Whole transcriptomic analyses were used to analyze and screen differentially expressed microRNAs (miRNAs) in GC cells after 18β-GRA intervention. Lentivirus-transfected GC cells and the Cell Counting Kit-8 were used to detect cell proliferation ability, cell colony formation ability was detected by the clone formation assay, and flow cytometry was used to detect the cell cycle and apoptosis. A nude mouse transplantation tumor model of GC cells was constructed to verify the effect of miR-328-3p overexpression on the tumorigenicity of GC cells. Tumor tissue morphology was observed by hematoxylin and eosin staining, and microtubule-associated protein light chain 3 (LC3) expression was detected by immunohistochemistry. TransmiR, STRING, and miRWalk

databases were used to predict the relationship between miR-328-3p and signal transducer and activator of transcription 3 (STAT3)-related information. Expression of *STAT3* mRNA and *miR-328-3p* was detected by quantitative polymerase chain reaction (qPCR) and the expression levels of STAT3, phosphorylated STAT3 (p-STAT3), and LC3 were detected by western blot analysis. The targeted relationship between *miR-328-3p* and *STAT3* was detected using the dual-luciferase reporter gene system. AGS cells were infected with monomeric red fluorescent protein-green fluorescent protein-LC3 adenovirus double label. LC3 was labeled and autophagy flow was observed under a confocal laser microscope.

RESULTS

The expression of miR-328-3p was significantly upregulated after 18β-GRA intervention in AGS cells (P = 4.51E-06). Overexpression of miR-328-3p inhibited GC cell proliferation and colony formation ability, arrested the cell cycle in the G0/G1 phase, promoted cell apoptosis, and inhibited the growth of subcutaneous tumors in BALB/c nude mice (P < 0.01). No obvious necrosis was observed in the tumor tissue in the negative control group (no drug intervention or lentivirus transfection) and vector group (the blank vector for lentivirus transfection), and more cells were loose and necrotic in the miR-328-3p group. Bioinformatics tools predicted that miR-328-3p has a targeting relationship with STAT3, and STAT3 was closely related to autophagy markers such as p62. After overexpressing miR-328-3p, the expression level of *STAT3* mRNA was significantly decreased (P < 0.01) and p-STAT3 was downregulated (P < 0.05). The dual-luciferase reporter gene assay showed that the luciferase activity of *miR-328-3p* and *STAT3* 3′ untranslated regions of the wild-type reporter vector group was significantly decreased (P < 0.001). Overexpressed miR-328-3p combined with bafilomycin A_1 (Baf A_1) was used to detect the expression of LC3 II. Compared with the vector group, the expression level of LC3 II in the overexpressed miR-328-3p group was downregulated (P < 0.05), and compared with the Baf A_1 group, the expression level of LC3 II in the overexpressed miR-328-3p + Baf A_1 group was upregulated (P < 0.01). The expression of LC3 II was detected after intervention of 18β-GRA in GC cells, and the results were consistent with the results of miR-328-3p overexpression (P < 0.05). Additional studies showed that 18β-GRA promoted autophagy flow by promoting autophagosome synthesis (P < 0.001). qPCR showed that the expression of *STAT3* mRNA was downregulated after drug intervention (P < 0.05). Western blot analysis showed that the expression levels of STAT3 and p-STAT3 were significantly downregulated after drug intervention (P < 0.05).

CONCLUSION

18β-GRA promotes the synthesis of autophagosomes and inhibits GC cell proliferation by regulating the miR-328-3p/STAT3 signaling pathway.

Key Words: 18β-glycyrrhetinic acid; miR-328-3p; Signal transducer and activator of transcription 3; Cell proliferation; Autophagy flow

Core Tip: 18β-glycyrrhetinic acid (18β-GRA) is an important bioactive component of glycyrrhiza liquorice. Our results showed that 18β-GRA upregulated the expression of miR-328-3p in gastric cancer (GC) cells. Overexpression of miR-328-3p inhibited GC cell proliferation and colony formation, arrested the cell cycle, promoted apoptosis, inhibited subcutaneous tumor formation, and inhibited signal transducer and activator of transcription 3 (STAT3) expression. Dual-luciferase reporter assay showed that *miR-328-3p* targeted the regulation of *STAT3*. Confocal microscopy and western blotting indicated that 18β-GRA promotes autophagy flow by promoting autophagosome synthesis. Thus, 18β-GRA appears to promote cell autophagy and inhibit GC cell proliferation by regulating miR-328-3p/STAT3.

INTRODUCTION

Gastric cancer (GC) is the fifth most common type of cancer and the fourth leading cause of cancer-related death worldwide[1]. GC is a local disease whose leading causes include diet, environmental and genetic factors, and *Helicobacter pylori* infection[2]. The current standard treatment for GC is surgical excision of operable tumor tissue combined with local radiotherapy, chemotherapy and conventional anticancer drugs. However, many GC cells appear to have significant invasion and metastasis after surgery. Although chemotherapy is an important management approach for preventing

invasion and metastasis, it tends to substantially decrease the patients' quality of life due to severe toxic and side effects (*e.g.*, hair loss, bone marrow transplantation, gastrointestinal reactions) and drug resistance[3,4]. Therefore, there is an urgent need to find natural, effective, and less toxic anti-GC drugs.

Glycyrrhiza uralensis Fisch. is a traditional Chinese medicine, and 18β-glycyrrhetinic acid (18β-GRA; Figure 1A), an important bioactive component of licorice, with many pharmacological effects including anti-inflammatory, liver protection, antiviral, anti-allergic, antitumor, antioxidant, and immunomodulatory effects[5-8]. In recent years, it has been found that 18β-GRA has excellent antitumor activity against human malignant tumors such as breast cancer, glioma, lung cancer, and prostate cancer[8-12]. In GC, 18β-GRA regulates the migration of SGC-7901 cells by regulating the reactive oxygen species (ROS)/protein kinase C alpha/extracellular signal-regulated kinase signaling pathway. It also inhibits the activities of matrix metalloproteinase 2 (MMP2) and MMP9 in a dose-dependent manner[13]. Expression of the antioncogene potassium-transporting ATPase alpha chain 1 (ATP4a) is downregulated in GC, and 18-GRA can activate ATP4a, thus inhibiting the occurrence of GC[14]. In transgenic mice, 18β-GRA was found to improve the severity of gastritis and inhibit the occurrence of GC. Also, studies have shown that 18β-GRA can improve the tumor inflammatory microenvironment by downregulating the expression of cyclooxygenase-2 and inhibiting the expression of the direct target Wnt-1 by upregulating the antioncogene miR-149-3p and thus inhibiting the occurrence and development of GC[15]. Cao *et al*[16] reported that 18β-GRA regulates toll-like receptor 2 (TLR2) expression through methylation and inhibits the proliferation, energy metabolism, and carcinogenesis of TLR2-activated GC cells. Our previous study found that 18β-GRA could inhibit GC cell proliferation by regulating the mitochondrial ribosome protein L35[17]. These results suggest that 18β-GRA may be an effective drug for preventing and treating GC.

MicroRNAs (miRNAs) is a novel endogenous, highly conserved non-coding RNA molecule with a length of 18-25 nucleotides[18]. miRNAs have an important role in cancer, and to date, many human miRNA sequences have been identified to participate in cancer pathogenesis and regulate protein expression levels in a complementary manner to

their target mRNAs. miRNAs regulate and participate in the regulation of tumorigenesis, cellular processes, and pathways such as proliferation, differentiation, and apoptosis[19]. Expression profiles of miRNAs differ between cancerous and noncancerous tissues, different types and subtypes of cancer, and early and advanced cancers, depending on the aggressiveness of the disease[20-22]. Current studies have found that some miRNAs not only exist as oncogenes but also inhibit the occurrence of tumors. For example, miR-381 is upregulated in glioma, osteosarcoma and other cancers, while overexpression of miR-381 in GC and colon cancer can inhibit cell migration and invasion and promote cell apoptosis[23-26]. miRNAs also have a dual role in inducing or inhibiting tumorigenesis in GC. Previous studies have shown that the expression level of miR-148a in the plasma of GC patients is lower than that of healthy individuals, and miR-148a overexpression can inhibit proliferation, migration, cell invasion, and the epithelial-mesenchymal transition (EMT)[27]. Li *et al*[28] reported that low expression of miRNA-149 and overexpression of forkhead box C1 (FOXC1) were found in GC tissues and cells. Overexpression of miRNA-149 inhibits GC cell proliferation and migration, arrests the cell cycle, and promotes cell apoptosis. FOXC1 silencing can inhibit the biological functions of AGS and MKN28 cells in GC [28]. Overexpression of miR-140-3p can inhibit the migration and invasion ability of GC cells and directly downregulate the expression of B-cell lymphoma 2 (BCL2), thus inhibiting cell apoptosis. Downregulation of BCL2 further activates autophagy induced by Beclin 1, an autophagy marker, and inhibits the EMT[29]. An increasing number of GC-associated miRNAs have been found to participate in the formation and development of GC.

Autophagy is essential in many physiological and pathological processes, such as development, metabolism, inflammation, and cancer[30]. According to the mode of transport to lysosomes, autophagy can be divided into microautophagy, macroautophagy, and chaperone-mediated autophagy. Autophagy is closely related to the diagnosis, treatment, and prognosis of GC. In their study, Wang *et al*[31] found that there were 10 autophagy-related (*ATG*) genes with significant differences in expression between GC and paracancerous tissue. It was also found that genes such as *ATG14* were significantly associated with the tumor-node-metastasis stage, and the expression of these genes was significantly lower in early T, indicating that autophagy may participate in early GC progression[31]. The expression of miR-183 is significantly decreased in GC tissues compared with paracancerous tissues, whereas the mammalian target of rapamycin (mTOR) is significantly increased. By targeting the expression of mTOR, miR-183 inhibits cell proliferation and promotes cell apoptosis and autophagy[32]. Sec62 homolog, preprotein translocation factor (Sec62), is an endoplasmic reticulum membrane protein highly expressed in GC. Overexpression of Sec62 can increase the expression of eukaryotic translation initiation factor 2 alpha kinase 3/cyclic AMP-dependent transcription factor ATF-4, bind to light chain 3 II (LC3 II), and activate the focal adhesion kinase family interacting protein of 200 kD/Beclin 1/ATG5 pathway to activate autophagy. Therefore, dual inhibition of Sec62 and autophagy may be an effective therapeutic strategy for GC metastasis[33]. It can also be concluded that autophagy is a "double-edged sword" that promotes and inhibits cell survival[34].

Based on previous studies, this study further analyzed the differential expression of miRNAs after the intervention of 18β-GRA. Cell function and animal experiments were used to detect the cell phenotype and subcutaneous tumor formation in nude mice. We detected the targeting relationship between miRNA and signal transducer and activator of transcription 3 (STAT3) and the changes in autophagy flow rate. An important finding was that 18β-GRA could affect autophagy flow and inhibit GC cell proliferation by regulating the miR-328-3p/STAT3 signaling pathway, which may contribute to the clinical development of effective therapies.

MATERIALS AND METHODS

Cell culture

Human AGS cell lines were purchased from GeneChem (Cat. No. GCC-ST0003RT; Shanghai, China). They were cultured in Dulbecco's Modified Eagle Medium (DMEM)/F12 medium (Cat. No. SH30023.01; Hyclone, Logan, UT, United States) containing 100 mL/L fetal bovine serum (Cat. No. 35-081-CV; Corning, Corning, NY, United States), and 10 mL/L penicillin and streptomycin (Cat. No. P1400; Solarbio, Beijing, China). The culture flasks were placed in an incubator at a constant temperature of 37 °C, with 50 mL/L carbon dioxide and saturated humidity.

Whole transcriptomic analyses

Human gastric adenocarcinoma AGS cells were cultured and treated with 18β-GRA (purity > 97%, Cat. No. G10105-10G; Sigma, St. Louis, MO, United States) for 24 h. Cells in the negative control (NC) group and the 18β-GRA group were collected, and total RNA was extracted. Agarose gel electrophoresis was used to analyze the degradation degree of RNA and whether there was contamination. The NanoDrop 2000 spectrophotometer and Qubit 2.0 (Thermo Fisher Scientific, Waltham, MA, United States) were used to determine the purity and concentration of total RNA, and the Agilent 2100 Bioanalyzer (Agilent, Savage, MD, United States) was used to accurately detect the RNA integrity. After the samples were tested as qualified, a library was constructed with a Small RNA Sample Prep Kit. Using the 3'-end hydroxyl structure of the small RNA and the complete 5'-end phosphoric acid group, total RNA was taken as the starting sample, the two ends of the small RNA were added, and reverse transcription was performed to synthesize the cDNA. After polymerase chain reaction (PCR) amplification, polyacrylamide gel electrophoresis was used to isolate the target DNA fragment, after which the cDNA library was recovered.

After the library was successfully constructed, Qubit2.0 was used for preliminary quantification and Agilent 2100 was used to determine the library insert size. Once the insert size reached the expected value, quantitative PCR (qPCR) was used to accurately quantify the effective library concentration and ensure library quality (effective library concentration > 2 nmol/L). After the library was approved, different libraries were pooled into the Illumina SE50 sequencer (Illumina,

San Diego, CA, United States) as needed.

Bioinformatics analyses

TransmiR v2.0 database (http://www.cuilab.cn/transmir) was used to predict miR-328-3p-related proteins, and the STRING database (https://cn.string-db.org/) was used to predict the relationship between miR-328-3p- and autophagy-related proteins. Finally, the binding sites of miRNA-related proteins were searched on the miRWalk website (http://129.206.7.150/).

qPCR

Trizol reagent was used for total RNA extraction (Cat. No. DP424; TIANGEN Biochemical Technology, Beijing, China). cDNA reverse transcription was conducted with the PrimeScript™ RT Reagent Kit with gDNA Eraser (Cat. No. RR04B; TaKaRa Bio Inc., Shiga, Japan) and the BlazeTaq SYBR Green qPCR Mix 2.0 (Cat. No. P031-S; GeneCopoeia, Rockville, MD, United States). The primer sequences were: *miR-328-3p*: forward: ATATCTGGCCCTCTCTGCCCTTC, reverse: AGTGCAGGGTCCGAGGTATT; *U6*: forward: CTCGCTTCGGCAGCACA, reverse: AACGCTTCACGAATTTGCGT; *STAT3*: forward: ACCAGCAGTATAGCCGCTTC, reverse: GCCACAATCCGGGCAATCT; *GAPDH*: forward: CACCCACTCCTCCACCTTTGA, reverse: TCTCTCTTCCTCTTGTGCTCTTGC. All experimental groups were studied in triplicate.

Lentivirus transfection

AGS cells were cultured in a T25 cell breathable culture flask. After 24 h, GC cells were transfected with a green fluorescent protein (GFP)-labeled overexpressed miR-328-3p lentivirus (GeneChem, Shanghai, China). The virus volume = (multiplicity of infection [MOI] × number of cells)/virus titer. At 8 h after transfection, a complete fresh medium was replaced and observed under a fluorescence microscope. The lentivirus transfection efficiency was determined according to the cells with GFP fluorescence in bright and GFP fields. Follow-up experiments were performed when the transfection efficiency reached about 90%.

Cell Counting Kit-8 assay

Lentivirus-transfected AGS cells and normal AGS cells were inoculated into 96-well plates and cultured for 24 h, 48 h and 72 h. Next, the Cell Counting Kit-8 (CCK-8) reagent (Cat. No. CK04; DOJINDO Laboratories, Kumamoto, Japan) was added to each well, and absorbance (optical density [OD]) was measured at 450 nm with an enzyme marker. Cell viability = $(OD_{experiment} - OD_{blank})/(OD_{control} - OD_{blank}) \times 100\%$.

Clone formation

The AGS cells were inoculated in a 6-well plate with 600 cells per well (three wells in each group were prepared for further culture), and the cells were observed under a microscope. When the number of clones of most single cells was > 50, and the diameter was 0.3-1.0 mm, the experiment was terminated. Cells were fixed in 4 mL/L paraformaldehyde (Cat. No. D16013; Saint-Bio, Shanghai, China) for 15 min, followed by incubation in crystal indigo water solution for 4-5 min. Next, they were washed with normal saline, left to dry, photographed and visually counted.

Flow cytometry

The AGS cells transfected with lentivirus were inoculated in 6-well plates for 24 h, digested, centrifuged at 3000 r/min for 5 min, and washed once with phosphate-buffered saline (PBS). The cell concentration was adjusted to 1×10^6/mL, and 0.5 mL cold ethanol was added to fix overnight. After 16 h, the cells were washed once with PBS, and then 500 μL was added to the staining solution prepared according to Rnase A: propidium iodide = 1:9 (Cat. No. KGA511; Keygen, Changchun, China) and incubated for 30 min. Flow cytometry was used to measure the cell cycle.

The AGS cells were collected, the concentration was adjusted to 4×10^5/mL, 1 mL cell suspension was centrifuged, 500 mL of Binding Buffer was added, and 5 μL Annexin V-APC was added. The mixing process was not too forceful. Next, 5 μL 7-aminoactinomycin D staining solution (Cat. No. KGA1023; Keygen) was added, mixed, and incubated for 20 min. Apoptosis was detected with a machine.

Tumor formation experiment

The BALB/c nude mice were kept in polypropylene cages with a humidity of 50% ± 5% and temperature of 22 ± 1 °C for 1 d at a 12 h/12 h light/dark cycle, with *ad libitum* access to food and water. After 2 wk of adaptive feeding, the mice were randomly grouped. The AGS cells and lentivirus-transfected GC cells were collected, and the cell concentration of each group was adjusted to 4×10^6/200 μL. The 200 μL cell suspension was absorbed by microinjection and slowly injected into the subcutaneous area of the right back of nude mice. The subcutaneous tumor-bearing conditions of nude mice were observed daily. The long diameter (L) and short diameter (W) of the tumor were measured with an electronic vernier caliper. The formula for calculating the tumor volume (V) was as follows: $V = (W^2 \times L)/2$. When the tumor volume of nude mice grew to a certain size, all animals were euthanized with 1000 mL/L carbon dioxide, and the tumor was removed and photographed. The animal protocols were approved by the Institutional Animal Care and Use Committee of Ningxia Medical University (IACUC-NYLAC-2022-108; Yinchuan, China).

Hematoxylin and eosin staining

Tissue samples fixed in 4 mL/L paraformaldehyde were dehydrated in 75 mL/L, 85 mL/L, 90 mL/L ethanol, and

anhydrous ethanol and then embedded in paraffin. Paraffin sections 3-5 μm thick were taken from the microtome, baked at 65 °C for 1 h, and quickly sliced into xylene and ethanol for dewaxing treatment. The water was double steamed for 3 min, stained with hematoxylin dye (Cat. No. BA-4041; BaSO Diagnostics Inc., Zhuhai, China) for 5 min, double steamed with water for 3 min, incubated with acid alcohol fast differentiation solution (Cat. No. C0163M; Beyotime, Beijing, China) for 5 s, incubated with eosin dye solution (Cat. No. BA-4024; BaSO Diagnostics Inc.) for 5 min, and washed for 5 min. Next, the slices were dehydrated in 85 mL/L, 95 mL/L ethanol, and anhydrous ethanol. The dehydrated paraffin sections were placed in xylene transparent for 10 min and sealed with neutral gum (Cat. No. Zli-9555; ZSGB-Bio, Beijing, China). The cell structure and morphology were observed by optical microscope (BX43; Olympus, Tokyo, Japan).

Immunohistochemical staining

Paraffin sections were routinely dewaxed, and the sections were repaired with citric acid repair solution (pH = 6.8) under high pressure for 10 min and washed with distilled water for 5 min. The sections were incubated with 3 mL/L hydrogen peroxide for 20 min, washed with water for 5 min, and soaked in PBS for 1 min. Sections were incubated with primary antibody (LC3, 1:50, Cat. No. 12741T from Cell Signaling Technology [CST], Danvers, MA, United States; STAT3, 1:90, Cat. No. AF6294 from Affinity Biosciences, Melbourne, Australia; p-STAT3, 1:100, Cat. No. AF3293 from Affinity Biosciences) at 4 °C overnight and washed with PBS three times, 5 min each time. Next, sections were incubated with secondary antibody at 37 °C for 20 min, followed by washing with PBS, DAB (Cat. No. ZLI-9018; ZSGB-Bio) color development, and washing with tap water. Hematoxylin was used for staining, gradient alcohol was used for dehydration, and neutral gum was used for sealing. The images were observed and acquired with the Olympus Imaging System (UC90).

Western blotting

The protein lysis buffer included 10 μL phosphatase inhibitor, 1 μL protease inhibitor, and 5 μL 100 mmol/L protease inhibitor (Cat. No. KGP2100; Keygen). The cells were collected, and the protein lysate was added to extract the whole protein. The protein content was determined with the bicinchoninic acid assay (Cat. No. KGPBCA; Keygen). Appropriate protein loading buffer (Cat. No. DL101; TransGen Biotech Co., Ltd., Beijing, China) was added and boiled at 100 °C for 10 min. According to the experimental design, the sample was added to prefabricated glue (Cat. No. M00659; GenScript, Nanjing, China), and constant pressure electrophoresis was carried out at 120 V until the marker strip with the lowest molecular weight appeared. After electrophoresis, the proteins were electrotransferred to a PVDF membrane (Cat. No. ISEQ00010; Millipore, Burlington, MA, United States) and incubated overnight at 4 °C with primary antibody, followed by washing and then incubation with secondary antibody for 1 h. The luminescent solution (Cat. No. KF005; Affinity Biosciences) was prepared according to the manufacturer's instructions, and the PVDF membrane was soaked in it for 2-3 min and then placed in the intelligent chemiluminescence imaging system (iBright 1500; Invitrogen, Waltham, MA, United States) to obtain protein bands. Protein bands were analyzed using image J.

Dual-luciferase reporter assay system

Retrieval of hsa-miR-328-3p sequence from NCBI Nucleotide website: UGGCCCUCUCUGCCCUUCCGU, the binding sites of miR-328-3p and STAT3 were retrieved from the miRWalk website, and the binding sites with high binding energy were screened based on the scores.

AGS cells were cultured in 24-well plates with 2 × 10^4 cells per well, and the degree of cell confluence reached about 40%. The experimental group included: Luc-STAT3-3′ untranslated region (3′UTR) Mutant (Mut)-NC + miR-328-3p-NC, Luc-STAT3-3′UTR Mut-NC + miR-328-3p, Luc-STAT3-3′UTR Wild Type (WT) + miR-328-3p-NC, Luc-STAT3-3′UTR WT + miR-328-3p, Luc-STAT3-3′UTR Mut + miR-328-3p-NC, and Luc-STAT3-3′UTR Mut + miR-328-3p. The plasmid and transfection reagent (Cat. No. IV1216075; Invigentech, Irvine, CA, United States) were mixed 1:1 to prepare the complex, after which the complex was added and mixed, and the culture was continued for 24 h. Next, the liquid was changed and the culture was continued.

After 48 h of co-transfection with plasmids, the 24-well plates were removed and balanced to room temperature. Extraction 250 μL medium was removed from each well, and Passive lysis buffer 100 μL was added to each well and shaken for 15 min for lysis. The lysate was added into 1.5 mL EP tubes and then into black 96-well plates with 20 μL per well and 3 multiple Wells per group. Next, Luciferase Assay Reagent II 100 μL was added. Fluorescence values were detected at 560 nm with multifunctional reagent II. Then 100 μL of Stop & Glo® reagent (Cat. No. E1910; Promega, Madison, WI, United States) was added to each well, and the fluorescence value was detected at 465 nm. Luciferase activity = $OD_{\text{firefly luciferase}}/OD_{\text{renilla luciferase}}$.

Transfection with adenovirus

AGS cells with a concentration of 4 × 10^4 cells/mL were inoculated in a 15 mm confocal dish (Biosharp Biotechnology Inc., Hefei, Anhui, China) and cultured in the incubator. When the cells were fused to 40%, the fresh medium volume was changed to 1 mL. Monomeric Red Fluorescent Protein (mRFP)-GFP-LC3 tandem fluorescent protein adenovirus (Cat. No. P21071905; HanBio Therapeutics, Shanghai, China) was added, and the volume of virus = MOI × cell number/virus titer × 10^3, and then 1 mL culture medium was added and placed in the incubator for 4 h. After 16 h of infection, the culture medium was changed into a fresh medium for further culture. At 24 h and 48 h, the cell state and infection situation were observed under fluorescence microscope. The infection efficiency was determined by observing the fluorescence expression level of GFP.

Laser confocal

The AGS cells infected with adenovirus were synchronously treated for 6 h, after which the corresponding drug treatment was given (the NC group was replaced with fresh medium). Next, they were placed in an incubator for 24 h, fixed with 4 mL/L paraformaldehyde for 20 min, and observed with a laser confocal microscope. Cells infected with adenovirus using mRFP-GFP-LC3 tandem fluorescent protein were identified by observing the fluorescence of mRFP and GFP after microscopic imaging.

RESULTS

18β-GRA promotes the expression of miR-328-3p in AGS cells

Whole transcriptomics was used to analyze and screen the differentially expressed miRNAs in AGS cells after the 18β-GRA intervention. Through the selection criteria of log2 |fold change| > 1, $P < 0.05$, 283 differentially expressed miRNAs were obtained, of which 120 were upregulated and 163 were downregulated. Notably, the expression of miR-328-3p was upregulated after drug treatment, log2(fold change) = 3.04871, the P value was 4.51E-06 (Figure 1B and C).

qRT-PCR was used to verify whether the intervention process of 18β-GRA on AGS cells was related to *miR-328-3p*. Our results showed that the expression of *miR-328-3p* in AGS cells treated with 18β-GRA was significantly upregulated compared with the NC group ($P < 0.01$) (Figure 1D).

Overexpression of miR-328-3p inhibited the survival rate of AGS cells

The expression level of *miR-328-3p* after transfection was detected by qRT-PCR. *miR-328-3p* in the overexpression group was significantly higher than in the vector group (Figure 1E). Cell status and transfection efficiency were observed under the Cytation 5 microscope (Figure 1F), and cell survival rate was detected. The results showed that, compared with the vector group, the survival rate of cells in the overexpressed miR-328-3p group decreased significantly ($P < 0.01$) (Figure 1G).

Effect of overexpression of miR-328-3p on cloning formation of AGS cells

The results of the cloning formation experiment showed that compared with the vector group, the crystal violet staining positive of the overexpressing miR-328-3p group was significantly decreased (Figure 2A), and the cloning formation rate of AGS cells was significantly reduced ($P < 0.01$) (Figure 2B). These results indicated that overexpression of miR-328-3p could inhibit the colony formation of GC cells.

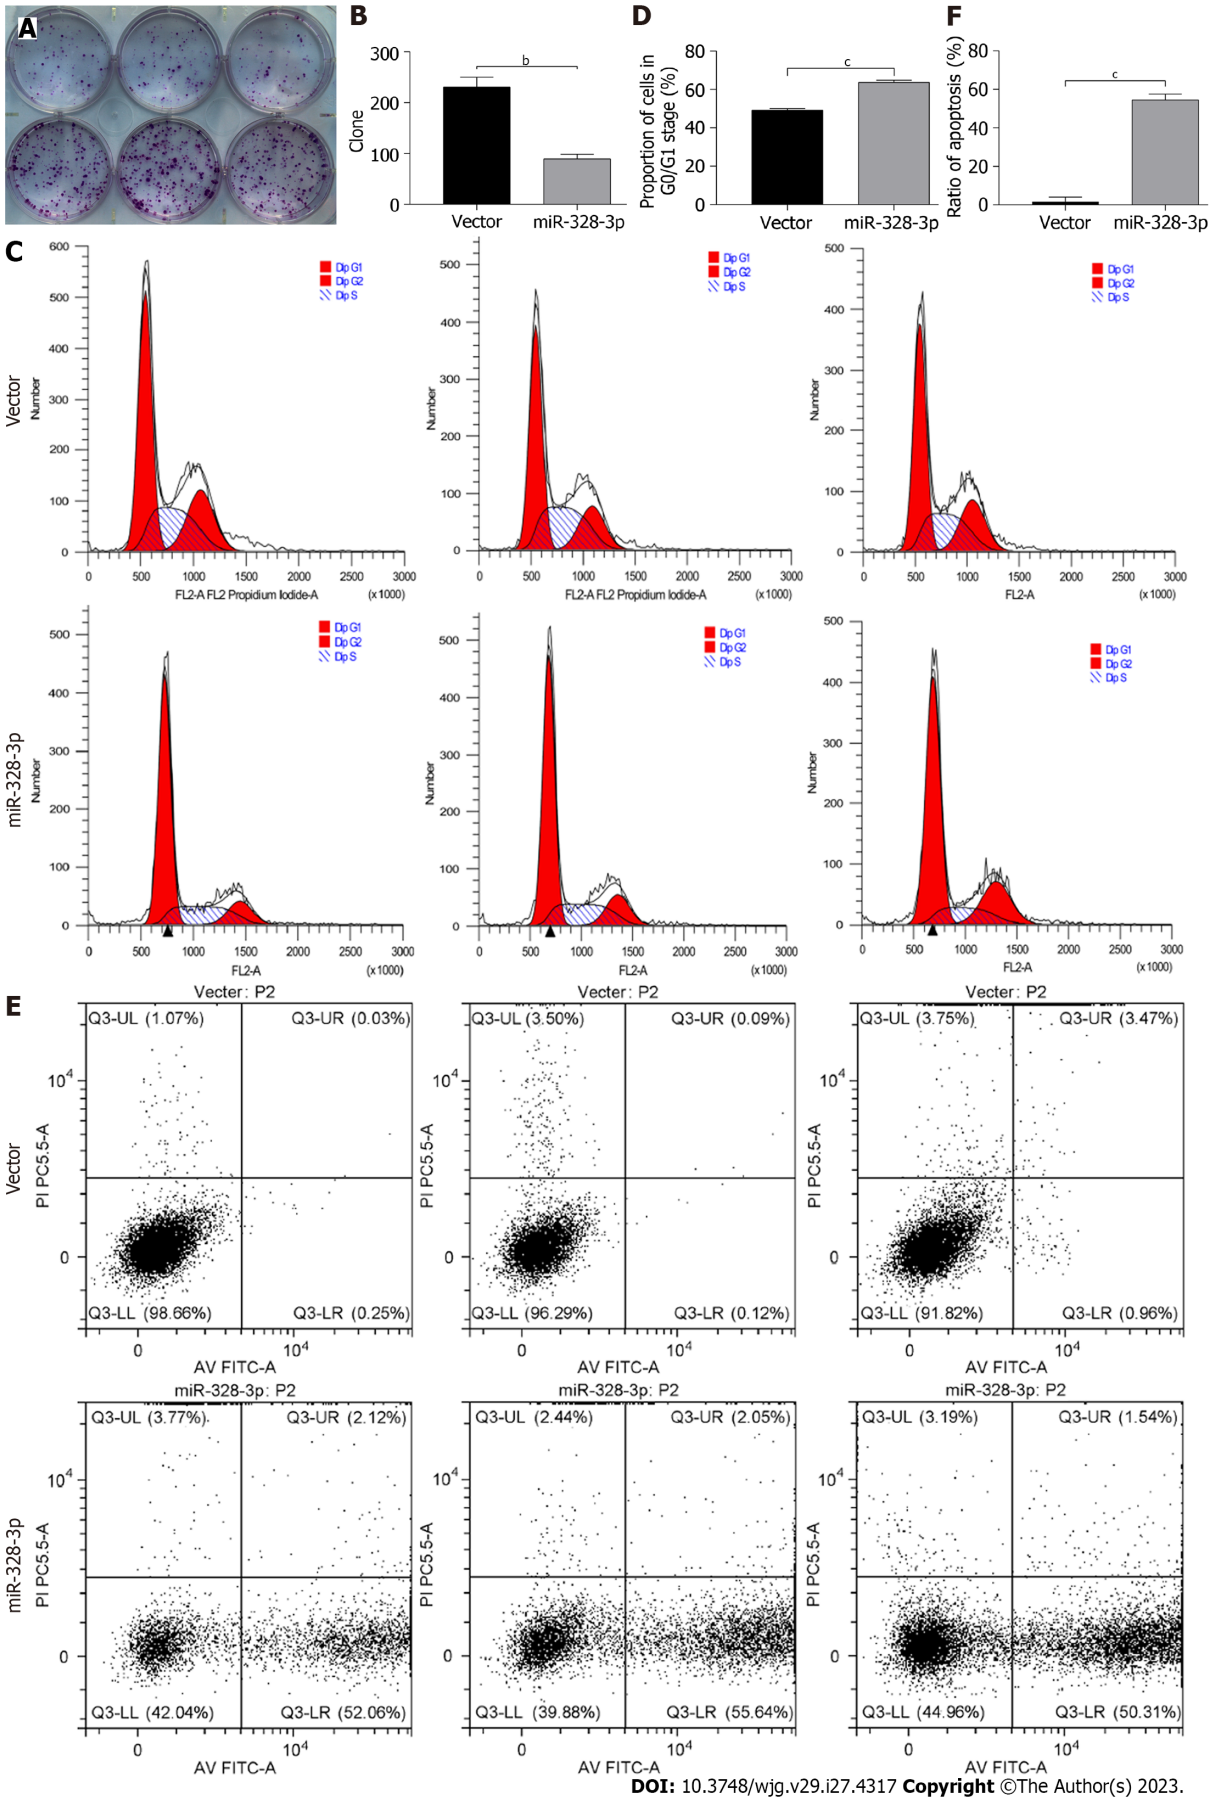
Overexpression of miR-328-3p arrested the cell cycle and promoted apoptosis

The cell cycle results showed that the average percentage of G0/G1 phase, S phase, and G2/M phase cells in the vector group was 49.23%, 29.41%, and 21.37%, respectively. The average percentage of G0/G1 phase, S phase, and G2/M phase cells in the overexpressed miR-328-3p group was 63.73%, 20.19%, and 16.08%, respectively. Compared with the vector group, the percentage of G0/G1 phase cells in the overexpressing miR-328-3p group was significantly higher ($P < 0.001$) (Figure 2C and D).

The results of the cell apoptosis experiment showed that the cell fragments in the vector group were increased, indicating that lentivirus transfection had a certain damage effect on AGS cells. Also, the early apoptosis rate of cells overexpressing miR-328-3p was significantly higher than that of the vector group ($P < 0.001$) (Figure 2E and F).

Overexpression of miR-328-3p inhibited subcutaneous tumor in nude mice

The results of the subcutaneous tumor experiment with nude mice showed that the subcutaneous tumor volume in the back of nude mice overexpressed with miR-328-3p was significantly smaller than that in the NC and vector groups ($n = 6$, Figure 3A and B). The tumor growth curve also showed that the tumor growth rate of the overexpressed miR-328-3p group was significantly lower compared to the vector group and the NC group ($P < 0.01$) (Figure 3C). There was no significant difference in body weight among the groups during the whole duration of the experiment(Figure 3D).

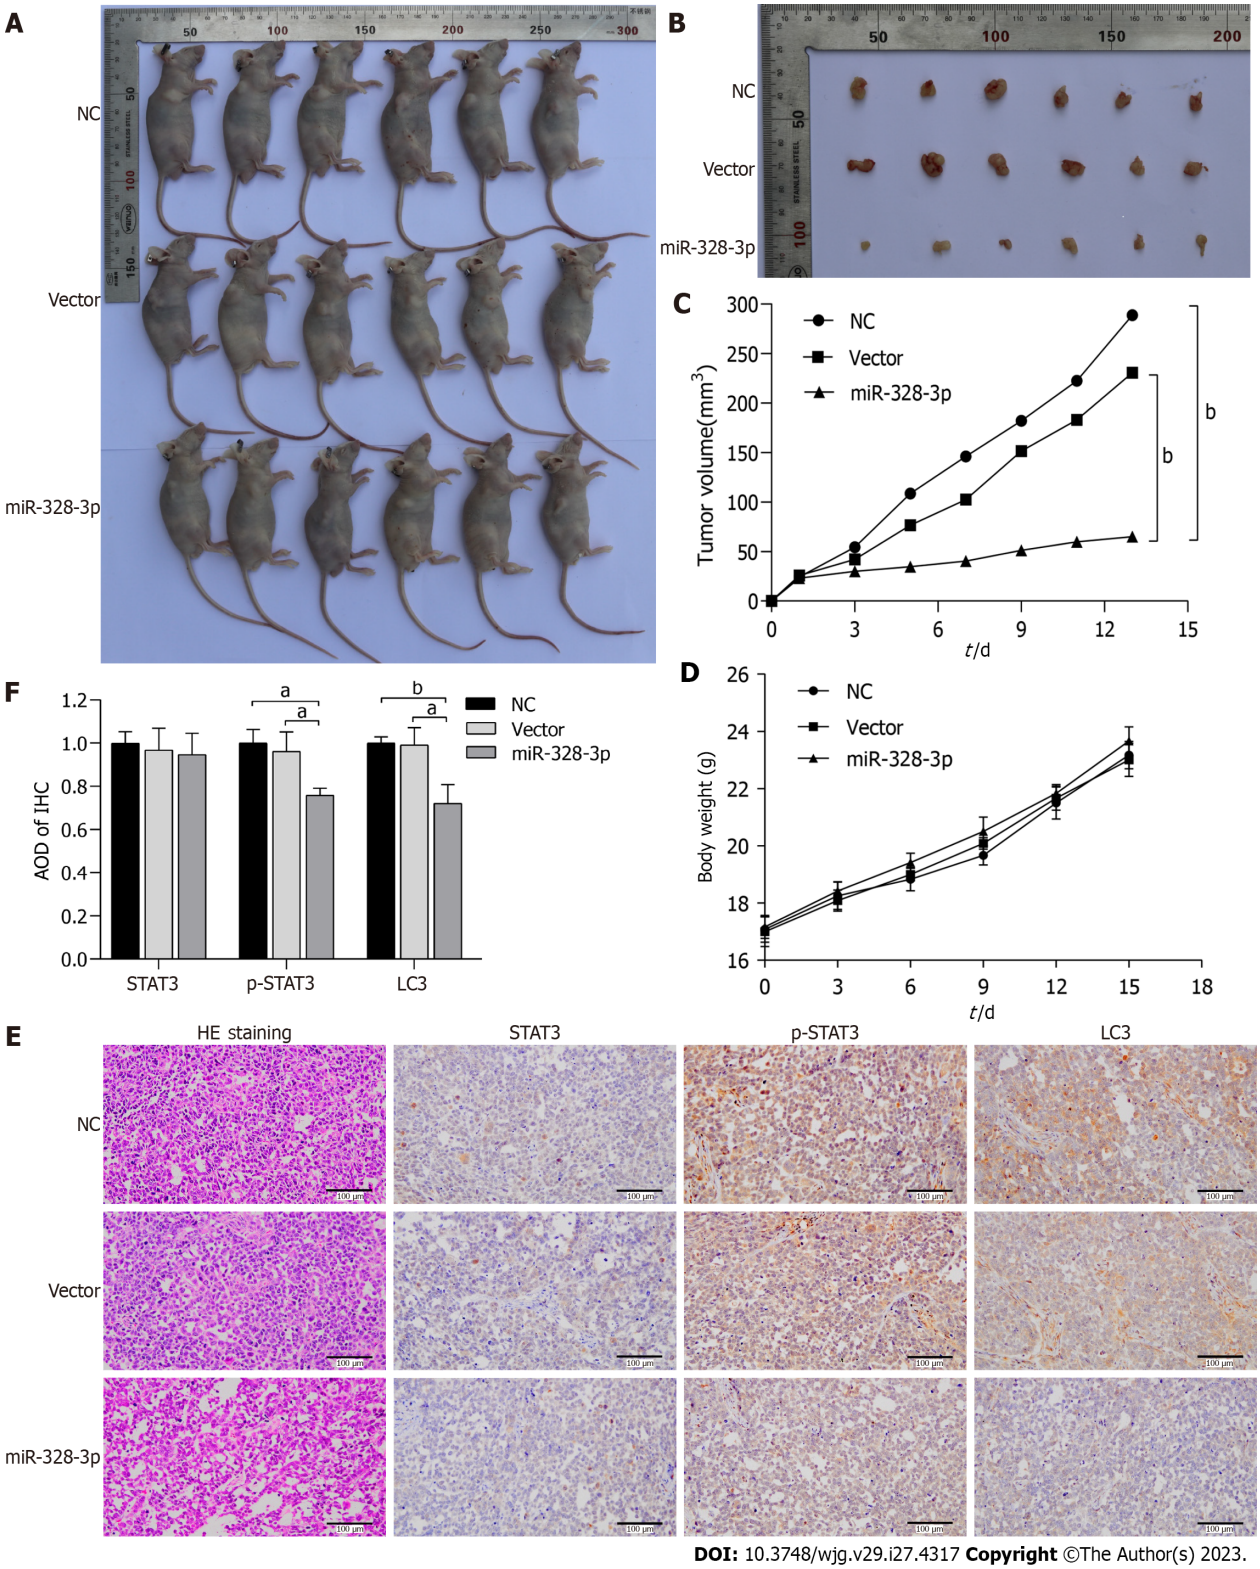


Histopathological observation of transplanted tumor and the expression of STAT3, p-STAT3, and LC3 proteins

Hematoxylin and eosin staining showed that tumor cells in the NC and vector groups grew strongly, with different sizes, certain atypia, and larger nuclei. Also, there was no obvious necrosis in the tumor tissue. In the overexpress group, the cell arrangement was loose, the tissue structure was irregular, and there were more necrotic cells (Figure 3E).

