref.	Country	Standard endoscopy	Biopsy	Low risk of bleeding	High risk of bleeding, including ESD
[71]	Japan	[1]	[2]Avoid peak plasma level	[2]Avoid peak plasma level	[3](1) Withdraw on the day of treatment; and (2) Heparin replacement
[72]	Europe	[1]	[3]Withdraw on the day of treatment	[3]Withdraw on the day of treatment	[3](1) Withdraw 3 d before treatment; (2) Withdraw 5 d before treatment for dabigatran patients at Ccr 30–50 mL/min; and (3) No heparin bridging
[73]	United States	[1]	[1]	[1]	[3](1) Withdraw; and (2) Bridge therapy required for patients at high risk for thromboembolic events
[74]	Korea	[1]	[1]	[1]	[3]Withdraw 2 d before treatment
[75]	Asia-Pacific	[1]	[1]	[1]	[3]Withdraw 2 d before treatment

[1]Withdrawal is not required.
[2]Withdrawal is not required but possible.
[3]Withdrawal is required.
ESD: Endoscopic submucosal dissection; Ccr: Creatinine clearance.

In contrast, the Korean clinical practice guideline does not recommend withdrawal of DOACs before low-risk procedures (weak recommendation and low-quality evidence) but suggests withdrawing DOACs > 48 h before high-risk procedures (weak recommendation and low-quality evidence) (Table 4)[74]. The recommendation to withdraw DOACs > 48 h before ESD is based on the fact that the half-life of DOACs is about 12 h and predictions that DOAC levels and anti-FXa activity will be almost undetectable after 48 h[74].

The Asian Pacific Association of Gastroenterology and Asian Pacific Society for Digestive Endoscopy guidelines recommend withholding DOACs at least 48 h before the procedure in DOAC patients receiving gastrointestinal ESD (strong recommendation and low-quality evidence) and do not recommend bridging anticoagulation (strong recommendation and low-quality evidence) (Table 4)[75]. In addition, these guidelines provide recommendations related to the timing of DOAC discontinuation before high-risk procedures according to Ccr[76]. In these guidelines, EMR for large colon polyp (≥ 2 cm) and ESD procedures, which have a higher risk of gastrointestinal bleeding compared with other high-risk endoscopic procedures, are categorized as ultra-high-risk endoscopic procedures[74,75].

Thus, as summarized in Table 4, guidelines for the management of patients undergoing ESD for early-stage gastrointestinal tumors who receive DOACs differ by country. Although subtle differences in the management of DOACs with ESD are important in clinical practice, we consider that these differences are dependent on the year in which the guidelines were published, the different dosage of DOAC in each country, the different numbers of concomitant antithrombotic drugs, and differences in the rate of genetic variations (*e.g.*, CYP3A4/5, ABCG2, and ABCB1 polymorphism).

GASTROINTESTINAL BLEEDING AFTER ESD IN PATIENTS RECEIVING DOACS

Post-ESD bleeding in patients receiving DOACs remains an unpreventable adverse event. Although the combination of heparin-bridging therapy and discontinuation of DOACs is one approach used to prevent thrombosis[70,71], heparin-bridging therapy with discontinuation of any anticoagulants causes an increased risk of delayed bleeding after surgical treatment, interventional procedures and ESD (gastric ESD: 10.8%-61.5%)[77-80] and does not reduce the risk of perioperative arterial thromboembolism[77-79]. In fact, a meta-analysis focused on heparin-bridging therapy with discontinuation of any anticoagulants for ESD found an increased risk of post-ESD bleeding without any benefit for thrombosis [81]. Another meta-analysis reported an increase in thrombosis in patients receiving heparin-bridging therapy with discontinuation of anticoagulants compared with those who discontinued anticoagulation without heparin bridging[82]. In Japan, although the updated guideline recommends discontinuing DOACs on the morning of ESD, most studies conducted on ESD for patients receiving DOACs have been retrospective and enrolled small numbers of patients (Table 5).

However, one study examined a large national database including 16977 patients receiving anticoagulation therapy who underwent high-risk endoscopic procedures. It showed that although warfarin led to a significantly higher post-procedure bleeding rate than DOACs (12.0% *vs* 9.9%, $P = 0.002$), the post-procedure bleeding rate was not significantly different in either upper or lower gastrointestinal ESD between patients receiving DOACs and warfarin[83]. In sub-analyses of procedure types in propensity-matched patients, the gastrointestinal bleeding rate in the DOAC group was 39.6% in

Table 5 Delayed bleeding after endoscopic submucosal dissection in patients receiving direct oral anticoagulants

Ref.	Year	Country	Type	Organ	DOAC patients	Bleeding rate	Non-DOAC patients	Bleeding rate

[1]Included 2 endoscopic mucosal resection patients.
[2]Included no antithrombotic drug patients.
DOAC: Direct oral anticoagulants.

patients who received upper gastrointestinal ESD and 13.2% in those who received lower gastrointestinal ESD[83].

In a recent retrospective Japanese study of 261 patients with early-stage gastric cancer receiving DOACs, post-ESD bleeding occurred in 14% of patients, which is comparable to that in patients receiving warfarin (18%)[84]. Multivariate analysis demonstrated that age ≥ 65 (OR 2.96, 95%CI: 1.13-7.73), male sex (OR 2.12; 95%CI: 1.01–4.45), receiving multiple antithrombotic agents (OR 2.70, 95%CI: 1.74-4.21) and lesion size ≥ 20 mm (OR 1.67, 95%CI: 1.08-2.59) were independent risk factors for post-ESD bleeding in patients taking anticoagulants, and that cessation of anticoagulants without heparin-bridging therapy was associated with a low risk of bleeding (OR 0.32; 95%CI: 0.14–0.76). However, the multivariate analysis identified no significant independent increased risk factors for post-ESD bleeding and demonstrated that dabigatran was associated with a significantly lower risk of bleeding (OR 0.04, 95%CI: 0.16-0.97)[84]. Further, in a nationwide multicenter retrospective study of 10320 patients, multivariate analysis conducted by Hatta *et al*[36] showed that taking anticoagulants was an independent risk factor for post-ESD bleeding (OR 8.16; 95%CI: 4.74-14.04). Although the number of patients registered in each of these previous studies is relatively small (n = 21-261), both reported post-ESD bleeding in 8.7%-20.8% of gastric cancer patients receiving DOACs, considered to be equivalent to that in patients receiving warfarin (17.5%-22.7%) and higher than that in patients not receiving anticoagulants (Table 5).

Few studies have been conducted on esophageal, duodenal and colorectal ESD in patients receiving DOACs. Horie *et al*[85] reported that the post-endoscopic resection bleeding rate in esophageal cancer patients receiving DOACs (14 patients received ESD and 2 patients received EMR) was significantly higher than that in those not receiving antithrombotic drugs [13% (95%CI: 1.6%–38%) *vs* 0.3% (95%CI: 0.1%–1%), P = 0.003]. Moreover, the post-ESD bleeding rate in colorectal tumor patients receiving DOACs was 16.0%-23.3%, which is equivalent to that in those receiving warfarin (7.7%-26.3%) (Table 5).

Thus, despite the small number of DOAC patients who received ESD in previous studies, the post-ESD delayed bleeding rate appears to vary among different organs in patients not receiving DOACs, but not in patients receiving DOACs.

FUTURE OF ESD FOR PATIENTS RECEIVING DOACS

There is no doubt that patients receiving DOACs are at higher risk of post-ESD bleeding than patients not taking DOACs or receiving antithrombotic drugs. As mentioned above, although examining plasma DOAC level and anti-Xa activity in relation to CYP metabolic enzymes or glycoprotein transporter gene polymorphisms may serve as predictive markers for selecting DOAC patients with higher risk of post-ESD delayed bleeding, no studies have been conducted with such considerations. Although scoring

systems such as the BEST-J score are being developed to assess the risk of post-ESD delayed bleeding by stratifying multiple possible risk factors in clinical practice, we propose the need for a new scoring system that considers pharmacological parameters of DOACs, namely plasma DOAC level and anti-Xa activity.

DOACs is current recommended for not only patients with nonvalvular atrial fibrillation and venous thrombosis (VTE), but also those with cancer due to prevention of VTE by clinical guidelines[86]. Treatment or prophylaxis of VTE for patients with cancer must always balance the risk of incidence or recurrent VTE with the increased risk of major bleeding and take into consideration the consequences of these outcomes (including mortality, financial cost, quality of life)[86]. Developing a system that easily measures the anti–FXa activity and plasma level could be an important way to monitor the anticoagulant effect of DOACs and may help physicians to treat DOAC patients receiving ESD, endoscopic treatment, and surgical treatment and with cancer in clinical practice.

CONCLUSION

Post-ESD delayed bleeding for gastrointestinal tumors is a major adverse event, with an incidence of around 5%-8% for gastric cancer and 2%-4% for esophageal, duodenum and colorectal tumors. Of the many risk factors for bleeding, taking anticoagulants, including DOACs, is currently the biggest. In fact, the post-ESD bleeding rate in DOAC patients is 13% in esophageal cancer, 8.7%-20.8% in gastric cancer and 7.7%-26.3% in colorectal cancer. Compared with warfarin, the anticoagulant effects of which can be monitored using prothrombin time and international normalized ratio tests, there is currently no established method for monitoring the effects of DOACs. Thus, it is important to develop simple and accurate methods to evaluate the pharmacokinetics (*e.g.*, plasma DOAC level at trough and T_{max}) and pharmacodynamics (*e.g.*, anti-factor Xa activity) of DOACs. In the future, a scoring system that includes pharmacological parameters of DOACs may be useful for stratifying risk of post-ESD delayed bleeding in clinical practice.

Abstract

BACKGROUND

Gastrointestinal stromal tumor (GIST) is a common neoplasm with high rates of recurrence and metastasis, and its therapeutic efficacy is still not ideal. There is an unmet need to find new molecular therapeutic targets for GIST. TATA-box-binding protein-associated factor 15 (TAF15) contributes to the progress of various tumors, while the role and molecular mechanism of TAF15 in GIST progression are still unknown.

AIM

To explore new molecular therapeutic targets for GIST and understand the biological role and underlying mechanisms of TAF15 in GIST progression.

METHODS

Proteomic analysis was performed to explore the differentially expressed proteins in GIST. Western blotting and immunohistochemical analysis were used to verify the expression level of TAF15 in GIST tissues and cell lines. Cell counting kit-8, colony formation, wound-healing and transwell assay were executed to detect the ability of TAF15 on cell proliferation, migration and invasion. A xenograft mouse model was applied to explore the role of TAF15 in the progression of GIST. Western blotting was used to detect the phosphorylation level and total level of RAF1, MEK and ERK1/2.

RESULTS

A total of 1669 proteins were identified as differentially expressed proteins with 762 upregulated and 907 downregulated in GIST. TAF15 was selected for the further study because of its important role in cell proliferation and migration.

TAF15 was significantly over expressed in GIST tissues and cell lines. Overexpression of TAF15 was associated with larger tumor size and higher risk stage of GIST. TAF15 knockdown significantly inhibited the cell proliferation and migration of GIST *in vitro* and suppressed tumor growth *in vivo*. Moreover, the inhibition of TAF15 expression significantly decreased the phosphorylation level of RAF1, MEK and ERK1/2 in GIST cells and xenograft tissues, while the total RAF1, MEK and ERK1/2 had no significant change.

CONCLUSION

TAF15 is over expressed in GIST tissues and cell lines. Overexpression of TAF15 was associated with a poor prognosis of GIST patients. TAF15 promotes cell proliferation and migration in GIST *via* the activation of the RAF1/MEK/ERK signaling pathway. Thus, TAF15 is expected to be a novel latent molecular biomarker or therapeutic target of GIST.

Key Words: Gastrointestinal stromal tumor; Proteomics; TATA-box-binding protein-associated factor 15; Biomarker; Cell proliferation; Cell migration

Core Tip: TATA-box-binding protein-associated factor 15 (TAF15) was upregulated in gastrointestinal stromal tumor (GIST) cells and tissues and was associated with a poor prognosis in GIST patients. TAF15 promotes cell proliferation and migration of GIST *in vitro* and tumor growth *in vivo via* the activation of the RAF1/MEK/ERK signaling pathway. Therefore, TAF15 is expected to be a novel potential molecular biomarker or therapeutic target of GIST.

