In this study, using the ICC-related data in the GEO and The Cancer Genome Atlas (TCGA) databases, bioinformatics and machine learning algorithms were used to comprehensively analyze and obtain reliable disease-characteristic genes, and in-depth exploration found that this gene may regulate the progression of ICC by mediating the composition of immune-infiltrating cells. The above preliminary research results can provide important references for the identification of early diagnostic markers for ICC and the mining of potential intervention targets for immunotherapy.

MATERIALS AND METHODS

Download of the sample datasets

The gene expression data of ICC cancer tissues and paracancerous tissues were obtained by using the three datasets GSE26566, GSE32958, and GSE107943 in GEO database. The transcriptome gene expression data of cancer and paracancerous samples of ICC patients were obtained from TCGA database. The relevant datasets were sorted, and samples other than cancer and paracancerous tissues of ICC patients were deleted. The two datasets of GSE26566 and GSE32958 were combined as the training group. The GSE107943 dataset was used as the verification group, while the TCCG dataset was used as the external database verification group.

Screening of differential genes

The Limma package was used to analyze the differences between the GSE26566 and GSE32958 datasets after merging the training groups. Genes that met the conditions $|\log2FC| > 2$ and adj. $P < 0.05$ were considered to be differential genes. The first 50 genes with the most significant difference between upregulated and downregulated genes were selected for heat mapping using the pheatmap package. The volcanic map was plotted using ggplot2 and ggrepel packages to visualize significantly different genes.

Functional enrichment analysis

According to the results of differential expression analysis, the org.Hs.eg.db, enrichplot, clusterProfiler, DOSE and GSEABase package were used for GO functional enrichment analysis, KEGG pathway enrichment analysis, DO disease enrichment analysis and GSEA enrichment analysis, respectively. The top 10 most significantly enriched functions in biological processes (BP), CC and molecular functions (MF) were visualized by drawing bubble plots. The top 30 pathways or diseases with the most significant enrichment were selected for KEGG enrichment analysis and DO enrichment analysis bubble diagram drawing. GSEA enrichment analysis was carried out on the experimental group (cancer tissue samples) and the control group (paracancerous tissue samples), and the first five functions and pathways that were most significantly enriched in the experimental group and the control group were visualized respectively.

Screening disease characteristic genes by machine learning

Based on the differential gene expression, least absolute shrinkage and selection operator (LASSO) regression, support vector machine-recursive feature elimination (SVM-RFE) algorithm and random forest (RF) algorithm were used to screen disease characteristic genes. The genes screened by the three algorithms were intersected to obtain the final disease characteristic gene, which was the new characteristic gene for ICC diagnosis. The diagnostic genes obtained by the comprehensive analysis of the above three machine learning algorithms had stronger persuasion and higher accuracy. The LASSO regression algorithm was based on the glmnet package. When the parameters were set to a = 1, type.measure = deviance and nfolds = 10, the number of genes corresponding to the point with the smallest cross-validation error was the target gene. The SVM-RFE algorithm was based on the e1071, kernlab and caret packages. The method adopted was svmRadial, and the number of genes corresponding to the point with the smallest cross-validation error was selected as the disease characteristic gene. The RF algorithm was based on the randomForest package. The differentially expressed genes were used to train the RF model. The number of forest trees was set to 500, and the number of corresponding trees with the smallest cross-verification error was found to reconstruct the RF model for training. The importance score of the gene was obtained. We sorted from high to low according to the scores, and selected the 30 genes with the highest importance scores as the feature gene set.

Assessing the diagnostic value of ICC signature genes

The limma package was used to analyze the differences between the two verification groups of GSE107943 and TCGA to determine whether the differential expression of disease characteristic genes in the verification group was consistent with that of the training group. We used the ggpubr package to visualize and draw a boxplot. The receiver operating characteristic (ROC) curve was drawn based on the pROC package to evaluate the efficiency of characteristic genes in the diagnosis of ICC. Area under the curve (AUC) value was used as an index to evaluate the diagnostic value of characteristic genes in

Table 1 Number of data set samples

Dataset	Number of cancer samples	Number of paracancerous samples	Total
GSE26566	104	59	163
GSE32958	16	7	23
GSE107943	30	27	57

Total	183	101	284

TCGA: The Cancer Genome Atlas.

the training and test groups. The 95% confidence interval (CI) of AUC value was extracted and calculated by bootstrap method.

Comprehensive analysis of immune infiltration pattern in ICC

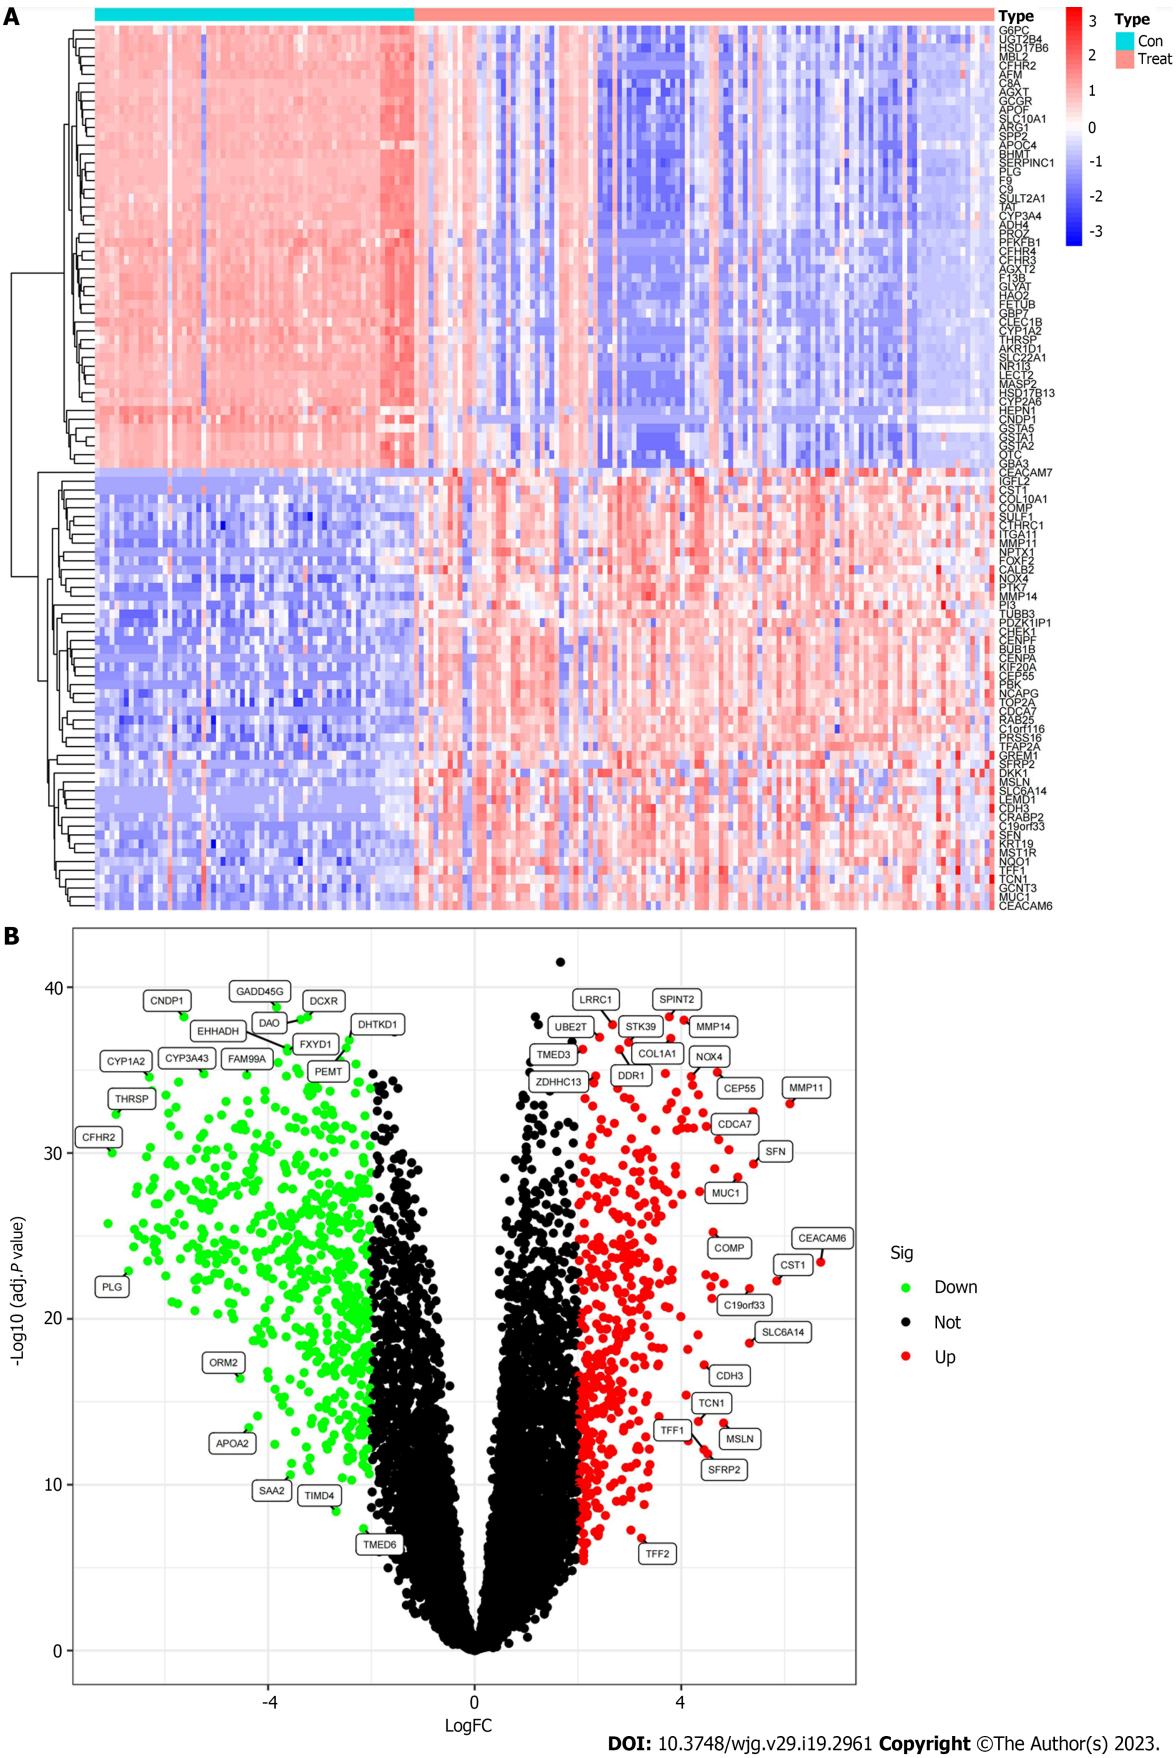
According to the gene expression level of each sample, CIBERSORT algorithm was used to quantify the relative content of immune cells in each sample with the help of e1071 and preprocessCore package, so as to obtain the proportion of different immune cells in each sample, and a bar chart was drawn. The corrplot package was used to analyze the correlation of immune cells and draw the correlation heat map. The vioplot package was used to analyze the difference in immune cell infiltration between cancer tissue and paracancerous tissue of ICC patients, and the violin picture was drawn. The CIBERSORT and ssGSEA algorithms were used to evaluate the relationship between ICC characteristic genes and tumor immune-infiltrating cells, in order to explore the effect of ICC characteristic genes on tumor immune microenvironment. Finally, 46 immune checkpoint related genes (including *CD274*, *PDCD1*, *CTLA4*, *CD14*, *LAG3*, and *TNFRSF9*) were found through the literature. We used the limma and corrplot packages, *etc*. to analyze whether the disease signature genes had a regulatory effect on the expression of immune checkpoints.

Analysis of protein expression level of disease characteristic genes by Human Protein Atlas database

The Human Protein Atlas (HPA) database provides the expression and distribution of all available proteins in human tissues and organs. Therefore, protein expression data of disease-characteristic genes in ICC and paracancerous tissues were obtained from this database for comparative analysis.

Statistical analysis

All statistical analyses in this study were conducted in R version 4.2.0. ICC characteristic genes were screened by LASSO regression, SVM-RFE and RF machine learning algorithms. The diagnostic efficacy of diagnostic biomarkers was evaluated by ROC curve. The relationship between the expression of characteristic genes and immune cell infiltration and immune checkpoint was analyzed by Spearman and Pearson correlation. Statistical significance was identified based on $P < 0.05$.



RESULTS

Downloading and sorting of sample data

Table 1 shows the three datasets (GSE26566, GSE32958, and GSE107943) in the GEO database and the ICC-related information obtained from the TCGA database. Two hundred and eighty-four samples were collected, including 120 cancer tissues and 66 paracancerous tissues in the training group. In the two verification groups, cancer tissue samples were from 30 and 33 cases, respectively, and paracancerous tissue samples from 27 and eight cases, respectively.

Screening of differential genes

By the difference analysis of the training group, 1091 differential mRNAs were obtained, including 463 upregulated and 628 downregulated mRNAs (Figure 1A and B). There were many genes with multiple differences in ICC cancer and paracancerous tissues; therefore, it was important to screen characteristic genes that mediated the occurrence and development of ICC, which laid a foundation for the following mechanistic exploration and target gene identification.

DOI: 10.3748/wjg.v29.i19.2961 **Copyright** ©The Author(s) 2023.

Figure 1 The differentially expressed mRNA of intrahepatic cholangiocarcinoma patients was screened based on GEO database training group. A: The heat map of differential gene expression in cancer tissues (Treat) and paracancerous tissues (Con); B: The Volcano map of differential gene expression between cancer and paracancerous tissues.

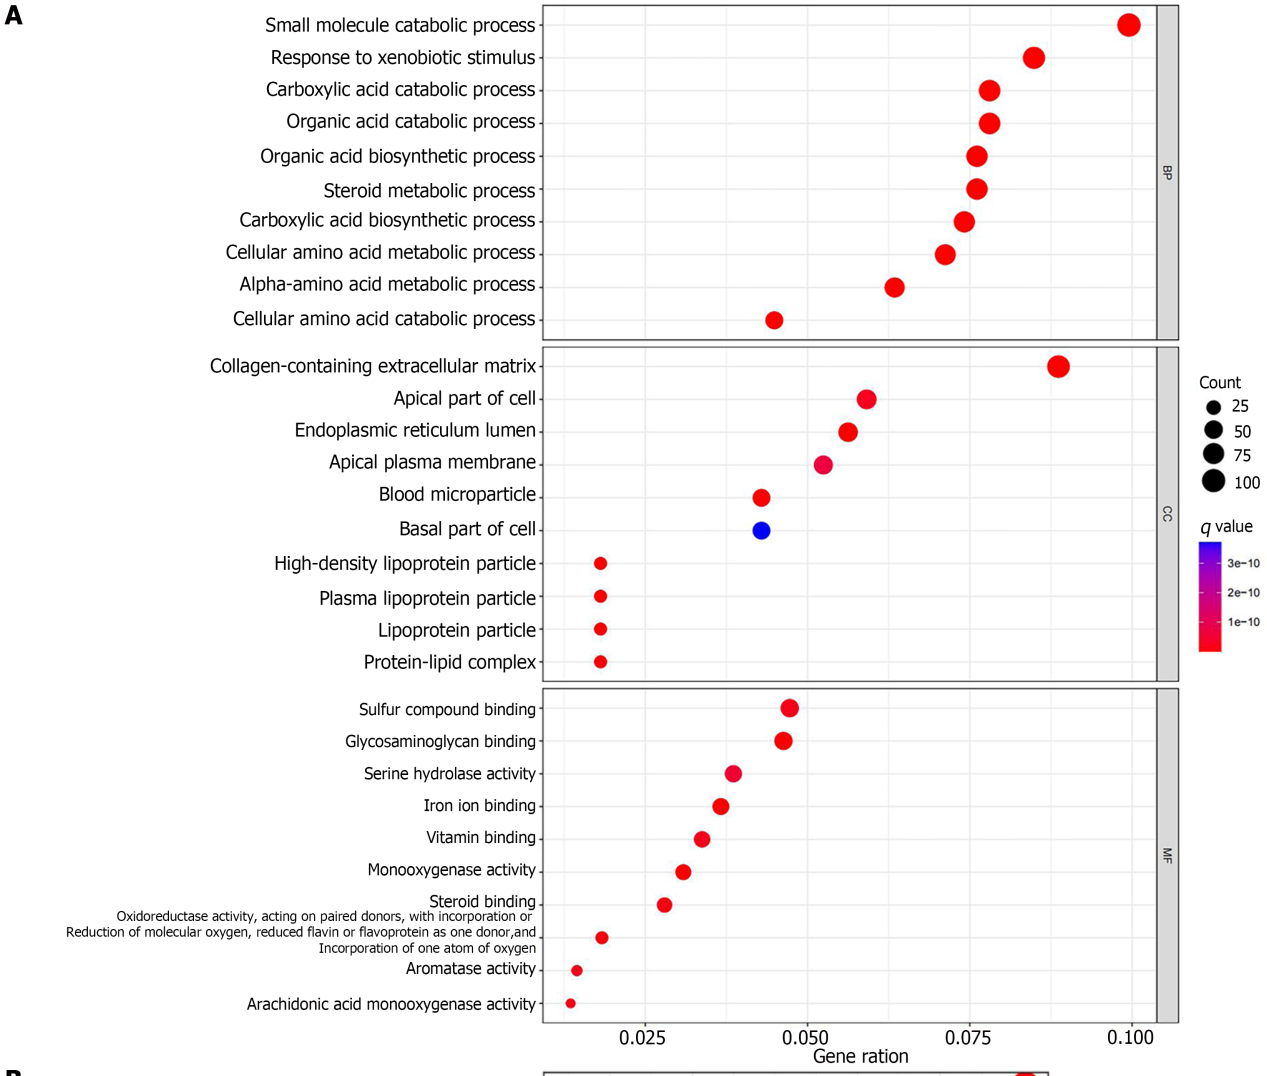
Biological functions of differential genes

Through GO functional enrichment analysis, we found that in terms of BP, processes such as small molecule catabolic process, response to xenobiotic stimulus, and carboxylic acid catabolic process had the largest number of enrichment genes. In terms of CC, collagen-containing extracellular matrix (ECM), apical part of cell and other CC had the largest number of enriched genes. In terms of MF, sulfur compound binding, glycosaminoglycan binding, serine hydrolase activity and iron ion binding had the largest number of enriched genes (Figure 2A). KEGG pathway enrichment analysis showed that the differential genes were mainly enriched in 56 related regulatory mechanisms, which were mainly involved in complement and coagulation cascades, bile secretion, biosynthesis of cofactors, drug metabolism cytochrome P450, chemical carcinogenesis DNA adducts, retinol metabolism and other pathways (Figure 2B). DO disease enrichment analysis showed that differential genes were closely related to cardiovascular disease, urinary system disease, fatty liver and cholangiocarcinoma (Figure 2C). GSEA enrichment analysis was carried out on the experimental and control groups. GO enrichment analysis showed that acylglycerol homeostasis and alcohol metabolic process were mainly enriched in paracancerous tissues (Figure 3A). In ICC cancer tissues, differential genes were mainly enriched in cell division, chromosome segregation, embryonic organ development and other functions (Figure 3B). KEGG enrichment analysis showed that complement, coagulation cascades and drug metabolism cytochrome P450 were actively expressed in para-cancerous tissues (Figure 3C), while cell cycle, ECM receptor interaction and pathways in cancer were actively expressed in cancer tissues (Figure 3D).

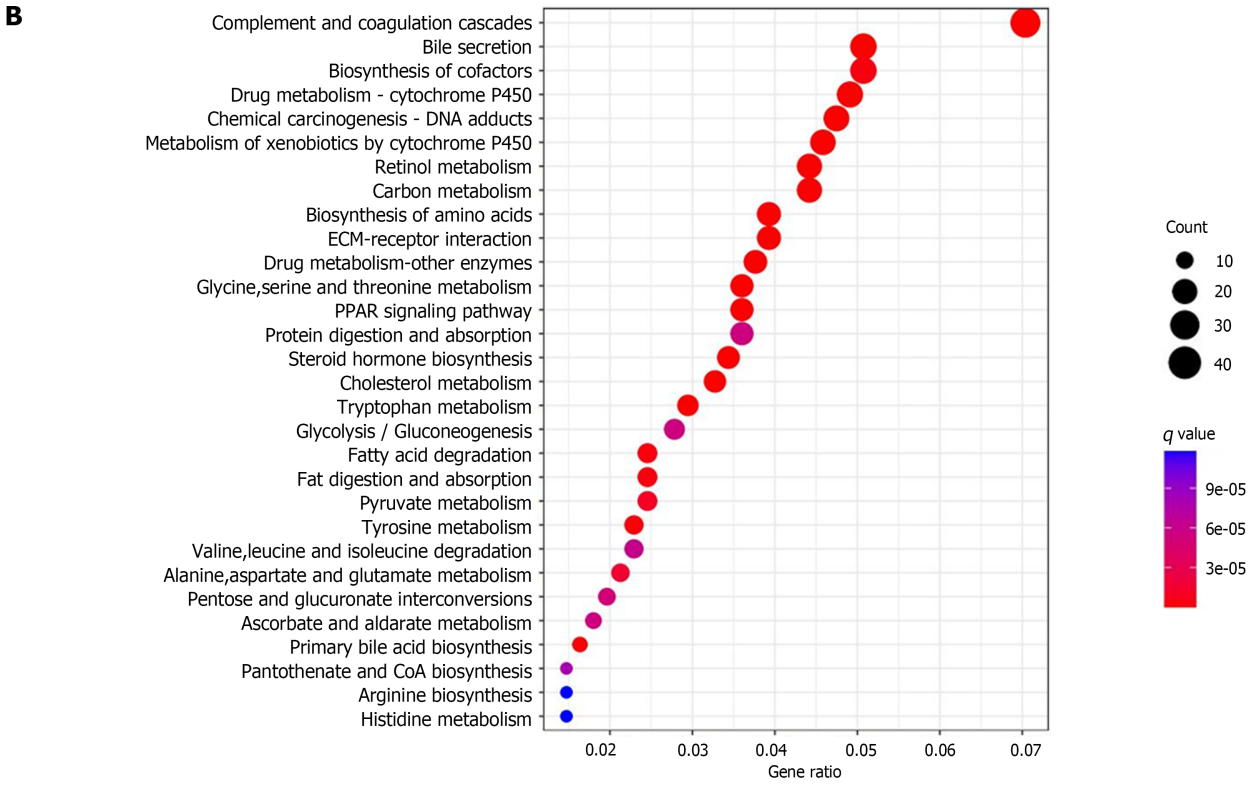
Determination of diagnostic markers for ICC

To identify the specific genes of value in the diagnosis of ICC, we used machine learning to filter the above 1091 differential genes. A total of 25 genes were screened by LASSO regression algorithm, namely: *MMP14*, *CDCA8*, *ZDHHC13*, *NOX4*, *HEPN1*, *LRRC49*, *PDZK1IP1*, *OR1L4*, *FAP*, *NDST3*, *FXN*, *PYCR1*, *PRR11*, *SPAM1*, *MAD2L1*, *APOBEC3G*, *PI3*, *CYP7A1*, *RNF165*, *MT1M*, *GREM1*, *EME1*, *ENAH*, *CDKN2B* and *FOSB* (Figure 4A). After screening by SVM-RFE algorithm, 19 genes were retained, namely: *CFHR2*, *PROC*, *UBE2T*, *HGD*, *AGMAT*, *ACSL1*, *GADD45G*, *DCXR*, *HGFAC*, *DTL*, *MMP14*, *ADHFE1*, *SLC22A1*, *CBS*, *PIPOX*, *SHMT1*, *RDH5*, *F12*, and *F9* (Figure 4B). After screening by RF algorithm, the first 30 genes obtained good diagnostic effect, namely: *SLC10A1*, *CYP3A43*, *COL8A1*, *CDH13*, *ALDH1A1*, *ITPR3*, *MT1H*, *NRCAM*, *TMOD1*, *TNFAIP6*, *SH2D3A*, *OLFML2A*, *WNT10A*, *ACAA2*, *RGN*, *GADD45G*, *CNDP1*, *SPINT2*, *DCXR*, *DAO*, *MMP14*, *LRRC1*, *UBE2T*, *COL1A1*, *DHTKD1*, *STK39*, *PEMT*, *EHHADH*, *TMED3*, and *DDR1* (Figure 4C and D). After the intersection of the genes determined by the above three results, the best disease characteristic gene was obtained: *MMP14* (Figure 4E).

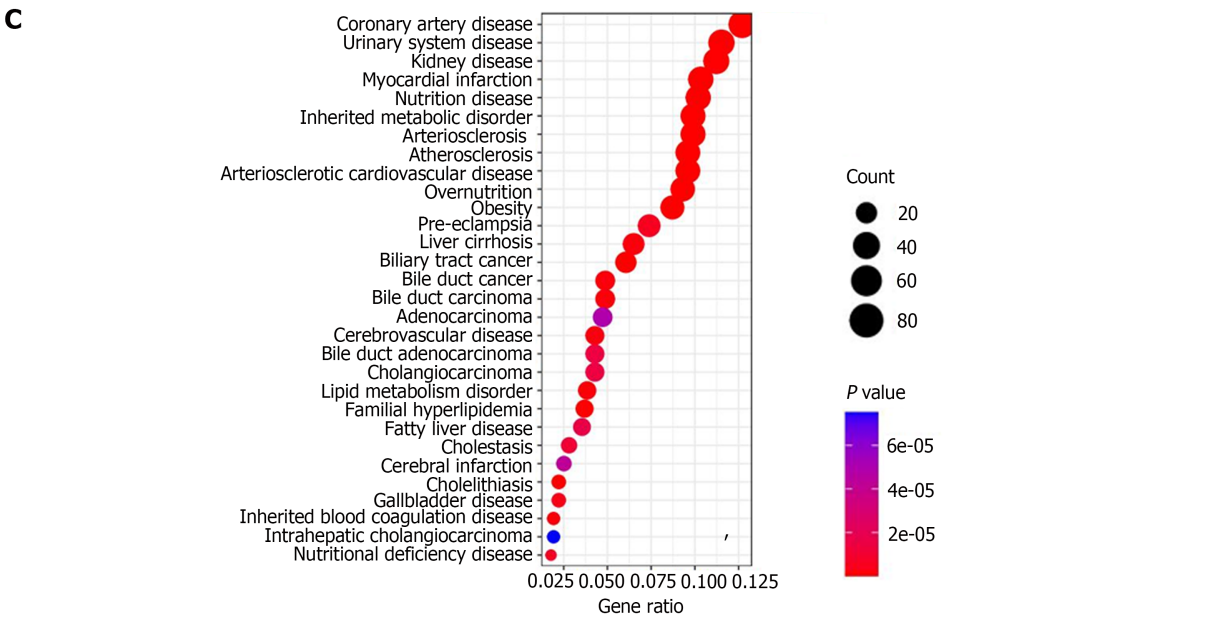
Feasibility analysis of disease characteristic genes as ICC diagnostic markers



Previous studies had shown that *MMP14* was highly expressed in cancer tissues of ICC patients in the training group, so it was important to clarify its expression in two independent verification groups before evaluating the accuracy of this gene as a disease signature gene. In the GSE107943 dataset, the expression of MMP14 in ICC cancer tissues was apparently higher than that in paracancer tissue (Figure 5A). The same result was obtained by external database verification of *MMP14* in the TCGA database (Figure 5B). ROC curves were drawn for the training and validation groups, which showed that in the training group, AUC was 0.960 (95%CI: 0.932-0.983) (Figure 5C). In the GSE107943 verification group, AUC was 0.999 (95%CI: 0.993-1.000) (Figure 5D), and in the TCGA verification group, AUC was 0.977 (95%CI: 0.924-1.000) (Figure 5E). AUC in the verification group was higher than in the training group, and AUC values were all > 0.9. This showed that *MMP14* had good diagnostic efficiency and could be used as a characteristic gene of ICC, which provided a new reference marker for the selection of gene targets for diagnosis of ICC.



Immune cell infiltration in ICC



To explore the infiltration of immune cells in the immune microenvironment of ICC, the proportion of 22 types of immune cells in each sample of ICC cancer and paracancerousl tissues was clarified (Figure 6A). The positive correlation between resting dendritic cells resting and resting memory CD4 T cells resting was the strongest (r = 0.45), and the negative correlation between mast cells resting and mast cells activated was the strongest (r = 0.40) (Figure 6B). We then analyzed the infiltration of immune cells in cancer and paracancerous tissues, and was significant for monocytes, M0 macrophages, activated mast cells, and eosinophils. Compared with paracancerous tissues, expression of M0 macrophages in tumor tissues was greatly higher (P = 0.040), while expression of monocytes (P = 0.002) and activated mast cells (P = 0.037) was significantly lower in tumor tissues (Figure 6C).

Correlation analysis of ICC disease signature genes and immune infiltration patterns

There were differences in the distribution of immune infiltrating cells between ICC cancer tissues and paracancerous tissues. To analyze its potential regulatory factors, we explored the correlation between ICC disease signature genes and immune microenvironment. CIBERSORT algorithm analysis showed that among the immune cells, *MMP14* was significantly correlated with the number of seven types of

immune cells. Expression of MMP14 was positively related with M0 macrophages M0 (r = 0.40, P = 0.0023), activated dendritic cells (r = 0.32, P = 0.0180) and follicular helper T cells (r = 0.29, P = 0.0300) (Figure 7A-C), and negatively related with activated memory CD4 T cells (r = -0.33, P = 0.0130), monocytes (r = -0.32, P = 0.0190), M1 macrophages (r = -0.28, P = 0.0420) and resting memory CD4 T cells (r = -0.27, P = 0.0440) (Figure 7D-G). The final results of *MMP14* and immune cell infiltration based on the above CIBERSORT algorithm are summarized (Figure 8A). ssGSEA algorithm analysis showed that there was a significant correlation between *MMP14* and the number of four types of immune cells and 28 types of immune cells. It was significantly negatively correlated with the number of neutrophils, monocytes, central memory CD8 T cells and central memory CD4 T cells (Figure 8B). *MMP14* was positively correlated with the expression of *CD200*, *CD40*, *CD44*, *CD70*, *CTLA4*, *HHLA2*, *LGALS9*, *TNFRSF14*, *TNFRSF18*, *TNFRSF25*, *TNFSF4* and *TNFSF9*. However, it was negatively correlated with the expression of *CD14*, *CD160*, *TMIGD2*, and *TNFSF14* (Figure 8C). In summary, *MMP14* regulates the composition of immune infiltrating cells in the tumor microenvironment of ICC and may affect the efficacy of immunotherapy by mediating the expression of immune cell surface markers.

Expression of disease characteristic genes in ICC

HPA database analysis showed that expression of MMP14 protein in ICC cancer tissue was higher than that in paracancerous tissue (Figure 9). It was consistent with the trend in mRNA expression levels in the training and verification groups, which confirmed that *MMP14* could be used as a disease characteristic diagnostic gene of ICC.

DISCUSSION

Although there has been some improvement in the treatment of ICC in recent years, the disease control rate is still low[14]. There is no definite marker for early diagnosis of ICC[15]. Individualized treatment has not yet achieved satisfactory results in ICC patients[16]. At present, immunotherapy is a research hot spot in the field of cancer treatment worldwide, and it has widespread prospects for treatment of cholangiocarcinoma[17]. Therefore, the present study focused on discovering new diagnostic markers and improving immunotherapy and determining synergistic therapeutic targets for ICC. Recently, similar ideas have been developed in the research of a variety of tumors and other diseases. More researchers have begun to identify new disease signature genes and explore their potential links with immune cell infiltration. For example, in chronic obstructive pulmonary disease (COPD), STAU1 and SLC27A3 are considered to be important diagnostic biomarkers. The pathogenesis of COPD is largely affected by the pattern of immune cell infiltration. It has been confirmed that STAU1 and SLC27A3 are important factors in regulating the content of plasma cells, resting NK cells, CD8 T cells, and other immune cells[18]. Studies have pointed out that LTBP2 is a highly effective biomarker for prostate cancer, which may inhibit the proliferation and metastasis of prostate cancer through the PI3K/AKT

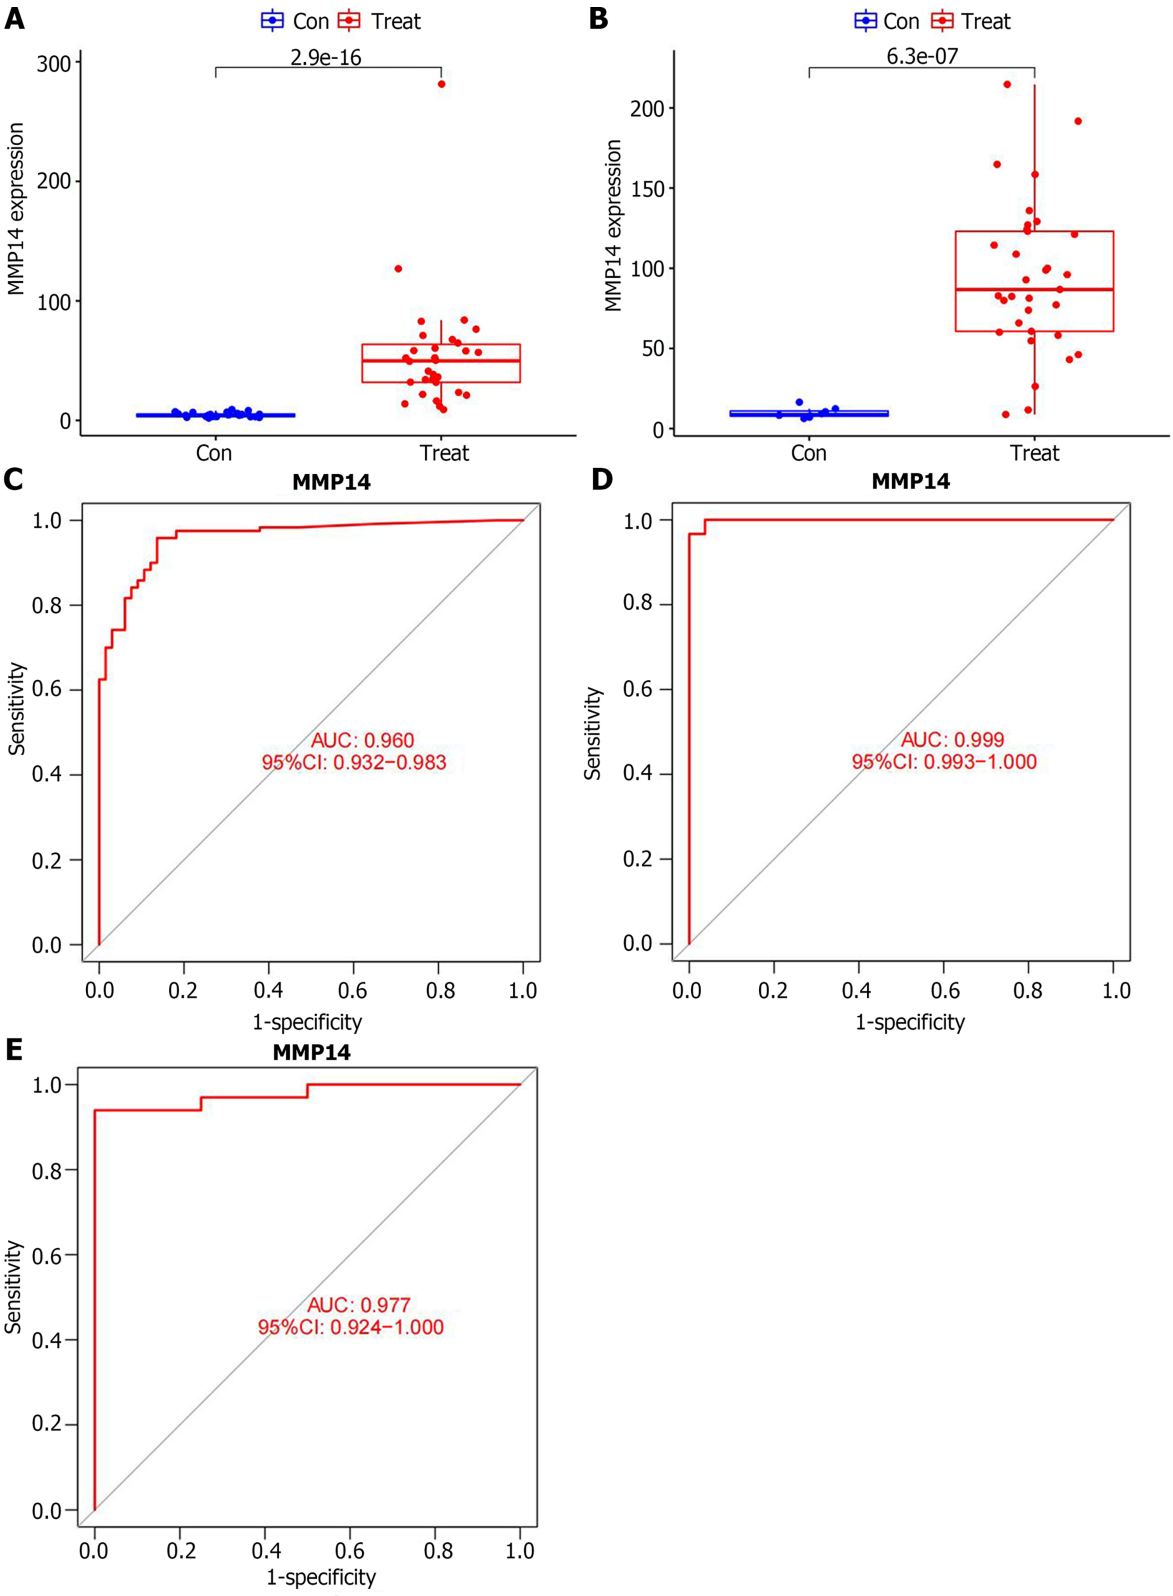
signaling pathway, and is related to CD4 T-cell infiltration and the response to anti-PD-1/PD-L1 immunotherapy[19]. However, for ICC with poor prognosis, there have been few studies on potential diagnostic markers and their correlation with immune cell infiltration. Therefore, we hope to find diagnostic biomarkers for ICC and investigate their relationship with immune cell infiltration.



The present study was a series of retrospective studies based on the gene expression matrix of ICC patients in the GEO and TCGA databases, looking for new diagnostic genes for ICC and analyzing the significance of immune cell infiltration. The results obtained are consistent with previous studies that complex metabolic changes occurred in the entire process of cholangiocarcinoma development, and metabolic reprogramming mechanisms such as glucose metabolism, amino acid metabolism, and lipid metabolism all mediate tumor proliferation and invasion are involved[20]. Mechanisms such as ECM-receptor interaction, cell cycle disorder, and stem cell self-renewal have also been confirmed to affect the development of ICC, which is consistent with our enrichment analysis[21-23]. To accurately screen for disease characteristic genes, we used LASSO regression, SVM-RFE, and RF learning algorithms for joint analysis. After the joint verification of another data set in the GEO and TCGA databases, we identified *MMP14* as having high diagnostic accuracy for ICC.

The MMP family are proteolytic enzymes closely related to angiogenesis and tumor progression. MMP14 was the first transmembrane protein found in the family[24]. Previous studies have indicated that MMP14 plays a key role in the malignant transformation of liver cancer, pancreatic cancer, colorectal cancer and other tumors[25-28]. In primary liver cancer, the expression of MMP14 in cancer tissues is significantly higher than that in paracancerous tissues. The expression level of MMP14 is positively correlated with tumor size, Edmondson-Steiner grade and α-fetoprotein level, and mediates the poor prognosis of patients with primary liver cancer[29]. In renal cell carcinoma, MMP14, as a member of the circPTCH1/miR-485-5p/MMP14 endogenous competitive network, participates in promoting metastasis and activating epithelial-mesenchymal transformation of renal cell carcinoma

[30]. Direct degradation of ECM or indirect activation of MMP2 is also the main way for MMP14 to promote the invasion and metastasis of many types of tumors[31,32]. Ragusa and colleagues found that, in a chemotherapy-resistant, aggressive, matrix-rich colorectal cancer subtype, fluctuations in tumor

signals triggered a decrease in PROX1 Levels and upregulation of MMP14 through the WNT and Notch pathways, which promoted a series of adverse tumor microenvironmental changes, including activation of fibroblasts, vascular dysfunction, and inability of cytotoxic T cells to enter the tumor[33]. It can be seen that, as a clear tumor-promoting factor, MMP14 is a key regulator in the tumor microenvironment, tumor immune infiltration and tumorigenesis, but its effect on disease diagnosis and tumor immune microenvironment in ICC has not been reported, so our research is important.

Tumor microenvironment plays an important role in the occurrence, development and prognosis of tumor. As an important part of tumor microenvironment, immune cells are involved in the prognosis of the disease and guidance of clinical treatment[34-36]. We calculated the profiles of immune cell infiltration in ICC cancer and paracancerous tissues, and elucidated ICC-associated immune cell subtypes and their potential relationships. Compared with paracancerous tissues, the infiltration of M0 macrophages in ICC tissues was significantly increased, while the proportion of monocytes and mast cells activated was significantly decreased. The correlation analysis between MMP14 and immune cells showed that it was positively correlated with M0 macrophages, activated dendritic cells and follicular helper T cells, and negatively correlated with activated memory CD4 T cells, monocytes, M1 macrophages and resting memory CD4 T cells. The ssGSEA algorithm showed that MMP14 was closely related to the degree of immune cell infiltration, and the number of central memory CD8 T cells, neutrophils, monocytes and central memory CD4 T cells decreased significantly in ICC patients with high expression of MMP14. We found that MMP14 was positively correlated with expression of 12 molecules, including CTLA4 and CD40, and negatively correlated with expressions of four molecules, including CD14 and CD160. Differential regulatory mechanisms of the tumor microenvironment in ICC patients may help explain individual differences in immunotherapy. The expression of MMP14 was negatively regulated by the distribution of monocytes and CD4 T cells in the analysis of CIBERSORT and ssGSEA algorithms. Coincidentally, in the correlation analysis with immune checkpoints, we found that MMP14 was related to the expression of many important molecules, such as monocyte surface marker CD14 and transmembrane receptor CTLA4 on T cells. As an important part of effective antitumor immunity, CD4 T cells can directly eliminate tumor cells through cytolytic mechanisms, or indirectly target tumor cells by regulating the tumor microenvironment to kill tumor cells[37]. Different subpopulations of monocytes perform exclusive functions for tumor promotion or antitumor immunity [38]. It has been reported that CD14 and CD16 monocyte subsets can induce cancer cell death through antibody-dependent cytotoxicity[24,39]. Therefore, we have the reason to speculate that MMP14 may accelerate the progression of ICC by interfering with the abundance of monocytes and CD4 T cells.

In our study, we found new ICC characteristic gene, *MMP14*, and clarified that it might influence the infiltration pattern of immune cells in complex tumor microenvironments. It could be helpful for the clinical diagnosis and immunotherapy of ICC, and provides new ideas for the future study of the occurrence and molecular mechanism of ICC.

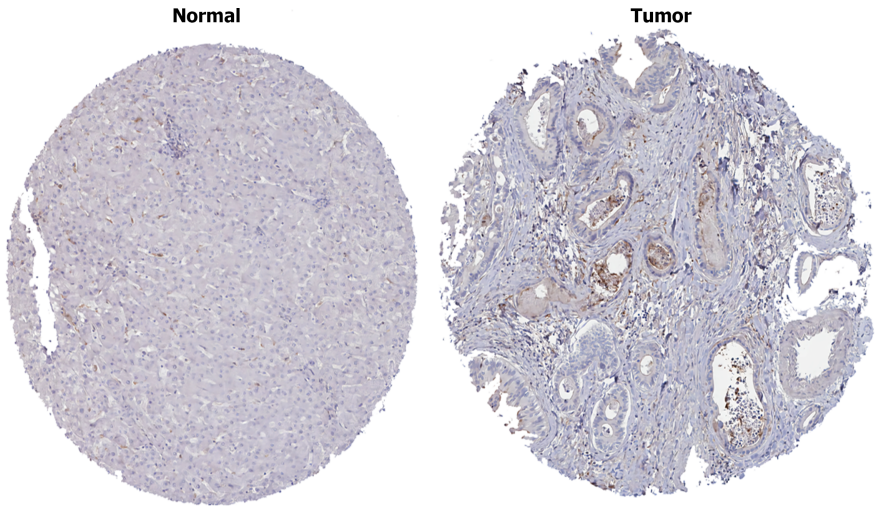
However, our research still had some limitations. Firstly, all data came from public databases, which could have led to inevitable errors or biases. Secondly, the expression and specific function of disease characteristic genes need to be verified by further experiments. Although bioinformatics and machine learning have been used to evaluate the diagnostic efficacy of ICC feature genes and their relationship with immune infiltration, a larger prospective study is needed to confirm our conclusions.



CONCLUSION

Here we investigated new candidate molecular markers that are important for the diagnosis of ICC, which was related to a variety of immune cell components and participated in the occurrence and development of ICC. The findings may have a beneficial impact on the diagnosis of ICC and the provision of precise immunotherapy in future clinical work.

Figure 9 Human Protein Atlas analysis of MMP14 protein expression levels in intrahepatic cholangiocarcinoma cancer and paracancerous tissues.

ARTICLE HIGHLIGHTS

Research background

Intrahepatic cholangiocarcinoma (ICC) has a high mortality rate. Its early diagnosis is very important.

Research motivation

At present, there are no diagnostic markers of ICC, and most patients are in the middle and late stage when the tumors are found, and the treatment options for these patients are limited, resulting in a poor prognosis.

Research objectives

It is urgent to find new biomarkers for early screening and diagnosis of ICC.

Research methods

Bioinformatics analysis and machine learning algorithm were used to screen for ICC disease characteristic genes, and the diagnostic performance of characteristic gene *MMP14* was verified by different databases. The relationship between different immune cell infiltration in MMP14 and ICC tumor microenvironment was analyzed.

Research results

We discovered for the first time a new gene *MMP14* for the diagnosis of ICC. We further analyzed the expression of *MMP14* and its significance in immune cell infiltration in ICC tumor microenvironment, indicating that *MMP14* is closely related to a variety of immune cell infiltration, which may provide a new direction for immune-related research.

Research conclusions

In this study, we found that *MMP14* can be used as a disease characteristic gene for ICC diagnosis using a variety of machine learning algorithms. There is a relationship between different immune cell infiltration in *MMP14* and ICC tumor microenvironment, which plays an important role in the occurrence and development of tumor. *MMP14* may be a potential target for ICC immunotherapy.

Research perspectives

Based on bioinformatics analysis and machine learning algorithm, *MMP14* was identified as the characteristic gene of ICC and was associated with ICC immune cell infiltration. In the future research, it will be of great significance to explore the signal pathway mediated by *MMP14* in the occurrence and development of ICC and the mechanism of immune cell infiltration.

FOOTNOTES

Author contributions: Han L conceived and directed the entire study, and should be regarded as corresponding author; Wu J and Guo Y designed the study and prepared the manuscript; Zuo ZF defined the intellectual content of the study and participated in the literature research; Wu J, Guo Y, and Zuo ZF contributed equally to this study; Zhu ZW conducted data analysis; Han L and Wu J revised the manuscript; and all authors approved to submit the manuscript.

Institutional review board statement: This study is not involved any human and animal.

Conflict-of-interest statement: The authors declare no conflict of interest.

Data sharing statement: The bioinformatic data could be downloaded from the public databases, and no additional data are available.

Abstract

BACKGROUND

Low anterior resection syndrome (LARS) severely impairs patient postoperative quality of life, especially major LARS. However, there are few tools that can accurately predict major LARS in clinical practice.

AIM

To develop a machine learning model using preoperative and intraoperative factors for predicting major LARS following laparoscopic surgery of rectal cancer in Chinese populations.

METHODS

Clinical data and follow-up information of patients who received laparoscopic anterior resection for rectal cancer from two medical centers (one discovery cohort and one external validation cohort) were included in this retrospective study. For the discovery cohort, the machine learning prediction algorithms were developed and internally validated. In the external validation cohort, we evaluated the trained model using various performance metrics. Further, the clinical utility of the model was tested by decision curve analysis.

RESULTS

Overall, 1651 patients were included in the present study. Anastomotic height, neoadjuvant therapy, diverting stoma, body mass index, clinical stage, specimen

length, tumor size, and age were the risk factors associated with major LARS. They were used to construct the machine learning model to predict major LARS. The trained random forest (RF) model performed with an area under the curve of 0.852 and a sensitivity of 0.795 (95%CI: 0.681-0.877), a specificity of 0.758 (95%CI: 0.671-0.828), and Brier score of 0.166 in the external validation set. Compared to the previous preoperative LARS score model, the current model exhibited superior predictive performance in predicting major LARS in our cohort (accuracy of 0.772 for the RF model *vs* 0.355 for the preoperative LARS score model).

CONCLUSION

We developed and validated a robust tool for predicting major LARS. This model could potentially be used in the clinic to identify patients with a high risk of developing major LARS and then improve the quality of life.

Key Words: Machine learning; Low anterior resection syndrome; Rectal cancer; Laparoscopy; Prediction

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: We developed and externally validated a machine learning-based prediction model that integrated preoperative and intraoperative risk factors as input features and showed satisfactory predictive performance in Chinese patients. According to the decision curve analysis, patients with major low anterior resection syndrome (LARS) would have a net benefit superior to "treat all" or "treat none" with a range of threshold probabilities by using the model. This study provides a new tool for predicting major LARS, which can potentially be used for rectal cancer patients to acquire early postoperative consultation and strengthen self-management to improve their quality of life.

INTRODUCTION

With advances in surgical techniques and the introduction of a multidisciplinary approach, the sphincter-saving procedure for rectal cancer has increased[1], with up to 50%-80% of rectal cancer patients undergoing this procedure[2] compared with only 25% before the circular stapling device was widely used[3]. However, low anterior resection syndrome (LARS), a postoperative complication that seriously impairs patient quality of life, has also increased[4,5], and 70%-90% of these patients undergoing sphincter-saving procedures have developed LARS[2]. The majority of LARS may go into remission within a variable interval of 6-18 mo following surgery[6,7]. However, beyond this point further improvements may be impossible, and the complication may become irreversible. It is reported that approximately 40% of patients with major LARS remain 'toilet dependent,' which results in a low quality of life[8,9].

Early management of major LARS, such as conservative drugs, transanal or transtomal irrigation, pelvic floor rehabilitation, biofeedback, and sacral nerve stimulation, can improve LARS symptoms[10-14]. Therefore, it is important to identify the patients who are at a high risk of developing major LARS after surgery. A recent study established a model based on preoperative risk factors to predict a LARS score for improving patient preoperative education and counseling[15]. However, it failed to achieve an accurate prediction when it was applied to other populations[16]. Furthermore, certain intraoperative factors that were previously reported as important contributors to LARS were not included in this aforementioned model[17,18].

Due to better vision and less surgical trauma[19], laparoscopic surgery has improved the post-operative course in the treatment of rectal cancer and was widely applied in China. In theory, laparoscopic surgery ensures minimal surgical trauma and improves postoperative patient recovery as well as functional bowel outcome. However, there is still no tool to predict LARS in Asian patients who receive laparoscopic surgery.

Artificial intelligence (AI) is an innovative modeling technology and has produced promising results; our previous studies have shown that AI algorithms allow for good discrimination of anastomotic leakage and would be helpful in assisting surgeons' decision-making[20,21]. Therefore, the present study aimed to develop a machine learning model based on AI technology using preoperative and

intraoperative factors for predicting major LARS following laparoscopic surgery of rectal cancer in Chinese populations. This model was created to guide early postoperative management of medical intervention and improve patient postoperative consultation and quality of life.

MATERIALS AND METHODS

Data and participants

The present study included a discovery cohort and an external validation cohort. To develop the machine learning model, clinical data of 2120 patients with rectal cancer who received laparoscopic anterior resection in the Department of Gastrointestinal Surgery, Tongji Hospital, Huazhong University of Science and Technology from January 1, 2012 to December 31, 2020 were reviewed and collected. For external validation, data from 289 patients from the Central Hospital of Enshi Tujia and Miao Autonomous Prefecture affiliated to Wuhan University between January 1, 2012 and December 31, 2020 were collected with the same criteria. The present study was performed according to the guidelines of the Declaration of Helsinki and approved by the ethics committees of Tongji Hospital, Huazhong University of Science and Technology and The Central Hospital of Enshi Tujia and Miao Autonomous Prefecture. The requirement for informed consent was waived due to the retrospective nature of the study.

Inclusion and exclusion criteria

The inclusion criteria were as follows: (1) Age ≥ 18; (2) Primary rectal adenocarcinoma located 0-15 cm from the anal verge; and (3) Patients without communication difficulties. The exclusion criteria were as follows: (1) Patients who had their diverting stoma open; (2) Less than 1 year after laparoscopic anterior resection or after stoma reversal; (3) Patients with a history of abnormal bowel function, including drug-induced diarrhea, a chronic history of constipation, irritable bowel syndrome, and a history of pelvic injury; (4) Patients with local recurrence within 1 year after surgery; and (5) Missing data, death, or lost to follow-up.

Candidate variables

In order to develop the early postoperative major LARS prediction model, only the clinical preoperative and intraoperative variables of each patient were included. The variables were as following: age at surgery; sex; body mass index (BMI); hypertension; diabetes; previous abdominal surgery; neoadjuvant therapy; American Society of Anesthesiologists (ASA) classification; tumor size (cm); clinical stages; anastomotic height (cm); diverting stoma; and specimen length (cm). Two authors independently completed the collection and collation of clinical data, and conflicting data were documented and confirmed by a final discussion. Anastomotic height was defined as the distance between anastomosis and anal verge measured using digital rectal examination, computed tomography, or magnetic resonance imaging. Specimen length was defined as the length of the bowel removed during surgery.

Outcome

The Chinese version of the LARS score system was used to evaluate postoperative intestinal function [22], which is described by five questions concerning intestinal function. Each response was weighted and given a score according to the severity of the patient's symptoms. Scores of 0-20 indicated no LARS, 21-29 indicated minor LARS, and 30-42 indicated major LARS. All the participants were followed up by telephone, short message service, and outpatient or inpatient visits using a LARS score questionnaire from November 1, 2021 to May 1, 2022. LARS scores of each participant at 1 year after anterior resection or after stoma reversal were obtained. To highlight major LARS, patients were classified into two groups according to LARS score, one with major LARS and another with no or minor LARS.

Feature selection

Excessive variables could lead to adverse predictions and be inconvenient in an application. The Boruta algorithm can address the minimal optimization problem of multidimensional clinical features in feature selection[23]. Thus, feature selection was conducted using the Boruta algorithm. The algorithm can screen out all the variables associated with the ground truth. The importance of the features was quantified by repeated iterations based on shadow feature creation, and some weakly correlated features were removed. Finally, the selected features, combined with clinical experience, were used as predictors. R software and Boruta packages (7.0.0) were used for feature selection (R version 4.1.2[2021-11-01]).

Sample size

The one-in-ten rule is a generally accepted rule for estimating the minimum sample size[24]. According to at least ten events per variable, at least 325 to 667 patients were required in the discovery cohort for the 13 predictor variables, with an estimated event (major LARS) rate of 30%-50% and a lost follow-up

rate of 20%-35%.

Machine learning algorithms

In the present study, four prevailing machine learning algorithms, including logistic regression (LR), random forest (RF), support vector machine (SVM), and extreme gradient boosting (XGBoost), were employed to develop the predictive models. Machine learning algorithms based on AI can overcome the limitations of traditional linear models by combining clinical nonlinear features. The participants from Tongji Hospital were randomly divided into a training set and a testing set at a ratio of 8:2. To gain high-performance models, hyperparameter adjustment was adopted using a grid search approach. To balance sensitivity and specificity, the optimal Youden index (cutoff value) was calculated *via* maximizing the value of sensitivity + specificity - 1[25]. The area under the curve (AUC) and Brier scores, which represent the discrimination and calibration power of the prediction model, were calculated. The Brier score measures the difference between the predicted probability and the ground truth[26], and a value of the Brier Score closer to 0 indicates a better calibration. In addition, to assess the clinical utility of the prediction model, decision curve analysis was used, which can determine whether patients benefit from using predictive models in clinical practice[27]. All machine learning algorithms were implemented using Python (version 3.9.7) with the scikit-learn (version 0.24.2) package.

Statistical analyses

The continuous variables were presented as mean ± SD and categorical variables as the count (%). A one-way analysis of variance with post hoc contrasts by the student-Newman-Keuls test was used to compare the differences between the continuous variables. For categorical variables, as appropriate, χ^2 or Fisher's exact test was used. All P values were reported as two-tailed, and $P < 0.05$ was considered as statistical significance. 95%CI for the AUC, sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and accuracy of the four models were calculated using IBM SPSS Statistics 20.0 (IBM Corp, Armonk, NY, United States) or Vassar Stats (online tool, http://vassarstats.net/index.html).

RESULTS

Summary of demographic and clinical characteristics for training, testing, and external validation sets

Figure 1 presents the patient flow chart. A total of 1651 eligible cases were included, with 1163 subjects included in the training set, 291 subjects included in the testing set, and another 197 subjects in the external validation set. Comparisons between the training, testing, and external validation sets are presented in Table 1. The mean age of the 1163 patients in the training set was 57.6 years, and 59.7% were males. For the testing and the external validation sets, the mean age was 57.6 and 59.7 years, and 56.0% and 53.8% were males, respectively. Major LARS was observed in 37.2% of patients in the training set, 35.1% in the testing set, and 37.1% in the external validation set.

Risk factors associated with major LARS

The importance of all the included variables calculated by the Boruta algorithm was shown in Figure 2A. Boruta calculates variables that are both strongly and weakly relevant to provide the best prediction accuracy. The blue boxes were shadow features automatically generated by the algorithm and were not included in the analysis. As the data indicated that anastomotic height, neoadjuvant therapy, diverting stoma, BMI, clinical stage, specimen length, tumor size, and age were selected as significantly relevant to major LARS.

Model development in the training set

The LR, RF, SVM and XGBoost algorithms were trained using the eight strongly related variables, and the AUCs, sensitivities, specificities, PPVs, NPVs, and accuracies were calculated (Figure 2B and C). The RF model exhibited optimal diagnostic performance (AUC = 0.869), and the optimal cutoff was 0.406. Therefore, the RF model was used for subsequent analysis. The details of the predictions generated by the RF model using the optimal threshold were shown in Figure 2D. Additionally, the predicted probabilities for major LARS were significantly relevant to the ground truth in the training set ($P < 0.001$) (Figure 2E).

Performance of the RF model in the testing set

We tested the performance of the RF model in the testing set. The results demonstrated that the RF model performed with a favorable discrimination ability (AUC = 0.870, 95%CI: 0.833-0.901) (Figure 3A). The details of the predicted outcomes were presented in Figure 3B. Subsequently, the comparison of the predicted probabilities between the major LARS and no/minor LARS groups was conducted, and significant differences were observed (Figure 3C). Furthermore, a decision curve was plotted to evaluate

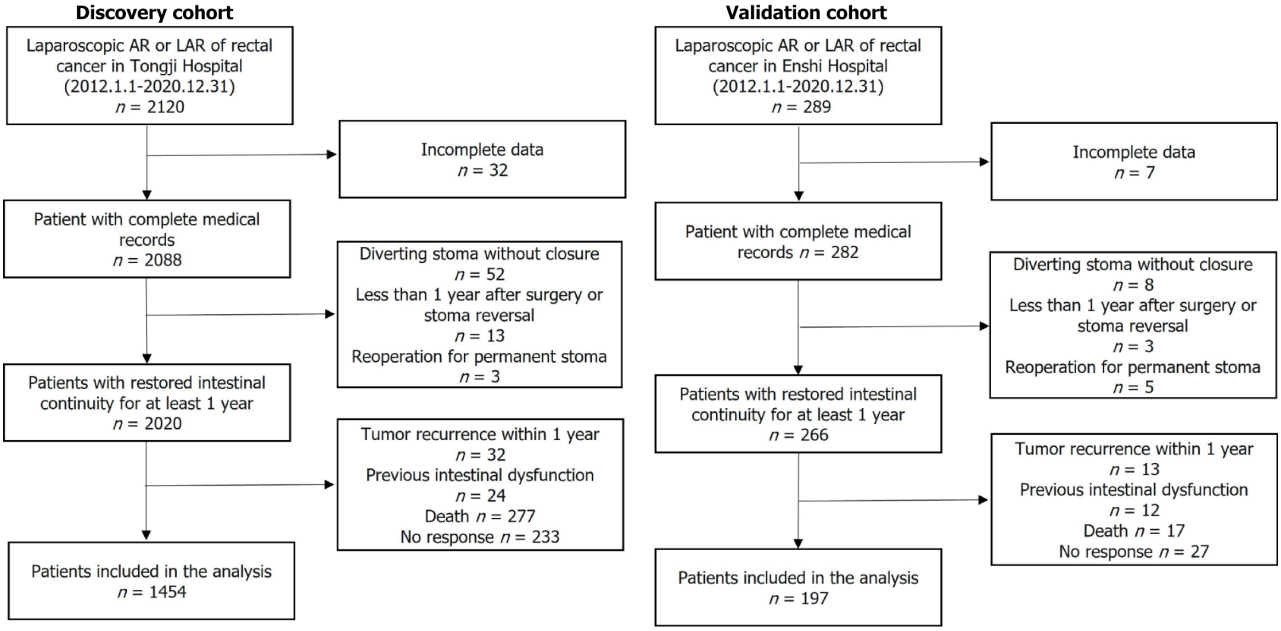
whether using the RF model in the clinic would do better than harm[28]. According to the decision curve analysis, patients with major LARS would have a net benefit superior to "treat all" or "treat none" with a range of threshold probability in approximately 20%-75% (Figure 3D).

External validation of the RF model

To assess the generalization capability of the RF model, an external validation based on 197 patients from another independent center was performed. The RF model identified patients with major LARS with an AUC of 0.852 (95%CI: 0.820-0.890) (Figure 4A). The confusion matrix presented the classification results generated by the RF model for identifying major LARS in the external validation set (Figure 4B). Figure 4C showed that the probabilities generated by the RF model for major LARS were significantly higher than those of no/minor LARS, suggesting that the predicted probabilities were significantly associated with the ground truth in the external validation set. Decision curve analysis also showed that patients would derive clinical benefits in a range of threshold probabilities (Figure 4D).



Evaluation of the prediction model

To assess the performance and calibration degree of the RF model in both the testing set and the external validation set, six performance metrics such as sensitivity, specificity, PPV, NPV, accuracy, and Brier score were applied. Their results calculated based on the optimal Youden index (cutoff) were summarized in Table 2. These results suggested that the RF model was determined to be capable and reliable in predicting major LARS, with satisfactory Brier score of 0.152 and 0.166 and accuracy of 0.787 and 0.772, in both the testing set and the external validation set, respectively. In addition, to highlight the advantages of the RF model, the sensitivity, specificity, PPV, NPV, and accuracy of the preoperative LARS score (POLARS) model were calculated in both our testing set and external validation set. Taken

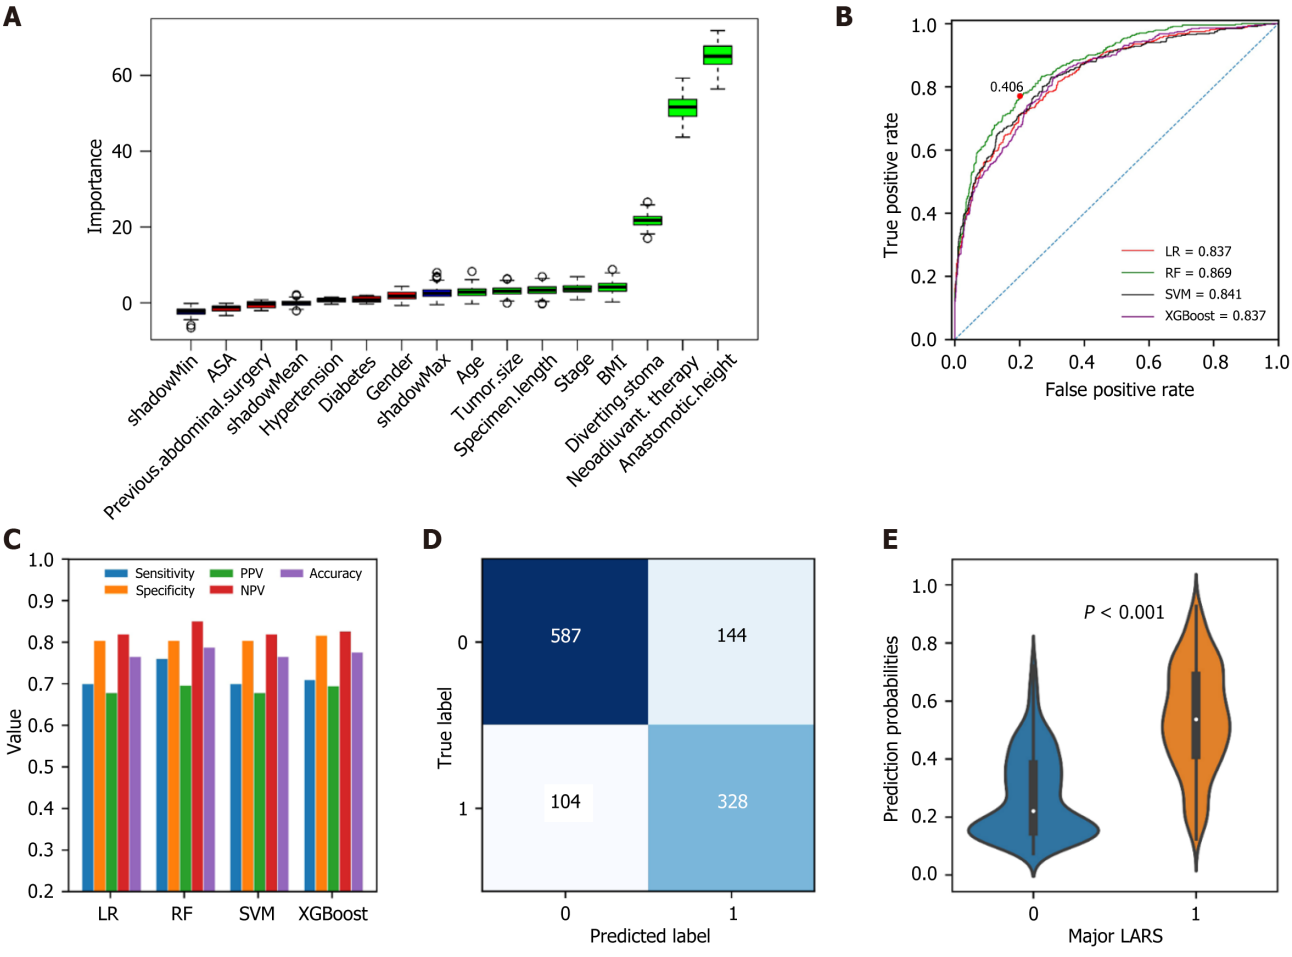
together, these values demonstrated that the performance of the RF model surpassed that of the POLARS score model, as shown in Table 3.

DISCUSSION



LARS is the most common complication following rectal cancer surgery. It is a severe complication and seriously impairs patient quality of life[1]. A meta-analysis based on 11 studies indicated that the morbidity of major LARS was as high as 41% (95%CI: 34-48)[5]. Fortunately, surgeons are now paying more and more attention to the functional consequences of cancer treatment and the quality of life[1,4]. LARS is a time-dependent syndrome, and the symptoms of some patients with LARS are relieved partly or completely 1 year or more after surgery. However, the symptoms in approximately 40% of patients remain stable and cannot be further improved[6,9,29].

Due to the variable symptom spectrum of LARS, ranging from incontinence for gas and liquid fecal matter to evacuation dysfunctions, the complex etiology, and unknown pathophysiology, there is no standard treatment available at present[30]. However, if patients with a high-risk major LARS can be treated with a conservative method (*e.g.*, pelvic floor rehabilitation, transanal irrigation), minimally invasive therapies (*e.g.*, biofeedback therapy, sacral nerve stimulation), or multimodal treatments during the period of the first year after surgery, their intestinal dysfunction may be significantly improved[9].

Table 3 Performance of the preoperative low anterior resection syndrome score model in the testing and external validation sets

Indicators (95%CI)	Testing set, *n* = 291	*P* value	Validation set, *n* = 197	*P* value
Sensitivity	0.931 (0.859-0.970)	0.046	0.836 (0.727-0.909)	0.522

Figure 2 Variable selection using the Boruta algorithm and overview of development of the models in the training set. A: The importance of all variables. The red boxes indicated the variables weakly relevant to major low anterior resection syndrome (LARS). The blue boxes were random variables automatically generated by the algorithm and were not included in the analysis. The green boxes indicated the variables strongly relevant to major LARS; B: Receiver operating characteristic curves of the four machine learning models in the training set. The red dot denotes the optimal Youden index for the random forest (RF) model; C: Performance measurements of the four machine learning models illustrated by sensitivity, specificity, positive predictive value, negative predictive value and accuracy; D: Confusion matrix of the optimization RF model; E: Comparison of predicted probabilities calculated by the RF model in patients with and without major LARS in the training set. ASA: American Society of Anesthesiologists classification; BMI: Body mass index; LR: Logistic regression; LARS: Low anterior resection syndrome; RF: Random forest; SVM: Support vector machine; XGBoost: Extreme gradient boosting; PPV: Positive predictive value; NPV: Negative predictive value.

Consequently, the negative impact of LARS on their quality of life could be minimized. In addition, since major LARS may counteract the relative benefits of anal sphincter-preserving surgery, the accurate prediction of major LARS may be helpful for patients and surgeons when deciding on temporary ileostomy, permanent colostomy, or sphincter-preserving surgery for low rectal cancer[31-33]. Therefore, it is crucial to perform risk stratification of rectal surgery cases to identify patients with a high risk of major LARS and to highlight patients who may require additional postoperative support.

Battersby *et al*[15] developed and validated the POLARS score for restorative sphincter-sparing surgery for rectal cancer to predict intestinal dysfunction. The POLARS score includes six risk factors, such as age at surgery, sex, tumor height, preoperative radiotherapy, total/partial mesorectal excision, and the presence of stoma, as predictors. The model performs with moderate discriminative accuracy with Harrell's C statistic of 0.615 and 0.625 in their two datasets. Essangri *et al*[16] reported that the POLARS score was questionable, and it failed to successfully validate the model in another population. This previous study implied that the model predictions may be dependent on patient background, including treatment strategies and physical, lifestyle, and dietary habit differences. In the present study, all participants were Chinese and underwent laparoscopic sphincter-sparing surgery for rectal cancer without splenic flexure mobilization. Several previous studies have pointed out that routine splenic flexure mobilization is not necessary for anterior resection of rectal cancer[34-36]. Instead, no splenic flexure mobilization would result in a shorter operation time and lower morbidity of postoperative complications associated with intestinal function, such as anastomotic leakage[37]. Moreover, to date, there is no machine learning model for predicting major LARS in Asian patients undergoing laparoscopic anterior resection based on a multicenter study.

In the present study, four machine learning algorithms were used to develop the machine learning model for major LARS prediction. These data suggested that the RF model performed with an optimal AUC in the training set. As expected, the RF model also achieved favorable predictions when it was tested in the testing and external validation sets. To the best of our knowledge, this is the first multicentric study to develop a machine-learning model for predicting major LARS in Asian patients undergoing laparoscopic anterior resection of rectal cancer. More importantly, the model performed with a satisfactory prediction in an independent medical center (AUC = 0.852; 95%CI: 0.820-0.890). Moreover, compared with the POLARS score, the RF model achieved superior performance in predicting major LARS in our cohort (accuracy of 0.772 for the RF model *vs* 0.355 for the POLARS score). In addition, the decision curve analysis demonstrated the net benefit (benefit minus risk) by using the model for patients diagnosed with major LARS within a range of threshold probabilities.

Although the explicit pathophysiological mechanism of LARS is still unclear, numerous studies[38-40] agree that intestinal dysfunction in patients with rectal cancer who received restorative sphincter-

AUC: Area under the curve; LARS: Low anterior resection syndrome; RF: Random forest.

sparing surgery is the result of a combination of multiple pathophysiological mechanisms. These include loss of rectal storage function, autonomic denervation, enhanced colonic movement, rectal-anus sensitivity reduction, anal resting pressure reduction, and diverting colitis[38]. Certain factors directly or indirectly related to these pathophysiological changes have been reported as important variables associated with LARS, such as low anastomosis, neoadjuvant therapy, postoperative chemoradiotherapy, anastomotic leakage, diverting stoma, and the time interval from the creation of diverting stoma to closure[5,18,41,42]. In order to identify major LARS in the early postoperative period, some postoperative factors were not included, such as chemoradiotherapy and the time interval from creating diverting stoma to its closure. Among the included factors, low anastomosis and neoadjuvant therapy have been unanimously considered as important predictors for major LARS[5,43]. For example, Filips *et al*[44] reported that LARS was negatively correlated with the distance from anastomosis to the anal verge (OR: -1.145, 95%CI: -2.149 to -1.141, P = 0.026). In the present study, our data also indicated that the anastomotic height was the most important factor in the development of major LARS. In addition, the specimen length was selected as a predictor for major LARS in the present study, and it may be caused by greater surgical trauma.

As with any retrospective observational study, the present study had some uncontrollable limitations. First, the model is based on the Chinese population and does not necessarily reflect the worldwide target population. Its generalizability needs to be further tested. Second, the influence of a patient's socioeconomic and cultural background, self-management ability, and social support are difficult to control. Third, the data reflecting anal sphincter injury and its severity during surgery cannot be evaluated. Finally, the LARS score may be affected by a variety of biases, such as patient selective memory, exaggeration, or understatement. To overcome these limitations, a prospective study is proposed to assess the predictive ability of the model.

CONCLUSION

In the present study, a machine learning model based on preoperative and intraoperative risk factors for

predicting LARS was developed. The model may be helpful for clinical medical staff to identify patients at an early stage with a high risk of developing major LARS within 1 year following laparoscopic surgery for rectal cancer. Moreover, it can potentially be used for patients to acquire early postoperative consultation and strengthen self-management to improve patient quality of life.

ARTICLE HIGHLIGHTS

Research background

Low anterior resection syndrome (LARS) severely impairs patient postoperative quality of life, especially major LARS. However, there are few tools that can accurately predict major LARS in clinical practice.

Research motivation

To stratify patients with LARS and predict patients at high risk of developing major LARS, improve patient counseling, and highlight patients who may need additional support after surgery.

Research objectives

The study aimed to identify the risk factors associated with major LARS and develop a prediction model that helps improve patient counseling and highlight patients who may need additional support after surgery.

Research methods

Clinical data and follow-up information of patients from two medical centers (one discovery cohort and one external validation cohort) were analyzed to identify independent factors associated with major LARS. For the discovery cohort, the machine learning prediction algorithms were developed and internally validated. In the external validation cohort, we evaluated the trained model using various performance metrics. Further, the clinical utility of the model was tested by decision curve analysis.

Research results

Eight factors, such as anastomotic height, neoadjuvant therapy, diverting stoma, body mass index, clinical stage, specimen length, tumor size, and age, were selected as significantly relevant to major LARS. A machine learning-based prediction model that integrated eight risk factors as input features was developed, externally validated, and demonstrated an acceptable predictive performance.

Research conclusions

We have developed and validated a robust tool for predicting major LARS. This model could potentially be used in the clinic to identify patients with a high risk of developing major LARS and then improve their quality of life.

Research perspectives

A prospective study including more medical centers is proposed to assess the model's predictive ability.

ACKNOWLEDGEMENTS

I would like to thank all the medical staff of the Department of Gastrointestinal Surgery in Tongji Hospital and Enshi Central Hospital for providing convenient conditions for implementing this study.

Abstract

BACKGROUND

Since Heald proposed the total mesorectal excision (TME) procedure, the prognosis of patients with rectal cancer has been significantly improved. But Heald did not specifically describe the anterior surgical plane in female patients.

And the surgical plane for mobilizing the anterior rectal wall during TME surgery in female patients remains controversial.

AIM

To investigate the anatomy of the female pelvis and identify the optimal plane for mobilizing the anterior rectal wall.

METHODS

We retrospectively collected surgical procedure videos and clinical data of female patients diagnosed with middle or low rectal cancer who underwent the TME procedure between January 2020 and October 2022 across six hospitals. The patients were divided into two groups based on the surgical approach used to mobilize the anterior rectal wall: The experimental group was to open the peritoneum at the lowest point of the peritonea reflection and enter the plane for mobilizing, while the control group was cut at 0.5-1 cm above the peritoneal reflection and enter another plan. Then, we compared the preoperative and postoperative information between the two groups. We also dissected and observed ten adult female pelvises to analyze the anatomic structure and compare the entry plane between the two approaches. Finally, we researched the pathological structure between the rectum and the vagina.

RESULTS

Finally, 77 cases that met the criteria were included in our study. Our observations revealed that the experimental group underwent a smooth procedure, entering the plane amidst the mesorectal fascia and adventitia of the vagina, whereas the control group entered the plane between the vaginal adventitia and muscle layers. Compared to the control group, the experimental group showed a significant decrease in intraoperative bleeding [22.5 (19.5-50) mL *vs* 17 (5-20) mL, P = 0.01], as well as a shorter duration of hospitalization [9 (7-11.25) d *vs* 7 (6-10) d, P = 0.03]. Through the examination of surgical videos and cadaveric studies, we discovered that Denonvilliers' fascia is absent in females. Additionally, pathological sections further revealed the absence of Denonvilliers' fascia in females, with only loose connective tissue present between the mesorectal fascia and adventitia of the vagina.

CONCLUSION

The plane amidst the mesorectal fascia and vaginal adventitia is the optimal surgical plane to mobilize the anterior rectal wall for female patients undergoing the TME procedure.

Core Tip: In combination with the macroscopic and microscopic perspectives, we discovered that liberating the anterior rectal wall within a certain plane not only guarantees negative perirectal margins but also mitigates the potential for hemorrhage. This plane, situated amidst the mesorectal fascia and vaginal adventitia, proves to be the most advantageous approach for female patients undergoing total mesorectal excision.

INTRODUCTION

In 1982, Heald proposed the total mesorectal excision (TME) procedure[1], which significantly improved the prognosis of patients with rectal cancer[2]. The local recurrence of rectal cancer in 5 years decreased from 25% to 5%, as compared to the traditional operation plus radiotherapy group in the TME operation group[3]. TME soon became a classical operation method and was widely accepted by colorectal surgeons. Heald subsequently described the bloodless planes of TME surgery, known as the "holy plane," as follows: “If we cut straight on to the vesicles we find an essentially bloodless plane between

them and the fascia of Denonvilliers and we can proceed down the enemy to this until it comes forward to become somewhat should come to the state, when we must cut through it to liberate the lower third of the correction enemy"[4].

Professor Heald believes that in male patients, the anterior plane of TME should be anterior to Denonvilliers' fascia, and the anterior aspect of the specimen should include the complete Denonvilliers' fascia and peritoneal folds[3]. However, he did not specifically describe the anterior surgical plane in female patients[1], and the presence of Denonvilliers' fascia in females (rectovaginal septum[5]) remains controversial[6,7]. We also haven't found any research describing the plane of TME for female patients when the front rectal wall performs mobilization till now[8-10]. Many colorectal surgeons struggle to find an ideal plane for mobilizing the anterior rectal wall during TME, which can result in intraoperative bleeding or vaginal damage.

Therefore, we conducted this study to explore the optimal plane to mobilize the anterior rectal wall in female patients. We retrospectively analyzed rectal cancer surgery videos collected from different medical centers and studied the anatomy of the female pelvis for the accurate determination of the optimal plane to mobilize the anterior rectal wall in female patients with rectal cancer.

MATERIALS AND METHODS

Clinical data and video review

We retrospectively collected clinical data and surgical videos from six hospitals between January 2020 and October 2022. The surgeries were performed by experienced colorectal surgeons, each of whom performed more than 100 colorectal cancer operations annually. Our study initially included female patients with middle or low rectal cancer who underwent laparoscopic TME. Patients who had preoperative magnetic resonance imaging assessment indicating invasion of the anterior rectal wall, a history of rectal surgery, absence of surgical videos or relevant clinical data, and the presence of distant metastases were excluded. And they were divided into two groups based on the surgical approaches used. In the experimental group, the peritoneum was incised at the lowest point of peritoneal reflection to access the mobilization plane, while in the control group, the peritoneum was incised 0.5-1 cm above the peritoneal reflection, accessing a different plane. The surgical procedures were reviewed by two experienced colorectal surgeons separately.

The patient's pre- and postoperative data were obtained from medical records, while intraoperative bleeding was measured as the total amount of blood loss recorded in surgical records. Postoperative complications were classified into postoperative bleeding, anastomotic leakage, and other complications (such as pleural effusion, fever, *etc.*). Anastomotic leakage was defined as a communication between the intra- and extraluminal compartments due to a defect in the integrity of the intestinal wall at the anastomosis between the colon and rectum or colon and anus[11], diagnosis through computed tomography (CT) imaging. Pleural effusion was confirmed through CT imaging to establish the diagnosis. Complications were graded by the Clavien-Dindo classification[12].

Cadaver specimens

Ten female cadavers were dissected in the anatomy laboratory of Wenzhou Medical University, which had been donated to the Department of Anatomy following ethical guidelines. The cadavers underwent arterial perfusion with 8% formalin and preservation with 30% alcohol. The corpses were well-preserved, without tissue decay and structural damage. All female cadavers were sourced from young adult females without a history of pelvic diseases. After separating the pelvis from the body, the pelvises were cut in the midsagittal position to expose the rectum and vagina. The pelvises were divided into two to show the rectum and vagina. After clearly exposing the rectal and vaginal structures, a skilled colorectal surgeon and anatomist performed the subsequent operations in accordance with the two different operation procedures of TME, on the same pelvis. At first, the peritoneum was cut at the lowest point of peritoneal reflection and entered the plane to mobilize as the procedure of the experimental group. Then, the surgeon incised the peritoneum at approximately 0.5–1 cm above the peritoneal reflection and started the separation as the procedure of the control group. Photos and records were taken during the dissection.

Pathological histochemistry

A pathologist participated in and supervised the pathological research. We separated the rectovaginal tissue from the other half of the complete pelvis and preserved it in 8% formalin. Then, the remaining tissue was used for pathology and immunohistochemistry analysis. Sections were stained with hematoxylin-eosin and observed under an electron microscope with a magnification of ten times. Microscopic examination of the rectal and vaginal structures enabled us to determine the presence of Denonvilliers' fascia. Immunohistochemical and pathological studies were completed by the Pathology Department of Wenzhou Medical University.

Stastical analysis

IBM SPSS Statistics 25 software was used for the analysis of clinical data, Two-sided $P < 0.05$ indicated significance. Continuous variables with normal distribution were summarized as mean (SD) and two independent samples *t*-test was used for the statistics. For continuous variables with non-normal distribution were summarized as median (IQR) and Mann-Whitney U test were used for the statistics. Categorical variables were summarized as numbers (percentages) and analyzed using the chi-square test, while the Mann-Whitney U test was used for the Statistics of ordered classification variables. The statistical review of this study was performed by a biomedical statistician.

RESULTS

Video review and clinical data

Seventy-seven patients who met the criteria were included in our study, with 35 in the experimental group and 42 in the control group. There were no significant differences in the general information between the two groups. The patients' general information is summarized in Table 1.

In the experimental group, the peritoneum was cut at the lowest point of the peritoneal reflection to enter the anterior rectal space (as shown in Figure 1), in which the anterior rectal wall can be easily dissociated from the posterior wall of the vagina. The rectum was light yellow due to the light-yellow adipose tissue surrounded by the mesorectal fascia. Blood vessels could be seen in the mesorectum, and the mesorectum was dissected completely. It can be dissociated through blunt separation combined with sharp separation. In this process, the operation field could remain bloodless, and the vaginal structure and rectal structure were easy to distinguish from each other. The mesorectal fascia and vaginal were complete after dissection, and no Denonvilliers' fascia-like structure was present between them. In contrast, the control group cut the peritoneum at approximately 0.5–1 cm above the peritoneal reflection and freed the rectal wall between the vaginal muscular and the vaginal adventitia (as shown in Figure 2). Although a structure similar to Denonvilliers' fascia was found, it was closely connected to the vaginal muscular and could only be torn off through sharp separation. The muscular structure of the vagina was revealed after the operation, which often caused bleeding. Furthermore, the vaginal structure was no longer intact after dissection since the vaginal adventitia was separated from the muscular layer. After reviewing all the surgical procedures, finding an obvious membrane structure between the mesorectal fascia and vaginal adventitia in females was difficult. The fascial structure that we found during the operation was the vaginal adventitia, while the so-called female Denonvilliers' fascia does not exist.

Compared with the control group, the experimental group had less intraoperative bleeding [22.5 (19.5-50) mL *vs* 17 (5-20) mL; $P = 0.01$], and shorter length of hospitalization [9 (7-11.25) d *vs* 7 (6-10) d; $P = 0.03$]. Although the incidence of postoperative complications was lower than that of the control group, the results were not statistically significant. No deaths occurred in either group in the first 30 d after surgery. All Pathological specimens' Circumferential Resection Margins (CRM) were negative after the operation. Statistical result is summarized in Table 2.

Gross anatomy

As depicted in Figure 3A, the layers of the rectum and vagina were displayed, and the main structures could be distinguished. The vaginal muscular layer was brown, and the mucosal layer was gray. The mucosa of the rectum was yellowish, the submucosa was white, and the muscular layer was brown. However, distinguishing between the vaginal adventitia and the mesorectal fascia with the naked eye was difficult.

The dissociation process of the experimental group proceeded seamlessly. As depicted in Figure 3B, the mobilization plane traversed the interface between the vaginal adventitia and the fascia of the mesorectum. A discernible space between the vaginal adventitia and the mesorectal fascia was observed, which could be adroitly separated through blunt dissection. The vaginal adventitia and the mesorectal fascia were generally white without fascia-like tissues or blood vessels between them. Occasionally, blood vessels were visible beneath the vaginal adventitia. The boundary between the muscular layer and the adventitia was clear, with the muscular layer appearing dark and the adventitia appearing white.

As shown in Figure 3C, the mobilization plane entered the plane between the vaginal adventitia and the muscular layer by the procedure of the control group. When the vaginal adventitia was separated from the muscular layer, we found that the attachment between the vaginal adventitia and the muscular layer was stronger than the attachment between the vaginal adventitia and the mesorectal fascia, which could not be easily mobilized by blunt separation and can only be mobilized by sharp separation. After dissociation, the vaginal adventitia could be seen to be a single-layer fascia-like structure with a white color that was different and easy to distinguish from the dark muscle layer. No distinct or separate Denonvilliers' fascia was identified. At the same time, after the vaginal adventitia was forcibly torn off from the muscular layer, the muscular layer structure was damaged. Some residual muscle fiber tissue could be seen on the vaginal adventitia.

Table 1 General information of the patient

	Control group (*n* = 42)	Experimental group (*n* = 35)	*P* value

Pathological histochemistry

As shown in Figure 4, the rectal and vaginal tissues showed clear stratification: The rectum was divided into the mucosa, submucosa, inner ring muscle layer, outer longitudinal muscle layer, mesorectum, and the mesorectal fascia surrounding the mesorectum. The vaginal wall was divided into three layers: Mucosa, muscular, and adventitia layers. The adventitia layer was composed of dense connective tissue with scattered loose connective tissue among it. A gap was present between the mesorectal fascia and the vaginal adventitia. Numerous loose connective tissue, but no obvious fascia-like structures, were

DISCUSSION

In 1836, after observing the anatomy of the male pelvis, Denonvillier found a single-layer membrane-like structure between the rectum and prostate that he called the "prostatoperitoneal membrane"[13]. Later, in memory of Denonvillier, people called this fascial structure Denonvilliers' fascia, which is considered a structure that starts from the peritoneal reflection and ends at the perineum. The prostate and seminal vesicle glands are located in front of this structure. The rectum locates behind it, and vascular and nerve bundles are located on both sides of this structure. Undoubtedly, colorectal doctors have reached a consensus on the existence of Denonvilliers' fascia in the male pelvis. However, whether this fascia exists in females remains highly debated. Denonvillier elaborated on this structure by dissecting the male pelvis but did not mention its relevance in females. Later researchers also encountered many contradictions and disputes regarding the description of this structure.

In 1969, after dissecting 143 bodies, Milley and Nichols[14] confirmed the presence of a rectovaginal septum. They found a rectovaginal septum in 23 of 25 adult females and all dissected female infants. Despite the individual differences, the existence of this structure appears to be unaffected by age and hormones. At the same time, a close adhesion existed between this diaphragm and the fascia surrounding the vagina, they believed that this close adhesion may be a major reason why some anatomists deny the existence of the vaginal rectal septum[14].

Zhai *et al*[5] proved the existence of the female rectovaginal septum by studying the whole pelvic viscera embedded in celloidin (25 female pelvic visceral organs). He pointed out that the rectovaginal septum could be divided into two layers: Denonvilliers' fascia and the mesorectal fascia from the traditional point of view. Denonvilliers' fascia tightly surrounds the posterior and lateral walls of the vagina, and the Denonvilliers' fascia and the mesorectal fascia are not attached to the rectouterine pouch. Instead, they extend upward along the peritoneum. In this anatomy, the anterior layer integrates into the uterus, and the posterior layer gradually thins and disappears. The rectovaginal septum plays an important role in preventing the spread of malignant tumors[5].

Bertrand *et al*[6] found that Denonvilliers' fascia is an independent structure of the mesorectal fascia and the cervix as well as the vagina by studying female fetuses' anatomy[6]. However, they were likely to mistake the vaginal adventitia for Denonvilliers' fascia (rectovaginal septum). In our study on adult females, we only found loose connective tissue in the plane between the mesorectal fascia and the adventitia of the vagina. No other fascia-like structures were found between these structures. Due to the absence of other structures in this plane, we were able to easily separate the rectum and vagina without causing damage to the vaginal structure during the complete removal of the mesorectum. And the vaginal adventitia seems like Denonvilliers' fascia if it was separated from the vaginal muscle. Recognizing the adventitia of the vagina as Denonvilliers' fascia and forcefully separating it from the muscular layer could often cause bleeding.

At the same time, some people proposed the opposite opinion. Zhang *et al*[15] found only some membrane-like fascial fragments in the adipose tissue between the rectum and the vagina in the frozen sections of the corpses of three adult females aged 58–86 years old. They believed that previous studies may have regarded these fascial fragments as Denonvilliers' fascia; however, considering the age limit of their samples, their results still need further research[15]. An analysis of surgical and pathological samples from three females showed that the so-called fascia and vaginal wall had the same histological manifestations under pathology and were not distinguishable[16]. Therefore, Farrell *et al*[16] believed that the so-called fascia was an artificial surgical separation from the vagina that occurred when separating the vagina and surrounding organs[16]. In 2005, through the analysis of four female anatomical samples, Kleeman *et al*[17] also obtained a similar conclusion, that is, no fascia exists between the rectum and vagina. The rectovaginal septum used to repair the rectocele is an artificial surgical separation of tears from the vagina[17]. Meanwhile, after dissecting twenty-five female cadavers, García-Gausí *et al*[7] came to the same conclusion as Farrell *et al*[16]: That an independent rectovaginal septum could only be produced by tearing the vaginal adventitia. They found only a layer of loose connective tissue between the vagina and the rectum[7]. This is consistent with the findings of our study.

Based on the anatomy of four cadavers, Fang proposed that for surgery in early rectal cancer, mobilizing the rectum behind Denonvilliers' fascia can not only ensure the integrity of the mesorectum but also control related postoperative complications[18]. Although his viewpoint on whether Denonvilliers' fascia exists in females is different from ours, his conclusion on the female surgical approach is similar to ours. Simultaneously, some researchers have discovered that in the case of early rectal cancer, mobilizing the rectal wall behind Denonvilliers' fascia results in similar 5-year local recurrence rates as the traditional TME approach, while also reducing the incidence of complications [19]. Nevertheless, we believe that these researchers may have misidentified the vaginal adventitia as Denonvilliers' fascia in female patients.

We found that in females, the plane between the vaginal adventitia and the mesorectal fascia is suitable for rectal cancer surgery. By dissecting the rectum along the plane between the mesorectal fascia and the vaginal adventitia, not only can the risk of bleeding and damage to physiological structures be minimized, resulting in a faster recovery and shorter hospitalization, but it can also guarantee complete removal of the mesorectum and negative CRM status. Thus, this plane is the optimal plane in female patients with rectal cancer undergoing TME. Our research focused on the macro- and microlevels, combined with clinical data to explore the anatomy of the rectum and the vagina from multiple angles to obtain a highly scientific conclusion. Not only did we provide stronger evidence supporting the absence of Denonvilliers' fascia as an independent structure in females, but we also discovered that the anterior rectal space is the optimal plane to mobilize the anterior rectal wall for female patients undergoing TME.

However, as this study was retrospective and had a limited sample size, the observed differences in complication rates between the two procedures were not statistically significant. Future studies with larger sample sizes may yield more conclusive results. Additionally, due to the relatively short follow-up period since the patients' surgeries, long-term prognostic and sexual function outcomes have not been thoroughly investigated. Nonetheless, we intend to address this limitation in our subsequent studies.

CONCLUSION

In adult females, Denonvilliers' fascia is absent, we could only find loose connective tissue between the mesorectal fascia and vaginal adventitia. The vaginal adventitia is tightly adherent to the vaginal muscular layer and was difficult to separate from the muscle layer. By incising the peritoneum at the lowest point of peritoneal reflection, a plane between the mesorectal fascia and vaginal adventitia can be accessed. Mobilizing the anterior rectal wall in this plane could not only ensures the integrity of the mesorectum but also reduces intraoperative bleeding and hospital stay. Dissecting in this plane follows a natural avascular space without damaging the vaginal structure and simplifies the surgical procedure. Therefore, this is the optimal plane for mobilizing the anterior rectal wall for female patients undergoing TME procedures.

ARTICLE HIGHLIGHTS

Research background

Currently, there are no comprehensive descriptions available regarding the approach for dissecting the anterior wall of the female rectum. Many surgeons encounter intraoperative bleeding due to the lack of an appropriate dissection plane.

Research motivation

The surgical approach for mobilizing the anterior rectal wall during total mesorectal excision surgery in female patients remains controversial. However, with a more profound comprehension of the pelvic anatomy, we can identify the avascular plane, reducing intraoperative bleeding and preventing harm to physiological structures.

Research objectives

We aim to gain a better understanding of the female pelvic anatomy to identify an optimal approach for dissecting the anterior wall of the rectum. This will facilitate improved surgical outcomes for female patients with middle or low rectal cancer.

Research methods

Firstly, we retrospectively grouped patients based on different approaches after reviewing surgical videos. Clinical information was collected and pre-and post-operative data were compared, along with reviewing surgical videos to understand the anatomy and intraoperative situation. Subsequently, the female pelvic structure was studied through cadaveric dissection and histological sections.

Research results

We discovered that opening the peritoneum at the lowest point of peritoneal reflection allows access to the plane between the vaginal adventitia and mesorectal fascia. Opening the peritoneum 0.5-1 cm above the peritoneal reflection enters another plane located between the vaginal adventitia and vaginal muscle layer. The first approach has lower intraoperative bleeding and shorter hospital stay compared to the second approach. Neither cadaveric dissection nor pathological examination revealed the existence of Denonvilliers' fascia. Only loose connective tissue exists between the rectosacral fascia and the vaginal adventitia.

Research conclusions

Denonvilliers' fascia is absent in females. The plane amidst the mesorectal fascia and vaginal adventitia is the optimal surgical plane to mobilize the anterior rectal wall for female patients.

Research perspectives

In future studies, we will explore the long-term prognosis of the two approaches for women, as well as the impact on postoperative sexual and vaginal function.

Abstract

BACKGROUND

The interruption of mother-to-child transmission (MTCT) is considered important to decrease the individual and population morbidity of hepatitis B virus (HBV) infection as well as the global burden of hepatitis B. Serum vitamin D (VD) is associated with hepatitis B.

AIM

To assess whether baseline VD levels and single nucleotide polymorphisms of the VD receptor gene (VDR SNPs) are associated with the efficacy of tenofovir disoproxil fumarate (TDF) in the prevention of MTCT in pregnant women with high HBV viral loads.

METHODS

Thirty-eight pregnant women who were at high risk for MTCT of HBV (those with an HBV DNA level ≥ 2×10^5 IU/mL during 12-24 wk of gestation) receiving antiviral therapy of TDF between June 1, 2019 and June 30, 2021 in Mianyang were included in this retrospective study. The women received 300 mg TDF once daily from gestational weeks 24-28 until 3 mo after delivery. To further characterize the clinical relevance of maternal serum HBV DNA levels, we stratified patients according to HBV DNA level as follows: Those with levels < 2×10^5 (full responder group) *vs* those levels ≥ 2×10^5 IU/mL (partial responder group) at delivery. Serum levels of 25-hydroxyvitamin D [25(OH)D], liver function markers, virological parameters, VDR SNPs and other clinical parameters were collected to

analyze their association with the efficacy of TDF. The Mann-Whitney *U* test or t test was used to analyze the serum levels of 25(OH)D in different groups. Multiple linear regressions were utilized to analyze the determinants of the maternal HBV DNA level at delivery. Univariate and multivariate logistic regression analyses were employed to explore the association of targeted antiviral effects with various characteristics at baseline and delivery.

RESULTS

A total of 38 pregnant women in Mianyang City at high risk for MTCT of HBV were enrolled in the study. The MTCT rate was 0%. No mother achieved hepatitis B e antigen or hepatitis B surface antigen (HBsAg) clearance at delivery. Twenty-three (60.5%) participants were full responders, and 15 (39.5%) participants were partial responders according to antiviral efficacy. The present study showed that a high percentage (76.3%) of pregnant women with high HBV viral loads had deficient (< 20 ng/mL) or insufficient (≥ 20 but < 31 ng/mL) VD levels. Serum 25(OH)D levels in partial responders appeared to be significantly lower than those in full responders both at baseline (25.44 ± 9.42 *vs* 17.66 ± 5.34 ng/mL, $P = 0.006$) and delivery (26.76 ± 8.59 *vs* 21.24 ± 6.88 ng/mL, $P = 0.044$). Serum 25(OH)D levels were negatively correlated with maternal HBV DNA levels [log(10) IU/mL] at delivery after TDF therapy ($r = -0.345$, $P = 0.034$). In a multiple linear regression analysis, maternal HBV DNA levels were associated with baseline maternal serum 25(OH)D levels ($P < 0.0001$, β = -0.446), BMI ($P = 0.03$, β = -0.245), baseline maternal log10 HBsAg levels ($P = 0.05$, β = 0.285) and cholesterol levels at delivery ($P = 0.015$, β = 0.341). Multivariate logistic regression analysis showed that baseline serum 25(OH)D levels (OR = 1.23, 95%CI: 1.04-1.44), maternal VDR Cdx2 TT (OR = 0.09, 95%CI: 0.01-0.88) and cholesterol levels at delivery (OR = 0.39, 95%CI: 0.17-0.87) were associated with targeted antiviral effects (maternal HBV DNA levels < 2×10^5 at delivery).

CONCLUSION

Maternal VD levels and VDR SNPs may be associated with the efficacy of antiviral therapy in pregnant women with high HBV viral loads. Future studies to evaluate the therapeutic value of VD and its analogs in reducing the MTCT of HBV may be justified.

Core Tip: This retrospective study investigated the influence of vitamin D (VD) levels and single nucleotide polymorphisms of the VD receptor gene (VDR SNPs) on the efficacy of tenofovir disoproxil fumarate in preventing mother-to-child transmission in 38 pregnant women with high hepatitis B viral loads. We demonstrate a significant association between low serum levels of 25-hydroxyvitamin D and high levels of hepatitis B virus replication in pregnant women with high hepatitis B viral loads, and maternal VD levels as well as VDR SNPs may be associated with the efficacy of antiviral therapy.

INTRODUCTION

Hepatitis B virus (HBV) infection is a serious public health problem that causes a very large medical and economic burden worldwide. Mother-to-child transmission (MTCT) is the main route of HBV transmission, accounting for 30%-50% of chronic infections in China[1]. In particular, China is a major contributor to achieving the global goal of eliminating hepatitis B as a threat to public health by 2030[2]. The interruption of MTCT is considered important to decrease the individual and population morbidity of HBV infection as well as the global burden of hepatitis B. In recent years, Chinese scholars have continuously published and updated the management algorithm for the prevention of the MTCT of HBV, which has achieved good clinical application[3,4]. To date, the use of antiviral drugs in combination with immunoprophylaxis in pregnant women has been shown to be safe and effective in

reducing the MTCT of HBV[4].

Vitamin D (VD) is a fat-soluble steroid hormone that is widely found in systemic organs and tissues, including the brain, bones, cardiac system and immune system, and has multiple effects on human health and many diseases, including infectious diseases. In fact, VD deficiency has been detected in a variety of chronic liver diseases, including chronic viral hepatitis[5-8]. Moreover, VD deficiency is common among patients with chronic hepatitis B infection and is associated with adverse clinical outcomes[9]. Similarly, VD levels are lower in pregnant women with chronic HBV infection than in healthy pregnant women[10]. Clinical and epidemiological studies support the role of VD in inhibiting HBV infection, and this antiviral effect is widely attributed to the VD receptor (VDR)[11].

Different studies have focused on single nucleotide polymorphisms of the VDR gene (VDR SNPs) and HBV. VDR ApaI has been associated with the presence of hepatitis B surface antigen (HBsAg) and viral loads at different times[12]. In addition to its effect on viruses, VD plays an important role for the mother and fetus during pregnancy and has been associated with influencing adverse perinatal events.

However, few data are available with regard to the association of VD levels and VDR SNPs with clinical parameters and treatment outcomes in pregnant women with high HBV viral loads. The aims of our present retrospective study were to study whether baseline VD levels and VDR SNPs were associated with the efficacy of tenofovir disoproxil fumarate (TDF) in the prevention of MTCT in pregnant women with high HBV viral loads.

MATERIALS AND METHODS

Study population

This was a retrospective study. As part of "The National Science & Technology Pillar Program during the 13th Five-year Plan Period", HBsAg-positive pregnant women receiving TDF were included from Mianyang between June 1, 2019 and June 30, 2021. The present study was approved by the Institutional Review Board of the West China Hospital, Sichuan University (No. 2019-151), and informed consent was obtained from all patients before recruitment.

Pregnant women screened for HBV DNA at high risk for MTCT (HBV DNA thresholds ≥ 2×10^5 IU/mL) according to WHO recommendations during 12-24 wk of gestation and completed antiviral therapy as required were included in the study. Women received 300 mg TDF once daily from gestational weeks 24-28 until 3 mo after delivery, in addition to HBV immune globulin and three doses of HBV vaccination, including a birth dose given to the neonate. The main exclusion criteria were as follows: (1) Coinfection of syphilis, *Toxoplasma gondii*, human immunodeficiency viruses, or types of viral hepatitis other than HBV; (2) major systemic disease, including heart disease, malignant neoplasm, or renal insufficiency; (3) evidence of liver cirrhosis, hepatic decompensation and other liver diseases such as drug-induced hepatitis, autoimmune liver disease, or alcoholic liver disease; (4) evidence of congenital anomalies of the fetus; (5) antiviral treatment within a short period of time prior to treatment with TDF or failure to complete TDF antiviral therapy as required; and (6) incomplete data, including basic information, VD levels before and after treatment, VDR SNPs, virological indicators, *etc.*

Data collection and definition

The basic information of the pregnant woman including age, height, weight, season of blood sample collection and other basic information was collected. Meanwhile, maternal virological indicators, including HBsAg, hepatitis B e antigen (HBeAg) and HBV DNA, were recorded before antiviral treatment and at delivery after antiviral treatment. Moreover, common clinical parameters before antiviral treatment and at delivery after antiviral treatment including peripheral blood count, liver function, kidney function and other parameters were also collected. Laboratory tests were performed according to our previous description[13,14].

Previously collected blood samples were used to assess maternal VD levels and VDR SNPs. In particular, VD was assessed at baseline and at the time of delivery by measuring serum 25-hydroxyvitamin D [25(OH)D] levels. Serum 25(OH)D was analyzed by LCMS/MS (Agilent Technologies Inc., LCMS/MS1260-6470, CA, United States) after hexane extraction with deuterated 25(OH)D as a control as previously described[15]. Levels of VD were categorized as follows: < 20 ng/mL = deficient; ≥ 20 but < 31 ng/mL = insufficient; and ≥ 31 ng/mL = normal. Genomic DNA was isolated from blood samples (MagNA Pure Compact, Roche). VDR SNPs were assessed through a real-time PCR allelic discrimination system (LightCycler 96, Roche). We investigated the following gene SNPs: VDR: rs7975232 (ApaI)C>A, rs11568820 (Cdx2)T>C, rs2228570 (FokI)A>G, rs1544410 (BsmI)C>T, rs731236 (TaqI)A>G.

The primary outcomes were the changes in the maternal viral load (HBV DNA level) at baseline and the time of delivery. A sustained virological response was defined as an HBV DNA level lower than 2×10^5 IU/mL at delivery. We aimed to determine whether the levels of VD and VD SNPs were associated with the antiviral effects of TDF in interrupting MTCT during the peripartum period.

Statistical analysis

All statistical analyses were carried out using SPSS Version 26. Categorical variables are represented as frequencies and percentages, and continuous variables are represented as medians (interquartile ranges) or mean ± SD. The outcomes were compared between the two groups using χ^2 tests or Fisher's exact test for categorical variables and the Wilcoxon signed-rank test or Student's *t* test for continuous variables. Associations between VD and each of the baseline demographic and lab values were assessed in univariate analyses using general linear models. Univariate and multivariate logistic regression analyses were employed to explore the association of targeted antiviral effects (HBV DNA levels < 2×10^5 at delivery) with various characteristics at baseline and delivery. Factors with a *P* value < 0.1 in univariate analysis were considered in multivariate analysis. The statistical test was 2-sided, and a *P* value < 0.05 was considered statistically significant.

RESULTS

Patient characteristics

The baseline characteristics, laboratory data, and VDR SNPs of the patients are presented in Table 1. No mother achieved HBeAg or HBsAg clearance at delivery. The decrease in HBV DNA levels from baseline to delivery was significant ($P < 0.001$). A total of 100% of the infants had negative HBsAg and undetectable HBV DNA levels at delivery; thus, the MTCT rate was 0%. To further characterize the clinical relevance of maternal serum HBV DNA levels, we stratified patients according to serum HBV DNA levels as follows: those with levels < 2×10^5 (full responder group) *vs* those with levels ≥ 2×10^5 IU/mL (partial responder group) at delivery. Mothers with serum HBV DNA viral loads below this threshold are generally considered low risk for MTCT. Twenty-three (60.5%) participants were full responders, and 15 (39.5%) participants were partial responders according to antiviral efficacy. Full and partial responders were similar in age (29.09 *vs* 28.73 years) and body mass index (BMI) (23.15 *vs* 21.42 kg/m^2).

In the virological indicators related to HBV, there was no significant difference in the HBsAg log10 and HBeAg log10 values between the two groups both at baseline and delivery. The serum HBV DNA concentration was not significantly different between the two groups at baseline, but the serum HBV DNA concentration of full responders was significantly lower than that of partial responders at delivery after antiviral treatment [log10, 3.61 (2.88, 4.46) *vs* 7.41 (5.79, 7.9), $P < 0.0001$].

For the laboratory test results, there were no significant differences between full and partial responders in most of the main laboratory indices before and after antiviral therapy, including hemoglobin, white blood cell count, platelets, neutrophils, lymphocytes, total bilirubin, albumin, alanine aminotransferase, triglycerides, creatinine, alkaline phosphatase, and gamma-glutamyl transferase. However, cholesterol levels were lower in complete responders than in partial responders at delivery after treatment (4.87 ± 0.79 *vs* 5.56 ± 0.96 mg/dL, $P = 0.001$), but there was no significant difference at baseline.

Serum 25(OH)D levels

There was no VD or multivitamin supplementation between baseline and delivery. The mean baseline serum 25(OH)D level of the entire cohort was similar to the serum 25(OH)D level at delivery, with no significant difference (22.37 ± 8.85 *vs* 24.58 ± 8.32 ng/mL, $P = 0.139$). Of the 38 patients in the entire cohort, 18 (47.4%), 11 (28.9%), and 9 (23.7%) had severe VD deficiency, VD insufficiency or normal serum VD levels, respectively.

In the absence of significant seasonal differences for the collected blood samples, VD deficiency and insufficiency were highly prevalent in partial responders (73.3%, 20% *vs* 30.4%, 34.8%, $P = 0.021$). Overall, the serum 25-hydroxyvitamin D3 [25(OH)D3] level in partial responders appeared to be significantly lower than that in full responders both at baseline (25.44 ± 9.42 *vs* 17.66 ± 5.34 ng/mL, $P = 0.006$) and delivery (26.76 ± 8.59 *vs* 21.24 ± 6.88 ng/mL, $P = 0.044$). In addition, the VDR SNP assay showed no significant difference between full and partial responders based on VDR SNPs, including VDR Cdx2, Bsm1, FokI, Taq1 and Apa1.

Relationship between baseline serum 25(OH)D levels and virological parameters

Maternal HBsAg serum levels were not associated with serum 25(OH)D levels (data not shown). Interestingly, maternal Log10 HBV DNA levels at delivery and baseline serum 25(OH)D levels showed a significant, inverse correlation ($P = 0.034$, Figure 1). Therefore, we performed multiple linear regression analysis of the determinants of maternal HBV DNA levels at delivery. In both univariate and multivariate analyses, baseline maternal serum 25(OH)D levels were the strongest determinant of low maternal HBV DNA levels ($P = 0.034$ and < 0.0001, respectively; Table 2), together with BMI, baseline maternal log10 HBsAg levels and cholesterol levels at delivery.

We further performed univariate and multivariate regression analyses to characterize the relationship between the serum level of 25(OH)D and targeted antiviral effects. The baseline serum 25(OH)D level

DISCUSSION

The present study showed that a high percentage (76.3%) of pregnant women with high HBV viral loads had deficient (< 20 ng/mL) or insufficient (≥ 20 but < 31 ng/mL) VD levels. There was a profound association between low serum 25(OH)D levels and higher levels of maternal HBV replication at delivery after TDF therapy. In a multiple linear regression analysis, maternal HBV DNA levels were associated with baseline maternal serum 25(OH)D levels, BMI, baseline maternal log10 HBsAg levels and cholesterol levels at delivery. Finally, we observed that baseline serum 25(OH)D levels, maternal VDR Cdx2 TT and cholesterol levels at delivery were associated with targeted antiviral effects (maternal HBV DNA levels < 2 × 10^5 at delivery) in a multivariate regression model.

In the human body, VD and its receptors are widely involved in a variety of life processes, regulating the nervous, immune and endocrine systems through related signaling pathways. Many studies have been conducted to reveal the association effect of VD and its receptors on HBV infection and its development. VD deficiency or declines can be detected in a variety of chronic liver diseases[5,7,16] and is associated with adverse clinical outcomes[9,16]. Abnormally low VD levels are highly prevalent among untreated patients with active chronic hepatitis B infection[6].

For a special group of people, such as pregnant females, VD is a vital nutrient that is important for both the mother and fetus in the perinatal period, and prenatal VD supplementation may reduce the risk of many adverse events and yield potential benefits. A previous study showed that pregnant women with HBV in China had lower VD levels than healthy pregnant women[10]. Our present study also showed that a high percentage (76.3%) of pregnant women with high HBV viral loads had deficient (18/38) or insufficient (11/38) VD levels, while only approximately 25.00% (9/38) had adequate VD levels. Our results suggested that abnormally low VD levels may be a common phenomenon in untreated pregnant women with high HBV viral loads in China.

Based on the evidence provided by a companion systematic review that addressed HBV DNA thresholds for identifying pregnant women at risk of MTCT, the WHO recommends administering TDF to pregnant women infected with HBV with high viral loads (≥ HBV DNA thresholds ≥ 2 × 10^5 IU/mL) from week 28 of pregnancy until at least childbirth to prevent MTCT, in addition to three doses of hepatitis B vaccination, including a birth dose given to the neonate. A recent meta-analysis showed that peripartum antiviral prophylaxis is highly effective at reducing the risk of the MTCT of HBV[17], which supports the 2020 WHO recommendation of administering antivirals during pregnancy, specifically TDF, for the prevention of the MTCT of HBV.

There is growing evidence that VD is associated with infectious diseases and immunity against infection and that VD supplementation has therapeutic potential in the treatment of infectious diseases [18,19]. Low maternal VD levels (< 32 ng/mL) were associated with a higher risk of the MTCT of HIV, and children born to women with low VD levels had a higher risk of death during follow-up[20]. Clinical and epidemiological studies support the role of VD in inhibiting HBV infection, and this antiviral effect is widely attributed to the VDR[11]. Hepatic VDR protein expression was significantly lower in patients with chronic HBV infection, and hepatic VDR expression was inversely correlated with hepatic inflammation and fibrosis[21], which could partly explain the more pronounced decrease in viral DNA in patients with higher VD levels after receiving antiviral therapy in our study.

The present study revealed a profound association between low serum 25(OH)D levels and higher levels of maternal HBV replication at delivery after TDF therapy. Consistent with our previous study, serum 25(OH)D levels were highly negatively correlated with HBV DNA levels[14]. Therefore, for HBV-infected patients, especially pregnant women, monitoring of VD levels is advocated, and increasing VD levels to a normal range in appropriate ways may be beneficial in maintaining low levels of HBV DNA.

It is expected that more in-depth studies will be performed to elucidate the mechanism of the effect of VD on HBV infection and its development, treatment and prognosis, which may offer attractive therapeutic opportunities for the treatment of chronic hepatitis B infection.

A number of studies have recently focused on the association between VDR SNPs and the disease characteristics of HBV infection. Some genotypes in VDR FokI increased the risk of HBV infection in a meta-analysis[22]. In addition, the VDR ApaI SNP was associated with viral load and the presence of HBsAg at different times, and pharmacogenetic data could help physicians identify HBV patients with a higher probability of achieving a good response[12]. In addition, VDR SNPs are correlated with HBV viral load and the severity of liver disease[23] and may be associated with occult hepatitis B infection [9]. Our results revealed that VDR Cdx2 TT was a hindering factor in achieving targeted antiviral therapeutic effects (HBV DNA levels < 2×10^5 at delivery) after TDF therapy. In pregnant women, increasing VD levels to within the normal range may help to achieve targeted antiviral treatment effects, especially in those with VDR Cdx2 TT. More basic and clinical studies are warranted for VD supplementation combined with antiviral therapy and immunoprophylaxis to block MTCT.

VD and cholesterol metabolism overlap significantly in the pathways that promote their biosynthesis and have a complex bidirectional relationship[24]. In our study, there was no significant difference in cholesterol levels between the full and partial responders before antiviral therapy, but cholesterol levels were lower in full responders after treatment. Similarly, in another study, for treatment-naive patients with chronic hepatitis B infection, total cholesterol levels showed a decreasing trend during 42 mo of TDF treatment[25]. Moreover, higher total cholesterol concentrations were associated with lower 25(OH)D concentrations[26], and VD supplementation appeared to have a beneficial effect on reducing total serum cholesterol levels[27]. In addition, VDR SNPs were associated with dyslipidemia in Chinese populations, and some variants may increase susceptibility to dyslipidemia[28]. Together, the difference in cholesterol levels after antiviral therapy may be due to differences in VD levels, VDR SNPs, and reactions to antiviral therapy.

Some limitations of the present study should be acknowledged. Most importantly, due to the type of study, the clinical correlations cannot be interpreted as causal relationships. Therefore, a suggestive functional link between VD metabolism and HBV replication remains elusive. Furthermore, the sample size included in this study was limited. Third, there are still some possible confounding factors that have not been considered. Although factors such as the season of blood collection were taken into account, other factors such as dietary habits, the duration of sunlight exposure and the ultraviolet intensity of pregnant women's living environments may also affect maternal VD levels.

CONCLUSION

In summary, we demonstrate a significant association between low serum levels of 25(OH)D and high levels of HBV replication in pregnant women with high HBV viral loads, and maternal VD levels as well as VDR SNPs may be associated with the efficacy of antiviral therapy. Future studies to evaluate the therapeutic value of VD and its analogs in reducing the MTCT of HBV may be justified.

ARTICLE HIGHLIGHTS

Research background

Mother-to-child transmission (MTCT) is the main route of hepatitis B virus (HBV) transmission, and HBV infection is associated with human vitamin D (VD) levels.

Research motivation

The role of VD and single nucleotide polymorphisms of the VD receptor gene (VDR SNPs) in blocking MTCT in pregnant women with high HBV viral load receiving antiviral therapy is unclear.

Research objectives

This study aimed to assess whether baseline VD levels and VDR SNPs are associated with the efficacy of tenofovir disoproxil fumarate (TDF) in the prevention of MTCT in pregnant women with high HBV viral loads.

Research methods

This retrospective study investigated VD levels, common clinical indicators, and virological parameters before and after antiviral therapy in 38 pregnant women with high HBV viral load, and further analyzed the effect of VD levels and VDR SNPs on the efficacy of TDF for the prevention of MTCT.

Research results

The present study showed that a high percentage (76.3%) of pregnant women with high HBV viral loads had deficient (< 20 ng/mL) or insufficient (≥ 20 but < 31 ng/mL) VD levels. There was a profound association between low serum 25-hydroxyvitamin D [25(OH)D] levels and higher levels of maternal HBV replication at delivery after TDF therapy. Multivariate logistic regression analysis showed that baseline serum 25(OH)D levels (OR = 1.23, 95%CI: 1.04-1.44), maternal VDR Cdx2 TT (OR = 0.09, 95%CI: 0.01-0.88) and cholesterol levels at delivery (OR = 0.39, 95%CI: 0.17-0.87) were associated with targeted antiviral effects (maternal HBV DNA levels < 2×10^5 at delivery).

Research conclusions

We demonstrate a significant association between low serum levels of 25(OH)D and high levels of HBV replication in pregnant women with high HBV viral loads, and maternal VD levels as well as VDR SNPs may be associated with the efficacy of antiviral therapy.

Research perspectives

Future studies to evaluate the therapeutic value of VD and its analogs in reducing the MTCT of HBV may be justified.

Abstract

BACKGROUND

Prolonged symptoms after corona virus disease 2019 (Long-COVID) in dialysis-dependent patients and kidney transplant (KT) recipients are important as a possible risk factor for organ dysfunctions, especially gastrointestinal (GI) problems, during immunosuppressive therapy.

AIM

To identify the characteristics of GI manifestations of Long-COVID in patients with dialysis-dependent or KT status.

METHODS

This observational, prospective study included patients with COVID-19 infection,

confirmed by reverse transcription polymerase chain reaction, with the onset of symptoms between 1 January 2022 and 31 July 2022 which was explored at 3 mo after the onset, either through the out-patient follow-up or by telephone interviews.

RESULTS

The 645 eligible participants consisted of 588 cases with hemodialysis (HD), 38 patients with peritoneal dialysis (PD), and 19 KT recipients who were hospitalized with COVID-19 infection during the observation. Of these, 577 (89.5%) cases agreed to the interviews, while 64 (10.9%) patients with HD and 4 (10.5%) cases of PD were excluded. The mean age was 52 ± 11 years with 52% women. The median dialysis duration was 7 ± 3 and 5 ± 1 years for HD and PD groups, respectively, and the median time post-transplantation was 6 ± 2 years. Long-COVID was identified in 293/524 (56%) and 21/34 (62%) in HD and PD, respectively, and 7/19 (37%) KT recipients. Fatigue was the most prevalent (96%) of the non-GI tract symptoms, whereas anorexia (90.9%), loss of taste (64.4%), and abdominal pain (62.5%) were the first three common GI manifestations of Long-COVID. Notably, there were 6 cases of mesenteric panniculitis from 19 patients with GI symptoms in the KT group.

CONCLUSION

Different from patients with non-chronic kidney disease, there was a high prevalence of GI manifestations of Long-COVID in dialysis-dependent patients and KT recipients. An appropriate long-term follow-up in these vulnerable populations after COVID-19 infection is possibly necessary.

Key Words: COVID-19; Kidney transplant; Post-acute COVID-19 syndrome; Long-COVID-19; Gastrointestinal; SARS-CoV-2

Core Tip: Prolonged symptoms after coronavirus disease 2019 (COVID-19) or prolonged symptoms after COVID-19 (Long-COVID) in dialysis-dependent patients and kidney transplant (KT) recipients are important as a possible risk factor for organ dysfunctions, especially gastrointestinal (GI) problems. In this study, we observed that a GI manifestation of Long-COVID is a frequent condition in patients with dialysis-dependence and kidney-transplant recipients. Long-COVID was significantly more prevalent in peritoneal dialysis patients than in hemodialysis patient or KT cases. We also found that patients who experienced either abdominal pain or diarrhea had a longer duration of other GI manifestations of Long-COVID, suggesting a need for closer observation of these patients during COVID-19 infection.

INTRODUCTION

The coronavirus disease (COVID-19) pandemic has a significant impact on the management of dialysis-dependent patients and kidney transplant (KT) recipients, while the chronic kidney disease (CKD) condition in these patients is also affecting the clinical manifestation of COVID-19 infection. The persistence of post-COVID-19 syndrome for weeks to months after the infection is a growing public health concern worldwide[1]. Currently, the definition of post-acute COVID-19 syndrome (PACS), also known as the post-acute sequelae of severe acute respiratory syndrome coronavirus 2 (PASC) or prolonged symptoms after COVID-19 (Long-COVID) syndrome, depends on the population being studied, the post-infection timing, and the assessment tools[2,3]. Moreover, the overlap in its pathophysiology between overwhelming pro-inflammatory immune responses and direct viral cytopathic effects remains inconclusive[4]. In general, PACS mainly includes fatigue, pain, headache, neurological and cognitive impairments, cardio-pulmonary symptoms, and anosmia-dysgeusia[5]. The British National Institute for Health and Care Excellence (NICE) defines Long-COVID as any signs and symptoms that develop during or after an infection consistent with COVID-19, continue for over 12 wk,

and cannot be explained by an alternative diagnosis[6]. A clinical case definition of Long-COVID by a Delphi consensus has crystallized the case definition of Long-COVID as clinical symptoms that occur in individuals with a history of probable or confirmed severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection, usually 3 mo from the onset of COVID-19 with symptoms, that last for at least 2 mo without an alternative explainable condition[7].

Both dialysis-dependent patients and KT recipients are classified as vulnerable populations due to their immunosuppressive status derived from their CKD condition and the high number of comorbidities[8]. Thus, a more frequent prevalence of long-term after-effects of COVID-19 infection than in the general population is possible. Accordingly, aggressive approaches, along with prompt management of acute illness, should be used in these populations, making the subject of Long-COVID even more challenging. Recent reports have revealed an incidence of post-COVID-19 syndrome in dialysis patients and KT recipients of approximately 40%-70% of those who experience a COVID-19 infection[9-13]. The Long-COVID symptoms include respiratory-related symptoms, fatigue, peripheral neuropathy, venous thromboembolism, memory impairment, and *de novo* diabetes mellitus[9-11]. Notably, 60% of dialysis patients *vs* 10% of KT recipients had residual symptoms at 6 mo post-COVID-19 infection[11,14].

Even without the gastrointestinal (GI) symptoms, the severity of COVID-19 is associated with the GI tract as the translocation of pathogen molecules from the gut into the blood circulation (leaky gut) is reported[15], possibly from a quiescent the SARS-CoV-2 infection in the intestine[16]. Indeed, the cell entry of SARS-CoV-2 virus through angiotensin-converting enzyme 2 (ACE2) receptors on the squamous and columnar epithelial cells, including enterocytes, is well-known[17]. One large study of hospitalized COVID-19 revealed that 30% of the patients reported GI symptoms, such as abdominal pain, nausea and vomiting, and diarrhea, in addition to their respiratory tract symptoms[18]. Nevertheless, the impacts of COVID-19 infection, and particularly Long-COVID-19, in the GI spectrum is not fully understood in either dialysis patients or KT patients, and data on this topic remains scarce. Of note, data from the most recent report on post-acute SARS-CoV-2 infection sub-phenotype by Zhang *et al*[19] found that GI tract-related symptoms are one of the four most common characteristics in post-acute viral symptoms.

Hence, the aim of the present study was to determine the prevalence and characteristics of Long-COVID in a cohort of these patients. We hypothesize that Long-COVID, especially in the GI symptoms, may be underestimated in these populations and may need more clarification, particularly in the post-pandemic period.

MATERIALS AND METHODS

Study populations

The study is a cohort longitudinal study performed in dialysis-dependent patients and KT recipients with COVID-19 infection under the care of three renal referral tertiary care centers. Eligible participants were those with a diagnosis of COVID-19 confirmed by an RT-PCR test from oro-nasopharyngeal swabs from January 2022 to 31 July 2022. The KT recipients with the following conditions were excluded: (1) Those who died before the follow-up interview, (2) those we were unable to contact, and (3) those without or unable to provide informed consent. The remaining dialysis-dependent patients and KT recipients who had experienced a post-COVID-19 infection for at least 3 mo were included in the study. Purposive sampling was used in order to ensure the representation of a range of characteristics and experiences of analytic relevance. Informed consent for participation in interviews was obtained either written or verbally over the phone from all participants in the study and the study was approved by the Research Ethics Commission of the Faculty of Tropical Medicine, Mahidol University, Thailand (MUTM 2022-081-01) along with adhered to STROBE guideline.

Interview conduct and data collection

An interview consisting of a set of open-ended questions regarding symptoms during COVID-19 and post-COVID-19 infection periods. Then, interviews were designed to explore the specific persistent or emerging symptoms potentially due to GI tract-associated Long COVID-19 syndrome, as previously described[20]. Participants were interviewed either in person or by telephone by trained research nurses. Participants were considered to have GI tract-associated symptoms of Long COVID-19 if they showed one of the following signs: loss of appetite, nausea, weight loss, abdominal pain, heartburn, dysphagia, diarrhea, constipation, altered bowel motility, or irritable bowel syndrome[20]. In addition, the participant's electronic medical records were used to obtain clinical data, including baseline demographics and transplant-related immunological risk, comorbidity, and data about COVID-19 admission. Although abnormal laboratory tests, such as elevated alanine aminotransferase, can present as GI tract-associated Long COVID-19 syndrome[21], only clinical signs and symptoms were explored in the present study.

Statistical analysis

Descriptive characteristics were presented as means and standard deviation (means ± SD) unless otherwise noted. The Kolmogorov-Smirnov and Levene's tests were performed to establish data distribution and homogeneity, respectively. Chi-square tests were performed to compare categorical variables, whereas Tukey-Kramer multiple comparisons were used for continuous variables. Independent risk factors were assessed by applying a backward elimination stepwise binary regression and removing the least significant variables at each step. Odds ratios (ORs) and 95% confidence intervals (CIs) were estimated. $P < 0.05$ was considered statistically significant. Data analysis was performed using the PASW 18.0.0 statistical software package (SPSS Inc., Chicago, IL, United States) and GraphPad Prism 9.3.1 software (GraphPad Software, Inc., La Jolla, CA, United States).

RESULTS

Comparison baseline characteristics among participants of hemodialysis, peritoneal dialysis, and kidney transplantation

This study enrolled 645 eligible participants with COVID-19 infection, including 588 cases with hemodialysis (HD), 38 patients with peritoneal dialysis (PD), and 19 KT recipients. Of these, 577 (89.5%) participants agreed to interviews (Figure 1). All eligible KT recipients were enrolled in the study, and none of the transplant recipients in the KT cohort died or returned to dialysis.

The mean patient age was 52 ± 11 years, 300 (52%) were women, and the median dialysis duration was 7 ± 3 and 5 ± 1 years in the HD and PD groups, respectively. Hypertension (92%) and type 2 diabetes mellitus (77%) were the two most common comorbidities among the three groups of participants. The mean post-transplantation time was 6 ± 2 years (Table 1). Most of the HD patients had three dialysis sessions per week while continuous ambulatory PD (CAPD) was the most treatment modality used in PD patients. The three most common initial symptoms detected in both the dialysis and KT cohorts were fever (98%), coryza (96%), and cough (94%). Of note, the PD patients had a significant predominance of all symptoms compared to the HD and KT groups (P <0.0001); this could be because the highest comorbidities and uttermost severity of COVID-19 were observed in the PD group. For this reason, the combination therapy of Remdesivir (88.2%) and tocilizumab (63.1%) was prescribed significantly more frequently in this group with also correspondent the highest mean levels of both high-sensitivity C-reactive protein and D-dimer compared with HD and KT groups ($P < 0.0001$) (Table 1).

Different prevalence of GI manifestations of Long-COVID among the dialysis-dependent and KT populations

The Thai national guidelines for COVID-19 management in high-risk patients (during this study period) stipulate that all patients with CKD or CKD-equivalent disorders must be hospitalized for intensive care and monitoring during acute COVID-19 infection. As such, all participants in the study were hospitalized. During the early post-COVID-19 infection period, Long-COVID was identified in 293/524 (56%) of the HD, 21/34 (62%) of the PD, and 7/19 (37%) of the KT groups. Fatigue was the most prevalent symptom (96%) of the non-GI tract symptoms and was accompanied by loss of appetite or anorexia (81%), loss of taste (63%), hoarse voice (28%), unusual muscle pains (23%), hair loss (22%), a persistent cough (22%), headache (11%), and impaired cognitive and memory function (9%). Among the GI manifestations of Long-COVID, anorexia was the most prevalent symptom (525 cases, 90.9% from all groups), followed by loss of taste (372 cases, 64% from all groups), and abdominal pain (367 cases, 62.5% from all groups) (Figure 2A). Although anorexia and loss of taste were common in all three groups, they were more predominant in dialysis patients, but most cases showed much improvement by two months after the onset of COVID-19 infection. Abdominal pain and diarrhea were the symptoms that persisted for over 3 mo (Figure 2B).

Notably, our investigation of the causes of abdominal pain, which was reported by 87% of the patients, revealed that non-specific abdominal pain or probably acute gastritis was the main etiology in dialysis-dependent patients, whereas mesenteric panniculitis was the main etiology of abdominal pain (6 from 19 cases) in the KT group with a good response to oral corticosteroids (20 mg prednisolone), which were slowly tapered off in 8 wk. All six cases of mesenteric panniculitis had complete resolution, as indicated by the follow-up abdominal computer tomography.

Figure 2C shows the factors associated with the GI manifestation of Long-COVID. We found that COVID-19 patients who were older than 65 years (ORs 2.00, 95%CIs 1.2-2.8), who had chronic lung disease (ORs 2.10, 95%CIs 1.1-4.2), who were on PD (ORs 1.80, 95%CIs 1.4-2.5), or who had high levels of both C-reactive protein (CRP) and D-dimer at the onset (ORs 4.40, 95%CIs 1.4-8.8) were significantly likely to have GI manifestations of Long-COVID.

DISCUSSION

In this study, we observed that a GI manifestation of Long-COVID is a frequent condition in patients with dialysis dependence and KT recipients. Long-COVID was significantly more prevalent in PD patients than in HD or KT cases. Notably, patients who experienced either abdominal pain or diarrhea had a longer duration of other GI manifestations of Long-COVID, suggesting a need for closer observation of these patients during COVID-19 infection.

COVID-19 has brought forth a multitude of challenges to healthcare systems across the globe. Apart from the significant morbidity and mortality associated with COVID-19 during its initial phase, recognition and concern are growing regarding the long-term consequences of COVID-19[2,3,22]. Dialysis-dependent patients and KT recipients are clearly high-risk groups associated with higher numbers of comorbidities and immunosuppressive issues and require more aggressive courses of COVID-19 treatment in terms of acute and chronic complications[8,23,24]. Although the most visible manifestation of Long-COVID in the general population is asthenia, or brain fog[22,25], we found that anorexia was the most common GI manifestation of Long-COVID in both dialysis-dependent patients and KT recipients, followed by abdominal pain and loss of taste (Figure 2A).

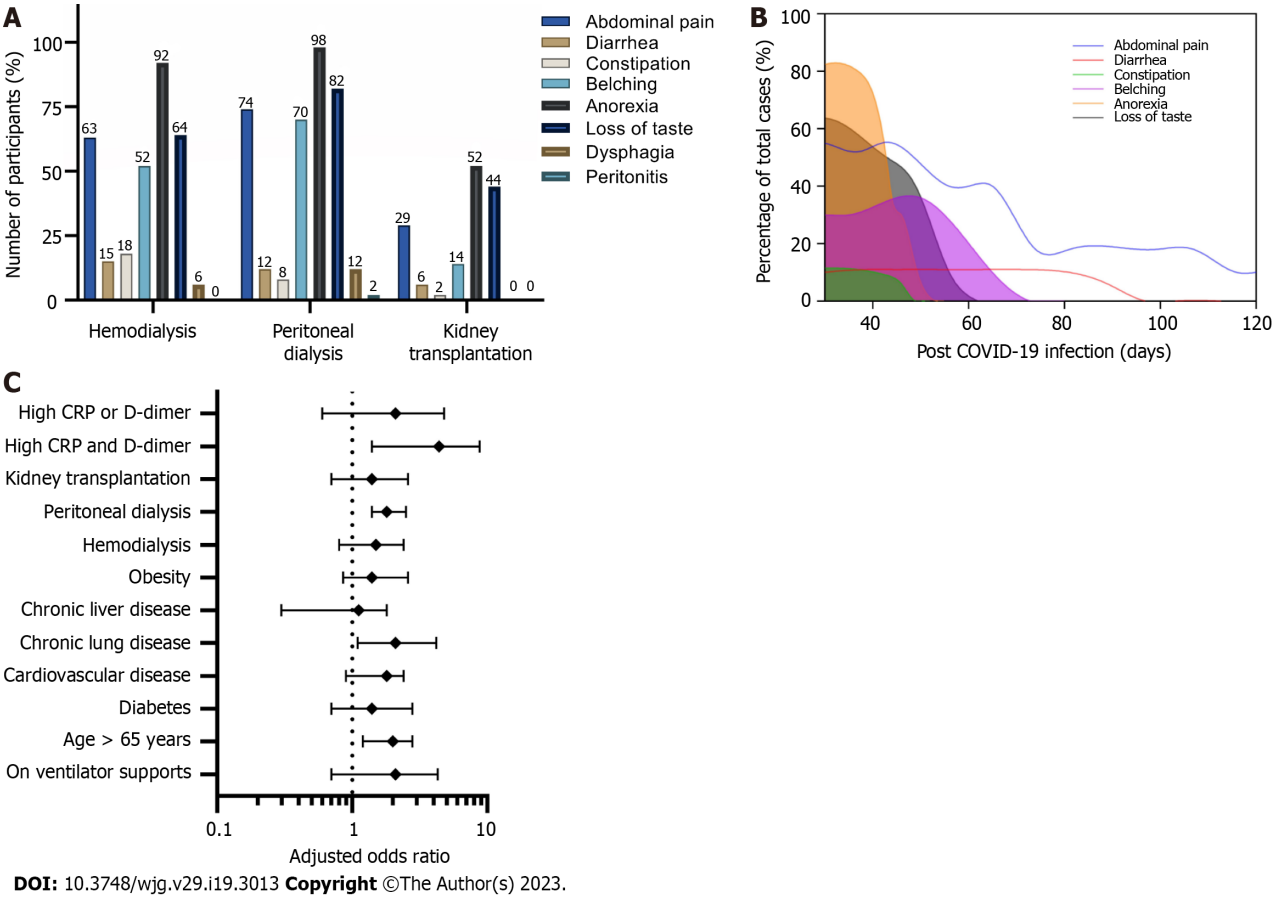

Figure 1 Flow chart showing the number of eligible participants and the final cases enrolled in the study. COVID-19: Coronavirus disease 2019.

The prevalence and characteristics of Long-COVID in the present cohort seem to differ from its manifestations in other populations, in which diarrhea was the most persistently encountered GI symptom[26-31]. This difference could be explained by the combination of pre-existing uremic toxins in dialysis-dependent patients, as well as a delayed clearance of inflammatory cytokines[32] and enhanced oxidative stress associated with end-stage renal disease (ESRD)[33]. As such, restoration of renal function in KT recipients resulted in a decrease in the incidence of GI manifestations of Long-COVID compared with ESRD patients (Figure 2A). However, kidney transplantation does not entirely reverse T cell functions[34], and the underlying mechanisms of epigenetic changes induced by any combination of inflammation and oxidative stress associated with uremia are not easily reversible[35]. For these reasons, KT recipients with COVID-19 infection still have a persistently increased risk for Long-COVID.

As shown in Figure 2B, most of the participants experienced much improvement in the manifestations of Long-COVID after 4 wk and nearly complete resolution by three months. However, the differential diagnosis between the functional limitation during the COVID rehabilitation phase *vs* the Long-COVID syndrome may be difficult. Accordingly, the need for a robust clarification of the sequelae after COVID-19 infection is another concern in the post-pandemic era. The British NICE suggests that the term PASC must refer to any clinical signs and symptoms that develop during or after an infection consistent with COVID-19, that continue for more than 12 wk, and that cannot be explained by any other conditions[6]. Similarly, the World Health Organization (WHO) defines the PASC syndrome as any symptoms without an alternative diagnosis from three months onwards and that last for at least 2 mo[7]. Based on our findings, we found a significant difference in the clinical spectrum between patients with a symptom duration longer than 3 mo *vs* less than 3 mo post-COVID-19 infection (Figure 2B), in agreement with the COVID Symptom Study[36]. One explanation for the persistence of clinical signs and symptoms following COVID-19 infection may involve the underlying biological factors, such as an aberrant immune response[37], diverse functional autoantibodies[38], or gut dysbiosis[39], that drive other virus-initiated chronic syndromes.

We support using the 12-week cut-off duration as recommended by NICE and WHO for the diagnosis of PASC, and we propose an additional revision of the specific nomenclature for early and late Long-COVID syndrome. We propose using the term "post-acute COVID-19 syndrome (PACS)" for the clinical syndrome that develops three months from post-COVID-19 infection and using "chronic COVID-19 syndrome" thereafter (Figure 3). We further recommend reserving the term "Long-COVID syndrome" for the clinical syndrome that develops beyond three months post-COVID-19 infection and lasts for at least six months, because Long-COVID syndrome may be another post-viral illness spectrum, like myalgic encephalomyelitis/chronic fatigue syndrome[40].

The mechanisms underlying the GI manifestations of Long-COVID are not completely understood. One plausible explanation might be that an impairment of gut homeostasis is explained by disruption of gut-lung communication[41]. The manifestations during acute COVID-19 are believed to be related to an increased expression of ACE2 on the small bowel mucosa[17], endotoxemia[16,42], leaky gut[16], and alterations in hepatic blood flow due to sinusoidal thrombi[43], all triggered by an increased proinflammatory state and intestinal dysbiosis. Undoubtedly, the greater severity of COVID-19 infection in the elderly (high C-reactive protein > 5 mg/L, high D-dimer > 500 ng/mL with > 65 years old), as shown in

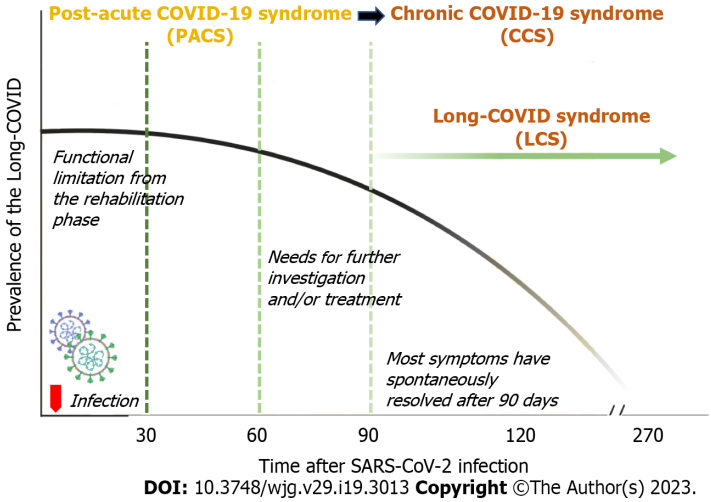

Figure 2 The burden of gastrointestinal manifestations of prolonged symptoms after corona virus disease 2019. Post-acute sequelae were followed from 30 d after infection until the end of follow-up. A: Comparison of the prevalence and characteristics of prolonged symptoms after corona virus disease 2019 (Long-COVID) among dialysis-dependent (HD, *n* = 293; PD, *n* = 21) and kidney transplant recipients (*n* = 7); B: Time course of individual Long-COVID syndrome and resolution of symptoms. The color shading indicates Long-COVID syndrome that resolved within 90 d; C: Risk factors for gastrointestinal manifestations of Long-COVID. Long-COVID: Prolonged symptoms after corona virus disease 2019; CRP: C-reactive protein (high CRP > 5 mg/L, D-dimer > 500 ng/mL).

Figure 2C, also leads to a greater risk of GI manifestations of Long-COVID[44]. Although COVID-19 outcomes are comparable between PD and HD patients[45], the findings of the present study demonstrated that PD patients have a greater risk of developing GI manifestations of Long-COVID. Being elderly and having more symptoms (Table 1) may constitute key risk factors for developing Long-COVID in PD patients[46].

Irritable bowel syndrome, a condition with diverse symptoms, including diarrhea, constipation, and mixed bowel habits according to the Rome criteria[47], has been recently proposed as a possible consequence of COVID-19 infection due to disruption of the diversity and stability of the gut microbiota [48]. For this reason, evaluation of whether diarrhea and indigestion manifestations of Long-COVID alter the gut microbiome would be worth investigating[49]. This possibility also suggests that the use of specific probiotics and prebiotics in COVID-19 clinical treatment may help KT recipients with COVID-19 infections to rebalance their gut and lung microbial ecology, thereby boosting their immune responses against the virus in response to a new metabolic milieu[50].

Moreover, little is known about the pathophysiology of the abdominal pain manifestation of Long-COVID-19. Prolonged shedding of SARS-CoV-2 from the GI tract has been observed and could be responsible for some of the GI manifestations of Long-COVID[51]. Interestingly, we found that over one-third of our KT recipients had been diagnosed with mesenteric panniculitis-related Long-COVID. Although this is a rare condition, concern is growing regarding the conditional pain associated with COVID-19[52,53]. Notably, all of our recipients with mesenteric panniculitis fully recovered after corticosteroid administration, suggesting that systemic inflammation is the process involved here[54]. Although renal allograft dysfunction and graft loss following COVID-19 infection are possibly resulted from direct toxicity of SARS-CoV-2, cytokine storm-induced tubular injury, reduced immunosuppressive drugs during infection and decreased renal allograft blood flow from multiple organ failure[55-57], there was no reported case of acute kidney injury in the cohort.

The strengths of the present study are that we compiled the data available on the prevalence, symptomatology, and specific treatment of the particular GI manifestations of Long-COVID symptoms; this

Figure 3 Illustration of the proposed new nomenclature for clinical syndromes following post-corona virus disease 2019 infection. We propose that the term post-acute-corona virus disease 2019 (COVID-19) syndrome should describe illness occurring within 90 d from the onset of COVID-19 infection. Chronic COVID-19 syndrome (CCS) would then be a modified classification that refers to the clinical syndrome thereafter. By contrast, the term Long-COVID syndrome should be reserved for patients showing CCS lasting for at least six months. In the case of severe symptoms, the investigation and corresponding treatments should be addressed at 60 d to prevent serious CCS. Long-COVID: Prolonged symptoms after corona virus disease 2019.

will help to guide clinicians in dealing with the pandemic. The identification of GI manifestations of Long-COVID in KT recipients could also help to define the contours of this new SARS-CoV-2 virus. Some limitations of the present study should also be acknowledged. This was a renal referral center study with a limited diversity of patient characteristics. No non-COVID-19 patients were included in the study, and the small number of participants made the study underpowered for investigating the risk factors associated with GI symptoms. Thus, the results need confirmation with larger cohorts that can apply the structural equation modeling for analysis, which has greater statistical power in terms of the probability of rejecting of a false null hypothesis than multiple regression analysis does[58]. In addition, the influence of different SARS-CoV-2 variants on GI manifestations of Long-COVID in dialysis-dependent and KT patients was not clarified, nor was the vaccination status against different variants addressed in our cohorts. However, based on the timing of the pandemic, the main strain circulating at the time of our study was the Delta (B.1.617) strain, accompanied by an early wave of the Omicron (B.1.1.529) variants[59,60]. Accordingly, an in-depth analysis of confounders should also be performed in larger, multinational cohorts. It is also challenging to find unrecovered pathophysiology of the long-term GI effects of COVID-19. Future research should not overlook other organ interactions to GI manifestations of Long-COVID, for instance, mental health symptoms (*e.g.*, depression and anxiety symptoms) nor additional post-infectious symptoms that were not assessed in the present study (*e.g.*, cardiovascular disease), as depression[61-63], gut-brain axis[64] or cardiovascular diseases[65] are the main etiology of long-term comorbidity of COVID-19[5], especially in HD patients[66]. In addition to lack of appetite, ESRD is recognized as a high risk of pre-existing undernutrition (malnutrition), including micronutrient deficiencies from malnutrition-inflammation-cachexia complex[67], which has been linked to increased mortality in patients with COVID-19[68]. Thus, nutrition support could be another critical intervention during COVID-19 infection in ESRD that robust research is needed for clarification as, vice versa, reduced long-term GI sequelae is probably part of the overall benefit from nutritional support.

CONCLUSION

In conclusion, at 3 mo after infection with SARS-CoV-2, renal replacement therapy patients and KT recipients with COVID-19 show high rates of GI manifestations of Long-COVID after discharge following their initial episode. These data point to optimized management as a potential line of research for decreasing Long-COVID syndrome in these populations.

ARTICLE HIGHLIGHTS

Research background

The characteristics of persistent coronavirus disease 2019 (COVID-19) symptoms or Long-COVID in

dialysis-dependent patients and kidney transplant (KT) is remain underestimate and urgent needs for investigation to prevent long-term complication in these vulnerable population.