Immunohistochemical staining results showed that compared with the vector and NC groups, the expression of p-STAT3 and LC3 in the miR-328-3p group was significantly decreased ($P < 0.05$), and there was no significant difference in the positive rate of STAT3 expression in transplanted tumor tissues among all groups (Figure 3E and F).

miR-328-3p targeted STAT3 mRNA and was closely related to autophagy-related proteins



TransmiR v2.0 database predicted miR-328-3p related proteins and found that miR-328 was associated with STAT3 (Figure 4A). The relationship between STAT3 and autophagy-related proteins LC3, p62, BECN1, and ATG13 was subsequently predicted in the STRING database (Figure 4B). The above prediction results suggest that *STAT3* is a target gene of *miR-328-3p*.

STAT3 is targeted by miR-328-3p

qRT-PCR was used to detect the expression level of *STAT3* mRNA in transfected lentivirus in AGS cells. Our results showed that the expression level of *STAT3* mRNA in the overexpressed miR-328-3p group was significantly lower than that in the vector group ($P < 0.01$) (Figure 4C).

We also detected STAT3 and p-STAT3 in AGS cells overexpressed with miR-328-3p by western blot (Figure 4D). The experimental results showed that the expression level of STAT3 in the miR-328-3p group did not significantly change, and the expression of p-STAT3 was downregulated ($P < 0.05$). After the ratio of p-STAT3 to STAT3, the p-STAT3/STAT3 ratio in the overexpressed miR-328-3p group was significantly down-regulated ($P < 0.01$) (Figure 4E).

Dual-luciferase reporter system verified the targeting relationship between miR-328-3p and STAT3

The miRWalk online tool was used to find the binding site of *miR-328-3p* and *STAT3*, suggesting that there is a targeting relationship between *miR-328-3p* and *STAT3* (Figure 4F). Dual-luciferase reporter assay was used to detect the relationship between *miR-328-3p* and *STAT3* in AGS cells (Figure 4G). Our results showed that the luciferase activity of the STAT3 WT + miR-328-3p NC group was lower than that of the STAT3 WT + miR-328-3p group, and the difference was statistically significant ($P < 0.001$) (Figure 4H). We found that *miR-328-3p* could bind specifically to the 3'UTR of *STAT3*.

miR-328-3p could regulate STAT3 and promote autophagy flow in AGS cells

In order to further investigate the effect of *miR-328-3p* targeted regulation of *STAT3* on the autophagy flow of AGS cells, western blot was used in combination with 0.5 μmoL/L Baf A_1 to detect the expression of LC3 II in AGS cells after overexpression of miR-328-3p (Figure 5A). Our experimental results showed that the expression level of LC3 II in the overexpressing miR-328-3p group was significantly downregulated compared with the vector group ($P < 0.05$). Compared with the Baf A_1 group, the expression level of LC3 II in miR-328-3p combined with the Baf A_1 group was significantly upregulated ($P < 0.01$) (Figure 5B).

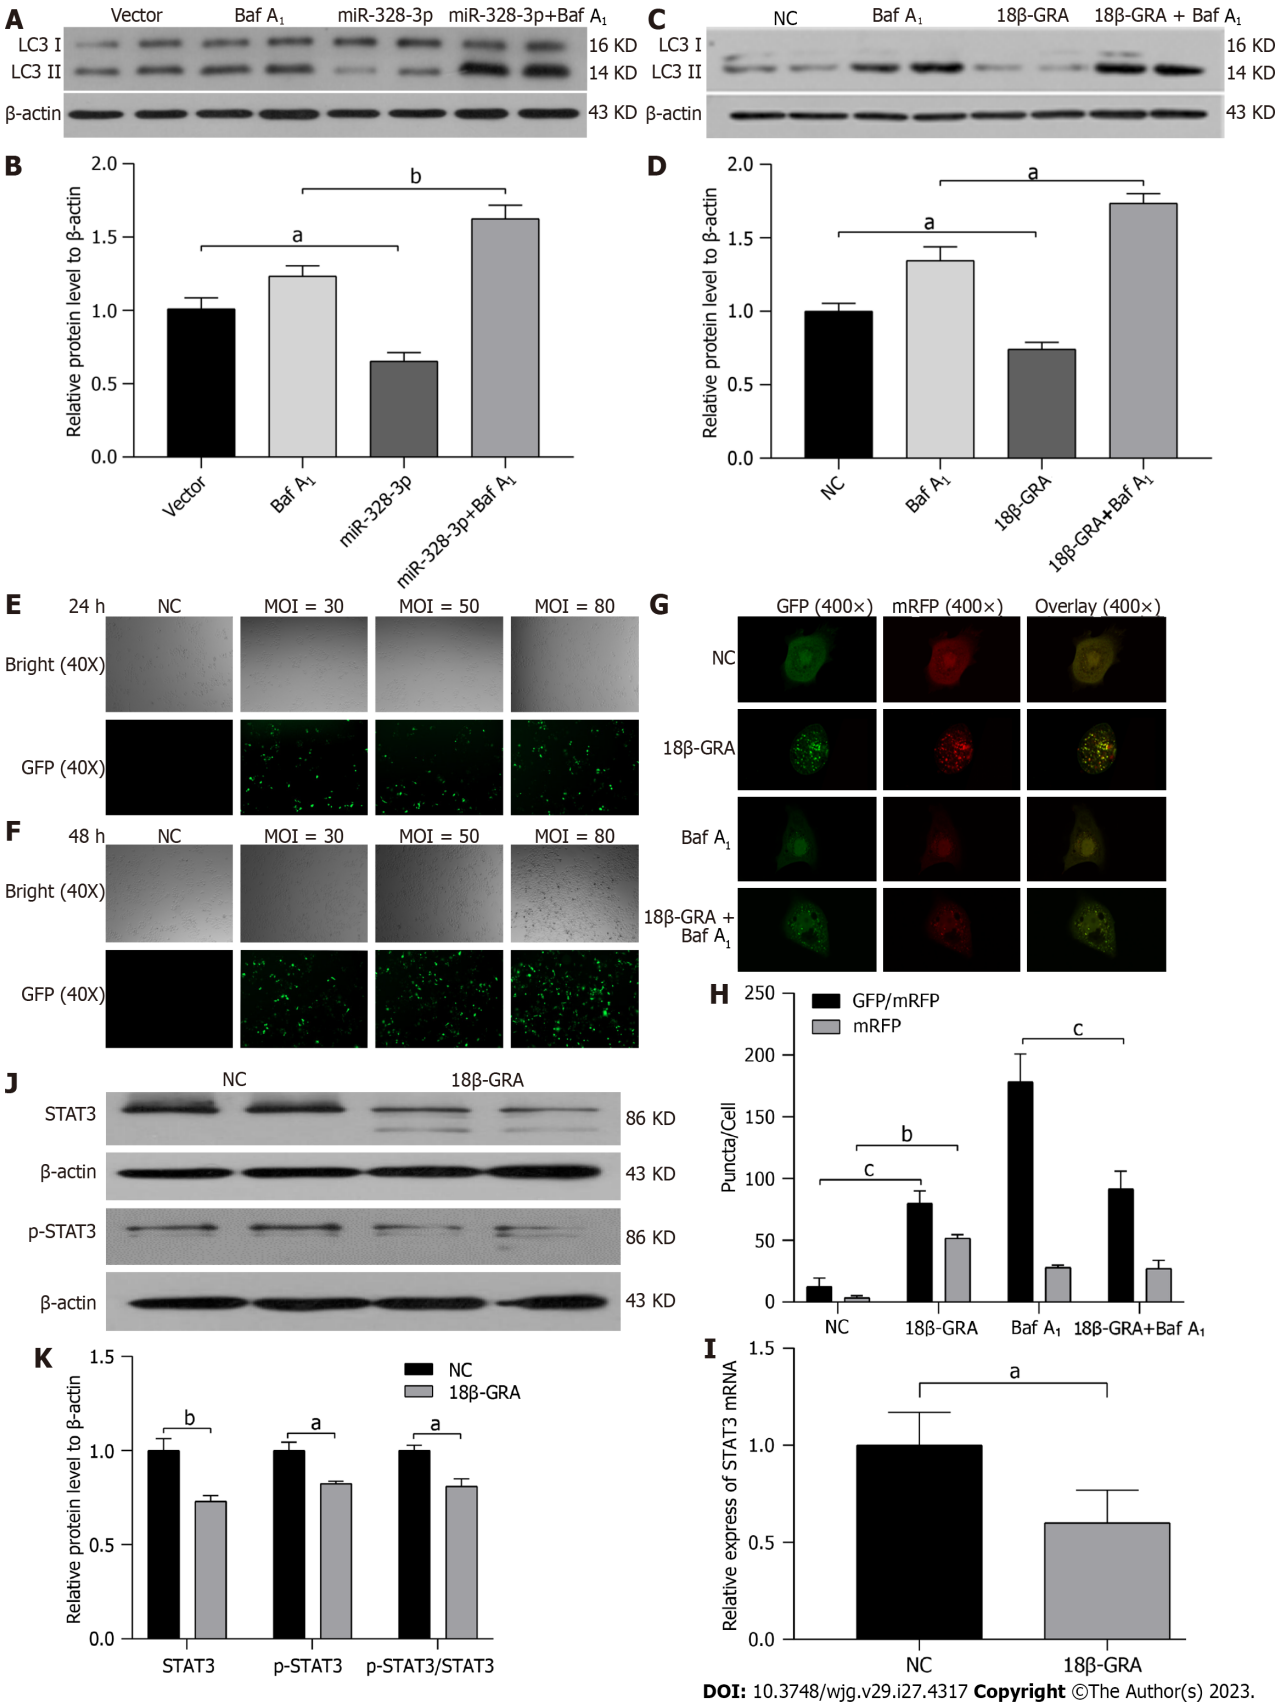
18β-GRA promoted autophagosome synthesis in AGS cells

To further investigate the effect of 18β-GRA on autophagic flow in AGS cells, we treated AGS cells with different drugs. The results showed that compared with the NC group, LC3 II expression level in the 18β-GRA group was significantly downregulated ($P < 0.05$). Compared with the Baf A_1 group, LC3 II in 18β-GRA + Baf A_1 group was significantly upregulated ($P < 0.05$) (Figure 5C and D).

mRFP-GFP-LC3 tandem fluorescent protein adenovirus was also used to infect AGS cells and locally tag LC3 to detect autophagy flow. First, we explored the MOI of mRFP-GFP-LC3 tandem fluorescent protein adenovirus-infected AGS cells. The NC, MOI = 30, MOI = 50, and MOI = 80 groups were set up separately. Corresponding virus volumes were given for transfection, and photographs were taken under the fluorescence microscope at 24 h and 48 h. The results showed that, compared with MOI = 50, the virus transfection efficiency was lower when MOI = 30, while the cell state was poorer when MOI = 80. When MIO = 50 and the transfection time was 48 h, both transfection efficiency and cell state were good. Therefore, an MOI of 50 was determined as the MOI for subsequent experimental infection (Figure 5E and F). We used mRFP-GFP-LC3 tandem fluorescent protein adenovirus (MOI = 50) was used to infect AGS cells for 48 h and gave corresponding drug treatment. The experimental results showed that the number of yellow spots (GFP/mRFP) in the 18β-GRA group increased significantly compared with the NC group ($P < 0.001$). Separate red signals were also significantly increased ($P < 0.01$) (Figure 5G), suggesting that 18β-GRA could increase the number of early autophagosomes and late autolysosomes. Compared with the Baf A_1 group, the number of yellow spots in the 18β-GRA + Baf A_1 group increased significantly ($P < 0.001$), and the single red signal showed no significant change, indicating that the late autophagy inhibitor caused the blocking of late autophagic lysosome degradation. 18β-GRA promoted autophagosome synthesis, increasing the number of yellow spots (Figure 5H).

18β-GRA promoted autophagy flow and inhibited the proliferation of AGS cells by regulating the miR-328-3p/STAT3 signaling pathway

To investigate whether 18β-GRA promotes autophagy flow through the miR-328-3p/STAT3 signaling pathway, we first used qRT-PCR to collect 18β-GRA intervention AGS cells to detect the expression level of *STAT3* mRNA. Our results showed that *STAT3* mRNA expression was significantly downregulated in AGS cells after 18β-GRA intervention compared with the NC group ($P < 0.05$) (Figure 5I). Then, western blot results showed that the expression levels of STAT3 and p-STAT3 in AGS cells after 18β-GRA intervention were downregulated, and the p-STAT3/STAT3 ratio was also significantly downregulated ($P < 0.05$) (Figure 5J and K).

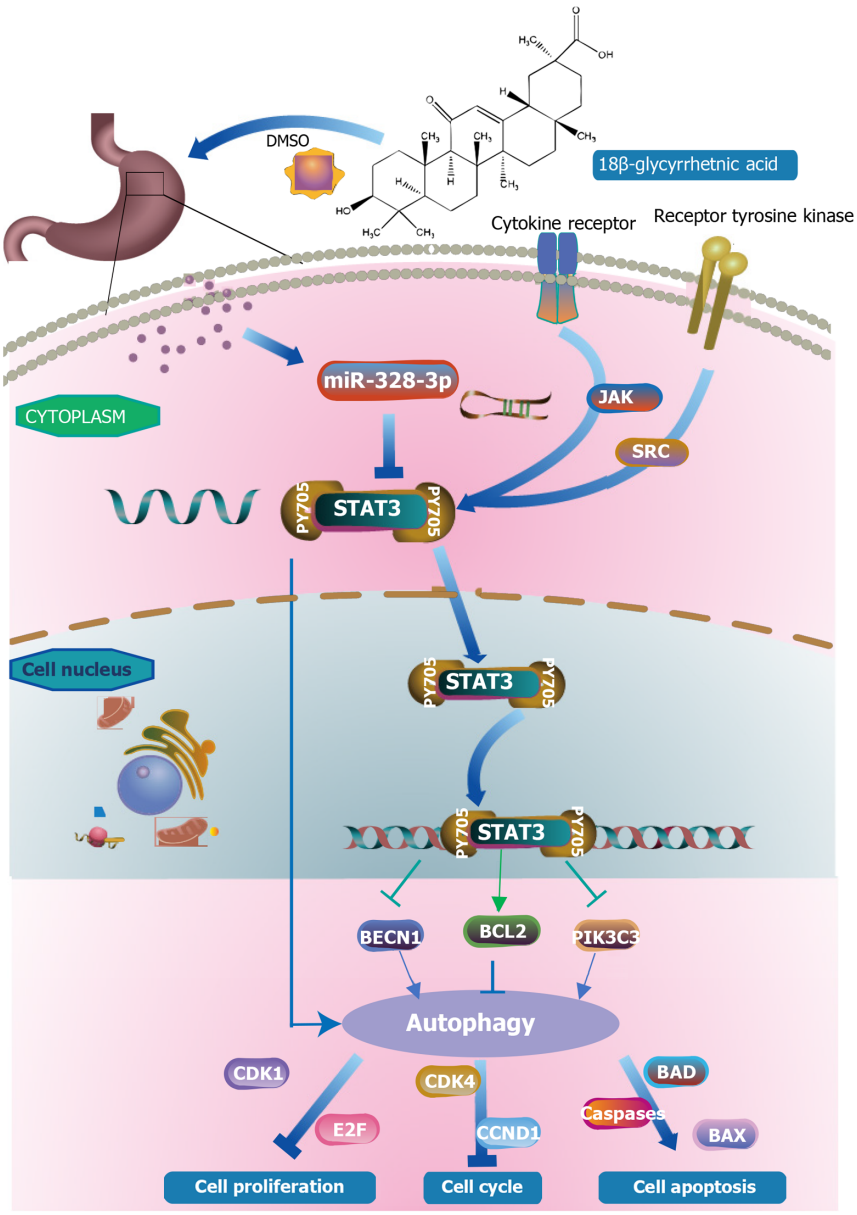


DISCUSSION

The present study found that 18β-GRA could regulate the expression of miR-328-3p, inhibit the proliferation of GC cells, arrest the cell cycle, and promote cell apoptosis. The dual-luciferase reporter gene experiment confirmed that *miR-328-3p* targeted the regulation of *STAT3* and participated in promoting autophagy. Our results suggest that 18β-GRA promoted the synthesis of autophagosomes and inhibited cell proliferation by regulating the miR-328-3p/STAT3 signaling pathway.

miR-328-3p expression was found to be significantly inhibited by palmitate-induced endoplasmic reticulum stress in liver cell lines[35]. In tumors, overexpression of miR-328-3p can inhibit the proliferation and invasion of hepatocellular carcinoma cells, promote cell apoptosis, and have an excellent targeting relationship with endoplasmic reticulum metalloproteinases[36]. Overexpression of miR-328-3p inhibited proliferation, migration, and invasion of colorectal cancer cells and inactivated the phosphatidylinositol 3 kinase/protein kinase B (Akt) signaling pathway[37]. Xu *et al*[38] analyzed the miRNA expression profiles of 389 GC patients, using forward and reverse variable selection and multiple Cox regression analysis models, finding that miR-328-3p exists in GC patients as a protective miRNA. However, Xiao *et al*[39] defined miR-328-3p as an oncogene for the first time and found that miR-328-3p promotes the progression of GC by targeting the kelch-like ECH-associated protein 1/nuclear factor erythroid 2-related factor 2 axis. Although there is some controversy about the effect of the miR-328-3p expression on GC progression, it also suggests that miR-328-3p may be a target for GC drug therapy.

Autophagy ("self-eating") usually refers to the process in which cells wrap their own pathological organelles into double-layer vesicles to form autophagosomes when they resist stress such as hunger and then deliver them to lysosomes and combine with them to form autolysosome to degrade the contents and produce energy for recycling and utilization to maintain cell survival[40]. During autophagy, the autophagy containing misfolded proteins and damaged organelles is degraded in the lysosome, which has a limiting membrane to prevent the leakage of its degrading enzymes. The autophagy process is fast and frequent and involves relatively complex membrane dynamics[41]. It is generally believed that the conversion of LC3 I to LC3 II detected in Western blot, or the increased expression level of LC3 II represents the activation of autophagy flow, and after the autophagy flow is blocked, the expression level of LC3 II is decreased (the conversion of LC3I to LC3 II was blocked) or LC3 II is excessively degraded by autolysosome[42]. In this study, autophagy marker protein LC3 was detected by combining with autophagy inhibitor Baf A_1 to explore the effects of drugs and miR-328-3p on the autophagy of GC cells, revealing that both drugs and miR-328-3p could promote the occurrence of autophagy flow.



To further explore whether drugs promote the synthesis of autophagosomes or inhibit the degradation of autophagosomes, we infected GC cells with mRFP-GFP-LC3 autophagic double-labeled adenovirus, and the mRFP and GFP were used to label LC3. Because GFP fluorescent protein is sensitive to acidic environments, green fluorescence is quenched after the fusion of autophagosome and lysosome, and only mRFP fluorescence can be detected. The yellow signal

Figure 6 Graphic abstract. STAT3: Signal transducer and activator of transcription 3.

composed of GFP and mRFP fluorescence signals co-located in the cell represents the early autophagosome, while the mRFP fluorescence signal alone represents the late autophagosome. The increased yellow and red signals indicate an increased autophagic flow level[43]. Using a dual verification approach, we found that drugs promoted autophagy flow by promoting autophagy synthesis at the causal level.

Several studies have found a close relationship between STAT3 and autophagy[44]. This study validated the targeting relationship between *miR-328-3p* and *STAT3* by dual-luciferase reporter gene experiments. In conclusion, regulating the miR-328-3p/STAT3 signaling pathway promotes the synthesis of autophagosomes, and 18β-GRA inhibits the proliferation of GC cells. Typically, STAT3 monomers in the cytoplasm are phosphorylated to form STAT3 dimers, which are then shuttled into the nucleus and bind to specific DNA elements to transcriptionally activate or inhibit the expression of target genes, thereby inhibiting cell proliferation, arresting the cell cycle, and promoting autophagy[45]. At the same time, STAT3 in the unphosphorylated cytoplasm activates some autophagy-related genes, such as serine/threonine-protein kinase ULK2 and ATG12, *via* FOXO1 and FOXO3 transcription[46]. STAT3 monomer can also be transferred to mitochondria and interact with complex I/II of mitochondria to inhibit the production of reactive oxygen ROS[47] (Figure 6).

The present study showed that 18-GRA could inhibit GC cell proliferation, arrest cell cycle in G0/G1, promote apoptosis, and promote autophagosome synthesis of GC cells by regulating the miR-328-3p/STAT3 signaling pathway. Our future research program will be divided into three following phases: (1) Electrophoretic mobility shift assay was used to detect the binding ability of the STAT3 promoter regulatory region and miR-328-3p, to explore whether the transcriptional regulation of miR-328-3p on STAT3 is directly binding or indirectly binding; (2) the interaction mechanism between miR-328-3p and STAT3 proteins will be verified, and chromatin immuno-precipitation technology will be considered to further verify the binding regulation of the promoter region of the transcription factor STAT3 and miR-328-3p; (3) using Cre mice, adeno-associated virus was used for genome editing *in vivo*, and conditional gene targeting of miR-328-3p was performed in gastric mucosal epithelial cells to explore the overall phenotype and physiological status of Cre mice. This study mainly provided the scientific basis for the clinical treatment of GC and also sought effective drug targets for the prevention and treatment of GC.

CONCLUSION

18β-GRA can promote the synthesis of autophagosomes in GC cells, inhibit cell proliferation, arrest cell cycle and promote cell apoptosis by regulating miR-328-3p/STAT3 signaling pathway.

ARTICLE HIGHLIGHTS

Research background

Gastric cancer(GC) is among the most severe gastrointestinal malignancies, with high morbidity and mortality. In recent years, increasing evidence has shown that natural products can prevent and inhibit the development of GC by regulating miRNA and other genes, showing great therapeutic potential.

Research motivation

Targeting miRNA and other genes in GC with natural drugs is a promising strategy, which provides a valid reference to further elucidate the molecular mechanism of natural products in the treatment of GC.

Research objectives

The purpose of this study was to investigate the molecular mechanism of 18β-glycyrrhetinic acid (18β-GRA) regulating the miR-328-3p/ signal transducer and activator of transcription 3 (STAT3) signaling pathway, promoting the autophagy flow of GC cells and inhibiting cell proliferation.

Research methods

The differentially expressed miRNAs were screened by full transcriptomic analysis. The cells were transfected with lentivirus, and the functional indices of the cells were determined by Cell Counting Kit-8, clone forming method, and flow cytometry. The effect of overexpression of miR-328-3p on the tumorigenicity of GC cells was detected in the transplanted tumor model of nude mice. Hematoxylin-eosin staining and immunohistochemistry were used to observe tumor tissue morphology and detect protein expression, respectively. Bioinformatics analysis was performed using TransmiR, STRING, and miRWalk databases. Real-time quantitative polymerase chain reaction and western blot were used to detect mRNA and protein expression levels. Dual luciferase reporter system was used to verify the targeting relationship between genes. The autophagy flow of monomeric red fluorescent protein- green fluorescent protein - light chain 3 adenovirus double-labeled infected cells was observed under confocal laser microscopy.

Research results

18β-GRA could upregulate the expression of miR-328-3p in AGS cells. Overexpression of miR-328-3p inhibited the cell proliferation and colony formation ability, arrested the cell cycle, promoted apoptosis, inhibited the growth of subcutaneous tumors, and led to GC tissue cell necrosis increase. *miR-328-3p* can target and regulate *STAT3*. 18β-GRA intervention in GC cells and overexpression of miR-328-3p could downregulate the expression level of *STAT3* mRNA. Compared with the vector group, the expression level of LC3 II was downregulated in the overexpressed miR-328-3p + bafilomycin A_1 (Baf A_1) group and upregulated in the overexpressed miR-328-3p + Baf A_1 group. The number of yellow spots and separate red signals in the 18β-GRA group were significantly increased compared with the negative control group, and the number of yellow spots in the 18β-GRA + Baf A_1 group was significantly increased compared with the Baf A_1 group.

Research conclusions

18β-GRA promotes GC cells' autophagosome synthesis and inhibits cell proliferation by regulating the miR-328-3p/ STAT3 signaling pathway.

Research perspectives

MiR-328-3p/STAT3 can be regulated by 18β-GRA and can be used as an effective drug target for the prevention and

treatment of GC, thus providing a scientific basis for the clinical treatment of GC.

Abstract

BACKGROUND

There is no consensus on the recommended duration of and optimal time to stop azathioprine (AZA) therapy in inflammatory bowel disease (IBD). Determining the optimal duration and cessation time can help to balance the risks of long-term intake with the possibility of relapse after cessation.

AIM

To describe the events following AZA cessation.

METHODS

Retrospective analysis was performed to examine data from adult patients affected by IBD who were followed at the University of Padua and had started but then discontinued AZA between 1995 and 2022. Data on therapy duration, reasons for cessation, and type of relapse after cessation were collected. Cox regression models were used to estimate the risk of relapse in different sub-groups.

RESULTS

A total of 133 ulcerative colitis patients and 141 Crohn's disease patients were included. Therapy with AZA was stopped in the 1st year in approximately 34% of patients but was continued for more than 10 years in approximately 10% of cases. AZA discontinuation was due to primary failure or disease relapse in 30% of patients and due to disease remission in 25.2% of patients. Most of the remaining cases stopped AZA therapy due to side effects (primarily clinical intolerance, cytopenia, and pancreatic disease). Patients who stopped AZA for clinical remission had an 83% lower risk of relapse during the observation time than other groups, with a relapse-free rate of 89% after 1 year and 79% after 2 years.

CONCLUSION
AZA administration is effective and safe, but it requires careful monitoring for potential minor and major side effects. Only 10% of patients who achieved remission with AZA needed a new treatment within 1 year of drug interruption.

Key Words: Azathioprine; Inflammatory bowel diseases; Ulcerative Colitis; Crohn's Disease; Relapse; Side effects

Core Tip: Prolonged use of azathioprine (AZA) remains controversial, and the time of interruption is uncertain. This retrospective study analyzed our single-center data of patients affected by inflammatory bowel disease who had started and then discontinued AZA between 1995 and 2022. AZA administration was effective and safe, and only 10% of patients who achieved remission with AZA needed a new treatment within 1 year of drug interruption.

INTRODUCTION

The immunosuppressant drug azathioprine (AZA) has been used in the treatment of inflammatory bowel diseases (IBDs) since the 1950s, and it represented one of the main treatments for these disorders until the introduction of biological drugs[1]. AZA is primarily effective as a steroid-sparing therapy for obtaining steroid-free long-term remission in Crohn's disease (CD) and ulcerative colitis (UC), but its delayed onset of action precludes its use in the induction phase[2-6]. AZA indications are well defined, but controversy exists regarding the risk-benefit ratio associated with AZA suspension[5,6]. The risk of relapse after withdrawal of AZA in patients with CD and UC who reached sustained remission was lower than 50% at 5 years[7]. Other studies found that sustained remission with AZA was associated with a 1-year moderate-to-severe relapse rate of approximately 23% to 41%[8-10]. Hawthorne and co-workers showed that patients who achieved disease remission with AZA experienced a doubling of the relapse rate after AZA withdrawal[11]. Mantzaris[1] suggested that drug withdrawal should be better considered after at least 4 years of "depth" of remission (clinical, serological, endoscopic and histological for UC), and close monitoring using biological markers of inflammation after AZA withdrawal was essential[1]. In contrast, Vilien *et al*[10] observed that patients with CD who were in remission after more than 2 years of continuous AZA treatment benefit from further continued treatment[10].

The occurrence of adverse effects plays a crucial role in the decision to discontinue AZA treatment. These effects are classified as "dose-dependent" (*e.g.*, myelotoxicity, hepatitis, opportunistic infections and cancer) and "dose-independent", which includes allergic reactions, such as rash or fever. There are also idiosyncratic reactions, such as pancreatitis, that are frequently associated with AZA use[12]. The prevalence of these adverse effects among patients ranges from 6% to 30% [13]. The most critical and potentially life-threatening adverse event of AZA is myelosuppression, which occurs more frequently during the 1st months and commonly manifests as leukopenia. The overall incidence rate of myelotoxicity in IBD patients receiving AZA is approximately 3% per patient and year of treatment, while severe myelotoxicity occurs in fewer than 1% of patients, and the risk of mortality during the year of treatment is lower than 0.1%[14]. The side effects of hepatotoxicity are related to the TPMT genotype, which was reported in approximately 5% of patients with AZA/mercaptopurine therapy[15]. Discontinuation of AZA is considered when severe cholestatic jaundice develops but also with a persistent increase in liver function values despite a 50% reduction in drug dose[16]. Pancreatitis is a much less frequent adverse effect of AZA than hepatotoxicity, and it occurs within the 1st month of AZA treatment. Acute pancreatitis (AP) is diagnosed when two of three findings appear, including abdominal pain suggestive of pancreatitis, serum amylase and/or lipase levels at least three times the average level, and characteristic findings on imaging[15]. AZA treatment is associated with an increased risk of developing several types of cancer, including non-melanoma skin cancers, urinary tract cancers, and hematological malignancies, such as non-Hodgkin's lymphoma, hepatosplenic T-cell lymphoma or gastrointestinal lymphomas. The risk of hematological neoplasia correlates with the duration of AZA treatment, and it is higher in patients with leukopenia that lasts longer than 20 d[17]. Therefore, the duration of AZA therapy should balance the risks associated with long-term intake with the risks of relapse upon withdrawal/suspension.

The primary aim of our study was to examine the events following AZA suspension. Moreover, we also described reasons for cessation and side effects of AZA treatment.

MATERIALS AND METHODS

We performed a longitudinal observational retrospective study on IBD patients included in the registry "The Paduan Gastrointestinal Disease Natural History Registry": A longitudinal, retrospective and prospective study" (CESC code: 5370/AO/22), which was approved by the Ethical Committees of the Padova University Hospital. The registry collected data on the diagnosis and follow-up of IBD patients followed at our center. We selected IBD patients aged ≥ 18 years who started and then discontinued AZA monotherapy between January 1995 and January 2022. The exclusion criteria were a combination therapy of AZA and biological drugs in naïve patients, the continuation of AZA therapy, the presence of a pouch after colectomy for CU, indeterminate IBD and refusal to sign the informed consent for inclusion in the registry.

Data collection

All data were retrieved manually from the registry and collected in a specific database. The following information was considered: Type of disease, date of diagnosis, location and phenotype of diseases, familiarity with IBD, and comorbidities. The following data on AZA therapy were included: The reason for initiation of AZA therapy, duration (in months) of AZA therapy, dose of the drug and any changes during its administration, concomitant therapies with systemic or topical corticosteroids and/or oral or topical mesalazine, reason for discontinuation of AZA and any disease relapse events after AZA discontinuation. Disease relapse was considered when one of the following events after AZA suspension occurred: Disease-related hospitalizations and/or surgeries, initiation of biological drugs or resumption of AZA therapy.

Patient follow-up

All patients were assessed every 6 mo in our outpatients' clinic or earlier when needed using clinical and laboratory parameters.

Clinical activity was evaluated using the Harvey Bradshaw index for CD patients and the partial Mayo score for UC patients[18,19]. C-reactive protein (CRP) levels (positive when > 0.5 mg/dL) and fecal calprotectin values were also evaluated at each follow-up examination. Endoscopy was performed according to current guidelines[5,6]. The endoscopic activity was evaluated using the Simple Endoscopic Score or Rutgeers score for CD patients and the Mayo endoscopic score for UC patients[20-22].

Statistical analysis

The results are summarized as frequencies and percentages (categorical variables) and means with SD (continuous variables). Categorical variables were compared using the χ^2 test, and continuous variables were compared using Student's *t* test. The time of observation after AZA interruption was calculated using the date of AZA discontinuation as the start date. In contrast, the study end date was considered the earliest date of surgery, date of hospitalization, date of initiation of a new therapy (biologic therapy or AZA), or date of the last follow-up (January 31, 2022).

We calculated overall rates of disease relapse per 10 person-years. We used a Cox regression model to estimate the hazard ratios (HRs) of disease relapse in patients according to AZA suspicion. All HRs were adjusted for sex, age, and type of disease. A *P* value < 0.05 was considered statistically significant for all statistical tests. Data were analyzed using STATA11 software (Stata Corp., College Station, TX, United States).

RESULTS

Study population/ patient characteristics

The initial data collection identified 2006 IBD patients included in our registry. A total of 366 of these patients had started AZA as monotherapy during the study period, and 274 (133 UC and 141 CD) patients were ultimately included based on our inclusion and exclusion criteria. Of the included patients, 57% were male. The average age at diagnosis for CD patients was 33.2 ± 14.2 years and 28.8 ± 14.4 years for UC patients, with a statistically significant difference between the two diseases ($P = 0.01$). Table 1 summarizes the main demographic and clinical characteristics of our patients at the time of enrollment. The main reason for AZA prescription was the maintenance of remission in steroid-dependent patients (> 90% in both diseases). No patient had a history of neoplasia before AZA administration.

AZA therapy: From introduction to suspension

We evaluated the temporal trend of starting AZA in UC and CD patients as monotherapy during the study period. Figure 1 shows a peak in use in 2011-2015. AZA was started in 45.9% (61/133) of UC patients and 41.8% (59/141) of CD patients included in the study (Figure 1). Considering the time between the IBD diagnosis and the introduction of AZA therapy, 26.9% of CD patients started treatment with AZA within the 1st year of diagnosis, 29.8% within the 5th year, and 43.3% after the 5th year. In contrast, 12.8% of UC patients took AZA within the 1st year, 46.6% within 5 years, and 40.6% after the 5th year ($P = 0.002$).

We found a different age distribution for the introduction of AZA ($P = 0.001$). A higher percentage of CD (20.6%) patients started taking AZA before age 18 compared to UC (4.5%) patients. Conversely, a higher percentage of UC patients (44.4%) started AZA in the age group 19-40 years compared to CD patients (32.6%) (Figure 2).

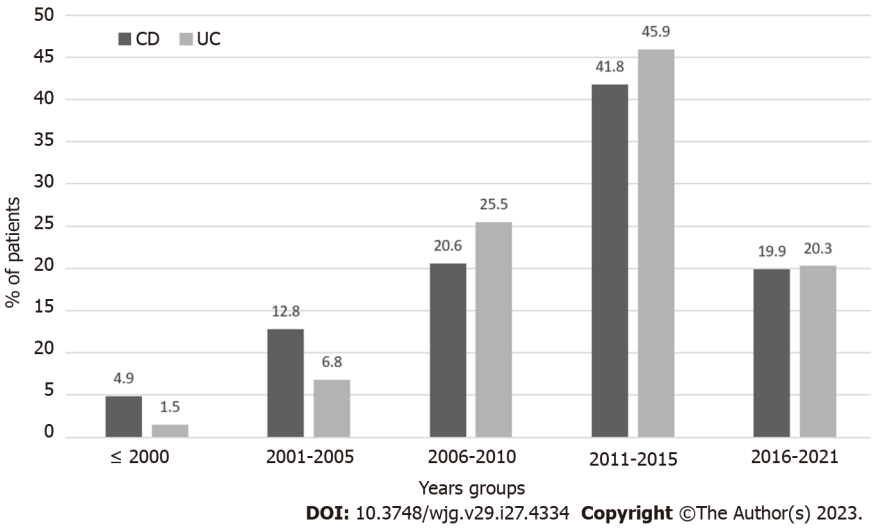
At the introduction of AZA therapy, 13 of the patients with UC (9.6%) and 17 with CD (11.6%) had never received corticosteroid therapy, and 98.5% of patients with UC and 100% of patients with CD were naïve to biologic drugs.

Table 1 Demographic and clinical characteristics of the studied population stratified according to disease type

Characteristic	Crohn's disease	Ulcerative colitis	*P* value
Included patients	141	133	
Sex, % males	54.6%	59.4%	0.42
Mean age at IBD diagnosis in yr	33.2 ± 14.2	28.8 ± 14.4	0.01
Disease location			
Upper GI-L4	5.7%		
Small bowel-L1	17.8%		
Ileum + colon-L3	61%		
Pancolitis-L2	15.6%	61%	
Left-sided colitis		37.5%	
Proctosigmoiditis		1.5%	
Perianal	7.8%		
Phenotype			
Inflammatory	56.7%		
Stenosing	24.8%		
Fistulizing	7.8%		
Fistulizing + Stenosing	5.7%		
Inflammatory + Fistulizing	2.2%		
Inflammatory + Stenosing	2.8%		
Reasons for AZA introduction			0.23
Steroid-dependent	95.8%	90.2%	
Steroid-refractory	2.1%	5.3%	
Steroid intolerance	0.7%	3%	
Other reasons	1.4%	1.5%	
Comorbidities			
PSC	0%	2.3%	0.07
Autoimmune rheumatic diseases	7.8%	3.0%	0.08
Cardiac involvement	4.3%	7.5%	0.25

AZA: Azathioprine; IBD: Inflammatory bowel disease; PSC: Primary sclerosing cholangitis.

The duration of AZA therapy was less than 1 mo for 2 patients with UC (1.5%) and 7 patients with CD (5%) due to intolerance, and it was discontinued within 1 year in 43 patients with UC (32.3%) and 47 patients with CD (33.3%). AZA treatment was continued for 1 year to 5 years in 28.6% of UC patients and 31.9% of CD patients and continued for 5-10 years in 35 patients with UC (26.3%) and 27 patients with CD (19.1%). Therapy was administered for longer than 10 years in 15 patients with UC (11.3%) and 15 patients with CD (10.7%) (P = 0.266). Of the 274 patients undergoing treatment with AZA, 96.4% received combined therapy with oral 5-ASA. None of these patients received chronic steroid therapy.



Side effects and reasons for discontinuation of AZA treatment

Overall, the onset of recurrent infections was observed in 13 patients: 6 patients experienced cytomegalovirus infections; 2 patients experienced varicella-zoster virus; 1 patient contracted herpes simplex; 1 patient had candida; and 1 patient had Staphylococcus. For 2 patients, the infections had an unknown etiology. Eleven of these 13 infections (84.6%) occurred in the 1st 5 years of treatment. Two AZA-treated patients developed cancers and discontinued the treatment within 12 mo. The first cessation was due to the onset of melanoma, and the second discontinuation was due to anal squamous cell carcinoma. Another patient developed basal cell carcinoma after 108 mo of AZA therapy, which was then discontinued. The reasons for the cessation of AZA therapy are summarized in Table 2. Forty-four patients (16.1%) discontinued therapy due to inefficacy, thirty-seven patients (13.5%) discontinued therapy due to disease relapse, sixty-nine patients (25.2%) discontinued therapy due to disease remission [average time of sustained remission: 5 years and 4 mo (SD: 3.2)], and 41% discontinued therapy due to side effects.

Table 2 Reasons for discontinuation of azathioprine treatment

Reason for discontinuation	Patients, *n*	% of 274 total
Inefficacy	44	16.1
Relapse	37	13.5
Remission	69	25.2
Pancreatitis or isolated raised in amylase/lipase or ALT > 2×ULN	48	17.5
Leukopenia	23	8.4
Infections	13	4.5
Unspecified intolerance	9	3.3
Nausea/vomiting	15	5.5
Neoplasia	3	1.1
Asthenia	2	0.7

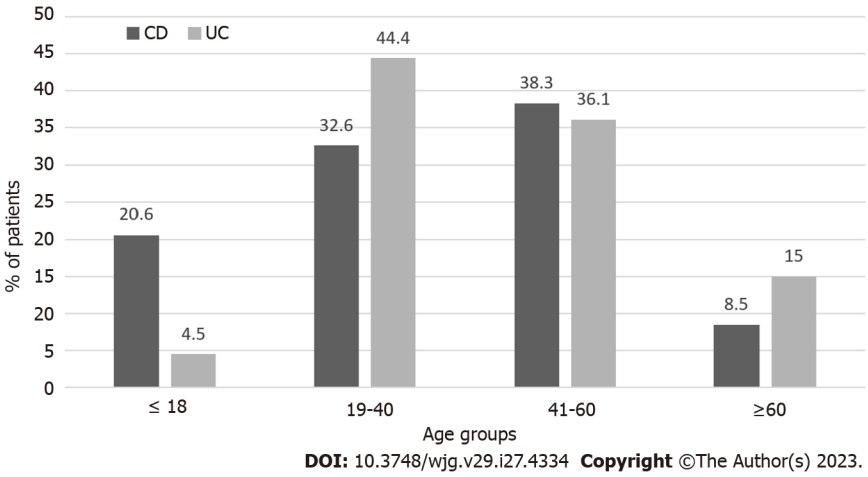
Figure 1 Temporal trend of ulcerative colitis and Crohn's disease patients who started azathioprine therapy. CD: Crohn's disease; UC: Ulcerative colitis.

Side effects and reasons for discontinuation of AZA treatmentThe incidence rate of disease relapse after AZA suspension

The median follow-up duration after cessation of AZA treatment was 3.5 ± 4 years. The incidence rate of disease relapse was 1.43 per 10 person-years, with no differences between sex or type of disease (Supplementary Table 1). Patients older than 35 years had a lower rate of disease relapse after AZA discontinuation than younger patients (Table 3). The highest rate of disease relapse occurred in patients who were active at the time of AZA suspension (due to inefficacy or relapse), with a rate of 7 per 10 person-years. Otherwise, patients who stopped AZA for clinical remission had an 83% lower risk of relapse during the observation time than active patients (HR: 0.17, confidence interval: 0.01-0.03). This lower risk was also confirmed after adjustment for age. Figure 3 shows a survival of 89% after 1 year and 79% at 2 years in remission patients.



DISCUSSION

IBD is an inflammatory disease of the gastrointestinal tract with a chronic intermittent course. Although biologic and

small molecule therapies have become treatment mainstays, AZA remains an immunomodulating agent that is used to sustain corticosteroid-free remission or in cases of corticosteroid dependence/resistance. There is no consensus on the recommended duration, optimal dose, or cessation of AZA therapy[23]. The present study investigated events following AZA cessation.