INTRODUCTION

Gastrointestinal stromal tumor (GIST) is a common neoplasm that arises from the mesenchymal tissue of the gastrointestinal tract and likely originates from the interstitial cells of Cajal[1,2]. Mutations in mast/stem cell growth factor receptor (KIT) and platelet-derived growth factor receptor A (PDGFRA) are considered the primary causes in the pathogenesis of GIST[3]. GIST most commonly occurs in the stomach (50%-60%) and small intestine (30%-35%) but rarely occurs in the colorectum (5%) and esophagus (< 1%)[4]. Previous studies have indicated that GIST accounts for roughly 0.1%-3.0% of gastrointestinal malignances, and 15%-50% of patients present with metastasis at the time of diagnosis [5].

In clinical practice, GIST is liable to recur and distantly metastasize even after the initial tumor excision[6]. In fact, about 40% of patients develop tumor metastasis within 15 years after surgery[7], with a strong tendency to metastasize to the liver and peritoneal surfaces primarily and the lymph nodes and lung less frequently[4,8]. Based on tumor size, mitotic count, tumor site, and tumor rupture, the modified National Institutes of Health (NIH) consensus criteria stratifies GIST into four subgroups: Very low (NIH-VL), low (NIH-L), intermediate (NIH-I), and high risk (NIH-H)[9]. GIST patients with large sized tumors and high mitotic counts are more likely to metastasize to the liver and abdominal cavity and frequently have poor disease-free survival ratios[10].

Before the clinical application of imatinib, a tyrosine kinase inhibitor, surgical resection was the only accepted therapy that could prolong the life of GIST patients who had developed metastasis. Even then, the 5-year overall survival rate of patients was only 27%–34%[11]. Improved treatment with imatinib has been highly effective in advanced or metastatic GIST patients, and approximately 80% of them can reach complete or partial recovery[12,13]. Unfortunately, high rates of drug resistance due to secondary mutations of KIT have rendered imatinib therapy ineffective in recent years[14]. Taken together, the current research shows that the therapeutic efficacy of GIST treatments are still not ideal. Therefore, finding new molecular therapeutic targets for GIST is critical.

In this study, we implemented a proteomic analysis in GIST patients using tandem mass tag (TMT) labeling 10-plex kits to explore potential molecular therapeutic targets for GIST. A total of 4111 proteins were quantified in the GIST samples. Of these, 1669 were identified as significant differentially expressed proteins (DEPs), with 762 upregulated and 907 downregulated proteins. After a systematic

analysis of the top 10 upregulated or downregulated proteins, we selected TATA-box-binding protein-associated factor 15 (TAF15) for further study because of its important role in cell proliferation and migration[15]. TAF15 is a member of the FUS/Ewing sarcoma protein (EWS)/TAF15 (FET) family of RNA- and DNA-binding proteins, which plays an essential role in mRNA transcription, RNA splicing and polyadenylation[16-18].

Previous studies have demonstrated that TAF15 can influence a large number of genes that are closely related to the cell cycle and cell death and that overexpression of TAF15 can promote proliferation in sarcomas, human neuroblastoma and leukemia cells[17,19]. TAF15 mediates resistance to radiation therapy through inhibiting tumor suppressors p53 and p21, and upregulation of TAF15 is closely related to worsened survival in non-small cell lung cancer patients[20]. Additionally, a prior study has described a human anti-TAF15 antibody, PAT-BA4, that targeted a tumor-specific TAF15 antigen and then inhibited cell adhesion and spreading in gastric cancer[21]. Moreover, in a recent study, TAF15 activated the mitogen-activated protein kinase (MAPK) signaling pathway by upregulating the expression of MAPK6 in lung squamous cell carcinoma[22]. Taken together, TAF15 may play an important role in the progression of human cancers. However, the latent functions and molecular mechanism of TAF15 in GIST progression are still unclear and must be further studied.

MATERIALS AND METHODS

Clinical sample collection

One hundred and sixty one patients with GIST were recruited from the Department of Gastrointestinal Surgery, Yantai Yu Huang Ding Hospital of Qing Dao University from March 2020 to June 2022, with ethical permission from the Biomedical Ethics Committee (No.2019–410). All patients were diagnosed with GIST by two independent pathologists based on Chinese clinical guidelines[23]. No patients had received chemotherapy before surgery. Out of the 161 cases, 18 cases had matched tumor (T) and normal (N) tissue samples, and the clinicopathologic features of the paired GIST samples were documented in Table 1. In the remaining 143 cases, only tissue from the tumor site was available. In the beginning we only collected 12 matched samples, which were sent for proteomic analysis, followed by another 6 matched samples. All specimens were immediately frozen in liquid nitrogen within 30 min after excision. All patients provided written informed consent.

Protein extraction and digestion

Tissues from GIST patients were homogenized in RIPA lysis buffer containing protease inhibitors using a mortar and pestle. After homogenizing lightly for 1 min on ice, the lysate was centrifuged twice at 13000 RPM for 10 min at 4 °C, and then the supernatants were transferred to a fresh tube. A BCA assay kit (catalog no.P0010, Beyotime Biotechnology, Shanghai, China) was used to measure the protein concentration of each sample. The protein content of each sample was reduced using 5 mmol/L DL-dithiothreitol at 55 °C for 30 min. Samples were then incubated with 10 mmol/L of iodoacetamide at room temperature for 15 min in the dark to alkylate the protein. Each protein sample was dissolved using triethylammonium bicarbonate buffer and then digested overnight at 37 °C using trypsin.

TMT labeling and fractionation

Tryptic peptides from each sample were labeled with TMT (Thermo Fisher Scientific, Waltham, MA, United States) kits following the manufacturer's protocol. After quenching the reaction using 5% hydroxylamine (Sigma-Aldrich, Saint Louis, MO, United States), the TMT-labeled peptide solution was fractionated using basic pH reversed phase high performance liquid chromatography through an Agilent Zorbax Extend C18 column (5 μm, 150 mm × 2.1 mm). The mobile phase consisted of Buffer A (98% water with 2% acetonitrile) and Buffer B (90% acetonitrile with 10% water). The procedure gradient was run as follows: 0%-8% Buffer B for 0-10 min; 8%-35% Buffer B for 10-80 min; 35%-60% Buffer B for 80-95 min; 60%-70% Buffer B for 95-105 min; 70%-100% Buffer B for 105-120 min. The flow rate was set at 1 mL/min. TMT labeled peptides were separated into 10 fractions by reversed phase high performance liquid chromatography.

Liquid chromatography-tandem mass spectrometry analysis

Liquid chromatography-tandem mass spectrometry (MS) analysis was conducted on a Q Exactive Mass Spectrometer (Thermo Scientific) coupled to an EASY-nanoLC System (Thermo Fisher Scientific). Peptides were loaded onto a reverse-phase C18 column (Thermo Scientific Easy Column, 10 cm long, 75 μm inner diameter, 3μm resin) in Buffer A (0.1% formic acid) and separated with a linear gradient of Buffer B (84% acetonitrile and 0.1% formic acid) at a flow rate of 300 nL/min. The MS was utilized in positive ion mode. MS data were acquired following a data-dependent top10 method, dynamically selecting the most abundant precursor ions from the survey scan (300–1800 m/z). The automatic gain control target was set to $3e^6$ with maximum inject time to 10 ms. Survey scans were acquired from a resolution of 70000 at m/z 200 with an isolation width of 2 m/z.

Table 1 Clinicopathologic features of the collected paired gastrointestinal stromal tumors samples

Case No.	Sex	Age in yr	Location	Tumor size length × width × height in cm	Mitosis count, per 50 HFPs	Risk classification based on NIH
1	Male	74	Stomach	2.8 × 2.8 × 2.0	> 5	High
2	Female	24	Stomach	6.0 × 4.0 × 5.0	> 5	High
3	Male	69	Stomach	7.5 × 5.5 × 4.0	> 10	High
4	Male	46	Small intestine	6.5 × 5.0 × 4.0	> 5	High
5	Female	65	Small intestine	6.5 × 5.5 × 5.0	> 5	High
6	Female	61	Stomach	5.5 × 3.5 × 4.0	> 5	High
7	Female	49	Stomach	8.5 × 8.0 × 7.0	< 5	Intermediate
8	Male	77	Stomach	6.0 × 6.0 × 5.0	< 5	Intermediate
9	Female	54	Stomach	6.0 × 4.5 × 3.5	< 5	Intermediate
10	Female	43	Stomach	5.5 × 4.5 × 3.0	< 5	Intermediate
11	Male	70	Stomach	7.0 × 7.0 × 5.5	< 5	Intermediate
12	Female	55	Stomach	8.0 × 8.0 × 7.0	< 5	Intermediate
13	Male	63	Small intestine	5.0 × 3.5 × 3.0	< 5	Low
14	Male	67	Stomach	2.3 × 1.5 × 1.5	< 5	Low
15	Male	44	Stomach	3.0 × 2.7 × 1.3	< 5	Low
16	Female	49	Stomach	1.0 × 0.8 × 0.8	< 5	Very low
17	Female	66	Stomach	2.0 × 1.8 × 1.0	< 5	Very low
18	Female	57	Stomach	2.0 × 1.8 × 1.5	< 5	Very low

Data processing and analysis

Data for each sample were processed using the Swiss-Prot *Homo sapiens* database (20413 entries, January 14, 2017). The parameters of the procedures were as follows: Cysteine carbamidomethylation was set to fixed modification; oxidation was set to variable modification; peptide mass tolerance was 20 ppm, trypsin digestion, max 2 missed cleavages; and the false discovery rate was less than 1%. Proteins with a fold change of > 1.2 or < 0.83 and a P value < 0.05 were identified as significantly upregulated or downregulated.

Western blotting analysis

Western blot analysis was performed using 10% sodium dodecyl sulfonate-polyacrylamide gel electrophoresis to separate equal amounts (25 μg/load) of protein samples. Protein samples were transferred onto polyvinylidenedifluoride membranes. The membranes were blocked at room temperature for 1 h with 5% nonfat milk in TBS-T buffer and subsequently incubated with primary antibodies at 4 °C overnight. Secondary antibodies were incubated for 1 hat room temperature. Protein samples were visualized using ECL reagents (MA0186, Meilunbio, Dalian, China) using the ChemiScope 6200 Touch Imaging System (CLINX, Shanghai, China). Some membranes were recycled using stripping buffer (SL1340, Coolaber, Beijing, China) and incubated with other primary antibodies. The primary antibodies were used and obtained as follows: TAF15 (1:3000, ab134916, Abcam, United States); GAPDH (1:5000, D110016, Sangon Biotech, Shanghai, China); RAF1 (1:500, D155090, Sangon Biotech, Shanghai, China); p-RAF1 (1:1000, 66592-1-lg, Proteintech, Wuhan, China); MEK1/2 (1:1000, 11049-1-AP, Proteintech, Wuhan, China); p-MEK1 (1:1000, 28930-1-AP, Proteintech, Wuhan, China); ERK1/2 (1:1000, 16443-1-AP, Proteintech, Wuhan, China); and p-ERK1/2 (1:1000, 28733-1-AP, Proteintech, Wuhan, China). The secondary antibodies were used and obtained as follows: HRP goat anti-rabbit immunoglobulin G (IgG) (1:3000, D110058, Sangon Biotech, shanghai, China); and HRP goat anti-mouse IgG (1:3000, D110058, Sangon Biotech, Shanghai, China). Three independent tests were performed.