Research motivation

End stage renal disease is a well-known condition for high mortality risk following COVID-19 infection. Thus, it is essential to explore the Long-COVID in these population as an early preventive strategy for preventing further morbidity and mortality.

Research objectives

To identify the characteristics of gastrointestinal (GI) manifestations of Long-COVID in patients with dialysis-dependent or KT status.

Research methods

A prospective, observational study was conducted during January 2022 to July 2022 in patients with COVID-19 infection to explore the Long-COVID symptoms in 3-months after the onset by interviewing.

Research results

As of 577 cases agreed to the interviews, the mean age was 52±11 years with 52% women. Long-COVID was identified in 56%, 62% and 37% in hemodialysis, peritoneal dialysis, and KT respectively. While fatigue was the most prevalent (96%) of the non-GI tract symptoms, anorexia (90.9%), loss of taste (64.4%), and abdominal pain (62.5%) were the first three common GI manifestations of Long-COVID. Of note, there were 6 cases of mesenteric panniculitis from 19 patients with GI symptoms in the KT group.

Research conclusions

Renal replacement therapy patients and KT recipients with COVID-19 show high rates of GI manifestations of Long-COVID after discharge following their initial episode.

Research perspectives

Further study should aim to explore the pathophysiology of the long-term GI effects of COVID-19 in renal replacement therapy and KT patients, which may have different immune response to Long-COVID symptoms compared to those with immunocompetent.

Abstract

BACKGROUND

Acute cholangitis (AC) constitutes an infection with increased mortality rates in the past. Due to new diagnostic tools and therapeutic methods, the mortality of AC has been significantly reduced nowadays. The initial antibiotic treatment of AC has been oriented to the most common pathogens connected to this infection. However, the optimal duration of the antibiotic treatment of AC is still debatable.

AIM

To investigate if shorter-course antibiotic treatments could be similarly effective to long-course treatments in adults with AC.

METHODS

This study constitutes a systematic review and meta-analysis of the existing literature concerning the duration of antibiotic therapy of AC and an assessment of the quality of the evidence. The study was conducted in accordance with the recommendations of the Preferred Reporting Items for Systematic Review and Meta-Analyses. Fifteen studies were included in the systematic review, and eight were eligible for meta-analysis. Due to heterogeneous duration cutoffs, three study-analysis groups were formed, with a cutoff of 2-3, 6-7, and 14 d.

RESULTS

A total of 2763 patients were included in the systematic review, and 1313 were

accounted for the meta-analysis. The mean age was 73.66 ± 14.67 years, and the male and female ratio was 1:08. No significant differences were observed in the mortality rates of antibiotic treatment of 2-3 d, compared to longer treatments (odds ratio = 0.78, 95% confidence interval: 0.23-2.67, $I2$ = 9%) and the recurrence rates and hospitalization length were also not different in all study groups.

CONCLUSION

Short- and long-course antibiotic treatments may be similarly effective concerning the mortality and recurrence rates of AC. Safe conclusions cannot be extracted concerning the hospitalization duration.

Key Words: Acute cholangitis; Antibiotic; Short-course; Long-course; Antimicrobial; Treatment duration

Core Tip: The exact duration of antibiotic therapy for acute cholangitis in adult patients remains a controversial subject in the field of gastroenterology. A total antibiotic treatment of 4-7 d is recommended by the Tokyo Guidelines of 2018. However, recent studies present that schemata of shorter-course therapies could promise similar efficacy and safety. In our study, we systematically reviewed the existing literature in order to compare the death and recurrence rates and the length of hospitalization between patients with antibiotic treatments of shorter and longer durations. Our findings showed no significant differences between the study groups in all outcomes.

INTRODUCTION

The mortality rates of acute cholangitis (AC) have significantly decreased by comparing patients' data before 1980 and after 2000, from 10%-30% to 2.7%-10%[1]. Multiple factors, such as the development of modern diagnostic techniques, therapeutic methods for bile duct decompression, and new antibiotics adapted to microbiological studies, have significantly contributed to this improvement in the prognosis of AC[2].

The bacterial species commonly detected in AC differ in relationship with the severity of AC[1,3]. Because of this fact, the empirical antibiotic therapy provided should be oriented to the severity grade as defined in the Tokyo Guidelines (TG)[4]. Previous operations, the origin of the infection, possible allergies, pharmacodynamics, pharmacokinetics, local antibiogram and liver or renal dysfunction should also determine the choice of antimicrobial therapy in patients with AC[5].

A major issue concerning the therapy of AC is the exact duration of the definite antibiotic treatment. The TG 2018 (TG18) suggest that the antimicrobial therapy should last 4-7 d, and if gram-positive cocci are present, a minimum therapy of two weeks should be administrated[5]. This interval between the recommended treatment days is relatively wide, and the recommendation provided is not based on a high level of evidence (level C). Recent studies suggest that even a therapy of two or three days could be equally effective and safe, and it could reduce the length of in-hospital stay of patients, with a consequent reduction in the economic burden on the health systems[6-8]. A randomized controlled trial also showed similar clinical outcomes for patients with intraabdominal infections who received antibiotic therapy for two days after the resolution of fever, compared to those who received therapy for a maximum of 10 d[9].

Our purpose in conducting this systematic review and meta-analysis is to collect all available data existing in the current bibliography in order to ascertain if short-course antibiotic therapies could promise lower mortality, lower rates of recurrent AC, and shorter hospitalizations in adults with AC, compared to long-course antibiotic therapies and, if possible, to attempt to clarify the optimal duration of the antimicrobial treatment of the AC.

MATERIALS AND METHODS

Review protocol

Our systematic review was conducted according to the guidelines of the Preferred Reporting Items for Systematic reviews and Meta-Analyses (PRISMA)[10]. Two independent reviewers (Kasparian K and Christou CD) performed research in Medline-PubMed and Cochrane databases by applying a predefined research algorithm. The last search date was the 5th of October, 2022. The studies were initially controlled according to their title and abstract and followingly according to their full texts and the extractability of their content. We included studies concerning adults who received antibiotic therapy against AC, and whose therapy duration or mean/median duration was documented. We included only original studies in our systematic review (observational studies and randomized controlled trials). The exclusion criteria for the articles in our review, were studies concerning infantile population, animal studies, non-English studies, case reports or case series, comments or editorials, book chapters, studies with non-extractable data, abstract publications, protocols of incomplete clinical trials, irrelevant articles, surveys, and articles whose full-texts could not be retrieved. Conflicts during the eligibility process were resolved after a discussion between the two reviewers.

From the 1380 articles retrieved from the research, 50 were removed as duplicates and 1150 were excluded according to their titles and abstracts. From the 177 remaining studies, 15 were included in our systematic review[6,8,11-23], and the quantitative analysis of our research question was based on eight studies[8,11,12,16,17,21-23]. Forty-five papers contained data that was not extractable for our review, one study concerned a population of non-adult patients, 49 studies were irrelevant to our research questions, and the remaining excluded papers concerned non-original studies. One of the final papers constitutes a randomized-controlled trial, while the other fourteen concern retrospective observational studies. The details of the reasons for the exclusion of the papers are summarized in the PRISMA flowchart in Figure 1.

Data extraction

The two reviewers (Kasparian K and Christou CD) collected and tabulated independently the data of the final papers chosen for this review. Each reviewer gathered data concerning the study protocol, the baseline characteristics of the participants, and data concerning the outcomes and their definitions. The baseline characteristics to be collected for our review were predefined: Mean age and standard deviations (SD), gender, comorbidities, severity grade of AC, antibiotic therapy, and biliary drainage method. Heterogenous numerical data were transformed into the same predefined measurement units for statistical analysis. The two reviewers compared the data that each one collected, and conflicts were resolved between them.

Outcomes

The primary outcome of our study was the mortality of the patients. Secondary outcomes were the recurrence rate and the length of hospitalization of AC, measured with days. All outcomes were predefined. As mortality, we define the total, all-cause mortality of the participants until the end of the follow-up period of each study. In-hospital mortality due to AC was not examined.

Due to the heterogeneity in the time cutoff points between the intervention groups in each study, our quantitative analysis was divided into three subgroups. More specifically, an analysis was conducted among the studies which compared a therapy of 2-3 d to longer antibiotic treatments[6,8,11,21], studies with a cutoff of 6-7 d were separately analyzed[22,23], and the two papers which assessed clinical outcomes in AC-patients who received antibiotic treatment of for 14 d or less were summarized together [12,16].

Statistical analysis

All continuous variables are presented with the means and SD. For numerical variables which were not normally distributed and for which their medians and interquartile ranges or ranges were provided, we used the Hozo equation to calculate their means and SD[24]. For the data synthesis of the numerical variables, standardized mean differences (SMD) and 95% confidence intervals (95%CI) were calculated, with the use of Hedge´s method, for bias to be minimized[25]. For the categorical variables, we collected the absolute values and calculated the odds ratios (OR) and their 95%CIs. The data synthesis of the qualitative variables was based on the random effects model. In cases where no events were presented concerning a qualitative variable in a study group, the proper changes were conducted, in order for the statistical analysis to be feasible[26]. For the evaluation of the study heterogeneity, the I^2 value was calculated for each outcome. We presume $I^2 > 70\%$ as an indicator of heterogeneity among the studies. For all other measurements, we selected a P value of 0.05 as the cutoff point for the presence of statistical significance. All calculations and Forest plots were conducted through the program R Studio, version 1.4.1103.

Quality assessment

To assess the quality of the observational studies included in our systematic review and meta-analysis,

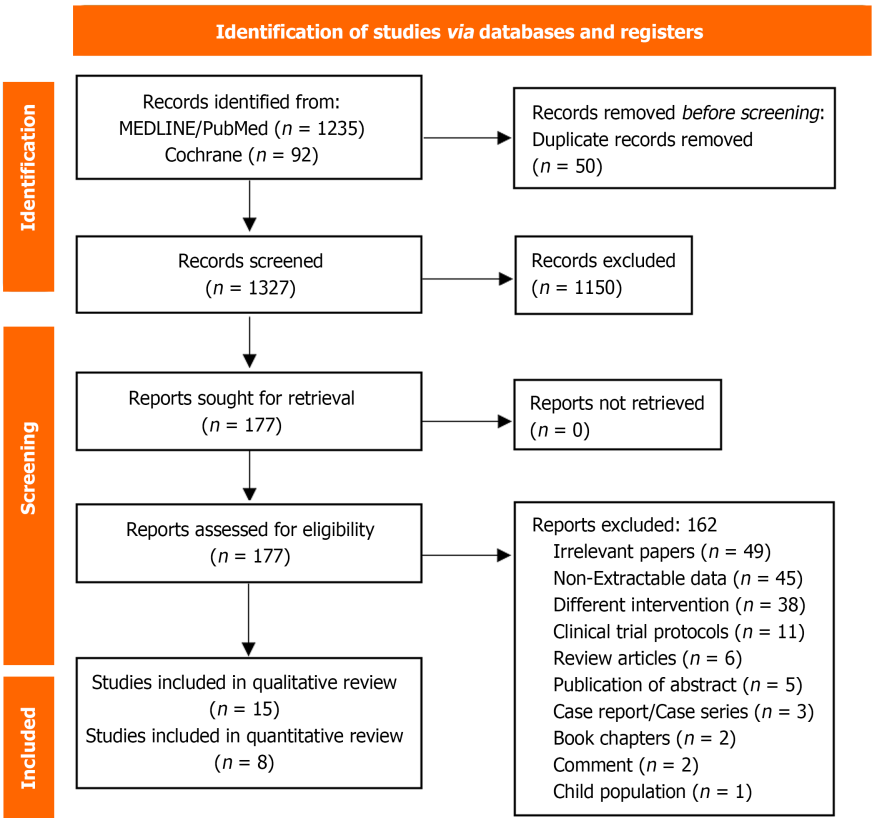

Figure 1 The Preferred Reporting Items for Systematic Review and Meta-Analyses flow chart of the systematic review and meta-analysis.

the Newcastle-Ottawa Scale was used[27]. The randomized clinical trials were evaluated for quality according to the Risk-of-Bias tool version 2 (RoB 2) provided by Cochrane[28]. Two reviewers (Kasparian K and Christou CD) independently assessed the final studies using the methods mentioned above, and possible conflicts were resolved afterward.

RESULTS

Baseline characteristics

As mentioned, 15 studies were included in our systematic review, and eight were considered eligible for the meta-analysis. The included studies were primarily conducted in Japan (8/15), two in the Netherlands, and the remaining studies originated from medical centers in France, Germany, Pakistan, South Korea, and Thailand. In 11/15 studies, the diagnosis of AC was based on the TG18/TG13 guidelines[6,8,12-14,16-18,20,21,23], two studies defined AC, depending on the TG07[15,19], Doi *et al*[22] controlled the presence the proper code of the 10th Edition of the International Classification of Diseases in hospital registries and positive bile or blood cultures for the selection of the patients, while van Lent *et al*[11] based the diagnosis of cholangitis on clinical, laboratory and imaging criteria.

The overall number of patients included in the systematic review was n = 2763, which corresponded to 2812 cases of AC. In the eight studies selected for the quantitative analysis, a total of 1219 patients and 1313 cases received antibiotic treatment against AC. The pooled mean age of the participants in the meta-analysis was 73.66 ± 14.67 years, and 721 (54.9%) of them were males, with a male to female ratio of 1:0.8. According to the TG18 severity grading system, 400/972 (41.1%) patients were classified as grade I, 525/972 (54.1%) as grade II while 45/972 (4.6%) of the patients suffered from grade III AC. Positive blood culture was detected in 383/742 (51.6%) participants. *Escherichia coli* (188/383, 49.1%) and *Klebsiella spp.* (75/383, 19.6%) were the most frequently identified pathogens, while 26/278 (9.3%) patients presented infection with gram-positive bacteria. A total of 244/1155 (21.1%) patients suffered from diabetes mellitus, 126/779 (16.2%) had a history of chronic kidney disease, and 107/779 (13.7%) participants presented a cardiac comorbidity, either chronic heart failure or coronary artery disease. Most patients received Cephalosporines (229/540, 42.4%) as antibiotic treatment and based on the available data, 275/326 (84.3%) patients underwent papillotomy during endoscopic retrograde cholangiopancreatography. For the last characteristic, only two studies included available data. Details for the baseline characteristics of the studies are summarized in Table 1.

Table 1 Baseline characteristics of the studies

Ref.	Country	Study period	Study design	Definition of AC	Population	Intervention	Outcomes
Ferstl *et al* [23], 2022	Germany	2008-2019	Retrospective observational study	TG18/TG13	Grade I and grade II AC after ERCP	Antibiotic therapy of 6 d	Recurrent cholangitis within 28 d
Kihara and Yokomizo [20], 2022	Japan	January 2009 to August 2018	Retrospective observational study	TG18/TG13	Postoperative cholangitis after pancreaticoduodenectomy	Antibiotic therapy and pancreaticoduoedenectomy	Clinical characteristics and outcomes in patients with acute cholangitis
Masuda *et al* [6], 2022	Japan	January 2018 to July 2020	Retrospective observational study	TG18/TG13	Grade I and grade II AC after successful ERCP	Antibiotic therapy of 3 d	30-d-mortality, recurrent cholangitis within 3 mo, length of hospitalization, in-hospital mortality
Sokal *et al*[14], 2022	France	2016-2018	Retrospective observational study	TG18/TG13	Patients with AC with and without malignant etiology	Cancer-associated AC	Duration of antibiotic therapy, 28-d-mortality, liver abscess
Masuda *et al* [17], 2021	Japan	April 2018 to March 2020	Retrospective observational study	TG18/TG13	AC patients with positive blood or bile culture and early ERCP	AC due to antibiotic resistant bacteria	Duration of antibiotic therapy, duration of hospitalization, in-hospital mortality, increased disease severity
Akhtar *et al* [18], 2020	Pakistan	June 2012 to June 2017	Cross-sectional observational study	TG18/TG13	AC patients without liver metastases or other reason for deranged liver function test. 70% of patients received ERCP	3-mo-mortality	Duration of antibiotic therapy, clinical severity, bacteremia
Haal *et al*[21], 2020	Netherlands	January 2012 to January 2017	Retrospective observational study	TG18/TG13	AC only due to stone in the common bile duct, without prior antibiotic therapy after ERCP	Antibiotic therapy of ≤ 3 d	3-mo-mortality, length of hospitalization, recurrent cholangitis, other complications
Satake *et al*[8], 2020	Japan	April 2014 to March 2019	Retrospective observational study	TG18/TG13	Grade I and grade II AC only due to choledocholithiasis who underwent ERCP	Antibiotic therapy of ≤ 3 d	30-d-mortality, length of hospitalization, recurrent cholangitis within 3 mo
Netinatsunton *et al*[16], 2019	Thailand	August 2017 to August 2018	Randomized controlled trial	TG18/TG13	AC only due to choledocholithiasis without presence of the Reynold´s pentad. Time to ERCP same between the study groups	Antibiotic therapy of ≤ 14 d	Recurrent cholangitis, length of hospitalization
Doi *et al*[22], 2018	Japan	January 2012 to February 2017	Retrospective observational study	ICD-10 and positive blood culture	AC and positive blood culture	Antibiotic therapy of ≤ 7 d	30-d-mortality, recurrent cholangitis within 3 mo (recurrence of symptoms)
Tagashira *et al* [13], 2017	Japan	January 2009 to December 2015	Retrospective observational study	TG18/TG13	Bacteriemic AC and ERCP where indicated	Adequate initial antibiotic therapy	Duration of antibiotic treatment, 30-d mortality
Uno *et al*[12], 2017	Japan	July 2012 to March 2014	Retrospective observational study	TG18/TG13	AC patients with gram-negative bacteriemia and after ERCP	Antibiotic therapy of ≤ 14 d	30-d mortality, recurrent cholangitis within 3 mo,

							antimicrobial treatment duration
Park *et al*[15], 2014	South Korea	September 2010 to November 2012	Randomized controlled trial	TG07	AC with bacteremia and ERCP within 24 h after admission	Intravenous antibiotic therapy of 6 d plus 8 d oral antibiotic therapy	30-d mortality, length of hospitalization, eradication of bacteria after 30 d
Kogure *et al* [19], 2011	Japan	September 2007 to August 2009	Retrospective observational study	TG07	Moderate and severe AC with ERCP	Antibiotic therapy of 3 d	Recurrent cholangitis
Van Lent *et al* [11], 2002	Netherlands	February 1999 to September 1999	Retrospective observational study	Fever > 38 °C and elevated bilirubin levels or bile duct dilatation in ultrasound	AC after successful ERCP. Exclusion of patients with primary sclerosing cholangitis, liver transplant recipients, bile duct atresia, inflammatory bowel disease	Antibiotic therapy of ≤ 3 d	6-mo mortality and recurrent cholangitis

AC: Acute cholangitis; TG18: Tokyo Guidelines 2018; TG13: Tokyo Guidelines 2013; TG07: Tokyo Guidelines 2007; ICD-10: The 10th Edition of the International Classification of Diseases; ERCP: Endoscopic retrograde cholangiopancreatography.

Mortality

Among the eight studies which were included in the quantitative analysis, six of them included mortality as an outcome[6,8,11,12,21,22], while five of the studies that were not suitable for the meta-analysis provided information for the participants' death[13-15,17,18]. Six studies calculated a 30-d mortality rate[6,8,12,13,15,22], Sokal *et al*[14] presented data concerning 28-d mortality, and Haal *et al* [21] conducted a follow-up of 3 mo concerning the death rates of the participants. Van Lent *et al*[11] observed the mortality of the patients for the following six months after the intervention.

After summarizing the data of the four studies with a duration of 2-3 of antibiotic treatment as cutoff point[6,8,11,21], no significant difference in the mortality between the two patient groups is present (OR = 0.78, 95%CI: 0.23-2.67, I^2 = 9%) (Figure 2A). No heterogeneity among these studies concerning our primary outcome is noted (I^2 = 9%).

In the study of Doi *et al*[22], patients who received an antibiotic treatment of fewer than seven days presented similar death rates compared to those with longer therapeutic schemata (OR = 0.82, 95%CI: 0.18-2.95, I^2 = 9%). The 30-d mortality rates of AC patients did not seem to differ between antibiotic therapies, of 14 d or shorter, according to Uno *et al*[12] (2 *vs* 0, P = 0.79, Fisher´s exact test).

Similar findings are also observable in the rest of the studies, which were not included in the meta-analysis. Sokal *et al*[14] presented that although patients with cancer-related-AC took an antibiotic treatment of mean duration with no significant difference compared to those that suffered from non-cancer-related-AC (10.6 ± 9.7 *vs* 7.8 ± 7.5 d, P = 0.13), the patients who belonged in the first group had significantly higher mortality rates (17 *vs* 0 deaths, P = 0.0002). In the rest of the studies, no differences concerning mortality were to be noted[13,15,17,18].

Recurrent cholangitis

Five of the included papers calculated a recurrence rate up to a follow-up period of 3 mo[6,8,12,21,22], van Lent *et al*[11] estimated a 28-d recurrence rate, Ferstl *et al*[23] recorded the shortest follow-up period among the studies (28 d) and two studies did not clarify the exact duration of follow-up for this outcome[16,19].

According to the studies retrieved from our review, a two to three-day antibiotic therapy was not associated with a significantly more frequent appearance of recurrent cholangitis (OR = 0.89, 95%CI: 0.49-1.60) (Figure 2B)[6,8,11,21]. No differences were also noted in the rates of recurrent AC neither in the 6-7-d-cutoff (OR = 1.11, 95%CI: 0.45-2.75) nor the 14-d-cutoff study groups (OR = 0.15, 95%CI: 0.02-1.35) (Figures 3 and 4A respectively). In all these comparisons, no significant study heterogeneity was observed (I^2 = 38%, 0%, and 0%, respectively). In the study of Kogure *et al*[19], no recurrent cholangitis was observed in both study groups, with and without withdrawal of the antibiotic therapy on the third day of treatment.

Length of hospitalization

Although in the studies of Masuda *et al*[6] and Haal *et al*[21], the patients who belong to the two-day and three-day antibiotic therapy have a significantly shorter hospitalization duration, the SMD of all three studies with a cutoff of 2-3 d is not significantly lower in the short-term antibiotic group (SMD = -0.53, 95%CI: -1.88 to 0.82, I^2 = 91%) (Figure 2C). Similarly, no difference was found between the short-

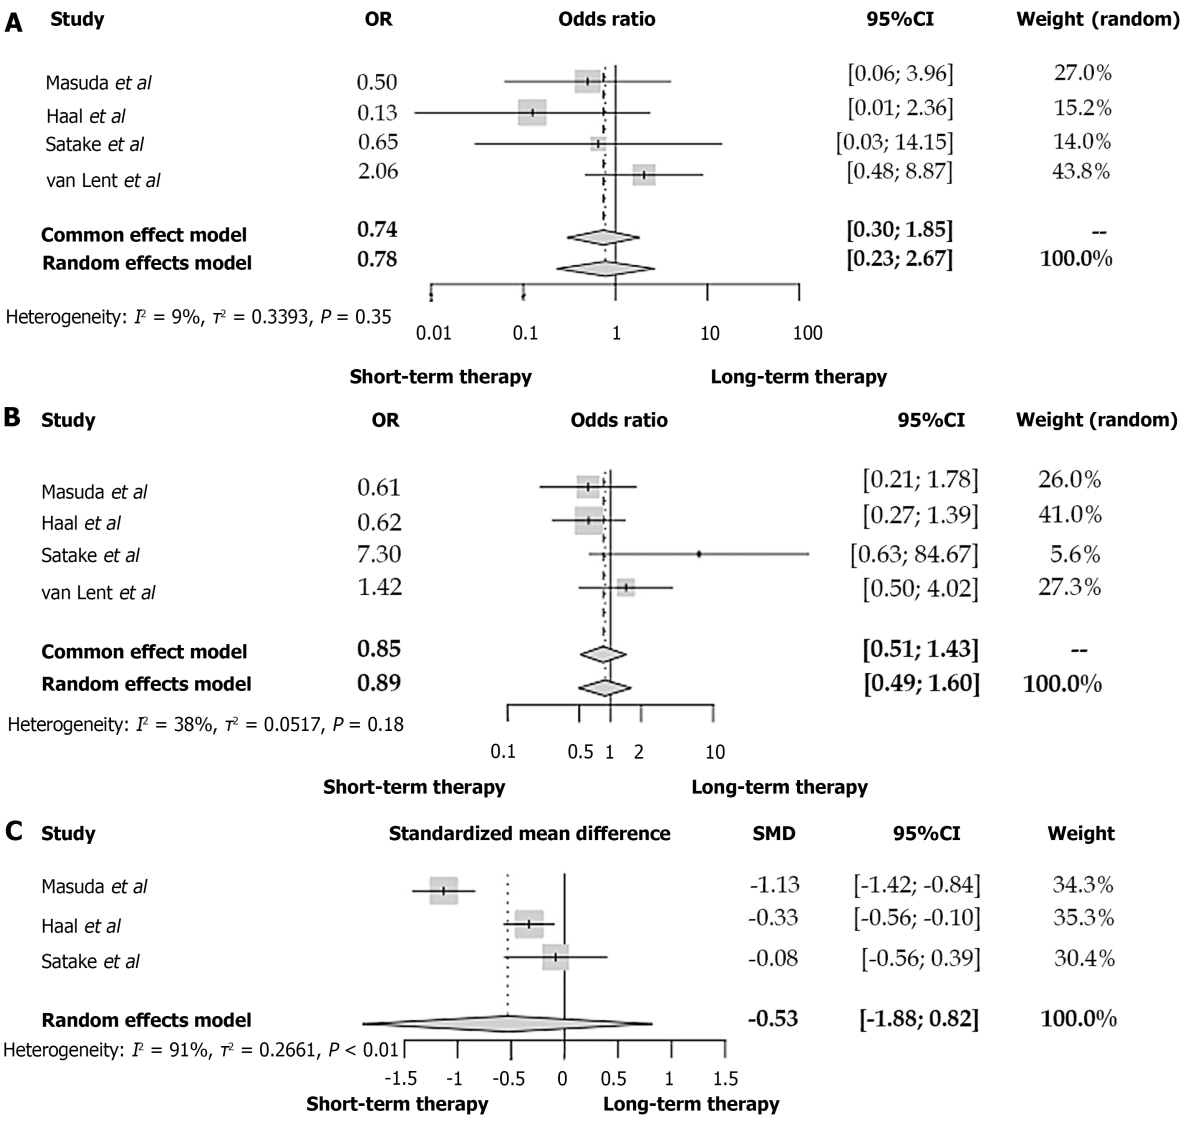

Figure 2 Forest plot between patients with acute cholangitis who received an antibiotic therapy of 2-3 d and acute cholangitis-patients with longer antibiotic treatment. A: Mortality; B: Recurrent cholangitis; C: Duration of hospitalization. OR: Odds ratio; CI: Confidence interval; SMD: Standardized mean difference.

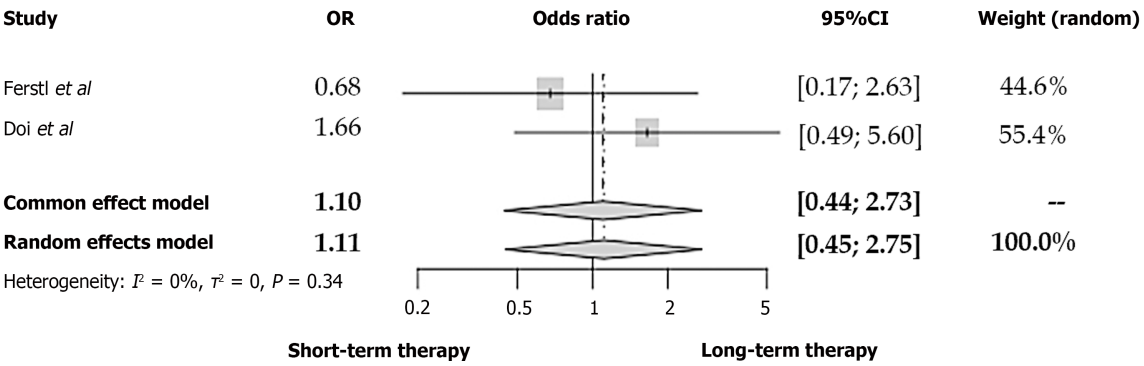

Figure 3 Forest plot of recurrent cholangitis between patients with acute cholangitis who received an antibiotic therapy of 6-7 d and acute cholangitis-patients with longer antibiotic treatment. OR: Odds ratio; CI: Confidence interval.

and long-term treatment groups concerning the length of in-hospital stay (SMD = -1.30, 95%CI: -14.43 to 11.84, I^2 = 95%) (Figure 4B). However, the considerable study heterogeneity (I^2 = 91% and 95%, respectively) does not allow us to extract strong conclusions. On the contrary, Park *et al*[15] estimated that a switch from intravenous to oral antibiotic therapy after six days from the treatment initiation led

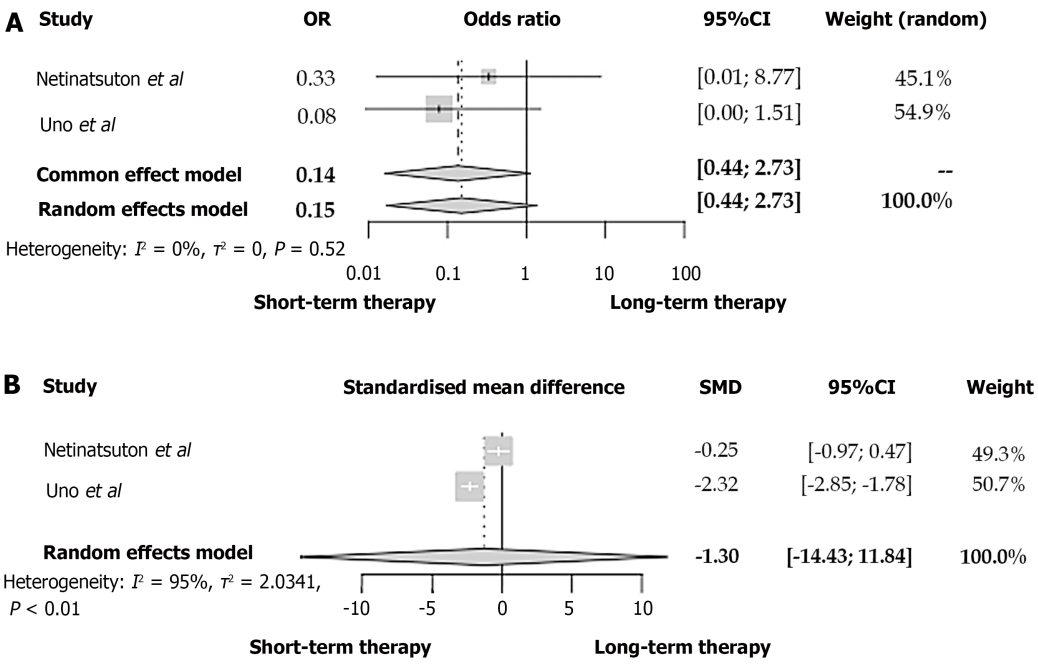

Figure 4 Forest plot between patients with acute cholangitis who received an antibiotic therapy of 14 d and acute cholangitis-patients with shorter antibiotic treatment. A: Recurrent cholangitis; B: Duration of hospitalization. OR: Odds ratio; CI: Confidence interval; SMD: Standardized mean difference.

to a significantly lower length of hospitalization in comparison with a switch at ten days of treatment.

Quality assessment

Based on the Newcastlte-Ottawa Scale, six of the observational studies included in the systematic review were considered of good quality[6,8,13,17,21,23], while the remaining seven were graded as low-quality studies, concerning our outcomes of interest, mostly due to lack of comparability between the cohort participants[11,13,14,18-20,22] (Table 2). In the study of Netinatsunton *et al*[16], as far as the randomization process is concerned, although the patients were randomized with the use of a computer-generated process and the baseline characteristics of the patients did not significantly differ, the results of the randomization were stated to be concealed in envelopes. However, the status and the accessibility of the envelopes are not provided, which raises concerns regarding the absolute transparency of the randomization. Additionally, no information is provided to manage the patients who did not adhere to the trial. Furthermore, the fact that no more information is provided concerning the construction of the study, as the trial protocol is provided neither in the clinicaltrials.gov website nor in the text in its complete form, leads us to the conclusion that the risk of bias in this study is high.

The trial of Park *et al*[15] has been based on a computer-generated block randomization model. However, no allocation concealment was possible due to the different application ways of the different interventions (oral *vs* intravenous). The authors followed an intention-to-treat model, but the lack of blinding may have led to a bias in measuring the outcome. Due to these facts, we conclude that the trial of Park *et al*[15] may also be connected to a high risk of bias.

DISCUSSION

To our knowledge, this is the first complete meta-analysis examining the duration of antibiotic therapy against the AC. In previously conducted systematic reviews with similar thematology, the limited data and the heterogenous outcomes and populations did not allow the authors to perform a meta-analysis [7,29]. Our data synthesis showed that antibiotic treatment of less than 2 or 3 d is not associated with significantly higher mortality rates, according to the random effects model (OR = 0.82, 95%CI: 0.18-2.95, I^2 = 9%). Our findings agree with the conclusions of the systematic review of Haal *et al*[7]. The fact that van Lent *et al*[11] did not base their diagnosis on the TG07 or TG18/13, possibly because the study was conducted before the establishment of the diagnostic criteria, may weaken the weight of this outcome. Although the combination of the diagnostic criteria of van Lent (fever > 38°C + elevated bilirubin levels or dilated bile duct by ultrasound) theoretically covers the criteria needed for the diagnosis of AC[30], the authors did not provide the exact cutoff, above which the bilirubin levels are considered elevated and the sensitivity of ultrasound on the diagnosis of AC is limited[31,32]. This could lead to a false

*Represents study meets a criterion in each section of the Newcastle-Ottawa scale; -Represents study meets no criterion in each section of the Newcastle-Ottawa scale.

estimation of the actual patients suffering from AC. In the studies of Doi *et al*[22] and Uno *et al*[12], who set higher cutoffs for the definition of short- and long-term treatments, significance in the OR of the mortality rates was also not reached[12,22]. The findings of Sokal *et al*[33] that cancer-related AC patients presented a higher 28-d mortality compared to patients with AC not related to malignancies, in combination with the fact that the patients in the two groups received an antibiotic therapy of no different duration, may imply that the antibiotic therapy in cancer-related AC-patients should be longer. This study alone can provide no evidence for this assumption.

Concerning the rates of recurrent cholangitis, no significant differences were found between the study groups in all three duration cutoffs we set for our analysis. Although Uno *et al*[12] estimated a slightly higher recurrence rate in the group with > 14 d of antibiotic treatment, our synthesis with the study of Netinatsunton *et al*[16] resulted in no significantly different rates compared with the longer-course group. Haal *et al*[7] and Tinusz *et al*[29] enforce our results that the duration of antibiotic treatment of AC does not seem to affect the possibility of the appearance of cholangitis recurrence. The increasing resistance of the usual bacteria causing AC, such as *Escherichia coli*, the higher rates of gram-positive pathogens in recurrent cholangitis, and the possible lack of coverage against those bacteria in the initial empiric scheme provided against AC may constitute the major factors for the appearance of episodes of cholangitis recurrence[3,34,35]. As Tagashira *et al*[13] stated, inadequate initial antibiotic treatment could increase mortality and adverse events in bacteremic patients with AC.

Among the studies with a cutoff of 2-3 d of antibiotic treatment, Masuda *et al*[6] and Haal *et al*[21] presented a significantly shorter in-hospital stay for patients receiving short-term treatment compared to the control group of the study. However, when summarizing those two studies with the observational study of Satake *et al*[8], the SMD in the length of hospitalization was not significant (SMD = -0.6, 95%CI: -2.27 to 1.07, I^2 = 0%). Antibiotic treatment of less than 14 did also not seem to lead to a shorter hospitalization of patients compared to the control group, according to our study (SMD = -1.3, 95%CI: -14.49 to 11.89, I^2 = 96%), even though the short-course antibiotic treatment in Uno *et al*[12], presented a significantly lower hospitalization duration. However, the high heterogeneity of the studies included in these tests concerning this outcome (I^2 = 91% and 96%, respectively) may have affected our results. Park *et al*[15] reinforced the claim that shorter antibiotic treatment may benefit the patients concerning their length of stay in the hospital, as no mortality cases were recorded. In every case, more studies examining the hospitalization length should be conducted, as the extraction of evidence that proves that a short-course antibiotic treatment leads to shorter hospitalizations would protect patients from exposure to several dangers, such as thromboembolic episodes and unwanted infections[36,37].

Our study presents several limitations which should be accounted for. First of all, as many studies were conducted before 2013, the choice of the participants as patients suffering from AC was not based on the updated TG18/13, especially in the study of van Lent *et al*[11]. This may alter the actual population we wish to study. The difference in patients' inclusion and exclusion criteria and the variable severity grades of the patients included in the studies also constitute an important limitation. Additionally, small discrepancies are also noticed in the follow-up periods concerning the mortality and recurrent cholangitis in each study. These inequalities in the follow-up of the patients may lead to lost data which may have altered our results. Finally, significant statistical heterogeneity was detected among the studies selected for the quantitative analysis of the length of hospitalizations, which may lead to invalid conclusions.

CONCLUSION

Depending on our findings, the duration of antibiotic therapy may not significantly affect the mortality rate, the rate of recurrent cholangitis, and the length of hospitalization of patients suffering from AC. More specifically, a 2 to 3-d antibiotic treatment could be similarly effective in preventing mortality and recurrent cholangitis, as the 4 to 7-d therapy proposed by the TG18. However, these results are based on a small number of heterogeneous studies. It is vital that more primary and secondary studies are conducted for new recommendations with high-level evidence to be established.

ARTICLE HIGHLIGHTS

Research background

The mortality rates of acute cholangitis (AC) have significantly decreased in the last decades. The development of new diagnostic and therapeutic tools has contributed to this result.

Research motivation

The Tokyo Guidelines of 2018 suggest an antibiotic treatment of four to seven days in AC cases without gram-positive cocci. This interval between the recommended treatment days is relatively wide, and the recommendation provided is not based on a high level of evidence (level C).

Research objectives

The aim of this study is to investigate if shorter-course antibiotic treatments could be similarly effective to long-course treatments in adults with AC.

Research methods

We conducted a systematic review and meta-analysis of the existing literature based on the recommendations of the Preferred Reporting Items for Systematic Review and Meta-Analyses. Two reviewers (Kasparian K and Christou CD) conducted the literature research, study selection, and data collection. The inclusion and exclusion criteria were predefined. The data synthesis, statistical analysis, and Forest plot creation were conducted through the program R Studio version 1.4.1103.

Research results

Fifteen studies were included in the systematic review and eight in the final meta-analysis. Most of the patients were classified as Grade I (41,1%) or Grade II (54,1%), while only 4,6% of the participants suffered from Grade III AC. No significant differences were observed between patients receiving a 2-3 d antibiotic therapy and those who were treated with longer antibiotic schemata concerning the mortality (odds ratio = 0.78, 95% confidence interval: 0.23-2.67, I^2 = 9%). In all calculations conducted, no differences could be detected among patients receiving shorter and longer antibiotic treatments concerning the rates of recurrent AC and the length of hospitalization.

Research conclusions

Short- and long-course antibiotic treatments may be similarly effective concerning the mortality and recurrence rates of AC.

Research perspectives

This study could constitute the occasion for the conduction of more primary and secondary studies for new robust recommendations with a high level of evidence to be established.

Abstract

BACKGROUND

Hepatitis C infection not only damages the liver but also often accompanies many extrahepatic manifestations. Incidences of pulmonary hypertension (PH) caused by hepatitis C are rare, and incidences of concurrent nephrotic syndrome and polymyositis are even rarer.

CASE SUMMARY

Herein we describe the case of a 57-year-old woman who was admitted to our department for intermittent chest tightness upon exertion for 5 years, aggravated with dyspnea for 10 d. After relevant examinations she was diagnosed with PH, nephrotic syndrome, and polymyositis due to chronic hepatitis C infection. A multi-disciplinary recommendation was that the patient should be treated with sildenafil and macitentan in combination and methylprednisolone. During treatment autoimmune symptoms, liver function, hepatitis C RNA levels, and cardiac parameters of right heart catheterization were monitored closely. The patient showed significant improvement in 6-min walking distance from 100 to 300 m at 3-mo follow-up and pulmonary artery pressure drops to 50 mmHg. Long-term follow-up is needed to confirm further efficacy and safety.

CONCLUSION

Increasing evidence supports a relationship between hepatitis C infection and diverse extrahepatic manifestations, but it is very rare to have PH, nephrotic syndrome, and polymyositis in a single patient. We conducted a literature review on the management of several specific extrahepatic manifestations of hepatitis C.

Key Words: Hepatitis C; Nephrotic syndrome; Polymyositis; Pulmonary hypertension; Case report

Core Tip: Hepatitis C virus (HCV) infection should be considered a systemic disease which is often associated with many extrahepatic manifestations, but it is very rare to have multiple different extrahepatic manifestations in a single patient. In this article, we report a case of pulmonary hypertension (PH), nephrotic syndrome, and polymyositis due to HCV infection. The optimal treatment strategy for hepatitis C-related extrahepatic manifestations remains to be determined. Our case confirms sildenafil and macitentan as effective treatment option for patients suffering from PH due to hepatitis C infection. However, randomized, controlled trials are warranted to confirm the present results.

INTRODUCTION

Hepatitis C virus (HCV) is a sporadic and a common cause of chronic hepatitis after blood transfusion. In recent years various authors have described associations between hepatitis C infection and a heterogeneous group of non-hepatic diseases such as cryoglobulinemia, rheumatoid arthritis, Sjogren's syndrome, and glomerulonephritis, which are seen as extrahepatic manifestations of chronic hepatitis C infection[1].

Pulmonary hypertension (PH) is defined as a mean pulmonary arterial pressure (mPAP) ≥ 20 mmHg at rest with right heart catheterization[2]. PH affects approximately 1% of the global population, up to 10% of individuals aged ≥ 65 years, and at least 50% of patients with heart failure[3]. PH has several different causes with different management and outcomes. However, PH due to hepatitis C has rarely been reported. Herein we describe a case of PH, nephrotic syndrome, and polymyositis following chronic hepatitis C infection in a 57-year-old woman.

CASE PRESENTATION

Chief complaints

A 57-year-old Chinese woman presenting with untreated chest tightness, shortness of breath, and fatigue for 5 years and with dyspnea for 10 d was admitted to the China-Japan Union Hospital of Jilin University.

History of present illness

She had no precordial pain, orthopnea, or palpitation. She had no joint pain, dental ulcers, or rash.

History of past illness

Forty years previously she had received an intravenous blood transfusion for a right ovariectomy. Sixteen years previously she was diagnosed with hepatitis C, nephrotic syndrome, and hypertension, but did not receive standard treatment. Five years previously she developed mild PH with pulmonary arterial pressure of 54 mmHg measured by transthoracic echocardiography, which was not treated further. Three years previously she developed severe myopathy. She was diagnosed with polymyositis and administered methylprednisolone 40 mg once a day (QD) and cyclophosphamide 50 mg QD. She lapsed into intermittent coma due to hyperemic ammonia however, thus cyclophosphamide was discontinued, and methylprednisolone 20 mg QD was initiated and has been maintained to date.

Personal and family history

She had no family history of genetically related diseases, but her daughter had hepatitis C and had been treated with interferon.

Physical examination

Physical examination revealed no fever, heart rate 70 bpm, blood pressure 140/90 mmHg, O_2 saturation 94% on room air, second heart sound accentuation, and moderate edema in both lower limbs.

Laboratory examinations

Primary laboratory data on admission are shown in Table 1. The 6-min walking distance was 100 m.

Table 1 The patient's laboratory data at admission and at 1-mo follow-up

Parameter	Value (admission)	Value (month 1)	References value	Unit
N-terminal-pro B-type natriuretic peptide	590		0-125	pg/mL

Blood ammonia	56		9-30	μmol/L
Erythrocyte sedimentation rate	22	6	0-20	mm/h

Imaging examinations

Muscle biopsy showed striated muscle atrophy with inflammatory cell infiltration (Figure 1A). Electrocardiography indicated a normal sinus rhythm (Figure 1B). Transthoracic echocardiography showed enlargement of the left atrium (43.7 × 45.2 × 60.0), right atrium (59.8 × 39.4), and right ventricle (49.3), normal left ventricular ejection fraction (71.3%), elevated pulmonary artery pressure (61 mmHg), and reduced diastolic function (Figure 1C-F). Chest computed tomography (CT) depicted pulmonary arterial hypertension, right atrium and right ventricle enlargement, and no parenchymal lung disease (Figure 2A-C). Pulmonary ventilation/perfusion scanning indicated no evidence of typical signs of thromboembolic disease (Figure 2D). Abdominal CT suggested normal liver size with a hepato-renal shunt and a spleno-renal shunt (Figure 2E and F). Right heart catheterization showed that mPAP was 55.33, pulmonary artery wedge pressure (PAWP) was 24, and pulmonary vascular resistance (PVR) was 5.13 Woods units (WU) (Table 2).

FINAL DIAGNOSIS

Based on the medical history, symptoms, and auxiliary examinations, a diagnosis of moderate PH, nephrotic syndrome, polymyositis, hypertension, and hepatitis C was determined.

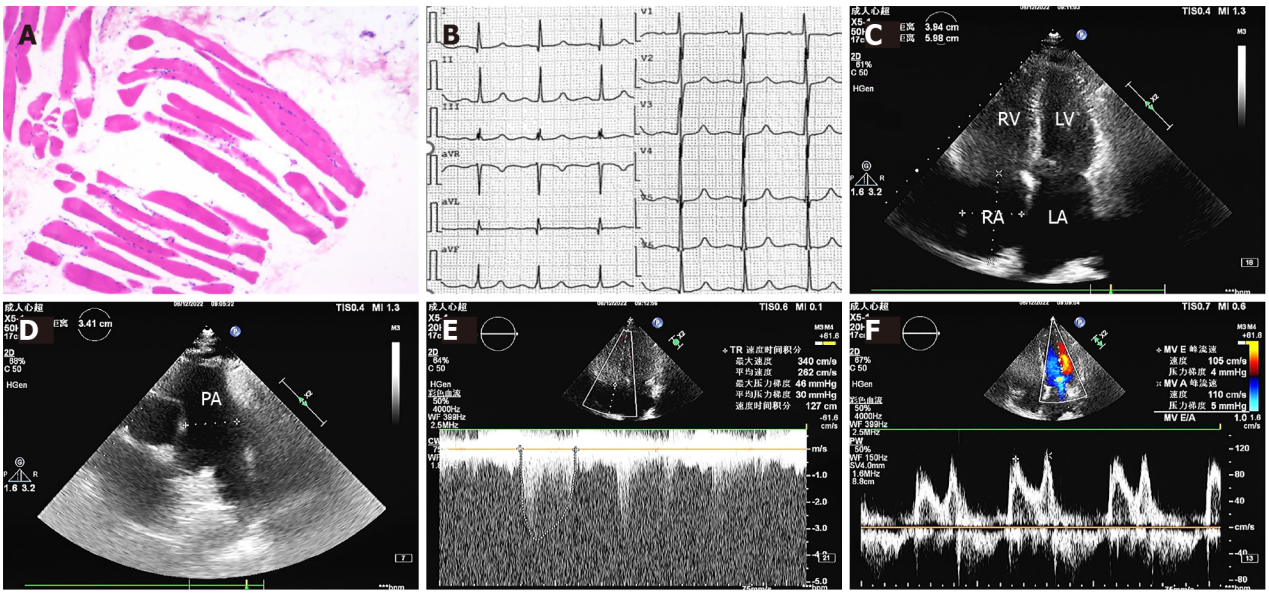
TREATMENT

The patient was treated with sildenafil 20 mg QD, macitentan 10 mg QD, irbesartan and hydrochlorothiazide 150 mg QD, furosemide 20 mg QD, and methylprednisolone 80 mg QD with the dose gradually reduced to 20 mg QD. Due to suspected hepatitis C-induced multiple organ injury the patient was referred to the gastroenterology department for further assessment of liver disease. There was no evidence of a liver tumor. Liver stiffness as evaluated by transient elastography was 8.3 kPa. Hepatitis C antibody was 6.8 S/CO, but serum tests were negative for HCV RNA. Therefore, she was not prescribed antiviral therapy.

OUTCOME AND FOLLOW-UP

At the 3-mo follow up the patient's dyspnea was dramatically improved and the 6-min walking distance was 300 m and pulmonary artery pressure drops to 50 mmHg.

DISCUSSION



HCV infection should be considered a systemic disease which is often associated with many extrahepatic manifestations. According to different studies, 40%-80% of patients infected with HCV develop at least one extrahepatic manifestation[4]. However, PH associated with HCV is relatively rare.

PH is divided into five clinical subgroups; pulmonary arterial hypertension (PAH), PH associated with left heart disease, PH associated with chronic lung disease and/or hypoxia, chronic thromboembolic, and PH with unclear and/or multifactorial mechanisms. Pre-capillary PH is hemodynamically defined as mPAP > 20 mmHg, PAWP ≤ 15 mmHg, and PVR > 2 WU. PAWP > 15 mmHg is the threshold of post-capillary PH. PVR is used to distinguish patients with post-capillary PH who have significant components of pre-capillary PH (PVR > 2 WU, combined with post-capillary and pre-capillary PH; CpcPH) from those who do not (PVR ≤ 2 WU, isolated post-capillary PH)[5]. The current patient had no relevant family history to support a heritable cause of PH. Valvular/congenital heart diseases, lung diseases, chronic pulmonary artery obstruction, and human immunodeficiency virus infection were systemically eliminated *via* relevant tests. Drugs were also unlikely to have caused her PH. The onset of PH predated the polymyositis, and connective tissue disease could also be excluded as a cause of PH. Thus, the possibility remained that PH associated with portal hypertension was due to chronic hepatitis C.

Portal PH (PoPH) is a well-known serious complication of portal hypertension in chronic liver disease. According to statistics, PoPH occurs in 1%–2% of patients with liver disease and portal hypertension[6]. The incidence of PoPH is higher in patients with HCV-related cirrhosis. In PAH registry studies, PoPH patients accounted for 5%–15% of PAH patients[7-9]. Hemodynamically, patients with PoPH had significantly higher cardiac output and lower systemic and PVR than patients with idiopathic PH[10]. The diagnosis of PoPH is based on the presence of otherwise unexplained pre-capillary PH in patients with portal hypertension or a portosystemic shunt[5]. In patients with an established diagnosis of PoPH, treatment should follow the same general principles as in other patients

Table 2 Results of right heart catheterization

Parameter	Value	Unit
Heart rate	76	bpm
Pulmonary arterial pressure	90/38/55.33	mmHg
Right atrium pressure	12.17	mmHg
Pulmonary artery wedge pressure	34/19/24	mmHg
Pulmonary vascular resistance	5.13	Wood units
Pulmonary vascular resistance	410.23	dyne s/cm
Cardiac output	9.53	L/min
Cardiac index	4.51	L/min/m^2

Figure 1 Pathological image of muscle, electrocardiogram, and Echocardiography upon admission. A: Muscle biopsy with hematoxylin and eosin staining (× 100) showed inflammatory cell infiltration; B: Electrocardiography indicated a normal sinus rhythm; C: A four-chamber view showed an enlarged right atrium, right ventricle, and left atrium; D: A long axis view of the pulmonary artery indicated widening of that artery; E: Doppler echocardiography showed that the peak tricuspid regurgitation velocity was 3.4 m/s, and the tricuspid regurgitation pressure gradient was 46 mmHg; F: Bicuspid valve doppler indicated reduced diastolic function. RV: Right ventricular; LV: Left ventricle; RA: Right atrium; LA: Left atrium; PA: Pulmonary artery.

with PAH. PAH medications can affect gas exchange, which may deteriorate with vasodilators in patients with PoPH[11]. Various case series support the use of approved PAH medication in patients with PoPH. The survival and prognostic factors in PoPH remain controversial and are still poorly studied in the current era of PH management[7,12,13]. The current patient had a history of HCV infection, mild liver fibrosis, and hepato-renal shunt, thus the diagnosis of PoPH was considered. The results of right heart catheterization in the present patient were consistent with CpcPH, considering that there may have been other factors involved in PH, not only PoPH. The patient had a history of hypertension with left atrium and right atrium enlargement, and the N-terminal-pro B-type natriuretic peptide was elevated. Therefore, heart failure with preserved ejection fraction was involved in PH. Sildenafil, macitentan, diuretics, and angiotensin receptor blocker were prescribed. Short-term follow-up indicated improvement in respiratory status and increased activity tolerance. Confirmation of further efficacy requires long-term follow-up.

What is intriguing in the current case is the coexistence of PH, nephrotic syndrome, and polymyositis in a chronic hepatitis C patient, which is reported herein for the first time to our knowledge. Increasing epidemiological evidence indicates an association between HCV infection and renal disease, with membranoproliferative glomerulonephritis and membranous nephropathy being the most common [14]. The main clinical manifestations of nephrotic syndrome in HCV-infected patients are proteinuria and hypoalbuminemia, with or without a reduced glomerular filtration rate. Treatments include antiviral and nonspecific immunosuppressive therapy[15], but their efficacy and safety are contro-

Figure 2 Computed tomography images and pulmonary ventilation/perfusion scan. A: Axial chest computed tomography (CT) depicted widening of the pulmonary artery; B: Coronal chest CT depicted right atrial and right ventricle enlargement; C: The pulmonary window showed no significant parenchymal pulmonary disease; D: A pulmonary ventilation/perfusion scan indicated normal perfusion function; E: An axial abdominal CT showed normal liver size, slight spleen enlargement, and multiple venous tortuosity; F: A coronal abdominal CT showed thickened venous shunt between the portal vein, splenic vein and left renal vein (red arrow).

versial. HCV infection is often associated with autoimmune diseases such as cryoglobulinemia, rheumatoid arthritis, Sjogren's syndrome, systemic lupus erythematosus, dermatomyositis, and polymyositis[1,16-18]. Most of these diseases appear to be related to virus-induced non-specific activation of the immune system, including autoantibody production, cryoglobulinemia, autoimmune thyroid disorders, and B cell lymphomas[19]. Although most data are based on small series and case reports, the association between chronic HCV infection and systemic autoimmune disease has received increasing attention. The exact etiology is unknown, but interaction between viral infection and autoimmune responses is thought to be one of the mechanisms involved. Chronic HCV infection should be considered as the cause of polymyositis if no other etiology is found. The diagnosis and treatment of HCV-associated autoimmune features has become a clinical challenge in patients with HCV infection. There are few reports on the outcome of corticosteroid treatment in patients with chronic HCV infection. Several studies have described rapid progression of liver disease after immunosuppression therapy in patients with chronic HCV infection[20]. The current patient's nephrotic syndrome and polymyositis may have been caused by chronic HCV infection *via* an autoimmune mechanism. The patient was initially treated with methylprednisolone and cyclophosphamide at the time of her polymyositis diagnosis. However, cyclophosphamide was discontinued and methylprednisolone was reduced because of her repeated episodes of abnormal behavior and coma due to hyperammonemia.

The optimal treatment strategy for hepatitis C-related extrahepatic manifestations remains to be determined. Due to the limited data available, more information is needed before definitive therapeutic recommendations can be established. The guidelines for treatment of HCV-related extrahepatic manifestations should be based on clinical features rather than underlying pathogenic mechanisms. Because of the poor prognosis and high mortality associated with these manifestations, the establishment of a safe and effective regimen for the therapy of HCV-related extrahepatic features requires further investigation.

CONCLUSION

Herein we have described a case of chronic hepatitis C with coexisting PoPH, nephrotic syndrome, and polymyositis. Increasing evidence supports a relationship between hepatitis C infection and diverse extrahepatic manifestations, but it is very rare to have multiple different extrahepatic manifestations in a single patient. To our knowledge, this is the first reported case. The exact mechanism by which hepatitis C mediated the development of diverse extrahepatic manifestations remains unclear. Further research on the specific mechanism involved is needed, to facilitated the development of safer and more effective

treatment plans.

FOOTNOTES

Author contributions: Zhao YN and Liu GH were the patient's physicians; Yu M reviewed the literature and contributed to manuscript drafting; Wang C and Zhang YX performed the contributed to data collection; Yu M and Yang P were responsible for the revision of the manuscript for important intellectual content; All authors issued final approval for the version to be submitted.

Informed consent statement: Written informed consent was obtained from the patient for publication of this report and any accompanying images.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.

CARE Checklist (2016) statement: The authors have read CARE Checklist (2016), and the manuscript was prepared and revised according to CARE Checklist (2016).

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

Hericium erinaceus is an edible and medicinal mushroom commonly used in traditional Chinese medicine for centuries. Several studies have highlighted its therapeutic potential for gastrointestinal disorders such as gastritis and inflammatory bowel diseases. In addition, some components of this mushroom appear to possess strong antineoplastic capabilities against gastric and colorectal cancer. This review aims to analyse all available evidence on the digestive therapeutic potential of this fungus as well as the possible underlying molecular mechanisms.

Key Words: *Hericium erinaceus*; Fungus; Gastritis; Inflammatory bowel diseases; Gastric cancer; Colorectal cancer

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Various natural and non-pharmacological principles have been used to treat gastrointestinal disorders. *Hericium erinaceus* is a Chinese mushroom with a centuries-old medicinal tradition. Several preclinical studies have demonstrated their anti-inflammatory and antineoplastic potential. The therapeutic activity of this mushroom also targets inflammatory bowel diseases, as demonstrated in several animal experiments. However, evidence from *in vivo* studies is not generally available for patients with gastrointestinal disorders. It is also unclear which component of this mushroom has the greatest potency and the best safety profile.

INTRODUCTION

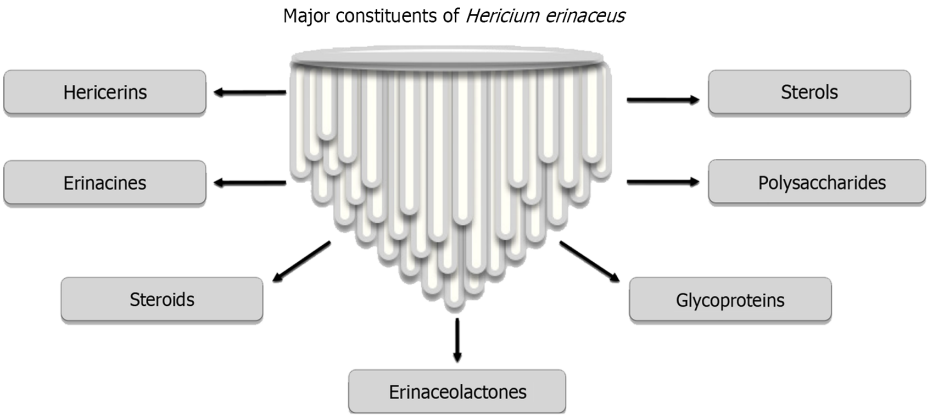
Gastrointestinal disorders are one of the most prevalent diseases in the general population. They are associated with a significant epidemiological and economic burden, with an estimated annual cost of over a hundred and thirty billion in the United States alone[1]. Many gastrointestinal disorders require a pharmacological approach; however, the possibility of adopting naturally derived complementary therapies whenever possible is emerging[2,3].

Among the abundant natural compounds studied, there is a Chinese mushroom, *Hericium erinaceus* (*H. erinaceus*) that has shown the potential to prevent and treat digestive diseases, such as gastric ulcers [4]. Furthermore, its therapeutic potential has been demonstrated in several conditions, including diabetes, hyperlipidaemia, neurodegenerative disorders, and cancer[5-8]. In addition, mild cognitive impairment is another disorder in which *H. erinaceus* has shown encouraging results in randomised clinical trials[9,10].

Therefore, *H. erinaceus* has traditionally and historically been used as a natural remedy for epigastric pain caused by chronic gastritis, gastric ulcers, or even atrophic gastritis[8].

Despite the strong need for clinical studies, several experiments, mainly preclinical and mouse model-based, have been conducted on the beneficial effects of many *H. erinaceus* extracts and components on gastrointestinal diseases. Therefore, this narrative review aimed to provide overall evidence of the therapeutic potential of *H. erinaceus* in gastrointestinal tract diseases.

H. ERINACEUS: GENERAL CONSIDERATIONS



H. erinaceus, also known as Yamabushitake (in the Japanese language), Houtou (in the Chinese language), or also as "lion's mane" is a fungus that belongs to the class *Basidiomycetes*, subclass *Holobasidiomycetidae*, order *Hericiales*, and family *Hericiaceae*[4]. This fungus is mainly distributed in European, Asian, and American regions[11]. It is a saprophytic fungus or weak parasite that typically grows on hardwoods, such as beech, chestnut, and cherry[12].

Many active metabolites of *H. erinaceus* that are structurally different from each other and potentially bioactive have been discovered[13].

The main constituents of *H. erinaceus* are erinacines (cyathane-type diterpenoid aromatic compounds as erinacines A-I), steroids (such as ergosterol, erinarols A-F, and ergostane-type steroids), alkaloids (such as hericirine, 12β-hydroxyverruculogenTR-2, fumitremorgin, methylthioglioto, pseurotin A, and FD-838), and lactones such as vitamin B_{12}-*c*-lactone (Figure 1)[13].

In addition, each 100 g of dried *H. erinaceus* contains approximately 61.3-77.5 g of total sugars, of which β-glucans, α-glucans, and glucan-protein complexes are the most abundant[14,15]. Among these, the β-glucans in the fungal cell wall have known and marked anti-inflammatory and anti-cancer potency and can positively modify the gut microbiota[16].

Much of the research devoted to the chemical characterisation of *H. erinaceus* has focused on its polysaccharide components, which are generally obtained from its fruiting body, and various extraction methods have been developed[17-19].

DOI: 10.3748/wjg.v29.i20.3084 **Copyright** ©The Author(s) 2023.

Figure 1 Several constituents can be obtained from *Hericium erinaceus* by different means of extraction (for example, by alcohol, chloroform, or petroleum). However, fractions such as erinacines and polysaccharides are those most commonly used in studies conducted in the gastrointestinal setting.

H. ERINACEUS IN UPPER GASTROINTESTINAL TRACT DISEASES: THE EVIDENCE

The role of H. erinaceus in non-infectious gastric diseases: Gastroprotective effects and therapeutic potential in repairing gastric mucosal damage

Gastric ulcers are a significant epidemiological burden[20]. Among the most common forms of gastric ulcers, those caused by non-steroidal anti-inflammatory drugs are also included. This is due to the pharmacological inhibition of cyclooxygenases 1 and 2, which are responsible for producing proinflammatory cytokines and prostaglandins, which help maintain the integrity of the gastric mucosal barrier [21]. An adequate balance between proinflammatory and anti-inflammatory cytokines is necessary for maintaining gastric mucosal integrity, such that polymorphisms in genes encoding proinflammatory cytokines can increase the risk of peptic ulcer and gastric cancer[22].

As anticipated, *H. erinaceus* has shown various anti-inflammatory, antioxidative, and gastroprotective properties. Boddy *et al*[23] showed, for example, that the action of several polysaccharides of *H. erinaceus* inhibits the secretion of proinflammatory cytokines interleukin 6 (IL-6), IL-8, and IL-12 and promotes the secretion of the anti-inflammatory cytokine IL-10 in a co-culture system of Cancer coli 2 (Caco-2) cells and Caco-2/RAW264.7 cells under bacterial lipopolysaccharide stimulation. This emphasises how this fungus can intervene in cytokine imbalance in an inflamed environment by shifting the balance toward an anti-inflammatory cytokine pattern.

To evaluate the gastroprotective, antioxidant, and anti-inflammatory activities *in vivo*, Wang *et al*[24] conducted experiments in a mouse model in which ethanol or ligation of the pylorus induced gastric ulcers. The study involved two polysaccharides, namely the crude polysaccharide of *H. erinaceus*, [*i.e.*, crude polysaccharide (HECP)] and the refined polysaccharide of *H. erinaceus* [*i.e.*, refined polysaccharide (HERP)], obtained from the fruiting body using water extraction and ethanol precipitation methods[25]. The mice were divided into several groups, including control groups and those receiving *H. erinaceus* polysaccharides at different dosages (100 mg/kg, 200 mg/kg, and 400 mg/kg). In the ethanol-induced gastric ulcer model, there was a reduction in the severity of the ulcers in a dose-dependent manner in the HERP/HECP-*treated* groups, with a significant reduction when pre-treatment with 400 mg/kg of HERP/HECP was performed. In contrast, in the pylorus-ligation-induced ulcer model, significant ulcer-inhibiting power was achieved when mice were administered HERP or HECP in a 200 mg/kg dosage. Nevertheless, the ulcers appeared to be more mitigated by HECP polysaccharide than HERP.

These results generally indicate a marked gastroprotective effect of HERP/HECP polysaccharides in ethanol-induced and pylorus-ligated gastric ulcers. However, the authors also showed results related to the control of gastric secretions. HERP/HECP administration provided a regulatory advantage over the imbalance in acid secretion induced by pylorus ligation.

Once the gastric mucosa has been damaged, the inflammatory process is activated, thereby increasing the mediators of inflammation, including tumor necrosis factor α (TNF-α), IL-1β, and IL-6[26]. TNF-α stimulates neutrophil infiltration and apoptosis of epithelial cells, reduces gastric microcirculation around the ulcer region, and delays its healing[27]. Leucocyte infarction in the gastric mucosa is generally assessed using myeloperoxidase (MPO) activity[28]. IL-1β significantly promotes ulcer formation[29]. Another defensive element that protects against gastric ulceration is the mucus-bicarbonate barrier. The mucus is a gel that adheres to the mucosa, preventing gastric acid penetration and injury. Mucus typically works in conjunction with nitric oxide (NO), prostaglandin E_2 (PGE_2), and epidermal growth factor (EGF) to maintain mucosal integrity[30]. NO protects the mucosal barrier and integrity of the gastric epithelium by inducing the inactivation of gastric parietal cells that secrete

hydrochloric acid, thereby reducing acidity[31]. PEG_2 increases mucus and bicarbonate production, leading to a decrease in gastric epithelial permeability[32]. EGF induces the proliferation of epithelial cells, thereby promoting tissue healing[30].

Wang *et al*[24] discovered that rats administered with HERP or HECP had lower serum TNF-α and IL-1β levels and lower gastric tissue MPO activity than in the control group, indicating that these polysaccharides reduced the inflammatory response. In addition, the mucus content in the stomach was higher in the *H. erinaceus* polysaccharides-treated group than in the control group, suggesting that polysaccharides may protect the integrity of the gastric mucosa. The latter was also promoted by the increased release of NO, PGE_2, and EGF in the *H. erinaceus* polysaccharides-treated group. HERP/HECP also showed scavenging effects for 2,2-diphenyl-1-picrylhydrazyl, chelating capacity for Fe^{2+} and OH *in vitro*, antioxidant activity, and increased superoxide dismutase (SOD) and glutathione peroxidase (GPx) activities. It is known that SOD can rapidly convert peroxyl radicals into biologically safe and inactive substances[33].

Furthermore, GPx protects the gastric mucosa from reactive oxygen species (ROS)-induced injury and reduces lipid peroxidation[34]. Phenolic compounds appear to be the main contributors to the antioxidant capacity of *H. erinaceus*[35]. The antioxidant and scavenger properties of *H. erinaceus* exerted through its polysaccharide component have also been confirmed by other studies, in which it was shown to prevent H_2O_2-induced apoptotic cell death in gastric epithelial cell lines (*i.e.*, GES-1 cells)[25].

In general, there are several studies on the use of *H. erinaceus* in ethanol-induced ulcers[36-38], with some focusing on acetic acid-induced ulcers[39]. Mao *et al*[36] also highlighted a possible therapeutic mechanism for ethanol-induced ulceration in mice *via* epidermal differentiation by studying the differences in the expression of several keratins, including 16, 6b, and transglutaminase E, in mucosa treated with *H. erinaceus* and untreated mucosa.

In addition to its multidimensional gastroprotective properties, *H. erinaceus* can regulate chaperonins, including HSP70. For example, in a model of ethanol-induced ulcers in Sprague Dawley mice, immunohistochemical studies have demonstrated an increased presence of HSP70 and downregulation of pro-apoptotic Bcl-2-associated X proteins[40]. Heat shock proteins (as, for example, HSP70) have a well-defined role in the pathogenesis of gastric ulcers. They are among the key players in the intracellular defence mechanisms of gastric cells. Some maintain protein integrity under homeostatic and non-stressful conditions, while others are activated after noxious stimuli[41].

However, the literature on this fungus has focused on both the erosive and atrophic patterns of gastric mucosal damage. Wang *et al*[42] examined the EP-1 fraction obtained from *H. erinaceus* mycelium in chronic atrophic gastritis. They found the potential to reduce the proliferation of MC cells (a model of atrophic gastritis) by arresting them in the G_0/G_1 phase of the cell cycle. However, there is a clinical, double-blinded, preliminary Chinese report for atrophic gastritis, although it was conducted in 1985 on 25 patients with atrophic gastritis who were administered *H. erinaceus* orally for three months. Clinical and histological improvements were observed in 63% and 52% of treated patients[43].

Although there is a considerable amount of preclinical experience, there is a substantial lack of clinical trials that have evaluated this mushroom as a pharmacological intervention in erosive gastritis, gastric ulcers, and atrophic gastritis.

H. erinaceus properties against *Helicobacter pylori* infection

Helicobacter pylori (*H. pylori*) is a gram-negative spiral-shaped bacillus that contributes to several gastrointestinal disorders, including chronic gastritis, peptic ulcer, gastric adenocarcinoma, and gastric mucosa-associated lymphoid tissue lymphoma[44]. In addition, it is associated (to varying degrees) with several extra-gastric disorders, including vitamin B_{12} deficiency anemia, primary immune thrombocytopenia, as well as ophthalmic conditions (such as glaucoma and central serous chorioretinopathy), dermatological disorders (such as rosacea and psoriasis), inflammatory bowel diseases (IBD), metabolic and neurological disorders[45]. The International Agency for Research on Cancer has designated *H. pylori* as a Group I carcinogen for gastric cancer[46]. Therefore, eradication is imperative when an infection is diagnosed[47]. However, we frequently encounter this bacterium's substantial antibiotic resistance; therefore, the guidelines suggest an algorithm based on several successive lines of treatment until eradication is achieved[48,49]. In addition to standard drug therapy, probiotics have been proposed to reduce adverse events associated with drug therapy[48]. *H. erinaceus* components (obtained by various extraction techniques) have shown marked antimicrobial properties against *H. pylori*[50-54]; however, the significant available evidence is preclinical. The minimum inhibitory concentrations (MIC) of the various components of *H. erinaceus* against *H. pylori* are shown in Table 1. MIC values fluctuate by varying the extractive, qualitative, and quantitative characteristics of the extracted components while reaching interesting values in some cases, as in the experience of Liu *et al*[52].

Therefore, it would be desirable to determine through clinical trials whether supplementation with *H. erinaceus* can have an additive effect on the anti-*H. pylori* efficacy of available antibiotic therapies, and whether such supplementation can reduce the adverse events associated with these antibiotic therapies.

H. erinaceus antineoplastic properties concerning gastric cancer

Gastric cancer is now the fourth leading cause of cancer-related deaths, based on its incidence and prevalence[55]. Surgical and medical therapy take the lead in managing this neoplasm[56]; however,

[1]Nine clinical isolates are the employed strain of *Helicobacter pylori* (*H. pylori*).
[2]Colloidal bismuth subcitrate with a minimum inhibitory concentration (MIC) of 20 μg/mL was used as the comparison reference. NTCC11637 is the employed strain of *H. pylori*.
[3]The comparison references were metronidazole (MIC range 0.7800-1.5625 μg/mL) and tetracycline (MIC range 0.780-3.125 μg/mL). In addition, different isolates of *H. pylori* were used (*i.e.*, ATCC 43504, SS1, *H. pylori* $W_2$504, *H. pylori* 9, *H. pylori* 64, *H. pylori* 78, and *H. pylori* 83). Therefore, the results are presented as MIC ranges.
[4]The reference comparison was amoxicillin, with a MIC of 0.032 μg/mL.
ATCC43504 is the employed strain of *H. pylori*. Bi^{3+}: Bismuth; *H. pylori*: *Helicobacter pylori*; MIC: Minimum inhibitory concentration.

while not changing this premise, several natural substances have been studied as complementary treatments[57-59].

Potential applications of *H. erinaceus* also extend in this context with a specific component of this fungus named in connection with these properties (*i.e.*, erinacines). They are diterpenoids with known neuroprotective properties, of which erinacine A is obtained from the ethanol extract of *H. erinaceus* mycelium[13]. With its exact origin, it is possible to obtain another extract, a sesterterpene, erinacine S [60].

Tung *et al*[61] demonstrated a unique mechanism by which erinacine S could intervene in gastric carcinogenesis through epigenetic regulation. This molecule can induce selective apoptosis in gastric cancer cell lines (*i.e.*, AGS) mediated by ROS toxicity while sparing normal cells. A mouse model of AGS-xenografts in which erinacine S suppressed tumour growth also confirmed this phenomenon[61]. In general, erinacine S may promote apoptosis in gastric carcinoma cells by inducing a specific pathway involving several molecules, such as TNF-related apoptosis-inducing ligand T (TRAIL), Fas ligand (Fas-L), and caspases 3,8,9 which are known to be involved in apoptotic death. At the same time, erinacine S suppressed the expression of anti-apoptotic molecules (*i.e.*, Bcl-2 and Bcl-XL). In addition, cell arrest is promoted in the G_1 phase of the cell cycle by the inactivation of specific cyclins and cyclin-dependent kinases[61]. Furthermore, erinacine S promotes the expression of Fas-L and TRAIL in gastric cancer cells undergoing apoptosis by trimethylation of histone H3 in the promoter regions of the Fas-L and TRAIL genes[61].

Erinacine A exhibits characteristics similar to erinacine S with respect to apoptosis induction. Several studies have shown that erinacine S can inhibit the growth of colorectal cancer both *in vitro* and *in vivo*, which could be attributed to the inhibition of proliferation and induction of the apoptosis signalling pathway, such as the generation of ROS *via* the phosphatidylinositol 3-kinase (PI3K)/mechanistic target of rapamycin (mTOR)/ribosomal protein S6 kinase beta-1 (p70S6K) pathway[62,63].

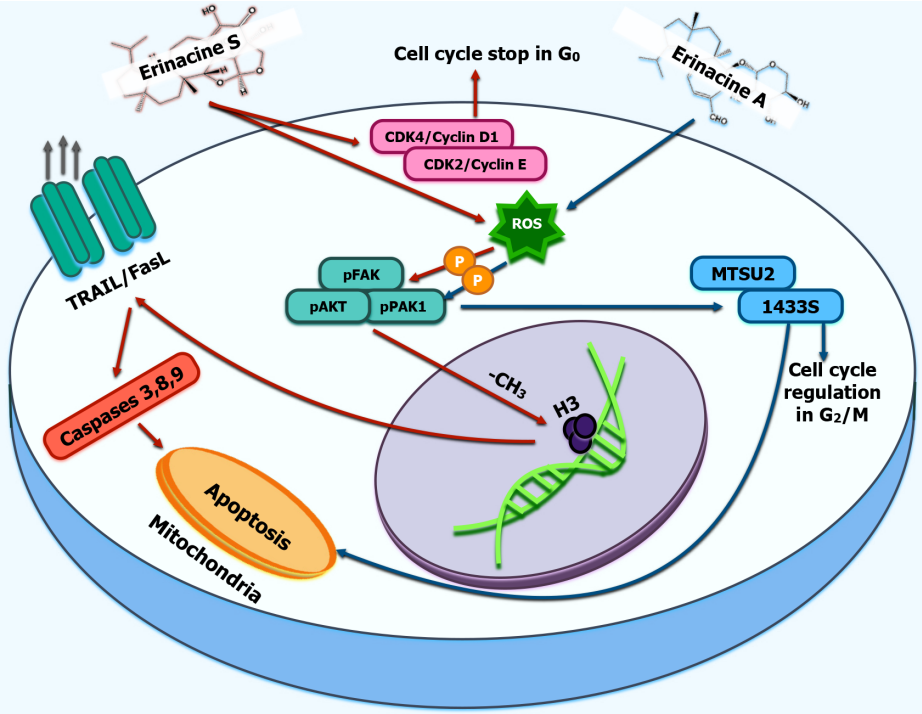
Proteomic analyses have confirmed that erinacine A reduces the growth and invasiveness of TSGH9201 gastric cancer cells *via* ROS-mediated phosphorylation of focal adhesion kinase (FAK)/protein kinase B (also known as AKT)/p70S6K and p21-activated kinase 1 (PAK1)[64]. Previous studies have shown that erinacine A-mediated apoptosis involves the actin depolymerisation pathway[65]. Furthermore, several PAK partners can phosphorylate or activate mitogen-activated protein kinases. The kinases PI3-kinase/AKT and LIM are involved in the regulation of the cytoskeleton[66,67]. In addition, erinacine A is believed to induce upregulation of the onco-suppressive proteins microtubule-associated scaffold protein 2 (MTUS2) and 14-3-3 protein sigma (1433S), associated with antitumour activity in gastric cancer cells[63]. Recent studies have shown that the 1433S protein appears to intervene in gastric cancer by exerting G_2/M checkpoint regulation in the cell cycle[68,69].

Furthermore, the MTUS2 gene plays a central role in controlling microtubule plus-end-tracking proteins (also known as + TIPs) by regulating cell division and migration through its mitotic kinesin-associated centromere, a microtubule depolymerase[70,71]. Moreover, the cytoskeleton depolymerisation pathway has been recognised as a critical cellular response that controls apoptosis and inhibits Rho GTPase-activated cell migration through its effector kinases, Rho-associated coiled-coil containing protein kinases 1 and 2[72]. These findings are significant and imply that phosphorylation of the FAK/AKT/p70S6K and PAK1 pathways determines the downstream expression of the MTUS2 and 1433S genes, the execution of cancer cell apoptosis, and the role of erinacine A as an anti-invasive agent. This effect most likely reflects cytoskeleton rearrangement, reducing erinacine A-dependent cell motility[63,73,74]. Figure 2 summarises the primary antineoplastic mechanisms of erinacines.

An additional polysaccharide protein extracted from the fermented mycelia of *H. erinaceus* (HEG-5) was studied in SGC-7901 gastric cancer lines. Again, positive regulation of apoptosis and the cell cycle appears to be the mechanisms underlying this antineoplastic action. Indeed, it seems that HEG-5 blocks the development of SGC-7901 cells in the S phase of the cell cycle by promoting the opposite regulation of anti- and pro-apoptotic genes. That is, predictably, the downregulation of anti-apoptotic molecules (such as Bcl-2, PI3K, and AKT) and, conversely, by upregulating caspases 3,8, p53, the bcl-2-associated X-protein, and the bcl-2-associated death promoter. Thus, caspase 3,8-dependent, p53-dependent, and PI3K/AKT-mediated apoptotic pathways are activated[75].

A synergy between doxorubicin and *H. erinaceus* was also observed in their pro-apoptotic action toward SGC-7901 cells *via* ROS-induced stress and caspase activation[76].

Moreover, two extracts of *H. erinaceus* (*i.e.*, HTH5 and HTJ5A) have been shown in an experiment conducted in NCI-87 gastric carcinoma cells to possess both *in vitro* and *in vivo* (in xenograft models including severe combined immunodeficient bearing mice) concentration-dependent cytotoxicity toward such cells, lower toxicity, and more efficacy than 5-fluorouracil[77].



Finally, *H. erinaceus* (via the EP-1 polysaccharide) targets not only cancer cells but also precancerous cell lines by promoting their arrest in the G_0/G_1 phase of the cell cycle[78].

H. ERINACEUS IN LOWER GASTROINTESTINAL TRACT DISEASES: THE EVIDENCE

H. erinaceus and IBD

IBD is a chronic digestive disease that results in sustained gastrointestinal inflammation and consists mainly of ulcerative colitis (UC) and Crohn's disease[79].

Available evidence related to *H. erinaceus* primarily focuses on UC. Wang *et al*[80] evaluated three polysaccharides (*i.e.*, wHEP-1, wHEP-2, and wHEP-3) and proposed the third as the one showing the greatest anti-inflammatory action in a UC-like model in Caco-2 cells inflamed by bacterial lipopolysaccharide.

DOI: 10.3748/wjg.v29.i20.3084 **Copyright** ©The Author(s) 2023.

Figure 2 Main antineoplastic molecular mechanisms of erinacines S and A from *Hericium erinaceus* in gastric cancer cell models. Erinacine S (in AGS gastric cancer cells) can activate a pathway (red arrows) with reactive oxygen species (ROS) mediated phosphorylation of focal adhesion kinase (FAK)/protein kinase B (also known as AKT)/p21-activated kinase 1 (PAK1). Subsequently, by trimethylation of histone H3, the latter pathway can induce the increased expression of TNF-related apoptosis-inducing ligand T and Fas ligand receptors by the cancer cell with the subsequent activation of apoptosis by initiating caspases 3, 8, and 9. Erinacine A (in TSGH9201 gastric cancer cells), once activated (blue arrows), the FAK/AKT/PAK1 pathway, in a similar manner as previously described, upregulates microtubule-associated scaffold protein 2/14-3-3 protein sigma proteins with subsequent activation of caspases-mediated apoptosis. In addition, erinacines can also modulate cell cycle regulation by preventing cell cycle continuation through the blockade at checkpoints, *i.e.*, blocking cyclin-dependent kinases. ROS: Reactive oxygen species; FAK: Focal adhesion kinase; PAK: Activated kinase 1; MTUS2: Microtubule-associated scaffold protein 2; TRAIL: TNF-related apoptosis-inducing ligand T; Fas-L: Fas ligand; CDKs: Cyclin-dependent kinases; 1433S: 14-3-3 protein sigma.

A more complete *in vivo* model has been reported by Diling *et al*[81]. The authors experimentally induced UC-like colitis in mice using trinitrobenzene-sulfonic acid enemas. They were then treated with mixed extracts of *H. erinaceus* (polysaccharide, alcoholic, and cumulative fractions) for 14 d. Significant clinical improvements were observed in the treated mice compared with the untreated control mice. Also, histologically, the treated group had significantly less severe lesions. They recorded reduced MPO levels in the treated mice to verify tissue infiltration of neutrophils. This was accompanied by a modulation of cytokines in the treated group with the restoration of proinflammatory and anti-inflammatory cytokines to pre-treatment levels with trinitro-benzene-sulfonic acid.

Further study has confirmed the anti-UC properties of ethanolic extracts of *H. erinaceus* in C57BL/6 mice exposed to dextran sulphate sodium orally to induce experimental UC-like colitis. The dosage used by the authors was 250/500 mg/kg/d[82]. This study showed as much clinical improvement as histologic (including neutrophil infiltration by MPO dosing) and cytokine improvement. However, these authors also stigmatised antioxidant potential by upregulating NO, malondialdehyde, and SOD. Wang *et al*[83] also focused on the antioxidant potential of *H. erinaceus* polysaccharides as a therapeutic mechanism in UC experimental colitis and discovered the positive regulation of SOD and reduced ROS production. It is no coincidence that combating oxidative stress is part of the therapeutic proposals for IBD[84].

UC pathogenesis remains largely unclear, but bowel inflammation and oxidative stress are considered fundamental mechanisms underlying its pathophysiology. During the active phase of UC, activated leukocytes generate many proinflammatory cytokines and pro-oxidative stress reactions. The joint deterioration caused by inflammation and oxidative stress significantly alters the redox balance within the intestinal mucosa, which accelerates the apoptosis of intestinal epithelial cells[85,86]. Excessive ROS production directly leads to tissue damage and induces an inflammatory cascade[87]. When mitochondria are damaged by oxidative stress, they enter a vicious cycle in which the loss of respiration disrupts redox homeostasis and, in turn, increases intracellular oxygen availability, resulting in increased ROS formation and subsequent oxidative damage to DNA[88]. Several studies have shown that UC onset and course are related to changes in mitochondrial structure and function[89,90].

Finally, in the context of *H. erinaceus* polysaccharides, Ren *et al*[91] confirmed this finding in C57BL/6 mice with experimental UC-like colitis induced by dextran sulphate sodium. Furthermore, the authors recorded (as also done by Diling *et al*[81]) an anti-inflammatory downregulation of nuclear factor kappa B (NF-κB).

NF-κB is part of several pathways (*i.e.*, the canonical and noncanonical pathways) that have been extensively studied in IBD, upon which the mainstay of biological therapy for IBD, namely anti-TNF-α agents, has been built[92].

However, another mechanism by which the anti-IBD effect of *H. erinaceus* has been studied is the modulation of the gut microbiota, as described in the last section of this review.

Colonic diverticulosis and H. erinaceus

Diverticular disease has acquired several modifications of its nomenclature over time, including the concept of symptomatic uncomplicated diverticular disease (SUDD) in its gnoseological entity. SUDD is characterised by colonic diverticulosis associated with chronic abdominal pain without signs, symptoms, or evidence of underlying diverticulitis or colitis[93]. Several pathogenetic mechanisms have been implicated, including visceral hypersensitivity and a reduction in the interstitial Cajal cells, resulting in slowed colonic motility[94]. SUDD therapy includes poorly absorbable antibiotics (such as rifaximin[95]), mesalamine[96], or probiotics[97], as well as modification of habits with increased physical activity[94]. However, definitive medical therapy for SUDD has not yet been defined.

Paradoxically, in the case of diverticular disease, the *H. erinaceus* research trend was reversed with the availability of clinical studies and the absence of preclinical studies.

Brandimarte *et al*[98], in a single study, evaluated a combination nutraceutical compound mainly consisting of polysaccharide extracts of *H. erinaceus* in 305 patients with SUDD. The authors recorded clinical remission rates (defined by them as the disappearance of all symptoms) of 9.34% and 17.64% at three and six months of treatment, respectively. Beyond clinical remission, it is interesting to note that the clinical response rate (defined as symptom reduction) was > 90% at three months and approximately 85% at six months. Furthermore, at three and six months, the authors recorded a significant decrease in faecal calprotectin values from baseline. However, these data should be interpreted within the limitations of a single study and the lack of clarification regarding the actual mechanism underlying this clinical improvement.

Nevertheless, it is clear how the inflammatory process plays a role in the pathogenesis of diverticular disease[99]. In addition, TNF-α levels appear to increase progressively with the severity of diverticular disease in both diverticulitis and SUDD[100]. Therefore, as in the other gastrointestinal disorders already discussed in this review, *H. erinaceus* might potentially intervene in diverticular disease through the regulation of the local inflammatory load; however, as already mentioned, there is currently no evidence.

H. erinaceus and irritable bowel syndrome: A potential ally in this brain-gut interaction disorder?

Unlike IBD, where *H. erinaceus* has been extensively studied in preclinical models, no evidence is available regarding its role in irritable bowel syndrome (IBS). However, it is becoming increasingly clear that IBS is coded within functional gastrointestinal disorders and how ROME IV has now defined these disorders as "disorders of brain-gut interaction", stigmatising the decisive role that the gut-brain axis has acquired in the pathogenesis and clinical features of IBS and other similar functional disorders[101]. Indeed, it is also clear how many brain-derived factors (from neurotransmitters to psychological disorders) are directly involved in IBS pathogenesis[101]. Patients with IBS experience a notably higher prevalence of anxiety-depressive disorders than the healthy population[102]. *H. erinaceus* has been widely studied in clinical settings in patients with anxiety and depression. One randomised controlled trial provided results in favour of positive regulation of psychiatric disorders[103]. Moreover, several pathogenic mechanisms have been suggested in studies on mood disorders. In mice, *H. erinaceus* appears to exert anti-inflammatory effects (negative regulation of proinflammatory cytokines and positive regulation of anti-inflammatory cytokines), stimulate hippocampal neurogenesis, and increase neurotransmitters such as 5-hydroxytryptamine, dopamine, and noradrenaline. However, in humans, it appears to increase salivary levels of free 3-methoxy-4-hydroxyphenethyleneglycol and circulating levels of pro-brain-derived neurotrophic factor. These molecular changes are associated with an improved anxiety-depressive effect[104-107].

Beyond that, the potential of *H. erinaceus* to intervene in the gut-brain axis could also be explored in patients with IBD, where the prevalence and impact on the disease course of anxiety-depressive disorders are not negligible[108,109]. In addition, factors leading to anxiety-depressive disorders can impact therapeutic adherence, as observed during the COVID-19 pandemic[110,111].

IBS therapy is challenging, and much more needs to be added to the research field[112]. In addition, naturally derived substances have repeatedly been considered possible therapies for IBS[113-115]. Ultimately, despite the interesting prospect of the impact of *H. erinaceus* on the dysregulation of the gut-brain axis in IBS, studies evaluating the effects of this fungus on both the gastrointestinal clinical features and the impact of modulation of anxiety and depression on the latter are still awaited.

H. erinaceus and the colorectal cancer

As observed for gastric cancer, even in the case of colorectal cancer, studies have been conducted regarding the antineoplastic potential of *H. erinaceus*. Table 2 summarises the main pathophysiological mechanisms identified.

Liu *et al*[116] focused on two polysaccharides from the fruiting body of *H. erinaceus* extracted by hot water and ferrocyanide-zinc acetate (HEFP-1 and HEFP-2). These polysaccharides showed the ability in their assay to selectively inhibit the growth of colonic cancer cells (*i.e.*, HCT-116) while sparing normal colonic cells. Furthermore, the HEFP polysaccharide 2b fraction (HEFP-2b) was determined to be responsible for this action. In other words, HEFP-2b induced S-phase cell cycle arrest of such cells through the downregulation of CDK1,2 and cyclin A2 and concomitant inhibition of mini-chromosomal maintenance protein 5 (MCM5), a protein essential for the transition from the S-phase to the M-phase [117].

Using the exact extraction mechanism, Hou *et al*[118] obtained and characterised another polysaccharide fraction of the mushroom fruiting body with antineoplastic properties in colonic cancer. The model was similar to the cellular model employing both the same cells as the previous authors (*i.e.*, HCT-116) but with the addition of the DLD1 cell group. They showed an upregulation of cleaved caspase-9 and cleaved caspase-3 without a change in the cleavage of caspase-8, confirming that the apoptotic mechanism was mitochondrial and not extrinsic with relative inhibition of the Bcl-2 protein and stimulation of the pro-apoptotic Bax protein. Confirming this evidence, the authors identified that ROS production might be one of the triggers of this apoptotic phenomenon.

Another study examined fungal extracts obtained by boiling water, microwave extraction in ethanol, and acid or alkaline extracts with hydrochloric acid or sodium hydroxide, respectively[119]. These extracts specifically demonstrated inhibitory effects on implanted tumours in mice (using CT-26 murine cancer cells). Furthermore, intraperitoneal administration of the extracts obtained by boiling water and microwaving in ethanol reduced tumour growth by 38% and 41%, respectively. These extracts increased the cytolytic activity of natural killer cells and phagocytic activity of macrophages and blocked tumour angiogenesis.

In addition, as in gastric cancer, HTJ5 and HTJ5A extracts were shown to block the growth of HT-29 colon cancer cell implants in mice with severe combined immunodeficiency[77]. Another study also confirmed the antineoplastic action of H. erinaceus in HT-29 cells by evaluating its anti-tyrosinase and α -glucosidase activities[120].

As previously described, erinacines are the principal antineoplastic components of *H. erinaceus* in gastric cancer. However, erinacine A showed marked antineoplastic effects against colon cancer. In detail, Lee *et al*[65] highlighted this in HCT-116 and DLD-1 cells by demonstrating how erinacine A was able to exert its cytotoxic action similar to that observed in gastric cancer by increasing ROS production and decreasing cancer cell proliferation through upregulation of the PI3K/mTOR/p70S6K pathway.

H. ERINACEUS AND GUT MICROBIOTA MODULATION

H. erinaceus may promote a shift in the gut microbiota phenotype toward the increased selection of short-chain fatty acids-producing bacteria

The gut microbiota, although not fully detailed and understood, plays a crucial role in the development, progression, and treatment of several gastrointestinal pathological conditions, including IBS and IBD [121].

H. erinaceus is closely related to the modulation of the gut microbiota. In general, it seems to be able to change the gut microbiota's quantitative and qualitative phenotypes in a health-promoting manner. Therefore, it has often been defined as a prebiotic or probiotic[81,122-124]. It appears that *H. erinaceus* selects certain beneficial bacterial strains from the gut microbiota at the expense of pathogenic strains. For example, Xie *et al*[124] studied the fourteen days administration of 1 g of *H. erinaceus* dry powder in submerged cultures in 13 healthy young volunteers and recorded an increase in the alpha diversity of the gut microbiota. They recorded an increase in *Bifidobacterium* and *Bacteroides* and an increase in short-chain fatty acid (SCFAs) production (*i.e.*, *Roseburia faecis*, *Faecalibacterium prausnitzii*, *Eubacterium rectale*, *Fusicatenibacter saccharivorans*, *Kineothrix alysoides*, *Gemmiger formicilis*, and *Dorea longicatena*). Confirming the modulation of the microbiota, in addition to this whole series of beneficial bacterial species, *H. erinaceus* resulted in a reduction in the relative abundance of pathogenic bacteria (*Streptococcus thermophilus*, *Roseburia intestinalis*, *Bacteroides caccae*, and *Anaerostipes hadrus*).

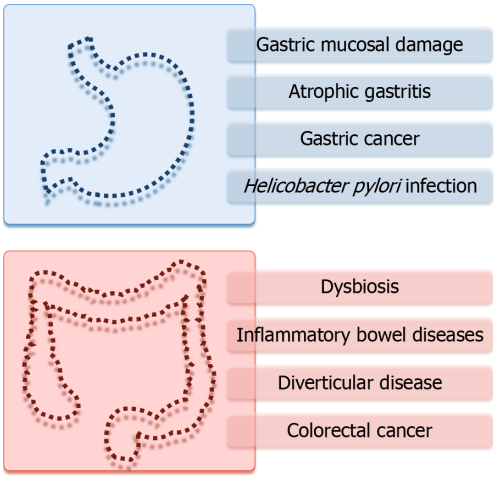
SCFA-producing bacteria may intervene in immune homeostasis through the regulation of lymphocyte chemotaxis and phagocytosis and possess anti-inflammatory and anti-tumourigenic properties[125]. In addition, SCFAs produced mainly in the colon from indigestible polysaccharides are associated with a reduced risk of IBD and IBD-associated dysbiosis[126]. Not surprisingly, they regulate the immune response by suppressing TNF-α production in neutrophils, contributing to intestinal barrier integrity by inducing secretion of IL-18, mucin, and antimicrobial peptides by intestinal epithelial cells and impacting the ability of dendritic cells to bind to T lymphocytes[126].

Table 2 Main studies examining antineoplastic mechanisms of *Hericium erinaceus* against colorectal cancer

Ref.	*H. erinaceus* fraction employed	Colonic cancer model	Identified mechanism
Kim *et al*[119], 2011	Hot water/ microwave ethanol extraction extracts	CT-26 cancer cells graft in mice	NK cells activity ↑; macrophages activity ↑; angiogenesis ↓
Li *et al*[77], 2014	Polysaccharides	HT-29 cancer cells graft in mice	-
Lee *et al*[65], 2017	Erinacine A	Cancer cells (HCT-116, DLD1)	PI3K/AKT/mTOR/; p70S6K pathway; ROS ↑
Sharif *et al*[120], 2018	Ethanolic and methanolic extracts	Cancer cells (HT-29)	α-glucosidase activity ↑; anti-tyrosinase activity ↓
Liu *et al*[116], 2020	Polysaccharides	Cancer cells (HCT-116)	CDK1 ↓; CDK2 ↓; Cyclin A2 ↓; MCM5 ↓
Hou *et al*[118], 2020	Polysaccharides	Cancer cells (HCT-116, DLD1)	Clived caspases 3,9 ↑; ROS ↑; Bax ↑; Bcl-2 ↓

NK: Natural killer; PI3K: Phosphatidylinositol 3-Kinase; AKT: Protein kinase B; mTOR: Mechanistic target of rapamycin; p70S6K: Ribosomal protein S6 kinase beta-1; CDK: Cyclin-dependent kinase; MCM5: Mini-chromosomal maintenance protein 5; ROS: Reactive oxygen species; Bax: Bcl-2-like protein 4; Bcl-2: B-cell lymphoma 2.

Moreover, the authors posited the impact of such changes in the gut microbiota with a shift in several hematochemical parameters by observing a beneficial correlation with several analytes (*i.e.*, alkaline phosphatase, low-density lipoprotein, creatinine, and uric acid). These data suggest a possible clinical impact of *H. erinaceus*-driven modulation of the gut microbiota.



A further study recreated some experimental conditions of digestion to evaluate whether some polysaccharides of *H. erinaceus* could overcome the digestive barrier of the upper digestive tract and influence gut microbiota composition.

Following this experimental model, several *H. erinaceus* polysaccharides obtained by alcohol precipitation (*i.e.*, HEP30, HEP50, and HEP70) increased the relative abundance of SCFA-producing bacteria and reduced pathobiont concentrations (*i.e.*, *Escherichia-Shigella*, *Klebsiella*, and *Enterobacter* in this experience), stigmatised the role of such polysaccharides as possible functional foods[127]. Therefore, they set up an experimental *in vitro* digestion model, as previously described. First, they suggested the likely passage of polysaccharides through the gastrointestinal tract without being digested by the saliva of healthy donors or gastric and small intestinal juices (simulated in the laboratory). Therefore, they may reach the distal tract of the intestine. Second, at that level, the authors demonstrated how the gut microbiota utilised HEP50 for fermentation by increasing the levels of SCFAs and decreasing the pH of the faecal fermentation broth.

Furthermore, Yang *et al*[127] examined the impact of a polysaccharide from the mycelium of *H. erinaceus* on the quality of murine gut microbiota. The authors observed a change in the relative abundance of different bacteria depending on the age of the mice used for the microbiota analysis. In both the control and experimental groups of adult and middle-aged mice, there was an increase in the relative abundance of *Lachnospiraceae*, *Ruminococcaceae,* and *Akkermansiaceae* and a decrease in the relative abundance of *Muribaculaceae*, *Rikenellaceae*, *Lactobacillaceae,* and *Bacteroidaceae*. On the other hand, only the treated adult mice showed an increase in *Erysipelotrichaceae*, *Enterobacteriaceae*, *Christensenellaceae,* and *Coriobacteriaceae* and a decrease in *Bifidobacteriaceae* and *Peptostreptococcaceae*. Finally, in the group of middle-aged and old mice, the increased bacterial species were *Rhizobiaceae*, *Desulfovibrionaceae,* and *Lachnospiraceae,* while the decreased species were *Corynebbacteraceae* and *Rikenellaceae*. Among the many modified families of bacteria, the relevant ones are the butyrate-producing bacteria (*i.e.*, *Lachnospiraceae* and *Ruminococcaceae*). Butyrate is an SCFA used as an energy source by the intestinal mucosa to promote gut health and protect against colorectal cancer[128-130]. These two species of bacteria are among the leading producers of butyrate[131]. Further *in vitro* studies have shown the beneficial effects of *H. erinaceus* in modulating SCFA-producing bacteria[132]. Positive *H. erinaceus*-driven modulation of the gut microbiota has also been confirmed in elderly dogs, with ameliorative effects on immunity and obesity[133].

H. erinaceus in restoring the gut microbiota after dysbiosis induced by antineoplastic drug therapy: The evidence

Cancer therapy is associated with significant adverse events, including gastrointestinal complications. The latter includes dysbiosis induced by antineoplastic treatments[134]. However, while the microbiota may be impacted by antineoplastic therapy, it is also true that several reports suggest an opposite mechanism whereby the gut microbiota may modulate the response to treatment, specifically immunotherapy[135]. In this context, *H. erinaceus* showed some preclinical results, demonstrating its potential in cancer therapy-induced toxicity. For this purpose, an investigation based on polysaccharides was conducted in mice treated with cyclophosphamide[136]. This brought the composition of the gut microbiota of chemotherapy-treated mice closer to that of control and healthy mice through increased

DOI: 10.3748/wjg.v29.i20.3084 **Copyright** ©The Author(s) 2023.

Figure 3 The potential of *Hericium erinaceus* in upper and lower gastrointestinal tract diseases. *Hericium erinaceus* is a promising candidate as a therapeutic modality or functional food in the treatment of various diseases of the gastrointestinal tract. This evidence stems from several experiences, largely preclinical, that have shown that this mushroom possesses anti-inflammatory and antineoplastic capabilities concerning the gastrointestinal tract.

alpha and beta diversity. Similar results were reported in another study[123]. Moreover, these data are also available for 5-fluorouracil toxicity. Wang *et al*[137] examined the proteins of *H. erinaceus* in a xenograft cancer model in mice successfully treated with 5-fluorouracil and revealed an anti-dysbiosis action.

H. erinaceus may intervene in IBD through the gut microbiota

Although a therapy based on the direct modification of the gut microbiota is not yet recommended in the current guidelines for managing IBD, it is clear that the potential of this option has been extensively studied and is currently under investigation[138-141].

Ren *et al*[142] studied whether the administration of *H. erinaceus* to Cynomolgus monkeys affected the clinical features of spontaneous UC by exerting an anti-inflammatory effect through modulation of the gut microbiota. They recorded an increase in the abundance of bacteria, such as *Lactobacillus reuteri* (already implicated in improving the clinical features of IBS, acute gastrointestinal infections, and IBD in children and adults). In contrast, *Streptococcus lutetiensis* is negatively modulated and is known to cause sepsis in newborns[143].

In addition, Diling *et al*[81], in the above cited model of murine colitis induced by trinitro-benzene-sulfonic acid, demonstrated how the administration of extracts (*i.e.*, polysaccharide, alcoholic extracts, and whole extracts) of *H. erinaceus* improved both the clinical and histological picture but, more importantly, the gut microbiota by promoting a switch to a microbial composition similar to that of the controls. In other words, a reduction in proinflammatory strains (*Corynebacterium*, *Staphylococcus*, *Ruminococcus*, *Roseburia*, *Dorea*, and *Sutterella*) and an increase in anti-inflammatory strains (*Bacteroides*, *Bifidobacterium*, *Prevotella*, *Parabacteroides*, *Coprococcus*, *Desulfovibrio*, and *Lactobacillus*) were observed.

In a similar study, in an acetic acid-induced murine colitis model, the mycelium polysaccharide EP-1 drastically improved the gut microbiota of mice by increasing SCFA-producing populations while suppressing the expression of G protein-coupled receptor 41 (GPR41) and GPR43[144]. SCFAs can bind to GPR41 and GPR43 and increase the production of inflammatory cytokines and chemokines in the intestine[145].

Finally, positive microbiota modulation was observed in mice with dextran sulphate sodium-induced colitis[91].

Despite the possibility that *H. erinaceus* may have intervened in the pathogenesis of IBD through the gut microbiota, studies conducted in humans as well as those exploring the clinical impact of such microbiota modification, are still awaited, especially with clinical tools and scores that are widely validated and used in clinical and IBD research practise[146,147].

CONCLUSION

H. erinaceus is a mushroom with a long tradition of use as a medicinal product. Numerous preclinical studies have probed its gastrointestinal anti-inflammatory and antineoplastic properties and its impact on the composition of the intestinal microbiota (Figure 3). In the face of a large body of evidence, there is a strong need for clinical studies conducted on humans, especially considering the promising results of previous studies. Furthermore, it is necessary to determine whether this fungus can represent an

excellent nutritional supplement in gastrointestinal pathologies, the patients who may benefit from it, and whether there is a possible therapeutic role for the compounds extracted from *H. erinaceus*. Finally, various technical processes for such fungi yield many extracts and fractions. Therefore, it is essential to understand which of these presents the best safety and efficacy profiles.

Abstract

The widespread uptake of different machine perfusion (MP) strategies for liver transplant has been driven by an effort to minimize graft injury. Damage to the cholangiocytes during the liver donation, preservation, or early posttransplant period may result in stricturing of the biliary tree and inadequate biliary drainage. This problem continues to trouble clinicians, and may have catastrophic consequences for the graft and patient. Ischemic injury, as a result of compromised hepatic artery flow, is a well-known cause of biliary strictures, sepsis, and graft failure. However, very similar lesions can appear with a patent hepatic artery and these are known as ischemic type biliary lesions (ITBL) that are attributed to microcirculatory dysfunction rather than main hepatic arterial compromise. Both the warm and cold ischemic period duration appear to influence the onset of ITBL. All of the commonly used MP techniques deliver oxygen to the graft cells, and therefore may minimize the cholangiocyte injury and subsequently reduce the incidence of ITBL. As clinical experience and published evidence grows for these modalities, the impact they have on ITBL rates is important to consider. In this review, the evidence for the three commonly used MP strategies (abdominal normothermic regional perfusion [A-NRP], hypothermic oxygenated perfusion [HOPE], and normothermic machine perfusion [NMP] for ITBL prevention has been critically reviewed. Inconsistencies with ITBL definitions used in trials, coupled with variations in techniques of MP, make interpretation challenging.

Overall, the evidence suggests that both HOPE and A-NRP prevent ITBL in donated after circulatory death grafts compared to cold storage. The evidence for ITBL prevention in donor after brain death grafts with any MP technique is weak.

Key Words: Liver transplant; Ischemic type biliary lesions; Hypothermic oxygenated machine perfusion; Normothermic machine perfusion; Abdominal normothermic regional perfusion; Donation after circulatory death

Core Tip: In recent years, the development of different machine perfusion (MP) strategies has generated interest in their use for both the assessment of grafts and optimization during the preservation period. The different mechanisms behind the diverse array of MP strategies may reduce the extent of cholangiocyte and may have the subsequent clinical effect of preventing the development of ischemic type biliary lesions (ITBL). This review summarizes the strength and limitations of clinical studies that have been undertaken, their results, and provides a summary of the available literature on MP and the prevention of ITBL.

INTRODUCTION

In recent decades, liver transplantation has made several forward strides. These have been in the area of surgical technique, immunosuppressive drug strategies, treatment and prevention of recurrent viral infections, and the increasing use of alternative preservation techniques. Consequently, recipient and graft survival are greater than 90% at 1 year and long-term survival is considered the norm[1]. A longstanding problem that liver transplantation has faced is the mismatch between the number of donors and the higher number of patients listed for transplant. This has led to long waiting lists for a graft, and up to 20% of patients do not survive until transplantation[2,3]. Furthermore, the recent expansion of transplant indications to include certain oncological scenarios may further aggravate this issue[4]. As a response to this shortage in supply, living donor liver transplantation and using more marginal organs, including those donated after circulatory death (DCD) are strategies that have been used to increase the donor pool[5]. Improving long-term graft survival is vital, as the need for retransplantation creates additional demand on a scarce resource.

Adequate biliary drainage is paramount for the success of a liver transplant, and was previously labeled the 'Achilles heel' of this procedure[6]. Although vascular complications have the largest impact on short-term graft outcomes, biliary complications are the main source of long-term morbidity. These conditions often require costly interventions, cause suffering, and adversely affect patients' quality of life[7]. The incidence of these complications is increasing as a result of the growing utilization of extended criteria donor organs, mainly from DCD donors[8].

In recent years, the development of numerous machine perfusion (MP) strategies has generated interest in their use for both the assessment of grafts and optimization during the preservation period [9]. Different techniques of MP have been described and vary in their application, with *in situ* MP occurring during organ procurement while the graft is within the donor and *ex situ* MP which occurs after the donor hepatectomy is completed. Both hepatocytes and cholangiocytes are vulnerable to ischemia-reperfusion injury (IRI), and injury to the latter during organ procurement and preservation lies behind the pathogenesis for biliary dysfunction[10]. Consequently, a current trend of research in the MP field is focused on how these different MP perfusion regimens influence post-transplant biliary complications and more specifically, ischemic type biliary lesions (ITBL).

This narrative literature review describes the strength and limitations of clinical studies that have been undertaken, their results, and provides a summary of the available literature on MP and the prevention of ITBL.

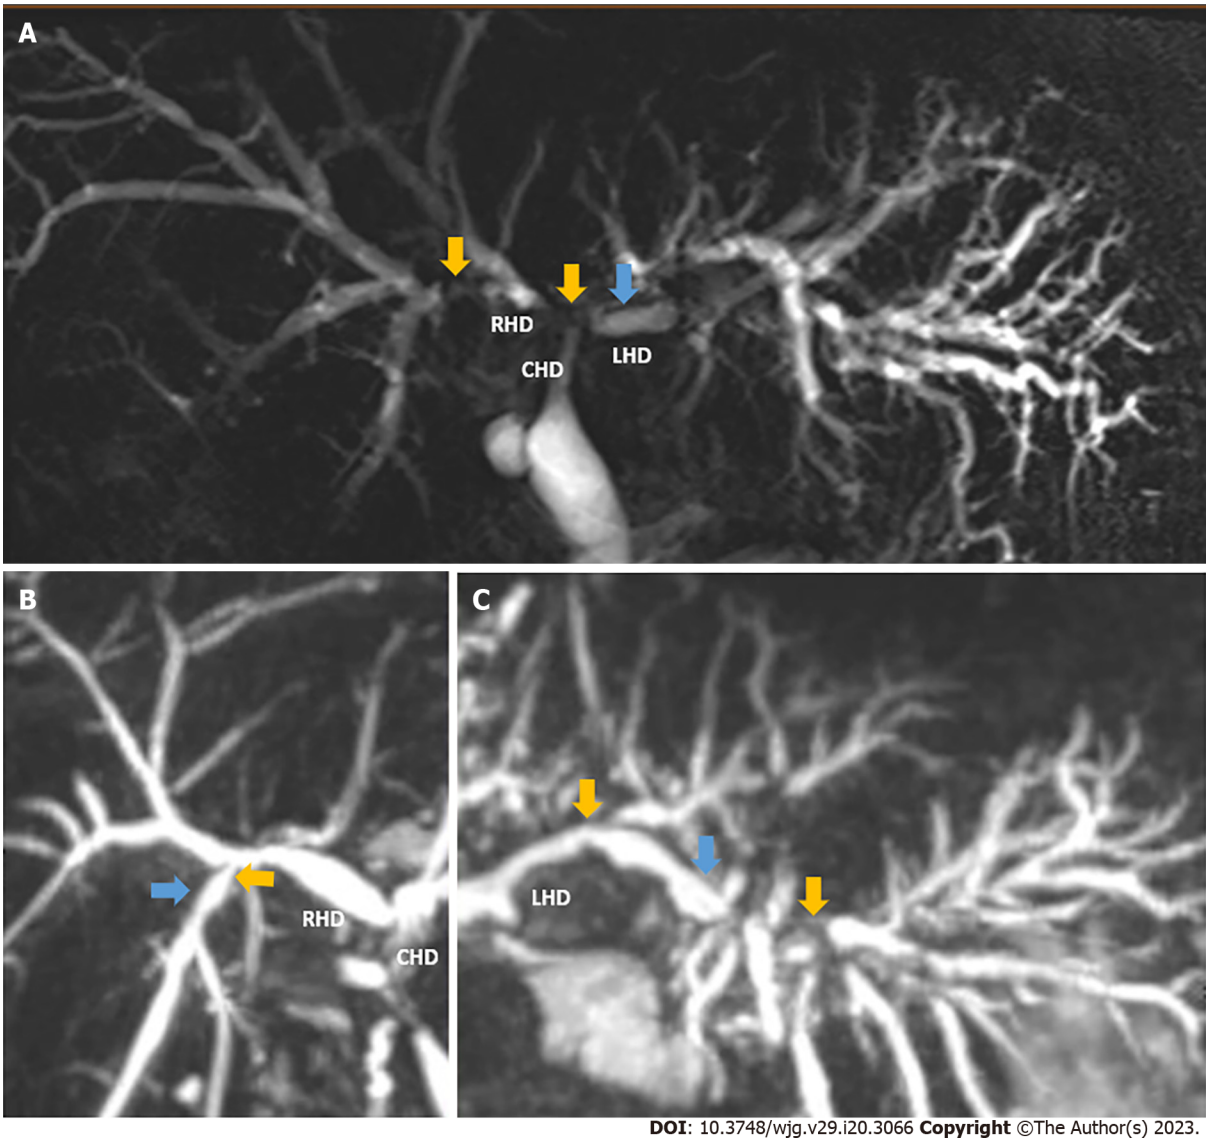
Nonanastomotic biliary strictures and ischemic type biliary lesions

Postliver transplantation biliary complications can comprise one (or both) of the following entities; strictures (anastomotic and non-anastomotic), and biliary leaks[11]. Anastomotic biliary strictures occur

at the site of biliary reconstruction and the surgical technique, and/or local tissue ischemia likely play a role. These strictures are usually managed with endoscopic or radiological procedures, however surgical revision may be required depending on the timing and type of anastomosis[12]. Nonanastomotic strictures (NAS), as the name implies, occur at a site away from the anastomosis and are most common within the initial 12 mo posttransplant. NAS are one of most feared late complications due to it being associated with high rates of graft loss and mortality, and minimal treatment options except re-transplantation[8,13].

NAS is characterized by diffuse fibrotic strictures and dilatation of the biliary tree at any location from the liver periphery to the main extrahepatic ducts (Figure 1). In addition, with the disease evolution, the formation of biliary casts and intrahepatic bilomas may occur in its severest form[14]. The radiological manifestations of NAS are highly variable and range from a peripheral abscess, individual or multiple strictures around the hilum and first order biliary branches, to vanishing ducts seen along the entire biliary tree[15]. NAS can occur as a direct result of ischemia from an identifiable hepatic artery stenosis or thrombosis (HAT). However, very similar lesions can develop in the setting of an entirely patent hepatic artery and this specific situation is termed ITBL, given its similarity to an actual ischemic cholangiopathy (Figure 1).

In a seminal paper by authors from Groningen which excluded patients with HAT, ITBL was classified according to the affected area of the biliary tree[16]. In this study, they demonstrated that the anatomical location of ITBL varied between those that presented early (< 1 year) as opposed to late (> 1 year). In those presenting late, the peripheral liver (zone D) was involved more frequently and there was an association with immunological risk factors. By contrast, patients with an early presentation had lesions around the bifurcation and the common bile duct (zone A). This early group had a longer period of both cold and warm ischemia; therefore, hypoxia is thought to be one of the underlying mechanisms. More recently, a United States group from the Mayo Clinic proposed a radiologic classification of ITBL into four distinct patterns that correlate with a distinct natural evolution and prognosis[17]. In this case, those patients with diffuse necrosis and multifocal progressive patterns experienced more episodes of cholangitis and almost all required stents and eventual retransplant.



Multiple factors have been associated with ITBL development and are generally divided into three categories: ischemia-related injury; bile salt mediated injury; and immune-mediated injury[18,19]. The cold ischemia time (CIT) and donor warm ischemia time (dWIT), and inadequate microvasculature preservation predispose cholangiocytes to a subsequent IRI[10,18]. The increased incidence of ITBL in DCD grafts, which are characterized by a period of dWIT is well established, with ITBL rates of up to 39% following controlled DCD liver transplantation[13,20,21]. The toxic effect of bile salts on cholangiocytes at low temperatures during preservation is well known. Certain bile acids have been shown to promote the secretion of inflammatory mediators, and others are directly cytotoxic to cholangiocytes [22]. In addition, new bile after implantation and its altered bile salt/phospholipid ratio have detrimental effects on biliary epithelium and induce NAS[23-25]. An immune-mediated component to the cholangiocyte injury has also been proposed due to several clinical associations, but the mechanism remains under investigation. ITBL has been demonstrated in association with ABO incompatibility, recurrence of immune-mediated liver diseases, cytomegalovirus infection, presence of C-C chemokine receptor type 5, polymorphism, and acute or chronic rejection[18].

The pathogenesis of ITBL is multifactorial. Both the cold and warm ischemic periods induce the formation of reactive oxygen species (ROS). These ROS are generated as a result of Kupffer and polymorphonuclear cells activation, mitochondrial permeability transition production, oxidative changes in the structure of the biliary canaliculus and adenosine triphosphate adenosine triphosphate (ATP) depletion. These all lead to the apoptosis and/or necrosis of the cholangiocytes. This mechanism is interrelated with the cytotoxic effect of bile salts, the cholestasis status induced by ischemia-reperfusion and different immune-mediated mechanisms, which all further propagate the biliary injury. Appropriate donor selection, the use of preservation fluids and MP are just some of the strategies which are thought to prevent this condition[26].

The different mechanisms behind the diverse array of MP strategies may reduce the extent of cholangiocyte injury during the transplantation process, in comparison with static cold storage (SCS). This may have the subsequent clinical effect of preventing the development of ITBL. The number of clinical studies on MP strategies continues to increase. With only a few exceptions, the primary outcomes focus mainly on graft and patient survival. In this review, we focus on the available clinical evidence for abdominal normothermic regional perfusion (A-NRP), and *ex situ* hypothermic oxygenated perfusion (HOPE), and normothermic MP (NMP) in relation to the outcome of ITBL.

PREVENTION OF ITBL *VIA* MP

The incidence of ITBL posttransplant varies considerably between institution and nations. These differences likely relate to the type of organ donation permitted, ranging from donor after brain death (DBD) donors only in some parts of the world, to uncontrolled DCD donors in others. Different national laws regarding the donor age and the 'no-touch' period following asystole in DCD donors likely

influences outcome, and these matters also complicate the results and interpretation of clinical trials on MP. In addition, it should be noted that the lack of clear and consistent definitions of ITBL in the currently available literature makes the assessment of the true impact challenging. Many studies either do not differentiate between anastomotic, ischemic NAS and ITBL; furthermore they may include both symptomatic and nonsymptomatic cases[27]. With these limitations in mind, a literature search was performed in October 2022 using PUBMED®, Embase®, and Medline®. Publications were restricted to those in English, however no further search filters were applied. The following search terms were used (in different combinations with Boolean operators): Liver, transplant, biliary stricture, ITBL, MP, machine preservation, normothermic, hypothermic, and NRP. Both prospective and retrospective studies were included if they included outcome data pertaining to biliary strictures. Studies without a control (or comparator) group were excluded. A pooled analysis was not performed due to a significant variation in study methodology, MP application technique, and outcome definitions. Institutional ethical approval was not required.

A-NRP and ITBL

A-NRP is an *in situ* preservation technique using an extracorporeal oxygenated membrane, restoring the perfusion of abdominal organs after the donor is declared deceased. This technique may lead to a reduction in the dWIT depending on the timing of cannulation; however, it provides a period of resuscitation immediately after the cellular injury incurred from the dWIT. The provision of near physiological conditions during A-NRP provides a period in which cells can recover their energy stores,

therefore they tolerate the CIT with minimal additional injury. It can also provide information about graft viability and reduce the effects of the IRI process[28].

In recent years, countries such as Spain, France, United Kingdom, and Italy have developed different A-NRP protocols as a strategy to improve the outcomes of DCD grafts[29-33]. These protocols differ in the liver viability criteria utilized "no-touch" periods required, pre-mortem substance administration, and vessel cannulation. All countries aforementioned have a mandatory no-touch period of 5 min except Italy, which requires 20 min. This inevitably lengthens the dWIT. Sedative analgesia administration is not allowed in the United Kingdom, in contrast to other countries. In Spain, premortem cannulation is allowed while in Italy and France only the identification of femoral vessels to ease cannulation is permitted. The obvious benefit of premortem cannulation is that it minimizes the dWIT and could achieve better outcomes as a result[34]. During A-NRP, certain viability parameters are measured, the most common among the different protocols are transaminase levels. Despite transaminase levels being widely accepted, it only reflects hepatocyte injury and not cholangiocytes. Other viability criteria employed include A-NRP duration[31], lactate clearance[30], and/or the presence of macrosteatosis[30,31]. However, some of these parameters are considered controversial[28].

To date, there has been no randomized controlled trial (RCT) comparing A-NRP to the standard retrieval method, known as the super rapid retrieval (SRR) technique. The clinical studies investigating A-NRP that include a comparator group, and provide data on biliary strictures are summarized in Table 1. The definition of ITBL used in these studies is relatively homogeneous as most authors have considered ITBL to have occurred when NAS developed in the context of a patent hepatic artery. However, two studies did not include an ITBL definition[35,36] and two authors[31,37] considered NAS regardless of the presence of concomitant HAT. Other limitations of these studies include variation in the A-NRP protocols, small sample size, and variability in follow-up periods. These trials can be put into three categories, according to the comparator groups: DCD-A-NRP *vs* DBD-SCS; DCD-A-NRP *vs* DCD-SRR; and DCD-A-NRP *vs* DCD with other MP.

In the first group of studies[31,35,38-40] that compared DCD-NRP-A grafts *vs* DBD-SCS grafts, these authors aimed to demonstrate that DCD grafts after NRP could have similar results of DBD grafts and therefore should not be considered marginal. These studies showed a similar incidence of ITBL between both groups, and the results in regard to early allograft dysfunction were promising. However, they had small sample sizes[35,38,39], differences in follow-up periods[31,35,38,39], and a high proportion of uncontrolled DCD donors[38]. Other authors have assessed the outcomes of DCD NRP grafts *vs* DCDs grafts recovered by *via* the SRR technique and subsequent SCS[33,34,36,41]. Watson *et al*[33] compared two groups, DCD-A-NRP (n = 43) *vs* DCD-SRR (n = 187), and reported both early allograft dysfunction and biliary complication rates. A significantly lower rate of early allograft dysfunction (12% *vs* 32%) and ischemic cholangiopathy (IC) (0% *vs* 27%) occurred in the DCD-A-NRP group. Similar comparisons have been performed by Spanish transplant groups. Muñoz *et al*[36] did not demonstrate significant differences in their cohort, probably due to the short follow-up period in the A-NRP group and the low number of patients. However, Hessheimer *et al*[41] subsequently found an ITBL incidence of 2% in the NRP group (n = 95) *vs* 13% in the SRR group (n = 117). These findings were repeated in a second study [34] with a larger sample size (545 NRP *vs* 258 SRR). In this second study the ITBL incidence was 1% *vs* 9% in favor of A-NRP, and this is at present the largest cohort of patients with A-NRP with premortem cannulation in the literature. Recently, Schurink *et al*[42] have reported the safety of NRP to rescue DCD grafts that were declined by the Eurotransplant region for transplantation, with no differences in primary nonfunction or IC compared to DBD and standard, non-NRP DCD grafts[42].

Finally, other authors[37,43-45] have compared A-NRP with *ex situ* preservation techniques such as NMP or HOPE. However, in many of these trials, accurate data on ITBL are lacking. The only study comparing HOPE *vs* NRP was conducted by Muller *et al*[37]. These authors reported the incidence of NAS regardless of hepatic artery status, rather than ITBL specifically. The rate of NAS was reported to be 6.3% in the NRP group and 12.5% in the HOPE group, but was not significantly different. DCD grafts that underwent A-NRP have been compared to DCD grafts undergoing *ex situ* NMP in a study by Gaurav *et al*[44] This study showed significantly lower rates of ITBL in the NRP group (6.3% *vs* 12.5%) after propensity score matching (PSM)[44]. However, in another study that used PSM analysis[45] (34 NMP *vs* 68 NRP), there were no significant differences in the ITBL rate of both groups (2.9% NRP *vs* 8.8% NMP). In this latter study, NMP was applied at source as opposed to the study by Gaurav *et al* [44], which applied it at the recipient hospital in the majority of cases[44].

A-NRP is a widely used *in situ* perfusion technique that has improved outcomes and graft utilization in DCD grafts. Protocol aspects such as the "no-touch" period or premortem cannulation may impact in these results, due to its association with WIT. Despite the differences between the protocols adopted in different countries, NRP has still achieved superior outcomes in comparison to SRR in regards to ITBL.

HOPE and ITBL

Hypothermic MP (HMP) was first introduced in clinical practice in 2010 by Guarrera *et al*[46], who demonstrate in their pilot case-controlled series that it was a feasible and safe preservation method[46]. Subsequently, in preclinical studies that investigated the active oxygenation of the hypothermic perfusate over a short period, it demonstrated restored mitochondrial integrity. This indicated a reduction of oxygen free radicals and damage-associated molecular patterns after transplantation[47-

Isolated anastomotic biliary strictures were not included in the definition of IC. The diagnosis of IC was confirmed with at least 1 adequate imaging study of the biliary tree, and concomitant hepatic artery thrombosis was excluded by Doppler ultrasound or computed tomography	Median-14 mo (cDCD), 20 mo (DBD-ECMO) and 17 mo (DBD-non-ECMO)	2/20 (10%)	NA	DBD-ECMO 0/17 0%; DBD-non-ECMO 2/52 (4%)

[1]For logistic reasons, 5 patients received additional consecutive dual hypothermic machine perfusion (DHOPE) anticipating a longer cold ischemia time (CIT) due to difficulties in recipient hepatectomy.
[2]Viability criteria used: Assessment 60 min of perfusion, with stable alanine transaminase (ALT) levels < 200 U/L, a plasma glucose peak > 10 mmol/L, and decreasing lactate level, around < 5 mmol/L. Adequate bile quality was defined as a pH > 7.45 and glucose < 3.0 mmol/L. Macroscopy of the liver did not influence. Postmortem cannulation. 5 No touch period. No antemortem interventions are allowed in Netherlands.
[3]Normothermic Regional Perfusion (NRP) + DHOPE patients.
[4]Viability criteria used: (1) serum ALT < 1000 IU/L at the end of NRP; (2) macroscopic appearance; (3) decrease in lactate levels; and (4) presence of macrosteatosis < 30% or fibrosis Ishak score < 2; Ante mortem cannulation not allowed but identification of femoral vessels to facilitate cannulation is permitted; No touch period: 5 min; Ante mortem substances administration allowed.
[5]After propensity score matching.
[6]Viability criteria used: (1) ALT levels stabilized between the first and second hour; and (2) macroscopic appearance. Ante mortem cannulation not allowed; No touch period: 5 min; Ante mortem substances administration not allowed.
[7]Clinically significant nonanastamotic biliary strictures defined as strictures requiring endoscopic or/and surgical intervention.
[8]Viability criteria used: (1) Baseline aspartate aminotransferase (AST) and ALT < 3-4 times normal value and/or AST and ALT < 4-5 times normal value at the end of NRP; and (2) macroscopic appearance; Ante mortem cannulation allowed; No touch period: 5 min; Ante mortem substances administration allowed.
[9]Viability criteria used: (1) AST and ALT > 200 IU/L; (2) macrosteatosis < 20%; and (3) More than 60 min of NRP; Ante mortem cannulation not allowed but identification of femoral vessels to facilitate cannulation is permitted; No touch period: 20 min; Ante mortem substances administration allowed.
BS: Biliary strictures; DBD: Donor after Brain Death; DCD: Donated after circulatory death; ERCP: Endoscopic retrograde cholangiopancreatography; HA: Hepatic artery; HAT: Hepatic artery thrombosis; ITBL: Ischemic type biliary lesions; MRCP: Magnetic resonance cholangiopancreatography; NAS: Nonanastamotic biliary strictures; NR: Not reported; NRP: Normothermic Regional Perfusion; SRR: Super rapid retrieval technique.

49]. Clinical studies have also reported promising results in preventing biliary complication and graft function compared to standard SCS[50,51].

HOPE is employed as an end-ischemic treatment after SRR or standard procurement in the case of DCD and DBD livers respectively, followed by a variable period of SCS. The devices available are not portable and HOPE needs to be applied at the recipient hospital. Its use limits the CIT and extends graft preservation time, avoiding the damage associated with extended periods of preservation. Two main perfusion strategies are currently employed which combine hypothermia with a highly oxygenated perfusate: (1) Single HOPE or 'HOPE', which consists of single perfusion through the portal vein; and (2) dual or 'D-HOPE' consisting of dual perfusion through the portal vein and the hepatic artery[15,52]. Currently, there are no clinical studies comparing the two strategies, although preclinical studies performed on pigs did not find differences regarding the preservation of hepatobiliary or endothelial function when comparing both strategies[53]. Advocates of D-HOPE emphasize that dominant vasculature of the bile ducts comes from arterial supply and single portal perfusion may not provide optimal preservation of the biliary tree. On the other hand, many argue the potential risk of mechanical damage to the hepatic artery intima that may occur during cannulation could cause a higher incidence of acute HAT following liver transplant[51]. Researchers from Zurich have proposed methods for liver

graft assessment during HOPE using real-time quantification of flavin mononucleotide (FMN) in the perfusate[54]. FMN is a molecule part of complex I of the mitochondrial respiratory chain[37]. Its concentration is determined by fluorescence spectroscopy and levels in perfusate correlate with graft function, complications, and graft survival in DCD livers[54].

The available studies on the use of HOPE as a preservation method, with a control group and reporting data on biliary strictures are summarized in Table 2. At present, these include four RCTs and five retrospective cohort studies with an appropriate control group of SCS grafts, and a single study comparing HOPE against NRP. The influence of HOPE on ITBL prevention has been studied only to a limited extent because in the majority, the primary endpoint was not related to biliary complications.

The relationship between ITBL and DCD livers is well established[20]. However, only 4/10 published cohort studies and 1 RCT have studied the influence of HOPE on DCD graft outcomes[51,52,55]. Thus, most published studies included only DBD livers so there is little or no ITBL incidence, and are not powered for this endpoint[56-60]. The most relevant study on ITBL prevention by *ex situ* MP was the multicenter clinical trial led by the Groningen group[52]. This European trial had symptomatic NAS within 6 mo after transplantation as the primary outcome. The study included a clear definition of NAS, which included the presence of a patent hepatic artery and therefore the NAS in this study were all ITBL. The authors demonstrated that two hours of end-ischemic D-HOPE led to a lower risk of symptomatic NAS after liver transplantation of grafts from DCD donors. NAS occurred in 5/78 (6%) of the patients in the HOPE group compared to 14/78 (18%) of SCS grafts with 2 patients from the SCS group requiring a retransplant because of severe NAS. Furthermore, the D-HOPE group showed a reduction by a factor of almost four in treatment interventions required for NAS.

Trials published by Italian and German groups have reported the efficacy of HOPE for the prevention of complications and a shorter intensive care unit stay[56,57]. There was no mention of ITBL in both trials, and grafts studied were from DBD donors so one could assume that most of the biliary complications were from an anastomotic origin. While the primary endpoint in the German[57] study was the peak alanine transaminase within 1 wk after transplantation and demonstrated a 47% reduction in the serum peak of this enzyme in the HOPE group, the authors did not find any difference in biliary complication. rate (4/23, 17% *vs* 26% 6/23). A trial[56] demonstrated benefits of HOPE, with a reduction in EAD and better graft survival rates. This study did provide a clear definition of biliary complications, although reported a rate of biliary complication different from bile leak of 5/55 (9%) in the HOPE group compared to 6/55 (11%). Two patients in each group (4%) had biliary strictures, but it was unclear if these were ITBL. A recent multicenter trial on DBD livers from the Zurich group[61] reported the effects of HOPE on preventing postoperative complications. Although the primary endpoint was not reached, and the proportion of patients with at least one Clavien^3 III complication did not differ, findings suggested that HOPE may decrease the risk of severe liver graft related events. The study did not include a clear definition of NAS and state if hepatic artery patency was required. In this study the NAS incidence was 1/85 (1.2%) in the HOPE group compared to 3/85 (3.5%) in the SCS group.

The only study comparing A-NRP and HOPE for liver grafts from DCD donors included an A-NRP cohort from six high-volume French centers and the HOPE cohort from the Zurich group[37]. In the A-NRP cohort, femoral artery cannulas were introduced post-mortem after a ''no-touch'' period of 5 min. NAS was defined as strictures with or without the presence of concomitant HAT or arterial complications and both groups showed similar rates of HAT, PNF and NAS (6/132 in the A-NRP group *vs* 8/93 in the HOPE group). D-HOPE has an encouraging role in preventing symptomatic ITBL in liver transplants from DCD grafts, due to mitochondrial injury prevention and ATP recovery under the hypothermic aerobic conditions.

NMP and ITBL

NMP provides oxygenated blood at a physiological temperature *via* both the hepatic artery and portal vein, whilst the liver graft is *ex situ*[62]. Several different NMP devices are commercially available, and the majority are transportable even with graft connected. The only major differences between the devices are the nature of the arterial flow (pulsatile or non-pulsatile) and the caval outflow (open or closed). Since the phase 1 first-in-man study that demonstrated safety and feasibility of NMP, there has been a significant uptake in this preservation modality around the world and two large RCTs[63-65]. In contrast to *ex situ* HMP, the more physiological nature of NMP allows cellular function to continue and this can be assessed *via* surrogate parameters[66,67]. Numerous biochemical parameters within the NMP perfusate or bile have been used to predict hepatocellular and cholangiocyte function respectively, in an effort to identify the grafts destined to demonstrate severe EAD or biliary complications[68]. Therefore, an accurate discussion of the impact NMP on ITBL posttransplant needs to consist of two components: (1) The incidence of ITBL in NMP preserved grafts in comparison to other modalities; and (2) the accuracy of NMP parameters to identify livers destined to develop clinically significant ITBL.

Published outcomes for NMP are confounded by the fact that this preservation modality is more frequently applied to organs of marginal quality to facilitate transplantation[69], and it may be applied for the entirety of the preservation period from the donor hospital (“at source”) or following a period of cold storage during transport to the recipient center (“back to base”). The early clinical trials of NMP included both DBD and DCD grafts, with a focus on its feasibility, safety, and impact on the IRI as indicated by markers of early graft function[63,64]. These multicenter trials included standard risk

donors that were accepted for transplant regardless of the preservation modality (NMP or SCS). Subsequently, clinical practice and research shifted to investigate the ability of NMP to resuscitate poor quality grafts that were otherwise deemed untransplantable with SCS[70-72]. Complicating matters further, supposedly untransplantable livers are a heterogenous group with a varying overall risk of ITBL[71,73]. As an example, a DBD graft with severe macrosteatosis has a different risk of ITBL than a DCD graft with 60 min of dWIT, but both will fall into the declined group due to differing clinical concerns. The increased utilization of NMP for livers otherwise deemed to high risk for transplant following SCS has pragmatic consequences for trial design. This loss in equipoise over the safety of randomizing high-risk livers to SCS results in a greater reliance on cohort studies.

The trials that have investigated NMP in the clinical setting, *via* either an RCT or cohort study with a representative control group, are listed in Table 3. Many of these trials unfortunately lacked clear definitions of what was considered ITBL, and whether complete artery patency was required for the diagnosis. To date, three RCTs of NMP have been completed[64,65,74] (Table 3). The first multicenter RCT published by Nasralla *et al*[64] in 2018 included standard risk grafts from both DBD and DCD donors and applied NMP at source. This study included a protocol magnetic resonance cholangiopancreatography at 6 mo to assess for biliary complications of which only a small proportion of subjects

[1]Median duration unless otherwise stated.
[2]Numerator represents the number of patients that completed the 6 mo protocol magnetic resonance cholangiopancreatography.
[3]Number of clinically significant strictures, defined as those requiring intervention.
[4]Presumed based on propensity matching.
BS: Biliary strictures; DBD: Donor after Brain Death; DCD: Donated after circulatory death; ERCP: Endoscopic retrograde cholangiopancreatography; IC: Ischemic cholangiopathy; HA: Hepatic artery; HAS: Hepatic artery stenosis; HAT: Hepatic artery thrombosis; IBC: Ischemic biliary complication; ITBL: Ischemic type biliary lesions; NAS: Nonanastamotic biliary strictures; NR: Not reported; NRP: Normothermic Regional Perfusion; MRCP: Magnetic resonance cholangiopancreatography; RCT: Randomized controlled trials; NA: Not available.

completed. The difference in stricture incidence was greatest in the DCD subgroup, with a rate of 26.3% in the DCD-SCS group as opposed to 11.1% in the DCD-NMP group. Whether these ischemic strictures were ITBL or the result of a vascular lesion is unclear, as HA patency was not possible to determine from the data provided[64]. The smaller RCT conducted by Ghinolfi *et al*[74] comprised a sample of elderly DBD donors (≥ 70 years) and applied NMP in a back-to-base approach[74]. However, the small sample size and lower overall risk of ITBL in DBD grafts makes the findings of this study less informative. In this study, only one patient developed a biliary stricture, and they were in the NMP group. A recent large RCT from the United States randomized nearly 300 livers (both DBD and DCD) to either at-source NMP or SCS[65]. These authors did provide a definition of what they considered an ischemic biliary complication (Table 3) and this occurred in 4 and 14 of the NMP and SCS livers respectively. Once again, the granularity of the data presented does not allow determination of the proportion of patients with ischemic biliary complications that were truly ITBL. It should be noted that none of these RCTs performed any formal viability testing of the grafts prior to transplant and were not powered appropriately to assess for biliary complications.

Both prospective and retrospective cohort studies have investigated biliary complications following NMP (Table 3). In the VITTAL trial, Mergental *et al*[71] reported the outcomes of a prospective cohort of 22 livers (12 DBD, 10 DCD) destined for discard that were transplanted following back-to-base NMP. After 6 mo follow-up, 3/10 of the DCD livers had developed symptomatic nonanastomotic biliary strictures. Requiring retransplantation[71]. Fodor *et al*[75] subsequently reported a retrospective cohort study of predominantly DBD grafts (49 DBD and 9 DCD) preserved *via* back-to-base NMP and reported both a lower incidence and severity of ITBL in the NMP group in comparison to SCS[75]. This study had a clear definition of ITBL and applied viability testing, which included bile output and pH, however specific parameters for these were not reported. Recently, Gaurav *et al*[44] published a single center retrospective cohort study of DCD grafts preserved by NMP (back-to-base and at-source), NRP and CS with the primary outcome being NAS[44]. These authors also provided a clear definition of NAS and this required hepatic artery patency. In the NMP group, 12/69 developed NAS and in 7/12 it was clinically significant. This was comparable to the SCS group (22/97, 12/22 clinically significant) but higher than the NRP group (4/69, 0/4 clinically significant). It must be noted that this study applied biliary viability testing to NMP preserved livers and 77% of these NMP preserved DCD livers proceeded to transplant.

Utilizing NMP perfusate and bile parameters to predict (and avoid) certain outcomes remains controversial. The risks associated with liberal use of NMP preserved livers is associated morbidity and mortality. The risks associated with being too stringent on the NMP viability criteria, when predictive accuracy is less than perfect, is the discard of a liver that would have resulted in acceptable outcomes. NMP indicators of biliary injury and/or function have been studied by several groups in human livers [76,77]. The early experience of associating bile pH, bicarbonate and glucose with cholangiopathies was reported by Watson *et al*[77] in 2018, from 16 transplanted livers. In this group of livers, a biliary pH < 7.4 occurred in 3/16, and all three of these developed a cholangiopathy. A lower biliary bicarbonate and higher biliary glucose concentration was also associated with subsequent cholangiopathy. Recently, the same group have reported outcomes in a much larger cohort of 144 transplanted livers[78]. Interestingly, 15 of these transplanted livers did not meet their previously reported cholangiocyte viability criteria and in a further three livers no bile was produced which precluded this assessment. Clinically significant NAS developed in 9/144 recipients and all of these had a bile pH > 7.5. Matton *et al* [76] investigated biliary NMP parameters in both the laboratory and a small clinical trial (n = 6)[76]. These authors did not have any cases of ITBL in the recipients within the trial, but demonstrated an inverse correlation between bile pH and bicarbonate concentration with histological evidence of biliary injury in a group of non-transplanted livers. A pH and bicarbonate concentration of < 7.48 and < 18 mmol/L had a positive predictive value of 75% and 91% for significant biliary injury. In summary, the prediction (and avoidance) of ITBL using NMP requires further research. This will undoubtedly be of assistance to the transplant community, however at present the accuracy remains sub-optimal and it must be improved to avoid the unnecessary discard of grafts.

Machine combination approaches

In theory, the different rationale behind the various MP strategies could work synergistically to prevent ITBL. A-NRP abbreviates the dWIT induced damage and provides in-situ resuscitation prior to the cold ischemic period, whereas the *ex situ* techniques may dampen IRI. Conversely, the application of sequential MP strategies may follow the rule of diminishing returns and the resources may not be justified. Despite the report that individual grafts had the combination of A-NRP and NMP, clarity in the ITBL rate with this combination is lacking as they were excluded from the analysis of this study[44,79]. The Groningen group have also reported their experience with sequential *ex-situ* end-ischemic D-HOPE, controlled oxygenated rewarming and NMP for high-risk livers (mostly DCD grafts)[80]. The application of this protocol is proposed to protects these livers against IRI (D-HOPE phase) and enables viability assessment (NMP phase) prior to transplantation, resulting in promising outcomes.

In Italy, as aforementioned circulatory death during DCD procurement is declared after a stand-off period of 20 min. This prolonged dWIT time has been a general reluctance to use such DCD grafts for transplantation due to the probable high risk of graft failure. The combination of A-NRP and D-HOPE has contributed to increase the donor pool in this high-risk donor context. In a retrospective cohort study, this combination has reported satisfactory outcomes in terms of ITBL when compared with relatively low-risk donor control group (A-NRP + D-HOPE 3% *vs* SCS 8%)[43]. Recently, a new procedure called ischemia-free liver transplantation has been proposed, during which liver grafts are procured, preserved and implanted under continuous NMP. Its applicability and clinical impact are yet to be determined[81]. Further studies are required to determine if additional benefits are achieved by combining different techniques.

EVIDENCE SUMMARY

The volume of data on MP and its impact on the development of ITBL following liver transplant is growing. However, with only a few exceptions, ITBL was not the primary outcome under investigation in these studies and therefore were not designed and reported with this entity in mind. It is difficult in many published studies to tease out what biliary complications represent the development of ITBL, as opposed to strictures of another cause. With this considered, the evidence for prevention of ITBL with MP is distinctly different for DCD as opposed to DBD grafts.

The highest quality evidence for ITBL prevention with MP in DCD grafts is D-HOPE, in comparison to SRR and SCS. This is based on finding from a RCT[52]. However, a larger quantity of lower quality evidence supports A-NRP in comparison to both SRR with SCS, and NMP *via* a 'back to base' approach. At present, there is no evidence that D-HOPE is superior to A-NRP or that the combination of these two MP techniques results in a further reduction of ITBL than each one in isolation. Based on the DCD subgroup from one randomized trial[64], there is a suggestion that NMP applied 'at source' reduces ITBL in comparison to SRR and SCS[64]. There is no good quality evidence that NMP applied in a 'back to base' approach for DCD grafts prevents ITBL. In DBD donors, the incidence of ITBL is lower and therefore studies with a large sample size will be required to demonstrate a noticeable effect. The available evidence to suggest that either NMP 'at source' or 'back to base' for DBD grafts is weak, and consists of only one cohort study[75]. There is no trial evidence to support a reduction in ITBL for DBD grafts with HMP strategies.

CONCLUSION

ITBL remains an ongoing issue and the notion that biliary complications are the 'achilles heel' of liver transplantation remains true. However, with the introduction of MP technology, gains are being made in the prevention of this highly morbid condition. The greatest area of improvement is for DCD grafts with RCT evidence for D-HOPE, and large cohort studies supporting A-NRP. Given the demonstrated benefits these modalities have over SCS for DCD grafts, a loss of equipoise within the transplant community is diminishing the opportunity for further RCTs that include a SCS group. As an organ donor often generously gives numerous organs, the impact A-NRP has on other abdominal viscera may influence the decision regarding the most appropriate MP strategies. Multiple factors likely interact to cause ITBL, and a greater understanding of these will undoubtedly help refine both preventative and treatment interventions.

Abstract

BACKGROUND

Capecitabine (CAP) is a classic antimetabolic drug and has shown potential antirejection effects after liver transplantation (LT) in clinical studies. Our previous study showed that metronomic CAP can cause the programmed death of T cells by inducing oxidative stress in healthy mice. Ferroptosis, a newly defined non-apoptotic cell death that occurs in response to iron overload and lethal levels of lipid peroxidation, is an important mechanism by which CAP induces cell death. Therefore, ferroptosis may also play an important role in CAP-induced T cell death and play an immunosuppressive role in acute rejection after transplantation.

AIM
To investigate the functions and underlying mechanisms of antirejection effects of metronomic CAP.

METHODS
A rat LT model of acute rejection was established, and the effect of metronomic CAP on splenic hematopoietic function and acute graft rejection was evaluated 7 d after LT. *In vitro*, primary $CD3^+$ T cells were sorted from rat spleens and human peripheral blood, and co-cultured with or without 5-fluorouracil (5-FU) (active agent of CAP). The levels of ferroptosis-related proteins, ferrous ion concentration, and oxidative stress-related indicators were observed. The changes in mitochondrial structure were observed using electron microscopy.

RESULTS
With no significant myelotoxicity, metronomic CAP alleviated graft injury (Banff score 9 *vs* 7.333, $P < 0.001$), prolonged the survival time of the recipient rats (11.5 d *vs* 16 d, $P < 0.01$), and reduced the infiltration rate of $CD3^+$ T cells in peripheral blood (6.859 *vs* 3.735, $P < 0.001$), liver graft (7.459 *vs* 3.432, $P < 0.001$), and spleen (26.92 *vs* 12.9, $P < 0.001$), thereby inhibiting acute rejection after LT. *In vitro*, 5-FU, an end product of CAP metabolism, induced the degradation of the ferritin heavy chain by upregulating nuclear receptor coactivator 4, which caused the accumulation of ferrous ions. It also inhibited nuclear erythroid 2 p45-related factor 2, heme oxygenase-1, and glutathione peroxidase 4, eventually leading to oxidative damage and ferroptosis of T cells.

CONCLUSION
Metronomic CAP can suppress acute allograft rejection in rats by triggering $CD3^+$ T cell ferroptosis, which makes it an effective immunosuppressive agent after LT.

Core Tip: Our studies proved that metronomic capecitabine (CAP) alleviated the acute rejection after transplantation in rats without the common side effect of myelosuppression. T cell ferroptosis is the underlying mechanism behind the antirejection effect of CAP, which can induce cell ferrous ions overload and suppress the nuclear erythroid 2 p45-related factor 2, heme oxygenase-1/glutathione peroxidase 4 antioxidant systems, thereby directly increasing the levels of intracellular reactive oxygen species, and leading to severe oxidative damage in T cells. These results revealed a new mechanism of CAP-induced T cell programmed death and suggested the possibility of using CAP as an immunosuppressant after transplantation.