The disease characteristics of our patients, including location and disease behavior, are consistent with published data regarding the efficacy and safety of AZA therapy in IBD[24-26]. However, we found a higher percentage of CD patients who started AZA before 18 years of age than UC patients. This significant difference may be explained by the earlier onset of CD and the different therapeutic management of pediatric UC and CD based on ECCO/ESPGHAN guidelines [25,27,28]. The frequency of initiating AZA therapy within 1 year after diagnosis was significantly higher in CD patients, which confirmed the different modes of treatment approach in the two diseases[5,6,29]. AZA was prescribed primarily between 2011 and 2015 (Figure 1). After this period, AZA prescriptions decreased with the parallel introduction of new biologics on the market, which suggests that the role of AZA in the management of IBD patients was progressively replaced by new, more potent and safer drugs, such as anti-tumor necrosis factor-α, vedolizumab or ustekinumab[5,9].

Regarding the optimal time for drug interruption, Holtmann *et al*[30] assessed the flare incidences and steroid doses before, during treatment and after discontinuation of AZA. They concluded that AZA continuation beyond 4 years seemed beneficial, but its discontinuation may be considered after 3-4 years in CD patients in complete remission without steroid requirement[30]. Our study showed the safety of drug continuation in half of our patients. A total of 28.6% of UC patients and 31.9% of CD patients continued AZA treatment beyond the 5th year, and 26.3% of UC patients and 19.1% of CD patients continued AZA treatment beyond the 10th year, with no difference between the two diseases. We reported 2 patients who developed cancer (melanoma and anal squamous cell carcinoma) and discontinued the treatment within 12 mo, and we reported 1 patient with basal cell carcinoma after 108 mo of AZA therapy. However, 85% of the infections required drug suspicion in the 1st 5 years of treatment.

Figure 3 Cox regression analysis assessing the risk of relapse in patients who discontinued azathioprine according to the reasons for suspicion.

The most common adverse events that led to AZA suspension were pancreatic and hepatic disorders, including AP, isolated raised in serum lipase and amylase or in liver enzymes, which were detected in 17.5% of patients[31]. This percentage is higher than large retrospective and prospective treatment trials, such as the SONIC trial[32]. However, only AP was considered in this study. We reported leukopenia as the second most frequent adverse effect (8.4%), which is consistent with the literature. Myelosuppression most commonly manifests as leukopenia, and the frequency in the literature varies from 2.2% to 15% of patients. The risk of recurrent infections (4.5%) was lower than the literature (7.4%-14.1%)[15]. Connell *et al*[33] did not observe an increased risk of cancer over the expected risk in a population of 755 patients treated with AZA for 30 years[33]. However, different studies showed the carcinogenic potential of AZA, particularly for the development of lymphoma, urinary tract cancer and skin cancer[34,35]. We did not report any case of tuberculosis, but AZA has recently been shown to be associated with this disease[36].

A recent Italian multicenter observational retrospective study investigated the relapse risk after withdrawal of AZA in UC and found that it occurred in one-third of patients beyond the 1st year after AZA withdrawal and in half of patients after 2 years of withdrawal. A higher risk of relapse disease was identified in patients with extensive colitis, those with a lack of sustained remission during AZA, and those with discontinuation due to toxicity[37]. A multicenter retrospective cohort study on 237 patients with sustained clinical remission (≥ 3 years) described moderate/severe relapse in 23% of CD patients and 12% of UC patients at 12 mo and 39% of CD patients and 26% of UC patients at 24 mo. Elevated CRP at withdrawal was associated with higher relapse rates at 12 mo for CD patients, and an elevated white cell count was predictive at 12 mo for UC patients[8]. A 2018 systematic review[38] described four randomized controlled trials with a total of 215 participants providing data on the rate of clinical relapse following the discontinuation of AZA monotherapy in CD patients[9,10,39,40]. The follow-up period was 12 mo for two studies[9,10], 18 mo for one study[39] and 24 mo for one study[40]. A total of 32.4% (36/111) of participants assigned to AZA withdrawal experienced clinical relapse compared to 13.5% (14/104) of patients assigned to therapeutic continuation. Our study revealed a lower rate of disease relapse than these previous studies and reported a risk of 10% at 1-year follow-up among the 69 patients who had interrupted AZA due to remission. In this subgroup, the suspicion occurred after an average time of 5 years and 4 mo (SD: 3.2) of sustained remission, and there were no differences between sex or type of diseases. In line with the recommendations provided by Holtmann *et al*[30], we suggest discontinuation of AZA after 5 years of complete remission[30].

The main strengths of our study were the inclusion of a homogeneous population followed at the same tertiary center and the very low relapse rate in the cohort. The main limitation was the small size. Moreover, our data were collected retrospectively, which is associated with the risks of missing data and recall bias. Future prospective research could examine outcomes after the withdrawal of AZA and after the long-term remission of IBD.

CONCLUSION

Our study confirmed the decreasing use of AZA in recent years due to the introduction of biological drugs and the risk of related adverse events. The present study found that the highest rate of disease relapse was observed among patients who were active at the time of AZA cessation (due to inefficacy or relapse) and patients younger than 35 years of age. Only 10% of patients who achieved a sustained remission with AZA needed a new treatment within 1 year of drug interruption.

ARTICLE HIGHLIGHTS

Research background

Before the advent of biological drugs, azathioprine (AZA) was used worldwide to treat inflammatory bowel disease (IBD) patients and is still used. It is recognized that this immunomodulating agent could induce and sustain steroid-free long-term remission. However, clinicians cannot ignore the possible adverse effects of long-term AZA treatment and the risk of relapses after its discontinuation. In this retrospective study, we want to share the experience of our tertiary center with IBD patients treated with AZA.

Research motivation

Determining the optimal duration and cessation time helps balance the risks of long-term intake with the possibility of relapse after cessation.

Research objectives

In this study, we analyzed IBD patients who started and discontinued AZA. We have focused on patients' demographic and clinical characteristics, reasons for cessation, side effects, and disease incidence rate after AZA withdrawal.

Research methods

We conducted a retrospective study, including IBD patients older than 18 who had started AZA between 1995 and 2022 and then discontinued for any reason and were followed at our IBD clinic. For categorical variables, we have used the χ^2 test and Student's t-test for continuous variables. We have estimated disease relapse hazard ratios using the Cox regression model.

Research results

AZA discontinuation was due to primary failure or disease relapse in 30% of patients and due to disease remission in 25.2% of patients. We found that patients who discontinued AZA after a sustained remission of an average time of 5 years and 4 mo had a low risk of relapse (10%) in 1 year.

Research conclusions

This study addresses an unanswered question: "When is it possible to discontinue AZA? How long should we wait before AZA cessation?". Our study proves that AZA could be safely discontinued after 5 years of sustained remission because we have observed a lower relapse rate at 1-year follow-up. The main limitation of the study was the small size of patients.

Research perspectives

For advanced evidence, future prospective research should be conducted to evaluate the long-term natural history of IBD after withdrawal of AZA.

Abstract

BACKGROUND

Right-sided ligamentum teres (RSLT) is often associated with portal venous anomalies (PVA) and is regarded as a concerning feature for hepatobiliary intervention. Most studies consider RSLT to be one of the causes of left-sided gallbladder (LGB), leading to the hypothesis that LGB must always be present with RSLT. However, some cases have shown that right-sided gallbladder (RGB) can also be present in livers with RSLT.

AIM

To highlight the rare variation that RSLT may not come with LGB and to determine whether ligamentum teres (LT) or gallbladder location is reliable to predict PVA.

METHODS
This study retrospectively assessed 8552 contrast-enhanced abdominal computed tomography examinations from 2018 to 2021 [4483 men, 4069 women; mean age, 59.5 ± 16.2 (SD) years]. We defined the surrogate outcome as major PVAs. The cases were divided into 4 subgroups according to gallbladder and LT locations. On one hand, we analyzed PVA prevalence by LT locations using gallbladder location as a controlled variable (n = 36). On the other hand, we controlled LT location and computed PVA prevalence by gallbladder locations (n = 34). Finally, we investigated LT location as an independent factor of PVA by using propensity score matching (PSM) and inverse probability of treatment weighting (IPTW).

RESULTS
We found 9 cases of RSLT present with RGB. Among the LGB cases, RSLT is associated with significantly higher PVA prevalence than typical LT [80.0% *vs* 18.2%, P = 0.001; OR = 18, 95% confidence interval (CI): 2.92-110.96]. When RSLT is present, we found no statistically significant difference in PVA prevalence for RGB and LGB cases (88.9 % *vs* 80.0%, P > 0.99). Both PSM and IPTW yielded balanced cohorts in demographics and gallbladder locations. The RSLT group had a significantly higher PVA prevalence after adjusted by PSM (77.3% *vs* 4.5%, P < 0.001; OR = 16.27, 95%CI: 2.25-117.53) and IPTW (82.5% *vs* 4.7%, P < 0.001).

CONCLUSION
RSLT doesn't consistently coexist with LGB. RSLT can predict PVA independently while the gallbladder location does not serve as a sufficient predictor.

Key Words: Right-sided ligamentum teres; Left-sided gallbladder; Portal venous anomalies; Inverse probability of treatment weighting; Average treatment effect in the treated

Core Tip: Right-sided ligamentum teres (RSLT) is often associated with intrahepatic anomalies. Most studies hypothesis that left-sided gallbladder (LGB) must exist with RSLT. However, our exploration reveals that RSLT doesn't consistently coexist with LGB. Our analysis further suggests that RSLT can predict poral venous anomalies (PVAs) independently while the gallbladder location does not serve as a sufficient predictor. Therefore, operators, interventional radiologists or interventional gastroenterologists should not use the gallbladder location as an alternative of ligamentum teres location for PVAs prediction.

INTRODUCTION

Right-sided ligamentum teres (RSLT) is a congenital anomaly caused by misconnection of the fetal umbilical vein to the right paramedian trunk of the portal vein (Figure 1). This anomaly was first reported by Matsumoto[1] in 1986. RSLT is associated with several intrahepatic vascular anomalies and anomalous biliary confluences[2-5]. Therefore, unawareness of RSLT before an intervention may result in serious morbidities[6-8]. Specifically, RSLT strongly correlates with portal venous anomalies (PVAs), a high interventional risk morbidity feature.

PVAs result in difficulties in liver surgery and lead to surgical complications[8,9], such as active bleeding, segmental devascularization, and hepatic failure due to misinterpretation and erroneous ligation of the portal venous branch. Therefore, accurately evaluating PVAs is crucial before any major hepatobiliary intervention. In this paper, we share a case of bleeding following an ultrasound-guided liver biopsy and unsuccessful first embolization as a result of PVAs not being identified before the intervention (Supplementary Figure 1). The bleeding was finally stopped through embolization once the PVAs had been recognized.

While RSLT is the key to PVA evaluation, the presence of a left-sided gallbladder (LGB) is a more commonly used anatomical anomaly in PVA screening. This is because: (1) Nagai *et al*[10] suggested that the variant gallbladder location is an outcome of RSLT, which has been accepted in many studies[2,5,11]; and (2) LGB is relatively easy to identify. However, Yamashita *et al*[3] and Lin *et al*[4] reported some cases in which RSLT could present with a GB in the typical right-side location, which conflicted with Nagai *et al*'s hypothesis[10]. Hence, the relationship between the location of the GB and ligamentum teres (LT) remains controversial and warrants further investigation.

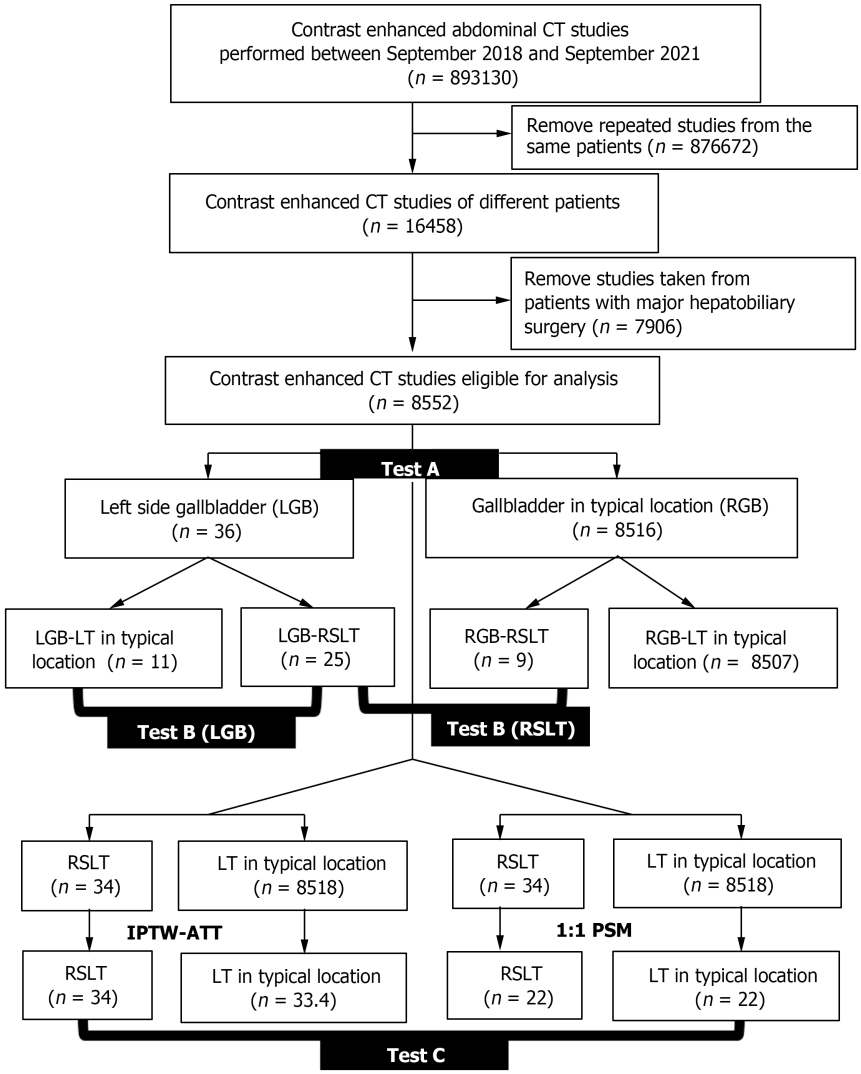
Figure 1 Coronal schematic of the most common anatomical variation in a liver with right-sided ligamentum teres. The white asterisk indicates the umbilical portion of the portal vein. IVC: Inferior vena cava; MHV: Middle hepatic vein; P_{RA}: Right anterior portal vein; P_L: Left portal vein; P_{RP}: Right posterior portal vein; RSLT: Right-sided ligamentum teres; MPV: Main portal vein.

In this paper, we present additional cases of RSLT together with a normal GB location, identified from a large data set. Then, to determine the key predictors of major PVA, we further investigate the association between GB location, LT location and PVA *via* a series of statistical analyses.

MATERIALS AND METHODS

Patients



The institutional review board approved this retrospective study and waived the requirement for informed consent. We retrospectively reviewed 71822 contrast-enhanced multidetector computed tomography (MDCT) examinations conducted at the Radiology departments of Taipei Veterans General Hospital and Taichung Veterans General Hospital between September 2018 and September 2021. We excluded both repeat cases and patients who had undergone major hepatobiliary surgery. A total of 8552 cases were eligible for analysis (Figure 2). Although three of these cases have been previously reported[4], the report only highlights the existence of the rare variation. In this manuscript, we conducted a series of statistical analyses on a large number of patients. We also defined the surrogate outcome as the prevalence of major PVAs, which is the dominant risk factor for morbidity and mortality after hepatobiliary intervention.

Computed tomography examination protocol

Contrast-enhanced abdomen computed tomography (CT) studies were conducted using a Philips Brilliance iCT256, United States, or a Siemens Somatom Sensation 16 Slice CT, Germany. The examination parameters included a detector coverage of 128 × 0.625 (Philips Brilliance iCT256) or 16 × 0.75 (Siemens Somatom Sensation 16 Slice CT), a pitch of 0.91 (Philips Brilliance iCT256) or 1 (Siemens Somatom Sensation 16 Slice CT), a rotation time of 0.5 s, a section thickness of 5 mm, and a reconstruction interval of 5 mm for all images. Additional reconstructions were performed at a section thickness of 1 mm and a reconstruction interval of 0.7 mm for detailed interpretation. A total of 120 mL of nonionic iodinated contrast material with an iodine concentration of 350 mg/mL was injected. Scans were acquired in the portal venous phase by using a SmartPrep protocol, with the enhancement threshold set at 120 HU.

Image interpretation

Coronal reconstructions were performed on all raw imaging data acquired from MDCT. The commercially available GE ADW 4.6 CT Workstation was used to process oblique axial multiplanar reformation (MPR), oblique coronal MPR, and maximum-intensity projection (MIP) images. These reconstructed images were then used for the discrimination of difficult portal vein ramifications and all cases involving PVAs. The images were independently analyzed by the following six radiologists: Lin HY, a radiologist with 2 years of experience; Hwang HE and Yen HH, radiologists with 4 years of experience; Chiu NC and Liu CA, radiologists with 15-20 years of experience; and Lee RC, a radiologist with more than 30 years of experience in interpreting CT and magnetic resonance imaging scans. Identification of RSLT was based on recognition of the round ligament (or LT) notch directly connected to the umbilical portion of the portal vein, which originates from the right portal branches (Figures 3 and 4). This technique followed the three-step method proposed by Yamashita *et al*[3] (Figure 3). In all cases, RSLT was positioned to the right of the middle hepatic vein

(MHV), consistent with the definition of Shindoh *et al*[2] (Figures 5 and 6). Major PVA cases were predominantly identified as one of three types as defined by Shindoh *et al*[2] (Figure 4). However, cases other than these types were classified following the approach of Gallego *et al*[12] and Atri *et al*[13]. Single or subsegmental PVAs—such as separate segment VI branches from the right portal vein, as reported by Covey *et al*[14]—were not defined as major PVAs. GB location was defined by its long axis position relative to the umbilical fissure (LT notch) and MHV of the liver (Figures 5 and 6).

Statistical analysis

The surrogate outcome was defined as major PVAs on which three radiologists reached a consensus. To examine the relationship between GB location, LT location, and PVAs, three-step statistical tests were conducted, namely Test A, Test B, and Test C (Figure 2). First, we compared the prevalence of PVAs based on GB locations and referred to it as Test A. According to a previous study[11], GB location and PVAs are strongly correlated. However, Test A didn't eliminate the confounding factor of LT location. To explore the effect of LT location, we divided our data into 4 subgroups based on not only GB location but also LT location and calculated PVAs prevalence for each subgroup, which was referred as Test B. Finally, we measured the PVAs prevalence per LT location as depicted in Test C. In Test C, we performed two analytical approaches: Propensity score matching (PSM) and inverse probability of treatment weighting (IPTW) with average treatment effect in the treated (ATT), to cope with data imbalance and to minimize the confounding effects of GB location, sex, and age. Hence, the PVAs analyzed in Test C were solely conditioned on LT location.

A 1:1 PSM method was used to construct matched pairs between RSLT and LT at a typical location through the nearest neighbor approach. IPTW with ATT was then used to avoid missing rare variation data from PSM. Each patient was assigned an inverse weighting of the RSLT or LT at a typical location through calculated propensity scores and the following ATT weight equation:

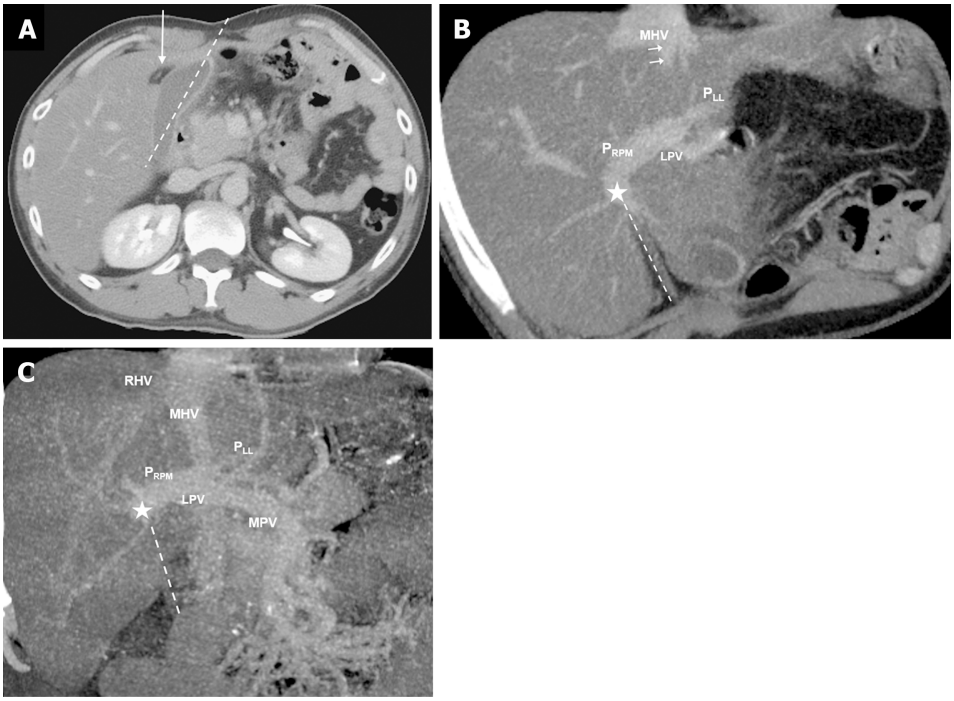
$$W_i = \begin{cases} 1, & RSLT_i = 1 \text{ (cases with RSLT)} \\ PS_i/(1-PS_i), & RSLT_i = 0 \text{ (cases with LT in typical location)} \end{cases}$$

Therefore, the weighting applied on these two groups improved their comparability despite the imbalance in case numbers (Figure 2).

Continuous variables were expressed in the mean ± SD. Categorical variables were expressed in number and percentage. We used the Student's *t* test to determine the differences between continuous variables and exploited the Chi-square or Fisher exact test for categorical variables. Logistic regression was performed to determine the odds ratio (OR) of the PVA prevalence. Standardized mean differences (SMDs) were calculated to diagnose the balance of matched data. Comparison of groups in matched data were performed by the paired t test for continuous variables and the McNemar's test for categorical variables. A two-sided *P* value < 0.05 indicates statistical significance. All analyses were conducted using IBM SPSS Statistics version 25.0 (IBM, Armonk, NY, United States) and R software version 3.0.2 (R Foundation for Statistical Computing, Vienna, Austria).

RESULTS

The prevalence of LGB and RSLT were 0.42% (36 out of 8552 cases) and 0.40% (34 out of 8552 cases), respectively. Overall, trifurcation-type PVA was the most common anomaly. However, when LGB or RSLT was detected, "independent right lateral type" PVA was the dominant anomaly. Patient demographics for each subgroup were demonstrated in Table 1.



Test A

Test A investigated the population of PVA for each gallbladder location. The prevalence of major PVAs in the LGB group

Figure 6 Contrast-enhanced computed tomography images of a 72-year-old woman with right-sided ligamentum teres and right-sided gallbladder: Maximum-intensity projection with oblique coronal multiplanar reformation, coronal maximum-intensity projection, and maximum-intensity projection with oblique axial multiplanar reformation. A: Portal vein ramification of the Shindoh's independent right lateral type[2]. Right paramedian portal pedicle forms the right umbilical portion of the portal vein (asterisk) and joins the right-sided ligamentum teres (RSLT, dotted line). The RSLT is located right to the middle hepatic vein (MHV); B: The cholecystic axis of the gallbladder (dotted line) is located right to the RSLT and the round ligament notch, that is, right to the MHV; C: On the axis (dotted line) along the main portal vein to the umbilical portion of the portal vein (asterisk) and the umbilical notch (circle), the diverging point of right anterior portal segment is distal to that of left lateral portal vein in this RSLT liver, consistent with the findings described by Yamashita *et al*[3]. P_{RPM}: Right paramedian portal pedicle; P_{LL}: Left lateral portal vein; P_{RL}: Right lateral portal pedicle; P_{A-D}: Right anterior portal segment; MHV: Middle hepatic vein; MPV: Main portal vein; GB: Gallbladder; LPV: Left portal vein.

(n = 648, 61.1%) was higher than that in the right-sided GB (RGB) group (n = 22, 7.32%). A total of 670 PVA cases were identified, giving a prevalence of 7.83%, which is within the range reported in previous studies[15-19] (*i.e.*, 6% to 16.5%) without considering single or subsegmental PVAs. However, the results of Test A did not exclude possible influencing factors, particularly LT location.

Test B

Test B investigated whether an LGB is sufficient for PVA prediction.

Test B (LGB): In this analysis, we categorized LGB cases by different LT locations. Among 36 patients with LGB, 25 had RSLT (69.4%), and 11 had typical LT (30.6%) as shown in Table 2. The prevalence of PVAs was 80.0% (20 out of 25 cases) for RSLT and 18.2% (2 out of 11 cases) for typical LT, which was significantly different based on Fisher's exact test (P = 0.001). These differing results between LGB cases with different LT locations indicated that LGB alone was unreliable for predicting PVAs. To quantitatively measure the difference, we further performed logistic regression and obtained an OR of 18.00 [95% confidence interval (CI): 2.92-110.96] for RSLT over typical LT. No significant differences were observed in sex, age, and all the possible comorbidities.

Test B (RSLT): On the other hand, we performed an analysis with the RSLT cases divided by GB location. This resulted in 9 RGB cases (26.5%) and 25 LGB cases (73.5%) from a total of 34 RSLT patients, as shown in Table 3. We detected PVAs in 8 of the 9 RGB cases (88.9%) and in 20 of the 25 LGB cases (80.0%); the difference was nonsignificant according to Fisher's exact test (P > 0.99). These results indicated that GB location had no influence on the prevalence of PVAs given the existence of RSLT. The analysis showed no significant differences in demographics or confounding factors between the two subgroups.

According to the analysis results of Test B, we could conclude that GB location was not sufficient for PVA prediction. Furthermore, given the presence of RSLT, different GB locations even contributed to identical PVA prevalence.

Test C

Test C investigated the correlation between LT location and PVAs. We used PSM to handle unbalanced data and remove possible confounding factors, specifically GB location. As shown in Table 4, 22 patients of RSLT and typical LT were matched based on propensity score. Basic demographics and GB location were well balanced between the two groups,

with SMDs less than 0.2. Also, both McNemar's test and the paired-*t* test revealed that the confounding factors and demographics between matched cohorts were statistically similar. The prevalence of PVAs was 77.3% (17 out of 22) for the matched RSLT group and 4.5% (1 out of 5) for the matched typical LT group; the difference between these two groups was significant according to McNemar's test ($P < 0.001$). Conditional logistic regression revealed an OR of 16.27 (95%CI: 2.25-117.53) for RSLT over typical LT. However, 12 rare variation data points in which RSLT coexisted with RGB were lost

during the PSM process. Therefore, we implemented IPTW with ATT to prevent data exclusion from PSM and minimize the covariate imbalance between the groups with RSLT and typical LT. Following IPTW, the SMDs between the two cohorts were smaller than 0.1, indicating they are balanced for their demographics and GB locations. Compared with the typical LT cohort, the RSLT cohort had a significantly higher prevalence of PVAs after IPTW (4.7% *vs* 82.4%, $P < 0.001$; Table 5). As possible confounding effects were removed, the result suggests that LT location per se was effective for determining PVAs.

DISCUSSION

According to our statistical analysis results, RSLT is not consistently accompanied by LGB, and the key feature of predicting major PVAs is not LGB but rather RSLT. First, nine additional cases of RSLT without LGB were identified (Figure 2 and Table 3), indicating that the four cases reported by Yamashita *et al*[3] and Lin *et al*[4] were true existing variations and that RSLT does not consistently coexist with LGB. Second, the results of Test B indicated that the prevalence of PVAs is invariant regardless of the location of GB given RSLT was detected, which suggests that GB location is not sufficient for PVA prediction. Finally, the results of Test C concludes that the LT location is an independent risk factor of PVAs after possible confounding factors are eliminated in large propensity score–matched data sets.

Because GB location is an unreliable feature of PVAs, operators should not underestimate the risk of major vascular anomalies in livers with a normal GB location. As shown in Supplementary Figure 1, hepatobiliary interventions may be technically challenging and lead to complications if the PVAs are not recognized. Our results also suggest that LT location is strongly correlates with PVAs. Therefore, operators must be aware of the high surgical risk once RSLT has been detected. In addition to PVAs, RSLT also introduces nondeterministic anomalous arterial ramifications and biliary confluences, as reported by Nishitai *et al*[5] , hence, arterial and biliary patterns must be examined in preoperative imaging studies at the presence of RSLT.

Neglecting the aforementioned anomalies before an intervention may have life-threatening consequences, such as ischemic hepatic failure or bile leak[6-8]. Specifically, because independent ramification of the right lateral portal pedicle is the most common type of PVA in livers with RSLT, ligation of the left trunk of the portal vein during hepatobiliary surgery will disrupt portal flow in two-thirds of the entire liver if the common trunk of the left portal vein and the right paramedian pedicle are misinterpreted as the left portal vein. Multiple biliary complications during major hepatobiliary interventions in patients with RSLT have also been documented[6].

With the increasing popularity of three-dimensional magnetic resonance cholangiopancreatography (a low-risk examination that does not require the injection of contrast medium), biliary confluences in livers with RSLT should be comprehensively investigated during pre-interventional assessments, especially within the context of living donor liver transplantation.

This study has several limitations. First, a normal GB location in a liver with RSLT is a substantially rare variation that results in a remarkable loss of unmatched data when performing multivariate logistic regression. However, in the present study, this problem was addressed by preprocessing data with PSM and IPTW with ATT, yielding well-balanced cohorts and minimizing imbalances. Second, the diagnoses of all the variations were made by CT images without surgical or

cadaveric anatomical proof. To compensate for this limitation and establish accurate image-based diagnoses, we explored several image-processing techniques, such as axial and coronal oblique MPR and MIP. We also followed the three-step method proposed by Yamashita *et al*[3] for diagnosing RSLT. In addition, the images were independently analyzed by six radiologists with 2-30 years of experience. To the best of our knowledge, this is the largest retrospective cohort study focusing on RSLTs. This is also the first article to highlight rare cases in which an RGB coexists with RSLT and further discuss the individual effects of LGB and RSLT on PVAs.

CONCLUSION

Understanding portal vein ramifications is crucial during preoperative planning of hepatobiliary interventions. We first observed that LGB is not consistently accompanied by RSLT and then performed a series of statistical analyses to evaluate the correlation between LGB, RSLT and PVAs. Our analysis results indicated that RSLT is an independent risk factor for PVAs, whereas GB location has no influence on PVAs if RSLT exists. Therefore, operators should avoid considering GB location, which is easily identified, as a surrogate feature of LT location.

ARTICLE HIGHLIGHTS

Research background

The presence of right-sided ligamentum teres (RSLT) is often accompanied by portal venous anomalies (PVAs) and is considered a worrisome characteristic in hepatobiliary interventions. Most studies hypothesis that left-sided gallbladder (LGB) must exist with RSLT. However, in a reported study, right-sided gallbladder (RGB) was observed in livers with RSLT. Therefore, the relationship between the ligamentum teres hepatis (LT), gallbladder (GB), and PVAs is controversial and requires further investigation, despite the rarity of the anatomical variation of LT and GB, which can complicate statistical analysis.

Research motivation

To verify whether the RSLT coexists with a typical RGB, represent genuine existing variations or were merely misinterpreted and to determine the key predictors of major PVA, we conducted a comprehensive investigation. Additionally, to the best of our knowledge, all previous articles focusing on the RSLT had small sample sizes, not exceeding 1000.

Research objectives

First, to draw attention to the uncommon occurrence of the RSLT without the presence of the gallbladder (LGB), and secondly, to assess the reliability of both the LT and gallbladder location in predicting PVAs.

Research methods

This retrospective study examined a total of 8552 contrast-enhanced abdominal computed tomography examinations conducted between 2018 and 2021, involving 4483 men and 4069 women, with a mean age of 59.5 ± 16.2 (SD) years. The primary focus was to assess major PVAs as a surrogate outcome. The cases were categorized into four subgroups based on the locations of the gallbladder and LT. On one hand, we analyzed the prevalence of PVAs based on LT locations while controlling for gallbladder location (n = 36). On the other hand, we controlled for LT location and determined the prevalence of PVAs based on gallbladder locations (n = 34). Lastly, we investigated the independent influence of LT location on PVA using propensity score matching (PSM) and inverse probability of treatment weighting (IPTW).

Research results

We identified a total of 9 cases where the RSLT coexisted with a typical RGB location. Among the cases with a LGB, the presence of RSLT was associated with a significantly higher prevalence of PVAs compared to those with a typical LT [80.0% *vs* 18.2%, P = 0.001; odds ratio (OR) = 18, 95% confidence interval (CI): 2.92-110.96]. However, when RSLT was present, there was no statistically significant difference in PVA prevalence between RGB and LGB cases (88.9% *vs* 80.0%, P > 0.99). We employed PSM and IPTW to ensure balanced cohorts in terms of demographics and gallbladder locations. After adjusting for these factors using PSM, the RSLT group still exhibited a significantly higher PVAs prevalence compared to the LT group (77.3% *vs* 4.5%, P < 0.001; OR = 16.27, 95%CI: 2.25-117.53). Similar results were observed when utilizing IPTW (82.5% *vs* 4.7%, P < 0.001).

Research conclusions

RSLT doesn't always coexist with LGB. RSLT can predict PVA independently while the gallbladder location does not serve as a sufficient predictor.

Research perspectives

Further investigation is needed to determine whether the existence of RSLT can predict the most predominant type of biliary or arterial anatomical variation.

ACKNOWLEDGEMENTS

We would like to express our special thanks to Chai JW, the head of the Department of Radiology at Taichung Veterans General Hospital in Taiwan, and to Lee RC, the head of the Division of Abdominal Radiology at Taipei Veterans General Hospital, for their invaluable assistance with technical support and assurance for the entire study. We would also like to thank Hsu CY from the Biostatistics Task Force and Department of Medical Research at Taichung Veterans General Hospital for kindly providing statistical advice for this manuscript.

Abstract

BACKGROUND

The global spread of severe acute respiratory syndrome coronavirus 2, responsible for coronavirus disease 2019 (COVID-19), poses a significant risk to public health. Beyond the respiratory issues initially associated with the condition, severe cases of COVID-19 can also lead to complications in other organs, including the liver. Patients with severe COVID-19 may exhibit various clinical signs of liver dysfunction, ranging from minor elevations in liver enzymes without symptoms to more serious cases of impaired liver function. Liver damage is more commonly observed in patients with severe or critical forms of the disease.

AIM

To present the research landscape on COVID-19 and liver dysfunction while also offering valuable insights into the prominent areas of interest within this particular domain.

METHODS

On 18 February 2023, Scopus was utilised to conduct a comprehensive exploration of the relationship between COVID-19 and the liver dysfunction. The investigation encompassed the period from 1 January 2020 to 31 December 2022. Primary sources were meticulously examined and organised in a Microsoft Excel 2013 spreadsheet, categorised by journal, institution, funding agency, country and citation type. VOSviewer version 1.6.18 was employed to explore the prominent topics and knowledge network related to the subject.

RESULTS

There were 2336 publications on COVID-19 and liver dysfunction analysed in this study, of which 558 were published in 2020, 891 in 2021 and 887 in 2022. Researchers from 111 different countries participated in the retrieved documents. The United States contributed the most studies, with 497 documents, representing 21.28% of the total, followed by China with 393 documents (16.82%) and Italy with 255 documents (10.92%). In the context of research related to COVID-19 and the liver, co-occurrence analysis identified three distinct clusters of topics: (1) 'COVID-19 vaccines in liver transplant recipients'; (2) 'liver function tests as a predictor of the severity and clinical outcomes in hospitalised patients'; and (3) 'care of patients with liver disease during the COVID-19 pandemic'.

CONCLUSION

This bibliometric study provides a comprehensive overview of liver-related publications in COVID-19 research over the past 3 years. This study highlights the significant contributions of high-income nations, particularly the United States, China, and Italy, to the production of liver-related scholarly literature in this field. Most of the articles focused on liver dysfunction in patients with COVID-19 and the implications of the virus for gastroenterologists and hepatologists.

INTRODUCTION

The novel coronavirus disease 2019 (COVID-19) has had a marked global impact. As of 3 May 2023, there have been over 765 million confirmed cases and nearly 6.92 million fatalities[1]. COVID-19 symptoms range from modest respiratory difficulties to severe respiratory distress syndrome, which can lead to organ failure and death. Older people with preexisting health issues are especially vulnerable. It is crucial to mention that in addition to its effects on the lungs, COVID-19 can cause liver damage[2-6]. COVID-19-related liver injury is defined as any liver damage that occurs in people who have COVID-19, regardless of whether they have a preexisting liver ailment[7-11]. Severe COVID-19 infections can cause liver damage through a variety of mechanisms, including immune-mediated damage, ischemic hepatitis caused by a systemic inflammatory response, drug-induced liver injury, reactivation of preexisting chronic liver disease, and direct cytopathic effects from the virus replicating in hepatocytes[12-15].

COVID-19-induced liver dysfunction has a variable prognosis and symptoms[16-20]. Because there is no cure for COVID-19-induced liver damage, treatment is only supportive. Preexisting liver diseases and nutritional support can help identify and treat liver disorders[21]. Research on COVID-19 and liver dysfunction is evolving, but there are not enough quantitative and visual studies based on bibliometrics. This chasm has stifled research in this field. Hence, this bibliometric analysis provides a view of the available COVID-19 and liver dysfunction research that is indexed in the Scopus database. This analysis has identified research hotspots for COVID-19 and liver dysfunction, as well as historical trends and future directions.

MATERIALS AND METHODS

Study design

This cross-sectional study was conducted on 18 February 2023 using a bibliometric methodology.

Bibliographic database

The Scopus database was chosen as the source of data for this study for various reasons. First, Scopus stands out as the largest scientific database compared with alternatives such as Web of Science. Second, it offers convenient options for exporting and analysing data, and it is compatible with Microsoft Excel and visualisation tools such as VOSviewer. Third, Scopus is a comprehensive database that encompasses citations from diverse fields, including social and health disciplines. Consequently, Scopus emerged as the most appropriate choice for conducting the present study[22-24].

Search strategies

The search was limited to publications between 1 January 2020 and 31 December 2022. The search strategy involved three steps.

In the first step, terms related to COVID-19 were selected from the Medical Subject Headings (MeSH) of PubMed and previous studies related to COVID-19[25-29]. Next, the retrieved terms were entered into the Scopus search engine as 'Article Title/Abstract' to retrieve publications related to COVID-19.

In the second step, the publications obtained in the first step were filtered to include only those with "liver and related words" in their title. Keywords relevant to the liver were selected from the previous liver and COVID-19 meta-analyses [30-34] and were entered into the Scopus engine to retrieve publications related to the liver.

In the third step, publications that were published as an erratum were excluded.

The final search query used for data extraction from Scopus looked like this: (TITLE-ABS ("COVID 19") OR TITLE-ABS ("2019 novel coronavirus") OR TITLE-ABS ("novel coronavirus") OR TITLE-ABS ("coronavirus 2019") OR TITLE-ABS ("* novel CoV") OR TITLE-ABS ("coronavirus disease 2019") OR TITLE-ABS ("2019-novel CoV") OR TITLE-ABS ("Wuhan coronavirus") OR TITLE-ABS ("2019 ncov") OR TITLE-ABS ("Wuhan pneumonia") OR TITLE-ABS ("COVID 2019") OR TITLE-ABS (COVID19) OR TITLE-ABS (*COVID*) OR TITLE-ABS (nCoV) OR TITLE-ABS ("corona virus 2019") OR TITLE-ABS ("nCoV-2019") OR TITLE-ABS (nCoV2019) OR TITLE-ABS ("nCoV 2019") OR TITLE-ABS (2019-ncov) OR TITLE-ABS (COVID-19) OR TITLE-ABS ("Severe acute respiratory syndrome coronavirus 2") OR TITLE-ABS ("SARS Coronavirus 2") OR TITLE-ABS ("SARS-CoV-2") OR TITLE-ABS ("SARS-CoV 2")) AND (TITLE (liver) OR TITLE (Hepati*) OR TITLE (aminotransferase) OR TITLE (bilirubin) OR TITLE (prothrombin) OR TITLE (ALT) OR TITLE (AST) OR TITLE (Hepato*) OR TITLE (Cirrhosis)) AND (LIMIT-TO (PUBYEAR,2022) OR LIMIT-TO (PUBYEAR,2021) OR LIMIT-TO (PUBYEAR,2020)) AND (EXCLUDE (DOCTYPE,"er"))

During every stage of the search process, quotation marks were employed to accurately retrieve the specific phrase. Moreover, the use of asterisk truncation acted as a flexible wildcard, enabling the retrieval of any possible term.

Validation of the search strategy

Limiting the search to the publication titles in the Scopus database can improve the accuracy of retrieved data by reducing the number of false positive results. By focusing the search on the title, the search algorithm will only retrieve articles with 'liver' in their titles, meaning that irrelevant articles that may mention 'liver' in their abstracts or full texts will not be retrieved. As mentioned, this approach may slightly reduce the level of sensitivity, meaning that some relevant articles that do not have a 'liver' in their titles may be missed[35,36]. This study employed a validated research approach to ensure dependable and precise findings. To minimise the risk of false positive results, every 15th document (15, 30, 45, 60, *etc.*) up to the end of the retrieved document list was carefully assessed by evaluating its title and abstract. The research strategy underwent continuous refinement until an entirely accurate collection of randomly selected outcomes was obtained. To confirm the absence of false-negative results or missed findings, the research productivity of 20 active authors in the field was analysed. A Spearman correlation test was utilised to compare the results derived from the research strategy with those from the authors. The study revealed a strong significant correlation ($r = 0.953$, $P < 0.001$) between the two sets of findings, underscoring the research strategy's high level of validity. Importantly, Sweileh WM[37, 38], and Zyoud SH[39] had previously employed this validation approach.