Immunohistochemistry

Tissue specimens were cut into 4 μm sections and processed by deparaffinization and rehydration. Slides were incubated with 3% hydrogen peroxide for 20 min at room temperature to block endogenous peroxidase activity. Tissue sections were incubated with primary antibody TAF15 (1:100, ab134916, Abcam, United States) at 4 °C in a wet chamber overnight and then incubated with secondary antibody HRP goat anti-rabbit IgG (1:100, D110058, Sangon Biotech, Shanghai, China) for 1 h in a wet chamber at room temperature. Color was developed using diaminobenzidine and hematoxylin. Two independent pathologists evaluated the samples by randomly selecting and evaluating five × 400 microscopic fields per slide. The percentage of stained tumor cells was scored as follows: 0, < 5% positive cells; 1, 5%-24% positive cells; 2, 25%-49% positive cells; 3, 50%-74% positive cells; and 4, ≥ 75% positive cells. The staining intensity was scored as follows: 0 for absence; 1 for weak; 2 for moderate; and 3 for strong. The total stained index was equivalent to intensity score × positive score. A total score ≥ 4 was considered positive expression, and < 4 was treated as negative expression.

Cell lines and culture

GIST-882 and GIST-T1 cell lines were obtained from the Shanghai Cancer Institute, and GIST-48 cell lines were kindly provided by Professor Jonathan Fletcher (Harvard Medical School, United States). GIST-882 and GIST-T1 cells were cultured with RPMI 1640 medium (Gibco, United States), and GIST-48 cells were cultured with DMEM (BioInd, Israel). Both medium preparations contained 10% fetal bovine serum (FBS) (Gibco, United States) and 1% penicillin-streptomycin in a humidified incubator at 37 °C with 5% CO2.

Cell transfection

The lentivirus for knocking down TAF15 (shRNA1, shRNA2, shRNA3) and control scrambled lentivirus (sh-scrambled) were purchased from Genomeditech (Shanghai, China). GIST-882 and GIST-T1 cells were seeded in a 12-well plate(Corning Life Sciences) at 1 × 10^5 cells per well, and the transfection was performed when the cell density reached about 50%. Cells were cultured in fresh medium after being infected with lentivirus for 72 h. The multiplicity of infection of lentivirus to GIST-882 and GIST-T1 was 30. Stable cell lines were generated through selection with puromycin (2 μg/mL). Transfection efficiency was detected using western blot analysis.

Cell immunofluorescence

Transfected cells were cultured in 12-well plates. When the cell density reached 50%-65%, cells were fixed using 4% paraformaldehyde for 30 min to make slides. 0.5% Triton X-100 was added to slides to allow for cell penetration, and 10% goat serum was used to block cells for 2 h at room temperature. Slides were then incubated with the TAF15 primary antibody (1:500, ab134916, Abcam, United States) at 4 °C overnight and then incubated with secondary antibodies for 1 h at room temperature. DAPI was used to stain the cell nuclei, and images were photographed using a fluorescent microscope. The fluorescent intensity of cells were measured using Image J software (version 3.2.0.8).

Cell counting kit-8 assay and colony formation assay

The cell counting kit (CCK)-8 (Dojindo, Tokyo, Japan) assay was performed according to the manufacturer's instructions. Briefly, different groups of cells were seeded onto 96-well plates at 1 × 10^3 cells per well. The CCK-8 reagent was added (10 μL/well) into the individual wells during the last hour. A microplate reader (Bio-Rad) was used to measure the optical density of the samples at 450 nm, as a measure of cell proliferation. With respect to the colony formation assay, different groups of cells were cultured in 6-well plates (500 cells/well) for 2 wk. Cell colonies were fixed with 4% paraformaldehyde for 30 min and stained with 1% crystal violet for 15 min at the room temperature. Colonies consisting of 50 or more cells were counted.

Transwell experiment

GIST-882 and GIST-T1 cells (3 × 10^4 cells/well) were inoculated into the upper polycarbonate membrane chambers of a 12-well plate without FBS, while the lower chamber contained RPMI 1640 medium with 10% FBS. To detect the cell invasion ability, matrix gel was in advance added to the polycarbonate membrane chambers. After being cultured for 48 h, the cells attached to the lower side were fixed with 4% paraformaldehyde for 30 min and stained with 1% crystal violet for 15 min at the room temperature. Five fields were selected randomly to count using an inverted microscope.

Wound healing assay

GIST-882 and GIST-T1 cells were cultured up to 90% confluency and then serum-starved for 12 h. The cell monolayer was scratched using a 1 mL plastic pipette tip. Culture medium was used to wash away the cell debris twice, and then cells were incubated in respective culture medium containing 10% FBS. Samples were photographed at 0 h, 12 h and 24 h post scratch using an Olympus microscope. The percentage of wound healing was evaluated using Image J software.

Modeling of GIST xenografts in nude mice

Nude mice aged 4 wk were purchased from the Beijing Vital River Laboratory Animal Technology Co., Ltd (Beijing, China). All animal care and processing were performed according to the Institutional Animal Care and Use Committee of Qingdao University guidelines. Twenty mice were divided randomly into two groups (10 mice per group) and then subcutaneously injected in the axillary region with stable cells (2×10^6 cells) transfected with sh-TAF15 or sh-scrambled. The volume (volume = length × width × width/2) of tumors were measured every 2 d. The mice were humanely sacrificed using the cervical dislocation method after anesthesia with 0.7% sodium pentobarbital. Tumor tissues were then excised, photographed and weighed.

Statistical analysis

Statistical analyses were performed using GraphPad Prism 9.3.1. The data analyses were conducted using Student's *t*-test, χ^2 test, one-way analysis of variance or Mann-Whitney *U* test. Data were expressed as mean ± standard deviation. $P < 0.05$ was considered statistically significant, and significance was indicated in each graph.

RESULTS

Quantification of DEPs by TMT

In total, 4111 proteins were quantified with a false discovery rate < 0.01 in all 12 GIST matched samples. Of these, 1669 were identified as significant DEPs on the basis of the filtering criteria of fold change > 1.2 or < 0.83 and *P* value < 0.05, including 762 upregulated proteins and 907 downregulated proteins (Figure 1A and Supplementary Table 1). Notably, the key proteins used for diagnosing GIST, including KIT, DOG1 and hematopoietic progenitor cell antigen CD34 (CD34), were all contained in the upregulated protein category (Supplementary Table 1), suggesting that our proteomic data were reliable. Moreover, 667, 686, 840 and 974 significant DEPs were identified in the NIH-H, NIH-I, NIH-L and NIH-VL subgroups, respectively (Figure 1B and Supplemental Table 2). After our systematic analysis of the top 10 upregulated and downregulated proteins (Table 2), we decided to focus on the protein TAF15 due to its important role in cell proliferation and migration.

Identification of TAF15 by western blotting analysis

Western blotting was used to further identify the expression levels of TAF15 in GIST. We detected the extracted proteins from tumor tissues (T) and matched normal tissues (N) of 18 GIST patients, including 6 NIH-H, 6 NIH-I, 3 NIH-L, and 3 NIH-VL cases. The results showed that the expression levels of TAF15 were significantly increased in tumor tissues compared with matched normal tissues (Figure 1C and D), which were in agreement with the results of our quantitative proteomics analysis (Table 2 and Supplemental Table 2).

Validation of TAF15 expression by immunohistochemical analysis

We evaluated the expression level of TAF15 in GIST patients using immunohistochemical (IHC) analysis of tumor tissues (T) from 161 patients and 18 matched normal tissues (N). We found significantly higher levels of expression of TAF15 in tumor tissues compared to matched normal tissues (red arrows, Figure 1E and F, Supplemental Table 3). Moreover, subgroup analyses showed that the expression level of TAF15 was significantly higher in the NIH-H subgroup than in the NIH-I, NIH-L and NIH-VL subgroups and that the expression level of TAF15 was significantly higher in the NIH-I subgroup than the NIH-VL subgroup (Figure 1G and Supplemental Table 3). We found no significant difference in the expression of TAF15 between the NIH-L and NIH-VL subgroups and between the NIH-I and NIH-L subgroups. Furthermore, based on our IHC data, we found that the overexpression level of TAF15 was positively correlated with tumor size and GIST risk stage but was not significantly correlated with gender, age or tumor metastasis (Table 3). These results provided evidence that the higher expression of TAF15 may contribute to malignant progression of GIST and that TAF15 may be a latent promoter or biomarker of GIST.

Knockdown of TAF15 inhibited the proliferation and migration of GIST cells

In order to understand the real role of TAF15 in GIST progression, short-hairpin RNAs (shRNAs) were used to knock down TAF15 in GIST-882 and GIST-T1 cells. GIST-882 and GIST-T1 cells were used instead of GIST-48 cells, as the expression level of TAF15 was higher in the former cell lines (Figure 2A). Three shRNAs targeting TAF15 (sh1, sh2 and sh3) were applied to knock down TAF15 protein. The results showed that sh2 and sh3 could significantly reduce the expression of TAF15 when compared to scrambled shRNA (scr), as tested by western blotting analysis (Figure 2B and C) and cell immunofluorescence assays (Figure 2D and E). Therefore, sh2 and sh3 were used to perform further experiments.

T: Tumor tissues; N: Matched tumor normal tissues; FC: Fold change.

The results of the CCK-8 assay and the colony formation assay indicated that TAF15 knockdown (sh2 and sh3) exhibited a significant decrease in proliferative and colony forming ability in GIST-882 and GIST-T1 cells when compared with the scr (Figure 3A-D). Transwell assay showed that the sh-TAF15 group (sh2 and sh3) exhibited significantly weaker migratory abilities compared to the scr in GIST-882 and GIST-T1 cells (Figure 3E and F). However, there was no significant difference in the invasion ability of GIST-882 and GIST-T1 cells between the sh-TAF15 group (sh2 and sh3) and sh-scrambled group (Figure 3G and H). The results of the wound healing assay also showed that migratory abilities significantly decreased in the sh-TAF15 group (sh2 and sh3) compared to the scr in GIST-882 and GIST-T1 cells (Figure 3I-K). These findings indicated that TAF15 knockdown can significantly inhibit GIST cell proliferation and migration.

TAF15 promoted GIST progression by activating the RAF1/MEK/ERK signaling pathway

Previous studies have shown that EWS, one of the members of the FET family proteins, forms a fusion oncoprotein EWS-FLI1 whose expression leads to the activation of ERK1/2 signaling in zebrafish embryos and adult tumors[24]. In consideration of the important role of the ERK signaling pathway in many human tumors[25], we speculated that TAF15 could promote cell proliferation and migration directly through the activation of the ERK signaling pathway in GIST. Therefore, we assessed the phosphorylation level of RAF1, MEK and ERK1/2 in GIST-882 and GIST-T1 by western blotting. The results showed that the phosphorylation levels of RAF1, MEK and ERK1/2 were significantly decreased following TAF15 knockdown (sh2 and sh3). However, there was no significant change in levels of total RAF1, MEK and ERK1/2 (Figure 4). Collectively, these findings suggest that TAF15 may promote cell proliferation and migration through the activation of the RAF1/MEK/ERK signaling pathway in GIST.