INTRODUCTION

Recurrence of hepatocellular carcinoma (HCC) represents a serious issue after liver transplantation (LT), and is closely related to the usage of immunosuppressant drugs[1-3]. As a classic antimetabolic chemotherapeutic agent, capecitabine (CAP) is widely used in the treatment of cancers and has also shown good effects on HCC[4,5]. Metronomic CAP is suitable for long-term oral administration with low adverse effects and without sacrificing treatment efficacy[6,7]. In patients with recurrent liver cancer after LT, Ravaioli *et al*[8] showed that metronomic CAP achieved similar efficacy to sorafenib, a protein kinase inhibitor approved for HCC but with a high incidence of adverse effects[9]. Interestingly, no acute rejection was seen, suggesting that CAP may have both immunosuppressive and anticarcinogenic effects. CAP is a fluoropyrimidine prodrug that is metabolized in a three-step process to 5-fluorouracil (5-FU)[10]. The last step requires thymidine phosphorylase (TP), the distribution of which determines CAP distribution. This partially explains its different pharmacological characteristics

compared to 5-FU. Because TP is highly expressed in cancer cells and lymphocytes[11,12], the administration of CAP to LT patients with HCC may increase tumor killing while preventing graft rejection. In preliminary work, we found that the differential expression of TP avoided CAP's side effects of myelosuppression and suppressed normal mouse immune responses by inducing T cell apoptosis[13]. However, it is not clear what effect CAP has during the immune activation that follows transplantation, which is key to its use as an immunosuppressant.

Ferroptosis is a newly defined nonapoptotic cell death that occurs with iron overload and lethal levels of lipid peroxidation[14-16]. Ferroptosis is tightly regulated by iron metabolism, while ferritin is the major intracellular iron storage protein complex. Ferritinophagy activation depends on nuclear receptor coactivator 4 (NCOA4) to transport ferritin to the autophagosome and degrade ferritin to increase intracellular iron levels[17,18]. Subsequently, free ferrous ions overload results in oxidative injury by the Fenton reaction. Although the regulatory mechanisms of ferroptosis are poorly understood, some molecules with antioxidant effects may be implicated, such as nuclear erythroid 2 p45-related factor 2 (Nrf2)[19,20], heme oxygenase-1 (HO-1)[21], and glutathione peroxidase 4 (GPX4)[22]. Overall, free ferrous ions result in reactive oxygen species (ROS) generation and oxidative injury, whereas the Nrf2-HO-1/GPX4 antioxidative system protects cells from oxidative damage induced by ferroptosis[23]. In mouse models and *in vitro*, 5-FU mediates injuries in intestinal mucosal cells, such as those occurring during chemotherapy, by reducing Nrf2 expression and increasing ferroptosis[24]. 5-FU also leads to ROS and iron homeostasis-dependent ferroptosis in myocardial cells by reducing the expression of GPX4 and ferritin heavy chain (FTH1) but enhancing the expression of transferrin receptor 1[25]. Thus, mechanistically, ferroptosis plays an important role in the cell-killing effect of 5-FU.

Our previous study indicated that metronomic CAP can increase ROS levels and reduce mitochondrial membrane potential (MMP), thus affecting the immune system of mice[13]. Those results prompted us to further explore whether ferroptosis plays a significant role in 5-FU-induced immunosuppression. In this study, we investigated the effect of metronomic CAP on acute rejection in a rat model of LT, and determined how ferroptosis affects 5-FU-induced immunosuppression. Elucidating the possible mechanism of CAP as an immunosuppressant with anticancer effects is of great relevance to optimize drug regimens for HCC patients after LT in the future.

MATERIALS AND METHODS

Animals

Specific-pathogen-free male Lewis rats (donors) and male Brown Norway rats (recipients) aged 8–10 wk and weighing 250–300 g were obtained from Beijing Vital River Laboratory Animal Technology Co. Ltd. (Beijing, China). The rats were housed in a standard room, and fed filtered clean water and standard laboratory food. To acclimatize, the rats were housed 1 wk before transplantation. According to different postoperative medication regimens, the rats were randomized to untreated control group (CON) (0.9% saline, ig) and metronomic capecitabine-treated (MET) groups (CAP 100 mg/kg/d, ig). A total of 12 recipients (6 rats/group) were used for postoperative specimen collection at 7 d after transplantation, and another 12 recipients (6 rats/group) were used to observe survival. All invasive procedures and specimen collection were performed under isoflurane anesthesia to minimize pain or discomfort.

Orthotopic LT in rats

Anesthesia was induced with isoflurane and orthotopic LT was performed based on Kamada's two-cuff method. The anhepatic phase was controlled within 26 min[26,27]. After transplantation, the rats received 2 mL Ringer's lactate to replenish blood volume and were rewarmed in an incubator at 37 ℃ for 30 min. On day 7 after LT, an overdose of pentobarbital (150 mg/kg) was injected intraperitoneally for euthanasia. Femur, blood, spleen, and the transplanted liver were collected for further examination.

Routine blood tests

Whole blood was used for blood routine tests 7 d after LT. These were performed with an automatic hematology analyzer (BC-2800Vet; Mindray, Shenzhen, China).

Peripheral blood lymphocyte $CD3^+$ T cell count

Peripheral blood lymphocyte $CD3^+$ T cell count was obtained based on peripheral blood lymphocyte count and flow cytometric analysis of the $CD3^+$ T cell ratio.

Liver function assay

Serum levels of aspartate aminotransferase (AST), alanine aminotransferase (ALT), total bilirubin (TBIL), and direct bilirubin (DBIL) were measured using kits (Mindray, Shenzhen, China) and read with an automatic biochemical analyzer (BS-240VET; Mindray, Shenzhen, China).

Flow cytometric analysis

Rat peripheral blood mononuclear cells were isolated by gradient centrifugation with a rat peripheral blood mononuclear cell separation solution (Solarbio, Beijing, China). Anti-CD3 antibodies (APC anti-rat CD3 Antibody, Cat# 201414; RRID: AB_2563366 BioLegend, San Diego, CA, United States) were used for extracellular staining to identify CD3-positive lymphocytes. Flow cytometry was performed using the Accuri C6 Plus flow cytometry (BD Biosciences, Palo Alto, CA, United States), and FlowJo software (TreeStar, Woodburn, OR, United States) was used for data analysis.

The ferrous levels in T cells were measured using FerroOrange (Cat# MX4559, Maokang Biotechnology, Shanghai, China). Cells were incubated with FerroOrange (37 ℃, 20 min) for fluorescence detection. To measure intracellular ROS, cells were resuspended in phosphate-buffered saline (PBS) containing DCFH-DA (Cat# CA1410, Solarbio, Beijing, China) at 37 ℃ for 30 min and washed twice with PBS for fluorescence detection. To measure the lipid ROS of T cells, C11-BODIPY 581/591 (Cat# MX5211, Maokang Biotechnology, Shanghai, China) was added and incubated at 37 ℃ with 5% CO_2 for 30 min. Cells were then washed twice before fluorescence detection. The MMP Assay Kit (Cat# M8650, Solarbio, Beijing, China) was used to measure the MMP in T cells. Cells were incubated with JC-1 working solution at 37 ℃ for 20 min, then washed twice with JC-1 buffer for fluorescence detection. BODIPY emission was recorded on an oxidized C11 signal (FITC channel).

Luminex assay

The rat sera were analyzed for cytokine concentrations [interleukin (IL)-10, IL-2, IL-1α, IL-4, interferon gamma (IFN-γ), tumor necrosis factor alpha (TNF-α), IL-5, IL-6, growth-regulated oncogene (GRO)/keratinocyte chemoattractant (KC), IL-12p70] using the Millipore Luminex 200 instrument (Luminex Corporation, Austin, TX, United States), after incubation of the samples with beads according to the manufacturer's instructions. The quantification was performed with Luminex xPonent version 3.1 software.

Cell culture

Healthy mononuclear cells from the spleen of rats and peripheral blood of humans were collected by gradient centrifugation with respectively, rat tissue mononuclear cell separation solution (Solarbio, Beijing, China) and human peripheral blood mononuclear cell separation solution (Solarbio, Beijing, China). T cells were purified through positive magnetic selection using microbeads (Miltenyi Biotec, Bergisch Gladbac, Germany) and cultivated at 2.0×10^6 cells/well in 6-well plates with RPMI-1640 with 5% fetal bovine serum and 100 IU/mL IL-2. Within the first 72 h, the anti-CD3/CD28 antibody (Cat# 201401, RRID: AB_893302; 2 μg/mL and Cat# 200902, RRID: AB_313891; 1 μg/mL) were used to stimulate the T cells.

Cell proliferation assay

The Cell Counting Kit-8 (CCK-8) assay (Boster, Hubei, China) was used to evaluate T cell proliferation *in vitro*. The CON group (n = 3), 5-FU group (5-FU 15 μmol/L, MCE, Shanghai, China; n = 3); ferrostatin-1 (Fer-1) group (Fer-1 2 μmol/L, MCE, Shanghai, China; n = 3); 5-FU+fer-1 group (5-FU 15 μmol/L + fer-1 2 μmol/L) were included. After 72 h of culture, CCK-8 solution was added to each well of the 96-well plates and allowed to incubate for 2 h at 37 ℃, and the optical density value at 450 nm was recorded.

Histopathology

The femurs and grafts (n = 6 for each group) were removed on postoperative day 7. The femurs were decalcified with EDTA decalcifying solution (Solarbio, Beijing, China). Then both femurs and grafts were fixed in 10% paraformaldehyde, dehydrated, paraffin-embedded, cut into 4 μm slides, and stained with hematoxylin and eosin (H&E; G1120; Solarbio, Beijing, China).

Immunohistochemistry

$CD3^+$ cell infiltration was assessed on spleen and liver graft sections as follows: Tissue sections were heated for 15 min in EDTA (pH 8.0) in a microwave for antigen retrieval, incubated in 3% hydrogen peroxide for 30 min to eliminate endogenous peroxidase activity, and blocked in normal goat serum. Then the sections were incubated overnight at 4 ℃ with a rat anti-CD3 antibody (CD3-12, Cat# ab11089, RRID: AB_2889189; Abcam, Cambridge, MA, United States) and incubated with a secondary antibody (Goat Anti-Rat IgG H&L, Cat# ab97057, RRID: AB_10680316; Abcam, Cambridge, MA, United States) or 30 min at room temperature the next day. Finally, the sections were stained with freshly prepared diaminobenzidine solution and counterstained with hematoxylin. ImageJ software was applied to 200 × images to quantify the CD3-positive fields.

Transmission electron microscopy

Cells were collected after centrifugation and fixed in 2.5% glutaraldehyde. After dehydration through graded ethanol, the cells were embedded in epoxy resins and cut into ultrathin sections. The

morphologic changes in mitochondrial ultrastructure were observed using a transmission electron microscope (HT7800; Hitachi, Tokyo, Japan).

Western blot analysis

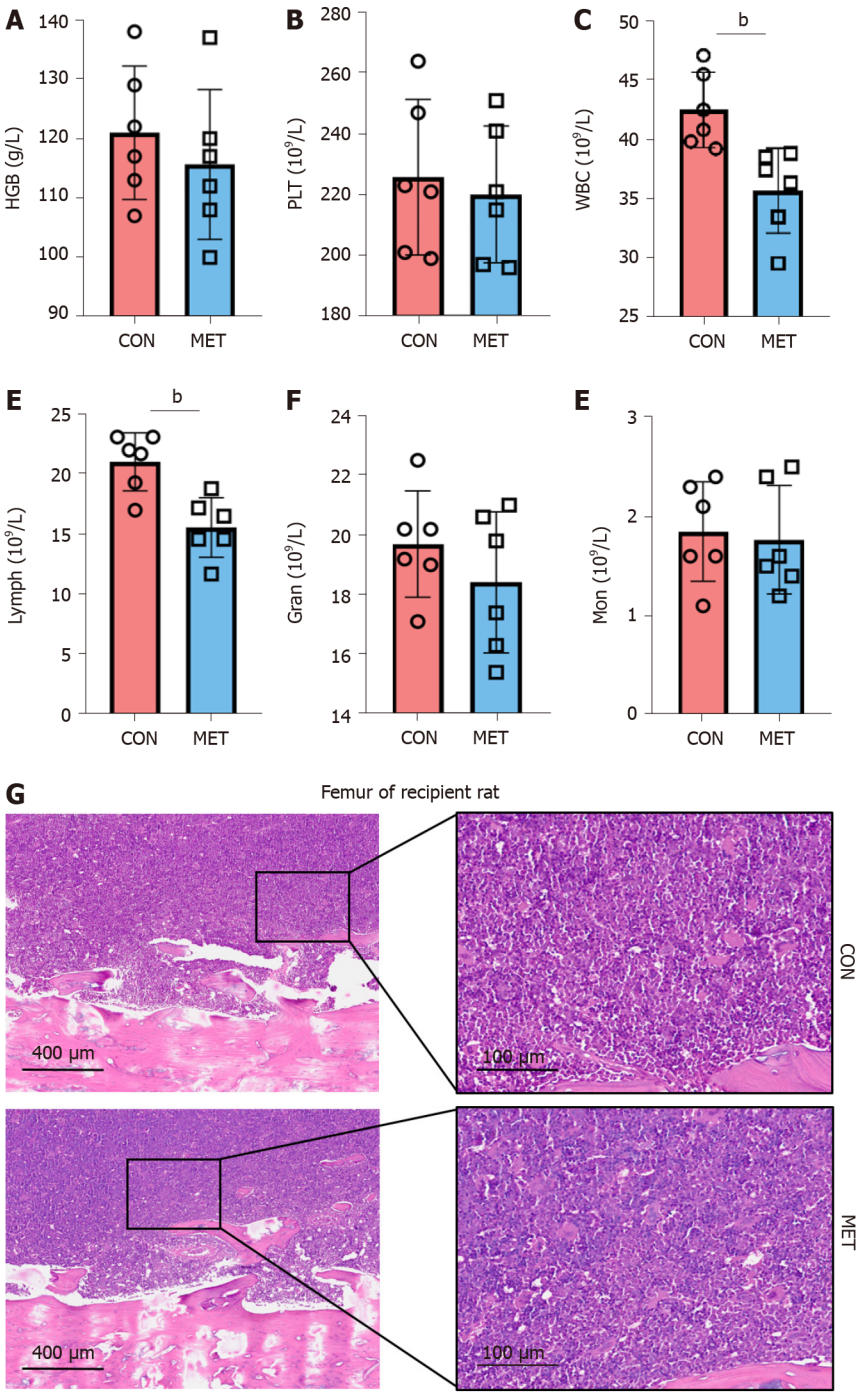
Total protein was extracted using RIPA buffer containing protease and phosphatase inhibitors. The mixture was placed on ice for 30 min for cell lysis, and then centrifuged at 12000 g for 15 min at 4 ℃ to discard the cell debris. Total protein concentration was quantified by the BCA Protein Assay Kit (Beyotime Biotechnology, Beijing, China). The proteins were resolved by sodium dodecyl sulfate-polyacrylamide gel electrophoresis, electrotransferred to polyvinylidene fluoride membranes, and blocked in 5% skimmed milk for 1 h. Then the membranes were incubated overnight at 4 ℃ with primary antibodies against FTH1 (EPR18878, Cat# ab183781; Abcam, Cambridge, MA, United States), NCOA4 (Cat# PA5-96398, RRID: AB_2808200; Thermo Fisher Scientific, Waltham, MA, United States), Nrf2 (E5F1A, Cat# 20733S, Cell Signaling Technology, Danvers, MA, United States), HO-1 (EPR1390Y, Cat# ab68477, RRID: AB_11156457; Abcam, Cambridge, MA, United States), and GPX4 (EPNCIR144, Cat# ab125066, RRID: AB_10973901; Abcam, Cambridge, MA, United States). β-actin (SP124, Cat# ab115777, RRID: AB_10899528; Abcam, Cambridge, MA, United States) antibody served as the internal control. The membranes were washed and then incubated with a secondary antibody (Goat anti-Rabbit IgG H+L, Cat# A16110; Thermo Fisher Scientific, Shanghai, China) for 1 h at RT. Proteins were detected with an imaging system (Bio-Rad, Hercules, CA, United States), and band intensities were analyzed with ImageJ software (National Institutes of Health, Bethesda, MD, United States).

Statistical analyses

The statistical analyses were performed with SPSS 23.0 (IBM Analytics) and GraphPad 8.0 (GraphPad Software). The statistical methods of this study were reviewed by Yuan Wang from the Department of Biostatistics and Epidemiology, The First Central Clinical School, Tianjin Medical University. Data are presented as the mean ± standard error of the mean. The unpaired *t*-test was used to assess the differences between the two groups, and a one-way analysis of variance was used to assess the differences among three or more groups. $P < 0.05$ was considered statistically significant.

RESULTS

Metronomic CAP exerts a marginal myelosuppressive effect, compatible with continuous administration



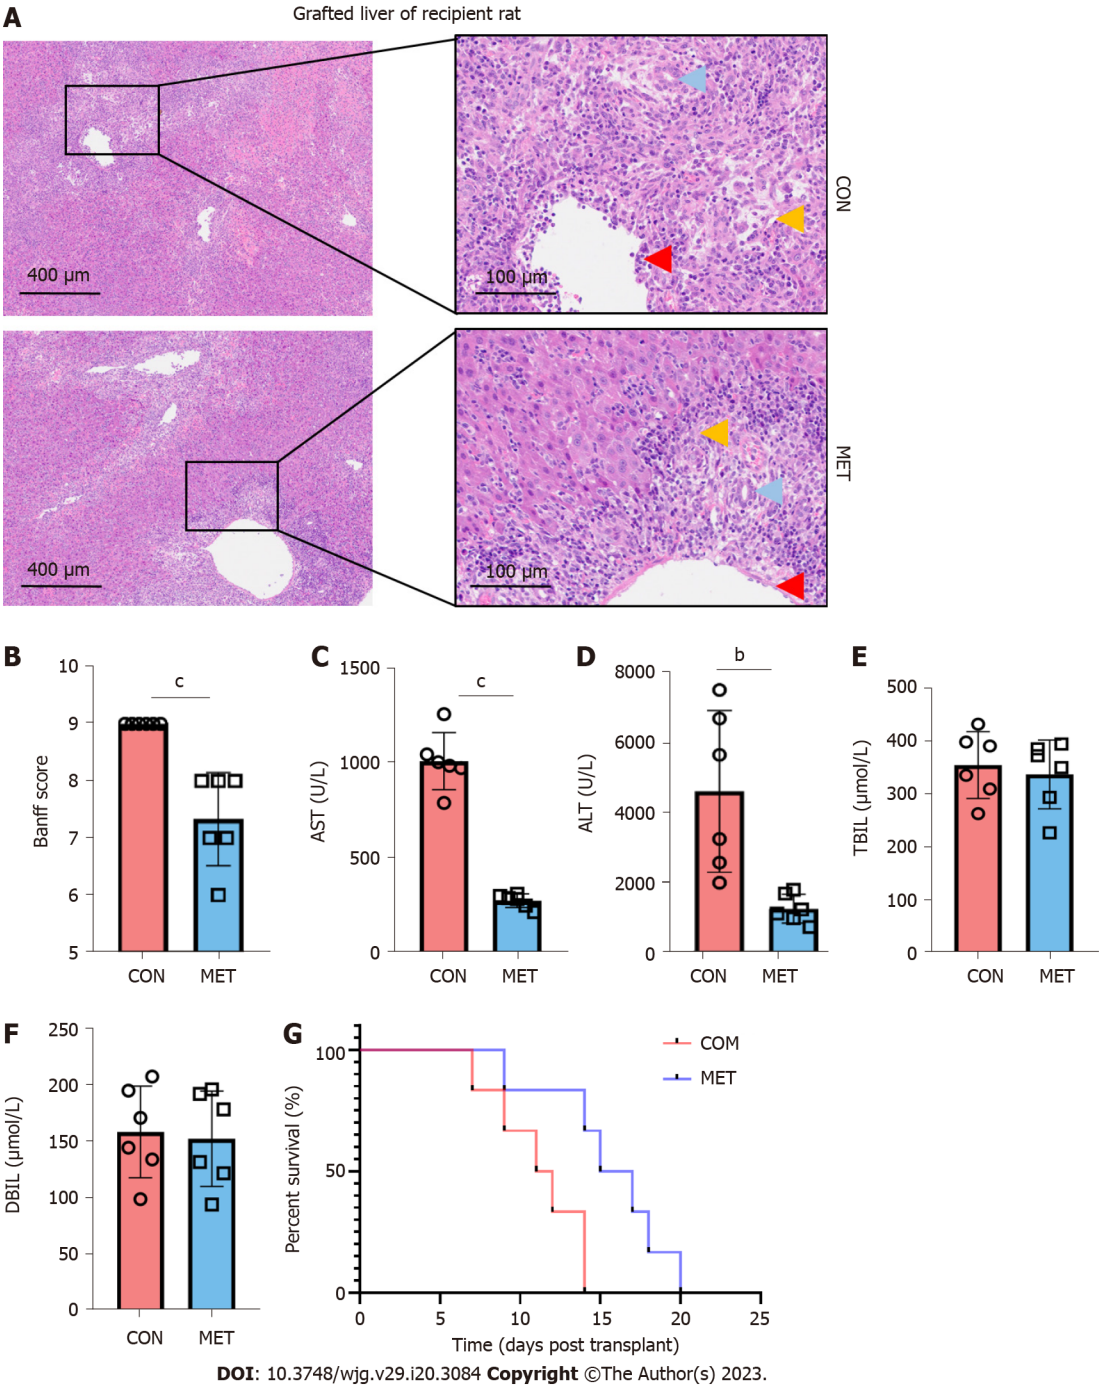
5-FU, the end product of CAP, may induce myelotoxicity. Thus, we first evaluated metronomic CAP's myelotoxicity on peripheral blood hemoglobin (HGB), platelets (PLTs), and leukocytes in a rat model of orthotopic LT, where recipient Brown-Norway rats received the livers from Lewis rats. Seven days after LT, there was no significant difference in the index of HGB and PLTs between the CON group and the MET group (Figure 1A and B). However, leukopenia with a reduced number of lymphocytes was found in the MET group, while the number of other leukocyte subsets (granulocytes and mononuclear cells) was not significantly different (Figure 1C–F). These results suggest that CAP had a relatively targeted killing effect on lymphocytes, but no obvious effect on PLTs, erythrocytes, monocytes, or granulocytes. In the bone marrow, the rats in the MET group had no pathological manifestation of myelosuppression (Figure 1G), suggesting that the lymphocytopenia caused by CAP did not result from myelosuppression.

Metronomic CAP reduces acute rejection and alleviates graft injury

To evaluate the effect of metronomic CAP during acute rejection, the grafted livers were harvested on day 7 after LT for histopathological examination. As shown in Figure 2A, prominent acute rejection with severe bile duct damage, endothelitis, and hepatocyte vacuolation occurred in the grafts of the CON group. Portal areas were infiltrated by inflammatory cells, hepatic sinusoids were greatly expanded, and the sinusoidal endothelial cells were markedly swollen. Compared with the CON group, acute rejection in the MET group was ameliorated, as evidenced by inflammatory cell infiltration being confined to only some of the portal areas and the degeneration of a few bile duct epithelia. The Banff scores[28] decreased in the MET group compared with the CON group (Figure 2B). On day 7 after LT, liver damage was assessed by measuring serum levels of AST and ALT (Figure 2C and D). Compared with the CON group, CAP significantly decreased the serum levels of ALT and AST. However, TBIL and DBIL in both groups showed an increasing trend after the operation, but there was no significant difference between the two groups (Figure 2E and F). In the survival analysis, a log-rank (Mantel Cox) test was conducted. Rats in the MET group had a longer survival time compared with the CON group (Figure 2G, median survival time: 16.5 and 11.5 d; $P < 0.01$).

Metronomic CAP reduces the number of $CD3^+$ T cells in graft recipients

Next, to investigate whether the inhibition of acute rejection by metronomic CAP involved an effect on

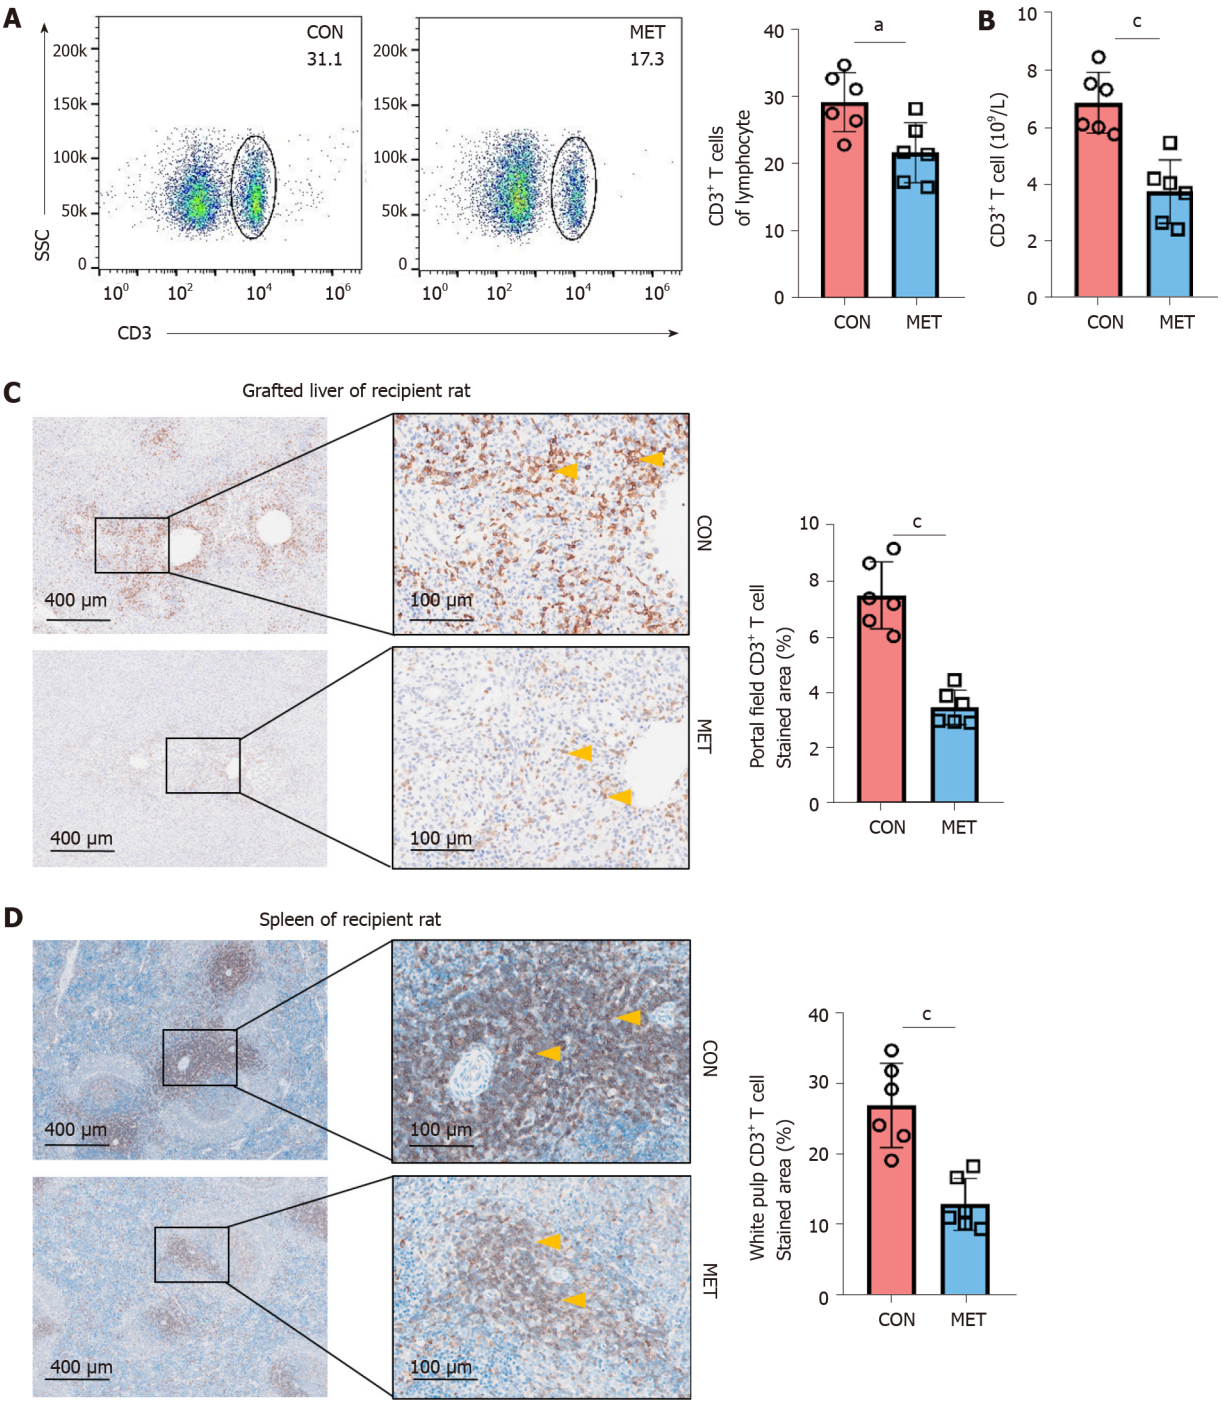


DOI: 10.3748/wjg.v29.i20.3084 **Copyright** ©The Author(s) 2023.

Figure 1 Metronomic capecitabine showed no significant myelosuppression. A and B: Hemoglobin level and platelets count in the peripheral blood; C-F: White blood cells, lymphocytes, granulocytes, and monocytes counts in the peripheral blood; G: Bone marrow tissue was stained with hematoxylin and eosin (50 × and 200 ×). Statistical analysis was done by unpaired *t*-test, $n = 6$. Data are shown as mean ± SD; $^bP < 0.01$ *vs* the control group. CON: Untreated control groups, rats received 0.9% normal saline for 7 d; MET: Metronomic capecitabine (CAP)-treated groups, rats received metronomic CAP (100 mg/kg/d) treated for 7 d; HGB: Hemoglobin; PLT: Platelets; WBC: White blood cells; lymph: Lymphocytes; Gran: Granulocytes; Mon: Monocytes.

T cells, $CD3^+$ T cells in the peripheral blood, grafts, and spleens were analyzed. Compared to the CON group, the $CD3^+$ T cells in the peripheral blood were significantly lower in the MET group (Figure 3A and B). In addition, a large number of $CD3^+$ T cells was localized in the portal canal area of the CON group. Infiltrated $CD3^+$ T cells in both the liver and spleen were significantly reduced in the MET group (Figure 3C and D). These results indicate that metronomic CAP can decrease the number of $CD3^+$ T cells in the peripheral blood, liver, and spleen of the recipient rats.

Metronomic CAP regulates serum cytokine levels



Cytokines are an important reflection of immune cell function and immune status. Thus, the levels of

DOI: 10.3748/wjg.v29.i20.3084 **Copyright** ©The Author(s) 2023.

Figure 2 Metronomic capecitabine improves liver function and ameliorates liver allograft rejection. A: Liver allograft tissue was stained with hematoxylin and eosin (50 × and 200 ×). Liver tissue, portal vein, and bile duct were significantly injured in the untreated control group (CON), with a large number of inflammatory cells infiltrated. In the metronomic capecitabine-treated groups (MET), liver tissue destruction was relatively mild, with limited infiltration of inflammatory cells (yellow arrows), relatively little degeneration of portal vein endothelium (red arrows), and bile duct epithelium (blue arrows); B: The severity of acute rejection was graded according to the Banff liver rejection criteria; C-F: Alanine transaminase, aspartate transaminase, total bilirubin, and direct bilirubin levels in the peripheral blood; G: Survival analysis of rats after liver transplantation. The median survival time of the CON and MET groups were 11.5 d and 16 d, respectively ($P < 0.01$). The survival analysis was done by log-rank (Mantel Cox) test, $n = 6$. Statistical analysis was done by unpaired *t*-test, $n = 6$. Data are shown as mean ± SD; $^{b}P < 0.01$ *vs* the control group, $^{c}P < 0.001$ *vs* the control group. CON: Untreated control groups, rats received 0.9% normal saline for 7 d; MET: Metronomic capecitabine (CAP)-treated groups, rats received metronomic CAP (100 mg/kg/d) treated for 7 d; ALT: Alanine transaminase; AST: Aspartate transaminase; TBIL: Total bilirubin; DBIL: Direct bilirubin.

IFN-γ, TNF-α, human GRO/KC, IL-1β, IL-2, IL-4, IL-5, IL-6, IL-10, and IL-12p70 in peripheral blood and graft were quantified by Luminex assay. As shown in Figure 4, the levels of pro-inflammatory IFN-γ, TNF-α, IL-2, and IL-12p70 in the MET group were significantly lower than those in the CON group. Other cytokines (IL-1β, IL-5, IL-6, IL-4, IL-10, and GRO/KC) did not show significant changes (Supplementary Figure 1). The results showed that metronomic CAP plays an immunosuppressive role by downregulating the concentration of pro-inflammatory cytokines.

Figure 3 Metronomic capecitabine decreased the infiltration of CD3⁺ T cells in peripheral blood, liver allografts, and spleen. A: The percentage of CD3⁺ T cells among lymphocytes in the peripheral blood at postoperative day 7; B: The number of CD3⁺ T cells in the peripheral blood at postoperative day 7; C and D: Grafted liver (C) and spleen (D) sections were stained for CD3. The samples from each group were collected on postoperative day 7. The arrows show positive staining (50 × and 200 ×). Quantification of the proportion of CD3⁺ positive area within a given section (%). Statistical analysis was done by unpaired *t*-test, $n = 6$. Data are shown as mean ± SD; $^{a}P < 0.05$ *vs* the control group, $^{c}P < 0.001$ *vs* the control group. CON: Untreated control groups, rats received 0.9% normal saline for 7 d; MET: Metronomic capecitabine (CAP)-treated groups, rats received metronomic CAP (100 mg/kg/d) treated for 7 d.

Metronomic CAP increases T cell free ferrous ions and induces lipid peroxidation in vivo

The immune activation of T cells is particularly important in the acute rejection of organ transplants. Similar to many commonly used immunosuppressants, the killing effect of CAP on T cells is also key to its immunosuppressive activity[13]. Therefore, we further explored the mechanism of T cell killing by metronomic CAP. Ferroptosis is a new form of ROS-dependent programmed cell death that may plays an important role in CAP-mediated cytotoxicity. Thus, we measured by flow cytometry the concentration of free ferrous ions, ROS level, and lipid ROS level in peripheral blood CD3⁺ T cells from transplanted rats of both groups at day 7. Compared with the CON group, free ferrous ion concen-

tration (Figure 5A), total ROS (Figure 5B), and lipid ROS (Figure 5C) levels were increased in the MET group. At the same time, the detection of the MMP showed a decreasing trend in the MET group (Figure 5D). These results indicated that metronomic CAP leads to the generation of ferrous ions and results in lipid peroxidation, which conforms to the typical characteristics of ferroptosis.

5-FU triggers ferritinophagy and ferroptosis in T cells in vitro

To further explore *in vitro* the mechanism underlying the CAP-mediated ferroptosis linked to immunosuppression observed *in vivo*, primary $CD3^+$ T cells were sorted from rat spleens and human peripheral blood (Supplementary Figure 2). Both primary $CD3^+$ T cells were treated with 5-FU *in vitro* (Supplementary Figure 3). This treatment significantly inhibited cell viability, which was attenuated by the ferroptosis inhibitor Fer-1 (Figure 6A). Transmission electron microscopy revealed typical characteristics of ferroptosis in 5-FU-treated group, namely, smaller mitochondria with increased membrane density, and diminished mitochondrial cristae (Figure 6B). Free ferrous ions concentration was increased in the 5-FU-treated group, whereas Fer-1 partially reversed the increase of ferrous ions induced by 5-FU (Figure 6C). As a selective cargo receptor, NCOA4 mediates the transport of ferritin into lysosomes, inducing ferroptosis. Western blot analysis revealed that 5-FU treatment induced FTH1 decrease, but a tendency toward increasing NCOA4 expression was observed (Figure 6D), consistent with the *in vivo* studies (Supplementary Figure 4). These results confirmed that the cytotoxicity of 5-FU is at least partly related to the induction of T cell ferroptosis, in which the increase of free ferrous ions caused by NCOA4-mediated ferritinophagy plays an important role.

5-FU-triggered ferroptosis is associated with the inhibition of the Nrf2-HO-1/GPX4 antioxidative pathway

To evaluate the effect of 5-FU on the antioxidant system, antioxidant-related proteins were measured in rat and human primary $CD3^+$ T cells treated with 5-FU. The expression of Nrf-2, HO-1, and GPX4 was evaluated in both groups and compared, and treatment with 5-FU was found to be associated with a marked decrease (Figure 7A), consistent with the *in vivo* studies (Supplementary Figure 4). The results showed that 5-FU treatment increased total ROS and lipid ROS levels and decreased MMP (Figure 7B–D). It also decreased glutathione (GSH) levels and increased the oxidative stress biomarker malondialdehyde (MDA) (Figure 7E and F). Fer-1 inhibits ferroptosis partly by activating Nrf2[29]. Accordingly, it reversed 5-FU-mediated inhibition of Nrf-2, HO-1, and GPX4, increased GSH level, and decreased MDA content, thereby alleviating cell peroxidation induced by 5-FU (Figure 7A–D). These results suggest that 5-FU inhibits the antioxidant system of T cells, inducing the T cells damaged by lipid peroxidation, which results in ferroptosis.

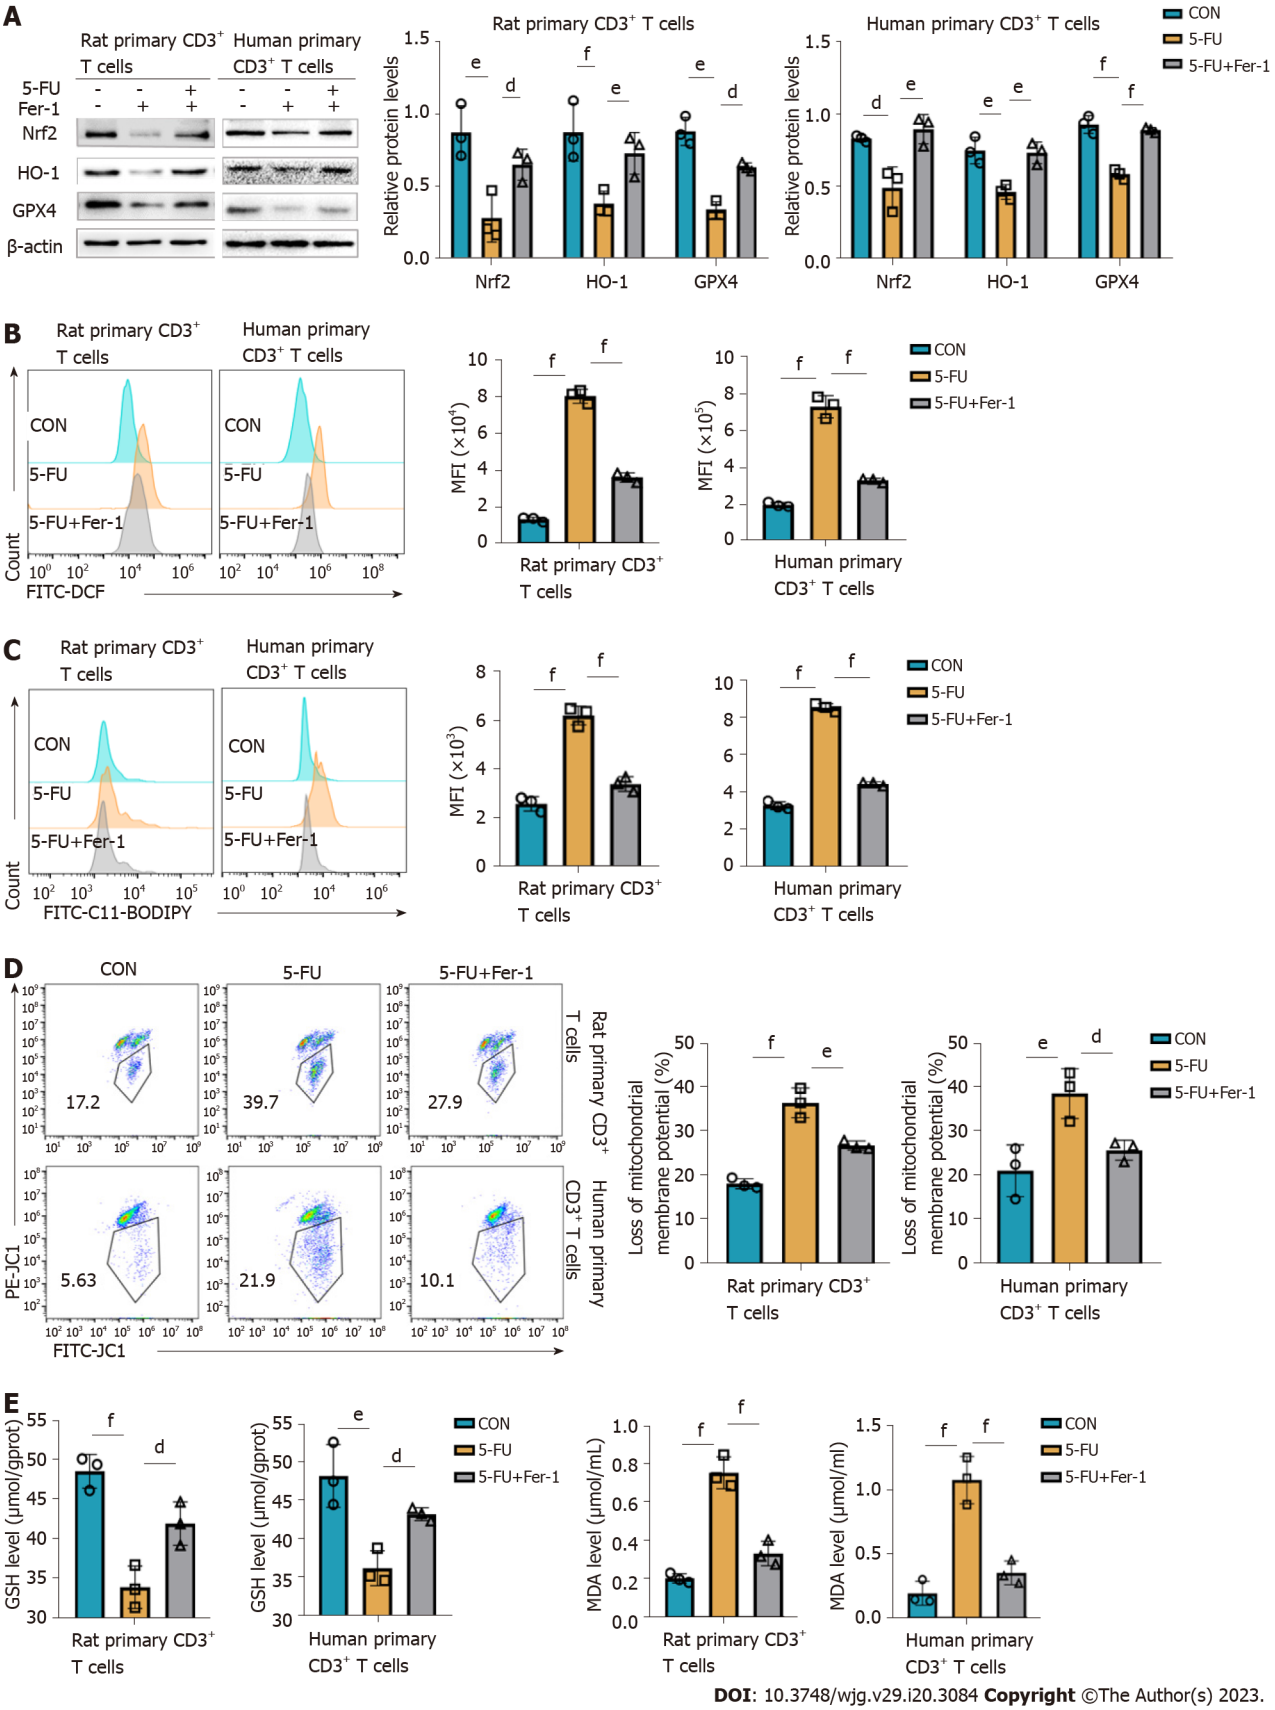
DISCUSSION

The conflict between the risk of tumor formation and immune rejection after transplantation has always been a concern. Therefore, it is of great clinical value to identify a drug with both immunosuppressive and anticancer effects. CAP is a classic chemotherapy drug for HCC[4,6], which has been shown to have immunosuppressive effects in a previous study[8], suggesting that metronomic CAP can be used as an immunosuppressant after transplantation and bring long-term benefits to LT patients with HCC. In our previous study, we found that metronomic CAP exerts immunosuppressive effects on normal mice by inducing T cell apoptosis[13]; however, the effect of CAP on the immune system in the context of organ transplantation was unclear. Therefore, we explored the safety, availability, and mechanism of metronomic CAP as an immunosuppressant in a model of rat orthotopic LT. Our results suggest that metronomic CAP can inhibit the acute rejection of LT by inhibiting T cells while avoiding the main side effects of 5-FU. Its mechanism is related to the induction of ferritin degradation and the inhibition of antioxidant-related proteins, which ultimately leads to the death of T cells (Figure 8).



The main effects of 5-FU are on rapidly proliferating tissues, specifically bone marrow. 5-FU suppressed bone marrow hematopoiesis including a significant decrease in the number of erythrocytes,

platelet, and leukocyte in the peripheral blood[30,31]. As the prodrug of 5-FU, it is of high clinical relevance to show the safety of the medication of CAP. Overall, metronomic CAP is considered safe, with fewer side effects than traditional chemotherapy regimens. Metronomic CAP is well tolerated and safe in clinical practice, including for patients with HCC or patients after LT[8,32-34]. In mice, there was also no obvious myelosuppression in the MET group 7 d after taking CAP, though the related studies

Figure 8 Possible immunosuppressive mechanisms of metronomic capecitabine on T cells by ferroptosis induction. In the rat model of acute rejection after liver transplantation, metronomic capecitabine (CAP) exerts an immunosuppressive effect by decreasing T cell numbers in peripheral blood, liver graft, and spleen. Metronomic CAP increases the concentration of free ferrous ions by inducing ferritin degradation while inhibiting the expression of antioxidant proteins. Eventually, these effects lead to peroxidation damage and iron toxicity, which induce T cell death. 5-FU: 5-fluorouracil; Nrf2: Nuclear erythroid 2 p45-related factor 2; NCOA4: Nuclear receptor coactivator 4; HO-1: Heme oxygenase-1; GPX4: Glutathione peroxidase 4; GSH: Glutathione; GSSH: Oxidized glutathione; ROS: Reactive oxygen species.

showed that 5-FU could cause severe myelosuppression after 7 d of administration[35]. TP is a key enzyme in the metabolism of CAP[36]. The lack of TP in bone marrow may explain the lack of bone marrow suppression of CAP[11,13]. In a past study, we established the safety of CAP in CAP-fed mice, which did not cause significant myelosuppression after 21 d of administration[13]. However, the depletion of lymphocytes is not related to bone marrow suppression, and the high expression of TP in lymphocytes directly leads to the killing effect of CAP[11]. CAP is safe for long-term use because it can circumvent the inhibitory effect of 5-FU on bone marrow hematopoietic function.

When acute rejection occurs, immune cells mainly infiltrate the hilar region of the grafted liver, inducing pericentral inflammation, damaging the vascular and bile duct endothelium, damaging hepatocytes, and destroying the lobular structure[37,38]. CAP can preserve the function and structure of the transplanted liver by inhibiting acute rejection. Compared with the CON group, the Banff score was significantly lower in the MET group at 7 d after transplantation while the elevation of ALT and AST in

the MET group was significantly less pronounced than that in the CON group. ALT and AST are primarily expressed in liver cells, and liver allograft destruction caused by rejection is positively associated with ALT and AST expression[39,40]. However, TBIL and DBIL in both groups showed an increasing trend after surgery with no significant difference between the two groups. It may be related to biliary tract injury and bilirubin stasis caused by the lack of hepatic artery reconstruction and the use of cannula reconstruction of the bile duct in the traditional rat "two-cuff method" orthotopic LT[41].

Antigen presentation and T cell activation are key steps in rejection. Donor-derived antigen-presenting cells provide immune stimulation to recipient naive $CD4^+$ T cells, known as the direct antigen presentation pathway, which is the main mode of activation in acute rejection[42,43]. Once rejection is initiated, $CD8^+$ T cells mainly differentiate into cytotoxic T cells, which directly cause graft injury. $CD4^+$ T cells can differentiate into many subtypes, mainly helper T cells (Th1, Th2, and Th17) and regulatory T cells (Treg). In acute rejection, T cells differentiate mainly to Th1, driven by pro-inflammatory cytokines such as IL-12 and IFN-γ. Th1 cells secrete IL-2 and IFN-γ, providing a positive feedback loop to stimulate Th1 cells to proliferate further. IFN-γ is usually associated with proinflammatory and immune activation processes while IL-2 is necessary for survival and effects of activated T cells. T cell activation, proliferation, differentiation, and migration are the immune basis of acute rejection after organ transplantation, and are often used as the targets of clinical immunosuppression[42,44,45]. The results of our study showed that IL-2 and IFN-γ were decreased in CAP treated rats. The changes in cytokines suggest that in addition to decreasing the number of T cells, CAP may also target Th0 cells' differentiation. Since IFN-γ has a stimulatory effect on the secretion of TNF-α by M1 macrophages[46], the decrease in TNF-α may be related to the inhibition of IL-2 secretion in T cells by CAP. By inducing the programmed death of T cells, CAP mitigates transplant rejection and protects graft function. Moreover, cytokines associated with rejection were also affected by CAP treatment. Metronomic CAP significantly reduced the levels of pro-inflammatory cytokines (IFN-γ, TNF-α, IL-2, and IL-12p70), which are mainly secreted by immune cells and contributing to rejection[47-50].

The data from our study demonstrated that the selective cytotoxic effect of the T cells of metronomic CAP is crucial for the prevention of acute organ transplant rejection. Next, we further explored the mechanism underlying the immunosuppressive effect of metronomic CAP by studying $CD3^+$ T cells in more details. Mitochondria is a main source of ROS and mitochondria ROS is a critical component of T cell activation, proliferation, and effector function of T cells[51-53]. However, excessive ROS production, inducible by a high level of iron, leads to ROS-mediated membrane phospholipid peroxidation and T cell death upon activation[54]. Thus, we investigated the effect of CAP on the level of $CD3^+$ T cell ferrous ions with a ferrous probe and found that CAP treatment induced ferrous ion accumulation, accompanied by increased ROS and lipid ROS and decreased MMP. Mitochondrial ROS production and MMP reduction are two important parameters of mitochondrial damage, and lipid peroxidation following ROS generation plays an important role in ROS-induced cellular damage[55-57]. These results indicate that metronomic CAP increased ferrous ion accumulation and oxidative damage in the $CD3^+$ T cells of rats after transplantation, which may be the mechanism behind CAP-induced T cell reduction. Next, we used rat and human primary $CD3^+$ T cells to further explore the role of ferroptosis in CAP-induced immunosuppression *in vitro*. Free ferrous iron overload, lipid peroxide accumulation, and specific mitochondrial morphological changes are three key characteristics that distinguish ferroptosis from other programmed cell deaths[14]. In this study, typical mitochondrial changes were observed in T cells of the 5-FU group under transmission electron microscopy. Ferrous ion in rat primary $CD3^+$ T cells of the 5-FU group was increased with the downregulation of FTH1 and upregulation of NCOA4, revealing the occurrence of ferritinophagy. That is, the autophagic degradation of ferritin, contributed to rat T cell ferrous overload, excessive lipid peroxidation, and eventually ferroptosis in the 5-FU group. Nrf2 is a core player in the regulation of antioxidant molecules in cells, which can induce the synthesis of HO-1 and GPX4[20,58]. The Nrf2-HO-1/GPX4 antioxidative system, which participates in the regulation of oxidative damage and inhibits erastin-induced ferroptosis[59], was suppressed by 5-FU *in vitro*. It also reduced GSH levels, indicative of impairment of antioxidant capacity, and improved the levels of MDA, an end-product of lipid peroxidation.

In this study, we showed that metronomic CAP alleviated rat LT rejection without the common side effect (myelosuppression) of antitumor drugs. T cell ferroptosis plays an important role in the antirejection effect of CAP, which can induce cell iron overload and suppress the Nrf2-HO-1/GPX4 antioxidant systems, directly increasing the levels of intracellular ROS, leading to severe mitochondrial damage in T cells. These results revealed a new mechanism of CAP-induced T cell programmed death and suggested the possibility of using CAP as an immunosuppressant after transplantation. As a traditional antitumor drug, CAP has immunosuppressive effects, that may kill tumor cells and induce T cell death at the same time. CAP may have both antirejection and antitumor effects on patients with HCC after LT, thereby having broad clinical application prospects. In light of our findings, CAP alone as an immunosuppressive agent does not achieve satisfactory therapeutic effects. Therefore, the combination and interaction of CAP with other immunosuppressive agents is an important research direction in the future. In addition, we observed interesting effects of CAP on different cytokines, but further observations were lacking. The effects of CAP on T cell subsets and other immune cells are worth further attention. In the future, we plan to establish tumor-bearing animal models for allotransplantation, to clarify the dual antirejection and antitumor effects of CAP. In conclusion, the immunosup-

pressive effect of CAP should be further explored to optimize the drug treatment regimen for LT patients with liver cancer.

CONCLUSION

Metronomic CAP can alleviate liver graft injury and reduce the proliferation and infiltration of $CD3^+$ T cells in peripheral blood, graft, and spleen, thereby inhibiting acute rejection after LT. T cell ferroptosis plays an important role in the antirejection effect of CAP, which can induce cell iron overload and suppress the Nrf2-HO-1/GPX4 antioxidant systems, thereby directly increasing the levels of intracellular ROS and leading to severe oxidative damage in T cells.

ARTICLE HIGHLIGHTS

Research background

As a classical antimetabolite, capecitabine (CAP) has shown potential antirejection effects after liver transplantation (LT) in clinical trials. Our previous study showed that metronomic CAP can cause programmed T cell death in healthy mice by inducing oxidative stress, which is also the key step in ferroptosis. Thus, ferroptosis may play an important role in CAP-induced T cell death and an immunosuppressive role in acute rejection after transplantation.

Research motivation

This study investigated the immunosuppressive effect of metronomic CAP in rat LT and its mechanism, which may be used as an immunosuppressive agent after LT to improve the prognosis of liver transplant patients with hepatocellular carcinoma.

Research objectives

The objective of this study was to investigate the possibility of using CAP as an anti-rejection agent after transplantation. The results showed that metronomic CAP could exert an immunosuppressive effect by inducing T cell ferroptosis, which provided a basis for investigating CAP as part of an immunosuppressive regimen.

Research methods

A rat LT model of acute rejection was established, and the effect of metronomic CAP on splenic hematopoietic function and acute graft rejection was evaluated 7 d after transplantation. *In vitro*, primary $CD3^+$ T cells were sorted and co-cultured with or without 5-fluorouracil (5-FU) (active agent of CAP). The levels of ferroptosis-related proteins, ferrous ion concentration, and oxidative stress-related indicators were observed. The changes in mitochondrial structure were observed using electron microscopy.

Research results

With no significant myelotoxicity, metronomic CAP alleviated graft injury, prolonged the survival time of the recipient rats, and reduced the infiltration rate of $CD3^+$ T cells in peripheral blood, liver graft, and spleen, thereby inhibiting acute rejection after LT. In *vitro*, 5-FU, an end product of CAP metabolism, induced the degradation of the ferritin heavy chain by upregulating nuclear receptor coactivator 4, which caused the accumulation of ferrous ions. It also inhibited nuclear erythroid 2 p45-related factor 2, heme oxygenase-1, and glutathione peroxidase 4, eventually leading to oxidative damage and ferroptosis of T cells.

Research conclusions

Metronomic CAP can alleviate liver graft injury and reduce the proliferation and infiltration of $CD3^+$ T cells in peripheral blood, graft, and spleen by inducing T cell oxidative damage and ferroptosis, thereby inhibiting acute rejection after LT.

Research perspectives

The combination and interaction of CAP with other immunosuppressive agents is an important research direction in the future. In addition, the effects of CAP on T cell subsets and other immune cells are worth further attention. Besides, we plan to establish tumor-bearing animal models for allotransplantation, to clarify the dual antirejection and antitumor effects of CAP.

Abstract

BACKGROUND

The transforming growth factor β (TGFβ) signaling pathway plays a crucial role in the development of liver fibrosis by activating TGFβ type II receptor (TGFβR2), followed by the recruitment of TGFβR1 finally triggering downstream signaling pathway.

AIM

To find drugs targeting TGFβR2 that inhibit TGFβR1/TGFβR2 complex formation, theoretically inhibit TGFβ signaling pathway, and thereby ameliorate liver fibrosis.

METHODS

Food and Drug Administration-approved drugs were screened for binding affinity with TGFβR2 by virtual molecular docking. We identified 6 candidates and further explored their potential by Cell Counting Kit-8 (CCK-8) cell cytotoxic experiment to validate toxicity and titrated the best cellular working concentrations. Next, we further demonstrated the detailed molecular working

mechanisms using mutagenesis analysis. Finally, we used a mouse model to investigate its potential anti-liver fibrosis effect.

RESULTS

We identified 6 drug candidates. Among these 6 drugs, dihydroergotamine (DHE) shows great ability in reducing fibrotic gene expressions such as collagen, p-SMAD3, and α-SMA in TGFβ induced cellular model of liver fibrosis in LX-2 cells. Furthermore, we demonstrated that DHE binds to TGFβR2. Moreover, mutation of Leu27, Phe30, Thr51, Ser52, Ile53, and Glu55 of TGFβR2 disrupted the binding of TGFβR2 with DHE. In addition, DHE significantly improved liver fibrosis, as evidenced by Masson's trichrome staining of liver sections. This is further supported by the width and the velocity of the portal vein, and serum markers of liver function. In line with those observations, DHE also decreased macrophages infiltration and extracellular matrix deposition in the liver.

CONCLUSION

DHE alleviates liver fibrosis by binding to TGFβR2 thereby suppressing TGFβ signaling pathway. We show here that as far as drug repurposing, DHE has great potential to treat liver fibrosis.

Key Words: Liver fibrosis; Transforming growth factor β (TGFβ) signaling pathway; TGFβ type II receptor (TGFβR2); Virtual screening; Drug-repurposing; Dihydroergotamine

Core Tip: An effective and safe drug for treating liver fibrosis is urgently needed in current clinical practice. Here, we investigated and discovered that dihydroergotamine (DHE) could alleviate liver fibrosis by specific binding of transforming growth factor β type II receptor (TGFβR2) to disrupt the binding of TGFβR2 with TGFβ1, and ultimately suppressing its downstream TGFβ signaling pathway. DHE may be an effective anti-liver fibrosis drug, which could be employed in liver cirrhotic patients.

INTRODUCTION

Liver fibrosis is the consequence of various chronic pathogenic factors[1], it is a dynamic process that is characterized by an excessive accumulation of extracellular matrix[2]. Early liver fibrosis can be reversed to a normal architecture by removal of underlying causes[2], but liver fibrosis could further develop into cirrhosis without effective treatment[3]. Liver cirrhosis can be complicated by variceal bleeding, hepatic encephalopathy, ascites, bacterial peritonitis, and hepatocellular carcinoma, which has high mortality[4]. Liver cirrhosis can regress to early stage of disease, but it cannot be reversed to a normal liver[5]. Therefore, it is very important to control the disease progression in the early reversible stage of liver fibrosis.

Etiological treatment of liver fibrosis is most important and effective, such as antivirals, quitting alcohol consumption, and weight loss[1]. However, effects of etiological treatment are limited and insufficient, and difficult to prevent the development of liver fibrosis into cirrhosis. At present, liver transplantation is a radical cure for cirrhosis but is associated with a high cost, organ shortages, and the risk of immune rejection[6]. In addition, almost all current clinical trials targeting fibrosis are focused on non-alcoholic steatohepatitis, specifically focusing on hepatic stellate cell (HSC) activation and/or fibrogenesis[7]. However, there are still no approved antifibrotic therapies for liver fibrosis[7]. Therefore, it is urgent to develop new effective drugs.

Developing new drugs is a difficult, high-cost, and extremely low success rate procedure[8]. A good strategy to address this problem is to investigate new indications of old drugs, a process called "drug repurposing"[9]. Scientists have repurposed many old drugs such as propranolol[10], cimetidine[11], sildenafil[12], and thalidomide[13]. Thus, drug repurposing is an attractive approach and has been widely employed. Drugs that have been approved by Food and Drug Administration (FDA) have passed preliminary clinical trials and are considered extremely safe. Therefore, FDA-approved drugs may be good candidates for developing new indications. Molecular docking, a fast, efficient, and widely

used technique in drug repurposing, is a computational strategy to predict binding sites between ligands and targets based on their structures[9,14].

The activation of HSCs is considered the central effector of liver fibrosis[15]. There are many associated signaling molecules, including transforming growth factor β (TGFβ), platelet-derived growth factor, and connective tissue growth factor[16]. The TGFβ signaling pathway plays a crucial role in the development of liver fibrosis[17]. A review paper illustrated that TGFβ1 activates TGFβ type II receptor (TGFβR2), followed by the recruitment of TGFβR1. Afterward, TGFβR2 phosphorylates TGFβR1 thereby triggering down-stream signaling pathway to regulate the expression of collagens and extracellular matrix (ECM)[18]. Therefore, TGFβR2 is considered an important target for developing drugs against liver fibrosis. Consistently, our group and others demonstrated that both inhibiting the expression of TGFβR2 and exogenous extracellular domain of TGFβR2 supplement effectively alleviated liver fibrosis [19,20].

In the current study, FDA-approved drugs were screened for binding affinity with the TGFβR2 by virtual molecular docking. We used cellular and mouse models to investigate its potential anti-liver fibrosis effect. In addition, by using mutagenesis analysis we further demonstrated detailed molecular working mechanism.

MATERIALS AND METHODS

Molecular docking of FDA-approved drugs and TGFβR2

The structures of FDA-approved drugs were downloaded from the ZINC database (https://zinc12.docking.org/). Then, the files of each small molecular structures were generated using Open Babel GUI (3.1.1). The TGFβR2-TGFβ1 complex (PDB: 3KFD) was downloaded from the Protein Data Bank (https://www.rcsb.org/). The TGFβR2 structure was derived from the TGFβR2-TGFβ1 complex using AutoDock Vina software (https://vina.scripps.edu/). AutoDock Vina software was employed to screen for the lowest energy complex among complexes of the extracellular TGFβR2 domain and the FDA-approved drugs.

Cell culture and viability experiments

The human HSC line LX-2 was purchased from the BeNa Culture Collection (Beijing, China) and cultured in Dulbecco's modified Eagle medium (DMEM, Gibco, United States) with 10% fetal bovine serum (FBS, Gibco, United States) at 37 °C in a 5% CO_2 atmosphere. LX-2 was activated by human recombinant protein TGFβ1 (5 ng/mL) for 24 h, followed by drug treatment for 24 h. The expression of fibrosis-related genes was analyzed.

Cell Counting Kit-8 (CCK-8, Beyotime Biotechnology, Shanghai, China) test was used to test the cytotoxicity of a series of working concentrations of the candidate drugs on LX-2 cell. After 24 h of treatment, the CCK-8 solution was added to each well for an additional 1 h of incubation (37 °C in a 5% CO_2 atmosphere). A microplate analyzer was used to measure the optical density of each well at 450 nm. Cell vitality was expressed as a percentage of optical density between the treatment wells and the negative control cells.

Determination of Kd value between TGFβR2 and dihydroergotamine

The Kd value of the small molecules and the TGFβR2 protein was measured using a microscale thermophoresis (MST)-Nanotemper instrument (Nanotemper, Germany). Micro thermophoresis is the directional movement of particles in the micro temperature gradient. The affinity is determined by measuring the change of micro thermophoresis caused by the change of hydration layer (usually caused by the change of biomolecular structure/conformation). First, 100 μL each of 10 μM TGFβR2 and different concentrations of the small molecules (diluted from 400 μM stock) were prepared. Second, TGFβR2 was labeled with a fluorescent dye and mixed with the small molecules. Third, fluorescence was measured to assess the binding behavior of the small molecule-TGFβR2 complex.

Molecular dynamics simulation

Molecular dynamics simulations were performed using Gromacs 2020.1, in which a charm36-mar2019 force field was chosen. The TGFβR2 or TGFβR2-small molecule complex was solved with TIP3P water and immersed in a dodecahedron box extending to at least 1 nm of the solvent on all sides. The system was neutralized with Na^+ and Cl^- by adding 0.15 M NaCl. It was energy-minimized using the steepest descent algorithm for 5000 steps and creating a maximum force of < 1000 kJ/mol/nm. After energy minimization, the system was equilibrated with a constrained "number of particles, volume, and temperature" (NVT) and "number of particles, pressure, and temperature" (NPT) running for 100 ps. Through NVT and NPT equilibration, the system was well-equilibrated at 300 K and 1 bar. Finally, MD simulations of the TGFβR2 or complex were carried out for 200 ns; trajectories were saved every 10 ps for analysis. The Verlet cut-off scheme and a Leap-frog integrator with a step size of 2 fs were applied. The modified Berendsen thermostat was used for temperature coupling, the Parrinello-Rahman barostat was used for pressure coupling, and the Particle Mesh Ewald method was used to determine long-range

electrostatic interactions.

The root-mean-square displacement (RMSD) and root-mean-square fluctuation (RMSF) of TGFβR2 and the complex were calculated using GROMACS 2020.1. The content of the secondary structure was calculated using DSSP software. The last MD simulation frame of the complex was extracted using GROMACS 2020.1. LigPlot+ software (https://www.ebi.ac.uk/thornton-srv/software/LigPlus/) was used to analyze the detailed interactions between the extracellular TGFβR2 domain and small molecule. PyMOL (http://www.pymol.org/) was used to prepare the structural images.

Production and purification of site-directed mutagenesis of TGFβR2

The binding sites of TGFβR2 and small molecule were established using the molecular docking results. The amino acids at the binding sites were mutated to alanine whose nucleotide sequence was GCG. The sequences of mutated extracellular TGFβR2 and a 6X His-tag were inserted into a pMAL-c5x plasmid that was synthesized by GenScript Biotech Corporation.

The mutated plasmid was transformed into BL21 (DE3) bacteria and induced with 0.8 mmol/L IPTG for 16 h at 28 °C. Then, bacteria were collected and resuspended in phosphate buffered saline (PBS). The mutated TGFβR2 protein was purified by HisTrap FF affinity chromatography and eluted with PBS containing gradient concentrations of imidazole. Finally, the eluted proteins were concentrated and the imidazole was removed by dialysis.

CCl_4 injury mouse model

Six-week-old male C57BL/6N mice were purchased from Vital River Laboratory Animal Technology Co. Ltd. to induce a liver fibrosis model. The animal protocol was designed to minimize pain or discomfort to the animals. The animals were acclimatized to laboratory conditions (23 °C, 12 h/12 h light/dark, 50% humidity, ad libitum access to food and water) for 2 wk prior to experimentation. After being transferred to our institute, the animals were randomly and evenly divided into four groups (eight mice per group) according to their body weight: Corn oil, carbon tetrachloride (CCl_4), low-concentration treatment, and high-concentration treatment groups. The same volume of CCl_4 (0.5 μL/g of body weight, Sigma-Aldrich, St. Louis, MO, United States) and corn oil were intraperitoneally injected three times a week to induce a liver fibrosis model and in control animals for four weeks, respectively. Intragastric gavage administration was carried out with conscious animals, using straight gavage needles appropriate for the animal size. Then, the small molecule aqueous solution and water was administered orally once a day as treatment and control for eight weeks, respectively. All animals were euthanized for tissue collection. All animal studies were performed following the National Institutes of Health's Guide for the Care and Use of Laboratory Animals and conducted with the approval of the Institutional Animal Care and Use Committee of the Institute of Zoology, Chinese Academy of Sciences.

B-mode ultrasonography

Small-animal B-ultrasound was used to inspect the portal veins. A high-resolution ultrasound imaging system (Vevo LAZR, VisualSonics, Canada) was used to measure the width and velocity of the portal vein. Mice were fasted for 12 h and shaved before the ultrasonic examination. Then, the mice were fixed on the platform and examined after being anesthetized with Avertin. After coating the mouse's abdomen with the coupling gel, the probe was used to inspect the mouse's portal vein.

Masson's trichrome staining

Mouse liver tissues were fixed in 4% paraformaldehyde, embedded in paraffin, and sectioned at 5 μm thickness. Then, the liver paraffin-embedded tissue sections were stained with a Masson's trichrome kit (G1281, Solarbio, Beijing, China) and observed under a 10x objective lens. Masson's trichrome staining is used to distinguish collagen fibrosis from muscle fibers. Muscle fibers were stained red and collagen fibrosis was stained green or blue. The collagen area was quantified using ImageJ 1.52a software. And one liver section was taken from each mouse for analysis.

Western blot analysis

Total proteins were extracted from the LX-2 cells or liver tissues using radioimmunoprecipitation assay lysis buffer (50 mmol/L Tris-HCl, pH 7.4; 1% NP-40; 0.25% sodium deoxycholate; 150 mmol/L NaCl; and 1 mmol/L ethylene diamine tetraacetic acid (EDTA)) containing a protease and phosphatase inhibitor mixture (Roche Diagnostics). The proteins were separated on 10% sodium dodecyl sulfate (SDS) polyacrylamide gels and transferred onto polyvinylidene fluoride membranes (Millipore). After blocking with 5% skim milk in Tris-buffered saline-Tween 20 (0.02 M Tris base, 0.1% Tween 20, 0.14 M NaCl, pH 7.4) for 1 h, the membranes were incubated with primary antibodies overnight at 4 °C. The membranes were then incubated with horseradish-peroxidase (HRP)-conjugated secondary antibodies for 1 h at room temperature. Supplementary Table 1 lists the antibodies.

Real-time quantitative PCR (RT-PCR) analysis

Total RNA was extracted from the LX-2 cells or liver tissues using TRIzolTM Reagent (Thermo Fisher Scientific, United States) according to the manufacturer's instructions. Complementary DNA (cDNA)

was obtained from the reverse-transcribed RNA using a high-capacity cDNA reverse-transcription kit (Promega, United States). The relative expression of genes was analyzed by RT-PCR (Light Cycler 480, Roche, Sweden) with SYBR Green Master Mix (Promega, United States). Supplementary Table 2 lists the primer sequences.

Isolation of liver mononuclear cells and flow cytometry analysis

Liver mononuclear cells (MNCs), including Kupffer cells, were isolated from mouse liver tissues. Liver samples were collected from mice under deep anesthesia. The liver samples were cut into pieces, transferred into 5 mL of enzyme mix [RPMI 1640 containing 1 mg/mL collagen IV (Sigma) and 20 U/mL DNase I (Roche, Burgess Hill, United Kingdom)], and digested in a water bath at 37 °C for 30 min. RPMI 1640 containing 10% FBS was added to arrest the digestion. The digested mixture was filtered through a 70 μm strainer, centrifuged at 4 °C for 10 min at 1000 × g, and the pellet was washed in PBS twice. Liver immune cells were subsequently isolated using a 33% Percoll cell separation solution after centrifuging for 25 min at 2200 × g at room temperature. The red blood cells were removed using a red blood cell lysis buffer (YESEN, Shanghai, China). Finally, liver immune cells were counted and stained with anti-F4/80 antibody eFluor® 450 (eBioscience, San Diego, CA), brilliant violet 510™-conjugated anti-CD45 antibody (Biolegend, San Diego, CA), and percp-cyanine5.5-conjugated anti-CD11b antibody (eBioscience, San Diego, CA), which were then filtered into flow tubes through a 0.45 μm strainer. The result of flow cytometry was analyzed using a BD Fortessa instrument (BD, NY, United States).

Plasma biochemical markers

Mouse blood samples were collected from the tail vein, collected into EDTA-containing tubes, and gently shaken. Plasma was collected after centrifuging at 3000 × g for 15 min at 4 °C. Plasma alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels were measured using a biochemistry analyzer (Cobas c 501, Roche, Sweden).

Statistical analyses

Data are expressed as mean ± standard error of the mean. The statistical significance between groups was analyzed using one-way ANOVA test. Statistical significance was set at $P < 0.05$ and $P < 0.05$, $P < 0.01$, $P < 0.001$, and $P < 0.0001$ were denoted as a, b, c, and d, respectively. GraphPad Prism software was used to perform all statistical analyses.

RESULTS

The docking analysis of FDA-approved small molecule drugs and TGFβR2

AutoDock Vina software was employed to dock drugs with the extracellular domain of TGFβR2 and output the complex structures. The complex and the binding sites of TGFβR2 and TGFβ1 were shown (Figure 1A), and the structure of TGFβR2 was split from the complex (Figure 1B). The binding affinity of each FDA-approved drug was evaluated (Figure 1C). Among those, darifenacin, cyproheptadine, lifitegrast, difenoxin, phenytoin, dihydroergotamine (DHE), naldemedine, and irinotecan showed higher scores out of 1615 drugs (Figure 1C). Darifenacin is a competitive muscarinic M receptor antagonist used to treat urinary frequency, urgency, and incontinence caused by bladder hyperstimulation[21]. Cyproheptadine is an antihistamine used to treat allergies[22]. Lifitegrast is a small molecule integrin inhibitor primarily used to treat symptoms and signs of dry eye[23]. Difenoxin is a human metabolite of diphenoxylate, which is a derivative of pethidine and can be used to treat functional diarrhea and chronic enteritis[24]. Phenytoin is an effective voltage-gated Na^+ channel blocker used to treat epilepsy, neuralgia, and arrhythmia[25]. DHE is an adrenergic receptor antagonist used to treat severe orthostatic hypotension, migraine, and headache[26], which can bind with various receptors. DHE is also an agonist at 5-HT1B, 5-HT1D, and 5-HT1F receptors, but it also binds to 5-HT1A and 5-HT2A receptors. Naldemedine is an opioid receptor antagonist used to treat non-cancerous pain and opioid-induced constipation[27]. Irinotecan is a semi-synthesis of water-soluble camptothecin derivatives used to treat advanced colorectal cancer and postoperative adjuvant chemotherapy[28] (Table 1). All the above drugs were purchased from Selleck Chemicals, except for difenoxin and naldemedine which are banned from purchase as they are under management control. Therefore, we performed the following experiments using the rest 6 small molecule drugs.

Cytotoxicity of candidate drugs

To investigate the cytotoxicity of these drugs, LX-2 cells were treated with 20 μM of each candidate for 24 h. The results demonstrated that irinotecan and cyproheptadine were cytotoxic to LX-2 cells at this concentration (Figure 1D). Therefore, irinotecan and cyproheptadine were regarded as cytotoxic drugs and excluded from subsequent experiments. Next, to identify the best range of concentrations that would not influence the viability of these cells, LX-2 cells were treated with different concentrations of the remaining drugs for 24 h. The results demonstrated that neither lifitegrast nor phenytoin was

Table 1 The drugs with the highest affinity of transforming growth factor β type II receptor

Name	ZINC_ID	Affinity (kcal/mol)	Indications
Darifenacin	ZINC000001996117	-7.6	Urinary frequency, urgency, and incontinence caused by bladder hyperstimulation
Cyproheptadine	ZINC000000968264	-7.4	Allergy
Lifitegrast	ZINC000084668739	-7.4	Symptoms and signs of dry eye
Difenoxin	ZINC000000601317	-7.3	Functional diarrhea and chronic enteritis
Phenytoin	ZINC000002510358	-7.3	Epilepsy, neuralgia, and arrhythmia
DHE	ZINC000003978005	-7.3	Severe orthostatic hypotension, migraine, and headache
Naldemedine	ZINC000100378061	-7.3	Non-cancerous pain and opioid induced constipation
Irinotecan	ZINC000001612996	-7.3	Advanced colorectal cancer and postoperative adjuvant chemotherapy

DHE: Dihydroergotamine.

cytotoxic to LX-2 cells when concentrations were up to 100 μM and 150 μM, respectively (Figure 1E and F). Darifenacin and DHE were cytotoxic to LX-2 cells when concentrations were beyond 50 μM and 20 μM, respectively (Figure 1G and H). Therefore, to avoid interference on fibrosis-related gene expression due to the cytotoxicity of candidate drugs, lifitegrast and phenytoin concentrations below 100 μM and darifenacin and DHE concentrations below 20 μM were used to treat LX-2 cells.

Anti-fibrotic effect of candidate drugs in cellular model

Increased expression of collagen and alpha-smooth muscle actin (α-SMA) are principal markers of HSC activation[29]. LX-2 cells were treated with different concentrations of drugs for 24 h after TGFβ1 stimulation. The results demonstrated that lifitegrast and phenytoin did not decrease the protein levels of collagen III and α-SMA after TGFβ1 stimulation (Figure 2A and B). Moreover, darifenacin did not decrease the protein levels of collagen III, p-SMAD3, and α-SMA as much as DHE (Figure 2C and D). Consistently, DHE significantly decreased the mRNA expression of collagen I alpha 1 (COL1A1), collagen I alpha 2 (COL1A2), collagen III alpha 1 (COL3A1), and α-SMA compared with darifenacin (Figure 2E and F). Taken together, DHE (PubChem CID: 10531) was the most effective small molecule drug that suppressed the TGFβ1 induced LX-2 activation.

The binding affinity of DHE to TGFβR2

We further verified the molecular docking result by MST-Nanotemper. The results demonstrated that the fluorescence intensity of TGFβR2 changed gradually in proportion to the DHE concentration (Figure 3A). The affinity is determined by measuring the change of micro thermophoresis caused by the change of hydration layer, and results showed the binding affinity of DHE to TGFβR2 with a Kd value of 17.64 μM.

Molecular dynamics simulation of DHE and TGFβR2

To identify the specific binding mode of DHE and TGFβR2, we used the complex structure obtained from AutoDock vina to perform the molecular dynamics simulation with GROMACS 2020.1 software for 200 ns. The results demonstrated that the RMSD of the backbone atoms of TGFβR2 and TGFβ R2□DHE in the simulation system reached equilibrium after 100 ns (Figure 3B). The RMSFs of the TGFβ R2 skeleton carbon atoms in the two simulated systems were almost identical (Figure 3C). The secondary structural elements of TGFβR2 in the complex simulation were only slightly changed (Figure 3D and Table 2). The coil and 3-helix components of TGFβR2 decreased in the complex simulation system (Table 2). Finally, we extracted the simulated complex structure and analyzed the amino acid sites of TGFβR2 bound to DHE by Ligplot+ software (Figure 3E and F). In conclusion, our molecular dynamics simulations showed that the binding of DHE to TGFβR2 has little effect on the structure of TGFβR2. We also obtained the binding sites of TGFβR2 to DHE by stimulations.

Leu27, Phe30, Thr51, Ser52, Ile53, and Glu55 of TGFβR2 bind with DHE

Molecule docking demonstrated that Leu27, Phe30, Thr51, Ser52, Ile53, and Glu55 of TGFβR2 were binding sites for DHE (Figure 3F). To verify these binding sites, we mutated the above-mentioned amino acids to alanine. The DNA sequences of mutated extracellular TGFβR2 were synthesized (Table 3) and the binding affinity was measured. The results demonstrated that the mutated TGFβR2 no longer bound to DHE (Figure 3G). Thus, the above-mentioned binding sites of TGFβR2 predicted by molecule docking were the exact binding sites of TGFβR2 and DHE, and this further verified the binding of TGFβR2 and DHE. Therefore, we inferred that the binding of TGFβ1 and TGFβR2 was

Table 2 Content of secondary structural analysis from DSSP method

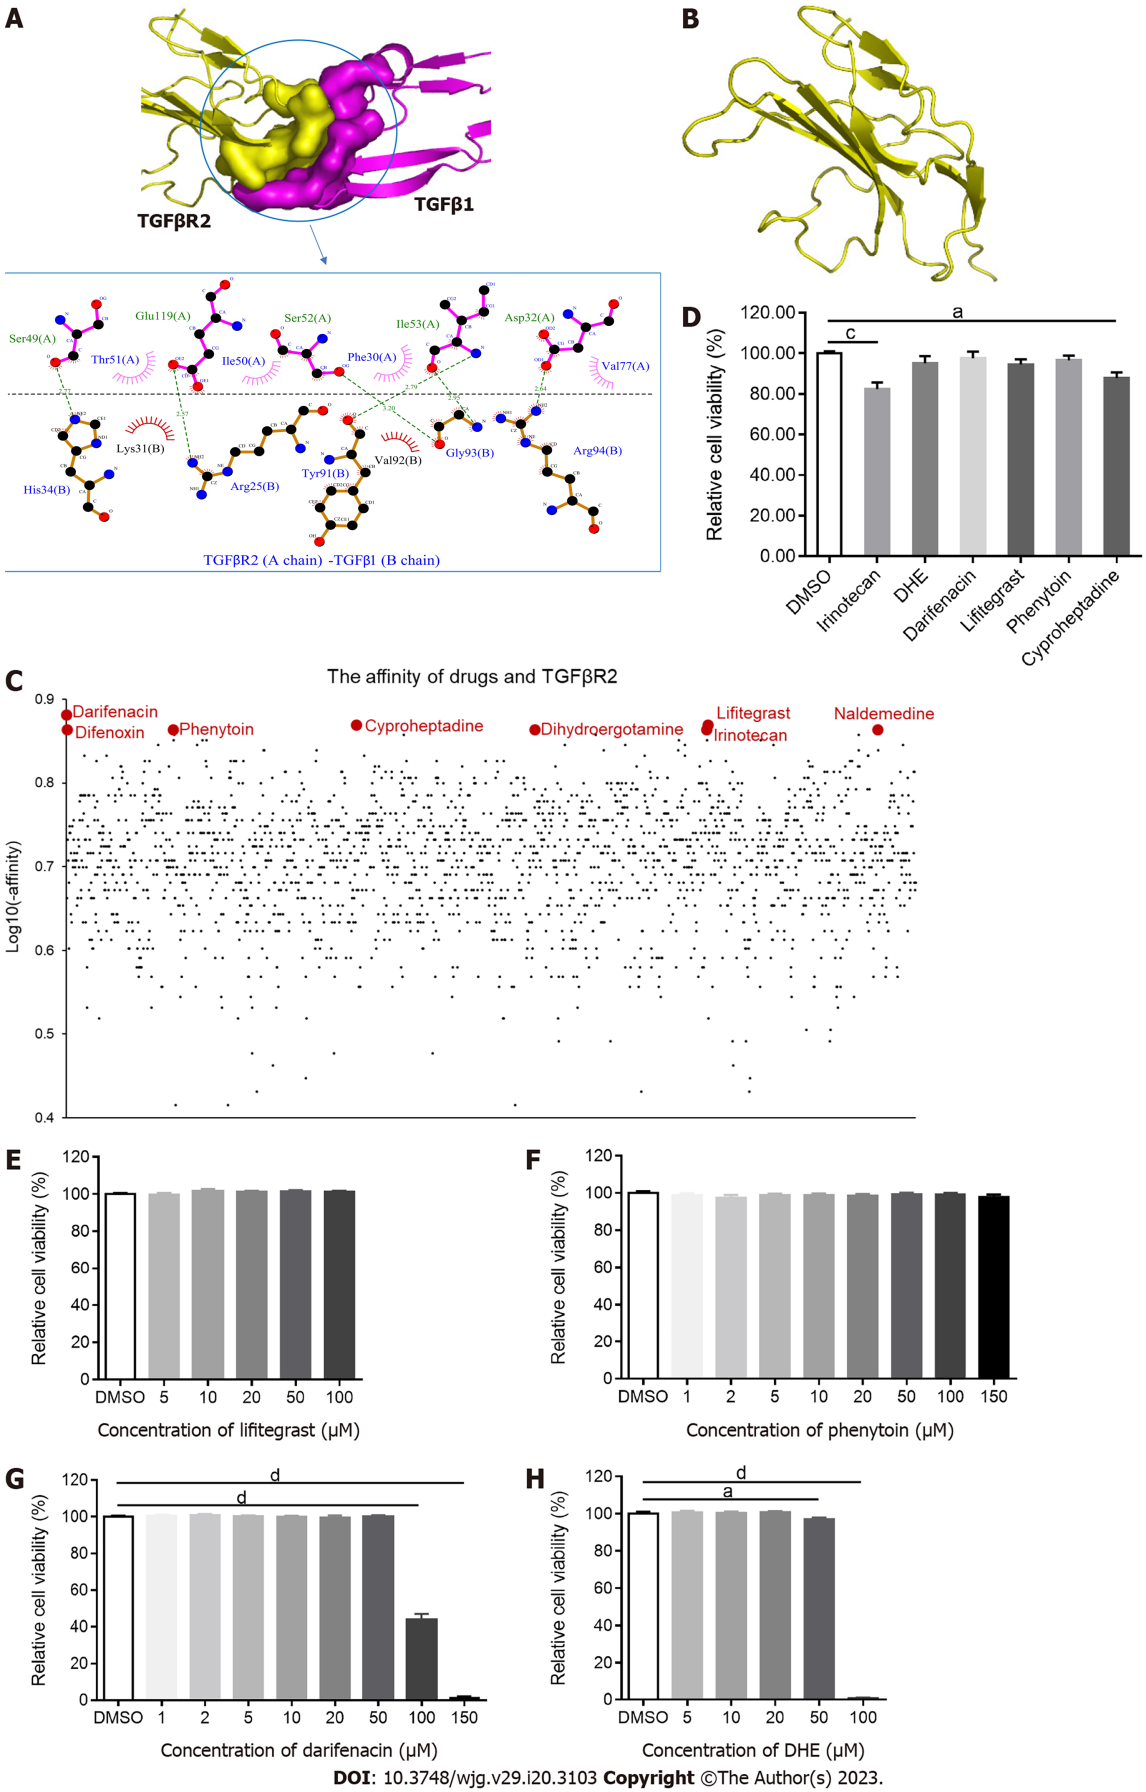
blocked by the binding of DHE and TGFβR2, further preventing the TGFβ signaling cascade.

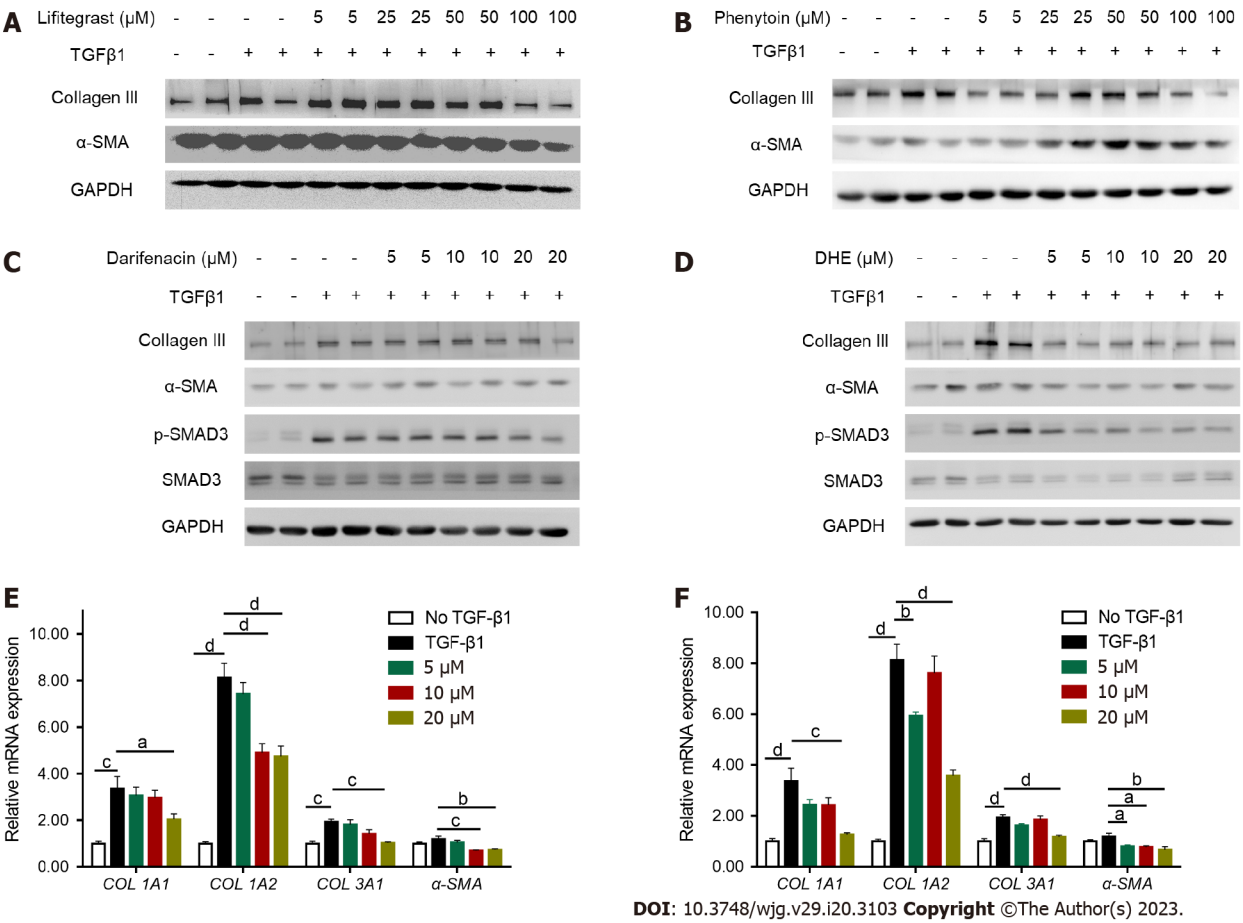


DHE alleviated liver fibrosis in mouse

To explore whether DHE could alleviate fibrosis in vivo, we used two different concentrations of DHE to treat a CCl_4-induced mouse fibrosis model. Six-week-old C57BL/6N mice were intraperitoneally injected three-time per week with CCl_4 and corn oil (control group) during the whole experimental periods (Supplementary Figure 1). After four weeks, the mice intraperitoneally injected with CCl_4 were randomly divided into three groups: CCl_4 and the 2 and 5 mg/kg DHE treatment groups. The aqueous solution of DHE was orally gavaged to the mice in the treatment groups. For vehicle treatment, water was provided by oral gavage to the mice in the corn oil and CCl_4 group (disease group).

It is well known that more serious the degree of liver fibrosis, the wider the portal vein and the slower its velocity. The results demonstrated that the portal vein in the CCl_4 group was significantly wider than that in the corn oil group. Interestingly, the width of the portal vein in the 2 mg/kg DHE treatment group was significantly decreased (Figure 4A). Furthermore, the velocity of the portal vein in the treatment groups was also improved (Figure 4B). After eight weeks of treatment, there were no significant differences in body weight, liver weight, spleen weight, or the ratio of liver weight to body weight among the four groups (Figure 4C and Supplementary Figure 2A). Gross liver specimens of the CCl_4 group were paler and had a rough appearance. However, it was back to normal appearance by DHE treatment compared to the CCl_4 group (Figure 4D). The level of plasma ALT of the CCl_4 group mice was significantly higher than corn oil group. Whereas, DHE treatment significantly decreased the level of ALT compared with CCl_4 group mice. In addition, the level of plasma AST was significantly decreased after 2 mg/kg DHE treatment (Figure 4E). Collagen area were visualized by Masson's trichrome and quantified by using ImageJ 1.52a software. DHE treatment in both dosages significantly reduced collagen accumulation compared with those of the CCl_4 group (Figure 4F and G). Taken together, these results demonstrated that DHE significantly protected from liver fibrosis in CCl_4-induced mouse fibrosis model.

DHE decreased the liver macrophages infiltration and ECM deposition



The infiltration of macrophages reflects the severity of liver inflammation. To investigate the degree of macrophages infiltration, the liver immune cells were extracted and labeled with $CD45^+$, $F4/80^+$, and $CD11b^+$ antibodies followed by flow-cytometric analysis. The results demonstrated that the DHE treatment at both dosages significantly reduced proportion of $CD11b^+$ cells (Figure 5A and B, and Supplementary Figure 2B-F). Consistent with the result of flow cytometry, the mRNA levels of tumor necrosis factor alpha (TNFα) and F4/80 which are two important indicators of liver inflammation significantly decreased upon DHE treatment (Figure 5C). On the other hand, the accumulation of ECM is another important sign of liver fibrosis. The results demonstrated that the mRNA levels of COL1A1, COL1A2, and α-SMA significantly decreased in the DHE treatment group more than those of the CCl_4 group (Figure 5D). The mRNA levels of COL3A1 also decreased in the DHE treatment groups

Figure 2 Treatment inhibiting the activation of LX-2 cells. A and B: After LX-2 cell was activated with transforming growth factor β 1 (TGFβ1) (5 ng/mL) for 24 h, different concentrations of lifitegrast and phenytoin were added for 24 h, and the protein levels of collagen III and α-SMA were detected by western blot; C and D: After LX-2 was activated with TGFβ1 (5 ng/mL) for 24 h, different concentrations of darifenacin and dihydroergotamine (DHE) were added for further treatment for 24 h, and the protein levels of collagen III, α-SMA, and p-SMAD3 were detected by western blot; E: Real-time polymerase chain reaction (RT-PCR) was performed to detect the expression of COL1A1, COL1A2, COL3A1, and α-SMA of LX-2 after different concentrations of darifenacin treatment (n = 6); F: RT-PCR was performed to detect the expression of COL1A1, COL1A2, COL3A1, and α-SMA of LX-2 after different concentrations of DHE treatment (n = 5-6). All data are presented as means ± standard error of the mean. One-way ANOVA test was performed. [a]P < 0.05, [b]P < 0.01, [c]P < 0.001, and [d]P < 0.0001. TGFβ: Transforming growth factor β; TGFβR: Transforming growth factor β receptor; DHE: Dihydroergotamine.

(Figure 5D). Meanwhile, the protein levels of α-SMA and p-SMAD3 were significantly decreased in the DHE treatment group compared to those of the CCl_4 group (Figure 5E and F). Thus, we demonstrated here that, DHE significantly decreased the liver macrophages infiltration and ECM deposition.

DISCUSSION

TGFβ1 is regarded as the most potent fibrogenic cytokine, which activates TGFβR2, followed by the recruitment of TGFβR1, therefore triggers HSC activation[30]. In the current study, we aimed to screen drugs targeting TGFβR2 and further blocking TGFβ down-stream signaling pathway from FDA-approved small molecule library. Among these 6 candidate drugs, DHE significantly decreased the protein and mRNA expression of fibrotic-related genes in LX-2 cells. The results of the affinity experiment demonstrated that DHE binds with TGFβR2 at Leu27, Phe30, Thr51, Ser52, Ile53, and Glu55. DHE also significantly alleviated liver fibrosis by decreasing macrophages infiltration and ECM accumulation in CCl_4-induced mouse fibrosis model. Thus, we demonstrate here for the first time that

dopamine, and serotonin[26]. It can modulate noradrenergic, serotonergic, and dopaminergic neurotransmission[34]. DHE is an adrenergic receptor antagonist used to treat severe orthostatic hypotension, migraine, and headache[26], which can bind with various receptors. DHE is also an

agonist of 5-HT1B, 5-HT1D, and 5-HT1F receptors, but it also binds to 5-HT1A and 5-HT2A receptors [26]. In the current study, surprisingly, we found that DHE also bind with TGFβR2 at reasonable affinity. Furthermore, we also identified specific binding sites by mutagenesis analysis. These results imply that DHE not only specifically targets 5-HT, but also TGFβR2. It further highlights wide-spread function of DHE in physiology/pathophysiology.

Continuous local and systemic inflammation aggravates liver injury, which is a critical factor in liver fibrosis. The innate immune system plays a pivotal role from the onset to the end stage of chronic liver disease[35]. Hepatic macrophages are considered as the first line of defense against pathogens, are a key cellular determinant in the process of fibrosis[36]. Bone marrow monocyte-derived macrophages and Kupffer cells are two distinct subsets of macrophages in the liver, which have been identified as key regulators of liver inflammation and key to the progression or regression of liver fibrosis. Kupffer cells, which are resident macrophages in liver tissue, exert anti-inflammatory effects[37]. Activated macrophages produce large amounts of TGFβ, which activates HSC into myofibroblast-like cells and synthesizes ECM[38]. This inflammatory response is also evident in the CCl_4-induced mouse model, especially in the increased number of macrophages in liver. Consistent with previous results, we also found that the macrophages infiltration was significantly increased after CCl_4 treatment. We speculate that, upon binding to TGFβR2, DHE prevents recruitment of TGFβR1 to TGFβR2, thereby inhibiting TGF β down-stream signaling pathway. Consistently, F4/80 and TNFα mRNA expression also significantly decreased upon DHE treatment. Taken together, DHE might reduce macrophages infiltration and finally prevent liver inflammation.

Activated HSCs secreting ECM represent a critical event in development of liver fibrosis[37]. In the fibrotic liver, type I and III collagens are deposited instead of laminins, type IV collagen, and proteoglycans in the normal liver[17]. Various mechanisms of HSC activation have been postulated, including TGFβ/SMAD pathway, Notch, Wnt/β-catenin, Hedgehog, and Hippo signaling[16]. In the current study, we revealed that DHE significantly reduced TGFβ induced HSCs activation in LX-2 cellular model through specific blocking of TGFβ signaling pathway. It explained clearly the significant reduction of ECM by DHE treatment. Taken together, our data show that DHE alleviated liver fibrosis by binding to TGFβR2, preventing the binding of TGFβ1 and TGFβR2, and blocking TGFβ1 signaling to reduce liver inflammation.

CONCLUSION

Our study demonstrated that DHE alleviated liver fibrosis while decreasing inflammation-related gene expression and HSC activation. The mechanism of its action is likely to be associated with decreased macrophages infiltration and ECM accumulation. Considering that liver fibrosis can be reversed, DHE might open-up new avenue to treat liver fibrosis in the future.

ARTICLE HIGHLIGHTS

Research background

The transforming growth factor β (TGFβ) signaling pathway plays a crucial role in the development of liver fibrosis by activating TGFβ type II receptor (TGFβR2), followed by the recruitment of TGFβR1 finally triggering downstream signaling pathway.

Research motivation

TGFβR2 is considered an important target for developing drugs against liver fibrosis. Previous studies demonstrated that both inhibiting the expression of TGFβR2 and exogenous extracellular domain of TGFβR2 supplement effectively alleviated liver fibrosis.

Research objectives

To find drugs targeting TGFβR2 that inhibit TGFβR1/TGFβR2 complex formation, theoretically inhibit its downstream TGFβ signaling pathway, and thereby ameliorate liver fibrosis, we screened drugs approved by the Food and Drug Administration (FDA) to identify potential TGFβR2 blockers.

Research methods

FDA-approved drugs were screened for binding affinity with TGFβR2 by virtual molecular docking. We identified 6 candidates and further explored their potential by Cell Counting Kit-8 cell cytotoxic experiment to validate toxicity and titrated the best cellular working concentrations. Next, we further demonstrated the detailed molecular working mechanisms using mutagenesis analysis. Finally, we used a mouse model to investigate its potential anti-liver fibrosis effect.

Research results

Dihydroergotamine (DHE) shows great ability in reducing fibrotic gene expressions such as collagen, p-SMAD3, and α-SMA in TGFβ induced cellular model of liver fibrosis in LX-2 cells. Furthermore, we demonstrated that DHE binds to TGFβR2 with a Kd value of 17.64 μM. In addition, DHE significantly improved liver fibrosis, as evidenced by Masson's trichrome staining of liver sections, the width and the velocity of the portal vein, and serum markers of liver function. In line with those observations, DHE also decreased macrophages infiltration and extracellular matrix deposition in the liver.

Research conclusions

DHE could alleviate liver fibrosis by binding to TGFβR2 thereby suppressing its downstream TGFβ signaling pathway. We show here that as far as drug repurposing, DHE has great potential to treat liver fibrosis.

Research perspectives

Considering that liver fibrosis can be reversed, DHE might open-up new avenue to treat liver fibrosis in the future.

Abstract

BACKGROUND

Pancreatic mucinous cystic neoplasms (MCNs) represent one of the precursor lesions of pancreatic ductal adenocarcinoma, and their detection has been facilitated by advances in preoperative imaging. Due primarily to the rarity of MCNs, however, there is limited knowledge regarding the prognostic variables and high-risk factors for malignant transformation. A more comprehensive and nuanced approach is necessary to fill this gap and provide a basis for improved treatment decisions and patient outcomes.

AIM

To investigate the high-risk factors associated with malignant MCNs and to explore the prognostic factors of MCN with associated invasive carcinoma (MCN-AIC).

METHODS

All cases of resected MCNs from a single high-volume institution between January 2012 and January 2022 were retrospectively reviewed. Only cases with ovarian-type stroma verified by progesterone receptor staining were included. Preoperative features, histological findings and postoperative course were documented. Multivariate logistic regression was employed to investigate variables related to malignancy. Survival analysis was performed using the

Kaplan-Meier curve, and the prognostic factors were assessed to evaluate the postoperative course of patients with MCN-AIC.

RESULTS

Among the 48 patients, 36 had benign MCNs, and 12 had malignant MCNs (1 high-grade atypical hyperplasia and 11 MCN-AIC). Age, tumour size, presence of solid components or mural nodules and pancreatic duct dilatation were identified as independent risk factors associated with malignancy. The follow-up period ranged from 12 mo to 120 mo, with a median overall survival of 58.2 mo. Only three patients with MCN-AIC died, and the 5-year survival rate was 70.1%. All 11 cases of MCN-AIC were stage I, and extracapsular invasion was identified as a prognostic factor for poorer outcomes.

CONCLUSION

The risk factors independently associated with malignant transformation of MCNs included age, tumour size, presence of solid components or mural nodules, and pancreatic duct dilatation. Our study also revealed that encapsulated invasion was a favourable prognostic factor in MCN-AIC patients.

Key Words: Mucinous cystic neoplasms; Pancreatic adenocarcinoma; Invasive carcinoma; Risk of malignancy; Prognostic factor; Retrospective study

Core Tip: Pancreatic mucinous cystic neoplasms (MCNs) are a rare tumour with a low incidence and one of the precursor lesions of pancreatic ductal adenocarcinoma. The detection of MCN has been increasing by advances in imaging technology. MCNs associated risk factors, clinicopathological manifestations, and prognosis must be explored to improve our understanding of this rare tumour type and optimize clinical treatment.

INTRODUCTION

Pancreatic mucinous cystic neoplasm (MCN) is a rare sporadic tumour with a low incidence, accounting for 10%-45% of all resected primary pancreatic cystic neoplasms and 2.5% of exocrine pancreatic tumours[1,2]. With the increasing popularity of imaging evaluation and advances in radiological technology, the rate of MCN identification is on the rise. Pancreatic ductal adenocarcinoma (PDAC) is the leading cause of cancer-related death globally, and its incidence has been consistently increasing[3]. However, the majority of PDAC cases are detected at an advanced stage, highlighting the importance of early diagnosis and treatment of associated precancerous lesions to improve survival rates. MCN is a precancerous lesion of PDAC and evolves from benign adenoma to invasive carcinoma similarly to intraductal papillary mucinous neoplasm (IPMN) and pancreatic intraepithelial neoplasia (Pan IN)[4].

However, MCNs have not been studied in sufficient detail or breadth owing to their infrequency. The risk factors associated with malignancy have not been well characterized, and physicians have not been unanimous in adopting an optimal management profile. Discrepancies in recommendations offered by several medical associations may contribute to further challenges in managing the disease. Moreover, despite PDAC being the most common histopathological type of invasive MCN, notable differences exist in prognosis. However, the precise prognostic determinants of MCNs have yet to be fully elucidated.

Therefore, we conducted a retrospective study of the clinicopathological, radiological and survival data of a sizable cohort of patients. The findings of this study were intended to help identify key risk factors of malignant transformation in MCNs as well as the prognostic determinants of MCN with associated invasive carcinoma (MCN-AIC). The insights gained from this study may be used to inform the development of more effective management strategies for patients with MCNs, ultimately improving their clinical outcomes.

MATERIALS AND METHODS

Patient identification and ethics statement

All cases of MCN identified at the Department of Pathology of the First Affiliated Hospital of Bengbu Medical College from January 2012 to January 2022 were retrospectively retrieved. A total of 48 patients who fit the diagnostic criteria were included in the study. This study was approved by the Ethics Committee of the First Affiliated Hospital of Bengbu Medical College. Written informed consent was obtained from all patients for the use of their clinical data.

Inclusion and exclusion criteria

The inclusion criteria were patients who had been confirmed by surgical pathology to have MCN, underwent imaging examinations, and did not receive preoperative radiotherapy or chemotherapy. The exclusion criteria included poor-quality radiographic images, insufficient pathological diagnostic data, the presence of other pancreatic diseases, and a history of other malignant tumours. These criteria were carefully selected to ensure the accuracy and reliability of the study's findings.

Methods

All patients underwent preoperative imaging examinations, and the imaging data were uploaded to the Picture Archiving and Communication System. After reviewing and interpreting the data, two radiologists evaluated the radiographic tumour size, location, calcification, separation, solid composition or mural nodule status and duct dilatation of the lesion. Clinical information, including patient age and sex, symptoms, and serum tumour marker levels, was obtained through the analysis of medical records. The tumour tissues were paraffin-embedded and stained with haematoxylin-eosin staining (H&E) after being fixed in 10% neutral formaldehyde. MCN is classified by the World Health Organization (2019) as either atypical hyperplasia or MCN-AIC[5]. Low-grade atypical hyperplasia (LGD) and high-grade atypical hyperplasia (HGD, carcinoma in situ) have replaced the former three-tiered classification of atypical hyperplasia in MCN. All slides were reassessed by two senior pathologists who were uninformed of the patients' clinical diagnoses. All tissues were analysed immunohistochemically using the EnVision technique, and the progesterone receptor (PR) primary antibody was purchased from Fuzhou Maixin Biotechnology Co., Ltd., China. Expression of PR was restricted to the subepithelial ovarian-type stroma.

Patient outcomes

From the date of diagnosis to January 31, 2022, 48 patients were followed up by reviewing their medical records, interviewing them *via* phone, or sending emails to acquire follow-up data, including postoperative recurrence, overall survival (OS), and therapy. OS was measured from the date of surgery until the date of death or the end of follow-up.

Statistical analysis

The data were analyzed statistically using IBM SPSS Statistics (version 25.0) and R (version 4.0.0). The χ^2 test or Fisher's exact test was used to compare categorical data. The preoperative risk variables associated with malignant MCNs were evaluated using a multivariate binary logistic regression model. The cumulative survival rate was calculated using the Kaplan-Meier method, and the log rank test was performed to analyse the association between clinicopathological data and survival rate. $P < 0.05$ was regarded as indicating statistical significance.

RESULTS

Clinicopathological and radiological information of patients

A total of 48 patients diagnosed with MCN were included in accordance with strict inclusion and exclusion criteria. MCNs accounted for 2.8% (48/1685) of all pancreatic lesions resected over the same period. The median age of the patients was 47.2 years ± 13.1 years (range, 27-72 years), and 16 patients (33.3%) were more than 50 years old. There were 34 females and 14 males, with a female-to-male ratio of 2.2:1.0. Approximately 41.7% of patients were asymptomatic, including 18 patients whose disease was detected incidentally by imaging evaluation and 2 patients whose disease was identified by elevated preoperative carbohydrate antigen 19-9 (CA19-9) serology. The remaining 28 patients presented with nonspecific clinical symptoms, such as stomach pain, abdominal distension, abdominal discomfort, and jaundice. Serologic CA19-9 Levels were elevated in 16 patients (33.3%).

Imaging revealed oval-shaped, lobulated hypodense masses that were well circumscribed, separated linearly, and surrounded by egg-shell-like foci of calcification. The contents of the cyst were also visible. The average radiological diameter of the tumour was 5.8 cm ± 3.7 cm (1.2-14.5 cm), and in 23 patients (47.9%), the tumour measured more than 4 cm. Thirty-five patients (72.9%) had tumours that were located in the distal pancreas. Solid components or mural nodules were identified in 14 patients (29.2%),

septations in 21 (43.85%), calcification in 13 (27.1%) and duct dilatation in 18 (37.5%) (Figure 1). Detailed data on the imaging findings and clinicopathological information of MCN patients are shown in Table 1.

MCN was correctly diagnosed using preoperative imaging in 35 patients (72.9%). The most common misdiagnoses involved other subtypes of pancreatic cystic lesions (PCLs) and the use of imprecise terms such as pancreatic cystic or solid masses. The preoperative imaging modalities employed in this study comprised computed tomography (CT), magnetic resonance imaging (MRI), and endoscopic ultrasound (EUS). Of the 48 patients, all underwent CT, 33 underwent MRI, and 21 underwent EUS. The corresponding detection accuracy rates were 64.6%, 87.9%, and 71.4%, respectively. Nevertheless, there was no significant difference in diagnostic accuracy among the three methods ($P = 0.64$).

Microscopic and immunohistochemical features

Postoperative pathological diagnosis revealed 36 cases of LGD, 1 case of HGD, and 11 cases of MCN-AIC (the histological type of the invasive component was PDAC in all cases). All cases were solitary without multiple foci. The morphology of the cysts generally manifested as unilocular or multilocular with septa, and the fluid aspirated from the cystic cavity was frequently viscous.

Microscopically, the cyst walls were found to be coated with mucinous columnar epithelium (Figure 2A and B). Subepithelial tissue in the MCN consisted of ovarian-type stroma (OTS) characterized by dense spindle cells expressing PR and possessing round or elongated nuclei with scant cytoplasm. Positive PR staining was observed in all tumours (Figure 2D). The mucin-producing columnar epithelial cells exhibited varying degrees of dysplasia. In cases of LGD, mild to moderate structural and cellular atypia was observed with occasional micropapillae (Figure 2A and B). HGD showed obvious atypia of both structures and cells, including multilayered cell arrangement, nuclear enlargement, loss of alignment polarity, and emergence of aberrant mitotic figures. In cases of MCN-AIC, interstitial infiltration was noted in comparison to HGD, with invasive components growing interspersed in the stroma (Figure 2C). Solid components, mural nodules, or nipple protrusion were also occasionally visible. Notably, 5 cases of MCN-AIC showed atypical hyperplasia adjacent to invasive components.

Risk factors for malignant MCNs and the prediction probability

Based on malignant biological behaviours, LGD was defined as benign MCN in 36 cases (75%), while HGD and MCN-AIC were classified as malignant MCN in 12 cases (25%). Univariate analysis revealed that age ≥ 50 years [8 (66.7%) *vs* 8 (22.2%), $P = 0.013$], tumour size ≥ 4 cm [10 (83.3%) *vs* 13 (36.1%), $P = 0.010$], pancreatic duct dilatation [8 (66.7%) *vs* 10 (27.8%), $P = 0.039$], and presence of a solid component or mural nodule [8 (66.7%) *vs* 10 (27.8%), $P = 0.039$] were associated with malignant MCN. However, sex, clinical symptoms, serum CA19-9 Level, tumour location, septations and calcification did not correlate with malignancy ($P < 0.05$) (Table 1).

Further multivariate analysis demonstrated that all four statistically significant indicators were independent risk factors for the preoperative diagnosis of malignant MCNs ($P < 0.05$) (Figure 3). The prediction probability of each indicator for malignancy risk in a cohort of patients was then explored. The results of the analysis showed that age, tumour size, duct dilatation, and solid component/mural nodule all had good performance in predicting malignancy risk, as evidenced by the area under the curve (AUC) values of 0.722 (95%CI: 0.546-0.898, $P = 0.220$), 0.736 (95%CI: 0.578-0.894, $P = 0.015$), 0.694 (95%CI: 0.517-0.872, $P = 0.046$), and 0.694 (95%CI: 0.517-0.872, $P = 0.046$), respectively. Furthermore, when the four indicators were combined into a total predictor, the AUC value increased to 0.903 (95%CI: 0.814-0.992, $P < 0.010$), improving the accuracy of the prediction model.

Survival analysis and prognostic variables of MCN-AIC

The follow-up period ranged from 12 mo to 120 mo with a mean of 58.2 mo ± 32.7 mo. Of the 36 patients with benign MCNs, 6 were lost to follow-up, and 1 died of an abrupt cerebral infarction. The remaining 29 patients had an excellent prognosis; their 5-year disease-specific survival rate was 100%. Of the 12 patients with malignant MCNs, 3 died at 8, 14, and 46 mo after surgery; the 5-year disease-specific survival rate was 70.1%. All deaths occurred in MCN-AIC patients.

Consequently, the clinicopathological characteristics of the 11 MCN-AIC patients were further explored (Table 2). The tumours examined in this study did not display any signs of lymph node involvement, distant metastasis, or nerve invasion. In addition, all the tumours were successfully resected, and the margins were negative. Based on the AJCC cancer staging system[6], all 11 cases of MAC-AIC were categorized as stage I, with 7 patients having stage IA cancers and 4 having stage IB cancers, depending on the tumour size. The encapsulated invasion of MCN-AIC was defined as infiltrating components not exceeding the outermost layer of the capsule, with or without infiltration into the subepithelial stroma or cystic septa[7]. Using this definition, 9 tumours were encapsulated, while 3 were extracapsular (Cases 1-3). In Case 1 and Case 2, the cancerous tissue extended into the capsule and intersected with the surrounding pancreatic parenchyma. The tumour in Case 3 was located in the head of the pancreas and showed infiltration into the adjacent duodenal muscular layer. There was no significant difference in age ($P = 0.301$), tumour size ($P = 0.109$), sex ($P = 0.402$), postoperative adjuvant therapy ($P = 0.952$) or TNM stage ($P = 0.400$). However, the difference in infiltration of the capsule was

statistically significant ($P < 0.001$) (Figure 4).

DISCUSSION

The advancements and widespread use of imaging technology have led to an apparent rise in the prevalence of PCLs[1]. PCLs encompass both neoplastic and nonneoplastic lesions, with pancreatic cystic neoplasms (PCNs) representing a substantial subset. PCNs comprise serous cystic neoplasms (SCNs), solid pseudopapillary neoplasms (SPNs), IPMNs and mucinous cystic neoplasms. SCNs and SPNs are nearly benign and low-grade malignant tumours, respectively. IPMNs and MCNs, also known as pancreatic mucinous neoplasms, produce viscid mucin and have the potential to progress to PDAC. Notably, they are easier to detect by preoperative imaging than Pan IN due to the particular hypodensity of the cystic tumour.

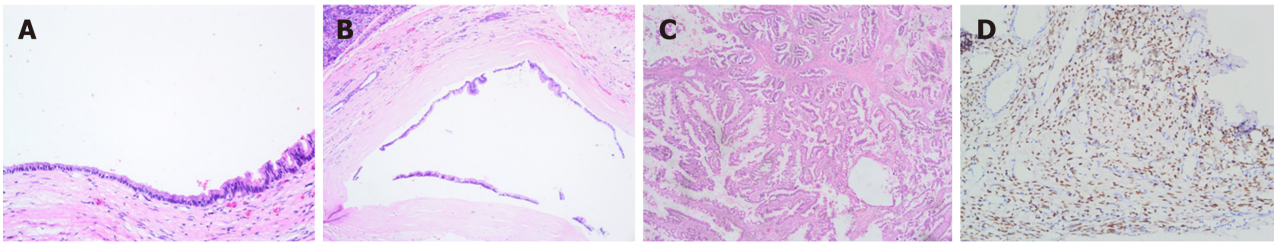

Table 2 Characteristics of 11 patients with mucinous cystic neoplasm associated invasive carcinoma

Case	Age (yr)	Sex	Tumor size (cm)	Largest dimension (cm)	Invasion pattern	pT stage	pTNM stage	Status	Overall survival (mo)	Adjuvant chemotherapy
1	72	Female	8.0	3.0	Extracapsular	T2	IB	Death	8	Yes

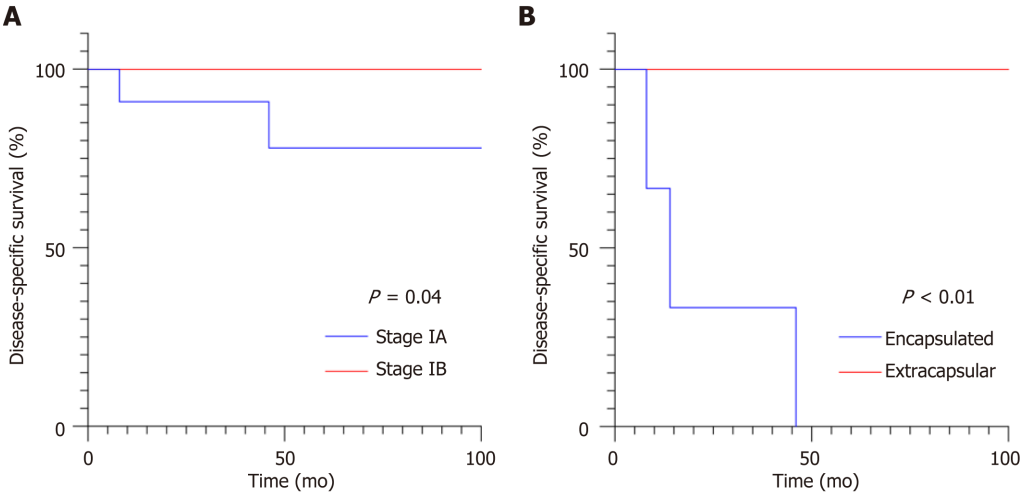

Figure 2 Representative micrographs showing the mucinous cystic neoplasm. A: The epithelium exhibits mild to moderate cellular and structural dysplasia, and there is subepithelial ovarian-type stroma (OTS), haematoxylin-eosin staining (H&E) × 200; B: The epithelium demonstrates papillary hyperplasia with some cells shedding into the lumen, and the stroma is partially replaced by fibrous collagen, H&E × 100; C: MCN-associated invasive carcinoma extended into the adjacent pancreatic tissue, and the epithelium exhibited severe dysplasia, H&E × 100; D: The OTS was positive for PR-staining, EnVision × 200.

Compagno and Oertel[8] initially distinguished MCN from SCN in 1978, citing its higher potential for malignancy. However, confusion between IPMNs and MCNs persisted until the International Association of Pancreatology designated OTS as the diagnostic criterion for MCN in 2006[9]. Earlier reports on MCNs inevitably included IPMN cases, leading to a high reported incidence of malignant transformation ranging from 6% to 39% over the last few decades[10-13]. In our sample, 25% of MCN cases were malignant, a rate nearly consistent with the findings of Höhn *et al*[14]. Loss of OTS was reported after the malignant transformation of MCNs[15]. In our study, although some cases showed this particular phenomenon following malignant transformation, with replacement by interstitial fibrous collagen, the remaining OTS was still visible. Once OTS cannot be recognized, detection of positive PR is recommended for a definitive diagnosis[16]. All cases in our study exhibited positive

staining, ensuring accurate diagnosis.

Currently, there are no reliable preoperative variables that can be used to accurately predict the malignant potential of PCNs.

As one of the most frequently utilized preoperative assessment modalities, imaging has garnered considerable attention in the field of radiomics research for identifying certain subtypes of PCNs and stratifying the risk of IPMNs[17]. Conversely, MCNs have received far less attention than IPMNs, mainly owing to their less substantial incidence and malignancy rate. The management criteria for MCNs remain ambiguous and differ from those of IPMNs. Due to the inability to accurately predict the malignant potential of MCNs through preoperative inspection, it was formerly recommended that all MCNs amenable to surgery be removed regardless of lesion size[13]. Fortunately, the latest guidelines recommend monitoring for eligible MCNs[4,18], although the inclusion criteria are similar to those for IPMNs. This parallelism with IPMN criteria may warrant further consideration. A substantial proportion of patients diagnosed with pancreatic mucinous cysts prior to surgery are subsequently found to have benign disease and do not need surgery[19], highlighting the need for improved identification of those cases with malignant potential. Therefore, given the limitations of current risk stratification schemes in predicting malignant transformation of MCNs, further investigation regarding potential risk factors is essential. While a variety of clinicopathological features and imaging findings have been proposed as potential risk factors for malignancy, their importance remains controversial across different studies[12,14,20-23]. In addition to the variables included in current guidelines, such as

tumour size, wall nodule, and duct dilation, other factors, including sex, location, wall thickening/enhancement, weight, and serum CA19-9 Level, have also been reported to be relevant. Our own research identified age, tumour size, solid component or mural nodule, and duct dilation as independent risk indicators.

To the best of our knowledge, age has not been widely recognized in the literature as a significant risk factor for malignant transformation of MCNs. The mean ages of patients with benign and malignant MCNs were 45.2 years ± 12.7 years and 52.2 years ± 13.4 years, respectively, which were comparable to those previously described in the literature[24]. Age has been shown to be related to malignancy in a cohort of pancreatic mucinous neoplasms[25]. Crippa *et al*[12] suggested that age was statistically significant in univariate analysis but did not emerge as a significant factor in multivariate analysis for malignant MCNs. Whether age is an independent risk factor for malignant MCNs needs further study. The occurrence of malignant MCNs appears to increase with age and seems to represent a dynamic pathological transition from adenoma to adenocarcinoma over time.

The average diameter of MCN masses in our investigation was found to be 5.8 cm, which is consistent with the previously reported average diameter of 6-11 cm. It has been emphasized that MCNs should be stratified into surveillance and surgery groups based on a diameter threshold of 4.0 cm, as stated in current guidelines[18]. Tumour size ≥ 4 cm was confirmed to be an independent risk for malignant MCNs in our study. In our research, we further identified that the presence of a solid component or mural nodule in MCNs is an independent risk factor for malignancy; it even ranks first in the likelihood of malignancy in certain studies[23]. The combination of solid component or mural nodule and tumour size has been utilized as a tool for identifying malignancy in some studies. In one cohort, it was reported that all malignant MCNs were either larger than 4 cm in diameter or had nodules[12]. Consistent with this, guidelines recommend surgical intervention for MCNs larger than 4 cm in diameter or for those with a mural nodule.

The majority of patients with MCNs are typically asymptomatic. In our analysis, while the percentage of malignant patients with clinical symptoms was higher than that of benign patients, the difference was not statistically significant. The relationship between clinical symptoms and malignancy in MCNs is still debatable[14,25], although surgical excision is advised if symptoms are present[18]. During follow-up, the increase in mass size can often result in nonspecific mass-related clinical complaints. In one case from our cohort, surgical intervention was advised after the tumour became larger than 4 cm and clinical symptoms appeared in the sixth year of imaging surveillance.

Unlike IPMNs, MCNs typically do not communicate with the pancreatic duct, which is one of their distinguishing features. Duct dilatation is a high-risk factor for malignant transformation in IPMNs, with dilatation greater than 10 mm being an unequivocal indication for surgery[18,26]. Similarly, our study found that pancreatic duct dilatation is a concerning imaging finding in MCNs, as verified by other investigations[23].

The management of malignant pancreatic tumours is predominantly centred on postoperative follow-up, whereas the management of MCNs places greater emphasis on the potential risks associated with preoperative monitoring and misdiagnosis. The management plan for IPMN is relatively mature, considering that dedicated management guidelines for IPMN have been published[1]. However, despite MCN being a precursor lesion of pancreatic cancer, similar to IPMN, the management plan for MCN remains unclear, particularly in identifying high-risk factors. Although the risk factors and surgical indications for IPMN and MCN are not differentiated in some guidelines[4], the demographic, cystic, histological and other characteristics of these two tumours differ, so they should be managed differently, particularly with respect to exploring risk factors. Unfortunately, our findings suggest that the risk factors for malignant MCNs are quite similar to those for IPMNs. The size of the lesion and the presence of solid components/wall nodules have been widely recognized as high-risk factors for malignant transformation of MCNs and IPMNs in various guidelines and publications, including our study. While various other malignant risk factors for MCN reported in the literature are statistically significant, they require further confirmation. In the case of IPMNs, the characteristic risk factor is main pancreatic duct dilation, especially when the diameter exceeds 10 mm, given that IPMNs grow within the pancreatic ducts. However, MCNs lack their own characteristic risk factors. Based on their relationship with the pancreatic ducts, IPMNs are classified into the main duct type, mixed duct type, and branch duct type, and direct surgical resection is recommended for the first two types due to a high risk of malignant transformation[18]. However, immediate surgical intervention for MCNs with risk factors remains controversial. Höhn *et al*[14] conducted a retrospective analysis exploring the risk factors for malignant transformation of MCNs, similar to our own analysis. They recommended radical resection surgery for all eligible patients suspected of having MCNs due to concerns about the potential risk of malignant progression and the level of expertise of pancreatic surgeons in low-volume centres. However, this view seems too radical, and the decision for MCN patients to undergo surgery should be more cautious, as the incidence and malignant transformation rate of MCNs are much lower than those of IPMNs[27]. The main argument for surgical resection in all MCN patients based on eliminating the risk of future malignancy seems invalid. It is essential to increase awareness and continuously conduct research on this rare tumour, especially in terms of preoperative malignant risk factors. Based on the above premise, a multidisciplinary team with expertise in pancreatic cysts and surgery can combine various reported risk factors, patient comorbidities, surgery-related complications, and mortality rates

to comprehensively evaluate the potential risks and benefits of surgery and monitoring, thereby making the best treatment decision for the patient.

In addition, preoperative imaging evaluation of various risk indicators for MCNs seems to require the use of different modalities. No single test can accurately diagnose all cases, and in fact, most patients undergo more than one diagnostic procedure[28]. Therefore, the comprehensive use of different detection methods is more conducive to preoperative diagnosis. In our study, this may be attributed to the preference of imaging doctors at our hospital. CT is the preferred initial test for patients undergoing physical examination or with symptoms, and if the CT results are inconclusive or require further confirmation, MRI or EUS will be performed. Unfortunately, there was no significant difference between these three detection methods in our study; nevertheless, combining CT with MRI/EUS increased the preoperative diagnosis rate of our patients from 64.4% to 72.9%. A review of the literature suggests that MRI has slightly higher accuracy in distinguishing between malignant PCNs and benign lesions than CT[29]. MRI was found to be more effective than EUS in distinguishing malignant MCNs [30]. CT combined with MRI was shown to be better than CT alone in the preoperative diagnosis of pancreatic cysts[31]. Moreover, patients with MCNs who have a certain risk of malignant transformation need long-term monitoring or even lifelong monitoring until surgery is no longer a suitable treatment option. For long-term follow-up of MCNs, MRI is the preferred method[18]. This may be because MRI has high contrast resolution and does not involve the use of radiation, which may increase the risk of developing malignant tumours in patients with long-term exposure to CT. EUS is an invasive procedure that highly depends on the operator's skills, especially when combined with aspiration for cyst fluid analysis. EUS is recommended for cysts with significant risk characteristics or when a more accurate diagnosis may change the patient's treatment plan[32].

Complete surgical resection of noninvasive MCNs is a curable treatment, resulting in a 5-year disease-specific survival rate of 100%, as previously reported[33], indicating that postoperative surveillance may not be necessary. As in PDAC patients, prognosis in cases of MCN-AIC was formerly believed to be dismal[34]. However, a series of recent studies have shown that the tumour behaviour and biological characteristics of MCN-AIC are entirely distinct from those of PDAC[23,35,36]. MCN-AIC is often diagnosed at an early stage, and surgical resection is the primary treatment. A study based on SEER research data showed that early-stage MCN-AIC (stage I-II) accounted for 82.9% of cases[37]. All 12 MCN-AIC cases in our study were at stage I, and the 5-year disease-specific survival rate was 70.1%, which was higher than the range of 20%-60% reported in previous literature[12,13,38]. Currently, there is a paucity of studies in which the biological behaviour of invasive MCNs is explored. Previous research indicates that patients with early-stage tumours (stages I and II) have better survival rates than those with high-grade tumours (stages III and IV)[37]. The prognostic variables for patients with MCN-AIC, such as pT grade and capsular invasion, have gained considerable attention. In PDAC, stage I is divided into stages IA and IB, which correspond to stages T1 and T2, respectively, without lymph node metastases and distant metastases[6]. A large cohort study has shown that the survival rate of patients with stage IA PDAC is much higher than that of patients with stage IB PDAC[39]. However, survival disparities between stage IA and IB invasive PDAC derived from MCN-AIC are rarely observed. Our findings, consistent with those of another study[7], demonstrate that there is no significant difference between the two stages. The invasion pattern of the capsule may provide a more accurate prediction of prognosis in MCN-AIC patients than stage classification. The notion of encapsulated invasion is not included in the MCN-AIC classification and guidelines, and the terminology varies somewhat across various research efforts. We adopted the term from the most recent publication[7]. The results of multiple studies have demonstrated that the prognosis is favourable when the invasion is confined to the capsule, and patients with encapsulated invasion exhibit a better survival rate than those with extracapsular invasion. Recurrence has been reported in one of sixteen cases of MCN-AIC confined to the OTS, and the probability of widespread invasion cannot be ruled out because of the minimal quantity of tumour sampled in this case[35]. It has been claimed that encapsulated MCN-AIC has a tumour-free survival rate that is comparable to that of noninvasive MCNs[7]. Our findings revealed that all patients with encapsulated invasion survived, while those with extracapsular invasion died regardless of whether MCN-AIC was stage IA or stage IB. It is recommended that MCN-AIC patients undergo standardized surveillance based on pancreatic cancer guidelines for 5 years after surgery[4]. During monitoring for stage I MCN-AIC, it seems that patients with extracapsular infiltration should be prioritized.

For patients with resected pancreatic cancer, the current standard of care mandates the administration of either a modified FOLFIRINOX (mFOLFIRINOX) or a gemcitabine-based regimen, provided that no contraindications are present[40]. However, limited research has been conducted on the benefits and risks of adjuvant treatment for stage I PDAC, which represents a small proportion of all resectable cases[41]. A study based on the NCDB database indicated that none of the patients with stage IA PDAC had to receive adjuvant treatment following resection, as the side effects and economic costs substantially outweighed the benefits[42]. Despite inadequate data to support this approach, current guidelines advocate adjuvant treatment for MCN-AIC patients comparable to that for patients with PDAC[18]. The role of adjuvant treatment in treating MCN-AIC patients after surgery, particularly for stage I tumours, remains unclear. Two of three patients with stage IA MCN-AIC did not receive adjuvant treatment after surgery, and none of them experienced disease recurrence or death[43]. Of the patients with tumours

who did not receive adjuvant therapy, seven recovered from stage IA and 1 died from stage IB MCN-AIC[7]. These reported cases could be defined as "encapsulated invasion" based on the definition. Patients with stage IA MCN-AIC (T1a and T1b) seem to have the same favourable prognosis as those with LGD or HGD, particularly in the absence of extracapsular invasion. In our research, three IA patients and one IB patient with tumours confined to the capsule did not receive adjuvant treatment and survived, while those with extracapsular infiltration died regardless of whether adjuvant therapy was offered. Diligent monitoring might be preferred over intensive systemic therapy for stage I MCN-AIC with encapsulated invasion.

MCNs are known to harbour gene mutations associated with PDAC, as they are precursor lesions of cancer[17]. However, the genetic pathways underlying IPMNs and MCNs are distinct from one another. The most prevalent and early genetic event in IPMN and MCN carcinogenesis is the KRAS mutation [44], which is present in 30% of MCNs, whereas the GNAS mutation is almost nonexistent[45,46]. In contrast, the combined detection of *KRAS* and *GNAS* mutations exhibits 100% sensitivity for IPMNs [46]. The decreased frequency of genetic mutations in MCNs compared to IPMNs partly explains why MCNs have a lower probability of malignant transformation. Other mutations, including *TP53*, *PIK3CA*, *PTEN*, *CDKN2A*, and *SMAD4*, have also been described in MCNs but only in advanced stages[47,48]. *KRAS* mutation could be detected in all phases of MCNs and increased with the degree of dysplasia. Sawai *et al*[49] discovered *KRAS* mutations in 19% of LGD and 100% of HGD cases, whereas *TP53* and *CDKN2A* mutations were exclusively observed only in HGD cases. Gene sequencing may aid in the early identification and tailored treatment of MCNs.

This study was subject to several limitations. First, it was a retrospective study that only included patients who underwent surgical resection and were pathologically confirmed to have MCNs, which may result in selection bias. Second, the rarity of MCNs limited the sample size, leading to a large confidence interval that may have hindered statistical analysis. Third, the MRI/EUS results were based on previous CT information, potentially affecting the interpretation of imaging results. Therefore, further multicentre and large-scale studies are needed to explore the clinical, pathological, imaging, and biological behaviours of MCNs.

CONCLUSION

In conclusion, this study involved analysing data from 48 patients who underwent complete resection of MCNs. The incidence of malignant MCNs was low, and the specific risk factors for malignancy were age, tumour size, presence of solid components or mural nodules, and duct dilatation. The prognosis of stage I MCN-AIC was closely related to encapsulated invasion, and complete surgical excision alone or in combination with postoperative treatment may be a viable option for invasive masses confined within the capsule.

ARTICLE HIGHLIGHTS

Research background

Mucinous cystic neoplasms (MCNs) are recognized as precursor lesions of pancreatic cancer. Despite their rarity, the detection of MCNs is on the rise due to advancements in preoperative imaging techniques. Thus, there is a pressing need to increase our knowledge of MCNs to ensure that patients receive the most appropriate treatment decisions.

Research motivation

An inadequate understanding of MCNs can hinder the treatment of patients, underscoring the importance of research on MCNs.

Research objectives

To investigate the risk factors for malignancy in MCNs and the prognostic factors associated with MCN-associated invasive carcinoma (MCN-AIC) to advance our comprehension of this uncommon tumour.

Research methods

This study involved a retrospective analysis of clinical and pathological data, imaging records, and outcomes of patients diagnosed with MCNs at our research centre over a 10-year period. We then investigated the risk factors for malignancy in MCNs and the prognostic factors associated with MCN-AIC.

Research results

A total of 48 patients with MCNs, accounting for 2.8% of pancreatic lesions resected during the study

period, were included in this study. Among these patients, 36 had benign MCNs, while 12 had malignant MCNs. We conducted a comparative analysis of clinical and imaging features and discovered that age, tumour size, solid components or wall nodules, and pancreatic duct dilation were significantly associated with malignancy. Subsequently, we performed a prognostic analysis of malignant MCNs and observed that all malignant MCNs in our study were at stage I, and extracapsular invasion was identified as a significant prognostic factor for poor outcomes.

Research conclusions

Age, tumour size, solid components or wall nodules, and pancreatic duct dilation were independent risk factors associated with malignancy in MCN. In addition, extracapsular invasion was indicative of poor prognosis of MCN-AIC.

Research perspectives

The aim of this study was to enhance the management of MCN, a rare disease, by utilizing patient information from our research centre and conducting research from both preoperative and postoperative perspectives. We hope that this study can provide valuable insights into the management of MCNs.

ACKNOWLEDGEMENTS

We would like to thank Dr. Xian-Jie Jia for significant contributions to data analysis.

FOOTNOTES

Author contributions: Xia Q collected the clinical data and prepared the manuscript; Xia Q and Li F designed the study and supervised the statistical data; Xia Q and Min R designed the research and contributed to the analyses; Sun S, Han YX, and Feng ZZ provided clinical advice; Li N made the pathologic diagnosis and supervised the report; and all authors read and approved the final version.

Abstract

BACKGROUND

Vonoprazan (VPZ)-based regimens are an effective first-line therapy for *Helicobacter pylori* (*H. pylori*) infection. However, their value as a rescue therapy needs to be explored.

AIM

To assess a VPZ-based regimen as *H. pylori* rescue therapy.

METHODS

This prospective, single-center, clinical trial was conducted between January and August 2022. Patients with a history of *H. pylori* treatment failure were administered 20 mg VPZ twice daily, 750 mg amoxicillin 3 times daily, and 250 mg *Saccharomyces boulardii* (*S. boulardii*) twice daily for 14 d (14-d VAS regimen). VPZ and *S. boulardii* were taken before meals, while amoxicillin was taken after meals. Within 3 d after the end of eradication therapy, all patients were asked to fill in a questionnaire to assess any adverse events they may have experienced. At least 4-6 wk after the end of eradication therapy, eradication success was assessed using a ^{13}C-urea breath test, and factors associated with eradication success were explored.

RESULTS

Herein, 103 patients were assessed, and 68 patients were finally included. All included patients had 1-3 previous eradication failures. The overall eradication rates calculated using intention-to-treat and per-protocol analyses were 92.6% (63/68) and 92.3% (60/65), respectively. The eradication rate did not differ with the number of treatment failures (P = 0.433). The rates of clarithromycin, metronidazole, and levofloxacin resistance were 91.3% (21/23), 100.0% (23/23), and 60.9% (14/23), respectively. There were no cases of resistance to tetracycline,

amoxicillin, or furazolidone. In 60.9% (14/23) patients, the *H. pylori* isolate was resistant to all 3 antibiotics (clarithromycin, metronidazole, and levofloxacin); however, eradication was achieved in 92.9% (13/14) patients. All patients showed metronidazole resistance, and had an eradication rate of 91.3% (21/23). The eradication rate was higher among patients without anxiety (96.8%) than among patients with anxiety (60.0%, P = 0.025). No severe adverse events occurred; most adverse events were mild and disappeared without intervention. Good compliance was seen in 95.6% (65/68) patients. Serological examination showed no significant changes in liver and kidney function.

CONCLUSION

VAS is a safe and effective rescue therapy, with an acceptable eradication rate (> 90%), regardless of the number of prior treatment failures. Anxiety may be associated with eradication failure.

Core Tip: Vonoprazan (VPZ)-containing triple therapies have been shown to contribute to global antimicrobial resistance, while *Saccharomyces boulardii* (*S. boulardii*) supplementation has significantly improved *Helicobacter pylori* eradication rates and decreased adverse events. This study revealed that the VPZ and amoxicillin dual regimen with *S. boulardii* supplementation is safe and effective H. pylori rescue therapy, regardless of the number of prior treatment failures. Acceptable eradication rates (> 90%) were achieved in patients with resistance to clarithromycin, metronidazole, and levofloxacin. However, the regimen may need to be adjusted for patients with anxiety.

INTRODUCTION

Helicobacter pylori (*H. pylori*), which infects over 50% of the global population, is a leading cause of chronic gastritis, peptic ulcer disease, and gastric cancer. The eradication of *H. pylori* can effectively prevent peptic ulcer recurrence and lower gastric cancer incidence[1,2]. In regions with high antibiotic resistance, such as China, 14-d bismuth-containing quadruple therapy (BQT) is the recommended first-line treatment for *H. pylori* infection[3-5]. However, as the rates of resistance to clarithromycin, metronidazole, and levofloxacin have markedly increased worldwide, BQT fails to eradicate *H. pylori* infection in approximately 15%-20% patients[6,7]. Multiple failed attempts at eradication therapy tend to increase the prevalence of multidrug-resistant strains, making rescue treatment more difficult[8,9]. Unlike the above antibiotics, the rates of primary and secondary resistance of *H. pylori* to amoxicillin have remained low and stable[10]. Amoxicillin shows a pH- and time-dependent bactericidal effect. Recently, high-dose, high-frequency dual therapy with amoxicillin and a proton pump inhibitor (PPI) was reported to show promising outcomes when used as a first-line or rescue treatment for the eradication of *H. pylori*[11,12]. The Maastricht VI/Florence Consensus Report recommends high-dose dual therapy with a PPI plus amoxicillin as a rescue therapy for *H. pylori* infection[5].

Vonoprazan (VPZ), the first clinically available potassium-competing acid blocker (P-CAB), produces a more rapid and sustained acid inhibition effect than PPIs[13]. Therefore, VPZ-amoxicillin dual therapy (VA-dual) is expected to be more effective than PPI-amoxicillin dual therapy. In recent years, first-line treatment with VA-dual, consisting of amoxicillin (3 g/d or less) and VPZ (40 mg/d), has been reported to achieve eradication rates of 78.5%-93.5%[14-17]. However, limited reports are available on the success rate of VA-dual as a rescue treatment for *H. pylori* infection; only one retrospective study conducted in China has reported a successful eradication rate of 92.5% after VA-dual[18]. However, the regimens were not consistent, and the frequencies of the amoxicillin and VPZ doses varied. Therefore, further optimization of VA-dual as a rescue treatment is warranted.

Some recent consensus guidelines for the management of *H. pylori* infection have proposed that certain probiotics can effectively decrease the gastrointestinal side effects of *H. pylori* eradication therapies[3-5]. A recent meta-analysis demonstrated that *Saccharomyces boulardii* (*S. boulardii*) supple-

mentation during standard eradication therapy (triple regimen, sequential regimen, or quadruple regimen) significantly improved eradication rates and decreased the overall incidence of adverse events [19]. However, few studies have evaluated the effects of *S. boulardii* as a supplement to the VA-dual regimen in terms of the eradication rate of *H. pylori* and treatment-related adverse events.

Therefore, the aim of this prospective study was to determine the safety and efficacy of VA-dual plus *S. boulardii* supplementation as a rescue treatment for patients with *H. pylori* infection. We additionally explored potential factors influencing eradication rates, and put forward our recommendations to improve *H. pylori* eradication rates in clinical practice.

MATERIALS AND METHODS

Statement of ethics and trial registration

Ethical approval for this pilot study was obtained from Affiliated Changzhou No. 2 People's Hospital of Nanjing Medical University [No. (2021) YLJSD004]. The study adhered to the tenets of the Declaration of Helsinki. Written informed consent was obtained from all patients prior to their enrollment in this study. The study has been registered in the Chinese Clinical Trial Registry (No. ChiCTR2200055125).

Study participants

Patients who attended our center between January and August 2022 were screened for their eligibility to participate in this study. The detailed inclusion criteria were as follows: (1) Patients aged over 18 years; (2) patients with a history of at least one failed *H. pylori* eradication treatment; and (3) a minimum 6-mo interval after the end of the last treatment. The following exclusion criteria were applied: (1) A history of gastric surgery; (2) severe concomitant diseases such as hepatic or renal dysfunction; (3) allergy or contraindication to the drugs used in the study regimen; (4) pregnancy or lactation; (5) treatment with a PPI, bismuth, or an antibiotic within 4 wk before the study treatment; (6) alcohol abuse or drug addiction; and (7) lack of informed consent.

Study design and outcomes

Before enrollment, the patients' demographic data, clinical characteristics, and any concomitant diseases were recorded through medical records and physician interviews. The diagnosis of *H. pylori* infection was based on a positive result of at least one of the following tests: ^{13}C-urea breath test (^{13}C-UBT), rapid urease test, and histological examination. Some patients also underwent gastroscopy, and *H. pylori* culture and antimicrobial susceptibility testing before treatment. Serum chemistry tests were performed before and after treatment.

All patients were administered VPZ (20 mg twice daily; Takeda Pharmaceutical, Tokyo, Japan), amoxicillin (750 mg 3 times daily; Federal Pharmaceutical, Hong Kong, China), and *S. boulardii* (250 mg twice daily; Laboratoires BIOCODEX, France) for 14 d (14-d VAS regimen). VPZ and *S. boulardii* were taken before meals, while amoxicillin was taken after meals. Patients who felt unwell during treatment or forgot to take their medication were advised to contact the investigators immediately.

All patients were asked to keep the remaining drugs after treatment and fill out the relevant questions in the questionnaire within 3 d after the end of eradication therapy. Adverse events and patient compliance were assessed using the questionnaires and the patients' medication diaries. The intensity of the adverse events was graded as follows: None; mild, causing discomfort but not interfering with daily life; moderate, causing discomfort and interfering with daily life; and severe, causing discomfort requiring cessation of treatment. Patient compliance was rated as good if the patient had taken > 80% of all medications prescribed, and as poor, if not[20]. All patients underwent repeat ^{13}C-UBT for the assessment of *H. pylori* infection 4-6 wk after the end of eradication therapy. The *H. pylori* status was interpreted as positive when the δ value was greater than the baseline value of 4, and as negative when the δ value was less than the baseline value of 4. If the δ value exceeded the baseline value, which was between 4 and 6, the test was repeated 1 mo later.

The primary endpoint of this study was the *H. pylori* eradication rate, as confirmed by a negative ^{13}C-UBT. All patients were included in the intention-to-treat (ITT) analysis. Patients who did not undergo a ^{13}C-UBT during follow-up were considered to have treatment failure in the ITT analysis. Patients who failed to attend follow-up assessments and those with poor compliance were excluded from the per protocol (PP) analysis. The secondary endpoints were the rate of adverse events, patient compliance, resistance to antibiotics, and factors related to the eradication rate.

H. pylori culture and antimicrobial susceptibility testing

From patients who underwent gastroscopy, we collected 2 biopsy specimens for *H. pylori* culture, one from the gastric antrum and another from the gastric corpus. Both specimens were stored at -80 °C in brain-heart infusion broth (Oxoid, Basingstoke, United Kingdom) and immediately transported to Zhiyuan Medical Laboratory Institute (Hangzhou, Zhejiang Province, China) for testing. Fully ground specimens were cultured and maintained for 3-7 d in brain-heart infusion agar medium (Oxoid,

Basingstoke, United Kingdom) supplemented with 5% defibrinated sheep blood at 37 °C in a low-oxygen environment (85% N_2, 10% CO_2, and 5% O_2). *H. pylori* isolates were identified on the basis of colony morphology and urease, catalase, and oxidase positivity.

The standard agar plate dilution method was used to assess *H. pylori* susceptibility to commonly used antibiotics. Minimum inhibitory concentrations (MICs) were calculated after 72 h of culture at 37 °C in a low-oxygen environment. We used *H. pylori* ATCC43504 (NCTC11637) for quality control. Antibiotic resistance was defined at the following MIC values: ≥ 1 μg/mL for clarithromycin, ≥ 8 μg/mL for metronidazole, and ≥ 2 μg/mL each for amoxicillin, furazolidone, levofloxacin, and tetracycline. The MIC values for antibiotic resistance were obtained from the fourth edition of the National Guide to Clinical Laboratory Procedures[21].