Bibliometric analysis

The data collected included the following bibliometric parameters: the types of documents (*e.g.* articles, books, or conference proceedings), the year of publication, the number of publications, the citation count (which indicates how many times other works have cited the publication), the country where the publication originated, the institution or organization that produced the publication, and the journals where the publications appeared. The *Impact Index Per Article* displayed represents the top 10 most-cited papers; it is derived from the *Reference Citation Analysis* (RCA, https://www.referencecitationanalysis.com/) database. RCA is an open citation analysis database covering various fields and is owned by Baishideng Publishing Group Inc., situated in Pleasanton, CA 94566, United States[40-42].

Visualize analysis

VOSviewer (version 1.6.18, Leiden University, Leiden, the Netherlands) was used for bibliometric visualisation[43]. In scientific research, the use of VOSviewer software for bibliometric visualisation and term co-occurrence analysis is widespread. By identifying patterns of international collaboration and analysing the co-occurrence of terms in the titles and abstracts of publications, researchers can gain insight into the hotspots in a particular field and track scientific progress[43]. Using VOSviewer software, a network of terms illustrates the relationship between terms according to the number of publications in which they appear together. This enables researchers to identify clusters of related terms that represent particular research areas or trending topics. As a result, researchers can better understand the current state of research in a particular field and identify areas for future study by identifying hotspots[44,45]. These data can be used to guide funding decisions, to identify possible collaborators and to inform policy decisions.

RESULTS

General characteristics of the retrieved articles

A total of 2336 publications on COVID-19 and liver dysfunction were analysed in this study. Among them, 558 were published in 2020, 891 in 2021, and 887 in 2022. Regarding the types of publications, 1438 (61.56%) were articles, 417 (17.85%) were letters, 357 (15.28%) were reviews, and 124 (5.31%) fell under other categories, such as editorials and notes.

Top 10 active countries

Researchers from 111 different countries participated in the retrieved documents. The United States contributed the most studies, with 497 documents, representing 21.28% of the total. China followed closely behind with 393 documents, representing 16.82% of the total, and Italy came in third with 255 documents, representing 10.92% of the total publications on research related to COVID-19 and liver dysfunction. Table 1 lists the top 10 active countries, which together represented 84.63% of all articles published. Figure 1 is a network visualisation map showing the collaboration between countries regarding co-authorship. The minimum inclusion threshold was set at 30 documents per country; a total of 22 countries met this threshold. In the visualisation, each country is represented by a circle, and the size of the circle indicates the level of contribution the country has made in terms of co-authorship. Lines represent the links between countries, and the thickness of the line indicates the strength of collaboration between the two countries. According to the centrality measures used in the map, the United States appears to be the most central country in terms of collaborations, followed by China and Italy.

Analysis of institutions

Eight thousand six hundred forty institutions participated in research in this field, of which the top 10 institutions represented 15.97% of all published articles. *INSERM* contributed the most articles (n = 26, 5.49%), followed by *Imperial College London* (n = 23, 4.85%) and *Sorbonne Université* (n = 21, 4.43%) (Table 2).

Journal analysis

The top 10 most productive journals in research related to COVID-19 and the liver are shown in Table 3. Approximately 19.91% of the articles were published on this list. The *Journal of Hepatology* published the most articles (n = 85, 3.64%), followed by *Liver International* (n = 64, 2.74%) and the *World Journal of Gastroenterology* (n = 62, 2.65%).

Analysis of citations

The retrieved documents had a total of 30,766 citations, a mean of 13.17, and an h-index of 75. A total of 638 (27.3%) documents had no citations, while 55 had 100 or more citations. The top 10 articles, ranked by the number of citations, collectively received 4,758 citations. The citations for these publications varied from 283 to 1,126 in total (Table 4) [13,46-54]. Among the top 10 most-cited articles, the *Impact Index Per Article* ranged from 88.7 to 394.7.

Term co-occurrence cluster analysis of research hotspots

In the context of COVID-19 and liver research, co-occurrence analysis was used to identify the most commonly used terms in the titles and abstracts of the relevant articles. In this case, VOSviewer was used to create a bubble map, which represents each term as a bubble, and the bubble size indicates the frequency of occurrence of that term. The analysis identified 172 terms that occurred at least 50 times in the titles and abstracts of the included publications (Figure 2). The bubbles are grouped into clusters based on the similarity of their co-occurrence patterns. There are three different groups: (1) The blue cluster, which is named 'COVID-19 vaccines in liver transplant recipients'; (2) the red group, which is titled 'liver function tests as a predictor of COVID-19 severity and clinical outcomes of COVID-19 in hospitalised patients'; and (3) the green group, which is titled 'care of patients with liver disease during the COVID-19 pandemic'.

DISCUSSION

The correlation between liver injury and COVID-19 is associated with the severity and mortality of the disease. These findings strongly indicate a relationship between liver injury and COVID-19. Despite the observation that severe and fatal cases of the disease primarily affect older adults with liver injury, the specific underlying mechanisms remain unclear[55].

The findings indicate that the United States, China and Italy have been actively involved in COVID-19 and liver dysfunction research and have produced many publications on the subject. Numerous studies on the productivity of COVID-19 research in various fields[56-60], as measured by publications, have found that the United States, China and Italy have been the leading producers of COVID-19 publications. The United States and China have dominated research output in numerous fields, including the health sciences[61,62]. According to a report released by Japan's Science and Technology Ministry, China has emerged as the global frontrunner in scientific research output, surpassing the United States in both overall volume and the number of impactful studies. The report, published by Japan's National Institute of Science and Technology Policy, revealed that China now leads the world in annual scientific research paper publications, followed by the United States and Germany[63]. There are several factors that contribute to both the United States and China being leaders in scientific research. These factors include the size of their economies, the significant amount of money invested in research and development, and the large number of researchers working across various fields[64,65]. Notably, both countries have allocated significant funds to healthcare and biotechnology[61,65-67], ensuring that

researchers have the resources they need to conduct thorough studies that yield reliable results. Furthermore, both countries have large and diverse scientific communities that encourage interdisciplinary research and expert collaboration. Funding also plays a pivotal role in driving research output, as researchers studying COVID-19 and liver dysfunction in both countries can seek substantial grants. These grants provide the necessary resources to pursue ambitious research projects, and thus attract top talent, and address critical health issues. Notable organizations such as the National Natural Science Foundation of China[68-70], the National Institutes of Health[71,72], and Gilead Sciences[47,73] offer sizable grants for researchers studying COVID-19 and liver dysfunction in the United States and China.

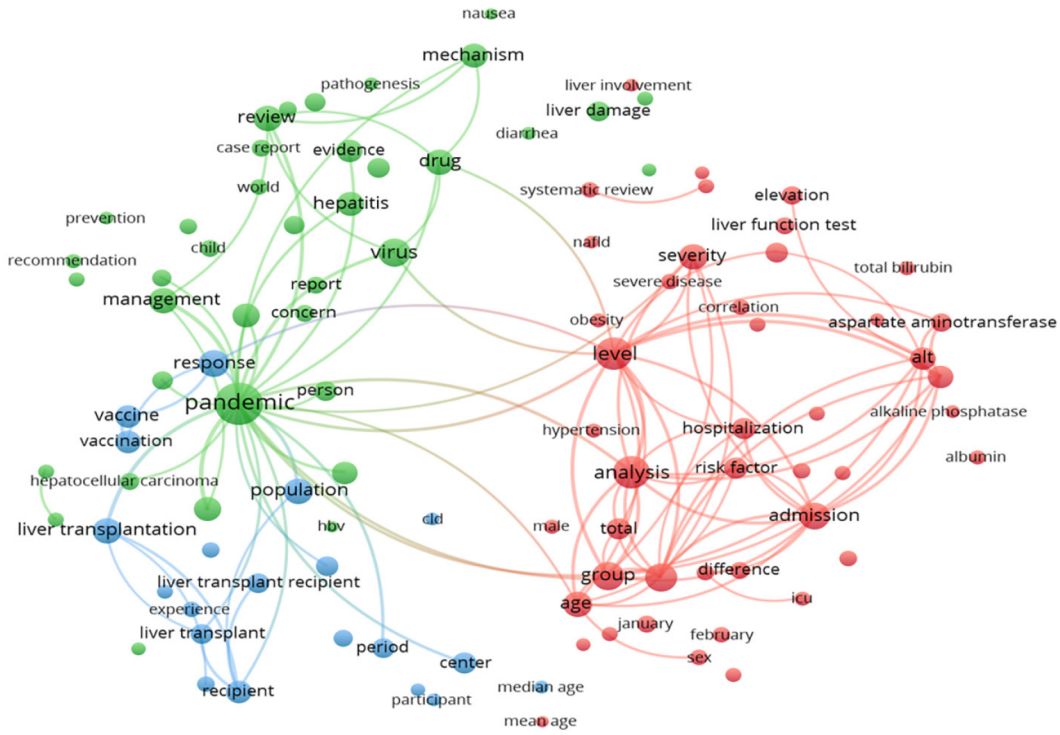
One of the key hotspots in the current study is 'COVID-19 vaccines in liver transplant recipients'. Solid organ transplant recipients face a significant risk of death from COVID-19, with mortality rates ranging from 13% to 39%[74,75]. As a result, many countries have given priority to vaccinating this vulnerable group using messenger RNA (mRNA) vaccines. Nonetheless, there is limited information available regarding their response to vaccination and its effectiveness [76]. It is critical that liver transplant recipients receive the COVID-19 vaccine to avoid hospitalisation and serious illness. COVID-19 vaccines are safe and effective in people who have had liver transplants. It should be noted, however, that these vaccines may not elicit as strong an immune response as in healthy individuals[77]. As a result, liver transplant recipients should consult their health care providers about the best time to get vaccinated, considering their specific immunosuppression regimens and recent transplant surgeries[78]. Patients who have had a liver transplant should talk to their doctors about whether they need more vaccine doses or a different vaccine to maximise their immune response[79].

'Liver function tests as a predictor of COVID-19 severity and clinical outcomes in hospitalised patients' is another study topic. Liver function tests (LFTs) are regularly conducted in hospitalised patients with COVID-19 to assess disease severity and the likelihood of poor clinical outcomes[80]. COVID-19 causes liver inflammation and abnormal LFT results [81]. In 2022, the *World Journal of Gastroenterology* reported that abnormal levels of aspartate aminotransferase (AST) and total bilirubin (T-Bil) are associated with higher mortality rates than other liver damage indicators during hospitalisation. Vasopressor medications and mechanical ventilation are linked to abnormal AST, T-Bil, and alkaline phosphatase (ALP) levels. Thus, patients with COVID-19 often have abnormal LFT results upon hospital admission, which can predict their severity and prognosis. Health care practitioners can assess risk and predict the need for advanced treatment for these individuals by measuring alanine transaminase (ALT), AST, ALP and T-Bil[82]. Patients with COVID-19 and abnormal LFT results may also have prior liver disease, medication toxicity or bacterial or viral coinfection. Thus, LFT results should be included with other clinical and laboratory data when predicting severity and clinical outcomes[83,84].

The treatment of liver disease has become increasingly important during the COVID-19 pandemic. Individuals with liver disease are more vulnerable to COVID-19-related severe illness and mortality due to factors such as a compromised immune system, advanced age and underlying health conditions[85]. Given this scenario, patients must carefully prioritise pandemic preparedness measures. Any deviation from their treatment plan – missed appointments or delayed therapy – can aggravate their liver disease and increase their COVID-19 risks[86]. Therefore, individuals with liver

DOI: 10.3748/wjg.v29.i27.4356 **Copyright** ©The Author(s) 2023.

Figure 1 Network visualization map of country collaboration. A minimum of 30 documents per country was set as a threshold, and 22 countries met the threshold. Countries can be represented as nodes in a network visualization made with VOSviewer, and lines can be created between the nodes to show correlations between co-occurrences. The strength of the co-occurrence link between the countries can be determined by the line's thickness or weight. Thicker lines are frequently used to depict stronger links.



disease should take COVID-19 precautions such as frequent and thorough handwashing, avoid large crowds and wear face masks[87]. Adopting a healthy lifestyle is also important for strengthening their immune systems and preventing COVID-19 complications. This includes regular exercise, a balanced diet, abstaining from alcohol and smoking, and getting enough sleep[88,89].

Strengths and limitations

Although this is the first bibliometric analysis to assess the worldwide research output in the field of COVID-19 and liver dysfunction, according to previous similar studies, this study had several limitations, and it is essential to acknowledge them to ensure transparency and to promote further research in the field. First, Scopus is a widely used database for bibliometric analyses, and its coverage of peer-reviewed literature is generally comprehensive. However, the bibliometric analysis may not capture all the relevant COVID-19 and liver research publications because not all journals are indexed in Scopus, and some of the relevant publications may have been published in non-indexed or non-English-language journals. Second, searching for publications based on MeSH terms in the title is a common practice in bibliometric analysis to ensure the accuracy and relevance of the search results. However, including some publications that use related terms in other parts of the document may be a mistake. Therefore, it is recommended to use a combination of search terms, including title, abstract and keywords, to increase the sensitivity of the search. If false-negative results had occurred in the current study, they would have had little effect on the overall results. Third, the analysis may not account for the quality of the publications, as it only counts the number of publications without assessing their impact, significance or credibility. Furthermore, the ranking of publications based on total citations rather than annual citation averages could have excluded some recently published high-quality studies. However, this does not undermine the importance or contribution of these publications to the field. It is essential to note that the limitations identified in this bibliometric analysis could affect the precision and completeness of the obtained results. However, these limitations do not significantly compromise the study's validity.

CONCLUSION

This bibliometric study provides a comprehensive overview of liver-related publications in COVID-19 research over the past 3 years. It highlights the significant contributions of high-income nations, particularly the United States, China and Italy, to the scholarly liver-related literature in this field. Most of the articles focus on liver dysfunction in patients with COVID-19 and the implications of the virus for gastroenterologists and hepatologists. Although the study acknowledges the importance of abnormal LFTs in COVID-19, it also identifies knowledge gaps regarding their pathophysiological and

DOI: 10.3748/wjg.v29.i27.4356 **Copyright** ©The Author(s) 2023.

Figure 2 Research topics clustered by mapping the co-occurrences of terms in the title/abstract of publications on research related to coronavirus disease 2019 and liver. Of the 26722 terms, 172 terms occurred at least 50 times. The largest set of connected terms was stratified into three clusters. VOSviewer may produce a network visualization in which terms are represented as nodes and co-occurrence connections are depicted by lines connecting the nodes. The strength of the association between the terms' co-occurrence can be determined by the line's thickness or weight. Thicker lines are frequently used to depict stronger links.

prognostic value. This study indicates that well-designed prospective studies with specific research questions can be used to fill in these gaps and further investigate the topic. This bibliometric analysis provides a solid foundation for future research on liver injury and treatment for COVID-19. The findings of this study can be used by decision-makers or researchers to prioritise research areas and allocate resources to enhance our understanding of the impact of COVID-19 on liver function.

ARTICLE HIGHLIGHTS

Research background

Abnormal liver chemistry findings are commonly observed in individuals with coronavirus disease 2019 (COVID-19). As a result, there is a significant body of literature comprising published clinical studies that specifically examine the implications of hepatic involvement in COVID-19.

Research motivation

Understanding the current state of research and hotspots in the field of COVID-19 and liver dysfunction is crucial for identifying knowledge gaps and informing future research directions.

Research objectives

The purpose of this study is to present a comprehensive overview of the existing research on COVID-19 and liver dysfunction through the utilization of bibliometric analysis.

Research methods

A thorough and validated search query was conducted using the SciVerse Scopus database to identify relevant publications on the topic of COVID-19 and liver dysfunction. Subsequently, the research hotspots in related fields were examined using VOSviewer software.

Research results

Three distinct clusters of topics were identified: COVID-19 vaccines in liver transplant recipients, liver function tests as predictors of severity and clinical outcomes in hospitalized patients, and the care of patients with liver disease during the

COVID-19 pandemic.

Research conclusions

The first bibliometric analysis is presented here, which is represented by the study and offers valuable insights into the research landscape on COVID-19 and liver dysfunction. Valuable reference can be derived from the findings in this field by scholars, as a comprehensive summary is provided and the frontiers of research related to COVID-19 and liver dysfunction are identified.

Research perspectives

The goal of this study is to have current areas of focus within the field of COVID-19 and liver dysfunction identified, which can help future research be guided and clinical practice be informed. By using bibliometric analysis, a comprehensive overview of the literature on this topic is provided by the study, and the latest developments in the field can be kept up-to-date by researchers and clinicians.

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJG* as 4.3; IF without journal self cites: 4.1; 5-year IF: 5.3; Journal Citation Indicator: 0.82; Ranking: 33 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.3 and Scopus CiteScore rank 2022: Gastroenterology is 22/149.

Abstract

The human intestine is a natural environment ecosystem of a complex of diversified and dynamic microorganisms, determined through a process of competition and natural selection during life. Those intestinal microorganisms called microbiota and are involved in a variety of mechanisms of the organism, they interact with the host and therefore are in contact with the organs of the various systems. However, they play a crucial role in maintaining host homeostasis, also influencing its behaviour. Thus, microorganisms perform a series of biological functions important for human well-being. The host provides the microorganisms with the environment and nutrients, simultaneously drawing many benefits such as their contribution to metabolic, trophic, immunological, and other functions. For these reasons it has been reported that its quantitative and qualitative composition can play a protective or harmful role on the host health. Therefore, a dysbiosis can lead to an association of unfavourable factors which lead to a dysregulation of the physiological processes of homeostasis. Thus, it has previously noted that the gut microbiota can participate in the pathogenesis of autoimmune diseases, chronic intestinal inflammation, diabetes mellitus, obesity

and atherosclerosis, neurological disorders (*e.g.*, neurological diseases, autism, *etc.*) colorectal cancer, and more.

Key Words: Microbiology; Human microbiota; Intestinal microbiota; Immune system; Metabolites; Dysbiosis; Probiotics; Diseases; Cancer

Core Tip: The microbial populations that colonize the human body constitute a complex ecosystem; several cells much higher than the total number of cells in the human body. It is generally accepted that the human gut microbiota is a focus of research interest due to its complexity, involvement with health, and involvement in various pathological conditions. The need to extensively elucidate and document hitherto unknown aspects of the gastrointestinal microbiota, its associations with health fuels the need for further study. Furthermore, on the subject in question it has constituted a trigger for carrying out the present review of the research sources received so far.

INTRODUCTION

The human organism is colonized by trillions of microbes. The microbiome refers to all the genes of microbes found in various locations in an individual's body. Instead for microbiota we mean the total of microorganisms quantitatively and qualitatively present. The human host and the microbiota have co-evolved for the benefit of both parties especially the intestinal one[1,2]. In fact, on the one hand, the host provides space, suitable conditions, and food for the growth of the intestinal microbiota and this in turn generally participates in obtaining useful substances and induces resistance to various infections. The relationship between the human gut microbiota and the host is symbiotic, in which both the host and the microorganisms are mutually beneficial. For its part, the host offers a place of growth and nourishment to the symbiotic intestinal bacteria, which in turn favors the function of the host on the one hand by inducing resistance to infections and on the other hand by facilitating the absorption of digested food[3]. It appears, therefore, that eukaryotic hosts and symbiotic bacteria have "co-evolved" with mutual interactions based on nutritional benefits enjoyed by both parties. When this balance is disturbed (dysbiosis) for various reasons, such as repeated and inappropriate use of antibiotics or alcohol abuse, pathological conditions may arise, such as mild chronic intestinal inflammation or metabolic disorders[4]. The interactions of (symbiotic) microbes with each other is of particular interest. A negative correlation has been observed between members of the phylum *Bacteroidota*, (such as that of the *Prevotellaceae* spp.) in the intestine, which may reflect alternative "metabolic specializations"[2,5]. Thus, the gut microbiota is of particular importance for the maintenance of human health. In fact, various biological mechanisms are microbiota-dependent because they cannot be performed autonomously and are useful for health homeostasis. In general, the concept of a "superorganism" refers to the bidirectional and therefore beneficial activity between the host organism and the gut microbiota. The microbiota, in addition, has both a protective and trophic role influencing, as we have mentioned, several homeostatic processes of the host organism, *e.g.*, tissue trophism, immune balance, metabolic activity, neuro-endocrine function, *etc.*[6,7]. Intestinal microbiota represents the most populous community of the entire organism. In fact, the stomach has about 10^3-10^4 bacteria, the duodenum 10^5-10^6 and the terminal ileum 10^8-10^9 bacteria (per gram of tissue). However, the most populated is the large intestinal one representing around 10^{12-14} bacteria per gram of tissue[2,6]. The colon is the part of the gastro-intestinal tract where a complex set of microorganisms develops from the moment of birth. The microbiota of the large intestine is denser and more diverse than the human microbiota of the small intestine. Intestine are enriched in the phyla of *Bacillota* and *Actinomycetota*, while *Bacteroidota* and *Lachnospiracae* are more abundant in colonic samples[8]. It is estimated that about 400-500 different genera of microorganisms constitute the intestinal microbiota, while the 90% of them species are predominantly anaerobic. Most of them belong to two genera, *Bacteroidota* and *Bacillota*. The remaining bacterial populations belong to *Pseudomonadota*, *Actinomycetota*, *Fusobacteria* and *Verrucomicrobia*[9]. An estimated 70% of these microbial communities are bacteria that cannot be cultured with conventional microbiological techniques. It has been observed that the microbial populations of the intestinal mucosa differ from those found in the intestinal lumen. The large intestine hosts the most numerous microbial cells which vary in species from individual to individual and are organized in localized microbial communities along its path. These microorganisms appear not to follow stable topological patterns along the intestine as they are influenced by the local oxygen concentration. Thus, facultative aerobic communities reside near the intestinal walls, which are sites of high oxygen concentration, and anaerobes prefer the intestinal lumen, where oxygen concentration is lower[10]. Although there is great diversity in the microbes that colonize the gut, it has been found that the gut microbiota of most individuals can be classified into three main microbial groups or "enterotypes" depending on the predominance of genera: *Bacteroides* (enterotype 1); *Prevotella* (enterotype 2) or *Ruminococcus* (enterotype 3). More recent data, however, show that the division into three enterotypes is a simplification

and that there are many intermediate states in the gut. The prevalence of each enterotype is mainly determined by dietary factors[2]. However, it appears that everyone has a fixed bacterial strain, even though the composition may vary. One of the main functions of the intestinal microbiota is to protect the intestine from pathogenic microorganisms, it also contributes to the development of a healthy immune system, regulates intestinal motility and participates in metabolism. More specifically, the gut microbiota promotes the regulation of the immune system through: (1) Stimulation of the immune response against potential pathogens; and (2) Suppression of the immune response against food and symbiotic antigens[11]. It is estimated that 80% of antibody production occurs locally in the gut, mainly supplying immunoglobulin A. In addition, they participate in host metabolism, drugs metabolism, maintenance of mucosal structural integrity, bile salts metabolism, plant fibers, mucus, and fatty acid catabolism[12]. In addition to bacteria that have already been studied quite a lot, recently it has been hypothesized that yeasts are involved in starch metabolism. Understanding the relationship between yeasts and the immune system is characterized as difficult and there are few data on their action. In some special cases, they can also act therapeutically[13]. Thus, there is an amphidromic relationship between microbes and hosts (Figure 1).

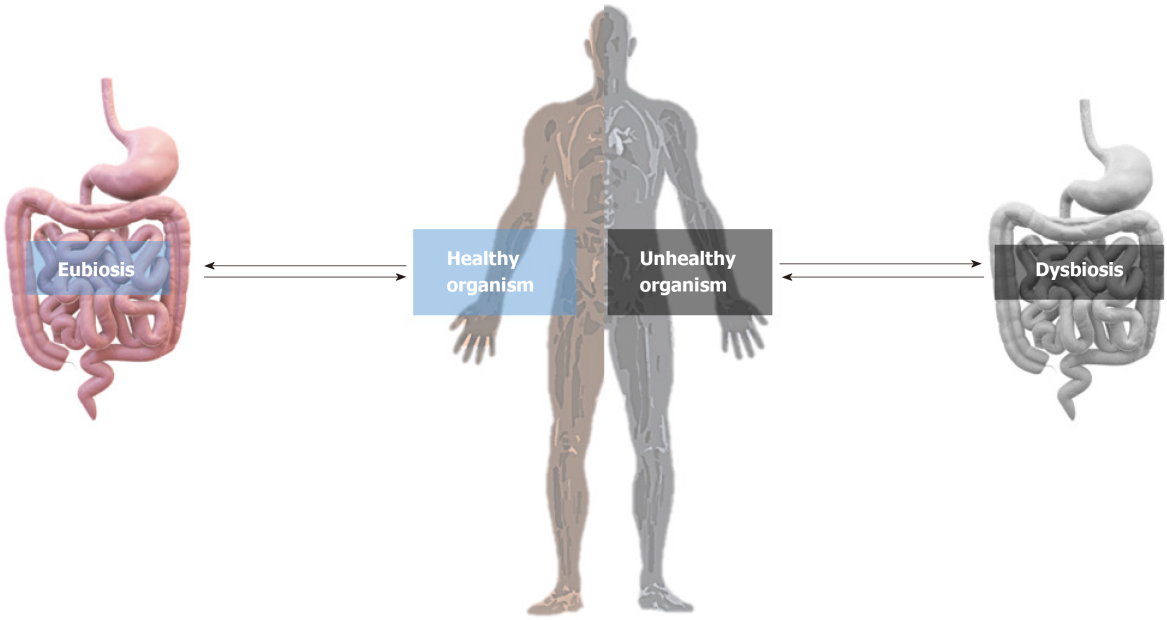
Finally, the probiotics bacteria are the "good" bacteria that are found in gut microbiota but also are added in specific dietary or ferment foods. Probiotics aid the organism by strengthening our immunity and help with gastrointestinal health, especially in conditions such as the irritable bowel syndrome (IBS)[14]. In the 1989, Fuller listed some beneficial effects and therapeutic applications of probiotic bacteria. We find probiotics in dairy products, such as yogurt and aged cheeses, but also in other foods such as pickled vegetables, *etc.* The consumption of probiotics promotes the growth of desirable microorganisms, overcoming potentially harmful bacteria and strengthening the body's defences. Several scientific articles commenting on these results, refer to studies using cultures such as of *Lactobacillus acidophilus* and *Bifidobacterium*, *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*[14,15]. Consuming probiotic products can cause a plethora of positives effects on the human body. Probiotics, thanks to their antimicrobial properties action can fight intestinal and other diseases, aid in various infections (such as those from coronavirus disease 2019 and other), reduce levels serum cholesterol, stimulate the immune system, reduce allergy symptoms, aid with lactose intolerance, can prevent hypercholesterolemia and osteoporosis and other[15].

MAIN FACTORS AFFECTING THE INTESTINAL MICROBIOTA

Inheritance

The mechanisms of host-bacteria interactions have not been fully described. Little is known about the relationship between the host genotype and its gut bacteria. However, there is strong evidence that it affects intestinal populations. Simple genetic mutations can lead to changes in the composition of microorganisms in the gut[16]. Further investigations are needed to delineate the mechanisms by which this occurs. There are few studies comparing the gut microbiota between family members. It has been observed that monozygotic and dizygotic twins had a greater similarity in gut microbiota between monozygotic than dizygotic siblings, indicating the importance of genetic background. Furthermore, it was observed in an animal model that the similarities in the gut microbiota of the same mouse strain were greater than in mice of a different species even with a common environmental effect. The role of parental genetic influence on the colonization of microorganisms in the intestine has not been elucidated.

Geographical location



The diversity of the gut microbiota in children living in rural areas is greater than that of children in developed countries. It was noted in a study among Caucasians and Asians (Chinese) in the United States and Hong Kong that there were qualitative differences and quantitative in the intestinal microbiota[17-19]. It was found that children from a country in West Africa (Burkina Faso) that had a high presence of *Bacteroidota* with a greater presence of the genus *Xylanibacter* and *Prevotella* (which allow the hydrolysis of xylan and cellulose) with a reduced presence of *Bacillota*. Indeed, the higher presence of short-chain fatty acids (SCFAs) was noted. Therefore, the intestinal microbiota can help the host to optimize its energy intake from dietary fibers according to nutrition and needs, thus also protecting against infective and inflammatory processes[20].

Intrauterine period and delivery

There is a growing body of data suggesting that the human gut microbiota begins before infant birth. Meconium (the baby's first stool) contains bacteria, where *Bacillota* phyla predominate, the bacteria through the placenta and circulatory system enter the intestinal lumen of the foetal intestine. After human birth, the gut is colonized by many microbial strains, and everyone has their own gut microbiota which changes further throughout their life[2,6]. How the baby is born is very important as it affects the variety of microorganisms which will be installed. During normal delivery the new-born receives microorganisms from the mother's vagina or intestinal tract, whereas in caesarean section the new-born is exposed to those from the hospital environment. The gut microbiota in these newborns can be disturbed for months to years. Newborns born with normal delivery develop a microbiota that reflects the vaginal microbiota, while those born with caesarean section develop a skin microbiota resulting in delayed microbial colonization by *Bacteroides, and Bifidobacterium* spp.[16,21].

Diet

Many are observed in the first months of a person's life changes in the gut microbiota, while the stability and diversity of

Figure 1 The cross-talking axis host/gut microbiota: The gastrointestinal microbiota plays an important role in host physiology, metabolism, and nutrition. An organism with a regular maintenance of the physiological homeostasis leads to eubiosis of the gut microbiota and vice versa. Conversely, an altered physiological homeostasis leads to gut microbiota dysbiosis and vice versa. An alteration in the gut microbial community is linked to several disturbances gut conditions, including cancer, obesity, and a variety of gut disorders. The contribution of beneficial components of the gut microbiota to host physiology, metabolism, and immune function has become the focus of scientific research and will undoubtedly lead to new therapeutic approaches.

microbiota genes increase after the first three years of life[21]. Breastfeeding or consuming breastmilk substitutes in infancy has significant effects on intestinal microbiota of the new-born and in the development of the immune system [22]. In animal models, the two different ways of feeding babies develop different populations of microorganisms in the gut which lead to differences in the immune system. Immunity is affected up to the first five years of life[23]. In humans there are few studies on the different administration of milk to newborns. Undoubtedly, however, the intestinal microbiota of the child influences the development of the immune system and its metabolism, just as in adult life[24]. Breastfed infants are exposed to the gut microbiota offered by milk, which contains more than 700 species of bacteria. Breast milk contains many protective factors that breast milk does not contain. In addition, changes in the infant's gut microbiota appear to predispose to diseases and his later life[2,16]. Subsequently adult dietary habits are one of these most important environmental factors shaping the growth of microorganisms in the human gut. Short or long-term consumption of animal or vegetable products changes the structure of the intestinal microbiota. The short-term diet based on animal foods increases the microorganisms of genera such as *Bacteroides*, *Alistipes*, *Bilophila* and decreases the levels of *Roseburia*, *Eubacterium rectale*, *Ruminococusbromii* belonging to the *Bacillota* phyla (populations that mainly metabolize polysaccharides of plant origin)[25]. Instead, it has been noted that long-term consumption of fruit and vegetables by the elderly is associated with an increase in populations of the genus *Prevotella*. It was noticed that a change of nutrition style (*i.e.*, sugar-rich foods, a shift from a low-fat vegetable polysaccharide to a high-fat vegetable polysaccharide, and so) modifies the microbiota, qualitatively and quantitatively, through a change of the microhabitat in 24 h and so on changes in metabolic pathways also occur. Although the gut microbiota responds to short-term changes in diet, long-term nutrient changes appear to determine the type of qualitative and quantitative microorganism population also for other such as the oral ones[26,27]. There are differences in the presence of gut bacteria in the two diets, reflecting differences in metabolism. of carbohydrates and proteins. In both cases, the colonization of fungi, viruses and yeasts is observed[25]. It has been observed that the consumption of foods of plant origin is also associated with a beneficial set in the intestinal microbiota. A high correlation has been noted between a plant-based diet and increased levels of SCFAs and some dietary fibres that degrade *Bacillota* phyla. Indeed, the characteristics of the Mediterranean-type diet, *i.e.*, increased intake of cereals, fruit, vegetables, and legumes offer many benefits for the human intestine[28]. An observational study found that dietary fiber from beans, fruits, and vegetables was associated with an abundance of and *Actinomycetota* phyla and *Clostridium* spp. But also, the consumption of sour milk, many dairy products, or the consumption of fermented foods (such as Greek yogurt, kefir, and others) affect the intestinal microbiota and change its structure. The use of substances of abuse (such as alcohol, cocaine and other) or chemical xenobiotics can cause in human health is associated with quantitative and qualitative changes in the intestinal microbiota (dysbiosis)[29,30].

Lifestyle

Modern lifestyles can influence the intestinal microbiota, sedentary life contributes to obesity and combined with a positive energy balance and the consumption of foods of animal origin rich in saturated fat leads to the rearrangement of populations at the intestinal level. Although studies show conflicting results, an increase in *Bacillota* and a decrease

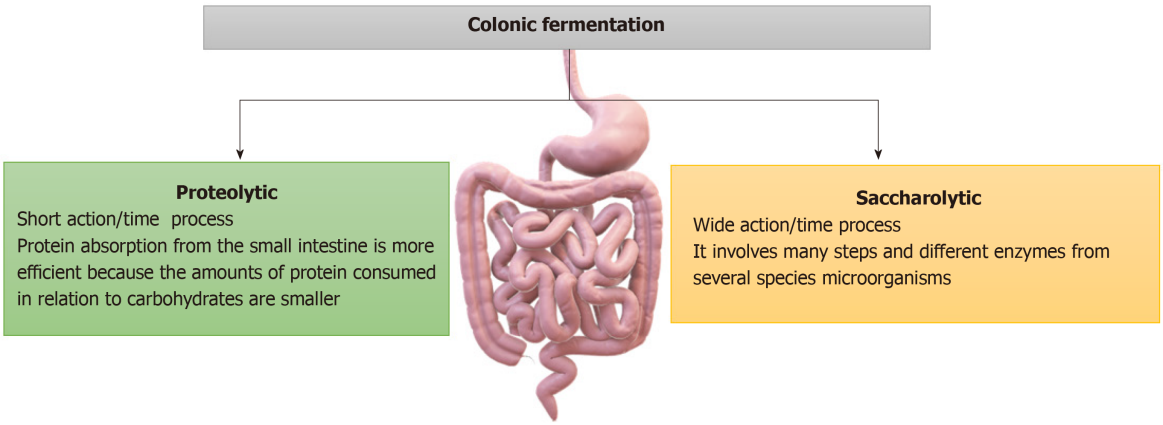
in *Bacteroidota* have been observed in individuals consuming foods of animal origin[6]. Frequent and moderate exercise influences the intestinal defence as well as on the genes of intestinal microorganisms. In a study on the effect of exercise on the intestinal microbiota of 22 athletes, the beneficial influence of exercise on the diversity of intestinal microorganisms is underlined and the combination with diet is claimed to affect the gut microbiota structure[31,32]. Smoking also affects the composition of the gut microbiota, increasing populations of the *Bacteroides-Prevotella* genera. Stress affects gut motility, which can change the structure of microbial populations, which has even been blamed for the development of inflammatory bowel disease (IBD)[33].

Use of antibiotics

Antibiotics target pathogenic microorganisms, but they also have a negative effect on intestinal symbionts. Unfortunately, they affect the intestinal microbiota especially if they are broad-spectrum antibiotics that are used for all diseases[34]. Gut microbiota diversity is reduced, many strains are lost, and their re-emergence is gradual and long-term, which is a major concern of experts in the field of intestinal health. It was observed that most of the bacteria affecting antibiotics response mainly belong to the *Bacillota* and *Pseudomonadota* phyla[35,36].

THE ROLE OF THE HOST/INTESTINAL MICROBIOTA CROSS-TALKING AXIS

Nutritional and gut-influenced energy conservation by metabolic processes (metabolome)



Several studies have shown that the intestinal mucosa needs to be colonized by microorganisms to take on its integral structure. For example, mice raised in a sterile environment developed fewer blood vessels in their intestinal villi. Sterile growth also showed that there is defective growth in gut-associated lymphoid tissue and antibody production. Also, in the context of the sterile environment, fewer Peyer's patches develop, there are fewer cells in the dermis, and fewer plasma cells in the germinal centres of the mesenteric lymph nodes than in the development data in a nonsterile environment[37]. The intestinal microbiota could be considered a "metabolic organ" performing multiple functions needed for maintaining the health status of the host organism orchestrating an amphidromous communication with it. The catabolism of a number of both endogenous and exogenous indigestible molecules (*i.e.*, cholesterol, fibers, bile acids, excreted mucus, *etc.*), is one of the most important activities of the intestinal microbiota accounting for 10% of the host's energy requirement every day[38,39]. So, the gut microorganisms (especially bacteria and commensal fungi) produce SCFAs to gain energy but also give trophic substances and energy to the host organism. Finally, certain bacterial species can synthesize vitamins such as B12, folic acid, thiamin, biotin, vitamin K, amino acids and more[40]. As proof, *Bacteroides thetaiotaomicron* can metabolize polysaccharides that reach the large intestine as is in Figure 2. Indeed, it has many enzymes such as glycoside hydrolases and polysaccharide lyases that break down pectins, arabinose, *etc.*

Archaea, such as *Methanobrevibacter smithii*, establish beneficial relationships with other bacteria to eliminate the H_2 by-products, thus facilitating the yield of ATP[41,42]. The gut microbiota benefits the host in many ways contributing to the conservation of energy from several common non-digestible polysaccharides through enzymes such as glycoside hydrolases and other non-encoded enzymes in the human genome[43]. Studies of mice with a germ-free gut microbiota revealed that the gut microbiota improves the regulation of fat accumulation and obesity mainly due to an increase in energy production from food. These (germ-free) mice are protected against obesity and metabolic syndrome[44]. It was noted that restoring an eubiotic intestinal microbiota in these animals leads to an increase in insulin resistance and fasting blood glucose, but also of the level of liver triglycerides and body fat amount.

The intestinal microbiota improves the absorption of monosaccharides, which in turn leads to an increased lipogenesis with consequent accumulation of triglycerides both in the liver and in the fat tissue. With food utilization, obese mice have been reported to conserve energy from food more efficiently than lean-wild-type mice[45]. Distal gut microbiota's composition of obese mice revealed that the relative increase of *Bacteroidota* and *Bacillota* resulted in a modified metabolic potential of the gut microbiota, giving it a greater ability to use energy from the diet. Interestingly, this obesity trait of his was transmissible through faecal transplants from obese mice as opposed to lean germ-free mice. Obese mice also possess multiple methanogenic archaea which can increase the efficiency of bacterial fermentation through H_2 removal[46]. It was observed that, after gut co-colonization, both *Bacteroides thetaiotaomicron* and *Methanobrevibacter smithii* boost up the efficiency and specificity of bacterial fermentation by removing bacterial polysaccharides, increasing adiposity compared to mice colonized with only one of the two organisms[47,48]. Further studies have highlighted further correlations regarding the possibility of increased energy saving through induced microbiota nutrition or genetically induced obesity microbiota[49]. For that, age and diet are important factors not only for the composition of the gut microbiota, but also for energy saving possibilities. In addition, the link between gut microbiota and liver diseases has been studied mainly in obesity and non-alcoholic steatohepatitis/nonalcoholic fatty liver disease patients, and in liver failure conditions (*e.g.*, cirrhosis, hepatic encephalopathy, infections, hepatocellular carcinoma), total parenteral nutrition-associated liver disease, cholangitis primary sclerosing, primary biliary cirrhosis[50]. It has been noted that dysbiosis of the intestinal microbiota leads to intestinal motility disorders (stasis, with bacterial proliferation). These conditions lead to increased intestinal permeability, impaired immune response with an excessive increase in tolerance in bacterial translocation by the intestinal microbiota with subsequent liver injury[50,51].