TAF15 promoted the growth of GIST in vivo

To further confirm the role of TAF15 in the progression of GIST, we established a xenograft mouse model utilizing GIST-882 cells due to their enhanced proliferative and migratory ability. sh2 was used in this experiment because of its higher knockdown efficiency, with scr as a control. Twenty nude female mice were randomly divided into two groups, and each mouse was then subcutaneously injected with

Table 3 Correlation between the expression of TATA-box-binding protein-associated factor 15 and clinicopathological characteristics in gastrointestinal stromal tumors

Characteristics	TAF15 expression		*P* value

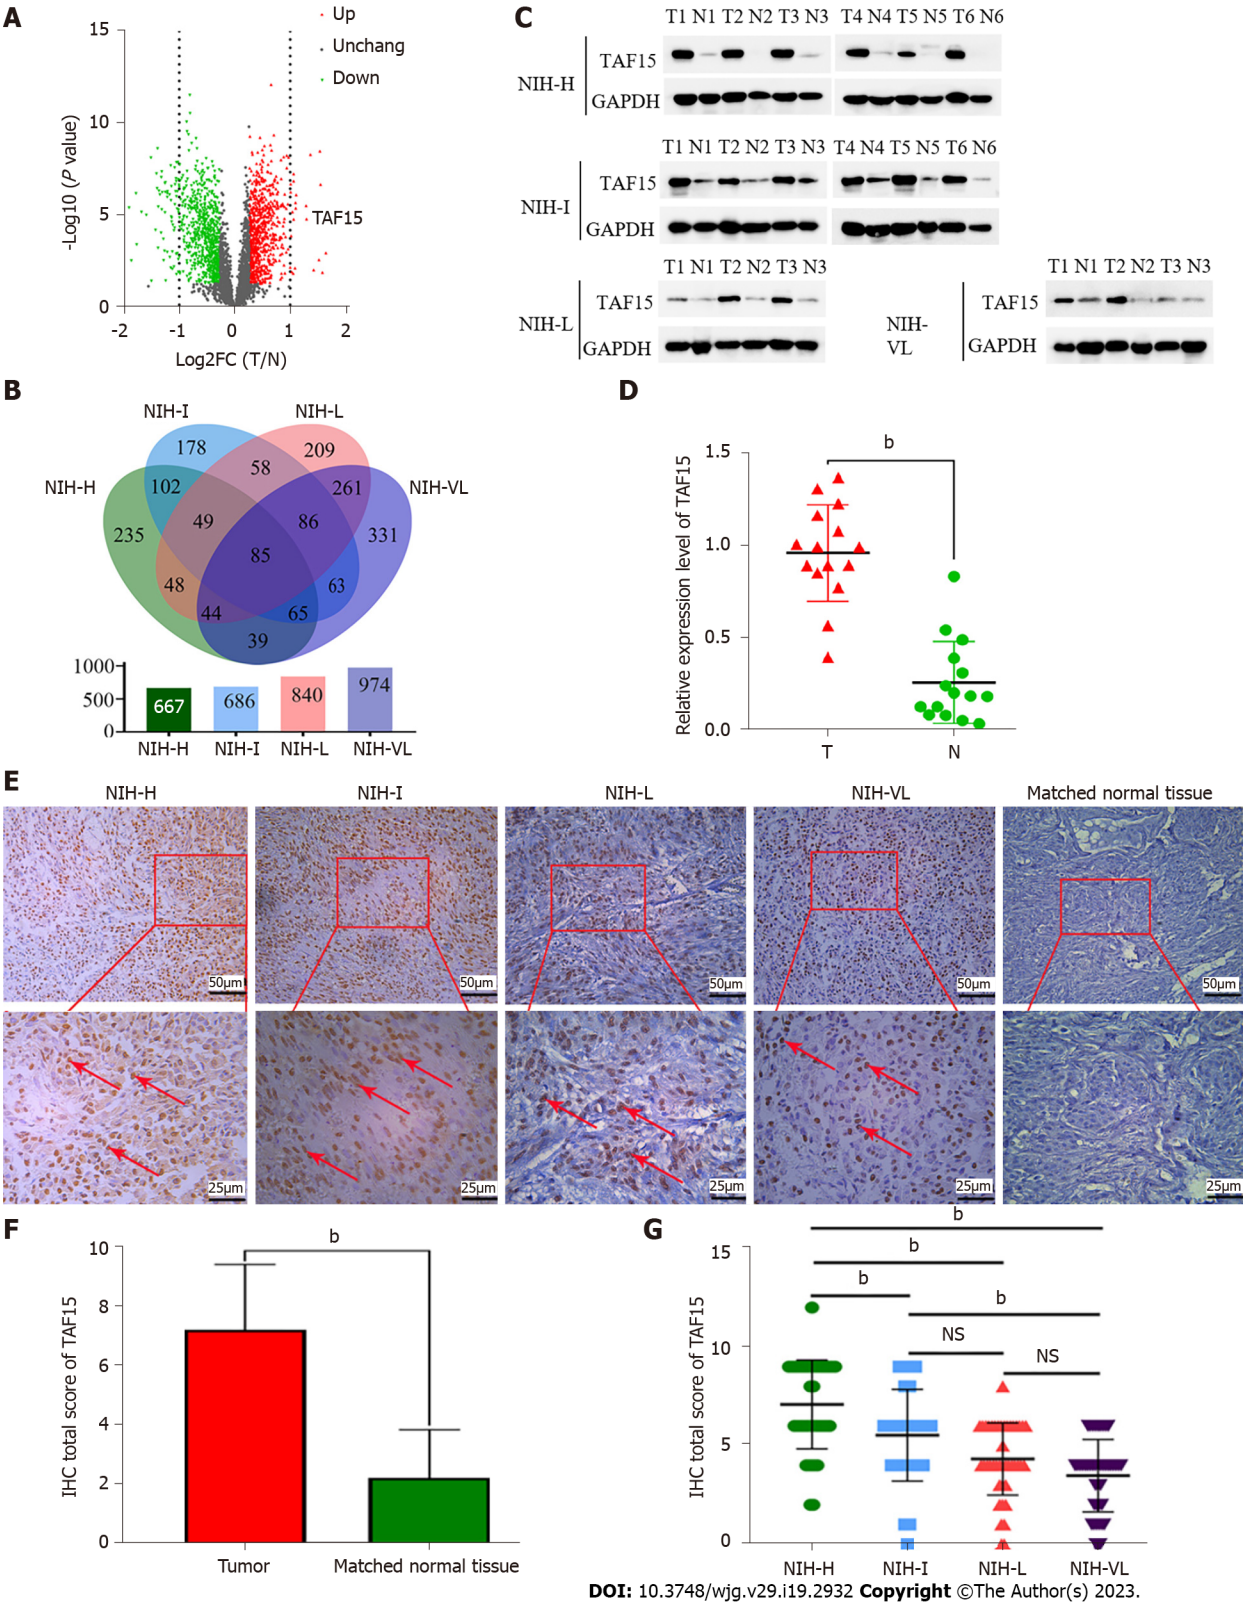
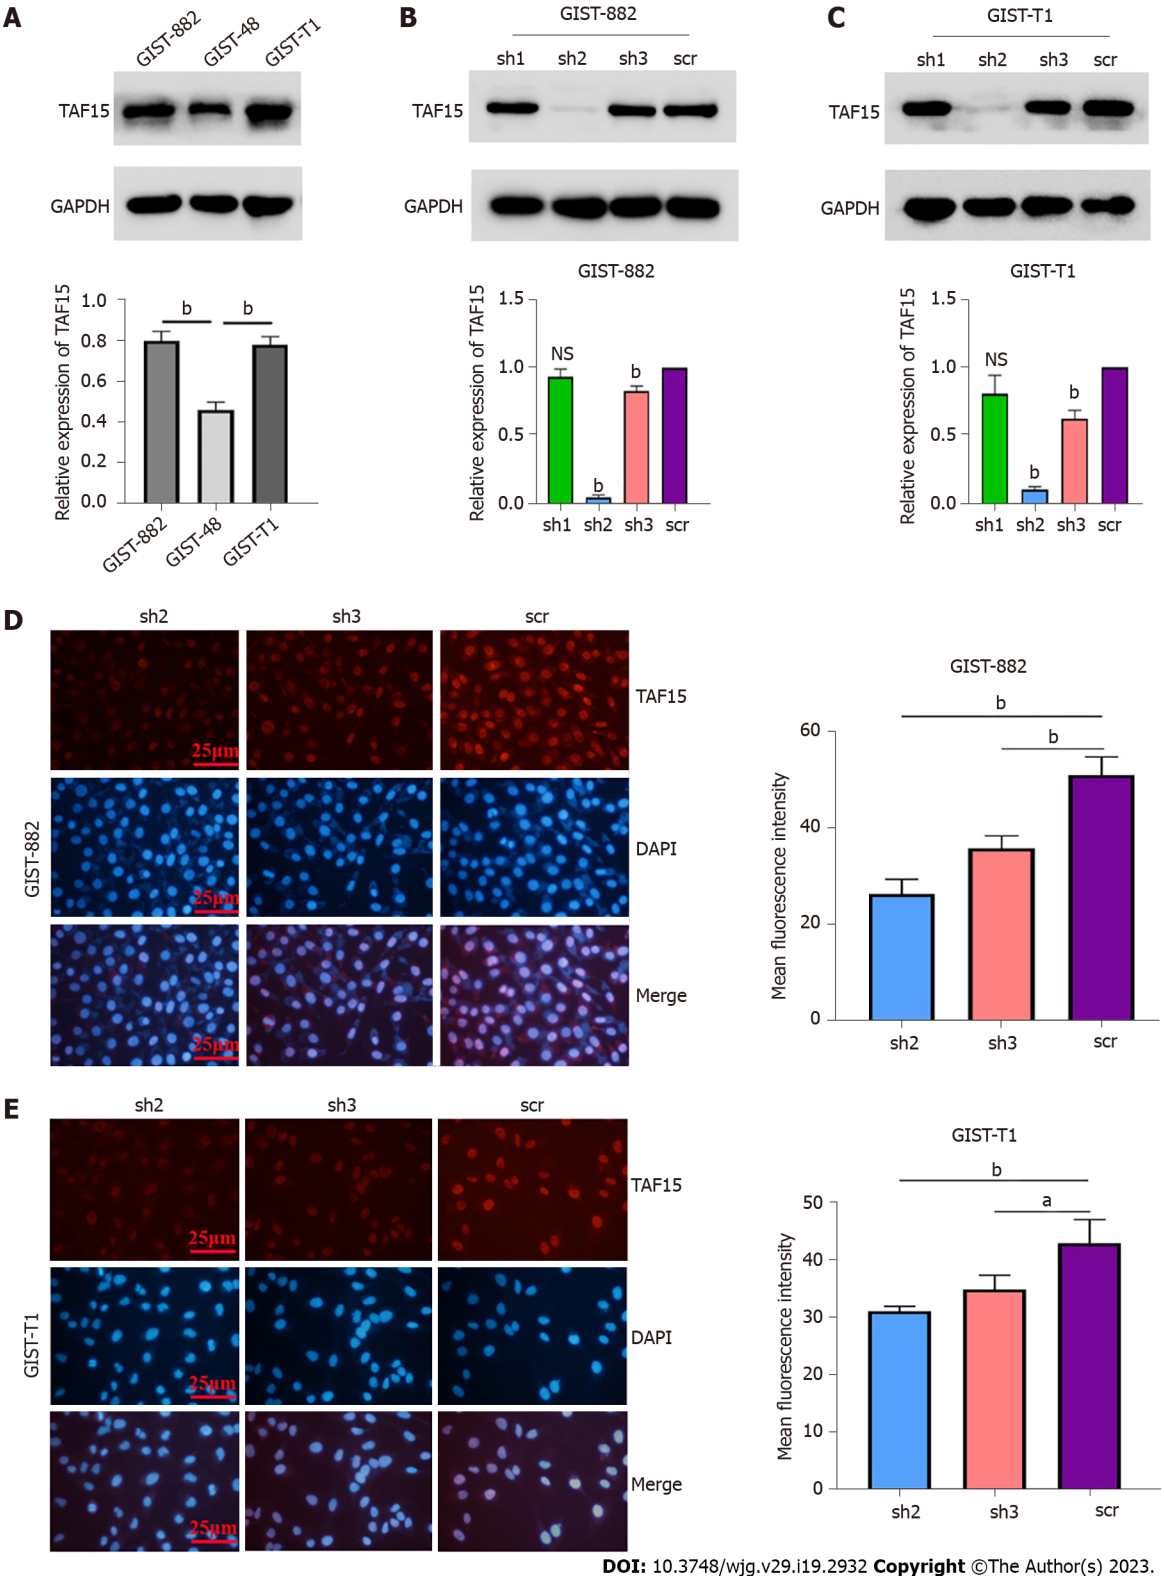
either sh2 or scr cells. Unfortunately, one mouse in the scr group died on day 7 post-injection for an unknown reason. Ten days after injection, xenograft tumors in the remaining mice were detectable. The results showed that TAF15 knockdown significantly suppressed tumor growth and tumor weight (Figure 5A-C). Furthermore, western blotting analysis was used to confirm the level of TAF15 in the xenograft tumors. The results showed that the levels of TAF15 were significantly decreased in the sh2 group compared to the scr group (Figure 5D and E). Additionally, three xenograft tumors of the sh2 group and three xenograft tumors of the scr group were randomly selected to test the levels of RAF1, MEK and ERK1/2 by western blotting. The results indicated that the phosphorylation levels of RAF1, MEK and ERK also decreased significantly in the sh2 group, while the levels of total RAF1, MEK and ERK showed no significant change (Figure 5F-I). These data indicated that TAF15 may promote the growth of GIST *in vivo via* the activation of the RAF1/MEK/ERK signaling pathway.