Sample-size calculation and statistical analysis

We assumed a 93% eradication rate with VPZ-based rescue therapy[22]. The 95% confidence interval was 86.6%-99.4%, and the sample size was 64 patients. Assuming a 5% follow-up loss, at least 68 patients would be required. Continuous variables were expressed as mean ± SD, and compared between groups by using the *t* test or Mann-Whitney *U* test. Categorical variables were expressed as numbers with percentages, and compared between groups by using the Fisher exact test or Pearson χ^2 test. Statistical significance was inferred at *P* values < 0.05. All statistical analyses were conducted using Statistical Package for the Social Sciences *v*23.0 (IBM, Armonk, NY, United States) and Power Analysis and Sample Size software *v*15.0.5 (NCSS LLC, Kaysville, UT, United States).

RESULTS

Patient characteristics

We screened a total of 103 patients for eligibility, and excluded 35 patients who did not meet the inclusion criteria. Thus, finally, 68 patients were enrolled in this study, of whom 62 patients underwent endoscopy, 41 patients underwent serological testing before and after treatment, and 24 patients underwent antimicrobial susceptibility testing. Three patients were excluded from the PP analysis due to poor compliance despite a negative ^{13}C-UBT during follow-up (Figure 1).

Of the 68 patients, 20 were men and 48 were women (Table 1). Prior to the present treatment, 47 patients had undergone treatment once, 15 patients had undergone treatment twice, and 6 patients had undergone treatment 3 times. Most patients were asymptomatic (*n* = 37, 54.4%). The most common concomitant diseases were hypertension (*n* = 14, 20.6%) and diabetes (*n* = 9, 13.2%); 4 patients (5.9%) had anxiety disorder. The most common previous treatment regimen was BQT, and the most commonly used antibiotics were amoxicillin, levofloxacin, clarithromycin, and metronidazole, with a few patients using furazolidone.

H. pylori culture and antimicrobial susceptibility testing

Of the 68 patients, 24 (35.3%) underwent *H. pylori* culture and antimicrobial susceptibility testing. *H. pylori* was successfully isolated in 95.8% (23/24) of patients. The rates of resistance to metronidazole, clarithromycin, and levofloxacin were 100% (23/23), 91.3% (21/23), and 60.0% (14/23), respectively. There were no cases of resistance to tetracycline, amoxicillin, or furazolidone. The triple drug-resistance rate (to metronidazole, levofloxacin, and clarithromycin) was 56.3% (9/16) among patients with one prior treatment failure, which increased to 71.4% (5/7) among patients with 2 or more prior treatment failures.

Eradication rate and factors influencing efficacy

The overall eradication rates of 14-d VAS calculated using the ITT and PP analyses were 92.6% (63/68) and 92.3% (60/65), respectively. In 2 of the 5 patients in whom eradication failed, further treatment with VPZ 20 mg twice daily, amoxicillin 1000 mg 3 times daily, and *S. boulardii* 250 mg twice daily for 14 d successfully eradicated the infection. The remaining 3 patients had not yet received additional rescue therapy at the time of writing as less than 6 mo had passed since the end of the previous treatment.

We stratified the *H. pylori* eradication rate by the number of prior treatment failures (Figure 2). The ITT analysis showed that the eradication rates were 93.6%, 93.3%, and 83.3% (*P* = 0.433) among patients with 1, 2, and 3 prior treatment failures, respectively. The corresponding eradication rates according to the PP analysis were 93.2%, 93.3%, and 83.3% (*P* = 0.585). We found that the eradication rate did not significantly differ with the number of previous treatment failures. In addition, eradication rates did not differ between patients who had previously received amoxicillin and those who had not (85.0% *vs* 95.8%, *P* = 0.433).

Among the 23 patients who successfully underwent *H. pylori* culture and antimicrobial susceptibility testing, the ITT analysis showed that similar eradication rates were achieved in the clarithromycin-resistant (90.4%) and clarithromycin-sensitive groups (100%; *P* = 1.00). PP analysis also showed that the eradication rate did not differ between the clarithromycin-resistant and clarithromycin-sensitive groups

(90.0% *vs* 100%, respectively, P = 1.00). Similarly, we found no significant difference in the *H. pylori* eradication rate between the levofloxacin-resistant and levofloxacin-sensitive groups (ITT: 92.8% *vs* 88.8%, respectively, P = 1.00; PP: 92.3% *vs* 88.8%, respectively, P = 1.00; Figure 3). All patients showed metronidazole resistance, and had an eradication rate of 91.3% (21/23). Notably, eradication was achieved in 92.9% (13/14) patients who showed triple drug resistance (clarithromycin, metronidazole, and levofloxacin).

Anxiety disorder was found to be a risk factor for eradication failure (40.0% *vs* 3.2%, P = 0.025; Table 2). No significant differences in age, sex, height, weight, body mass index, concomitant diseases, gastroscopy findings, and number of prior treatment failures were found between patients with successful and failed rescue therapy.

Adverse events and compliance

A total of 10 patients (14.7%) developed adverse events, including diarrhea (4 patients), skin rash (3 patients), and dry mouth, bloating, and abdominal pain (1 patient each). Most adverse events were mild and disappeared without intervention, except in 2 patients who developed rashes on day 9 and 11, refused continued rescue treatment, and finally recovered after anti-allergy therapy. Another patient

discontinued treatment on day 7 because of diarrhea, which improved without intervention. The remaining patients took > 80% of all medications prescribed (compliance rate, 95.6%, 65/68; Table 3). Serum chemistry tests revealed no significant differences in liver and kidney function before and after treatment (Table 4). Among the 10 patients who developed adverse events, only 1 patient (with a rash) had eradication failure.

DISCUSSION

To our knowledge, this study is the first to determine the safety and efficacy of 14-d VA-dual plus *S. boulardii* supplementation as a rescue therapy for *H. pylori* infection. This VAS regimen achieved an

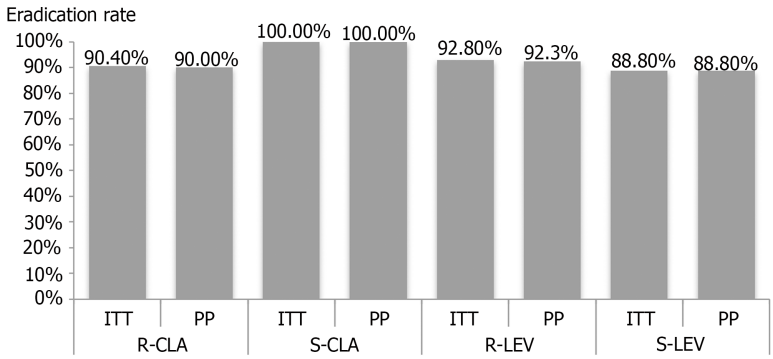

Figure 3 Impact of bacterial antibiotic resistance on eradication rate. ITT: Clarithromycin resistant *vs* clarithromycin sensitive, $P = 1.00$; levofloxacin resistant *vs* levofloxacin sensitive, $P = 1.00$; PP: Clarithromycin resistant *vs* clarithromycin sensitive, $P = 1.00$; levofloxacin resistant *vs* levofloxacin sensitive, $P = 1.00$). acceptable eradication rate (92.6% by ITT and 92.3% by PP), regardless of the number of prior treatment failures. Most patients could tolerate this regimen, and compliance was good in this Chinese patient population. Except for anxiety disorder, no other factors were observed to be associated with treatment failure. Notably, eradication was successful in 92.9% (13/14) of patients with multiple antibiotic resistance. Therefore, the 14-d VAS regimen is a safe and effective rescue therapy for *H. pylori* infection.

Currently, *H. pylori* culture-guided therapy is recommended by most consensus guidelines as a rescue therapy for *H. pylori* infection. However, culture-guided therapy is not widely used in routine clinical practice[3-5]. Until recently, susceptibility tests still required the microbiological examination of samples obtained through endoscopy, which is invasive and expensive. In addition, many hospitals lack the facilities required to perform *H. pylori* culture and antimicrobial susceptibility testing, which limits the clinical use of culture-guided therapy in many countries[3,5,20]. Furthermore, *H. pylori* culture is technically challenging. Several studies have reported culture success rates of < 80% among patients with failure of at least one prior *H. pylori* eradication treatment[23]. It should be emphasized that in our study, culture was performed in only 35.3% of the patients. This reflects the current state of routine clinical practice in China. Culture-guided therapy has not yet become a routine clinical practice, and rescue therapy is mainly prescribed on an empirical basis in China.

Compared with PPIs, VPZ, the first clinically applied P-CAB, has a faster and stronger acid-inhibition effect[13]. This provides an opportunity to potentially improve *H. pylori* eradication therapy by simplifying complex regimens and possibly helping to develop effective therapies[5]. In one study, a PP analysis showed that a 7-d VPZ-based regimen (VPZ 20 mg twice daily, sitafloxacin 100 mg twice daily, and amoxicillin 750 mg twice daily) as a third-line therapy resulted in a significantly higher eradication rate than a PPI-based regimen (83.3% *vs* 57.1%, $P = 0.043$)[24]. In a small study, a 10-d triple therapy regimen consisting of VPZ 20 mg twice daily, rifabutin 150 mg twice daily, and amoxicillin 750 mg twice daily yielded a 100% eradication rate in 19 patients with ≥ 3 prior treatment attempts[25]. Similarly, in 57 patients administered a 7-d rifabutin-containing triple therapy regimen (VPZ 20 mg twice daily, amoxicillin 500 mg 4 times daily, and 150 mg rifabutin 150 mg once daily) as a third- or later-line *H. pylori* eradication regimen, the eradication rate was 91.2%[26]. It should be emphasized that all the above studies were conducted in Japan, and they all used triple regimens containing VPZ and amoxicillin. Although the use of 2 antibiotics may lead to higher eradication rates, this practice promotes the use of an unnecessary second antibiotic[27]. Hence, optimization of VPZ-based rescue therapy needs to be further explored. However, the relevant research in China is limited. Only one retrospective study has reported that the 14-d VA-dual regimen (VPZ 20 mg/d or 40 mg/d and amoxicillin 3000 mg/d) was safe and effective as a rescue therapy (92.5%, 172/186); however, the frequencies and doses of VA-dual therapy varied among the patients[18].

The 14-d VAS regimen used in this study offers certain advantages over previous rescue therapies. First, it minimizes the use of antibiotics, which is especially important in the light of the global increase in *H. pylori* antibiotic resistance. Indeed, VPZ-containing triple therapies have been shown to contribute to global antimicrobial resistance[27]. The 14-d VAS regimen eliminated the need for a second antibiotic while providing remarkable *H. pylori* eradication efficacy. Second, the optimal amoxicillin dose for dual therapy remains uncertain. Available evidence suggests that a dose of 2 g/d is insufficient, and 3 g or 2.25-3.00 g in split doses (every 6 h or 8 h) may be optimal[27]. Therefore, amoxicillin was administered at a dose of 750 mg 3 times daily in the 14-d VAS regimen. Third, for the first time, we supplemented *S. boulardii* to VA-dual as a rescue therapy for *H. pylori* eradication. Several potential mechanisms by which *S. boulardii* acts as an adjunct to *H. pylori* eradication therapy have been elucidated: (1) It inhibits the growth and proliferation of *H. pylori* by upregulating short-chain fatty acids and other antimicrobial substances[28]; (2) it expresses a neuraminidase that reduces the expression of α(2-3)-linked sialic acid

on the epithelial cell surface, which prevents the adhesion of *H. pylori* to the duodenal epithelium[29]; and (3) it reduces the incidence of adverse events and indirectly improves patient compliance, thereby increasing the eradication rate of *H. pylori*[19].

Poor patient compliance is a main cause of treatment failure, and adverse events are a key factor affecting patient compliance[30]. Our 14-d VAS regimen was well tolerated, and all adverse events were mild or moderate, with diarrhea (5.9%) and rash (4.4%) being the most common. Patient compliance was also good, which may be attributable to the low rate of adverse events and the simplicity of the regimen.

We analyzed the factors potentially influencing the eradication rate of the 14-d VAS regimen. Only anxiety disorder was significantly associated with eradication failure; other factors such as gender, age, smoking, and alcohol consumption were not associated with treatment failure. There is evidence that state anxiety and trait anxiety are related to *H. pylori* infection. Anxiety appears to heighten the intensity and perception of gastrointestinal signals, which gives patients more reasons to worry about their health, leading to a higher anxiety response, and making patients more inclined to seek medical advice [31]. Thus, identifying patients with anxiety prior to the treatment of *H. pylori* infection and management by a professional team including a gastroenterologist and a psychologist to improve anxiety may be necessary to improve eradication rates and reduce the costs associated with frequent medical consultations.

This study has some limitations. First, it is impossible to compare the safety and effectiveness of the VA-dual regimen and the VAS regimen because this study is a single-arm pilot study. Large-scale, multicenter randomized controlled trials in areas with different patterns of antibiotic resistance are needed to confirm our results. Second, the number of patients with anxiety disorder in this study was small, and the relevant conclusions and potential mechanisms need to be further explored in future studies. Third, *H. pylori* culture and antimicrobial susceptibility testing were performed in only 35.3% of our patients, and no resistance was detected to amoxicillin. So, it was impossible to determine whether amoxicillin resistance affected the eradication rate of the 14-d VAS regimen. However, considering that the rates of primary and secondary resistance to amoxicillin are low and stable[10], we believe that the 14-d VAS regimen is an effective rescue therapy. Fourth, this study was underpowered to analyze the association between eradication rate and prior eradication regimens because the study patients had previously been treated with multiple different regimens.

CONCLUSION

In conclusion, the 14-d VAS regimen is safe and effective *H. pylori* rescue therapy, with an acceptable eradication rate (> 90%), regardless of the number of prior treatment failures. This regimen avoids the use of additional antibiotics, but may need to be adjusted for patients with anxiety. Large-scale, multicenter randomized controlled trials are needed to confirm our results.

ARTICLE HIGHLIGHTS

Research background

Vonoprazan (VPZ)-containing triple therapies have been shown to contribute to global antimicrobial resistance. Hence, the value of VPZ-based regimens as rescue therapies needs to be explored.

Research motivation

Saccharomyces boulardii (*S. boulardii*) supplementation significantly improved *H. pylori* eradication rates and decreased the incidence of adverse events. We are the first to combine *S. boulardii* supplementation with VPZ-amoxicillin dual therapy (VAS regimen) as a rescue therapy for *H. pylori* eradication.

Research objectives

To determine the safety and efficacy of the VAS regimen as a rescue treatment for *H. pylori* infection.

Research methods

We performed a prospective, single-center, clinical trial with the VAS regimen.

Research results

The overall eradication rates calculated using intention-to-treat and per-protocol analyses were 92.6% and 92.3%, respectively. The eradication rate did not differ with the number of treatment failures (P = 0.433). Acceptable eradication rates (> 90%) were achieved in patients with resistance to clarithromycin, metronidazole, and levofloxacin. Most adverse events were mild, and 95.6% patients showed good compliance.

Research conclusions

The VAS regimen is a safe and effective rescue therapy, with an acceptable eradication rate (> 90%), regardless of the number of prior treatment failures.

Research perspectives

Large-scale, multicenter randomized controlled trials in areas with different patterns of antibiotic resistance are needed to confirm our results. It will be necessary to compare the safety and effectiveness of the VPZ-amoxicillin dual therapy regimen with the VAS regimen in the future.

Abstract

BACKGROUND

Cancer detection is a global research focus, and novel, rapid, and label-free techniques are being developed for routine clinical practice. This has led to the development of new tools and techniques from the bench side to routine clinical practice. In this study, we present a method that uses Raman spectroscopy (RS) to detect cancer in unstained formalin-fixed, resected specimens of the esophagus and stomach. Our method can record a clear Raman-scattered light spectrum in these specimens, confirming that the Raman-scattered light spectrum changes because of the histological differences in the mucosal tissue.

AIM

To evaluate the use of Raman-scattered light spectrum for detecting endoscop-

ically resected specimens of esophageal squamous cell carcinoma (SCC) and gastric adenocarcinoma (AC).

METHODS

We created a Raman device that is suitable for observing living tissues, and attempted to acquire Raman-scattered light spectra in endoscopically resected specimens of six esophageal tissues and 12 gastric tissues. We evaluated formalin-fixed tissues using this technique and captured shifts at multiple locations based on feasibility, ranging from six to 19 locations 200 microns apart in the vertical and horizontal directions. Furthermore, a correlation between the obtained Raman scattered light spectra and histopathological diagnosis was performed.

RESULTS

We successfully obtained Raman scattered light spectra from all six esophageal and 12 gastric specimens. After data capture, the tissue specimens were sent for histopathological analysis for further processing because RS is a label-free methodology that does not cause tissue destruction or alterations. Based on data analysis of molecular-level substrates, we established cut-off values for the diagnosis of esophageal SCC and gastric AC. By analyzing specific Raman shifts, we developed an algorithm to identify the range of esophageal SCC and gastric AC with an accuracy close to that of histopathological diagnoses.

CONCLUSION

Our technique provides qualitative information for real-time morphological diagnosis. However, further *in vivo* evaluations require an excitation light source with low human toxicity and large amounts of data for validation.

Key Words: Raman spectroscopy; Squamous cell carcinoma; Adenocarcinoma; Esophagus; Stomach; Label-free cancer detection; Real-time diagnosis

Core Tip: Cancer diagnosis is a critical step in patient management, and involves a combination of diagnostic modalities or a single investigation. Diagnostic techniques that provide comprehensive data on the disease process can be particularly valuable, and Raman spectroscopy (RS) is one such modality that offers detailed molecular-level information. In this study, we utilized RS to rapidly detect cancer in resected esophageal and stomach specimens, providing information beyond morphology. By providing detailed molecular-level data, RS can provide a more comprehensive understanding of disease processes and aid in accurate diagnosis.

INTRODUCTION

Gastrointestinal cancers are typically evaluated using various investigative modalities, like radiological imaging, endoscopy, and histopathology[1,2]. Although tissue diagnosis through histopathological evaluation remains the gold standard for diagnosis, it is primarily based on morphological interpretation, even in current molecular-level evaluation practices[3]. In addition to morphology, many other such modalities are rapidly making inroads into practice[3,4]. Unlike morphology alone, immunohistochemistry, which has become almost synonymous with objective histopathological evaluation, is further aided by fluorescence *in situ* hybridization and sequencing. At the other end of the spectrum lies non-invasive/minimally invasive, non-label-based evaluation options, such as near-infrared spectroscopy and Raman spectroscopy (RS)[5].

Endoscopic biopsy is the preferred diagnostic method for gastrointestinal cancer[6]. Recent technological advances in endoscopy have enabled reliable diagnoses based on endoscopic findings alone, which have been further improved by the incorporation of artificial intelligence[5-7]. However, these

methodologies rely primarily on morphological assessments and do not consider molecular biological information. Tumor tissues contain abnormal molecules and proteins that are absent in normal tissues. The addition of molecular biological information to existing highly evolved morphological diagnostic methods may become an epoch-making technique with higher diagnostic accuracy[5,8,9].

Hence, we evaluated the biological samples using RS to obtain molecular information[8,10]. RS is a nondestructive inspection method that identifies a substance by measuring the type and amount of molecules contained in the substance by analyzing the wavelength of the reflected light obtained by irradiating the target substance with light, such as a laser[11-13]. Furthermore, RS can be used to evaluate substances with all types of properties, including solids[14-16], liquids[9,11], and gases[17], without sample pretreatment. Therefore, RS is an excellent inspection method for evaluating substances within a short time.

Therefore, attempts have been made to evaluate tissue samples using RS. Bergholt *et al*[4] presented a diagnostic technique for esophageal disease in the gastrointestinal tract using RS and published diagnostic techniques for gastric cancer. Moreover, Duraipandian *et al*[3] reported a diagnostic technique for gastric cancer using RS. However, a standard method for biological evaluations using RS has not yet been established.

A major challenge in using RS to evaluate biological samples is interference of autofluorescence[18]. To address this issue, we developed a novel micro-Raman device with unique features that enables effective evaluation of biological samples using RS.

We selected a near-infrared laser, which is not easily affected by autofluorescence, as the excitation light source. Because the Raman-scattered light intensity is inversely proportional to the square of the excitation light wavelength, the scattered light intensity of a long-wavelength near-infrared laser is low [18]. We developed a highly sensitive circuit to detect this weakly scattered light. We attempted to record the Raman-scattered light wavelengths from living esophageal tissues using a micro-Raman device with these characteristics.

MATERIALS AND METHODS

Study population and data collection

Sixteen patients aged 80 years or younger who underwent endoscopic submucosal dissection of the esophagus or stomach at the Digestive Disease Center of Showa University Koto Toyosu Hospital were recruited for this study. Written consent was obtained from all participants. Eleven participants were male and five were female, with an age range of 38-80 years. Eighteen specimens (esophagus, n = 6; stomach, n = 12) were analyzed (Table 1). This study was approved by the in-hospital clinical research review board (approval number: 18T5009) and conducted in accordance with the Declaration of Helsinki.

Measurement protocol and data capture

Esophageal and stomach tissue samples (including mucosal and submucosal tissues) were collected immediately after endoscopic resection. The tissue was attached to a black rubber plate with a metal pin, and a 0.02 mm thick aluminum foil was sandwiched between the rubber plate and the esophageal tissue to prevent Raman scattered light from the rubber plate from being included in the measurements.

A linear or grid-like measurement grid was set up to include endoscopically diagnosed lesions in the mucosa and the surrounding normal mucosa. Multiple measurement points were selected at 5 mm or 10 mm intervals depending on the shape of the clinically determined lesion. Raman scattered light wavelengths were recorded from 19 or 6 locations at intervals of 200 μm in the vertical and horizontal directions for each selected point depending on the feasibility. To prevent the sample from drying out, distilled water was sprayed on the sample as necessary during the measurement.

A RS device (BaySpec Inc., San Jose, CA, United States) was used, with a computer-controlled stage, an objective lens of 20 × magnification, a correction collar for near-infrared microscopy (LCPLN20XIR, Olympus Corporation, Tokyo, Japan), and an excitation laser wavelength of 1064 nm. The measurements were captured with a laser power of 200 mW and an exposure time of 10 s per point. Pathologic System Software Version 1.0.1.0 (BaySpec, Inc., San Jose CA, United States) was used and baseline correction was performed without smoothing the waveform. Examples of the Raman spectra of the esophageal and gastric mucosa are shown in Figure 1.

Analysis

Fifteen types of Raman shifts corresponding to the constituent molecules of living tissues (Table 2) were selected for the analysis. From the recorded Raman-scattered light waveforms, the scattered light intensities of 15 types of Raman shifts were extracted, and the optimum combination matching the range of squamous cell carcinoma (SCC) of the esophagus and gastric adenocarcinoma (AC) by histopathological diagnosis was determined.

RESULTS

The study involved 16 patients, and 18 specimens were resected for histopathological analysis. The results showed that five of the specimens were SCC of the esophagus, 10 were well-differentiated tubular AC of the stomach, one was a gastric adenoma, and one was a gastric carcinoid tumor (NET G1) (Table 3).

Raman spectra were recorded for all six esophageal and 12 gastric specimens. All combinations of the scattered light intensities of the 15 Raman shifts were calculated to determine the combination that best matched the range of cancer by histopathological diagnosis. In esophageal squamous cell cancer, the

Table 4 Raman shift peaks observed in the esophageal and the gastric samples

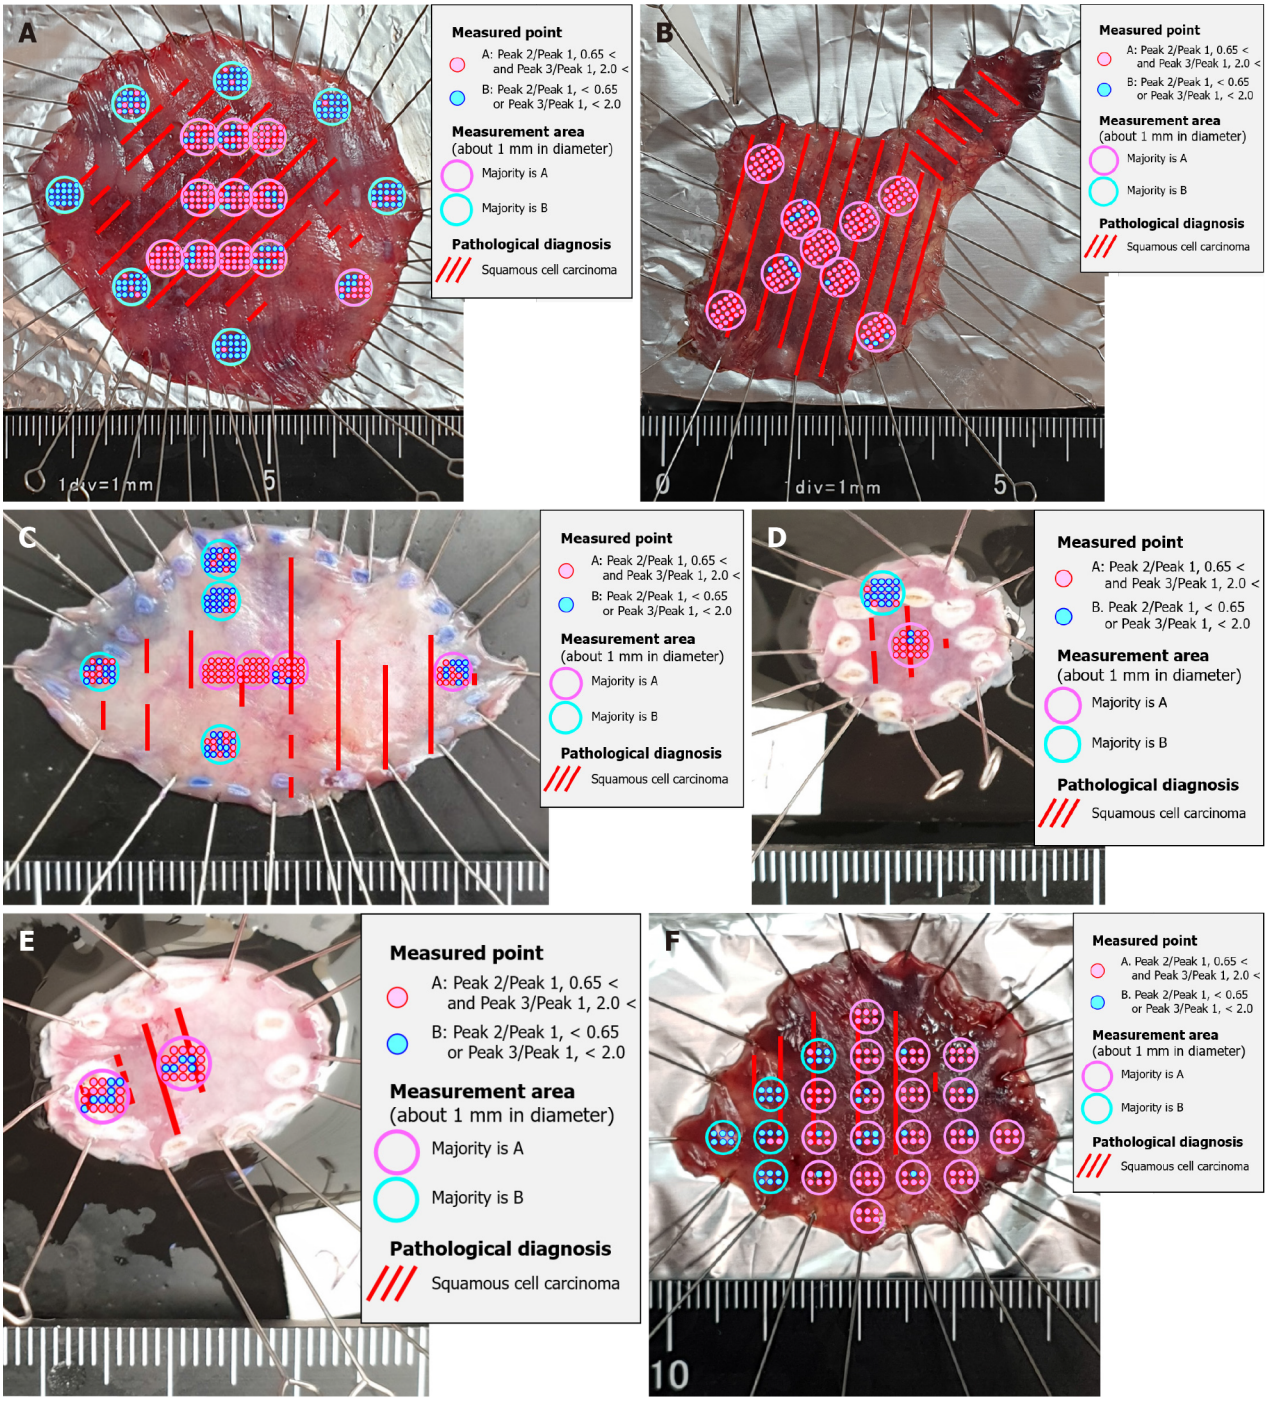
	Peak 1	Peak 2	Peak 3
Esophagus	RS 8	RS 1	RS 13
Stomach	RS12	RS 5	RS 15

Table 5 Cut-off ratios obtained from the esophagus and stomach samples

	Cut-off 1 (peak 2/peak 1)	Cut-off 2 (peak 3/peak 1)
Esophagus	0.65	2.0
Stomach	1.85	2.0

scattered light intensity of Skeletal C-C stretch was Peak 1, the scattered light intensity of Phenylalanine C-C twist was Peak 2, the scattered light intensity of CH_3 deformation was Peak 3 (Table 4), and Peak 2/Peak 1 was defined as Cut-off 1. Peak 3/Peak 1 was defined as Cut-off 2 (Table 5). The site with more than half of the measurement points having Cut-off 1 greater than 0.65 and Cut-off 2 greater than 2.0 was determined to be the best match for histopathological SCC of the esophagus (Figure 2).

For gastric AC, the scattered light intensity of the CH_2 stretch was Peak 1, Phenylalanine ring breadth was Peak 2, and Amide I alpha helix was Peak 3 (Table 4). The ratio of Peak 2/Peak 1 was defined as Cut-off 1 and Peak 3/Peak 1 was defined as Cut-off 2 (Table 5). The site with more than half of the measurement points with Cut-off 1 greater than 1.85 and Cut-off 2 greater than 2.0 was determined to be the best match for the histopathological diagnosis of gastric AC (Figure 3).



DISCUSSION

Patients with gastrointestinal cancers affecting the esophagus and stomach have symptoms, such as difficulty in swallowing, heartburn, and fullness[6]. Contrast examination or endoscopy is often performed in patients with a clinical evaluation suggestive of esophageal or gastric cancer[6]. Histopathological evaluation of the tissues obtained *via* endoscopic biopsy can be used to confirm the diagnosis[3,4,6]. In recent years, the accuracy of endoscopic finding-based diagnoses has dramatically improved. One of the reasons for this is the better quality of images obtained through high-resolution camera optics[3,6].

It is highly possible that the ability to diagnose cancer will improve further if it is feasible to depict what cannot be delineated using conventional equipment by making the image richer in features. Another reason is the use of image classification algorithms based on artificial intelligence[13,16,19]. By recognizing and patterning endoscopic images using artificial intelligence, the existence of lesions is clarified, and diagnosis by doctors is supported. Since the diagnosis using artificial intelligence evaluates endoscopic images morphologically, it is possible to prevent the lesion from being overlooked [13,16]. However, its diagnostic ability is not higher than that of an experienced doctor. Another drawback is that diagnostic ability is greatly affected by the quality of the endoscopic image[5,9,14].

As mentioned above, the accuracy of endoscopic diagnosis of lesions in the gastrointestinal tract has greatly improved; however, it is still at the morphological interpretation level[6,7]. Histopathological diagnosis, which is the current definitive diagnostic method, is a form of morphological evaluation; moreover, qualitative information that assists in morphological evaluation is required to improve diagnostic accuracy beyond the existing practice. RS can be used to add qualitative information to the morphological information[2,20]. Short *et al*[1] published a technique for diagnosing lung cancer using bronchoscopy combined with RS. Lui *et al*[21] reported a method for diagnosing skin cancer using RS. Krishna *et al*[22] reported a method for diagnosing oral cancer using RS. Jermyn *et al*[20] reported that RS can be used to identify lesion areas during brain surgery. Furthermore, Bergholt *et al*[6] presented a diagnostic technique for esophageal disease in the gastrointestinal tract using RS, and published diagnostic techniques for gastric cancer[4]. Duraipandian *et al*[3] reported a diagnostic technique for gastric cancer using RS. Molckovsky *et al*[2] reported a diagnostic technique for colon cancer using RS. However, a standard method for analyzing living organisms and biological samples using RS is yet to be developed.

In this study, we selected 15 Raman shifts corresponding to constituent molecules in living tissues. The analysis results of the scattered light intensity of Raman shift of Skeletal C-C stretch, Phenylalanine C-C twist, and CH_3 deformation in SCC of the esophagus, and Raman shift of CH_2 stretch, Phenylalanine ring breadth, and Amide I alpha-helix in gastric AC. The results of the analysis of the scattered light intensity of the shift were in good agreement with the range of morphological cancer

diagnoses offered by histopathological evaluation. SCC of the esophagus and gastric AC are distinct types of cancers with different biological characteristics. Therefore, a significant Raman shift is expected to differ in the analysis conducted using RS. The technique presented in this study has the potential to provide qualitative evaluation in addition to the morphological evaluation currently used. In particular, it may offer valuable information regarding lesions that are challenging to assess using endoscopic or histopathological diagnoses alone.

However, at some sites, the results of this technique did not match the histopathological diagnoses. The limitations of this study include the small number of samples analyzed (n = 18), which included both the esophagus and stomach. Hence, there is no doubt that more samples must be analyzed in the future to confirm the accuracy of this technique. Using this technique, molecular information not solely dependent on morphological interpretation can be obtained. Furthermore, it may indicate the degree of mucosal abnormality from normal to cancerous. Evaluation of precancerous tissues may enable highly

accurate preventive medicine. We aim to further advance this research and establish a method for predicting the current and future states of the gastrointestinal mucosa with high accuracy by clarifying the correlation between the Raman-scattered light intensity and the tissue state at each Raman shift.

CONCLUSION

Based on the results, it was concluded that RS could accurately identify esophageal SCC and gastric AC by analyzing the scattered light intensities of the 15 types of Raman shifts. The optimum combinations of Raman shifts were identified as Peak 1, Peak 2, and Peak 3 for both cancer types, with specific cut-off values for each peak. Although it is currently used in endoscopic treatment, the qualitative diagnosis of lesions, risk of residual lesions, *etc.*, can be confirmed in a short time by analyzing excised specimens, and treatment can be provided as necessary.

ARTICLE HIGHLIGHTS

Research background

Cancer diagnosis plays an important role in patient management, many researchers focused on the cancer detection, and novel, rapid, and label-free techniques are being developed for routine clinical practice.

Research motivation

To address the issue of using Raman spectroscopy (RS) to evaluate biological samples is interference of autofluorescence.

Research objectives

Our study is to evaluate the use of Raman-scattered light spectrum for detecting endoscopically resected specimens of esophageal squamous cell carcinoma (SCC) and gastric adenocarcinoma (AC).

Research methods

We created a Raman device, which is suitable for observing living tissues, and we attempted to acquire Raman-scattered light spectra in endoscopically resected specimens of six esophageal tissues and 12 gastric tissues. Furthermore, we performed a correlation between the obtained Raman scattered light spectra and histopathological diagnosis.

Research results

We obtained Raman scattered light spectra from all six esophageal and 12 gastric specimens successfully, and developed an algorithm to identify the range of esophageal SCC and gastric AC with an accuracy close to that of histopathological diagnoses.

Research conclusions

In this study, we utilized RS to rapidly detect cancer in resected esophageal and stomach specimens, providing information beyond morphology.

Research perspectives

By providing detailed molecular level data, RS can provide a more comprehensive understanding of disease processes and aid in accurate diagnosis.

Abstract

BACKGROUND

It has been confirmed that three-dimensional (3D) imaging allows easier identification of bile duct anatomy and intraoperative guidance of endoscopic retrograde cholangiopancreatography (ERCP), which reduces the radiation dose and procedure time with improved safety. However, current 3D biliary imaging does not have good real-time fusion with intraoperative imaging, a process meant to overcome the influence of intraoperative respiratory motion and guide navigation. The present study explored the feasibility of real-time continuous image-guided ERCP.

AIM

To explore the feasibility of real-time continuous image-guided ERCP.

METHODS

We selected 2 3D-printed abdominal biliary tract models with different structures to simulate different patients. The ERCP environment was simulated for the biliary phantom experiment to create a navigation system, which was further tested in patients. In addition, based on the estimation of the patient's respiratory motion, preoperative 3D biliary imaging from computed tomography of 18 patients with cholelithiasis was registered and fused in real-time with 2D fluoroscopic sequence generated by the C-arm unit during ERCP.

RESULTS

Continuous image-guided ERCP was applied in the biliary phantom with a registration error of 0.46 mm ± 0.13 mm and a tracking error of 0.64 mm ± 0.24

mm. After estimating the respiratory motion, 3D/2D registration accurately transformed preoperative 3D biliary images to each image in the X-ray image sequence in real-time in 18 patients, with an average fusion rate of 88%.

CONCLUSION
Continuous image-guided ERCP may be an effective approach to assist the operator and reduce the use of X-ray and contrast agents.

Key Words: Endoscopic retrograde cholangiopancreatography; Three-dimensional images; Registration; Cholelithiasis; Hilar cholangiocarcinoma

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Three-dimensional imaging allows easier identification of bile duct anatomy and intraoperative guidance of endoscopic retrograde cholangiopancreatography (ERCP). Continuous image-guided ERCP may be an effective means to assist the operator and reduce the use of X-ray and contrast agents.

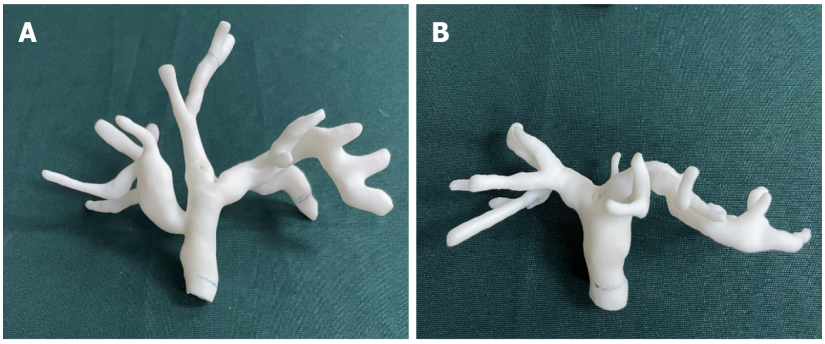
INTRODUCTION

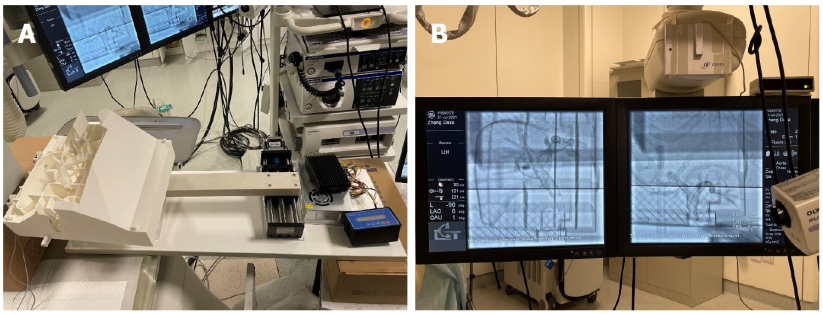
Endoscopic retrograde cholangiopancreatography (ERCP) was first described by McCune *et al*[1] at George Washington University in 1968. Superselection of difficult bile ducts contributes to a higher incidence of adverse events, as well as increased radiation exposure for patients and endoscopists[2,3]. Recent studies have shown that even low doses of radiation may induce carcinogenic effects[4]. The radiation dose is one of the recommended quality indicators for ERCP[5,6]. Furthermore, injection of a contrast medium is considered a risk factor for post-ERCP pancreatitis and cholangitis[7]. Therefore, developing new technologies to enhance the efficacy and safety of ERCP is urgent.



Preoperative three-dimensional (3D) imaging is widely used for planning in interventional radiosurgery. Three-dimensional computed tomography (3D-CT) has been utilized in transcatheter arterial chemoembolization (TACE), and allows for better visualization of small vessels[8,9]. Transjugular intrahepatic portosystemic shunt (TIPS) combines preoperative 3D-CT images with images taken at the time of intervention, and has demonstrated a significant reduction in operation times and radiation doses[10]. Three-dimensional imaging is also beneficial in guiding therapeutic ERCP[11], as it allows easier identification of bile duct anatomy and guides intraoperative navigation, reducing necessary radiation dose and operation time with improved safety[11]. For example, biliary stent placement *via* ERCP in the setting of indeterminate biliary stricture, the X-ray exposure time was reduced from 8.1 min to 35.1 min. However, current 3D biliary imaging does not have good real-time fusion with intraoperative images.

Here, we explored the feasibility of real-time continuous image-guided ERCP, which overcomes the influence of intraoperative respiratory motion and provides an accurate navigation method. Preoperative 3D-CT bile duct sequences were registered and fused with real-time 2D images from the C-arm taken during ERCP; this strategy may improve the quality of ERCP.

MATERIALS AND METHODS



Study population

This was a single-centered prospective observational study of patients receiving ERCP at a tertiary care hospital between July 2021 and March 2022. Twenty patients with cholelithiasis undergoing therapeutic ERCP were recruited. Only patients with a preoperative 3D-CT sequence of the bile duct were eligible. Dynamic 2D images of the bile duct generated by the fluoroscopic C-arm were obtained. Exclusion criteria were: age < 18 y, poor general health, inability to tolerate basic or intravenous anesthesia, uncontrollable coagulation disorder, anticoagulation therapy that could not be discontinued, altered anatomy (*e.g.*, Billroth II gastrectomy or Roux-en-Y anastomosis), pregnancy, and intraoperative

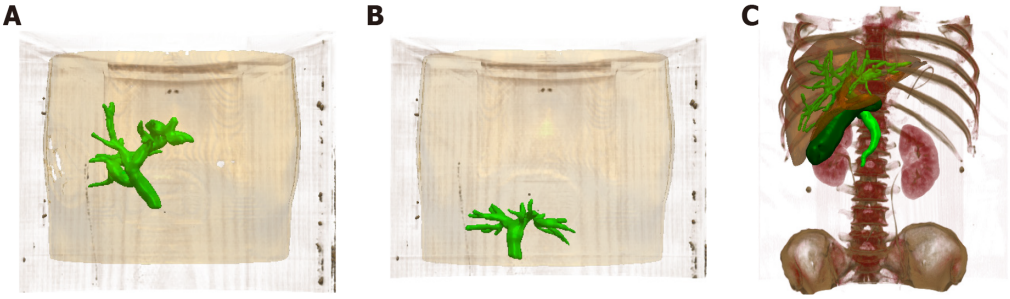
placement of a biliopancreatic stent. Written informed consent was obtained from all patients. The study was approved by the Ethics Committee of the Chinese People's Liberation Army (PLA) General Hospital (No. S2021-415-01) and was conducted per the Declaration of Helsinki.

Human biliary phantom

To verify the accuracy of our 3D/2D registration algorithm, we created 2 3D-printed biliary tract models with different structures to simulate different patients. Enhanced CT scan data of 2 patients with biliary dilatation were inputted into a 3D biomechanics research software tool (Visual 3D, Beijing, China). The operator manually segmented the contours of the biliary tract to acquire surface models. The acquired surface models were inputted into a Stratasys J750 3D printer (Markforged, Watertown, Massachusetts) and printed using resin (Figure 1). The printed phantom was life-sized and hollow, allowing sphincterotomes to enter. The phantom experiment was carried out in the PLA General Hospital operating room (Figure 2). Unlike in clinical experiments, model experiments could be repeated many times to simulate real intraoperative conditions to adjust the algorithm parameters.



CT and fluoroscopic imaging

An iopromide contrast medium (Ultravist 370; Bayer Healthcare, Leverkusen, Germany) was diluted to visualize the biliary tract. All CT scans were performed in the Imaging Department of PLA General Hospital (uCT 510; United Imaging Healthcare, Shanghai, China) with a slice thickness of 1.25 mm and a tube voltage of 120 kV. Patients were asked to remain in the end-inspiratory state for CT scan. To acquire the best alignment transformation, patients were asked to maintain the same pre-operative state at the beginning of surgery. Then, fluoroscopy was performed and the image was defined as the best matching frame. On the day of the ERCP procedure, the acquired CT scan data were imported into Mimics (Materialise, Belgium) to reconstruct the 3D volume-render models of the biliary tract, liver, gallbladder, and bone. All patients received intraoperative deep sedation. ERCP was performed using a standard endoscope (Olympus Duodenoscope TJF260). When the guidewire was successfully superselected in the bile duct and the contrast agent was injected into the duct, the C-arm system performed 1 consecutive respiratory cycle of fluoroscopy around the patient, producing approximately 20 images which were transmitted in real time to our image navigation system.

CT co-registration and fusion with the fluoroscopic image

During the registration between CT and X-ray fluoroscopic images, the CT image was aligned with X-ray fluoroscopy through common features. For the biliary phantom, the registration fiducials were extracted from the CT and X-ray images, respectively, to get rigid transformation, by which the 3D biliary model segmented from CT was projected onto the X-ray fluoroscopic image to finish the overlap of biliary roadmapping. The biliary ducts were observed with X-ray images without contrast agents during model experimentation (Figure 3). After the 3D/2D registration was completed, the biliary ducts segmented from CT were projected onto the X-ray image, and the validity of the registration was judged according to the edge blending effect.

The bone, liver, gallbladder, and biliary tract were segmented by a 3D-UNet model based on preoperative CT data (Figure 4). Afterward, the Medical Imaging Interaction Toolkit was used to extract 2D bone structures. Mimics software (Materialise, Leuven, Belgium) was used to extract 3D and 2D biliary centerlines for analysis. Finally, 3D/2D registration based on bone structures was performed to achieve effective fusion of the 3D biliary model and the best matching frame (Figure 3).

The respiratory motion of the patient during the operation affects fusion accuracy. Some researchers have estimated the patient's respiratory state by extracting diaphragm data in real time[12-15]. The diaphragm-based method not only requires manual annotation, but also cannot guarantee real-time performance, thus prolonging the operation time and increasing X-ray radiation exposure. The method based on X-ray image centroid extraction was used in the current study to estimate the respiratory state [9] and monitor the motion change between frames through X-ray image gray distribution. The respiratory motion curve was acquired and used to complete continuous compensation for the fluoroscopy sequence, and real-time biliary roadmapping projected onto X-ray fluoroscopy was completed. This 3D/2D image registration technology is available in the current intraoperative imaging

system takes approximately 60 s. Our method has a fast calculation speed and is convenient to operate, features that aid in real-time navigation.

Data collection

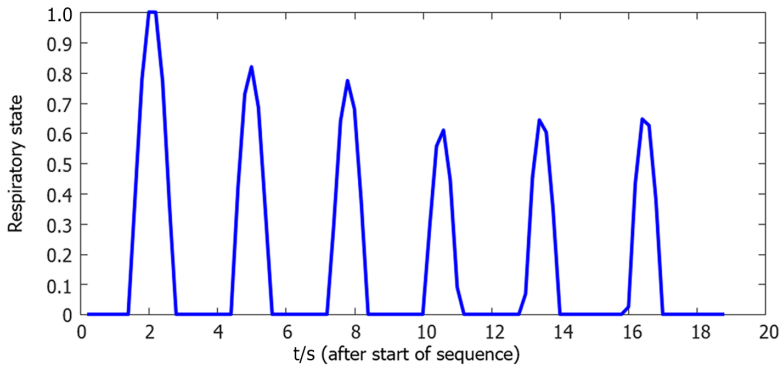
Quantitative data included the registration error and the tracking error (TE). The registration error was calculated as the mean square error (MSE) between the projection of the 3D and 2D centerline. After finishing respiratory compensation and projecting, the mean MSE was set as the TE. Qualitative parameters included image quality and real-time fusion rates for both preoperative and intraoperative images.

Definitions

Image-guided ERCP: Image quality was defined as "good" if the 3D-CT and fluoroscopic images of the bile duct filled by a contrast medium were visible. The outcome of real-time fusion rates was assessed by the degree to which the bile duct in the fluoroscopic mode matched perfectly with the 3D-CT biliary imaging.

Statistical analysis

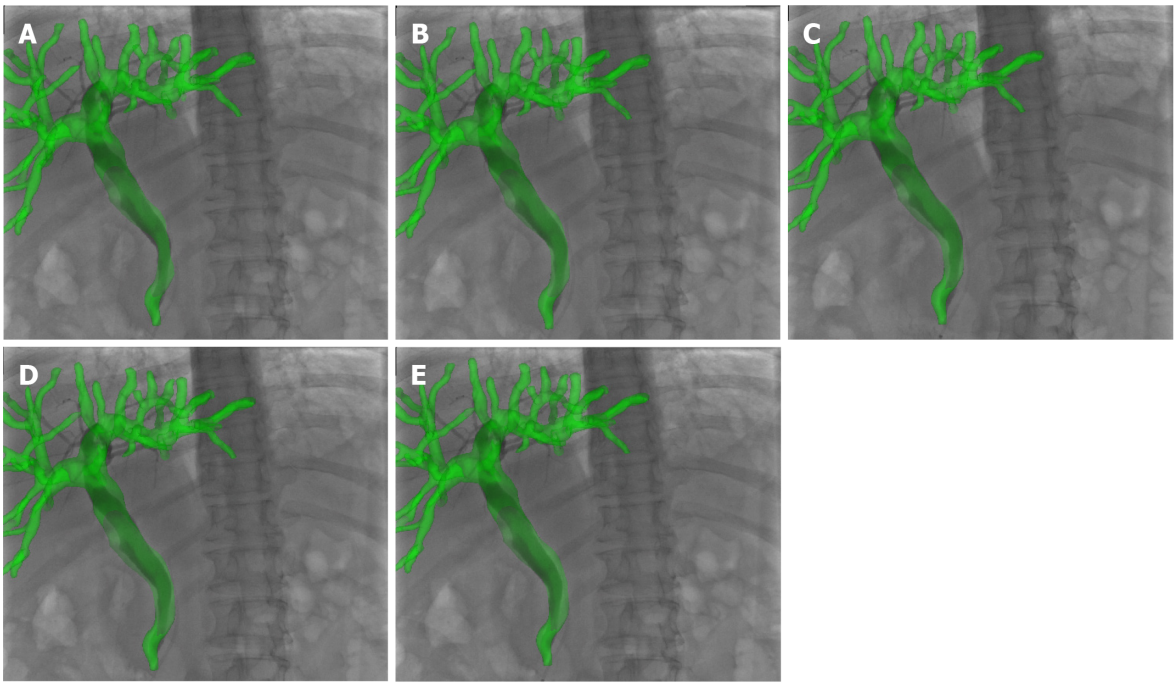
Data were assessed for normality, and appropriate descriptive statistics were calculated and expressed as mean ± standard deviation (SD) and frequency (percentages). Data were analyzed using SPSS version 22 (IBM Corp., Armonk, NY, United States).



RESULTS

Image-guided ERCP had a mean registration error of 0.46 mm ± 0.13 mm and a TE of 0.64 mm ± 0.24 mm. For patients, the biliary model was projected onto the X-ray based on 3D/2D registration (Figure 5), and the respiratory motion curve was estimated through a continuous X-ray fluoroscopy sequence (Figure 6). Continuous biliary roadmapping guidance was acquired (Figure 7). Our navigation system was performed in the operating room (Figure 8), and it provided image-based guidance in multiple patients (Figure 9). Image quality was good in all 18 cases and CT to X-ray fluoroscopic image registration and fusion were technically feasible, with an average fusion rate of 88% (Supplementary material).

DISCUSSION



In the current study, continuous image guidance for ERCP based on 3D/2D registration was evaluated, and we found that this strategy may be an effective means of real-time localization of the bile duct.

The prognosis of hilar cholangiocarcinoma (HCCA) is extremely poor, and surgery is the only radical treatment modality. However, most patients present with an unresectable tumor or cholangitis, high bilirubin, and insufficient volume of the residual liver; as such, biliary drainage by ERCP is often best

guidance for biliary stenting in patients with HCCA, but do not achieve real-time fusion of 3D images with 2D fluoroscopic images or display guidewire or sphincterotomes in three dimensions[16-19]. Our technology can obtain 3D models of the biliary duct, tumor, and hilar vessels through preoperative magnetic resonance imaging/CT segmentation. The registration between preoperative 3D models and intraoperative 2D X-ray images was completed based on the centerlines of the biliary ducts, and 3D models were projected onto X-ray images for display. Meanwhile, based on the respiratory compensation method, a continuous fusion between 3D models and the X-ray image sequences was achieved, and real-time guidance was realized through graphics processing unit acceleration. We believe that our method may provide physicians with more visual information during surgery and

effectively improve the operability of the intervention.

The present study reports real-time fusion of preoperative 3D-CT images with the 2D fluoroscopic images during ERCP. The radiation dose required for the registration between 3D-CT and fluoroscopic image can be considered negligible compared with the total radiation dose for difficult ERCP procedures. In addition, image registration was completed in an average time of 1 min, with a minimal overall increase in total operation time. Therefore, with the real-time visual aid during ERCP, it is likely that less radiation, contrast medium, and operative time may be required during the navigation.

Furthermore, our methods estimated the respiratory state better than the classical diaphragm extraction method[17]. Since the diaphragm is incomplete or invisible during ERCP in some patients, the applicability and robustness of our method are better based on image gray distribution. Furthermore, this method can achieve a more accurate estimation of the respiratory state of the biliary tract, thus ensuring better fusion of 3D-CT and 2D X-ray images. The main reason for this is that the respiratory motion of the diaphragm can reflect well upon the upper edge of the liver, but cannot directly represent the motion of the biliary tract. Experimental results also proved that our method is more accurate for biliary motion estimation of patients under free breathing. Compared with the TE of the diaphragm-based method, based on our cholangiography image fusion results, TE was relatively low (1.68 mm ± 0.34 mm *vs* 0.64 mm ± 0.24 mm), providing more accurate guidance. As shown in Figure 10, the respiratory state estimation based on our method was smoother and closer to the true breathing curve, which ensures the stability of image-guided navigation. Moreover, our method is simpler and faster to compute and process intraoperative X-ray fluoroscopic image sequences in real-time. Conversely, the diaphragm-based method requires real-time segmentation of the diaphragm whether manual or network methods are used, which represents a complex task and ultimately leads to an increase in operation time and radiation dose.

There are further implications of our technology in the context of other minimally invasive procedures such as TACE, TIPS, and spine surgery[8-10,20]. Coronavirus disease-2019 (COVID-19) had devastating impacts on healthcare system operations. The pandemic disrupted normal workflow of spine surgeries, restricting and postponing elective procedures[20]. This disruption may have resulted in the prolonged impairment of patients who were forced to postpone their procedures. Minimally invasive surgery and perioperative telemedicine are inevitable trends in spine surgery after COVID-19. Spine surgery is usually completed under the guidance of X-ray images, and physicians need to conceive the 3D structure of the patient's spine based on clinical experience. The spine is different from the soft liver and there is no respiratory interference; however, the similarity of the structure between the joints and the overall length makes surgery more difficult to perform only under the guidance of X-ray images. Meanwhile, the increase in operation time has also caused longer waiting periods for treatment. Our method can extract the 3D spine structure from preoperative CT and complete 3D/2D registration through the bone structure line, achieving the fusion of 3D information with intraoperative X-ray images. This technology could help physicians better localize lesions and enhance visual perception of depth. Fusion of 3D/2D imaging could also help physicians, especially those with insufficient clinical experience, to observe the patient's spine structure more intuitively and improve surgical efficiency. In summary, the number of spinal surgeries increased following COVID-19 and has continued to rise; our technology may help the hospital to perform more operations and allow patients to receive timely and effective treatment.

COVID-19 has also been associated with an increased risk for ischemic and hemorrhagic strokes[21], conditions often treated with a vascular intervention procedure very similar to TACE that is achieved by embolizing the vessels connected to the aneurysm. Unlike liver vessels, intracranial vessels are not affected by respiratory motion and remain static with the use of X-ray images for guidance. However,

intracranial vessels are generally thin and have multiple branching structures, and thus the risks associated with intracranial surgery are high. Surgeons require more clinical experience to ensure the accuracy of the surgery; otherwise, they may injure other blood vessels or tissues and cause secondary harm to the patient. Our technology can extract data regarding blood vessels connected to the lesion (*e.g.*, aneurysm) before the surgery and guide the surgeon intraoperatively through high-precision registration and fusion. Given the risk of intracranial vascular intervention procedures, our technology could display the vessels around the catheter and render them in different colors to remind the surgeon to be cautious, thus benefiting the safety of the procedure. We believe that our technology may have potential clinical value in treating cerebrovascular diseases and could precisely treat ischemic and hemorrhagic strokes associated COVID-19.

CONCLUSION

Our image-guided ERCP strategy was fully validated in models that may be useful in cannulating specific biliary ducts in patients with complex biliopancreatic diseases such as HCCA. However, clinical studies are still needed to determine if this new approach could improve technical success while reducing radiation exposure and contrast agent administration during ERCP.

ARTICLE HIGHLIGHTS

Research background

Three-dimensional (3D) imaging is beneficial in guiding therapeutic endoscopic retrograde cholangiopancreatography (ERCP), reducing the radiation dose and procedure time while increasing overall procedure safety. However, current 3D biliary imaging does not have good real-time fusion with intraoperative images.

Research motivation

We explored the feasibility of real-time continuous image-guided ERCP, which was shown to overcome the influence of intraoperative respiratory motion and provides an accurate navigation method.

Research objectives

To explore the feasibility of real-time continuous image-guided ERCP.

Research methods

We simulated an ERCP environment using an experimental biliary phantom with the aim of designing a navigation system; this system was further tested in patients undergoing ERCP.

Research results

Continuous image-guided ERCP was applied in the biliary phantom with low registration and tracking errors. This 3D/2D registration accurately transformed preoperative 3D biliary images to each image in the X-ray sequence in real-time.

Research conclusions

Continuous image-guided ERCP may be an effective approach to assist the operator and reduce the use of X-ray and contrast agents.

Research perspectives

Clinical studies are needed to determine if this image-guided ERCP strategy could improve technical success while reducing radiation exposure and contrast agent administration during ERCP.

Abstract

BACKGROUND

The efficacy of conversion therapy for patients with unresectable hepatocellular carcinoma (HCC) is a common clinical concern.

AIM

To analyse the prognostic factors of overall survival (OS) in patients with unresectable HCC who received conversion therapy.

METHODS

One hundred and fifty patients who met the inclusion criteria were enrolled and divided into a training cohort (n = 120) and a validation cohort (n = 30). Using the independent risk factors in the training cohort, a nomogram model was constructed to predict OS for patients treated with transarterial chemoembolization following hepatic resection. The nomogram was internally validated with the bootstrapping method. The predictive performance of nomogram was assessed by Harrell's concordance index (C-index), calibration plot and time-dependent receiver operating characteristic curves and compared with six other

conventional HCC staging systems.

RESULTS

Multivariate Cox analysis identified that albumin, blood urea nitrogen, gamma-glutamyl transpeptidase to platelet ratio, platelet to lymphocyte ratio, macrovascular invasion and tumour number were the six independent prognostic factors correlated with OS in nomogram model. The C-index in the training cohort and validation cohort were 0.752 and 0.807 for predicting OS, which were higher than those of the six conventional HCC staging systems (0.563 to 0.715 for the training cohort and 0.458 to 0.571 for the validation cohort). The calibration plots showed good consistency between the nomogram prediction of OS and the actual observations of OS. Decision curve analyses indicated satisfactory clinical utility. With a total nomogram score of 196, patients were accurately classified into low-risk and high-risk groups. Furthermore, we have deployed the model into online calculators that can be accessed for free at https://ctmodelforunresectablehcc.shinyapps.io/DynNomapp/.

CONCLUSION

The nomogram achieved optimal individualized prognostication of OS in HCC patients who received conversion therapy, which could be a useful clinical tool to help guide postoperative personalized interventions and prognosis judgement.

Key Words: Hepatocellular carcinoma; Conversion therapy; Nomogram; Inflammation; Transarterial chemoembolization

Core Tip: We developed and validated a prognostic nomogram based on inflammation-related biomarkers for patients with unresectable hepatocellular carcinoma after conversion therapy. The proposed conversion therapy model shows increased accuracy, good clinical utility, and better prognostic performance compared with conventional staging systems. Based on the total predictive risk scores, the patients were classified into two groups: low-risk (score < 196) and high-risk group (score ≥ 196), to guide postoperative adjuvant interventions and follow-ups. Furthermore, we have made this prognostic nomogram online for free use (https://ctmodelforunresectablehcc.shinyapps.io/DynNomapp/).

INTRODUCTION

Hepatocellular carcinoma (HCC), the most common type of primary liver cancer, ranks as the sixth most prevalent malignancy and third leading cause of cancer-related deaths worldwide[1]. More so than other cancers, hepatitis B virus (HBV) infection is a hallmark of HCC, with 70%-90% of diagnoses occurring with a background of cirrhosis in highly prevalent Asian countries[2]. Hepatic resection (HR) is deemed the most efficacious therapeutic option for patients diagnosed with early to intermediate stages of HCC. Unfortunately, the majority of Chinese patients with HCC are diagnosed at intermediate or advanced stages with massive or multifocal lesions. Nevertheless, HR is possible for a minority of carefully selected patients with the help of a "conversion therapy" strategy, which refers to conversion of an unresectable HCC to achieve adequate tumour shrinkage and downstaging to undergo HR. However, only a limited number of meticulously screened patients with intermediate or advanced stage HCC qualify for HR.

As per the Barcelona Clinic Liver Cancer (BCLC) staging system, transarterial chemoembolization (TACE) is recommended as the first-line treatment for intermediate stage HCC and has been extensively investigated and widely acknowledged as an effective approach for conversion therapy[3]. Previous studies have demonstrated that HR after local treatments, such as TACE, hepatic artery infusion chemotherapy and radiotherapy with or without other systemic therapeutic measures, can improve tumour shrinkage as well as downstaging. Moreover, these treatments have been shown to enhance patient survival rates without causing significant complications[4-7]. While TACE could potentially

provide surgical options to previously ineligible HCC patients, its high incidence of short-term recurrence remains a significant challenge for conversion therapy. Meanwhile, active conversion strategies to increase the volume of future liver remnant and planning for patients who cannot achieve R0 resection are worth greater consideration. Thus, the development of a validated clinical risk score based on preoperative indices to assess those at high risk of recurrence and death may help formulate optimal management strategies and prevent disease progression.

Links between inflammation and the development of cancer are well established, and HCC is one of the most classic inflammation-linked tumours. During liver inflammation, inflammatory cells and mediators are present before hepatocarcinogenesis and prompt the malignant activity of cancer cells. Additionally, a persistent cancer-related inflammatory microenvironment leads to immune suppression, which promotes the development of HCC[8]. Recently, numerous previous studies have indicated that preoperative inflammatory biomarkers can be capable of predicting HCC prognosis after HR[9,10]. A previous study by Wang *et al*[9] assessed the prognostic value of inflammation-related markers prior to surgery and demonstrated their high effectiveness in predicting survival after surgical resection of HCC. In addition, the researchers concluded that two inflammation-related markers, gamma-glutamyl transpeptidase (GGT) to platelet ratio (GPR) and neutrophil to lymphocyte ratio (NLR), were independently associated with prognosis. However, it is unclear whether preoperative inflammatory biomarkers have a high efficacy in predicting the overall survival (OS) of unresectable HCC patients following conversion therapy.

Nomograms have recently been used as an easy-to-operate predictive tool in HCC and have compared favorably to traditional tumour staging systems[10,11]. However, studies focusing on inflammatory biomarkers for the prognosis of HCC treated with TACE following HR are rare. Therefore, the aim of this study was to develop a conversion therapy model (CT model) that combined clinical factors, tumour radiologic features, inflammation biomarkers and TACE strategy for prognosis in patients with unresectable HCC successfully treated with conversion therapy. A browser-based calculator was developed to conveniently help guide individualized follow-up. A precise estimation of OS prognosis can assist clinical surgeons in selecting more appropriate therapeutic measures for recurrent patients through risk-benefit analysis.

MATERIALS AND METHODS

Study population and design

This study was conducted in accordance with the Declaration of Helsinki and approved by the Institutional Review Board of Ethical Committee of the Third Affiliated Hospital of Sun Yat-sen University (No. II2023-027). Due to the retrospective design of this study, written informed consent from patients was waived. Consecutive Chinese adult individuals with pathologically confirmed primary unresectable HCC who were treated with TACE following HR in our institution from January 2011 to July 2020 were enrolled. The inclusion criteria were as follows: (1) Age between 18 years and 80 years; (2) pathologically proven HCC; and (3) unresectable HCC according to the Chinese expert consensus and acceptance of TACE as the conventional therapy following HR[3]. The exclusion criteria were as follows: (1) Extrahepatic metastasis; (2) history of other malignancies; (3) previous anticancer therapy; (4) current or recent system infection disease and incomplete clinical data; and (5) death or loss to follow-up within 30 d after resection. One hundred fifty patients from our center were included in this study and randomly assigned to a training cohort (n = 120) and a validation cohort (n = 30). The flow chart of patient selection is shown in Supplementary Figure 1.

Data collection and preoperative examination

For each patient, the following clinical parameters were collected: (1) Preoperative patient characteristics (age, sex, factor of HCC, aetiology of HCC, ascites, and Child-Pugh class); (2) TACE technique [conventional-TACE (cTACE) or drug eluting bead-TACE (DEB-TACE)] and number of TACE treatments; (3) baseline laboratory data, including alpha fetoprotein (AFP) level, white blood cell count, haemoglobin level, platelet count, neutrophil count, lymphocyte ratio, monocyte ratio, neutrophil ratio, aspartate aminotransferase (AST) level, alanine aminotransferase level, GGT level, albumin (ALB) level, total bilirubin level, blood urea nitrogen (BUN) level, serum creatinine level, urea level and prothrombin time (PT); (4) inflammation biomarkers, including GPR, NLR, lymphocyte to monocyte ratio, prognostic nutritional index, platelet to lymphocyte ratio (PLR), systemic immune inflammation index, neutrophil times GGT-to-lymphocyte ratio, AST to platelet ratio index, AST to neutrophil ratio index, and AST (the detailed formulas of inflammation biomarkers are summarized in Supplementary Table 1); (5) baseline tumour radiologic features [tumour number, largest tumour diameter, tumour capsule, macrovascular invasion (MVI)]; and (6) surgical factors (resection margin and blood transfusion).

TACE procedure and HR

The cTACE or DEB-TACE procedure was performed according to our previously reported protocol[12]. Repeated TACE was implemented according to a multidisciplinary treatment board (consisting of

interventional radiologists, liver surgeons, and medical oncologists) during the follow-up periods and after in-depth discussion with the patient. HR was performed according to the liver surgeons' assessment that the unresectable HCC had transformed into radically operable HCC. HR was performed by clinicians who possessed more than ten years of experience in hepatectomy. Under general anesthesia, HR was conducted through an L-shaped laparotomy or bilateral subcostal incision with a midline extension. Intraoperative ultrasound (US) was performed as standard practice to assess tumor burden, liver remnant, and resection margin[13]. Curative resection was defined as complete remove of all tumor nodules with no residual tumor margin (R0 resection), which was confirmed through pathological examination.

Follow-up and assessment

All patients were monitored in the first month post HR, then at three-month intervals for the first two years, and bi-annual assessments thereafter. During each follow-up, routine blood tests, liver function tests, AFP and imaging examinations (abdominal contrast-enhanced magnetic resonance imaging and computed tomography) were performed. Follow-up ended in July 2022. OS was described as the period from the initial TACE treatment to death attributable to any cause, and patients alive at the end of follow-up were recorded as censored.

Statistical analysis

The statistical analyses were conducted using R software (Version 4.2.1, http://www.r-project.org). Categorical variables are presented as *n* (%) and were compared using the chi-square test or Fisher's exact test. Continuous variables are reported as the mean ± SD, compared by Student's *t* test, or median (interquartile range, IQR), compared by the Mann-Whitney *U* test. We determined the optimal cut-off value for continuous variables and inflammation biomarkers, except AFP and tumour diameter, based on the outcome of OS among all patients, using the "surv_cutpoint" function form the "survminer" R package. OS was calculated using the Kaplan-Meier method, and the log-rank test was used to construct survival curves. Univariate and multivariate Cox proportional hazard regression were conducted to select the independent factors of OS. All factors with $P < 0.1$ in univariate Cox regression were selected for multivariate Cox regression. The nomograms were created using multivariate analysis in the training cohort. The final model selection for the nomograms was determined by a backwards step-down process with the Akaike information criterion.

The predictive performance was measured by the concordance index (C-index) and time-dependent area under the curve (AUC). To assess the clinical utility of the nomogram, decision curve analysis (DCA) was performed by quantifying the net benefits relative-e to six other conventional HCC staging systems (including BCLC[14], American Joint Committee on Cancer Tumour-Node-Metastasis eighth edition (AJCC TNM 8th)[15], China liver cancer staging (CNLC)[16], Japan integrated staging (JIS)[17], Cancer of the Liver Italian Program (CLIP)[18] and Okuda staging system[19]). The total score of nomogram was used to categorize patients into low-risk and high-risk groups using X-tile[20]. A 2-sided *P* value of less than 0.05 in multivariate Cox regression was considered statistically significant.

RESULTS

Baseline characteristics

A total of 150 patients were recruited in this study and randomly divided into training (n = 120) and validation (n = 30) cohorts in an 8:2 ratio. The baseline characteristics of patients in the training and validation cohorts are summarized in Table 1. Among all patients, the mean age was 52.1 years (SD: 11.9), 128 (85.3%) patients were male, and 134 (89.3%) patients were HBsAg positive. Regarding TACE techniques, a total of 100 (66.7%) patients received cTACE therapy. In terms of surgical aspects, a resection margin larger than 1 cm was present in 133 patients (88.7%). Fifty-two patients (34.7%) required a blood transfusion during the perioperative period. The median size of the largest intrahepatic tumours was 62.5 mm (range: 10.0-191.0), and 100 (66.7%) were larger than 5.0 cm. More than half of the patients (n = 96, 64.0%) were with solitary tumour. Tumour radiologic features showed that well-defined tumour capsule, satellite nodules, and MVI were observed in 110 (73.3%), 36 (24.0%) and 68 (45.3%) patients, respectively. There were no statistically significant differences in baseline clinicopathological features between the training and validation cohorts.

Overall survival

In this study, the median follow-up was 31.5 (range: 4.0-112.0) months. The median survival of the entire cohort was 54 [95% confidence interval (CI): 42-95] mo (Figure 1A). The 1-, 2-, and 3-year OS rates for the training and validation cohorts were 87.5%, 49.3%, 44.2%, and 83.3%, 66.7%, 53.3%, respectively (Figure 1B and C). There was no significant difference observed in OS between the training and validation cohorts [mean OS 37.9 (range, 4-112) mo *vs* 38.0 (range, 5-93 mo, P = 0.7].

Table 1 Demographics and clinical characteristics of hepatocellular carcinoma patients

Variables	Training cohort (*n* = 120)	Validation cohort (*n* = 30)	Overall cohort (*n* = 150)	*P* value
Patient factors				
Age [yr, mean (SD)]	51.5 (12.1)	54.4 (10.9)	52.1 (11.9)	0.419

Independent risk factors and development of the prognostic nomogram

Univariate and multivariate Cox regression analyses were performed in 120 patients from the training cohort to determine the risk factors associated with OS (Supplementary Table 2). As previously described, the optimal cutoff values for inflammation biomarkers were recorded (Supplementary Table 3). Briefly, multivariate analysis identified that preoperative ALB level, BUN level, GPR, PLR, MVI and tumour number were independent risk factors associated with OS (Figure 2). All of these significant independent factors of OS were incorporated into the nomogram (Figure 3A). In addition, a mobile online tool was built to facilitate clinical application, available at https://ctmodelforunresectablehcc.shinyapps.io/DynNomapp/ (Figure 3B).

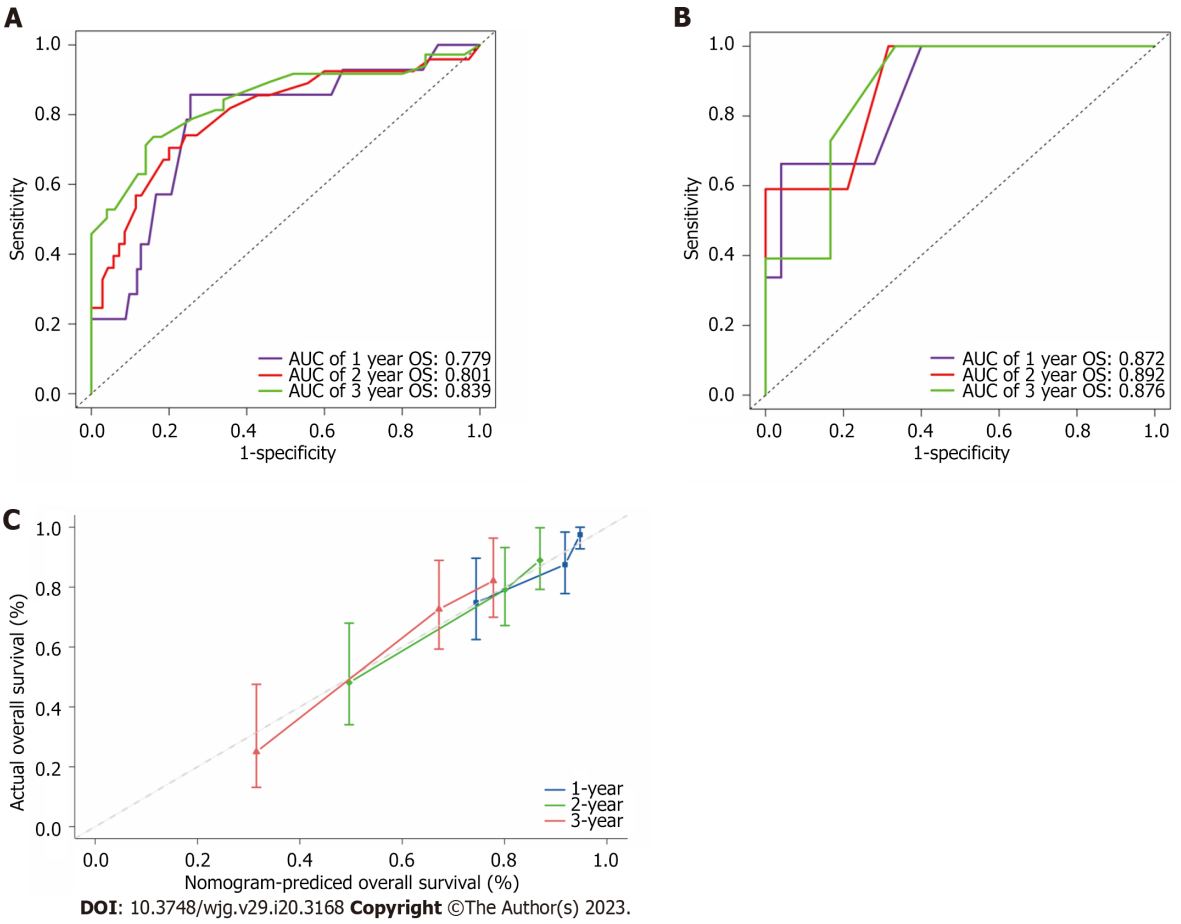
Validation of the prediction CT model



Bootstrapping with 1000 resamples in the primary training cohort revealed good predictive performance for OS, resulting in a C-index of 0.752 (95%CI: 0.688-0.815). The AUC in predicting the 1-, 2-, and 3-year OS rates were 0.779 (95%CI: 0.0.646-0.912), 0.801 (95%CI: 0.693-0.908) and 0.839 (95%CI: 0.748-0.931) in the training cohort and 0.872 (95%CI: 0.682-0.951), 0.892 (95%CI: 0.753-0.974) and 0.876

(95%CI: 0.727-0.962) in the validation cohort, respectively (Figure 4A and B). Accordingly, the C-index in the validation cohort reached 0.807 (95%CI: 0.705-0.908), while the calibration plot for the probability of OS at 1, 2, and 3 years depicted a favorable concordance between the predicted and actual outcomes (Figure 4C).

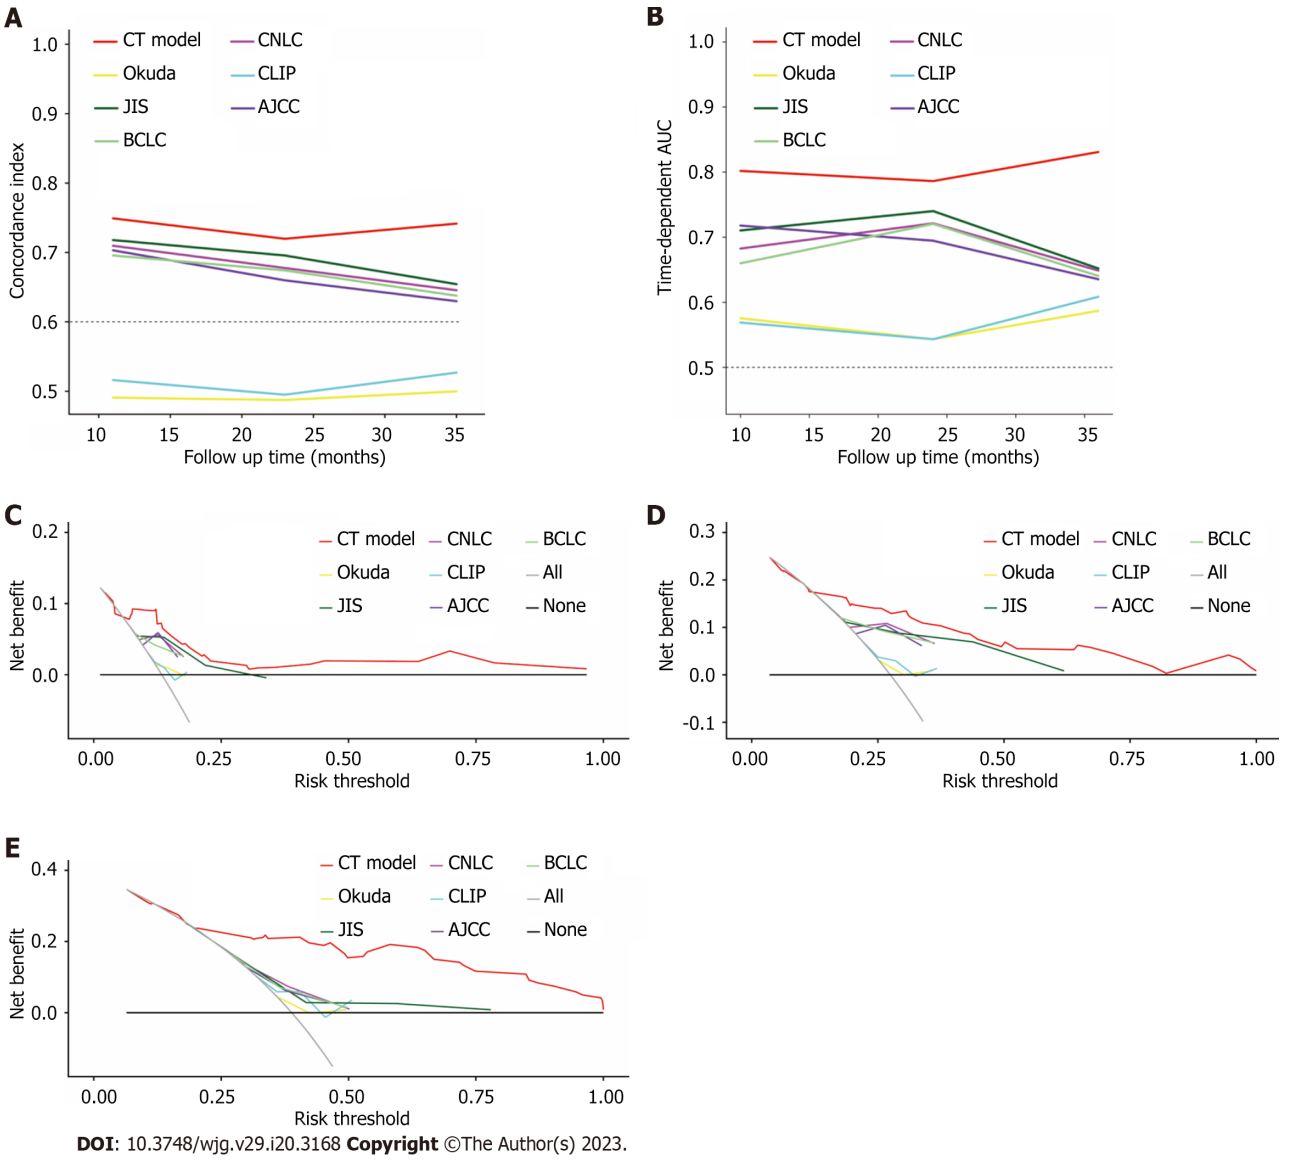
OS: Overall survival; AUC: Area under the curve.

Comparison of model predictive performance



The discrimination power of the nomogram and common staging systems were compared by the C-index and time-dependent AUC (1, 2, and 3 years). In both the training and validation cohorts, the predictive performance of the CT model was superior to that of the other six conventional HCC staging systems ($P < 0.01$, Figure 5A and B, Supplementary Table 4). DCA indicated a good net benefit compared with six other conventional HCC staging systems at 1, 2 and 3 years after conversion therapy in the training cohort (Figure 5C-E).

Risk stratification based on nomogram scores and prognostic assessment

The patients were categorized into two groups based on their overall predictive risk score: Low risk (score < 196) and high risk (score ≥ 196). The distribution of clinical features and corresponding risk scores in each patient are presented in Figure 6A. The OS curves exhibited significant discrimination between the low-risk and high-risk groups among the entire ($P < 0.001$), training ($P < 0.001$) and validation ($P = 0.041$) cohorts (Figure 6B-D). Additionally, given that inflammation biomarkers are associated with postoperative prognosis, we found that high values of both GPR and PLR were significantly correlated with worse prognostic outcomes in patients after conversion therapy. The low-GPR group exhibited higher 1-, 2-, and 3-year OS rates compared to the high-GPR group (0.93, 0.69, and 0.54 *vs* 0.79, 0.55, and 0.36, $P = 0.038$). Similarly, the low-PLR group demonstrated greater 1-, 2-, and 3-year OS rates in contrast to the high-PLR group (0.92, 0.73, and 0.58 *vs* 0.84, 0.58, and 0.40, $P = 0.01$) (Figure 7A and B). Besides, individuals who exhibited MVI demonstrated an inferior prognosis in contrast to those without vascular invasion (Figure 7C).

DISCUSSION

Conversion therapy is a new therapeutic strategy for individuals diagnosed with HCC at an advanced stage and who may not initially be suitable for radical surgery. Several studies have shown that patients with unresectable HCC who underwent conversion following surgical excision have a much longer OS

than those who received palliative treatments such as TACE[3,6,21]. Furthermore, 5-year survival rates for patients with unresectable HCC after conversion therapy (25%-57%) are comparable to those for patients with resectable HCC (30%-60%)[22]. Previous studies have developed prognostic models using preoperative factors to predict postoperative outcomes of early-stage HCC patients after curative resection that achieved good results[9-11], but it remains unclear in the CT model. In this study, we developed and validated a CT model that could accurately predicts prognosis for patients with unresectable HCC treated with TACE following HR.

The nomogram demonstrated great accuracy in predicting conversion therapy outcomes of patients with unresectable HCC. The nomogram developed in our study achieved AUC of 0.779, 0.801, and 0.839 in the training cohort and 0.872, 0.892 and 0.876 in the validation cohort, which were superior to those of the other six conventional HCC staging systems. DCA was also performed and revealed that the nomograms have good clinical utility in patients with unresectable HCC who received the CT model.

Using the nomogram score, clinicians can classify unresectable HCC patients into low- and high-risk groups. Effective postoperative therapeutic management and intensive clinical follow-up can be guided for high-risk individuals following this strategy. Additionally, a web-based dynamic nomogram provides a well-calibrated tool for predicting future clinical outcomes.

Figure 6 A Heatmap presents the distribution of corresponding risk score and clinical feature in each patient within high and low risk groups. A: It shows that the patients in low-risk group have more favourable prognosis; B-D: Kaplan-Meier survival curves for patients with low and high risk stratified by the total nomogram score in the entire cohort (B), training cohort (C), and validation cohort (D). $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$ was considered significant. ALB: Albumin; MVI: Macrovascular invasion; BUN: Blood urea nitrogen; GPR: Gamma-glutamyl transpeptidase to platelet ratio; PLR: Platelet to lymphocyte ratio; CNLC: China liver cancer staging; CLIP: Cancer of the Liver Italian Program; JIS: Japan integrated staging; BCLC: Barcelona Clinic Liver Cancer; AJCC: American Joint Committee on Cancer.

The present study combined liver and renal function factors, tumour burden and inflammation biomarkers (six significantly independent predictors: ALB, BUN, MVI, tumour number, GPR, and PLR) to establish a more comprehensive model and construct a nomogram CT model that could accurately predict the prognosis for patients with unresectable HCC after conversion therapy. Our findings are consistent with research in previous HCC populations that lower ALB level, MVI presence and multiple tumours were risk factors for long-term survival in patients with unresectable HCC with the CT model [10,23-26].

In terms of clinical utility, the prediction ability of the CT model was significantly improved compared with that of six conventional staging systems (AJCC TNM 8th, CNLC, JIS, CLIP, Okuda, and BCLC staging systems) in both the training and validation cohorts (Figure 5). The conventional staging systems mainly contain factors that may only take certain aspects of the tumour into consideration. Previous studies have noted that inflammatory biomarker combination scores have promising prognostic values in predicting patient survival for different HCC stages in various therapeutic

Figure 7 Kaplan-Meier survival curves for patients with different level of gamma-glutamyl transpeptidase to platelet ratio, platelet to lymphocyte ratio, macrovascular invasion, and blood urea nitrogen in the entire cohort. A: Gamma-glutamyl transpeptidase to platelet ratio; B: Platelet to lymphocyte ratio; C: Macrovascular invasion; D: Blood urea nitrogen.

modalities[27,28], indicating that combining these potential indicators would greatly improve the model's predictive abilities. Meanwhile, the AUC for the prediction of the 1-, 2-, and 3-year OS rates reached 0.755, 0.750, and 0.838 in the training cohort when we only used clinical information (MVI, ALB, tumour number and BUN) to develop a model, and they were unable to perform robustly in the validation cohort (Supplementary Figure 2). Hence, we constructed a nomogram CT model with clinical information (ALB, BUN, MVI, tumour number) and inflammation biomarkers (PLR and GPR).

PLR and GPR have been reported to be risk indicators of prognosis for OS in previous studies[10,29]. Meanwhile, high GPR was also proven to be an independent risk factor for HCC development and recurrence[30-32]. Our findings indicate that the high-PLR (> 84.38) and high-GPR (> 0.38) groups had significantly lower 12-, 24-, and 36-mo survival rates. Since inflammatory factors in the tumor microenvironment are crucial for HCC therapies, this information can assist clinicians in devising follow-up regimens and postoperative therapies for HCC patients at high or low risk of tumor recurrence after hepatectomy.

We also found that BUN was an independent prognostic factor in this study. Renal function impairment represents a clinically significant event in cirrhosis patients[33]. Preoperative renal dysfunction with high levels of BUN may lead to the development of major complications such as intractable ascites and spontaneous bacterial peritonitis (SBP). Moreover, the development of hepatorenal impairment is strongly associated with circulatory dysfunction, which can lead to various complications such as complicated or refractory ascites, SBP, hyponatremia and hepatorenal syndrome, and a high risk of mortality[34]. In clinical practice, serum creatinine concentration is generally used to assess kidney function in patients with liver diseases, which is also a major prognostic factor of cirrhosis included in the Model for End-Stage Liver Disease. However, several reports have shown that BUN levels have greater prognostic accuracy than serum creatinine concentrations[35-37]. In this study, our findings also showed that high BUN levels were related to worse liver function stage and poor OS outcomes (Figure 7D). Further research is needed to better understand this factor in advanced HCC and better classify and manage patients after conversion therapy.

While this nomogram CT model performed well, we do acknowledge a few potential limitations to this study. First, the nomogram was formulated based on a relatively small sample size obtained from

our single institution, which unavoidably led to selection bias. Further prospective and multicenter cohorts are required to evaluate its performance. Second, statistical power may be limited because several routine clinical variables were not included in our study. Because our study was retrospective, there were variations in performance score, body mass index, dosage and type of injected drugs during TACE, as well as postoperative treatments, among patients. To further bolster our findings, it is necessary to conduct larger and multicenter prospective cohorts. Hence, we will undertake additional research that incorporates more complete clinicopathological information, treatment details, and postoperative treatment modalities to improve the predictive performance of our model. Third, this study was mainly based on HBV-infected patients. Our results may not be applicable in different geographic regions and aetiologies. Fourth, systematic bioinformatic analyses were not included in this nomogram, which showed excellent predictive ability for early-stage HCC patients[38,39]. We will therefore develop a robust prognostic model that integrates both clinical parameters and multi-omics biomarkers to facilitate an understanding of HCC from a biological perspective and contribute to tailoring therapeutic strategies. Despite these limitations, we believe that our work is meaningful for individualized management in HCC patients following conversion therapy.

CONCLUSION

We developed and validated a prognostic nomogram combined with inflammation biomarkers for patients with unresectable HCC after conversion therapy. The proposed CT model shows increased accuracy, good clinical utility, and better prognostic performance than conventional staging systems. Furthermore, we have uploaded this prognostic nomogram online for free use (https://ctmodelforunresectablehcc.shinyapps.io/DynNomapp/).

ARTICLE HIGHLIGHTS

Research perspectives

Larger and multicentre prospective cohorts were required to further strengthen our results. We will conduct further investigation that incorporates more complete clinicopathological information, treatment details, and postoperative treatment modalities to improve the predictive performance of our model.

Research conclusions

The nomogram achieved optimal individualized prognostication of OS in HCC patients who received conversion therapy. It could be a useful clinical tool to help guide postoperative personalized interventions and prognosis judgement.

Research results

Multivariate Cox analysis identified that albumin, blood urea nitrogen, gamma-glutamyl transpeptidase to platelet ratio, platelet to lymphocyte ratio, macrovascular invasion and tumour number were the six independent prognostic factors correlated with OS in nomogram model. The C-indices in the training cohort and validation cohort were 0.752 and 0.807 for predicting OS, which were higher than those of the six conventional HCC staging systems (0.563 to 0.715 for the training cohort and 0.458 to 0.571 for the validation cohort). We have deployed the model into online calculators that are freely available at https://ctmodelforunresectablehcc.shinyapps.io/DynNomapp/.

Research methods

All patients met the inclusion criteria were enrolled and divided into training and a validation cohort. Using the independent risk factors in the training cohort, nomogram models were constructed to predict OS for patients treated with transarterial chemoembolization following HR. The nomograms were internally validated with the bootstrapping method. The predictive performance of the nomograms was assessed by Harrell's concordance index, calibration plot and time-dependent receiver operating characteristic curves and compared with six other conventional HCC staging systems.

Research objectives

To develop a nomogram to help guide postoperative personalized interventions and prognosis judgement.

Research motivation

To investigate the prognostic factors of overall survival (OS) in patients with unresectable HCC who received conversion therapy.

Research background

Hepatocellular carcinoma (HCC) is the sixth most common malignancy and the third leading cause of cancer-related mortality worldwide. Hepatic resection (HR) is the best therapeutic option for patients with early- and some intermediate-stage HCC. Unfortunately, the majority of Chinese patients with HCC are diagnosed at intermediate or advanced stages with massive or multifocal lesions. HR is possible for a minority of carefully selected patients with the help of a "conversion therapy" strategy, which refers to conversion of an unresectable HCC to achieve adequate tumour shrinkage and downstaging to undergo HR.

Abstract

BACKGROUND

Irritable bowel syndrome (IBS) is the most prevalent gastrointestinal disorder in

developed countries and reduces patients' quality of life, hinders their ability to work, and increases health care costs. A growing number of trials have demonstrated an aberrant gut microbiota composition in IBS, also known as 'gut dysbiosis'. Fecal microbiota transplantation (FMT) has been suggested as a treatment for IBS.

AIM

To assess the efficacy and safety of FMT for the treatment of IBS.

METHODS

We searched Cochrane Central, MEDLINE, EMBASE and Web of Science up to 24 October 2022 for randomised controlled trials (RCTs) investigating the effectiveness of FMT compared to placebo (including autologous FMT) in treating IBS. The primary outcome was the number of patients with improvements of symptoms measured using a validated, global IBS symptoms score. Secondary outcomes were changes in quality-of-life scores, non-serious and serious adverse events. Risk ratios (RR) and corresponding 95%CI were calculated for dichotomous outcomes, as were the mean differences (MD) and 95%CI for continuous outcomes. The Cochrane risk of bias tool was used to assess the quality of the trials. GRADE criteria were used to assess the overall quality of the evidence.

RESULTS

Eight RCTs (484 participants) were included in the review. FMT resulted in no significant benefit in IBS symptoms three months after treatment compared to placebo (RR 1.19, 95%CI: 0.68-2.10). Adverse events were reported in 97 participants in the FMT group and in 45 participants in the placebo group (RR 1.17, 95%CI: 0.63-2.15). One serious adverse event occurred in the FMT group and two in the placebo group (RR 0.42, 95%CI: 0.07-2.60). Endoscopic FMT delivery resulted in a significant improvement in symptoms, while capsules did not. FMT did not improve the quality of life of IBS patients but, instead, appeared to reduce it, albeit non significantly (MD -6.30, 95%CI: -13.39-0.79). The overall quality of the evidence was low due to moderate-high inconsistency, the small number of patients in the studies, and imprecision.

CONCLUSION

We found insufficient evidence to support or refute the use of FMT for IBS. Larger trials are needed.

Key Words: Fecal microbiota transplantation; Irritable bowel syndrome; Meta-analysis; Systematic review

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: We did not find evidence to support the use of fecal microbiota transplantation (FMT) for irritable bowel syndrome (IBS) patients outside of clinical trials in this systematic review and meta-analysis. We report possible beneficial effects when FMT is delivered by endoscopy (colonoscopy or gastroscopy). FMT appears to be safe compared to placebo in patients with IBS, regardless of route of administration. Further randomised clinical trials are necessary to clarify the effect, if any, of FMT in IBS.

INTRODUCTION

Irritable bowel syndrome (IBS) is the most prevalent gastrointestinal disorder in developed countries, affecting around 11% of the adult population[1]. The condition reduces patients' quality of life, hinders their ability to work, and increases health care costs[2,3]. A diagnosis of IBS is based on symptoms, assessed using the Rome criteria, that include abdominal pain and altered bowel habits combined with the absence of organic or structural causes[4]. The criteria have changed over time and the most recent are the Rome IV criteria[5]. IBS can be sub-categorised as diarrhoea-predominant, constipation-predominant, mixed, or unclassified[5]. In most patients, IBS is chronic, with symptoms that fluctuate

over time.

The pathogenic mechanisms underlying IBS remain more or less unknown. Genetics[6,7], dietary habits[8], post-infectious conditions[9] and psychological mechanisms[10] are all suspected to be involved. In recent years an increasing number of trials have demonstrated an aberrant gut microbiota composition in IBS[11-14], although not all trials report this aberration and descriptions of it vary between studies[15]. The microbial pathophysiology of IBS remains unknown.

Treating IBS poses a challenge; the syndrome probably represents a heterogeneity of disease mechanisms, which makes it difficult to develop effective therapeutic strategies[16]. Understanding the causes of gut dysbiosis in IBS is crucial[17]. Some trials indicate that probiotics and prebiotics can reduce the symptoms of IBS[18,19]. Fecal microbiota transplantation (FMT) might be an effective therapeutic intervention in IBS[16,20].

FMT is the transfer of stool from a healthy donor to a patient[21]. FMT has been described as far back as the fourth century in China[22]. In modern times, the first published FMT treatment is from 1958, when it was used successfully in four patients with pseudomembranous colitis[23]. Pseudomembranous colitis is now known to be caused by *Clostridioides difficile* infection (CDI). Based on subsequent placebo-controlled studies, FMT is now accepted in daily clinical practice for the treatment of recurrent CDI[24]. In addition, FMT is being investigated as a treatment option in a range of other diseases, *e.g.*, metabolic syndrome, inflammatory bowel diseases, hepatic encephalopathy and multiple sclerosis[25]. The most promising results with FMT, apart from treating recurrent CDI, are for the treatment of inflammatory bowel disease[26-28].

FMT donors can be healthy relatives or anonymous donors. The advantages of the latter are the possibility of selecting donors with a high microbiota diversity and to store screened donor stool in freezers, to be made use of for multiple patients[29]. A European consensus report recommends that donors are chosen based on detailed information about illnesses with a presumed link to intestinal dysbiosis and rigorous testing of faecal and blood samples to avoid the transfer of infectious diseases [30].

FMT can be delivered in several ways, including through upper or lower endoscopic procedures, or by a gastro-duodenal or a rectal tube[31]. Additionally, capsules can release the stool in the small intestines and have been used successfully for the treatment of CDI[32-34]. In the treatment of recurrent CDI, the highest cure rates have been reported with repeated treatments delivered through lower endoscopy[35]; FMT has proven highly effective and patients are willing to undergo the treatment[36].

The microbial pathophysiology of IBS is not clearly understood, as microbiota alterations in IBS could either be a cause of the disease or a consequence of intestinal secretion and motility altered by IBS[37]. The prevailing hypothesis is that FMT might correct the dysbiosis associated with IBS[38,39], leading to a reversal or improvement of symptoms. Gut dysbiosis in IBS is characterised by a lower diversity of bacteria in the microbiota and abnormal proportions of specific bacteria as compared to the microbiota of healthy individuals[37,40]. In IBS and in other patient groups, FMT has resulted in increased bacterial diversity[41,42] and the coexistence of donor and recipient microbiota strains up to one year after treatment[43-45]. However, this is a new and developing field of study and the long-term effects of FMT on the microbiota remain largely unknown, not least of all because donor stools contain many things other than bacteria.

There is increasing evidence for a connection between gut dysbiosis and IBS[46,47]. The administration of FMT by various methods has been described in published case reports and abstracts, as compiled in an earlier review[48]. A number of smaller trials have examined the effect of FMT on IBS specifically[49-57], and several randomised controlled trials (RCTs), using different methods of administration, have been published with mixed results[43,44,58-63]. The effect of FMT can be difficult to assess due to the absence of reliable outcome measures and high placebo response rates[64]. The short- and long-term safety of FMT in patients with IBS is currently unclear.

The objectives of this systematic review were to examine the benefits and harms of FMT *vs* placebo (including autologous FMT, *i.e.*, a participant's own faecal material) for the treatment of patients with IBS.

MATERIALS AND METHODS

We conducted a systematic review and meta-analysis following the recommendations from the Cochrane Handbook for Systematic Reviews of Interventions[65]. The systematic review was registered a priori as a protocol[66].

We included RCTs comparing FMT to placebo for the treatment of IBS, regardless of publication status and language of publication. For cross-over trials only data from the first intervention were used. For multi-arm trials only the data from intervention groups relevant to the review were used. We excluded trials with quasi-random designs and cluster RCTs. Trials with mixed disease populations were excluded.

Trials were included if their participants were diagnosed with IBS by a physician or according to accepted, symptom-based diagnostic criteria, such as the Rome III or IV criteria[67] (Supple-

mentary Table 1). We only included trials that had follow-up after FMT for one week or more. Participants were included regardless of their gender and age.

FMT could be administered in different ways and at different frequencies as there was no standardised procedure. Therefore, we included trials irrespective of FMT procedure, in terms of the quantity of faeces used, the form of faeces (fresh or frozen), the route of administration, the frequency of treatment (*i.e.*, single *vs* multiple infusions) and donor selection (relatives or not). Only trials that used the whole gut microbiome from the donor were included. Trials that used a placebo, or autologous FMT as a placebo, were included. Trials that used selective microbial communities were excluded.

Primary outcomes

The primary outcome was the proportion of patients experiencing an improvement of symptoms (patient-reported), as measured by a validated, global IBS symptoms score (*e.g.*, IBS severity scoring system), as defined by each trial's organisers.

Secondary outcomes

Secondary outcomes were the change in quality of life, as measured by a validated quality of life assessment, *e.g.*, IBS-specific quality-of-life (IBS-QoL), the proportion of patients with non-serious adverse events and serious adverse events according to International Conference on Harmonization-Good Clinical Practice, and dropouts due to adverse events. Outcomes were measured after three and six months.

Literature search

We searched Cochrane Central, MEDLINE, EMBASE and Web of Science. No language or publication date restrictions were applied to the searches. The detailed search strategy is provided in Supplementary Table 2.

We searched the following sources from the inception of each database up until 24 October 2022 and placed no restrictions on the language of publication (Supplementary Table 2): Cochrane Central (*via* the Ovid Evidence-Based Medicine Reviews Database, from inception); MEDLINE (*via* Ovid from 1946); and EMBASE (*via* Ovid from 1974).

We also searched for ongoing trials on ClinicalTrials.gov (https://clinicaltrials.gov/) and the World Health Organisation International Clinical Trials Registry Platform (https://trialsearch.who.int/).

The reference lists of all trials identified were then scanned for additional relevant trials. We also contacted the first authors of published and ongoing trials to request recent data or additional data, as needed.

Data collection and analysis

Two independent authors performed the study selection (BL, SIH). Disagreements were resolved by consensus using a third author (AMP). The search results were first screened by title and abstract and subsequently excluded if found non-relevant; the remaining results were screened by full text. Data were extracted independently by two investigators (BL, SIH). Any discrepancies were resolved by consensus using a third author (LLG). An attempt to contact the corresponding author by e-mail was made if data were not available.

A data extraction protocol was developed based on the Cochrane Consumers and Communication Review Group's data and results template and refined accordingly[68]. The following information was extracted from each trial: (1) Author, year of publication, trial design, and study site (country); (2) the mean or median (SD or IQR) change in symptoms, as measured by IBS scoring systems, at the end of the trial; (3) the mean or median (SD or IQR) change in quality of life, as measured by IBS quality of life scoring systems; (4) treatment description (including route of administration, mixed or single donor and fresh or frozen transplant); (5) reported non-serious adverse events and serious adverse events; and (6) dropouts due to adverse events.

Assessment of risk of bias in the studies

The risk of bias was independently assessed by two investigators (BL, FC) using the Cochrane risk of bias tool[69] and the following seven domains were assessed: random sequence generation, allocation concealment, blinding of participants and personnel, blinding of outcome assessment, incomplete outcome data, selective reporting, and other sources of bias (Supplementary Table 3).

The risk of bias for each domain was rated as either 'high', 'unclear' or 'low'. We classified the overall risk of bias in the trials as low if all the bias domains were classified as being at low risk of bias; we classified the overall risk as high if one or more of the bias domains were classified as having an unclear or high risk of bias. Any disagreement was solved by consensus using a third author (LLG).

Data synthesis

We compared the fixed-effects and random-effects estimates of the intervention effect. If the estimates were similar, we assumed that any small-study effects had a minimal impact on the intervention effect estimate. If the random-effects estimate showed a larger statistical effect, we re-evaluated whether it

was reasonable to conclude that the intervention was more effective in the smaller trials. If the larger trials appeared to be conducted with greater methodological rigour, or were conducted in circumstances more typical of the use of the intervention in practice, we reported the results of meta-analyses only from the larger trials.

Based on predictable clinical heterogeneity, we expected that several analyses would show, at a minimum, moderate heterogeneity (I^2 > 30%). For random-effects models precision decreases, and confidence intervals widen, with increasing heterogeneity. We therefore expected the random-effects model would provide the most conservative (and thus a more accurate) estimate of the intervention effect. As such, we planned to report the results of our analyses based on meta-analyses of random-effects models.

Subgroup and sensitivity analysis

We conducted a number of subgroup analyses: fresh *vs* frozen FMT; quantity of FMT; route of administration (upper gastrointestinal tract (*e.g.*, capsulated, nasogastric, nasoduodenal, gastric tube) *vs* colonic (*e.g.*, rectal)); type of donor (single *vs* mixed); frequency of administration (single *vs* multiple); IBS subtypes (diarrhoea-predominant, constipation-predominant, or mixed type).

Statistical analyses

We combined data from individual trials for meta-analysis when the interventions, patient groups, and outcomes were sufficiently similar, using the Review Manager version 5.4.1. Risk ratios (RR) were calculated for dichotomous outcomes with 95%CI. For continuous outcomes, we calculated the mean difference (MD) if all studies reported their outcomes using the same scale, and standardised MD with 95%CI if the studies used different scales to report their outcomes. We extracted data for all randomised participants and all participants with missing outcome data. Missing data were described, including dropouts and reasons for dropout, as reported by the authors.

Heterogeneity was assessed through a systematic examination of forest plots and quantified by calculating I^2 values. The classification of heterogeneity levels was established using the subsequent thresholds: 0%-40% (insignificant), 40%-60% (moderate), 60%-80% (substantial), and > 80% (considerable). Additionally, the *P* value for the chi-squared test was included in the evaluation[66].

The outcomes reported in protocols were compared with published trial reports. In addition, for direct meta-analyses with at least 10 randomised clinical trials, we assessed reporting biases through regression analyses and visual inspection of funnel plots from the pairwise meta-analyses.

Assessing the certainty of the evidence

We used the GRADE approach to evaluate the overall certainty of the evidence and we followed the recommendations of the Cochrane Handbook for Systematic Reviews of Interventions[65]. We classified the certainty of evidence as 'high', 'moderate', 'low', or 'very low'.

High certainty: We are very confident that the true effect lies close to that of the estimate of the effect.

Moderate certainty: We are moderately confident in the effect estimate; the true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different.

Low certainty: Our confidence in the effect estimate is limited; the true effect may be substantially different from the estimate of the effect.

Very low certainty: We have very little confidence in the effect estimate; the true effect is likely to be substantially different from the estimate of the effect.

RESULTS

Trial selection

A search conducted on 24 October 2022 identified 2067 records, which were imported for screening into the computer program Covidence (https://www.covidence.org/). Of these records, 840 were removed as duplicates. We screened the titles and abstracts of the remaining 1227. We excluded 1160 reports as non-relevant. In total, 67 records met the criteria for full-text review.

After reading the full texts, we excluded 45 as they did not fulfil our eligibility criteria. The remaining 22 texts, originating from eight different trials, were included in our systematic review (Figure 1)[43,44,58-63].

Supplementary Table 2 contains the complete set of search terms used in each electronic database.

A summary of the trials can be found in Table 1; a full description of them is provided in Supplementary Table 4.

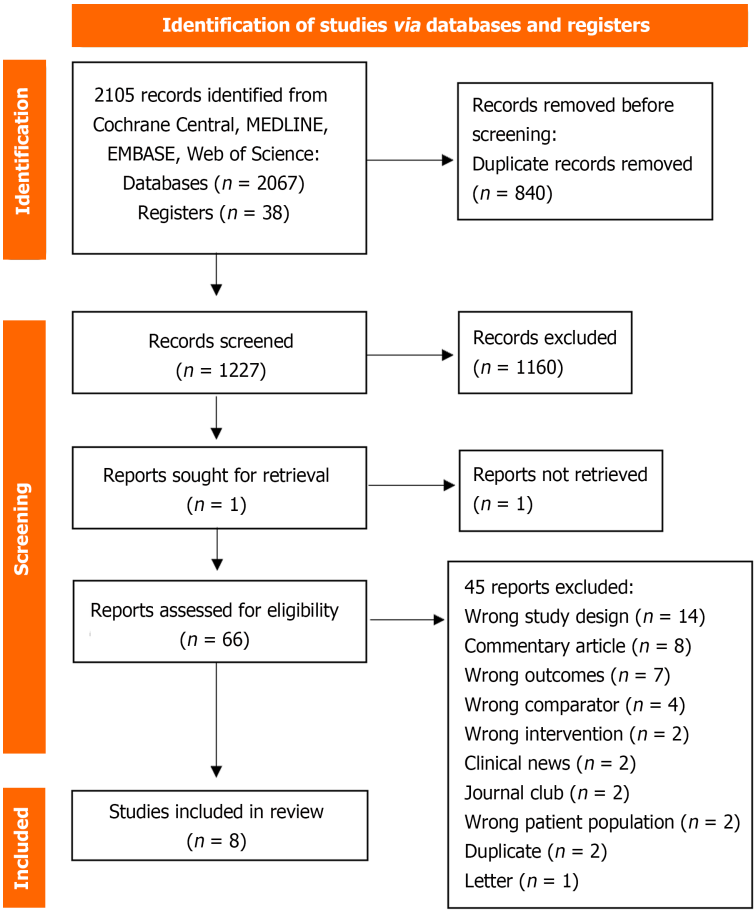

Table 1 Characteristics of randomised controlled trials of faecal microbiota transplantation for treating irritable bowel syndrome

Ref.	Trial design	Country	Sample size	IBS subtypes	Inclusion criteria	Frequency and route of administration	FMT-content	Placebo content	Pretreatment	Number of donors
Aroniadis *et al*[59], 2019	RCT, crossover	United States	48 (25 FMT *vs* 23 placebo)	IBS-D	Moderate-to-severe IBS symptoms (IBS-SSS > 175)	3 d of 25 oral capsules	3 × 25 frozen capsules (0.38 g donor stool/capsule) (Openbiome)	Non-toxic brown pigment	PPI for three days	One donor for one patient (four different donors)
El-Salhy *et al*[60], 2020	RCT, 3 parallel groups	Norway	164 (54/30 gram FMT, 55/60 gram FMT, 55 placebo)	All subtypes	Moderate-to-severe IBS symptoms (IBS-SSS > 175)	Single treatment *via* gastroscope to distal duodenum	Once 30 g or 60 gram of frozen feces in sterile saline solution	Autologous faeces	None	One donor
Halkjær *et al*[43], 2018	RCT, 2 parallel groups	Denmark	51 (25 FMT, 26 placebo)	All subtypes	Moderate-to-severe IBS symptoms (IBS-SSS > 175)	12 d of 25 oral capsules	25 FMT capsules (one daily dose containing approximately 12 g frozen faecal material)	Saline, glycerol and food colouring E150	Bowel cleansing	Donor mix from four donors
Holster *et al*[61], 2019	RCT, 2 parallel groups	Sweden	16 (8 FMT, 8 placebo)	All subtypes	IBS with small amounts of butyrate-producing bacteria	Single treatment *via* colonoscopy to the caecum	30 g frozen stool in sterile saline and glycerol	Autologous feces	Bowel cleansing and 4 mg loperamide	Two donors (three patients received stool from donor 1, the remaining five from donor 2)
Holvoet *et al*[44], 2021	RCT, 2 parallel groups	Belgium	62 (43 FMT, 19 placebo)	IBS-D and IBS-M	Refractory IBS with failure of at least three conventional IBS therapies	Single treatment *via* nasojejunal administration	Fresh feces mixed with saline	Autologous feces	Bowel cleansing	Two donors
Johnsen *et al*[62], 2018	RCT, 3 parallel groups	Norway	83 (26 fresh FMT, 29 frozen FMT, 28 placebo)	IBS-D and IBS-M	Moderate-to-severe IBS symptoms (IBS-SSS > 175)	Single treatment administered into the caecum *via* colonoscopy	50–80 g fresh or frozen feces mixed with saline and glycerol	Autologous feces	Bowel cleansing and 8 mg loperamid	Donor mix from two donors
Lahtinen *et al*[58], 2020	RCT, 2 parallel groups	Finland	51 (25 FMT, 26 placebo)	IBS-D, IBS-M and IBS-U	Patients who remained symptomatic despite receiving conventional treatment	Single treatment administered into the caecum *via* colonoscopy	30 g frozen suspension	Autologous feces	Bowel cleansing	One donor
Singh *et al* [63], 2022	RCT, 4 parallel groups	United States	23 (11 FMT, 12 placebo)	IBS-D	IBS-SSS > 150 or > 175	Single treatment with 19 oral capsules	Capsule contain 0.75 frozen fecal filtrate) (Openbiome)	Glycerol with brown coloring agent	Bowel cleansing	Six donors (unknown if donors were mixed)

FMT: Fecal microbiota transplantation; IBS: Irritable bowel syndrome; IBS-C: Constipation-predominant irritable bowel syndrome; IBS-D: Diarrhoea-predominant irritable bowel syndrome; IBS-M: Mixed irritable bowel syndrome; IBS-U: Unclassified irritable bowel syndrome; RCT: Randomised controlled trials; PPI: Proton pump inhibitors.

Study design and setting

We included eight trials that were published between 2018 and 2022[43,44,58-63]. These were either single-centre trials[44,60-63] or multicentre trials[43,58,59] and were conducted in Belgium[44], Denmark[43], Finland[58], Norway[60,62], Sweden[61] and the United States[59,63].

DOI: 10.3748/wjg.v29.i20.3185 **Copyright** ©The Author(s) 2023.

Figure 1 PRISMA flow diagram for the literature search.

All participants in the trials were diagnosed with IBS by a physician and according to accepted, symptom-based diagnostic criteria (*e.g.*, the Rome criteria)[5]. Participants in the Lahtinen *et al*[58] trial were diagnosed by a gastroenterologist, Aroniadis *et al*[59], Halkjær *et al*[43], Holster *et al*[61], Holvoet *et al*[44], Johnsen *et al*[62] and Singh *et al*[63] all used the Rome III criteria; El-Salhy *et al*[60] used the Rome IV criteria.

Four trials included participants with moderate-to-severe IBS symptoms, indicated by a score of 175 or more on the IBS severity scoring system (IBS-SSS)[43,59,60,62]. We are unsure whether Singh *et al*[63] used a score of 150 or 175 or more on the IBS-SSS, as both are referred to in their article. The remaining three trials used other criteria: Holster *et al*[61] only included participants with small amounts of butyrate-producing bacteria in faecal samples, Holvoet *et al*[44] included participants with refractory IBS who had experienced failure of at least three conventional IBS therapies, and Lahtinen *et al*[58] included participants who remained symptomatic despite receiving conventional treatment.

The trials differed in the IBS subtypes they investigated. All subtypes were included in the trials conducted by El-Salhy *et al*[60], Halkjær *et al*[43] and Holster *et al*[61]. Aroniadis *et al*[59] and Singh *et al*[63] included only diarrhoea-predominant participants. Holvoet *et al*[44] and Johnsen *et al*[62] included diarrhoea-predominant or mixed participants. Lahtinen *et al*[58] included diarrhoea-predominant, mixed or un-subtyped participants.

Characteristics of the interventions

All eight trials used faeces from healthy donors for the FMT. Supplementary Table 5 describes their inclusion and exclusion criteria for donors.

The route of administration varied between the trials. Three trials used colonoscopy[58,61,62], one used gastroscopy[60], one used the nasojejunal route[44] and three used oral capsules[43,59,63].

The frequency of administration varied between trials. El Salhy *et al*[60], Holster *et al*[61], Holvoet *et al*[44], Johnsen *et al*[62], Lahtinen *et al*[58] and Singh *et al*[63] administered FMT just once. Aroniadis *et al*[59] administered a total of three doses across three consecutive days. Halkjær *et al*[43] administered a total of 12 doses across 12 consecutive days.

The volume of FMT administered ranged from approximately 100 mL in the El-Salhy *et al*[60] trial to 300 mL in the Holvoet *et al*[44] trial. The faecal quantity varied from 30 g[58,61] to 50-80 g[62]. The

capsule trials used approximately 28.5 g of minimally processed faecal matter[59], 14.25 frozen faecal filtrate[63] and faecal matter derived from approximately 600 g of faeces[43]. Holvoet *et al*[44] used fresh FMT transplant, Johnsen *et al*[62] used both fresh and frozen FMT transplant, while the remaining trials used frozen FMT transplants[43,58-61,63].

Two trials used a single donor for all FMT treatments[58,60]. Holster *et al*[61], Holvoet *et al*[44] and Johnsen *et al*[62] used two donors. Aroniadis *et al*[59] used four donors, where each participant received a FMT from one donor. Singh *et al*[63] used six donors, where each participant received a FMT from one donor. Halkjær *et al*[43] used a FMT donor mix from four donors.

Six trials included bowel cleansing before transplantation[43,44,58,61-63]. Two trials used loperamide before endoscopy to retain the transplant[61,62]. One trial used proton pump inhibitors (PPI) for the three days prior to the transplantation[59].

Five trials used autologous faeces as an alternative to placebo for the comparison group[44,58,60-62]. In the capsule trials, Aroniadis *et al*[59] and Singh *et al*[63] used placebo capsules with a non-toxic, brown pigment and Halkjær *et al*[43] used placebo capsules made from saline, glycerol and food colouring E150.

Risk of bias in the studies

A summary of the risk of bias assessments is reported in Figure 2 and bias assessments for the individual trials are reported in Supplementary Table 4.

Overall, none of the studies had a high risk of bias in any of the seven dimensions considered. However, five of the eight trials[44,58,60,62,63] had an unclear bias for the blinding of outcomes, and four out of eight[43,58,60,61] had a similarly unclear bias in terms of how they reported the handling of incomplete data. In both cases this unclear bias was primarily due to a lack of information.

Effects of the interventions

A summary of the findings is provided in Table 2 for comparing FMT and placebo in treating IBS. We did not assess publication bias as this review only consisted of eight trials. Furthermore, we chose to report the random-effect models' results despite some of the fixed-effect models being found significant as we did not find any larger trial that was more methodologically rigorous. The significant outcomes of the fixed-effect models were most likely due to the small number of trials available in each analysis and their high heterogeneity.

The GRADE rating for the certainty of the evidence examined was low due to moderate-high inconsistency, small numbers of patients and imprecision.

Primary outcomes

Improvement of symptoms: Eight randomised trials, comprising 484 participants, examined whether IBS symptoms improved after three months. Six trials defined improvement of symptoms as a decrease in IBS-SSS of 50 or more[43,44,59,60,63], while Johnson *et al*[62] defined it as a decrease of more than 75 points. Holster *et al*[61] used the gastrointestinal symptom rating scale-IBS and defined improvement as a change of more than 30%. Sixty-four percent (185/290) of FMT participants experienced an improvement of symptoms after three months compared to 42% (82/194) in the placebo group. A meta-analysis showed there was no significant difference between FMT and placebo (RR 1.19, 95%CI: 0.68-2.10, $P = 0.54$, $I^2 = 82\%$; Figure 3).

Three trials (99 participants) reported on the improvement of symptoms after six months. Thirty per cent (14/47) of FMT participants saw an improvement of their symptoms after six months compared to 38% (20/52) of the placebo group (RR 0.88, 95%CI: 0.33-12.39, $P = 0.8$, $I^2 = 51\%$; Figure 3).

Secondary outcomes

Adverse events: Seven trials, comprising 450 participants, reported on the proportion of participants who experienced adverse events. Thirty-five per cent (97/274) of the FMT group experienced an adverse event compared to 26% (45/176) of the placebo group (RR 1.17, 95%CI: 0.63-2.15, $P = 0.62$, $I^2 = 69\%$; Figure 4).

The most frequent adverse events reported in the trials were mild and transient symptoms of the gastrointestinal system.

Serious adverse events: All eight trials, comprising 501 participants, provided data for serious adverse events. A serious adverse event was reported once in a FMT group and twice in placebo groups. In the FMT group, 0.33 per cent (1/302) reported a serious adverse event, compared to 1% (2/199) in the placebo group (RR 0.42, 95%CI: 0.07-2.60, $P = 0.35$, $I^2 = 0\%$; Supplementary Figure 1).

Holvoet *et al*[44] reported that one participant from the placebo group committed suicide 10 d after the transplantation procedure. Aroniadis *et al*[59] reported one participant from the placebo group was admitted to hospital during week 20 of the trial with acute cholecystitis. Johnsen *et al*[62] reported that one participant from the FMT group was admitted to hospital after the FMT procedure due to transient vertigo and nausea.

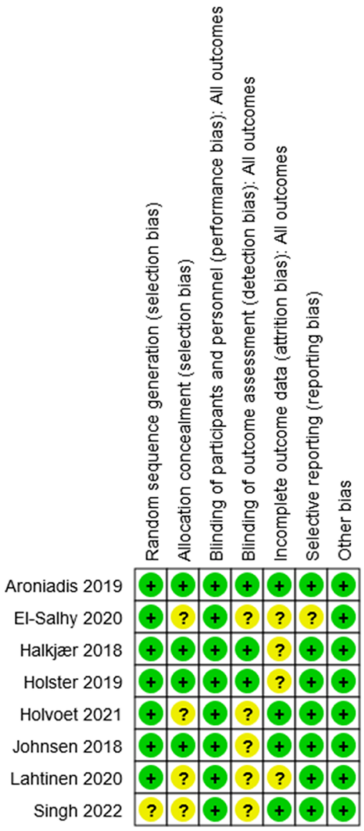
Table 2 Summarised findings for comparing fecal microbiota transplantation with placebo for the treatment of irritable bowel syndrome

Outcomes and timeframe	Anticipated absolute effects		Relative effect (95%CI)	Number of participants (trials)	Certainty of the evidence (GRADE)	Comments
	Effect in placebo	Effect difference with FMT (95%CI)				
Improvement of symptoms after three months	42 per 100	8 or more per 100 (from 13 or fewer to 46 or more)	RR 1.19 (0.68-2.10)	484 (8 RCTs)	++--[1] Low	Improvement of symptoms as measured by a validated global IBS symptoms score (*e.g.*, IBS-SSS scale from 0, no symptoms, to 500, maximum symptoms) (as defined by each trial)
Improvement of symptoms after six months	38 per 100	5 or fewer per 100 (from 25 or fewer to 52 or more)	RR 0.88 (0.33-2.39)	99 (3 RCTs)	++--[2] Low	Improvement of symptoms as measured by a validated global IBS symptoms score (*e.g.*, IBS-SSS scale from 0, no symptoms, to 500, maximum symptoms) (as defined by each trial)
Adverse events prior to end of trial	26 per 100	4 or more per 100 (from 10 or fewer to 30 or more)	RR 1.17 (0.63-2.15)	450 (7 RCTs)	++--[3] Low	Common adverse events were mild and self-limiting gastrointestinal symptoms
Serious adverse events prior to end of trial	1 per 100	1 or fewer per 100 (from 1 or fewer to 2 or more)	RR 0.42 (0.07-2.60)	501 (8 RCTs)	++--[4] Low	Serious adverse events included one suicide (placebo), cholecystitis (placebo), and one admission to the hospital due to discomfort after the FMT procedure
Dropouts due to adverse events prior to end of trial	1 per 100	1 or fewer per 100 (from 1 or fewer to 1 or more)	RR 0.24 (0.03-2.17)	502 (8 RCTs)	++--[5] Low	Dropouts due to adverse events include one suicide (placebo) and one for discomfort after the FMT procedure (placebo)
Improvement in QoL scores after three months	NA	NA	MD -6.30 (-13.39 to 0.79)	406 (7 RCTs)	++--[6] Low	Improvement of quality of life as measured by a validated scale IBS-QoL, where 34 items are summed and averaged for a total score and then transformed to a 0-100 scale for interpretation (high scores indicate better IBS-QoL)

[1]Downgraded two levels due to considerable inconsistency (I^2 = 82%) and imprecision (267 events).
[2]Downgraded two levels due to moderate inconsistency (I^2 = 51%) and serious imprecision (34 events).
[3]Downgraded two levels due to substantial inconsistency (I^2 = 69%) and imprecision (142 events).
[4]Downgraded two levels due to serious imprecision (three events) and wide confidence interval.
[5]Downgraded two levels due to serious imprecision (two events) and wide confidence interval.
[6]Downgraded two levels due to moderate inconsistency (I^2 = 45%), heterogeneous method, and a small number of participants.
Patients or population: Participants diagnosed with irritable bowel syndrome according to a physician's opinion or an accepted, symptom-based diagnostic criteria. Settings: Inpatient and outpatient. Intervention: Fecal microbiota transplantation. Comparison: Placebo (or autologous feces). FMT: Fecal microbiota transplantation; IBS: Irritable bowel syndrome; SSS: Symptom severity score; QOL: Quality of life measure; MD: mean difference; NA: Not available; RR: Risk ratio.

Dropouts due to adverse events: Eight trials, comprising 502 participants, reported on dropouts due to adverse events; there were none in the FMT groups, but two instances in the placebo groups. None (0/302) of the FMT groups had dropouts due to adverse events compared to 1% (2/200) in the placebo group (RR 0.24, 95%CI: 0.03-2.17, P = 0.2, I^2 = 0%; Supplementary Figure 2).

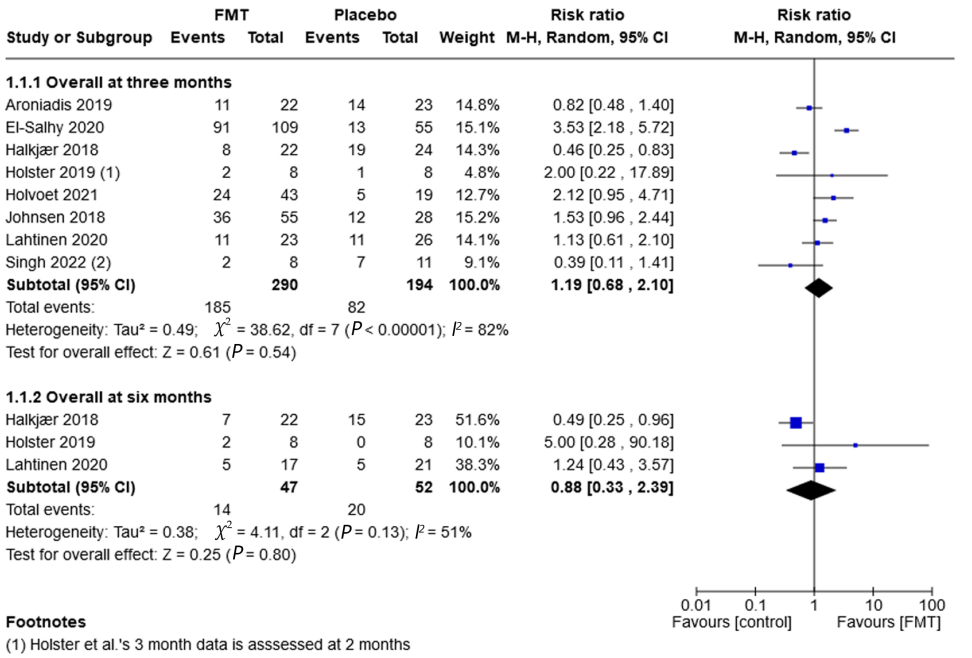
Holster *et al*[61] reported that one participant from the placebo group discontinued the trial after the FMT procedure due to discomfort. The dropout due to an adverse event in Holvoet *et al*[44] was the suicide occurring 10 d after the transplantation procedure in the placebo group.



QoL measurements

Seven trials, comprising 406 participants, reported on QoL outcomes. There were no significant differences between the FMT and placebo treatment groups; however, there was a slightly favorable effect seen in the placebo groups (MD -6.30, 95%CI: -13.39 to 0.79, P = 0.08, I^2 = 45%; Figure 5).

Subgroup analyses



Planned subgroup analyses included fresh *vs* frozen transplant, quantity of transplant, route of administration, type of donor (single *vs* mixed donor), frequency of administration and subtype of IBS (Supplementary Figures 3-8, Figure 6).

Overall, we found that endoscopic delivery (colonoscopy and upper endoscopy) of the FMT improved IBS-SSS after three months (RR 1.56, 95%CI: 1.04-2.34, P = 0.03, I^2 = 0% and RR 3.03, 95%CI: 1.92-4.80, $P \leq 0.00001$, I^2 = 13%; Figure 6). Furthermore, administering a single, large dose of FMT resulted in a greater improvement of the IBS-SSS, while increasing the dose across several treatments was comparable to a placebo (Supplementary Figures 4 and 6). None of the other subgroup analyses

DISCUSSION

This review systematically examined the benefits and harms of FMT *vs* placebo or autologous FMT for the treatment of patients with IBS. Our main objective was to assess the efficacy of FMT for the improvement of symptoms in patients with IBS.

This review combined findings from eight randomised clinical trials that assessed the efficacy of FMT in 465 IBS patients. We found no significant difference in the improvement of symptoms in the FMT groups compared to the placebo groups (P = 0.54). The meta-analysis suggests a favorable, but non-significant, effect on quality of life in patients treated with placebo.

In general, placebo response rates are high in IBS patients. Placebo response estimates in prior meta-analyses range from 16% to 72%[64,70]. Likewise, bowel cleansing might contribute to symptom improvement; however, its effects on the microbiota seem to be transient[71,72].

FMT appears to be safe, with mild and self-limiting gastrointestinal symptoms like nausea, constipation, diarrhoea, and stomach pain - all of which are common IBS symptoms. This conclusion was also reached in a previous review assessing FMT for the treatment of inflammatory bowel disease [73]. FMT was not associated with serious adverse events in the treatment of IBS; three such events were reported in total (two in the placebo group and one in the FMT group) and none were considered to be related to the treatment.

Figure 6 Forest plot of randomised controlled trials of fecal microbiota transplantation for treating irritable bowel syndrome: Improvement of symptoms after three and six months (route of administration subgroup analysis). FMT: Fecal microbiota transplantation.

In general, the results from the trials used for this review were highly heterogeneous. Therefore, it is possible that the absence of a positive overall effect is simply the result of how different the trials were from one another. The trials had pronounced differences in their selection processes for participants and donors, the routes of administration, the transplant quantities, and the frequency of administration. These differences make it difficult to draw conclusions about FMT as a treatment for IBS.

There is scientific evidence to support the hypothesis that FMT may be beneficial for patients with IBS. Observational trials have reported that IBS patients have reduced diversity or aberrant microbiota composition when compared to healthy controls[74]. Altered gut microbiota is also referred to as 'microbiota dysbiosis' and has been connected with disturbances in the microbiota gut-brain axis signaling[75]. Furthermore, other modulating agents targeting the microbiota, such as specific probiotic strains and antibiotics, have had demonstrable effects in IBS patients[76]. However, the underlying causes and mechanisms of dysbiosis in IBS and other diseases remain largely unknown. It has yet to be determined whether dysbiosis is a cause or a consequence of IBS, and even a 'healthy' microbiome has yet to be satisfactorily defined.

All eight trials included in this review reported on changes in gut microbiota after FMT. Aroniadis *et al*[59], El-Salhy *et al*[60], Halkjær *et al*[43], Lahtinen *et al*[58] and Singh *et al*[63] reported that participants receiving FMT saw changes in their gut microbiota that made their profiles more like the donors, when compared to placebo participants. Johnsen *et al*[62] reported these data in a later publication with the same outcome[77]. Holster *et al*[61] reported that microbiota diversity was not significantly affected by either FMT or placebo (autologous FMT). Holvoet *et al*[44] reported that responders to FMT had a higher baseline microbial diversity compared to those whose FMT treatment failed.

The possible effects, both positive and negative, of autologous FMT as placebo should be borne in mind.

In the treatment of recurrent CDI, the highest cure rates have been reported with repeated treatments delivered through lower endoscopy, but delivery through capsules is also highly effective[35,78]. In contrast, in IBS, FMT administered *via* upper or lower endoscopy, rather than capsules, has resulted in significant improvements in IBS-SSS. While much research has focused on FMT capsules[79], it is possible that the engraftment of the donor microbiota is better accomplished through endoscopic methods in IBS patients. Future RCTs in IBS patients that examines the combination of different routes of delivery for strain engraftment could be very interesting. Such studies would also contribute towards a more comprehensive understanding of microbial engraftment dynamics, which is currently lacking. A recent, systematic meta-analysis with shotgun metagenomic results showed that receiving FMT from multiple routes (for example, both *via* colonoscopy and capsules during the same treatment) resulted in increased engraftment[80]. Likewise, El-Salhy *et al*[81] present additional data from their trial and argue for using super donors since the efficacy of FMT appears to be donor-dependent. This argument needs further corroboration. Finally, data about patient and donor diets could prove relevant when determining the optimal patient-donor match[82].

The findings of this review have limited applicability and generalisability. More trials are needed to investigate whether FMT is a beneficial treatment strategy for IBS. Several aspects of the methods used in these trials could have influenced the effect of FMT, such as the route of administration, duration and interval between treatments, and the quantity of faecal microbiota transplanted to the patient. Despite the subgroup analyses we conducted as part of this review, firm conclusions cannot be drawn due to the small number of events and participants in the trials. Nonetheless, the results do suggest a possible beneficial effect in delivering FMT by endoscopy (colonoscopy or gastroscopy) over other routes.

Most of the patients in the trials we reviewed had moderate-to-severe IBS and were diagnosed according to the Rome III criteria. The newest, Rome IV criteria are more rigorous and it is not clear whether the greater homogeneity of IBS study populations they encourage will affect the efficacy of FMT. We recommend that future trials use the Rome IV criteria.

Additional investigations of microbiota, both when selecting patients of interest and after interventions, are needed in order to establish the precise mechanism of action of FMT as a potential treatment for IBS.

CONCLUSION

We did not find evidence to support the use of FMT for IBS patients outside of clinical trials in this systematic review and meta-analysis. We report a possible beneficial effect when delivering FMT by endoscopy (colonoscopy or gastroscopy). FMT appears to be safe, when compared to placebo, in patients with IBS, regardless of route of administration. Further randomised clinical trials are necessary in order to determine the effect of FMT in IBS.

ARTICLE HIGHLIGHTS

Research background

Irritable bowel syndrome (IBS) is a widespread gastrointestinal disorder accompanied by chronic abdominal pain and altered bowel habits. Gut microbiota disturbances have been linked to the pathophysiology of IBS, with fecal microbiota transplantation (FMT) emerging as a potential treatment strategy.

Research motivation

Manipulating gut microbiota composition *via* FMT could offer a promising avenue for IBS treatment, warranting further investigation into its efficacy and safety.

Research objectives

This review and meta-analysis aimed to evaluate the effectiveness and safety of FMT for treating IBS.

Research methods

A comprehensive search of Cochrane Central, MEDLINE, EMBASE, and Web of Science to identify randomised controlled trials (RCT) comparing FMT to placebo or autologous FMT in IBS patients. Primary outcome was improvement of symptoms, while secondary outcomes were quality-of-life scores and adverse events.

Research results

Our analysis incorporated data from eight RCTs with 484 participants. FMT did not result in significant improvement of symptoms when compared to placebo after three months, and no significant

improvement in quality of life was observed. Subgroup analysis indicated that endoscopic FMT delivery led to symptom improvement, whereas FMT capsules did not. FMT was found to be safe.

Research conclusions

This systematic review and meta-analysis do not support FMT as a treatment for IBS outside of clinical trials. Nevertheless, FMT was found to be safe.

Research perspectives

Large-scale, RCTs are needed to confirm or refute these findings. Investigating the potential significance of combining different FMT delivery routes for strain engraftment could provide a more comprehensive understanding of microbial engraftment dynamics in IBS patients.

Abstract

BACKGROUND

Crohn's disease represents a challenge for patients concerned with the modified diet regimen as well as practitioners who seek the best nutritional therapy. Crohn's disease can alter the body's ability to digest food and to absorb nutrients, resulting in severe vitamin deficiencies, malnutrition and sometimes life-threatening complications. However, a comprehensive bibliometric analysis is lacking to map the current links between nutrition and Crohn's disease in terms of the number of citations, geographic distribution and growth trends of publications.

AIM

To introduce the current state of research as well as hotspots in the field of nutrition and Crohn's disease from a bibliometric standpoint.

METHODS

We searched the Scopus database and selected the relevant literature on nutrition and Crohn's disease that met the inclusion criteria. We analyzed the publication trends and research hotspots by using video object segmentation viewer software.

RESULTS

We included 1237 publications. The number of documents published each year has increased steadily. The United States and the University of Otago, Christchurch, have had the highest productivity, with 208 (16.81%) and 29 (2.34%) documents, respectively. The "role of exclusive enteral nutrition for complicated Crohn's disease" and "manipulation of the gut microbiota as a key target for

Crohn's disease" were the major research areas in 2016-2021, and they could be extensively investigated in the future. Meanwhile, research on "malnutrition in patients with Crohn's disease" appeared to be an area that attracted more research attention before 2016.

CONCLUSION

This is the first bibliometric analysis to map the knowledge structure and trends regarding nutrition in Crohn's disease research over the past two decades. The results provide a comprehensive summary and identification of the frontiers of nutrition and Crohn's disease-related research, which may be used as a resource by researchers in the field.

Key Words: Nutrition; Diet; Crohn's disease; Bibliometric; Microbiota; Malnutrition

Core Tip: There is much interest in using nutrition therapy approaches to treat Crohn's disease, while the current state of knowledge is still inadequate to make general recommendations. Therefore, a bibliometric analysis of the global trend in research on nutrition and Crohn's disease was conducted. This study outlines the current state of research themes and hotspots in nutrition and Crohn's disease research because no bibliometric research has been conducted to determine worldwide trends in nutrition and Crohn's disease. This facilitates researchers and healthcare providers in identifying potential future research directions.

INTRODUCTION

Crohn's disease is a relapsing transmural inflammatory disease of the gut with an unclear etiology; it involves acute attacks followed by periods of remission[1,2]. Crohn's disease can affect the entire gastrointestinal tract, from the mouth to the anus[3]. However, the disease affects the terminal ileum and the colon in most cases, which can result in complications such as stenosis, abscesses and fistula[4]. The prevalence rate of Crohn's disease ranges from 0.6 to 322 per 100000 people[5].

Malnutrition is frequently visible in approximately 65%-75% of patients with Crohn's disease[6]. Malabsorption, gut dysbiosis, small intestinal bacterial overgrowth and symptoms such as weight loss, reduced dietary intake, deficiency of individual nutrients or many nutrients are just a few of the mechanisms that can be related to Crohn's disease-related malnutrition[7,8]. In this case, nutrition, which may take the form of dietary adjustments, parenteral nutrition, or enteral nutrition, plays an important role in treating Crohn's disease[7,9,10]. Parenteral nutrition is a type of nutrition support that is given through an intravenous line. It is used when the digestive tract cannot properly absorb nutrients. In severe cases of Crohn's disease, where the digestive tract is severely damaged, parenteral nutrition may be necessary[7,11]. Furthermore, enteral nutrition is a type of nutrition support that is given through a feeding tube. It can help reduce inflammation and promote healing of the digestive tract. Enteral nutrition may be used as a primary treatment for Crohn's disease or as a supplement to other treatments[7,11].

There is much interest in using nutritional approaches to control and reduce the symptoms of Crohn's disease and to increase the remission time. Nevertheless, there is insufficient scientific support to give health care providers more options regarding dietary therapies. As a result, we performed a bibliometric analysis of the global trends in research on nutrition and Crohn's disease. We summarize the current state of research themes and hotspots in nutrition and Crohn's disease to look for global trends. Our findings will make it easier for researchers and newcomers to understand the current state of the field, to strategize future goals in research and to identify potential future research directions.

MATERIALS AND METHODS

Data sources

We conducted a shortlisted quantitative analysis with an approach based on previously published

scientific outputs to characterize the development of research on nutrition and Crohn's disease over the past two decades. On December 30, 2022, we searched the Scopus database for studies that had been published between 2002 and 2021. The Scopus database is often an essential source of information for bibliometric research and evaluations of scientific publications[12]. Numerous successful bibliometric studies have been performed using the Scopus database as a data source[13-17].

Search strategy

We used relevant publications on nutrition[18,19] and Crohn's disease[20] to choose keywords to search the Scopus database and to identify studies. Each of the chosen keywords relates to nutrition, and we used them as an entry for the "Article Title" field. Due to the possibility that the title/abstract/keyword search would retrieve unnecessary papers, we searched the titles with specific limits to reduce false-positive results[21-24]. When writing the keywords, we used asterisks (*) and quote marks to narrow and broaden the search scope. The keywords we used were nutrt* or nutrient* or diet* or eat* or feeding-pertain to nutrition or diet *per se* rather than other related terminology such as specific names or classes of dietary compounds. Furthermore, we searched all terms related to Crohn's disease in the "Article Title" and/or "Abstract" fields.

Bibliometric indicators

We imported the retrieved data into Microsoft Excel so that we could analyze and tabulate it. We retrieved relevant bibliometric data (such as the number of articles published per year, the types of documents retrieved, countries/regions, institutions, funding agencies, journals and their impact factors (*IF*), citation patterns and the h-index) for research publications related to nutrition and Crohn's disease. We used descriptive statistics to analyze our findings. The *Impact Index Per Article* that is being shown refers to the top 10 papers with the highest number of citations, which were obtained from the *Reference Citation Analysis* (*RCA*, https://referencecitationanalysis.com/). *RCA* is a citation analysis database that is open and covers multiple disciplines. The company is located in Pleasanton, CA 94566, United States [25-27].

Data visualization

We analyzed and visualized the data by using VOSviewer software version 1.6.8, a free online tool[28-30]. The software generated visualization maps that displayed the most commonly occurring keywords in the retrieved publications. The size of the node in each map represented the frequency of a particular keyword, indicating the relevance and popularity of the corresponding topic in the field. Based on these maps, the hot topics in the field were identified, revealing the areas that received the most attention and research focus. This analysis provided valuable insights into the current trends and research directions in the field, which can be used to guide future research and inform the decision-making processes. In addition, visualization maps were used to determine international collaboration. VOSviewer can determine the extent of the collaboration between two countries by considering the width of the connecting line and the total number of publications.

RESULTS

Analysis of publication trends

There were 1237 publications on nutrition and Crohn's disease published between 2002 and 2021. The documents recovered were of 9 types, mainly research articles (n = 791; 63.95%), followed by reviews (n = 285; 23.04%). The total number of publications by year is shown in Figure 1. The number of publications per year increased from 28 in 2002 to 123 in 2021.

Analysis of the country distribution

The publications were from authors representing 108 countries/regions. The top 10 active countries are shown in Table 1. The top 10 countries contributed 905 (73.16%) of the recovered documents. Among the eligible countries, the United States had the highest number of publications (n = 208, 16.81%), followed by the United Kingdom (n = 192, 15.52%), China (n = 109, 8.81%), Japan (n = 98, 7.92%), and Canada (n = 88, 7.11%). Furthermore, we analyzed countries that had more than 20 publications on nutrition and Crohn's disease. Based on our findings from 18 eligible countries, the United States, the United Kingdom, and Canada are the central countries with links to other countries (Figure 2).

Contributions of institutions

Based on the number of publications, Table 2 includes the top 10 institutions that have produced publications on nutrition and Crohn's disease. The University of Otago, Christchurch (New Zealand), has had the highest scientific production (n = 29, 2.34%), followed by Tel Aviv University (Israel), with 25 publications (2.02%). Massachusetts General Hospital (United States) and Jinling Hospital (China) have the third highest production (n = 22, 1.78%).

Table 1 Top 10 productive countries/regions involved in nutrition and Crohn's disease from 2002 to 2021

Ranking	Country	No. of documents	%
1st	United States	208	16.81

9th	Medical School of Nanjing University	China	18	1.46
9th	University of Washington	United States	18	1.46

Analysis of funding agencies

We identified 274 (22.15%) articles that were part of financed projects. The United States funding agencies were the most active in this field, with the National Institute of Diabetes and Digestive and Kidney Diseases (n = 34, 2.75%) being the most active. This was followed by the National Institutes of Health (n = 30, 2.43%), the National Natural Science Foundation for China Diseases (n = 30, 2.43%) and the Crohn's and Colitis Foundation (n = 20, 1.62%) (Table 3).

Journal analysis

The top 10 journals that have published the most articles concerning nutrition and Crohn's disease are listed in Table 4 with their *IF* in 2022. Nutrients was the most productive journal, with 57 documents contributing to 4.61% of the total publications, followed by *Inflammatory Bowel Diseases* (n = 55, 4.45%), *Alimentary Pharmacology and Therapeutics* (n = 39, 3.15%), *Clinical Nutrition* (n = 29, 2.34%), and the *Journal of Pediatric Gastroenterology and Nutrition* (n = 29, 2.34%).

Citation analysis

There was an average of 29.46 citations per document, for a total of 36444 citations. The h-index of the retrieved documents was 93. A total of 183 (14.8%) of the retrieved documents did not have citations, but 83 had been cited ≥ 100 times. The top 10 articles were cited 3912 times[31-40]. There was a wide range in the total number of citations for these publications, from 310 to 603 (Table 5). The impact index per article for the top 10 most cited articles varied between 10.4 and 70.6 (Table 5).

Keyword analysis of research hotspots

The co-occurrence network map of author keywords with at least 10 occurrences is displayed in Figure 3. Of the 1589 keywords, 43 met the threshold and were mainly concentrated in three aspects: (1)

Table 3 Top 10 funding agencies involved in nutrition and Crohn's disease from 2002 to 2021

[1]Journal Citation Reports (Clarivate, 2022). IF: Impact index.

The "role of exclusive enteral nutrition (EEN) for complicated Crohn's disease" (red cluster); (2) "manipulation of the gut microbiota as a key target for Crohn's disease" (green cluster); and (3) "malnutrition in patients with Crohn's disease" (blue group).

We then divided the keywords by specific colors based on the average number of times they appeared in all publications (Figure 4). The blue color represents prior research (before 2016), while more recent studies are indicated by the yellow color (after 2018). Keywords in the groups of "role of EEN for complicated Crohn's disease"; and "manipulation of the gut microbiota as a key target for Crohn's disease" were the major areas in 2016-2021, and they could be extensively considered in the future. Meanwhile, research on "malnutrition in patients with Crohn's disease" appeared to be a research area that attracted more attention before 2016.

DISCUSSION

This bibliometric analysis represents a comprehensive shortlisted overview of nutrition and Crohn's disease research. In the last decade, there has been significant growth in worldwide research interest in this topic. The steady scientific progress over time shows that "manipulation of the gut microbiota as a key target for Crohn's disease" and "EEN for complicated Crohn's disease" are promising clinical approaches that should receive more investigation.