Immunological actions and resistance to colonization by pathogens

The host's organism meets both the pathogenic microbes of the environment and the microbes of the intestinal microbiota. Previous studies of the immune system have focused on the mechanisms by which this system can defend itself against pathogenic microbes. In addition, the microorganisms of the intestinal microbiota produce antimicrobial

Figure 2 The metabolic activity by the colonic microbiota. The intestinal microbiota finds an environment rich in polysaccharides which are not digested by stomach enzymes. Fermentation of polysaccharides by intestinal bacteria leads to the production of acetate, butyrate, and propionate, which are used as a carbon source by intestinal mucosal cells. The initial fermentation of the carbohydrate that escaped digestion in the small intestine is followed by the utilization and cross-distribution of metabolites by various members of the microbiota, and then the synthesis of short-chain fatty acids (butyrate, propionate, acetate). Proteolytic fermentation differs from saccharolytic fermentation because it releases many potentially toxic nitrogen and sulfur metabolites, such as ammonia, amines, nitrates, nitrites, and hydrogen sulfide[32,40].

substances such as bacteriocins and hydrogen peroxide which inhibit the growth of others with pathogenic behaviour [51]. The immune system has evolved in such a way that it can accommodate symbiotic bacterial communities of increasing complexity while retaining the ability to fight pathogenic bacteria. The microbiota regulates the development and function of the innate and acquired immune systems[11]. Even in healthy conditions of the host, there is a continuous stimulation of the immune system by the intestinal microbiota. This condition leads to a basal state of "low physiological inflammation" representing an effective first line of defence against pathogenic microbes. Furthermore, both resident and pathogenic microbes compete for available sites and nutrients, so the microbiota exerts a protective role metabolizing those nutrients that are necessary for the pathogens survival and producing molecules that inhibit their growth[2,52]. In fact, it has been shown that the introduction of certain molecules produced by *Bacteroides thetaiotamicron* and *Eubacterium rectale* can induce the production of specific mucosal glycans. These can be metabolized by these 2 bacterial species only but not by pathogens, thus preventing their proliferation. Hence, diet appears to have a pivotal role in microbial composition modifications[53]. The immune system works by learning, *i.e.*, at the beginning of life it has the necessary components (cells, internal cellular mediators, *etc.*) but does not have data available from the environment, which it acquires in the first years of life through contact with other people and the natural environment. If these early childhood data are inappropriate, the regulatory mechanisms of the immune system could fail. As a result, the immune system attacks not only pathogenic microorganisms but also harmless targets such as pollen, house dust and food antigens, leading to the onset of allergic diseases[54]. The microorganisms together with digestive enzymes, the mucus layer, intestinal peristalsis, and the epithelial barrier with "tight" connections (tight junctions) constitutes the non-immune component of the body's immune response. The functions of the intestinal microbiota in terms of defence of the organism are on the one hand to influence in a decisive way the arise of the gut immunity (for which reference was made to the trophic role) and on the other to prevent possible invasion of pathogens through a direct effect on them and/or through the "activation" of the host's immune mechanism[55,56]. As far as natural immunity is concerned, it has the ability, by recognizing characteristic pattern molecules [pathogen associated molecular patterns (PAMPs)] on microorganisms, to separate potentially pathogenic microbes from "unwanted" antigens. More specifically, the cells of the natural immunity using proline rich proteins (PRPs) receptors (pattern recognition receptors) detect PAMPs[57]. PRPs also participate in the release of cytokines and the activation of acquired immunity. However, there are many types of PRP, and of the most important are the Toll-like receptors (TLRs) found in dendritic cells, neutrophils, macrophages, and intestinal mucosal epithelial cells. The most known PAMPs recognized by PRP receptors are bacterial carbohydrates (*e.g.*, mannose, glucides of lipopolysaccharide), bacterial peptides (*e.g.*, flagellin), peptidoglycans and lipoteichoic acid of Gram+, fungal lipoproteins, glycans, viral genomes. Since these molecules are also found in symbiotic microorganisms, they are called microbe-associated molecular patterns (MAMPs)[58]. Thus, MAMPs seem to be able to modify the expression of TLRs in natural immunity cells. Thus, the recognition of MAMPs triggers the activation of the nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) pathway, which results in the production of cytokines, the activation of other auxiliary and necessary molecules on the antigen-presenting cells, which ultimately results in the activation of T-cells, *i.e.*, acquired immunity[59]. However, microorganisms can modulate the natural immunity changing the quality and the amount of mucus from the intestinal mucoid cells. Mucus forms a natural barrier to stop an infection directly adhering to them, collects the bacterial by-products, and protect epithelial cells from secretions thanks to its low pH rich and richness in lytic enzymes. These events activate body's defences[60]. As far as the acquired immunity in the gastrointestinal system is concerned, it is "based" in the gut associated lymphoid tissue which is made up of the Peyer's Patches and the mesenteric lymph nodes. The spleens of germ-free mice were found to contain increasingly smaller germinal centres in the lymph nodes and reduced numbers of memory CD T4 cells in the intestinal epithelium, that the production of

cytokines belongs to a Th2-type of immune response, and that these animals have a reduced ability to secrete germicidal agents[61]. Recolonization of these muscles with muscle-specific bacteria can reverse some of these perturbations, as experimentally demonstrated by the restoration of systemic T-cell deficiency and Th1/Th2 imbalance of sterile muscle microbes after single colonization of the muscle gut with the bacterium *Bacteroides fragilis*. Such studies collectively highlight the importance of the gut microbiota for the normal development of the peripheral immune system in immunocompetent hosts[62].

Influence of the host's health condition

According to clinical studies that have been done in recent years, they show a correlation of the change in the composition of the gut microbiota with several serious pathological conditions such as: autoimmune diseases, type 2 diabetes (T2D), weight gain and obesity, IBD, asthma and chronic sinusitis, mental health disorders, dermatological problems, Alzheimer's disease, poor immune system health, gastroesophageal reflux disease, constipation or diarrhea, cancerous conditions and other[63].

INTESTINAL MICROBIOTA ROLE IN DISEASES

IBS and IBD

Functional bowel disorders such as IBS are defined solely by symptom-based diagnostic criteria. IBS is characterized by abdominal pain or discomfort and changes in bowel habits. Although the aetiology is multifactorial, recent studies to understand the pathophysiology of IBS have revealed that changes in the normal gut microbiota may play a role in IBS-associated low-grade intestinal inflammation[2,40]. Indeed, intestinal microbial dysbiosis is involved in the pathogenesis of IBS by facilitating the adhesion of the pathogenic microorganism to the intestinal wall and several studies revealed that. Indeed, there is a clear separation between the gastrointestinal microbiota of patients with IBS and that of healthy controls[64]. That is, IBS is characterized by an increase in the genera *Dorea*, *Clostridium* (as *Bacillota* phylum) and *Ruminococcus* with an important loss in the population of the genera *Bifidobacterium* and *Faecalibacterium*. According to a trial on IBS in young patients who were divided into subgroups with different bacterial fingerprints, an increase of *Bacillota* phylum compared to *Bacteroidota* phylum exists, differing from healthy patients[65,66]. Finally, another study on a paediatric population with IBS showed a variation of *Bacillota* and *Pseudomonadota* phyla amount, with many of the genera *Dorea* and *Ruminococcus*, and *Haemophilus parainfluenzae* species. The *Bacteroides* genus was found to be smaller in paediatric patients with IBS than in healthy controls. Typically, these studies could ultimately lead to the design of targeted therapies[67].

Idiopathic IBDs are immune-driven chronic diseases and represented by ulcerative colitis and Crohn's disease. Today they are an adverse immune response to endogenous symbiotic gut microorganisms with or without the involvement of the autoimmunity process. Studies have shown a change in the composition of the gut microbiota in IBD[68]. Furthermore, there is a qualitative reduction in it, *i.e.*, on the bio-diversity of the population with a typical reduction of *Bacillota* phylum strains (such as *Bifidobacteria*, spp., *Faecalibacterium prausnitzii*, and *Lactobacillaceae* families) while an increase in the microorganisms that are attached to the mucus is observed. *Bacillota* strains are the main producers of SCFAs, such as butyric acid, which has immunomodulatory properties[69]. However, it has not been clarified whether the disturbance in the microbiota is the cause of the disease or is the result of it. The normal, non-inflamed gut contains many immune cells which are in such a state of activation that there is no complete immune response to the microbes of the normal microbiota and food antigens. This is due to the activation of potent mechanisms of immune regulation, such as the stimulation of regulatory T cells expressing the transcription factor FoxP3 to suppress inflammation[66]. But, under environmental stimuli (*e.g.*, certain infections) the activation of the intestinal immune system starts on a large scale but is subsequently suppressed. In IBD patients this suppression of this immune response may not be adequately regulated. The eubiosis of the intestinal microbiota is under the control of the host through immune and epithelial responses, diet, drugs use (especially antibiotics), genetics, and more[2]. In turn, the microbiota, has significant effects on host epithelial and immune function thanks to its structural components and metabolism, that can become permanent by epigenetic effects. From childbirth, when the human microbiota is established, these host effects may influence the risk of developing IBD later in life[63]. It is worth noting here that in most studies the incidence of IBD increases particularly in the second to fourth decades of life, while some studies even report a second peak in the sixth and seventh decades. Specifically, therefore, components of the microbes can promote or protect against disease. The community microbes in patients with ulcerative colitis and Crohn's disease have been shown to be different from unaffected individuals, a state of dysbiosis: The presence of disease-causing microorganisms (such as those form *Pseudomonadota* phyla and adherent *Escherichia coli*) and to which directed immune response and/or loss of microorganisms that inhibit inflammation (*e.g.*, such as *Faecalibacterium prausnitzii*). But many changes and inflammation results in changes in the microbial community. Also, antibiotics (such as nitroimidazoles, quinolones) and certain diets change the gut microbiota and may improve Crohn's disease symptoms. In fact, the use of antibiotics really has a place in the treatment of Crohn's disease[2,16,70].

Immune dysregulation (allergies and autoimmunity)

Effectively stimulated immunity of both local and systemic mucosa is required for a mature gut microbiota. If this does not happen, a dysregulation can occur which can lead to allergic manifestations or an asthmatic phenotype from early life. It has been noted that developing countries have a lower incidence of allergic diseases such as asthma than countries developed. Thus the "hygiene hypothesis" was developed, which according to this lack of exposure to pathogenic bacteria or products of non-pathogenic bacteria can cause this condition by a negative effect on the development of the

immune system[71]. Subsequently, the "microbiota hypothesis" was formulated, in which it is proposed that changes in diet, as well as increased use of antibiotics in developed societies, lead to a less diverse gut microbiota in its microbial components. This "immature" gut microbiota, as it has been defined, alters the development of the immune system interrupting the proper evolution of events that allow the development of immune tolerance and thus increasing the risk of developing allergic hypersensitivity[72]. More specifically, levels of *Bifidobacterium* and *Enterococci* appeared to be related to allergic symptoms in the first months of life. An increased *Bacteroidota*/*Bifidobacterium* ratio was reported during the second year of life in children who developed symptoms of atopy children who eventually developed allergies were less frequently colonized with *Lactobacillaceae* phyla, *Bifidobacterium* and *Clostridiodies difficile* strains during the 2nd mo of life[73]. Autoimmune diseases (such as rheumatoid arthritis and other) can be sharing a common pathogenesis, an immune-mediated attack on the body's own organs. Autoimmune diseases usually show a variety of characteristics and symptoms. Concerning these characteristics, the most common may include, for example, an increase in epithelial (such as intestinal) and vessel permeability, mitochondrial dysfunction, progressive inflammation and chronic infections, imbalance of the hypothalamic-pituitary-adrenal (HPA) axis, and microbiota dysbiosis. Symptoms, on the other hand, can manifest as chronic fatigue, allergic phenomena, poor cognitive function, mood and mental disorders and pain, skin rashes, gastrointestinal disorders, and so[74,75]. An example of the genetically predisposed autoimmune diseases of the small intestine is celiac disease, an age-independent condition. The symptoms occur after the ingestion of the toxic epitopes of gluten (*i.e.*, the proteins present in wheat, rye, barley and, less so, in oats). In celiac disease there is an increase in intraepithelial lymphocytes and an atrophy of the intestinal villi. The autoimmune mechanism is due to the presence of various autoantigens, where the most important is tissue transglutaminase that is also an important diagnostic marker. Furthermore, it is often associated with other autoimmune diseases, such as insulin dependent diabetes mellitus (IDDM), or type 1 diabetes (T1D), thyroiditis, *etc.* This suggests that these diseases share common pathogenetic pathways[76-79]. Finally, the intestinal microbiota seems to play a fundamental role in the development and course of celiac disease. There is an unfavourable qualitative and quantitative composition of the intestinal microbiota characterized by a greater presence of the genus *Bacteroides* and *Escherichia coli* and a minor presence of *Bifidobacterium* spp. (*e.g.*, *B. longum* compared to healthy controls). Furthermore, this condition does not seem to change even after a gluten-free diet[80,81]. Finally, it has been noted that children born by caesarean section have a higher risk to develop the disease[82,83].

Diabetes mellitus

The exact role of the gut microbiota in the pathogenesis of T1D remains unknown. Data from experimental models support the idea that some bacterial families may act protectively against divalent metal transporter 1 (DMT1). Studies have shown that the use of antibiotics in experimental animals can prevent the occurrence of type 1[84]. But also, the administration of probiotics with bacterial strains in experimental animals prevented the onset or delayed the progression of the disease[85]. In another study, it was found that accidentally infecting mice with a spore forming bacterium resulted in a reduction in the incidence of DMT1[86]. Similarly, incubation of mycobacterium and streptococci in laboratory animals protected them from developing diabetes. Studies of the gut microbiota in mice that developed DMT1 and mice that did not develop diabetes reported that, at the onset of the disease, the two groups differed in the concentrations and type of microbes[87]. Stool samples from animals (mice) that developed diabetes contained higher concentrations of so-called probiotic bacteria, such as from *Lactobacillaceae* phyla and *Bifidobacterium* spp., in contrast to mice that did not develop diabetes which showed higher concentrations of *Bacteroides*, *Eubacterium* and *Ruminococcus*. It is worth mentioning that the *Lactobacillus johnsonii* strain prevents the development of diabetes when administered to mice[88,89]. Because of the possible relationship between the microbiota and IBD, most of the research around the gut microbiota has been done in patients with IBD, whereas studies in patients with type 1 diabetes mellitus (T1DM) are limited. In addition to increased intestinal permeability, patients with T1DM show an increase in inflammatory cells in the gut and decreased numbers of CD4, CD25, and T-cells, which are the master regulator of the immune system. Another study showed that individuals who developed T1DM had higher concentrations of *Bacteroidota* and lower concentrations of *Bacillota* compared to healthy controls. In addition, individuals who developed DMT1 were colonized with a lower number of bacteria compared to healthy controls[90,91].

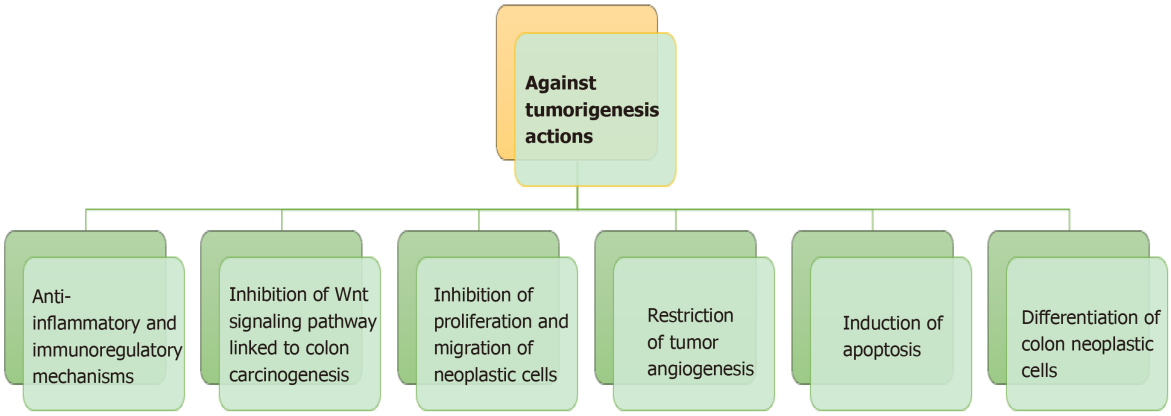
The manifestation of T2DM is due to the combination of reduced insulin secretion from the β-cells of the pancreas and increased insulin resistance, as well as the disruption of incretin secretion from the gastrointestinal system. Several studies associated the microbiota with the development of T2DM, which is particularly characterized by a decrease in the concentrations of the phylum *Bacillota* (such as the genus *Roseburia* from the *Lachnospiraceae* family and the *Enterococcus faecalis* from genus *Enterococcus*, and other). Changes in the number of *Bifidobacteria*, *Lactobacillaceae* phylum, *Clostridioides* genus, as well as the *Bacillota*/*Bacteroidota* ratio have also been observed in the intestinal microbiota of children with T1D [91-93]. Obesity and T2D share the presence of low-grade inflammation that occurs in tissues involved in the regulation of metabolism, such as the liver, adipose tissue, and muscle. Inflammation is characterized by an increase in cytokines, interleukin (IL)-6, IL-1 and tumor necrosis factor-alpha with the result being insulin resistance. There are several studies in which the gut microbiota has been associated with the presence of obesity, insulin resistance and T2D, such as, and that probiotic treatment affects the metabolic control of patients with T2D. The gut microbiota contributes to the development of T2D[94]. Both studies showed that people with T2D had reduced concentrations of *Clostridiales* bacteria (*Roseburia* spp. and *Enterococcus faecalis*)[95]. T2D, independent of obesity, may also affect the structural composition of the microbiota. T2D may have a high presence of Gram-negative intestinal bacteria, such as *Bacteroidota*. In fact, in diabetic mice a reduction in *Bacteroides/Prevotella* spp. has been linked to an improvement in metabolic endotoxemia and lowering of laboratory tests of inflammation[96]. Changes in the number of *Bifidobacterium*, *Lactobacillaceae* phylum, *Clostridium* as well as the ratio *Bacillota*/*Bacteroidota* have also been observed in the intestinal microbiota of children with T1D[97]. Similar changes in the composition of the intestinal microbiota have been reported in patients with T2D. A lot of different theories have been proposed about the biomechanisms to explain the effect of the intestinal microbiota on insulin

resistance and T2D, the main ones being metabolic inflammation, modification of incretin secretion and the production of hydroxybutyric acid. Lipopolysaccharides are endotoxins that are usually found in the outer membrane of Gram-negative bacteria and cause so-called metabolic inflammation, which is characterized by the release of pro-inflammatory factors [98]. The role of lipopolysaccharides in the pathogenesis of metabolic diseases was demonstrated by a study in mice fed a normal diet, in which the infusion of lipopolysaccharides caused insulin resistance in the liver, glucose intolerance, as well as an increase in adipose tissue. In addition, lipopolysaccharides may can lead to the expression of NF-κB and stimulate the activity of mitogen-activated protein kinase metabolic pathways in adipocytes. A study in fed leptin-deficient mice physiologically showed that increased intestinal permeability to lipopolysaccharide resulted in a change in the proportion of Gram-negative bacteria in the intestinal lumen, which was associated with the presence of insulin resistance. The modification of the intestinal microbiota by administering probiotic treatment to obese mice acted favourably on the intestinal barrier, reducing lipopolysaccharide-induced metabolic inflammation[99]. It has been found that increasing concentrations of *Bifidobacterium* modifies the inflammatory response in obese mice by increasing the production of glucagon like peptides (GLPs), while reducing intestinal permeability. The increase in *Bifidobacterium* concentrations induced by probiotic treatment is probably associated with an increase in the levels of gut-secreted peptides GLP-1 and YY, which exert a favourable effect, reducing insulin resistance and improving β-cell function. In addition, probiotic treatment caused an increase in GLP-2 levels in the colon, improved intestinal barrier function, and ultimately reduced plasma lipopolysaccharide levels[100]. It was found that people with T2D had an increase in the number of various opportunistic gut pathogens and a decrease in the concentrations of hydroxybutyric acid-producing bacteria. Hydroxybutyric acid is the main source of energy for maintaining the function of the cells of the digestive system. In the large intestine, hydroxybutyric acid is mainly produced by the bacteria *Clostridium coccoides* and *Eubacterium rectale*. However, changes in gut bacteria were found in colon cancer patients and in elderly subjects, suggesting that hydroxybutyric acid-producing bacteria could potentially have a protective role in the functioning of the gut microbiota[101,102].

Obesity and atherosclerosis

In obese individuals the accumulation and thus the increase of energy is related to the transfer of hydrogen between certain bacterial taxa. In fact, this effect has been noted both from the hydrogen-producing *Prevotellaceae* and from the methanogenic archaea that use hydrogen[103]. In obese individuals this increase and accumulation of energy due to the relative abundance of *Gammaproteobacteria* and the less presence of *Clostridium* genus. Additionally, obese individuals harbour clusters of H_2-producing bacteria, primarily members of the family *Prevotellaceae* and some groups of *Bacillota*. These H_2-producing bacteria coexist in the gastrointestinal tracts of obese individuals with relatively large numbers of H_2-oxidizing methanogens belonging to archaea. Methanogens account up to 10% of all anaerobes in the colon[104,105]. Plant polysaccharides and dietary fibers are fermented by intestinal bacteria to produce SCFAs. An increase in methanogenic oxidation of H_2 facilitates fermentation, which produces more SCFAs[106]. It can also be utilized directly by hydrotrophic methanogenic agents, while propionate, butyrate and lactate can be fermented with acetate and H_2, where the latter is utilized by hydrotrophic methanogenic bacteria. As a consequence, the increase in methane oxidation should increase the conversion of plant polysaccharides into SCFAs, especially the acetate. SCFAs produced by fermentative bacteria are absorbed through the human intestinal epithelium, whereas H_2 is an energy exchange factor within bacterial communities[107].

Atherosclerotic vascular disease is caused by environmental and genetic factors such as food and associated microorganisms. We currently know three circulating phospholipid-related molecules considered promoters of atherosclerosis: Trimethylamine N-oxide (TMAO), choline and betaine that could be used as biomarkers to predict cardiovascular disease risk[108]. These three phospholipid-related molecules were identified by analysis of plasma metabolites from 50 patients with atherosclerotic disease using liquid chromatography/mass spectrometry compared to 50 healthy samples. It has been noted that used apoE-deficient mice as a model of atherosclerosis and showed that plasma TMAO levels in apoE-deficient mice correlated positively with the area of aortic damage. The activity level of hepatic flavin monooxygenases, which convert trimethylamine (TMA) to TMAO, correlated positively with plasma TMAO levels in both mice and humans[109,110]. In the apoE-deficient mice an antibiotic treatment modify plasma TMAO level and atherosclerosis size, suggesting that gut microbiota significantly influence the development of atherosclerosis in apoE-deficient mice reducing it. This was demonstrated by adding 1% choline to the diets of apoE-deficient mice, as it increased the formation of foam cells as well as the expression of the scavenger receptors CD36 and SRA1 on macrophages, which is normally prevented by the administration of broad-spectrum antibiotics. A new pathway linking dietary lipid intake, gut microbiota and atherosclerosis has been found. Dietary L-carnitine is metabolized to TMA by gut microbiota and further converted to TMAO in the liver, which accelerates atherosclerosis in mice[111]. 16S rRNA sequencing of cecum bacteria in mice fed a diet supplemented with L-carnitine showed that the family *Prevotellaceae* were increased and positively correlated with plasma TMA level[112]. Furthermore, circulating TMAO in individuals with non-selective diet seems to be much higher than in those with a vegetables-based diet. Faecal microbiota analysis and plasma TMAO levels have been correlated in individuals with *Prevotella* enterotype in respect of those with *Bacteroides* enterotype, showing that these are higher in the first. L-carnitine use in individuals with different diet habits showed that a varied diet led to the production of more TMAO than in vegans or vegetarians. This confirm that both diet and lifestyle can change both the gut microbiota composition and its ability to metabolize TMA and TMAO from dietary L-carnitine[113]. Based on metagenomics, the genus *Collinsella* in faecal microbiota seems to be increased in patients with symptomatic atherosclerosis, while the genera *Eubacterium* and *Roseburia* is abundant in healthy subjects. Furthermore, in patients with atherosclerosis, metabolomics of faecal microbiota suggests an increase of the expression of genes coding for peptidoglycan synthesis, and a fall of hydrogenase levels. In addition, serum carotenoids, especially β-carotene, were decreased suggesting that symptomatic patients with atherosclerosis could have changes in the gut microbiota and a basic inflammatory state[113,114].



Neurological and psychiatric disturbance

As for the brain, everyone knows that it sends messages throughout the body. The intestine seems to respond. One of the most interesting effects of probiotics on the body focuses on the presence of the gut-brain axis (GBA). The GBA is the connection and the two-way communication between the gut [enteric nervous system (ENS)] and the central nervous system (CNS). This axis is a complex two-way pathway essential for metabolism homeostasis, the influence it has on emotions, mood and in general higher cognitive functions. It is a complex system in which it participates the CNS, the autonomic nervous system, the brain, the spinal cord, and the HPA axis[2,115]. The GBA axis indicates the bidirectional relationship and interdependence between CNS and ENS. It is important to understand this interaction and how a healthy intestinal microbiota can affect the body's nervous system and vice versa. Through a multitude of mechanisms, hundreds of substances and neurotransmitters, the relationship between the two complex systems is in constant change which can have both positive and negative effects. Stress is a quite common factor that can affect mood, psychology and, apparently, the body's intestinal microbiota[116,117]. When the organism exposed to a stressful social situation even for a period of only two hours, the microbiota undergoes significant changes, a significant change in its profile and change in the ratio of the main races of bacteria. Additionally, the brain, under the right conditions, can influence composition and functionality of the intestinal microbiota. It may alter intestinal permeability thereby allowing bacterial antigens to enter the epithelium and stimulate a mucosal immune response. Acute stress can increase colonic permeability, leading to overproduction of interferon-γ[116]. Finally, dysbiosis, *i.e.*, alterations caused in the gut due to stress, facilitate the expression of infectious bacteria. An example is the secretion of norepinephrine during surgery which causes expression of *Pseudomonas aeruginosa*, which can lead to intestinal sepsis. In addition, norepinephrine can stimulate the proliferation of enteric pathogens and increase the infectious properties of *Campylobacter jejuni*[117-119]. Finally, it can favour the overgrowth of non-pathogenic *Escherichia coli* isolates, as well as pathogenic *Escherichia coli* type 0157:H7[3,116]. In continuation of the above, it seems that probiotics have the mechanisms to deal with the complications of stress. Cortisol is a substance produced when the organism is in a state of stress and experiences situations related to anxiety and depression. It was found that probiotics led to a decrease in its release of this substance. In addition, the metabolic products of probiotics, SCFAs, offer beneficial actions. The ENS becomes a recipient of bacterial metabolites. SCFAs such as butyric, acetic, and propionic acids are the main metabolic products of bacterial metabolism[120]. In addition to their essential presence for the multitude of beneficial actions they offer, they can stimulate the sympathetic nervous system, release serotonin in the mucosa and positively affect memory and the learning process[116]. The above-mentioned negative effects of unpleasant psychological states indicate this strong dependence and relationship between CNS and ENS. It is worth focusing on the reverse course, that is, how the health of the body's microbiota can, through probiotic bacteria, give the appropriate signals to the brain to influence possible diseases. Studies show that balance in the microbiota is related to our emotions, as well as how our brains process information from our senses, such as sights, sounds, tastes. Scientists suspect that gut microbiota disorders may play a role in autism spectrum disorders, depression, anxiety, and chronic pain[121]. The GBA is a communication system between the gut and the brain *via* neural, hormonal, and immune circuits, offering the gut microbiota and its metabolites a potential pathway to access the brain. This communication system is bidirectional and allows the brain to regulate gastrointestinal functions such as peristaltic movements and mucus production as well as immune functions[122]. Considerable progress has been made in the past decade in understanding the ways in which the gut microbiota is linked to the brain. Stress conditions affects the gut microbiota composition and that two-way communication between gut microbiota and the CNS influences the host's response to stress. Stress has been shown to affect the integrity of the intestinal epithelium and alter peristalsis, secretions, and mucus production, thereby altering the gut microbiota environment and causing changes in microbial composition and/or metabolism[2,123]. Finally, regarding autism, it has been found that children with autism typically have a higher abundance of *Pseudomonadota*, *Bacteroidota* and a lower abundance of *Bacillota* and *Bifidobacteria* than healthy children. In fact, many classes of bacteria that make up *Bacillota* and *Clostridia* spp., have been found to appear in higher percentages in autistic children with a history of gastrointestinal problems, while at the same time and despite the overall higher abundance of *Bacteroidota*, and lower *Prevotella* were observed. Therefore, in addition to quantifying the relative increase or decrease of the populations of some phyla, it has been deemed necessary to determine the populations of specific intestinal symbiotic organisms to understand the significance of some physiological changes in the gut and/or brain[124].

Colorectal cancer

Colonic metabolism may be protective against carcinogenesis under eubiotic conditions[125] (Figure 3). Several environmental and individual factors associated with the development of colorectal cancer, and the interactions between them. It is estimated that 20% of human cancers are related to conditions of chronic inflammation and/or persistent infections. As for example *Helicobacter pylori* infection is often associated with ulcer and gastric cancer, hepatitis B virus and hepatitis C virus can facilitate hepatocellular carcinoma, IBDs can develop colorectal cancer[126]. The composition of the gut microbiota according to studies may contribute to the mechanism of carcinogenesis either through diet or through its anti-inflammatory effect on the gut mucosa. A number of research has showed a link between *Fusobacterium* genus and the development of colorectal cancer. Most recently an association between *Fusobacterium nucleatum* and colorectal cancer was established by a molecular cytogenetic technique[127,128].

The gut microbiota in patients with colorectal cancer is characterized by increased diversity in *Clostridiaceae* family (such as those from *Clostridium* genus), and an increase in *Bacteroides* and *Bifidobacterium* spp. In contrast, the gut microbiota of individuals with a reduced risk of developing cancer has a high population of lactate-producing bacteria, such as *Eubacterium aerofaciens* and *Lactobacillaceae* phyla[129]. Studies on animals led to propose a model of carcinogenesis based on the consideration that certain mutations in the intestinal epithelial cells lead to a loosening of the intercellular junctions and a reduced production of mucus, compromising the integrity of the intestinal mucosa. So, there

Figure 3 The inhibitory properties of butyrate on tumorigenesis through various mechanisms by the colonic microbiota. Many of the metabolites of protein fermentation can be taken up by other microorganisms and synthesized into active carcinogens. For example, amines and nitrates can be used by facultatively anaerobic and anaerobic colonic bacteria and catalysed the formation of N-nitrosamines, which are among the strongest procarcinogens. Reduced levels of butyrate in the body are not only an indication of the possibility of cancer, but also indicate the severity of the cancer and its course in the body.

is a translocation of bacteria from the lumen to the epithelium where microbial products bind to tumor-associated macrophage receptors inducing the release of inflammatory factors (such as IL-1, IL-6, IL-23) which in turn leads to the production of IL-17 stimulating T-helper lymphocytes. IL-17 activates the transcription factor signal transducer and activator of transcription 3 in epithelial cells which will lead to increased survival and proliferation of epithelial cells resulting in further mutations facilitating carcinogenesis[130,131]. These changes in the epithelium burden the already compromised epithelial integrity, exacerbating bacterial allostasis and contributing to the vicious cycle: Bacterial allostasis - inflammation - cancer. The IL-23/IL-17 axis in tumour-induced inflammation is caused by barrier loss. Thus, otherwise "good" bacteria in the gut microbiota can be transformed into a carcinogen due to the altered host defence mechanism, indicating the uniqueness of the mucosal environment in preventing the development of cancer and may can lead to a cancer progression in other sites such as make the gut/breast microbiota's axis[132-135].

CONCLUSION

A large population of microorganisms of various composition gradually colonizes the human organism, externally and internally, and forms the so-called microbiota. The most important and then populous is the intestinal one. The organism represents a stable and nutrient-rich habitat for the gut microbiota to thrive, and therefore the health of the host is of primary importance to them. In turn, the host benefits because they not only prevent colonization by pathogens, but also provide a continuous and dynamic effect on their host's homeostasis. Thus, this symbiosis creates the host/gut microbiota axis that influences its health throughout an individual's life. In fact, a gut microbiota disorder has been related to many diseases (such as asthma, diabetes, obesity, neurological disorders, *etc.*) but also psychic and mental disorders. However, not all correlation mechanisms are yet understood, which is why more research is needed into the composition of the microbiota that is the cause or result of a disease. The aim of this study is on the human microbiota and its composition for the correlation of conditions during the life course that can be physiological or pathological. In fact, the scientific community is still trying to understand and relate its development and change to various pathological conditions that occur in humans.

FOOTNOTES

Author contributions: Colella M contributed to the conceptualization and data collection; Charitos IA involved in the original manuscript writing and drafting, and resources; Ballini A take part in the manuscript revision and formal analysis; Cafiero C and Palmirotta R contributed to the investigation; Palmirotta R and Santacroce L involved in the validation of this manuscript; Santacroce L contributed to the conceptualization, project administration, and funding of this manuscript; and all the authors have read, discussed, and approved the original manuscript and the final version of it.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.

Abstract

Liver disease is a major health concern globally, with high morbidity and mortality rates. Precise diagnosis and assessment are vital for guiding treatment approaches, predicting outcomes, and improving patient prognosis. Magnetic resonance imaging (MRI) is a non-invasive diagnostic technique that has been widely used for detecting liver disease. Recent advancements in MRI technology, such as diffusion weighted imaging, intravoxel incoherent motion, magnetic resonance elastography, chemical exchange saturation transfer, magnetic resonance spectroscopy, hyperpolarized MR, contrast-enhanced MRI, and radiomics, have significantly improved the accuracy and effectiveness of liver disease diagnosis. This review aims to discuss the progress in new MRI technologies for liver diagnosis. By summarizing current research findings, we aim to provide a comprehensive reference for researchers and clinicians to optimize the use of MRI in liver disease diagnosis and improve patient prognosis.

Core Tip: Accurate evaluation of liver disease is essential for effective treatment strategies and better patient prognosis. Magnetic resonance imaging (MRI), a non-invasive diagnostic tool, has become a necessary technique for detecting liver diseases. The advancements in various magnetic resonance techniques have significantly enriched the diagnostic methods for liver diseases, each with a different focus and expertise in examining the liver. This article reviews the principles, advantages, limitations, and clinical applications of these new technologies in the diagnosis of liver disease, providing necessary references for researchers and clinical physicians to enhance the application of MRI in liver disease diagnosis and improve patient prognosis.

INTRODUCTION

Liver disease is a major global health concern with high rates of morbidity and mortality[1]. Chronic liver diseases often lead to liver fibrosis and cirrhosis, which are the primary risk factors for hepatocellular carcinoma (HCC)[2]. The accumulation of large molecules such as collagen protein and glycosaminoglycans in the extracellular matrix is the basic pathological feature of liver fibrosis[3]. Reports suggest that 80%-90% of new HCC cases occur in individuals with cirrhosis[4]. Liver cancer is the sixth most common malignancy in humans and the fourth leading cause of cancer-related deaths worldwide. HCC accounts for 90% of all liver cancer cases[5]. Surgery is the preferred method for treating early-stage HCC[6]. However, due to the absence of apparent symptoms in the early stages, most patients are diagnosed late or with distant metastasis[7]. In major Western centers, the incidence of HCC recurrence within 5 years after curative liver resection is estimated to be 60%-70%[8]. Therefore, early diagnosis and recurrence monitoring are crucial for these patients.

Imaging examinations are vital in diagnosing chronic liver disease and liver cancer. HCC can be diagnosed non-invasively without requiring pathological confirmation, unlike most solid tumors[9]. MRI is a commonly used imaging technique that provides detailed information on the pathological and physiological aspects of liver cancer. It reflects changes in the tissue structure, metabolic status, tumor microenvironment, and other relevant factors.

Recent advancements in magnetic resonance imaging (MRI) technology, such as diffusion weighted imaging (DWI), intravoxel incoherent motion (IVIM), magnetic resonance elastography (MRE), chemical exchange saturation transfer (CEST), magnetic resonance spectroscopy (MRS), hyperpolarized MR (HP MR), contrast-enhanced MRI (CE-MRI), and radiomics, have significantly improved the accuracy and effectiveness of liver disease diagnosis. These new technologies are expected to provide further important information on tumor biological behavior.

This review aims to discuss the progress in new MRI technologies for liver disease diagnosis. By summarizing current research findings, we aim to provide a comprehensive reference for researchers and clinicians to optimize the use of MRI in liver disease diagnosis and improve patient prognosis.

NEW MRI TECHNOLOGIES FOR LIVER DISEASE DIAGNOSIS

DWI and IVIM

DWI is a non-invasive imaging technique that provides information on liver tumors, diffuse liver lesions, and liver function status without the need for contrast agents[10]. DWI has become a popular tool in tumor chemotherapy response assessment and follow-up after treatment due to its ability to detect recurrent lesions earlier than traditional imaging techniques[11].

IVIM, an extension of DWI, has shown great potential in liver function assessment[12], diagnosis of diffuse liver lesions [13] and liver tumors, and liver lesion characterization[14]. It is commonly used to estimate blood flow and microvascular perfusion[15]. The IVIM analysis includes the *D* value (representing pure diffusion factors), the *D** value (representing transport and perfusion factors), and the *f* value (representing microvascular perfusion factors). Research has demonstrated that IVIM has a higher diagnostic efficacy for displaying different liver lesions than DWI. Additionally, the diagnostic efficacy of the *D* value derived from IVIM is significantly higher than that of the apparent diffusion coefficient (ADC) value[16]. IVIM can also be used to predict histological grade, as the *D* value exhibits good diagnostic performance in distinguishing high-grade from low-grade liver cancer[17].

The perfusion-diffusion ratio (PDR) is a recent concept proposed to enhance the effectiveness of DWI. PDR is the ratio of the decreased signal rate caused by IVIM to the decreased signal rate caused by diffusion. A study was conducted to compare the effectiveness of IVIM parameters, ADC value, and PDR in distinguishing solid benign and malignant liver diseases in patient imaging data. The results indicate that PDR had better accuracy compared to IVIM parameters and the ADC value, with an accuracy rate of 79%, while also exhibiting high sensitivity and specificity[18].

The technologies of DWI and IVIM show great promise in aiding the diagnosis and treatment of liver cancer. Furthermore, the introduction of PDR has provided new insights for DWI, allowing for a more precise evaluation of liver cancer. However, DWI does have some limitations, such as the low repeatability of the ADC value, which prevents it from being a dependable imaging biomarker[19]. In addition, DWI is prone to several artifacts such as blurring, ghosting, and distortion which pose a challenge in achieving the repeatability of IVIM parameters and the ADC value[20]. To address this issue, Simchick *et al*[21] proposed a two-dimensional (2D) *b*-M1-optimized data acquisition technique that offers better stability and repeatability in measuring IVIM parameters. This technique can be instrumental in establishing IVIM quantitative biomarkers for liver disease.

MRE

Liver biopsy is widely accepted as the most reliable method for diagnosing and staging liver fibrosis[22]. However, its invasiveness, cost, and potential for complications limit its use. Furthermore, the diagnostic reliability of liver biopsy is questionable due to its sampling variability and subjectivity[23]. Ultrasound elastography is a low-cost and easy-to-use alternative, but it is highly influenced by obesity[24]. For example, vibration-controlled transient elastography (VCTE) is one of the most widely used ultrasound-based methods for diagnosing liver fibrosis. Its rapid, safe, and reproducible nature has made it widely used for bedside diagnosis. However, its reliability is lower than that of MRE as 15% of its conclusions are inaccurate, which is mainly due to the impact of obesity and insufficient experience of doctors[25,26]. According to a large sample meta-analysis, the summary area under the curve (AUC) values of VCTE for diagnosing significant fibrosis, advanced fibrosis, and cirrhosis were lower than those of MRE, with values of only 0.83, 0.85, and 0.89, respectively, while MRE had AUC values as high as 0.91, 0.92, and 0.90, respectively[27]. Serum biomarkers have also been explored for liver fibrosis evaluation, but their lack of specificity poses a challenge as they may also be released during inflammation in other tissues[28].

MRE proves to be a better method for diagnosing and staging liver fibrosis as it is not influenced by factors such as obesity, ascites, inflammation, or etiology[29]. The accuracy and reliability of MRE in diagnosing all stages of liver fibrosis, especially late-stage fibrosis and cirrhosis, have been confirmed by multiple meta-analyses[27,30]. However, the clinical application of MRE is still restricted due to its long examination time and high cost.

Encouragingly, recent studies suggest that combining serum biomarkers and MRE could have unexpected benefits. For instance, fibrosis-4 (FIB-4) index, an indicator used to assess liver injury and fibrosis, includes aspartate aminotransferase, alanine aminotransferase, age, and platelet count[31]. Tamaki *et al*[32] conducted a study where they used a two-step strategy combining FIB-4 index and MRE to detect late-stage fibrosis. They found that the accuracy of the two-step strategy was equivalent to that of using MRE alone, which could lead to cost reduction by reducing excess MRE. Therefore, the two-step strategy can serve as a screening method for large populations. Another study also demonstrated that the combined use of MRE and FIB-4 index has excellent negative predictive value in liver decompensation, which has significant clinical implications[33]. In addition, MRE has acceptable specificity and sensitivity in evaluating splenic stiffness and portal hypertension[34], which is crucial for assessing the overall health status of patients with cirrhosis.

Currently, liver fibrosis assessment can be carried out using 2D MRE, but a more advanced option now available is three-dimensional (3D) MRE. Unlike 2D MRE, 3D MRE images allow analysis of the entire volume of the liver in a 3D manner, providing better accuracy by collecting and processing information in all directions. In a study by Li *et al*[35], the diagnostic performance of 2D MRE and 3D MRE was compared, and both were found to have strong performance in detecting and staging liver fibrosis. However, 3D MRE provided significantly better image quality than the 2D MRE method and had higher inter-observer consistency in measuring liver stiffness (LS). Furthermore, in their study, Catania *et al*[36] found that 3D MRE is more repeatable due to its lower sensitivity to artifacts and provides a more comprehensive liver evaluation by including a larger area of liver parenchyma.

MRE has been found to be useful in predicting the occurrence and recurrence of HCC. Reports suggest that the risk of developing HCC increases with LS as measured by MRE[37]. Late-stage HCC recurrence is predicted by LS ($P < 0.001$), which has a high specificity (90.0%)[38]. MRE has also shown potential in diagnosing microvascular invasion (MVI) in HCC. A study by Zhang *et al*[39] found that tumor stiffness (TS) increased with MVI severity, with TS/LS > 1.47 ($P = 0.001$), TS > 4.33 kPa ($P < 0.001$), and irregular tumor margins ($P = 0.006$) being important independent predictors of MVI positivity.

In summary, MRE is a valuable tool for the thorough evaluation of liver fibrosis, cirrhosis, HCC, and portal hypertension in individuals with liver disease. Although MRE has demonstrated high accuracy in identifying advanced fibrosis or cirrhosis, there are discrepancies in the diagnostic threshold for fibrosis staging based on retrospective data meta-analyses[40], which require further validation.