DISCUSSION

KIT and PDGFRA mutations are considered to be two major factors in GIST pathogenesis[3,26], and drugs targeting KIT and PDGFRA pathways have achieved great success in the treatment of this disease [27,28]. However, GIST patients gradually become resistant to current targeted drug treatment in recent years[14,28]. Therefore, there is an unmet need to explore other latent targets.

An increasing number of biomarkers or targets have been reported to be important to GIST progression. For example, p53 is a biomarker and potential target in GIST; targeting the p53 pathway is a novel additional treatment strategy for GIST[29]. High expression of carbohydrate antigen 125 is an independent risk factor for GIST progression, and it is a significant biomarker in the overall management of GIST patients[30]. Brain-derived neurotrophic factor is over expressed in high-risk GIST patients, and it may serve as a significant prognostic factor[31].In the present study, proteomic analysis





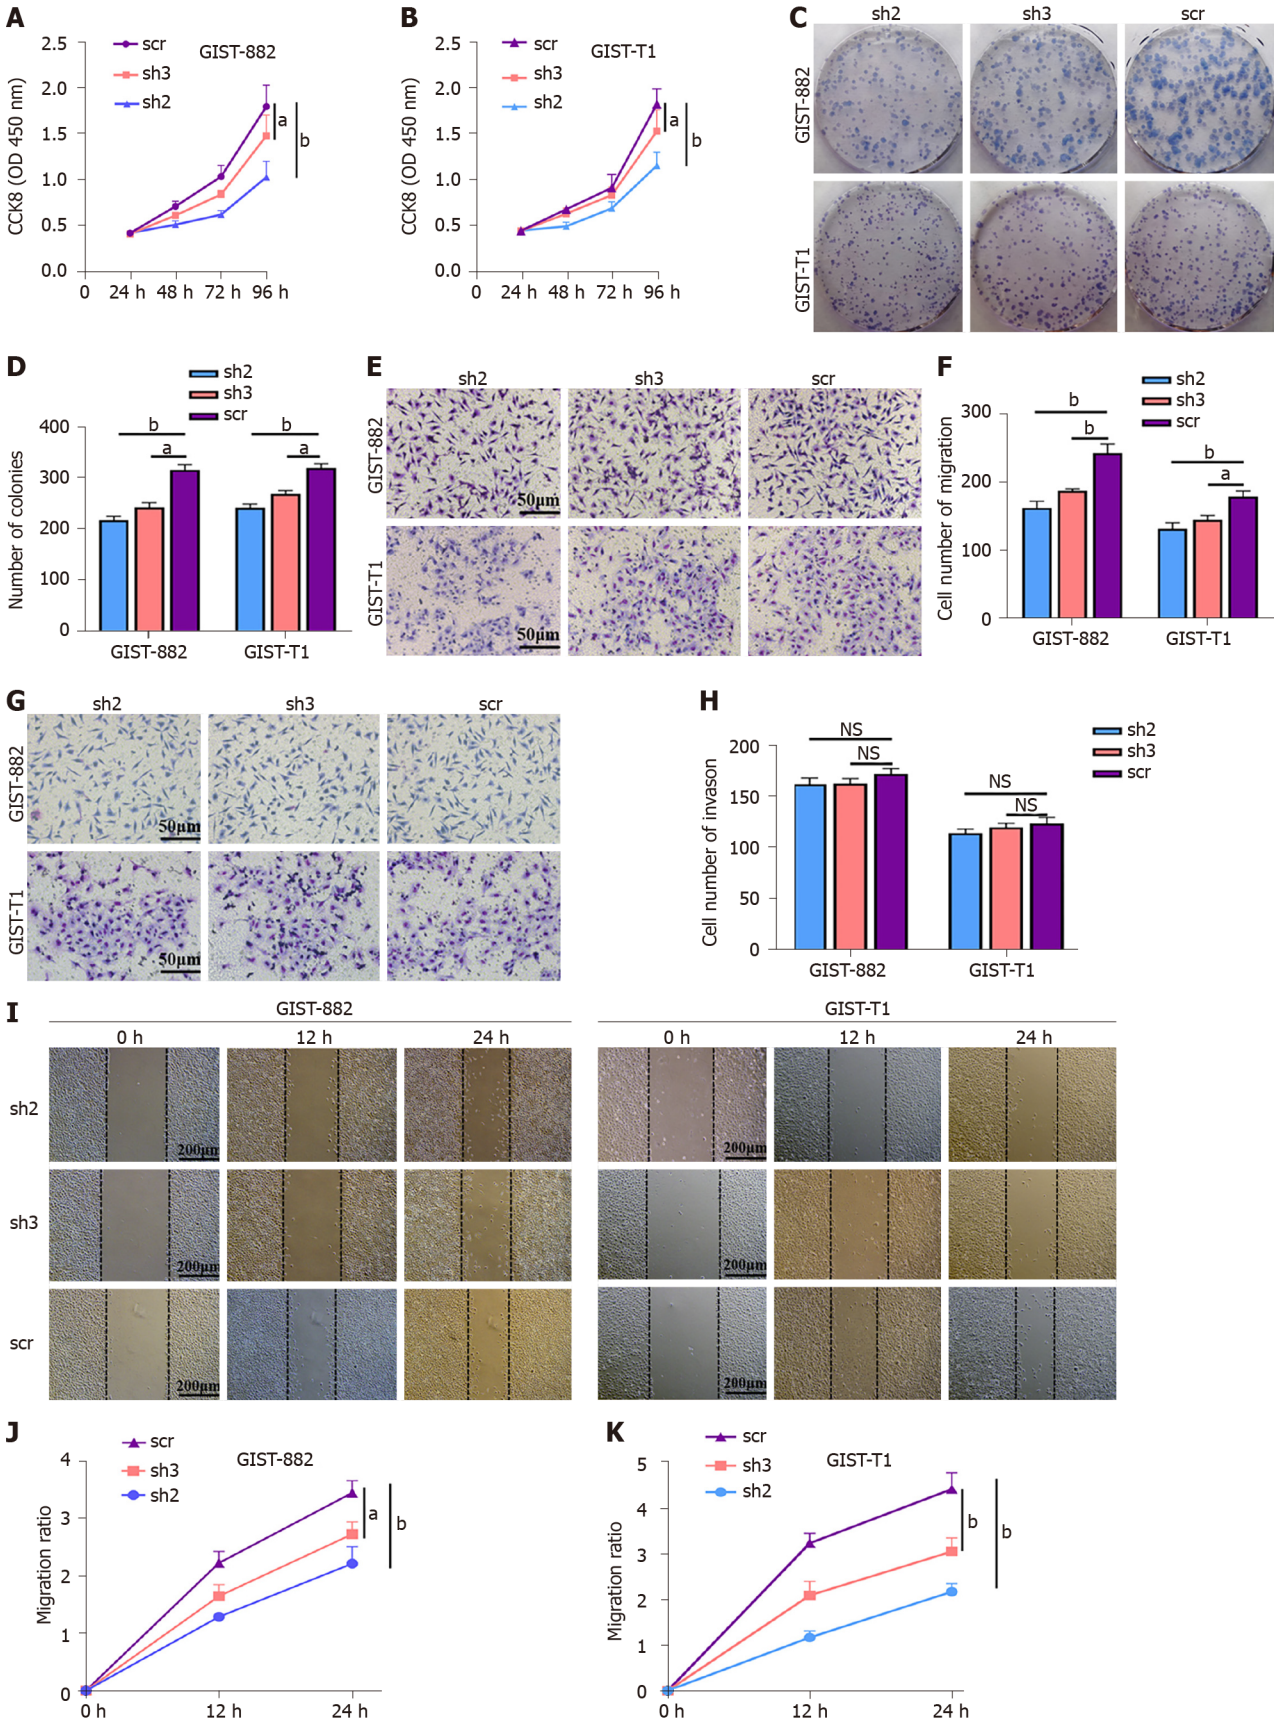


Figure 1 Differentially expressed proteins in gastrointestinal stromal tumor samples. A: Proteomic analysis identified the differentially expressed proteins in gastrointestinal stromal tumor (GIST) patients; B: Venn diagram showed the number of identified differentially expressed proteins in the subgroups of GIST; C and D: Western blotting identified that the expression level of TATA-box-binding protein-associated factor 15 (TAF15) was significantly increased in tumor tissues compared with matched normal tissues in all 18 GIST samples. *P* values were calculated using the Student's *t*-test; E: Immunohistochemical analysis verified the expression of TAF15 using 161 GIST tumor tissues and 18 matched normal tissues (representative images are shown and red arrows indicate positive staining); F: Total immunostaining score of TAF15 protein in tumor tissues and matched normal tissues of GIST; G: Total immunostaining score of TAF15 proteins in the GIST subgroup. *P* values were calculated using the Student's *t*-test or one-way analysis of variance. $^{b}P < 0.01$. was performed in patients with GIST to explore the potential molecular biomarkers for prediction, early diagnosis or treatment.

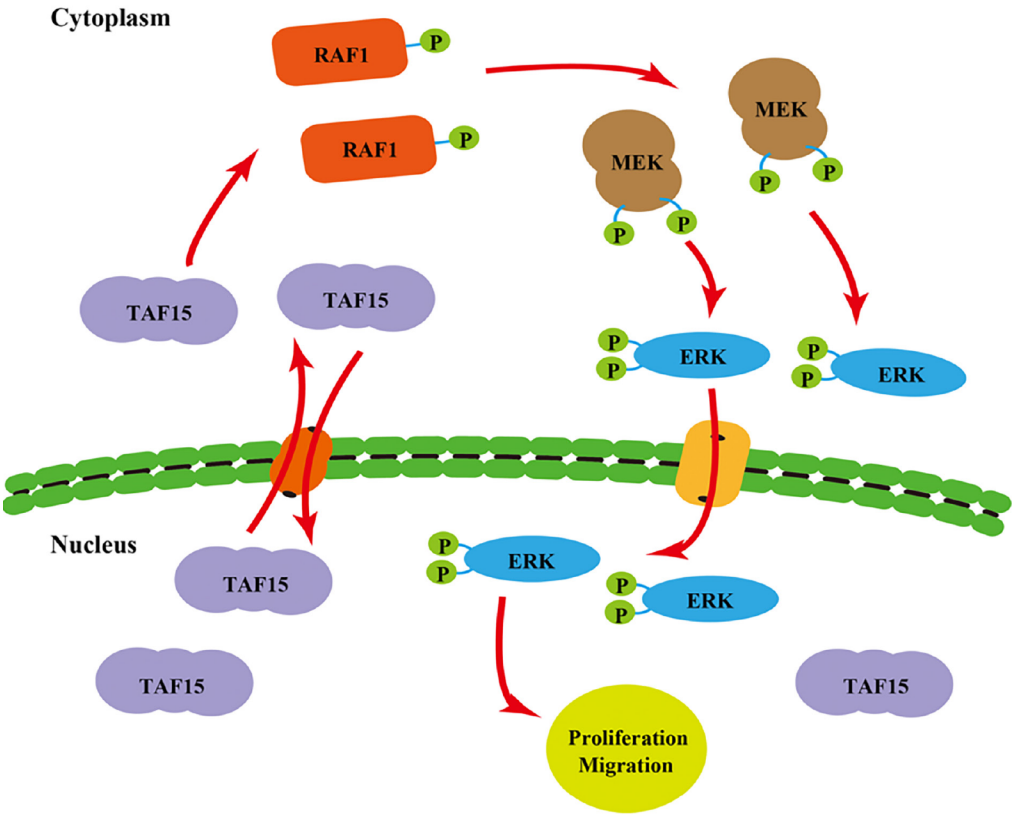
A total of 4111 quantified proteins with 1669 DEPs (762 upregulated and 907 downregulated proteins) were revealed in our study. Among the top 10 DEPs identified, TAF15 was interesting due to its key role in promoting growth in other human tumors such as extraskeletalmyxoid sarcomas, leukemia, Ewing's sarcomas, human neuroblastoma and lung squamous cell carcinoma[15,17,19,20,32]. TAF15 was first reported as an RNA or DNA binding protein, while more recent studies have shown that TAF15 also plays important roles in cellular stress responses, cell spreading and cell adhesion[33,34]. GAS5 binding to TAF15 could upregulate expression of HIF1A,thus promoting wound healing in diabetic foot ulcers [35].