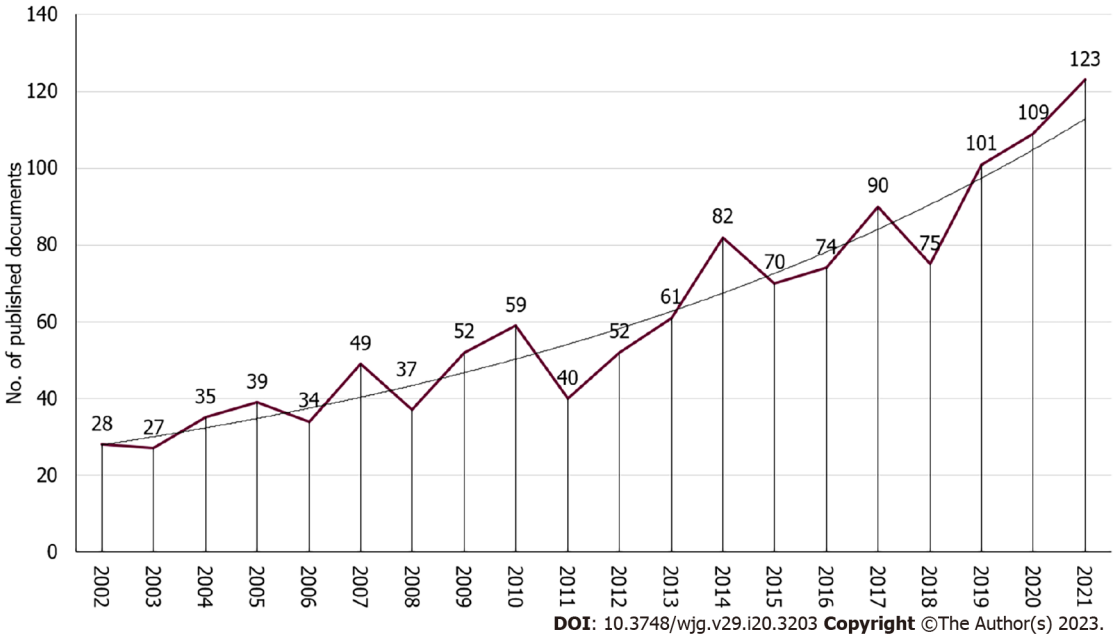

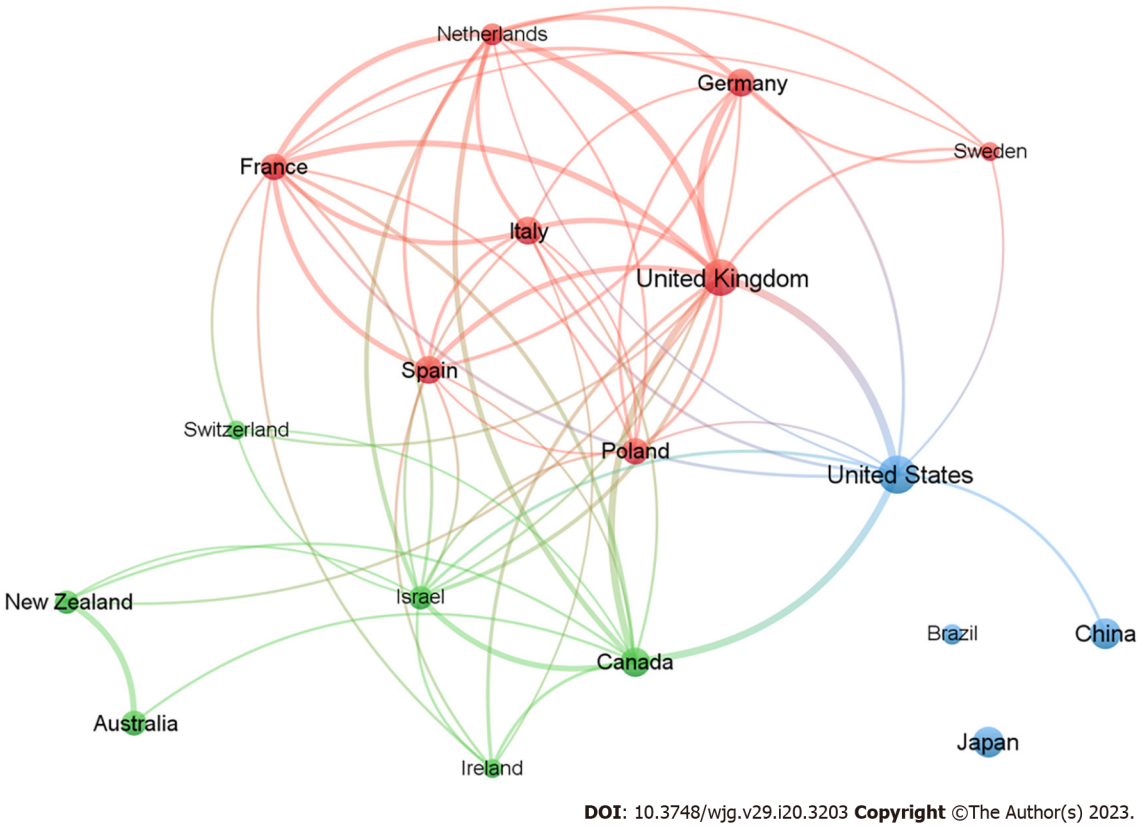

Figure 1 Growth trends of publications on nutrition and Crohn's disease from 2002 to 2021.

The research found that the United States is the dominant country in this field, potentially due to various factors. These factors could include a higher prevalence of Crohn's disease in Western Europe and North America, where the disease affects 100 to 300 per 100000 people[5]. Other reasons may

DOI: 10.3748/wjg.v29.i20.3203 **Copyright** ©The Author(s) 2023.

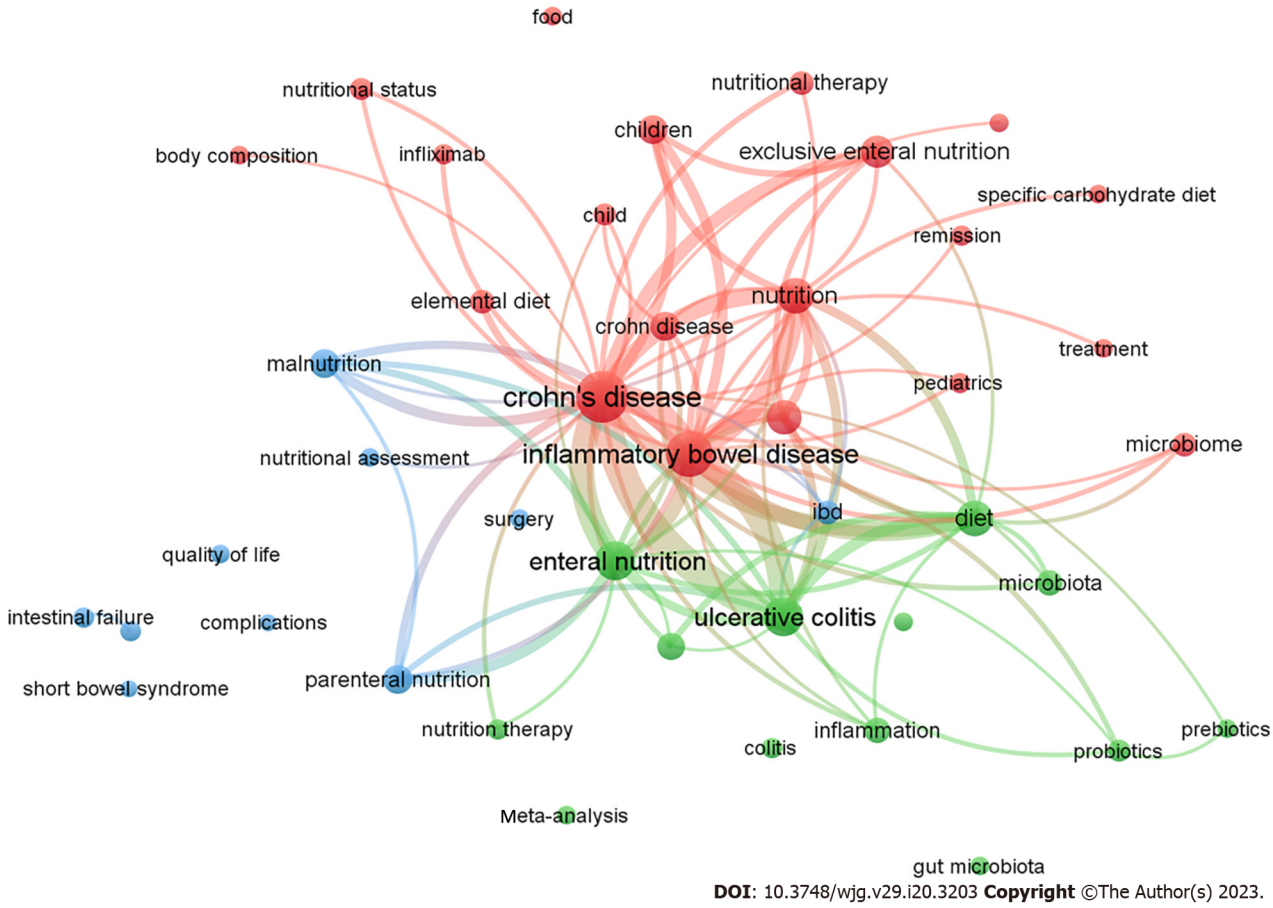

Figure 2 Network visualization map depicting international collaboration in research related to nutrition and Crohn's disease during 2002-2021.

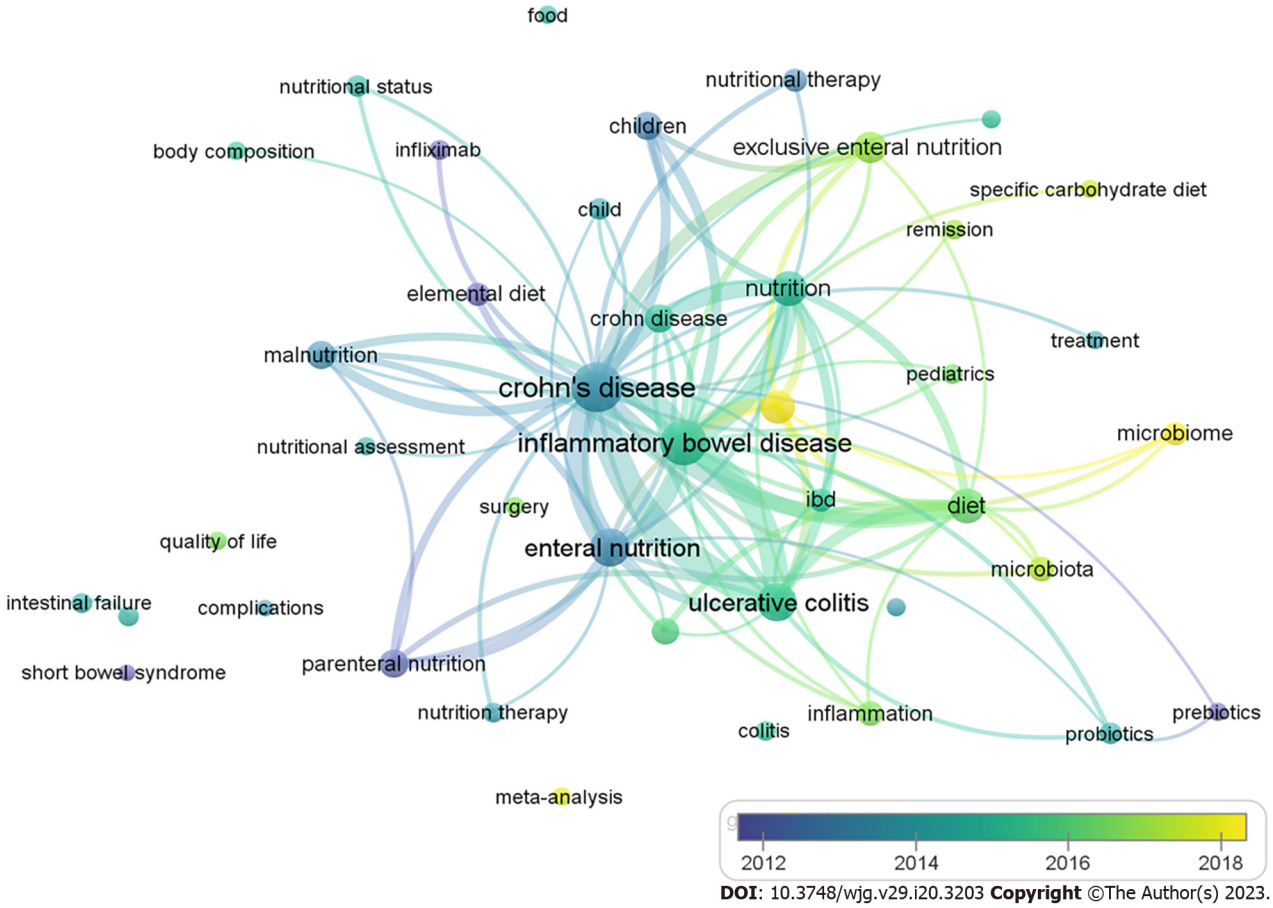
involve the country's investment in research, a diverse range of researchers in the field, access to well-resourced research environments, and a well-trained workforce. Researchers may profit from their country's economic success, which may provide financial assistance and travel chances. This finding is consistent with past studies that have shown the United States to be the top in research productivity[41-43]. Nonetheless, it is critical to remember that research productivity is only one component of scientific research. Other elements, such as research impact and societal ramifications, should be included when assessing the overall success of a research field or country.

Studying collaboration networks can offer useful insights into research partnerships and help pinpoint essential collaborators in a particular field. The United States and the United Kingdom have a distinct advantage in this regard because of their greater economic resources and scientific investments. Both countries have invested significantly in research and development, establishing world-class research institutions and universities. Additionally, they have implemented policies to foster global scientific and technological collaboration, leading to the formation of robust networks of researchers and institutions worldwide. Furthermore, these countries' substantial funding and resources enable them to attract the best talent globally, which has facilitated scientific progress and innovation. The extensive cooperation and collaboration among researchers in these countries have resulted in diverse and strong networks that are crucial in addressing complex scientific challenges[44-47].

We may gain insight into the areas of interest and potential future research directions in this field by analyzing the cooccurrence of the keywords. Its key terms often refer to the most important aspects of a publication; the threshold was met by 43 of the 1589 keywords retrieved from the authors' keywords. Therefore, it is helpful to define important concepts and create a framework for nutrition and Crohn's disease studies by analyzing the associated keywords.

One of the main research hotspots in our study was the role of EEN for complicated Crohn's disease. Enteral nutrition is the preferred feeding route in the induction of remission of active Crohn's disease, as it is a minimally invasive procedure with low risk. On the other hand, enteral nutrition has a beneficial effect on the gut microbiota and intestinal inflammation. Therefore, enteral nutrition has several advantages over parenteral nutrition: It can maintain enterohepatic circulation, reduce the inflammatory response, decrease bacterial overgrowth and translocation and avoid intravenous access complications [4]. EEN was first used in the 1970s and has been established over the last 20 years as an effective nutritional therapy that induces mucosal healing in approximately 80% of patients and provides 100% of daily nutrition requirements from high-energy artificial supplements and modified feeds with probiotics, amino acids, and fatty acids[48]. On the other hand, a prospective study showed that 3 mo of



DOI: 10.3748/wjg.v29.i20.3203 **Copyright** ©The Author(s) 2023.

Figure 3 Analysis of the co-occurrence network of authors' keywords. Keywords of the authors with at least 10 occurrences were analyzed.

EEN could effectively relieve stenosis[4,49]. However, there is still variation in the use of EEN in different parts of the world. In addition, enteral nutrition and oral nutrition supplements are rarely recommended by doctors as first-line therapies, so much research is needed to address the uncertainty and barriers around the use of enteral nutrition globally[50,51].

Another research hotspot is the "manipulation of the gut microbiota as a key target of Crohn's disease". The intestinal microbiota is an important factor in developing irritable bowel disease. Long-standing inflammation in Crohn's disease can cause small intestinal bacterial overgrowth due to intestinal stenosis, leading to fibrosis, scarring and contraction in both the transverse and longitudinal directions. Bacterial overgrowth is enabled by reduced intestinal secretion of soluble immunoglobulin A (sIgA), which permits an increase in adherence and pathogenicity of bacteria that form the normal gut microbiome, particularly *Escherichia coli*, *Klebsiella* spp. and *Pseudomonas* spp., and a decrease in protective bacterial strains such as *Lactobacillus* and *Bifidobacterium* spp., resulting in diarrhea, abdominal pain and distension, weight loss and fatigue. Bacterial overgrowth acts as a snare due to the increased risk of mucosal inflammation, bacterial translocation, and sepsis, so many experimental studies are needed to assess the effectiveness of probiotic supplements and palatability in patients to achieve clarity and standardization of therapy[52,53].

Another research hotspot is "malnutrition in patients with Crohn's disease". The prevalence of malnutrition and nutritional deficiencies in patients with Crohn's disease is high because inflammation induces a catabolic response with endogenous proteolysis. Researchers have found weight loss due to decreased fat and muscle mass in 65%-75% of hospitalized patients; anemia due to iron, folic acid and vitamin B12 deficiency in 60%-80% of patients; and negative nitrogen balance in approximately 70% of patients[54]. Protein-energy malnutrition is common due to increased energy and nutrient needs, particularly in acute attacks, in addition to cytokine-induced anorexia, nausea, diarrhea, reduced dietary intake, malabsorption, and food-drug interactions. Protein requirements will depend on the disease phase. An increased requirement will be essential only in the catabolic stage and for septic and severe undernutrition in the active Crohn's disease phase. Screening for malnutrition is essential to select patients with the highest risk and develop the appropriate care plan. In addition, malnutrition is rarely treated as an additional disease, especially in low- and middle-income countries. Therefore, more studies are needed to manage and control this life-threatening issue[55].

Figure 4 Co-occurrence overlay visualization of the authors' keywords. Yellow highlights indicate the most recent keywords.

One of the most important techniques for assessing the impact of an article or demonstrating its recognition is citation analysis[56,57]. It is possible to determine which study areas have received the most attention from the scientific community by analyzing the most cited papers. Those interested in becoming authorities on nutrition-related studies of Crohn's disease should become familiar with the most widely referenced works. We found several articles on the connections between nutrition and Crohn's disease[31-40] that highlighted a number of subtopics that are closely related to the aforementioned hotspots. For example, the article on this subject that has been cited the most has 603 references and was published in the *American Journal of Gastroenterology*. High dietary intakes of total lipids, omega-6 fatty acids, polyunsaturated fatty acids, and meat were associated with an elevated risk of Crohn's disease, according to this systematic analysis[31]. Conversely, fruit and high-fiber diets were linked to a lower risk of developing Crohn's disease[31]. The article by Lewis *et al*[37], published in *Cell Host and Microbe*, was the second most cited. This study established that fungi are involved in the dysbiosis of Crohn's disease in addition to bacteria. Inflammation, exposure to antibiotics, and dietary modifications contribute to dysbiosis in different ways by altering the composition of the gut microbiota [37]. These results shed light on the therapeutic options for Crohn's disease by showing that dysbiosis develops from independent influences of diet, inflammation, and antibiotics[37]. The third most cited paper was published in *Nutrients*[32]. The study presented proof that the microbiota structure in the intestines can influence the likelihood of developing chronic illnesses in the gastrointestinal tract, including celiac disease, Crohn's disease, ulcerative colitis, and irritable bowel syndrome. Nevertheless, the enduring advantages of probiotics and prebiotics are still uncertain, despite their potential as efficacious treatments for inflammatory disease symptoms[32].

Research strengths and limitations

Our study has several strengths. We systematically reviewed the literature on nutrition and Crohn's disease. Our findings offer a comprehensive and quantitative analysis of the most important articles related to nutrition and Crohn's disease. We have also acknowledged the important contributions that have been made to the development and progress of this specialized field. However, our study has several limitations. First, we only searched Scopus and we did not include data from other databases, such as PubMed, Web of Science, and Google Scholar. This approach could have led to the exclusion of papers relevant to the investigated topic. Second, the research strategy has certain errors, even though it has been validated. Consequently, researchers should keep in mind that both false-positive and false-

negative results could have been included. Nevertheless, we believe that the use of title searches significantly reduces research errors. Third, regarding the credibility of the data gathered for our study, the precision and completeness of the keywords we used have a considerable impact. Hence, certain significant and influential articles could have been left off the representative list because the titles of those articles could contain specific types of nutrition or diet.

CONCLUSION

We employed bibliometric techniques to gather 1237 articles on nutrition and Crohn's disease that were published from January 2002 to December 2021. Our findings highlight a network of collaboration among countries, institutions, journals and funding agencies, shedding light on the latest trends and areas of interest in the field of emerging nutrition and Crohn's disease. Research in this area has been increasing steadily over the past decade. The United States and the United Kingdom are the leading contributors to this field, with the highest number of publications and a strong emphasis on international cooperation. The "role of EEN for complicated Crohn's disease" and "manipulation of the gut microbiota as a key target for Crohn's disease" are the current research hotspots. This bibliometric study provides a detailed analysis of nutrition and Crohn's disease research, which can serve as a resource for academics and policymakers in this field.

ARTICLE HIGHLIGHTS

Research background

Crohn's disease symptoms can include abdominal pain, diarrhea, fatigue, and weight loss. While Crohn's disease has no cure, there are techniques to control symptoms, including food and nutrition.

Research motivation

Assessing the current status of research and hotspots in nutrition and Crohn's disease is critical for identifying knowledge gaps and informing future research paths.

Research objectives

Using bibliometric analysis, the purpose of this study is to provide an overview of the current state of nutrition and Crohn's disease research.

Research methods

We conducted a thorough and rigorous analysis utilizing SciVerse Scopus to identify relevant material on nutrition and Crohn's disease. Next, we used VOSviewer software to examine prevalent areas of study and publishing patterns in related domains.

Research results

Over the past 20 years, there has been a rise in cross-border partnerships and interdisciplinary studies concerning the relationship between nutrition and Crohn's disease. Currently, the key areas of research in this field are the use of exclusive enteral nutrition for complicated cases of Crohn's disease and the manipulation of the gastrointestinal microbiome.

Research conclusions

There has been no bibliometric analysis of nutrition and Crohn's disease research in the last two decades. This study provides a complete assessment of the knowledge structure and developments in this topic. As such, the findings are a helpful resource for academics because they provide a detailed assessment and emphasize the frontiers of nutrition and Crohn's disease research.

Research perspectives

The purpose of this research is to identify current trends and focus areas in the field of nutrition and Crohn's disease to guide future research and treatment practice. Using bibliometric analysis, this study provides a comprehensive assessment of the relevant literature, assisting researchers and clinicians in staying up to date on the most recent advances in this field.

ACKNOWLEDGEMENTS

Abstract

BACKGROUND

Inflammatory myofibroblastic tumor (IMT) is a relatively rare tumor. The global incidence of IMT is less than 1%. There is no specific clinical manifestation. It usually occurs in the lungs, but the pancreas is not the predilection site.

CASE SUMMARY

We present a case of a male patient, 51 years old, who was diagnosed with a pancreatic neck small mass on ultrasound one year ago during a physical examination. As he had no clinical symptoms and the mass was relatively small, he did not undergo treatment. However, the mass was found to be larger on review, and he was referred to our hospital. Since the primal clinical diagnosis was pancreatic neuroendocrine tumor, the patient underwent surgical treatment. However, the case was confirmed as pancreatic IMT by postoperative pathology.

CONCLUSION

Pancreatic IMT is relatively rare and easily misdiagnosed. We can better understand and correctly diagnose this disease by this case report.

Key Words: Inflammatory myofibroblastic tumor; Diagnosis; Imaging; Pancreas; Case report

Core Tip: Inflammatory myofibroblastic tumor (IMT) is a rare mesenchymal tumor composed of spindle-shaped myofibroblasts accompanied by a mixed inflammatory infiltrate, and is particularly rare in the pancreas. The diagnosis of pancreatic IMT is made on the basis of histopathology and immunohistochemistry. Different lesions exhibit diverse biological characteristics, and there are several surgical treatment protocols. This case emphasizes the importance of correct preoperative diagnosis of IMT and reminds us to broaden our thinking in relation to the diagnosis of pancreatic lesions.

INTRODUCTION

Inflammatory myofibroblastic tumor (IMT) is a rare mesenchymal tumor. This concept of IMT was first put forward by Pettinato *et al*[1] in 1990. According to the current World Health Organisation (WHO) guidelines, IMTs are typically low-grade neoplasms with occasional malignant potential[2]. An IMT can occur anywhere at any age. This report describes a case of pancreatic IMT.

CASE PRESENTATION

Chief complaints

A 51-year-old male patient was found to have a pancreatic mass more than one year ago.

History of present illness

The patient found a small pancreatic tumor in a physical examination one year ago. However, two months ago, the follow-up of the physical examination center found that the tumor became bigger, then he was referred to our hospital. There were no clinical symptoms throughout the course of the disease.

History of past illness

The patient had a history of hypertension, hyperglycemia, hyperlipidemia, thyroid nodule, prediabetes, and urticaria.

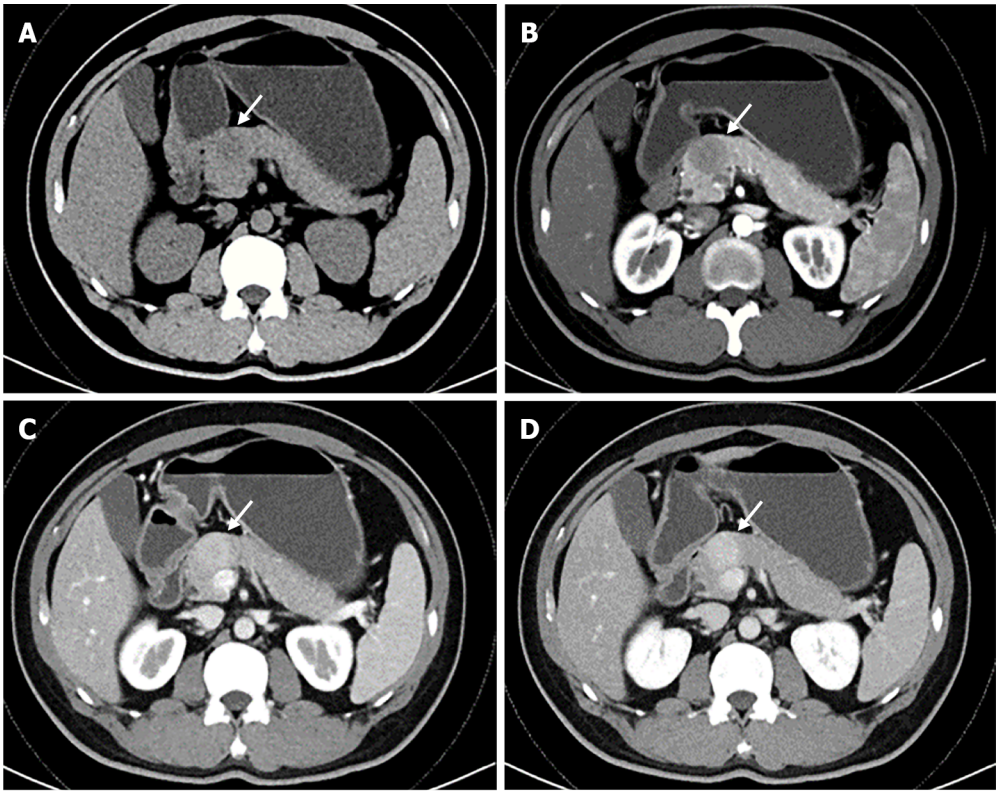
Personal and family history

The patient had no family history of malignant tumors, psychological, or genetic disorders.

Physical examination

The physical examination did not reveal any obvious abnormalities.

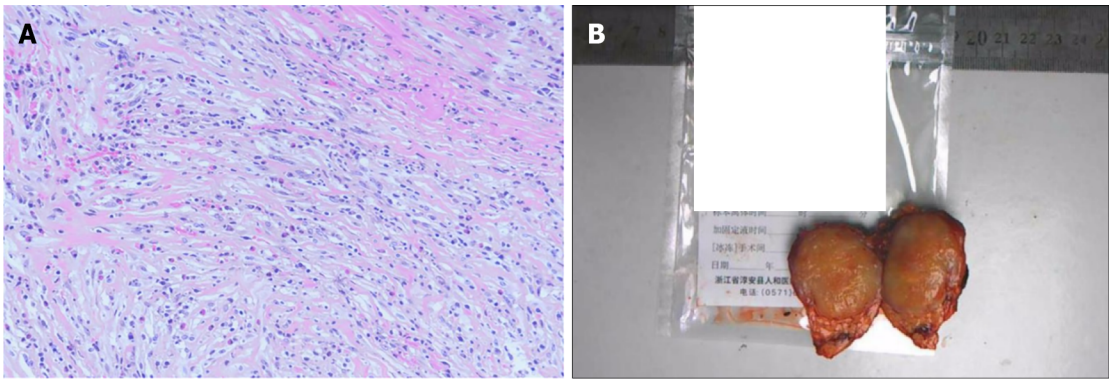
Laboratory examinations



Uric acid and triglyceride levels were elevated. Other blood parameters and tumor markers (carcinoembryonic antigen and cancer antigen 19-9) levels were within the normal range.

Imaging examinations

An abdominal contrast-enhanced computed tomography (CECT) scan showed a round, well-defined, low-density mass 3.5 cm in diameter in the neck of the pancreas. On the CECT scan, the mass showed lower attenuation than the normal pancreatic parenchyma in the pre-contrast phase and arterial phase, and heterogeneous hyperenhancement in the portal venous phase (Figure 1). A pancreatic neuroendocrine tumour was strongly suspected.



FINAL DIAGNOSIS

The patient was diagnosed with IMT of the pancreas by postoperative pathology (Figure 2).

Figure 1 Abdominal contrast-enhanced computed tomography. A: Axial non-contrast showed a low-density mass in the neck of the pancreas; B: Arterial phase indicated a distinct hypoattenuating mass; C and D: Venous phase revealed persistent hyperenhancement of the mass (magnetic resonance imaging is similar to computed tomography in enhancement mode and characteristics).

DOI: 10.3748/wjg.v29.i20.3216 **Copyright** ©The Author(s) 2023.

Figure 2 Histopathological image and resected tumor specimen. A: Spindle-shaped myofibroblasts accompanied by large amounts of plasma cells. B: The resected specimen showing a well-defined neoplasm (some information has been excluded due to patient privacy).

TREATMENT

After completion of preoperative investigations, a laparoscopic middle pancreatectomy was performed.

OUTCOME AND FOLLOW-UP

Postoperative pancreatic leakage occurred in the patient. However, he was discharged in good clinical condition after 40 d. No apparent events were observed at the 2-mo postoperative follow-up.

DISCUSSION

IMT is a rare mesenchymal tumor. Due to its rarity and the fact that the etiology is unknown, there are only a few cases reported. It has been revealed that IMT may have gene rearrangement with anaplastic lymphoma kinase (ALK)[3], and ALK positivity was also associated with a higher recurrence and less chance of distant metastasis[4]. A recent literature review by Chen *et al*[5] in 2021, included 30 patients with IMT occurring in the pancreas. The reported mean age of the patients was 40 years (range, 0-82 years) with an obvious male preponderance. The tumor was mostly located in the head of the pancreas (21/30 patients). In this series, abdominal pain was the most frequent symptom followed by jaundice. Only five cases of asymptomatic pancreatic IMT have been reported in the medical literature[5-9]. Our patient had no clinical symptoms and the pancreatic mass was found on physical examination. Among the previously reported cases of pancreatic IMT, many were initially misdiagnosed as pancreatic cancer, while the present case was misdiagnosed as pancreatic neuroendocrine tumor. Therefore, it is meaningful to collect more cases and information to obtain reliable diagnosis and treatment methods for IMT.

As the low incidence of pancreatic IMT, there is no specific clinical manifestations has been established. It commonly manifests as abdominal pain or jaundice, and can sometimes be asymptomatic. Although IMT is considered a low-grade tumor, one case of pulmonary metastasis has been reported[10].

At present, pancreatic IMT is mainly diagnosed by histopathology and immunohistochemistry[11]. Under the light microscope, the tumour tissue in this case consisted mainly of spindle-shaped myofibroblasts accompanied by a mixed inflammatory infiltrate. The histopathological findings of this case were consistent with previous reports. Myofibroblasts in IMT stain positive for alpha-smooth muscle antigen (SMA), vimentin, and fibronectin, and stain negative for desmin and caldesmon[12]. In this case, immunohistochemistry report showed positive for IgG4, SMA and actin, and negative for desmin, ALK, CD30, S-100, and Catenin B, similar to those in the literature.

To date, pancreatic IMT is easily misdiagnosed as pancreatic neuroendocrine tumour and pancreatic cancer due to the lack of specific imaging features, and its diagnosis is unclear in clinical practice. A circular low-density mass was observed in the pancreatic IMT reported here. After enhancement, the arterial mass is mildly enhanced, the venous phase is significantly enhanced, and the density is progressively higher than that of the surrounding normal pancreas.

However, in some cases, CECT did not show an enhancing mass and was suspected to be ductal adenocarcinoma, which was ultimately confirmed by pathology to be pancreatic IMT. Hence, the radiologic features of pancreatic IMT require further data.

Pancreatic IMT needs to be differentiated from pancreatic neuroendocrine tumor, pancreatic cancer, and solid-pseudopapillary neoplasm. Pancreatic neuroendocrine tumor is uncommon and has no gender predilection[13]. Additionally, the mass shows high enhancement in the arterial or portal phases due to the rich capillary network in the stroma. Pancreatic cancer is typically seen in patients over 60 years old, with a slight male predominance. It is a hypovascular mass with extensive fibrosis on histopathologic examination[14]. Typical ductal adenocarcinomas appear as poorly defined masses with extensive surrounding desmoplastic reaction and they enhance poorly compared to adjacent normal pancreatic tissue. The presence of abrupt pancreatic duct cutoff, upstream pancreatic duct dilatation, upstream pancreatic parenchymal atrophy, and decreased enhancement in the distal pancreatic parenchyma favors a diagnosis of malignancy[15]. Solid-pseudopapillary neoplasms of the pancreas are cystic-solid masses with a complete capsule. They are prone to bleeding, necrosis and calcification. The solid portion shows enhancement in the arterial phase and can continue to enhance in the delayed phase. However, the imaging features of pancreatic IMT from some pancreatic lesions overlap.

In the present case, a wrong diagnosis was made for several reasons. First, the patient had no clinical manifestations, and the clinical history and laboratory indices are unremarkable. Second, the preoperative imaging findings were difficult to distinguish from a pancreatic neuroendocrine tumour. The border of the lesion was distinct, with persistent hyperenhancement of the mass, and typical double duct sign and vascular involvement were not observed. Accordingly, preliminary diagnosis of imaging was limited to benign mass. In general, IMT of the pancreas is lack of characteristic in terms of clinic-radiological features. Therefore, for more accurate diagnosis and treatment of pancreatic IMT, there is a need to obtain more meaningful information.

CONCLUSION

Given the rarity of pancreatic IMT, this case can contribute to further understanding of the etiology, mechanism, imaging characteristics of this disease. Obtaining a better understanding of all aspects of this disease will help provide a more precise diagnosis.

ACKNOWLEDGEMENTS

We are very grateful to Dr. Liu Yu (Hunan Provincial People's Hospital, First Affiliated Hospital of Hunan Normal University) for providing professional guidance to the pathological analysis.

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

Crohn's disease (CD) is an inflammatory bowel disease characterized by immune-mediated flares affecting any region of the intestine alternating with remission periods. In CD, the ileum is frequently affected and about one third of patients presents with a pure ileal type. Moreover, the ileal type of CD presents epidemiological specificities like a younger age at onset and often a strong link with smoking and genetic susceptibility genes. Most of these genes are associated with Paneth cell dysfunction, a cell type found in the intestinal crypts of the ileum. Besides, a Western-type diet is associated in epidemiological studies with CD onset and increasing evidence shows that diet can modulate the composition of bile acids and gut microbiota, which in turn modulates the susceptibility of the ileum to inflammation. Thus, the interplay between environmental factors and the histological and anatomical features of the ileum is thought to explain the specific transcriptome profile observed in CD ileitis. Indeed, both immune response and cellular healing processes harbour differences between ileal and non-ileal CD. Taken together, these findings advocate for a dedicated therapeutic approach to managing ileal CD. Currently, interventional pharmacological studies have failed to clearly demonstrate distinct response profiles according to disease site. However, the high rate of stricturing disease in ileal CD requires the identification of new therapeutic targets to significantly change the natural history of this debilitating disease.

Key Words: Ileum; Crohn's disease; Bile acids; Paneth cells; Diet; Genetics; Strictures

Core Tip: The ileum is most frequently affected by Crohn's disease (CD). Ileal CD differs from other CD types in its epidemiology and natural history. Anatomical and histological features of the ileum provide the keys to understanding this distinct phenotype. Moreover, we discuss herein the crosstalk that occurs in the ileum between an individual and her/his environment and the clinical significance.

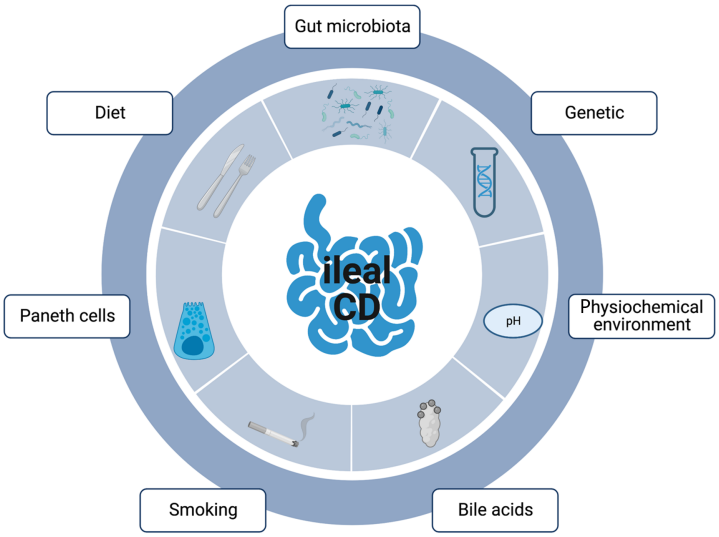
INTRODUCTION

Crohn's disease (CD) is an inflammatory bowel disease (IBD) characterized by repetitive inflammatory flares, and often chronicity. Unlike ulcerative colitis (UC), the other main subtype of IBD, CD can affect any part of the digestive tract. The site of the disease is a critical biological aspect of CD whereas inflammatory, stricturing or penetrating behaviour is thought to be a reflection of disease progression[1].

Data on the epidemiology of IBD are provided by population-based studies showing an increasing incidence and prevalence of IBD in the West over the last 50 years[2,3]. In a systematic review pooling all epidemiological studies on IBD worldwide since 1990, the global prevalence of IBD is higher in Western countries (322 per 100000 in Germany) than in newly industrialized countries[4]. In newly industrialized countries like Asia and the Middle East, epidemiological studies report a rising incidence of CD[4,5]. The Montreal classification distinguishes CD involving the ileum, the colon and both the colon and the ileum[6]. About one third of patients with CD presents a disease involvement limited to the ileum and this proportion does not vary between 'Western' and newly industrialized countries[3,5,7]. Once the diagnosis of ileal CD is made, less than one fifth of patients will present colonic lesions over time[3]. In addition, ileal CD occurs in younger patients than colonic CD[1]. These epidemiological observations have led some experts to plead for personalized approaches to therapy based on the disease site.



Even though CD pathogenesis remains elusive, current consensus considers CD a result of genetic, immunological and environmental factors[2]. Of relevance, the ileum is the site for the crosstalk of these multiple etiological factors in CD. In this review, we will depict the different physiopathological aspects of ileal CD and their clinical impact (Figure 1).

GENETIC SUSCEPTIBILITY

Genetic factors are involved in IBD physiopathology and genome-wide association studies have linked several genes with the site of the disease. In a large epidemiological study performed in more than 34000 patients with IBD across Europe, North America and Australia, susceptibility genes were determinants of the site of the disease whereas inherited genes showed a loose link with the inflammatory, penetrating or stricturing behaviour of the disease[1]. The genetic variants presented herein sum up the current state-of-the-art but new techniques such as genomic DNA are likely to provide new insights in the next few years.

NOD2

NOD2 is a sensor of the innate immune system, able to detect bacterial fragments, specifically muramyl dipeptide[8]. During *in vitro* differentiation of intestinal epithelial cells into Paneth cells, NOD2 signalling can modulate the expression of enteric antimicrobial peptides[9]. Even though intracellular pattern recognition receptor gene *NOD2* is widely associated with CD risk[2], mutations in the *NOD2* gene are strongly associated with ileal CD and are correlated with a younger age at diagnosis[1,10,11]. The specific association between *NOD2* mutations and ileal CD is partially explained by its distribution along the gastrointestinal tract. Histologically, *NOD2* is overexpressed in ileal crypts compared to colonic crypts[12].

Figure 1 Potential factors involved in ileal Crohn's disease. While Crohn's disease (CD) occurs in any part of the gastrointestinal tract, the ileum is frequently involved. Potential factors involved in ileal CD are genetic susceptibility genes and most of these genes are associated with Paneth cell dysfunction. Environmental factors may also be involved such as diet, gut microbiota and smoking. Diet can modulate the composition of bile acids and gut microbiota, which in turn affect the susceptibility of the ileum to inflammation. Created with BioRender.com. CD: Crohn's disease.

LRRK2

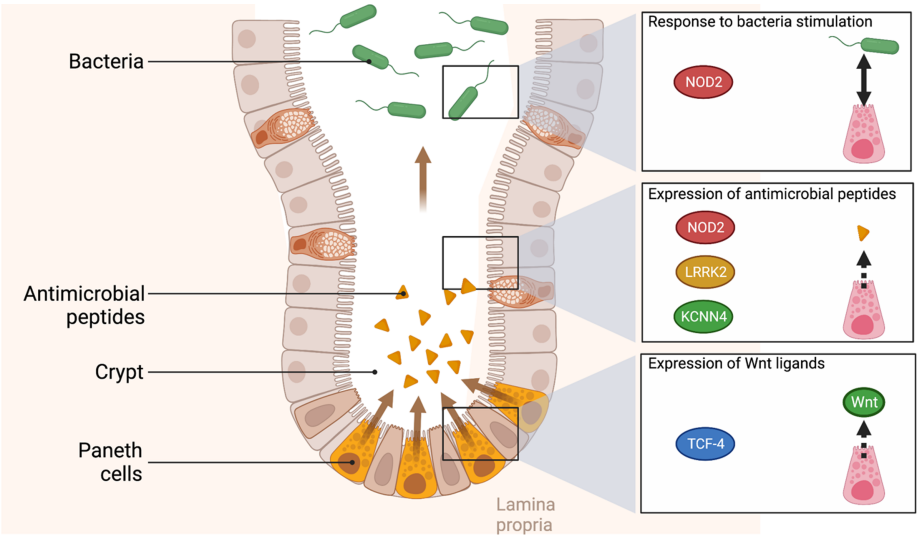
Like *NOD2*, the *LRRK2* gene is expressed in Paneth cells. *LRRK2* gene is implicated in vesicular trafficking, cytoskeleton homeostasis and consequently in inflammation and immune response[13]. More specifically, LRRK2 is overexpressed in Paneth cells and its deficiency causes deprivation of lysozyme in Paneth cells[14]. In a case-control study, mutations of *LRRK2* were associated with ileitis and an early onset of CD[15].

Major histocompatibility complex

The expression of other genes involved in immune response is likewise implicated in ileal CD. The major histocompatibility complex is involved in the presentation of antigen in a large variety of cell types including T-cells. In a recent meta-analysis, several mutations of these genes were associated with CD especially in the Korean population but also in the European population[16]. Of note, single nucleotide polymorphisms of these genes were more common in patients with ileal CD compared to patients with colonic CD[1].

ATG16L1

Among susceptibility genes identified in CD, the allele ATG16L1^{T300A} was associated with impaired autophagy[17,18]. The expression of *ATG16L1* was decreased in CD patients[19]. In 9-10-month-old mice, the specific deletion of *Atg16L1* allele in intestinal epithelium cells (IEC) led to a transmural CD-like ileitis associated with endoplasmic reticulum stress[20]. Interestingly, *NOD2* mutations are also associated with autophagy defects.



Tcf-4

In IBD patients, the reduction of the Wnt-signalling pathway transcription factor Tcf-4 was associated with a predisposition for ileal CD[21,22]. A reduced expression of Tcf-4 resulted in a reduced expression of Paneth cell defensins[21]. In a murine Tcf-4 knockout model, a decreased expression of alpha-defensin levels and a reduced capacity of bacterial killing were observed[21].

KCNN4

Finally, in the array of genes implicated in the immune response mediated by Paneth cells, the conductance calcium-activated potassium channel protein (KCNN4) is part of the potassium pump in the human intestine[23]. The blocking of this calcium-activated potassium channel protein reduced mouse Paneth cell secretion in response to bacterial stimulation[24]. In human, mutation of the *KCNN4* gene was associated with ileal CD in the Australian and New Zealand population[25].

In the susceptibility genes mentioned above, most genes are associated with Paneth cell dysfunction as illustrated in Figure 2. We will detail below the potential involvement of Paneth cells in ileal CD.

DOI: 10.3748/wjg.v29.i21.3222 **Copyright** ©The Author(s) 2023.

Figure 2 Putative role of gene susceptibility in Paneth cell dysfunction. Paneth cells are secretory epithelial cells located in the intestinal crypts. Paneth cells produce antimicrobial peptides in response to bacterial components and support stem cell function through Wnt signalling. Most of the susceptibility genes associated with ileal Crohn's disease (CD) involve Paneth cell dysfunction. NOD2 and *LRRK2* genes are expressed in Paneth cells and their deficiency in ileal CD modulates the expression of antimicrobial peptides such as alpha-defensins or lysozyme. Similarly, the reduction of the Wnt-signalling pathway transcription factor Tcf-4 is associated with a predisposition for ileal CD and leads to a reduced expression of Paneth cell defensins. The blocking of calcium-activated potassium channel protein (KCNN4) inhibits mouse Paneth cell secretion in response to bacterial stimulation. Created with BioRender.com.

THE ILEUM, A SPECIFIC PART OF THE GASTROINTESTINAL TRACT

Beyond genetic factors, the histological and anatomical features of the ileum itself may partially explain the propensity of this specific part of the gastrointestinal tract to be affected by CD.

Physicochemical environment

The ileum presents a unique chemical microenvironment. The intraluminal pH in the ileum is 7.4, the highest of the human digestive tract as a result of small bowel mucosal bicarbonate secretion[26]. Comparatively, the intraluminal pH in the caecum is lower, 6.5, due to the bacterial production of short fatty acids by colonic bacteria[26,27]. The functional characteristics of the digestive tract microbiota are modulated by pH level. In the environment of the ileum (pH = 7.4), short chain fatty acids increase the growth and the motility of pathobionts whereas, in the colonic environment (pH = 6.5), short chain fatty acids downregulate the virulence of gene expression of these strains[28].

Histological changes in ileal CD

From a clinical point of view, most of histological features encountered in ileal CD were also found in other diseases as backwash ileitis in UC for instance[29]. Although epithelioid granuloma is considered as the histological hallmark for the diagnosis of ileal CD, it is not a mandatory prerequisite[30]. In about one quarter of patients with ileal CD, pyloric gland metaplasia resulting from the expression of mucin genes normally specific to the stomach (*MUC5AC* and *MUC6*) were noted[30,31]. Although numerous other histological features are described in ileal CD, focal crypt irregularities are considered by expert consensus as one of the most reliable signs of CD[30].

From a biological point of view, the most noteworthy change is found in Peyer's patches. Peyer's patches are ileal immune structures characterized by a B-cell germinal centre surrounded by a T-cell interfollicular region. These mucosal-associated lymphoid tissues can act as "gateways" of the intestine. The epithelium and the underlying lymphoid follicle differ from the surrounding villus epithelium of the ileum. Indeed, the function of this follicle-associated epithelium consists in sampling and transporting luminal antigens through M cells and dendritic cells to CD^{4+} cells[32]. Early histological changes in Peyer's patches were reported in ileal CD such as an increase in mast cells or erosive epithelial lesions[33,34]. Further, the increased number of glial cells in the Peyer's patches of patients with ileal CD resulted in an enhanced intestinal permeability[34]. Together these phenomena may explain the increased vulnerability of the ileal mucosa to bacterial invasion in CD patients[35].

Enteric nervous system

As mentioned in the previous section, the histological changes observed in ileal CD include glial cells and the enteric nervous system (ENS). In patients with ileal CD, both the submucous and the myenteric plexus present an overall increase in the number of neuronal cell bodies, enteroglia and interstitial cells

of Cajal associated with an upregulation of apoptosis in enteric neurons and enteric glial cells[36,37]. To that extent, although functional evidence is lacking in the literature to fully support this hypothesis, the increased transit time observed in CD patients could be seen as a consequence of ultrastructural injury to interstitial cells of Cajal in the myenteric plexus[38,39].

Beyond the role of the ENS in intestinal mobility, the density of enteric glial cells conveys a higher risk of ileal CD recurrence after surgery. Thus, after ileocolonic resection for CD, inflammation in or around nerve bundles or enteric ganglia was reported in several clinical studies as a risk factor for CD recurrence[40-43]. In the uninflamed section from ileocolonic samples, the number of S100-positive enteric glial cells was enhanced in patients with relapsing disease unlike vasoactive intestinal polypeptide or substance P positive cells[44]. Furthermore, the ileum of CD patients harbours a different distribution of enteric glial cells with a higher density of these cells around Peyer's patches. In parallel, the mediators of enteric glial cell increased the permeability of the ileal mucosa in CD patients whereas they decreased the permeability of the mucosa in non-IBD patients[34]. The importance of these findings on the natural history of CD remains to be determined. In particular, the effect of the modulation of the ENS in neuro-immune interplay needs to be investigated.

Paneth cells

Paneth cells are mostly located in the ileum and nearly absent from the colon[45]. This cellular type is found between intestinal stem cells in the small intestinal crypts. Paneth cells produce not only antimicrobial peptides that regulate host-microbe interplay but also factors such as Wnt ligands modulating the activity of intestinal stem cells. Many of the ileal CD-associated mutations discussed before involve cellular pathways of Paneth cells.

Paneth cells are rich in mitochondria to sustain their energy-expending secretory functions. In *SAMP1* mice, mice genetically predisposed to CD-like ileitis, the number of Paneth cells was decreased and abnormal Paneth cells were associated with disease progression[46,47]. Likewise, the number of Paneth cells is decreased in the small intestine of CD patients. This observation was made in several ethnic populations and particularly in paediatric cohorts[19,48,49]. Mucosal biopsies from adult CD showed ultrastructural abnormalities in mitochondria, especially in CD patients with inflammation (73.3%) but also in inactive CD patients (20.3%) which was not the case for goblet cells and enterocytes[50]. In patients with ileal CD, the count of abnormal Paneth cells correlated with disease activity and was predictive of recurrence after surgery[51]. Some authors hypothesised that this dysfunction in Paneth cells could result from mitochondrial impairment[50-52]. Besides, in mice, Paneth cell defects triggered by loss of prohibitin 1, a major component protein of the inner mitochondrial membrane implicated in cell respiration, caused ileitis[52]. This effect is mediated by oxidative stress. Furthermore, the use of a specific mitochondrial-targeted antioxidant (Mito-Tempo) ameliorates ileitis in mice. The use of the same mitochondrial-targeted antioxidant (Mito-Tempo) in human ileal biopsies of CD patients normalized the expression of 25% of altered CD genes, including genes implicated in antigen processing, lipid metabolism, apoptosis, and interleukin (IL)-17/IL-23 signalling[50].

Immune response

As highlighted by research in immunological processes, Paneth cells are part of the crosstalk with the immune system to maintain intestinal microbial homeostasis and intestinal barrier[53,54]. When biopsies from CD patients were compared according to the site of inflammation in the gastrointestinal tract, differences in neutrophil activities were observed. For instance, matrix metalloproteinase-9 and myeloperoxidase were relatively less increased in ulcer edges of ileal CD compared to colonic CD, suggesting less neutrophilic degranulation in ileal CD[55].

Likewise, innate lymphoid cells (ILCs) are gaining interest as components of the immune system. Three groups have been individualized according to their properties: ILC1, ILC2 and ILC3. A switch was noted in the inflamed ileal mucosa of CD patients, from an ILC3 phenotype limiting commensal bacteria specific $CD4^+$ T cell response to an ILC1 phenotype associated with interferon (IFN)-γ production[56]. The aryl hydrocarbon receptor (AhR), a ligand-dependent transcription factor, was involved in this process and downregulated in inflamed mucosa of IBD patients[57,58]. Pharmacological or genetic activation of the AhR enhanced ILC3 maintenance conferring a protection against pathogenic bacteria in mice and downregulated ILC2 maintenance implicated in immune response in worm[59]. AhR agonists arise from the environment, commensal flora and tryptophan metabolism[60]. In patients with ileal CD, impaired tryptophan metabolism was observed with decreased levels of kynurenine and expression of kynureninase[61].

Concordantly with a typical cellular immune response, ileal CD instigates a specific cytokine profile. Interferon lambda (IFNL) is secreted in response to microbial stimulation or to T-cell-mediated mucosal inflammation. IFNL was upregulated in the ileal mucosa of patients with CD and triggered ileitis in a murine model and induced Paneth cell depletion independently of tumour necrosis factor (TNF)[62]. The effect of IFNL in the ileum is mediated by the JAK-STAT pathway which represents a promising therapeutic target already being used in the clinic[62].

Besides the role played by IFNL, IL-22 contributes to the pathogenesis of ileal CD. IL-22 is produced by T-cells and ICL3 during IBD flares[63,64]. IL-22 is thought to assume an immunoregulative role as its inhibition by the IL-22 binding protein induced a severe inflammation in a rodent colitis model[64]. In

the ileum, interestingly, the levels of IL-22 binding protein were specifically high in comparison with the colon[65]. This heterogenous distribution along the gastrointestinal tract may result from the infiltration of eosinophils in the ileum and the production of IL-22 binding protein[64,65].

The ileum as an endocrine organ

If a high proportion of eosinophil cells was present in the ileum, an enhanced enteroendocrine cell activity was also found[66]. Additionally, terminal ileal chromogranin A cells and glucagon-like peptide 1 (GLP-1) positive L-cells were increased in ileal CD specifically[66]. However, studies on the serum levels of GLP-1 are rare and include small cohorts (< 20 patients). Data were inconclusive and showed similar serum levels of GLP-1 between patients with ileocolic CD and colonic CD but a higher serum level of GLP-1 in IBD compared to healthy controls[67,68]. Thus, no firm conclusion can be drawn regarding the nutritional and immune impact of this discovery.

Besides harbouring enteroendocrine cells, the ileum harbours oestrogen receptor subtype β, whether the ileum is affected by CD or not. The expression of subtype β was associated with a milder disease course in a cohort of 37 patients with ileal CD. Accordingly, the inflammation score was inversely correlated with the expression of oestrogen receptor β. Similarly, a higher expression of oestrogen receptor β was found in patients with non-stricturing non-penetrating disease[69]. In a chemical colitis model in rats, the activation of oestrogen receptor b reduced inflammation score as well as inflammatory pain and inhibited the ionotropic P2X3 receptor[70]. Notwithstanding this observation, female sex was not independently associated with ileal CD[1,71].

Myofibroblasts

While ileitis is often studied from an inflammation perspective, little is published about cell repair. The gene encoding tumour progression locus-2 kinase, a proinflammatory enzyme, was associated in a genetically invalidated murine model with a surprising homeostatic role, modulating the effect of chemically induced colitis. Mechanistically, this gene does not directly impact the immune response but plays a critical role in intestinal myofibroblasts which contribute to the healing of intestinal epithelium. In response to inflammatory signals from the microenvironment, intestinal myofibroblasts trigger compensatory epithelial proliferation in the intestinal crypts[72].

Transcriptome studies

The integration of the different pathways mentioned above in the pathogenesis of ileal CD is facilitated by multi-omic studies. Thus, differences in pathogenesis between the ileum and the colon are highlighted by these techniques. For instance, in CD patients, the metabolomic study of non-inflamed ileum and non-inflamed colon biopsies distinguish clearly different profiles. It is noteworthy that these differences were blurred in inflamed ileum and colon samples[73].

Although the physiopathology of ileal CD has been studied as a unique phenomenon, emerging evidence advocates for a more heterogeneous process in which physiopathological pathways differ from one patient to the other. Thus, transcriptomic data analysis from CD ileal tissue sample was able to identify subgroups of patients with distinct recurrence rates after surgery[74].

In a recent transcriptomic study of ileal mucosa samples, inflammatory genes (IL-6, IL-8, IL-1β) were upregulated whereas metabolic process genes were downregulated in ileal samples from CD patients compared to controls. Early post-operative recurrence of CD was associated with an overexpression of TNF-α, IFN-γ, IL-23A and IL-17A upregulation. In addition, using a regression model to predict post-operative recurrence of CD, mitochondrial dysfunction and JAK/STAT upregulation in the ileum were independently associated with post-operative recurrence[75]. Transcriptomic studies also provide new insights into cell population specificities in ileal CD. When mapping the cell type of the ileal mucosa of CD patients, tuft and $BEST^{4+}$ cells were the cell types associated with CD, irrespectively of the treatment status[76]. Intestinal tuft cells are a rare cell type implicated in the defence against helminthic and protozoan infections[77]. $BEST^{4+}$ cells represent about 1% of ileal epithelial cells and plausibly contribute to the mucus secretion of goblet cells[78]. Surprisingly in this ileal cell type study, immune compartment was slightly affected by CD despite the fact that treatment status in CD patients modified the epithelial and immune compartment[76].

Among the differentially expressed genes in ileal inflammatory response, activating transcription factor 4 (ATF4) is a transcription factor widely expressed in the human body, including the ileum. ATF4 downregulation in intestinal epithelial cells has been observed in active CD in patients and causes spontaneous enterocolitis in mice while altering ileal Paneth cell function. Furthermore, murine ATF4 deletion impaired the glutamine uptake of the intestinal epithelium and concordantly glutamine supplementation restored Paneth cell function and decreased intestinal inflammation[79]. A few years earlier, the inhibition of the ATF4 pathway demonstrated an altered autophagy in human intestinal epithelium in the presence of adherent-invasive Escherichia coli (AIEC). This pathological response resulted in the intracellular bacterial replication of AIEC and consequently in pro-inflammatory patterns[80].

BILE ACIDS

The role of bile acids is largely reported in liver disease in which bile acids are inflammatory cues and treatment targets[81]. The involvement of the gut in the pathogenesis of inflammatory liver diseases and similarities in etiological factors has led to consideration of the role of bile acids in IBD[82].

Primary bile acids are produced in the liver and secreted through the biliary tree into the gastrointestinal tract. Most primary bile acids are reabsorbed by the ileum and hence recycled several times. A minority of primary bile acids are transformed into secondary bile acids by a narrow range of gut bacteria. The pool of bile acids influenced the composition of gut microbiota which in turn modulated the composition of the bile acid pool[83]. Thus, impaired bile acid pools in relation to impaired microbiota enzymatic activities have been described as contributing to the inflammatory loop of IBD[84]. Bile acid composition in the lumen of the ileum differs between CD and non-CD patients with a relative decrease of primary bile acids in the ileum of CD patients[85]. Nevertheless, this finding should be interpreted with caution as malabsorption of bile acids was documented as a consequence of ileal CD especially in patients with a history of ileal resection[86,87]. Moreover, in a cohort of 166 patients, enhanced primary biliary level in the stool was independently associated with ileitis[88]. In a multi-omics approach based on a stool collection of 200 IBD patients, ileal CD profile was characterized by increased primary and secondary bile acid levels and shifts in taxa in favour of bacteria associated with bile acid-rich environments (*Gammaproteobacteria* and *Blautia sp*.)[89]. Further, the level of secondary bile acids in patients with inflammation limited to the ileum tended to increase after biological treatment reaching a similar level with control subjects[90].

In addition, bile acids exert inflammatory modulating properties through the stimulation of farnesoid X receptor (FXR). In a murine model of chemically induced inflammation, the activation of FXR demonstrated anti-inflammatory effects through a reduction of epithelial hyperpermeability and of proinflammatory cytokine production[91]. Furthermore, the obstruction of bile flow in mice induced mucosal ileal injuries reversed by administration of bile acids. In detail, this result may be explained by the activation of FXR by bile acids which promoted enteroprotective genes and limited ileal bacterial overgrowth[92]. Furthermore, bile acid pool modulation directly affects the ileum and Paneth cells. According to a recent article, Paneth cell number was linked to diet and to microbiota by bile acid in obese CD and non-CD patients irrespectively of other risk alleles (ATG16L1 and NOD2)[93]. In fact, in mice fed with a high fat diet, a similar phenomenon was observed and notably, high fat diet alone in germ-free mice as well as microbiome transfer alone in mice fed with standard diet were unable to induce an alteration in Paneth cells. The reason for this phenomenon was also dependent on FXR activation by the bile acid pool. Thus, the conjunction of a high fat diet and *Clostridium*-mediated production of secondary bile acids may explain the role of both diet and microbiome in this mechanism [93].

Lastly, bile acids promoted the expression of long polar fimbriae favouring the interplay of these strains with Peyer's patches and bacterial translocations[94]. For example, primary bile acid level was inversely correlated with the abundance of *Faecalibacterium prausnitzii* (*F. prausnitzii*) and its acetate and L-methionine producing enzyme[88]. In patients treated by surgery for ileal CD, bile acid metabolism specificities were associated with an ileal recurrence of CD[89].

Nevertheless, there is only limited evidence on the therapeutic role of bile acids in ileal CD. While several authors reported the protective role of ursodeoxycholic acid and of its precursor, the lithocholic acid, against chemically induced colitis in mice[95-97], there is a lack of data about the effect of oral supplementation with ursodeoxycholic acid in patients with IBD. Thus, only one small single-centre trial examined the effect of ursodeoxycholic acid in UC and none was performed in patients with CD [98].

MICROBIOTA

An increasing number of authors have investigated the link between gut microbiota and CD. However, many of these studies focused on the analysis of DNA extracted from stool. This methodology shed light on the colonic microbiota of the colonic lumen but was unable to draw any conclusions on the microbiota associated specifically with the ileum. Moreover, in a systematic review, the study mucosa-associated microbiota was regarded as more relevant in the understanding of CD pathogenesis[99]. In addition, dysbiosis was described in some mice models as a by-stander of ileitis. For example, in genetically predisposed mice Atg16L1$^{\Delta IEC}$, dysbiosis was observed but litter cross-fostering predisposed to colitis but not ileitis[20].

Host/microbiota interplay

Microbiota homeostasis plays a critical role in CD physiopathology[2]. Thus, mucosal immunity regulator molecules such as vitamin D receptors (VDR) have been associated with a susceptibility to bacterial and chemical colitis. The genetic inhibition of VDR in the Paneth cells of VDR$^{\Delta PC}$ mice resulted in a lower expression of lysozymes in Paneth cells[19]. Inhibition of VDR influences the response to

pathogenic bacteria. VDR$^{\Delta IPC}$ mice are not only more sensitive to bacterial infection but also to chemical damage. Conversely, this susceptibility in VDR$^{\Delta IPC}$ mice was reduced in case of co-housing with non-VDR$^{\Delta IPC}$ mice, indirectly suggesting a protective role of the microbiome[19]. In SAMP1/YitFcsJ (SAMP1) mice which develop spontaneous terminal ileitis, dysbiosis occurred during disease progression with a decrease in *Lachnospiraceae* and in *Bacteroides*. In the same animal model, α-defensins misfolding was associated with dysbiosis and even induced dysbiosis in wild-type mice[47].

In this regard, the barrier function of the ileum is also a major feature in the understanding of host-microbiota interplay. Accordingly, human β-defensin 3 peptide was decreased and redistributed to the basolateral surface of the ileal epithelium[100]. In parallel, increased enzyme indoleamine 2,3-dioxygenase 1 (IDO1) was found in patients with active CD. This enzyme is the first enzyme in tryptophan metabolism on the kynurenine pathway and is responsible for mucus layer thickening and mucus-associated modulation of microbiota. In a murine enterocolitis model, IDO1 upregulation reduced the abundance of enteropathogenic *E. coli* in the ileum. Likewise, IDO1 downregulated inflammation in response to chemical colitis in mice and augmented *A. muciniphila* and *M. schaedleri* abundance[101].

AIEC

In the nineties, a French team identified a strain of *Escherichia coli*, AIEC, which was adherent to the ileum without harbouring virulence factor-encoding genes[102]. AIEC was shown to be associated with ileal CD in further studies and to be able to invade epithelial cells[102,103]. Interestingly, AIEC was able to induce granulomas *in vitro*, which is one of the main histologic features of CD[2,104]. AIEC is classically identified on ileal biopsy but a dedicated serology could also be informative and less invasive [105]. The invasive property of AIEC is favoured by the overexpression of the glycoprotein *CEACAM6* in the ileal epithelium. The interaction of this glycoprotein with the bacterial adhesive factor FimH promoted AIEC-enterocyte interplay in the ileum[106]. Using this receptor, AIEC modulated the metabolism of the ileal epithelium and induced strong gut inflammation[107]. AIEC induced the expression of hypoxia inducible factor, overexpressed in the ileum of CD patients and promoted barrier defects in the intestinal epithelium paving the way for the onset of inflammation[108].

The relapse of CD in patients after surgical treatment may be used to understand the early steps in CD onset. In a recent prospective, multicentric cohort of patients with ileal resection, AIEC in the remaining ileum was associated with an early ileal lesion of CD recurrence. The presence of AIEC within the surgical ileal specimen was predictive of the endoscopic recurrence of CD[109].

As highlighted in a recently published article, factors influencing ileal susceptibility to AIEC were numerous and among them epigenetic regulators had a modulating effect on a large range of proteins [110]. For this reason, before considering a clinical application in ileal CD, further studies are needed to prevent possible adverse effects induced by the modulation of these epigenetic targets or to identify more specific genes associated with AIEC colonisation. Another promising approach would be the use of bacteriophages to target specifically AIEC in ileal disease[111]. To date, no bacteriophage has been approved for intestinal therapeutic use in human, either in the European Union or in the United States, despite numerous studies that have reported encouraging results *in vivo*. Therefore, data about the effect of bacteriophages on human microbiota are needed in the future[111].

F. prausnitzii

In a stool based multi-omics analysis of 200 IBD patients, the abundance of a member of Firmicutes, *F. prausnitzii,* was highly discriminant of ileal CD compared to colonic CD[89]. Even in non-inflamed ileal samples of CD patients, the commensal bacterium *F. prausnitzii* was decreased in comparison with healthy controls which suggests a relevant causal link between this bacteria and CD onset[112]. Accordingly, a low level of *F. prausnitzii* in the ileal mucosa-associated microbiota was associated with a higher recurrence rate of CD after ileal resection, corroborating the putative role of *F. prausnitzii* in the pathogenesis of ileal CD[113]. In addition, a recent study confirmed the role of *F. prausnitzii* in ileitis after ileocolectomy, pointing to a possible association with a bile salt profile. Thus, elevated levels of primary bile acids were associated with a decreased abundance of *F. prausnitzii*. These two parameters were the only factors associated with ileitis in this cohort of 166 patients[88]. The administration of *F. prausnitzii* or of its supernatant *in vitro* and *in vivo* counterbalanced gut inflammation by blocking nuclear factor kB activation and IL-8 production[113]. Interestingly, in CD patients, *F. prausnitzii* was associated specifically with ileitis, irrespectively of their genetic background[89,114]. In an original work conducted in twins in whom biopsies were performed in the lower gastrointestinal tract, the abundance of *F. prausnitzii* was specifically decreased in ileal CD, compared to colonic CD or in healthy twins[114].

Mycobiota

The study of microbiota in IBD is not limited to bacteria but also includes fungi. Fungal microbiota was suspected to be strongly involved in CD pathogenesis in particular because of the diagnosis value of anti-Saccharomyces cerevisiae antibodies in CD[2]. In a study of 168 ileal biopsies, mycobiota was modified in CD patients with an increased abundance of *Malassezia* and a decreased abundance of Saccharomyces. The increase of Malassezia was notably associated with a severe evolution of the disease

during follow-up[115].

The fungus *Debaryomyces hansenii* was increased in CD patients with inflamed ileum compared to non-inflamed ileum. Moreover, oral gavage with *Debaryomyces hansenii* impaired crypt regeneration and wound healing after biopsy injury[116].

ENVIRONMENTAL FACTORS

The microbiota bridges the gap between host susceptibility factors and its environment. Most environmental factors are identified by epidemiological studies and associated with the onset of CD or its recurrence after surgery. Few of them though can impede the natural history of CD once the disease is established.

Smoking

Cigarette smoking is a well-established risk factor for developing CD[1-3]. In patients with CD, the relative statistical weight of smoking was larger than the relative weight of the genetic variants presented in the previous section[1]. Besides, cannabis is frequently used as a symptomatic treatment by patients with CD involving the ileum and is associated with tobacco[117]. Regarding cannabis use, in a double-blind, randomized, placebo-controlled trial, cannabis oil induced clinical improvement without any endoscopic change[118].

Regarding tobacco, in mice, cigarette smoke extract induced intestinal inflammation and morphometric changes in the ileal epithelium regardless of the route of administration (intragastric or intraperitoneal), advocating for a systemic effect[119]. Moreover, mice exposed to cigarette smoking were more likely to develop pathological inflammation in response to bacterial inflammation which could be the hallmark of an impaired expression of antimicrobial peptides[119]. Besides, smoking was associated with a reduced number of normal Paneth cells in the ileum, both in patients presenting a CD susceptibility allele ($ATG16L1^{T300A}$) as well as in mice presenting this genetic susceptibility. This defect in the ileum was mediated by the Paneth cell apoptosis driven by the activation of peroxisome proliferator-activated receptor gamma (PPARγ) and prevented in mice by the use of anti-TNF-α drugs[120].

Moreover, smoking is associated with an upregulation of angiogenesis in smokers with CD compared to their non-smoking counterparts. Importantly, mice exposed to cigarette smoke for 8 wk presented mucosal tissue hypoxia associated with an increased expression of pro-inflammatory cytokines and of angiogenic factors whereas smoking cessation reversed this process in the ileal mucosa. In addition, cigarette smoke exposure was associated with an increased sensitivity to chemically induced colitis [121]. Although genes of hypoxia-inducible factor were overexpressed in the inflamed ileum and in the adjacent mesenteric tissue of CD patients, hypoxia in mice did not impact experimental ileitis[122-124]. All together, these results advocate for a specific impact of tobacco smoking in the pathogenesis of ileitis.

Evidence for other environmental factor is rare in the literature. Recently, serum levels of bisphenol A, a component used in the manufacture of various plastics, have been linked to inflammatory status in CD patients. Furthermore, patients with bacterial DNA translocation presented a higher serum level of bisphenol A associated with a reduced expression of tight junction genes[125].

Diet

Western diet is characterized by a low intake of fibres contrasting with a high intake of refined sugar, animal protein and total fat. Numerous links between diet and IBD have been established[126]. To that extent, diet modulates the microbiota associated with the ileal epithelium. Thus, AIEC was associated with hyperacetylated histone H3 in the ileal epithelium and consequently histone deacetylase enzymes controlled the entry of AIEC in IECs in a murine model. Interestingly, a high fat diet enhanced histone acetylation in mice compared to a standard diet[110]. Overweight (body mass index > 25 kg/m^2) in IBD and in non-IBD patients was associated with Paneth cell defects in the ileal epithelium. This defect can be induced by Western diet in mice[93].

Regarding fat intake, the ratio between n-3 and n-6 polyunsaturated fatty acids (PUFAs) is unbalanced in favour of an excessive intake of n-6 PUFAs in Western diet. Oral feeding with n-3 PUFAs in SAMP1/Yit mice ameliorated the histological features of ileitis, and decreased addressin molecule expression (MAdCAM-1) as well as lymphocyte infiltration in the ileum[127]. To that extent, oral supplementation with linseed oil rich in α-linolenic acid (n-3 PUFAs), in a physically active murine model, reduced inflammation after oral challenge with AIEC[128]. However, oral n-3 PUFAs supplementation has not shown definitive results in patients with CD[129]. In all likelihood, n-3 PUFAs alone are unable to stop the inflammatory loop once started but remain putative candidates to prevent the onset of ileal CD.

Fibre intake was identified as a protective factor against CD onset but not UC[130]. Although epidemiological data were based on a 40-year-old population, fibre intake and more accurately inulin supplementation modulated PPARγ signalling pathway in pigs[131].

Vitamin D deficiency in IBD patients has been reported in numerous studies reviewed elsewhere as an explanation of the North-South gradient of IBD prevalence[132]. In mice fed with a vitamin D deficient diet, miR-142-3p expression was upregulated, culminating in a reduction of ATG16L1 and autophagy specifically in ileal Paneth cells. In a paediatric cohort of IBD patients, colonic samples displayed likewise an enhanced expression of miR-142-3p statistically associated with low serum vitamin D levels[133]. As discussed previously, VDR were overexpressed in the ileum and were involved in the adequate response to enteropathogens[19]. When associated with a high fat diet, vitamin D deficiency and genetic VDR inhibition led to defective Paneth cell defensins secretion and gut permeability driving endotoxemia and systemic inflammation[134].

Last, Western diet is also characterized by a high intake of dietary additives related to the consumption of ultra-processed food. To that extent, dietary emulsifiers carboxymethylcellulose and polysorbate-80 were associated with an increased virulence and enrichment of ileal pathobionts[135].

More generally speaking, diet in patients with ileal CD should be based on the guidelines of the European Society of Nutrition. The findings discussed above and others have led to recommendations for a balanced diet rich in fruit, vegetables and n-3 fatty acids, avoiding a restrictive diet[136]. As highlighted in this European consensus, good quality data regarding the effects of experimental diets are rare in the literature. In particular, there is a lack of randomized control trials to recommend a more specific diet in patients with active ileal CD[136].

CLINICAL IMPLICATIONS

The factors summarised in the previous paragraphs give rise to a distinctive natural history of ileal CD with specific clinical consequences and interventions necessary.

Natural history of ileal CD

In CD, the shortest time from diagnosis to first surgery is in ileal CD compared to other disease sites. Thus, the median time to surgery in ileal CD is about 6 years. Thirty years after being diagnosed with ileal CD, almost all patients had undergone at least one surgery according to a broad international study [1]. At 12 mo after surgery, a recurrence was observed on colonoscopy, at and above this anastomosis in 73% of patients in absence of any treatment[137]. These data regarding recurrence rates published 30 years ago led to the development of preventive strategies after surgery.

In terms of behaviour, ileal CD was more likely than colonic CD to be complicated by penetrating or stricturing lesions[3]. These severe manifestations contribute to the high rate of surgery. Accordingly, strictures are challenging complications that are usually unresponsive to medical therapy in the absence of surgery[3]. Strictures result from the accumulation of fibrotic protein in the extracellular matrix produced by fibroblasts which are partially derived from epithelial cells *via* epithelial-mesenchymal transition (EMT)[138]. Accordingly, based on a comparative study of ileal *versus* colonic ulcers, EMT appeared to be a highly noticeable feature in ileal ulcers of CD unlike colonic ulcers of CD[55]. Ileal strictures were likely to present mesenteric fat wrapped around the stricture, known as creeping fat [139], which harbours viable bacterial translocation and leads to a pro-fibrosis M2-type microenvironment[140-143]. Remarkably, creeping fat associated with the ileum presented a 10-fold higher concentration of T-cells than colonic fat[144]. In addition, adipocyte hyperplasia was observed in ileal fat unlike colonic fat[144].

Beyond the ileum

Ileal crypts have been reported in the colon of CD patients[12,45]. Recently, the presence of ectopic ileal crypts discriminated IBD subtype in patients with undetermined (unclassified) colitis. The presence of ileal metaplasia in the colon was strongly associated with a final diagnosis of colonic CD[145]. This interesting discovery could enhance understanding of ileal physiopathology, pivotal to understand CD.

In a specific statistical model based on HLA types and single nucleotide polymorphism, colonic CD appeared to be an intermediate between UC and ileal CD[1]. Consecutively, knowledge of ileal CD may pave the way to understanding other phenotypes of CD.

A dedicated treatment for ileal CD?

Logically, the specificities of ileal CD discussed in this review should lead to a dedicated treatment strategy. Nevertheless, current ECCO guidelines on the medical management of CD do not advocate for a specific treatment in ileal CD[146]. Indeed, studies are controversial. Some studies reported a lower rate of response to infliximab, an anti-TNF treatment[147,148]. Conversely, numerous other studies did not describe such a difference in response rates with anti-TNF[149]. This discrepancy may result from a bias such as the extent of the disease irrespectively of the site of the disease. Interventional trials specifically dedicated to the study of ileal CD treatment are henceforth required. In the literature, colonic CD is more likely to respond to treatment compared to ileocolonic CD and mucosal healing may be more difficult to achieve in ileal disease. Likewise, ileal stricturing CD may have lower response rates [149].

As ileal stricture may develop in spite ofCD treatment, an American team sought to determine the gene pattern associated with ileal stricturing in a paediatric CD cohort. This analysis identified a long-chain fatty acid, the eicosatetranoic acid as a possible antifibrotic tool[150]. In a follow-up study, the same team showed a decrease in fibrosis and an improvement in stiffness in human intestinal organoids exposed to eicosatetraynoic acid[151]. In parallel, butyrate, a short-chain fatty acid, also downregulated fibrosis according to the same protocol[151].

CONCLUSION

The histological and anatomical features of the ileum are direct answers to the question "why the ileum?". Furthermore, the recent works presented in this review highlight the specific interplay between environmental factors, like smoking or diet, and the ileum. Currently, the prevailing requirement for surgery in a significant proportion of patients with ileal CD testifies to the urgent need for a dedicated pharmacological approach according to disease site. As the ileum is the site of interplay between host characteristics and environmental influences, a full understanding of the molecular crosstalk that occurs in the ileum is crucial to identify new therapeutic targets to significantly change the natural history of this debilitating disease.

ACKNOWLEDGEMENTS

Mathilde Leboutte was supported by a PhD from Normandie Region. Authors are grateful to Nikki Sabourin-Gibbs, CHU Rouen, for her help in editing the manuscript.

FOOTNOTES

Author contributions: Richard N wrote the first draft; all authors have read and approve the final manuscript.

Abstract

Post-infectious irritable bowel syndrome (PI-IBS) is a particular type of IBS, with symptom onset after an acute episode of infectious gastroenteritis. Despite infectious disease resolution and clearance of the inciting pathogen agent, 10% of patients will develop PI-IBS. In susceptible individuals, the exposure to pathogenic organisms leads to a marked shift in the gut microbiota with prolonged changes in host-microbiota interactions. These changes can affect the gut-brain axis and the visceral sensitivity, disrupting the intestinal barrier, altering neuromuscular function, triggering persistent low inflammation, and sustaining the onset of IBS symptoms. There is no specific treatment strategy for PI-IBS. Different drug classes can be used to treat PI-IBS similar to patients with IBS in general, guided by their clinical symptoms. This review summarizes the current evidence for microbial dysbiosis in PI-IBS and analyzes the available data regarding the role of the microbiome in mediating the central and peripheral dysfunctions that lead to IBS symptoms. It also discusses the current state of evidence on therapies targeting the microbiome in the management of PI-IBS. The results of microbial modulation strategies used in relieving IBS symptomatology are encouraging. Several studies on PI-IBS animal models reported promising results. However, published data that describe the efficacy and safety of microbial targeted therapy in PI-IBS patients are scarce. Future research is required.

Key Words: Gut microbiome; Infectious gastroenteritis; Irritable bowel syndrome; Post infection syndrome; Pathophysiology; Inflammation

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Acute infectious gastroenteritis can trigger the onset of irritable bowel syndrome (IBS), leading to the development of post-infectious IBS (PI-IBS). PI-IBS is a clinical entity associated with gut dysbiosis. Alterations in the gut microbiome can affect the gut-brain axis, visceral sensitivity, intestinal barrier, intestinal secretion, gut motility, and immune activation, which in turn can cause IBS symptoms. A better understanding of PI-IBS is necessary to develop more targeted and effective treatments. Therapies targeting the microbiome, such as probiotics, antibiotics, diet, and fecal microbiota transplants, improve IBS symptoms. There is a lack of evidence of their efficiency in PI-IBS.

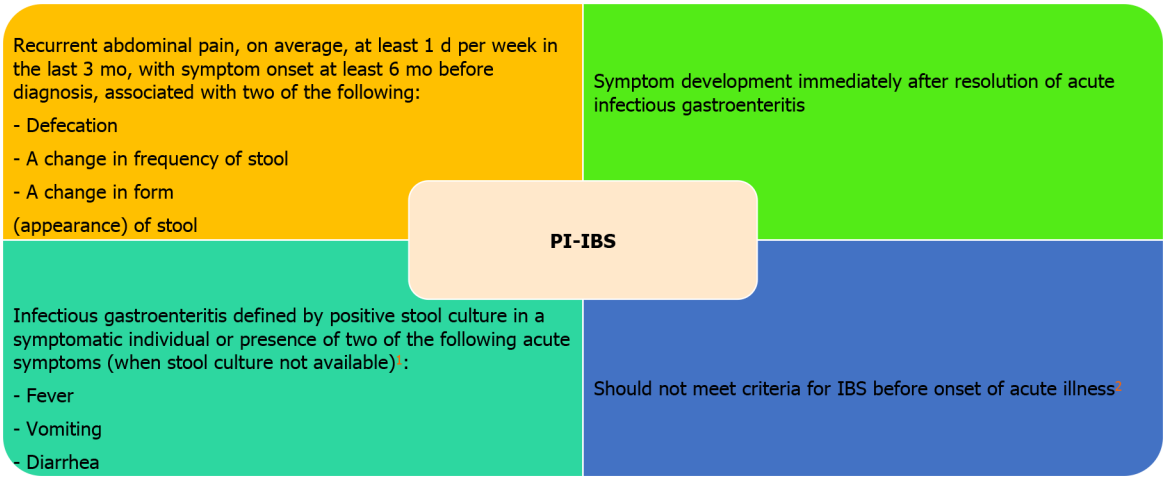
INTRODUCTION

Irritable bowel syndrome (IBS) is the most frequently encountered disorder of gut-brain interactions[1], with a worldwide prevalence ranging between 7% and 15% of the general population[2,3]. According to the Rome IV criteria, it is characterized by mild to severe recurrent abdominal pain and bloating associated with alterations in bowel habits in the absence of organic disease or biochemical abnormalities[4]. Due to its symptoms, IBS is thought to be a disabling disease. It generates significant healthcare costs, reduces work productivity and school attendance, and decreases the health-related quality of life of the affected individuals[5,6]. Despite being a frequent entity in current gastroenterology practice, the physiopathology of IBS is not fully understood. It is considered to be a complex multifactorial disorder affected by several factors such as age, sex, genetics, diet, psychosocial status, altered microbiota, subclinical inflammation, and hypersensitivity of the neural network[7,8]. In recent years, accumulating evidence has suggested that the alteration of the gut microbiota plays an important role in the pathophysiology of IBS, as gut microbes exert effects on the host immune system, on gut barrier function, and on the brain-gut axis[9,10].

Acute infectious gastroenteritis [bacterial-*Campylobacter* species[11], *Salmonella* species[12,13], *Escherichia coli* (*E. coli*)[14], *Shigella*[15], *Clostridium difficile* (*C. difficile*)[16], viral-norovirus[17], rotavirus [18], severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)[19], and protozoal-*Giardia*[20]] has been shown to be one of the strongest risk factors for the development of post-infectious IBS (PI-IBS), a distinct condition in which IBS diagnostic criteria are met[21,22]. PI-IBS occurs after the resolution of a gastrointestinal-related infection and the clearance of the inciting pathogen, in a patient without a prior history of IBS symptoms[22,23]. IBS clinical features usually develop 6-18 mo after the infectious gastroenteritis episode[24]. PI-IBS management strategies involve nonpharmacologic and pharmacologic therapies. Current guidance relies on IBS treatment experience, as there is a lack of evidence-based recommendations for PI-IBS treatment[1]. The aim of this review is to analyze the current literature and to describe the role of the human gut microbiota on PI-IBS physiopathology. The main questions to be answered include which long-term consequences of acute enteric infections may serve as triggers to PI-IBS and whether the acute enteric infection associated dysbiosis and its recovery can be used to predict PI-IBS development. Additionally, under discussion is whether there is a specific microbial signature associated with PI-IBS, as most studies of PI-IBS combine patients infected by varying pathogens, thus generating a considerable variability of outcomes. The gut microbiota modulation and its potential therapeutic implications in PI-IBS in terms of efficacy and safety continue to be a subject of debate and highlight the need for specific treatment protocols. A better characterization of the relationship between gut-associated dysbiosis and PI-IBS progression will lead the way to personalized medicine and the individualized management of each patient.

PI-IBS GENERAL DATA

A globally accepted definition of PI-IBS is not currently available in the literature. Most authors consider



PI-IBS as a form of IBS for which the symptoms, as specified in the Rome IV criteria, appear after the resolution of an acute gastroenteritis episode in patients without any IBS symptomatology before the gastrointestinal infection[1,4]. In 2019, the Rome Foundation Working Group proposed symptomatic diagnostic criteria for PI-IBS based on the Rome IV criteria (Figure 1), as there are no sensitive and specific diagnostic markers available yet[25]. Considering the predominant bowel pattern graded on the Bristol stool scale, PI-IBS can be classified as diarrhea-predominant IBS (IBS-D), constipation-predominant (IBS-C), mixed bowel habits (IBS-M), and unclassified[1,26]. A bowel pattern is considered predominant when it is ≥ 25% of the time as either hard/lumpy (IBS-C), loose/watery (IBS-D), or both (IBS-M)[1]. PI-IBS patients are more likely than sporadic IBS patients to present a diarrhea-predominant phenotype. The association between each patient and a PI-IBS subtype is important for disease management and therapy[22].

While most pathogen agents cause self-limiting acute gastroenteritis, subsequent chronic alteration may persist in some genetically predisposed individuals[27]. According to several studies, about 1 in 10 individuals with an acute episode of gastroenteritis will develop PI-IBS[21,28]. A 2017 meta-analysis reported that the incidence of PI-IBS more than a year after the acute episode of gastroenteritis was 14.5%[29]. Epidemiologic data of the reported incidence and prevalence vary across the literature, in part due to the methodological heterogeneity, including the criteria used to define IBS (Rome criteria I, II, III, or IV)[3,16,22]. Moreover, there is evidence that the data might be underestimated due to the high incidence of infectious gastroenteritis and the poor recall of milder episodes, as the diagnosis relies on self-reported symptom clusters[2,21,30].

Female sex, a young age, certain psychological factors before or during acute infectious gastroenteritis (anxiety, depression, somatization, and/or neuroticism), and genetic predisposition (carriers of the *TLR9*, *CDH1*, and *IL6* genes) seem to increase the risk of developing PI-IBS[29,31]. The severity of the acute infectious episode also seems to increase the probability of developing PI-IBS after the gastroenteritis resolution[29]. The risk of PI-IBS is doubled when diarrhea lasts > 7 d and is tripled when diarrhea lasts > 21 d. Other symptoms such as abdominal cramps, weight loss, and bloody stools are also associated with an elevated risk, with abdominal cramps increasing the PI-IBS risk four times. Fever is not mentioned as a risk factor[32]. Moreover, it might have a protective action, representing the host's response to the infectious injury[33]. The risk of IP-IBS remains high for at least 2 to 3 years post infection[22].

Various pathogens have been reported as related to PI-IBS development. A systematic review evaluating the prevalence and risk factors of PI-IBS after acute gastroenteritis by specific pathogens revealed the fact that the evidence indicated a similar risk for bacterial pathogens, while for viral and parasitic gastroenteritis, the data were limited[34]. However, a recent study found the incidence of PI-IBS to be higher in patients with *Campylobacter jejuni* (*C. jejuni*) gastroenteritis, compared to other etiologic agents such as bacteria, viruses, or protozoa[35]. When comparing different pathogens, protozoal enteritis shows the highest risk for PI-IBS development, followed by bacterial and then viral [33,36]. Bacterial infections seem to generate more PI-IBS cases than viral gastroenteritis probably due to the fact that the mucosal damage and inflammation caused by bacteria is often greater than that caused by viral agents[37].

There is a strong association between travelers' diarrhea and PI-IBS. Self-reports of exposure seem to result in a higher PI-IBS occurrence than laboratory-confirmed cases of travelers' diarrhea, but further studies are needed to confirm this finding[38]. Culture-confirmed infections, either bacterial or viral, seem to present an equally increased risk of PI-IBS as nonspecific gastrointestinal infections[39]. However, viral gastroenteritis is more likely to develop transient forms of PI-IBS than bacterial episodes [40]. The significant decrease in the PI-IBS prevalence from 19% to 4% one year after a viral infection may be due to the less invasive nature of the pathogen, perhaps avoiding a stronger host response[29]. During the recent pandemic, the novel coronavirus SARS-CoV-2 displayed its potential to generate gastrointestinal manifestations[41,42]. It seems that the prevalence of gastrointestinal symptoms in coronavirus disease 2019 (COVID-19) patients is around 10%, and it is following an increasing trend[43, 44]. A multicenter study from 2020 reported that digestive symptoms such as diarrhea, vomiting, and abdominal pain were present in 50.5% of COVID-19 patients, while other studies concluded that the incidence of diarrhea in the same category of patients varied from 2% to 20%[41,45,46]. A recent study found an incidence of 11.6% of IBS, according to the Rome IV criteria, with symptom onset following COVID-19 infection[41]. Another group of researchers reported similar results, with 10% of the included patients with an acute episode of SARS-CoV-2 in their medical history meeting the Rome IV criteria for IBS 6 mo after the viral infection. Three percent of them had gastrointestinal symptoms during COVID-19[47]. Noviello *et al*[48] found an incidence of PI-IBS in 26.2% of patients. The risk of developing *de novo* IBS post-COVID-19 increases in patients with gastrointestinal symptoms present during the active viral infection. Similar to noninfectious IBS, the risk is higher in female patients. The presence of severe disease markers, such as an oxygen requirement and high procalcitonin levels, increases the risk of post-COVID-19 IBS[49]. Another similar study reported that patients with dyspnea at time of admission and a history of allergies and chronic treatment with proton pump inhibitors had an increased risk of developing post-COVID-19 IBS[50].

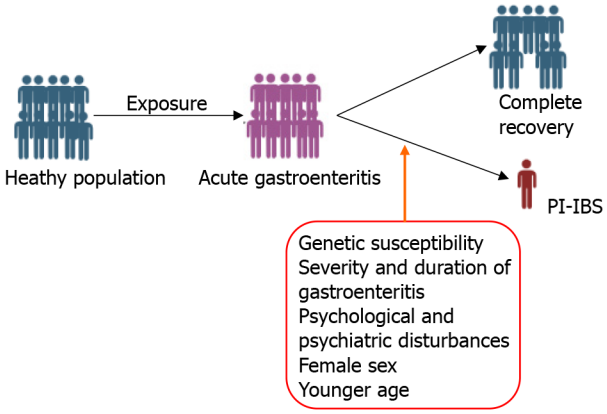

Figure 1 Diagnostic criteria for post-infection irritable bowel syndrome (based on Rome IV criteria). [1]Mentioning the exact date of onset of irritable bowel syndrome (IBS) symptomatology can also be suggestive for post-infectious IBS; [2]Irregular bowel movements can be experienced even before the onset of the acute gastroenteritis episode (but not in association with frequent pain, as an IBS characteristic). IBS: Irritable bowel syndrome; PI-IBS: Post-infectious irritable bowel syndrome.

Compared to sporadic IBS, PI forms of the disease might have a better outcome[2]. The prognosis of PI-IBS appears favorable with the spontaneous and gradual resolution of symptoms in most patients [22]. However, one longitudinal follow-up study showed that 15% of patients with post-infection IBS remained symptomatic 8 years after disease onset[28].

PI-IBS PATHOPHYSIOLOGY

Available studies have failed to give a clear holistic picture on the underlying pathophysiology of PI-IBS. As IBS is a multifactorial disease, it has been hypothesized that the development of PI-IBS could result from the interplay of fecal microbiota, the immune response of the host, and the psychological factors[51], as illustrated in Figure 2. The current conceptual framework regarding the pathophysiologic mechanism for PI-BS suggests that the exposure to pathogenic organisms leads to the alteration of the gut microbiome. PI-IBS is associated with hyperplasia of enterochromaffin (EC) cells and increased counts of neutrophils, mast cells, and T cells in the colonic mucosa. It is believed that gastrointestinal infections stimulate the immune system causing low-grade inflammation leading to PI-IBS[52].

It was reported that patients with PI-IBS often present an increased visceral pain perception known as visceral hypersensitivity (VHS). The incomplete resolution of the immune response to acute infectious injury might facilitate the persistence of a microscopic inflammation of the bowel, activating and sensitizing pain-sensing nerves[53]. A persistent low-grade inflammation of the bowel is thought to trigger PI-IBS symptoms, by aberrant activation of intrinsic and extrinsic nerves. The increased numbers of immune cells and the enhanced cytokine signaling play an important role in the underlying mechanism of PI-IBS pathophysiology[54]. A group of researchers found an increased IL-1β mRNA expression in rectal tissue biopsies after an acute episode of infectious gastroenteritis. Patients with a *Campylobacter* enteritis were found to present increased EC cell numbers, intraepithelial lymphocytes, and intestinal permeability up to one year after the infectious episode[55], while patients with PI-IBS following a *Shigella* gastroenteritis had an increased number of mast cell in the terminal ileum[56]. These cells release mediators such as histamine, IL-1β, IL-6, and TNF-α, mediators that can stimulate or sensitize visceral nociceptors and possibly generate the abdominal pain in PI-IBS[54]. Excessive secretion of IL-8 is a hallmark of *Campylobacter* pathogenesis, being initiated by the host recognition of the pathogen-associated lipooligosaccharide[57,58]. Another study on PI-IBS patients, however, found no evidence of increased inflammatory gene expression or infiltrating inflammatory cells in biopsies and no increase in cytokine levels[54]. Similarly, no difference was reported in the number of T lymphocytes or proinflammatory cytokines between PI-IBS patients and infected healthy volunteers, 3 years after a *Salmonella* infection[59]. Another study on a large cohort found similar results, with no difference in serum cytokines and mucosal cytokine expression between PI-IBS patients and healthy volunteers[60]. γδT cells are a subset of T cells involved in initiating inflammatory responses and can acquire the capacity of inducing various cytokines. A recent study of Dong *et al*[61] found that the Vδ1 γδ T cells subset from PI-IBS patients remarkably proliferated, activated, and produced abundant IL-17. In these patients, the IFN-γ level remained unchanged, as proof of the fact that the local IL-17 could participate in the intestinal pathological disorder during PI-IBS, as the major proinflammatory cytokine

Figure 2 Conceptual model for post-infectious irritable bowel syndrome. PI-IBS: Post-infectious irritable bowel syndrome.

[61]. Furthermore, a rodent study concluded that the upregulation of A2AR increased PI-IBS by promoting the T17 polarization of CD4+ T cells[62]. In their study, Balemans *et al*[54] reported that although initiated by inflammation, the pronociceptive changes seen in PI-IBS patients were mediated by the Hrh1 receptor sensitization of TRPV1 signaling, suggesting that similar to the "standard" IBS12, Hrh1 antagonism may represent an interesting new target for treatment of PI-IBS[54]. In conclusion, the presence of low-grade inflammation is an inconsistent finding in PI-IBS, as it might be an interim event following gastroenteritis that is superseded by another more persistent change in the gut microenvironment[54].

Increased intestinal permeability was shown to be an early event in PI-IBS physiopathology, associated with low-grade inflammation[1]. Patients with PI-IBS and high fecal proteolytic activity presented *in vivo* and *ex vivo* distal gut permeability that depended on the fecal level of proteolytic activity[63]. Following a mixed infection of enterohemorrhagic *E. coli* (EHEC) O157:H7 and *C. jejuni* during a waterborne outbreak of bacterial gastroenteritis, there was reported an increased intestinal permeability[58]. EHEC is known for its deleterious impact on the epithelial barrier[64]. *Giardia duodenalis* (*G. duodenalis*), a protozoan pathogen also implicated in promoting PI-IBS development, is well known to disturb the homeostatic barrier function through several mechanisms[65].

Viral gastroenteritis is a known risk factor for the PI onset of IBS. There are many studies describing the relation between norovirus infection and PI-IBS. As a conclusion to their study, Porter *et al*[66] suggested that dysmotility disorders may follow viral infections. A high incidence of functional gastrointestinal disorders was reported in patients who suffered from a norovirus gastroenteritis[66]. Similarly, another two studies reported an increased prevalence of PI-IBS in patients who experienced an acute episode of gastroenteritis during a confirmed norovirus outbreak[40,67]. It is thought that norovirus infection can cause epithelial barrier dysfunction, increased intestinal permeability, a reduction in the villous surface area and villous height, and a mucosal immune response with an increase in cytotoxic intraepithelial T cells, impairing the gut's sensory-motor function[67].

COVID-19, an immunologic and inflammatory response associated with low-grade inflammation and mucosal injury, caused the development of IBS features in genetically predisposed individuals. Patients with PI-IBS can present high levels of macrophages and T lymphocytes in intestinal samples, increased levels of calproctin and fecal cytokines, such as IL-8; all these were found in COVID-19 patients, as well as the presence of virus-specific IgA, together with increased blood levels of proinflammatory cytokines [68,69]. Similar to IBS, the altered intestinal permeability associated with gut dysbiosis and with an alteration of the neuromuscular function might also be involved in PI-IBS onset[67].

On the other hand, the pandemic led to a stressful situation, anxiety, and depression. These factors resulted in other diseases related to psychological stress and the nervous system similar to IBS[70,71]. Farsi *et al*[41] in their study found that psychological stress had no significant influence on COVID-19-induced IBS symptoms[41]. However, another similar study reported that COVID-19 had adverse effects on both GI and psychological symptoms among individuals with functional dyspepsia-IBS overlap syndrome[70]. Similarly, another study concluded that the COVID-19 pandemic increased psychosocial stress and gastrointestinal symptoms in patients already known to have IBS[72]. The interaction between the gut-brain axis disturbances and genetic and psychosocial factors can contribute to IBS development[41]. Psychological stress acts as a trigger in developing IBS through its adverse effects on intestinal permeability and motility and hypersensitivity to visceral pain. Acute and chronic stressful situations lead to cortico-tropin-releasing hormone secretion, activating the hypothalamic-pituitary-adrenal axis and creating new premises for IBS onset. Stress-induced dysbiosis can modulate the neuro-immune-endocrine systems and interfere with the brain-gut axis[73,74].

PI-IBS MICROBIOME ALTERATION

Due to the bioavailability of nutrients, the human gastrointestinal tract harbors the largest concentration and diversity of microbiota of the human body. Healthy adult gastrointestinal microbiota are represented by five primary bacteria phyla: *Firmicutes* (synonym *Bacillota*) and *Bacteroides* (synonym *Bacteroidota*) phylum predominate the microbiota, while *Actinobacteria* (synonym *Actinomycetota*), *Proteobacteria* (synonym *Pseudomonadota*), and *Verrucomicrobia* phylum are found in modest proportions[75]. The gut microbiota have a dynamic composition, influenced by many intrinsic and extrinsic factors, such as genetic inheritance, birth mode, breastfeeding duration, age, sex, diet, and drugs[75-77]. The alteration of the healthy microbial structure leads to dysbiosis, resulting in various gastrointestinal disorders, systemic metabolic diseases, and neurological impairments[75].

During an acute infectious gastroenteritis, there is a decline in the gut's microbial diversity[78]. There are several mechanisms explaining the disruption of the indigenous microbiota. One would be directly throughout pathogen agent-microbiota interaction. Secondly, the alteration of the microbiota might occur *via* the host's mucosal immune response, or there is the possibility of a combination of the two presented mechanisms[27,79]. In rodents, *Salmonella enterica* serovar typhimurium was shown to induce the loss of 95% of the total bacterial numbers of the intestinal tract, 7 d after the infectious episode[80]. *G. duodenalis* and *C. jejuni* can directly alter the composition of human gut microbiota[81]. Aside from the predominance of the etiologic bacterial pathogen, certain native taxa of the gut microbiome such as *Streptococci, Fusobacteria,* and *Campylobacter*, can also increase their numbers throughout the acute episode but also in the weeks following the bacterial infection[82,83].

Immediately after acute gastroenteritis with *Vibrio cholerae* (*V. cholerae*), increased levels of *V. cholerae, Streptococcus, Fusobacterium,* and *Campylobacter* species were found during a 16S rRNA gene polymerase chain reaction (PCR) analysis of the infected patients' stool samples. Two months after the first assessment, there was a decrease in *V. cholerae*, *Streptococcus, Fusobacterium,* and *Campylobacter* species, while *Ruminococcus obeum, Collinsella aerofasciens, Ruminococcus torques, Eubacterium rectale,* and *Faecalibacterium prausnitzii* increased their levels as a marker of recovery from the infection[82].

As for gastroenteritis triggered by viral agents, the alterations in the microbiota seem to be less consistent. The immune response to the viral injury is usually less harmful, resulting in a decreased diversity and the expansion of *Proteobacteria* species in some patients with viral gastroenteritis[83]. A study including patients with all-cause traveler's diarrhea investigated their gut microbial composition using fecal samples. In diarrheal patients, there was a decreased *Bacteroidota/Bacillota* ratio and changes in β-diversity, compared to healthy travelers who displayed an unexpected increased abundance of *Bacillota* phylum (*Streptococcus* and *Lactococcus* genera). Stool samples of patients with confirmed norovirus infection had an increased diversity of species characterizing their microbiota during the active infection, including *Clostridium XIVb, Bilophilia, Alistipes, Barnesiella,* and *Roseburia* species[84]. When assessing the gut microbiome correlation in symptomatic and asymptomatic patients infected with norovirus, Patin *et al*[85] found no significant difference between the alpha and beta diversity of the two groups studied. The symptomatic subjects presented relatively more species of *Bacillota* phylum, especially in the order *Clostridia,* while *Bacteroidota* phylum displayed fewer species than the asymptomatic subjects, particularly in the *Bacteroidia* order. In asymptomatic patients, three members of the genus *Parasutterella* and one in the *Nitrosomonadaceae* family were found in higher levels. The increased levels of *Bacteroidota* in the asymptomatic individuals suggest that its presence could improve the host's effort of resisting enteric viral infection or neutralizing its pathogenicity and symptoms[85]. Another study on Chinese patients with diarrhea of viral etiology reported a decreased diversity in the gut microbiota at stool sample examination, when compared to healthy individuals. *Bacillota* phylum with species of *Enterococcus, Peptostreptococcaceae, Incertae Sedi, Shigella, Weissella,* and *Clostridium* dominated the microbiota during the acute episode, while beneficial bacteria such as *Bacteroides vulgatus, Bifidobacterium,* and *Lactobacillus* species were found in decreased amounts[83]. Nelson *et al*[86] also tried to characterize the stool microbiota in norovirus-infected human patients. Their research found similarities between infected patients' and uninfected healthy individuals' microbiota. However, in a small number of infected patients there was found a significantly altered microbiome characterized by a reduced relative number of *Bacteriodota* and a corresponding increase in *Pseudomonadota.* Interestingly, the increased level of *Pseudomondota* phylum was due to a single operational taxonomic unit of *E. coli*[86]. This finding raises the concern that the alteration in gut microbiota during an acute viral gastroenteritis exposes the affected patients to some possible long term gastrointestinal complications.

SARS-CoV-2 infected patients seem to present an altered gut microbiota, characterized by the depletion of anti-inflammatory butyrate-producing bacteria and the enrichment of taxa with proinflammatory properties[87,88]. The Alpha and beta diversity index values appear to be significantly lower than in healthy individuals, all through the active infection and the recovery period[87,89]. Furthermore, an important reduction in the major bacterial phylum composition and diversity was also observed[90]. *Ruminococcusm gnavus* and *Bacteroides vulgatus* were found in increase amounts in post-acute COVID-19 patients' microbiomes, while *Faecalibacterium prausnitzii*, known for its anti-inflammatory proprieties, was characterized as decreased, when compared to healthy individuals[70].

Streptococcus, *Enterococcus,* and *Corynebacterium* species, well known as opportunistic pathogens, seem to be found in higher amounts in COVID-19 patients' stools than in healthy individuals[87]. *Fusicatenibacter*, *Romboutsia*, *Intestinibacter*, *Actinomyces,* and *Erysipelatoclostridium* species could actually be used as biomarkers in order to identify COVID-19 positive patients[91]. There is proof that the development of PI-IBS may be predicted by the composition of the salivary microbiome during acute SARS-CoV-2 infection[40,92]. Butyrate-producing bacteria showed an inverse correlation with IBS symptom onset 6 mo post-acute viral infection[93]. The gut microbiota composition was reported to be correlated with proinflammatory cytokine levels, as proof of its contribution to the immune response. The *Faecalibacterium* genus, belonging to the *Clostridia* class, was found to be decreased in COVID-19 patients during the acute episode and was inversely correlated with the IL-8 and IL-12 serum levels. The same study reported an enrichment of the *Actinomycetota* phylum and the *Propionibacteriaceae* family, which was positively correlated with the gp130/sIL-6Rb level[90]. The *Streptococcus* species was also associated with an increased expression of proinflammatory cytokines such as IL-18, TNF-α, and IFN-γ[87]. In contrast, IFN-gamma and IL-28A/IFN-12 levels were found to be negatively correlated to the class *Clostridia*, reduced in abundance in COVID-19 patients[90]. Changes in the microbiome composition were also identified in COVID-19 patients without antibiotic exposure. Depletion of beneficial commensal species and enrichment of opportunistic pathogenic bacteria, such as *Clostridium hathewayi*, *Actinomyces viscosus*, and *Bacteroides nordii,* were found in COVID-19 patients' stool samples. According to Zuo *et al*[94], the disease severity and the baseline abundance of certain genera and strains might be in close relationship, as the gut microbiota might actively influence the immune system response. Moreover, it appears that 50% of COVID-19 patients had an active intestinal infection, even in cases with no gastrointestinal complaints[94]. The deleterious effect of SARS-CoV-2 infection on beneficial gut microbiota seems to persist even after disease resolution, sustaining the possibility of the gut microbiome alteration's role in PI-IBS pathogenesis[95]. The intestinal infection persisted despite respiratory viral clearance[19,94]. There were cases described, where dysbiosis was persistent 30 d after the acute viral episode, suggesting the long-term influence of COVID-19 on gut microbiota[96]. Opportunistic pathogens such as *Collinsella aerofaciens*, *Collinsella tanakaei*, *Streptococcus infantis,* and *Morganella morganii* have been found in large amounts in stool samples with high SARS-CoV-2 infectivity. In stool samples with low-to-no viral infectivity, there were higher amounts of *Parabacteroides merdae*, *Bacteroides stercoris,* and *Lachnospiraceae bacterium 1_1_57FAA*, some of these within important role in augmenting host immunity[19,94]. Current evidence suggests that a high microbial exposure to Gram-negative bacteria could offer protective effects against COVID-19, possibly due to the increased interferon type I levels[43]. These findings sustain the idea that the gut homeostasis may suffer some alterations during the acute COVID-19 episode, independent from the presence of gastrointestinal symptoms, alterations that can persist beyond disease resolution[73]. There is evidence that COVID-19-induced impairment of the gut-lung axis might create predisposing factors for IBS development[43,97].

Moreover, there is evidence that microbiota composition prior to infection may also influence the possibility of developing an acute infection as well as PI-IBS[33]. Dicksved *et al*[98] reported that an increased abundance of *Bacteroidota* in pre-employment stool samples of abattoir workers increased the risk of developing a *C. jejuni* infection during the period of employment[98]. A *Clostridiales*-predominant microbiota type has a protective role, as an individual with such intestinal microbiota is more likely to return to a state of eubiosis after the remission of the infectious episode and pathogen clearance. A *Bacteroidota* predominant community, in contrast, may increase the risk of long-term dysbiosis after the acute episode's resolution[21].

Although the gut microbiota profile of IBS patients has been evaluated in several studies, there is not the same consistency of data regarding PI-IBS patients' gut microbiome alteration. In their study of the real-time PCR assay of rectal epithelium RNA expression, Jalanka-Tuovinen *et al*[51] concluded that the intestinal microbiota of PI-IBS patients were significantly different from healthy individuals but similar to patients with IBS-like symptoms (PI bowel disease, PI-IBS and IBS-D). They identified an "index of microbial dysbiosis" (IMD) that characterized the intestinal microbiota of PI-IBS. The IMD included 27 genus-like microbial groups including a twelvefold increased level of *Bacteroidota* phylum, including as *Bacteroides* and *Prevotella* species. The *Bacillota* phylum was less abundant, with decreased levels of various uncultured *Clostridiales* and *Clostridium* clusters. Moreover, dysbiosis was associated with gastrointestinal symptoms' severity and not with psychological symptoms. Dysbiosis was also associated with biopsy findings, such as increased levels of eotaxins, mast cells, and goblet cells and decreased EC cells[51]. Similar results were obtained by Sundin *et al*[99], when analyzing the mucosal and fecal microbiota of patients with PI-IBS. The fecal microbiota composition of PI-IBS patients was significantly different from the fecal microbiota of IBS patients and healthy individuals. Patients with PI-IBS had a reduced mucosal and fecal microbial diversity, with reduced levels of *Bacillota*, including *Clostridium* clusters IV and XIVa, and increased *Bacteroidota*, including *Bacteroides* species. The reduced diversity of the fecal microbiota was associated with increased activated lymphocytes in the lamina propria. At the level of major butyrate producer bacteria abundance, there was no difference identified between the PI-IBS patients and healthy individuals. Unlike Jalanka-Tuovinen *et al*[51], the reduced diversity of the microbiota was associated with the presence of psychological symptoms[99]. In PI-IBS patients, the *Bacteroidota* phylum seems to have a relatively greater abundance of microbes than in healthy individuals, while *Bacillota* phylum display a relative reduction in representative members in

the gut microbiota[78]. The main findings are summarized in Table 1.

MICROBIOME-DIRECTED THERAPY

Acute gastroenteritis, as mentioned above, can alter the gut microbiota, initiating the underlying mechanisms of PI-IBS. Modulation of the microbiota can be performed using probiotics, symbiotics, prebiotics, and antibiotics or by performing a fecal microbial transplantation, with the purpose of downregulating inflammation, improving barrier function, and reducing visceral sensitivity[100]. To date, there is no specific practice guideline or treatment strategies for PI-IBS. Different drug classes can be used for treating PI-IBS similar to patients with IBS in general[37].

Probiotics are known to be "live microorganisms that, when administered in adequate amounts, confer a health benefit on the host"[101]. *Lactobacillus casei* DG (LC-DG) and its postbiotic were shown to attenuate the inflammatory mucosal response in an *ex vivo* organ culture model of PI-IBS-D[102]. Similarly, Hong *et al*[103] reported that probiotic administration (*Lactobacillus acidophilus* LA5, *Bifidobacterium animalis* subsp. *lactis* BB12, and *Saccharomyces cerevisiae* var. *boulardii*) decreased proinflammatory cytokine levels in both the control and PI-IBS induced mice[103].

Saccharomyces boulardii, given 750 mg/day for a period of 6 wk, was reported to improve the quality of life and the cytokine profile in PI-IBS patients[104]. *Bifidobacterium infantis,* M-63 1 × 109 cfu/sachet/day given daily for 3 mo, restored the normal composition of the gut microbiota and improved mental health in individuals with post-flood acquired IBS[105].

Given the current evidence that serotonin levels are increased in PI-IBS patients, serotonin-based therapy is a treatment option that deserves further study[106]. Cao *et al*[107] proved that an *Lactobacillus rhamnosus* supernatant had a positive effect on serotonin transporter (SERT) expression in colon tissues of rats with PI-IBS. By modulating the microbial composition, the serotonergic imbalance can be restored, followed by the improvement in IBS symptoms[107]. Another similar study on an animal model evaluated the efficacy of a *Bacillus subtilis* (*B. subtilis*), *Enterococcus faecium,* and *Enterococcus faecalis* (*E. faecalis*) supernatant, administrated in PI-IBS rats. The researchers reported that the supernatants could upregulate the expression level of SERT in intestinal cells, mentioning the fact that the combined supernatants of *B. subtilis* and *E. faecalis* had a superior effect to the administration of a single supernatant[108]. Studies regarding prebiotic and symbiotic use in PI-IBS patients are not available.

Fecal microbiota transplantation (FMT) is used in order to restore microbial dysbiosis by transferring a healthy microbiome to an individual with an alteration of microbial composition[109]. FMT has shown benefits in IBS patients. However, there is a lack of data on FMT use in PI-IBS. A recent randomized clinical trial assessed FMT's safety as well as its clinical and microbiological efficacy in patients with PI-IBS. The results demonstrated FMT's effectiveness compared to traditional pharmacotherapy, its safety, and tolerability[110].

However, FMT could be used in reestablishing the microbiota homeostasis following acute gastroenteritis, with the purpose of decreasing the risk of PI-IBS development. It is known that FMT is recommended for recurrent or refractory *C. difficile* enterocolitis, as a proved effective therapy[111]. There is evidence that FMT treatment can improve gut microbiota alteration in recovered COVID-19 patients, particularly in those who presented severe gastrointestinal symptomatology during the acute phase[112].

Jin *et al*[113] assessed the action of rifaximin on the VHS, barrier function, gut inflammation, and microbiota in a PI-IBS mouse model. Rifaximin administration improved the VHS, recovered the intestinal barrier function, and inhibited low-grade inflammation in the colon and ileum, without changing the composition and diversity of the gut microbiota[113]. However, Harris *et al*[114] and Tuteja *et al*[115] reported no benefit of rifaximin therapy on PI-IBS patients.

The results of mesalazine's efficacy in treating PI-IBS patients are contradictory. Lam *et al*[116] reported a significant improvement in symptoms such as abdominal pain, urgency, and stool consistency, when mesalazine was given to a small group of PI-IBS patients[116]. Bafutto *et al*[117] found that mesalazine administration in PI-IBS patients decreased the stool frequency and improved its form and consistency, after 30 d of treatment[117]. In contrast, another double-blind controlled trial including a small number of patients with diarrhea predominant PI-IBS reported no positive effect on clinical symptoms or quality of life[118]. However, mesalazine use during the acute infectious gastroenteritis may have a protective effect on PI-IBS development, as reported by a study on patients affected by hemorrhagic enterocolitis with *Shiga*-like toxin-producing *E. coli*[119]. Dunlop *et al*[120] found a significant reduction in the T- lymphocyte counts in the rectal tissue of PI-IBS patients treated with prednisone, although there was no positive effect on the EC cell count or symptom improvement[120].

Bile acid malabsorption may occur after an episode of acute gastroenteritis. It is confirmed that cholestyramine administration can alleviate symptoms in PI-IBS patients, especially with diarrhea symptoms[121]. The information regarding the therapeutic options in PI-IBS are summarized in Table 2.

Table 1 Alterations of the gut microbiota observed during acute gastroenteritis and during post-infectious irritable bowel syndrome

Ref.	Subjects/methods	Sample and techniques	Microbiota alterations	Other findings
Jalanka-Tuovinen *et al*[51], 2014	11 postinfection IBS, 11 postinfection bowel dysfunction, 12 postinfection without bowel dysfunction, 12 IBS-D, 11 healthy controls adults	16S rRNA gene phylogenetic microarray analysis with HITChip, 16S rRNA gene qPCR with group and species-specific primers of feacal sample	Index of microbial dysbiosis" comprised of 27 genus-like groups including: ↑ *Bacteroidota* including various *Bacteroides and Prevotella* species, ↓*Bacillota* including various uncultured *Clostridiales*, and *Clostridium* clusters	Dysbiosis was associated with bowel, not psychological symptoms; Dysbiosis associated biopsy findings: ↑eotaxin, mast cells, goblet cells, ↓enterochromaffin cells; Dysbiosis associated RNA expression pathways: ↑serotonin transport, condensed chromosome, B cell antigen receptor, ↓caspase
Hsiao *et al* [82], 2014	7 adults with *V. cholerae* AGE history, 50 healthy children, 12 healthy adults	16S rRNA gene PCR, V4 region analysis of faecal sample	One week after AGE: ↑*V. cholerae Streptococcus* spp *Fusobacterium* spp *Campylobacter* spp	Two months after AGE (recovery period): ↓*V. cholerae Streptococcus* spp *Fusobacterium* spp *Campylobacter* spp, ↑ species indicating recovery *Ruminococcus obeum*, *Collinsella aerofasciens Ruminococcus torques*, *Eubacterium rectale Faecalibacterium prausnitzii*
Ma *et al* [83], 2011	13 Adenovirus diarrhea, 13 Rotavirus diarrhea, 13 Astrovirus diarrhea, 13 Norvirus diarrhea, 6 control children	16S rRNA gene PCR, V3 region analysis of faecal sample	↓Diversity in diarrheal patients, ↑*Enterococcus*, *Peptostreptococcaceae*, *Incertae Sedi*, *Shigella*, *Weissella* spp	↓*Bacteroides vulgatus Bifidobacterium*, *Lactobacillus* spp
Youmans *et al*[84], 2015	111 all-cause traveler's diarrhea/12 healthy travelers	16S rRNA gene PCR, V3 and V5 regions analysis of faecal sample	↓*Bacteroidota: Bacillota* ratio in diarrheal patients; ↑Species diversity during norovirus infection; ↑*Clostridium XIVb Bilophilia Alistipes Barnesiella*, *Roseburia* spp during norovirus infection	↑*Bacillota* phylum *Streptococcus Lactococcus* spp in healthy travelers (unexpected)
Patin *et al* [88], 2020	4 symptomatic and 5 asymptomatic norovirus infected adults	16S rRNA gene analysis of faecal sample	Post norovirus challenge: ↑*Bacillota* phylum, particularly *Clostridia*, ↓*Bacteroidota Pseudomonadota*	Prior to norovirus challenge: Asymptomatic patients had ↑*Bacteroidota* phylum and ↓*Clostridia* compared to symptomatic
Nelson *et al*[86], 2012	38 norovirus infection, 22 healthy controls	16S rRNA gene 454 pyrosequencing, V3-V5 regions analysis of faecal sample	A subset (approximately 1/5) patients with norovirus had: ↓diversity, ↑*Pseudomonadota* phylum, *Enterobacteriaceae* family	*Escherichia coli* diversity and virulence was not associated with norovirus infection
Cheng *et al* [87], 2022	COVID-19 acute and recovery phase; Non COVID-19	Meta-analysis of 16S rRNA microbial data	↓Ruminococcus Faecalibacterium Roseburia, Coprococcus genus, ↑ Fusobacterium Streptococcus in recovery/post-recovery COVID-19 compared to non COVID-19	↓Clostridium clostridioforme, ↑ Bifidobacterium breve in COVID-19 compared to recovery/post-recovery COVID-19
Liu *et al* [93], 2022	68 COVID-19 patients, 68 non-COVID-19 patients	Shotgun metagenomic sequencing	At 6 mo follow up 76% developed PACS; Non-PACS showed recovered gut microbiome profile at 6 mo comparable to that of non-COVID-19 controls; ↑ *Ruminococcus gnavus*, *Bacteroides vulgatus* and ↓*Faecalibacterium prausnitzii* in PACS	Butyrate-producing bacteria, including *Bifidobacterium pseudocatenulatum* and *Faecalibacterium prausnitzii* showed the largest inverse correlation with PACS at 6 mo
Zuo *et al* [95], 2020	15 Acute COVID-patients, 6 community acquired pneumonia patients, 15 healthy controls	Shotgun metagenomic sequencing	Antibiotic naïve patients ↑*Clostridium hathewayi*, *Actinomyces viscosus*, and *Bacteroides nordii* compared with controls; COVID-19 with antibiotic use ↓ *Faecalibacterium prausnitzii*, *Lachnospiraceae bacterium 5_1_63FAA*, *Eubacterium rectale*, *Ruminococcus obeum*, and *Dorea formicigenerans* compared with COVID-19 naïve patients	Baseline abundance of *Coprobacillus*, *Clostridium ramosum*, and *Clostridium hathewayi* correlated with COVID-19 severity: There was an inverse correlation between abundance of *Faecalibacterium prausnitzii* and disease severity; Depletion of symbionts and enrichment of opportunistic pathogens persisted after clearance of SARS-CoV-2
Yeoh *et al* [96], 2021	100 COVID-19 patients, 78 non COVID-19 controls	Shotgun sequencing total DNA extraction from stool sample	Patients with COVID-19 were depleted in *Faecalibacterium prausnitzii*, *Eubacterium rectale* and several bifidobacterial species, which remain low up to 30 d from disease resolution	Composition of the gut microbiota in patients with COVID-19 is concordant with disease severity and magnitude of plasma concentrations of several inflammatory cytokines, chemokines and blood markers of tissue damage
Sundin *et al*[99], 2015	13 PI-IBS patients, 19 general IBS patients, 16 healthy controls	HITChip for mucosal and fecal microbiota	↓Mucosal and faecal diversity *Bacillota* phylum including *Clostridium* clusters IV and XIVa, ↑*Bacteroidota* phyum including *Bacteroides* spp	Reduced diversity was associated with psychological symptoms and increased activated lamina propria lymphocytes. Did not find a difference in major butyrate producer abundance

AGE: Acute gastroenteritis; COVID-19: Coronavirus disease 2019; IBS-D: Diarrhea-predominant irritable bowel syndrome; PACS: Post-acute coronavirus disease 2019 syndrome; PI-IBS: Post-infectious irritable bowel syndrome; qPCR: Quantitative polymerase chain reaction; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2.

Table 2 Post-infectious irritable bowel syndrome therapeutic options

Ref.	Therapeutic intervention	Outcome
Compare *et al* [102], 2017	*Lactobacillus casei* DG + postbiotic	↓The inflammatory mucosal response in an *ex vivo* organ culture model of PI-IBS-D
Hong *et al* [103], 2019	*Lactobacillus acidophilus* LA5, *Bifidobacterium animalis* subsp. *lactis* BB12 and *Saccharomyces cerevisiae* var. *boulardii*)	↓Pro-inflammatory cytokine levels in both the control and PI-IBS induced mice
Abbas *et al* [104], 2014	*Saccharomyces boulardii*	Improved the quality of life and the cytokine profile in PI-IBS patients
Lee *et al*[106], 2017	*Bifidobacterium infantis*	Restored the normal composition of gut microbiota and improved mental health among individuals with post-flood acquired IBS
Cao *et al* [107], 2018	*Lactobacillus rhamnosus* supernatant	Had a positive effect on SERT expression in colon tissues of rats with PI-IBS, improving IBS symptoms in PI-IBS rats
Chen *et al* [108], 2022	*Enterococcus faecium* and *Enterococcus faecalis* supernatant, in PI-IBS rats	The supernatants of B. subtilis, *Enterococcus faecium*, and *Enterococcus faecalis* can upregulate SERT expression in intestinal epithelial cells and the intestinal tissues in the rat model of PI-IBS
Tkach *et al* [110], 2022	RCT, low FODMAP diet + Otilonium Bromide + a multi-strain probiotic *vs* FMT procedure	FMT proved effectiveness in restoring normal gut microbiota and ameliorating PI-IBS symptoms, compared to traditional pharmacotherapy, as well as a high degree of safety and good tolerability
Liu *et al*[111], 2021	FMT procedure	FMT can partially restore the gut dysbiosis in COVID-19 patients by increasing the relative abundance of *Actinobacteria* (15.0%) and reducing *Proteobacteria* (2.8%) at the phylum level. At the genera level, *Bifidobacterium* and *Faecalibacterium* had significantly increased after FMT
Jin *et al*[113], 2017	Rifamixin in PI-IBS rats	Rifaximin alleviated visceral hypersensitivity, recoverd intestinal barrier function and inhibited low-grade inflammation in colon and ileum of PI-IBS rats. Exerts anti-inflammatory effects with only a minimal action on the overall composition and diversity of the gut microbiota
Harris *et al* [114], 2019	Rifamixin *vs* placebo in veterans with IBS	Rifaximin was not associated with signifcant improvement in global symptoms, abdominal pain, stool frequency, urgency, bloating, or stool consistency
Tuteja *et al* [115], 2019	Rifamixin *vs* placebo in veterans with IBS	Rifaximin was not effective in improving IBS symptoms and QOL in GW veterans with non-constipated IBS
Lam *et al* [116], 2016	Mesalazine *vs* placebo	Mesalazine was no better than placebo in relieving symptoms of abdominal discomfort or disturbed bowel habit. Mesalazine did not reduce mast cell percentage area stained. A subgroup of patients with postinfectious IBS may benefit from mesalazine
Bafutto *et al* [117], 2011	Mesalazine in PI-IBS patients compared to non-infective IBS patients	Mesalazine reduced key symptoms of postinfectious irritable bowel syndrome and noninfective irritable bowel syndrome with diarrhea patients, with no statistical difference between IBS and PI-IBS
Tuteja *et al* [118], 2012	Mesalazine *vs* placebo	There was no significant improvement in global symptoms or overall QOL with mesalazine in patients with PI-IBS
Andresen *et al*[119], 2016	Mesalazine during the AGE with STEC	Mesalazine administration during AGE with STEC might be a protective factor for PI-IBS
Dunlop *et al* [120], 2003	Prednisolone *vs* placebo	Prednisolone does not appear to reduce the number of enterochromaffin cells or cause an improvement in symptoms in PI-IBS

AGE: Acute gastroenteritis; FMT: Fecal microbial transplantation; IBS-D: Diarrhea-predominant irritable bowel syndrome; PI-IBS: Post-infectious irritable bowel syndrome; RCT: Randomised controlled trial; QOL: Quality of life; SERT: Serotonin transporter; STEC: Shiga-like toxin-producing *Escherichia coli*.

CONCLUSION

Acute gastroenteritis can significantly increase the risk of developing IBS, a chronic gastrointestinal pathology with high health-care utilization. Current studies in humans as well as animal models describe specific host-pathogen interactions that may lead to the onset of post-infection IBS symptoms. There is no curative treatment option for PI-IBS, and patients rely only on symptomatic therapy. There are numerous studies on IBS treatment options. However, there is a lack of data regarding PI-IBS therapeutic management, and there is a great need for evidence-based recommendations in post-acute

gastroenteritis IBS.

These advancements in understanding will be helpful in elaborating specific biomarkers used to identify patients with a high risk of developing IBS symptoms following an acute infectious gastroenteritis, as well as designing targeted pharmacotherapy. Microbial restoration, augmentation of barrier function, and targeting VHS remain the most promising areas for therapeutic interventions and represent a future research perspective.

Abstract

Biliary complications are the most common complications after liver transplantation. Computed tomography (CT) and magnetic resonance imaging (MRI) are cornerstones for timely diagnosis of biliary complications after liver transplantation. The diagnosis of these complications by CT and MRI requires expertise, mainly with respect to identifying subtle early signs to avoid missed or incorrect diagnoses. For example, biliary strictures may be misdiagnosed on MRI due to size mismatch of the common ducts of the donor and recipient, postoperative edema, pneumobilia, or susceptibility artifacts caused by surgical clips. Proper and prompt diagnosis of biliary complications after transplantation allows the timely initiation of appropriate management. The aim of this pictorial review is to illustrate various CT and MRI findings related to biliary complications after liver transplantation, based on time of presentation after surgery and frequency of occurrence.

Key Words: Liver transplantation; Biliary; Complications; Computed tomography; Magnetic resonance imaging; Hepatic imaging; Biliary tract; Cholangiopancreatography; Stricture

Core Tip: Biliary complications are the most common surgical complications after liver transplantation, and represent a major source of morbidity and mortality in liver transplant recipients. Magnetic resonance cholangiopancreatography is the gold standard for the non-invasive diagnosis of intra- and extrahepatic biliary complications. Computed tomography may also be helpful for the assessment of biliary complications, and it is often used due to its more widespread availability as compared to that of magnetic resonance imaging.

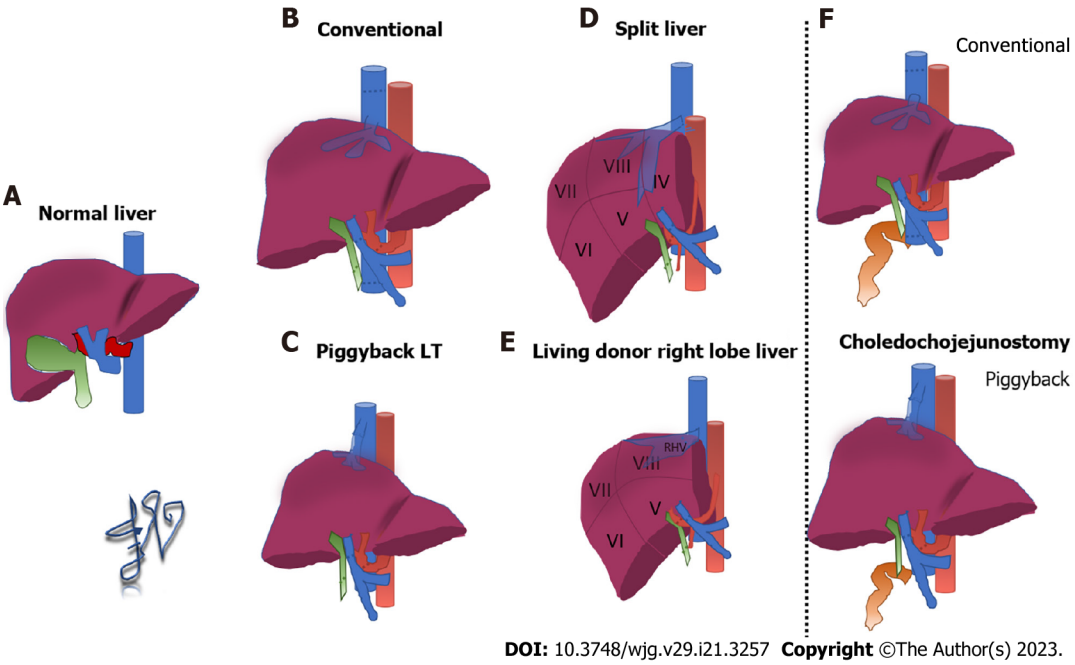
INTRODUCTION

Computed tomography (CT) and magnetic resonance imaging (MRI) are cornerstones in the postoperative assessment of patients after liver transplantation[1]. Complications may be categorized by etiology, and include surgical, graft-related, immunologic, infectious, and neoplastic. Complications can also be classified based on their timing: Early (within 6 mo) or late (after 6 mo; Table 1). Surgical complications are typically categorized as vascular, biliary, or parenchymal. Biliary complications are the most common and represent a major source of morbidity and mortality in liver transplant recipients with an incidence of 10%-32%[2-4]. Biliary complications after liver transplantation include anastomotic stricture, non-anastomotic stricture, bile leak, bile cast, biloma, sphincter of Oddi dysfunction, and mucocele of the cystic duct remnant[4-9]. Biliary complications have a significant negative impact on patient survival and may lead to the need for re-transplantation[3,6]. Magnetic resonance cholangiopancreatography (MRCP) is currently the gold standard for the diagnosis of intra- and extrahepatic biliary complications, while invasive cholangiography should be restricted for therapeutic uses or when MRCP is equivocal[10].

The aim of this pictorial review is to illustrate CT and MRI findings of surgery-related biliary complications after liver transplantation, classified based on their usual timing of appearance and their frequency. The knowledge of surgical techniques is of key importance to understand postoperative anatomic changes and imaging evaluation. Therefore, we will first provide a short summary of the main techniques of liver transplantation with focus on biliary anastomosis. Then, we will discuss imaging tips and tricks for the prompt diagnosis of biliary complications on CT and MRI.

SURGICAL TECHNIQUE



Most liver transplantations are performed with orthotopic implantation of a deceased donor whole liver graft, and may be performed with a conventional or piggyback technique. Other surgical options include split or segmental liver transplantation (Figure 1)[7]. The split liver procedure may be performed by either of 2 approaches: In the most common approach, the liver is divided into a left lateral segment graft (II + III ± IV segments) if the recipient is a child or a right extended liver lobe graft (I + V-VIII ± IV segments) if the recipient is an adult; in the less common and more challenging variant of this procedure, the liver is split into 2 hemigrafts and the left side (I-IV) is transplanted to a small adult or a teenager and the right side (V-VIII) to a medium-sized adult. In patients with prior biliary disease or re-transplantation, a different biliary anastomosis technique may be performed[7]. Liver transplantation is a multi-step surgery. After skin preparation and incision, the surgeon checks if there is any undiagnosed malignancy or anatomic variant and then dissects the recipient's liver and gallbladder. The donor's liver, without the gallbladder, is then implanted into the recipient with the anastomoses between recipient and donor performed in the following order: (1) Systemic venous outflow (inferior cava vein-hepatic veins); (2) portal venous inflow; (3) hepatic arterial inflow; and (4) biliary anastomosis. The types of anastomosis depend on donor and recipient anatomy and surgeon preference. Finally, when the surgical field is dry, the abdomen is closed. Each of the above-mentioned steps is critical, and complications may be directly or indirectly related to failure of any of these steps [11,12].

Biliary anastomosis is known as the "Achilles tendon" of liver transplantation. The most common form of biliary reconstruction is choledochocholedochostomy (duct-to-duct anastomosis)[7], which may be performed in an end-to-end or end-to-side fashion. Choledochocholedochostomy can be performed either with a T-tube, which allows rapid decompression of the biliary tree if needed and reduces the risk of anastomotic stricture formation but may lead to biliary leakage and cholangitis at the time of

Table 1 Post-transplant complications with the relevance of computed tomography and magnetic resonance imaging in diagnosis

Time of onset	Type of complications	Relevance of CT/MRI for diagnosis
Early (< 6 mo)	Surgical	++++
	Graft-related	++
	Immunologic	+
	Infectious	++
Late (> 6 mo)	Surgical	++++
	Graft-related	++
	Immunologic	+
	Infectious	+++
	Neoplastic	++++
	Disease recurrence	++

++++: Highly relevant, often mandatory; +++: Very useful; ++: Useful; + sometimes helpful, but clinical diagnosis is usually very relevant. CT: Computed tomography; MRI: Magnetic resonance imaging.

removal, or without a T-tube[13]. Choledochojejunostomy to a Roux-en-Y defunctionalized intestinal loop (*i.e.* the connection of the bile duct to jejunum loop) (Figure 1F) is the second most common type of biliary reconstruction technique, usually preferred in patients with pre-existing biliary disease and in case of size mismatch between donor and recipient ducts, re-transplantation, or previous biliary surgery [7]. Potential complications of choledochojejunostomy include stricture, leakage, and bleeding at the jejuno-jejunostomy site. Choledochocholedochostomy is preferred over choledochojejunostomy due to shorter operation time, lower risk of septic complication, preserved sphincter of Oddi, better physiologic enteric function, and easier endoscopic access to the biliary tree for any future need.

CT/MRI OF BILIARY COMPLICATIONS

MRI has sensitivity and specificity of 98%-99% and 94%-96%, respectively, for the diagnosis of biliary

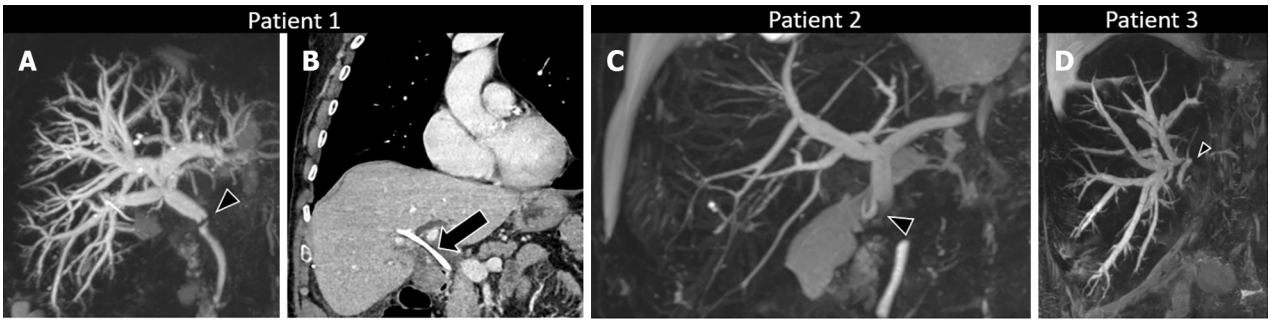
complications after liver transplantation[14,15]. MRI protocol includes 2D-MRCP and 3D-MRCP and an unenhanced T1-weighted sequence, while gadoxetate disodium hepatobiliary MRI is performed in selected cases[16]. Ultrasound is usually performed first, and may help identify any features that suggest the presence of complication. Despite not being as comprehensive as MRI, CT may also be helpful for the assessment of biliary complications and is often used due to its more widespread availability. Table 2 summarizes biliary complications related to surgery classified according to frequency, time of occurrence, and treatment[4-10].

Biliary strictures

Biliary strictures are distinguished as anastomotic or non-anastomotic. Anastomotic strictures (Figure 2) account for about 47% of biliary complications, being slightly more frequent after choledochocholedochostomy *vs* choledochojejunostomy, and may also occur after split liver donation[3]. Currently, percutaneous biliary techniques are considered effective treatment options with good outcomes in the setting of liver transplant with anastomotic biliary stricture[17]. Non-anastomotic strictures account for about 23% of all biliary complications, being slightly more frequent after choledochojejunostomy *vs* choledochocholedochostomy[3]. Non-anastomotic strictures (Figure 3) typically comprise ischemic-type biliary lesions in the early period after transplant, and are mostly related to recurrence of the primary biliary disease, chronic rejection, or secondary sclerosing cholangitis if occurring in the late postoperative period.

Biliary strictures are one of the most critical complications in ABO-incompatible living donor liver transplant recipients, and may occur as perihilar or diffuse, with the latter having worse clinical outcomes[18].

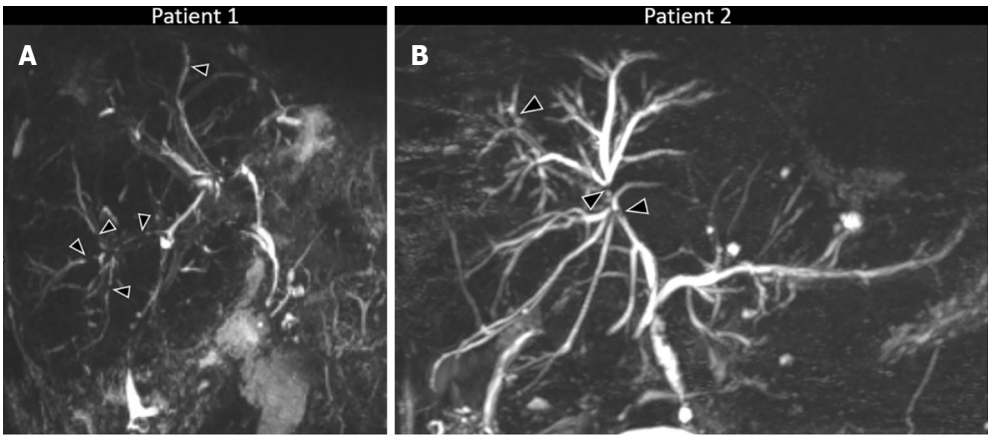
MRI demonstrates any stenosis at the level of the stricture as well as upstream irregular dilation of the biliary system; typically, the change in duct caliber at the level of the stricture is abrupt. Anastomotic strictures tend to be single, short in length, and occur at the level of anastomosis, usually in the late postoperative period. Non-anastomotic strictures are frequently multiple, long, hilar in location, and tend to occur early after transplantation and may result in graft loss. Radiologists should report the level of the biliary injury and the length of the obstruction. Although not routinely recommended for the diagnosis of biliary strictures, MRCP with hepatobiliary contrast may allow the assessment of the severity of bile duct obstruction based on the degree of hepatobiliary contrast filling distal to the stricture. Complete obstruction of the biliary tree is demonstrated in the case of absence of contrast distal to the stricture, while the obstruction is partial if there is limited passage of contrast beyond the stricture. In the case of complete obstruction, hepatic function may be impaired as evidenced by elevated bilirubin, which may hamper the excretion of hepatobiliary contrast[19]. Biliary strictures must be differentiated from their mimickers on MRI, which may include size mismatch of the donor and recipient common ducts (appearing as gradual tapering of the bile duct lumen at the anastomosis) and postoperative edema (can cause extrinsic compression at the level of the anastomosis and have a tapered "hour-glass" appearance). Other potential mimickers of biliary strictures on MRI include pneumobilia (which may occur normally if a choledochojejunostomy anastomosis has been performed) and MRI susceptibility artifacts caused by nearby surgical clips. CT may help in identifying the inadvertent placement of metallic surgical clips. In ABO-incompatible living donor liver transplant recipients, imaging and clinical follow-up is recommended if post-transplantation CT at 1 mo demonstrates subtle intrahepatic duct dilatation with perihilar abnormality to assess for the possible occurrence of diffuse intrahepatic duct dilatation stricture[18].



Biliary leak and biloma

Biliary leaks account for approximately 23% of all biliary complications[3]. They may be anastomotic or non-anastomotic (Figure 4) and are more common after choledochocholedochostomy *vs* choledochojejunostomy. Leaks at the biliary anastomosis are most common[20]. Non-anastomotic leaks may occur at the level of T-tube insertion, cystic duct, or the cut surface of a partial liver graft. The use of a T-tube may be a risk factor for biliary leak, most commonly after removal of the tube[21]. However, there are discordant data with respect to the causative mechanism of T-tube-related biliary leaks[22,23]. Non-anastomotic biliary leaks may be cut-surface leaks, such as those originating from small bile ducts that are transected perioperatively during hepatic resection, from the cystic duct stump, or may be caused by bile duct necrosis in patients with hepatic artery occlusion. Biliary leaks may result in the development of bilomas. Bilomas may be intra- or extrahepatic depending on the origin of the leak, although they most commonly occur in the perihepatic space. Bilomas may become infected and can potentially lead to sepsis. Another potential serious complication of biloma is erosion of the adjacent hepatic artery. Ultrasound (US) and CT are most commonly performed as first-line imaging techniques due to their wide availability; biliary leak or biloma are demonstrated as free fluid or fluid collection, usually in the perihepatic and subhepatic spaces, mostly anechoic on US and hypoattenuating with fluid density on CT. On MRI, biliary leaks and biloma are hypointense on T1-weighted sequence and hyperintense on T2-weighted sequence, with the former appearing as free fluid and the latter as a fluid collection (Figure 5). However, these findings are nonspecific, and biliary leaks and bilomas are virtually indistinguishable from other types of fluid collection and ascites. In the case of a biliary leak occurring after bile duct necrosis in the setting of hepatic artery occlusion, intrahepatic bilomas or bile lakes may develop in

Table 2 Post-transplant biliary complications related to surgery based on frequency, onset, and management



Type of complication	Frequency	Timing of onset	Common treatment
Biliary stricture	5%-15% (up to 30% in LDLT)	Early late	Refashioning after stenting
Biliary leak	2%-25%	Early	ERCP and stenting if anastomotic
Biloma/Biliary lake	2.6%-11.5%	Early	Percutaneous drainage and antibiotics if large
Bile duct filling defect	3%-6%	Early late	ERCP/percutaneous drainage
Sphincter of oddi dysfunction	2%-5%	Late	ERCP with sphincterotomy and consideration of stent placement
Redundant common bile duct	Rare	Late	Stent
Mucocele of bile duct remnant	Rare	Late	Surgery if causing compression

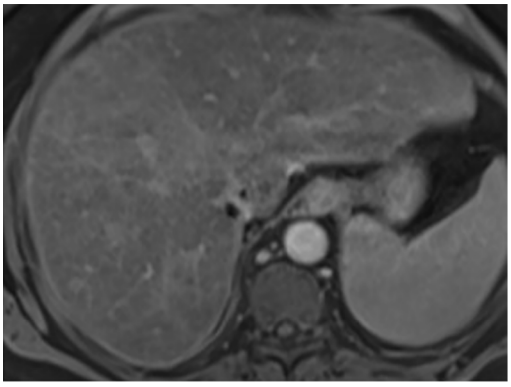
Figure 6 Biliary lakes occurring after liver transplantation. A: Contrast-enhanced computed tomography (CT) in the axial plane in the portal venous phase demonstrates biliary lakes (arrowheads) adjacent to the portal vein branches; B: Contrast-enhanced CT in the arterial phase demonstrates lack of enhancement of the hepatic artery (arrow) caused by the adjacent surgical clip.