CEST MRI

The CEST technique, first introduced by Ward *et al*[41] in 2000, utilizes off-resonance saturation pulses to saturate a specific substance, which in turn affects the signal intensity of free water through chemical exchange, providing relevant information about the substance. There are several types of CEST, including Glu CEST, Cr CEST, LATEST, and Gluco CEST, which can, respectively, map glutamate, creatine, lactate, and glucose, all of which are important substances involved in tumor metabolism. CEST can be divided into two categories: Exogenous CEST and endogenous CEST, depending on whether exogenous CEST agents are used. In liver imaging, CEST MRI can be used to evaluate tumor metabolism and tumor microenvironment, and monitor tumor treatment response.

Tumors are known to exhibit increased glucose uptake and glycolysis. To monitor tumor glucose metabolism and treatment response, ^{18}F-fluorodeoxyglucose positron emission tomography (^{18}F-FDG PET) is commonly used. However, the high cost and radioactivity of this method limit its application. CEST MRI has emerged as a potential alternative. A study by Chan *et al*[42] showed that using D-glucose, a simple carbohydrate, to detect tumor metabolism was possible.

The Gluco CEST image showed a significant enhancement in the tumor region, consistent with PET results. However, the CEST signal decreases rapidly due to the rapid metabolism of D-glucose after entering the cells[43]. In recent years, 3-O-methyl-D-glucose (3OMG) has emerged as a promising option for monitoring tumor progression and treatment efficacy. Unlike D-glucose, 3OMG is not metabolized after being taken up by cells, and accumulates in tumor cells, giving it a different kinetic profile[44]. Its similar CEST contrast efficiency to D-glucose makes it a suitable reporter for tumor cell glucose transporters. The Gluco CEST technique, which utilizes 3OMG, offers a low-risk option for patients with renal diseases to display tumor metabolism without using radioactive tracers.

In addition, CEST MRI provides a non-invasive method for evaluating tumor pH, which is important due to the Warburg effect. This effect leads to increased lactate production within cancer cells and results in an acidic extracellular pH in the tumor microenvironment. This acidic environment can enhance tumor invasiveness, metastasis, angiogenesis, and resistance to radiotherapy and chemotherapy[45]. The CEST measurement of pH is not limited by observation depth and can be used for whole-body imaging. While amide proton transfer (APT) CEST MRI is capable of measuring pH[46], it is limited in its ability to calculate the absolute value of pH. To address this limitation, exogenous agents have been utilized to measure extracellular pH in the tumor microenvironment. The use of iodinated agents in CEST MRI has emerged as a promising non-invasive technique for pH assessment[47], as these clinically approved agents are not affected by concentration and offer advantages over APT MRI.

CEST has found another novel application in image-guided nanoparticle (NP) drug delivery. This technique can monitor the transformation and distribution of NP drugs in the body, thereby assisting in adjusting treatment plans. CEST-guided NP drug delivery systems can be divided into labeled and unlabeled systems, depending on the labeling strategy used to achieve the CEST signal[48]. For example, Law *et al*[49] successfully used CEST MRI to detect the specific distribution of iohexol-labeled liposome drugs in the brain of an animal model. In a separate study, Liu *et al*[50] introduced a new labeling-free strategy that uses CEST MRI imaging technology to detect the delivery efficiency of anti-cancer drug lentinan-functionalized SeNPs and achieve image-guided drug delivery. The ability of CEST MRI to visualize NP drug delivery provides a unique opportunity for the integration of tumor diagnosis and treatment. However, this technology is still in its infancy, and nearly all related research is currently being conducted in preclinical animal models. Therefore, extensive validation is necessary to ensure its accuracy and acceptability for clinical translation.

CE-MRI

CE-MRI is a technique used to enhance liver lesion imaging by injecting a contrast agent intravenously. The contrast agent distribution patterns in the liver can be classified into four categories[51]: (1) Extracellular fluid agents, such as Gd-DTPA and Gd-DOTA, rapidly enter the hepatic capillary network and diffuse into the tissue space after injection, eventually being excreted by the kidneys; (2) Hepatobiliary agents, such as Gd-EOB-DTPA and Gd-BOTPA, can be absorbed and metabolized by normal liver cells. During the hepatobiliary phase, regions with premalignant liver lesions or malignant tumors display low signal due to decreased contrast agent uptake[52]; (3) Superparamagnetic iron oxide (SPIO) particles can be taken up by Kupffer cells in normal liver tissue, resulting in a 'black liver' effect. Tumor tissue displays high signal because it almost does not take up SPIO particles; and (4) Molecular targeted MRI contrast agents can be modified with specific antibodies or ligands, allowing them to bind specifically to tumor tissue and highlight the tumor.

The development of MRI contrast agents with tumor targeting, safety, and efficacy has been extensively researched. The use of molecular targeted MRI contrast agents with specific antibodies or ligands has shown promising results in actively targeting tumor tissue, enabling early detection of tumors. Various specific targets can be utilized to produce specific contrast agents. This review will introduce glypican-3 (GPC3) and alpha-fetoprotein (AFP) as examples.

GPC3 is a cancer embryonic polysaccharide present on the cell membrane. Studies have shown that GPC3 is highly expressed in over 70% of HCCs, but not in hepatitis, cirrhosis, benign liver lesions, or healthy adult tissue. GPC3 promotes the progression of liver cancer by binding to molecules such as Wnt signaling proteins and growth factors[53]. In terms of diagnosis, GPC3 has a diagnostic specificity similar to AFP but with higher sensitivity[54]. Additionally, GPC3 can be used to distinguish AFP-negative HCC[55], making it a more reliable diagnostic marker for HCC. Overall, GPC3 shows promise as a potential diagnostic tool for HCC. Zhao *et al*[56] have developed a novel liver cancer-targeting probe by combining USPIO with GPC3-specific ligands. The probe demonstrated preferential binding to GPC3 in both *in vitro* and *in vivo* experiments. Furthermore, it exhibited good stability and biocompatibility, making it a promising candidate for a targeted MRI contrast agent.

AFP is not typically expressed in adults, but in liver cancer patients. AFP levels may be very high, making it a potential target for detecting liver cancer[57]. AFP antibodies can be used to create targeted probes, but as previously mentioned, AFP is not highly expressed in all liver cancer patients. To address this issue, Ma *et al*[58] conjugated AFP antibodies and GPC3 antibodies to ultra-small SPIO NPs (USPIO), resulting in the development of a dual-antibody-conjugated MRI probe that can detect heterogeneity and small HCC with higher sensitivity than single-target probes. The experiment demonstrated that using dual-antibody-conjugated USPIO probes for targeting cancer cells was more efficient and sensitive compared to using single-labeled probes that targeted AFP-USPIO and GPC3-USPIO, as well as non-targeted USPIO. This finding highlights the potential of using multi-target probes to overcome tumor heterogeneity and improve sensitivity to HCC.

Gadolinium-based contrast agents (GBCAs) are commonly used in MRI, but they carry the risk of allergic reactions and nephrogenic systemic fibrosis[59]. Furthermore, even patients with normal kidney function can experience gadolinium accumulation in all tissues with GBCA exposure[60]. Therefore, the development of effective Gd-free MRI contrast agents is becoming increasingly important. Manganese (Mn) has emerged as a promising alternative to GBCAs[61], with researchers discovering that Mn oxide nanoparticles have negligible toxicity and produce good T1-weighted contrast effects[62]. Mn^{2+} has also demonstrated potential as an anti-cancer drug or adjuvant, making it a fascinating area of

research[63]. In a recent study, researchers found that administering Mn^{2+} to a mouse model induced a strong systemic anti-cancer response. This was achieved through promoting natural killer cell function, macrophage and dendritic cell maturation and activation, CD8+ T cell differentiation and activation, and memory T cell survival in tumors. As a result, tumor growth and metastasis were greatly inhibited. Another group of researchers developed an intelligent therapeutic probe called MnTBs, which decomposes quickly in acidic and reducing cellular environments, releasing Mn^{2+} and triggering chemodynamic therapy. This probe was found to be effective in inhibiting tumor growth and metastasis, as well as detecting millimeter-sized liver metastases with a high contrast of 316%[64]. These findings suggest that Mn-based contrast agents have potential in targeted tumor therapy.

MRS

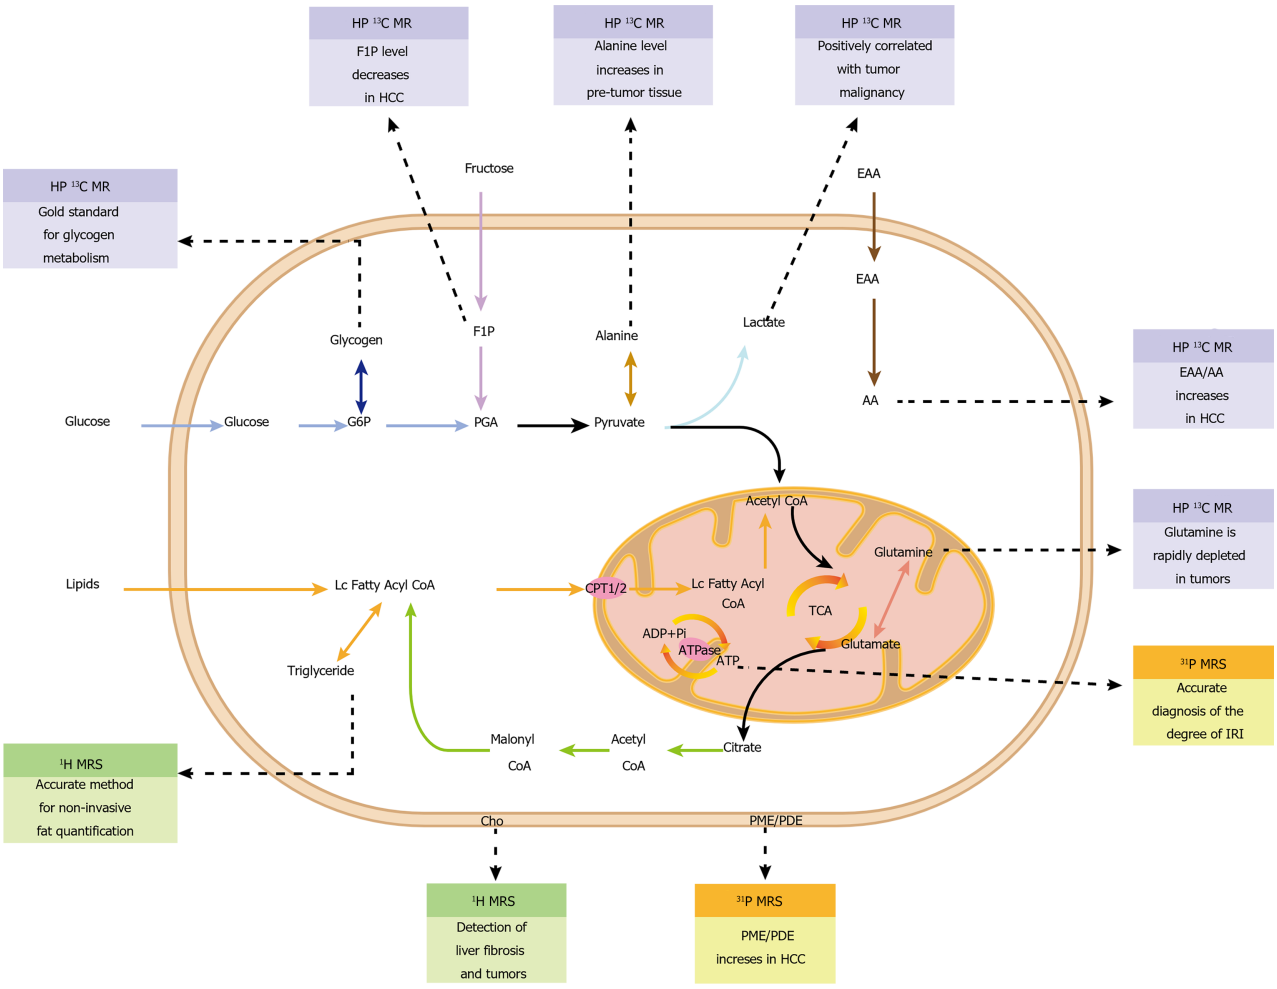
MRS is a non-invasive method that monitors organ metabolites, making it particularly suitable for the liver due to its high concentration of multiple metabolites such as ATP, glutamine, and glycogen. The liver MRS analysis primarily uses ^{1}H, ^{31}P, and ^{13}C. Its major applications include the diagnosis and grading of fatty liver and liver fibrosis, as well as the diagnosis of liver tumors.

The incidence of non-alcoholic fatty liver disease (NAFLD) is increasing, and some patients with NAFLD may develop non-alcoholic steatohepatitis, which can progress to liver cirrhosis and HCC[65]. Therefore, early diagnosis is crucial for preventing and treating NAFLD. ^{1}H-MRS is a non-invasive method that can accurately measure the content of triglycerides in the liver[66]. However, it has some limitations, such as long processing time, motion artifacts, and sampling errors.

The use of MRI proton density fat fraction (MRI-PDFF) has become a popular method for measuring liver fat content in recent years[67]. MRI-PDFF has a strong correlation with MRS ($r = 0.983$, $P < 0.001$) and can quantitatively measure the lipid content of the entire liver[68], overcoming the limitations of MRS and liver tissue biopsy. This makes MRI-PDFF a widely used reference standard for image-based fat quantification with broader application prospects than MRS[69]. In addition, the recent use of the multi-echo Dixon sequence has shown promising results in detecting NAFLD[70].

In the diagnosis and staging of liver fibrosis, ^{1}H-MRS and ^{31}P-MRS have distinct values. Ding *et al*[71] discovered that choline (Cho) levels measured by ^{1}H-MRS increased in proportion to the severity of liver fibrosis. They also found that the Cho/lipid ratio was the most significant diagnostic indicator of liver fibrosis based on the receiver operating characteristic curve. The diagnostic thresholds for liver fibrosis and early cirrhosis were ≥ 0.028 and ≥ 0.131, respectively. In comparison to ^{1}H-MRS, ^{31}P-MRS is advantageous in diagnosing cirrhosis as it can distinguish between different causes of liver disease. Through quantitative analysis of metabolite concentrations such as phosphate monoester (PME), phosphate diester (PDE), Pi, and ATP, ^{31}P-MRS has the potential to differentiate between alcoholic liver disease, viral liver disease, NAFLD, and cirrhosis[72]. However, larger-scale multi-center studies are needed to confirm the clinical relevance and usefulness of this finding.

Liver cancer patients can benefit from the use of ^{1}H-MRS and ^{31}P-MRS as well. In ^{1}H-MRS, the Cho peak is a significant indicator of focal liver lesions, and its elevation could suggest the proliferation of tumor tissue due to increased synthesis of cell membrane phospholipids. Furthermore, the information provided by the Cho peak can be further developed. Liao *et al*[73] conducted a study to compare the diagnostic performance of Cho peak area, Cho peak amplitude, and combined methods for early detection of rabbit liver cancer. The results showed that the combined method had higher accuracy in the early diagnosis of liver cancer, and the correlation between Cho peak amplitude and tumor volume was the best. In ^{31}P-MRS, the contents of PME and PDE can reflect cell membrane synthesis and breakdown, and their increase means cell proliferation. Liver tumors can be associated with an increase in PME/PDE and PME/Pi, and changes in PME/PDE after treatment are significant. However, further multi-center studies are needed to confirm their accuracy due to high heterogeneity[74]. ^{31}P-MRS is also reliable for measuring ATP consumption and identifying the degree of acute liver ischemia-reperfusion injury (IRI)[75], which is particularly meaningful for patients who require hepatectomy and liver transplantation. Diagnosis and treatment of IRI during surgery have always been a challenging task.



^{13}C MRS is considered the gold standard for imaging human liver glycogen metabolism after oral ingestion of ^{13}C-labeled glucose[76]. However, the low natural abundance and sensitivity of ^{13}C nuclei can limit their application. To overcome this challenge, researchers have developed hyperpolarization techniques, which will be discussed below. For readers' convenience, the targets of MRS and HP MR in liver metabolism evaluation are summarized in Figure 1.

However, motion still has an impact on the accuracy of MRS. Additionally, liver tissue has significant heterogeneity, so excluding extraneous tissue when setting the observation area is crucial. As technology continues to advance, MRS is expected to become an increasingly important tool for diagnosing and grading liver tumors, potentially replacing the need for invasive biopsies.

HP MR

The development of HP MR can be attributed to the dynamic nuclear polarization (DNP) technique, which was initially proposed by Ardenkjaer-Larsen *et al*[77]. This technique can increase MR signal by more than 10000 times. Currently, the leading HP biomarkers primarily consist of ^{13}C, with [1-^{13}C] pyruvate being the most commonly used due to its central role in cellular metabolism. When absorbed by liver cells, [1-^{13}C] pyruvate can produce three observable metabolic intermediates: Lactate, alanine, and CO_2, thus allowing visualization of liver metabolism.

Cancer cells often have higher levels of the enzyme lactate dehydrogenase[78], which convert pyruvate to lactate. Measuring the metabolic transformation from pyruvate to lactate is important for analyzing tumor invasiveness, grade, and prognosis[79]. In a study, HCC was induced in rats, and tumor cells were extracted and re-implanted into another group of nude mice. The study found that tumors re-implanted from cells with higher lactate/pyruvate ratios showed higher lactate signals. Therefore, using HP MR to evaluate glucose metabolism differences in liver cancer tissue could potentially reveal tumor phenotypes[80].

Figure 1 The targets of magnetic resonance spectroscopy and hyperpolarized magnetic resonance in liver metabolism evaluation. AA: Acetoacetate; CPT: Carnitine palmitoyl transferase; Cho: Choline; EAA: Ethyl acetoacetate; F1P: Fructose-1-phosphate; G6P: Glucose-6-phosphate; IRI: Ischemia-reperfusion injury; HCC: Hepatocellular carcinoma; PDE: Phosphate diester; PGA: Phosphoglyceric acid; PME: Phosphate monoester; TCA: Tricarboxylic acid; MRS: Magnetic resonance spectroscopy.

Alanine is another potential biomarker for liver cancer diagnosis. It was found that an increase in alanine generation was the earliest metabolic change detected in liver cancer models, even before the formation of primary tumors. In pre-tumor tissues, the conversion rate of pyruvate to alanine significantly increased, and the area with the most abundant alanine signal in pre-tumor tissues was often the region where tumor nodules form[81]. Thus, [1-^{13}C] pyruvate HP MR can be used for early diagnosis of liver cancer by monitoring alanine generation.

Recent studies have shown an increased interest in the use of other hyperpolarization probes, including HP [1,3-$^{13}C_2$]-ethyl acetoacetate, HP [2-^{13}C]-fructose, and HP [5-^{13}C, 4,4-$^{2}H_2$,5-^{15}N]-L-glutamine. Ethyl acetoacetate (EAA) is converted to acetoacetate (AA) at a reduced rate in HCC cells due to lower concentrations and activity of carboxylesterases. In a rat liver transplant tumor model, HP [1,3-$^{13}C_2$]-ethyl acetoacetate MR revealed that the EAA/AA ratio in tumor tissue was approximately four times higher than that in healthy tissue (P = 0.009)[82]. Similarly, HP [2-^{13}C]-fructose can be used to explain HCC cell metabolism. HCC cells have reduced generation of fructose-1-phosphate (F1P) due to lower expression of ketohexokinase[83]. HP MR has successfully detected F1P and its loss in an HCC model. Finally, evaluation of glutamine metabolism is also beneficial for liver cancer diagnosis because it is rapidly consumed by proliferating cells in tumor tissue. The newly developed HP [5-^{13}C, 4,4-$^{2}H_2$,5-^{15}N]-L-glutamine proved to be the best choice for determining *in vivo* glutamine metabolism[84].

Importantly, HP MR provides a unique advantage in obtaining information on tumor metabolism and perfusion, which is not easily obtainable through other methods. The latest technology utilizes the dual-probe imaging method, which involves the use of [1-^{13}C]-pyruvate and [^{13}C, $^{15}N_2$]-urea for simultaneous tumor perfusion and metabolic imaging [85]. The metabolic conversion rate of pyruvate indicates enzyme activity and transporter expression, whereas HP ^{13}C urea is a non-metabolically active extracellular probe that reflects tissue perfusion and distribution. The combination of these two probes can effectively explain changes in metabolism and perfusion during disease progression and treatment response.

PET is currently the preferred imaging method in clinical practice as it provides metabolic information through non-invasive analysis of cancer metabolism *in vivo*. This is achieved through the injection of ^{18}F-FDG[86]. Although PET is

useful for assessing glucose metabolism, it has limited ability to evaluate downstream metabolism, which can be important in many cases. However, HP ^{13}C-pyruvate MR can provide information about downstream metabolism. To obtain a complete picture of glucose metabolism, a combination of ^{18}F-FDG and [1-^{13}C] pyruvate methods can be used. Hansen *et al*[87] have demonstrated the feasibility of this approach through a technique called hyperPET, which shows the consistency between tumor ^{18}F-FDG uptake and [1-^{13}C] lactate production. Clemmensen *et al*[88] have also shown that combining [^{68}Ga]Ga-NODAGA-E[(cRGDyK)]$_2$ PET and HP [1-^{13}C]-pyruvate MR can enhance the ability of hyperPET to detect tumor angiogenesis. HyperPET is a promising tool for evaluating glucose metabolism direction in order to predict tumor occurrence and evaluate the malignancy degree of the tumor. It achieves this by describing the transformation of pyruvate into alanine, lactate, or entering oxidative phosphorylation in the body. While the complexity and high cost of hyperPET may seem impractical for routine use, advancements in MRI and PET-related technologies may make it a valuable tool for diagnosing liver cancer.

Recent advancements in HP MR have led to improvements in both efficiency and accuracy. The slow production of hyperpolarized pyruvate using DNP has been addressed with the MINERVA protocol, which has greatly facilitated the clinical translation of HP MR[89]. Additionally, quantification bias resulting from the use of surface transmit/receive coils has been addressed by Lee *et al*[90] through the development of a dedicated HP ^{13}C EPSI post-processing pipeline. This method has significantly improved the accuracy of measuring the pyruvate to lactate conversion rate in tumors and adjacent regions, with the average signal-to-noise ratio of pyruvate, lactate, and alanine increased by 37.4, 34.0, and 20.1 times, respectively.

MRI radiomics

The concept of radiomics was introduced by Lambin *et al*[91] in 2012. This method involves extracting features from conventional imaging at the tumor's overall level, providing a non-invasive, comprehensive, and quantitative observation of the tumor's temporal and spatial heterogeneity. Presently, MRI-based radiomics research in the liver primarily focuses on classification of liver fibrosis and hepatitis, liver cancer diagnosis, differentiation degree and immunohistochemistry prediction, and MVI evaluation.

MRI-based radiomics has shown promise in diagnosing and predicting hepatitis and liver fibrosis. While conventional MRI images can detect severe cases by observing changes in water content and distribution caused by inflammation, subtle tissue changes can prove challenging to diagnose. Radiomics technology can capture these tiny changes, allowing for more accurate diagnosis. Wei *et al*[92] proposed a grading system that simultaneously stages fibrosis and inflammation activity, with an AUC of 0.932 and 0.910 for diagnosing early-stage hepatitis and fibrosis, respectively. This study demonstrates the potential for radiomics to improve diagnosis and prediction of liver diseases. A novel technique, known as the dynamic image radiomics model, has been developed using deep learning technology to evaluate liver fibrosis. This method combines imaging features from multi-phase dynamic contrast-enhanced images with temporal features. It utilizes time-varying curves of contrast enhancement and imaging features during enhancement and eliminates manual selection bias by using an automated region of interest extraction method. Overall, compared with traditional radiomics methods and clinical serum parameters, the dynamic radiomics model has stronger predictive performance for various stages of liver fibrosis. The proposed liver fibrosis classification model is highly automated, saving time and effort. This model is significant in predicting new cases and training additional datasets[93].

Research has shown that MRI-based radiomics models are highly effective in distinguishing between HCC and non-HCC, with better discrimination efficiency than visual assessment by novice radiologists ($P < 0.05$)[94]. These models also have significant value in identifying high- and low-grade HCC. In a study by Ameli *et al*[95], radiomics features demonstrated strong differentiation ability in a multi-classification model, with an AUC of 0.83. This outperformed classification based solely on ADC or arterial-phase enhancement value, which had an AUC of only 0.75.

Moreover, research has shown that MRI radiomics features have good predictive efficacy for immunohistochemistry and molecular expression in HCC. For example, CK19+ HCC has higher invasiveness, higher lymph node metastasis rates, higher resistance to radiotherapy and chemotherapy, and poorer prognosis. Researchers have successfully constructed and validated a multi-sequence radiomics model for accurately identifying the CK19 status of HCC patients using multi-center MRI imaging data[96]. GPC3 is also associated with poor prognosis in HCC patients. Gu *et al*[97] developed a useful method for predicting GPC3 positive HCC patients without invasive procedures by combining AFP and radiomics features in a column chart. The tool showed significant predictive performance in both training and validation cohorts, with AUC values of 0.926 and 0.914, respectively. Additionally, radiomics features were found to be correlated with the protein level of the immunotherapy target programmed cell death ligand 1 (r = 0.41-0.47, $P < 0.029$) and the mRNA expression levels of programmed cell death 1 and cytotoxic T-lymphocyte-associated protein 4 (r = -0.48 to 0.47, $P < 0.037$)[98]. The findings of these studies indicate that utilizing a combination of multi-sequence MRI radiomics features can lead to precise classification of immunohistochemistry and molecular expression in liver cancer. This non-invasive approach can facilitate personalized management strategies for patients.

The use of MRI radiomics analysis can also provide a distinct advantage in preoperative diagnosis of MVI in liver cancer, as current diagnosis of MVI can only be made through postoperative histological examination. Feng *et al*[99] developed an MRI radiomics model for predicting preoperative MVI by extracting radiomics features from Gd-EOB-DTPA-enhanced MRI. The model's AUC, sensitivity, and specificity were 0.83, 90%, and 75%, respectively, which outperformed radiologists in predicting MVI. According to Liang *et al*[100]'s meta-analysis of 15 studies and 981 patients, MRI radiomics has a high accuracy in diagnosing MVI with an AUC of 0.87, sensitivity of 79%, and specificity of 81%. Based on our analysis, it can be concluded that the use of MRI radiomics for predicting MVI has a high level of accuracy. This non-invasive method can be considered as an alternative approach for evaluating MVI.

Table 1 Advanced magnetic resonance imaging techniques for liver diagnosis: Comparison of clinical applications, advantages, limitations, and developments

Technique(s)	Applications	Advantages	Limitations	Developments
DWI and IVIM	Assessment of liver tumors, diffuse liver lesions, and liver function. Assessment of liver or tumor blood perfusion	Evaluate liver or tumor blood perfusion without the use of contrast agents	Poor reproducibility of IVIM and DWI	2D *b*-M1 acquisition improves reproducibility. The new parameter PDR improves DWI performance
MRE	Diagnosis and staging of liver fibrosis and cirrhosis. Prediction of the recurrence of HCC	Diagnosis of liver fibrosis is not affected by obesity, ascites, inflammation, and etiology	The diagnostic threshold for fibrosis is variable and conflicting	The two-step strategy can screen for liver fibrosis. LS and TS can predict HCC recurrence
CEST	Assessment of tumor metabolism and microenvironment. Monitoring of tumor treatment response	An FDG substitute that does not involve ionizing radiation	Easily affected by other factors. Long scan time	The new reagent 3OMG has unique advantages. Realization of image-guided drug delivery and integration of tumor diagnosis and treatment
CE-MRI	Diagnosis and staging of liver tumors. Detection of liver metastases and diffuse liver lesions	Provides more information about lesions compared to plain MRI. Specific probes enable visualization at the molecular level	Gd chelates can cause allergic reactions and nephrotoxicity	Multi-target probes have the potential to overcome tumor heterogeneity. Potential applications of Mn-based contrast agents in targeted tumor therapy
MRS	Diagnosis and grading of fatty liver and liver fibrosis. Metabolic evaluation of liver and intrahepatic tumors	Provides quantitative data on liver metabolism non-invasively without the use of contrast agents	Low sensitivity of ^{13}C. Accuracy is affected by liver tissue heterogeneity and motion	Cho peak can provide more information. ^{31}P-MRS can differentiate liver cirrhosis etiology and evaluate IRI
HP MR	Providing metabolic, perfusion, and enzymatic information on HCC	DNP improves MR signal by 10000 times. [1-^{13}C] pyruvate has particular value in evaluating tumor metabolism	Current measurement methods still produce inevitable quantitative deviations	HyperPET is expected to elucidate complete glucose metabolism. More hyperpolarized probes are being used. Double-probe HP MR can simultaneously obtain metabolic and perfusion information
MRI radiomics	Diagnosis and prediction of immunohistochemistry features, MVI, liver fibrosis, and hepatitis.	Comprehensive, non-invasive, and quantitative observation of the spatiotemporal heterogeneity of tumors	Poor reproducibility of MRI features. MVI features are variable and conflicting in different studies	Good application value in the differential diagnosis, immunohistochemical feature prediction, and MVI prediction of HCC

CEST: Chemical exchange saturation transfer; CE-MRI: Contrast-enhanced magnetic resonance imaging; Cho: Choline; DNP: Dynamic nuclear polarization; DWI: Diffusion weighted imaging; HCC: Hepatocellular carcinoma; HP: Hyperpolarized; IRI: Ischemia-reperfusion injury; IVIM: Intravoxel incoherent motion; LS: Liver stiffness; MRE: Magnetic resonance elastography; MRI: Magnetic resonance imaging; MRS: Magnetic resonance spectroscopy; MVI: Microvascular invasion; PDR: Perfusion-diffusion ratio; TS: Tumor stiffness; PET: Positron emission tomography; FDG: Fluorodeoxyglucose; 2D: Two-dimensional.

The current limitation of MRI radiomics is the lack of reproducibility in extracting radiomics features. While previous studies have shown good interobserver reproducibility of HCC radiomics features from specific MRI systems, caution is needed when interpreting data in multi-platform radiomics studies as reproducibility can vary greatly between different platforms[101].

Additionally, there is variability and inconsistency in using MRI features to predict MVI in different studies. To combat this, Hong *et al*[102] conducted a meta-analysis of data from 36 studies involving 4410 participants. They identified seven MRI features, namely, large tumor volume, arterial edge enhancement, arterial tumor surrounding enhancement, hypointensity around the tumor in the hepatobiliary phase, irregular margins, multifocality, and low T1 signal, as important predictors of MVI in HCC. These MRI radiomics features are valuable references for future research and of great significance for developing more reliable MVI prediction strategies. Table 1 summarizes various novel MRI technologies' clinical applications, advantages, limitations, and latest developments discussed in this review for the diagnosis of liver diseases. Table 2 lists the diagnostic performance of some MR techniques for the diagnosis of liver diseases.

CONCLUSION

MRI is a promising technology for diagnosing liver diseases due to its non-invasive and radiation-free nature. The development of new technologies such as DWI, IVIM, MRE, CEST, MRS, HP MR, CE-MRI, and radiomics has expanded the capabilities of MRI, allowing for more comprehensive and accurate diagnostic results. Although these technologies have limitations, their role in liver disease diagnosis will continue to improve as they are updated and enhanced. It is important for researchers and clinical doctors to thoroughly study the application value of these new technologies in clinical practice to better guide the diagnosis, treatment, and rehabilitation of liver diseases and ultimately improve patient prognosis.

Table 2 Comparison of performance indicators of new magnetic resonance techniques in diagnosis of liver disease

Technique	Disease	Subjects	Sensitivity (%)	Specificity (%)	NPV (%)	PPV (%)	Ref.
DWI	HCC	34	54.8	90.9	34.5	95.8	[103]
DWI	LF	40	85	82	85	83	[104]
PDR	MT	83	81	77	NA	NA	[18]
MRE	LF	59	69.0	88.2	53.6	93.5	[105]
MRS	Liver steatosis	4715	72.7-88.5	92.0-95.7	NA	NA	[106]
Gd-EOB-DTPA MRI	HCC	77	88.2	96.7	90.6	95.7	[107]
SPIO MRI	HCC	30	66.0	98.0	91.4	90.0	[108]
MRI-PDFF	NAFLD	60	96	100	92.6	89.5	[70]
Radiomics	MVI	50	90	75	NA	NA	[99]
Radiomics	MVI	981	79	81	NA	NA	[100]

DWI: Diffusion weighted imaging; HCC: Hepatocellular carcinoma; LF: Liver fibrosis; MRE: Magnetic resonance elastography; MRI: Magnetic resonance imaging; MRI-PDFF: Magnetic resonance imaging proton density fat fraction; MRS: Magnetic resonance spectroscopy; MT: Malignant tumor; MVI: Microvascular invasion; NA: Not available; NAFLD: Non-alcoholic fatty liver disease; NPV: Negative predictive value; PDR: Perfusion-diffusion ratio; PPV: Positive predictive value; SPIO: Superparamagnetic iron oxide.

Abstract

Over the past decade, the advent of single cell RNA-sequencing has revolutionized the approach in cellular transcriptomics research. The current technology offers an unbiased platform to understand how genotype correlates to phenotype. Single-cell omics applications in gastrointestinal (GI) research namely inflammatory bowel disease (IBD) has become popular in the last few years with multiple publications as single-cell omics techniques can be applied directly to the target organ, the GI tract at the tissue level. Through examination of mucosal tissue and peripheral blood in IBD, the recent boom in single cell research has identified a myriad of key immune players from enterocytes to tissue resident memory T cells, and explored functional heterogeneity within cellular subsets previously unreported. As we begin to unravel the complex mucosal immune system in states of health and disease like IBD, the power of exploration through single-cell omics can change our approach to translational research. As novel techniques evolve through multiplexing single-cell omics and spatial transcriptomics come to the forefront, we can begin to fully comprehend the disease IBD and better design targets of treatment. In addition, hopefully these techniques can ultimately begin to identify biomarkers of therapeutic response and answer clinically relevant questions in how to tailor individual therapy to patients through personalized medicine.

Key Words: Single-cell omics; Inflammatory bowel disease; Crohn's disease; Ulcerative colitis; Single cell RNA-sequencing; Precision medicine

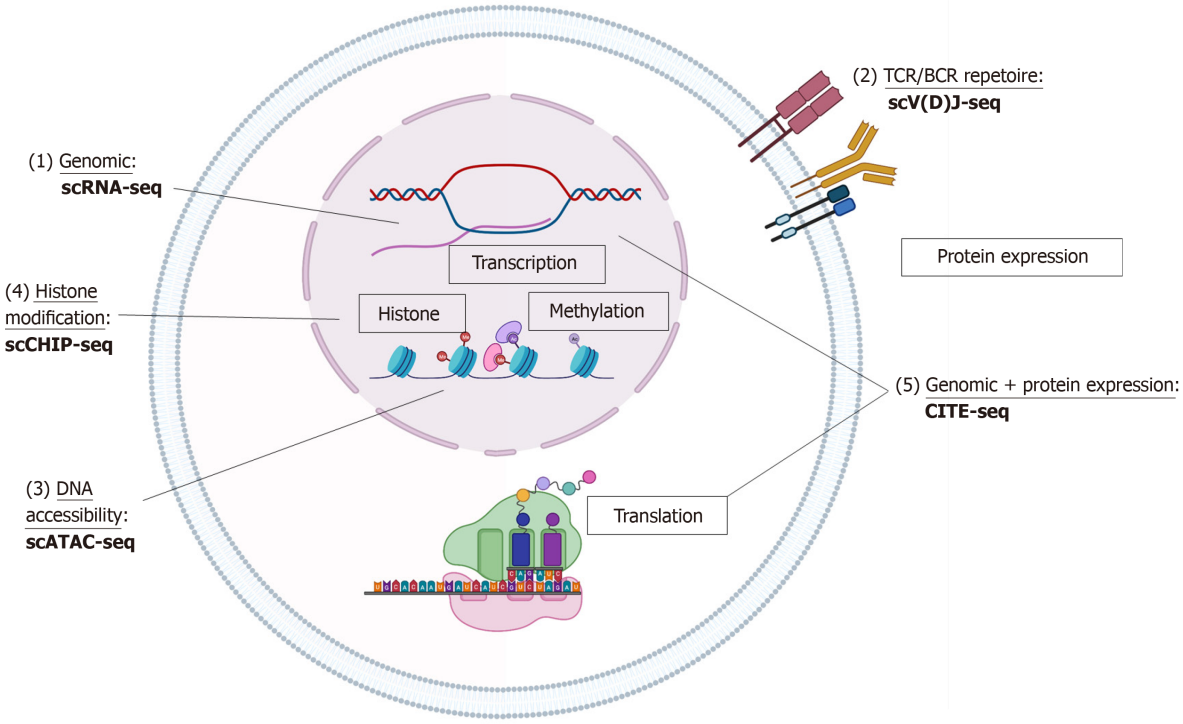
INTRODUCTION

The gastrointestinal (GI) tract houses a complex network of immune cells, cellular signaling, and intestinal flora. By balancing host tolerance and microbial defense response, the mucosal immune system of the GI tract performs constant surveillance and sampling of antigens and microbes to induce either tolerance or mounts a vigorous immune response to pathogens[1]. Intestinal inflammation and disease occur when this delicate balance breaks down leading to over activation of mucosal immunity and aberrant response to host antigen and commensal organisms[2]. Microscopic disruption of the epithelial barrier, over activation of proinflammatory cells, and the lack of regulatory mechanisms are some pathways that present in clinical chronic GI disorders and distinguishes mucosal immunity from systemic immunity.

The ability to detect pathogenic pathophysiology is rooted in the organ, the GI tract, and may be missed through studying the systemic immune system. In order to understand the target organ and mucosal immune system, technical advances have been made in the last few years giving us the ability to interrogate down to the microscopic single cell level, thus revolutionizing GI research. Since its inception in 2009, single cell RNA-sequencing (scRNA-seq) has enhanced our ability to comprehensively map and resolve cell types, cellular subsets, and cells states present in both healthy GI tissue and diseased states[3]. The novelty of single-cell technologies *vs* previous technologies such as bulk-sequencing is the ability to detect rare subsets of cells that may be the aberrant drivers of disease[4]. The homogeneity of bulk-sequencing lacks the capacity to decipher cellular heterogeneity and loses dimmer signals in rare subsets that may be important in disease pathogenesis[4,5]. The inherent advantage of single-cell techniques has led to its continued popularity in research. Here, we aim to review the single-cell technologies that have emerged over the last decade and its published applications to GI disease, namely in inflammatory bowel disease (IBD).

IBD which includes both ulcerative colitis (UC) and Crohn's disease (CD) is a chronic complex autoimmune condition characterized by inflammation of the GI tract. The pathogenesis of IBD is thought to develop from an inappropriate immune response towards self-antigens and commensal microbiota in a genetically susceptible host. The advent of scRNA-seq has led to a boom in the number of publications with the application of single cell techniques in IBD research [6,7]. As a disclaimer, this is by no means a comprehensive review of all single-cell studies or single-cell techniques available as the technology has massively expanded in the last few years and will continue to grow in popularity in years to come.



OVERVIEW OF AVAILABLE SINGLE-CELL TECHNOLOGY

scRNA-seq

With the commercialization of products and increasing user compatibility, scRNA-seq can be done using a variety of platforms and through multiple approaches (10 × Genomics, Fluidigm, BD Rhapsody, SmartSeq, *etc.*) whether with multiple well plates, microfluidics, or drop-seq[8,9]. Single-cell data sets can also be created from the 3′ end or 5′ end of mRNA. The basis behind the technology is partitioning individual cells with one uniquely barcoded mRNA-capture medium which has unique molecular code tag for each cell and its contained transcripts. The cell is then lysed and the mRNA is captured by these coded tags and each cell's mRNA is reverse transcribed into uniquely barcoded cDNA. cDNA libraries are amplified, indexed and sequenced using next-generation sequencing platforms (NextGen). Using the unique molecular code tags, the cDNA can be linked to the cell of origin and abundance of transcripts can be deciphered using the number of copies of the certain cDNA (Figure 1).

With large sets of data, bioinformatics analysis can be challenging. To perform this analysis, FASTQ files are generated from binary base call output from sequencing using software programs that then align the reads from the FASTQ files to a human reference genome/transcriptome using STAR[10]. Gene-cell matrices with principle component analysis can then be used to quantify transcripts of interest using standard workflows to give traditional visualization of single-cell datasets in the form of uniform manifold approximation and projection algorithms or T-distributed stochastic neighbor embedding plots (Figure 1).

In some cases, studies are interested not only in the current state of the cell but what the possible future of how the cell may develop ("pseudotime"). Software programs including Monocle[11] and Census[12] offer toolkits of computational bioinformatic programs specifically designed for the analysis of scRNA-Seq data to look at the temporal resolution of

transcriptome dynamics using unsupervised algorithms on scRNA-Seq data collected at multiple time points. Thes programs can be used to recover single-cell gene expression kinetics from a wide array of cellular processes, including differentiation, proliferation and oncogenic transformation to identify branching patterns in the cells. The algorithm finds the longest path through the minimum spanning tree, one that corresponds to the longest sequence of transcriptionally similar cells and produces a 'trajectory' of an individual cell's progress through differentiation that is expressed in units of pseudotime (Figure 1).

T cell receptor/B cell receptor: scV(D)J- seq

T cell receptor (TCR) and B cell receptor (BCR) drive a range of antigen specific adaptive immune responses to pathogens with large highly diverse repertoires to allow for recognition of antigens[9]. The advent of 5′ single-cell sequencing allows researchers to better understand lymphocyte diversity and antigen specificity or essentially the clonality of T and B cells present in disease states. The technique of TCR/BCR is similar to scRNA-seq but utilizes a specialized switch oligo nucleotides and poly dT tail primers[9]. Untemplated C (cytosine) nucleotides to the 3′ end will pair with the end of switch oligo and reverse transcription occurs to capture the TCR/BCR sequences[9]. cDNA libraries of TCR/BCR are created and sequenced per usual protocol (Figure 1).