We believe our study is the first to confirm that TAF15 is over expressed in GIST tissues and cell lines and that high expression levels of TAF15 are positively correlated with tumor size and GIST risk stage. Previous studies have shown that the inhibition of TAF15 expression could significantly reduce cellular proliferation in melanoma and lung cancer[20,21]. Similarly, our study demonstrated that TAF15 knockdown could significantly inhibit proliferation and migration of GIST cells *in vitro* and suppress tumor growth *in vivo*. These data provided evidence that overexpression of TAF15 may contribute to the malignant progression of GIST.

The latent molecular mechanism of TAF15 in GIST was also first investigated in this study. Previous studies have shown that FET family proteins are mainly present in the nucleus[34], but it is now known that they also shuttle between the nucleus and cytoplasm[36-38]. They have an extensive functionality

Figure 6 A schematic diagram of the mechanism of action of TATA-box-binding protein-associated factor 15 in gastrointestinal stromal tumors. TATA-box-binding protein-associated factor 15 shuttles between the nucleus and cytoplasm and promotes proliferation and migration of gastrointestinal stromal tumor cells by activating the RAF1/MEK/ERK pathway. TAF15: TATA-box-binding protein-associated factor 15.

including regulation and interaction with various proteins[39,40]. Moreover, recent work demonstrated that EWS-FLI1 fusion protein expression leads to activation of ERK1/2 signaling in zebrafish embryos and adult tumors[24]. Additionally, it is well known that the RAF/MEK/ERK signaling pathway plays an essential role in promoting cellular proliferation and survival[41].

In our study, we found TAF15 knockdown could significantly decrease the phosphorylation levels of RAF1, MEK and ERK, without significantly changing the total amounts of RAF1, MEK and ERK in GIST cell lines and xenograft tumors. Similarly, TAF15 is involved in the promotion of cell proliferation, migration and invasion of lung squamous cell carcinoma by activating the MAPK signaling pathway [22]. These results suggested that the activation of the ERK pathway may represent a new function of the TAF15 protein beyond DNA binding, mRNA splicing and mRNA transport. Taken together, these findings suggested that TAF15 shuttles between the nucleus and cytoplasm and may promote cell proliferation and migration directly through the activation of the RAF1/MEK/ERK signaling pathway in GIST (Figure 6). These observations greatly extend the functional repertoire of TAF15.

However, due to difficulty of obtaining matched tumor tissues after surgery[23], the number of paired samples used in this study for proteomic analysis, western blotting and IHC were small. Thus, we acknowledge that the accuracy of the proteomic analysis, western blotting and IHC in this research may be affected by the sample size and that the statistical analyses may be less robust due to the small sample size. Further studies will help validate some of the important and interesting findings of this study in larger GIST cohorts when available. Additional roles of TAF15 in GIST remain to be explored, as hundreds of genes lie downstream of TAF15[42].

CONCLUSION

In summary, this study utilized a proteomic analysis to find new molecular therapeutic targets for GIST and analyzed the expression level and underlying biological functions of TAF15 in GIST. Moreover, our study may be the first to demonstrate that TAF15 expression may contribute to malignant progression of GIST. TAF15promoted cell proliferation and migration in GIST *via* the RAF1/MEK/ERK signaling pathway. Therefore, TAF15 is expected to be a novel latent molecular biomarker or therapeutic target of GIST.

ARTICLE HIGHLIGHTS

Research background

Gastrointestinal stromal tumors (GIST) are a common neoplasm with high rates of recurrence and metastasis, and its therapeutic efficacy is still not ideal. There is an unmet need to find new molecular therapeutic targets for GIST. TATA-box-binding protein-associated factor 15 (TAF15) contributes to the progress of various tumors, while the role and molecular mechanism of TAF15 in GIST progression are still unknown.

Research motivation

To explore the novel early diagnostic markers or therapeutic targets for the diagnosis and treatment of GIST.

Research objectives

To investigate new molecular therapeutic targets for GIST and explore the role and potential molecular mechanism of TAF15 in GIST progression.

Research methods

Proteomic analysis was performed to explore the differentially expressed proteins in GIST. Western blotting and immunohistochemical analysis were used to verify expression levels of TAF15 in GIST tissues and cell lines. Cell counting kit-8, colony formation, transwell, wound healing and western blotting assays were applied to explore the effect and the molecular mechanism of TAF15 in GIST. The role of TAF15 *in vivo* was confirmed using a xenograft mouse model assay.

Research results

A total of 1669 proteins were identified as differentially expressed proteins with 762 upregulated and 907 downregulated in GIST. TAF15 was significantly upregulated in GIST tissues and cell lines. Overexpression of TAF15 was associated with larger tumor size and higher risk stage of GIST. TAF15 knockdown suppressed proliferation and migration of GIST cells *in vitro* and inhibited the growth of GIST *in vivo*. Moreover, the inhibition of TAF15 expression significantly decreased the phosphorylation level of RAF1, MEK and ERK1/2 in GIST cells and xenograft tissues, while the total levels of RAF1, MEK and ERK1/2 had no significant changes.

Research conclusions

TAF15 may contribute to malignant progression of GIST and promote cell proliferation and migration in GIST *via* the activation of the RAF1/MEK/ERK signaling pathway.

Research perspectives

TAF15 is expected to be a novel latent molecular biomarker or therapeutic target of GIST.

Abstract

BACKGROUND

Helicobacter pylori (*H. pylori*) is a significant human pathogen that is responsible for a variety of illnesses, including mucosa-associated lymphoid tissue lymphoma, gastric cancer, peptic ulcers, and gastritis.

AIM

To investigate the frequency of *H. pylori* infection and its resistance patterns among Egyptian patients and to determine the influence of *H. pylori* virulence genetic determinants on the eradication success of 14-d triple therapy regimen.

METHODS

H. pylori infections were investigated in 72 patients with gastroduodenal complications suggestive of *H. pylori* infection. The *cagA* and *vacA* genotypes of cultured strains were studied using polymerase chain reaction. The patients underwent 14 d of triple-therapy treatment. The treatment response was examined using histology and a rapid urease test 6 wk after therapy discontinuation.

RESULTS

The intention-to-treat eradication rate was 59.2% (95%CI: 48.2%–70.3%). Rates of *H. pylori* resistance to clarithromycin, amoxicillin, and metronidazole were 52.8%, 81.9%, and 100%, respectively. Successful eradication of *H. pylori* was more significantly associated with *vacA* s1-positive strains [adjusted odds ratio (aOR) = 0.507, 95%CI: 0.175–0.822]. A significant association was found between failed eradication rate and *H. pylori* strains resistant to clarithromycin (aOR = 0.204, 95%CI: –0.005 to 0.412) and amoxicillin (aOR = 0.223, 95%CI: 0.026–0.537).

CONCLUSION

This study's low *H. pylori* eradication rate following 14-d triple therapy is concerning and worrying. *H. pylori* pan-resistance to metronidazole followed by the high resistance to ciprofloxacin, amoxicillin, and clarithromycin in this research is challenging and of great concern.

Key Words: *Helicobacter pylori*; Eradication therapy; Virulence; Clarithromycin resistance; *cagA* gene; *vacA* gene

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: In this study, 72 patients with *Helicobacter pylori* infections were investigated. Half of the *Helicobacter pylori* strains had the *cagA* gene, and more than half of the strains were resistant to antibiotics except tetracycline and clarithromycin (CLR). However, CLR and tetracycline were effective at higher doses to achieve effective eradication by the CLR-based therapy. Most importantly, this study demonstrated that an alternative therapeutic regimen should be adopted to achieve effective infection eradication in Egypt.

INTRODUCTION

Helicobacter pylori (H. pylori) is a prominent human pathogen and is responsible for a variety of diseases, such as mucosa-associated lymphoid tissue lymphoma, duodenal or peptic ulcer, gastritis, and gastric cancer[1,2]. As a result of its causative relationship to gastric adenocarcinoma, the World Health Organization has identified this pathogen as a class I carcinogen[3]. According to the global estimate, *H. pylori* infects roughly 4.4 billion people with prevalence rates ranging from 20%-90% in developed and underdeveloped nations, accordingly[2].

Pathologically, the existence of gastric mucosa inflammatory changes in areas with abundant *H. pylori* organisms together with the pathognomonic existence of either lymphoid aggregates and/or follicles with germinal centers and neutrophilic infiltration constitutes the definition of chronic *H. pylori* gastritis [2,3].

Previous epidemiological research has produced a long list of microbial virulence factors that have a crucial role in *H. pylori* colonization, persistence, serotype/genotype diversity, host immune responses, pathogenicity, and disease severity. These factors involve the outer inflammatory protein (*oipA*) gene, the cytotoxin-associated gene (*cagA*), the vacuolating cytotoxin gene (*vacA*), the *babA*2 adhesin gene, the epithelium gene A (*iceA*), and the duodenal ulcer-promoting gene (*dupA*)[4-7].

The variability of *H. pylori* strains is believed to be related to the genetic structural diversity with associated polymorphic arrangements of different virulence determinant genes[4]. For example, the *vacA* gene, which encodes a vacuolating toxin, is found in the vast majority of *H. pylori* strains and is an important virulence factor. Because of sequence variability in the middle region (m), m1 and m2 alleles, signal region (s), s1 or s2 alleles, and the intermediate region I subtypes 1 or 2, notable diversity in the vacuolating activity of different strains is found. *iceA1* and *iceA2* are two major alleles of the *iceA* gene, which is another example of microbial genetic variation[8].

Triple therapy for 14 d with proton pump inhibitors and a mixture of two antibiotics, clarithromycin (CLR) and amoxicillin (AMX) or metronidazole (MNZ) is the standard treatment for *H. pylori* infections [9,10]. CLR is the preferred antibiotic in areas in which resistance to this antibiotic is < 15%[10]. However, the continuous surge in antimicrobial resistance, including CLR-resistance, has been accompanied by a failure to eradicate *H. pylori* infections in a significant proportion of cases worldwide. The prevalence of *H. pylori* resistance to CLR ranges from 11.1% in Europe to 92.3% in Africa, reaching 18.9% in Asia and 29.3% in America as described in clinical reports[11-13].

Only a few studies addressing *H. pylori* infections, pathogenicity, and epidemiology among Egyptian patients are available. Besides, data regarding *H. pylori* resistance to CLR is scarce. Therefore, this research aimed to determine the *H. pylori* infection frequency and its resistance patterns among Egyptian patients and to determine the influence of *H. pylori* virulence genetic determinants on the eradication success of a 14-d triple therapy regimen.

MATERIALS AND METHODS

This cross-sectional observational study was completed from August 2021 to June 2022 at the National Liver Institute (NLI), a 760-bed tertiary care hospital in Shebin El-Kom, Egypt. The research adhered to the Helsinki Declaration principles and received ethical approval from the ethics NLI research committee, No. 00308/2022. Written consent was obtained from all participants. The research followed the international principles of strengthening the reporting of observational studies in epidemiology[14]. During the research period, 86 adult cases with different dyspepsia symptoms (vomiting, epigastric, abdominal pain, and/or heartburn) and/or other symptoms indicative of *H. pylori* infection and likely to require *H. pylori* eradication therapy were enrolled in this research.

All cases provided a medical history and underwent a physical examination, a quick urease test, and inspection of the esophagus, stomach, and duodenum using an upper endoscopy.