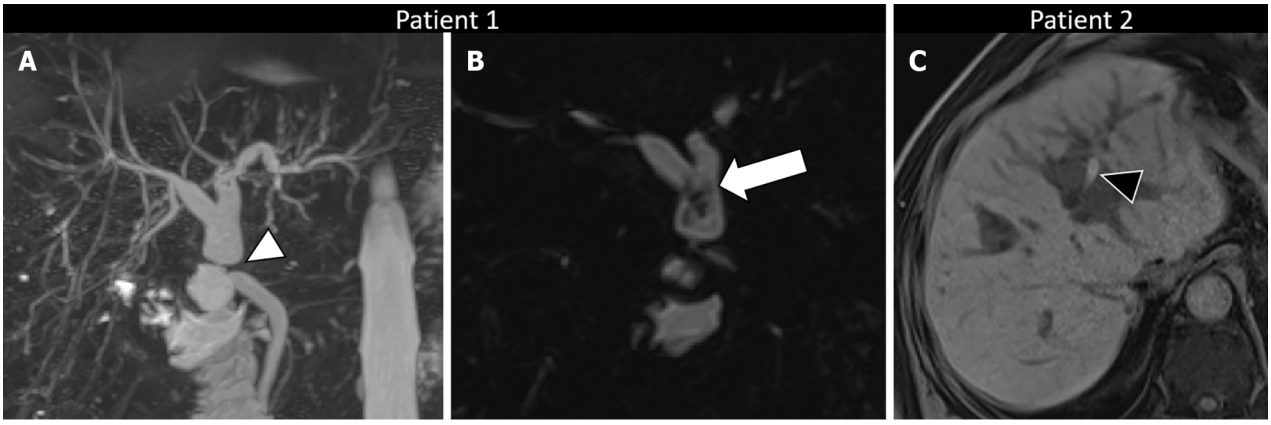
demonstrate the level and the entity of biliary leakage, showing contrast agent extravasation into bilomas in case of active leakage. However, small bilomas are often self-limiting, and active extravasation may not be demonstrated. The lack of active bile leak into a biloma as evidenced on imaging is highly clinically relevant, as it may help in choosing a conservative management. However, it is important to highlight that the diagnostic accuracy of MRCP with hepatobiliary contrast depends on the timing of acquisition of the hepatobiliary phase. When conventional acquisition at 20 min only is



adopted, sensitivity may be as low as 42.9%[26], while the acquisition at 60 min-90 min, 150 min-180 min, or even 210 min-240 min to 390 min increases the sensitivity[26,27]. The reason behind the lower sensitivity of the 20 min hepatobiliary phase compared to acquisitions at later times may be 2-fold. On one hand, the increased bilirubin in these patients may result in low uptake of hepatobiliary contrast by the hepatocytes at 20 min; indeed, bilirubin is taken up at the hepatocyte level by the same family of organic anion transport proteins of gadoxetate disodium (Figure 7). On the other hand, bile duct obstruction may result in the upregulation of a multidrug resistance protein, which could reduce the excretion of gadoxetate disodium, delaying or preventing the visualization of the bile ducts and any bile leak[28,29]. For this reason, based on consensus reports for liver MRI, an elevated bilirubin level is considered a relative contraindication to injection of gadoxetate disodium at some centers, with threshold bilirubin levels from 2.0 mg/dL-5.0 mg/dL. Overall, delayed acquisitions may prove to be helpful for the diagnosis of biliary leaks[29,30].

Biliary casts, stones and sludge

Biliary casts, stones, or sludge account for about 6% of all biliary complications[3], and usually complicate any biliary stricture present. Casts, stones, or sludge may occur at both the intra- and extrahepatic bile ducts as the consequence of bile stasis and may lead to cholangitis, graft failure, or the need for re-transplantation[31]. Biliary concretions after liver transplantation are related to a heterogenous group of lithogenic conditions mostly related to bile tract damage with a multifactorial, complex pathophysiology[32]. Biliary casts complicate up to 4.5% of liver transplantations, may recur, and may lead to biliary strictures in up to 85.0% of patients on follow-up[4]. Morphologically, biliary casts after liver transplantation may have a cordlike, columnar, or dendritic shape within the biliary tree[33]. The prompt identification of biliary casts is of utmost importance, as patients with biliary cast syndrome have lower overall and graft survival rates compared to patients with non-anastomotic and anastomotic strictures only[4]. MRCP has very good sensitivity in the identification of biliary concretions, which appear as filling defects surrounded by a thin film of hyperintense bile (Figure 8). Importantly, the sensitivity for biliary cast detection increases when using T1-weighted imaging compared to T2-weighted MRCP; unenhanced T1-weighted images show hyperintensities in the bile ducts (Figure 8C), leading to the correct diagnosis of biliary cast[34]. As recently pointed out, intraductal hyperintense filling material on T1-weighted MRI is a sensitive sign for biliary casts, and intraductal filling defect on T2-weighted MRI with the duct-in-a-duct feature is a specific sign and likely reflects biliary mucosal detachment[4].



Sphincter of Oddi dysfunction

Sphincter of Oddi dysfunction (SOD) comprises functional or mechanical obstruction of the sphincter of Oddi and involves the biliary sphincter and/or the pancreatic sphincter. Biliary and pancreatic SOD have each been subclassified into 3 types based on related symptoms, laboratory testing, and imaging (common bile duct diameter of at least 12 mm): Type I with biliary pain, abnormal liver enzymes and dilatation of the common bile duct; Type II with biliary pain and either abnormal liver enzymes or dilatation of the common bile duct; and Type III with biliary pain and no objective criteria[35,36]. More recently, the Rome IV consensus has proposed new classification, as most type I patients present with papillary stenosis rather than a functional disorder and have an excellent response after sphincterotomy; type II has now been renamed as suspected functional biliary sphincter disorder; and type III patients have no response to sphincterotomy[37,38]. SOD after liver transplantation has been reported in about 2%-5% of patients, with papillary stenosis (*i.e.* SOD type I) accounting for about 1% of cases and suspected functional biliary sphincter disorder (*i.e.* SOD type II) for about 1% as well[39]. The pathogenesis of biliary sphincter disorder in liver transplantation recipients is poorly understood; possible predisposing factors include the use of a T-tube, the presence of opportunistic infection, and postsurgical edema[40,41]. Patients with functional biliary sphincter disorder after liver transplantation may be asymptomatic due to hepatic denervation after the surgery and immunosuppression, thus making the diagnosis more difficult[41]. Therefore, suspicion of SOD after liver transplantation should be raised when cholestasis or dilation of bile ducts appears in the absence of bile stones or other structural abnormalities. Sphincter of Oddi manometry has been the gold standard for years, although it is invasive, patient- and operator-dependent, and may lead to post-procedure pancreatitis. Due to these factors, it is no longer routinely used in all patients with suspected SOD and its general utility has been questioned[39-41]. Hepatobiliary scintigraphy can demonstrate structural or functional partial biliary obstruction as evidenced by increased time to hepatic peak, delayed biliary visualization, delayed clearance of the radiotracer from the dilated bile ducts, and prolonged biliary to bowel transit[42-44]. MRCP may be used to exclude biliary lithiasis and other structural abnormalities, and may show an enlarged papilla in some cases of papillary stenosis (Figure 9). Secretin-MRCP may suggest the diagnosis of SOD, showing stenosis of the sphincter and lack of relaxation of the main pancreatic duct after secretin injection, increased prominence of pancreatic duct side branches, or acinarization[45]. Secretin-MRCP seems more useful for SOD type II, with a diagnostic accuracy of 73%, rather than for SOD type III for which accuracy drops to only 46%[46]. Given the low accuracy, the cost of secretin, and the acquisition time of at least 15 min, secretin-MRCP for SOD should be considered only in a few selected cases (*i.e.* noninvasive evaluation is preferred or when endoscopic evaluation is not available or

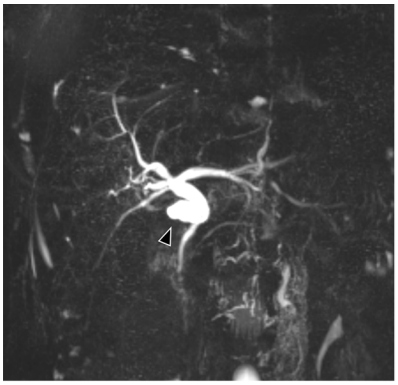
Figure 8 Biliary sludge and biliary cast. A: Patient with biliary sludge and anastomotic stricture 3 mo after liver re-transplantation. Magnetic resonance cholangiopancreatography (MRCP) maximum intensity projection image demonstrates anastomotic biliary stricture (arrowhead) with marked upstream biliary dilatation; B: Three-dimensional MRCP in the coronal plane in the same patient demonstrates biliary sludge (arrow) in the dilated hepatic duct extending into the left and right ducts. C: Patient with biliary cast 2 y after liver transplantation. Unenhanced T1-weighted gradient-recalled image shows hyperintense content (arrowhead) in the left biliary duct, consistent with biliary cast.

impractical)[45]. Gadoxetate disodium-enhanced MRCP may help in ruling out SOD in the case of normal passage of hepatobiliary contrast in the duodenum at 20 min-30 min, and in suggesting the diagnosis in the case of delayed or no passage of bile through the ampulla of Vater after 30 min-1 h[47]. Interestingly, the diagnostic accuracy of gadoxetate disodium-enhanced MRCP for SOD has not yet been investigated; this represents an area of interest particularly when invasive evaluation is not indicated.

Mucocele of the cystic duct remnant

Mucocele of the cystic duct remnant, whether recipient or donor in origin, is an extremely rare complication after liver transplantation[48-51]. It is characterized by an abnormally dilated cystic duct remnant with flattening of the walls of the residual cystic duct to form a collection of mucus from cells lining the cystic duct remnant. The causative mechanism of the mucocele is still unclear. Lack of nervous regulation of the biliary tract after liver transplant may affect bile secretion and outflow. The differential diagnosis includes abscess, biloma, hemobilia, tumor, or aneurysm. If left untreated, the enlarged mucocele may cause chronic mechanical compression of the biliary system; however, it may also remain stable in size[50]. Ultrasound and CT demonstrate the presence of a collection at the level of the hepatic hilum. MRCP demonstrates a rounded and well-circumscribed collection adjacent to the common hepatic duct in the absence of other cause of obstruction (Figure 10).



Bile duct redundancy

Bile duct redundancy is described as a surgically reconstructed donor-recipient extrahepatic bile duct that creates a looped, sigmoid-shaped appearance in the absence of any anastomotic stricture[8]. A

Figure 9 Enlarged ampullary papilla occurring years after liver transplantation and causing minimal cholestasis. T2-weighted imaging in the coronal plane demonstrates an enlarged ampullary papilla (arrowhead) protruding in the duodenal lumen (arrow). Ultrasonography-endoscopy confirmed the enlarged ampullary papilla and biopsy was performed, which excluded malignancy and confirmed the diagnosis of papillary stenosis (*i.e.* sphincter of Oddi dysfunction); sphincterotomy was then performed.

Figure 10 Mucocele occurring years after liver transplantation. Magnetic resonance cholangiopancreatography maximum intensity projection shows a fluid collection in communication with biliary tree. Biliary content was confirmed with percutaneous drainage.

redundant bile duct occurs when the donor or the recipient bile duct is too long, and may lead to delayed bile flow into the duodenum, functionally translating into cholestasis, abnormal liver laboratory test results, and cholangitis; it may also predispose to kinking of the redundant bile duct with subsequent obstruction[8,52,53]. Two-dimensional and 3-dimensional MRCP may demonstrate the abnormal long-constructed donor-recipient extrahepatic bile duct shape as well as any kinking, if present.

Vanishing bile duct syndrome

Vanishing bile duct syndrome is a very rare biliary complication occurring after liver transplantation, characterized by progressive destruction and disappearance of the intrahepatic bile ducts in the portal area leading to cholestasis[54,55]. It is caused by an acute or chronic T-cell-mediated rejection of the allograft[54,55]. The diagnosis of vanishing bile duct syndrome is suspected in a patient with liver biochemical abnormalities consistent with cholestasis in the absence of other conditions associated with cholestasis[54-56]. Histologic examination through liver biopsy is needed for the diagnosis, and MRI may help in excluding other causes of cholestasis[54,56].

CONCLUSION

In conclusion, biliary complications represent a clinically relevant problem after liver transplantation and occur in up to 1/3 of liver transplant recipients. Radiologists need to be aware of surgical techniques and post-surgical anatomy as well as clinical information for comprehensive image interpretation. MRCP is an established non-invasive procedure for the diagnosis of post-transplantation biliary complications. In selected cases, gadoxetate disodium-enhanced MRCP is needed for improving diagnostic accuracy of biliary complications and the protocol for this technique must be tailored based

on the clinical suspicion.

Abstract

BACKGROUND

Alcoholism is regarded as a risk factor for vitamin B_{12} (VB_{12}) deficiency. Because V B_{12} serves as a coenzyme of methylmalonyl-CoA mutase, a key enzyme in propionate metabolism, the ^{13}C-propionate breath test (PBT) has been studied as a non-invasive diagnostic modality for VB_{12} deficiency. However, the conventional PBT requires 2 h, which is inconvenient in clinical practice. We hypothesized that a faster PBT can be used to evaluate propionate metabolism and is more easily adaptable for clinical practice.

AIM

To evaluate a faster PBT for assessing the effects of long-term ethanol consumption on propionate metabolism in ethanol-fed rats (ERs).

METHODS

ERs were obtained by replacing standard drinking water (for control rats, CRs) with 16% ethanol solution in descendants of F344/DuCrj rats. Faster PBT was performed by administering ^{13}C-propionate aqueous solution to male and female ERs and CRs by inserting a metal tubule from the mouth to the stomach; exhaled gas was collected in a bag to measure its $^{13}CO_2/^{12}CO_2$ isotope ratio *via* infrared isotope spectrometry. Serum VB_{12} and alanine transaminase (ALT) levels were measured *via* chemiluminescence immunoassay and the lactate dehydrogenase-ultraviolet method, respectively. We evaluated statistical differences in mean body weight, change in $^{13}CO_2$ ($\Delta^{13}CO_2$‰), peak $\Delta^{13}CO_2$‰, and serum VB_{12} and ALT, between males and females and between ERs and CRs using the *t*-test and Mann-Whitney U test for normally and non-normally distributed variables, respectively.

RESULTS

Males weighed significantly more than females ($P < 0.001$); CRs weighed significantly more than ERs ($P < 0.008$). $\Delta^{13}CO_2$ reached a peak (C_{max}) at 20 min and

30 min in females and males, respectively, decreasing after 20-30 min without rebound in all groups. Males had significantly higher C_{max} and $\Delta^{13}CO_2$ at 15-45 min than females ($P < 0.05$; for all pairs). Propionate metabolism was enhanced in male ERs relative to male CRs, whereas metabolism did not differ markedly between ERs and CRs for females. Males had higher serum VB_{12} levels than females, without prominent differences between the ER and CR groups. Male CRs had notably higher ALT levels than male ERs. Thus, chronic ethanol consumption may trigger fatty acid production *via* intestinal bacteria and changes in gut microbiome composition.

CONCLUSION

Faster PBT shows that 16% ethanol consumption promotes propionate metabolism without inducing liver injury. This PBT may be used clinically to evaluate gut flora status.

Core Tip: Alcoholism is a risk factor for vitamin B_{12} (VB_{12}) deficiency. The ^{13}C-propionate breath test (PBT) is a diagnostic modality for VB_{12} deficiency, but requires 2 h for completion. We applied a faster PBT to evaluate propionate metabolism using an ethanol-fed rat model. After ^{13}C-propionate administration, the $^{13}CO_2/^{12}CO_2$ isotope ratio of gas collected every 5 min for 60 min was measured using infrared isotope spectrometry. The $\Delta^{13}CO_2$ peak occurred within 30 min. Ethanol-fed males showed marked propionate metabolism without associated liver injury. This study demonstrates the potential of the faster PBT to evaluate propionate metabolism under various clinical conditions.

INTRODUCTION

Chronic alcoholism is a risk factor for vitamin B_{12} (VB_{12}) deficiency[1,2]. Because VB_{12} works as a coenzyme of methylmalonyl-CoA mutase, a key enzyme in propionate metabolism (Figure 1), the ^{13}C-propionate breath test (PBT) has been studied as a non-invasive diagnostic modality for VB_{12} deficiency, with favorable results[3,4]. For instance, Wagner *et al*[3] reported that the conventional PBT could reliably predict VB_{12} deficiency in humans, with an area under the curve of the receiver operating curve value of 0.88. Propionate is a ubiquitous short chain fatty acid produced by intestinal bacteria, such as *Phascolarctobacterium*[5]. Emerging evidence suggests that intestinal microbial flora have a healing influence on alcoholic liver damage[6], and propionate produced by intestinal bacteria has protective effects against alcoholic liver damage[7]. Thus, we believe that PBT may provide important information not only regarding VB_{12}deficiency, but also regarding alcohol metabolism and alcoholic liver damage.

However, the conventional PBT requires 2 h to complete, which can be highly inconvenient for patients in clinical settings. Thus, in the present study, we aimed to evaluate the potential of a faster PBT for assessing the effects of long-term ethanol consumption on propionate metabolism as well as VB_{12} deficiency using ethanol-fed rats (ERs) as an animal model of chronic alcoholism. As the protective effects of estrogen against VB_{12} deficiency have been reported[8], we also evaluated the effect of sex-related differences on propionate metabolism, as detected by the faster PBT.

MATERIALS AND METHODS

Animals and treatments

All animal experiments were performed with approval of the Toho University School of Medicine, No. 21-51-4960. Descendants of F344/DuCrj rats purchased from CLEA Japan Inc. (Tokyo, Japan) for our previous study[9] were used to establish the ER and control rat (CR) groups for this study. All rats used in the present study were 18th-generation descendants of the originally established ER and CR groups, maintaining the lines within treatments (*i.e.*, parents of ERs were ERs, parents of CRs were CRs).

All rats were housed with their mothers until weaning at 4 wk of age. Subsequently, all rats were individually housed in a controlled environment (temperature, 23 ± 2 °C; humidity, 55% ± 5%) and provided a standard diet (CE-7; CLEA Japan Inc., Tokyo, Japan) and drinking liquid *ad libitum*. In the ER group, a 16% ethanol solution (Japanese Sake, Ozeki Corporation, Hyogo, Japan) was provided as a substitute for water by replacing the content of water bottles with ethanol solution in all cages of ERs.

A total of 16 ERs (8 males and 8 females) and 16 CRs (8 males and 8 females) aged 27-30 wk were used in the experiments; ERs continuously consumed alcohol for 23-27 wk. We used available descendants of F344/DuCrj rats that we had utilized in previous studies[9]. Therefore, we did not perform sample size calculation, randomization, or blinding.

Administration of ^{13}C-propionate and collection of exhaled gas

We purchased 1-^{13}C-sodium propionate from Cambridge Isotope Laboratories (Andover, MA, United States) and prepared a ^{13}C-propionate aqueous solution at 1 g/mL using distilled water immediately before administration. Body weight was measured immediately before administration. We performed gastrointestinal intubation in each rat and used a metal tubule, extending from the mouth to the stomach, to administer 0.1 mL/g of the ^{13}C-propionate solution. Immediately after administration, the rats were individually placed in the chambers of a dedicated exhaled-gas collection machine consisting of sealed chambers, pumps, and collecting bags, designed by Uchida *et al*[10]. We collected 100-200 mL of exhaled gas in the collecting bag for 90 s every 5 min for a total of 60 min.

Measurement of the ^{13}C recovery rate

Because ^{13}C-propionate is metabolized in the liver and exhaled as $^{13}CO_2$ (Figure 1), we measured the $^{13}CO_2/^{12}CO_2$ isotope ratio of the collected gas using infrared isotope spectrometry (POCone; Otsuka Electrics Co, Ltd., Hirakata, Japan) and monitored the change in $^{13}CO_2$ ($\Delta^{13}CO_2$‰), as reported previously[11].

Evaluation of serum VB_{12} and alanine transaminase levels

After collecting the exhaled gas for 60 min, the rats were immediately anesthetized *via* sevoflurane inhalation, and 5-10 mL of venous blood was collected from the inferior vena cava and the right atrium under laparotomy. After collecting sufficient blood samples, the animals were euthanized by rapid blood release. The blood was immediately centrifuged (relative centrifugal force: 1700 ×*g*) for 10 min, and the serum was collected. The serum was promptly frozen and submitted to FUJIFILM VET Systems Co. Ltd. (Tokyo, Japan) for measuring serum VB_{12} and ALT levels *via* chemiluminescence immunoassay and the lactate dehydrogenase-ultraviolet method, respectively.

Statistical analyses

We analyzed $\Delta^{13}CO_2$‰ measured every 5 min after ^{13}C-propionate administration for 60 min and serum VB_{12} levels, comparing the sexes and the ER and CR groups. The normality of the distribution of all variables was evaluated using the Kolmogorov-Smirnov test, and differences between groups were compared using the *t*-test and Mann-Whitney U test for normally and non-normally distributed variables, respectively. Statistical significance was set at $P < 0.05$. All statistical analyses were performed using Stata/IC software (version 15.1; Stata Corp., College Station, TX, United States). We used R 4.2.0 for construction of graphics[12]. The statistical methods were reviewed by Yosuke Sasaki from the Toho

University School of Medicine (the first author). As Yosuke Sasaki has completed several certified biostatistics courses, we did not obtain additional biostatical review suggestions by external biomedical statisticians.

RESULTS

Influence of ethanol and sex on body weight

Body weight was significantly higher ($P < 0.0001$) in males (335.8 ± 37.0 g) than in females (176.6 ± 21.9 g). In addition, body weight was significantly higher in CRs than in ERs for both males and females ($P = 0.0082$ and $P = 0.005$, respectively, Table 1).

Sex-related difference in PBT results

The $\Delta^{13}CO_2$ reached its peak (C_{max}) at 20 min and 30 min in females and males, respectively. The $\Delta^{13}CO_2$ decreased after 20-30 min without rebound in both groups (Table 2 and Figure 2). Therefore, the overall trends in $\Delta^{13}CO_2$ over time were similar between males and females, although C_{max} was delayed in males and $\Delta^{13}CO_2$ was significantly higher in males at 30 min and thereafter (Table 2 and Figure 2). The C_{max} and $\Delta^{13}CO_2$ values between 15 and 45 min were significantly higher in males than in females ($P < 0.05$, Table 2). Considering these sex-based differences, we further compared the effects of ethanol in males and females separately.

Effects of ethanol on propionate metabolism

Propionate metabolism was accelerated in the ERs relative to that in the CRs in males (Figure 3), with $\Delta^{13}CO_2$ at 10 and 20 min being markedly higher in male ERs. However, $\Delta^{13}CO_2$ after 40 min was higher in the CR group (Table 3). The $\Delta^{13}CO_2$ reached C_{max} earlier in the ERs (at 20 min) than in the CRs (at 30 min). These findings suggest that ethanol promoted propionate metabolism in male rats. However, propionate metabolism was similar between the ER and CR groups among females, without any significant differences ($P > 0.110$ for all pairs, Table 3, Figure 4).

Effects of ethanol on serum VB_{12} and ALT levels

The serum VB_{12} levels were significantly higher in males than in females ($P = 0.0013$, Table 4); however, no significant differences were observed between the ER and CR groups for either sex ($P > 0.05$ for all pairs, Table 4). In contrast, serum ALT levels were significantly higher in male CRs than in male ERs ($P = 0.0347$, Table 5).

DISCUSSION

In this study, we compared propionate metabolism using a faster PBT in rats and compared serum VB_{12} and ALT levels between males and females and between ER and CR groups. Overall, our study demonstrates that (1) The faster PBT is useful for evaluating differences in propionate metabolism after administration of a ^{13}C-propionate solution; (2) Males show greater propionate metabolism, with higher serum VB_{12} levels, than females; (3) Ethanol consumption promotes propionate metabolism in male rats only; and (4) Ethanol consumption reduces body weight and serum ALT levels.

In the faster PBT, $\Delta^{13}CO_2$ peaked at 30 min, then decreased over time without rebound in all groups. Accordingly, we consider the faster PBT, which is completed within only 60 min after ^{13}C propionate administration, to be sufficiently sensitive to evaluate propionate metabolism, as a substitute for the conventional PBT that requires collecting exhaled gas for 2 h.

Using the PBT, our study showed a higher C_{max} and $\Delta^{13}CO_2$ between 15 and 45 min in male rats than in female rats, which suggests that male rats have stronger propionate metabolism. Suppression of carbohydrate metabolism and promotion of lipid metabolism by estrogen in females have been proposed as mechanisms contributing to lower carbohydrate metabolism in females than in males[13]. Furthermore, a protective effect of estrogen against VB_{12} deficiency in fertile females has been reported, along with higher susceptibility to VB_{12} deficiency in postmenopausal women[8,14]. Considering that VB_{12} works as a coenzyme of methylmalonyl-CoA mutase, and that serum VB_{12} levels were not pathologically low in the rats used in our study, we postulate that the lower propionate metabolism detected by the faster PBT and the lower serum VB_{12} levels in females than in males may reflect underlying physiological sex-related differences in carbohydrate metabolism associated with estrogen.

As we aimed to use the faster PBT to evaluate impaired propionate metabolism due to VB_{12} deficiency and liver disease caused by chronic alcohol consumption, we expected to find lower propionate metabolism and higher serum ALT levels in the ER group than in the CR group. However, we obtained contrasting results, with acceleration of propionate metabolism in the ER group and higher serum ALT levels in the CR group. Changes in the gut flora caused by chronic alcohol consumption may explain the promotion of propionate metabolism in the ER group. Using male marmosets, Zhu *et al*[15] reported

that the concentrations of short-chain fatty acids, including propionate, depend on changes in intestinal bacteria, based on an observed reduction in fecal propionate levels along with a reduction in the relative abundance of *Phascolarctobacterium* in the gut. Moreover, Watanabe *et al*[5] reported that the substrates of short-chain fatty acids, including propionate, produced by intestinal bacteria depend not only on a single bacterial strain, but also on the specific composition of other bacteria present in the gut. According to these reports, ethanol can serve as both a potential substrate of fatty acid production by

intestinal bacteria, such as *Phascolarctobacterium*, and as a trigger for changes in gut flora. Thus, we hypothesized that chronic alcohol consumption promotes propionate production both as a substrate for various fatty acids and as a trigger for changes in gut flora.

Alternatively, these observations may be due to the well-known difficulties in recapitulating the effects of chronic alcohol consumption in an animal model. We intended to establish a rat model of chronic alcoholism to evaluate the metabolic effect of ethanol consumption by oral administration of a 16% ethanol solution (corresponding to the level of alcohol commonly consumed by Japanese drinkers in the form of sake) for > 20 wk based on a previous study[16]. Therefore, we expected higher serum ALT levels in the ER group. Our contrasting result (lower serum ALT after 16% ethanol consumption) highlights the difficulty in the development of alcoholic animal models. A recent review on the utility of animal models for alcoholic liver disease mentioned that, in contrast to primates, rodent models fail to sufficiently display the full disease spectrum of alcoholic liver disease found in humans, despite many trials under various conditions[17]. The absence of craving in rats, owing to their natural aversion to ethanol[18,19], the faster ethanol catabolism in rodents than in humans[20], and differences in the innate immune systems of the species, have been proposed as the main factors contributing to the difficulty in establishing a useful rat model of human alcoholism[21]. It is therefore possible that our results also reflect failure to generate a chronic alcoholism rat model; thus, studies using primates or other small animals rather than rodents may be more appropriate. Considering the *ad libitum* diet administration, and the higher body weight in the CR group, fatty liver due to excessive dietary intake may explain the higher serum ALT levels in CRs. Because all of the rats consumed the same diet, it is possible that

consumption of 16% ethanol solution had a protective effect against liver damage. Given that propionate itself reportedly has protective effects against steatohepatitis[7], and that improvement of gut flora is an effective way to suppress liver damage[6], enhanced propionate metabolism and favorable changes in the gut flora might suppress liver damage in male ERs. As discussed earlier, the lack of acceleration in propionate metabolism in female ERs can be explained by sex-related differences in carbohydrate metabolism.

In addition to the lack of confirmation of the chronic alcoholism model, our study has other limitations. For instance, the serum methylmalonic acid (MMA) level, rather than the serum VB_{12} level, is required for the precise diagnosis of VB_{12} deficiency in humans[3]. However, we were not able to evaluate MMA levels because major domestic commercial laboratories no longer perform MMA testing of human serum or urine, and we could not find or access domestic laboratories measuring serum MMA in animal samples. Similarly, comparing the PBT results with biomarkers, such as aldehyde dehydrogenase and alcohol dehydrogenase, which sensitively and precisely reflect hepatic alcohol metabolism, may provide more information[22]. We believe that comparing levels of serum MMA and the markers evaluated using the faster PBT may provide further insight into the association between VB_{12} deficiency and alcoholism. Moreover, the present study only focused on the association between propionate metabolism and VB_{12} deficiency based on a previous study on PBT[3]. However, considering the complexity of intestinal propionate production due to the variety of propionate-producing bacteria, including *Clostridium* spp., *Veillonella* spp., *Fusobacterium* spp., *Salmonella ruminantium*, and *Propionibacterium* spp., and the complexity of substrates[23], the findings obtained herein, including the promoted propionate metabolism in male ERs and sex-related difference, may have potential clinical utility and provide a basis for future research into propionate metabolism and intestinal microbiota under various conditions. For instance, comparison of findings between faster PBT and the composition or changes in gut microbiota may provide interesting information on the association between gut microbiota and their products. Despite these limitations and lack of confirmation of VB_{12} deficiency under our experimental conditions, our study highlights the influence of ethanol and sex-related differences in propionate metabolism.

CONCLUSION

We evaluated a faster PBT in which C_{max} peaked within 30 min. This PBT could serve as a substitute for conventional PBT (which takes at least 2 h) for evaluating propionate metabolism and diagnosing VB_{12} deficiency. Although we could not evaluate the usefulness of faster PBT as a diagnostic modality for VB_{12} deficiency as initially intended because we failed to create a rat alcoholism model with VB_{12} deficiency, our study suggests that chronic consumption of 16% ethanol changed the composition of fatty acids produced by the intestinal flora, likely by changing the intestinal flora composition without causing corresponding liver injury. Considering the accumulating evidence of alteration of the gut flora as one of the mechanisms of alcoholism-related health impacts[24], our study demonstrates the potential utility of the faster PBT as a non-invasive and more convenient modality to evaluate changes in the gut flora associated with ethanol consumption and various other conditions.

ARTICLE HIGHLIGHTS

Research background

The ^{13}C-propionate breath test (PBT) has been studied as a non-invasive diagnostic modality for vitamin B_{12} (VB_{12}) deficiency by utilizing the role of VB_{12} as a coenzyme of methylmalonyl-CoA mutase in propionate metabolism. Although alcoholism has been regarded as a risk factor for deficiency, studies on propionate metabolism using the PBT in individuals with alcoholism is limited. Furthermore, conventional PBT requires up to 2 hours of breath collection time, which may undermine its clinical utility.

Research motivation

The scarcity of studies regarding the PBT in alcoholism, and the possibility of improving the clinical utility of the PBT by shortening the breath collection time, motivated us to perform this study.

Research objectives

The aim of this study was to evaluate the change in propionate metabolism due to long-term ethanol consumption in ethanol-fed rats (ERs) as an animal model of chronic alcoholism. We also aimed to evaluate the utility of a faster PBT that requires only 1 hour to collect breath.

Research methods

The ERs were 18th generation descendants of F344/DuCrj rats that had been bred by replacing standard drinking water with a 16% ethanol solution. A faster PBT was performed by injecting the ^{13}C-propionate aqueous solution from the mouth to the stomach of ERs and control rats (CRs); we collected exhaled gas in bags, and measured the $^{13}CO_2/^{12}CO_2$ isotope ratio using infrared isotope spectrometry. We measured serum VB_{12} and alanine transaminase (ALT) levels *via* chemiluminescence immunoassay and the lactate dehydrogenase-ultraviolet method, respectively. We evaluated statistical differences in mean body weight, change in $^{13}CO_2$ ($\Delta^{13}CO_2$‰), peak $\Delta^{13}CO_2$‰, and serum VB_{12} and ALT, between ERs and CRs, and males and females, respectively.

Research results

Besides male dominance of body weight ($P < 0.001$), CRs weighed significantly more than ERs ($P < 0.008$). The $\Delta^{13}CO_2$ reached a peak (C_{max}) within 30 min in both sex groups, while males had a significantly higher C_{max} and $\Delta^{13}CO_2$ at 15-45 min than females ($P < 0.05$; for all pairs). Enhanced propionate metabolism was observed in male ERs relative to male CRs, and although males had higher serum VB_{12} levels than females, no prominent differences were observed between the ER and CR groups. Male CRs had notably higher ALT levels than male ERs. These results suggest that chronic ethanol consumption may trigger fatty acid production *via* intestinal bacteria and changes in gut microbiome composition.

Research conclusions

We believe that a faster (1-h) PBT could serve as a substitute for the conventional PBT, as the $\Delta^{13}CO_2$ reached a peak (C_{max}) within 30 min in both sex groups. We failed to evaluate the usefulness of the faster PBT as a diagnostic modality for VB_{12} deficiency in the chronic alcoholism rat model; however, our study suggests that instead of inducing alcoholism, chronic consumption of 16% ethanol changed the composition of fatty acids produced by the intestinal flora.

Research perspectives

Our study demonstrates the potential utility of the faster PBT as a non-invasive and more convenient modality to evaluate changes in the gut flora associated with ethanol consumption and various other conditions *via* changes in propionate metabolism.

Abstract

BACKGROUND

Fibroblast growth factor (FGF) 15/19, which is expressed in and secreted from the distal ileum, can regulate hepatic glucose metabolism in an endocrine manner. The levels of both bile acids (BAs) and FGF15/19 are elevated after bariatric surgery. However, it is unclear whether the increase in FGF15/19 is induced by BAs. Moreover, it remains to be understood whether FGF15/19 elevations contribute to improvements in hepatic glucose metabolism after bariatric surgery.

AIM

To investigate the mechanism of improvement of hepatic glucose metabolism by elevated BAs after sleeve gastrectomy (SG).

METHODS

By calculating and comparing the changes of body weight after SG with SHAM group, we examined the weight-loss effect of SG. The oral glucose tolerance test (OGTT) test and area under the curve of OGTT curves were used to assess the anti-diabetic effects of SG. By detecting the glycogen content, expression and activity of glycogen synthase as well as the glucose-6-phosphatase (G6Pase) and phosphoenolpyruvate carboxykinase (Pepck), we evaluated the hepatic glycogen content and gluconeogenesis activity. We examined the levels of total BA (TBA) together with the farnesoid X receptor (FXR)-agonistic BA subspecies in systemic serum and portal vein at week 12 post-surgery. Then the histological expression of ileal FXR and FGF15 and hepatic FGF receptor 4 (FGFR4) with its corresponding signal pathways involved in glucose metabolism were detected.

RESULTS

After surgery, food intake and body weight gain of SG group was decreased compare with the SHAM group. The hepatic glycogen content and glycogen synthase activity was significantly stimulated after SG, while the expression of the key enzyme for hepatic gluconeogenesis: G6Pase and Pepck, were depressed. TBA levels in serum and portal vein were both elevated after SG, the FXR-agonistic BA subspecies: Chenodeoxycholic acid (CDCA), lithocholic acid (LCA) in serum and CDCA, DCA, LCA in portal vein were all higher in SG group than that in SHAM group. Consequently, the ileal expression of FXR and FGF15 were also advanced in SG group. Moreover, the hepatic expression of FGFR4 was stimulated in SG-operated rats. As a result, the activity of its corresponding pathway for glycogen synthesis: FGFR4-Ras-extracellular signal regulated kinase pathway was stimulated, while the corresponding pathway for hepatic gluconeogenesis: FGFR4-cAMP regulatory element-binding protein- peroxisome proliferator-activated receptor γ coactivator-1α pathway was suppressed.

CONCLUSION

Elevated BAs after SG induced FGF15 expression in distal ileum by activating their receptor FXR. Furthermore, the promoted FGF15 partly mediated the improving effects on hepatic glucose metabolism of SG.

Key Words: Sleeve gastrectomy; Fibroblast growth factor 15; Bile acids; Hepatic glucose metabolism; Type 2 diabetes mellitus

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Sleeve gastrectomy (SG) improves hepatic glucose metabolism and alleviates type 2 diabetes mellitus through the intestine-liver crosstalk mediated by fibroblast growth factor 15 (FGF15). Following SG, bile acids are elevated, inducing the expression and secretion of FGF15 *via* the activation of farnesoid X receptor in the ileum. FGF15 then acts as an endocrine factor to promote glycogen synthesis and inhibit gluconeogenesis in the liver by specifically stimulating hepatic FGF receptor 4 and its corresponding signaling pathways.

INTRODUCTION

The incidence of obesity along with the relative metabolic abnormalities[1], especially type 2 diabetes mellitus (T2DM)[2], is on the rise globally. Bariatric surgery becomes the most efficient treatment option for obese patients with diabetes[3] due to its prominent weight reduction and durable metabolic improvement effect[4,5]. Roux-en-Y gastric bypass (RYGB) and sleeve gastrectomy (SG) are the most commonly performed surgical procedures currently[3]. Moreover, SG has now exceeded RYGB as the preferred approach for most surgeons[6,7]. Still, the mechanisms underlying effects of bariatric surgery remain to be fully elucidated.

Bile acid (BA) has been considered as prospective factor for the metabolic actions of bariatric surgery [8] because of the considerable significance of its receptors, Takeda G protein-coupled receptor 5[9] and farnesoid X receptor (FXR)[10]. Through intestinal FXR, BAs could induce the expression and secretion of fibroblast growth factor (FGF) 15/19 in the distal ileum[11,12]. Recent studies illustrate that both BAs and FGF19 -the human ortholog of rodent FGF15[13]- are elevated after bariatric surgery[14-17]. Hence, the elevation of FGF19 after bariatric surgery probably results from the induction of FXR by elevated BAs, which needs further investigation. Moreover, FGF15/19 also plays a role in regulating the metabolic homeostasis, especially the hepatic glucose metabolism[18]. Similar to insulin's actions, FGF15/19 could act to lower the blood glucose level by repressing gluconeogenesis[19] and promoting glycogen synthesis[20] in the liver. Taken together, the ileal FXR-FGF15/19 pathway triggered by BAs might be another potential mechanism underlying the metabolic effects of bariatric surgery. However, to prove this, we need to confirm that the elevation of FGF15/19 results from the induction of FXR by elevated BAs and FGF15/19 participates in the improvement of hepatic glucose metabolism after

bariatric surgery.

As insulin and FGF15/19 can exert comparable metabolic actions on liver, only to detect the activities of glycogen synthesis and gluconeogenesis of liver could not distinguish the action of FGF15/19 from insulin. Previous studies demonstrated that FGF15/19 functions in an insulin-independent manner through activating FGF receptor 4 (FGFR4)[21] and its corresponding signal pathways. FGF15/19 could promote glycogen synthesis by activating the Ras- extracellular signal regulated kinase (ERK) pathway [20] and inhibit hepatic gluconeogenesis by suppressing the cAMP regulatory element-binding protein (CREB)- peroxisome proliferator-activated receptor γ coactivator-1α (PGC-1α) pathway[19]. However, insulin induces these effects through phosphoinositide 3-kinase (PI3K)-Akt pathway. The signaling pathways engaged in regulation of hepatic glucose metabolism by FGF15/19 and insulin permit overlapping, but can distinct the biological effects of these two hormones. Hence, to detect the expression of FGFR4 and the activities of its corresponding signaling pathways after bariatric surgery would help to confirm the action of FGF15/19 on hepatic glucose metabolism.

We conducted SHAM and SG operations on an obese diabetic rat model induced by high-fat diet (HFD) and streptozotocin (STZ) in this study. BAs levels in serum and portal vein, and the ileal expression of FXR and FGF15 were detected to confirm the elevation of the FGF15 as well as the underlying mechanism after surgery. Moreover, we detected the hepatic expression of FGFR4 and the activity of its corresponding signaling pathways involved in glucose metabolism to investigate whether FGF15 mediates the improvement of hepatic glucose metabolic after SG.

MATERIALS AND METHODS

Animals

We used Wistar rats in this study, and the rats (8-wk-old, 200 g on average) were purchased and housed in Laboratory Animal Center of Shandong University (Jinan, Shandong Province, China). The obese diabetic rat model was induced as previously reported[22,23]. The rats received a HFD (40% fat, 42% carbohydrate, 18% protein, Huafukang Biotech, China) for 1 mo, followed by low dose intraperitoneal STZ injection (35 mg/kg, Sigma, United States). The glucose level of peripheral blood obtained from tail vein was tested using a glucometer (Roche Diagnostics, Germany). Diabetes induction was confirmed based on the Oral Glucose Tolerance Test (OGTT) results and blood glucose levels examined at random time-points (≥ 16.7 mmol/L). The diabetic rats then randomly divided into matched SHAM (n = 10) and SG (n = 10) group. All actions and interventions applied on rats were approved and guided by Laboratory Animal Ethical and Welfare Committee of Shandong University Cheeloo College of Medicine.

Before operation, rats were fasted for about 12 h after two-days feeding of 10% Ensure (Abbott, United States). Moreover, anesthesia for rats was induced by 10% chloral hydrate (3 mL/kg).

Surgical procedures

SG: First, the relevant vessels and gastro-epiploic structures were ligated and transected to externalize the greater curvature of the stomach. Then, we conducted gastrectomy of 80% of the whole stomach from greater curvature, including the whole gastric fundus. The residual stomach was closed and continuously sutured with a 5-0 silk suture (Ningbo medical, China). The cardia, pylorus of stomach and continuity of stomach with esophagus and duodenum were all remained unaffected.

SHAM: In order to minimize the concomitant influence and bias triggered by surgical operation and anesthesia, we set SHAM group as previously reported. First, we isolated the greater curvature of stomach similarly as what we did in SG group. Then we clamped the stomach along the greater curvature with a pair of blunt forceps between cardia and pylorus to exert a similar pressure on the stomach. The exposed area and time of surgical field were extended as that of SG group to eliminate the undeserving influence of operation and anesthesia.

Postsurgical care: After surgery, the rats were only supplied with some water during the first 24 h. Then following 3-d feeding of 10% Ensure, the rats resumed the HDF diet till the end of the study. We recorded the body weight and calorie intake of every rat in both groups every day. Antibiotics were unnecessary and all rats in both groups survived and were sacrificed until the end of the study (week 12 post-surgery).

OGTT

We conducted OGTTs preoperatively to confirm diabetes induction and to evaluate the anti-diabetic effects of SG at week 12 post-surgery. After 12-h fasting, the rats received 20% glucose (1 g/kg) chow *via* oral gavage. Blood glucose levels were measured at time point of 0 min, 10 min, 30 min, 60 min, and 120 min after administration.

Detection of BAs

At 12 wk after surgery, total BAs (TBA) levels were examined in both the systemic serum and portal vein. In addition, the specific levels of the following four FXR-agonist BA species were also examined: Chenodeoxycholic acid (CDCA), DCA, lithocholic acid (LCA), and cholic acid (CA). One hour before sacrificed, all rats were gavaged with 10% Ensure after 12-h fasting. When sacrificing the rats, we collected blood samples from the retrobulbar venous plexus and portal vein. Portal and systemic serum levels of TBA were detected on the Roche Cobas 8000 system using the enzyme cycling method. As previously described[22,23], the levels of BA species (CDCA, DCA, LCA, and CA) in these samples were evaluated using high-pressure liquid chromatography coupled with tandem mass spectrometry (HPLC-MS/MS). Standard substrates for these four BA species were purchased from Sigma Aldrich (United States).

Histological analysis of ileum and liver tissues

After sacrificing, ileum and liver tissues in both groups were divided into three parts. Some were fixed in 4% paraformaldehyde and then embedded in paraffin for Periodic Acid-Schiff (PAS) staining and immunohistochemistry staining; some were stored at -80 °C for western blotting and hepatic glycogen content detection; and the others were stored in RNA*later*™ Stabilization Solution (Thermo Fisher Scientific™) for real-time PCR.

Real-time PCR

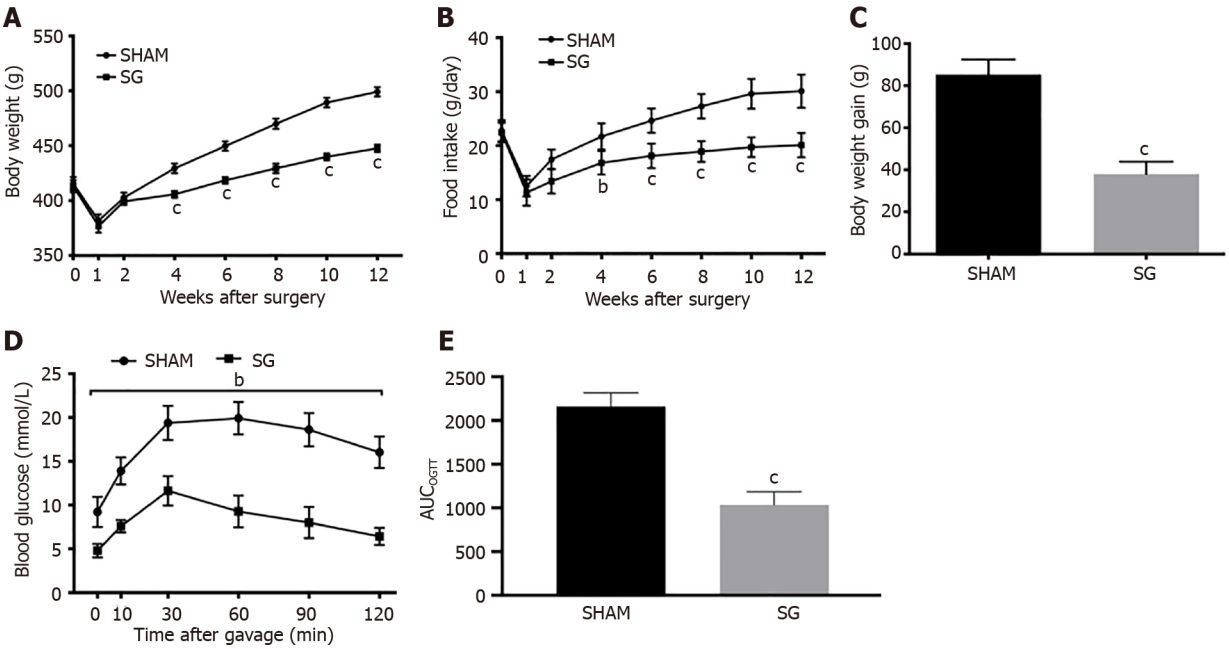
The levels of FGF15, FXR in ileum and FGFR4, glucose-6-phosphatase (G6Pase), phosphoenolpyruvate carboxykinase (Pepck) in liver were measured using RT-PCR. Total RNA was extracted from the tissue using TRIzol reagent (Invitrogen, United States) and then reversely transcribed to cDNA by the High Capacity cDNA Reverse Transcription Kit (TOYOBO, Japan). Subsequently, the relative level of mRNA amplification was determined through the SYBR Green Real-time PCR Master Mix Kit (TOYOBO, Japan) according to manufacturer's instructions. The following primers were used for analysis: FGF15: 5′-GCCATCAAGGACGTCAGCA-3′(F), 5′-CTTCCTCCGAGTAGCGAATCAG-3′ (R); FXR: 5′-TCCGGACATTCAACCATCAC-3′ (F), 5′-TCACTGCACATCCCAGATCTC-3′ (R); FGFR4: 5′-GGCCAGGTATACGGACATCA-3′ (F), 5′-GAGTCAGGCTGTCACATGTG-3′ (R); G6Pase: 5′-GTGGCAGTGGTCGGAGACT-3′ (F), 5′-ACGGGCGTTGTCCAAAC-3′ (R); Pepck: 5′-CACCATCACCTCCTGGAAGA-3′ (F), 5′-GGGTGCAGAATCTCGAGTTG-3′ (R).

Glycogen detecting and immunohistochemistry staining

We detected the hepatic glycogen content using the Glycogen Assay kit (ab65620, Abcam, United States) according to manufacturer's protocol. Sections of the paraffin-embedded tissues were prepared for PAS and immunohistochemistry staining. We stained the glycogen in hepatocytes with the PAS Stain Kit (Mucin Stain) (ab150680, Abcam, United States) according to the manufacturer's protocol. And we also examined the ileal expression of FGF15 and hepatic expression of FGFR4 by immunohistochemistry staining. The antibody for FGF15 (sc-16816) and FGFR4 (sc-136988) were both purchased from Santa Cruz Biotechnology (United States). Percentage of PAS- positive cells was calculated and quantification of immunoreactive signal was performed using Image J software.

Western blotting

We detected the hepatic expression of ERK1/2, p-ERK1/2, glycogen synthase (GS), p-GS, CREB, p-CREB and PGC-1α by western blotting. Anti-ERK1/2, anti-p-ERK1/2, anti-GS, anti-p-GS, anti-CREB, and anti-p-CREB for western blotting were purchased from Cell Signaling Technology (CST, United States), and anti-PGC-1α, anti-Actin were purchased from Abcam (United States).



Statistical analysis

All quantitative data are presented in the pattern of mean ± SEM. The area under the curve (AUC) was evaluated using trapezoidal integration. We used unpaired Student's *t* test to analyzed statistical significance, and $P < 0.05$ indicated statistical significance. All statistical analyses were performed by SPSS version 20.0.

RESULTS

Weight loss and anti-diabetic effects of SG

According to our previous studies, we evaluated the weight-loss and anti-diabetic effects of SG postoperatively. First, we assessed the weight-loss action by tracking the body weight and daily food intake of the rats in SHAM and SG group. After a sharp decrease during the first week after surgery, the body weight and food intake gradually increased in both groups. Since week 4 post-surgery, the increase of body weight and food intake in SG group became significantly slower than that in SHAM group (Figure 1A and B). And the body weight gain of SG group was correspondingly lower than that

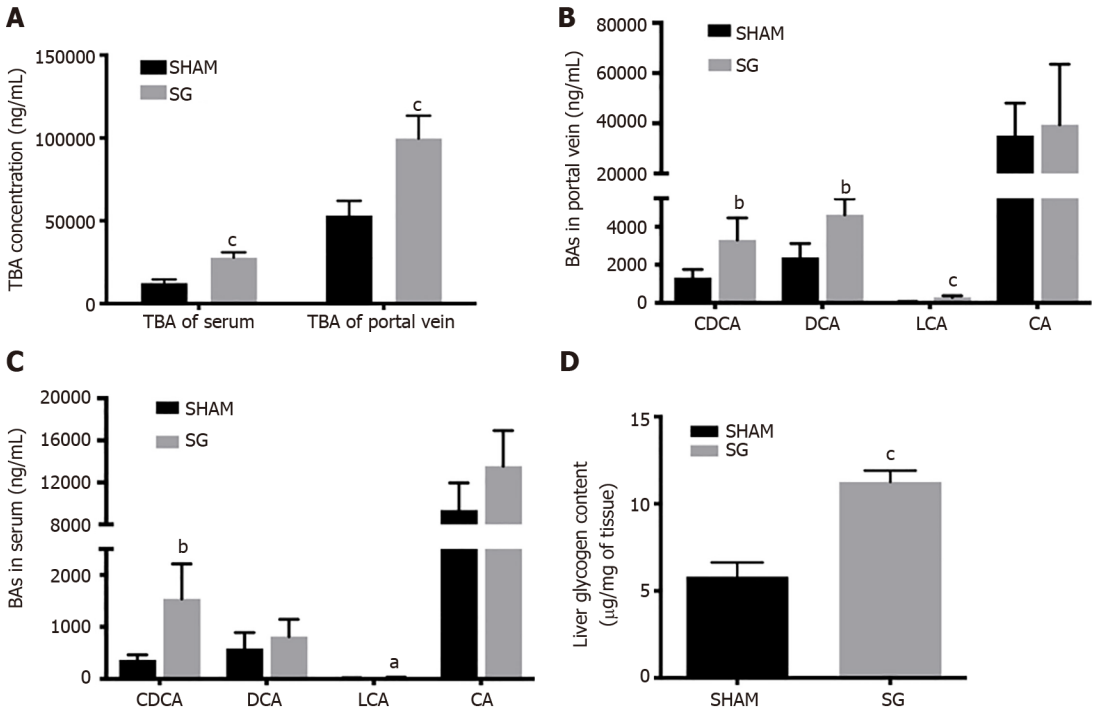
Figure 1 The weight-loss and anti-diabetic effects of sleeve gastrectomy. A: Body weight; B: Food intake; C: Body weight gain after surgery; D: The oral glucose tolerance test (OGTT) curves; E: Area under the curve for OGTT curves of SHAM and sleeve gastrectomy (SG) group at week 12 postoperation. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$; SG *vs* SHAM group. SG: Sleeve gastrectomy.

in SHAM group till week 12 post-surgery (Figure 1C). Then, we conducted the OGTT in both groups to evaluate the anti-diabetic effects of SG. The OGTT curves and result of AUC$_{OGTT}$ showed much better glucose tolerance in SG group than SHAM group (Figure 1D and E), which indicated a considerable anti-diabetic effect of SG.

Effects of SG on BA levels and ileal FGF15, FXR expressions

We detected the TBA levels both in systemic serum and portal vein at week 12 post-surgery, together with four BA species: CDCA, DCA, LCA, and CA, which are all FXR agonists. TBA levels of SG group in serum and portal vein were significantly higher than that in SHAM group (Figure 2A and B). Both CDCA and LCA levels in these two kinds samples were elevated and the portal vein DCA level was also higher in SG group (Figure 2C and D).

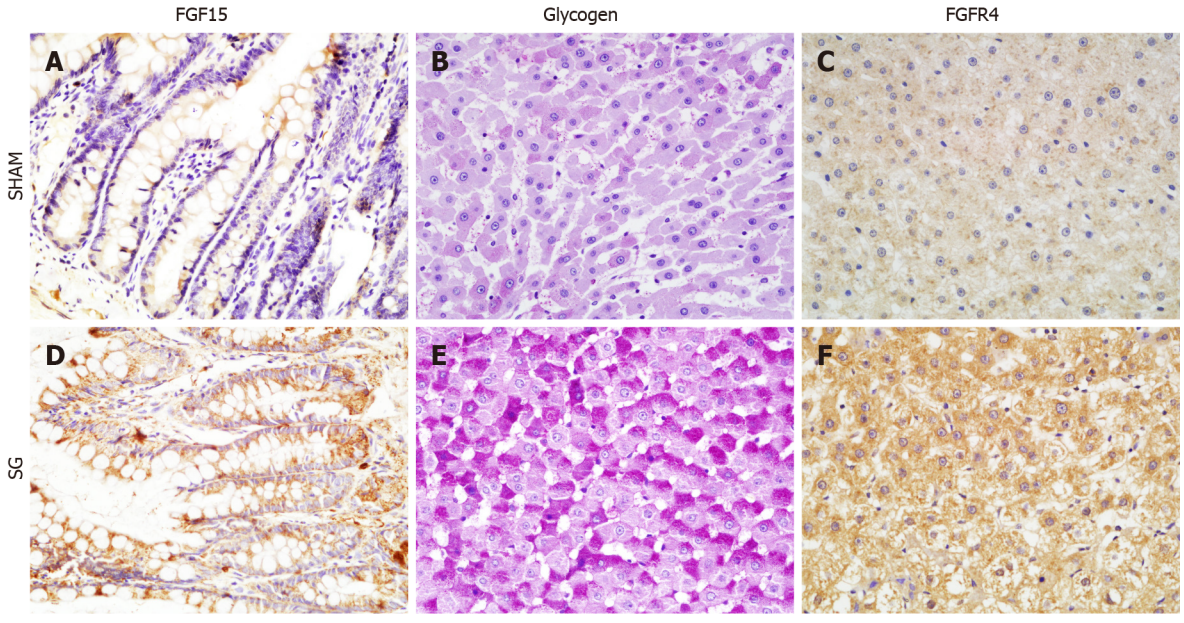
Then, we detected the influence of SG on FGF15 and FXR expressions in distal ileum. Both mRNA and protein expression levels of FGF15 in SG group were significantly higher than that in SHAM group (Figure 3A and D; Figure 4). Also, FXR mRNA level was also considerably elevated after SG (Figure 4).



SG significantly improved the hepatic glucose metabolism

To evaluate the hepatic glucose metabolism, we detected the activities of hepatic glycogen synthesis and gluconeogenesis, together with the glycogen content in both groups after SG. The expression of glycogen synthase (GS) was significantly higher in the SG-operated rats, while the phosphorylation degree of GS (p-GS) was declined (Figure 5). In other words, the hepatic glycogen synthetic activity was significantly promoted after SG. Correspondingly, the glycogen content and the percentage of PAS-positive cells in liver were significantly higher in SG-operated rats (Figures 2A, 3B and E).

We then measured two key enzymes within hepatic gluconeogenesis, G6Pase and Pepck mRNA levels of both enzymes were significantly declined in SG group compared with SHAM group, which illustrated an inhibited gluconeogenesis process in SG-operated rats (Figure 4).



SG activated the receptor and regulated activities of the corresponding signal pathways of FGF15

FGF15/19 can activate its receptor, FGFR4 in the liver with unique specificity[25]. The expression of FGFR4 was significantly promoted at both mRNA and protein levels in SG group (Figure 4). FGF15-FGFR4 regulates hepatic glycogen synthesis and gluconeogenesis through Ras-ERK pathway and CREB-PGC-1α pathway, respectively. ERK1/2 regulates the phosphorylation degree of GS. We detected no difference in the expression of total ERK1/2 protein level. Whereas, the phosphorylation of ERK1/2 was increased in SG-operated rats, which indicates the activation of ERK1/2 pathway (Figure 5). On the contrary, the declined phosphorylation degree of CREB and decreased expression of PGC-1α (Figure 5) together with the inhibition of G6Pase and Pepck (G6Pase and Pepck are two target genes of PGC-1α) illustrated the inhibition of CREB-PGC-1α pathway in SG group.

Figure 5 Sleeve gastrectomy regulated activities of the corresponding pathways of fibroblast growth factor 15. Western blotting for expression of extracellular signal regulated kinase (ERK), p-ERK, cAMP regulatory element-binding protein (CREB), p-CREB, glycogen synthase (GS), p-GS, and proliferator-activated receptor γ coactivator-1α (PGC-1α) in the liver of both SHAM and sleeve gastrectomy group at week 12 postoperation. PGC-1α: Proliferator-activated receptor γ coactivator-1α; ERK: Extracellular signal regulated kinase; CREB: cAMP regulatory element-binding protein; GS: Glycogen synthase; SG: Sleeve gastrectomy.

agonistic BA subspecies were all increased in the serum of both peripheral circulation and portal vein. Besides, the expression of FGF15 which was induced by FXR activation in the ileum was increased after SG. And the FGF15 receptor FGFR4 in the liver together with its corresponding signal pathways involved in hepatic glycogen synthesis and gluconeogenesis were also activated.

Liver plays a key role in the metabolic regulation of the whole body, especially in maintaining homeostasis of blood glucose level through synthesis or breaking down of glycogen and the action of gluconeogenesis. One of the insulin's actions is to promote glycogen synthesis and inhibit hepatic gluconeogenesis which is impaired in diabetic patients. While, we found that SG improved the glucose tolerance of diabetic rats in this study, the hepatic glycogen content was elevated and the expression of two key enzymes[19] (G6pase and Pepck) responsible for hepatic gluconeogenesis were decreased in the SG-operated rats. In other words, SG increased the insulin sensitivity by promoting the synthesis of glycogen and inhibiting the hepatic gluconeogenesis. Moreover, recent studies found that FGF15/19 could also exert the similar effects as insulin on hepatic metabolism in an insulin-independent pattern [19,20]. Furthermore, the serum FGF19 Level of diabetic patients was elevated after bariatric surgery[14-17]. Therefore, except the improvement of insulin sensitivity, the improvement of glucose tolerance post-surgery may also be partly mediated by the elevated FGF15/19.

Consistent with previous findings of FGF 19 in human, the ileal expression of FGF15 was increased in SG-operated rats in our study and the TBA levels in systemic serum and portal vein were also increased after SG. This may inconsistent with previous reports that FGF15 acts as an endocrinal factor to repress BA synthesis in the liver[11]. However, our previous studies have already proved that the elevation of serum BA level was mainly a result of the promoted ileal reabsorption rather than hepatic synthesis[22,23]. According to the process of the enterohepatic circulation, systemic serum BAs is a combinational result of hepatic uptake and ileal reabsorption of BAs and portal vein BAs levels can reflect the ileal reabsorption and the BA concentration of distal ileum[26,27]. Hence, the elevation of TBAs in systemic serum and portal vein in this study must be a result of the promoted ileal reabsorption. Then, we also explored the cause for the elevated expression of FGF15 in our study. FGF15/19 is mainly expressed in distal ileum and can be induced by FXR[28,29]. The increased ileal mRNA level of FXR in our study should be responsible for the elevation of FGF15 after SG. Moreover, FXR can be activated by different BA subspecies, among which CDCA is the most efficacious[30]. Furthermore, oral or intraduodenal infusion of CDCA triggers increase of serum FGF19 Level in humans[31,32]. Consistent with our previous study[22,23], CDCA levels as well as other FXR agonists were elevated after SG both in systemic serum and portal vein. Hence, activation of ileal FXR in this study would result from the elevation of these agonists among the SG-operated rats. Taken together, enhanced reabsorption of BAs after SG activated FXR in the ileum, which then promoted the expression and secretion of FGF15.

Stimulated by ileal FXR, FGF15/19 is promoted and secreted into the enterohepatic circulation. In addition of the regulation of BA homeostasis, FGF15/19 also plays a role in the hepatic glucose metabolism. Evidence have shown that FGF 15 knockout mice showed impaired glucose tolerance with decreased hepatic glycogen storage and advanced hepatic gluconeogenesis[20]. Diet-induced obesity and insulin resistance was failed in FGF19 transgenic mice[33,34]. These effects of FGF15/19 are all mediated through FGFR[35-37], the receptor of FGF15/19 with an unique specificity[21,25]. Moreover, expression of FGFR4 in liver was decreased among STZ-induced diabetes[36]. FGFR4-deficient mice displayed glucose intolerance and insulin resistance as well as increased weight gain[35]. As described above, FGF15/19-FGFR4 plays an important role in hepatic glucose metabolism. Considering the elevation of FGF15, we then examined whether FGF15-FGFR4 functions in the improvement of hepatic glucose metabolism after SG. The hepatic expression of FGFR4 among the HFD and STZ-induced diabetic rats was elevated after SG in this study, which indicates that FGF15-FGFR4 was activated in SG-operated rats. However, we still can't conclude that FGF15-FGFR4 acts in improving the hepatic glucose metabolism because the regulation of BAs synthesis by FGF15 also needs activation of FGFR4.

To further confirm whether FGF15-FGFR4 contributes to the improvement of glucose metabolism in SG-operated rats, we detected the corresponding pathways of FGF15-FGFR4 involved in the hepatic glucose metabolism. Comparable to insulin, FGF15/19 could regulate hepatic glucose metabolism by promoting glycogen synthesis and inhibiting hepatic gluconeogenesis. But unlike the insulin-inducing PI3K-Akt patway, FGF15/19 acts through two different pathways. Moreover, FGF15/19 the inhibiting effect on BA synthesis of FGF15/19 was through a c-Jun N-terminal kinase-dependent pathway[12]. FGF15/19 promotes the hepatic glycogen synthesis by activating Ras-ERK pathway[20]. FGF15/19-FGFR4 triggers the phosphorylation of ERK1/2, which then increase the activity of GS by inhibiting the phosphorylation of this enzyme. Therefore, the increased phosphorylation of ERK1/2 and the declined phosphorylation of GS observed in this study indicated that FGF15-FGFR4-Ras-ERK pathway was activated in SG-operated rats. Together with the elevated glycogen content, we can conclude that the action of FGF15 (and its corresponding pathways) contributed to the glycogen synthesis promoting effect of SG. Moreover, FGF15/19 inhibits hepatic gluconeogenesis by supressing the CREB-PGC-1α pathway[19]. FGF15/19 could induce dephosphorylate and suppress the transcription factor CREB and correspondingly inhibited the expression of PGC-1α. Besides, G6Pase, and Pepck, the two key enzymes for hepatic gluconeogenesis, are two target genes of PGC-1α. So, integrating together the depressed phosphorylation of CREB, reduced expression of PGC-1α and the inhibited expression of G6Pase and Pepck, we could predicate that FGF15 inhibited the CREB-PGC-1α pathway and participated in suppressing the hepatic gluconeogenesis in SG-operated rats. Hence, the activated Ras-ERK1/2 pathway and inhibited CREB-PGC-1α pathway indicated that elevated FGF15 after SG played a role in regulating the hepatic glucose metabolism in parallel to insulin.

In this study, we confirmed the effect of elevated BAs and FGF15 on the hepatic glucose metabolism. FGF15, induced by elevated BAs in ileum, acts as an endocrine factor on the liver through portal vein. By specifically binding and activating the FGFR4 and its corresponding signal pathways, FGF15 improves the hepatic glucose metabolism through the intestine-liver crosstalk. Similarly, human FGF19, which is an ortholog of rodent FGF15, was also elevated after SG together with BAs. Besides, FGF19 can also bind and activate the FGFR 4 specifically. Thus, the results of this study presented basics for the research of human FGF19 after SG, and the FGF19 would be developed to be a target for clinical treatment of T2DM in the future.

Certainly, this study has several limitations. First, we did not directly detect the FGF15 Levels in serum and portal vein because no ELISA kits for FGF15 was available at that time. However, we detected the expression of FGF15 in the ileum at both mRNA and protein levels. As FGF15 is mainly expressed and secreted from the ileum into enterohepatic circulation, the ileal expression could reflect the FGF15 Levels in serum and portal vein. Second, the postprandial FGF15 Level varies with time, it is

better to trace the FGF15 Levels at different time points after gavage. However, we can only sacrifice the rat and detect the expression of FGF15 in the ileum once. And, as previously reported, the expression level of FGF15 mRNA in ileum and the phosphorylation degree of downstream hepatic ERK1/2 reach the peak 1h after feeding in rodent[19]. So, we sacrificed the rats 1h after gavage and the following results then may be more meaningful and advisable. Third, the improvement of hepatic glucose metabolism after SG should surely be mainly mediated by insulin. Though the action of FGF15 underlying the effects of SG was proved in our study, the proportion of these effects accounted by FGF15 still needs further evaluation. Finally, the data presented in this study only show associations, but no causal relationships between the alteration of FGF15 and improvement of hepatic glucose metabolism after SG, which would have to be further investigated by using KO models.

CONCLUSION

BAs levels were elevated in the SG-operated rats and induced FGF15 expression by activating their receptor, FXR in distal ileum. Moreover, the action of FGF15 on hepatic glycogen synthesis and gluconeogenesis further contributes to the anti-diabetic effects of SG.

ARTICLE HIGHLIGHTS

Research background

Bariatric surgery can significantly ameliorate type 2 diabetes mellitus (T2DM) through its rapid and durable weight-loss and hypoglycemic action. Both biles acids (BAs) and fibroblast growth factor (FGF) 15/19 are increased after surgery. Whether BAs and FGF15/19 participates in amelioration of T2DM after bariatric surgery and the underlying mechanism remain incompletely illuminated.

Research motivation

FGF15 which is induced by farnesoid X receptor (FXR) in ileum can improve the hepatic glucose metabolism through entero-hepatic circulation. Our previous study confirms that BA profiles within peripheral circulation and portal vein have changed after SG, with significant increase of FXR- activated BAs levels.

Research objectives

This study aimed to evaluate the effect of FGF15 on improvement of T2DM triggered by elevated BAs after sleeve gastrectomy (SG) and investigate the underlying mechanism.

Research methods

The weight-loss and hypoglycemic action of SG were detected in a diabetic rat model induced by High-fat diet and streptozotocin (STZ), as well as the hepatic glycogen content and gluconeogenesis activity. Total BA (TBA) together with the FXR-agonistic BA subspecies levels in systemic serum and portal vein were examined at week 12 post-surgery. Then the expression and activity of ileal FXR and FGF15 and hepatic FGFR4 with its corresponding signal pathways involved in glucose metabolism were detected.

Research results

Compared with SHAM group, SG induced sustained weight loss and improved the hepatic glucose metabolism by promoting hepatic glycogen synthesis and inhibiting the gluconeogenesis. TBA levels and the FXR-agonistic subspecies in serum and portal vein were elevated after SG. Consequently, the ileal expression of FXR and FGF15 were also advanced. Moreover, the hepatic expression of FGFR4 and the activities of its corresponding pathways were stimulated in SG-operated rats.

Research conclusions

FGF15, triggered by elevated BAs after SG, acts as an endocrine factor to induce the improvement of hepatic glucose metabolism through the intestine-liver crosstalk.

Research perspectives

FXR-agonistic BA subspecies and FGF15 participate in improvement of hepatic glucose metabolism, and may be developed as new targets for the treatment of T2DM.

Abstract

BACKGROUND

Gastroesophageal reflux is associated with poorer outcomes after lung transplant, likely through recurrent aspiration and allograft injury. Although prior studies have demonstrated a relationship between impedance-pH results and transplant outcomes, the role of esophageal manometry in the assessment of lung transplant patients remains debated, and the impact of esophageal dysmotility on transplant outcomes is unclear. Of particular interest is ineffective esophageal motility (IEM) and its associated impact on esophageal clearance.

AIM

To assess the relationship between pre-transplant IEM diagnosis and acute rejection after lung transplantation.

METHODS

This was a retrospective cohort study of lung transplant recipients at a tertiary care center between 2007 and 2018. Patients with pre-transplant anti-reflux surgery were excluded. Manometric and reflux diagnoses were recorded from pre-transplant esophageal function testing. Time-to-event analysis using Cox proportional hazards model was applied to evaluate outcome of first episode of acute cellular rejection, defined histologically per International Society of Heart and Lung Transplantation guidelines. Subjects not meeting this endpoint were censored at time of post-transplant anti-reflux surgery, last clinic visit, or death. Fisher's exact test for binary variables and student's *t*-test for continuous variables were performed to assess for differences between groups.

RESULTS

Of 184 subjects (54% men, mean age: 58, follow-up: 443 person-years) met criteria

for inclusion. Interstitial pulmonary fibrosis represented the predominant pulmonary diagnosis (41%). During the follow-up period, 60 subjects (33.5%) developed acute rejection. The all-cause mortality was 16.3%. Time-to-event univariate analyses demonstrated significant association between IEM and acute rejection [hazard ratio (HR): 1.984, 95%CI: 1.03-3.30, P = 0.04], confirmed on Kaplan-Meier curve. On multivariable analysis, IEM remained independently associated with acute rejection, even after controlling for potential confounders such as the presence of acid and nonacid reflux (HR: 2.20, 95%CI: 1.18-4.11, P = 0.01). Nonacid reflux was also independently associated with acute rejection on both univariate (HR: 2.16, 95%CI: 1.26-3.72, P = 0.005) and multivariable analyses (HR: 2.10, 95%CI: 1.21-3.64, P = 0.009), adjusting for the presence of IEM.

CONCLUSION

Pre-transplant IEM was associated with acute rejection after transplantation, even after controlling for acid and nonacid reflux. Esophageal motility testing may be considered in lung transplant to predict outcomes.

Key Words: Ineffective esophageal motility; Esophageal hypomotility; Esophageal manometry; Gastroesophageal reflux disease; Lung transplantation; Acute rejection

Core Tip: While gastroesophageal reflux (GER) has been associated with poorer outcomes after lung transplant, the impact of esophageal dysmotility remains unclear. Our study found that ineffective esophageal motility identified on pre-transplant esophageal manometry was independently associated with increased acute allograft rejection, even after adjusting for GER. This suggests that esophageal hypomotility may increase the risk of poor lung transplant outcome independent of GER. Routine esophageal function assessment should be considered in the peri-transplant evaluation of lung transplant patients to identify, risk stratify, and more effectively manage esophageal dysfunction in such patients at risk of poorer outcomes.

INTRODUCTION

Lung transplantation survival remains the lowest among solid organ transplants despite small gains over the past decade. Current 5-year survival rates are estimated at 59.2%[1]. Gastroesophageal reflux disease (GERD) and esophageal dysmotility are commonly found in patients undergoing lung transplant evaluation and have been associated with worsened transplant outcomes. For example, GERD has been implicated in the development of acute rejection and chronic lung allograft dysfunction (CLAD). Acute rejection is an early risk factor for CLAD, an important mediator of mortality after the first year post-transplant[2,3]. While esophageal dysmotility may be associated with worsened severity of GERD due to aberrant peristaltic clearance of refluxed gastroduodenal contents, less is known regarding its independent effects on lung transplant outcomes[4-6].

Acute lung rejection is common within the first year post-transplant with rates as high as > 50%[7]. Prior work from our group demonstrated an association between pre-transplant impedance measures of reflux and early allograft injury post-transplant as well as early hospital readmission[8,9]. These measures included prolonged bolus clearance, and increased total proximal and distal reflux episodes [10]. Studies in humans and mouse models have demonstrated that markers of refluxate such as pepsin and bile acids are also associated with allograft dysfunction, and result in impaired innate immune responses[11-14].

Despite the established connection between esophageal motility and reflux clearance, few studies have analyzed transplant outcomes in patients with esophageal dysmotility. Notably, the International Society of Heart and Lung Transplantation (ISHLT) guidelines consider severe esophageal dysmotility to be a risk factor associated with a substantially increased risk of a poor outcome[15]. A few single center studies to date have demonstrated disorders of esophageal motility impacting lung transplant outcomes like CLAD in esophagogastric junction outflow obstruction (EGJOO), as well as 1-, 3-, and 5-

year survival in the more severe phenotype of esophageal aperistalsis[16,17]. Thus far, limited data has impeded our understanding of less severe phenotypes of impaired peristalsis on lung transplant outcomes. The goal of our study is to determine the impact of pre-transplant esophageal dysmotility on lung transplant outcomes of acute rejection, specifically subjects with weak or impaired, but not fully absent, contractility, characterized as ineffective esophageal motility (IEM). We hypothesized that measures of esophageal dysmotility such as IEM are associated with increased rates of acute rejection in lung transplant patients.

MATERIALS AND METHODS

This was a retrospective cohort study of adult patients age > 18 who underwent lung transplantation between 2007 and 2018 at a tertiary care referral center. Patients with pre-transplant high-resolution manometry (HRM) and multichannel intraluminal impedance and pH (MII-pH) testing were included, and patients with a history of pre-transplant antireflux surgery were excluded. Study subjects meeting inclusion and exclusion criteria were reviewed for collection of baseline characteristics and outcomes data.

Baseline demographics included age at time of transplantation, sex, body mass index, primary pulmonary diagnosis, and pre-transplant cardiac ejection fraction. Covariates of interest included IEM on HRM, and presence of acid reflux and non-acid reflux on MII-pH study. The primary outcome of interest was development of first episode of acute cellular rejection. This was defined by clinical and histologic criteria per ISHLT guidelines[18]. Other measured outcomes included all-cause mortality during the study period, use of proton pump inhibitor (PPI) medication post-transplant, and development of pulmonary infection.

Pre-transplant HRM

All patients included in the study underwent HRM (Diversatek Healthcare, Milwaukee, WI, United States) prior to transplant. This system utilized a solid-state catheter with 32 circumferential pressure sensors spaced 1 cm apart. Transnasal catheter placement was performed with distal sensor placement directed into the proximal stomach, ensuring that the catheter is properly positioned across the lower esophageal sphincter (LES). After a brief accommodation period, patients were asked to perform ten 5-mL liquid swallows in the supine position. Results were analyzed utilizing a dedicated software package (BioView 5.6.3.0; Diversatek Healthcare, Milwaukee, WI, United States). IEM was defined by ≥ 50% weak or failed swallows using Chicago Classification v3.0 criteria[19]. Presence of IEM was classified as a dichotomous variable for data analysis.

Pre-transplant MII-pH Monitoring

All patients included in the study also MII-pH monitoring (Diversatek Healthcare, Milwaukee, WI, United States) off PPI prior to transplant. This system includes a portable data collection device, as well as the MII-pH catheter with two pH sensors (0, 15 cm) and eight impedance electrodes (-3, -1, 1, 3, 5, 9, 11, 13 cm). Transnasal catheter placement was performed and positioned with the distal pH sensor localized to 5 cm above the LES. Patients were asked to continue their normal daily activities during the 24-h study and to record meal periods, which were excluded from the analysis. MII-pH tracings were manually reviewed and analyzed utilizing a dedicated software package (BioView 5.6.3.0; Diversatek Healthcare, Milwaukee, WI, United States). Increased acid reflux was defined by acid exposure time (AET) > 4%, while increased non-acid reflux was defined as > 27 weakly acidic or alkaline (pH > 4) episodes per prior publications[20].

Post-transplant management and diagnosis of early allograft injury

Patients were placed on a standard immunosuppressive regimen consisting of azathioprine or mycophenolate, tacrolimus, and methylprednisolone. Surveillance bronchoscopy and biopsies were obtained according to standardized post-transplant protocol at 1, 3, 6, and 12 mo. Additional diagnostic bronchoscopies were triggered by development of clinical symptoms concerning for infection or rejection. Acute rejection was categorized according to ISHLT criteria. Minimal rejection grades of A1B0 were counted as acute rejection if the patient presented with suggestive clinical symptoms and received treatment with pulsed steroids, or had persistent grade A rejection on repeat bronchoscopy.

Statistical analysis

All statistical analyses were performed utilizing SAS 9.3 statistical package (SAS Institute Inc., Cary, NC, United States). Baseline characteristics were compared using student's *t*-test for continuous variables and Fisher's exact test for dichotomous variables. Time-to-event analysis using Cox proportional hazards model was utilized to analyze the primary outcome of first episode of acute rejection. Cox proportional hazards regression was used to adjust for baseline covariates in the final analysis.

RESULTS

Of the 181 patients met inclusion criteria for the study with a total of 439 person-years of follow-up. The mean age of the cohort was 58 with a slight male predominance (54%), and the most common pulmonary diagnosis was idiopathic pulmonary fibrosis which accounted for 41% of patients. Acute rejection was demonstrated in 59 patients (33.5% of those receiving at least one bronchoscopy with biopsy) during the follow-up period for this study. There were 30 deaths during the study period reflecting an all-cause mortality rate of 16.6%.

Pre-transplant HRM revealed normal esophageal motility in 130 patients (71.8%) and IEM in 31 patients (17.1%). The remaining 20 patients had abnormal manometry of other causes (7 distal esophageal spasm, 7 Jackhammer, 6 EGJOO). No patients had achalasia or absent contractility. The IEM group had slightly fewer Caucasian patients, but the remaining demographics were statistically similar compared to the normal group (Table 1). For the primary outcome on univariate analysis, IEM was associated with a decreased time to acute rejection [hazard ratio (HR): 1.984, 95%CI: 1.03-3.30, $P = 0.04$). The Kaplan-Meier survival curve trended toward significance with 40% of the IEM cohort developing acute rejection within approximately 250 d, compared to 500 d for the normal esophageal motility group (Figure 1). On multivariable analysis after adjusting for potential confounders including the presence of acid and nonacid reflux, IEM remained independently associated with acute rejection (HR: 2.20, 95%CI: 1.18-4.11, $P = 0.01$) (Table 2).

The presence of pathologic acid or nonacid reflux per MII-pH testing was also analyzed. Notably, pathologic acid reflux defined by AET > 4.2% was not associated with acute rejection on univariate (HR: 1.06, 95%CI: 0.63-1.76, $P = 0.83$) or multivariable analyses (HR: 0.92, 95%CI: 0.53-1.61, $P = 0.77$). On the other hand, increased non-acid reflux was associated with decreased time to acute rejection in the IEM group on univariate analysis (HR: 2.16, 95%CI: 1.26-3.72, $P = 0.005$) and multivariable analysis (HR: 2.10, 95%CI: 1.21-3.64, $P = 0.009$) (Table 2). This relationship occurred independent of the presence of IEM.

DISCUSSION

GERD and esophageal dysmotility are frequent comorbid conditions in patients with end-stage lung disease. There is increasing recognition of the role these esophageal dysfunctions play in the pathogenesis and clinical progression of specific etiologies of end-stage lung disease, as well as their role in the clinical outcomes of lung transplantation. Our study sought to determine the impact of esophageal hypomotility in the development of acute rejection after lung transplantation. We found that IEM demonstrated on pre-transplant testing was associated with increased risk of acute rejection after lung transplantation. This relationship remained after controlling for covariates including pre-transplant measures of acid and non-acid reflux. The magnitude of association was increased after controlling for these baseline factors on multivariate analysis. This suggests that esophageal motility may play a role in lung transplant outcomes that is independent of reflux-related allograft injury and rejection.

Acute rejection was demonstrated in 33.5% of the cohort in the study follow up. This is consistent with prior estimates which have ranged from 28% in the ISHLT registry to 53.3%[7,21]. Baseline demographics did not differ significantly between the IEM and control groups. Amongst the other covariates of interest, non-acid reflux was independently associated with decreased time to the development of acute rejection, and did not substantially alter the association between IEM and acute rejection.

Abnormal esophageal motility was found in 29.3% of our cohort. Of those with abnormal esophageal motility, 59% of these patients were classified as having IEM (or 17% of the total cohort). Prior studies have demonstrated esophageal dysmotility in as high as 78% of patients undergoing lung transplant evaluation, though it is important to note significant heterogeneity in how esophageal dysmotility has been categorized[22-25]. The prevalence in our cohort was consistent with another study that also categorized HRM diagnoses based on Chicago Classification v3.0, which found IEM in 32.7% of patients undergoing lung transplant evaluation[25], supporting the generalizability of our findings.

Recent studies have begun to characterize the impact of esophageal dysmotility on lung transplant outcomes. In a single center study of 31 patients with pre-transplant esophageal aperistalsis, defined as ≥ 90% failed swallows without any effective peristalsis on HRM, the 1-, 3-, and 5-year post-lung transplant survivals were lower than that of the control group with normal esophageal motility[17]. This study also demonstrated that recovery of peristaltic function post-transplant was associated with improved transplant survival outcomes matching that of the control group. Another study from the same group noted HRM diagnoses of esophageal dysmotility frequently changed post-lung transplant (51.4%) and that peristaltic vigor tends to increase, implicating a dynamic relationship between esophageal motility and pulmonary function[25]. These studies suggest that chronic lung diseases and the resultant altered respiratory mechanics may impact esophageal motility, most commonly associated with hypomotility that may improve with recovery of pulmonary function after transplantation. Two other single center studies utilizing post-lung transplant HRM also demonstrated associations between

Figure 1 Kaplan-Meier showing trend toward increased acute rejection in the ineffective esophageal motility compared to normal motility group. 40% developed acute rejection in approximately 250 d in the ineffective esophageal motility cohort *vs* 500 d in the normal cohort. IEM: Ineffective esophageal motility.

esophageal dysmotility and outcomes of acute and chronic rejection[16,26].

The mechanism through which esophageal dysmotility may impact lung transplantation outcomes is not completely clear, although it is speculated to largely be related to increased risk of microaspiration due to reduced esophageal clearance. Esophageal hypomotility may result in decreased clearance and increased proximal migration of gastric refluxate, thereby leading to higher risk for exposure to the airway. Reduced esophageal bolus transit and clearance may also be associated with elevated risk of esophago-pharyngeal reflux, with potential resultant injury to the lung allograft. On the other hand, abnormal reflux, which has already been previously linked with worse lung transplant outcomes, may also lead to esophageal hypomotility. However, our results suggested that esophageal hypomotility may be associated with higher risk of allograft rejection independent of reflux burden.

There remains significant heterogeneity in reflux and esophageal motility testing in the pre- and post-lung transplant settings. HRM is standardized within the pre-transplant evaluation at our institution. The results of this study indicate that results of pre-transplant HRM are informative for risk stratification and prognostication for lung transplant outcomes. This information, in turn, may also guide post-transplant care and monitoring for acute rejection.

There are several notable strengths to our study. Pre-transplant evaluation of esophageal motility on HRM and reflux measurements on MII-pH were standardized across all lung transplant candidates. Ascertainment bias for determination of acute rejection was minimized by surveillance bronchoscopy per standard protocol with biopsy at 1, 3, 6, and 12 months, though clinical symptoms in between these intervals could trigger additional diagnostic bronchoscopies. Baseline characteristics of the study cohort were consistent with previously published data for rates of acute rejection, prevalence of esophageal dysmotility during pre-transplant evaluation, and indication for lung transplantation. Lastly, distinct HRM diagnoses were categorized according to established classification criteria for analysis, and we were able to control for potential confounding of specific measures of reflux based on MII-pH monitoring results that were collected on all patients.

There are also several limitations to our study. This is a retrospective cohort study with results that are limited to a single academic institution with high volume of lung transplantation. The sample size is relatively limited within the IEM group, though consistent with prior studies published on the association between esophageal motility and lung transplant outcomes. While a small number of recent studies have suggested dynamic changes in esophageal motility post-transplant, post-transplant motility measurements were not obtained routinely as part of our study. Finally, due to the retrospective nature and inclusion period of our study cohort, Chicago classification v3.0 was used to define IEM. However, the most current Chicago classification v4.0 mainly further restricted the diagnosis of IEM with more stringent criteria than v3.0. Therefore, the use of Chicago classification v3.0 to define IEM would likely have biased our results towards the null, as some patients in our IEM group would have been classified as normal under v4.0. The fact that our results remained significant despite this potential bias would strengthen the observed relationship between IEM and acute allograft rejection.

CONCLUSION

In summary, our study demonstrated that IEM on pre-transplant esophageal motility testing was associated with decreased time to development of acute rejection after lung transplantation. Our study provides additional evidence for the association between esophageal dysmotility and poor lung transplant outcomes. It builds upon prior studies on esophageal aperistalsis and survival outcomes in lung transplantation by providing additional evidence for acute rejection in the less severe phenotype of IEM. It also suggests esophageal dysmotility may mediate long-term lung transplant outcomes through a pathway starting with acute rejection. Further studies are needed in delineating transplant outcomes by underlying pulmonary diagnosis, analyzing longer term outcomes such as chronic rejection and 3- and 5-year survival outcomes in the context of esophageal dysmotility, and comparing pre- and post-transplant esophageal function testing results on lung transplant outcomes.

ARTICLE HIGHLIGHTS

Research background

Gastroesophageal reflux is associated with poor outcomes after lung transplantation. However, the impact of esophageal dysmotility and role of esophageal manometry remains unclear. Ineffective esophageal motility (IEM) is a disorder of esophageal motility associated with decreased esophageal clearance that may worsen transplant outcomes.

Research motivation

Esophageal evaluation remains poorly standardized in lung transplantation, and this work suggests that routine esophageal motility testing to identify IEM may help identify patients at risk for acute rejection.

Research objectives

To evaluate the relationship between IEM and acute rejection after lung transplantation, controlling for confounders including coexisting pathologic acid and nonacid reflux.

Research methods

This was a retrospective cohort study of lung transplant recipients that underwent pre-transplant esophageal testing including manometry and pH at a tertiary referral center.

Research results

IEM on pre-transplant esophageal manometry was associated with higher risk of acute rejection on time-to-event analysis. On multivariable Cox regression analysis, IEM remains independently

associated with increased acute rejection, even after controlling for pathologic reflux. In addition, increased non-acid reflux was also an independent risk factor for acute rejection in the multivariable model.

Research conclusions

Lung transplant candidates with IEM had a greater risk of developing acute rejection, independent of pathologic acid and nonacid reflux. Additionally, nonacid reflux was independently associated with acute rejection. These findings suggest that IEM and other disorders affecting esophageal clearance may contribute to the pathophysiology of allograft injury, independent of a reflux-associated pathway.

Research perspectives

Future research should focus on the implementation of standardized esophageal motility testing in lung transplantation, investigation of the impact of IEM and other disorders of esophageal motility on longer term transplant outcomes including chronic rejection and survival, and assessment of changes in esophageal motility after transplant and its effect on transplant outcomes.

Abstract

BACKGROUND

Peutz-Jeghers syndrome (PJS) is an autosomal dominant genetic disease with skin mucosal pigment spots and gastrointestinal (GI) multiple hamartoma polyps as clinical characteristics. At present, it is considered that the germline mutation of *STK11* gene is the genetic cause of PJS. However, not all PJS patients can be detected *STK11* germline mutations. The specific clinical characteristics of these PJS patients without *STK11* mutation is an interesting clinical question. Or, like wild type GI stromal tumor, whether these PJS without *STK11* mutation are also called PJS is worth discussing. Therefore, we designed the study to understand the clinical characteristics of these PJS patients without *STK11* mutation.

AIM

To investigates whether PJS patients with known *STK11* mutations have a more severe spectrum of clinical phenotypes compared to those without.

METHODS

A total of 92 patients with PJS admitted to the Air Force Medical Center from 2010 to 2022 were randomly selected for study. Genomic DNA samples were extracted from peripheral blood samples, and pathogenic germline mutations of *STK11* were detected by high-throughput next-generation gene sequencing. Clinical-pathologic manifestations of patients with and without *STK11/LKB1* mutations

were compared.

RESULTS

STK11 germline mutations were observed in 73 patients with PJS. Among 19 patients with no detectable *STK11* mutations, six had no pathogenic germline mutations of other genes, while 13 had other genetic mutations. Compared with PJS patients with *STK11* mutations, those without tended to be older at the age of initial treatment, age of first intussusception and age of initial surgery. They also had a lower number of total hospitalizations relating to intussusception or intestinal obstruction, and a lower load of small intestine polyps.

CONCLUSION

PJS patients without *STK11* mutations might have less severe clinical-pathologic manifestations than those with.

Key Words: Peutz-Jeghers syndrome; *STK11*; Mutant type; Wild type

INTRODUCTION

Peutz-Jeghers syndrome (PJS) is an autosomal dominant disorder which is mainly characterized by mucocutaneous pigmentation and hamartomatous polyps of the gastrointestinal (GI) tract[1,2]. While PJS is rare, with an estimated prevalence of 1:200000 births[3], the continuous growth of multiple GI polyps predisposes patients to serious complications including intussusception, intestinal obstruction, GI bleeding and malignancies. PJS patients also have a markedly increased risk of developing various neoplasms in extraintestinal sites such as the lungs, liver and breast[4].

Germline mutations in the *STK11* gene (also named *LKB1*), which is located on Chromosome 19p13.3 and encodes a serine/threonine protein kinase[5], have been identified as the major cause of PJS[6,7]. *STK11* is a tumor suppressor gene comprised of 433 amino acids with nine coding exons and one non-coding exon[8]. Depending on the screening method, *STK11* variants can be detected in over 80%-90% of PJS cases[8,9]. Previous studies have largely focused on exploring the phenotypic landscape of *STK11* variants based on their type or location. Due to the rare nature of PJS, very few studies have attempted to examine the correlations between *STK11* mutations and overall severity of PJS phenotype in terms of the earlier onset of GI pathology arising from the polyps, such as intussusception or earlier onset malignancy. Understanding the phenotypic differences between PJS patients with and without *STK11* variants could facilitate more personalized care for PJS patients and their families *via* appropriate counseling, risk stratification and targeted cancer screening[10].

A total of 92 PJS patients admitted to the Air Force Medical Center between February 2010 and February 2022 were randomly selected for inclusion in the study, and their peripheral venous blood was collected for high-throughput next-generation gene sequencing (NGS). 73 cases in which *STK11* gene mutations were detected were named mutant-type, and 19 cases in which no *STK11* gene mutations were detected were named wild-type. In this retrospective study, we aimed to investigate the differences in clinical phenotypes between wild-type and mutant-type *STK11* gene, and provide a theoretical basis for a more precise medical monitoring and follow-up strategy for different types of PJS

patients.

MATERIALS AND METHODS

Study participants

A total of 92 patients with PJS admitted to the Air Force Medical Center, PLA between February 2010 and February 2022 were randomly selected for inclusion in the study, and all patients met the diagnostic criteria for PJS recommended by the NCCN guidelines[11]. All enrolled patients and their guardians were aware of the purpose and process of the study, and had signed informed consent agreements. All data and information collection for this study followed the ethical principles of the Universal Declaration on the Human Genome and Human Rights, Declaration of Helsinki and Statement of the Human Genome Organisation Ethics Committee on DNA Sampling, Control and Access.

Inclusion and exclusion criteria

Inclusion criteria: All enrolled patients met the clinical diagnostic criteria of PJS[12-14] (in accordance with any of the following): (1) Two or more histologically confirmed PJS polyps; (2) Any number of PJS polyps in an individual with a family history of PJS in close relative(s); (3) Characteristic mucocutaneous pigmentation in an individual with a family history of PJS in close relative(s); and (4) Any number of PJS polyps in an individual with characteristic mucocutaneous pigmentation. Peripheral venous blood was retained and genomic DNA extracted, and the sequence of the coding region of the *STK11* gene was detected using polymerase chain reaction (PCR) amplification and NGS sequencing.

Exclusion criteria: Patients who could not meet both of the above two inclusion criteria, could not provide experimental specimens or did not agree to participate in this study.

Research methods

Observational index: The general information, diagnosis and treatment history, pathology, times of examination and other clinical data of the 92 enrolled PJS patients were collected for statistical analysis. The observed indices were as follows: (1) General patient information: Origin, gender, personal marital status, family history and ABO/RH blood groups; (2) History of diagnosis and treatment: Age of initial treatment, age of mucocutaneous pigmentation appearance, order of mucocutaneous pigmentation appearance, time interval from mucocutaneous pigmentation appearance to abdominal symptoms (abdominal pain, intestinal obstruction, GI bleeding, *etc.*), location of GI polyps, load and maximum diameter of GI polyps, pathology of polyps, carcinogenesis, total hospitalizations, number of operations and final age of follow-up; (3) Examinations: Endoscopic examinations and times of GI imaging examinations; and (4) Other: Comorbidities.

Genetic sequencing: EDTA anticoagulation tubes were used to extract 8 mL of peripheral venous blood from PJS patients. Leukocytes were isolated and DNA extracted, and the extracted DNA was interrupted by ultrasound using a Covaris M220 instrument to build a DNA library. The DNA library was then purified and hybridised by the probe library, which would bind specifically to the target DNA fragment through the principle of complementary binding of nucleic acid sequences. Magnetic beads conjugated with streptavidin were mixed with the hybridisation solution, and the streptavidin was tightly bound to the biotin. The captured exon target fragment was indirectly bound by the probe to the beads, which were adsorbed by a magnet, and the supernatant was discarded. The unbound DNA fragments were washed off and the desired DNA library eluted from the beads with the eluent. The eluted DNA library was then amplified using a PCR instrument. Lastly, NGS sequencing was used to detect full exons and associated single nucleotide polymorphism (SNP) and microsatellite instability sites for previously reported genes associated with hereditary GI tract tumors, including *STK11* (Table 1).

Statistical analysis: Statistical analysis was carried out using the SPSS 26.0 software package: (1) Cases and proportion of qualitative data were presented as percentages (%), and comparisons between groups were conducted using the *chi-square test* or *Fisher's exact test*; and (2) The *t*-test was used for quantitative data that matched the normal distribution with equal variance, the *t*-test was used for those with unequal variance and the rank sum test was used for skewed data; $P < 0.05$ was considered statistically significant.

RESULTS

Analysis of NGS test results

The 73 of 92 patients with PJS (79.3%) in this group had *STK11* gene mutations, of which 47 had *STK11* gene mutations in combination with other mutations. 19 of the 92 PJS patients (20.7%) had no *STK11*

gene mutations, of which 6 (6.6%) had no other gene mutations and 13 (14.1%) had other gene mutations in the 41 genes group. By comparing the Human Gene Mutation Database (HGMD) (http://www.hgmd.cf.ac.uk/ac/index.php), dbSNP database (https://www.ncbi.nlm.nih.gov/snp/) and COSMIC database (https://cancer.sanger.ac.uk/cosmic/), a total of 582 *STK11* gene mutant sites were included in HGMD as of March 1, 2022. We identified 21 new mutant sites in other genes (Table 2) and 26 new *STK11* gene mutant sites (Table 3).

Gene detection results and pathogenicity analysis of PJS with mutant-type *STK11*: *STK11* gene detection results and pathogenicity analysis. *STK11* gene mutations were detected in 73 PJS patients in our group. By making comparisons with the dbSNP and COSMIC databases, 49 PJS-related gene mutations were included and 26 *STK11* gene mutation sites were newly identified by sequencing in this group (Table 3). Types of *STK11* gene mutations included premature termination codons (24), frame shift mutations (14), splice site variants (13), missense mutations (17), nonsense mutations (4), mutations in the 3' untranslated region (2) and gene fusion (1).

The pathogenicity of *STK11* gene mutations was determined by comparing the HGMD and ClinVar gene mutations in the disease database, and following the corresponding grading criteria (Table 3). By making conservative predictions of amino acid sequences, we made determinations about the pathogenicity of *STK11* gene mutations according to the corresponding grading criteria (Table 3): Premature termination codons, frame shift mutations, splice site variants, missense mutations, nonsense mutations and mutations in the 3' untranslated region were associated with pathogenicity. Premature termination codons accounted for 58.3% (14/24) that were clearly pathogenic and 41.7% (10/24) that were probably pathogenic. Frameshift mutations accounted for 35.7% (5/14) that were clearly pathogenic, 50.0% (7/14) that were probably pathogenic and 14.3% (2/14) that were of uncertain significance. Splice site mutations accounted for 23.1% (3/13) that were clearly pathogenic, 61.5% (8/13) that were probably pathogenic and 15.4% (2/13) that were of uncertain significance. Missense mutations accounted for 17.6% (3/17) that were clearly pathogenic, 41.2% (7/17) that were probably pathogenic and 41.2% (7/17) that were of uncertain significance. 3' untranslated region mutations accounted for 50.0% (1/2) that were clearly pathogenic and 50.0% (1/2) that were probably pathogenic. All four nonsense mutations were clearly pathogenic (100.0%).

Other gene detection results and pathogenicity analysis in PJS patients with mutant-type *STK11*: Among the 73 PJS patients with mutant-type *STK11*, 47 were combined with other gene mutations: Combined with *AKT1* mutation in 3 cases, *APC* mutation in 4 cases, *ATM* mutation in 5 cases, *BLM* mutation in 3 cases, *BRCA2* mutation in 4 cases, *CDH1* mutation in 3 cases, *CHEK2* mutation in 3 cases, *EGFR* mutation in 1 case, *EPCAM* mutation in 1 case, *GALNT12* mutation in 6 cases, *KIT* mutation in 3 cases, *MUTYH* mutation in 5 cases, *MSH6* mutation in 5 cases, *MSH2* mutation in 4 cases, *MLH1* mutation in 1 case, *PDGFRA* mutation in 5 cases, *PIK3CA* mutation in 1 case, *PMS1* mutation in 1 case, *PMS2* mutation in 1 case, *POLD1* mutation in 3 cases, *PTCH1* mutation in 4 cases, *POLE* mutation in 8 cases and *TP53* mutation in 2 cases.

Among the other gene mutations in PJS patients with mutant-type *STK11*, there were 52 missense mutations (68.4%), 5 intron mutations (6.6%), 11 mutations in the 3' untranslated region (14.5%), 3 splice site mutations (4.0%), 1 premature termination codon (1.3%), 1 frameshift deletion (1.3%), 1 mutation in the 5' untranslated region (1.3%), 1 upstream gene mutation (1.3%) and 1 case (1.3%) of stop gain. All mutations were of uncertain significance (100.0%) (Figure 1).

Gene detection results and pathogenicity analysis in PJS patients with wild-type *STK11*: Wild-type PJS gene mutations included *BLM* mutation in 2 cases, *BMPR1A* mutation in 1 case, *POLD1* mutation in 3 cases, *CHEK2* mutation in 4 cases, *MUTYH* mutation in 6 cases, *SDHC* mutation in 1 case, *POLE* mutation in 2 cases, *BRCA* mutation in 3 cases, *APC* mutation in 2 cases, *CDH1* mutation in 1 case, *ATM* mutation in 3 cases, *ERBB2* mutation in 1 case, *SMAD4* mutation in 1 case and *SBDS* mutation in 1 case.

Among the other gene mutations in wild-type PJS patients, there were 23 missense mutations (74.2%), 5 intron mutations (16.1%), 1 splice site mutation (3.2%), 1 frameshift deletion (3.2%) and 1 mutation in the 3' untranslated region (3.2%). All mutations were of uncertain significance (Table 4).

Comparison of general information, diagnosis and treatment, pathology and examinations

Through the comparison of related items between the two groups (Table 5), it can be found that there were significant differences between the two groups in the following items ($P < 0.05$). Such as Age of initial treatment, Total hospitalizations, Age of first intussusception, Frequency of intussusception, Age of initial surgery, Time interval from mucocutaneous pigmentation appearance to abdominal symptoms, Maximum diameter of gastric polyps, Load of duodenal intestine polyps, Distribution of colorectal polyps, Times of endoscopic examinations.

Exploration of PJS genotype-clinical phenotype linkage

Clinical phenotypic variations between PJS with mutant-type and wild-type *STK11*: (1) There were no statistical differences in gender, family history, ABO blood group or Rh blood group between PJS with mutant-type and wild-type *STK11*; (2) There were differences ($P < 0.05$) between wild-type and mutant-type in age of initial treatment, total hospitalizations, age of first intussusception, frequency of intussus-

[1]Nonsense mutation leading to protein inactivation.

ception and age of initial surgery, with wild-type PJS having a much higher age of initial treatment, much smaller number of total hospitalizations, higher age of first intussusception and lower frequency of intussusception than mutant-type PJS. There was no statistical difference between wild-type and mutant-type PJS in number of operations; (3) There was no statistical difference between wild-type and mutant-type PJS in age or order of mucocutaneous pigmentation appearance, but there was a difference in time interval from mucocutaneous pigmentation appearance to abdominal symptoms ($P < 0.05$), which was longer in wild-type PJS than in the mutant-type PJS; (4) There was no statistical difference in distribution and load of gastric polyps between wild-type and mutant-type PJS, but the maximum diameter of gastric polyps was significantly lower in wild-type PJS than mutant-type PJS ($P < 0.05$). There was no statistical difference in distribution and maximum diameter of duodenal intestine polyps, but there was a difference in load of duodenal intestine polyps ($P < 0.05$), which was much lower in wild-type PJS than in mutant-type PJS. There was no statistical difference in load and maximum diameter of colorectal polyps, but distribution of colorectal polyps was significantly lower in wild-type PJS than in mutant-type PJS; and (5) There was no statistical difference in pathology or carcinogenesis of polyps between wild-type and mutant-type PJS. There was a difference in endoscopic examination between wild-type and mutant-type PJS ($P < 0.05$), with fewer times of endoscopic examination in wild-type than mutant-type PJS.

Clinical phenotypic differences between mutant-type PJS combined with other mutations and not combined with other mutations: (1) *MUYTH*: There was a difference in ABO blood group between mutant-type PJS with and without *MUYTH* mutations ($P < 0.05$); (2) *CHEK2:* There were differences in ABO blood group, total hospitalizations and number of operations between mutant-type PJS with and without *CHEK2* mutations ($P < 0.05$); (3) *APC:* There were differences in distribution, load and maximum diameter of gastric polyps between mutant-type PJS with and without *APC* mutations ($P < 0.05$); (4) *CDH1*: There were differences in load and maximum diameter of duodenal intestine polyps between mutant-type PJS with and without *CDH1* mutations ($P < 0.05$); (5) *GALNT12:* There were differences in time interval from mucocutaneous pigmentation appearance to abdominal symptoms and

PJS with and without *PTCH1* mutations ($P < 0.05$); (10) *ATM:* There was a difference in age of mucocutaneous pigmentation appearance between mutant-type PJS with and without *ATM* mutations ($P < 0.05$); (11) *PDGFRA*: There was a difference in final age of follow-up between mutant-type PJS with and without *PDGFRA* mutations ($P < 0.05$); and (12) *POLD1:* There was a difference in age of first intussusception between mutant-type PJS with and without *POLD1* mutations ($P < 0.05$).

DISCUSSION

PJS is an autosomal dominant disorder with a prevalence of approximately 1 in 200000[15,16]. Although PJS is a rare disease, the large population of China and the prolonged course of PJS lead to the accumulation of a great number of PJS patients in Chinese society. Germline mutations in the *STK11* gene are recognized as the molecular genetic cause of PJS. The tumor suppressor gene *STK11* is involved in multiple processes such as embryonic development, cell polarity, cell cycle arrest, apoptosis and metabolism, and its mutations have been detected in a variety of disseminated cancers. A related study [17] demonstrated that the lack of the *STK11* gene resulted in a significant increase of intracellular reactive oxygen species levels and enhanced expression of phosphorylated histone γ-H2AX, which resulted in DNA damage, oxidative damage to the genome and an increased mutation rate. The rate of *STK11* germline mutations detected in this group of PJS patients was 79.35%, which is generally

Table 6 Recommended follow-up and intervention strategies for mutant-type and wild-type Peutz-Jeghers syndrome

Age (yr)	Mutant-type		Wild-type	
	Surveillance	Intervention	Surveillance	Intervention
< 7	Routine abdominal ultrasound surveillance is recommended every year	Removal of polyps	Abdominal ultrasound is recommended every 3-5 yr	Follow-up observation
8-11	Routine abdominal ultrasound surveillance is recommended every year. For symptomatic individuals with PJS, an abdominal ultrasound should be performed earlier	Removal of polyps	Abdominal ultrasound is recommended every 3-5 yr. For symptomatic individuals with PJS, an abdominal ultrasound should be performed earlier	Removal of polyps
8-18	Total GI surveillance every year (CT scan of small-bowel or enteroscopy/capsule endoscopy should be offered as options	Polyps > 10 mm should be removed	Total GI surveillance 2-3 yr	Removal of polyps
19-30	Routine total GI polyps surveillance every 2-3 yr and screening for systemic tumors	Removal of polyps and treatment of tumors	Routine total GI polyps surveillance every 2-3 yr	Removal of polyps
> 30	Focus on detection of tumors in digestive tract and other organs	Treatment of tumors	Focus on detection of tumors in digestive tract and other organs	Treatment of tumors

PJS: Peutz-Jeghers syndrome; GI: Gastrointestina; CT: Computed tomography.

consistent with the literature[18].

The target genome covered 41 pathogenic genes associated with digestive tract tumors, including *STK11*, and PJS patients were classified into wild-type or mutant-type based on the presence or absence of *STK11* mutations. The results of the clinical characteristic analysis showed that there were significant differences between wild-type and mutant-types PJS in age of initial treatment, age of first intussusception, frequency of intussusception, age of initial surgery, time interval from mucocutaneous pigmentation appearance to abdominal symptoms, maximum diameter of gastric polyps, load of duodenal intestine polyps, distribution of colorectal polyps, times of hospitalization and times of endoscopic examinations. Mutant-type PJS typically has an earlier age of initial treatment and a shorter time interval from mucocutaneous pigmentation appearance to abdominal symptoms than wild-type PJS. They are often first admitted to hospital for serious complications such as intussusception and intestinal obstruction. Our study found that the age of first intussusception was significantly younger in mutant-type PJS than in wild-type PJS, and its cumulative risk of intussusception at the age of 20 years was 68.3%, which was significantly higher than that of wild-type PJS (Figure 2). This is consistent with the findings of domestic and international studies[19,20]. As a result, complications such as intestinal obstruction and intussusception are more likely to occur in mutant-type PJS than in wild-type, and occur earlier. The earlier intervention of treatment for GI polyps in mutant-type PJS patients would be beneficial in reducing the occurrence of these complications. In addition, mutant-type PJS has a higher distribution of colorectal polyps and a larger maximum diameter of gastric polyps than wild-type PJS, requiring more frequent endoscopic examinations and treatment in hospital.

Overseas studies have shown that PJS patients have an increased risk of cancer at several sites, including the GI tract, breast, ovaries, testes and lungs[21]. PJS malignancy is a serious threat to the life and health of patients; studies have shown[21,22] that the death rate of PJS patients is as high as 32%, and malignancy is the main cause of death. The incidence of malignant tumors in PJS patients is 19%-32%, with an average age of 42-45 years, and a predominance of GI tract tumors (51%-69%), followed by gynecological tumors (22%-26%). The risk of GI malignancy is 50 times higher than that of the general population. The 19 cases of wild-type PJS in this study were not combined with malignant tumors. Among the 73 mutant-type patients, 8 had GI polyps and 4 had cancers of other sites: 1 adnexal cystadenocarcinoma, 1 ovarian mucinous tumor, 1 cervical adenocarcinoma and 1 nasopharyngeal carcinoma. It was found that patients with a detectable *STK11* truncating mutation tend to develop more polyps and cancers, and require more surgical intervention[23]. There was no statistically significant difference in the cancer rate between mutant-type and wild-type in this study, which may be related to the shorter follow-up period of the enrolled patients. Germline mutations of *STK11* are essential factors in GI tumourigenesis, and the cell types and signal pathways that lead to the malignant transformation of polyps are still unclear. A foreign study showed[24] that after the knockout of *STK11* in mice, IL-11 inflammatory mediators mediated the activation of the JAK/STAT3 pathway due to *STK11* deficiency in mouse stromal cells, which eventually resulted in the formation of polyp malignancy in mice, and the treatment of *STK11*-deficient mice with JAK1/2 inhibitors significantly reduced the occurrence of polyps. We can block the development and malignancy of polyps at the root by blocking the associated inflammatory mediators or transduction pathways, which provides a new idea for us in studying the pharmacological treatment of PJS patients. Previous studies have shown that PJS patients have a progression pathway of hamartoma-(adenoma)-carcinoma[25], which is corrob-

orated by the presence in our study of PJS patients with malformation combined with adenomatous polyps and with adenoma combined with polyp carcinoma. Accordingly, the detection of *STK11* mutations can be useful for guiding the assessment of polyp carcinogenesis risk in PJS patients and their relatives.

PJS patients have a prolonged disease course, with GI polyps growing larger with age and recurring more easily, and can result in intestinal obstruction, intussusception or even cancer, but the characteristics and severity of the disease vary significantly among PJS patients. The clinical presentation is distinctly heterogeneous. Clinical data and epidemiological data collected from more than 500 PJS patients at our center suggests that polyps grow fastest in adolescence, leading to serious complications such as intussusception, and the age of first surgery is significantly younger in mutant-type PJS than in wild-type PJS. Meanwhile, the incidence of tumors in the digestive tract and other organs of the body is significantly higher in middle-aged PJS patients.

CONCLUSION

Therefore, in the individualized treatment of PJS patients, we recommend that they should have the *STK11* gene tested, and the genotypes classified into mutant-type and wild-type. Patients with mutant-type PJS should be strictly controlled in terms of treatment and follow-up strategies, while patients with wild-type PJS can be treated with relaxed treatment conditions and follow-up years. For the monitoring and treatment of PJS, we refer to the different follow-up strategies by age group proposed by a domestic study[26], and further refine the treatment and follow-up strategies for PJS based on this treatment strategy as follows (Table 6).

ARTICLE HIGHLIGHTS

Research background

Peutz-Jeghers syndrome (PJS) is an autosomal dominant genetic disease with skin mucosal pigment spots and gastrointestinal multiple hamartoma polyps as clinical characteristics. At present, it is considered that the germline mutation of *STK11* gene is the genetic cause of PJS. However, not all PJS patients can be detected *STK11* germline mutations.

Research motivation

The specific clinical characteristics of these PJS patients without *STK11* mutation is an interesting clinical question. Or, like wild type gastrointestinal stromal tumor (GIST), whether these PJS without *STK11* mutation are also called PJS is worth discussing. Therefore, we designed the study to understand the clinical characteristics of these PJS patients without *STK11* mutation.

Research objectives

To investigates whether PJS patients with known *STK11* mutations have a more severe spectrum of clinical phenotypes compared to those without.

Research methods

The general information, diagnosis and treatment history, pathology, times of examination and other clinical data of the 92 enrolled PJS patients were collected for statistical analysis. Genomic DNA samples were extracted from peripheral blood samples, and pathogenic germline mutations of *STK11* were detected by high-throughput next-generation gene sequencing. Clinical-pathologic manifestations of patients with and without *STK11/LKB1* mutations were compared.

Research results

Compared with PJS patients with *STK11* mutations, those without tended to be older at the age of initial treatment, age of first intussusception and age of initial surgery. They also had a lower number of total hospitalizations relating to intussusception or intestinal obstruction, and a lower load of small intestine polyps. Final results found that PJS patients without *STK11* mutations might have less severe clinical-pathologic manifestations than those with.

Research conclusions

PJS patients without *STK11* mutations might have less severe clinical-pathologic manifestations than those with.

Research perspectives

At present, it is considered that the germline mutation of *STK11* gene is the genetic cause of PJS.

However, not all PJS patients can be detected *STK11* germline mutations. The specific clinical characteristics of these PJS patients without *STK11* mutation is an interesting clinical question. Or, like wild type GIST, whether these PJS without *STK11* mutation are also called PJS is worth discussing.

Abstract

BACKGROUND

Artifacts are common when using two-dimensional shear wave elastography (2-D SWE) to measure liver stiffness (LS), but they are poorly recognized.

AIM

To investigate the presence and influence of artifacts in 2-D SWE of liver.

METHODS

We included 158 patients with chronic liver disease, who underwent 2-D SWE examination by a novice and an expert. A cross line at the center of the elastogram was drawn and was divided it into four locations: top-left, top-right, bottom-left, and bottom-right. The occurrence frequency of artifacts in different locations was compared. The influence of artifacts on the LS measurements was evaluated by comparing the elastogram with the most artifacts (EMA) and the elastogram with the least artifacts (ELA).

RESULTS

The percentage of elastograms with artifacts in the novice (51.7%) was significantly higher than that of the expert (19.6%) ($P < 0.001$). It was found that both operators had the highest frequency of artifacts at bottom-left, followed by top-left and bottom-right, and top-right had the lowest frequency. The LS values (LSVs) and standard deviation values of EMAs were significantly higher than those of ELAs for both operators. An intraclass correlation coefficient value of 0.96 was found in the LSVs of EMAs of the two operators, and it increased to 0.98 when the LSVs of the ELAs were used. Both operators had lower stability index values for EMAs than ELAs, but the difference was only statistically significant for the novice.

CONCLUSION

Artifacts are common when using 2-D SWE to measure LS, especially for the novice. Artifacts may lead to the overestimation of LS and reduce the repeatability and reliability of LS measurements.

Key Words: Ultrasound; Elastography; Artifact; Liver

Core Tip: Artifacts are common when using two-dimensional shear wave elastography (2-D SWE) to measure liver stiffness (LS), especially for the novice. We investigated the presence and influence of artifacts in 2-D SWE of liver. Our results showed artifacts were more likely to occur in the bottom-left corner of the elastogram. Artifacts may lead to the overestimation of LS and reduce the repeatability and reliability of LS measurements. For the elastograms with artifacts, we should place the Q-Box away from the artifacts.

INTRODUCTION

Chronic liver disease is a growing problem worldwide. The main causes of chronic liver disease include hepatitis virus infection, alcoholic liver disease, and non-alcoholic fatty liver disease[1]. It mainly causes diffuse liver fibrosis, which in turn leads to liver cirrhosis. Some of them eventually develop hepatocellular carcinoma, portal hypertension, and hepatic encephalopathy[2,3]. Accurate assessment of liver fibrosis is important for treatment prioritization, surveillance, and determination of prognosis[4]. Moreover, liver biopsy allows the assessment of the degree of fibrosis[5]. However, liver biopsy is an expensive and invasive diagnostic tool. Its main complications are bleeding and pain[6,7], which limit its clinical application.

Recently, the application of ultrasound elastography in the diagnosis of non-invasive assessment of liver fibrosis has developed rapidly[8]. US elastography is mainly classified into two major types: Strain elastography and shear wave elastography[9,10]. Two-dimensional shear wave elastography (2-D SWE) is a type of shear wave elastography that uses acoustic radiation force to create shear waves. The velocity of the shear wave can be used to calculate the tissue stiffness by the formula $E = 3\rho c^2$, where E is tissue elasticity (Young's modulus, kPa), ρ is tissue density (kg/m^3), and c is shear wave velocity (m/s). The 2-D SWE is based on the quantification of the propagation speed of shear waves in the liver to create an elastogram. The elastogram is displayed using a color-coded map superimposed on a conventional B-mode image, where different colors represent different stiffness, allowing an assessment of homogeneity[10].

It has been reported that 2-D SWE has shown sufficient accuracy in evaluating the degree of liver fibrosis[11-13]. However, there was significant heterogeneity in the results of these studies. This heterogeneity may be caused by different patient populations, research designs and equipment used[14]. Another important reason may be that the presence of artifacts leads to inaccurate liver stiffness (LS) measurements. Bruce *et al*[15] reported that 2-D SWE artifacts resulted in a significant variability in the assessed LS.

Although 2-D SWE artifacts of the liver are common in clinical practice, they are poorly recognized, and there is even no clear definition. To the best of our knowledge, only a few review articles have been published[15,16]. Therefore, the purpose of this study was to investigate the presence and effects of artifacts in 2-D SWE of the liver. This is important to avoid artifacts and improve diagnostic performance in future operations.

MATERIALS AND METHODS

Patient selection

This prospective study was approved by the institutional ethical review board of our hospital. All patients signed a written informed consent document to participate in the study. We included 158 consecutive patients with chronic liver disease, who underwent 2-D SWE examination in our department. The study was conducted according to the principles reported in the Declaration of Helsinki and approved by the authors' institutional review board. The exclusion criterion was that no valid measurement was obtained by either operator. Seven patients were excluded because the novice operator did not obtain any valid measurements after five consecutive measurements. The baseline

characteristics of the patients were presented in Table 1.

2-D SWE examination

LS measurements were performed with an Aixplorer US system (SuperSonic Imagine, Aix-en-Provence, France) with a convex probe (SC6-1, 1-6 MHz). Patients fasted for more than 6 h and were examined in the supine position with the right arm in maximal abduction. The right anterior lobe of the liver was examined by intercostal scanning, and the SWE mode was started with neutral breathing during breath-holding. The upper limit of the color-coding scale was set to 70 kPa. The sampling frame was approximately 2.5 cm × 3.5 cm, placed at least 1 cm below the liver capsule, avoiding the large vascular structures. Image acquisition was performed after the elastography image was stable for 3-5 s. The quantitative analysis system (Q-Box) was then activated and placed at the center of the sampling frame. The Q-Box was 2 cm in diameter and the measurement depth was 3-5 cm. The LS measurement was considered invalid if there was no color-coding or the coded area was smaller than the Q-Box size[17]. When the area of color-coding is larger than the Q-Box size, the LS measurement was considered valid even if there are artifacts within it.

Each patient was continuously measured five times by an expert and a novice, respectively. The operators performed consecutive LS measurements in a randomized blinded manner. The median value of all valid measurements performed by the two operators represents the LS value (LSV) of the subject and was used for the correlation analysis with artifacts. The expert operator had 9 years of experience in the 2-D SWE examinations and had successfully performed approximately 15000 2D SWE examinations. The novice operator was trained by an expert operator and successfully performed 50 2-D SWE examinations.

Analysis of elastogram for artifacts

Artifacts were defined as the mottled area in the elastograms, and the area of the artifacts was measured using a tracing instrument attached to the device. We can manually trace the edge of the artifacts and automatically display the area and perimeter of the artifacts (Figure 1A). We drew a cross line at the center of the elastogram and divided it into four locations: top-left, top-right, bottom-left, and bottom-right. The location of the artifacts in each elastogram was recorded. The elastogram with the most artifacts (EMA) and the elastogram with the least artifacts (ELA) in each patient measured by the two operators were found by all authors. For the elastograms with artifacts, the Q-Box was placed in the center of the sampling frame (Figure 1B) and away from the artifacts for measurements (Figure 1C). The influence of artifacts on LS measurement was evaluated by comparing the differences in LSVs, standard deviation (SD) values and stability index (SI) values.

Statistical analysis

All quantitative data are expressed as mean ± SD (range), and qualitative variables are expressed as numbers (percentages). The Shapiro-Wilk test was used to test whether the numeric variables were normally distributed. Non-parametric tests with the Kruskal-Wallis method were used to compare the difference in numeric variables with a non-normal distribution. Differences between numeric variables with a normal distribution were assessed using a parametric test (*t*-test). The χ^2-test was used to compare the proportions expressed as percentages. Interobserver repeatability was evaluated using intraclass correlation coefficient (ICC). Relationships between various parameters were examined using Pearson's correlation test. Statistical significance was set at $P < 0.05$, and all P values were two-sided. Statistical analysis was performed using MedCalc software (MedCalc Software, version 17.4, Ostend, Belgium).

RESULTS

Among the 158 patients, 151 patients with valid measurements obtained by both operators were enrolled in this study. In theory, each operator should obtain 755 (151 × 5 = 755) elastography images. However, in the examination of 12 patients by the two operators, 35 elastography images were invalid and excluded. To ensure that the two operators had the same number of valid elastograms for each patient, valid measurements corresponding to the 35 invalid measurements were also excluded. Therefore, 720 elastography images from each operator were included (Figure 2).

The presence of artifacts

For the expert operator, the percentage of elastograms with artifacts was 19.6% (141/720), and the area of artifacts was 0.92 ± 0.68 cm^2. For the novice operator, the percentage of elastograms with artifacts was 51.7% (372/720), and the area of artifacts was 1.36 ± 0.87 cm^2. The percentage of elastograms with artifacts and the area of artifacts in the novice were significantly higher than those in the expert, and the difference were both statistically significant (both $P < 0.001$). We counted all the artifacts according to their locations, and the results are shown in Table 2. There were no significant differences in the frequency of the occurrence of artifacts between the two operators at the same location (all $P > 0.05$).

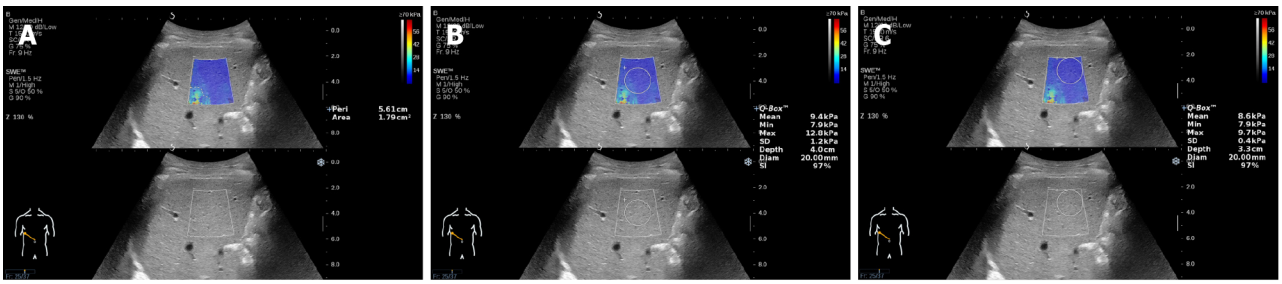

Table 1 Patient characteristics (*n* = 151)

Characteristic	Value
Age (yr)	46.2 ± 13.1 (19-75)
Liver stiffness value (kPa)	9.7 ± 7.8 (3.8-34.9)
Liver cirrhosis, *n* (%)	17 (11.3)
Subcutaneous fat thickness (cm)	0.4 ± 0.3 (0.1-2.4)
Sex, *n* (%)	
Male	72 (47.7)
Female	79 (52.3)
Body mass index (kg/m^2)	23.3 ± 3.4 (17.2-36.3)
Normal (< 25 kg/m^2), *n* (%)	101 (66.9)
Overweight (25-30 kg/m^2), *n* (%)	41 (27.2)
Obese (> 30 kg/m^2), *n* (%)	9 (5.9)
Etiology of chronic liver disease, *n* (%)	
Hepatitis B virus	122 (80.8)
Hepatitis C virus	8 (5.3)
Alcoholic liver disease	10 (6.6)
Nonalcoholic fatty liver disease	6 (4)
Autoimmune disease	5 (3.3)

Table 2 Artifacts at different locations of the two operators

Locations	Expert, *n* (%)	Novice, *n* (%)	*P* value
Top-left	40 (21.5)	120 (20.5)	0.769
Bottom-left	102 (54.8)	309 (52.8)	0.634
Top-right	7 (3.8)	42 (7.2)	0.098
Bottom-right	37 (19.9)	114 (19.5)	0.904

Figure 1 Elastograms of a 60-year-old man with hepatitis B virus. A: Elastogram with artifacts at the bottom-left of the sampling frame, and the area of artifacts was 1.79 square centimeters; B: For the elastogram with artifacts, the Q-Box was placed in the center of the sampling frame [mean liver stiffness: 9.4 kPa, standard deviation (SD): 1.2 kPa, stability index (SI): 97%]; C: For the elastogram with artifacts, the Q-Box was placed away from the artifacts (mean liver stiffness: 8.6 kPa, SD: 0.4 kPa, SI: 97%). SD: Standard deviation; SI: Stability index.

Comparing the occurrence frequency of artifacts in all locations of the two operators, it was found that both operators had the highest frequency of bottom-left, followed by top-left and bottom-right, and top-right had the lowest frequency. No statistical difference was found between the frequency of top-left and bottom-right ($P > 0.05$), but the frequency among other locations was statistically different (all $P <$

Figure 2 Study flow diagram. 2-D SWE: Two-dimensional shear wave elastography.

0.001) (Table 3).

Influence of artifacts on LS measurements

The LSVs of EMAs were higher than those of ELAs for both operators, and the differences were statistically significant (both $P < 0.001$). There was a significant difference in the LSVs of the EMAs between the two operators ($P = 0.006$). However, there was no statistically significant difference in the LSVs of the ELAs between the two operators ($P = 0.051$) (Table 4).

The ICC values and 95%CIs were calculated by comparing the LSVs of the EMAs and ELAs of the two operators. An ICC value of 0.96 (95%CI: 0.94-0.98) was found in the LSVs of EMAs, and it increased to 0.98 (95%CI: 0.97-0.99) when the LSVs of the ELAs were used. The SD values of EMAs were higher than those of ELAs for both operators, and the differences were statistically significant (both $P < 0.001$). The SI values of the EMAs were lower than those of the ELAs for both operators. The difference was only statistically significant for the novice ($P = 0.002$), but not for the expert ($P = 0.135$) (Table 5).

For the elastograms with artifacts, the LSVs and SD values of the Q-Box placed in the center of the sampling frame were higher than those of the Q-Box placed away from the artifacts. The SI values of the Q-Box placed in the center of the sampling frame were lower than those of the Q-Box placed away from the artifacts. There were significant differences in LSVs, SD values and SI values between the Q-Box placed in the center of the sampling frame and away from the artifacts for both operators (all $P < 0.05$) (Table 6).

Patient characteristics and artifacts

The total number of elastograms with artifacts measured by the two operators was 513 (141 by the expert, 372 by the novice). The number of elastograms with artifacts in male subjects was 238 (46.4%), and that in female subjects was 275 (53.6%). There was no significant difference between the male and female subjects ($P = 0.378$). Pearson's correlation test showed that there was no significant linear correlation between age and the number of elastograms with artifacts ($r = 0.21$, $P = 0.126$). In the entire cohort, Pearson's correlation test showed that there was a positive correlation between LSV, body mass index (BMI), subcutaneous fat thickness and the number of elastograms with artifacts ($r = 0.47$, $P = 0.001$; $r = 0.41$, $P = 0.002$; and $r = 0.42$, $P = 0.002$, respectively).

DISCUSSION

When using 2-D SWE to measure LS in clinical practice, artifacts are commonly observed in elastograms [18]. It is difficult for some subjects to obtain satisfactory elastograms, such as obesity, poor acoustic window and inability of the subjects to hold their breath. Despite our best efforts to avoid artifacts, even operators with 9 years of operating experience still have a certain percentage of artifacts. In this study, we compared the difference in the frequency of occurrence artifacts between two different experienced operators. The results showed that the percentage of elastograms with artifacts and the area of artifacts in the novice were significantly higher than that of the expert. This may be because the expert operator can obtain high-quality B-mode imaging, which is required for accurately tracking shear waves[18]. Previous studies have shown that experts have better repeatability and reliability in measuring LS, which may have an important relationship with the fact that there were few artifacts in their elastograms[19,20]. Therefore, some studies have suggested that novices should perform at least 300

Table 3 Compare the percentage of artifacts at different locations

Locations of artifacts	P^1 value	P^2 value
Top-left *vs* bottom-left	< 0.001	< 0.001
Top-left *vs* top-right	< 0.001	< 0.001
Top-left *vs* bottom-right	0.703	0.669
Bottom-left *vs* top-right	< 0.001	< 0.001
Bottom-left *vs* bottom-right	< 0.001	< 0.001
Top-right *vs* bottom-right	< 0.001	< 0.001

Table 6 Comparison of Q-Box parameters measured at different positions of the elastograms with artifacts

	Number	Q-Box in the center of the sampling frame			Q-Box away from the artifacts		
		LSV	SD	SI	LSV	SD	SI
Expert	141	14.6 ± 9.5	1.7 ± 1.1	93% ± 6%	14.1 ± 9.3	0.8 ± 0.6	94% ± 7%
Novice	372	12.1 ± 9.5	1.9 ± 1.3	90% ± 7%	11.6 ± 9.4	0.9 ± 0.7	93% ± 6%

LSV: Liver stiffness value; SD: Standard deviation; SI: Stability index.

abdominal US scans or more than 50 supervised 2-D SWE examinations; however, this may not be sufficient[19,21]. A learning curve has been observed for 2-D SWE, a proportion of operator error would decrease over time[22].

We divided the elastogram into four locations and calculated the frequency of occurrence of artifacts at each location. The occurrence frequency of artifacts is arranged in descending order: bottom-left, top-left, bottom-right, and top-right. The two operators in this study had the same results, indicating that this difference may have certain regularity. The reason for this result may be that the aerated lung leads to a shadowing artifact on the left side of the B-mode image, which makes it impossible to form a well-defined push beam in this area[15,23]. On the other hand, to avoid liver capsule reverberation artifacts,

the depth of the sampling frame has increased, especially in obese or overweight patients. When the depth exceeds the penetration limit, attenuation artifacts and larger vessels may have more pulsatile artifacts at the bottom of the sampling frame[16,23]. We found the same phenomenon on another 2-D SWE ultrasound system (Aplio500, Canon, Tochigi, Japan). We found that artifacts were more likely to occur in the bottom-left corner of the elastogram, where distortion waves were noted in the propagation map of the corresponding site. The distribution of artifacts may also be applicable to other devices of 2-D SWE technology, because they have the same imaging principles.

Usually a color-coding scale of up to 30 kPa is sufficient, but in this study the upper limit of the color-coding scale was set to 70 kPa. The reason is that some patients have an LSV greater than 30 kPa, and a lower color-coding scale setting will make the elastogram appear only in red. At this time, it is impossible to distinguish whether there is an artifact or not. Although the color-coding scale was set to 70 kPa may ignore tiny artifacts, it is easier to show obvious artifacts.

The presence of artifacts affects the assessment of LS, but there is no detailed research report yet. This study showed that the LSVs of the EMAs were higher than those of the ELAs. This indicates that artifacts may lead to the overestimation of LS. This study compared the differences between the two operators in the LSVs of EMAs and ELAs. The results showed that in either the EMAs or ELAs, the LSVs of the novice were higher than that of the expert, which may be due to the higher proportion of artifacts in the elastograms measured by the novice. The ICC value between the two operators calculated with the LSVs of the EMAs was lower than that calculated with the LSVs of ELAs. This shows that artifacts can reduce inter-observer repeatability.

Although the degree of liver fibrosis in chronic liver disease will be slightly different, the color-coded LSmapping image will hardly show obvious mottled area. These mottled areas are considered as artifacts and belong to noise. Some studies use signal-to-noise ratio as the standard to evaluate image quality[24,25]. The new software version of the device provides SD and SI as indicators to evaluate the reliability of LS measurement[26-28]. The SD reflects the homogeneity of LSVs in the measurement area of the Q-Box. The higher the SD values, the greater heterogeneity of the LSVs in the measurement area. Thiele *et al*[29] reported that the diagnostic accuracy for cirrhosis by 2D SWE increased at SD < 1.75 kPa. The SI is an indicator of temporal stability of the measurement area, and the manufacturer recommends that a reliable LS measurement should have a SI greater than 90%. Our study showed that the SD values of the EMAs were much higher than those of the ELAs, which indicated that artifacts made the elastograms heterogeneous. The SI values of the EMAs were lower than those of the ELAs, which showed that artifacts may reduce the temporal stability of the elastograms. In short, artifacts can reduce the reliability of the LS measurements. For the elastograms with artifacts, we found that placing the Q-Box away from the artifacts can obtain more reliable LS measurements than placing it in the center of the sampling frame (generally the default measurement position of the equipment).

Furthermore, we investigated the relationship between patient characteristics and the occurrence of artifacts. We found that the occurrence of artifacts had no significant relationship with sex or age. However, we found that patients' BMI, subcutaneous fat thickness and LSVs were positively correlated with the occurrence of artifacts. Higher BMI and subcutaneous fat thickness usually indicate overweight or obesity with a thicker abdominal wall. Artifacts are prone to occur when measuring LS in overweight or obese subjects due to the combined effects of attenuation artifacts, reverberation artifacts, and vessels [16,30]. Previous studies have also shown that a high BMI is the main reason for measurement failure and unreliable assessment[17,31,32]. Patients with liver cirrhosis usually have higher LSVs, and they often have artifacts because of their shrunken liver volumes and poor sonic window. Other studies have demonstrated that severe liver fibrosis is a risk factor for unreliable LS measurements[17,33].

To the best of our knowledge, this is the first prospective study to analyze artifacts in 2-D SWE of the liver. This study analyzed the predilection sites and people for artifacts, and explored the effects of artifacts on LS measurements. Knowledge of the artifacts is essential to improve operation technology to obtain high-quality images. It is very important to obtain accurate measurements in an attempt to optimize its performance and application value. In addition, knowledge from this and other studies on artifacts can be used to investigate how training and education could reduce the occurrence of artifacts. Hopefully, engineers and researchers can improve the product design, provide quality indicators and other ways to avoid the acquisition of improper data due to artifacts.

Our study had several limitations. First, artifacts may be ignored when the color changes are inconspicuous. Second, only one device was tested in this study. Third, this study did not analyze the causes of artifacts, because it is sometimes difficult to accurately determine. Finally, we analyzed only a small sample of data from two operators. Therefore, a larger sample study involving more operators and devices needs to be conducted in future.

CONCLUSION

In conclusion, artifacts are common when using 2-D SWE to measure LS, especially for the novice. Artifacts may lead to the overestimation of LS and reduce the repeatability and reliability of LS measurements. For the elastograms with artifacts, we should place the Q-Box away from the artifacts.

ARTICLE HIGHLIGHTS

Research background

Chronic liver disease is a growing problem worldwide. Accurate assessment of liver fibrosis is important for treatment prioritization, surveillance, and determination of prognosis. Liver biopsy is still considered as the gold standard for staging liver fibrosis. However, liver biopsy is an expensive and invasive diagnostic tool. Its main complications are bleeding and pain, which limit its clinical application. Recently, the application of two-dimensional shear wave elastography (2-D SWE) in the diagnosis of non-invasive assessment of liver fibrosis has developed rapidly. However, the presence of artifacts leads to inaccurate liver stiffness (LS) measurements.

Research motivation

Although 2-D SWE artifacts of the liver are common in clinical practice, they are poorly recognized, and there is even no clear definition. To the best of our knowledge, only a few review articles have been published. Knowledge of the artifacts is essential to improve operation technology to obtain high-quality images. It is very important to obtain accurate measurements in an attempt to optimize its performance and application value.

Research objectives

We aim to investigate the presence and influence of artifacts in 2-D SWE of liver.

Research methods

In this study, we performed 2-D SWE examination in patients with chronic liver disease by a novice and an expert. The elastogram was divided into four locations: top-left, top-right, bottom-left, and bottom-right. The occurrence frequency of artifacts in different locations was compared. The effect of artifacts on the LS measurements was evaluated by comparing the elastogram with the most artifacts (EMA) and the elastogram with the least artifacts (ELA).

Research results

Each operator had 720 elastography images were included for analysis. The percentage of elastograms with artifacts and the area of artifacts in the novice were significantly higher than those in the expert (both $P < 0.001$). Comparing the occurrence frequency of artifacts in all locations of the two operators, it was found that both operators had the highest frequency of bottom-left, followed by top-left and bottom-right, and top-right had the lowest frequency. This study showed that the LS values and standard deviation values of the EMAs were higher than those of the ELAs. Both operators had lower stability index values and intraclass correlation coefficient values for EMAs than ELAs.

Research conclusions

Artifacts are common when using 2-D SWE to measure LS, especially for the novice. Our results showed artifacts were more likely to occur in the bottom-left corner of the elastogram. Artifacts may lead to the overestimation of LS and reduce the repeatability and reliability of LS measurements.

Research perspectives

In this study, we only analyzed a small sample of data from two operators of one device. Therefore, a larger sample study involving more operators and devices needs to be conducted in future studies.

Abstract

BACKGROUND

Splanchnic vein thrombosis (SVT) is a major complication of moderate and severe acute pancreatitis. There is no consensus on whether therapeutic anticoagulation should be started in patients with acute pancreatitis and SVT.

AIM

To gain insight into current opinions and clinical decision making of pancreatologists regarding SVT in acute pancreatitis.

METHODS

A total of 139 pancreatologists of the Dutch Pancreatitis Study Group and Dutch Pancreatic Cancer Group were approached to complete an online survey and case vignette survey. The threshold to assume group agreement was set at 75%.

RESULTS

The response rate was 67% (n = 93). Seventy-one pancreatologists (77%) regularly prescribed therapeutic anticoagulation in case of SVT, and 12 pancreatologists (13%) for narrowing of splanchnic vein lumen. The most common reason to treat SVT was to avoid complications (87%). Acute thrombosis was the most important factor to prescribe therapeutic anticoagulation (90%). Portal vein thrombosis was chosen as the most preferred location to initiate therapeutic anticoagulation (76%) and splenic vein thrombosis as the least preferred location (86%). The preferred initial agent was low molecular weight heparin (LMWH; 87%). In the case vignettes, therapeutic anticoagulation was prescribed for acute portal vein thrombosis, with or without suspected infected necrosis (82% and 90%), and thrombus progression (88%). Agreement was lacking regarding the selection and duration of long-term anticoagulation, the indication for thrombophilia testing and upper endoscopy, and about whether risk of bleeding is a major barrier for therapeutic anticoagulation.

CONCLUSION

In this national survey, the pancreatologists seemed to agree on the use of therapeutic anticoagulation, using LMWH in the acute phase, for acute portal thrombosis and in the case of thrombus progression, irrespective of the presence of infected necrosis.

Key Words: Acute pancreatitis; Splanchnic vein thrombosis; Therapeutic anticoagulation; Bleeding; Recanalization; Outcomes

Core Tip: Splanchnic vein thrombosis is a relatively common complication of moderate and severe acute pancreatitis, but there is still much debate about its treatment with therapeutic anticoagulation. This national survey and case vignette study among 93 pancreatologists demonstrates that the majority prescribe therapeutic anticoagulation for acute portal vein thrombosis and thrombus progression in patients with or without infected necrosis, despite the absence of evidence supporting its use. Whether this collective opinion is accurate needs to be confirmed in future (preferably prospective) studies.

INTRODUCTION

Acute pancreatitis is an inflammatory disorder of the pancreas and is self-limiting in the majority of patients[1,2]. However, approximately 20% of patients develop a moderate or severe disease course, with (peri) pancreatic necrosis and collections[3,4]. Due to the combination of local inflammation and

mechanical compression, these complications may cause thrombus formation in the splanchnic circulation, including the portal, splenic and superior mesenteric vein[5,6]. The reported estimates on the incidence of splanchnic vein thrombosis (SVT) in acute pancreatitis range from 17% to 23%, and are even higher in complicated acute pancreatitis[7,8]. The clinical presentation of SVT varies between an asymptomatic thrombus to potential lethal complications, such as portal or left side hypertensive bleeding and small bowel ischemia[9-11]. For this reason, early treatment with therapeutic anticoagulation is recommended in patients with acute SVT[12-14]. However, consistent evidence to drive this decision in acute pancreatitis patients does not exist[15-18]. In fact, a recent meta-analysis from our study group showed that 53% of acute pancreatitis patients do not receive therapeutic anticoagulation [15]. This proportion of untreated patients is substantially higher than previously reported in other SVT populations[19], probably because of the fear of serious bleeding. Variation in clinical practice also became apparent in this meta-analysis[15], as anticoagulation use and the type of agent used were very heterogeneous between studies. Therefore, the aim of this survey was to gain more insight into current opinions of pancreatologists on anticoagulation therapy for SVT following acute pancreatitis.

MATERIALS AND METHODS

We conducted an online national survey and case vignette study among members of the Dutch Pancreatitis Study Group (DPSG) and the Dutch Pancreatic Cancer Group (DPCG). Members were excluded if they were not primary care-takers in the treatment of patients with AP (*e.g.*, radiologists, oncologists, basic scientists). The survey was built in Research Electronic Data Capture, and invitations to participate were sent by e-mail in November 2021, followed by four weekly reminders. Additionally, the survey was promoted through newsletters and during annual study group meetings of the DPSG and DPCG.

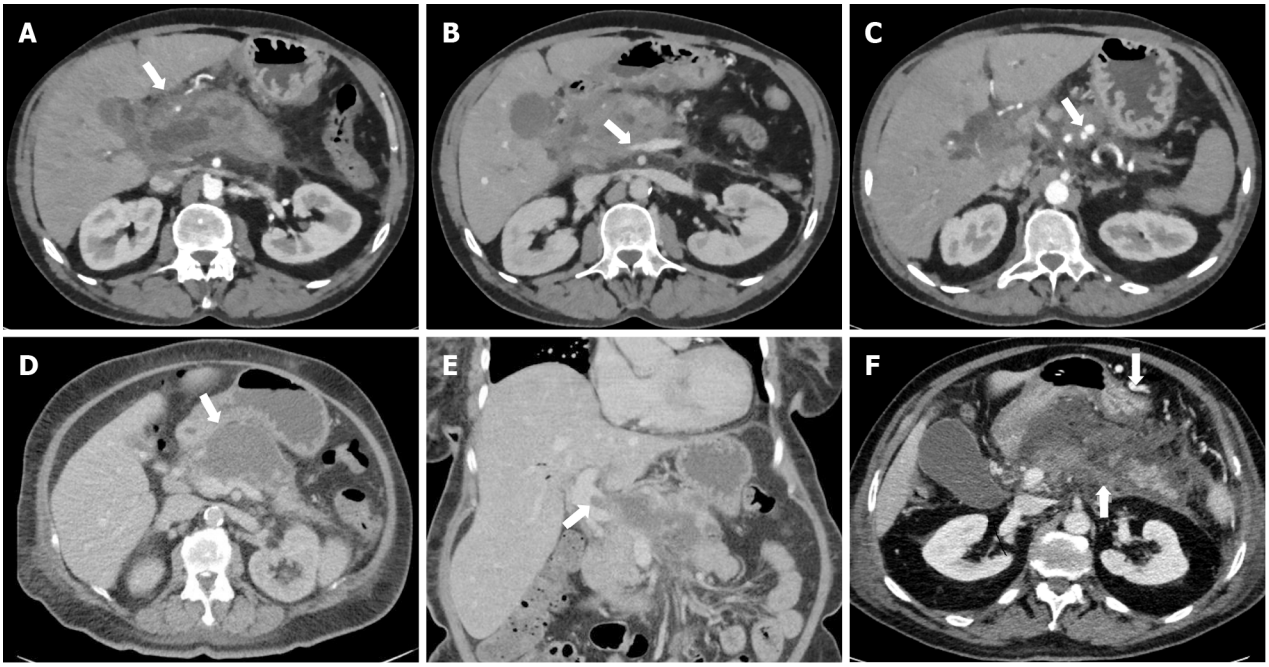
Survey design

The survey was developed by a multidisciplinary team of surgeons, gastroenterologists, and radiologists, and included 3 demographical questions, 17 general questions and 3 case vignettes (Supplementary material). Demographic information included the responders' specialty, type of hospital and working experience. The general questions focused on treatment of SVT and potential factors that may influence the responders' decision. The case-vignettes addressed the preferred treatment strategy in different clinical cases at different time points. All cases however, concerned a 50-year-old male patient with acute alcoholic necrotising pancreatitis, and can be summarized as follows.

Case vignette 1: A patient visited the emergency department, 5 d after onset of abdominal pain. Contrast-enhanced CT (CECT) showed necrotising pancreatitis with acute necrotic collection in the head of the pancreas (Figure 1A) and: A1: Luminal narrowing of the portal vein without the presence of collateral circulation (Figure 1B); A2: Intraluminal filling defect in the portal vein without the presence of collateral circulation; A3: Intraluminal filling defect in the portal vein without the presence of collateral circulation + a pseudoaneurysm in the proximal splenic artery (Figure 1C).

Case vignette 2: A patient admitted to the ward, 14 d after onset of abdominal pain. The patient showed signs of clinical detoriation with fever and rising inflammatory parameters. The CECT showed almost fully encapsulated pancreatic necrosis without gas configurations (Figure 1D) and a new intraluminal filling defect in the portal vein without the presence of collateral circulation (Figure 1E). The diagnosis of suspected infected pancreatic necrosis was made.

Case vignette 3: A homeless patient visited the emergency department, 30 d after onset of vague abdominal pain. CECT showed necrotising pancreatitis and: CA: Intraluminal filling defect in the portal vein with the presence of collateral circulation; CB: Thrombus progression and expansion of the collateral circulation (Figure 1F).



The threshold to assume group agreement was set at 75%. If a question ranged from always, usually, sometimes and never, agreement was defined when 75% of the pancreatologists rated it as always or usually (regularly), or sometimes and never (infrequently).

Definitions

SVT was predefined as an actual intraluminal filling defect on imaging of one or more of the splanchnic veins. The chronicity was divided into (sub)acute thrombosis or chronic thrombosis (with concomitant collaterals), anatomical location into portal, splenic and/or superior mesenteric vein, degree into a total or partial occlusion and extent into an isolated thrombus or a thrombus in several venous segments. Thrombus progression was defined as progression into other splanchnic vein(s), into total occlusion, or both.

Statistical analysis

Descriptive data are presented as counts with proportions for categorical data. All analyses were performed using IBM SPSS (20).

Figure 1 Imaging findings of case vignette. A: Acute necrotic collection in the head of the pancreas in case vignette 1; B: Luminal narrowing of the portal vein without the presence of collateral circulation in case vignette 1; C: Pseudoaneurysm in the proximal splenic artery in case vignette 1; D: Almost fully encapsulated pancreatic necrosis without gas configurations in case vignette 2; E: Luminal filling defect in the portal vein without the presence of collateral circulation in case vignette 2; F: Extension of the thrombus to the splenic vein (arrow pointing upwards) and expansion of the collateral pathway in the gastroepiploic veins along the great curvature of the stomach (arrow pointing downwards) in case vignette 3.

RESULTS

A total of 93 of the 139 invited pancreatologists (67%) responded and participated in this survey and case vignette study; 67 gastroenterologists (72%), 25 surgeons (27%) and 1 intensivist (1%). The majority worked in a non-academic centre (70%) and had more than 10 years of experience in treating AP patients (60%). Demographic characteristics are presented in Table 1.