Single-cell assay for transposase-accessible chromatin

The modification in gene expression through epigenetics can also be studied down to a single-cell level. Through epigenetics, although the DNA sequence is unaltered, expression patterns can be affected by DNA methylation or chromatin structure. DNA chromatic accessibility is maintained by regulatory elements such as transcription factors, DNA methylation, and histone modification where DNA is wound around into nucleosomes. Single-cell assay for transposase-accessible chromatin-seq (scATAC-seq) takes advantage of the Tn5 transposase which is a bacterial enzyme primed to find and cut open DNA positions[13]. Through scATAC-seq, cells are lysed and nuclei are harvested and then undergo transposition where open DNA fragments are "cut and tagged" with adaptors[13]. Single nuclei run through a similar process as the scRNA-seq mechanism to create barcoded cDNA and sequenced and mapped to reference genome and accessible chromatic regions. These peak calling reads can then be linked to areas such as promoters and enhancers. The distribution of reads across the whole genome, functional analysis the genes associated with the peaks, and peak distribution on functional gene elements can also be done with further analysis[13] (Figure 1).

Single-cell chromatin immunoprecipitation-seq

Single-cell epigenetics in the measurement of transcription factor binding and histone modification can also be studied through single-cell chromatin immunoprecipitation-seq. Generally, cells are encapsulated and lysed within the droplets and chromatin is fragmented. DNA barcodes and chromatin fragments are merged *via* the microfluidics device[14]. DNA

barcodes are ligated to chromatin fragments and droplets are then immunoprecipitated with antibody with a carrier chromatin and library construction[14] (Figure 1).

Single-cell cellular indexing of transcriptomes and epitopes

Cell cellular indexing of transcriptomes and epitopes-seq (CITE)-seq combines traditional protein marker detection (such as flow cytometry) with scRNA-seq to provide phenotypic information such as cell-surface protein expression with transcript information[15]. Antibodies are conjugated to oligonucleotides with antibody specific barcodes using streptavidin-biotin interaction and cells are processed per scRNAseq technique[15]. The cells are then lysed and the Oligo-dT primers capture the oligonucleotides and mRNA to create cDNA[15]. cDNA is then processed into libraries and sequenced (Figure 1).

SINGLE-CELL STUDIES IN IBD

UC

Kinchen *et al*[16] published a study describing the activation of intestinal mesenchymal cells subpopulations in adult human UC and dextran-sodium sulfate colitis murine models. Through scRNA-seq, the authors identified SOX6, CD142, and WNT expressing colonic crypt mesenchymal cells consisting of fibroblasts subsets that when dysregulated can lead to impaired epithelial function and inflammation driving the UC state[16]. The human colonic epithelial layer in the UC state is again studied by Parikh *et al*[17] with further identification of various progenitor cells, colonocytes, and goblets cell also implicated in states of inflammation. The authors go on to describe a new subset of absorptive BEST4+ colonocytes cells expressing proton channel OTOP2 and uroguanylin implicated in sensing intraluminal pH and dysregulated in UC. Goblet cell expression of antiprotease molecule WFDC2 was found to be vital in bacterial defense and tight junction barrier function[17]. The study utilized inflamed human UC tissue, adjacent human UC noninflamed tissue, and healthy colonic tissue, and interestingly, the transcripts upregulated in inflamed tissue was also found to be upregulated to a lesser degree in noninflamed UC tissue implying that scRNA-seq is able to detect disease activity prior to tissue level damage[17]. Similarly, Smillie *et al*[18] described the changing landscape of inflammation in human adult UC with inflamed and noninflamed tissues. In addition, the authors describe the potential cellular players in anti-tumor necrosis factor (TNF) resistance in oncostatin M expressing monocytes and fibroblasts, and expanded on an intracellular circuitry of diseased state involving inflammatory fibroblasts, inflammatory monocytes, microfold-like cells, and CD8/interleukin (IL)17 T cells[18]. Uzzan *et al*[19] provided the first expanded adaptive immunity studies of the application of scRNA-seq in mucosal and circulating B cell and plasma cell subsets in human UC. The authors found that B cell response was dysregulated in UC through peripheral gut-homing plasmablasts that correlated with disease activity and expansion of naïve B cells and immunoglobulin (Ig)G+ plasma cells along with auto-reactive plasma cell from inflamed UC tissue[19].

Boland *et al*[20] integrated scRNA-seq with scTCR-seq and scBCR-seq to describe cellular states and clonal relationships of mucosal and peripheral adaptive immune cells in human adult UC. The authors describe an increase in IgG 1+ plasma cells and increased colonic ZEB2 transcription factor regulatory T cells in colonic tissue and gamma delta T cell subset enrichment in the peripheral blood. Of note, the authors also saw a skew in heterogeneity of CD8+ tissue-resident memory T cells in inflamed UC tissue indicating potential pathogenic role of these tissue-resident memory T cells[20]. In the same year 2020, Corridoni *et al*[21] utilized scRNA-seq, scTCR-seq, and CITE-seq to examine the repertoire and cellular subsets of tissue-resident memory CD8+ T cells in human adult UC. The study describes the heterogeneity of CD8+ T cells as both destructive expanded effector type that leads to a disease state with TNF-alpha production and post-effector type that seem to act in a more regulatory fashion through IL-26 production[21]. These studies exemplify the power and unbiased nature of single-cell technologies to understand pathogenic signatures and signify the complexity of human disease states.

CD

Martin *et al*[22] published one of the first CD scRNA-seq data sets linking anti-TNF therapy resistance with a cellular module they entitled GIMATS which stands for IgG plasma cells, inflammatory mononuclear phagocytes, activated T cells, and stromal cells. Through utilizing resected inflamed terminal ileum from adult human CD patients who did not respond to anti-TNF therapy along with uninflamed samples, the authors identified this unique cellular signature to potentially eventually develop biomarkers in prediction of therapy response[22]. Jaeger *et al*[23] further looked at the T cell composition of the terminal ileum from adult human patients with CD and resected terminal ileums, distinguishing between lamina propria and epithelial layers. Within the epithelial layer, intraepithelial lymphocytes from inflamed tissue included specific NKp30+ gamma delta T cells that expressed ROR gamma which produced IL-26 with an increased in active T helper 17 (Th17) cells[23]. The lamina propria layer also found a Th17 signature with increased CD8+ cells implicating the Th17 pathway in CD[23]. Yokoi *et al*[24] further classified T cell subsets in CD to identify CD4+ tissue-resident memory T cells that were increased in CD that expressed CD161, CCR5, and CD103 using scRNA-seq and CyTOF. Rosati *et al*[25] used both bulk TCR repertoire and scRNA-seq on peripheral blood in CD samples to identify a subpopulation of unconventional Crohn-associated invariant T (CAIT) cells with a distinctly unique TCR. These peripheral CAIT cells seem to show a gene expression similar to cells of the innate immune system and mucosal associated invariant T cells and NKT cells and seem to be present in peripheral blood in CD rather than UC[25]. Maddipatla *et al*[26] describes a pediatric CD scRNA-seq data set from treatment naïve pediatric patients, established CD patients in remission, and refractory patients. Patients in remission showed elevated apoliprotein and globlet cell trefoil factor though not in refractory Crohn's[26]. Cellular subsets of enterocyte, goblet cells and BEST4+ enterocytes, microfold and

tuft cells see, to undergo changes from treatment naïve to established CD[26].

Both UC and CD

Huang *et al*[27] describes a pediatric cohort of patients with UC, Crohn's colitis, and undefined pediatric IBD using scRNA-seq, scTCR-seq, and scBCR-seq. The authors describe a common pathway of impaired cyclic AMP-response signaling in all three pediatric cohorts along with infiltration of PDE4B-expresing and TNF-expressing macrophages within the mucosal samples. The authors also describe a decreased abundance of CD39 expressing intraepithelial T cells along with platelet aggregation and release of 5-hydroxytryptamine at the mucosal level[27]. Futhermore, they demonstrated the ability to improve clinical symptoms of some of the pediatric patients with colitis and IBD by using a drug (phosphodiesterase inhibitor dipyridamole) that targeted the pathways identified in a pilot study[27].

Mitsialis *et al*[28] also reports a study with scRNA-seq to confirm their mass cytometry (CyTOF) findings in patients with UC and CD. Within both the CD and UC cohorts, the authors found an expansion of HLA-DR+CD38+ T cells, CXCR+ plasmablasts, and IL1B+ macrophages and monocytes[28]. Expansion of IL17A+CD161+ effector memory T cells and IL17A+ T regulatory cells along with HLA-DR+CD56+ granulocytes was found within the UC cohort. Within CD, IL1B+HLA-DR+CD38+ T cells, ILB+TNF+IFNG+ naïve B cells, and IL1B+ dendritic cells, and IL1B+ plasmacytoid dendritic cells were expanded in the mucosal samples. Expanded IL1B+ T regulatory cells, IL-B+ dendritic cells, IL1B+ plasmacytoid dendritic cells, and IL1B+ monocytes were found in the peripheral blood of patients with CD but not UC [28].

FUTURE DIRECTIONS FOR SINGLE-CELL RESEARCH IN IBD

The future of single-cell technologies within gastroenterology research is already here in the ability to perform single-cell multi-omics and spatial transcriptomic on the target organ (GI tract) and peripheral blood. The ability to multiplex single-cell technologies is in development and the ability to use them on clinical samples will lead to even further growth in the field of IBD. The ability to combine transcriptomics (scRNA-seq), epitopes, (protein expression), and chromatin accessibility (scATAC-seq) from single cells was described by Swanson *et al*[29] on peripheral blood using transcriptomics, epitopes, accessibility-seq. These multimodal single-cell assays may provide a novel way to uncover and link gene expression, gene regulation, and phenotypic gene expression within a single cell and begin to fully cover genotype with phenotype in specific diseases such as IBD.

Another exciting technique that is more readily available now is spatial transcriptomics where architectural information is preserved with intact tissue[30,31]. The position of cellular location and interaction continues to be present and cell to cell interactions can be further interrogated[30,31]. Cell and tissue function can be probed to understand potential pathogenic cells and culprits of inflammation rather than bystander immune cells may be a detailed way to understand IBD. At the same time, as the GI tract is an immune active organ, spatial transcriptomics may be a way to detect the invasive pathogenic variants without losing more delicate cells in the tissue dissociation process.

SINGLE-CELL OMICS IN OTHER GI DISEASES

Given the limited scope of this minireview, we have described these technologies only in the field of IBD and did not elaborate into its use in other GI disorders such as GI cancers and other GI diseases such as allergies of the GI tract. Spatial transcriptomics and various single-cell techniques have been successfully applied to colorectal cancers using the GI cancer tissue and resections allowing researchers to better understand the tumor microenvironment to derive better chemotherapeutic targets[32-36]. Allergic disease of the GI tract such as eosinophilic esophagitis is also under interrogation using single-cell technologies[37]. The ability to study tissue level molecular changes across multiple disease is unparallel using single-cell technologies.

LIMITATIONS

The limitation to single-cell technologies is most importantly cost of reagents and cost of sequencing[38]. The ability to integrate multiple single-cell data across multiple platforms and techniques is also a challenge as there are many commercial products out in the market[38].

CONCLUSION

Single-cell techniques and omics have taken off in the last few years and the ability to detect individual cellular transcript details has revolutionized the world of research. In the field of gastroenterology in just the last five years, several single-cell techniques have been applied to IBD research with the identification of novel cellular immune players in the pathogenesis of both UC and CD. As we continue to develop further immunological techniques, we may begin to detect signals of treatment response in IBD and tailor therapies to immune signatures present in disease state.

Abstract

Post-acute pancreatitis diabetes (PAPD) is the second most common type of diabetes below type 2 diabetes mellitus. Due to the boom in research on this entity carried out during the last decade, its recognition has increased. However, much of the medical community still does not recognize it as a medium and long-term complication of acute pancreatitis (AP). Recent prospective cohort studies show that its incidence is about 23% globally and 34.5% in patients with severe AP. With the overall increase in the incidence of AP this complication will be certainly seen more frequently. Due to its high morbidity, mortality and difficult control, early detection and treatment are essential. However, its risk factors and pathophysiological mechanisms are not clearly defined. Its diagnosis should be made excluding pre-existing diabetes and applying the criteria of the American Diabetes Association after 90 d of resolution of one or more AP episodes. This review will show the evidence published so far on the incidence and prevalence, risk factors, possible pathophysiological mechanisms, clinical outcomes, clinical characteristics and preventive and corrective management of PAPD. Some important gaps needing to be clarified in forthcoming studies will also be discussed.

Key Words: Acute pancreatitis; Diabetes mellitus; Chronic pancreatitis; Post-pancreatitis diabetes; Pancreatogenic diabetes

INTRODUCTION

Diabetes of the exocrine pancreas (DEP) derives from the dysfunction of the exocrine component of the pancreas. It is the second most common type of diabetes after type 2 diabetes mellitus (T2DM)[1]. Its incidence has tripled in the last decade, reaching annual incidence increase of 2.8%[2]. It is associated with higher mortality compared to T2DM[3].

Despite the fact that the relationship between diabetes and diseases of the exocrine pancreas has been known for long time, there have been few advances in the knowledge of the epidemiology and pathophysiological mechanisms of the DEP, which has made it difficult to establish a clear classification of this entity[4].

Terms such as pancreatic, pancreatoprive, pancreatogenic, postpancreatectomy diabetes, and others have been used for this condition. The term "type 3c diabetes" has been attributed to the American Diabetes Association (ADA). The truth is that this nomenclature was not assigned as such to the DEP, but adopted this name because it appeared within the group "other specific types of diabetes" in subsection c of group 3 in the 1998 publication of the ADA on the classification of diabetes. In addition, the use of the term "type 3c diabetes" was not promoted in 2019 guidelines of the ADA[5]. In order to avoid more confusion, the term "diabetes of the exocrine pancreas" has been used more frequently since 2017[6-8]. There is evidence that an increase in the accumulation of intrapancreatic fat around the pancreatic islets of Langerhans may have pathophysiological role in three of the most frequent types of DEP: Post-pancreatitis diabetes (PPD), pancreatic cancer-related diabetes, and cystic fibrosis-related diabetes, but not on T2DM and T1DM[9,10]. However, each of this type of diabetes has different pathophysiology, so it is appropriate to address them separately.

On the other side, the pancreatitis giving rise to diabetes can be acute or chronic, so it is reasonable to make distinction between both: Post-acute pancreatitis diabetes (PAPD) and post-chronic pancreatitis diabetes. A simplified core classification of DEP is shown in Table 1.

Acute pancreatitis (AP) is one of the most common gastrointestinal causes of hospital admissions worldwide, accounting for more than 275000 cases per year. The global incidence rate of AP is increasing[11]. Because AP is the most common disease of the exocrine pancreas nowadays, it is probably the most common cause of DEP. However, this complication has been ignored by most physicians who care for patients recovering from AP[1]. In the last decade, epidemiological, clinical, and translational research on PAPD has boomed, and some important aspects of this pathology are now more clearly known[12,13].

In this review, the evidences published so far on the incidence, risk factors, possible pathophysiology, clinical outcomes, clinical characteristics, and management of PAPD will be discussed. However, the knowledge of a large part of these aspects is still incomplete, so some important gaps will be pointed out which will have to be clarified in future research studies.

EPIDEMIOLOGY

AP is an inflammatory disease of the exocrine pancreas whose global incidence is 34/100000 inhabitants per year, with some geographical differences[14]. This condition has mortality rate from 1 to 2/100000 person-years[15]. Biliary lithiasis, alcohol abuse, endoscopic retrograde cholangiopancreatography, hypertriglyceridemia, and some drugs are the most common causes. On the other hand, 80% of patients have mild pancreatitis associated with few complications and short hospital stay. However, up to 20% of patients may have severe or necrotizing pancreatitis, giving rise to local and systemic complications, increased mortality and long hospital stay[16].

Studies in general population have shown that an episode of AP confers at least twice the risk of subsequent diabetes compared with controls[1]. Two meta-analyses published in 2014 and 2019[17,18], (with 31 studies and 13894 adult patients with no history of DM or prediabetes), evaluated the prevalence of diabetes after one or more episodes of AP. Only 3 were case-control and 28 were non-comparative prospective cohort studies. The cumulative pooled incidence for diabetes was 23% (95%CI: 16%-31%). The diabetes incidence was higher in the populations that had severe AP than in those with mild AP (39% *vs* 14%). The case-control studies and 12 cohort studies had significant methodological shortcomings (few patients, short follow-up or deficient methods for defining diabetes). In the 16 remaining best-quality

Table 1 Classification of diabetes of exocrine pancreas

Type of diabetes	Definition
Post pancreatitis diabetes	Diabetes identified in a patient with pancreatitis without previous detection of diabetes
Post-acute pancreatitis diabetes	Diabetes identified after one or more episodes of acute pancreatitis
Post-chronic pancreatitis diabetes	Diabetes identified in a patient with diagnosis of chronic pancreatitis
Pancreatic cancer related diabetes	Diabetes associated to pancreatic cancer in a patient without history of diabetes
Cystic fibrosis related diabetes	Diabetes associated to cystic fibrosis in a patient without history of diabetes

studies, an overall incidence of PAPD of 27.8% (range 8% to 54%), and of 38.4% (range 16%-54%), only in the severe forms, was found. The cumulative incidence of diabetes reached up to 41% in studies with at least 5 years of follow-up [19-34] (Table 2). The wide range in diabetes incidence of these studies may be due to differences in methodological design, patient selection, and diabetes diagnostic methods.

The time at which diabetes appears after AP is unknown[35]. A recent prospective study, which assessed the course of glycemia over months, reported that the proportion of patients who developed diabetes after an AP episode was 3% at 6 mo, 7% at 12 mo, 9% at 18 mo, and 11% at 24 mo[36] (Figure 1).

RISK FACTORS AND PREDICTORS

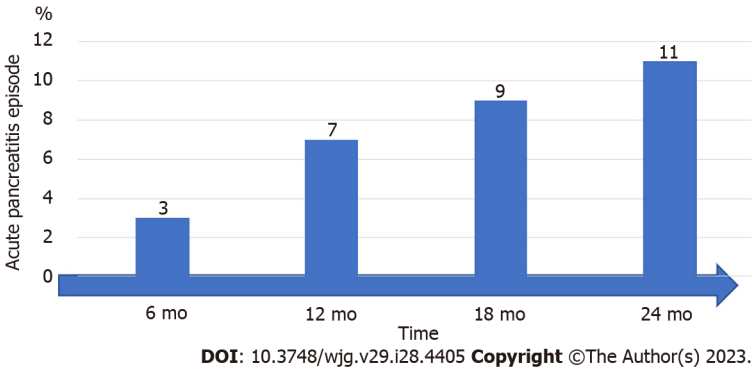
Some authors have not found association between the severity of AP and the incidence of PAPD[37-39], while others have found strong relationship[28,40-43]. A higher prevalence of PAPD was found in patients with severe AP than with mild AP in the most recent meta-analysis[18]. In another study, intensive care stay during the AP episode was associated with higher risk of developing diabetes in the 2 years after discharge[44]. The differences in the prevalence of PAPD in the severe forms shown in these studies could be explained, by the different definitions of severity and the diversity of scales used for assessing severity, such as Ranson, APACHE II, BISAP, or the Atlanta classification[45]. It seems that the strongest risk factors in the development of PAPD are pancreatic necrosis and recurrent episodes of AP[40,46]. For recurrent AP, one study evaluated computed tomography evidence of pancreatic volume loss in patients with a single episode of AP compared with recurrent pancreatitis. The investigators found that total pancreatic volume was significantly reduced in those with recurrent AP and these patients also had a strong association with endocrine and exocrine insufficiency[46]. Diabetes in patients with severe and recurrent AP may be due to structural damage of the β cells of the pancreatic islets. Nevertheless, it is important to highlight that the increased risk of diabetes also in patients with mild AP (without necrosis) suggests that there could be other mechanisms involved in its pathophysiology.

Other studies have shown that advanced age and male gender are significant risk factors[47]. Additionally, the alcoholic etiology of pancreatitis seems to increase this incidence[18]. On the other hand, some parameters of metabolic dysfunction, such as obesity and dyslipidemia, could be important risk factors, including genetic factors, particularly in patients with family history of DM.

In total, PAPD risk factors have been poorly or incompletely studied, mostly in retrospective studies with unclear defining parameters. However, the definition of risk factors is important to predict the incidence of diabetes in order to adopt an effective screening strategy of diabetes in patients who recover from AP, particularly in the mild form which is the most frequently seen. Specially designed prospective studies are required in order to clear this issue.

In the other side, some biological markers with the aim of predicting the development of PAPD have been investigated. One study found that elevated plasma levels of interleukin (IL)-1β and interferon γ in individuals with AP and normal glycemia may predict the onset of de novo diabetes during follow-up[48]. Another study found that elevated basal insulin and glucagon plasma levels were associated with de novo diabetes post AP (OR: 1.99 and 3.44 respectively)[49]. Another prospective, longitudinal cohort study found that the variability of glucose plasma levels in the early stages of AP may predict the development of diabetes at 2-year follow-up[50]. Although the results of these studies may appear promising, the research on this field is still very limited and these findings need to be validated before being used in clinical practice.

PATHOPHYSIOLOGY



The pathophysiologic relationship between AP and diabetes seems to be bidirectional[51]. On the one hand, patients with T1DM and T2DM have higher risk of developing AP, as demonstrated in a meta-analysis with 5.7 million participants and 14124 cases. Patients with diabetes had higher risk of AP than individuals without diabetes (HR: 1.74)[52]. Likewise, other studies have reported that patients with diabetes develop more severe AP[42].

Despite it is accepted that AP can give rise to diabetes, the pathophysiological mechanisms are still unknown. In necrotizing AP, diabetes may be attributed to structural damage of pancreatic parenchyma. However, in the mild AP the involved mechanisms are less clear. Overall, it has been hypothesized that the pathophysiology of PAPD may be multifactorial, involving diverse mechanisms that could have effect at different levels of the glucose metabolism

Figure 1 Trajectory of glycemia after at least one episode of acute pancreatitis.

regulation pathways. It may be possible that one or more of these mechanisms may predominate in the different diabetes phenotypes. According to some evidence collected so far, some of the possible mechanisms are discussed in the following sections (Figure 2).

Pancreatic necrosis

This complication of AP has already been discussed previously in the above sections[28,40-42,53,54]. In a recent meta-analysis, patients who displayed pancreatic necrosis during the AP attack(s) had a higher frequency of diabetes than those without necrosis (37% *vs* 11%)[18]. In other series, the incidence exceeds 50% of the cases[29]. Notwithstanding, the relation between diabetes incidence and the extension and site of necrosis has not been completely defined. In a recent study with 109 patients with AP the incidence of de novo diabetes in patients with pancreatic necrosis demonstrated by contrasted computed tomography scan was higher (66.6%) than in those without necrosis (27.8%). However, no relationship was found between diabetes incidence and necrosis rate or site of necrosis (head, body or tail of pancreas)

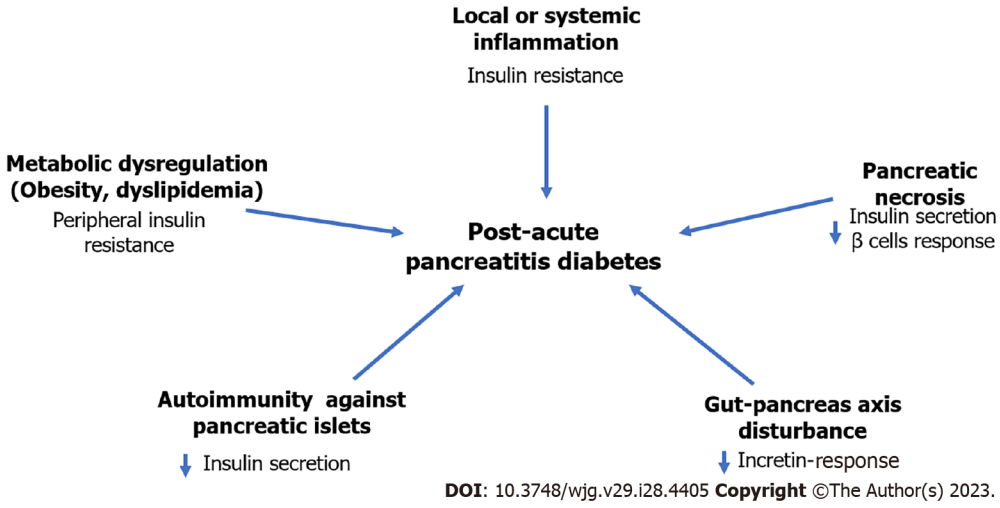

Figure 2 Possible mechanism involved in the pathophysiology of post-acute pancreatitis diabetes.

[26]. This may be explained because diabetes may be due, in addition to destruction of β cells of the pancreas, to insulin resistance. And also, because β cells are located homogeneously in the different segments of the pancreas.

Pancreatic necrosis may also induce exocrine pancreas insufficiency (EPI). From 15 to 30% of patients who have an episode of AP may have chronic pancreatitis after 3 years of follow-up[47].

Autoimmunity against β cells and other components of Langerhans islets

It has been speculated that the local and systemic inflammatory response occurring in AP patients may result in post-translational modifications of endogenous islet cell proteins, such as insulin, nucleic acids, and other proteins. Such modified neoepitopes may act as autoantigens, inducing an autoimmune response against components of the Langerhans islet[55]. To date, the frequency of autoimmunity during and after an AP episode has not been evaluated, particularly in patients who develop de novo diabetes.

Metabolic dysregulation

Obesity and hypertriglyceridemia are risk factors for the development of both T2DM and AP[56,57]. Their presence prior to AP may result in greater risk of developing diabetes and may accelerate the onset of this condition. Both factors are independently associated with increased risk of clinical severity of AP, which could explain the risk of diabetes[58,59]. In fact, hypertriglyceridemia is one of the most frequent causes of AP, only below biliary and alcoholic etiology. The impact that visceral obesity may have is unknown. However, there is evidence that increased accumulation of intrapancreatic fat around the islets of Langerhans may have pathophysiological role in acute and chronic PPD[9,10]. Insulin resistance may be the mechanism in these patients[60].

Local and systemic inflammatory response

During the course of AP, serum IL-6 levels increase as a consequence of the local and systemic inflammatory response. It has been hypothesized that this and other cytokines could favor the development of chronic hyperglycemia[61]. Multiple studies have found that the role of IL-6 on impaired glucose metabolism is primarily through insulin resistance[62,63].

Disturbance of the gut-pancreas axis

It has been suggested that of some of the pancreatic and intestine functional interconnections involved in the digestion, absorption, and utilization of nutrients which regulate glucose homeostasis may be disturbed in PAPD[53]. This assertion is based on the fact that 15% to 30% of patients who have AP show chronic pancreatitis 3 years after the acute episode[47,64]. The most common endocrine dysfunction results from decreased levels of insulin, glucagon, and pancreatic polypeptide[65]. Impaired secretion of enteral glucoregulatory hormones (incretins secreted by intestinal epithelium cells), such as glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide 1 (GLP-1) may also be observed. These peptides are associated with increased insulin secretion, glucagon secretion modulation and reduction of hepatic and peripheral insulin resistance[66]. It is important to underline that the reduction of glucagon secretion is the cause of severe hypoglycemia due to the loss of its counter-regulatory effect[67]. Therefore, the combined hormonal abnormalities that occur in PAPD result in a severely disrupted endocrine environment that is different from the pattern of abnormalities seen in T1DM or T2DM. Hence the need to understand and recognize these entities separately.

In summary, it is essential to determine the relative contribution of each of these pathophysiological mechanisms involved in PAPD, as well as their interrelationship with the possible genetic predispositions. In order to clarify this important issue, both clinical and basic studies in experimental models of PAPD are needed due to the difficulty in obtaining tissue samples from human beings.

DIAGNOSIS

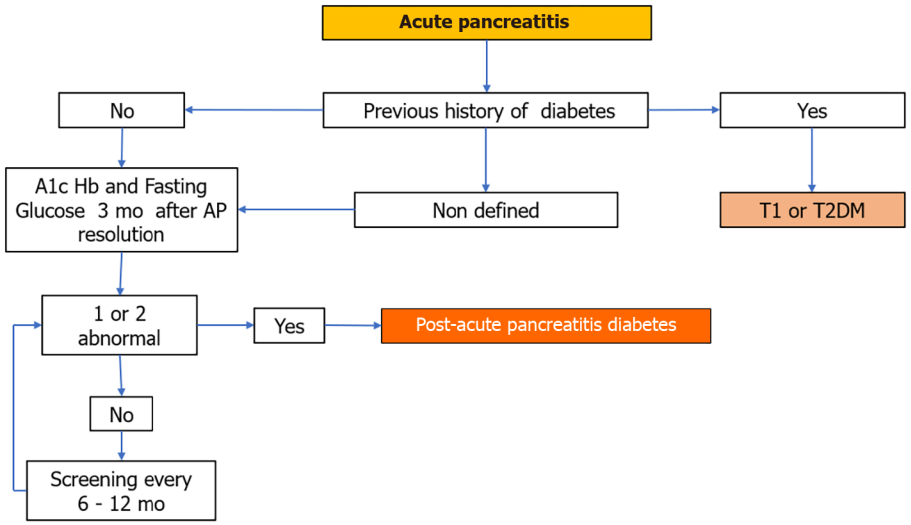
For stablishing the diagnosis of PAPD it is important to rule out preexisting diabetes (mainly T2DM) which sometimes is difficult. The diagnostic criteria for PAPD proposed some years ago that included the demonstration of EPI as well as the absence of autoantibodies directed against β cells of the pancreas are not currently valid[68,69] because only 30% of patients show evidence of EPI 3 years after AP[64,70]. In addition, patients who develop EPI have increased risk of diabetes[71], so it should be considered as a risk factor and not as its defining characteristic. On the other hand, early and intermediate stages of EPI are difficult to demonstrate as functional tests and sophisticated imaging techniques are often not available in real life practice and are costly. In total, the term PAPD should be reserved specifically to de novo diabetes in individuals after AP with or without morphological or functional evidence of chronic pancreatitis and without the need to demonstrate the absence of anti-β cell antibodies.

The diagnosis of diabetes should be established based on the criteria recommended by the ADA: Glycosylated hemoglobin (HbA1c) ≥ 48 mm/moL or 6.5% and/or fasting glucose > 7 mmmol/L or 126 mg/dL[72], which must be performed more than 90 d after AP resolution. This is important because HbA1c levels reflect the mean plasma glucose concentration in the previous 8-12 wk and also due to the stress hyperglycemia that can occur before this period. It has been shown that the oral glucose tolerance test is better for detecting early-stage diabetes as it is not affected by stress and does not require 90 d to give reliable results.

Some clinical characteristics and biochemical markers can help to differentiate PAPD from T2DM. PAPD has greater glycemic variability and more difficult control, showing frequent hypoglycemic episodes and more insulin requirements [73]. From the biochemical point of view, PAPD patients have lower baseline and stimulated levels of insulin, glucagon and C-peptide[1]. Besides, pre and postprandial serum levels of oxyntomodulin (an intestinal peptide derived from proglucagon that participates in the regulation of the pancreatic exocrine function), have been found to be significantly higher in patients with PAPD compared to T2DM and healthy controls. This opens the possibility of being used as a specific biomarker[74]. For some, the presence of diagnostic autoimmune markers for T1DM (*i.e.*, islet cell antibodies or antibodies against glutamic acid decarboxylase, insulin, tyrosine phosphatase-like proteins, or zinc transporter)[75], rules out the diagnosis of PAPD. However, as already mentioned, an autoimmune component triggered by neoepitopes induced by the systemic inflammatory response of AP at the level of the β cells has not been ruled out as patho-physiological mechanism of PAPD in some patients[55]. Finally, it is also important to identify overlapping causes of DEP such as pancreatic surgery, cystic fibrosis, toxic pancreatic medications, hemochromatosis, and pancreatic cancer.

In summary, the diagnosis of PAPD should be based on the exclusion of any type of preexisting diabetes before AP and on identification of diabetes ninety days after AP based on the ADA criteria. For now, screening for PAPD should be performed in all patients who have had at least one episode of AP. The knowledge of the risk factors will contribute to selecting patients for screening in the future. Although there is no consensus on the frequency of screening, it is recommended to be carried out every 6 mo the first year and every year thereafter. Figure 3 shows a simplified PAPD diagnostic algorithm.

COMPLICATIONS



It has been demonstrated that PAPD has higher short- and long-term morbidity and mortality than T2DM[3]. A recent population-based study of 139843 individuals showed that those with PAPD had significantly higher risk of pancreatic cancer than those with T2DM or those with no history of pancreatitis (adjusted RR: 6.94; $P < 0.05$)[76]. It is important to underline that in patients recovering from AP, diabetes may be the clinical manifestation of pancreatic cancer, so early detection strategies for these neoplasms should be applied. Another recent study with 10549 individuals showed that patients with PAPD, compared to T2DM, had higher all-cause mortality (RR: 1.13), cancer (RR: 1.14), infections (RR: 2.52), and gastrointestinal disease (RR: 2.56). Likewise, the risk of rehospitalizations was significantly higher, which represented greater economic burden[77].

MANAGEMENT

The data so far available regarding the treatment of PAPD are very scarce, however, some rationale may be useful to guide treatment decisions with the understanding that refinement will be required based on the results of well-conducted future therapeutic studies. The management of PAPD should ideally be preventive and corrective.

Preventive management aims to reduce the incidence of diabetes which would be achieved if the risk factors and predictive clinical and biochemical markers were clearly known. It seems that pancreatic necrosis and recurrent episodes of AP are the most solid risk factors. Possibly in patients with these complications a more aggressive and earlier management of AP, the performance of early cholecystectomy in biliary AP and stopping alcohol consumption could have some beneficial impact. In this context, well-conducted studies are required in order to demonstrate this issue.

For corrective management it is suggested to apply the ADA recommendations for the treatment of T2DM and T1DM with some nuances[78]. It is important to be aware of the fragile stability of glycemia of these patients. This leads that a large part of patients be treated with insulin. In a large population-based study, higher proportion of patients with PAPD were already on insulin therapy within 5 years compared to T2DM (20.9% *vs* 4.1% respectively), and had poorer glycemic control (defined as HBA1c ≥ 7%)[1].

Figure 3 Simplified algorithm for the diagnosis of post-acute pancreatitis diabetes. AP: Acute pancreatitis; T2DM: Type 2 diabetes mellitus.

It is important to remember that about 30% of patients with AP develop EPI[70]. At this point, one study reported increased postprandial responses of GLP-1 and GIP in patients with chronic pancreatitis and EPI following pancreatic enzyme substitution (PES). Concurrently, both plasma insulin, plasma C-peptide, and total insulin secretion increased after PES. These results suggest that secretion of GLP-1 and GIP is under influence of the digestion and absorption of nutrients in the small intestine and that PES increased insulin secretion[66]. Concomitant improvement of glycemic control was not assessed in diabetic patients from this study. As a result of these findings, the assessment of therapeutic effects of PES from the early stages of diabetes development may be warranted.

Finally, the management of PAPD is complex and requires a common approach, preferably by a medical team that includes gastroenterologists, endocrinologists, primary care physicians, nutritionists, and behavioral health specialists.

CONCLUSION

PAPD is currently the second most common type of diabetes. It is increasingly known as a result of the recently published research around this entity. However, much of the medical community still ignores its existence. With the increasing global incidence of AP, the frequency of this type of diabetes will certainly increase.

Due to its high morbidity, mortality and difficult treatment, its recognition as a complication of AP is of paramount importance. Pancreatic necrosis and recurrence seem to be the strongest risk factors. Its pathophysiological mechanisms and other risk factors are not yet clearly known. The diagnosis should be based on the exclusion of any type of preexisting diabetes and on identification of diabetes ninety days after AP based on the ADA criteria. Screening for diabetes should be performed in all patients who have had at least one episode of AP. Management is not yet standardized.

It was recently announced the launch of a multicenter clinical study designed to understand the frequency and phenotypes of this type of diabetes. This study has been called Diabetes RElated to Acute Pancreatitis and its Mechanisms and is supported by The National Institute of Diabetes and Digestive and Kidney Diseases[79]. In this research project, it is planned to study risk factors and some of the mechanisms possibly involved in the pathophysiology of PAPD[80-82].

Certainly, the results of this and other similar forthcoming studies will contribute to the clarification of some important gaps that still persist in the knowledge of PAPD making possible a more effective screening and better preventive and corrective management.

Abstract

BACKGROUND

The association between diabetes mellitus (DM) and the increased risk and progression of cholangiocarcinoma (CCA) has been reported with unclear underlying mechanisms. Previous studies showed that γ-aminobutyric acid (GABA) B2 receptor (GABBR2) was upregulated in CCA cells cultured in high glucose (HG) conditions. Roles of GABA receptors in CCA progression have also been studied, but their association with DM and hyperglycemia in CCA remains unclarified.

AIM

To investigate the effects of hyperglycemia on GABBR2 expression and the potential use of GABBR2 as a CCA therapeutic target.

METHODS

CCA cells, KKU-055 and KKU-213A, were cultured in Dulbecco Modified Eagle's Medium supplemented with 5.6 mmol/L (normal glucose, NG) or 25 mmol/L (HG) glucose and assigned as NG and HG cells, respectively. GABBR2 expression in NG and HG cells was investigated using real-time quantitative polymerase chain reaction and western blot. Expression and localization of GABBR2 in CCA cells were determined using immunocytofluorescence. GABBR2 expression in tumor tissues from CCA patients with and without DM was studied using immunohistochemistry, and the correlations of GABBR2 with the clinicopathological characteristics of patients were analyzed using univariate analysis. Effects of baclofen, a GABA-B receptor agonist, on CCA cell proliferation and clonogenicity were tested using the MTT and clonogenic assays. Phospho-kinases arrays were used to screen the affected signaling pathways after baclofen treatment, and the candidate signaling molecules were validated using the public transcriptomic data and western blot.

RESULTS

GABBR2 expression in CCA cells was induced by HG in a dose- and time-dependent manner. CCA tissues from patients with DM and hyperglycemia also showed a significantly higher GABBR2 expression compared with tumor tissues from those with euglycemia ($P < 0.01$). High GABBR2 expression was significantly associated with a poorer non-papillary histological subtype but with smaller sizes of CCA tumors ($P < 0.05$). HG cells of both tested CCA cell lines were more sensitive to baclofen treatment. Baclofen significantly suppressed the proliferation and clonogenicity of CCA cells in both NG and HG conditions ($P < 0.05$). Phospho-kinase arrays suggested glycogen synthase kinase 3 (GSK3), β-catenin, and the signal transducer and activator of transcription 3 (STAT3) as candidate signaling molecules under the regulation of GABBR2, which were verified in NG and HG cells of the individual CCA cell lines. Cyclin D1 and c-Myc, the common downstream targets of GSK3/β-catenin and STAT3 involving cell proliferation, were accordingly downregulated after baclofen treatment.

CONCLUSION

GABBR2 is upregulated by HG and holds a promising role as a therapeutic target for CCA regardless of the glucose condition.

Key Words: Baclofen; Cholangiocarcinoma; Diabetes mellitus; Drug repurposing; Hyperglycemia; Gamma-aminobutyric acid

Core Tip: Diabetes mellitus is associated with an increased risk and progression of cholangiocarcinoma (CCA). The γ-aminobutyric acid (GABA) B2 receptor (GABBR2) was upregulated in CCA cells cultured in high glucose and in CCA tissues from patients with hyperglycemia. High GABBR2 expressions were significantly correlated with a non-papillary histotype and smaller sizes of CCA tumors. The treatment of baclofen, a GABA-B receptor agonist, significantly suppressed CCA cell proliferation and clonogenicity, suggesting that GABBR2 is a potential target for CCA treatment. Baclofen inhibited multiple kinases and signal transducers in CCA, resulting in downregulated downstream target proteins involving cell proliferation and suppression of CCA cell growth.

INTRODUCTION

Diabetes mellitus (DM) is a global public health problem, and its incidence is increasing every year[1]. The associations between DM and cancers have been recognized for decades from epidemiological observations[2,3]; however, the molecular mechanisms underlying the linkage are not fully elucidated. Liver cancers, including hepatocellular carcinoma and cholangiocarcinoma (CCA), are among the high-risk malignancies developing in patients with DM[4-6]. DM is not only associated with an increased risk of CCA but also associated with a poor survival of patients who have a poorly controlled blood glucose level[7]. Individuals with DM infected with *Opisthorchis viverrine* (*O. viverrini*), a carcinogenic liver fluke, are at a greater risk of developing CCA compared to those either with liver fluke infection or having DM alone[8]. The hamster CCA carcinogenesis model also showed that hamsters with DM and *O. viverrini* infection had more hepatic morbidities compared with those infected with *O. viverrini* or having DM alone[9]. CCA once developed, itself, has a poor prognosis, and the 5-year survival rate of all types is approximately 10%[10]. The attempts to investigate novel medications, *e.g.*, targeted therapy[11] or immunotherapy[12-14], reported limited efficacy or benefit for a particular population. Other underlying factors of patients have been reported to influence the progression of CCA. In line with this, the study in patients with CCA who have DM also reported that DM is associated with a shorter overall survival and is an independent prognostic factor for patients with CCA[7].