Endoscopy

Under topical lignocaine anesthesia, each patient underwent an upper gastrointestinal endoscopy (Olympus X Q40; Olympus Optical, Tokyo, Japan). Each patient's antrum and stomach corpus were biopsied during the endoscopy to obtain two sets of biopsy samples. The first set of biopsies was utilized for a rapid urease test utilizing a rapid urease test kit (CLO test; Kimberly-Clark Ltd., Draper, UT, United States). Three hours later, the second set was transferred on ice to the laboratory for bacteriological culture after being packed in 3 mL of sterile normal saline. For histopathological analysis, the third specimen was immediately fixed in 10% formalin. The fourth section was added to a buffered solution (10 mmol/LTris, pH 8, 10 mmol/L ethylenediaminetetraacetic acid, and 0.5% sodium dodecyl sulfate) and then frozen at –80 °C for DNA extraction and polymerase chain reaction (PCR) assays. *H. pylori* was diagnosed using three techniques: (1) *H. pylori* culture; (2) Histopathology using hematoxylin and eosin and Giemsa staining; and (3) Rapid urease test. At baseline, a patient was considered *H. pylori* -positive if he had a positive culture or rapid urease test that was validated by histological features (foveolar-neutrophilic infiltration, lymphoid follicles and/or aggregates, and verified positive Giemsa stained I rods). Six weeks after the triple therapy cessation, a second gastrointestinal endoscopy was completed to determine and confirm the presence of *H. pylori* and whether or not the duodenal ulcer had been successfully cured. Eradication was defined as the absence of histological evidence and a negative result on the rapid urease test.

H. pylori culture and antimicrobial susceptibility testing

Using a tissue grinder, the biopsy specimen was homogenized and plated onto brain-heart infusion agar plates (Difco, Detroit, MI, United States) that were supplemented with vancomycin (6 mg/mL), amphotericin B (8 mg/mL), trimethoprim (5 mg/mL), and 10% glycerol. Under microaerophilic conditions (85% N_2, 5% O_2, and 10% CO_2) in a humid atmosphere, the plates were incubated at 37 °C for 3-5 d. *H. pylori* was recognized based on Gram staining, helical shape, and biochemical assays that were positive for oxidase, catalase, and urease[15].

As suggested by the European committee on antimicrobial susceptibility testing, the E-test minimum inhibitory concentration technique was used to test for antimicrobial susceptibility. Tests were done on Mueller–Hinton agar plates enriched with 7% horse blood (bioMérieux Inc., Marcy-l'Étoile, France) using E-test strips (AB Biodisk, Slona, Sweden)[16]. Tetracycline (TET), CLR, AMX, rifampicin (RIF), and ciprofloxacin (CIP) were among the antibiotics that were evaluated. The isolate was considered

resistant to AMX, CLR, and MNZ if minimal inhibitory concentrations (MICs) were > 0.125 mg/L, > 0.5 mg/L, and > 8 mg/L, respectively. Besides, the isolate was considered resistant to CIP, RIF, and TET if MICs were > 1 mg/L[16].

DNA extraction

Each *H. pylori* isolate was sub-cultured and incubated for 72 h after which 7-10 colonies were pooled together. DNA was extracted according to the manufacturer's instructions using the QIAamp DNA micro kit (Qiagen, Hilden, Germany) and then was eluted in 200 μL of 1x TE buffer (10 mM Tris-HCl, 1 mM ethylenediaminetetraacetic acid; pH 8.0) and stored at –20 °C until PCR amplification.

Molecular identification of cagA and vacA genotypes of H. pylori

As previously disclosed, all isolates were subject to multiplex PCR to determine *cagA* and *vacA* genotypes[17-19]. Table 1 contains a list of all primers utilized for this research. Multiplex PCR was carried out in a thermocycler (Cyclogene; Bio-Techne, Minneapolis, MN, United Kingdom) in a reaction mixture volume of 50 μL. Each reaction contained 25 μL of 2 × multiplex PCR Master mix (Hot start DNA polymerase, multiplex buffer, dNTP mix $MgCl_2$; ThermoScientific, Vilinus, Lithuania), 2 μL of each primer (40 pmol), and 200 ng of template DNA (6 μL) according to DNA concentration in yield. The reaction volume was brought to 50 μL with the addition of nuclease free water. PCR grade water and DNA from *H. pylori* strain American Type Culture Collection 43504 were used as negative and positive controls, respectively. Multiplex PCR was carried out by the simultaneous addition of primers in the same reaction mixture after test of each primer pair separately: (1) 35 cycles of 95 °C for 1 min; (2) Annealing at 54 °C for 1.5 min; (3) Extension at 72 °C for 1 min; and (4) A final extension at 72 °C for 10 min. The amplified PCR products were electrophoresed on 1.5% agarose gels using 1 × TBE after which the gel was stained with ethidium bromide using a 100 bp ladder as the molecular weight standard, visualized under an ultraviolet light source, and photographed using a BioRad Gel Doc device.

H. pylori eradication therapy and follow-up

Patients were given omeprazole (20 mg) and two antibiotics, AMX (1 g) and CLR (500 mg), twice daily for 14 d[9]. Clinical follow-up, including side-effect monitoring, was performed until the medication was completed. Using a rapid urease test, the therapeutic response was examined 6 wk following the termination of therapy. Successful eradication of *H. pylori* was indicated by a negative result from the rapid urease test and microbiological cultures and by the absence of neutrophilic infiltration with a decrease in lymphoid inflammatory changes in the biopsy tissue following treatment[9,20].

Statistical analysis

Coding, validating, and analyzing the data required the use of SPSS version 22 (IBM Corp., Armonk, NY, United States). Data were shown using average, median, and frequencies (%). A χ^2 test or Fisher's exact test was used to compare categorical data, and the Student's *t*-test was used for numerical data. *P* values ≤ 0.05 based on a two-tail test were considered to be significant. Potential risk factors were identified using a binary logistic regression analysis that included an antecedent 95%CI and adjusted odds ratio (aOR).

RESULTS

Patients characteristics and H. pylori infection

Table 2 shows the demographic and clinical characteristics of the patients. The age of the patients ranged from 19 years to 59 years (median: 39.5 years), and 57 (79.2%) were males. Based on endoscopic examination, more than half of the patients (54.2%) had gastritis, while 33.3% and 12.5% of patients had gastric ulcer and duodenitis, respectively. Based on histopathological examination of the tissue biopsy, features of chronic gastritis and rods of *H. pylori* were seen based on Giemsa stain (Figure 1).

Thirty-six (50%) strains were *cagA*-positive among 72 *H. pylori* isolates in this study, and in 50 (69.4%) of the *H. pylori* strains, the *vacA* gene was detected. For the *vacA* gene s and m region sub-typing, 42 and 18 strains were positive for s1 and s2, respectively, while 27 and 33 isolates were positive for m1 and m2, respectively (Figure 2).

Antimicrobial susceptibility test outcomes

During the research period, a total of 86 patients were recruited. Among them, 10 patients were negative for *H. pylori* infection, and 4 patients failed to complete treatment, leaving 72 patients eligible for the study protocol. Among the 72 *H. pylori* isolates, the resistance rates to MNZ, AMX, RIF, CLR, CIP, and TET were 100%, 81.9%, 62.5%, 52.8%, 41.7%, and 37.5%, respectively.

Triple therapy outcomes

The eligible patients underwent 14-d triple therapy with two antibiotics: (1) AMX (1 g); (2) CLR (500

Table 1 Primers used in this study for multiplex polymerase chain reaction for detection of *vacA* and *cagA* genotypes in *Helicobacter pylori* isolates

Primer	Nucleotide sequence, 5'—3'	Gene	Size, bp

m1/m2: Middle regions; s1/s2: Signal regions.

mg); and (3) Omeprazole (20 mg). In 45 individuals, the 14-d triple therapy was successful in completely eliminating *H. pylori*; however, in the other 27 patients, the infection persisted despite treatment. *H. pylori* eradication rates were 59.2% (95%CI: 48.2–70.3%) for intention-to-treat (ITT) and 62.5% (95%CI: 51.3%–73.7%) for per protocol treatment.

In patients with *vacA* s1-positive (P = 0.02), s2-positive (P = 0.03), or m1-positive (P = 0.01) strains, *H. pylori* eradication occurred more frequently. It was not surprising that the rates of resistance to AMX (P = 0.012) and CLR were higher in *H. pylori* isolates from patients who experienced unsuccessful eradication (P = 0.005). However, no significant association with eradication therapy and resistance rates to CIP, TET, and RIF was found (Table 3).

With 95%CI and aOR the multiple logistic regression analysis revealed possible risk factors associated with *H. pylori* eradication therapy (Table 4). Successful eradication of *H. pylori* was more significantly associated with strains harboring the *vacA* s1 genotype (aOR = 0.507, 95%CI: 0.175–0.822). In contrast,

DISCUSSION

Eradication therapy of *H. pylori* infections has been deemed beneficial for cases with gastroduodenal disorders, such as gastric MALT lymphoma, peptic ulcer disease history, gastric cancer, dyspepsia, atrophic gastritis, and hyperplastic polyps, and for cases with certain extragastrointestinal disorders, such as unexplained iron-deficiency anemia, chronic idiopathic urticaria, and idiopathic thrombocytopenic purpura[1,21].

Despite establishment of multiple *H. pylori* eradication treatment regimens in different worldwide regions, the usual 14-d triple therapy [piperacillin/AMX/CLR (PAC)] produces adequate eradication rates for both adults and children in Egypt[21-23]. However, cure rates in this study were found to be unsatisfactory and disappointing. Our findings showed that the 14-d triple therapy efficacy of *H. pylori* eradication (59%) was lower than that reported from previous Egyptian studies (ITT range: 72%–83%) [22,23]. A previous meta-analysis investigated the global trend in eradication rates of two different first-line therapeutic regimens (PAC and piperacillin/AMX/MNZ) for 8061 patients infected with *H. pylori* from 30 countries[24]. In this report, the cure rate of PAC (77.1%, 95%CI = 75%–79%) was significantly higher than piperacillin /AMX/MNZ (70%, 95%CI = 67.7%–72.3%) (OR = 0.70, 95%CI = 0.56–0.88; P < 0.002). Previous clinical studies worldwide showed an unacceptable and continuous decrease in *H. pylori* triple eradication therapy-associated cure rates[13,25]. It is noteworthy that the overall global cure rates of these protocols are < 80%, which have recently been considered regimens with disappointing efficacy.

Inadequate treatment duration, antimicrobial resistance, inadequate stomach acid suppression, poor adherence to eradication regimens, and quick metabolism of proton pump inhibitors have all been implicated in the failure of the traditional triple therapy to eradicate a pathogen according to previous ecological research[26,27]. CLR resistance has been recognized as the primary cause of routine triple treatment failure. In a recent meta-analysis investigating 66142 patients from 65 countries, failure to achieve eradication was 7-fold higher in patients with CLR-resistant *H. pylori* infections (OR: 6.97; 95%CI: 5.23–9.01; P = 0.001) when treated with a CLR-containing regimen than patients with susceptible strains[13]. Therefore, in nations with a high prevalence of CLR resistance (> 15%–20%), bismuth quadruple treatment is recommended.

Pooled data from 25 randomized trials including 3990 patients showed that the ITT eradication rate of standard triple therapy (65.7%) was significantly lower than bismuth-containing regimens (74.9%; OR: 1.60; 95%CI: 1.07–2.39). In addition, in the per protocol analysis, the pooled eradication rate for bismuth-containing regimens was 86.7% *vs* 33.3% for the usual triple regimen (OR: 10.64; 95%CI: 2.96–39.53)[28]. It is noteworthy that all isolates in this study were MNZ-resistant, and more than half of the isolates were resistant to AMX and CLR. These findings are not surprising as MNZ has been abused by the public without prescription for various gastrointestinal infections and diarrhea, while both AMX and CLR have been included in empiric therapies for respiratory infections or non-tuberculous mycobacterial infections in our region. Therefore, continuous monitoring of susceptibility patterns of *H. pylori* to various antimicrobials seems crucial as multidrug resistant *H. pylori* strains undoubtedly induce failure of *H. pylori* eradication therapy.