Indications for and details of treatment with therapeutic anticoagulation

Agreement was reached on whether therapeutic anticoagulation should be prescribed for SVT and luminal narrowing of one or more of the splanchnic veins in acute pancreatitis patients. For SVT, therapeutic anticoagulation was regularly prescribed by 71 (76%) and infrequently by 22 (24%) pancreatologists. In case of luminal narrowing, therapeutic anticoagulation was only regularly prescribed by 12 (13%) pancreatologists. Avoiding complications, such as portal hypertension and bowel ischemia, was the main reason for 81 pancreatologists (87%) to start therapeutic anticoagulation. Screening for an underlying prothrombotic disorder in patients diagnosed with SVT was regularly performed by 14 (15%) pancreatologists, only in patients with a history of one (or more) thrombotic events by 40 (43%), and infrequently by 39 (42%) pancreatologists. There was agreement on the preferred initial type of therapeutic anticoagulation for SVT 81 pancreatologists (87%) preferred subcutaneous low-molecular-weight heparin (LMWH)], but not on the preferred follow-up type. Imaging after the index admission was chosen as follow-up strategy by 79 pancreatologists (85%). Thirteen pancreatologists (13%) indicated that they usually stop anticoagulant therapy in case of achieved radiological recanalization, 35 (38%) after a period of 3 mo, 42 (45%) after 6 mo, and 3 (3%) after 12 mo. All details are provided in Table 2.

Determinants of prescribing therapeutic anticoagulation

Seventy-eight pancreatologists (84%) have chosen the time course of thrombosis as the most important factor supporting anticoagulant therapy; 84 pancreatologists (90%) prescribe therapeutic anticoagulation in case of a (sub)acute thrombosis *vs* 9 (10%) for both (sub)acute and chronic thrombosis. Moreover, 70 pancreatologists (76%) have chosen portal vein thrombosis as the most preferred location to initiate therapeutic anticoagulation, whereas splenic vein thrombosis was chosen as least preferred location by 80 pancreatologists (86%). The majority of pancreatologists (85%) treat both total and partial occlusive thrombosis. There was no agreement whether the risk of different types of bleeding should be considered as a major barrier to prescribe therapeutic anticoagulation. The need for invasive interventions for local complications of acute pancreatitis influenced the decision whether or not to

Table 1 Details of respondents, *n* (%)

Non-academic, teaching hospital	60 (65)
Non-academic, non-teaching hospital	5 (5)
Experience in treating patients with acute pancreatitis	
0-5 years	10 (11)
5-10 years	27 (29)
10-15 years	17 (18)
15-20 years	23 (25)
> 20 years	16 (17)

initiate anticoagulation therapy in about half of pancreatologists (52%). All details are outlined in Table 3.

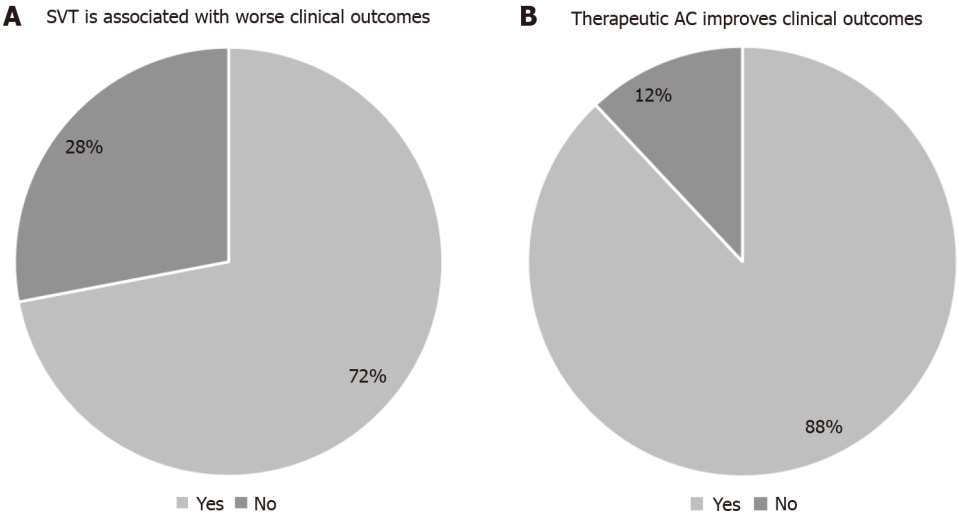
Statements on prognosis

An association between the presence of SVT and worse clinical outcomes in patients with acute pancreatitis was assumed by 67 pancreatologists (72%) (Figure 2). Moreover, the vast majority (88%) agreed that therapeutic anticoagulation for splanchnic vein thrombosis improves clinical outcomes in these patients. Insufficient evidence was the most frequently quoted reason among pancreatologists who disagreed with this second statement.

Case-vignettes

The results of the case vignettes are summarized in Figure 3. In the first case vignette (patient 1, day 5 of acute necrotising pancreatitis), 11 pancreatologists (12%) would prescribe a therapeutic dose anticoagulation if luminal narrowing without collateral circulation was detected in the portal vein. Of the 82 pancreatologists (88%) who opted for no therapeutic dose anticoagulation, 73 (89%) would change treatment strategy in case an actual filling defect in the portal vein was detected. In total, 84 pancreatologists (90%) would prescribe therapeutic dose anticoagulation to this patient with an actual portal vein thrombosis without collateral circulation. If a pseudoaneurysm was concomitantly present, 43 of those 84 pancreatologists (51%) who favoured a therapeutic dose anticoagulation would switch to a prophylactic dose anticoagulation (*n* = 28, 65%) or no anticoagulation at all (*n* = 15, 35%), leaving 41 pancreatologists (44%) in the therapeutic anticoagulation group.

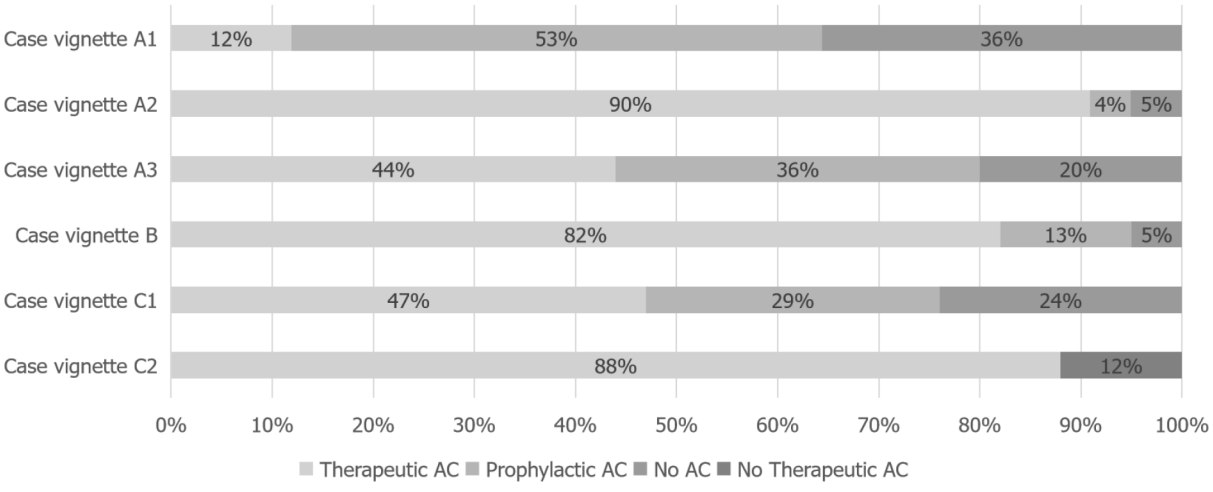
In the second case vignette (patient 2, day 14 of suspected infected necrotising pancreatitis), 77 pancreatologists (82%) would prescribe therapeutic dose anticoagulation if a portal vein thrombosis without collateral circulation was detected. The presence of (suspected) infected pancreatic necrosis influenced the choice of anticoagulation agent in 49 pancreatologists (52%). Almost all of these pancreatologists pointed out that once infected pancreatic necrosis is suspected, they would choose an agent with a short half-life because of the potentially need of invasive intervention.



In the third case vignette (patient 3, day 30 of acute necrotising pancreatitis), 44 pancreatologists (47%) would prescribe a therapeutic dose anticoagulation if a portal vein thrombosis with collateral circulation was detected. Of these 44 pancreatologists, 19 (43%) would perform upper endoscopy to screen for and-if present-treat oesophageal varices before starting anticoagulation therapy. In case of thrombus progression (extension of the thrombus to the splenic vein and expansion of the collateral pathway), 11 pancreatologists (12%) would stay conservative (*i.e.*, no therapeutic dose of anticoagulation), 82 (88%) would start or continue a therapeutic dose anticoagulation and none would proceed to an intervention.

Table 2 Survey results: Indication for and details of treatment with therapeutic anticoagulation, *n* (%)

Item	Total (*n* = 93)
Do you prescribe therapeutic AC in case of detected thrombosis in one (or more) of the splanchnic veins?	
Always	23 (25)
Usually	48 (52)
Sometimes	21 (23)
Never	1 (1)
Do you prescribe therapeutic AC in case of detected luminal narrowing of one (or more) of the splanchnic veins?	
Always	3 (3)
Usually	9 (10)
Sometimes	29 (31)
Never	52 (56)
Main reason(s) to start therapeutic AC (multiple answers were possible)	
To achieve vessel recanalization	52 (56)
To avoid complications	81 (87)
To prevent formation of altered venous anatomy	31 (33)
To prevent recurrence of SVT	27 (29)
To prevent another venous thromboembolism	30 (32)
Other reason[1]	1 (1)
Do you screen for an underlying prothrombotic disorder?	
Always	2 (2)
Usually	12 (13)
Sometimes	25 (27)
Only in patients with a history of one (or more) thrombotic events	40 (43)
Never	14 (15)
Which initial type of therapeutic AC do you prefer?	
(Low molecular weight) heparin subcutaneous	81 (87)
Unfractionated heparin intravenous	4 (4)
Direct oral anticoagulation	3 (3)
Vitamin K antagonist	4 (4)
Platelet aggregation inhibitor	1 (1)
Urokinase/recombinant tissue plasminogen activator	0
Which follow-up type of therapeutic AC do you prefer?	
(Low molecular weight) heparin subcutaneous	9 (10)
Unfractionated heparin intravenous	0
Direct oral anticoagulation	53 (57)
Vitamin K antagonist	29 (31)
Platelet aggregation inhibitor	2 (2)
Urokinase/recombinant tissue plasminogen activator	0
Do you generally follow-up SVT after index admission?	
Yes, clinically only	5 (5)
Yes, with imaging	79 (85)
No	9 (10)



After how long do you usually stop the therapeutic AC?	
In case of achieved radiological recanalization	13 (14)

DISCUSSION

This first nationwide survey and case vignette study gives insight into the clinical scenarios in which therapeutic anticoagulation is currently used, and not used to treat or prevent splanchnic vein thrombosis in acute pancreatitis patients. In an earlier study[15], we found 7 retrospective cohort studies evaluating therapeutic anticoagulation in this patient category with conflicting results in clinical

Table 3 Survey results: Determinants of prescribing therapeutic anticoagulation, *n* (%)

Item	Total (*n* = 93)
Do you consider of ... the thrombosis as an important factor to prescribe therapeutic AC? (multiple answers were possible)	
Age (acute or chronic)	78 (84)
Anatomical location (portal, splenic or superior mesenteric vein)	42 (45)
Degree (total or partial)	45 (48)
Extent (isolated thrombosis or thrombosis in several segments)	49 (53)
Progression (over time)	40 (43)
When do you prescribe therapeutic AC? In case of:	
(Sub)acute thrombosis	84 (90)
Chronic thrombosis	0
Both	9 (10)
Rank the anatomical location of the thrombosis from most likely to less likely to start therapeutic AC:	
Portal vein-splenic vein-superior mesenteric vein	9 (10)
Portal vein-superior mesenteric vein-splenic vein	61 (66)
Splenic vein-portal vein-superior mesenteric vein	0
Splenic vein-superior mesenteric vein-portal vein	1 (1)
Superior mesenteric vein-portal vein-splenic vein	19 (20)
Superior mesenteric vein-splenic vein-portal vein	3 (3)
When do you prescribe therapeutic AC? In case of:	
Total thrombosis	9 (10)
Partial thrombosis	5 (5)
Both	79 (85)
Do you consider the risk of ... as a major barrier to prescribe therapeutic AC? (multiple answers were possible)	
Bleeding in general	52 (56)
Bleeding related to portal hypertension	17 (18)
Bleeding related to pseudoaneurysm	49 (53)
Other risk[1]	1 (1)
Does the need for invasive interventions for local complications of acute pancreatitis influence your decision regarding AC therapy?	
Yes	48 (52)
No	45 (48)

AC: Anticoagulation; SVT: Splanchnic vein thrombosis.

outcome[20-27]. These studies were of moderate quality and therefore the pancreatologist' preference and belief predominate in current decision making rather than scientific evidence.

An important finding of the current study was that more than 75% of pancreatologists regularly prescribe therapeutic anticoagulation for SVT, particularly for a thrombus that acutely developed. This is in line with recommendations from general guidelines for SVT management[12-14]. In the absence of a visualized thrombus, most pancreatologists indicated not to treat compressed veins with anticoagulation. Although wall shear stress in a compressed vessel may promote platelet activation, and subsequently thrombus formation[28], there is no data yet to question the opinion of the pancreatologists.

In this study, the most important reason to administer therapeutic anticoagulation was to avoid complications including bowel ischemia and portal hypertension. Bowel ischemia has been reported in up to 33% of acute pancreatitis patients treated with therapeutic anticoagulation *vs* 16% of untreated patients[22,24,25]. A potential explanation for this discrepancy could be that bowel ischemia was already present prior to the start of therapy, therefore being an indication for therapeutic anticoagu-

lation rather than a consequence. In addition, the presence of varices and other collaterals have been equally reported[15], and only one of the aforementioned studies described one case of bleeding from oesophageal varices in an anticoagulated patient[24]. Again, it is likely that a perceived bleeding risk influenced the decision whether or not to prescribe therapeutic anticoagulation. This confounding by indication clearly limits the interpretation of these retrospective studies.

Achieving vessel recanalization was chosen as the second goal. A recent meta-analysis showed that the pooled rate of recanalization of SVT was similar between treated (36%) and untreated patients (31%) [15]. However, there is reason to believe that the benefit of anticoagulation therapy may alter when considering the anatomical location of the thrombosis[21,29]. Patients with portal vein or superior mesenteric vein thrombosis may have an increased risk of complications, while having lower spontaneous recanalization rates. In particular, mortality rates of patients with superior mesenteric vein thrombosis are reported up to 50%[30,31]. On the other hand, splenic vein thrombosis, which is by far the most common site of thrombosis in acute pancreatitis patients, forms a less serious concern for gastrointestinal bleeding and insufficient recanalization[8,26,32]. A selective anticoagulation policy, in which therapeutic anticoagulation was reserved for portal- and superior mesenteric vein thrombosis, was recently assessed in a retrospective study[33]. This study showed a recanalization rate of 67% in portal- and superior mesenteric vein thrombosis, which is substantially higher than previously reported [15]. In addition, a recent practice guideline from the Pancreas study group, Chinese Society of Gastroenterology, recommends a selective anticoagulation policy[34]. In this survey, portal vein thrombosis, followed by superior mesenteric vein thrombosis, was also the pancreatologists' preferred location for prescribing therapeutic anticoagulation, while splenic vein was the least preferred location.

With respect to chronic SVT, the current guidelines do not recommend therapeutic anticoagulation [10]. This is in line with the reported use in case vignette 3, with the exception of the case of the patient with thrombus progression and expansion of the collateral circulation. In this scenario, 88% of pancreatologists would treat such patient with therapeutic anticoagulation. A recent multicentre randomised controlled trial comparing daily rivaroxaban 15 mg/d to no anticoagulation in patients with noncirrhotic chronic portal vein thrombosis[35], formally challenged the guideline recommendations. This study showed that rivaroxaban, even in prophylactic dose, reduced the incidence of venous thromboembolism; therefore, this study may initiate a shift towards a more frequent use of anticoagulation in chronic SVT. On that note, primary prophylaxis of portal hypertensive bleeding should be performed, as laid out by the BAVENO IV guideline[13]. In this survey, however, the minority of pancreatologists followed this recommendation. Improvements should also be made to distinguish acute from chronic SVT. Currently, no clear definition for chronic SVT exists other than a presumed time course of more than 6 mo or the presence of multiple small collaterals around the obstructed veins [10,36], which is not useful to diagnose a nonocclusive chronic thrombosis (*i.e.*, absence of collateral pathways). A promising invention to overcome this problem is magnetic resonance noncontrast thrombus imaging, though validation is still needed[37].

According to our survey, subcutaneous LMWH was the favoured initial type of therapeutic anticoagulation, while no agreement regarding the choice of long-term anticoagulation and its duration was found. In current guidelines, switching LMWH to a vitamin K antagonist once reaching the target range is the reported strategy for patients with SVT[12-14,38]. The use of direct oral anticoagulation (*i.e.*, apixaban) in acute pancreatitis patients with SVT is reported in two studies and showed comparable results[21,33]. However, in the case of (suspected) infected pancreatic necrosis, LMWH seems to be preferred by more than half of the pancreatologists, due to its short half-life and reversibility. Besides, many acute pancreatitis patients have reduced caloric intake limiting the absorption of DOACS. Therefore, it seems fair to advise LWMH, especially in the acute phase. Looking at the duration of anticoagulation therapy for provoked SVT in patients with a transient risk factor, such as acute pancreatitis, the suggested duration is 3 mo to 6 mo[12-14,38]. Consistently, 38% and 45% of the pancreatologists in our survey preferred 3 mo and 6 mo treatment duration, respectively.

Based on the available literature, it remains unclear whether therapeutic anticoagulation is associated with higher rates of bleeding. An increased bleeding risk with therapeutic anticoagulation has been reported up to 33% of patients[21,25,26], but there are also studies showing lower rates of bleeding[24]. The theory for this latter finding is that therapeutic anticoagulation prevents thrombus progression, therefore reducing the portal pressure and consequently the risk of bleeding[19]. In this study, the risk of bleeding was not identified as a significant discouraging factor, as only about half of the pancreatologists considered bleeding in general and bleeding related to pseudoaneurysm as a major barrier to prescribe therapeutic anticoagulation. Also, the possible need for invasive intervention, due to suspected infected necrosis, did not significantly influence the treatment strategy. Another critical question is whether SVT influences the disease course of acute pancreatitis patients, but again this remains unanswered[15]. In this survey, the majority of pancreatologists assumed that the occurrence of SVT is associated with worse clinical outcomes, and interestingly, even more pancreatologists were convinced that the use of therapeutic anticoagulation leads to improved patient outcomes.

A strength of this study is the response rate of 67%, which is relatively high compared to previous surveys among pancreatologists[39-41]. Furthermore, the ratio of 30:70 between academic and non-academic pancreatologists attributed to a valuable insight into the pancreatologists' opinions on the use of therapeutic anticoagulation. This study also has several limitations. First, the results may not directly

reflect the actual practice in other countries as only members of two Dutch associations of pancreatology were invited. This decision was made to avoid selection based on publication record, and consequently include pancreatologists who are not actively involved in the treatment of acute pancreatitis[40]. Another advantage of our method is that it allowed us to calculate the survey's response rate by bypassing the confidentiality of membership lists of international pancreatic associations. Second, the clinical presentation of SVT is very heterogeneous, as well as the patient characteristics and clinical disease course among acute pancreatitis patients, which influences current decision making. For this reason, it might have been difficult for pancreatologists to answer some of the general questions. Therefore, case vignettes were used to explore what considerations underpin their decisions. As the descriptions throughout the case vignettes were consistently formulated and only one clinical detail was changed at a time, treatment of patients with superior mesenteric vein and splenic vein thrombosis was not assessed in the case vignettes. Consequently, the pancreatologists' preference on this manifestation of SVT in acute pancreatitis remained unknown. Finally, the rationale behind the "nonprescribing trend" was not assessed adequately, which could be a focus for future research.

CONCLUSION

In conclusion, this national survey demonstrates the tendency of pancreatologists to prescribe therapeutic anticoagulation for acute thrombosis, in particular for acute portal vein thrombosis and in case of thrombus progression, irrespective of the presence of infected necrosis. With therapeutic anticoagulation, the majority of pancreatologists believed that the clinical outcomes of acute pancreatitis patients with splanchnic vein thrombosis will improve. Furthermore, this study reflects on several knowledge gaps in literature, and sets out clear points for future research. Specifically, a deeper understanding of the pathophysiology and natural course of splanchnic vein thrombosis secondary to acute pancreatitis would allow us to clarify the therapeutic role of anticoagulation.

ARTICLE HIGHLIGHTS

Research background

Splanchnic vein thrombosis (SVT) is a severe complication of acute pancreatitis that may cause portal hypertensive complications and bowel ischemia. To prevent such complications, therapeutic anticoagulation is recommended in the general population of patients with an acute SVT.

Research motivation

Evidence to support this recommendation in acute pancreatitis patients does however not exist and as a result, clinical decision-making is mostly based on the preferences and beliefs of the pancreatologists.

Research objectives

To gain insight into current opinions on the use of therapeutic anticoagulation for SVT in acute pancreatitis.

Research methods

An online survey was sent to 139 Dutch pancreatologists. The threshold to assume agreement was set at 75%.

Research results

The response rate was 67% (n = 93). Seventy-one pancreatologists (77%) regularly prescribed therapeutic anticoagulation for SVT, using LMWH in the acute phase (87%). The majority favored therapeutic anticoagulation for acute thrombosis (90%), portal vein thrombosis in patients with or without infected necrosis (82% and 90%) and in case of thrombus progression (88%). There was no agreement whether the risk of bleeding is a barrier for initiation of therapeutic anticoagulation.

Research conclusions

The pancreatologists reached agreement regarding the use of therapeutic anticoagulation for SVT, particularly in cases of acute thrombosis, portal vein thrombosis and thrombus progression.

Research perspectives

To get a better understanding of the therapeutic role of anticoagulation, it is crucial to conduct prospective studies targeting the pathophysiology and natural course of SVT in acute pancreatitis patients.

ACKNOWLEDGEMENTS

We are very grateful to all 93 pancreatologists who participated in this study, 54 of whom agreed to be included in the acknowledgement: M Anten; A Bhalla; M Boermeester; K Bosscha; S Bouwense; H Braat; M Bruno; F van Delft; W Derksen; L van Driel; P van Duijvendijk; P Dura; R Eichhorn; P Fockens; E van Geenen; M Hadithi; M van der Have; J Haveman; M Hemmink; I de Hingh; H Hofker; L Holl; A Inderson; J Jansen; M Liem; D Lips; L Kager; V de Meijer; M Meijssen; H Moeniralam; V Nieuwenhuijs; M van de Poll; R Quispel; T Romkens; J Schreinemakers; M Schwartz; M Spanier; J Sprakel; M Stommel; J Straathof; J Tenthof van Noorden; W Thijs; M Tielemans; N Venneman; R Verbeek; F Vleggaar; R Voermans; J Vrolijk; L van der Waaij; R van Wanrooij; M Wielenga; R de Wilde; R Zoutendijk.

Abstract

BACKGROUND

The introduction of lumen-apposing metal stents (LAMS) for endoscopic ultrasound (EUS)-guided drainages has marked a turning point in the field of interventional ultrasound and it is gathering worldwide diffusion in different clinical settings. Nevertheless, the procedure may conceal unexpected pitfalls. LAMS misdeployment is the most frequent cause of technical failure and it can be considered a procedure-related adverse event when it hampers the conclusion of the planned procedure or results in significant clinical consequences. Stent misdeployment can be managed successfully by endoscopic rescue maneuvers to allow the completion of the procedure. To date, no standardized indication is available to guide an appropriate rescue strategy depending on the type of procedure or of misdeployment.

AIM

To evaluate the incidence of LAMS misdeployment during EUS-guided choledochoduodenostomy (EUS-CDS), gallbladder drainage (EUS-GBD) and pancreatic fluid collections drainage (EUS-PFC) and to describe the endoscopic rescue strategies adopted under the circumstance.

METHODS

We conducted a systematic review of the literature on PubMed by searching for

studies published up to October 2022. The search was carried out using the exploded medical subject heading terms "lumen apposing metal stent", "LAMS", "endoscopic ultrasound" and "choledochoduodenostomy" or "gallbladder" or "pancreatic fluid collections". We included in the review on-label EUS-guided procedures namely EUS-CDS, EUS-GBD and EUS-PFC. Only those publications reporting EUS-guided LAMS positioning were considered. The studies reporting a technical success rate of 100% and other procedure-related adverse events were considered to calculate the overall rate of LAMS misdeployment, while studies not reporting the causes of technical failure were excluded. Case reports were considered only for the extraction of data regarding the issues of misdeployment and rescue techniques. The following data were collected from each study: Author, year of publication, study design, study population, clinical indication, technical success, reported number of misdeployment, stent type and size, flange misdeployed and type of rescue strategy.

RESULTS

The overall technical success rate of EUS-CDS, EUS-GBD and EUS-PFC was 93.7%, 96.1%, and 98.1% respectively. Significant rates of LAMS misdeployment have been reported for EUS-CDS, EUS-GBD and EUS-PFC drainage, respectively 5.8%, 3.4%, and 2.0%. Endoscopic rescue treatment was feasible in 86.8%, 80%, and 96.8% of cases. Non endoscopic rescue strategies were required only in 10.3%, 16% and 3.2% for EUS-CDS, EUS-GBD, and EUS-PFC. The endoscopic rescue techniques described were over-the-wire deployment of a new stent through the created fistula tract in 44.1%, 8% and 64.5% and stent-in-stent in 23.5%, 60%, and 12.9%, respectively for EUS-CDS, EUS-GBD, and EUS-PFC. Further therapeutic option were endoscopic rendezvous in 11.8% of EUS-CDS and repeated procedure of EUS-guided drainage in 16.1% of EUS-PFC.

CONCLUSION

LAMS misdeployment is a relatively common adverse event in EUS-guided drainages. There is no consensus on the best rescue approach in these cases and the choice is often made by the endoscopist relying upon the clinical scenario, anatomical characteristics, and local expertise. In this review, we investigated the misdeployment of LAMS for each of the on-label indications focusing on the rescue therapies used, with the aim of providing useful data for endoscopists and to improve patient outcomes.

Key Words: Lams misdeployment; Endoscopic ultrasound-guided drainage; Lams maldeployment; Biliary drainage; Gallbladder drainage; Pancreatic fluid collections; Lumen-apposing metal stents

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Scant data are available about rescue techniques in cases of lumen-apposing metal stents (LAMS) misdeployment which is the main cause of technical failure in endoscopic ultrasound-guided drainage procedures. We performed a systematic review of the literature about LAMS misdeployment and rescue techniques in the biliopancreatic setting, focusing on technical aspects and success rate of endoscopic maneuvers. In accordance with our results endoscopic rescue techniques are feasible in most cases (up to 96.8%). Three endoscopic rescue strategies have been identified. The choice of the endoscopic rescue maneuver is based on the clinical scenario, type of misdeployment and expertise of the endoscopic team.

INTRODUCTION

The progress in interventional endoscopy, particularly in the field of endoscopic ultrasound (EUS), has changed the treatment algorithms for digestive and pancreaticobiliary diseases. The evolution of devices combined with improvements in endoscopic techniques, have allowed access to mini-invasive therapeutic solutions for complex diseases that affect areas beyond the gastrointestinal tract.

Nowadays, interventional EUS can manage local complications of acute pancreatitis[1], drain the biliary tree and gallbladder[2], establish gastrointestinal anastomoses[3], and treat tumors by radiofrequency ablation or injection of substances[4,5]. A paradigmatic example of this evolution is the approach to biliopancreatic drainage. The first EUS-guided transluminal drainage of the biliary tree was performed in 2001. Giovannini *et al*[6] used a 10-Fr plastic stent to achieve trans-duodenal biliary drainage (BD) under EUS guidance in a patient with a pancreatic head mass after failed endoscopic retrograde cholangiopancreatography (ERCP). Since then, the evolution of EUS-guided drainage has led to the continuous improvement of available devices and of endoscopic techniques. The introduction of self-expanding metal stents (SEMS) and lumen-apposing metal stents (LAMS) for EUS-guided drainage is a turning point in the field of endoscopic drainage. The first transluminal stenting between two nonadherent lumens of the digestive tract using a bi-flanged covered metal stent with lumen-to-lumen apposition property was described by Binmoeller and Shah[7] in an *ex vivo* model. Itoi *et al*[8] reported the first use of LAMS in humans, describing the successful treatment of 15 symptomatic pancreatic pseudocysts and five acute cholecystitis cases in patients unfit for surgery.

Itoi and Binmoeller[9] successfully performed the first EUS-guided choledochoduodenostomy (EUS-CDS) with LAMS in a patient with unresectable pancreatic cancer and obstructive jaundice. Prior to that, the technique of LAMS deployment was the same as that of tubular stents (plastic or metal stents), which is a multi-step procedure with device exchanges that are exposed to the risk of adverse events (*i.e.*, loss of the wire and/or scope position, biliary leak). To address this issue, a new LAMS delivery system with an electrocautery tip [electrocautery-enhanced (EC)-LAMS-Hot-Axios, Boston Scientific Corp., Marlborough, Massachusetts, United States] was developed, giving rise to a single-stage technique[10,11]. Presently, two LAMS in different diameters and lengths are commercially available: The Hot Axios stent (Boston Scientific, Marlborough, Mass, United States) and the Hot Spaxus stent (Taewoong Medical Co. Gimpo, Korea), and new LAMS types are on the way. Other fully covered (FC) metal stents are available for similar indications: Aixstent (Leufen Medical, Aachen, Germany), Hanarostent (Mi-TECH-Medical Co, Seoul, South Korea), and NAGI stents (Taewoong Medical Co., Ltd., Ilsan, Korea)[11,12]. These stents are non-cautery and require a multi-step procedure for their insertion. Anyway, LAMS loaded on an EC delivery system require precise execution of some sequential steps (puncture of the target lumen, opening and retraction of the distal flange to the adjacent cavity wall, deployment, and release of the proximal flange) to achieve technical success, which is defined as the correct placement of the stent across the newly created tract.

There are various issues that may occur during LAMS deployment, resulting in stent misdeployment. Unfavorable conditions range from unfamiliarity with the stent to patient movement, angled scope tip or confined space within the gastrointestinal cavity, small diameter of the target lumen[13], and target structure located at a distance of more than 15-20 mm[14]. Stent misdeployment usually results in a full-thickness defect of the gastrointestinal wall, possibly associated with the perforation of the target organ. Prompt identification of this complication is crucial to managing the perforation, possibly completing the procedure, and avoiding major consequences. This paper reviews EUS-guided drainage procedures using LAMS, with a focus on misdeployment and endoscopic rescue therapies.

MATERIALS AND METHODS

Data collection

This systematic review was performed in agreement with PRISMA guidelines. Two independent investigators (Cominardi A and Metelli F) performed a review on PubMed by searching for studies published up to October 2022. The search was limited to English-language articles and human studies, and it was carried out using the exploded medical subject heading terms "lumen apposing metal stent", "LAMS", "endoscopic ultrasound" and "choledochoduodenostomy" or "gallbladder" or "pancreatic fluid collections". We included in the review on-label EUS-guided procedures namely EUS-CDS, EUS-guided gallbladder drainage (EUS-GBD) and EUS-guided pancreatic fluid collections drainage (EUS-PFC). Boolean operators (NOT, AND, OR) were also used in succession to narrow and widen the search.

Both investigators used a standardized data collection form to increase uniformity and reduce bias in reporting. In the case of discrepancy, the investigators resolved the disagreement by discussion with a senior investigator (Armellini E). Only publications on EUS-guided LAMS positioning were considered, whereas studies on drainage with other metallic or plastic stents were excluded. Meta-analysis, review and drainage performed in non-human models were also excluded.

The studies reporting a technical success rate of 100% and other procedure-related adverse events were considered to calculate the overall rate of LAMS misdeployment, while studies not reporting the causes of technical failure were excluded. Case reports were considered only for the extraction of data regarding the issues of misdeployment and rescue techniques.

The full paper of each identified article was retrieved, and references were evaluated to search for potentially missed articles. Data were extracted independently and entered standardized Excel spreadsheet (Microsoft Inc. Redmond, Washington, United States). For EUS-CDS and EUS-PFC drainage the following data were extracted from each study: Year of publication, study design, study

population, clinical indication, technical success, reported number of misdeployment, LAMS type and size, flange misdeployed, and type of rescue strategy. For EUS-GBD the following data were collected from each study: Author, year of publication, study design, study population, clinical indication, access to GB (stomach or duodenum), technical success, reported number of misdeployment, LAMS type and size, flange misdeployed, and type of rescue strategy.

Data analysis

Baseline characteristics of study population, EUS-guided procedures, technical details, and procedure outcomes were summarized as means (SD) or medians (with interquartile range and range) for continuous data, and as frequencies and proportions for categorical data. Data were analyzed using the Statistical Package for Social Sciences (SPSS software v. 15.0, Chicago, Illinois, United States) for Windows.

RESULTS

EUS-CDS

Literature research identified 82 studies that were fully assessed for eligibility in this review. We excluded 57 studies since they did not meet our inclusion criteria. A total of 25 studies were included in our review[15-39]; in 20 studies LAMS misdeployment occurred[20-39] (study flow chart was shown in Figure 1).

A total of 1081 patients underwent EUS-CDS for malignant biliary obstruction (MBO), almost all after failed ERCP. The overall technical success rate of EUS-CDS was 93.7%. Excluding 5 case reports, a total of 63 LAMS misdeployments were reported, with a rate of 5.8%; the study detailed characteristics were summarized in Table 1. Including case reports, an Axios stent was employed in 61 (89.7%) cases of EUS-CDS. Spaxus stent was used in 3 (4.4%) cases. In 4 cases (5.9%) type of stent was not declared. The procedures were performed with a pre-loaded guidewire in 23 (33.8%) cases, without a pre-loaded guidewire in 12 (17.6%) cases, whereas this data was not available in most of cases (48.6%).

In 28 (41.2%) cases the misdeployment of the distal flange was reported, in 4 (5.9%) cases the misdeployment involved the proximal flange, in 3 (4.7%) EUS-CDS LAMS was entirely misdeployed inside the common bile duct (CBD) and in 2 (2.9%) patients no bile flow was observed after LAMS deployment despite no evidence of LAMS misdeployment. The type of misdeployment was not properly described in 31 (45.6%) EUS-CDS. Seven other causes of technical failure were reported in four studies[15,22,24,38]: 1 massive bleeding, 1 inability to puncture the bile duct, 2 duodenal perforations, 1 failure of fistula creation, 1 mechanical failure and 1 patient intolerance. In three studies[31,33,37], the effective rescue therapy after LAMS misdeployment was considered a technical success by the authors and in one study[15] duodenal perforation during dilation of the fistulous tract was the cause of technical failure.

LAMS misdeployment was managed by endoscopy in 86.8% (n = 59/68) cases, while 4.4% (n = 3/68) misdeployment cases were treated by percutaneous transhepatic BD (PTBD), 2.9% (n = 2/68) by rendezvous *via* PTBD and during surgery, and 2.9% (n = 2/68) by surgery. In 2 cases the procedure was abandoned in favor of supportive therapy. In 44.1% (n = 30/68) cases of LAMS misdeployment, the rescue strategy was LAMS removal followed by over-the-wire deployment of a new stent; in 7 (23.3%) cases a new LAMS was deployed and in 23 (76.7%) cases a SEMS was used.

The stent-in-stent technique was the treatment of choice in 16 (23.5%) cases of misdeployment; in 7 (43.7%) cases SEMS was used, in 1 (6.3%) a plastic stent and in 8 (50%) the stent type was not specified. In 8 (11.8%) cases rendezvous procedure was performed by EUS/endoscopic technique. EUS-CDS was repeated in 4 (5.9%) cases. In 1 (1.5%) case EUS-GBD was used as a rescue strategy (see Table 2).

EUS-GBD

We identified 213 studies using our search strategy; 185 studies were excluded since they did not meet inclusion criteria. A total of 28 studies reported cases of EUS-GBD[8,22,29,37,40-63] including 16 studies in which LAMS misdeployment occurred[22,29,50-63]. The study flow chart is shown in Figure 2.

A total of 667 patients underwent EUS-GBD for acute cholecystitis since they were unfit for surgery. Only in one study patients were treated by EUS-GBD for unsuccessful BD with ERCP[60]. Studies characteristics are summarized in Table 3. The overall technical success of EUS-GBD was 96.1%. Excluding two case reports, we identified 23 LAMS misdeployments among patients who underwent EUS-GBD, with a rate of 3.4%. In 19/25 (76%) cases an Axios stent was employed for EUS-GBD, while a Spaxus stent was used in the remaining 6/25 (24%) cases.

Only 8 studies reported if the GB was accessed from the stomach (n = 7/11, 63.6%) or duodenum (n = 4/11, 36.4%)[22,51-55,59,61]. The misdeployment of the proximal flange occurred in 9/25 (36%) cases, while the distal flange was misdeployed in 16/25 (64%) cases. The use of a guidewire was reported in 16/25 (64%) cases of misdeployment. Endoscopic management was the treatment of choice in 21/25 (84%) cases of LAMS misdeployment during EUS-CDS. In 15 of these 25 (60%) complicated EUS-GBD collected in our study, the initial failed LAMS deployment was overcome by reinsertion of a FC-SEMS

Table 1 Characteristics of studies reporting lumen-apposing metal stents misdeployment during endoscopic ultrasound-guided choledochoduodenostomy

Ref.	Study design	Study population (*n*)	Clinical indication	Technical success (%)	LAMS misdeployment (*n*)	LAMS type	Size of LAMS (mm)	Use of guidewire	LAMS flange misdeployed	Rescue therapy
Anderloni *et al*[20], 2019	Retrospective single center	46	MBO	93.5	3	Hot Axios	-	No	Distal (1/3), not specified (2/3)	Rendezvous technique with transpapillary placement of 10 mm × 40 mm FCSEMS after advancing a guidewire through the existing fistula into the bile duct and then across the papilla (1/3); 10 mm × 10 mm LAMS placement through the existing fistula (1/3); double-pigtail plastic stent placement across the LAMS (1/3)
Di Mitri R *et al*[21], 2022	Retrospective single center	31	MBO	80.6	7	Hot Axios	8 mm × 8 mm (6/7) 10 mm × 10 mm (1/7)	Yes	Distal	Over-the-wire FCSEMS placement (5/7); transpapillary percutaneous-transhepatic-endoscopic rendezvous (1/7); transpapillary laparoscopic-endoscopic rendezvous (1/7)
Rajadurai *et al* [22], 2022	Retrospective multicenter	66	MBO	90.9	6	Hot Axios	-	No (4/6). Yes (2/6)	Distal	Over-the-wire FCSEMS placement (2/6); laparotomy (2/6); EUS-GBD (1/6); palliation due to rapid deterioration (1/6)
Jacques *et al* [23], 2019	Retrospective multicenter	52	MBO	88.5	4	Hot Axios	-	-	Distal (1/4), proximal (1/4 intraperitoneal, 2/4 intraparietal)	Stent-in-stent strategy with SEMS (1/4); ERCP rendezvous (1/4); repeat classic EUS-CDS with SEMS (2/4)
Jacques *et al* [24], 2020	Retrospective multicenter	70	MBO	98.6	1	Hot Axios	-	-	No evidence of bile flow even if stent was correctly in situ	Stent-in-stent strategy
El Chafic *et al* [25], 2019	Retrospective multicenter	67	MBO	95.5	2	Hot Axios	-	Yes	-	Over the same guidewire FCSEMS placement (all)
Fugazza *et al* [26], 2022	Retrospective multicenter	256	MBO	93.3	17	Hot Axios	-	-	-	Over the guidewire SEMS placement (10/17); deployment of a second LAMS (4/17); EUS-guided rendezvous with subsequent placement of a transpapillary stent (3/17)
Hindryckx and Degroote [27], 2021	Retrospective single center	13	-	92.3	1	Hot Axios	8 mm × 6 mm	Yes	Distal	Clip closure of duodenal defect and new EUS-CDS with 8 mm × 6 mm LAMS
Armellini *et al* [28], 2023	Case report	1	Difficult biliary lithiasis	-	1	Hot Axios	8 mm × 8 mm	Yes	Distal	Rendezvous technique with transpapillary placement of FCSEMS after advancing a guidewire directly through the LAMS and choledochal breach into the bile duct and then across the papilla
Teoh *et al* [29], 2021	Prospective multicenter	26	MBO	88.5	3	Cold spaxus	-	Yes	Entirely into the bile duct	Over the guidewire SEMS placement
Fugazza *et al* [30], 2020	Case report	1	Pancreatic adenocarcinoma	-	1	Axios	6 mm × 8 mm	Yes	Proximal	Stent-in-stent strategy using SEMS
Brückner *et al*	Case series	5	MBO	80	1	Cold	6 mm × 8	Yes	Distal	Over the guidewire stent placement

[31], 2015						Axios	mm			
Vanella *et al* [32], 2023	Retrospective study of prospectively maintained databases	93	MBO	97.8	4	Hot Axios	-	No	Distal (2/4); misdeployments after both flanges release (2/4)	Repeat EUS-CDS (1/4); inserting a guidewire through the LAMS catheter followed by over the guidewire LAMS placement (1/4) (the effective rescue therapies were counted as technical success); PTBD (2/4)
de Benito Sanz *et al*[33], 2021	Retrospective single center	37	MBO	100	4	-	-	-	Distal (2/4); not specified (2/4)	Stent-in-stent strategy (the effective rescue therapies were counted as technical success)
Garcia-Sumalla *et al* [34], 2021	Retrospective multicenter	41	MBO	95.1	2	Hot Axios	-	-	No evidence of bile flow even if stent was correctly in situ; distal flange	Stent-in-stent strategy using SEMS; rendezvous technique with placement of a transpapillary FCSEMS
Sanchez-Ocana *et al* [35], 2022	Case report	1	Pancreatic adenocarcinoma	-	1	Axios	8 mm × 8 mm	Yes	Distal	EUS-guided gallbladder drainage as a portal for antegrade transcystic guidewire passage, followed by rendezvous ERCP with placement of a biliary metal stent and clips to seal the perforation
Graves *et al* [36], 2021	Case report	1	Pancreatic metastasis of renal cell carcinoma	-	1	Axios	10 mm × 10 mm	No	Distal	A bridging 10 mm × 8 mm FCSEMS was deployed over the guidewire and through theccessing LAMS
Chin *et al*[37], 2020	Retrospective analysis of a prospectively maintained database	56	MBO	100	1	Axios	-	-	-	Over the guidewire tubular biliary stent placement (the effective rescue therapy was counted as technical success)
On *et al*[38], 2022	Retrospective multicenter	120	MBO	90.8	7	Hot Axios	-	No (4/7). Yes (3/7)	-	Bridging stents (5/7), PTBD (1/7), conservative management (1/7)
Ligresti *et al* [39], 2018	Case report	1	Pancreatic adenocarcinoma	-	1	Axios	8 mm × 8 mm	Yes	Distal	Reinsertion of the delivery system over the guide wire and second deployment of distal flange into common bile duct under EUS guidance

MBO: Malignant biliary obstruction; FCSEMS: Fully covered self-expanding metal stent; SEMS: Self-expanding metal stent; LAMS: Lumen-apposing metal stent; EUS-GBD: Endoscopic ultrasound-guided gallbladder drainage; ERCP: Endoscopic retrograde cholangiopancreatography; EUS-CDS: Endoscopic ultrasound-guided choledochoduodenostomy; PTBD: Percutaneous transhepatic biliary drainage.

through the LAMS lumen, the so-called "stent-in-stent" strategy; only in 1/15 a double pigtail stent was inserted. In 2/25 (8%) cases, the misdeployed stent was removed and a new LAMS was re-deployed over the guidewire across the fistula created during the first attempt for EUS-GBD.

In 3/25 (12%) cases, the LAMS was endoscopically removed, and the gastrointestinal wall perforation was closed by endoscopic clipping followed by transpapillary stent placement in 1 case. No further endoscopic maneuvers were attempted in the remaining 2 cases in favour of supportive care. Surgical management was the therapeutic option in 3/25 (12%) cases of misdeployment. In 1 (4%) case, emergent percutaneous cholecystostomy was performed after unsuccessful stent-in-stent placement attempt. In 1 (4%) case, palliation was the preferred strategy (see Table 2).

Table 2 Summary of rescue strategies for lumen-apposing metal stent misdeployment

EUS-CDS	
Deployment of a new stent through the created fistula tract	44.1%
Stent-in-stent strategy	23.5%
Endoscopic rendezvous	11.8%
Non-endoscopic rescue strategies	10.3%
EUS-GBD	
Stent-in-stent strategy	60%
Clip closure of gastrointestinal wall defect	13%
Deployment of a new stent through the created fistula tract	8%
Non-endoscopic rescue strategies	16%
EUS-PFC	
Deployment of a new stent through the created fistula tract	64.5%
Repeated EUS-guided drainage	16.1%
Stent-in-stent strategy	12.9%
Non-endoscopic rescue strategies	3.2%

LAMS: Lumen-apposing metal stent; EUS-CDS: Endoscopic ultrasound-guided choledochoduodenostomy; EUS-GBD: Endoscopic ultrasound-guided gallbladder drainage; EUS-PFC: Endoscopic ultrasound-guided pancreatic fluid collections drainage.

EUS-PFC

We collected 48 studies from the literature that were fully assessed for eligibility in this review; 20 studies were excluded since they did not meet our inclusion criteria. A total of 28 studies were included in our review[10,12,57,64-88] including 15 studies in which LAMS misdeployment occurred[10,12,70,77-88] (Figure 3). The overall technical success of EUS-PFC drainage was 98.1%. The cause of technical failure corresponded to LAMS misdeployment in all the studies except in one reporting two cases of technical failure due to a difficult scope position that prevented the advancement of the EC-LAMS device outside the operative channel of the echoendoscope[57]. In 3 cases, the effective rescue therapy by re-insertion of the same LAMS after misdeployment was considered a technical success by the authors[78,79].

Excluding two case reports, we collected 1684 patients who underwent EUS-PFC drainage in which 34 LAMS misdeployments occurred, with a rate of 2.0%. All study characteristics were reported in Table 4. In 13 (36.1%) cases misdeployment of the distal flange occurred, in 2 (5.5%) cases the proximal flange was deployed and then migrated entirely into the PFC. In most cases included in our study (20/36; 55.5%), the issue of misdeployment was not clearly described. A case report described the misdeployment of the stent in a non-target organ. In 4 cases data regarding rescue strategy were not available and the procedure was abandoned in one case.

The LAMS misdeployment in EUS-PFC drainage was managed as following: In 20/31 (64.5%) cases an over-the-wire deployment of a new stent was performed (10/20 with LAMS, 2/20 with SEMS, 8/20 with plastic stents), in 5/31 (16.1%) cases the EUS-PFC drainage was repeated, in 1/31 (3.2%) case surgical drainage was performed. The stent-in-stent strategy was the rescue treatment in 4/31 (12.9%) cases of LAMS misdeployment; in 3 (75%) cases a LAMS-in-LAMS technique was performed and in 1 (25%) case a SEMS was deployed inside the misdeployed LAMS (see Table 2).

DISCUSSION

Technical success of EUS-drainage is defined as the correct deployment of the stent between the gastrointestinal wall and target organ with evidence of bile flow in patients who underwent EUS-BD[24,25,32] or content flow/established access to the cavity in EUS-PFC or EUS-GBD cases[52,57].

Actually, stent misdeployment emerges as the primary cause of technical failure in the procedure of EUS-guided drainage. Among the studies we collected, different terms were used to define this complication, including misdeployment, dislodgement, and flange migration. We adopted the term ‘misdeployment’, as reported in the European Society of Gastrointestinal Endoscopy guidelines for therapeutic EUS[14].

According to the American Society for Gastrointestinal Endoscopy lexicon for endoscopic adverse events, LAMS misdeployment can be considered a procedure-related adverse event when it hampers the completion of the planned procedure and/or results in significant clinical consequences (*i.e.*, prolongation of existing hospital stay and elicitation of the need for another procedure)[89]. Misdeployment can be defined as an incident if it does not interfere with the completion of the planned procedure or change the plan of care. Therefore, stent misdeployment can be managed successfully by endoscopic rescue maneuvers to allow the completion of the procedure; however, complications with different levels of severity can occur in some cases. In EUS-BD, stent misdeployment may be associated with spillage of bile and secretions into the peritoneal cavity or retroperitoneal space, resulting in peritonitis and pneumoretroperitoneum[90]. Recently Fabbri *et al*[91] proposed a classification of misdeployment types during EUS-guided gastroenterostomy as follows: Proximal flange misdeployment, distal flange misdeployment, stent misdeployment perforating other organs, and stent misdeployment into the peritoneum. This model considers which flange is misdeployed and the anatomical localization of the stent after misdeployment and can be supposedly adopted for all EUS-guided procedures involving the use of LAMS.

EUS-CDS

The rate of ERCP failure is 2%-10% and it is due to surgically altered anatomy, gastric outlet obstruction, duodenal and/or bile duct tumor infiltration, indwelling enteral stent, periampullary diverticula, impacted stones, and technical difficulties[92]. European guidelines suggest EUS-BD as the second-line treatment for patients with MBO. The optimal drainage strategy depends on the underlying disease (benign/malignant) and location of the obstruction (distal/hilar)[15].

EUS-BD proved to be equally effective with fewer adverse events and re-intervention compared to PTBD especially in gastric outlet obstructions[93]. In addition, EUS-BD is less invasive, leads to better nutrition, prevents electrolyte imbalances, and provides better quality of life[94]. As experience in EUS-BD continues to grow, comparative studies of EUS-CDS and ERCP have reported encouraging data in support of EUS-CDS as the primary treatment for distal MBO, challenging the role of ERCP[95].

In a meta-analysis, the technical and clinical success rates of EUS-CDS using LAMS were 93.6% and 94.8%, respectively, with pooled rate of overall adverse events of 17.1% and procedure-related adverse events of 6.2%[96]. In our research, LAMS misdeployment rate was 5.8%, and LAMS misdeployment represented the main cause of technical failure in EUS-CDS. Notably, technical failure was due to other

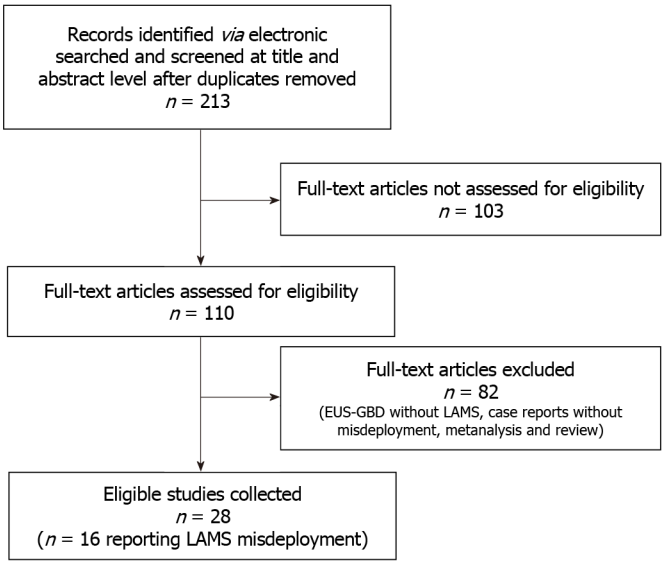
WON: Walled of necrosis; PFC: Pancreatic fluid collections; FCSEMS: Fully covered self-expanding metal stent; SEMS: Self-expanding metal stent; LAMS: Lumen-apposing metal stent.

causes in only seven cases (0.6%). In up to 86.8% of cases, the endoscopist managed LAMS misdeployment with an endoscopic rescue strategy during the index procedure.



The most common endoscopic rescue technique involved misdeployed LAMS removal and over-the-wire deployment of a new stent through the same fistula tract (44.1%). SEMS were employed in most cases (76.7%). Other rescue strategies used include stent-in-stent (23.5%), EUS-guided/endoscopic rendezvous with transpapillary placement of a biliary SEMS (11.8%), and repeated EUS-drainage procedure (5.9%).

As reported in literature, the most common causes of LAMS misdeployment are related to difficult scope position[17,28,39] and small CBD diameter (< 15 mm)[21,27,34]. In a retrospective analysis by Jacques *et al*[23] involving 52 patients who underwent LAMS placement using various techniques, the technical and clinical success rates were 88.5% and 100%, respectively. In univariate analysis, CBD diameter > 15 mm, use of a 6-mm LAMS, and use of a one-step technique (direct puncture using the electrocautery system without needle puncture) were predictors of technical success in EUS-CDS. In another study, the authors performed EUS-CDS using a one-step technique in 97.1% (n = 68/70) of patients and achieved 98.6% of technical success[24]. The more frequent use of a pre-loaded guidewire in the group of patients with CBD < 15 mm compared to those with CBD ≥ 15 mm (33% *vs* 3.6%, P = 0.036) might have contributed to the comparable technical success, clinical success, and adverse event rates between the two groups. On the other hand, Di Mitri *et al*[21] reported seven cases of LAMS misdeployment in 31 patients with distal MBO who underwent EUS-CDS. CBD was ≤ 15 mm in six of the seven patients. In five cases, rescue therapies involved placing a fully covered self-expanding metal stent (FCSEMS) over the previously inserted guidewire, restoring the connection through the iatrogenic fistulous tract. In the remaining two cases, bile duct decompression after the puncture prevented the correct visualization of the CBD on EUS imaging and the possibility of approaching the CBD again; these cases were managed successfully by percutaneous- and laparoscopic-endoscopic rendezvous techniques. The authors assumed that the small caliber of the CBD forced the tip of the LAMS delivery catheter to be too close to the facing wall of the CBD and in an oblique direction, increasing the risk of misdeployment, even with the use of a small-size LAMS. In the largest study (256 patients enrolled) included in our review, Fugazza *et al*[26] reported that significantly higher technical success was achieved in patients with a larger CBD diameter compared to those with a smaller CBD diameter. The authors demonstrated that larger CBD size, use of a needle with a guidewire, fluoroscopy guidance, and LAMS placement in the proximal CBD were more likely in the non-expert group than in the expert group; however, technical [101 (94.4%) *vs* 138 (92.6%); P = 0.574] and clinical success [96 (95.0%) *vs* 134 (97.1%); P = 0.415] did not statistically differ between these two groups.

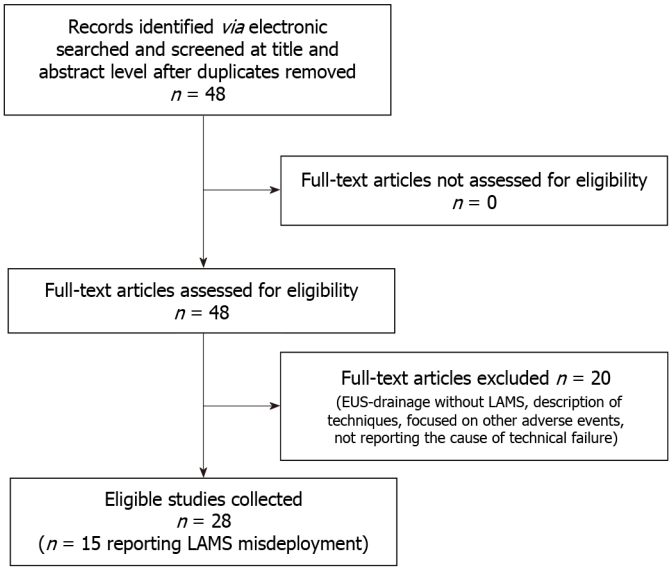

Figure 2 Study flow-chart of endoscopic ultrasound-gallbladder drainage. EUS-GBD: Endoscopic ultrasound-gallbladder drainage; LAMS: Lumen-apposing metal stents.

The use of a delivery system pre-loaded with a guidewire in complex cases (*i.e.*, endoscope instability in the duodenal bulb or smaller CBD diameter) was emphasized by Anderloni *et al*[97] because it allowed rescue using an over-the-wire stent placement in cases of LAMS misdeployment, and the single-step technique was preferred in cases of dilated CBD > 15 mm.

Wire access into the CBD could be regained in some cases, allowing endoscopic rescue maneuvers to be performed, even in cases of non-identifiable CBD on EUS imaging[28,35]. Our data show that over-the-wire deployment of a tubular stent, particularly a biliary SEMS, was the preferred rescue procedure for LAMS misdeployment during EUS-CDS (44.1%). We suppose that this technique was preferred since EUS-BD with SEMS has long been a consolidated technique for BD and that SEMS placement can be performed without EUS guidance, which may be lost in these circumstances.

EUS-GBD

Laparoscopic cholecystectomy is the standard approach for acute calculus cholecystitis. In cases of severe inflammation, adhesive disease, bleeding in the surgical area, or suspected bile duct injury, open cholecystectomy may be required to achieve safe dissection and gallbladder resection. In recent years, EUS-GBD has emerged as the preferred alternative to surgical treatment over percutaneous GBD

Figure 3 Study flow-chart of endoscopic ultrasound-pancreatic fluid collections. EUS: Endoscopic ultrasound; LAMS: Lumen-apposing metal stents.

(PGBD) or endoscopic transpapillary GBD (ETP-GBD) and is included in the international guidelines for grade II cholecystitis and recommended for grade 3 cholecystitis in patients with American Society of Anesthesiologists scores ≥ 3 or Charlson Comorbidity Index ≥ 6[98,99]. It has a technical and clinical success rate of 94.65% [95% confidence interval (CI): 91.54-96.67; I^2 = 0.00] and 92.06% (95%CI: 88.65-94.51; I^2 = 0.00), respectively. The rates of adverse events associated with EUS-GBD, including perforations, misdeployment, bile leakage, stent migration into the gallbladder or peritoneum, bleeding, gastroduodenal perforation, pneumoperitoneum, and recurrent acute cholecystitis due to stent occlusion, varies between 8% and 17%[100-102]. EUS-GBD showed higher technical and clinical success rates and lower recurrence rates than those of ETP-GBD[103].

Moreover, several studies have compared EUS-GBD with PGBD, demonstrating similar technical and clinical success rates for both procedures[43,104-106]; however, EUS-GBD was associated with significantly fewer adverse events, including lower mortality, lower post-procedure pain, shorter hospital stay, and fewer readmissions and reinterventions. According to our data, LAMS misdeployment occurred in 3.4% of the patients who underwent EUS-GBD. In almost 63% of cases, LAMS misdeployment occurred when EUS-GBD was performed through the stomach.

Although studies comparing gastric and duodenal LAMS access for EUS-GBD did not find any significant differences in technical or clinical success or adverse event rates[107], the duodenum is a less mobile organ and is closer to the gallbladder than the stomach. Therefore, there is a lower risk of LAMS migration when gallbladder access is *via* the duodenum.

In 68% of cases, LAMS misdeployment involved the distal flange. This suggests that a careful choice of the position and proper advancement of the LAMS inside the GB are critical to avoiding misdeployment. The use of guidewire, reported in 68% of cases of misdeployment, helped to maintain secure access to the newly created fistula between the gastrointestinal system and GB. The most frequently performed rescue maneuver was the placement of LAMS or a longer SEMS through the lumen of the misdeployed stent (stent-in-stent strategy). The stent-in-LAMS was particularly the rescue strategy of choice in up to 60% of LAMS misdeployment cases.

Surgery or PTBD after endoscopic closure of the luminal perforation was required after the failure of endoscopic therapies[55,56,61]. LAMS removal and clip closure of digestive tract wall defect was the treatment of choice in 3 patients (one of them was treated by ETP-GBD while no further endoscopic maneuver was performed in the remaining two patients). This strategy allows a second drainage attempt during the index procedure or later in selected patients. According to our data, two patients died after LAMS misdeployment, one for surgical complications and one left to supportive care[22,56].

EUS-PFC drainage

EUS-guided transmural drainage is considered the first-line treatment option for PFC, including walled-off necrosis (WON) and pancreatic pseudocysts[108]. Transluminal drainage in the "before-LAMS age" was achieved by the placement of double-pigtail plastic stents and afterward, by biliary/esophageal FC SEMS, which were associated with risks of migration, leakage, ulceration, and bleeding[109]. The LAMS design has the advantage of supporting drainage, preventing migration, and allowing direct access inside the WON cavity for endoscopic necrosectomy because it has a larger diameter, shorter length, and stent-anchoring flanges[110].

In our study, LAMS misdeployment during EUS-guided PFC drainage occurred in 34/1684 (2.0%) patients. This result is in accordance with the high technical success rate of these procedures reported in the literature (97.6%)[111]. Distal flange misdeployment in the peritoneal cavity, external to the cystic wall, was reported in up to 36.1% of cases[77,78,80,81,85]. Over-the-wire placement of a new stent (LAMS, SEMS, or double pigtail stents/plastic) through the novel fistula tract was the rescue therapy of choice in 64.5% of misdeployments. In 50% of cases, LAMS were deployed over the guidewire to complete the procedure as initially planned. The re-insertion of the same LAMS was performed in 15% of cases[78,79], resulting in a lower cost; these cases were counted as technical successes. In a study by Khan *et al*[78] involving 208 patients who underwent EUS-PFC drainage, 5/7 cases of LAMS misdeployment were managed by repeated EUS-guided drainage during index endoscopy.

There were two cases (5.5%) of complete LAMS misdeployment inside the PFC. In such cases, Mendoza Ladd *et al*[81] decided to leave the LAMS inside the PFC, and they deployed a new one through the fistula. After LAMS dilation, direct endoscopic necrosectomy was performed. Both stents were successfully removed four weeks later. The deployment of LAMS into an adjacent organ (the splenic flexure of the colon), described as WON, was reported by Despott *et al*[83], who identified the misdeployment only at the post-procedure scan (computerized tomography). After bowel preparation through a naso-jejunal tube to bypass the gastrocolic fistula, simultaneous upper and lower gastrointestinal endoscopies were performed, and the LAMS was removed. Both the colonic and gastric perforations were closed using over-the-scope clips. Although data regarding predictive factors related to LAMS misdeployment were lacking in the studies included in our review, Curieses Luengo *et al*[88] identified excessive flexion of the echoendoscope tip due to severe inflammatory duodenal stenosis as an unfavorable condition for correct LAMS deployment.

CONCLUSION

The use of LAMS has been demonstrated to have high technical and clinical success rates in EUS-CDS, EUS-GBD and EUS-PFC drainage, however significant rates of LAMS misdeployment are reported in 5.8%, 3.4%, and 2.0% of procedures, respectively. In a relevant rate of LAMS misdeployment, endoscopic rescue management has been shown to be technically feasible and effective in completing the procedure and avoiding major clinical consequences.

Although no algorithm is available to guide the appropriate rescue strategy for each case, three endoscopic techniques have been identified: (1) Gaining wire access to the target through the newly created tract and completing the procedure; (2) "Stent-in-stent" over the wire; and (3) Repeated procedures (*ex novo* or rendezvous). When endoscopic rescue procedures are not feasible, non-endoscopic options include percutaneous drainage or surgery.

In our analysis, the preferred strategy for LAMS misdeployment in EUS-CDS was LAMS removal and over-the-wire deployment of a new stent (44.1%), frequently SEMS (76.7% of cases), followed by stent-in-stent strategy (23.5%) and endoscopic rendezvous (11.8%). In EUS-GBD, the preferred technique was the stent-in-stent strategy (60%) using a SEMS in 93.3% of cases.

In EUS-PFC, the procedure of choice was LAMS removal followed by over-the-wire deployment of a new stent (64.5%), which was a LAMS or a plastic stent, in 50% and 40% of cases respectively. In conclusion, LAMS misdeployment is a relatively common adverse event, especially in EUS-BD. Endoscopic rescue strategies are feasible, and they vary depending on type of procedure, endoscopic technique used, and experience of the operators.

ARTICLE HIGHLIGHTS

Research background

Scant data are available about rescue techniques in cases of lumen-apposing metal stents (LAMS) misdeployment which is the main cause of technical failure in endoscopic ultrasound (EUS)-guided drainage procedures. We performed a systematic review of the literature about LAMS misdeployment and rescue techniques in the biliopancreatic setting, focusing on technical aspects and success rate of endoscopic maneuvers.

Research motivation

LAMS misdeployment is a relatively common adverse event in EUS-guided drainages. There is no consensus on the best rescue approach in these cases and the choice is often made by the endoscopist relying upon the clinical scenario, anatomical characteristics, and local expertise.

Research objectives

The overall technical success rate of EUS-guided choledochoduodenostomy (EUS-CDS), gallbladder drainage (EUS-GBD) and pancreatic fluid collections drainage (EUS-PFC) was 93.7%, 96.1%, and 98.1%

respectively. Significant rates of LAMS misdeployment have been reported for EUS-CDS, EUS-GBD and EUS-PFC drainage, respectively 5.8%, 3.4%, and 2.0%. Endoscopic rescue treatment was feasible in 86.8%, 80%, and 96.8% of cases. Non endoscopic rescue strategies were required only in 10.3%, 16% and 3.2% for EUS-CDS, EUS-GBD, and EUS-PFC.

Research methods

We conducted a systematic review of the literature on PubMed searching for studies published up to October 2022 about on-label EUS-guided procedures namely EUS-CDS, EUS-GBD and EUS-PFC. The search was carried out using the exploded medical subject heading terms 'lumen apposing metal stent', 'LAMS', 'endoscopic ultrasound' and "choledochoduodenostomy" or "gallbladder" or "pancreatic fluid collections".

Research results

The overall technical success rate of EUS-CDS, EUS-GBD and EUS-PFC was 93.7%, 96.1%, and 98.1% respectively. Significant rates of LAMS misdeployment have been reported for EUS-CDS, EUS-GBD and EUS-PFC drainage, 5.8%, 3.4%, and 2.0%, respectively. Endoscopic rescue treatment was feasible in 86.8%, 80%, and 96.8% of cases. Non endoscopic rescue strategies were required only in 10.3%, 16% and 3.2% for EUS-CDS, EUS-GBD, and EUS-PFC. The endoscopic rescue techniques described were over-the-wire deployment of a new stent through the created fistula tract in 44.1%, 8% and 64.5% and stent-in-stent in 23.5%, 60%, and 12.9%, respectively for EUS-CDS, EUS-GBD, and EUS-PFC. Further therapeutic option were endoscopic rendezvous in 11.8% of EUS-CDS and repeated procedure of EUS-guided drainage in 16.1% of EUS-PFC.

Research conclusions

Stent misdeployment can be managed successfully by endoscopic rescue maneuvers to allow the completion of the procedure. In accordance with our results endoscopic rescue techniques are feasible in most cases (up to 96.8%). Three endoscopic rescue strategies have been identified: Gaining wire access to the target through the created fistula and completing the procedure; placement of a new stent through the misdeployed LAMS to the target ("stent-in-stent") and repeated drainage procedures (*ex novo* or rendezvous).

Research perspectives

LAMS misdeployment is the main cause of technical failure of EUS-drainages and it is potentially harmful to the patient. Knowledge of risk factors, classification of misdeployment and of endoscopic rescue techniques is useful to improve patient outcome and the safety of the procedure. Further prospective studies describing these issues are expected.

FOOTNOTES

Author contributions: Armellini E contributed to the concept, design, drafting of the article, and approved final revision; Metelli F and Marini M involved in the acquisition, statistical analysis, or interpretation of data for biliary duct and pancreatic fluid collection section, and contribution to drafting the article; Cominardi A and Aragona G contributed to the acquisition and statistical analysis, or interpretation of data for gallbladder section; Anderloni A and Pace F revised the manuscript critically for intellectual content; and all the authors approved the version to be published.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article. Andrea Anderloni is consultant for BSCI, Olympus.

PRISMA 2009 Checklist statement: The authors have read the PRISMA 2009 Checklist, and the manuscript was prepared and revised according to the PRISMA 2009 Checklist.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. Abstract

BACKGROUND

Non-alcoholic fatty liver disease (NAFLD) and metabolic-associated fatty liver disease (MAFLD) are on the rise like any other liver disease, and tend to affect 25% of the United States population. The impact of NAFLD and MAFLD on patients with coronavirus disease 2019 (COVID-19) remains unclear.

AIM

To identify the association of NAFLD and MAFLD with mortality, hospitalization, hospital length of stay, and supplemental oxygen utilization in COVID-19 patients.

METHODS

A systematic review of literature on Cochrane, Embase, PubMed, ScienceDirect, and Web of Science databases was conducted from January 2019 to July 2022. Studies that evaluated NAFLD/MAFLD using laboratory methods, noninvasive imaging, or liver biopsy were included. The study protocol was registered in PROSPERO (ID CRD42022313259) and PRISMA guidelines were followed. The National Institutes of Health quality assessment tool was used to assess the quality of the studies. Pooled analysis was conducted using software Rev Man version 5.3. The stability of the results was assessed using sensitivity analysis.

RESULTS

Thirty-two studies with 43388 patients were included in the meta-analysis of whom 8538 (20%) patients were observed to have NAFLD. There were 42254 patients from 28 studies included in the mortality analysis. A total of 2008 patients died from COVID-19; 837 (10.52%) in the NAFLD group and 1171 (3.41%) in the non-NAFLD group. The odds ratio (OR) was 1.38 for mortality with a 95% confidence interval (95%CI) = 0.97-1.95 and P = 0.07. A total of 5043 patients from eight studies were included in the hospital length of stay analysis. There were 1318 patients in the NAFLD group and 3725 patients in the non-NAFLD group. A qualitative synthesis showed that the mean difference in hospital length of stay was about 2 d between the NAFLD and non-NAFLD groups with a 95%CI = 0.71-3.27 and P = 0.002. For hospitalization rates, the OR was 3.25 with a 95%CI of 1.73-6.10 and P = 0.0002. For supplemental oxygen utilization, the OR was 2.04 with a 95%CI of 1.17-3.53 and P = 0.01.

CONCLUSION

Our meta-analysis suggests that there are increased odds of hospitalization, longer hospital length of stay, and increased use of supplemental oxygen in NAFLD/MAFLD patients.

Key Words: Non-alcoholic fatty liver; Fatty liver; Coronavirus; COVID-19; Metabolic-associated fatty liver

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Metabolic-associated fatty liver disease (MAFLD) is like non-alcoholic fatty liver disease (NAFLD) and is a hepatic presentation of metabolic syndrome. They are widely prevalent. It is estimated that 25% of the United States population have this condition. The association and effect size between fatty liver disease and coronavirus disease 2019 (COVID-19) infection is still unconfirmed. The discrepancies in the available literature may be due to study design, confounding, small study population, and heterogeneity. We performed a systematic review and meta-analysis to study the impact of NAFLD/MAFLD on mortality, hospitalization, hospital length of stay, and supplemental oxygen utilization in COVID-19 patients.

INTRODUCTION

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is one of the subspecies of coronavirus that is responsible for causing coronavirus disease 2019 (COVID-19), the respiratory illness responsible for the ongoing COVID-19 pandemic. The first detected case was reported back in December of 2019 from Wuhan, China[1]. Since then, it has spread worldwide leading to a global pandemic. As of 12 December 2022, over 650 million confirmed cases have been reported with more than 6 million deaths [2]. Most COVID-19 cases are mild to moderate with usual signs and symptoms varying from general fatigue, fever, and dry cough to some very unusual ones like loss of smell and taste. In the severe form, it is associated with several comorbidities such as diabetes, hypertension, obesity, chronic obstructive pulmonary disease, and other cardiovascular diseases[3,4]. Patients with metabolic syndrome (MS) having obesity, hyperglycemia, dyslipidemia, and hypertension had worse outcomes in COVID-19[5,6]. A retrospective study from Cleveland Clinic, United States concluded that patients with MS were 77% more likely to be hospitalized, 56% more likely to be admitted to the intensive care unit, and 81% more likely to die from COVID-19[6]. A recent consensus of experts proposed redefining non-alcoholic fatty liver disease (NAFLD) as metabolic-associated fatty liver disease (MAFLD)[7-9]. It is now considered the hepatic form of MS[10] and is one of the most common etiologies of chronic liver diseases (CLDs). It has an estimated global prevalence rate of about 24%[11]. These patients may have a higher risk of hospitalization and severity of COVID-19 according to recently published reports. A cohort of Chinese patients indicated a higher risk of respiratory disease progression in MAFLD patients[12]. In another subsequent study, there was an increased risk for COVID-19 progression in younger patients with MAFLD[13]. However, there is still conflicting evidence addressing the severity of COVID-19 in MAFLD and NAFLD patients. Prior meta-analysis of a small number of studies did not detect worse outcomes in NAFLD/MAFLD patients with COVID-19[14-16].

Therefore, we conducted this systematic review and meta-analysis to assess the effects of NAFLD or MAFLD on mortality, hospitalization, length of hospital stay, and supplemental oxygen utilization among patients with COVID-19.

MATERIALS AND METHODS

This review is reported following the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) statement[17] as indicated in the PRISMA checklist and was registered with PROSPERO (ID CRD42022313259; www.crd.york.ac.uk/prospero).

Search and selection

A literature search was performed in six bibliographic databases PubMed, Cochrane, Embase, Science Direct, and Web of Science from January 2020 to July 2022. Using a combination of keywords and medical subject headings, we used vocabulary related to "COVID-19" OR "SARS-CoV-2" AND "NASH" OR "NAFLD" OR "non-alcoholic fatty liver disease" OR "fatty liver" OR "metabolic syndrome" (Supplementary Table 1 shows the search strategy for the study).

Six authors (Jagirdhar GSK, Qasba RK, Kashyap R, Flumignan Bucharles AC, Banga A, and Reddy ST) were involved in the study selection. After removing duplicates using Endnote reference manager software, two authors did the title and abstract screening independently using the Rayyan software (https://rayyan.ai/). Studies satisfying the inclusion criteria were retrieved and screened for full-text eligibility. Conflicts between two authors on study selection were resolved among the authors or were solved by an additional third arbiter in case a consensus could not be reached. We included observational studies that studied mortality, hospitalization, hospital length of stay, and supplemental oxygen utilization outcomes in COVID-19 patients. We included studies that assessed NAFLD/MAFLD using lab assessment (fibrosis-4 [FIB-4], aminotransferase/platelet ratio index, fibrosis score, hepatic steatosis index [HIS]), non-invasive imaging (elastography, liver ultrasound or computed tomography [CT] scan, magnetic resonance elastography, liver stiffness measurement), or liver biopsy. For studies that diagnosed NAFLD using biomarkers/lab diagnosis, we only included studies that measured NAFLD prior to index admission since acute COVID infection can increase biomarker/lab values leading to misdiagnosis as NAFLD. We excluded studies that were: (1) Systematic reviews; (2) meta-analyses; (3) literature reviews; (4) survey studies; (5) case reports; (6) animal studies; (7) single-arm studies; (8) studies that do not measure NAFLD/MAFLD/fatty liver; (9) not a retrospective or prospective study; (10) randomized controlled trials; (11) studies not related to COVID-19 patients; (12) not in English language; and (13) abstract only studies. We studied NAFLD/MAFLD patients together since recent studies are emerging that NAFLD is related to MS both mutually and bi-directionally. We included studies that compared no or mild NAFLD/MAFLD patient outcomes to moderate or severe NAFLD/MAFLD patient outcomes. We also searched systematic reviews and meta-analyses obtained from our search for eligible articles and added studies meeting our inclusion criteria. When multiple publications used overlapping study populations, we included the study with greater sample size. We grouped studies for the meta-analysis based on mortality, hospitalization, hospital length of stay, and supple-

mental oxygen utilization outcomes.

Data extraction

Three independent authors (Qasba RK, Banga A, Flumignan Bucharles AC) performed data extraction from all of the included studies into a prepiloted data extraction form in Microsoft Excel. A fourth author (Jagirdhar GSK) independently assessed the extracted data for validation. The following was extracted from each study: (1) General information: First author, title, digital object identifier, and year of publication; (2) study characteristics: Study site/country, study period, number of centers, journal, study design; (3) participant characteristics: Number of NAFLD/MAFLD and non-NAFLD/MAFLD patients and their demographic characteristics, method of assessment of NAFLD; and (4) outcomes: Number of patients with the events (mortality, hospital length of stay, hospitalization, and supplemental oxygen utilization) in NAFLD/MAFLD and non-NAFLD/MAFLD populations.

Statistical analyses

The Review Manager (RevMan) [Computer application] Version 5.4.1, the Cochrane Collaboration, 2020 was used to assess all results[18]. Using a random-effects model, crude odds ratios (ORs) for each study with corresponding 95% confidence intervals (CIs) were calculated from raw data for events and non-events from each research[19]. $P < 0.05$ was considered statistically significant for the analysis. Forest plots were generated to present the results of the meta-analyses. A previously proven technique was used to transform the median to mean to examine continuous outcomes[20]. The estimates for mean differences were then produced using the random effects model[19]. To measure study heterogeneity, the Cochrane Q and the I^2 statistics were used[19]. Low-level heterogeneity was defined as I^2 20%[19]. The stability of the results was assessed using sensitivity analysis. Egger's test and funnel plots were used to determine the likelihood of publication bias[21].

Quality assessment

The National Institutes of Health scale was used to assess case control, cohort, and randomized controlled trials for appraisal of study quality. As per the scale, studies were classified into three categories: good, fair, or poor. Five authors (Jagirdhar GSK, Qasba RK, Banga A, Rama K, Pattnaik H) independently performed the quality assessment of the included studies, and any discrepancies were resolved through discussion.

RESULTS

Search and selection

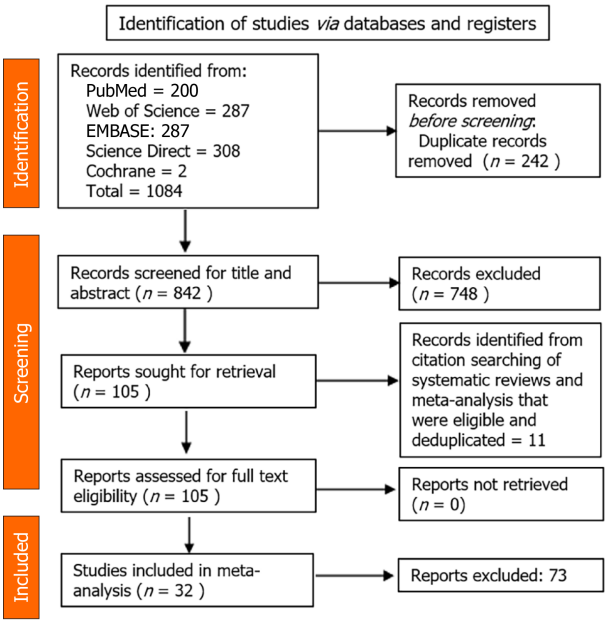
A total of 1084 records were identified from the initial search, of which 242 were excluded as duplicates and 842 articles were selected for the screening of title and abstract. Eighty-seven were chosen for full-text screening and a total of thirty-two studies met the inclusion criteria. These papers were eligible for qualitative and quantitative.

Figure 1 shows the PRISMA diagram for the study selection process. Since we included studies that compared mortality, hospitalization, hospital length of stay, and supplemental oxygen utilization in mild or no NAFLD/MAFLD to moderate to severe NAFLD/MAFLD. We excluded studies that did not present these outcomes or those that did not mention the method of NAFLD assessment[22-28].

Characteristics of included studies

We analyzed data for a total of 43388 patients from 32 studies in the meta-analysis of which 8538 (20%) patients were observed to have NAFLD and 34850 did not have NAFLD. The studies observed the outcomes of patients infected with COVID-19 with and without NAFLD/MAFLD. The outcomes recorded were the rate of hospitalization, length of stay in the hospital, supplemental oxygen requirement, and mortality of patients in both groups.

All 29 of 32 studies reported mortality data for COVID-19 infection. Ten studies reported hospital length of stay, four studies reported need for hospitalization, and four reported supplemental oxygen utilization. The main characteristics of the included studies are summarized in Table 1.



NAFLD/MAFLD and mortality outcomes in COVID-19: A total of 42254 patients from 28 studies were included in the qualitative analysis. A total of 2008 patients died from COVID-19: 837 (10.52%) in the NAFLD group and 1171 (3.41%) in the non-NAFLD group. The OR was 1.38 for mortality with a 95%CI = 0.97-1.95, I^2 = 84%, and P = 0.07. Figure 2A shows the forest plot and meta-analysis of mortality outcomes in COVID-19 patients. Figure 2B shows the sensitivity analysis of the studies. We failed to observe an association between NAFLD/MAFLD and in-hospital mortality in COVID-19 patients. Visual inspection of the standard error plots for the mortality meta-analysis (Supplementary Figure 1) suggests symmetry without an underrepresentation of studies of any precision. No publication bias was found on Egger's test, P = 0.466.

Table 1 Main characteristics of the included studies in the systematic review and meta-analysis

Serial No.	Ref.	Country	Study design	NAFLD, *n*	No NAFLD, *n*	mean ± SD	Male, *n*	Measure of NAFLD	Measure of NAFLD
1	Calapod *et al* [27]	Romania	Prospective descriptive study	47	79	66.32 ± 13.72	57.20%	Imaging evidence (ultrasound or computer tomography)	Biochemical enzymes (liver function test) within the past 12 mo

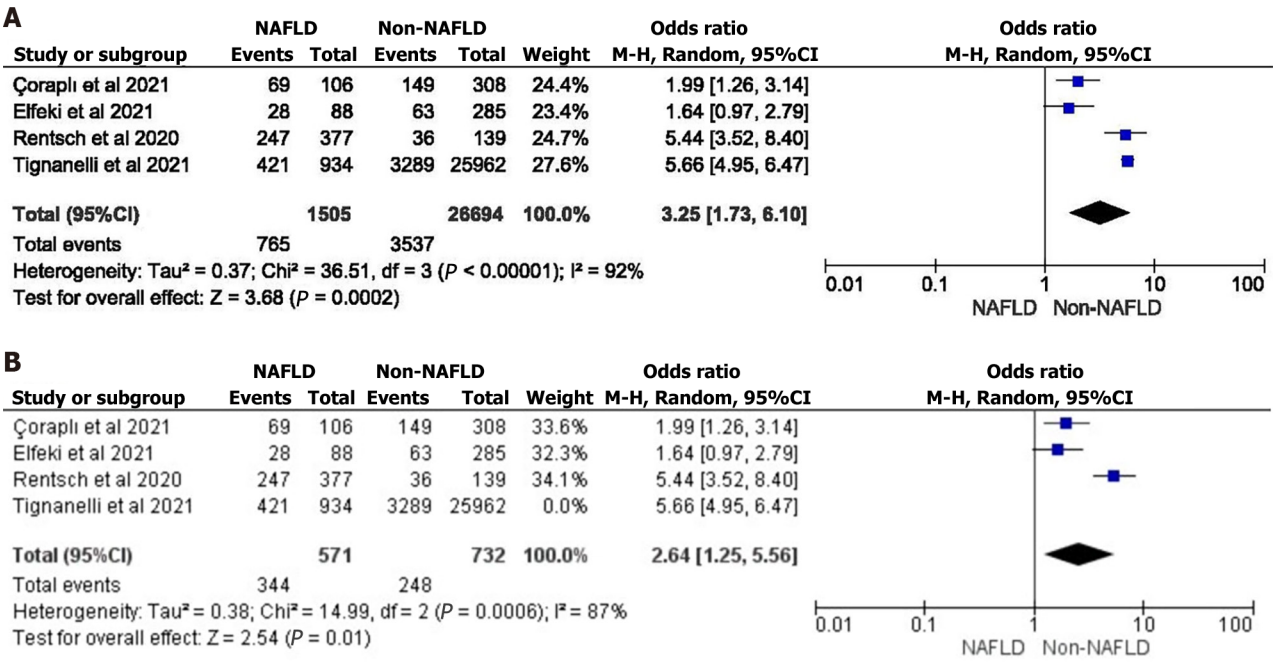
Figure 2 Forest plot for mortality outcomes in coronavirus disease 2019 patients. A: In coronavirus disease 2019 (COVID-19) patients with and without non-alcoholic fatty liver disease/metabolic-associated fatty liver disease (NAFLD/MAFLD); B: In COVID-19 patients with and without NAFLD/MAFLD

sensitivity analysis after excluding Tignanelli *et al*[47]. CI: Confidence interval.

NAFLD/MAFLD and hospitalization in COVID-19: Four studies were taken for the quantitative analysis with 28199 patients to assess the need for hospitalization in NAFLD and non-NAFLD groups with COVID-19. A total of 4302 patients were hospitalized for COVID-19: 765 (50.83%) patients from the NAFLD group and 3537 (13.25%) patients from the non-NAFLD group. The OR was 3.25 with a 95%CI of 1.73-6.10, I^2 = 92%, and a P = 0.0002. Figure 3A shows the forest plot for hospitalization in COVID-19 patients with and without NAFLD/MAFLD. Figure 3B shows the sensitivity analysis of the studies. Visual inspection of the standard error plots for the need for hospital admission meta-analysis showed (Supplementary Figure 2) symmetry without an underrepresentation of studies of any precision. No publication bias was found (Egger's test, P = 0.254). However, as there were < 10 studies included in the analysis, publication bias cannot be completely excluded.

NAFLD/ MAFLD and hospital length of stay in COVID-19: A total of 5043 patients from 10 studies were included in the qualitative analysis. A total of 1318 patients were in the NAFLD group and 3725 patients were in the non-NAFLD group. A qualitative synthesis showed that the mean difference in hospital length of stay was 1.99 d between the NAFLD and non-NAFLD groups with a 95%CI = 0.71-3.27, I^2 = 70%, and P = 0.002. This denotes an average of about 2 d of additional hospital stays among NAFLD/MAFLD patients with COVID-19. Figure 4A shows a forest plot and meta-analysis of hospital length of stay in COVID-19 patients with and without NAFLD/MAFLD. Figure 4B shows the sensitivity analysis of the studies. Visual inspection of the standard error plots for the hospital length of stay meta-analysis (Supplementary Figure 3) suggests symmetry without an underrepresentation of studies of any precision. Publication bias was found on Egger's test, P = 0.013.



NAFLD/MAFLD and supplemental oxygen utilization in COVID-19: A total of 3609 patients from four studies were included in the qualitative analysis to assess the requirement for supplemental oxygen in COVID-19 patients during their in-hospital stay. A total of 170 (7.30%) patients in the NAFLD group and 96 (7.48 %) in the non-NAFLD group required supplemental oxygen. The OR was 2.04 with a 95%CI of 1.17-3.53, I^2 = 56%, and P = 0.01. Figure 5A shows a forest plot and meta-analysis of supplemental oxygen utilization in COVID-19 patients with and without NAFLD/MAFLD. Figure 5B shows the sensitivity analysis of the studies. Visual inspection of the standard error plots for the need for supplemental oxygen requirement meta-analysis (Supplementary Figure 4) suggests symmetry without an underrepresentation of studies of any precision. No publication bias was found on Egger's test, P = 0.500. However, as there were < 10 studies included in the analysis, publication bias cannot be completely excluded.

Quality assessment

Figures for quality assessment of case-control, cross-sectional, and cohort studies included in our study are attached with Supplementary material. For case-control studies, the quality assessment of included studies identified three as good quality, one as fair, and no poor rated studies. None of the studies were able to recruit a concurrent control or blind the outcome assessors. Only Madan *et al*[41] discussed reasons for selecting included participants, providing a sample size justification additionally, Trivedi *et al*[48] were the only ones to include a random selection of participants. For included cohorts, 19 were identified as good and 10 as fair with no poor rated studies. Only Kim *et al*[40], Yoo *et al*[54], and Zhou *et al*[56] could provide a sample size justification additionally studies scored poorly on blinding of outcome assessors with only Marjot *et al*[42] and Zhou *et al*[56] being able to do so, Furthermore Ji *et al*[34] and Huang *et al*[38] were the only ones to measure exposure more than once for each person during the study period (Supplementary Tables 2 and 3 show the Quality assessment of the studies included based on the National Institutes of Health quality appraisal tool for case control, cohort, and cross-sectional studies).

DISCUSSION

Our systematic review and meta-analysis of 32 studies and 43388 COVID-19 patients, of which 8538 (20%) patients were observed to have NAFLD/MAFLD, provided a comprehensive assessment of mortality, need for hospitalization, hospital length of stay, and need for supplemental oxygen in COVID-19-afflicted patients with fatty liver disease. In the current meta-analysis, there was no relation between pre-existing NAFLD/MAFLD and COVID-19-related mortality. The results for the unadjusted analysis showed an increased risk of mortality, but the results were not statistically significant. Similar results were seen in a prior meta-analysis[57]. Meta-analysis of seven studies by Hayat *et al*[58] on MAFLD and COVID-19 mortality found an OR of 1.45 and a non-significant 95%CI = 0.74-2.84 (P < 0.01).

Figure 3 Forest plot for hospitalization and need for hospitalization in coronavirus disease 2019 patients. A: Forest plot for hospitalization in coronavirus disease 2019 (COVID-19) patients with and without non-alcoholic fatty liver disease/metabolic-associated fatty liver disease (NAFLD/MAFLD); B: Forest plot for need for hospitalization in COVID-19 patients with and without NAFLD/MAFLD sensitivity analysis after excluding Tignanelli *et al*[47]. CI: Confidence interval.

As per our meta-analysis, patients with NAFLD/MAFLD had higher hospitalization rates compared to non-NAFLD/MAFLD patients (OR = 2.71, 95%CI: 1.10-6.70; P = 0.03). COVID-19 is associated with increased inflammation and thrombosis, while NAFLD/MAFLD are states of chronic inflammation. When occurring together, these may worsen disease status causing increased hospitalization rates. Contrarily, some studies have reported no increase in disease severity or need for hospitalization in NAFLD patients with COVID compared to controls. This could be due to the small study population and the retrospective nature of the study results[39,54]. Since our meta-analysis may be one of the largest to date, the results provided are expected to be closer to the true value. Our meta-analysis found that patients with NAFLD/MAFLD had a statistically significant longer hospital length of stay compared to those without. An unadjusted assessment of eight studies found that patients with pre-existing NAFLD, on average, spent an additional 2 d in the hospital compared to COVID-19 patients without NAFLD. Patients with NAFLD have ongoing inflammation processes which compound the disease process of COVID-19, thus leading to a more severe course of illness. This could explain the higher hospitalization rates and longer duration of hospital stay. Previous studies have reported similar results with longer hospital stays for NAFLD patients afflicted with COVID-19[32,58,59]. On the contrary, some studies reported no difference in the duration of hospital stay in those with or without NAFLD[52,60].

Our meta-analysis of four studies revealed that NAFLD patients had a greater need for supplemental oxygen as compared to controls. NAFLD patients may have a more severe disease course and therefore, require supplemental oxygen during their hospital stay. One previous study reported that NAFLD patients had a more frequent need for oxygen support[51].

CLD due to NAFLD has seen a rising trend over the years. Over 83 million Americans suffered from NAFLD with a prevalence rate of 26% according to data from 2015. This value is said to rise by 21% to over 100 million patients by the year 2030. The growing epidemics of obesity and diabetes mellitus II have played a major role in increasing the prevalence of NAFLD worldwide, including the progression of NAFLD to non-alcoholic steatohepatitis (NASH), cirrhosis, and even hepatocellular malignancy[61,62]. NAFLD is found in more than 50% of individuals suffering from obesity or type 2 diabetes mellitus. In their study, Estes *et al*[61] reported the median age of NAFLD patients to be about 50 years. They also found that more males suffered from NAFLD as compared to females. These results are similar to our study. The absence of an established screening method and global health policies focusing on NAFLD, and primary care interventions lead to a substantial increase in patients with NAFLD going undetected [55]. It also means that it is up to the clinician's preference and choice of the screening tool to measure NAFLD, thus creating a selection bias amongst various studies. This discrepancy could be observed in the studies included in our meta-analysis as multiple screening modalities were used in different clinical settings, including HSI, FIB-4 scoring, CT scan of the liver, liver function tests, and liver biopsy among others.

A: In coronavirus disease 2019 (COVID-19) patients with and without non-alcoholic fatty liver disease/metabolic-associated fatty liver disease (NAFLD/MAFLD); B: In COVID-19 patients with and without NAFLD/MAFLD sensitivity analysis after excluding Madan *et al*[41]. CI: Confidence interval.

The presence of NAFLD confers additional susceptibility to COVID-19 infection in individuals exposed to SARS-CoV-2[63]. Pre-existing NAFLD at the time of COVID-19 diagnosis can be an indicator of increased severity of infection and utilization of health care services. As mentioned earlier, more than half of the individuals with type 2 diabetes mellitus (2nd most common comorbidity in COVID-19) have comorbid NAFLD to a certain degree[60]. Similarly, NAFLD is associated with multiple risk factors like cardiovascular diseases, obesity, and coexisting chronic lung disease which independently influences COVID-19 susceptibility and severity[61,64-68]. The impact of NAFLD on disease severity is seen through a blunted immune response to SARS-CoV-2 infection in COVID-19, leading to an increased risk of severe disease[30,13,47,55]. A retrospective observational study observed that ongoing inflammation in NAFLD puts patients with active COVID-19 infection at an increased risk of thromboembolism and associated mortality[51]. Various SARS-CoV-2 entry factors like angiotensin-converting enzyme (ACE), a disintegrin and metalloprotease 17, dipeptidyl peptidase 4, and transmembrane protease, serine 2 and NAFLD-related genes such as ACE, dipeptidyl peptidase 4, interleukin 10 (IL-10), tumor necrosis factor (TNF), and AKT1 as well as cytokine-mediated signaling, phosphoinositide 3 kinase-Akt, AMP-activated protein kinase, and mechanistic target of rapamycin signaling pathways have been identified which sheds light on the propensity for increased severity of illness in SARS-CoV-2 infected NAFLD patients. The spike protein of coronavirus has a high affinity for the receptor of ACE, which is found in the lung and the hepatobiliary cells. Furthermore, COVID-19 infection upregulates the expression of ACE receptors[69]. This leads to the hyperactivation of an immune cascade that damages the hepatocytes[70,71]. Chronic low-grade inflammatory state in individuals with NAFLD/MS creates a hypoxic environment for adipocytes leading to their dysfunction. This promotes the increased release of pro-inflammatory cytokines IL-6, IL-8, C-reactive protein, and TNF-α, and the recruitment of macrophages, B cells, and T cells. This effect is compounded by the systemic hyperactivation of the inflammatory cascade in active COVID-19 infection, which aggravates the ongoing inflammation of the hepatocytes, leading to decompensation of NAFLD and extensive hepatocyte damage[72]. Additionally, patients with NAFLD have insulin resistance, which further serves as a conducive ground for widespread inflammation[73,74].

Bramante *et al*[75] conducted a retrospective study that showed that with each additional year of having NAFLD/NASH the risk of hospitalization for COVID-19 increased. An assessment of the association between liver fibrosis scores and the clinical outcomes in patients with COVID-19 reported

DOI: 10.3748/wjg.v29.i21.3362 **Copyright** ©The Author(s) 2023.

Figure 5 Forest plot for need for supplemental oxygen utilization in coronavirus disease 2019 patients. A: In coronavirus disease 2019 (COVID-19) patients with and without non-alcoholic fatty liver disease/metabolic-associated fatty liver disease (NAFLD/MAFLD); B: In COVID-19 patients with and without NAFLD/MAFLD sensitivity analysis after excluding Shao *et al*[45]. CI: Confidence interval.

that a one-point score increase in FIB-4 was significantly associated with increased death, but not hospitalization. The authors also found that for every unit elevation in aspartate aminotransferase/alanine aminotransferase ratio, the risk of death increased by 178%[76]. Patients with higher FIB-4 > 2.67 scores had a higher risk of developing COVID-19[77]. Therefore, primary prevention is essential to control NAFLD during its development. Bramante *et al*[75] also showed that patients on prior treatments for NAFLD such as metformin and glucagon-like-peptide 1 receptor agonists had a reduced risk of hospitalization with the most significantly decreased risk from recent bariatric surgery. This highlights the importance of obesity as a cofactor to worse outcomes in COVID-19 patients and weight loss as the most significant contributing factor to improved outcomes in NAFLD[60]. Several studies found a higher incidence of obesity and NAFLD in patients hospitalized for COVID, which can also worsen disease severity[53,59,75]. This association may be confounded by the presence of obesity, which is an independent risk factor for COVID-19 severity. Previous studies reported odds ratios after adjusting for obesity and found statistically significant results in the association between NAFLD and COVID-19[77,78]. However, in a regression analysis, Li *et al*[79] observed that NAFLD independently does not affect the prognosis of severe COVID-19. Any association between NAFLD and COVID-19 is likely attributed to the confounding effect of obesity, measured in terms of body mass index, waist circumference, and hip circumference. Further studies with a larger sample size are needed to explain the varied results observed in these studies. Roca-Fernández *et al*[63] reported that higher liver fat percentages or evidence of liver fibro-inflammation, and features of NAFLD, increased the likelihood of symptomatic COVID-19. Interestingly, they found that obese patients with higher liver fat had a higher probability of having symptomatic COVID-19 compared to obese patients with normal liver fat. This is in favor of NAFLD being an independent risk factor for COVID-19 irrespective of obesity.

Strengths and limitations

We followed rigorous methodology, adhered to PRISMA guidelines, and registered our study in PROSPERO. Most of the studies were retrospective case-control and cohort studies which can be associated with the risk of bias, particularly in the absence of adjusting for confounders. NAFLD/MAFLD patients underlying medical conditions and co-morbidities that are components of MS can interfere with the outcomes studied. We excluded studies on NAFLD/MAFLD patients with other underlying causes for liver diseases including alcoholic liver disease. We understand there may be additional etiology for liver disease in patients that are underdiagnosed and may impact our study findings. The retrospective nature of most of the studies in our analysis does not imply a causal relationship between NAFLD/MAFLD and measured outcomes. We included studies that measured NAFLD/MAFLD using non-invasive procedures such as imaging and biomarker/lab diagnosis. Since they are not the gold standard for diagnosis, there may be misclassification of patients with and without NAFLD/MAFLD. The method of diagnosis of NAFLD/MAFLD varied across studies so, there may be

some misdiagnoses that can influence the results of the study. However, we included studies that compared absent or mild NAFLD/MAFLD to moderate or severe NAFLD/MAFLD to maintain homogeneity. We considered NAFLD/MAFLD patients in the same group, however, there may be important differences between these two groups that may alter the outcomes. We observed the per-study protocol in our meta-analysis. We detected significant differences in our study population for the various outcomes measured. However, there was statistical heterogeneity in our results that should be taken into consideration. We also excluded studies in a language other than English due to difficulty with translation and interpretation of results. This can introduce bias in our study results. The studies included in our meta-analysis were from 12 different countries with more studies from China and the United States, but we consider the results to be generalizable globally. However, since the studies were from different countries the level of care at each health institution may be different, which can lead to different levels of disease severity, disease progression, and death. Our study aims for hypothesis generation and further research in NAFLD/MAFLD patients to better understand the disease pathophysiology and patient risk profiles.

CONCLUSION

Our meta-analysis suggests that NAFLD/MAFLD patients appear to have higher rates of hospital admissions and longer in-hospital stays without any increase in mortality compared to non-NAFLD/MAFLD patients. Further research is needed to explore if fatty liver disease may be a risk factor that can lead to severe COVID-19 infection.

Implications for clinical practice

NAFLD/MAFLD are chronic pandemics rapidly on the rise. There is a lack of awareness and education among healthcare professionals and patients about its health impact, morbidity, and economic impact as they progress. There is a lack of systems/protocols in place to enforce the diagnosis of NAFLD globally and as a part of regular screening in primary care clinics, diabetic clinics, and routine health care visits. Propagation of information on NAFLD and involvement of international organizations, scientific societies, and the pharmaceutical industry to improve public health policies related to NAFLD. Patient education on NAFLD/MAFLD as a co-morbid risk factor for infectious diseases such as COVID-19 like other known risk factors such as hypertension, obesity, and diabetes, and measures to diagnose and treat NAFLD actively are needed.

Implication for research

Futures research on longitudinal prospective studies with larger numbers on NAFLD/MAFLD as a risk factor for COVID-19. Future studies should focus on genetics, immunology, and molecular epidemiology to better understand the mechanisms for poor outcomes in the NAFLD population.

ARTICLE HIGHLIGHTS

Research background

Non-alcoholic fatty liver disease (NAFLD) and its hepatic manifestation metabolic-associated fatty liver disease (MAFLD) have a rising prevalence worldwide. It is a co-morbidity like obesity, hypertension, and chronic kidney disease. NAFLD/MAFLD like obesity is considered chronic inflammatory states according to recent literature. Therefore, patients with NAFLD/MAFLD are hypothesized to have worse outcomes with coronavirus disease 2019 (COVID-19).

Research motivation

Existing literature shows conflicting information on the association of NAFLD/MAFLD in COVID-19 patients. Some studies show worse outcomes with NAFLD/MAFLD and COVID-19 infection. Some studies state it is not a risk factor for severe COVID-19. Understanding the pathophysiology and pathogenesis between fatty liver disease and COVID-19 is necessary for prevention, and management of NAFLD/MAFLD patients. Insight into this relationship will help further research and better preventative and nutritional management of these patients. It is imperative to explore the relationship of NAFLD/MAFLD with COVID-19 to improve patient care and treatment protocols for better outcomes.

Research objectives

In this meta-analysis, we investigated the association between NAFLD/MAFLD with the mortality and severity of COVID-19 infection.

Research methods

A systematic review of literature across five databases was done from January 2019 to June 2022. Observational studies were included. Studies that evaluated NAFLD/MAFLD using lab assessment/biomarker assessment, non-invasive imaging, or liver biopsy were included. We registered our study protocol in Prospero and followed the "PRISMA" guidelines (Figure 1). Meta-analysis was conducted on studies with outcomes for hospitalization, hospital length of stay, supplemental oxygen utilization, and mortality of COVID-19 infection outcomes using Rev Man version 5.3. To evaluate the validity of our studies the National Institutes of Health quality assessment tool was used. The stability of the results was assessed using sensitivity analysis.

Research results

A total of 43388 patients from thirty-two studies were included in the final analysis. There were 8538 (20%) with NAFLD/MAFLD. A total of 42475 patients from twenty-nine studies were included in the mortality analysis. There was an odds ratio of 1.36, a *P* value = 0.07 for mortality with COVID-19. A total of 5043 patients from eight studies were included in the hospital length of stay analysis. NAFLD patients spent a mean hospital stay of an additional about 2 d when compared to non-NAFLD. For hospitalization rates, the odds ratio is 3.25 and a *P* value = 0.0002. For supplemental oxygen utilization, the odds ratio was 2.04 with a *P* value = 0.01. Our meta-analysis was able to show that there is an association between NAFLD/MAFLD and COVID-19. Our study aims to increase awareness that NAFLD/MAFLD may be a potential risk factor for severe outcomes in infections. More research is needed to better explain the relationship and the pathophysiology behind it.

Research conclusions

This systematic review and meta-analysis of observational studies suggests that NAFLD/MAFLD patients had higher odds of developing severe forms of COVID-19 in comparison to non-NAFLD patients. Further research to understand the causality and strength of this relationship is needed.

Research perspectives

This review was not able to clarify why the association between NAFLD/MAFLD and COVID-19 was seen. Large size prospective studies with balanced confounding factors are necessary. Since the global burden of NAFLD/MAFLD is rapidly rising, understanding genetics and immunological mechanisms will help advance treatment and prevention strategies.

Abstract

Publication in a peer-reviewed journal is the goal of any research project. One of the most important (and possibly the least understood) aspects of the publication process is the choice of a suitable journal that is likely to accept your work. Detailed information and tips and tricks to success are given in this editorial.

Key Words: Research; Journal; Altmetrics; Publication

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Knowing the tips and tricks to choose the best journal for publishing your research is crucial. A narrative check list including all these tricks has been performed.

INTRODUCTION

Publication in a peer-reviewed journal is the goal of any research project. It is through publication that your research reaches your colleagues in the field, advancing knowledge and encouraging communication between groups[1]. Although peer review can be a time-consuming and often tiring process, the publication of your manuscript validates your work and can help to advance your career, attract students and experienced staff, and obtain funding for future studies[1]. One of the most important (and possibly the least understood) aspects of the publication process is the choice of a suitable journal that is likely to accept your work[2,3]. Submitting your paper to the wrong journal may result in a series of rejections, stalling both your

research and your career[1,2,4].

Realistic assessment of your work is crucial. Both novice and well-known researchers can make the error of submitting their work to an inappropriate journal[1]. First-time authors or those who are branching out into broader areas of research may be unfamiliar with the journals in the field. In these cases, seeking out mentorship could be crucial[5]. For their part, experienced authors may be tempted to publish in the same journals as always, and thus ignore the new publication opportunities that are constantly arising. Even rigorous, high-impact work may be rejected when the topic of the research does not align with the scope of the journal and making this mistake wastes time and money and affects motivation[1] (Table 1).

EVALUATE YOUR RESEARCH

The three key features of your work to consider are its novelty, relevance, and appeal[2]. "Novelty" refers to how new your findings are compared with those previously published in your field. If your findings only offer a small step forward in what is already known, your paper is suitable for a journal with a low-to-medium impact factor (IF). However, if you feel your findings might change the way researchers in your field think about a specific topic, you should aim at a high impact factor journal[2]. "Relevance" refers to the applicability of your findings. Relevance may be geographical[2]: That is to say, if your findings with only a regional focus, choose a regional journal, but if they have worldwide implications, choose an international journal. Or relevance might be disciplinary: If your findings are highly specific for your field, choose a specialized journal, but if they have implications for researchers in other fields, choose a more general or interdisciplinary journal[2,5]. Finally, "appeal" refers to the topical interest of your study: journal editors are keen on manuscripts on current hot topics or with real-world applications[2].

You should also narrow your focus with regard to your expected readership[2,6]. The main questions to answer are the following. Is your study clinical or basic? Are the findings relevant to a broad cross-section of the scientific community, or to researchers in a specialist field? Are the findings preliminary or definitive? And finally, if you collect more data, could you try a journal with a higher IF[2]?

IDENTIFYING THE RIGHT JOURNAL

It is best to choose your journal before you start writing[2,3]. The reasons are that journals have specific criteria related to the manuscript structure, word limits, and reference style; they have specific focuses, or scopes; and editors will often look at your references to see whether you have cited articles published in their journal[2]. So, once you have chosen a journal, identify articles published there that have a bearing on your manuscript and include them among your references.

A tip for how choosing the journal is to perform a search with the keywords (or title) of your manuscript in literature databases such as Medline and PubMed. This search can identify similar or related studies and the journals where they were published[6]. Try to find between three and five manuscripts published in the last five years and decide whether they resemble yours in terms of quality and scope[7]. Identifying previously published papers in your specific subject area is an excellent way to be sure that your research topic is of interest to the readership of a particular journal, and this will obviously increase your chances of review.

There are also a variety of online resources that suggest target journals based on keywords, abstract content and so on: Journal/Author Name Estimator (Jane)®, Manuscript Matcher®, and JournalGuide® (Clarivate), *etc*. But remember that journals that have not previously published in the same area of research might also be interested in your findings.

FACTORS TO CONSIDER IN SELECTING THE BEST JOURNAL

Impact factor

IF is still the default method to assess the quality and reputation of a journal[7]. It displays the total citations made of the journal's articles[7]. IF is the most important factor that researchers consider when they submit a paper, and it is often used as a measure of a researcher's success in his/her field[2,6]. Funding agencies, Institutions, employers, and university committees also consider IF the best method to evaluate a paper[2,6,7]. Journals with higher IF often have a higher profile, and this obviously will increase your article's visibility[4,6].

Nonetheless, the validity of the Journal IF as a metric for journal quality is controversial due to the many factors that can influence the rating achieved, and to the fact that not all these factors are directly related to the quality of the publications within the journal[3]. Although it is tempting to submit a manuscript to the journal with the highest IF factor, it is important to evaluate your research objectively

Table 1 Tips and tricks for selecting best journal

Item	Description
Evaluate your research	Novelty, relevance, and appeal
Identifying the right journal	
Factors to consider in selecting the best journal	Impact factor
	Aims and scope
	Publication types
	Publication mode and rights: Type of publication; supplementary materials/media and relevant links; type of subscription; open access; and copyright
	Publication charges
	Publication frequency
	Time from acceptance to publication
	Rejection rates
	Readership
	Indexing
	Editor's preferences
	Peer-review
	Transfer cascades
	Journal reputation

and decide whether it is truly suitable for a high IF journal. Otherwise, you will risk wasting valuable time and effort as you submit your manuscript time and again to multiple journals[1].

Other scores are: Scimago Journal Rank, Eigenfactor, SNIP, Cited Halflife, Altmetric Attention Score, and Cited Score, *etc*[3,5,8].

Aims and scope

Even remarkable research may be rejected if the topic is not in line with the scope of the journal[2,6,7]. This information is usually readily available on the journal's homepage[3,6,7]. Check to see whether the journal is publishing research like yours[5,7,9]. The topics, the focus and the novelty and potential impact are all important factors[7].

Publication types

Find out which article types (*e.g.*, originals, reviews, systematic reviews, metanalysis, case reports, images, and so on) are accepted and which are not; limits on length (word count) or number of illustrations or references; whether supplementary files are allowed, or the prior inclusion of a preprint (unsubmitted draft) in a preprint server such as arXiv or bioRxiv[1-3,7,9]. Submission to a journal that does not accept the type of article you have written is a sure way of guaranteeing immediate rejection. Please read the guide to authors carefully and follow the instructions closely[1,7,9]. The abstract and cover letter are your way of presenting yourself to the Editor: Take your time over them.

To avoid initial rejection, the registration of research in international databases (ClinicalTrials, Research Registry, PROSPERO, *etc*) is often mandatory. The inclusion of a reporting Checklist, depending on the type of manuscript (*e.g.*, STROBE, PRISMA, and so on) is normally required. You should check this before sending your manuscript.

Publication mode and rights

You should be familiar with the journal's characteristics: Type of publication: print only, print plus online version (PDF), which may be a longer version, with or without early view ("early online", "online first", or "ahead of print") version, or only online version, which is becoming the most usual type[9].

Supplementary materials/media and relevant links: Many journals have links to supplementary materials in an online repository[2].

Type of subscription: Membership-based, pay per view, site license, subscription, or open access.

Open access

Open access means that the entire content of the paper is freely available to all readers, with no need to subscribe to a journal or pay to access the paper[6]. Many researchers prefer this publication model because it can help disseminate their research to a wider audience[2,6]. There is no doubt that increasing the accessibility of your article will ensure that your target audience will have access to your article worldwide, but expenses are high. There are three formats:

Green open access: which means free access to preprint or accepted manuscript (final draft) on a personal website, institutional website, or nonprofit repository such as Pubmed®, with or without a time delay before uploading; in most cases the copyright will be retained by the publisher[6].

Gold open access: free access to the final published version (typically on the publisher's website), and authors retain copyright[6]. Gold open access gives you ownership of your work after publication and ensures that the most accurate, final form of the paper is available to all readers[6].

Hybrid open access: (some content is open access, and some is subscription-based; this can depend on authors' choice or on journal policy, which may include "delayed open access".

Copyright

It may be owned by the author or the journal publisher. Another important issue is whether a Creative Commons license is available.

Publication charges

Publication charges are the fees that you will be charged to publish in a journal[6]. It is essential to read the section about charges very carefully[2]. If you are on a tight Article budget, you may need to rule out open access journals or journals with high publication charges. There are several types of charge: Submission fee, production fee and charges for color figures (usually black and white images do not incur charges)[2]. Find out whether there are free batches of reprints or online copies, and free online access for authors to published articles. Some editorials waive article processing charges to authors from developing countries for open access publication.

Find out whether the following services are provided free or included in the publication charge: Editing/illustration service; news release service; marketing; social media promotion; post-publication commenting and altmetrics (article-level metrics) tracking.

Publication frequency

Check the journal's table of contents for the number of monthly/weekly articles, articles per issue and issues per year, and how often articles appear in the journal's Online First section[2,7].

Time from acceptance to publication

There are several publication times: From submission to first/final decision, first online publication, final (online) publication. If you need rapid publication, you should specifically look for journals that offer fast response times and short periods from acceptance to publication[2].

The normal time taken for a good manuscript to be published in a reputed journal is around 9 mo to 12 mo. The optimum time limit for rejection is 4-6 wk[7]. The best time is to wait for the special editions from reputed journals and then submit a relevant paper: due to the smaller number of research papers submitted at that time, your research stands a better chance of being published[7].

Rejection rates

It is important to know the selectivity (% acceptance rate) of the journal[2]. The acceptance rate in poor journals is over 90%, while predatory journals publish almost everything, they can lay their hands on. In good journals the acceptance rate is 10%-20%[7,9].

Readership

Identify the interests of the readers[2,3] Be sure that the target audience you are trying to reach is part of the readership of the journal. Your goal is not just to be published, but also to be widely read in your field. Review the "Most Downloaded" or "Most Cited" lists from your potential journals. If you find that your manuscript is similar in scope to articles in this list from one of your potential journals, this suggests that if you publish in this journal your article will be widely read as well.

Indexing

To increase the online visibility of your article, be sure that the journal is indexed in the online databases that your target audience will use to find articles. PubMed® and Scopus® are the main indexing services used by researchers in the biomedical sciences[2,6].

Editor's preferences

It is also very useful to identify the interests of the journal's editor. Just because your manuscript may be similar in scope to the journal, this does not mean that the Editor is currently interested in your topic. Check when similar articles were published in the journal. If similar articles have been published within the last two or three years, this suggests that the Editor is probably interested in your topic. Look at recently published Editorials, Review Articles, and Special Issues, because these usually focus on topics the Editor feels are currently important for the field. If you find that your manuscript is similar in scope to others published by one of your potential journals, this suggests that the Editor may regard your research topic as important.

Peer-review

Articles published in peer-reviewed journals enjoy high esteem among the academic and scientific community[6,7,9]. The quality of the reviewers is also a crucial factor[9]. There are several types of peer-review: The most common is a closed (single- or double-blind) review, but open peer-review is also performed. Other types of review are collaborative (in which reviewers may discuss issues with each other, or reviewers/editors may discuss specific points with the authors) and transparent (in which reviews are published with or without reviewers' names). As for the speed of peer review, you should find out whether fast-track review and pre-submission inquiries are allowed. Journals with very short review times (1-2 wk) are often poor quality (though bear in mind that there are also some top journals with very short review times).

Transfer cascades

One feature of scientific publishing that many researchers are unaware of is the existence of "families" or portfolios of journals inside the same publishing house. Many portfolios with prestigious journals that receive a high volume of submissions also contain less competitive journals that publish papers on the same or similar topics. In many cases, if a publisher with this type of portfolio rejects your paper from a high IF journal, they may offer to transfer it to a lower IF journal inside the same "family". This can help accelerate the overall publication process by avoiding the need to identify a new journal, reformat the paper and prepare a new submission[6]. Bear in mind that some transfer cascades direct you to journals with publication charges.

Journal reputation

Remember that publishing in poor quality journals does not count as scientific contribution to knowledge. Avoid sending work to predatory journals, as this is a waste of time and effort[3,7]. There are many points to check in order to ensure the quality of the journal before sending your manuscript [2]: Are the journal/publisher, editor and editorial board well known? Is the journal affiliated to a professional society? Is the journal recommended by your library/society? Do your colleagues read the journal, or have they been cited there, or have they published there? Is the journal known for ethics, quality content, language, and production? Is the journal included in respected general or specific indexes, with a long history and a permanent online archive[7]? What are the journal's bibliometric scores (IF)? How old is the journal (those aged 10 years or more are often good)?

CONCLUSION

After all the hard work that goes into performing successful research, the final crucial step is choosing the right journal in which to publish. With almost 10000 journals in the Directory of Open Access Journals alone, choosing the best journal can be a daunting prospect even for experienced researchers, and making the wrong decision can cost valuable time, money, and effort. Key factors are being aware of the aims and scope of the journal; identifying papers that are similar in quality and scope; assessing the journal's restrictions; and considering the impact factor and potential reach. Despite the existence of support platforms, the development of artificial intelligence platforms may help us to decide the best journal for our research. Items like specific area, number of patients included, clinical relevance and innovation may well be able to identify the most interesting journal.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Wolfgang Kreisel,MD, Emeritus Professor, Department of Medicine II, Gastroenterology, Hepatology, Endocrinology, and Infectious Diseases, Faculty of Medicine, Medical Center-University of Freiburg, Hugstetter Str. 55, Freiburg 79106, Germany.Wolfgang.Kreisel@uniklinik-freiburg.de

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJG* as 5.374; IF without journal self cites: 5.187; 5-year IF: 5.715; Journal Citation Indicator: 0.84; Ranking: 31 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.1 and Scopus CiteScore rank 2021: Gastroenterology is 18/149.

Abstract

Clostridioides difficile (formerly called *Clostridium difficile*, *C. difficile*) infection (CDI) is listed as an urgent threat on the 2019 antibiotic resistance threats report in the United States by the Centers for Disease Control and Prevention. Early detection and appropriate disease management appear to be essential. Meanwhile, although the majority of cases are hospital-acquired CDI, community-acquired CDI cases are also on the rise, and this vulnerability is not limited to immunocompromised patients. Gastrointestinal treatments and/or gastrointestinal tract surgeries may be required for patients diagnosed with digestive diseases. Such treatments could suppress or interfere with the patient's immune system and disrupt gut flora homeostasis, creating a suitable microecosystem for *C. difficile* overgrowth. Currently, stool-based non-invasive screening is the first-line approach to CDI

diagnosis, but the accuracy is varied due to different clinical microbiology detection methods; therefore, improving reliability is clearly required. In this review, we briefly summarised the life cycle and toxicity of *C. difficile*, and we examined existing diagnostic approaches with an emphasis on novel biomarkers such as microRNAs. These biomarkers can be easily detected through non-invasive liquid biopsy and can yield crucial information about ongoing pathological phenomena, particularly in CDI.

Key Words: *Clostridioides difficile*; microRNA; Diagnostic; Prognostic; Biomarker

INTRODUCTION

Clostridioides difficile (formerly called *Clostridium difficile*, *C. difficile*) infection (CDI) was classified as an urgent threat in the 2019 antibiotic resistance report in the United States by the Centers for Disease Control and Prevention. Early detection and disease management are urgently needed to reduce public health spending[1]. In addition, of those infected with a medically-related CDI, 1 in 11 people over the age of 65 dies within a month[2]. The acute inflammation caused by the bacteria triggers cytokine production, neutrophil recruitment, mucosal permeability and fluid secretion, leading to colonic tissue damage, nasal diarrhoea and colitis[3,4], which is similar to inflammatory bowel disease[5].

Presently, although most cases are hospital-acquired CDI, community-acquired CDI cases are rising in frequency[6]. Exposure to *C. difficile* in the community might come from various factors, including pets, water, soil, livestock, farms, food processing and production[7]. Previous studies focused on the hospitalisation length and indicated that environmental exposure to animals would be associated with a greater possibility of *C. difficile* colonisation[8]. A population-based study in India found that the composition of the gut microbiota was primarily associated with several geographical factors rather than body mass index and that these changes extended to circulating immunometabolic profiles such as serum N-glycans, immunoglobulins and short-chain fatty acid profiles[9]. These factors may also affect the infection rate.

Once patients have been diagnosed with digestive diseases, gastrointestinal treatments, including gastric-acid suppressing agents, broad-spectrum antibiotics, chemotherapy and/or gastrointestinal tract surgery may be required[10,11]. Such therapies could suppress or interfere with the patient's immune system and disrupt gut flora homeostasis, creating a suitable microecosystem for *C. difficile* overgrowth [12]. Antibiotics such as metronidazole, vancomycin and fidaxomicin have been approved for treatment of patients with CDI, while *C. difficile* strains resistant to various antibiotics have been reported that do not respond to the treatments[13-15]. Faecal microbiota transplantation (FMT) is an alternative treatment strategy for CDI patients; however, it is still in clinical trials because of the treatment safety concern[16].

To date, there are several diagnostic methods for CDI in medical laboratories. However, due to technical limitations and the difficulty of distinguishing symptomatic infections from asymptomatic *C. difficile* colonisation, the accuracy and turnaround time of the test varies[17]. As a result, searching for better tools may increase the accuracy of the detection. In this light, microRNA (miRNA) expression profiling can be helpful for prognosis and diagnosis.

This article reviewed this proposition by briefly presenting the *C. difficile* life cycle and describing the toxins produced. We then described the current laboratory-based diagnostic tools for CDI patient screening. We discussed the potential use of miRNA to monitor and improve the management of CDI patients.

C. DIFFICILE LIFE CYCLE AND TOXINS

C. difficile is a Gram-positive, anaerobic bacterium belonging to the phylum Firmicutes. There are three main stages that define the *C. difficile* life cycle: spore formation; germination; and growth (vegetative). At the spore stage (dormant phase), it is typically harmless in a balanced gut flora microenvironment. *C. difficile* can resist oxygen, heat and many other environmental insults, including ethanol-based disinfectants (Figure 1)[18].

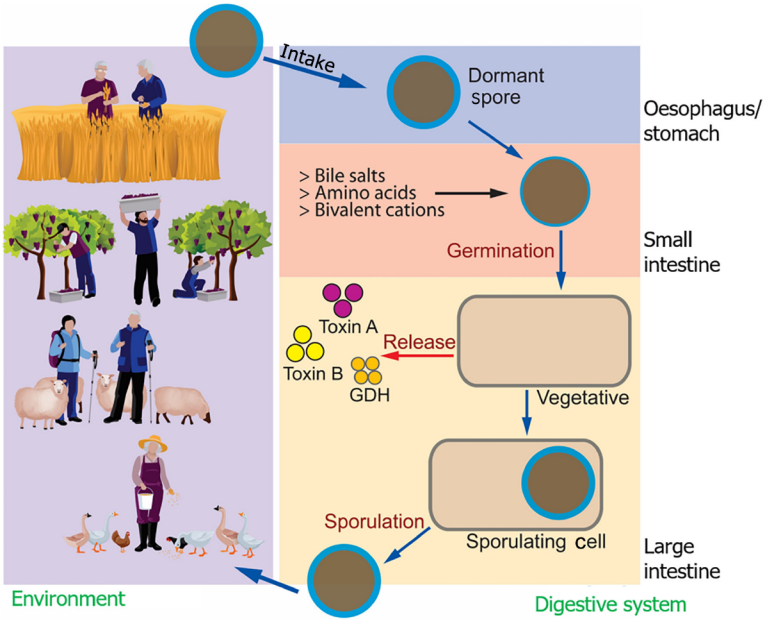
Once set in a stable environment, spores germinate rapidly and produce two major toxins, toxin A and toxin B encoded by *TcdA* and *TcdB*, which are located at the 19.6 kbp long pathogenicity locus region (Figure 2)[19]. Toxin A and toxin B trigger cytosol translocation of target host cells and inactivate small GTP-binding proteins (such as CDC42, Rho and Rac) through monoglucosylation, leading to actin condensation, cytoskeleton disintegration, cell rounding and apoptosis[20]. tcdR is an RNA polymerase sigma factor that initiates tcdA and tcdB translation *via* its two tandem promoters[21,22] and is involved in the final stages of flagellar assembly[23]. Some *C. difficile* strains, such as ribotype 027 and ribotype 078 are able to produce *C. difficile* transferase toxin, an actin-specific ADP-ribosyltransferase homologous to iota-toxin from *Clostridium perfringens* and *Clostridium spiroforme* toxin, and potentially enhances *C. difficile* virulence and disease severity[24,25].

CURRENT DIAGNOSTIC TOOLS FOR IDENTIFYING PATIENTS WITH *C. DIFFICILE* INFECTION

Similar to colorectal cancer screening, CDI can be detected by examining the colon through flexible sigmoidoscopy or colonoscopy to look for pseudomembranes and inflamed areas. X-ray abdominal imaging or computerised tomography scan can also be applied on a case-by-case basis. In addition to the invasive approaches, the cost effective, non-invasive faecal-based screening is the first-line approach for CDI diagnosis. Still, it varies widely due to different clinical microbiology methods and their different accuracy and variance[26,27]. These methods include cell cytotoxicity neutralisation assay, toxigenic culture (TC), enzyme immunoassay (EIAs) [including toxins and glutamate dehydrogenase (GDH)] and nucleic acid amplification test (NAAT) and each of the methods has advantages and disadvantages in terms of turn-around time and the screening performance (Table 1).

Cell cytotoxicity neutralisation assay and C. difficile culture

The cell cytotoxicity neutralisation assay is the first-line faecal-based diagnostic test for CDI[28,29]. It requires multiple steps in order to isolate *C. difficile* toxins from faeces and at least 24 h of cell culture (mainly human fibroblasts). The cytopathic effect is characterised by rounding and morphologic changes of the cultured cells[29,30], and the phenomena must also be reverted by *C. difficile* or *Clostridium sordellii* anti-toxin used as a control to prove that the cytopathic effect is not related to nonspecific substances in the faeces. In contrast, toxigenic culture requires faeces inoculation to selective cycloserine-cefoxitin-fructose, chromogenic or similar agar plates for a specific incubation period; suspicious colonies are selected for further bacteria culture and/or *C. difficile* toxin test to confirm the finding (Figure 3)[31-33]. It is important to remember that there is no standard to eliminate or reduce nonspecific bacteria colonisation from *C. difficile* culture. Heat shock and alcohol shock are the traditional preculture approaches, while a culture media containing bacteria "suppressors" such as antibiotics may also be applied[34-38]. Both culture-based assays are time-consuming, labour-intensive and require a certain level of laboratory skill. As such, it is unlikely to be used for first-line clinical screening and is commonly used as the reference method for research and outbreak investigations, even though it is considered the gold standard[31,32,38].



Nucleic acid-based detection assays

The nucleic acid amplification test is a quantitative real-time (qRT)-PCR-based diagnostic assay able to rapidly detect *C. difficile* toxin genes such as *tcdA, tcdB, tcdBv, cdt* and/or *tcdC*Δ117 at the DNA level. There is a wide range of United States Food and Drug Administration-approved detection assays, from *C. difficile* specific point-of-care testing to high-volume, high-throughput multiple gastrointestinal pathogens laboratory tests. The majority of PCR detection approaches for *C. difficile* screening are probe-based qRT-PCR (Table 2). The use of probes increases amplification specificity during the PCR cycle since the additional sequence of the probe is specific for and binds to the *C. difficile* DNA sequence. Additionally, it is possible to perform multiplex qRT-PCR by using different fluorescent dyes[39]. The

Table 1 Summary of *Clostridioides difficile* diagnostic tests

Test	Abbreviation	Sensitivity	Specificity	Turn-around time	Target substance
Culture-based					
Cell cytotoxicity neutralisation assay	CCTN	High	High	< 24 h	Toxins
Toxigenic culture	TC	High	Low[1]	> 3 d	*C. difficile* vegetative cells or spores
DNA-based

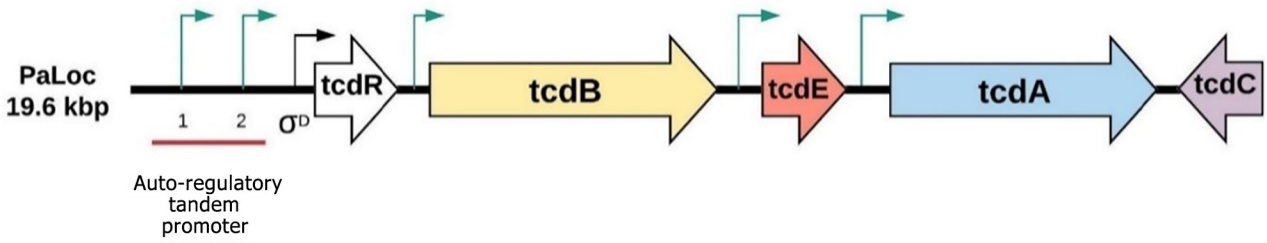
Figure 1 *Clostridioides difficile* life cycle. *Clostridioides difficile* (*C. difficile*) can be found in soil and is transmitted to humans (as well as animals) through different daily activities. Besides hospital-acquired *C. difficile* infections, community-acquired *C. difficile* infections are also known, with agriculture being one of the main sources, from the spore stage into the human digestive system. Once stable, *C. difficile* may repopulate and release toxins that can affect intestinal health. *C. difficile* may go back to the environment and repeat the life cycle. GDH: Glutamate dehydrogenase.

nucleic acid-based *C. difficile* toxin screening has over ten times higher sensitivity than a cytotoxin assay [40,41], but the screening specificity is relatively low due to high false positive cases from asymptomatic infection. As a result, optimisation is required, especially on PCR threshold cycle settings[42,43]. In addition, patient preselection based on clinical symptoms and intestinal inflammation biomarkers (*i.e.* faecal calprotectin, lactoferrin and cytokines) appears to be necessary to reduce the risk of a false positive[27,43-47].

Toxins and GDH EIA



EIAs utilise antibodies to detect the presence of antigens. It is still relatively common to detect toxin A, toxin B and/or GDH in faeces for CDI. There are several types of EIAs available for CDI, including microplates (enzyme-linked immunosorbent assay), membrane EIA, chemiluminescence immunoassay, enzyme-linked fluorescent assay and chromatographic immunoassay (Table 3). A meta-analysis

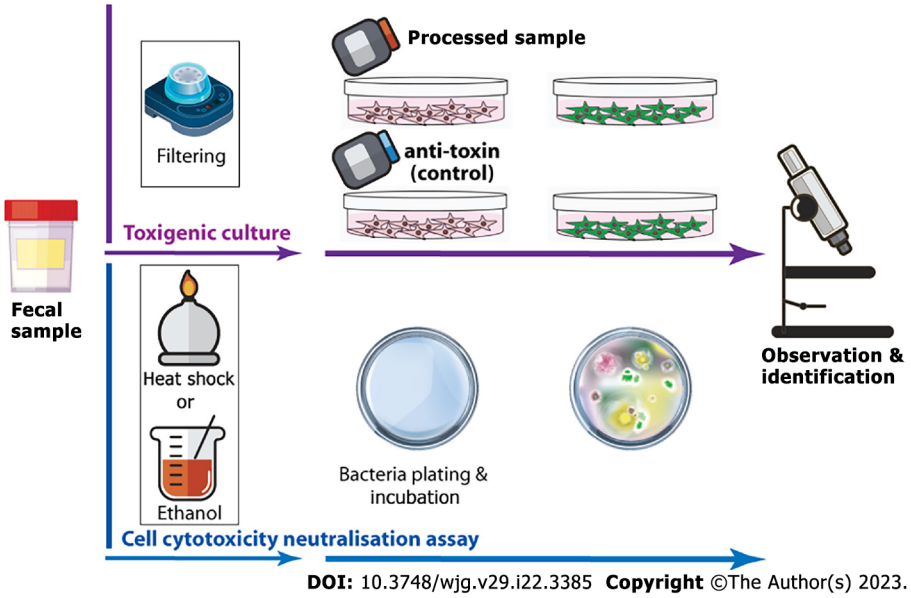

Figure 3 Idealised summary of toxigenic culture and cell cytotoxicity neutralisation assay for *Clostridioides difficile* infection identification. In toxigenic culture, the faecal sample is first exposed to heat shock or alcohol shock to kill *Clostridioides difficile* (*C. difficile*) and other microorganisms, and heat/alcohol resistant spores of *C. difficile* survive. The sample is then plated on selective agar and incubated anaerobically at 37 °C for at least 48 h to observe and confirm the colonisation of *C. difficile*. For the cell cytotoxicity neutralisation assay, the faecal sample is filtered and added to a toxin-sensitive cell line with/without antiserum. After 24-48 h of incubation, the cytopathological effect is then examined microscopically.

respectively, at a specificity of 99%[48]. This may be because these EIAs were developed in the early 21st century and are less sensitive to low toxin(s) levels, and immunocompromised CDI patients have a lower concentration trigger point[49]. This meta-analysis also indicated that GDH detection had a range

of 94% (95%CI: 86%-97%) for sensitivity and 96% (95%CI: 92%-98%) for specificity compared to toxigenic bacterial culture and cell culture cytotoxicity assay together[48]. However, a few studies reported sensitivities below 90% for GDH assays[38,50,51]. Due to the known limitations and relatively poor accuracy, stand-alone toxin or GDH EIA tests are not recommended by professional medical societies, including the European Society of Clinical Microbiology and Infectious Diseases and the Infectious Diseases Society of America[27,48,52].

As a result, several multiple-step diagnostic algorithms have been proposed to improve assay performance and detection accuracy. For example, a two-step algorithm initially detects GDH, and positive GDH cases are followed up with a toxin A and/or toxin B immunoassay. If the toxin immunoassay result is negative, a bacterial culture will be performed[53]. In addition, new protein-based assays such as lateral flow assay are under development and may potentially yield a result in 15 min[54].

MIRNA DYSREGULATION AND *C. DIFFICILE* INFECTION DETECTION AND MONITORING POTENTIAL

miRNAs are small single-stranded endogenous RNA molecules that are key regulators of gene expression and silencing at the post-transcriptional level. miRNA complex biosynthesis begins in the nucleus where primary miRNAs are produced by transcription of miRNAs from DNA sequences or miRNA genes. Precursor miRNAs are transcripts of approximately 60-110 nucleotides in length with a shorter stem-loop structure, produced from primary miRNAs by RNase type III enzymes (DROSHA) and undergo several maturation processes inside and outside the nucleus to form mature miRNAs, which are transported into the cytoplasm[55].

The stability of miRNA-specific target mRNAs is disturbed when RNA-induced silencing complexes possess loaded miRNAs. A portion of the miRNA, the seed sequence, which is two to eight nucleotides long, pairs with a specific sequence on the target mRNA and is referred to as an miRNA response element that results in translational repression and degradation of the target mRNA due to the binding of miRNAs in the 3′ untranslated region. miRNAs primarily repress genes by inhibiting protein synthesis, preventing elongation and ribosome decline and disrupting mRNAs through the processes of demethylation and decap, resulting in their degradation[56].

miRNAs have the potential to act *via* molecular mechanisms at every step of CDI, inhibiting specific transcripts or inflammatory molecule transcription, thereby influencing the pathology grade. The imbalance of these biomarkers can be measured and exploited for diagnosis, coupled with standard methods to strengthen the results. In particular, miRNAs are easily detectable (through sequencing, RT-qPCR, *etc*) in body fluids such as saliva, blood and even faecal material, and their levels correlate with target transcript alterations or non-physiological events[57]. These biomarkers are contributing increasingly to the establishment of less invasive "liquid biopsies," which is important and appealing for patient compliance compared to normal, invasive biopsies that require a long time for results. Although, it cannot fully substitute canonical diagnosis methods in most cases currently, it will undoubtedly happen in the near future.

Numerous studies have shown that miRNAs can be used to detect diseases and for their management. This may apply to patients with CDI. However, studies of the relationship between CDI and host miRNA are limited. To the best of our knowledge, the first reported study utilised C57BL/6J wild-type mice with a CDI model and identified the induction of mmu-miR-146b, mmu-miR-1940 and mmu-miR-1298 expression and upregulated proinflammatory cytokine expression, such as monocyte chemoattractant protein-1, interleukin (IL)-6, IL-17 and IL-1β in colonic tissues[58]. The authors also showed that the miR-146b potentially targets nuclear receptor co-activator 4 (NCOA4), *CD36* and *GLUT4* mRNA expression levels were downregulated. *In silico* simulation predicts upregulation of mmu-miR-146b and IL-17 resulting in the downregulation of *NCOA4* and peroxisome proliferator-activated receptor gamma (*PPAR-γ*) in the CDI mice model. Null mice silenced for *PPAR-γ* in T cells following CDI presented more severe colonic disease activity, inflammatory lesions and inflammatory cytokine expression[58]. There is also a filed patent claiming that miR-27a-5p could modulate the inflammatory response induced by CDI[59]. The inventors claim that miR-27a-5p can be linked to a matrix and delivered by vectors and/or incorporated into particles. The miR-27a-5p-linked particle could be administered to infected subjects for the treatment[59]. In faeces, a small-scale study with only 8 CDI participants demonstrated that a higher level of faecal hsa-miR-1246 was found in human CDI patients compared to the control group[60].

FMT has been proven in the treatment of recurrent CDI[61,62]. It is intended to restore colonic microbiota through introducing "healthy" bacteria *via* colonoscopy, enema or oral capsules that contain bacteria in a powder form. However, the safety concerns of FMT could be an obstacle to extending the application as a regular treatment strategy[63,64]. To monitor treatment conditions, detecting a panel of miRNA markers in circulation could help physicians make a more accurate decision[65,66]. Another study showed that 71 different circulating miRNAs were found to be expressed in 126 sera from 42 patients at 4 wk and 12 wk after FMT treatment[65]. The authors used qRT-PCR and 3′ untranslated

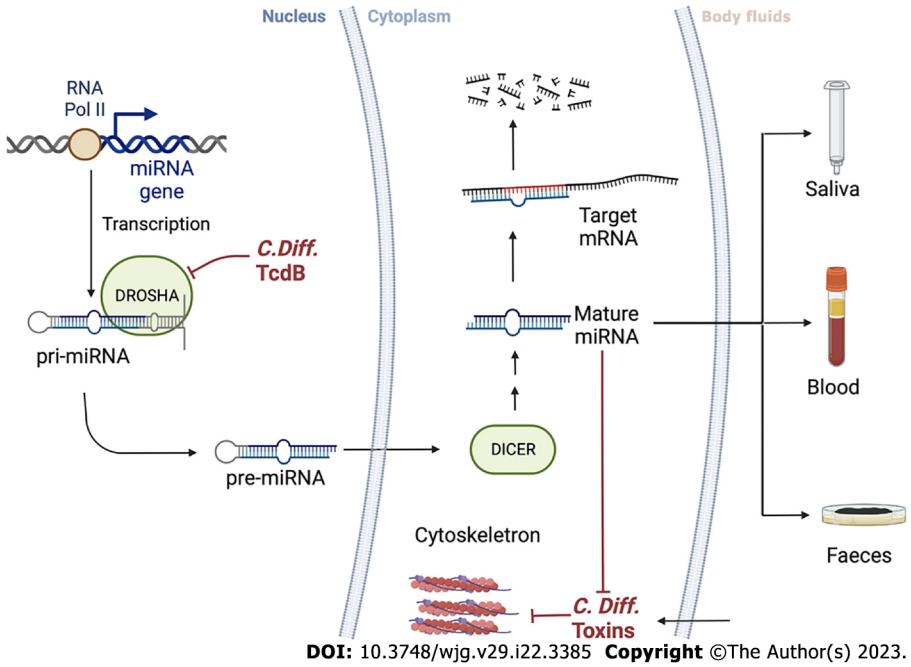

Figure 4 *Clostridioides difficile* and microRNAs cross-interact inside the cells. microRNA (miRNA) is a small single-stranded RNA that plays a key role in gene expression regulation. It starts in the cell nucleus, where primary miRNAs are produced by RNA Pol II through miRNA transcription from DNA sequences or miRNA genes. Precursor miRNA, around 60-110 nucleotides long transcripts with a shorter stem-loop structure, are produced from primary miRNAs by RNase type III (DROSHA) enzyme with several maturation processes and is then transported to the cytoplasm *via* DICER. Toxin B from *Clostridioides difficile* may interfere with DROSHA function. A fraction of miRNA binding specific sequences (2-8 nucleotides long) can pair with miRNA response elements in the 3' untranslated region of the target mRNA, causing translational repression and degradation of the target mRNA. Thus, miRNA expression patterns can indicate non-physiological events such as *Clostridioides difficile* infection. By detecting changes in miRNA patterns in body fluids, such as saliva, blood, and stool, the screening accuracy can be improved. miRNA: microRNA; pri-miRNA: Primary miRNA; pre-miRNA: Precursor miRNA; *C. difficile*: *Clostridioides difficile*.

region luciferase reporter assays to validate the top miRNA candidates and confirmed that hsa-miR-23a-3p, hsa-miR-150-5p, hsa-miR-26b-5p and hsa-miR-28-5p expression levels inversely correlated with the sera protein and cell-free circulating mRNA on several inflammation-related biomarkers, such as IL-12B, IL-18, FGF21 and TNFRSF9[65].

In a mouse model of relapsing CDI, qRT-PCR analyses of faecal and sera RNA extracts revealed inhibition of these miRNAs, while the FMT treatment enabled the recovery of their inhibitory effect. This study also showed that toxin B (TcdB) mediates the inhibitory effect of CDI on miRNA *via* DROSHA, based on the human colonoids and the mice colon models, where miR-23a and miR-150 were used to demonstrate the cytoprotective effects against TcdB[65]. A small, in-depth phenomics study of four adults treated with sequential FMT for severe or fulminant CDI found that miR-451a and miR-16 from the serum samples were upregulated in the responders *vs* the non-responders on average across all timepoints[66].

Using miRNAs as a diagnostic tool for CDI presents both opportunities and challenges. On one hand, as miRNAs play a role in controlling and influencing gene expression, changes in their activity and expression levels can be associated with different pathological events. This makes miRNA expression patterns a potentially powerful diagnostic tool, with the potential for use in therapeutic applications. Monitoring the response to FMT with miRNA can be an additional indicator for personalised treatment, and miRNA detection from non-invasive sources, such as blood, faeces, urine and saliva, can provide convenient and longitudinal measurements of miRNA levels for CDI. On the other hand, the fact that miRNA can be derived from blood cells released by different pathological events makes detecting CDI specifically a challenging task. Therefore, the use of miRNAs as a diagnostic tool for CDI requires further research and validation. Figure 4 provides a schematic summary of the intracellular mechanisms discussed and the potential use of miRNA profiling from a variety of body fluids, such as liquid biopsies, for diagnostic purposes as demonstrated in various research studies related to colorectal cancer screening[67-69].

CONCLUSION

To date, current laboratory-based CDI assays have varied in their detection accuracy. The expression of miRNAs has become increasingly important as novel biomarkers for assessment. The different signature profiles obtained through the differential expression of these small non-coding RNAs are essential for

early diagnosis and prediction of therapeutic response and disease management, these are also including cancer and infection. Notably, this can be accomplished by using liquid biopsy, enabling a non-invasive and low-cost screening approach. This approach may also be used to detect *C. difficile* infections, while further research and validation are clearly needed. These reported miRNA studies can be used in conjunction with current diagnostic tools to improve diagnostic accuracy aiding in patient management for both symptomatic and asymptomatic CDI patients.

Abstract

Small intestinal bacterial overgrowth (SIBO) is defined as an increase in the bacterial content of the small intestine above normal values. The presence of SIBO is detected in 33.8% of patients with gastroenterological complaints who underwent a breath test, and is significantly associated with smoking, bloating, abdominal pain, and anemia. Proton pump inhibitor therapy is a significant risk factor for SIBO. The risk of SIBO increases with age and does not depend on gender or race. SIBO complicates the course of a number of diseases and may be of pathogenetic significance in the development of their symptoms. SIBO is significantly associated with functional dyspepsia, irritable bowel syndrome, functional abdominal bloating, functional constipation, functional diarrhea, short bowel syndrome, chronic intestinal pseudo-obstruction, lactase deficiency, diverticular and celiac diseases, ulcerative colitis, Crohn's disease, cirrhosis, metabolic-associated fatty liver disease (MAFLD), primary biliary cholangitis, gastroparesis, pancreatitis, cystic fibrosis, gallstone disease, diabetes, hypothyroidism, hyperlipidemia, acromegaly, multiple sclerosis, autism, Parkinson's disease, systemic sclerosis, spondylarthropathy, fibromyalgia, asthma, heart failure, and other diseases. The development of SIBO is often associated with a slowdown in orocecal transit time that decreases the normal clearance of bacteria

from the small intestine. The slowdown of this transit may be due to motor dysfunction of the intestine in diseases of the gut, autonomic diabetic polyneuropathy, and portal hypertension, or a decrease in the motor-stimulating influence of thyroid hormones. In a number of diseases, including cirrhosis, MAFLD, diabetes, and pancreatitis, an association was found between disease severity and the presence of SIBO. Further work on the effect of SIBO eradication on the condition and prognosis of patients with various diseases is required.

Key Words: Gut microbiota; Gut-liver axis; Breath test; Lactulose; Methane; Hydrogen

Core Tip: Small intestinal bacterial overgrowth (SIBO) is common in functional and organic bowel diseases, liver diseases, other diseases of digestive organs, a number of endocrine, nervous, and rheumatic diseases, asthma, heart failure, and certain other diseases. In a number of diseases, including cirrhosis, metabolic-associated fatty liver disease, diabetes mellitus, pancreatitis, and cystic fibrosis, an association was found between disease severity and the presence of SIBO. Further work on the effect of SIBO eradication on the condition and prognosis of patients in various diseases is required.

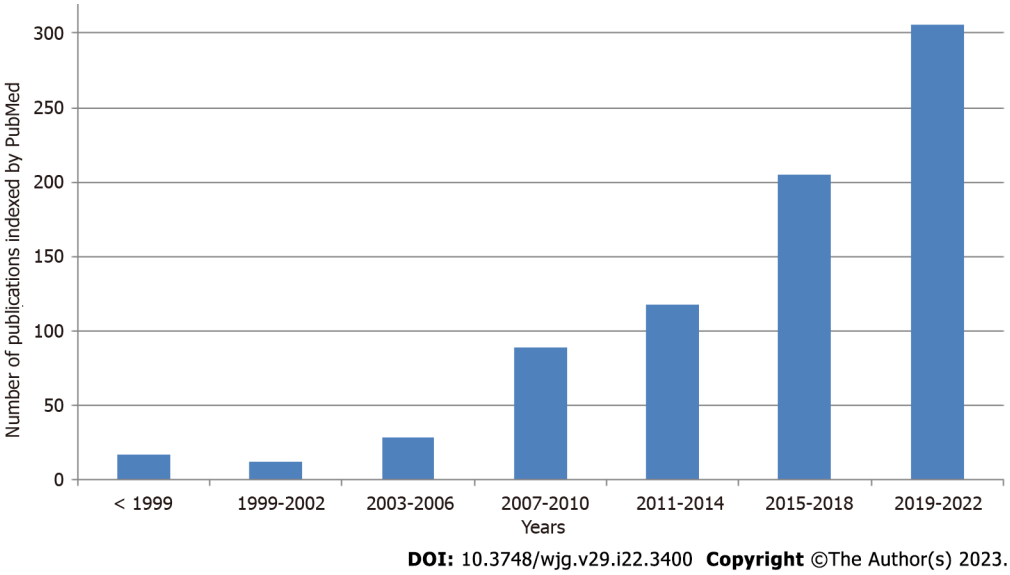
INTRODUCTION



Small intestinal bacterial overgrowth (SIBO) is defined as an increase in the bacterial content of the small intestine above normal values (100000 cells per mL)[1-4]. This leads to excessive gas formation in the small intestine, bloating, and pain in the umbilical region, which may be accompanied by malabsorption, malnutrition, and osmotic diarrhea. The main causes of SIBO are dysfunctional movement of contents through the small intestine [delayed orocecal transit time (OCTT)], reduced gastric acid secretion [for example, due to the use of proton pump inhibitors (PPI) or after gastric surgery], and reflux of the colon contents into the small intestine due to ileocecal valve dysfunction[1-4].

Interest in SIBO is increasing, as evidenced by the continuous growth in publications on this topic indexed in PubMed (Figure 1). An important issue is the standardization of SIBO diagnosis. The main diagnostic methods are lactulose and glucose breath tests (LBT and GBT, respectively), as well as jejunal bacterial culture quantification[5-7]. Unfortunately, the results obtained using these different methods do not always correspond with each other, which may explain the variation in results between different studies that use different tests. In addition, while SIBO was initially associated with hydrogen release, it is now accepted that SIBO can also accompany the formation of methane. Methane SIBO and hydrogen SIBO are not only detected with different frequencies, but can also have different effects. It is important that the test for hydrogen SIBO does not detect methane SIBO and vice versa[8,9].

SIBO complicates the course of a number of diseases and may be of pathogenetic significance in the development of their symptoms[1-4]. The aim of this review is to provide up-to-date information on the association of SIBO with various diseases and their manifestations.

PATIENTS WITH GASTROENTEROLOGICAL COMPLAINTS

The presence of SIBO was detected in 33.8% of patients with gastroenterological complaints who underwent a breath test, and was significantly associated with smoking [odds ratio (OR) = 6.66], bloating (OR = 5.39), abdominal pain (OR = 4.78), and anemia (OR = 4.08)[10]. The risk of SIBO increased with age [OR = 1.04, 95% confidence interval (CI): 1.01-1.07][11] and did not depend on gender or race[11,12]. Ileocecal junction pressure was lower, small bowel, colonic, and whole gut transit times were longer, and gastric and small bowel pH was higher in patients with SIBO than in those without[13,14]. There were no significant differences in gastric emptying time and other small intestinal motility parameters (small intestinal motility index, contractions per minute, and peak amplitudes)[13,15], or in fecal calprotectin levels[16]. SIBO was more frequent in patients who consumed a moderate amount of alcohol than in abstainers (58% *vs* 39%)[17]. SIBO was identified in 63% of children with

Figure 1 Number of publications indexed by PubMed on small intestinal bacterial overgrowth by year.

abdominal pain[18].

DIET

Patients with SIBO consumed lower amounts of dietary fiber and red meat than SIBO-negative individuals. Those with methane SIBO consumed more fruits, vegetables, and fish compared with those with other variants of SIBO and the control group, while individuals with hydrogen SIBO ate more poultry than those with other SIBO types and controls[19]. SIBO was detected more frequently in preschool children who were on a long-term dairy-free diet than in children on a regular diet (55.0% *vs* 20.0%)[20].

PPI THERAPY

A meta-analysis of 19 studies revealed that PPI therapy is a significant risk factor for SIBO (OR = 1.71, 95%CI: 1.20-2.43)[21]. The prevalence of SIBO increased after 1 year of continuous PPI use[22]. Interestingly, SIBO following PPI therapy is associated with decreased OCTT, and the concomitant use of prokinetics in patients receiving PPI reduces the risk of SIBO by increasing OCTT[23]. In older patients undergoing long-term PPI therapy, the prevalence of SIBO was higher than that in patients not receiving PPI (77.1% *vs* 58.3%) and increased significantly when the administration time was longer than 6 mo[24]. The prevalence of SIBO was also higher in older patients undergoing continuous PPI therapy (88.6%) than in those receiving on-demand PPI therapy (65.7%); no significant difference was found in the incidence of SIBO between the on-demand PPI and control groups[24].

FUNCTIONAL DIGESTIVE DISEASES

Breath tests revealed that 68.1% of patients with functional bowel diseases also had SIBO[25].

Functional dyspepsia

A meta-analysis of seven studies found that the prevalence of SIBO in functional dyspepsia is 34.7% (95%CI: 24.8%-45.4%)[26]. Another meta-analysis found SIBO prevalence in functional dyspepsia to be significantly higher using the LBT (53.4%, 95%CI: 33.9%-71.9%) compared with the GBT (17.2%, 95%CI: 8.6%-31.6%). There was no significant difference in SIBO prevalence between patients with different subtypes of functional dyspepsia. The risk of SIBO in patients with functional dyspepsia was significantly higher than that in controls (OR = 4.3, 95%CI: 1.1-17.5)[27].

Irritable bowel syndrome

A meta-analysis of 37 studies revealed that the prevalence of SIBO in irritable bowel syndrome (IBS)

was 36.7% (95%CI: 24.2%-44.6%). The lactulose hydrogen breath test (LHBT) for SIBO was positive in patients with IBS no more often than in the control group [risk ratio (RR) = 1.6, 95%CI: 0.9-2.8], while SIBO was detected in patients with IBS significantly more often than in controls using the glucose hydrogen breath test (RR = 4.2, 95%CI: 3.0-5.9) and upper gut aspirate culture (RR = 3.2, 95%CI: 1.4-7.3). Patients with diarrhea-predominant IBS (IBS-D) were more likely to have SIBO than patients with other subtypes (OR = 1.4, 95%CI: 1.02-1.63)[28].

Another meta-analysis of 25 studies showed that SIBO prevalence in patients with IBS was significantly higher than that in controls [31.0% (95%CI: 29.4%-32.6%) *vs* 20.9% (95%CI: 19.5%-22.2%); OR = 3.7 (95%CI: 2.3-6.0) for all studies, OR = 4.9 (95%CI: 2.8-8.6) for studies using only healthy controls, and OR = 1.3 (95%CI: 0.6-3.3) for studies using non-IBS disease controls]. Using breath testing, SIBO prevalence in patients with IBS was 35.5% (95%CI: 33.6%-37.4%) *vs* 29.7% (95%CI: 27.6%-31.8%) in controls. Culture-based studies found an SIBO incidence of 13.9% (95%CI: 11.5%-16.4%) in patients with IBS and 5.0% (95%CI: 3.9%-6.2%) in controls. SIBO prevalence as diagnosed by the LBT was much greater in patients with IBS (3.6-fold) and controls (7.6-fold) than that diagnosed by the GBT. Similar differences were observed when LBT was compared with the bacterial culture method of diagnosis. SIBO prevalence was greater in patients with IBS-D (35.5%, 95%CI: 32.7%-40.3%) compared with patients with constipation-predominant IBS [IBS-C; 22.5% (95%CI: 18.1%-26.9%); OR = 1.8 (95%CI: 1.2-2.8) *vs* IBS-D] and mixed IBS (25.2%, 95%CI: 22.2%-28.4%). PPI use by patients with IBS was not associated with SIBO (OR = 0.8, 95%CI: 0.5-1.5). The prevalence of SIBO both in patients with IBS and controls was greatest in the United States [(54.6%, 95%CI: 51.2%-58.0%) and 37.2% (95%CI: 34.7%-39.7%), respectively], followed by Europe [23.4% (95%CI: 21.1%-26.0%) and 8.1% (95%CI: 6.6%-9.6%), respectively], and lowest in India [14.1% (95%CI: 11.5%-16.7%) and 1.1% (95%CI: 0%-2.2%), respectively][29].

The third meta-analysis revealed that among patients with IBS, female sex (OR = 1.5, 95%CI: 1.0-2.1), older age [standardized mean difference = 3.1 years (95%CI: 0.9-5.4)], and IBS-D (OR = 1.7, 95%CI: 1.3-2.3) compared with other IBS subtypes increased the odds of SIBO[30].

Separately, a meta-analysis of studies investigating methane SIBO in IBS was performed. It showed that the incidence of methane SIBO in patients with IBS was 25.0% (95%CI: 18.8%-32.4%), not significantly different from that in the control group (OR = 1.2, 95%CI: 0.8-1.7). In patients with IBS, the LBT provided positive results for methane SIBO almost three times as often as the GBT [29.0% (95%CI: 20.9%-38.6%) *vs* 11.5% (95%CI: 5.0%-24.3%)]. In contrast with hydrogen SIBO, the prevalence of methane SIBO in patients with IBS-C was higher than that in patients with IBS-D [37.7% (95%CI: 33.5%-42.1%) *vs* 12.4% (95%CI: 10.2%-14.9%); OR = 3.1 (95%CI: 1.7-5.6)][31].

Serum interleukin (IL)-1β levels were higher and serum IL-10 levels were lower in SIBO-positive patients with IBS than in the SIBO-negative group[32]. Another study also showed that increased IL-1α and IL-1β levels were associated with SIBO[33]. A third study reported that IL-10 levels were reduced in IBS patients with SIBO compared with those without, but found no significant differences in serum tumor necrosis factor (TNF)-α, IL-6, and IL-8 concentrations[34].

The body mass index (BMI) of patients with IBS-D and SIBO was significantly lower than that of patients without SIBO. IBS-D patients with SIBO had higher scores of abdominal pain than those without SIBO in this study. The proportion of dietary fat was significantly higher in IBS patients with SIBO than in those without. Breath methane peak value was positively correlated with the proportion of fat in the diet[35]. Another study also showed that in non-constipation IBS, patients with SIBO had lower BMI and waist circumference than patients without SIBO. Moreover, multivariate analysis revealed that the OR of SIBO was 0.396 for obesity and 0.482 for abdominal obesity[36].

The presence of SIBO did not affect IBS symptoms in another study[37], although OCTT was significantly increased in SIBO-positive compared with SIBO-negative patients[37]. Intestinal permeability did not differ significantly between IBS patients with and without SIBO[38]. The severity of anxiety, depression, and other psychological disorders was not different between patients with IBS who were positive and negative for hydrogen SIBO[34]. Another study confirmed that the severity of IBS symptoms and associated psychological disorders did not differ between SIBO-positive and -negative patients[39]. However, it has been shown that IBS patients with SIBO who are predominant methane producers have higher urge thresholds for colon contraction and higher baseline levels of colon phasic contractions than SIBO-negative IBS patients, and report more 'hard or lumpy stools' compared with patients who are predominant hydrogen producers and those who are SIBO-negative[39]. This is consistent with the findings that hydrogen SIBO is more prevalent in IBS-D, whereas methane SIBO is more prevalent in IBS-C[30,31]. In children with IBS, the prevalence of SIBO was significantly higher than that in control subjects [65% *vs* 7%; OR = 3.9 (95%CI: 7.3-80.1)]. Among abdominal symptoms, significant differences were observed only in bloating[40].

Other functional digestive diseases

Tests for SIBO were positive in 43% of patients with functional abdominal bloating/distention[41] (although this proportion reached 68% in another study[42]), 73% of those with functional constipation [42], and 69% of those with functional diarrhea[42].

ORGANIC GUT DISEASES

Non-steroidal anti-inflammatory drug-induced small intestinal damage

The LHBT was positive in 59% of patients with and 24% of patients without severe non-steroidal anti-inflammatory drug (NSAID)-induced small intestinal damage. Multiple regression analysis showed that SIBO was significantly associated with severe NSAID-induced small intestinal damage (OR = 6.54, 95%CI: 1.40-30.50). However, there was no significant difference in symptoms between patients with severe small intestinal damage with and without SIBO[43].

Short bowel syndrome

SIBO was found in 50% of children with short bowel syndrome and predisposed these patients to ambulatory central line-associated bloodstream infection (RR = 1.87, 95%CI: 1.1-3.17)[44].

Chronic intestinal pseudo-obstruction

Methane SIBO was detected more frequently in patients with chronic intestinal pseudo-obstruction than in patients with other diseases (52.6% *vs* 11.8%), while no significant difference was found in the prevalence of hydrogen SIBO between these groups (23.7% *vs* 25.7)[45].

Lactase deficiency and lactose malabsorption

SIBO was detected at a significantly higher rate in patients with lactase deficiency than in healthy controls (27.6% *vs* 6.7%)[46]. SIBO was found in 90% of asymptomatic well-nourished older people with lactose malabsorption compared with 20% of those without it[47].

Symptomatic uncomplicated diverticular disease

SIBO was found in 58.9% of patients with symptomatic uncomplicated diverticular disease (SUDD), more specifically in 93.1% of patients with diarrhea-prevalent disease and 42.6% of patients with constipation-prevalent disease[48]. OCTT was delayed in 92.5% of SUDD patients with SIBO and 48.6% of patients without SIBO (OR = 12.9). Lactose malabsorption was identified in 92.5% of SUDD patients with SIBO and 27.0% of patients without (OR = 33.0)[48].

Celiac disease

A meta-analysis of 14 studies showed that SIBO was more prevalent in patients with celiac disease than in controls [18.3% (95%CI: 11.4-28.1)[1]; OR = 5.1, 95%CI: 2.1-12.4]. The prevalence of SIBO as diagnosed by breath tests was 20.8% (95%CI: 11.9%-33.7%), while that of SIBO identified by culture-based methods was 12.6% (95%CI: 5.1%-28.0%). The prevalence of SIBO in patients with celiac disease was lower in the United States [8.7% (95%CI: 6.1%-11.9%)] than in Asia [22.1 (95%CI: 15.4%-30.2%)] and Europe [23.3% (95%CI: 17.5%-29.9%)]. SIBO prevalence in non-responders to a gluten-free diet was similar to that in responders. Antibiotic therapy for SIBO in patients with celiac disease resulted in an improvement in gastrointestinal symptoms in 95.6% (95%CI: 78.0%-99.9%) of cases. There were no significant differences in the degree of intestinal damage as measured by histology or celiac serology between patients with celiac disease with and without SIBO. Patients with celiac disease and SIBO tended to be older and have more severe signs of malabsorption (lower hemoglobin, serum beta-carotene, albumin levels, and higher fecal fat level), compared with those without SIBO[49]. SIBO was present in 67% of celiac patients with persistence of gastrointestinal symptoms who had histological response to a gluten-free diet[50].

Environmental enteric dysfunction

Environmental enteric dysfunction is an incompletely defined syndrome of inflammation, reduced absorptive capacity, and barrier dysfunction in the small intestine. It is widespread in low- and middle-income countries[51]. The prevalence of SIBO is 85.3% in children with stunted growth due to this disease[52].

Inflammatory bowel disease

A meta-analysis of 11 studies revealed that the proportion of SIBO in patients with inflammatory bowel disease (IBD) was greater than that in controls [22.3% (95%CI: 19.92%-24.68%); OR = 9.51 (95%CI: 3.39-26.68)]. The severity of abdominal symptoms (bloating, flatus, satiety, and loose stools) was also greater in patients with SIBO than in those without. Patients with SIBO had increased stool frequency, lower body weight, and prolonged OCTT compared with SIBO-negative patients[53]. The prevalence of methane SIBO was assessed in a meta-analysis of six studies, which did not reveal a significant difference between patients with IBD and healthy individuals[31]. The incidence of SIBO was significantly higher in patients with Crohn's disease (CD) compared with patients with ulcerative colitis (UC)[54].

CD

A meta-analysis showed that the prevalence of SIBO in CD was higher than that in controls [25.4%

(95%CI: 22.5%-28.3%); OR = 10.9 (95%CI: 2.8-42.69)]. CD patients who had undergone prior surgery were more likely to test positive for SIBO than those who had not [31.8% (95%CI: 26.7%-36.9%) *vs* 19.2% (95%CI: 15.4%-23.0%); OR = 2.4 (95%CI: 1.7-3.4)]. The prevalence of SIBO in CD was highest [33% (95%CI: 19.2%-50.6%)] in patients following ileocecal valve surgery. Among different forms of the disease, fibrostenosing CD was associated with an increased risk of SIBO compared to others [OR = 7.5 (95%CI: 2.5-22.2)]. No association was found between the prevalence of SIBO and CD activity index score, or thiopurine or biologic treatment[53].

OCTT was significantly longer in patients with CD with SIBO than in those without[54]. SIBO also occurred more frequently in patients who had CD recurrence within 18 mo than in those who remained in remission (63.0% *vs* 37.0%; OR = 2.79). Relapses were more frequent in patients with SIBO than in those without (26.5% *vs* 7.7% at the 6-mo follow-up, and 50.0% *vs* 25.6% at the 18-mo follow-up)[55].

CD patients with and without SIBO were comparable with regard to demographics, systemic inflammatory biomarkers, and disease characteristics, except for the fibrostenosing phenotype that was more common in patients with SIBO than in those without [43.3% *vs* 19.3%; OR = 3.8 (95%CI: 1.5-6.8)]. Fecal calprotectin levels were significantly higher in SIBO-positive than in SIBO-negative patients (OR = 9.4, 95%CI: 3.0-11.3)[56].

Another study reported that CD patients with SIBO had increased stool frequency and significant reduction of stool solidity, were older, reported a longer history of CD, and were significantly more likely to have had prior surgery than CD patients without SIBO. An association was identified between the number of surgical procedures and the presence of SIBO (OR = 2.83, 95%CI: 1.15-6.96)[57].

In CD patients in remission, the prevalence of SIBO was 16.8%. No associations were observed between SIBO in these remission patients and the use of thiopurine or biological drugs. Multivariate analysis revealed that the presence of meteorism and a fistulizing phenotype were associated with the presence of SIBO in patients with CD in remission[58].

UC

A meta-analysis showed that the prevalence of SIBO in patients with UC was greater than in controls [14.3% (95%CI: 10.52%-18.1%); OR = 8.0 (95%CI: 1.67-38.4)][31]; OCTT has also been shown to be significantly longer in these patients than in controls[54]. Serum levels of lipopolysaccharide (LPS), and the expression levels of Toll-like receptor (TLR)2 and TLR4 on the surface of peripheral blood mononuclear cells were higher in UC patients with SIBO than in those without. LPS levels were positively correlated with the expression levels of TLR2 and TLR4[59]. Serum levels of pro-inflammatory cytokines (IL-6, IL-8, and TNF-α), anti-inflammatory cytokines (IL-10), and lipid peroxidates (a marker of oxidative stress) were significantly higher, and levels of reduced glutathione (antioxidant) were lower in UC patients with SIBO than in those without[60].

LIVER DISEASES

In a mixed cohort of patients with various liver diseases, SIBO prevalence was significantly higher in patients with cirrhosis than in those without (41.2% *vs* 13.1%). Moreover, both cirrhotic and non-cirrhotic patients had a greater SIBO prevalence than healthy controls[61].

Cirrhosis

A meta-analysis of 21 studies revealed that the prevalence of SIBO in patients with cirrhosis was greater than that in healthy controls [(40.8%, 95%CI: 34.8%-47.1%) and OR = 6.83 (95%CI: 4.16-11.21) for all studies; 48.0% (95%CI: 27.5%-69.1%) and OR = 5.32 (95%CI: 1.02-27.82) for studies using culture-based methods; 52.7% (95%CI: 43.9%-61.4%) and OR = 3.24 (95%CI: 1.34-7.84) for studies using the LBT; and 35.9% (95%CI: 30.6%-41.6%) and OR = 8.65 (95%CI: 4.30-14.42) for studies using the GBT]. The prevalence of SIBO in patients with decompensated cirrhosis (classes B and C) was higher than that in those with compensated cirrhosis class A [50.5% (95%CI: 40.3%-60.7%) *vs* 31.2% (95%CI: 19.9%-45.1%); OR = 2.56 (95%CI: 1.60-4.09)]. The prevalence of SIBO was higher in patients with cirrhosis class C than in patients with cirrhosis class B [59.2% (95%CI: 45.0%-71.7%) *vs* 47.6% (95%CI: 35.9%-59.5%); OR = 1.79 (95%CI: 1.18-2.71)][62].

Patients with cirrhosis and SIBO were more likely to have ascites, minimal hepatic encephalopathy, and spontaneous bacterial peritonitis than those without SIBO. The relationship of SIBO with hypocoagulation, alanine aminotransferase and glutamyl transpeptidase activity, white blood cell and platelet counts, hemoglobin and ascitic fluid albumin levels, or esophageal varices was not found[62]. Recent meta-analyses have shown that SIBO in cirrhosis is associated with hepatic encephalopathy (OR = 4.43, 95%CI: 1.73-11.32)[63]. Short-term treatment with rifaximin effectively reduced blood ammonia levels, improved psychometric test scores, and reduced the rate of SIBO as determined by breath testing[64]. No significant association was found between SIBO and hepatic venous pressure gradient[65]. SIBO in patients with cirrhosis was associated with the presence of bacterial DNA in peripheral blood[66], higher plasma LPS levels[67], a shift to alkaline pH in gastric juices[68], malnutrition[69], prolonged OCTT[70,71], lower systolic blood pressure and systemic vascular resistance, higher cardiac output and

serum C-reactive protein levels[72], splanchnic vasodilation, and abdominal hyperdynamic circulation [73].

In patients with cirrhosis, gut microbiota changes with SIBO (a higher abundance of *Firmicutes* and *Fusobacteria*, and a lower abundance of *Bacteroidetes*) did not correspond to cirrhosis-associated gut dysbiosis; therefore, it can be assumed that gut dysbiosis and SIBO are most likely independent disorders of gut microbiota in patients with cirrhosis[74].

Hepatocellular carcinoma

The incidence of SIBO in patients with hepatocellular carcinoma (HCC) was higher than that in cirrhosis patients without HCC (71.8% *vs* 41.1%; OR = 3.7) and healthy controls (71.8% *vs* 3.0%; OR = 81.5). The expression levels of TLR2 and TLR4 on the surface of peripheral blood mononuclear cells in patients with HCC and SIBO were higher than those in patients without SIBO[75].

Extra-hepatic portal vein obstruction

Patients with extra-hepatic portal vein obstruction had similar rates of SIBO compared with healthy controls (7.14% *vs* 1.97%)[76].

Metabolic-associated fatty liver disease

A meta-analysis of 18 studies revealed that, among patients with metabolic-associated fatty liver disease (MAFLD), the rate of SIBO was 35.0% (95%CI: 24.4%-47.2%); in patients with metabolic-associated steatohepatitis (MASH), the rate of SIBO was 41.1% (95%CI: 21.9%-63.4%)[77]. The prevalence of SIBO in MAFLD was higher than that in controls (OR = 3.82, 95%CI: 1.93-7.59) in another meta-analysis that included ten studies[78].

Patients with MAFLD and SIBO had increased OCTT; echomarkers of liver steatosis and fibrosis; severity of liver steatosis, fibrosis, lobular and portal inflammation, and ballooning by liver biopsy; levels of hepatic *CD14* mRNA, nuclear factor kappa beta mRNA, and TLR4 protein expression; homeostatic model assessment for insulin resistance scores; and serum LPS levels compared with patients without SIBO. However, there was no significant difference in BMI, or in serum levels of TNF-α , adiponectin, glutamyl transpeptidase, triglycerides, or low-density lipoprotein between MAFLD patients with and without SIBO. SIBO was associated with significant fibrosis and MASH in MAFLD [79-81]. However, the presence of abdominal obesity was significantly associated with the absence of SIBO (RR = 0.38; 95%CI: 0.02-0.48)[82]. There was no significant difference in the incidence of SIBO in MASH patients with and without signs of metabolic syndrome[83].

A meta-analysis of three studies showed that children with SIBO were more likely to have MAFLD (OR = 5.27; 95%CI: 1.66-16.68) and children with MAFLD were at an increased risk of developing SIBO (RR = 2.17; 95%CI: 1.54-2.81)[84]. Metabolic syndrome and MAFLD were risk factors for SIBO development in obese children[85].

Primary biliary cholangitis

The prevalence of SIBO was higher in patients with primary biliary cholangitis (PBC) than in controls (32.8% *vs* 2.5%; OR = 18.9). Patients with PBC and SIBO were significantly more likely to have diarrhea (78.9% *vs* 35.9%) than those without SIBO. Age, sex, BMI, comorbidities, severity of disease, signs of portal hypertension, and the prevalence of abdominal pain and bloating were similar in PBC patients with and without SIBO[86].

ABDOMINAL SURGERY

Bariatric surgery

SIBO was detected in 43% of patients who had undergone bariatric Roux-en-Y gastric bypass or one-anastomosis gastric bypass and was associated with a higher frequency of defecation in these patients than in those without SIBO[87]. In a separate study, SIBO was detected in 73.4% of patients who received a Roux-en-Y gastric bypass[88]. A third study reported that SIBO testing was negative in all pre-surgery patients and positive in 37.0% of patients 6 mo after one-anastomosis gastric bypass. SIBO in this study was associated with lower reported dietary intake and folate levels and higher vitamin A deficiency rates. No significant differences in alpha and beta diversities of gut microbiota were observed between patients with and without SIBO at 6 mo post-surgery[89]. Among patients that underwent Roux-en-Y gastric bypass at least 1 year before, the SIBO-positive group had a higher BMI than the SIBO-negative group[90]. SIBO prevalence does not increase after adjustable gastric banding (before, 15%; after, 10%), whereas it increased from 15% before Roux-en-Y gastric bypass to up to 40% afterwards. This study also found an association between SIBO and lower weight loss[91].

Gastrectomy

SIBO was found in 61.6% of patients who had undergone gastrectomy. No correlation was found with

any malnutrition parameter[92]. Another study reported significant differences in SIBO prevalence between postgastrectomy patients and controls (77.6% *vs* 6.7%)[93]. Abdominal fullness or borborygmus during oral glucose load was more common in patients with SIBO than in those without. The prevalence of dumping syndrome and postprandial hypoglycemia, pulse rate, and hematocrit levels were not different between patients following gastrectomy with and without SIBO[93]. A third study also revealed that SIBO was more frequent in patients after gastrectomy than in controls (71.4% *vs* 13.3%; OR = 16.3). Specifically, 75% of patients that had undergone a Billroth I or II operation and 50% of patients that had undergone total gastrectomy were positive for SIBO[94].

Colectomy

Patients who had undergone colectomy had a greater incidence of SIBO than healthy controls (62% *vs* 32%; OR = 3.47). There was a higher prevalence of aerobic organisms and a lower prevalence of anaerobic organisms in the duodenal contents in the colectomy group compared with controls[95]. SIBO was detected in 74% of patients after right-sided hemicolectomy for colorectal cancer; no association between SIBO and bile acid malabsorption, delayed OCTT, or loose stools was found in these patients [96].

Cholecystectomy

Patients that had undergone cholecystectomy were more likely to have SIBO than controls (46.8% *vs* 13.3%; OR = 5.7)[97]. Another study reported similar results (41.1% *vs* 13.3%; OR = 4.5)[94]. Cholecystectomy patients with SIBO had more severe abdominal and chest discomfort, bloating, early satiety, nausea, and tenesmus than those without SIBO[97].

Other abdominal surgery

The presence of asymptomatic chronic pouchitis after ileoanal anastomosis was not associated with SIBO[98].

OTHER DIGESTIVE DISEASES

Erosive esophagitis

Patients with erosive esophagitis had SIBO more frequently than controls (65% *vs* 31%; OR = 4.0)[99].

Helicobacter pylori infection

Among patients with abdominal symptoms, SIBO was detected more frequently in *Helicobacter pylori* (*H. pylori*)-infected patients than in uninfected ones (60.4% *vs* 30.6%; OR = 3.45). The incidence of SIBO after *H. pylori* eradication decreased to 20.8%. The remission rate of SIBO after eradication was 66.7%[100].

Gastroparesis

SIBO was present in 60% of patients with gastroparesis, 43.8% of whom had hydrogen SIBO and 22.2% of whom had methane SIBO (6% of patients produced both gases). SIBO was associated with greater disease duration. No significant differences were noted in age, sex, gastric emptying parameters, and etiology of gastroparesis between patients with and without SIBO[101].

Chronic pancreatitis

A meta-analysis of 13 studies showed that the prevalence of SIBO in patients with chronic pancreatitis (CP) was higher than that in controls in all patients [38.6% (95%CI: 25.5%-53.5%); OR = 5.58 (95%CI: 2.26-13.75)], nonsurgical cases [34.6% (95%CI: 20.7%-51.8%); OR = 4.61 (95%CI: 1.67-12.73)], and cases that needed surgical intervention [54.2% (95%CI: 23.3%-82.2%); OR = 10.86 (95%CI: 0.90-131.72)]. Diabetes mellitus (OR = 2.1; 95%CI: 1.2-3.5) and pancreatic exocrine insufficiency (OR = 2.5; 95%CI: 1.3-4.8), but not narcotic drug or PPI use, were associated with SIBO in patients with CP[102]. SIBO was more prevalent in patients with alcohol-induced CP than in patients with other forms of this disease [103]. A separate study showed no association between the severity of CP symptoms and the presence of SIBO[104].

Acute pancreatitis

SIBO was found in 17.8% of patients with acute pancreatitis (AP) and was associated with disease severity, as it was detected in 8.42%, 25.58%, and 25.92% of patients with mild, moderate, and severe AP, respectively. The production of hydrogen by gut microbiota was significantly lower in the late than in the early stage, and SIBO mainly developed within 72 h of AP onset. The incidence of organ failure was significantly higher in patients with SIBO than in those without. However, the incidence of infectious or local complications was not associated with SIBO, and neither was systemic inflammatory response syndrome[105]. Another study reported that SIBO incidence in AP was 12.0%, similar to the results of historic healthy controls, and that glucose tolerance was lower in AP patients with SIBO than

in those without[106].

Cystic fibrosis

The prevalence of SIBO in cystic fibrosis was 31.6%. SIBO was associated with pancreas insufficiency, and independently associated with lower BMI and serum albumin levels[107]. Another study reported the prevalence of SIBO in cystic fibrosis as 40.0%; fecal calprotectin levels did not differ between patients with and without SIBO[108].

Gallstone disease

SIBO prevalence in patients with gallstones was higher than that in controls and those who had undergone cholecystectomy (40.5% *vs* 20.5% and 24.6%; OR = 2.23)[109]. Another study also reported that SIBO was more frequent in patients with gallstones than in controls (14.8% *vs* 0.7%; OR = 26.9)[110]. OCTT and serum bile acid levels were increased in patients with SIBO compared with patients without SIBO, and there was a positive correlation between OCTT and serum bile acid levels in SIBO-positive patients[110].

Children with encopresis

Hydrogen SIBO was detected in 42% of children with encopresis and 23% of controls (OR = 2.4). Methane was produced in 56% of children with encopresis and 23.1% of controls[111].

ENDOCRINE AND METABOLIC DISEASES

Obesity and metabolic syndrome

A meta-analysis of five studies reveled that the increased risk of SIBO in obese individuals did not reach statistical significance (OR = 2.08; 95%CI: 0.82-5.31) but was significant when including only studies from Western countries (OR = 3.41; 95%CI: 1.21-9.59)[112]. However, SIBO was not related to BMI. Small intestinal manometry showed a marked increase of clustered contractions in obese individuals with SIBO compared with those without; no other differences were observed in parameters of fasting cyclic activity[113]. Patients with SIBO have higher visceral to subcutaneous fat ratios than the general population. Metabolic syndrome (OR = 2.5; 95%CI: 1.1-5.7) and higher visceral to subcutaneous fat ratio (OR = 3.3; 95%CI: 1.6-7.2) were independently associated with SIBO in the general population[114]. Obese individuals with SIBO ingested more carbohydrates and refined sugars and less total and insoluble fibers than those without SIBO. There were no significant differences in lipid and protein intake between the two groups[115].

The prevalence of SIBO in obese children was greater than that in controls (37.6% *vs* 3.3%; OR = 17.5). Obese children with SIBO had higher rates of MAFLD, hypertension, and metabolic syndrome, and higher alanine transaminase and aspartate transaminase levels than those without SIBO[116].

Diabetes mellitus

A meta-analysis of 14 studies showed that SIBO is detected in patients with diabetes mellitus more frequently than in controls [29% (95%CI: 20%-39%); OR = 4.18 (95%CI: 1.34-13.05)]. The rate of SIBO was 35% (95%CI: 21%-49%) in Western countries and 24% (95%CI: 14%-34%) in Eastern countries. The prevalence of SIBO in type 2 diabetes was similar to that in type 1 diabetes [30% (95%CI: 13%-47%) *vs* 25% (95%CI: 14%-36%)][117].

Serum levels of biomarkers of oxidative stress (lipid peroxidates, catalase, and superoxide dismutase) and systemic inflammation (TNF-α, IL-6, and IL-10) were higher and serum levels of the antioxidant glutathione were lower in type 2 diabetic patients with SIBO than in those without[118]. SIBO was associated with lower fasting insulin levels, lower insulin release after glucose load, and poorer glucose tolerance and long-term glycemic control (higher glycated hemoglobin) in patients with type 2 diabetes. At the same time, insulin resistance and BMI were lower in patients with SIBO than in those without [119]. In type 2 diabetics, OCTT was more delayed, urinary D-xylose levels were more reduced, and lactose intolerance was more severe in patients with SIBO than in those without[120].

In type 1 diabetes mellitus, OCTT was more delayed and a history of uncontrolled diabetes was more likely in patients with SIBO than in those without. SIBO was significantly higher in patients who had had type 1 diabetes for ≥ 5 years than in those who were diagnosed < 5 years previously[121]. Patients with autonomic neuropathy in type 1 diabetes have a higher prevalence of SIBO, which was associated with higher daily insulin requirements[122].

The rate of SIBO in patients with gestational diabetes mellitus was greater than that in those patients without (54.6% *vs* 27.5%; OR = 3.16). Patients with SIBO had higher levels of fasting blood glucose, glycated hemoglobin, and C-reactive protein, and lower levels vitamin D than those without; neonates from these patients with SIBO had higher weights and lower levels of blood glucose than those from patients without SIBO[123].

Hypothyroidism

SIBO prevalence in patients with hypothyroidism was higher than that in controls [54% *vs* 5%; OR = 22.3 (95%CI: 4.8-102.7)]. Abdominal discomfort, flatulence, and bloating were more prevalent in the patients with SIBO[124].

The positive rates of SIBO were 56.7% and 31.6% in pregnant women with and without subclinical hypothyroidism, respectively (OR = 2.83). The incidence of abdominal distension and constipation, presence of thyroid peroxidase antibody, levels of thyroid-stimulating hormone, and BMI were higher, and the levels of thyroxine were lower in women with SIBO compared with those without[125].

Acromegaly

Patients with acromegaly showed an increased prevalence of SIBO compared with controls (43.9% *vs* 3.3%; OR = 22.7)[126].

Atherosclerosis and hyperlipidemia

SIBO was found in 78.9% of patients with hyperlipidemia and 40% of controls. The level of exhaled hydrogen at 120 min was positively correlated with serum triglyceride and low- and very-low-density lipoprotein levels, and negatively correlated with serum high-density lipoprotein levels[127]. Among patients who did not have previous cardiovascular events and presented with gastrointestinal discomfort, asymptomatic atherosclerotic plaques were detected more often in patients with SIBO than in those without. This was true for the abdominal aorta (OR = 4.18; 95%CI: 2.56-6.80), carotid arteries (OR = 1.93; 95%CI: 1.23-3.02), lower extremity arteries (OR = 1.81; 95%CI: 1.14-2.88), and any-territory plaque presence (OR = 5.42; 95%CI: 2.78-10.58)[128]. Arterial stiffness was elevated in patients with SIBO compared with those without, but carotid intima-media thickness and arterial calcifications did not differ between the two groups[129].

NERVOUS DISEASES

Multiple sclerosis

SIBO was detected in patients with multiple sclerosis more frequently than in controls [38.1% (95%CI: 29.4%-46.9%); OR = 4.50 (95%CI: 2.38-8.50)]. SIBO was associated with more severe disease according to the Expanded Disability Status Scale and Multiple Sclerosis Severity Score[130].

Restless legs syndrome

Patients with restless legs syndrome were more likely to have SIBO than healthy controls (69% *vs* 10%; OR = 19.8)[131].

Alzheimer's disease

SIBO was detected in 49% of patients with Alzheimer's disease, a higher level than that in controls (OR = 3.35). SIBO was not associated with fecal calprotectin and zonulin levels, degree of cognitive impairment, comorbidities, or drug treatment[132].

Autism

Children with autism had an SIBO incidence of 31.0% (95%CI: 25.8%-36.1%), which was higher than that in controls (OR = 4.35). Autistic children with SIBO had higher Autism Treatment Evaluation Checklist scores than those without[133].

Spinal cord injury

SIBO was detected in 21% of patients after spinal cord injury. SIBO was observed more frequently in the subacute than in the chronic phase (37.5% *vs* 0%), and in tetraplegia more frequently than in paraplegia (55.6% *vs* 0.5%)[134]. Another study reported that the SIBO rate after spinal cord injury was 38.5% (95%CI: 29.9%-59.0%) and that SIBO was associated with deep vein thrombosis in these patients (OR = 3.72; 95%CI: 1.97-6.62)[135].

Parkinson's disease

A meta-analysis of 11 studies showed that the prevalence of SIBO in patients with Parkinson's disease was 46% (95%CI: 36%-56%), which was higher than that in controls (OR = 5.22; 95%CI: 3.33-8.19). This incidence was greater in Western countries than in Eastern ones [52% (95%CI: 40%-64%) *vs* 33% (95%CI: 22%-43%)][136]. Patients with SIBO used smaller doses of dopaminergic drugs and had lower serum triglyceride and total bilirubin levels. SIBO was not associated with motor or abdominal symptoms[137] or weight loss[138]. However, another study reported that disease duration, Hoehn and Yahr stage, unified Parkinson's disease rating-III and -IV scores, and Non-Motor Symptoms Scale score were associated with SIBO in these patients[139].

RHEUMATIC DISEASES

Systemic sclerosis

A meta-analysis of 14 studies reported that the prevalence of SIBO in patients with systemic sclerosis was 34% (95%CI: 27%-42%), which was higher than that in controls (OR = 12.51; 95%CI: 6.51-24.03). SIBO prevalence was greater in Western countries than in Asian countries [38% (95%CI: 31%-47%) *vs* 15% (95%CI: 10%-23%)]. Systemic sclerosis patients with SIBO were more likely to have diarrhea (OR = 8.82; 95%CI: 4.09-19) than those without. Sex, diffuse or limited disease, digital ulcer, pulmonary fibrosis, and the presence of anticentromere or Scl-70 antibodies were not associated with SIBO in these patients[140,141]. Fecal calprotectin levels were higher in patients with SIBO than in those without[141]. The average disease duration was longer in patients with SIBO, and these patients had lower levels of hemoglobin, ferritin, total serum protein, phosphorus, calcium, and triglycerides and an elevated erythrocyte sedimentation rate compared with patients without SIBO[142]. The duration of disease (> 5 years) was significantly associated with the presence of SIBO in systemic sclerosis (OR = 9.38; 95%CI: 1.09-80.47)[143].

Behçet's disease

SIBO was diagnosed in 36% of patients with Behçet's disease. No significant differences in disease activity, patient age, severity of abdominal symptoms, frequency of drug use, surgery, smoking status, serum total protein, albumin, and C-reactive protein levels, and erythrocyte sedimentation rate were found between patients with and without SIBO[144].

Spondylarthropathy

The prevalence of SIBO in patients with spondylarthropathy was higher than that in the control group (63% *vs* 5%; OR = 32.9) and did not depend on the presence of HLA-B27, or treatment with NSAID, salazopyrin, or PPI[145].

Fibromyalgia

SIBO was diagnosed in 100% of patients with fibromyalgia, compared with 20% of controls. The degree of somatic pain correlated significantly with hydrogen level as measured by the breath test[146].

ASTHMA

SIBO was detected in 67% and 43% of patients with allergic and non-allergic asthma, respectively. Patients with SIBO had higher levels of immunoglobulin E in serum and eosinophils in sputum, and more severe impairment of respiratory function[147].

HEART FAILURE

Among patients with heart failure (HF), 45% were positive for SIBO, including 41% of patients with reduced ejection fraction (EF) and 51% of patients with preserved EF. SIBO was associated with an increased risk of rehospitalization in patients with reduced EF and cardiovascular death in patients with preserved EF. Patients with SIBO showed higher rates of New York Heart Association functional class III–IV, atrial fibrillation, peripheral edema, spironolactone and intravenous diuretic use, lower use of beta-blockers, and increased left atrial diameter and pulmonary artery systolic pressure than patients without SIBO. Among patients with reduced EF, those with SIBO had higher serum levels of N-terminal pro-B-type natriuretic peptide (a biomarker of HF) than those without[148]. Another study also reported higher SIBO incidence in HF than in controls (41.7% *vs* 9.1%; OR = 7.14) but found that SIBO in HF was not associated with the New York Heart Association functional class, echocardiographic data, number of supraventricular and ventricular extrasystoles, or indicators of complete blood count or biochemical blood analysis. However, patients with SIBO had higher C-reactive protein levels and ventricular tachycardia incidence (OR = 6.8; 95%CI: 1.5-30.2) compared with those without[149].

CANCER

SIBO was found in 63.3% of patients with pancreatic cancer and 46.7% of patients with cholangiocarcinoma, which was greater than that in the healthy controls (OR = 11.2 and 5.7, respectively). TLR4 protein expression in pancreatic carcinoma and cholangiocarcinoma patients was significantly higher in patients with SIBO than in those without[150].

OTHER DISEASES

Obstructive sleep apnea

Among patients with obstructive sleep apnea, 30.8% tested positive for SIBO. The incidence of flatulence was significantly greater in patients with SIBO than in those without. Waist-to-hip ratio was independently associated with SIBO in these patients (OR = 12.9; 95%CI: 1.3-132.2)[151].

Post coronavirus disease 2019 syndrome

SIBO was detected more frequently in patients with post coronavirus disease 2019 IBS than in those with typical IBS (93.3% *vs* 60.0%; OR = 9.3)[152].

Deep vein thrombosis

The prevalence of SIBO in patients with deep vein thrombosis was higher than in controls (69.8% *vs* 39.9%; OR = 3.5) and SIBO was independently associated with this disease (OR = 3.27; 95%CI: 1.70-6.32)[153].

Rosacea and psoriasis

SIBO was detected in patients with rosacea more frequently than in controls in one study (46.0% *vs* 5.0 %; OR = 16.2)[154] and was not more common in these patients than in controls in the other (10.0% *vs* 7.8%)[155]. The prevalence of SIBO in psoriatic patients did not differ from that in the controls (10% *vs* 5%)[156].

SIBO AND OTHER DISEASES: COMMON PATTERNS

As shown above, SIBO is often detected in functional and organic bowel diseases, liver diseases, other diseases of the digestive organs, a number of endocrine, nervous and rheumatic diseases, asthma, HF, and certain other diseases. We have summarized all the reported information on the incidence and OR for SIBO in various diseases in Table 1. An important issue in comparing data is that the presence of SIBO was determined by different tests in different studies, giving different results. In addition, we have observed pronounced heterogeneity in the frequency of SIBO detection in healthy individuals within the control groups, which ranged from fractions of a percent to several tens of percent. The reason for this is yet to be established. However, the detection of SIBO in such a large number of clinically healthy individuals shows that this disorder can be relatively harmless and often asymptomatic.

For many diseases, the development of SIBO is associated with an increased OCTT that decreases the normal clearance of bacteria from the small intestine and is one of the mechanisms underlying the development of SIBO. The slowdown of this transit may be associated with motor dysfunction of the intestine in diseases of the gut, autonomic diabetic polyneuropathy, and portal hypertension, or a decrease in the motor-stimulating influence of thyroid hormones.

Bariatric surgery and gastrectomy lead to a decrease in the barrier function of the stomach which prevents the colonization of the small intestine by oral microbiota. Colectomy leads to a decrease in the barrier function of the ileocecal valve, which prevents the colonization of the small intestine by the colon microbiota. This may explain the increased risk of SIBO following these surgeries.

Interestingly, the frequency of SIBO is increased in a number of nervous and rheumatic diseases, which may support the existence of the gut-brain[157-159] and gut-joint[160-162] axes, suggesting that the products of gut microbiota metabolism can directly or indirectly affect emotional-cognitive and immune function[163], predisposing individuals to the development of these diseases, which is well illustrated by the example of hepatic encephalopathy[164,165] and reactive arthritis[166,167].

The presence of SIBO affects the course of various diseases in different ways. Some diseases, such as IBS, functional diarrhea, and functional constipation, can be mimicked by SIBO with the same symptoms. In these cases, it is not clear what disease is present: SIBO, which manifests itself as IBS and other functional bowel diseases, or these diseases, which are aggravated by the development of SIBO.

In a number of diseases, including cirrhosis, MAFLD, diabetes mellitus, pancreatitis, and cystic fibrosis, an association was found between disease severity and the presence of SIBO. This may be due to the fact that intestinal motility is more severely disturbed in more severe diseases (in cirrhosis or autonomic diabetic polyneuropathy) or that the digestive capabilities of the gut are more affected (in severe pancreatitis and cystic fibrosis) in these cases, which increases the nutrients available for bacteria of the small intestine, leading to their excess growth. However, in SIBO, the overgrown bacteria themselves can, through their metabolic products, affect the metabolism of lipids and carbohydrates, aggravating the course of diabetes[168] and MAFLD[169], and also, through bacterial translocation and systemic inflammation, aggravate the course of portal hypertension in cirrhosis[170-172].

Since SIBO is associated with many diseases, even those not related to the intestines, it seems useful to continue studying the association of SIBO with other diseases and their manifestations. It is also important to clarify the pathogenetic ways in which the underlying disease can contribute to the development of SIBO, and SIBO, in turn, can have a negative effect on the course of the underlying

Table 1 Association of small intestinal bacterial overgrowth with various diseases

Disease	Prevalence of SIBO	OR
Functional digestive diseases		
Functional dyspepsia	17.2%-53.4%	4.3
Irritable bowel syndrome	31.0%-36.7%	3.7
Functional abdominal bloating/distention	43%-68%	
Functional constipation	78%	
Functional diarrhea	69%	
Organic (non-functional) digestive diseases		
Short bowel syndrome	50%	
Chronic intestinal pseudo-obstruction	23.7%-52.6%	
Lactase deficiency	27.6%	5.3
Lactose malabsorption in elderly persons	90%	36
Symptomatic uncomplicated diverticular disease	58.9%	8.7
Celiac disease	18.3%	5.1
Environmental enteric dysfunction	85.3%	
Crohn's disease	25.4%	10.9
Ulcerative colitis	14.3%	8.0
Liver diseases		
Cirrhosis	40.8%	6.8
Hepatocellular carcinoma	71.8%	81.5
Metabolic associated fatty liver disease	35.0%	3.8
Primary biliary cholangitis	32.8%	18.9
Abdominal surgery		
Bariatric surgery	37.0%-73.4%	
Gastrectomy	61.6%-77.6%	16.3
Colectomy	62%-74%	3.47
Cholecystectomy	24.6%-46.8%	4.5-5.7
Other digestive diseases		
Erosive esophagitis	65%	4.0
Helicobacter pylori infection	60.4%	3.45
Gastroparesis	60%	
Chronic pancreatitis	38.6%	5.58
Acute pancreatitis	12.0%-17.8%	
Cystic fibroris	31.6%-40.0%	
Gallstone disease	14.8%-40.5%	2.2-26.9
Encopresis	42%	2.4
Endocrine and metabolic diseases		
Diabetes mellitus	29%	4.18
Hypothyroidism	54%	22.3
Acromegaly	43.9%	22.7
Hyperlipidemia	78.9%	
Nervous diseases		

Multiple sclerosis	38.1%	4.5
Restless legs syndrome	69%	19.8
Azheimer's disease	49%	3.35
Autism	31.0%	4.35
Spinal cord injuries	37.5%-38.5%	
Parkinson's disease	46%	5.22
Rheumatic diseases		
Systemic sclerosis	34%	12.51
Behçet's disease	36%	
Spondylarthropathy	63%	32.9
Fibromyalgia	100%	
Other diseases		
Allergic asthma	67%	
Non-allergic asthma	43%	
Heart failure	41.7%-45.0%	7.14
Pancreatic cancer	63.3%	11.2
Cholangiocarcinoma	46.7%	5.7
Obstructive sleep apnea	30.8%	
Post-COVID-19 irritable bowel syndrome	93.3%	9.3
Deep vein thrombosis	69.8%	3.5
Rosacea	10%-46%	16.2

SIBO: Small intestinal bacterial overgrowth; OR: Odds ratio; COVID-19: Coronavirus disease 2019.

disease. Currently, such studies are being conducted in cirrhosis[72], MAFLD[79-81], diabetes[118,119], and other diseases. An important question is how the course of the underlying disease will respond to SIBO treatment. These results have already been obtained for some diseases[49,154], but their presentation is the aim for the next review.

CONCLUSION

In conclusion, we have summarized almost all published information on the association of SIBO with various diseases and their manifestations. Almost one third of cited studies were published within the last 2 years, highlighting the recent interest in the field and the importance of our review. However, further study on SIBO in various diseases, and particularly on the effect of its eradication on the condition and prognosis of patients, is required.

Abstract

BACKGROUND

Hepatic fibrosis is a common pathological process of chronic liver diseases with various causes, which can progress to cirrhosis.

AIM

To evaluate the effect and mechanism of action annexin (Anx)A1 in liver fibrosis and how this could be targeted therapeutically.

METHODS

CCl_4 (20%) and active N-terminal peptide of AnxA1 (Ac2-26) and N-formylpeptide receptor antagonist N-Boc-Phe-Leu-Phe-Leu-Phe (Boc2) were injected intraperitoneally to induce liver fibrosis in eight wild-type mice/Anxa1 knockout mice, and to detect expression of inflammatory factors, collagen deposition, and the role of the Wnt/β-catenin pathway in hepatic fibrosis.

RESULTS

Compared with the control group, AnxA1, transforming growth factor (TGF)-β1, interleukin (IL)-1β and IL-6 expression in the liver of mice with hepatic fibrosis induced by CCl_4 was significantly increased, which promoted collagen deposition and expression of α-smooth muscle actin (α-SMA), collagen type I and connective tissue growth factor (CTGF), and increased progressively with time. CCl_4 induced an increase in TGF-β1, IL-1β and IL-6 in liver tissue of AnxA1 knockout mice, and the degree of liver inflammation and fibrosis and expression of α-SMA, collagen I and CTGF were significantly increased compared with in wild-type mice. After treatment with Ac2-26, expression of liver inflammatory factors, degree of collagen deposition and expression of a-SMA, collagen I and CTGF were decrea-

sed compared with before treatment. Boc2 inhibited the anti-inflammatory and antifibrotic effects of Ac2-26. AnxA1 downregulated expression of the Wnt/β-catenin pathway in CCl_4-induced hepatic fibrosis. *In vitro*, lipopolysaccharide (LPS) induced hepatocyte and hepatic stellate cell (HSC) expression of AnxA1. Ac2-26 inhibited LPS-induced RAW264.7 cell activation and HSC proliferation, decreased expression of α-SMA, collagen I and CTGF in HSCs, and inhibited expression of the Wnt/β-catenin pathway after HSC activation. These therapeutic effects were inhibited by Boc2.

CONCLUSION

AnxA1 inhibited liver fibrosis in mice, and its mechanism may be related to inhibition of HSC Wnt/β-catenin pathway activation by targeting formylpeptide receptors to regulate macrophage function.

Key Words: Annexin A1; Active N-terminal peptide of annexin A1; Macrophage; Hepatic stellate cell; Wnt/β-catenin; Liver fibrosis

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Hepatic stellate cells (HSCs) are the main receiver of inflammatory signals and the main promoter of fibrosis. Kupffer cells are activated by damage-associated molecular patterns or lipopolysaccharide, and other pathogen-associated molecular patterns, producing and releasing cytokines to activate HSCs, causing secretion and deposition of extracellular matrix and liver fibrosis. Annexin (Anx)A1 is a glucocorticoid regulatory protein that enhances efferocytosis in macrophages, inhibits activation of phospholipase A2, downregulates expression of inflammatory arachidonic acid, and negatively regulates inflammatory cells and factors. Whether AnxA1 is involved in the formation of liver fibrosis and its mechanism of action were the focus of this study.

INTRODUCTION

Various chronic liver diseases cause inflammation and necrosis of liver cells, and abnormal hyperplasia of fibrous connective tissue, leading to fibrosis, which is the early reversible stage of cirrhosis and one of the most important threats to human health worldwide[1,2]. When liver parenchyma is damaged, extracellular matrix (ECM) synthesis increases due to liver repair. When the cause is not removed, the continuously damaged liver leads to the failure of timely degradation of a large amount of synthetic ECM and excessive deposition in the liver tissue, which eventually develops into fibrosis[1-4]. The process involves a variety of fibrosis-promoting cells, including vascular smooth muscle cells, portal fibroblasts, and hepatic stellate cells (HSCs), and the activation and proliferation of HSCs is the main cell source of ECM[5-10]. Liver injury leads to necrosis or apoptosis of liver cells, and immune cells, mainly Kupffer cells are activated. Transforming growth factor (TGF)-β1, interleukin (IL)-1β, IL-6 and other cytokines are released, which promote the activation and proliferation of HSCs and secretion of inflammatory and fibrogenic factors. The activated HSCs express α-smooth muscle actin (α-SMA) and cytokines induce HSCs to differentiate into myofibroblasts, which secrete ECM components and cause liver fibrosis[5-11]. These changes may become an important target for the treatment of liver fibrosis.

Annexin (Anx)A1 is a member of the structurally related calcium-dependent phospholipid binding protein superfamily, which is widely distributed in all human tissues and cells, and involved in cell proliferation, differentiation, signal transduction, apoptosis, immunity and other physiological processes[12]. The proteins of the AnxA1 superfamily are homologous in structure, and each member has its unique N-terminal structure, which is related to its different functions and physiological effects [12]. After hydrolysis of full-length AnxA1, the N terminus is disconnected, and 26 amino acids in the N segment form a peptide chain fragment N-terminal peptide of AnxA1 (Ac2-26)[13]. AnxA1 and Ac2-26 both activate and bind to a specific G-protein-coupled receptor known as N-formylpeptide receptor (FPR)2[13], and Ac2-26 binds to FPR1[14]. AnxA1 inhibits expression of α-SMA and collagen I genes in TGF-β1-induced renal cortical fibroblasts[15] and regulates cigarette-smoke-induced pulmonary fibrosis

[16]. However, whether AnxA1 regulates cell proliferation and collagen deposition in liver tissue remains unclear. The purpose of this study was to investigate the effects of AnxA1 on CCl_4-induced inflammation, proliferation and collagen deposition in liver injury.

The Wnt/β-catenin signaling pathway is highly evolutionarily conserved and widespread in multicellular organisms. It is essential for cell growth, differentiation, ontogeny, genetic stability, apoptosis, self-renewal of stem cells, and homeostatic maintenance of adult tissues[17,18]. In normal liver tissue, the Wnt/β-catenin signaling pathway is almost inactive, but its abnormal activation plays an important role in the physiological and pathological processes of the liver. Increasing evidence has shown that abnormal expression of the Wnt/β-catenin signaling pathway is involved in the incidence of liver tumors, and the occurrence of liver inflammation, cirrhosis, and focal nodular hyperplasia[19]. AnxA1 has been reported as an important regulator of Wnt/β-catenin signaling[20], but whether AnxA1 contributes to the formation of liver fibrosis was the focus of this study.

MATERIALS AND METHODS

Animal treatment

Six-to-eight-week-old C57BL/6 mice (weighing 18-25 g; SLC, Guangxi, China) and C57BL/6JGpt Anxa1-KO mice (B6/JGptAnxa1em4Cd9634/Gpt, Strain NO. T016864; weighing 18-25 g; SLC, Jiangsu, China) were maintained in climate-controlled rooms under a 12-h light-dark cycle. All experiments were conducted in accordance with the institutional guidelines of Guangxi Medical University for the care and use of laboratory animals.

Thirty-two wild-type mice and 32 *Anxa1*$^{-/-}$ mice were each randomized into four subgroups of eight: Control, CCl_4-induced liver fibrosis, liver fibrosis + Ac2-26, and liver fibrosis + Ac2-26 + FPR antagonist N-Boc-Phe-Leu-Phe-Leu-Phe (Boc-2). Mice in the control group received olive oil for intraperitoneal injection, while mice in the other three subgroups received 20% CCl_4 (500 mL; Shanghai Acmec Biochemical Co., Ltd, China), and CCl_4 + Ac2-26 1 mg/kg (500 mg; MedChemExpress, CAT: HY-P1098A/CS-0093919) with or without N-Boc2 1 mg/kg (500 mL; MedChemExpress, CAT: HY-103473A) for intraperitoneal injection twice weekly. Eight mice were used for each time point. At 4 and 8 wk after injection, animals were anesthetized with pentobarbital sodium (50 mg/kg intravenous injection), and blood samples were collected from the inferior vena cava. The livers were removed, and a small portion of liver tissue was fixed with 4% formaldehyde solution, and the remaining liver tissue was immediately frozen and stored in liquid nitrogen for RNA and protein extraction.

Histopathological examination of liver

Hematoxylin-eosin (HE) staining and modified Masson three-color staining (Modified Masson's Trichrome Staining Kit; Beijing Solarbio Science & Technology,) were performed after liver tissue fixation, dehydration, paraffin embedding, sectioning, dewaxing and hydration (bar: 50 mm).

In situ expression of AnxA1 in liver tissue determined by immunohistochemistry

The sections were dewaxed and hydrated according to AnxA1 monoclonal antibody instructions and SP-9000 Histostain™ - SP Kits (6 mL, Beijing Zhongshan Jinqiao Biotechnology, cat: K197712D/K196915F) requirements, antigenic alkaline repair, endogenous peroxidase blocking, goat serum blocking, and AnxA1 monoclonal antibody dilution 1: 1000 (Abcam, United Kingdom, cat: ab214486) were incubated overnight at 4 °C, the biotin-labeled goat anti-mouse/rabbit immunoglobulin G (IgG) (Invitrogen, United States, cat: TJ26211) was incubated for 15 min, and the horseradish-labeled Streptomyces vitellin was incubated for 15 min. Diaminobenzidine staining, counterstaining, dehydration, transparency, sealing, and microscopic examination. For each sample, five high-power fields (bar: 100 mm) were randomly selected, each containing an average of 400 cells, and the number of positive cells was counted for each field.

Preparation of HSCs, hepatocytes and Kupffer cells

JS1 HSCs and AML1 hepatocytes were separately cultivated in Williams' E medium containing 10% calf serum, 2 mmol/L L-glutamate and antibiotics (100 U/mL penicillin G and 100 μg/mL streptomycin). RAW246.7 cells were cultured in RPMI 1640 medium containing 10% calf serum and antibiotics. Cells were plated at (2×10^6)-(3×10^6)/mL and preincubated for 24 h at 37 °C in a humidified atmosphere containing 5% CO_2. The purity and viability of cells ranged from 87% to 95%. RAW246.7 cells HSCs and hepatocytes were incubated with 100 ng/mL lipopolysaccharide (LPS) (Sigma, St. Louis, MO, United States), LPS + 100 ng/mL Ac2-26, or LPS + Ac2-26 + 100 ng/mL Boc2 for 1, 3, 6, 12 and 24 h to activate expression of AnxA1, α-SMA, TGF-β1, connective tissue growth factor (CTGF), collagen I, IL-1β and IL-6. Ac2-26 or Ac2-26 + Boc2 dissolved in medium was added to the incubation medium 1 h prior to the addition of LPS.

Quantitative real-time polymerase chain reaction

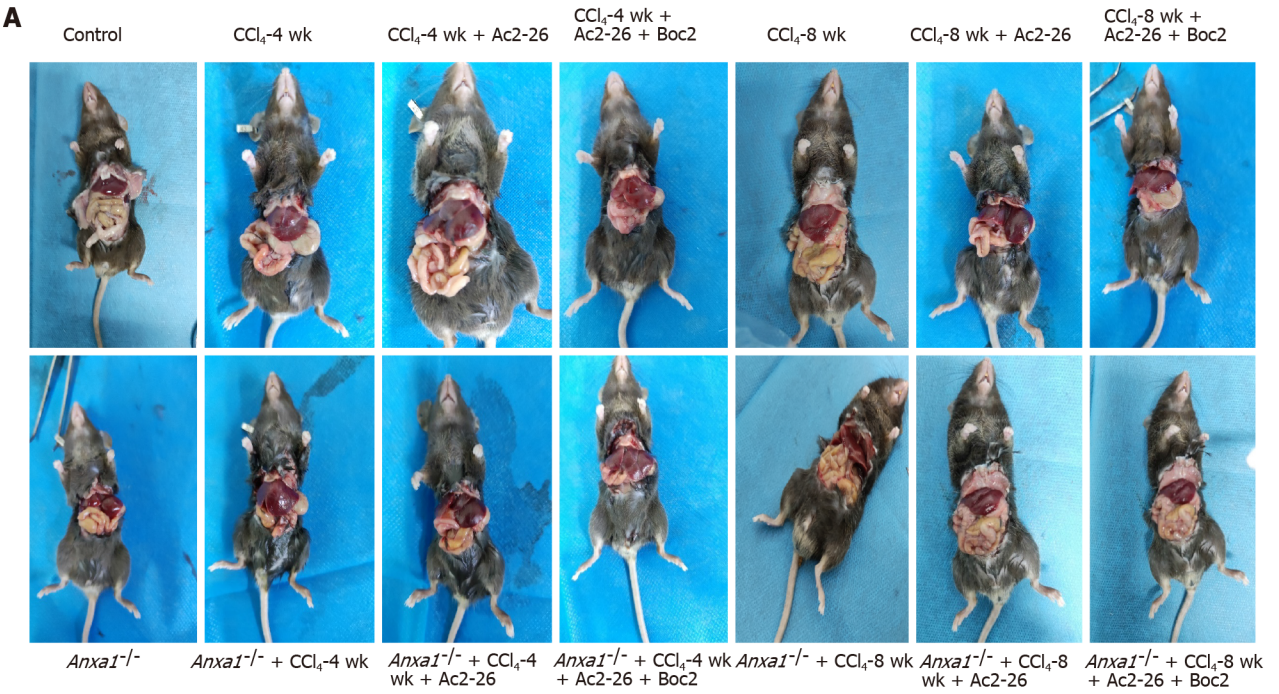
Total RNA (1 μg) was extracted from liver or primary cells using TRIzol reagent (Takara Bio, Beijing, China) and reverse transcribed using a ReverTra Ace qPCR RT kit (Takara Bio). Target mRNA expression was quantified using quantitative real-time polymerase chain reaction (qPCR) as described previously[21]. TaqMan Gene Expression Assays for AnxA1 (forward primer 5′-AGCAGATCAAGGCCGCGTA-3′, reverse primer 5′-CATGGCACCACGGAGTTCA-3′), IL-6 (forward primer 5′-AGGATACCACTCCCAACAGACC-3′, reverse primer 5′-GCACAACTCTTTTCTCATTTCCAC-3′), TGF-β1 (forward primer 5′-TACGGCAGTGGCTGAACCAA-3′, reverse primer 5′-CGGTTCATGTCATGGATGGTG-3′), IL-1β (forward primer 5′-CACTACAGGCTCCGAGATGAACAAC-3′, reverse primer 5′-TGTCGTTGCTTGGTTCTCCTTGTAC-3′), α-SMA (forward primer 5′-CTGACAGAGGCACCACTGAA-3′, reverse primer 5′-CATCTCCAGAGTCCAGCACA-3′), collagen I (forward primer 5′-AAGAGGCGAGAGGTTTCC-3′, reverse primer 5′-AGAACCATCAGCACCTTTGG-3′), CTGF (forward primer 5′-CAAAGCAGCAAATACCA-3′, reverse primer 5′-GGCCAAATGTGTCTTCCAGT-3′), and GAPDH (forward primer 5′-TGTGTCCGTCGTGGATCTGA-3′, reverse primer 5′-TTGCTGTTGAAGTCGCAGGAG-3′) were purchased from Takara Bio.

Western blotting

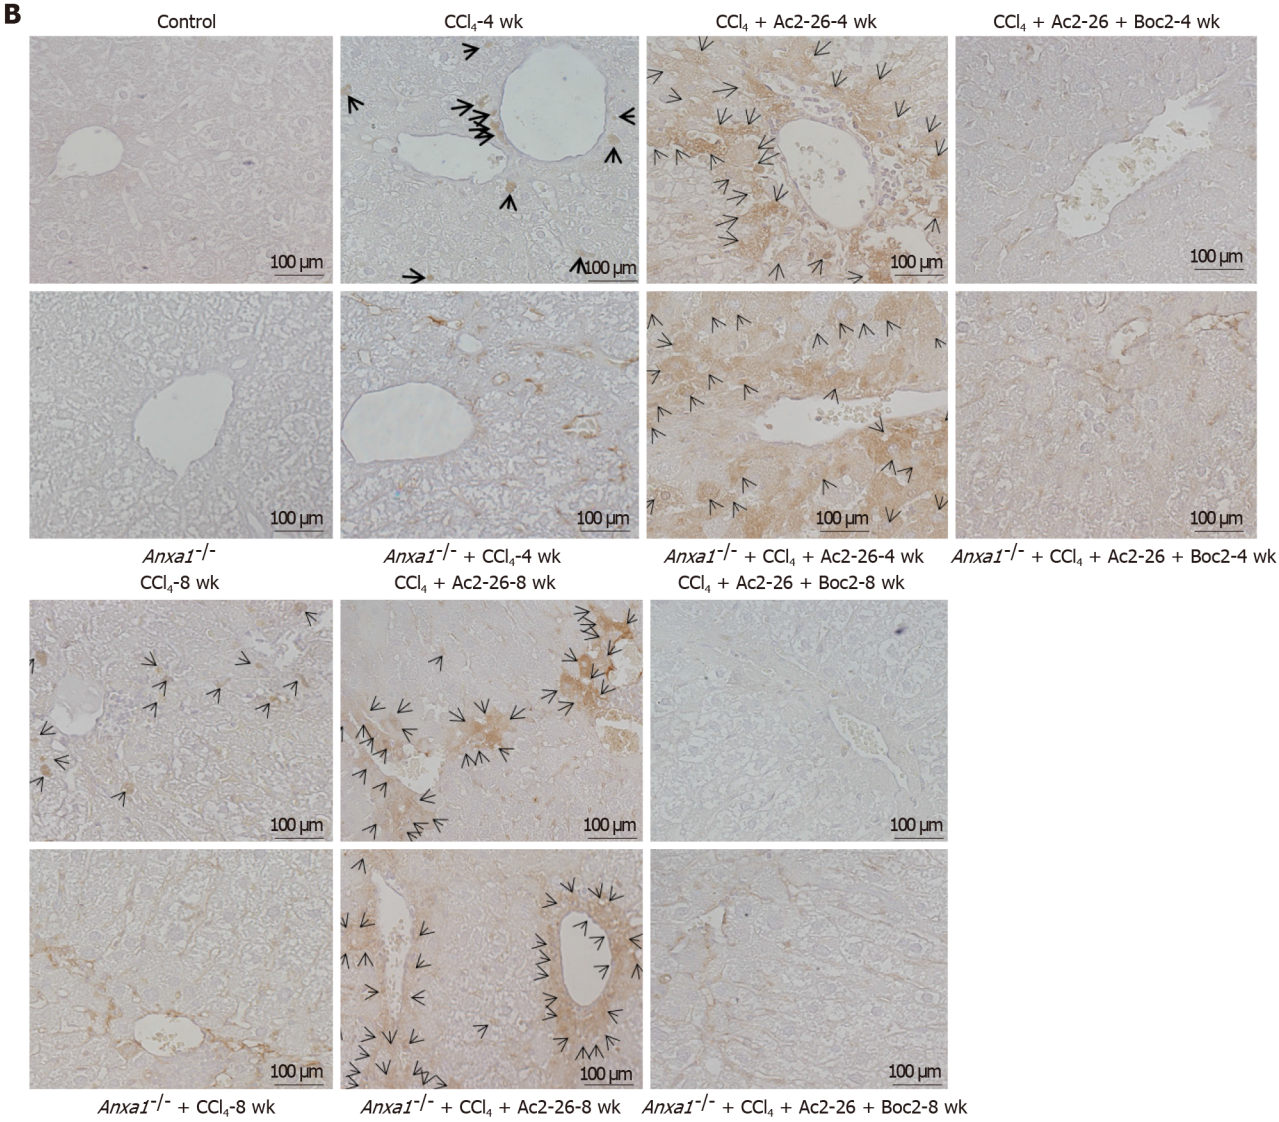
Protein samples (30-50 μg) were prepared from livers and cells and separated by SDS-PAGE, followed by transfer to polyvinylidene difluoride membranes as reported previously[21]. Blots were incubated with antibodies (1:1000) against AnxA1 (Abcam, cat: ab214486), α-SMA (50 μL, Affinity Biosciences, Jiangsu, cat: AF1032), β-catenin (50 mL, MedChemExpress, cat: 51067-2-AP) and GAPDH (Abcam, cat: ab181602), followed by incubation with a peroxidase-conjugated goat anti-mouse/rabbit IgG(H + L) (1:5000; Invitrogen, cat: TJ26211). Proteins were visualized using fluorescence scanner imaging system (Odyssey; Bio-Rad, Hercules, CA, United States).

Statistical analysis

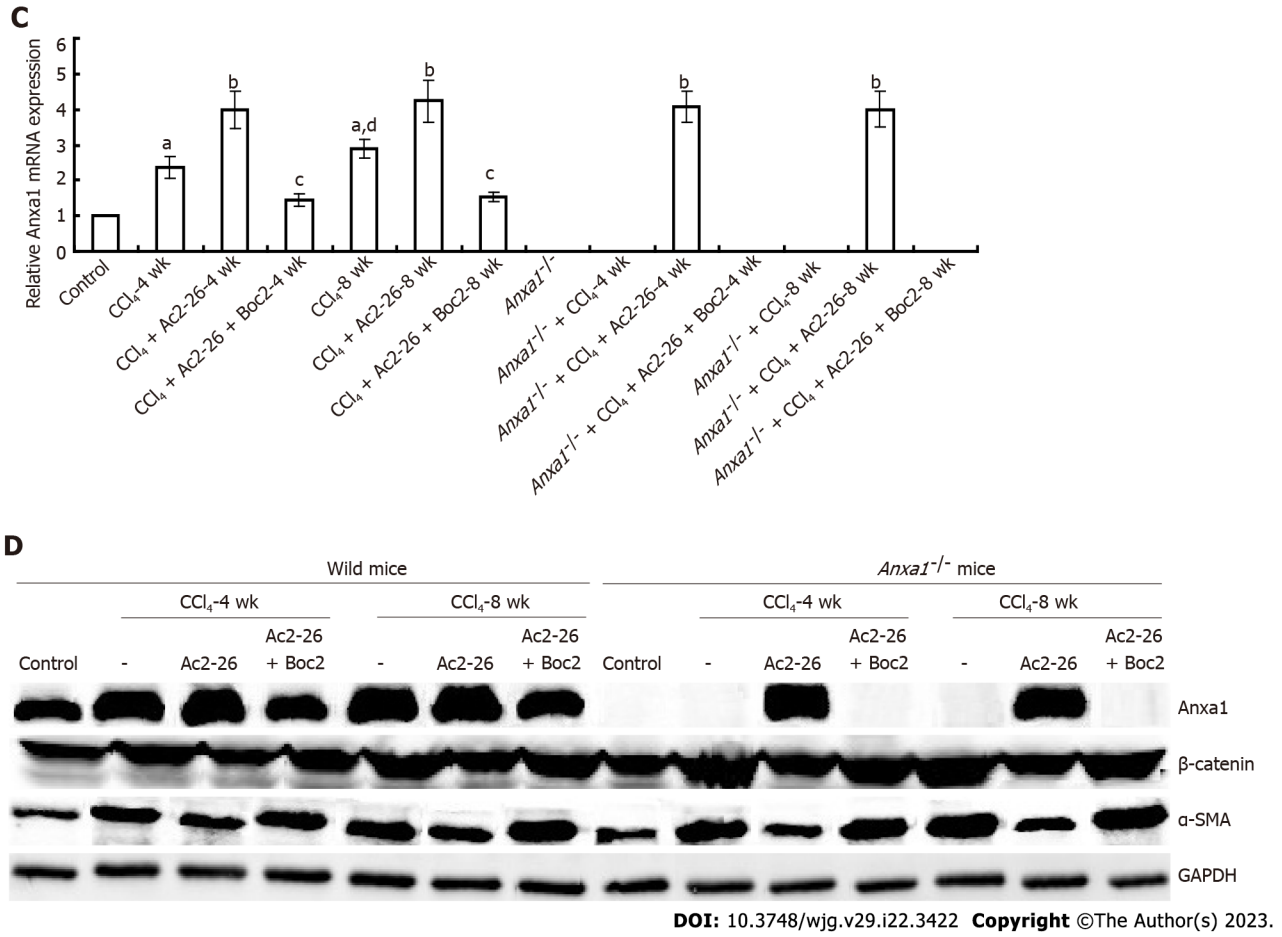
Results are expressed as mean ± SE (n = 8), unless otherwise indicated. Statistical analyses were performed using Kruskal-Wallis one-way analysis of variance. $P < 0.05$ was considered significant.



RESULTS



Effects of AnxA1 on liver appearance



The liver of the control mice was red with bright color and smooth surface. In the CCl_4-induced wild-type mice group, the liver tissue became light in color, rough on the surface, dull around the edge, and hard in texture, and nodules or even cellulose-like changes appeared over time. The lesions in the *AnxA1*$^{-/-}$ group were more severe than in the wild-type mice. After treatment with Ac2-26, the appearance of the liver in the CCl_4-induced mice was significantly improved with dark red color, and the surface roughness and nodulation were significantly reduced, the effects of Ac2-26 were inhibited by Boc2 (Figure 1A). Compared with the control group, AnxA1 expression was significantly increased in the CCl_4 model group, and was higher at 8 wk than 4 wk, suggesting that AnxA1 was related to the development of liver fibrosis. AnxA1 expression was higher in liver tissues of the CCl_4 model group after Ac2-26 treatment, while Boc2 inhibited AnxA1 expression (Figures 1B and C), and the difference was significant ($P < 0.05$). Western blotting and qPCR results were consistent with immunohistochemical results (Figure 1D).

AnxA1 inhibits CCl_4-induced liver injury and inflammatory cell infiltration in mice

HE staining showed that the structure of hepatic lobules in the control group was clear, and there was no vacuole formation or obvious inflammatory cell infiltration. In the CCl_4-induced wild model group, HE staining for 4 wk showed that the hepatocytes were swollen and enlarged, with scattered degeneration and necrosis, as well as infiltration of monocytes and lymphocyte cells. Degeneration and necrosis of hepatocytes were observed at 8 wk. In the *AnxA1*$^{-/-}$ model group with fibrosis induced by CCl_4, liver tissue destruction was accompanied by a large number of inflammatory cell infiltration and steatosis. At 4 wk, there was massive necrosis of liver cells, massive infiltration of inflammatory cells, and disorder of hepatic lobular structure. At 8 wk, there was obvious structural destruction that became more severe over time. The infiltration of liver inflammatory cells and destruction of liver lobular structure in the *AnxA1*$^{-/-}$ mice were more obvious than those in the wild-type mice. After treatment with Ac2-26, the damage to the hepatic lobular structure and inflammatory cell infiltration in the CCl_4-induced mice was reduced compared with that before treatment. AnxA1 mimics the peptide Ac2-26, which largely controls inflammation and is protective against hepatic fibrosis. In the model group treated with Ac2-26 and Boc2, Boc2 almost completely eliminated the effects of Ac2-26 at 4 wk (Figure 2A), suggesting that AnxA1 inhibited CCl_4-induced liver tissue injury and reduced inflammatory cell infiltration. AnxA1 works by targeting mainly FPR receptors.

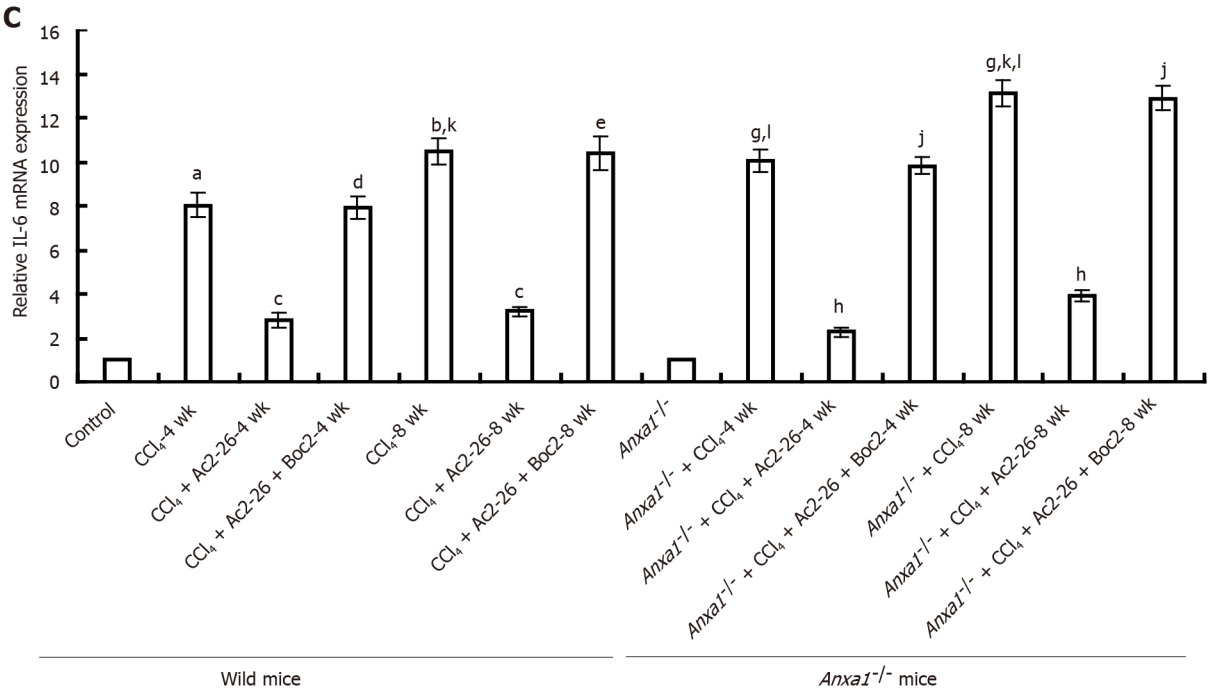

Figure 1 Annexin A1 inhibited CCl_4-induced liver injury. A: Gross view of liver tissue. The liver of mice in the control group was red with bright color and smooth surface. In the CCl_4-induced model group, the liver was light in color, rough and grainy on the surface. Liver tissue nodules appeared at 8 wk, and fibrosis appeared at 8 wk in *Anxa1*$^{-/-}$ mice. After Ac2-26 treatment, the liver was mostly dark red, and the surface roughness was reduced. The effect of Ac2-26 was reversed by Boc2, and the liver color became lighter, the surface was grainy, the edge was blunt, and the texture was hard; B: Annexin (Anx)A1 was expressed in liver tissue. Anxa1 was stained brown. Compared with the control group, the liver tissue in mice treated with CCl_4 showed obvious AnxA1 staining. More liver tissue was stained at 8 wk than at 4 wk. The *AnxA1*$^{-/-}$ model groups were hardly stained. More tissue staining was observed in the CCl_4-induced model group after Ac2-26 treatment, while staining was almost absent after Boc2 intervention; C: *AnxA1* mRNA expression; D: Protein expression of AnxA1, α-smooth muscle actin, β-catenin, and GAPDH (n = 8). Results are presented as ratios of target mRNA or protein normalized to internal GAPDH. $^{a}P < 0.05$ *vs* control; $^{b}P < 0.01$ *vs* CCl_4; $^{c}P < 0.05$ *vs* CCl_4 + Ac2-26; $^{d}P < 0.05$ *vs* intra-group. Ac2-26: Active N-terminal peptide of annexin A1; AnxA1: Annexin A1; Boc2: N-formyl peptide receptor antagonist N-Boc-Phe-Leu-Phe-Leu-Phe; α-SMA: α-smooth muscle actin.

AnxA1 inhibits CCl_4-induced collagen deposition in mouse liver tissue

Collagen deposition is an important indicator of the degree of liver fibrosis, and can be visualized by Masson staining. Staining clearly showed that there was no collagen staining in the control group of wild-type and *AnxA1*$^{-/-}$ mice. In the CCl_4-induced wild model group, blue collagen fibers proliferated in the portal area at 4 wk, but the degree of collagen fibrosis was mild. Similarly, the proliferation of blue-stained collagen fibers in the portal area was observed in the wild model group at 8 wk, but the collagen fibers were further increased, widened and extended to the surrounding hepatic lobular space than at 4 wk, suggesting that the liver fibers were gradually aggravated with the extension of modeling time. Compared with wild model mice, CCl_4 induced more significant collagen deposition in the liver tissue of *AnxA1*$^{-/-}$ mice. At 4 wk, blue collagen fibers proliferated obviously in hepatic portal area and began to extend to liver parenchyma, and collagen fibers began to segment liver parenchyma. At 8 wk, a large amount of collagen surrounded the liver cells to form pseudolobules, which seriously damaged the normal structure of the liver tissue, indicating formation of fibrosis. The collagen deposition in the liver of *AnxA1*$^{-/-}$ mice was significantly aggravated by CCl_4, and the degree of liver fibrosis was even more severe. The collagen deposition and wrapping in the liver of mice in the CCl_4-induced mice was significantly weakened after Ac2-26 treatment, and the severity of liver fibrosis was relieved. In the model group, the damage to the liver tissue structure and collagen deposition after treatment with Ac2-26 and Boc2 were similar to those before treatment (Figure 3A).

Figure 2 Annexin A1 inhibits CCl_4-induced hepatic inflammatory cytokines release. A: Annexin A1 (AnxA1) inhibited CCl_4-induced liver injury and inflammatory cell infiltration in mice. Normal mouse liver lobule structure was clear, with no obvious vacuole formation or inflammatory cell infiltration. In the wild-type model group, hepatic lobules were severely damaged; a large number of hepatic nuclei were shrunken, hepatocytes were vacuolated, and inflammatory cells infiltrated. *AnxA1*$^{-/-}$ mice had more severe vacuolation and extensive inflammatory cell infiltration than wild-type mice had. After treatment with active N-terminal peptide of AnxA1 (Ac2-26), the damage to hepatic lobules was reduced, hepatocyte vacuolation was reduced but necrosis was observed, clusters of regenerated hepatocytes were observed in some tissues, and inflammatory cell infiltration was also reduced. N-formylpeptide receptor antagonist N-Boc-Phe-Leu-Phe-Leu-Phe almost reversed the therapeutic effect of Ac2-26, but the inflammatory infiltration and damage to hepatic lobule structure were not significantly improved. Initial magnification: 200 ×; B: Effect of Ac2-26 on interleukin (IL)-1β mRNA expression; C: Effect of Ac2-26 on IL-6 mRNA expression; total RNA was extracted using TRIzol reagent and relative concentration of mRNA was quantified using quantitative real-time polymerase chain reaction (n = 8). Results are presented as ratios of target mRNA or protein normalized to internal GAPDH. $^{a}P < 0.05$ and $^{b}P < 0.01$ *vs* control; $^{c}P < 0.05$ *vs* CCl_4; $^{d}P < 0.05$ and $^{e}P < 0.01$ *vs* CCl_4 + Ac2-26; $^{f}P < 0.05$ and $^{g}P < 0.01$ *vs AnxA1-/-* + control; $^{h}P < 0.05$ *vs AnxA1-/-* + CCl_4; $^{i}P < 0.05$ and $^{j}P < 0.01$ *vs AnxA1-/-* + CCl_4 + Ac2-26; $^{k}P < 0.05$ *vs* intra-group; $^{l}P < 0.05$ *vs* inter-group. AnxA1 inhibits CCl_4-induced HSC activation in liver tissue

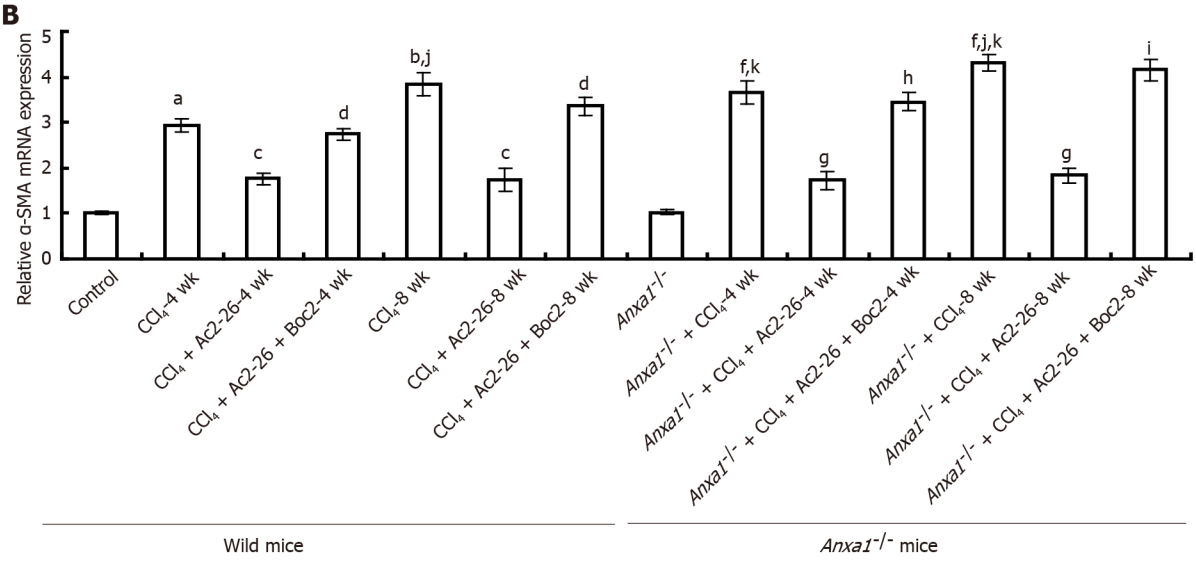
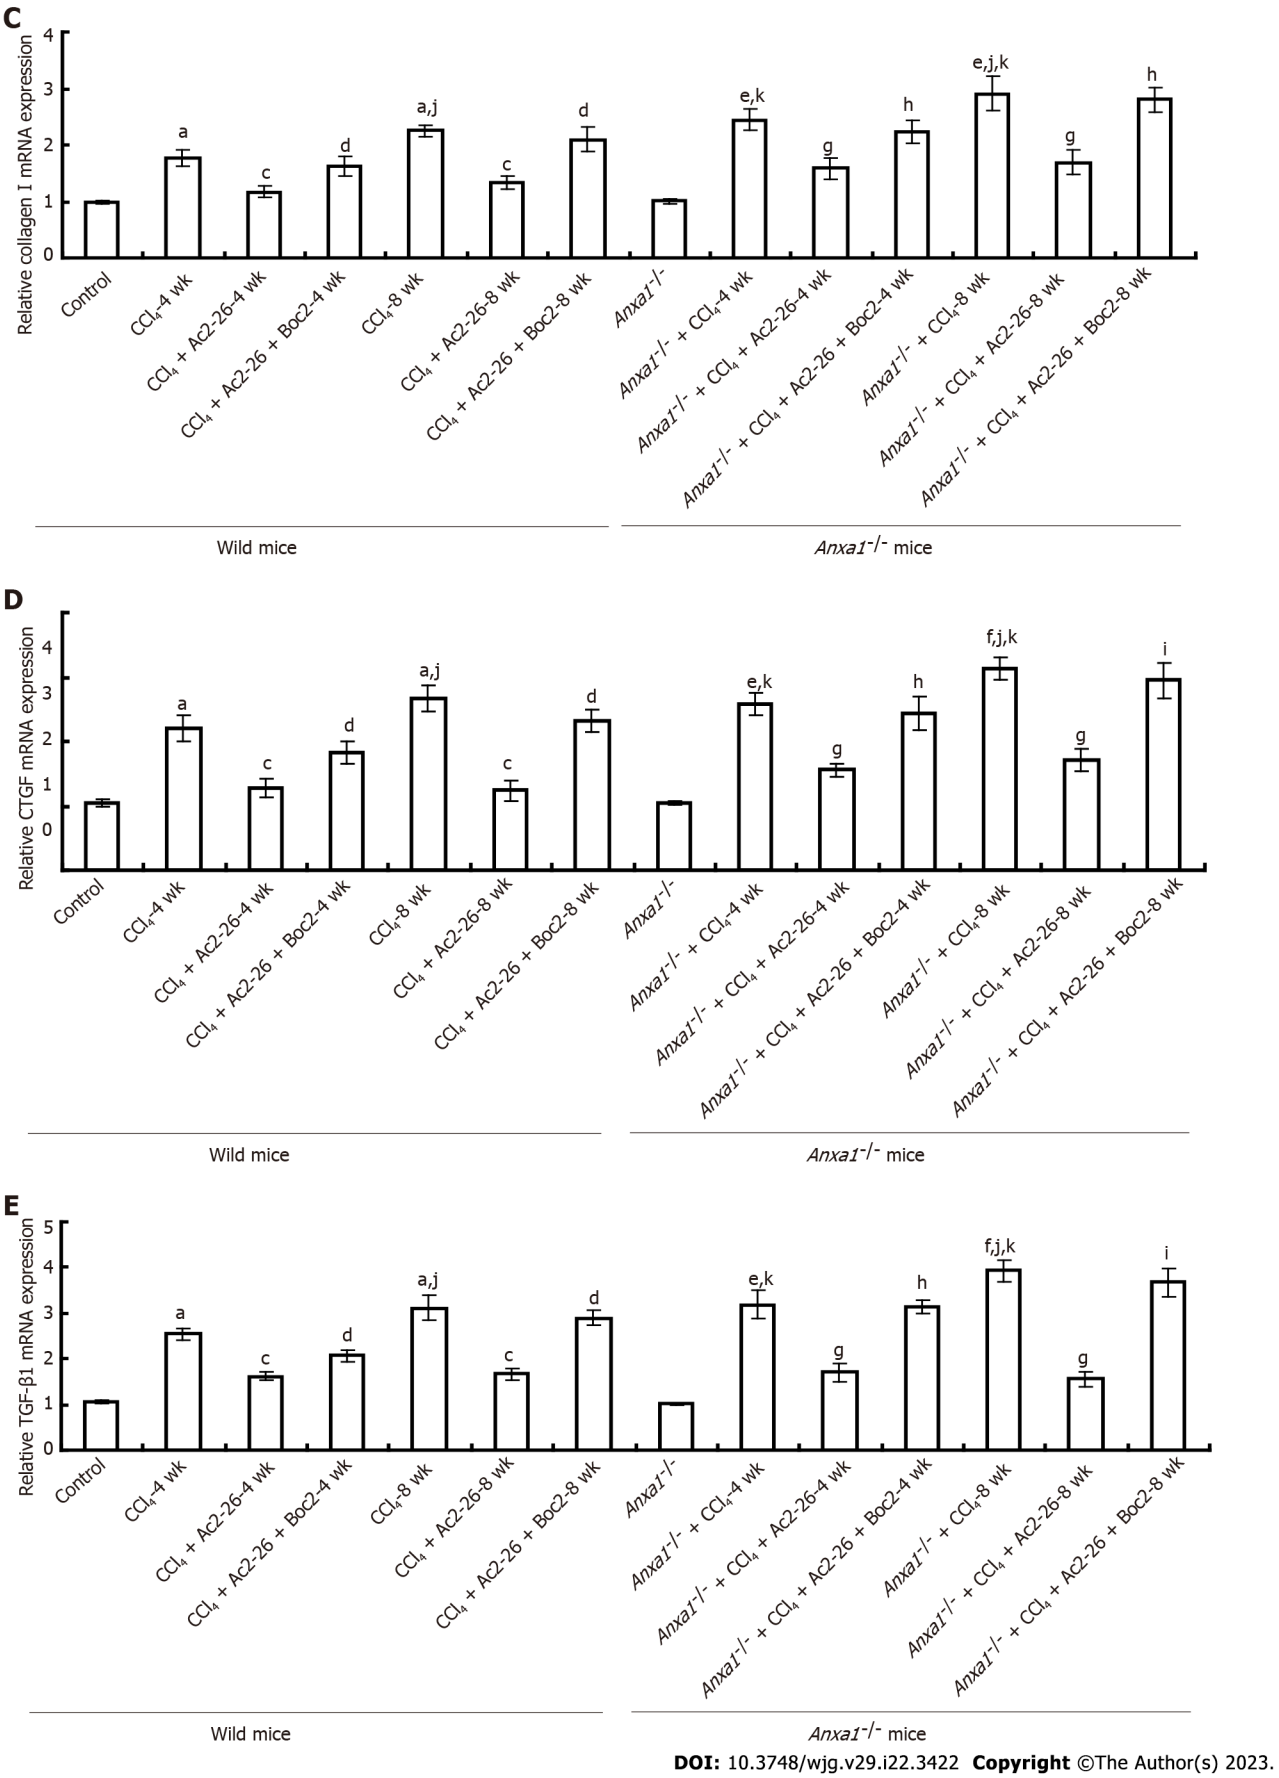
α-SMA is a marker of HSC activation and transformation into fibroblasts. HSC activation generates and secretes ECM, and type I collagen is the ECM marker of HSCs. In this study, qPCR and western blotting were used to detect the expression levels of α-SMA and collagen I in liver tissue, and to evaluate the activation status of HSCs. Expression of α-SMA and type I collagen in the liver of wild-type mice was significantly increased by CCl_4, while expression of α-SMA and collagen I in the liver of mice in the *AnxA1*$^{-/-}$ group was higher and increased with time, which was in accordance with the progression of liver fibrosis in the CCl_4-induced mice. All of the above effects were inhibited by Ac2-26, suggesting that AnxA1 inhibited HSC activation and collagen deposition. In contrast, Boc2 reversed the therapeutic effect of Ac2-26 (Figures 3B and C), and the difference was significant ($P < 0.05$). Western blotting and qPCR results were consistent with immunohistochemical results (Figure 1D).



AnxA1 inhibits CCl_4-induced release of hepatic inflammatory cytokines



CCl_4 induces expression of various cytokines in liver tissues, among which IL-1β, IL-6 and TGF-β1 are important factors leading to the formation of fibrosis. Expression of IL-1β, IL-6 and TGF-β1 in the liver of the CCl_4-induced wild model group was increased simultaneously, and upregulation of inflammatory cytokines was more obvious and increased with time in the *AnxA1*$^{-/-}$ model group, while the Ac2-26 significantly inhibited expression of IL-1β, IL-6 and TGF-β1. Boc2 inhibited the anti-inflammatory effect of Ac2-26 (Figures 2B, 2C and 3E), and the difference was significant ($P < 0.05$). This suggested that AnxA1 exerted its anti-inflammatory and antifibrotic effects by inhibiting expression of TGF-β1, IL-1β and IL-6 through FPR.

AnxA1 reduces the level of CTGF in the liver

CTGF mediates TGF-β1 promotion of ECM production and accumulation. CTGF regulates the growth of fibroblasts and epidermal cells, promoting cell adhesion, proliferation and ECM synthesis. Compared with the control group, the concentration of CTGF in the liver tissue of the CCl_4-induced wild model

Figure 3 Annexin A1 inhibits CCl_4 induced hepatic stellate cell activation in liver tissue. A: Annexin A1 (AnxA1) inhibited collagen deposition induced by CCl_4 in mouse liver tissue. Collagen was stained blue by Masson staining. The collagen content in the liver tissues in the control group was low, while collagen deposition in the liver of the CCl_4-induced model group was high. Collagen deposition in the liver of the *AnxA1*$^{-/-}$ model group was significantly aggravated

compared with that in the wild-type model group. Active N-terminal peptide of AnxA1 (Ac2-26) significantly reduced collagen deposition in the CCl_4-induced model group, and the collagen deposition in the mice after the intervention of Ac2-26 + N-formylpeptide receptor antagonist N-Boc-Phe-Leu-Phe-Leu-Phe was similar to that in the CCl_4-induced model group. Initial magnification: 100 ×; B: Effect of Ac2-26 on α-smooth muscle actin mRNA expression; C: Effect of Ac2-26 on collagen I mRNA expression; D: Effect of Ac2-26 on connective tissue growth factor mRNA expression; E: Effect of Ac2-26 on transforming growth factor-β1 mRNA expression; total RNA was extracted using TRIzol reagent and relative mRNA concentration was quantified using quantitative real-time polymerase chain reaction (n = 8). Results are presented as ratios of target mRNA or protein normalized to internal GAPDH. group and *AnxA1*$^{-/-}$ model group was higher, and paralleled the progression of liver fibrosis. The more severe the fibrosis, the higher the expression of CTGF, suggesting that CTGF was closely related to the occurrence and development of liver fibrosis. After Ac2-26 treatment, expression of CTGF in liver tissues of mice in the CCl_4-induced mice was significantly decreased. AnxA1 inhibited expression of CTGF in liver tissue and alleviated the occurrence of liver fibrosis, while Boc2 almost reversed the therapeutic effect of Ac2-26 (Figure 3D), and the difference was significant (P < 0.05).

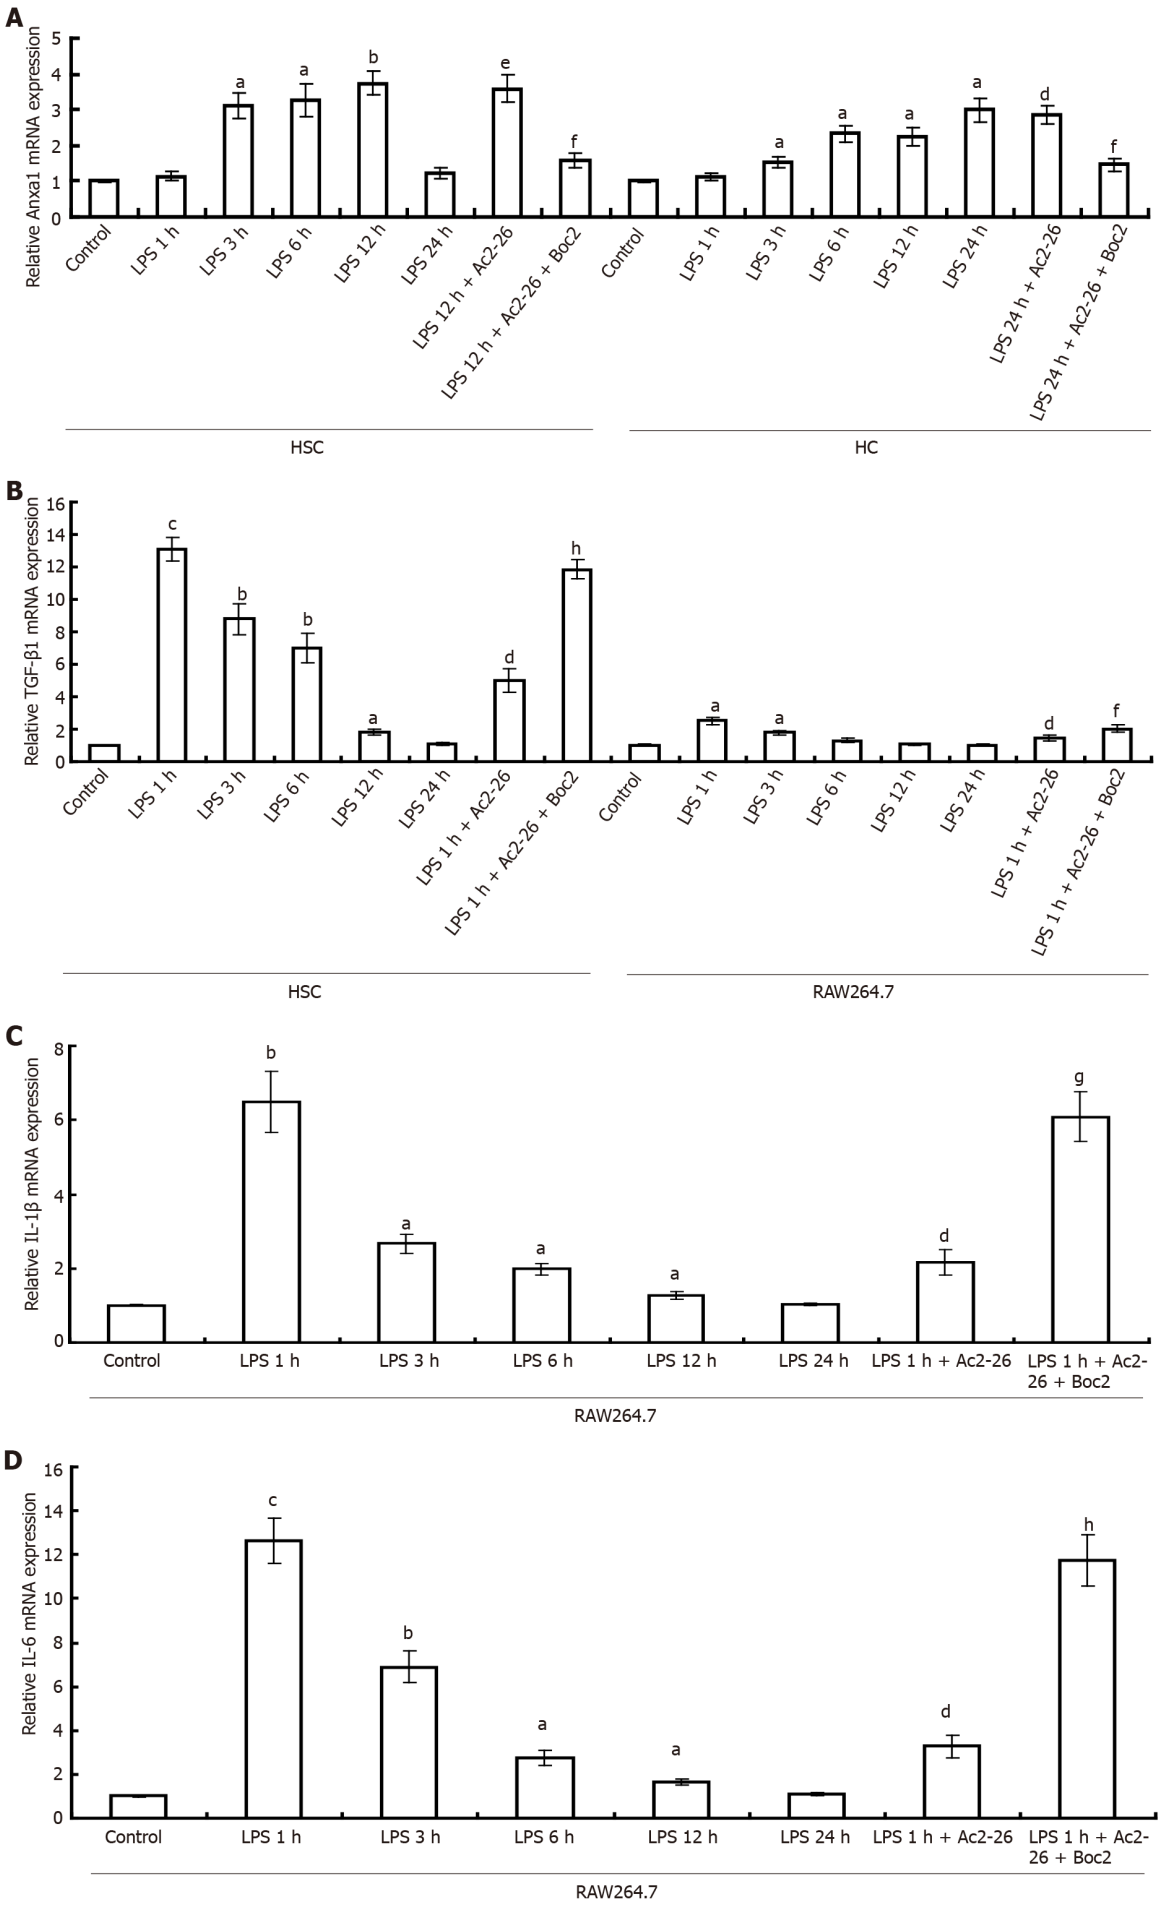
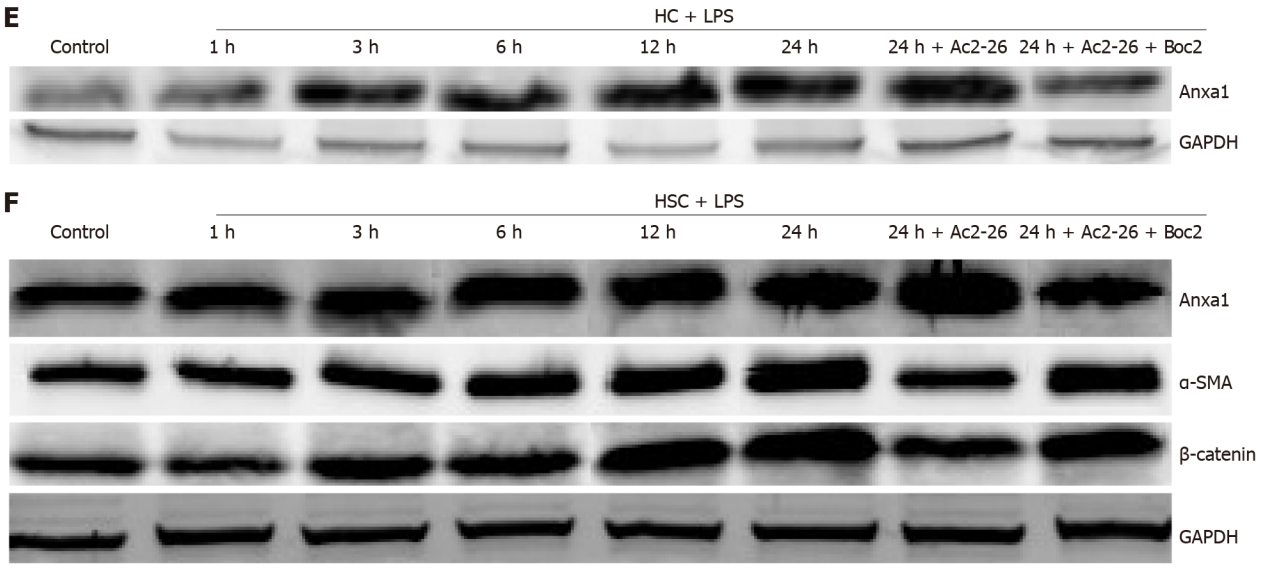
AnxA1 inhibits activation of RAW264.7 cells and HSCs



LPS induced activation of RAW264.7 cells and the release of inflammatory cytokines. Compared with the control group, expression of TGF-β1, IL-1β and IL-6 in RAW264.7 cells was significantly induced by LPS, and reached a peak within 1 h, then gradually decreased to the normal level. After activation of RAW264.7 cells, AnxA1 was not significantly increased, but Ac2-26 inhibited TGFβ1, and IL-6 expression in RAW264.7 cells, while Boc2 blocked the inhibitory effect of Ac2-26 on RAW264.7 cells (Figures 4B-D), and the difference was significant (P < 0.05). LPS induced activation of HSCs, which expressed TGFβ1, α-SMA, CTGF, and collagen I simultaneously (Figures 4B and 5A-C). Expression of TGF-β1 and CTGF began to increase at 1 h and peaked at 3 and 6 h, respectively. AnxA1 expression began to increase at 3 h and peaked at 12 h. Expression of α-SMA and collagen I began to increase significantly at 12 h and peaked at 24 h. Ac2-26 treatment significantly decreased LPS-induced expression of TGF-β1, α-SMA, CTGF and collagen I, and Boc2 significantly inhibited this effect (Figures 4B and 5A-C and the difference was significant (P < 0.05). LPS induced activation of hepatocytes. Compared with the control group, AnxA1 was highly expressed after hepatocyte (HC) activation, which was time-dependent and increased from 4 to 24 h (Figure 4A). Ac2-26 significantly upregulated HSC AnxA1 expression, while Boc2 inhibited AnxA1 expression (Figure 4A), and the difference was significant (P < 0.05). The results of western blotting and qPCR were consistent (Figures 4E and F).



AnxA1 inhibits Wnt/β-catenin activation in liver tissue

The Wnt/β-catenin pathway plays an important role in the formation of liver fibrosis. We used western blotting to detect β-catenin expression, which was associated with inflammation and fibrosis. Compared with the low expression of β-catenin in control mice, expression of β-catenin was upregulated in the model group and higher in the *AnxA1*$^{-/-}$ group, and expression was higher at 8 wk than at 4 wk. After Ac2-26 treatment, expression of β-catenin protein in the CCl_4-induced model group was significantly decreased compared with that before treatment, while Boc2 inhibited the effect of Ac2-26 (Figure 1D). The results of the animal experiments were verified by *in vitro* cell experiments. β-catenin was highly expressed in LPS-induced HSC activation, and increased progressively with time, starting at 3 h and reaching a peak at 24 h. Ac2-26 inhibited expression of β-catenin protein in LPS-induced HSCs, while Boc2 inhibition blocked this effect, β-catenin protein expression was maintained at a high level in LPS-induced HSCs (Figure 4F).

DISCUSSION

Hepatic fibrosis is a self-repair response of the liver to sustained injury. It is the abnormal structure and function of the liver caused by the excessive accumulation of ECM in the intercellular spaces caused by activation of HSCs and imbalance of synthesis and degradation of ECM. Chronic inflammation caused by sustained injury is the initiating factor of hepatic fibrosis[15]. When the pathogenic factors act on the body, a variety of injurious changes occur, but they also stimulate the body to produce defense, adaptation, compensation and other anti-injury responses. AnxA1 is a glucocorticoid regulatory protein that inhibits neutrophil apoptosis, enhances efferocytosis in macrophages, inhibits activation of phospholipase A2, downregulates expression of inflammatory arachidonic acid, and has a significant negative regulatory effect on several inflammatory cells and factors[22]. In this study, a mouse model of experimental liver fibrosis was established by intraperitoneal injection of 20%CCl_4, and treatment or intervention was performed by knockout of *AnxA1* gene, intraperitoneal injection of AnxA1-simulated peptide Ac2-26 and AnxA1 receptor inhibitor Boc2, to observe the effects of AnxA1 on liver fibrosis and

explore its main targets. We found that AnxA1 protein and mRNA levels in the liver fibrosis model group were higher than those in the normal control group, and were time-dependent. AnxA1 began to increase at 4 wk, peaked at 8 wk, and then began to decline, consistent with the severity of liver fibrosis in mice, suggesting that AnxA1 is associated with the onset of liver fibrosis. Further studies showed that AnxA1 inhibited fibrosis. Firstly, gross liver specimens revealed that the liver surface roughness and nodulation of mice in the *AnxA1*$^{-/-}$ model group were more severe than those in the wild-type model group, while the lesions in the Ac2-26 group were significantly reduced after treatment, suggesting that Ac2-26 alleviated liver damage. Secondly, HE staining showed that compared with the wild-type model group, liver damage and inflammatory cell infiltration were further aggravated in the *AnxA1*$^{-/-}$ model group, suggesting serious liver damage, which was significantly reduced after treatment with Ac2-26. In addition, Masson staining indicated collagen deposition in the portal area in the wild-type model group, CCl_4 induced more significant collagen deposition in the liver tissue of the *AnxA1*$^{-/-}$ model group, with a wide area, especially at 8 wk, when large amounts of collagen surrounded the liver tissue to form pseudolobules rather than concentrating in the portal area. Collagen deposition in liver tissue of the *AnxA1*$^{-/-}$ model group progressed significantly, and was significantly improved in the group treated with Ac2-26. AnxA1 inhibited liver inflammation and collagen deposition, and relieved liver fibrosis. AnxA1 may play an important role in the occurrence and development of liver fibrosis. While Boc2 blocked the anti-inflammatory and antifibrotic effects of Ac2-26, AnxA1 may have participated in the pathogenesis of liver fibrosis by targeting FPR. Chronic liver disease is progressive, in which inflammation and fibrosis form a vicious cycle, and eventually the excess deposition of ECM, especially type I collagen, makes the lesions difficult to reverse[19,20]. The results of our study showed that the collagen I concentration in liver tissues of mice in the CCl_4-induced model group was significantly increased, and collagen I content in the *AnxA1*$^{-/-}$ model group was higher than that in the wild-type model group, and Boc2 reversed the therapeutic effect of Ac2-26 by reducing the collagen I concentration in liver tissues. High collagen I expression was maintained in the CCl_4-induced model group. It was verified that AnxA1 inhibited liver collagen deposition and relieved liver fibrosis through FPR. Therefore, AnxA1 has a protective effect on hepatic fibrosis.

There have been few studies on the effects of AnxA1 on liver fibrosis. The possible protective mechanism of AnxA1 on liver fibrosis is discussed. HSCs play an important role in the formation of liver fibrosis[19,20], and activation of HSCs is the main cause of deposition of fibrous collagen (types I, III and IV) and other stroma-like proteins in chronic liver disease[23,24], and α-SMA is an activation marker of HSCs. The activation and development of HSCs into fibroblasts is accompanied by increased expression of α-SMA[25], and the degree of HSC activation can be determined by detecting the expression level of α-SMA. In this study, the expression of α-SMA was detected by western blotting and qPCR. The expression of α-SMA in liver tissue of mice in the CCl_4-induced model group was higher than that in the control group, and the activation of HSCs induced by CCl_4 in *AnxA1*$^{-/-}$ mice was higher

than that in wild-type mice. Supplementation of exogenous Ac2-26 significantly inhibited the expression of α-SMA, and Boc2 blocked the inhibitory effect of Ac2-26. It is suggested that Ac2-26 inhibits HSC activation, which may be one of the key factors in inhibiting liver fibrosis by AnxA1, in which FPR receptors are involved.

HSCs are the main receivers of inflammatory signals and the main promoters of liver fibrosis. Hepatocyte injury triggers an inflammatory response, releases various cytokines and inflammatory factors, activates HSCs, and causes secretion and deposition of ECM, leading to liver fibrosis[26,27]. Immune cells, especially Kupffer cells and macrophages in the liver, are key regulators of inflammation [28]. Kupffer cells are intrinsic macrophages in the liver, which play an important role in the elimination of and defense against bacteria and pathogenic substances from the gastrointestinal tract[29]. In the case

of liver injury, Kupffer cells are activated by damage-associated pathogenic patterns or LPS, viral DNA, and other pathogen-associated molecular patterns, producing and releasing TGF-β1, IL-1β and IL-6 to activate HSCs, causing the secretion and deposition of ECM and leading to liver fibrosis[30-32]. Our results showed that hepatic fibrosis was accompanied by inflammatory infiltration and secretion of inflammatory cytokines TGF-β1, IL-1β and IL-6, which increased with time, suggesting that hepatic inflammation is related to the severity of fibrosis. Exogenous Ac2-26 significantly reduced hepatic inflammatory cell infiltration and inflammatory factor expression in the CCl_4-induced model group, while alleviating the formation of liver fibrosis, and Boc2 inhibited the anti-inflammatory effect of Ac2-26. AnxA1 may reduce fibrosis by inhibiting the inflammatory response in the liver, and its mechanism may be related to inhibition of HSC activation by targeting FPR to regulate macrophage function.

TGF-β1 is a key regulatory factor in the process of liver fibrosis[32], and CTGF, as its downstream factor, mediates TGF-β1, promoting ECM production and accumulation[33]. HSCs are the main source of CTGF, and blocking CTGF can significantly inhibit HSC activation and proliferation, and reduce tissue inhibitors of metalloproteinase, matrix metalloproteinase (MMP)2, MMP9 and type I collagen. Our results showed that increased expression of CTGF in the liver tissue of mice in the CCl_4-induced model group was also inhibited by Ac2-26, suggesting that the inhibitory effect of AnxA1 on liver fibrosis is closely related to the expression of TGF-β1 and its downstream factor CTGF.

In order to verify the results of the animal experiments and to better investigate the mechanism of AnxA1 in liver fibrosis, we conducted *in vitro* cell experiments. Ac2-26 significantly inhibited LPS-induced activation of RAW264.7 cells and downregulated TGF-β1 and other inflammatory factors expressed in RAW264.7 cells after activation, and Boc2 reversed the above results. LPS induced HCs and HSCs to increase Anxa1 expression, but LPS induced RAW264.7 cells did not upregulate AnxA1 expression, and the activated HSCs that overexpressed SMA, collagen, and CTGF were inhibited by exogenous Ac2-26. AnxA1 mediated by FPR may affect the function of macrophages through HC paracrine or HSC autocrine effects, control inflammatory responses, inhibit HSC activation, and reduce ECM deposition by negative feedback, so as to prevent liver fibrosis formation.

Recent studies have shown that the Wnt/β-catenin signaling pathway can promote liver fibrosis and play an important role in HSC proliferation, metastasis and ECM formation[34]. Inhibition of Wnt/β-catenin signaling can inhibit the proliferation of HSCs and induce their apoptosis, thus alleviating CCl_4-induced liver fibrosis[34-36]. In addition, TGF-β1 activates the Wnt/β-catenin pathway by inhibiting the expression of Wnt/β-catenin inhibitors[36]. Our results suggest that Ac2-26 downregulates the expression of β-catenin in the Wnt signaling pathway in mouse liver fibrosis, and inhibits the expression of activated HSC β-catenin. Combined with previous findings, the therapeutic effects of AnxA1 may alleviate the development of liver fibrosis by inhibiting the Wnt/β-catenin pathway of HSCs.

CONCLUSION

AnxA1 may play an important role in the formation of liver fibrosis, including regulating macrophage function, reducing inflammation, inhibiting HSC activation, and improving collagen deposition. AnxA1 mediated by FPR receptors may regulate the activity of macrophages through HSC autocrine or paracrine functions, inhibit the Wnt/β-catenin pathway, and inhibit HSC activity. Although its further mechanism of action has not been clearly elucidated, our results suggest that AnxA1 has potential activity against hepatic fibrosis and can block the occurrence of fibrosis at multiple targets, which may provide a new option for liver fibrosis treatment.

ARTICLE HIGHLIGHTS

Research background

Liver fibrosis is a pathological change caused by chronic liver injury, and is a key link in the progression of chronic liver diseases to cirrhosis or liver cancer. How to prevent and reverse liver fibrosis is currently a hot and difficult research topic, and fully understanding and elucidating the pathogenesis of liver fibrosis is the foundation of prevention and treatment. At present, there is still a lack of safe and effective treatment for liver cirrhosis clinically. It is of great significance to deeply study the pathogenesis of liver fiber and prevent and treat it in order to reduce the incidence rate and mortality of liver cirrhosis.

Research motivation

Studies have shown that liver fibrosis is closely related to inflammation in chronic liver disease, and annexin (Anx)A1 has strong anti-inflammatory effects. Therefore, this study focuses on the pathogenesis of liver fibrosis and investigates the role of AnxA1 in liver fibrosis. Provide valuable information for antifibrosis therapy.

Research objectives
To investigate molecular and cellular mechanisms of liver fibrosis and evaluate the effect of AnxA1 in hepatic fibrosis.

Research methods
Biomarkers as drug development tools, biomarker discovery and validation using a combination of *in vitro* and *in vivo* studies. A large and wide range of animal models and cell experiments can be used, and experiments can be repeated multiple times.

Research results
AnxA1/formylpeptide receptor (FPR) inhibits the activation of hepatic stellate cells by regulating macrophage function through the Wnt/β-catenin pathway in the CCl_4-induced hepatic fibrosis mice.

Research conclusions
AnxA1 may involve in the pathogenesis of liver fibrosis and as a potential therapeutic target.

Research perspectives
This study investigates the mechanism of Anxa1 in liver fibrosis by using wild mice/Anxa1 knockout mice in combination with Anxa1 mimetic peptide and FPR receptor inhibitor to provide an experimental basis for the possible use of Anxa1 in the treatment of liver fibrosis.

Abstract

BACKGROUND

The literature indicates that the enteric nervous system is affected in inflammatory bowel diseases (IBDs) and that the P2X7 receptor triggers neuronal death. However, the mechanism by which enteric neurons are lost in IBDs is unknown.

AIM

To study the role of the caspase-3 and nuclear factor kappa B (NF-κB) pathways in myenteric neurons in a P2X7 receptor knockout (KO) mouse model of IBDs.

METHODS

Forty male wild-type (WT) C57BL/6 and P2X7 receptor KO mice were euthanized 24 h or 4 d after colitis induction by 2,4,6-trinitrobenzene sulfonic acid (colitis group). Mice in the sham groups were injected with vehicle. The mice were divided into eight groups (n = 5): The WT sham 24 h and 4 d groups, the WT colitis 24 h and 4 d groups, the KO sham 24 h and 4 d groups, and the KO colitis 24 h and 4 d groups. The disease activity index (DAI) was analyzed, the distal colon was collected for immunohistochemistry analyses, and immunofluorescence was performed to identify neurons immunoreactive (ir) for calretinin, P2X7 receptor, cleaved caspase-3, total caspase-3, phospho-NF-κB, and total NF-κB. We analyzed the number of calretinin-ir and P2X7 receptor-ir neurons per ganglion, the neuronal profile area (μm²), and corrected total cell fluorescence (CTCF).

RESULTS

Cells double labeled for calretinin and P2X7 receptor, cleaved caspase-3, total caspase-3, phospho-NF-κB, or total NF-κB were observed in the WT colitis 24 h and 4 d groups. The number of calretinin-ir neurons per ganglion was decreased in the WT colitis 24 h and 4 d groups compared to the WT sham 24 h and 4 d groups, respectively (2.10 ± 0.13 *vs* 3.33 ± 0.17, $P < 0.001$; 2.92 ± 0.12 *vs* 3.70 ± 0.11, $P < 0.05$), but was not significantly different between the KO groups. The calretinin-ir neuronal profile area was increased in the WT colitis 24 h group compared to the WT sham 24 h group (312.60 ± 7.85 *vs* 278.41 ± 6.65, $P < 0.05$), and the nuclear profile area was decreased in the WT colitis 4 d group compared to the WT sham 4 d group (104.63 ± 2.49 *vs* 117.41 ± 1.14, $P < 0.01$). The number of P2X7 receptor-ir neurons per ganglion was decreased in the WT colitis 24 h and 4 d groups compared to the WT sham 24 h and 4 d groups, respectively (19.49 ± 0.35 *vs* 22.21 ± 0.18, $P < 0.001$; 20.35 ± 0.14 *vs* 22.75 ± 0.51, $P < 0.001$), and no P2X7 receptor-ir neurons were observed in the KO groups. Myenteric neurons showed ultrastructural changes in the WT colitis 24 h and 4 d groups and in the KO colitis 24 h group. The cleaved caspase-3 CTCF was increased in the WT colitis 24 h and 4 d groups compared to the WT sham 24 h and 4 d groups, respectively (485949 ± 14140 *vs* 371371 ± 16426, $P < 0.001$; 480381 ± 11336 *vs* 378365 ± 4053, $P < 0.001$), but was not significantly different between the KO groups. The total caspase-3 CTCF, phospho-NF-κB CTCF, and total NF-κB CTCF were not significantly different among the groups. The DAI was recovered in the KO groups. Furthermore, we demonstrated that the absence of the P2X7 receptor attenuated inflammatory infiltration, tissue damage, collagen deposition, and the decrease in the number of goblet cells in the distal colon.

CONCLUSION

Ulcerative colitis affects myenteric neurons in WT mice but has a weaker effect in P2X7 receptor KO mice, and neuronal death may be associated with P2X7 receptor-mediated caspase-3 activation. The P2X7 receptor can be a therapeutic target for IBDs.

Key Words: Cell death; Enteric nervous system; Gastroenterology; Inflammatory bowel diseases; P2X7 receptor; Purinergic signaling

Core Tip: In the present study, we compared pathological changes resulting from 2,4,6-trinitrobenzene sulfonic acid (TNBS)-induced colitis at two different time points after colitis induction. At both 24 h and four days post-inflammatory induction, there was a decrease in the number of myenteric neurons in the wild-type groups but not in the knockout groups. Morphometric and ultrastructural changes were also observed. In addition, our results confirm that neuronal death mediated by caspase-3 activation is related to purinergic signaling *via* the P2X7 receptor in the myenteric plexus of mice with TNBS-induced colitis.

INTRODUCTION

According to Martin[1] and Kanduc *et al*[2], cells usually die by apoptosis or necrosis, each of which has distinct microscopic and biochemical characteristics. In the process of apoptosis, the death stimulus activates a cascade of events that orchestrate the destruction of the cell under both physiological and pathological conditions[3,4]. Apoptosis is a programmed, dynamic, and energy-demanding process[5] and can occur in areas not severely affected by acute injury[4]. The cell volume decreases, the cytoplasm and nucleus become condensed, cytoskeletal proteins are cleaved, and apoptotic bodies form[3-10]. On the other hand, in necrosis, an unintentional, passive, and pathological process, the death stimulus itself causes the death of the cell[3-5] and affects groups of cells across tissues[8]. Cells and their organelles swell, and disruption of cytoplasmic membranes and degradation of deoxyribonucleic acid (DNA) occur[1,5,6,8,11,12]. Nuclear dissolution results from autolysis[5]. Activation of caspases is the main mechanism underlying cell death[3,7,8,13-15].

Studies of the central nervous system have shown that degeneration of neurons can occur through different pathways, including apoptotic pathways[4,8,16,17]. In acute neurological diseases, cell loss can occur either through necrosis or apoptosis[18-23], whereas in chronic neurodegenerative diseases, caspase-mediated pathways play dominant roles in mediating neuronal dysfunction and death[4,8,21,24-28]. In addition, loss of enteric nervous system (ENS) neurons has been demonstrated to occur after intestinal ischemia and reperfusion[29-34] and in experimental colitis[35-40].

The unexpected ability of certain cells to survive the activation of caspases[41-43] demonstrates the remarkable plasticity of cell death programs and suggests that the action of these proteases alone is not sufficient to cause cell loss[3]. Cell death, including that of enteric neurons, can occur through several caspase-independent pathways[3,44-47], and the signals that result in nonapoptotic cell death can come from numerous membrane receptors associated, directly or indirectly, or not with the activation of caspases themselves[3]. The P2X7 receptor is an important inducer of cell death[37,47-55] and is strongly associated with both the activation of caspases and the release and regulation of proinflammatory cytokines and transcription factors such as nuclear factor kappa B (NF-κB)[47,50,52,56-59].

Thus, improving the understanding of the cellular and molecular basis of neuronal death can aid in the identification and development of specific therapeutic strategies[8]. However, studies on the mechanisms underlying the death of enteric neurons, especially the role of the P2X7 receptor as an inducer of the death of these neurons in inflammatory bowel diseases (IBDs), are still lacking[37-40,51,52,60-63].

We aimed to study the roles of the caspase-3 and NF-κB pathways in myenteric neurons of the distal colon in a P2X7 receptor knockout (KO) mouse model of ulcerative colitis. The effects of colitis on calretinin neurons and intestinal tissue were analyzed by immunohistochemistry and histology, respectively.

MATERIALS AND METHODS

The animal experiments were conducted in accordance with the current regulations of the Ethics Committee on Animal Use of the Institute of Biomedical Sciences of the University of São Paulo. In addition, all procedures were approved by the Ethics Committee on Animal Use of the School of Veterinary Medicine and Animal Science of the University of São Paulo (No. 2841270120) and by the Ethics Committee on Animal Use of the Institute of Biomedical Sciences of the University of São Paulo (No. 2372300921).

Forty eight-week-old male C57BL/6 mice weighing 20 g to 30 g, *i.e.*, 20 wild-type (WT) and 20 P2X7 receptor KO (P2X7$^{-/-}$, P2X7 KO) animals, were used. The animal protocol was designed to minimize pain and discomfort in the animals. The mice were provided water and food *ad libitum* in ventilated cages on a 12 h light/dark cycle at a controlled temperature (21 °C). The animals were divided into eight groups of five animals each (n = 5): The WT sham 24 h and 4 days (d) groups, the WT colitis 24 h and 4 d groups, the KO sham 24 h and 4 d groups, and the KO colitis 24 h and 4 d groups.

Ulcerative colitis model

Mice were anesthetized *via* subcutaneous administration of an anesthetic solution of 2% xylazine (5 mg/kg) and 10% ketamine (80 mg/kg). Then, the animals in the colitis groups (WT colitis 24 h, KO colitis 24 h, WT colitis 4 d, and KO colitis 4 d groups) were given an intrarectal injection of 100 μL of 2,4,6-trinitrobenzene sulfonic acid (TNBS, Sigma, United States of America) diluted to 1.5% in 35.0% ethanol (Synth, Brazil). The solution was deposited directly in the lumen of the large intestine with a four-centimeter-long polypropylene cannula. The animals in the sham groups (WT sham 24 h, KO sham 24 h, WT sham 4 d, and KO sham 4 d groups) received 100 μL of 35% ethanol (vehicle) by the same method. The animals were euthanized by administration of an overdose of anesthetic solution 24 h or four days after the procedures. After the abdominal cavity of each animal was opened, the large intestine was identified, dissected, collected, and measured. The tissue was then sectioned along the mesenteric margin, and its contents were flushed with 0.01 M phosphate buffered saline (PBS) (pH 7.1-7.2). Only the distal colon was used for the analyses.

Disease activity index: Changes in weight, stool consistency, and the presence of blood in the stools were scored daily, and these scores were summed to calculate the Disease activity index (DAI). These parameters were scored according to a scale adapted from Cooper *et al*[64] and Hoffman *et al*[65] (Table 1).

Macroscopic and microscopic evaluation of intestinal lesions: The macroscopic features of intestinal lesions, *i.e.*, the presence of hyperemia and ulcers and the severity of intestinal inflammation, were scored according to the scale proposed by Wallace *et al*[66]. The microscopic features of the intestinal lesions, *i.e.*, the presence of ulcers, the severity of edema in the submucosal layer, and the degree of inflammatory cell infiltration, were scored according to the scale proposal by Fabia *et al*[67] following hematoxylin and eosin staining (Table 2).

Table 1 Changes in weight, stool consistency, and the presence of blood in the stool were scored for the ulcerative colitis model mice and mice that received intrarectal injection of 35% ethanol according to the following scale

Disease activity index		Score
A	Weight change (< 1%)	0
	Weight change (1%-2%)	1
	Weight change (2%-4%)	2
	Weight change (4%-6%)	3
	Weight change (> 6%)	4
B	Stool consistency (normal)	0
	Stool consistency (normal and well-formed)	1
	Stool consistency (pasty that did not stick to the anus)	2
	Stool consistency (loose stool)	3
	Stool consistency (diarrhea)	4
C	Rectal bleeding (absent)	0
	Rectal bleeding (+)	1
	Rectal bleeding (++)	2
	Rectal bleeding (+++)	3
	Rectal bleeding (gross bleeding)	4

A: Weight; B: Stool consistency; C: Presence of blood in the stool.

Immunohistochemistry

The large intestines of all mice were washed in PBS, stretched, fixed with the mucosa facing down on wooden platforms, and submerged in 4% paraformaldehyde in 0.1 M PBS (pH 7.3) for 24 h at 4 °C. Subsequently, the tissues were bleached by three 10-min washes in 100% dimethyl sulfoxide (Synth, Brazil) and then washed three more 10-min washes in PBS for 10 min each. Finally, the samples were stored at 4 °C in PBS containing sodium azide (0.1%).

To prepare whole mounts, the mucosal and submucosal layers and the circular muscle layer were removed from segments of the distal colon, leaving only the longitudinal muscle layer and the myenteric plexus. The whole mounts were preincubated for 45 min at room temperature with 10% normal horse serum in PBS containing 1.5% Triton X-100. The tissues were incubated for 48 h at 4 °C with the primary antibodies (Table 3). After 48 h of primary antibody incubation, the preparations were washed three times in PBS for 10 min each and then incubated for one hour at room temperature with the secondary antibodies (Table 3). Finally, they were washed three times for 10 min each in PBS, incubated in 4′,6′-diamino-2-phenyl-indol (DAPI) for three minutes, and washed three times in PBS for five minutes each. Whole mounts were mounted on slides in glycerol buffered with 0.5 M sodium carbonate (pH 8.6).

Qualitative analysis of the myenteric neurons was performed on a Nikon 80i fluorescence microscope and an Olympus FluoView 1000 confocal laser microscope. The captured images were processed with CorelDRAW software.

Quantitative analyses

The neuronal density (number of neurons per ganglion) was obtained by counting calretinin-immunoreactive (ir) and P2X7 receptor-ir neurons in 50 myenteric ganglia of the distal colon of each animal at 40 × magnification under a Nikon 80i microscope. The slides were analyzed in a zigzag pattern, and the ganglia were chosen randomly. In total, 2000 myenteric ganglia were analyzed for each protein of interest.

For analysis of the neuronal profile area, 125 calretinin-ir neurons in the distal colon myenteric plexus of each animal were randomly photographed at 40 × magnification under a Nikon 80i microscope *via* NIS-elements AR 3.1 software. For analysis of the nuclear profile area, the DAPI-labeled nuclei of these same 125 neurons were photographed. Neuronal and nuclear morphometry was performed by manually delimiting each of the structures individually in Image Pro-Plus 5.0 software. The cytoplasmic profile area was obtained by subtracting the nuclear area from the neuronal area. The results are presented in μm[2]. In total, 5000 neurons and 5000 nuclei were analyzed.

Table 2 Scale used to score the severity of macroscopic and microscopic lesions in the distal colon of ulcerative colitis model mice and mice that received intrarectal injection of 35% ethanol

Macroscopic injury	Score
Normal	0
Hyperemia without ulcers	1
Ulcerations without hyperemia	2
Ulcerations at one site	3
Ulcerations at two or more sites	4
Sites of damage extending > 1 cm	5
Sites of damage extending > 2 cm; the score increases by 1 for each additional cm	6-10
A	
No ulcer	0
Single ulceration not exceeding the lamina muscularis mucosa	1
Ulcerations not exceeding the mucosa	2
Ulcerations exceeding the submucosa	3
B	
No submucosal edema	0
Mild edema	1
Moderate edema	2
Severe edema	3
C	
No inflammatory cell infiltration	0
Mild infiltration	1
Moderate infiltration	2
Dense infiltration	3

The presence of ulcers (A), the severity of edema in the submucosal layer (B), and the degree of inflammatory cell infiltration (C) were assessed by histological analysis.

Table 3 Characteristics of primary and secondary antibodies

Antigen	Host	Dilution	Source
Calretinin	Goat	1:300	Swant
P2X7 receptor	Rabbit	1:200	Merck Millipore
Cleaved caspase-3	Rabbit	1:100	Cell Signaling
Total caspase-3	Rabbit	1:100	Cell Signaling
Phospho- NF-κB	Rabbit	1:100	Cell Signaling
Total NF-κB (p65)	Rabbit	1:100	Cell Signaling
Secondary antibodies			
Alexa Fluor 488-conjugated donkey anti-rabbit IgG	Donkey	1:500	Molecular Probes
Alexa Fluor 594-conjugated donkey anti-sheep IgG	Donkey	1:100	Molecular Probes

NF-κB: Nuclear factor kappa B.

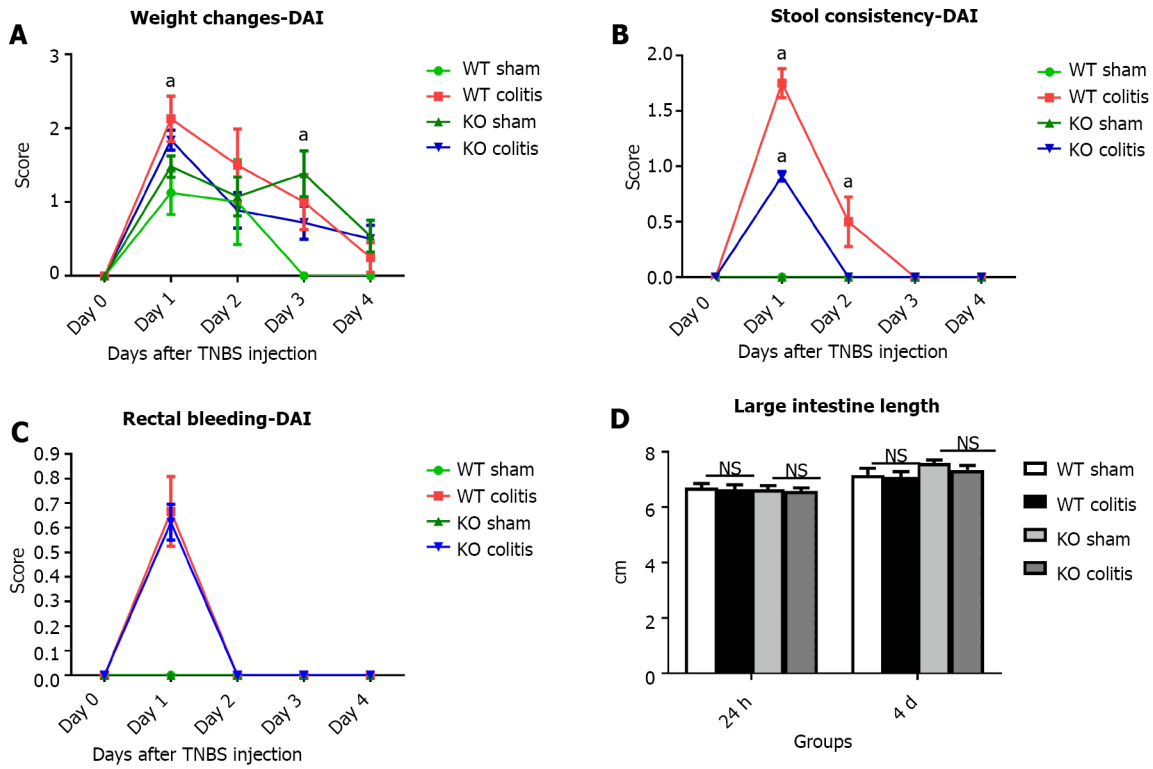
For corrected total cell fluorescence (CTCF) analysis, 20 calretinin-ir, P2X7 receptor-ir, cleaved caspase-3-ir, total caspase-3-ir, phospho- NF-κB-ir, and total NF-κB-ir ganglia of the myenteric plexus of the distal colon of each animal were photographed at 40 × magnification under a Nikon 80i microscope *via* NIS-elements AR 3.1 software. The ganglia were individually manually delineated in ImageJ software (v1.45, NIH). The area, integrated density, and average gray value of each ganglion were systematically measured. The areas, integrated densities, and average gray values of five regions adjacent to the myenteric ganglion that were not positive for the protein of interest were measured as background values. The CTCF was calculated by the following formula: CTCF = integrated density-(area of the selected ganglion × average background fluorescence)[68,69]. In total, 800 myenteric ganglia were analyzed for each protein of interest.

Transmission electron microscopy

An approximately 0.5 cm piece of the distal colon of each mouse was collected for ultrastructural analysis of the myenteric plexus by transmission electron microscopy. Immediately after collection, the samples were cut into three-millimeter pieces. The samples were fixed for three hours at 4 °C in modified Karnovsky solution (4.0% formaldehyde, 0.2 M phosphate buffer and 25% glutaraldehyde) and postfixed for two hours at 4 °C in 1% osmium tetroxide. Then, the tissues were placed in 0.5% uranyl acetate for 12 h at room temperature, dehydrated by sequential incubations in alcohol solutions of increasing concentrations, and immersed in propylene oxide twice for 15 min each. Finally, the tissues were incubated in a 1:1 mixture of Spurr resin and propylene oxide for one hour, a 3:1 mixture of Spurr resin and propylene oxide for one and a half hours, and pure resin for 12 h. The tissues were then embedded in pure Spurr resin for three days in an oven at 60 °C. Semifine 250 nanometer (nm)-thick semithin sections were made with a Leica Ultracut UCT ultramicrotome, and the sections were stained with 1% toluidine blue for one and a half minutes and then washed with distilled water. Then, the sections were cut into 60 nm thick ultrathin sections, collected on 200 mesh copper screens and contrasted with uranyl acetate for five minutes and lead citrate 1% for three minutes. The prepared screens were analyzed with a Morgagni 268D transmission electron microscope, and the captured images were processed with CorelDRAW software.

Tissue preparation and histological analysis

An approximately 0.5 cm piece of the distal colon of each mouse was collected for histological analysis. After being washed in PBS, the samples were fixed with the mucosa facing up on wooden platforms and immersed in 4% paraformaldehyde in 0.1 M PBS (pH 7.3) for 48 h at 4 °C. Then, the tissues were dehydrated by sequential incubation in alcohol solutions of increasing concentrations, diaphanized in xylol, and embedded in paraffin. The samples were cut into five μm thick transverse sections with a specialized microtome and subjected to hematoxylin and eosin staining. Picrosirius red and Masson's trichrome were used to visualize collagen fibers, and periodic acid-Schiff staining was used to identify neutral mucin-secreting goblet cells. The slides were analyzed under light and polarized light microscopy with a Nikon 80i microscope. Images were captured *via* NIS-elements AR 3.1 software and processed with CorelDRAW software.



Analysis of the number of goblet cells per intestinal crypt of the distal colon: The density of goblet cells (number of goblet cells per intestinal crypt) was determined by counting goblet cells in 40 intestinal crypts of the distal colon *via* periodic acid Schiff staining. Four histological sections per animal were analyzed with a Nikon 80i microscope with a 40 × objective[70-73]. Sections separated by an interval of 10 μm were analyzed, and crypts were chosen randomly. In total, 1600 crypts of the distal colon were analyzed.

Statistical analysis

Quantitative data were analyzed, and the results are expressed as the mean ± SE. Comparisons between groups were performed by two-way ANOVA followed by Bonferroni correction with GraphPad Prism 5.0 software. Statistical significance is displayed as $P < 0.05$.

RESULTS

At 24 h, the average reduction in weight was 1.5% in the WT sham group, 3.5% in the WT colitis group, 2.4% in the KO sham group, and 2.7% in the KO colitis group. By four days, the animals in all groups recovered weight. Regarding the DAI, scores for weight change, stool consistency, and the presence of blood in stool were higher in the WT colitis group than in the WT sham group and in the KO colitis group than in the KO sham group. There was no statistically significant difference in large intestine length between the WT colitis (24 h and 4 d) and WT sham (24 h and 4 d) groups or between the KO colitis (24 h and 4 d) and KO sham (24 h and 4 d) groups (Figure 1). According to macroscopic analysis, tissue hyperemia without ulcers was observed in the 24 h and 4 d WT colitis and 24 h KO colitis groups. Microscopic analysis was performed after hematoxylin and eosin staining. No ulceration was observed

Figure 1 The disease activity index of wild-type and knockout mice was determined beginning the day of ulcerative colitis induction or intrarectal injection of 35% ethanol. A: Changes in weight; B: Stool consistency; C: The presence of blood in the stool; D: Large intestine length was analyzed. DAI: Disease activity index; WT: Wild-type; KO: Knockout; TNBS: 2,4,6-trinitrobenzene sulfonic acid. The data are presented as the arithmetic mean ± SE. $^{a}P < 0.05$ *vs* sham groups; NS: Not significant.

in the analyzed tissues. Edema of the submucosal layer was observed in all groups, but with the mean score, edema was higher in the WT colitis 24 h group. Finally, inflammatory cell infiltration in the mucosa and lamina propria was severe in the WT colitis 24 h group but was mild in the other groups (Table 4).

Qualitative analysis

Indirect immunofluorescence analysis revealed that neurons in the myenteric plexus of the distal colon were positive for calretinin, P2X7 receptor, cleaved caspase-3, total caspase-3, phospho-NF-κB, and total NF-κB.

Calretinin-ir neurons showed a Dogiel type II morphology, and calretinin was localized in the nucleus and cytoplasm. In the WT colitis 24 h and 4 d groups, there was an apparent reduction in fluorescence intensity, and in the WT colitis 24 h and KO colitis 24 h groups, the neurons appeared swollen. There was also an apparent reduction in the number of neurons in the WT colitis 24 h and 4 d and KO colitis 24 h groups (Figures 2-6).

The P2X7 receptor was expressed in the plasma membrane and cytoplasm. The P2X7 receptor staining intensity appeared to be stronger in the WT colitis 24 h group and weaker in the WT colitis 4 d group. There was an apparent reduction in the number of P2X7 receptor-ir cells in both groups, and the P2X7 receptor-ir cells colocalized with calretinin-ir neurons. P2X7 receptor staining was not observed in the KO sham 24 h, KO sham 4 d, KO colitis 24 h or KO colitis 4 d groups (Figure 2).

Cleaved caspase-3 was localized in the cytoplasm, and the cleaved caspase-3 fluorescence intensity was apparently higher in the WT colitis 24 h and 4 d groups and KO colitis 24 h group. Cleaved caspase-3 colocalized with calretinin-ir neurons in all groups, especially the colitis groups (WT colitis 24 h and 4 d and KO colitis 24 h and 4 d groups) (Figure 3). Total caspase-3, on the other hand, was expressed in the nucleus and cytoplasm, and the total caspase-3 fluorescence intensity was apparently similar among all groups. Total caspase-3 colocalized with calretinin-ir neurons, and nuclear staining of total caspase-3 was the lowest in the WT colitis 24 h group (Figure 4).

Phospho-NF-κB and total NF-κB were expressed in the cytoplasm. Phospho-NF-κB staining appeared to be more intense in the WT colitis 24 h group (Figure 5). Phospho- NF-κB and total NF-κB colocalized with calretinin-ir neurons in all groups (Figure 6).

Table 4 Macroscopic and microscopic lesions in the distal colon of ulcerative colitis model mice and mice that received intrarectal injection of 35% ethanol

Groups	Macroscopic injury	Microscopic injury		
		Ulcer	Submucosal edema	Inflammatory cell infiltration
WT sham 24 h	0.0 ± 0.0^{NS}	0.0 ± 0.0^{NS}	0.8 ± 0.2^{NS}	1.2 ± 0.2^{NS}
WT colitis 24 h	1.0 ± 0.0^{NS}	0.0 ± 0.0^{NS}	1.6 ± 0.2^{NS}	2.0 ± 0.2^{NS}
KO sham 24 h	0.0 ± 0.0^{NS}	0.0 ± 0.0^{NS}	0.8 ± 0.2^{NS}	1.0 ± 0.0^{NS}