H. pylori cagA and *vacA* genotypes are among the most important factors implicated in the pathogenesis of gastroduodenal diseases and in influencing the sequelae of treatment protocols. The association of *cagA*-positive strains with the *H. pylori* eradication therapy outcomes were demonstrated by former clinical and ecological investigations[4-9]. However, the results from these studies were inconsistent and controversial. In this study, strains with or without *cagA* had no effect on eradication rates, a finding that is similar to previous reports. In a previous meta-analysis including 25 studies, the influence of the virulence factors, *vacA* and *cagA*, on *H. pylori* eradication therapy in 2693 cases was investigated by Wang *et al*[29]. In their report, the pooled *H. pylori* eradication rate was 77% (95%CI:

70%–83%) for *cagA*-negative patients and 85% (95%CI: 81%–89%) for *cagA*-positive with an 8% higher eradication rate among *cagA*-positive strains. In addition, using subgroup analyses based on clinical presentations, eradication detection method, location, and therapeutic regimen types, the authors concluded that *cagA*-negative strains responded to successful *H. pylori* therapy eradication rates than *cagA*-positive strains with pooled risk ratios (RR) of 1.118 (95%CI: 1.051–1.189; $P < 0.001$) for Asia and 1.138 (95%CI: 1.000–1.295; $P = 0.049$) for Europe. In South America, *cagA*-positive strains and *cagA*-negative strains exhibited comparable *H. pylori* treatment rates (RR: 1.104, 95%CI: 0.953–1.279; $P = 0.186$).

The *vacA* s1-positive *H. pylori* strains are typically more virulent and more closely linked to progressive gastroduodenal disorders as reported in many previous studies[29]. An increase in blood flow to the site of infection and stronger inflammatory responses were stimulated by more virulent strains as reported by clinical and epidemiological-based evidence. In addition, the more virulent strains are usually more susceptible to antimicrobials because of faster replication. *H. pylori* strains containing *vacA* s1 were substantially related to a greater *H. pylori* eradication rate in the current investigation.

This result is consistent with earlier findings in which *vacA* s1-positive strains posed a significant risk for the development of gastric illnesses with easier eradication in diseased people. Wang *et al*[29] discovered that the pooled *H. pylori* eradication rate was 73% (95%CI: 61%–85%) for *vacA* s2 and 83% (95%CI: 75%–91%) for *vacA* s1 with a 10% improvement in eradication rates in the *vacA* s1 group compared to the *vacA* s2 group (95%CI: 1.040–1.303; $P = 0.008$). In their meta-analysis, *vacA* s1 status was associated with better eradication rates in the triple therapy subgroup according to an examination of subgroups based on different worldwide locations (RR: 1.175, 95%CI: 1.012–1.360)[29]. Brennan *et al*[7] reported that the incidence of the more virulent s1 genotype was substantially lower among previously treated individuals than among those who had never received therapy (58.3% *vs* 74.3%). A significant increase in the frequency of the least pathogenic s2/m2 genotype was seen in previously treated individuals (36.7% *vs* 21.0%)[7]. Our findings and results of other studies clearly demonstrated that the *vacA* s1 genotype would be useful for predicting successful outcomes of *H. pylori* eradication therapy.

This study had some limitations. First, this research may have been limited in its capability to investigate other virulence marker-associated pathogenic roles due to the lack of molecular analysis beyond PCR and genome sequencing. Second, this study was conducted within a single center. Therefore, our findings cannot be applied to other situations. To further understand the phenotypic and genotypic links between *H. pylori* virulence, antibiotic resistance, and the efficacy of eradication therapy, further molecular-based epidemiological multicenter investigations with longer monitoring durations are required.

CONCLUSION

This low *H. pylori* eradication rate following 14-d triple therapy is concerning and worrying. The pan-resistance of *H. pylori* to MNZ followed by the high resistance to AMX, CLR, and CIP in this research is challenging and of great concern. These findings draw attention to the urgent need for performing *H. pylori* antimicrobial susceptibility testing before starting eradication therapy in addition to continuous surveillance of *H. pylori* resistance patterns in our region to provide data that can guide empirical treatment. In addition, the *vacA* s1-positive *H. pylori* isolates are easier to eradicate and could be used as an indicator to predict the successful outcome of eradication therapy.

ARTICLE HIGHLIGHTS

Research background

Helicobacter pylori (*H. pylori*) has been implicated in the development of gastric cancer and gastric mucosa-associated lymphoid tissue lymphoma. However, the bacterial eradication reduces the risk of theses gastric complications. The therapeutic regimens currently in use and the duration of therapy differ in different countries, which affects the therapy outcomes. The therapeutic outcomes have been found to be affected by the virulence characteristics of the infecting strains. The strains with more virulent characteristics possessing *vacA* s1 and m1 are eradicated more efficiently than the strains harboring less virulent characteristics.

Research motivation

To demonstrate that the infecting strains possessing more virulent characteristics are eradicated efficiently with a 14-d triple therapy. The *vacA* s1-positive *H. pylori* isolates are easier to eradicate and could be used as an indicator to predict the successful outcome of eradication therapy.

Research objectives
To evaluate the *H. pylori* infection frequency and its resistance patterns among Egyptian patients and to determine the *H. pylori* virulence characteristics influencing the eradication success of the 14-d triple therapy regimen.

Research methods
The patients suggestive of *H. pylori* infections were subjected to endoscopy-based biopsy specimen collection. The collected biopsy specimens were used to evaluate the *H. pylori* infection by a combination of diagnostic tests that included urease test, bacterial culture, and histopathological investigation. The extracted DNA was subjected to PCR-based *cagA* and *vacA* genotype investigation. The *H. pylori*-infected patients received triple therapy for 14 d. Six weeks after completion of the therapy, the treatment response was examined utilizing histology and the rapid urease test.

Research results
Among the 86 recruited patients, infection was found in 76 individuals. All of the strains were resistant to metronidazole (MNZ), while 52.8% and 81.9% of the isolates were resistant to clarithromycin (CLR) and amoxicillin (AMX), respectively. Successful eradication of *H. pylori* was significantly associated with *vacA* s1-positive strains [adjusted odds ratio (aOR) = 0.507, 95%CI: 0.175–0.822]. *H. pylori* strains resistant to CLR (aOR = 0.204, 95%CI: -0.005 to 0.412) and AMX (aOR = 0.223, 95%CI: 0.026–0.537) were significantly associated with failed eradication rate.

Research conclusions
The low eradication rate of 14-d triple therapy in this study is worrisome and indicates that an alternative therapy to achieve effective eradication must be identified. The findings of complete failure of MNZ and reduced efficacy of AMX, CLR, and ciprofloxacin draw attention to the urgent need of antimicrobial susceptibility testing-guided eradication therapy. In addition, the strains with virulent properties of *vacA* s1 are easier to eradicate and could be used as an indicator to predict the successful outcome of eradication therapy.

Research perspectives
CLR, AMX, and MNZ-based 14-d eradication therapy is ineffective and discouraged in these populations. Extensive nationwide studies should be considered to document the efficacy and to find alternative therapeutic regimens in respect to the duration. Furthermore, antimicrobial susceptibility testing based therapy should be encouraged to help reduce the development of antimicrobial resistance.

ACKNOWLEDGEMENTS

The authors would like to thank the colleagues in the Department of Laboratory and Microbiology and Endoscopy and the patients in the National Liver Institute who aided this research.

Abstract

BACKGROUND

Intrahepatic cholangiocarcinoma (ICC) is a malignant tumor of the hepatobiliary system with concealed onset, strong invasiveness and poor prognosis.

AIM

To explore the disease characteristic genes that may be helpful in the diagnosis of ICC and affect immune cell infiltration.

METHODS

We downloaded two ICC-related human gene expression profiles from GEO database as the training group (GSE26566 and GSE32958 datasets) for difference analysis, and performed enrichment analysis on differential genes. The least absolute shrinkage and selection operator (LASSO), support vector machine-recursive feature elimination (SVM-RFE) and random forest (RF), three machine learning algorithms, were used to screen the characteristic genes. Double verification was carried out on GSE107943 and The Cancer Genome Atlas, two verification groups. Receiver operating characteristic curve and area under the curve (AUC) were used to evaluate the diagnostic efficacy of genes for ICC. CIBERSORT and ssGSEA algorithms were used to evaluate the effect of characteristic genes on immune infiltration pattern. Human Protein Atlas (HPA) was used to analyze the protein expression level of the target gene.

RESULTS

A total of 1091 differential genes were obtained in the training group. Enrichment

analysis showed that the above genes were mainly enriched in small molecular catabolism, complement and coagulation cascade, bile secretion and other functions and pathways. Twenty-five characteristic genes were screened by LASSO regression, 19 by SVM-RFE algorithm, and 30 by RF algorithm. Three algorithms were used in combination to determine the characteristic gene of ICC: *MMP14*. The verification group confirmed that the genes had a high diagnostic accuracy (AUC values of the training group and the verification group were 0.960, 0.999, and 0.977, respectively). Comprehensive analysis of immune infiltration showed that *MMP14* could affect the infiltration of monocytes, activated memory CD4 T cells, resting memory CD4 T cells, and other immune cells, and was closely related to the expression of CD200, cytotoxic T-lymphocyte-associated antigen 4, CD14, CD44, and other immune checkpoints. The results of immunohistochemistry in HPA database showed was indeed overexpressed in ICC.

CONCLUSION

MMP14 can be used as a disease characteristic gene of ICC, and may regulate the distribution of immune-infiltrating cells in the ICC tumor microenvironment, which provides a new method for the determination of ICC diagnostic markers and screening of therapeutic targets.

Key Words: Intrahepatic cholangiocarcinoma; MMP14; Machine learning; Immune infiltration; Characteristic gene; Diagnostic markers

Core Tip: This study demonstrates that a new candidate molecular marker: MMP14 that is important for the diagnosis of intrahepatic cholangiocarcinoma, and MMP14 was related to a variety of immune cell components and participated in the occurrence and development in intrahepatic cholangiocarcinoma.

INTRODUCTION

Intrahepatic cholangiocarcinoma (ICC) is the second most common primary tumor of the liver, which originates from intrahepatic bile duct epithelial cells and accounts for about 20% of primary liver malignant tumors[1]. Its incidence is on the rise worldwide, with the highest incidence in Southeast Asia, and the second highest incidence in China after Thailand[2,3]. Pathological changes such as chronic cholangitis, cholestasis, intrahepatic bile duct stones, and liver cirrhosis all increase the incidence of ICC[4]. At present, due to the poor efficacy of radiotherapy and chemotherapy for ICC, surgical treatment is currently the main treatment method for ICC. However, patients with ICC may be asymptomatic in the early stage, and most patients have intrahepatic metastasis, lymph node metastasis, or even distant metastasis at the first time of diagnosis. Only 9% of patients with advanced ICC can survive for 5 years[5-8]. Despite the continuous improvement in imaging and laboratory tests, the early diagnosis of ICC is still not ideal. Currently, the biomarkers of ICC mainly include carcinoembryonic antigen, carbohydrate antigen 19-9 and a-fetoprotein, but the sensitivity and specificity are not satisfactory[9]. Hence, it is crucial to find new biomarkers for early screening and diagnosis of ICC.

Many studies on the tumor microenvironment have confirmed that a variety of immune regulatory mechanisms play an important role in the malignant biological behavior of tumors. Therefore, immunotherapy has gradually been paid attention in various treatments for solid tumors, and as an emerging and effective anticancer treatment, it has also been widely used for ICC. However, the improvement of the efficacy of immunotherapy and the development of effective drugs targeting specific immune targets are still problems to be solved[10].

Machine learning is a part of the field of artificial intelligence, which can find rules through the analysis of data, and can be conducive to the prediction of similar unknown data. And the existing knowledge structure can be constantly updated to improve its own performance[11]. With the continuous progress of machine learning, the development of more accurate machine learning algorithms makes it possible for us to find new disease-related genes[12]. At the same time, second-generation sequencing technology has made convenient screening of ICC diagnostic targets, and provided a solid foundation for precise treatment of patients and selection of personalized drugs[13].