Previous studies by the current authors found that diabetogenic glucose concentration is a promoting factor for CCA aggressiveness[15,16]. High glucose (HG) promotes CCA proliferation and metastatic potential by regulating several signaling pathways, such as the signal transducer and activator of transcription 3 (STAT3)[15,17] and the nuclear factor-kappa B pathways[18]. HG also promotes cell cycle progression by enhancing cell cycle machinery proteins, namely, cyclin D1, cyclin E, cyclin A, and cyclin-dependent kinase 2, suggesting potential targets for CCA treatment in patients with DM[19]. Transcriptomic analysis of CCA cells cultured in HG *vs* normal glucose (NG) also showed several potential targets for CCA under diabetogenic glucose conditions. Among the top 5 upregulated genes, γ-aminobutyric acid (GABA) B2 receptor (GABBR2) is one of the promising therapeutic targets that are striking[18]. Given that GABBR2 is upregulated in CCA cells cultured in HG, and both agonist and antagonist of this receptor are clinically available, GABBR2 is thus a great potential target for drug repurposing for CCA treatment.

GABBR2 is a G-protein coupled receptor for GABA, an inhibitory neurotransmitter abundantly found in the central nervous system[20-22]. GABBR2 is also expressed in the gastrointestinal tract and is speculated to be important for the differentiation of several gastrointestinal epithelial cells[23,24], including cholangiocytes[25]. The roles of GABBR2 outside the central nervous system, however, are not fully understood. As a G-protein coupled receptor, GABBR2 can interact with various adaptor proteins and then signal the different downstream pathways[23]. Previous studies in CCA tissues showed that only the GABA-B receptor was differentially expressed between CCA cells and adjacent normal cholangiocytes among all subtypes of receptors (GABA-A, GABA-B, and GABA-C receptors)[26], suggesting its potential as a therapeutic target. Treatment of CCA cells with GABA showed the suppression of growth and invasive ability[26-28]. Which GABA-B receptor subtypes are responsible for the suppression of CCA aggressiveness, however, remains unclear. In contrast, in some cancers, GABA exerted pro-tumor effects on cancer cells[29], and activating the GABA-B receptor can promote the migration of cancer cells[30]. These controversial findings and the finding that HG enhanced the expression of GABBR2 in CCA cells have led to the investigation of the roles of GABBR2 in CCA under diabetic conditions. Discovering the significance of GABBR2 in CCA, especially in patients with DM, might suggest the opportunities to improve the therapeutic outcome of CCA by repurposing GABA-B receptor agonists available in clinical practice.

MATERIALS AND METHODS

CCA tissues and clinicopathological data

CCA tissues were obtained from patients who underwent surgical resection at Srinagarind Hospital, Faculty of Medicine, and archived at the Cholangiocarcinoma Research Institute, Khon Kaen University. Clinical and pathological data, including preoperative fasting blood glucose (FBG) and diabetes status, were retrieved from the medical records of Srinagarind Hospital. Patients with DM and preoperative FBG ≥ 126 mg/dL were defined as having DM, while those who had FBG < 126 mg/dL were defined as having no DM[31]. Written informed consent was obtained from all participants. The protocol of the study has been reviewed and approved by the Khon Kaen University Ethics Committee for Human Research (approval No. HE641441), based on the Declaration of Helsinki and the ICH-Good Clinical Practice Guidelines.

CCA cell lines and cell culture

CCA cell lines, KKU-055 and KKU-213A, were established from Thai CCA patients[32] and obtained from the Japanese Collection of Research Bioresources Cell Bank (Osaka, Japan). Cells were cultured in Dulbecco Modified Eagle's Medium (DMEM, Gibco, Carlsbad, CA), supplemented with 10% fetal bovine serum (Gibco) and 1% antibiotic-antimycotic (Gibco). Cells were cultured in DMEM containing 5.6 mmol/L glucose (NG) and 25 mmol/L (HG) for at least 5 passages and assigned as NG and HG cells, respectively[15,18]. Cells were subcultured when the confluence reached 80%. HG-induced GABBR2 expression was done by sequentially culturing NG cells in DMEM with 5.6, 15, and 25 mmol/L glucose for at least 5 passages, and cell lysates were collected timely for the experiments.

Reverse transcription-quantitative polymerase chain reaction

Reverse transcription-quantitative polymerase chain reaction (RT-qPCR) was used to determine GABBR2 mRNA expression in CCA cells. Confluent CCA cells were lysed using TRIzol (ThermoFisher Scientific, Waltham, MA), and RNA extraction was performed according to the manufacturer recommendations. Total RNA was reverse-transcribed using the MultiScribe Reverse Transcriptase Kit (ThermoFisher Scientific) and qPCR was performed using LightCycler® 480 System (Roche Diagnostics, Rotkreuz, Switzerland). Primers for GABBR2 are: Forward, 5′-TGGAGGCGTCT-GTCCATCCGT-3′ and reverse, 5′-GTCTTGCGTCAGCGTGCCCA-3′. β2-microglobulin was used as the internal control, and the primer sequences are: Forward, 5′-AAGATGAGTATGCCTGCCG-3′ and reverse, 5′-CGGCATCTTCAAACCTCC-3′.

Sodium dodecyl sulfate-polyacrylamide gel electrophoresis and western blot analysis

Primary antibodies used to detect the proteins by western blot were: GABBR2 (1:500, Proteintech, Rosemont, IL), pSTAT3 (Y705) (1:500, Cell Signaling Technology, Danvers, MA), pSTAT3 (S727) (1:500, Cell Signaling Technology), STAT3 (1:1000, Cell Signaling Technology), p-glycogen synthase kinase 3 (GSK3)α/β (1:1000, Cell Signaling Technology), GSK3α /β (1:1000, Cell Signaling Technology), β-catenin (1:1000, Cell Signaling Technology), cyclin D1 (1:1000, Cell Signaling Technology), c-Myc (1:500, Santa Cruz Biotechnology, Dallas, TX), and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (1:10000, Millipore Sigma, Burlington, MA).

Cell lysates were collected in radioimmunoprecipitation assay (RIPA) lysis buffer containing protease inhibitor (Sigma Aldrich, St. Louis, MO) and phosphatase inhibitor (Sigma Aldrich, St. Louis, MO). NG and HG cells of both cell lines were lysed after culture in their respective media at 72 h after incubation for determination of GABBR2 expression. Cells treated with baclofen (Sigma) were collected in the lysates at 24, 48, and 72 h after incubation with the drug. Total proteins (20 μg/well) were electrophoresed on a 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis and transferred to Amersham-Hybond® polyvinylidene fluoride membrane (GE Healthcare, Buckinghamshire, United Kingdom). After blocking with 5% skim milk in Tris-buffered saline with 0.1% Tween-20 for 1 h at room temperature, the membranes were then incubated with the primary antibodies at 4 °C overnight, followed by incubation with horseradish peroxidase-conjugated secondary antibodies for 1 h at room temperature. Enhanced Chemiluminescence kit (Millipore Sigma, Burlington, MA) was applied to develop the signals, which were detected using ImageQuant® LAS 400 (GE Healthcare, Uppsala, Sweden). Band intensities of proteins were quantified using Image J (National Institute of Health, Bethesda, MD), in which the intensities of GAPDH were used as the loading controls.

Immunocytofluorescence

CCA (NG and HG) cells were seeded into 48 well plates at a density of 5000 cells/well and incubated for 72 h. After removing media and washing with phosphate-buffered saline, cells were fixed using 4% paraformaldehyde for 30 min at room temperature, and non-specific antigens were blocked using 5% skim milk. Anti-GABBR2 antibody (1:200) was then incubated at 4 °C overnight, and Alexa-Fluo-488 conjugated secondary antibody (Invitrogen, Waltham, MA) was applied and incubated at room temperature for 1 h. Fluorescent signals were detected using a fluorescent microscope (Nikon Ti-U Inverted Fluorescence Microscope, 20X) using NIS-Elements imaging software. Mean fluorescent intensities were calculated using Image J (National Institute of Health).

Immunohistochemistry

Immunohistochemical staining for GABBR2 was performed according to the standard immunohistochemistry protocol. Briefly, paraffin-embedded formalin-fixed CCA tissues (6 μm thickness) were rehydrated using serial-graded ethanol. Antigens were retrieved by heating the sample in 0.1 M citrate buffer (pH = 6.0) in a pressure cooker for 5 min. Endogenous peroxidase was blocked using 3% H_2O_2 in methanol, and non-specific antigens were blocked using 1% fetal bovine serum (Gibco). CCA tissues were then incubated with anti-GABBR2 antibody (1:100, Abcam, Cambridge, MA) at room temperature overnight in a moisture chamber. In the DAKO EnVision™ + System, horseradish peroxidase-conjugated secondary antibody (Dako, Carpinteria, Denmark) was then applied and further incubated at room temperature for 1 h. The signals were developed using 3,3′-diaminobenzidine (DAB, Sigma, St. Louise, MO) and graded as the IHC index (intensity × frequency; where intensity: No staining = 0, mild = 1, moderate = 2, strong =3; and frequency: 0% = 0, 0%-25% = 1+, 25%-50% = 2+, > 50% = 3+), by two researchers (CS and SaS). Microscopic photographs were obtained using Nikon NIS-Elements software (Nikon, Tokyo, Japan). High and low expression of GABBR2 in CCA tissues was classified by using a median score of IHC index as a cut-off point.

Baclofen treatment and proliferation assay

CCA (NG and HG) cells (1 x 10^3 cells/well) were seeded into 96 well plates and incubated overnight, and then cells were incubated with complete media containing varied concentrations of baclofen (Sigma), a GABA-B receptor agonist, for 72 h. Then, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT, Invitrogen, Carlsbad, CA) was added at a final concentration of 0.5 mg/mL and further incubated for 4 h in a 37 °C incubator. Formazan crystals were dissolved in dimethyl sulfoxide, and OD540 was measured using a microplate reader (Tecan, Männedorf, Switzerland).

To determine the possible time-dependent effect of the GABA-B receptor agonist, NG and HG cells of KKU-055 were incubated with 1000 μM baclofen, and KKU-213A cells were incubated with 800 μM baclofen for 24, 48, and 72 h. MTT assay was then performed at each time point to determine the effect of baclofen on CCA cell growth in different glucose conditions.

Clonogenic assay

NG and HG cells of KKU-055 and KKU-213A in control media or media containing 800 μM baclofen were seeded into a 24-well plate at a density of 200 cells/well. Cells were allowed to grow and form the colonies for 7 d before being fixed with 4% paraformaldehyde. The colonies were stained with 0.5% crystal violet and counted under a light microscope. Only a cluster with > 50 cells was counted as a colony.

Phospho-kinase arrays

The Proteome Profiler Human Phospho-Kinase Array Kit (#ARY003B, R&D system, Minneapolis, MN) was used to screen the signaling pathways affected by baclofen. HG cells (5×10^5 cells) of KKU-213A were seeded into 6-cm dishes and allowed to adhere overnight. Then, cells were incubated with 800 μM baclofen for 24 h. Cell lysates (control and treatment) were collected using RIPA buffer containing protease and phosphatase inhibitors. Then, 200 μg of total proteins for each group were incubated with the membrane arrays overnight following the recommendation of the manufacturer. The membranes were then incubated with a cocktail-detection antibody and streptavidin-horseradish peroxidase. The signals were detected with Chemireagent provided in the same kit and quantified using an ImageQuant® LAS 400 (GE Healthcare). The candidate pathways were then selected and verified in individual cell lines cultured in different glucose conditions by western blot.

Transcriptomic analysis

The GEO datasets were retrieved using GEO2R[33]. The GSE89749 (n = 120)[34] dataset of Thai CCA cases was used for the analysis of the correlation between the expression levels of GABBR2, STAT3, GSK3B, CTNNB1, MYC, and CCND1 using Pearson's correlation coefficient.

Statistical analysis

All quantitative data, presented as the mean ± SD, were analyzed using student's t-test, one-way ANOVA, or two-way ANOVA with Tukey's multiple comparisons using IBM SPSS Statistics for Windows, version 28.0 (IBM, Armonk, NY). Univariate analysis was performed using the Chi-square test or Fisher's Exact test regarding the assumption of each model. Data visualization was done using GraphPad Prism 9 (Dotmatics, San Diego, CA). Statistical significance was considered at $P < 0.05$.

RESULTS

HG induces expression of GABBR2 in CCA cell lines

From the previous comparative transcriptomic analysis, GABBR2 is one of the top 5 upregulated genes in KKU-213A cells cultured in HG compared to those cultured in NG conditions[18]. To verify the results from the transcriptomics, determination of GABBR2 expression in different CCA cell lines was performed. GABBR2 expression was dose-dependently upregulated by various glucose concentrations ranging from 5.6 mmol/L to 25 mmol/L at both mRNA (Figure 1A) and protein levels (Figures 1B and C) in both KKU-055 and KKU-213A cells. As the expression of GABBR2 in both CCA cell lines was significantly different between those cultured in 5.6 mmol/L and 25 mmol/L ($P < 0.05$), these two glucose conditions were included in a further study and assigned as NG and HG cells, respectively.

Immunocytofluorescent staining for GABBR2 in both cell lines showed that GABBR2 was localized at membranous and cytoplasmic compartments of CCA cells (Figure 1D). Mean fluorescent intensities of GABBR2 in HG cells of both cell lines were significantly higher than those in NG cells ($P < 0.05$) (Figure 1E) and were concordant with the expression levels determined by RT-qPCR and western blot.

Hyperglycemia induces upregulation of GABBR2 in tumor tissues from CCA patients

To affirm that HG-induced GABBR2 expression in CCA cell lines is translatable to patients with CCA, the tumor tissues from patients with pre-operative hyperglycemia (FBG ≥ 126 mg/dL) and euglycemia (FBG < 126 mg/dL) were studied. Immunohistochemistry of CCA tissues revealed that GABBR2 was significantly upregulated in tumor tissues from patients with DM who had hyperglycemia compared to those without DM ($P < 0.01$) (Figures 1F-G). Cytoplasmic localization of GABBR2 was observed similarly to that found in CCA cell lines.

High GABBR2 expression is associated with a poor histological type but smaller sizes of CCA tumors

To investigate the clinical significance of GABBR2 expression, the associations between GABBR2 expression in CCA tissues and the clinicopathological characteristics of patients were analyzed by univariate analysis. High GABBR2 expression was significantly associated with a non-papillary histological type of CCA ($P < 0.05$). In contrast, high GABBR2 expression was significantly associated with CCA tumor sizes smaller than 7 cm in the longest diameter ($P < 0.05$) (Table 1), suggesting that GABBR2 is a potential target for CCA treatment.

HG cells of CCA are more sensitive to a GABA-B receptor agonist than NG cells

As GABBR2 was upregulated in HG cells and CCA tissues from patients with hyperglycemia, the therapeutic potential of using GABBR2 as a target was investigated. Baclofen, a GABA-B receptor agonist, was applied in NG and HG cells of both CCA cell lines with various concentrations and time points. The treatment of baclofen did not alter the expression levels of GABBR2 in both NG and HG cells (data not shown). The proliferation of both NG and HG cells of KKU-055 and

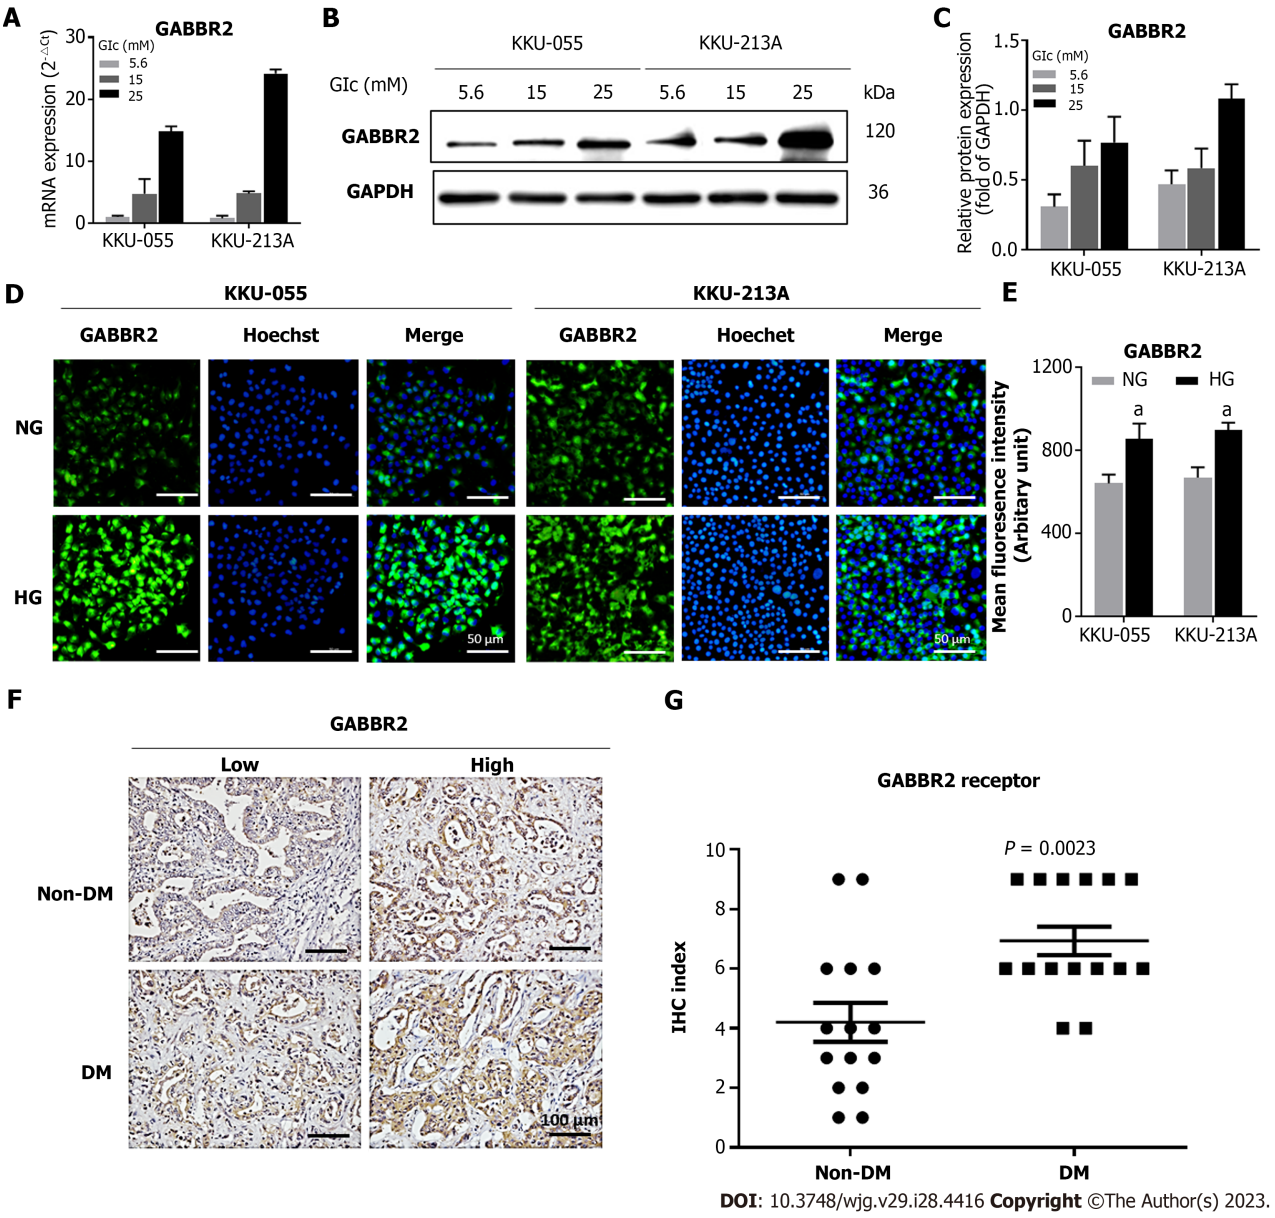
GABBR2: γ-aminobutyric acid B2 receptor.



KKU-213A was significantly suppressed in a dose- and time-dependent manner, compared with the control group (Figures 2A and B). HG cells of both cell lines showed a significantly higher sensitivity to baclofen treatment at every dosage of baclofen and at 48 and 72 h of the incubation (Figures 2A and B).

Baclofen suppresses the colony formation of CCA cells

Baclofen treatment not only suppressed the proliferation of CCA cells, but the ability to form colonies was also inhibited. Clonogenicity of both NG and HG cells of KKU-055 and KKU-213A was significantly inhibited by baclofen treatment compared with the control group (Figures 2C and D).

Baclofen inhibits multiple kinases and signal transducers in CCA cells

To unveil the underlying mechanisms in which baclofen inhibits the proliferation of CCA cells, the phospho-kinase arrays were used to screen HG cells of KKU-213A with and without baclofen treatment. Phosphorylation of several kinases and signal transducers was suppressed in KKU-213A-HG after being treated with baclofen (Figures 3A and B). The kinases and signal transducers belonging to the same pathways and reported for their roles in CCA progression were prioritized and included for further verification in downstream experiments. By these criteria, GSK3α/β, β-catenin, and STAT3 were then included for validation in the individual CCA cell lines in different glucose conditions.

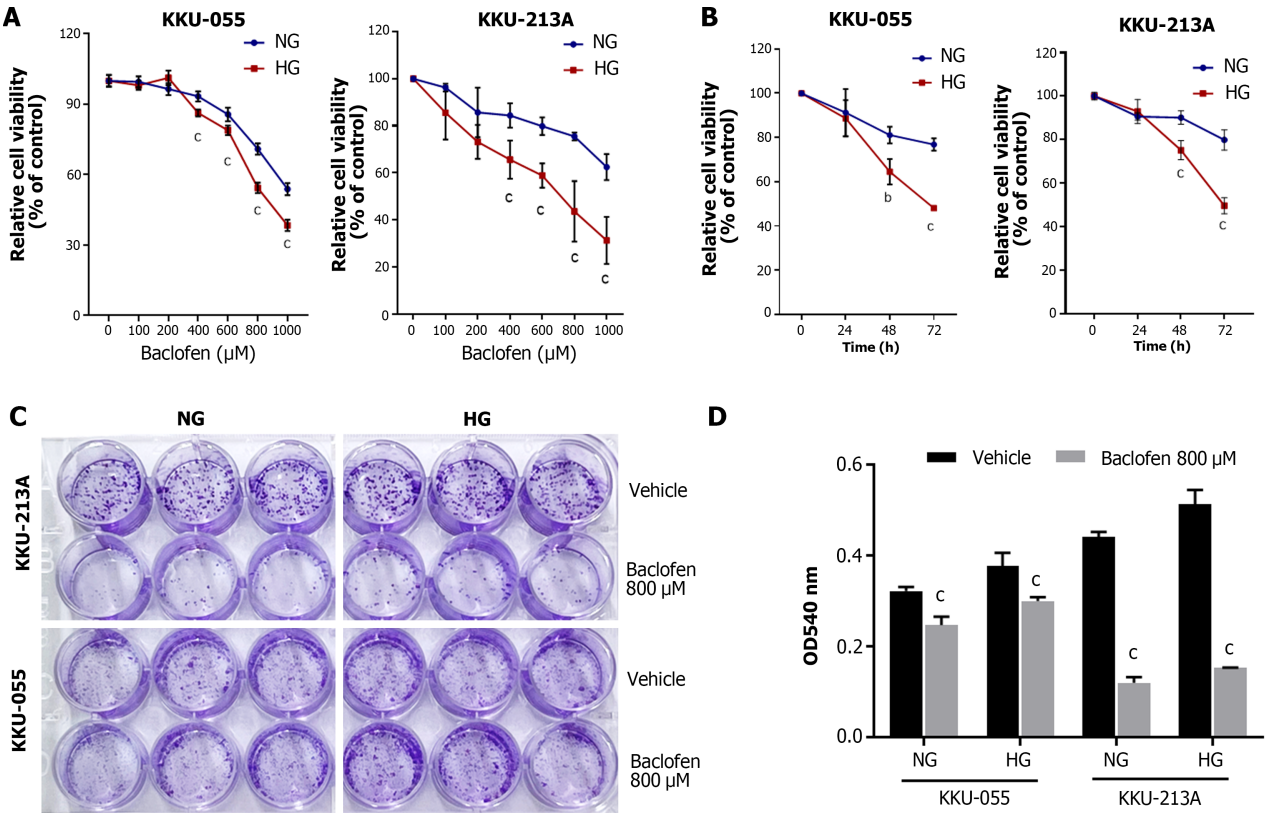

Figure 1 High glucose induces upregulation of γ-aminobutyric acid B2 receptor in cholangiocarcinoma. A-C: The expression of γ-aminobutyric acid B2 receptor (GABBR2) in cholangiocarcinoma (CCA) cell lines, KKU-055 and KKU-213A, is dose-dependently upregulated by glucose at both RNA (A) and protein (B-C) levels; D and E: Immunocytofluorescence shows the membranous and cytoplasmic localizations of GABBR2 in CCA cells, and those cultured in high glucose show significantly higher mean fluorescent intensities; F-G: GABBR2 in tumor tissues from CCA patients with hyperglycemia is also upregulated compared with those from patients without diabetes mellitus. Presented data are the average of three biological replications with triplicated experiments. NG: Normal glucose; HG: High glucose; Glc: Glucose; DM: Diabetes mellitus; GABBR2: γ-aminobutyric acid B2 receptor; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

Expression of GABBR2 significantly correlates with STAT3 expression

The associations between GABBR2 and its signal transducers suggested by the phospho-kinase arrays were first verified for their mRNA expression using public transcriptomic databases. The expression of *GABBR2* at the RNA level was significantly correlated with the expression of *STAT3* in a transcriptomic analysis of clinical CCA samples from Thai patients ($P < 0.05$) (Figure 3C).

Baclofen suppresses STAT3 and GSK3/β-catenin signaling pathways

The effects of baclofen on the STAT3 and GSK3α/β/β-catenin signaling pathways were then validated in the individual CCA cell lines, both in NG and HG cells. Baclofen suppressed STAT3 phosphorylation at both Y705 and S272 positions and NG cells were affected the most in both cell lines. Phosphorylation of GSK3α/β was also decreased time-dependently in HG cells, and the levels of β-catenin were then accordingly decreased in both cell lines. The GSK3α/β/β-catenin signaling pathway was also inhibited in NG cells of both cell lines as shown by the decreased phosphorylation levels of GSK3α/β. Total β-catenin proteins, the GSK3α/β downstream target, were also decreased starting 24 h after treatment (Figures 4A and B).

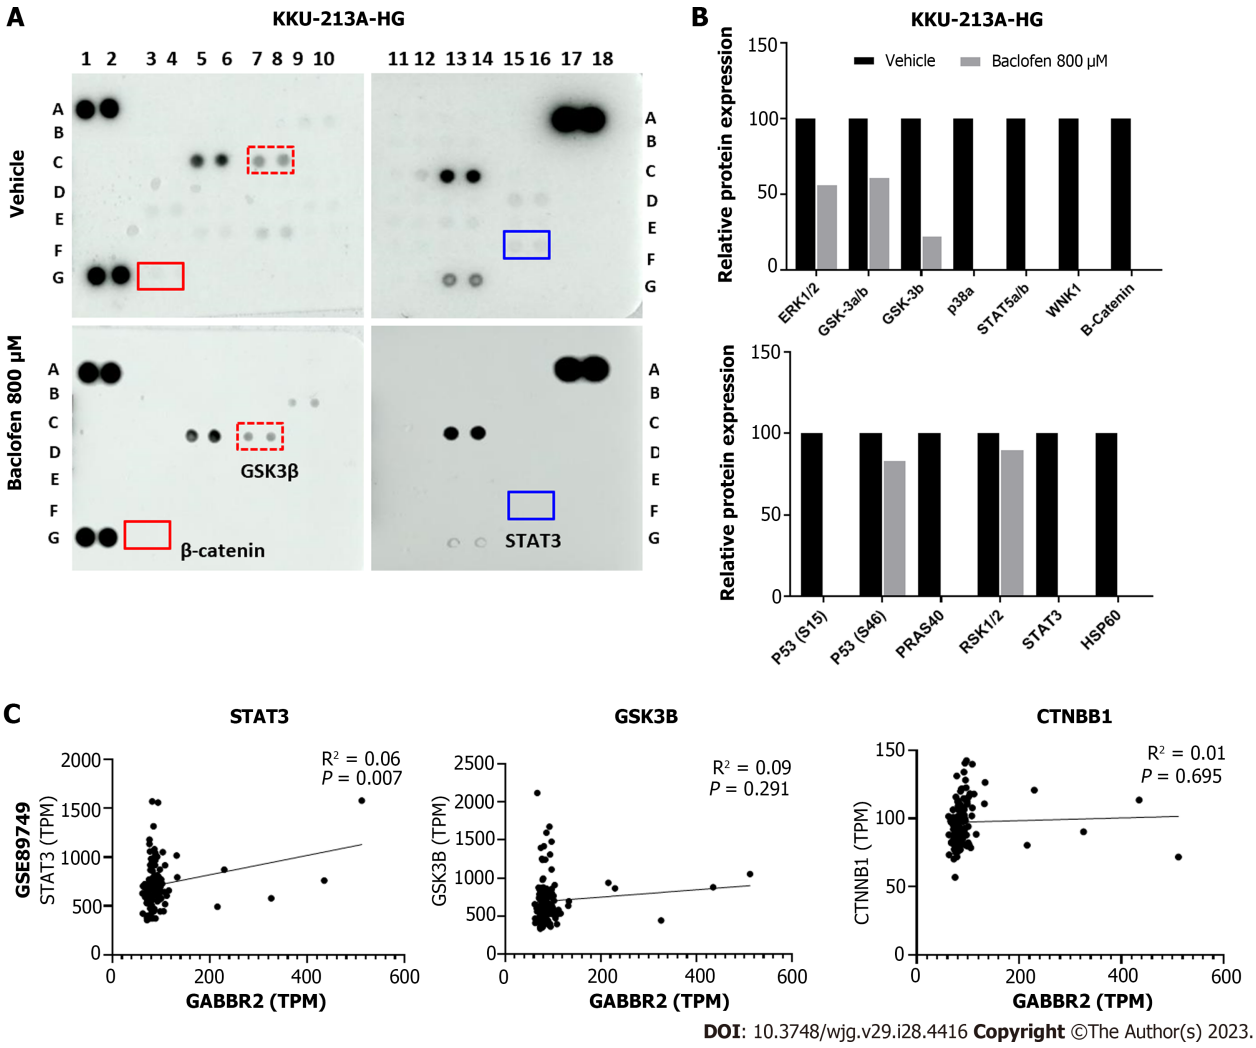
Figure 2 Antiproliferative and anti-clonogenic effects of γ-aminobutyric acid-B receptor agonist. A and B: Baclofen, a γ-aminobutyric acid-B receptor agonist, exerts significant antiproliferative effects on cholangiocarcinoma (CCA) cells in a dose-dependent (A) and time-dependent (B) manner; C and D: CCA cells cultured in high glucose condition (HG) are more sensitive to baclofen than those cultured in normal glucose (NG). Baclofen also shows anti-clonogenic effects on both NG and HG cells of CCA. Presented data are representatives of three biological replications of each triplicated experiment with the same trends of results. $^{b}P < 0.01$, $^{c}P < 0.001$. NG: Normal glucose; HG: High glucose.



Baclofen suppresses c-Myc and cyclin D1 expression

According to the antiproliferative effects of baclofen *via* the suppression of GSK3α/β/β-catenin and STAT3 pathways, the common downstream targets of both pathways functioning in cell proliferation were then explored. Expression of c-Myc, a transcription factor involved in cell proliferation, and cyclin D1, a cell cycle regulatory protein, was examined for their correlation with GABBR2 at the mRNA and protein levels after baclofen treatment. Analyzing a public transcriptomic dataset, mRNA expression levels of *MYC* (encoding for c-Myc) and *CCND1* (encoding for cyclin D1) were not correlated with mRNA level of *GABBR2* (Supplementary Figure 1). However, both c-Myc and cyclin D1 expression at the protein level were suppressed at every time point after baclofen treatment in NG and HG cells of both CCA cell lines. Suppression of c-Myc was greater affected at the early time point in which cyclin D1 was gradually affected time-dependently in HG cells. The time-dependent suppression of c-Myc in NG cells after baclofen treatment was also observed (Figures 5A and B).

DISCUSSION

HG and hyperglycemia-induced aggressiveness of CCA cells has been reported with partially understood mechanisms [15,16,18,19]. The present study not only revealed the mechanisms by which HG activates the STAT3 and GSK3/β-catenin pathways, but also identified GABBR2 as the upstream receptor that is promising for CCA treatment, especially in patients with DM. Roles of GABA and its receptor have been studied in several types of cancer, including non-liver fluke-associated CCA[26-28,35]. The known mechanisms of actions of GABA and its receptor on CCA are by regulating several signaling pathways, *e.g.*, STAT3 and protein kinase A. This study, however, determined for the first time the association between hyperglycemia and the expression of GABBR2, and also identified GSK3/β-catenin signaling, an uncovered downstream pathway, that is modulated by GABBR2 in CCA. Roles of GABBR2 in the progression of CCA in both *in vitro* models and in the tumor tissues of CCA patients were also reported.

These current investigations first identified that GABBR2, a subtype of GABA-B receptor, was upregulated in CCA cells cultured in HG. This is of particular importance since approximately 60% of patients with CCA in Thailand had their blood glucose levels in a range of pre-DM and DM[36,37]. Targeting GABBR2 would then be beneficial to a substantial group of CCA patients. Univariate analysis revealed that high expression of GABBR2 in tumor tissues was associated

Figure 3 Baclofen inhibits the glycogen synthase kinase 3/β-catenin and signal transducer and activator of transcription 3 pathways. A and B: Phospho-kinase arrays reveal the inhibition of phosphorylation in multiple kinases and signal transducers; C: Glycogen synthase kinase 3 (GSK3)/β-catenin and signal transducer and activator of transcription 3 (STAT3) are included for further analysis as they are key pathways in cholangiocarcinoma (CCA) progression in which β-catenin and STAT3 are common targets of GSK3. RNA expression of γ-aminobutyric acid B2 receptor and that of STAT3 are significantly correlated in clinical CCA samples from Thai patients. HG: High glucose; GABBR2: γ-aminobutyric acid B2 receptor; GSK3: Glycogen synthase kinase 3; STAT3: Signal transducer and activator of transcription 3.

with a poorer histological subtype of CCA. High GABBR2 expression was associated with smaller tumor sizes compared with the group with low GABBR2 expression. These findings are in agreement with previous reports demonstrating that both high GABA-A or GABA-B receptors are associated with better prognostic outcomes for CCA patients[26,38]. The upregulated GABBR2 in CCA tissues of patients thus suggested a therapeutic strategy by using a natural GABA or even GABA receptor agonists. Patients with DM who have upregulated GABBR2 would, therefore, potentially benefit from targeting GABBR2 with available GABA or GABA analogs. The present study also found that HG cells of CCA with upregulated GABBR2 were more sensitive to baclofen, a GABA-B receptor agonist. This affirms the advantage of using GABA-B agonist as an add-on therapy for CCA treatment in patients with DM. As shown by western blot, the investigated signaling molecules were markedly suppressed in both NG and HG cells. This might be the result of the screening and recruitment of candidate pathways that were only from the HG cells whereas the signaling molecules in NG cells affected by baclofen were not screened and compared. Regardless of the glucose condition of the cell cultures, these results still verified that baclofen is effective for CCA treatment and is probably useful for CCA treatment in both patients with and without DM. As the available standard and developing treatment for CCA is of limited efficacy and needs more investigation[10-13], the findings in the present work may add value for alternative treatment of CCA. Especially, baclofen is a known drug in clinical practice in which its toxicity and therapeutic windows are known[39]. This medication is, therefore, highly promising for a repurposing aim. Of note, this study showed for the first time that a GABA receptor agonist is an alternative strategy to natural GABA treatment for CCA.

Suppression of GSK3/β-catenin, a new intracellular signaling mode under the regulation of GABBR2 in CCA, is shown in addition to the known affected STAT3 pathway[26]. Both GSK3/β-catenin and STAT3 are reported as crucial signaling pathways for CCA carcinogenesis and progression[40,41]. GSK3 is a kinase phosphorylating β-catenin for proteasomal degradation. The functions of GSK3 are inhibited by phosphorylation by its kinase regulators[42], hence decreased

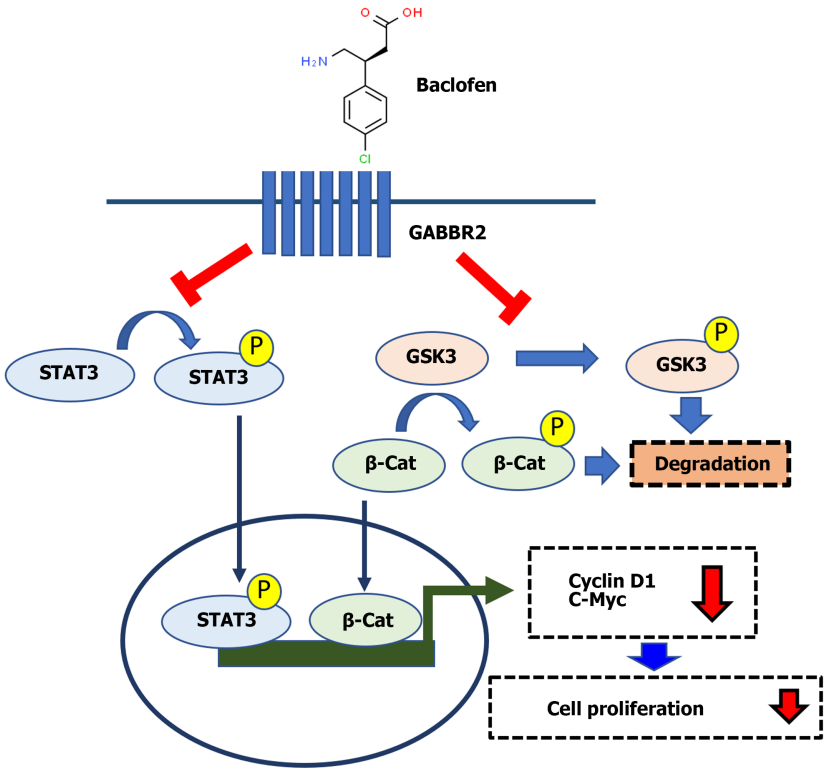
Figure 4 Baclofen suppresses the glycogen synthase kinase 3/β-catenin and signal transducer and activators of transcription 3 pathways. A and B: Phosphorylation of glycogen synthase kinase 3 (GSK3) and signal transducer and activators of transcription 3 is decreased after baclofen treatment in both cholangiocarcinoma cell lines, both cultured in normal glucose and high glucose conditions. Total β-catenin protein is also decreased consistently with the decreased phosphorylated GSK3α/β. Western blots show the representative of three biological replications with the same trends of results. Band intensities are the average of three biological replications which are normalized using the intensities of glyceraldehyde-3-phosphate dehydrogenase for each experiment. The levels of phosphorylated forms are normalized with the total forms of their corresponding proteins. NG: Normal glucose; HG: High glucose; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase; GSK3: Glycogen synthase kinase 3; STAT3: Signal transducer and activator of transcription 3.

phosphorylated GSK3α/β in CCA cells after the baclofen treatment indicated the active state of GSK3. This is also evidenced by the decreased β-catenin, a GSK3 downstream target which is a known transcription factor for cell proliferation. Moreover, STAT3 phosphorylation was also inhibited after baclofen treatment, which is consistent with the previous findings in CCA cells treated with GABA. STAT3 has also been reported as an alternative downstream target of GSK3 phosphorylation[43]. The decreased levels of β-catenin and STAT3 phosphorylation in the present report might thus be a consequence of GSK3 inhibition by a GABBR2 agonist. As β-catenin and STAT3 control cell proliferation *via* the expression of c-Myc and cyclin D[44,45], these two common effector-proteins were also down-regulated after baclofen treatment. These suggested that the activation of GABBR2 protein by its natural or synthetic ligands might be a crucial step for the regulation of downstream signaling, although there is no correlation among *GABBR2*, *MYC*, and *CCND1* at the mRNA level. These findings not only add to the understanding of the molecular linkages among DM, hyperglycemia, and CCA progression but also imply the therapeutic strategies of the combined targeting multiple signaling pathways to improve CCA treatment outcomes. The schematic summary of the findings from the current study is depicted in Figure 6.



GABA is an inhibitory neurotransmitter mostly found in the central nervous system. It is a derivative of the non-essential amino acid glutamate and can be synthesized by converting glutamine as a precursor[29]. GABA functions by binding to its receptors which have three subtypes (GABA-A, GABA-B, and GABA-C receptors). Different GABA receptors are responsible for various physiological functions both within and outside the nervous system. While the GABA-A receptors are found to be important for hepatocytes[46], GABA-B receptors are also needed for the differentiation of biliary epithelial cells[25]. In addition to physiological roles, GABA and its receptors are also reported for both pro-tumor[29,30] and anti-tumor effects[28,47], depending on the cancer type. The previous study showed that all subtypes of GABA receptors were expressed in CCA cells[28]. Still, only GABA-B receptor was differentially expressed between CCA cells and normal adjacent cholangiocytes in tumor tissues from patients[26]. The GABA-B receptor then holds a high potential for targeting in CCA treatment. Treatment of GABA in CCA cells exerted antiproliferative[28] and anti-invasive effects[35] on CCA cells by inhibiting multiple pathways, *i.e.*, cyclic AMP–dependent regulation of the protein kinase A/extracellular signal-regulated kinase (PKA/ERK)[27,28] and STAT3[26,38] pathways. Low GABA-A and GABAB-B receptor expression was also associated with a poor prognosis in CCA patients[38]. The roles of GABA receptors under hyperglycemia in CCA patients with DM are for the first time reported in the present study. The study of a GABA-B receptor agonist, instead of using natural GABA, is also reiterated and suggested for a potential translation to a clinical study.

This study, nevertheless, has some limitations. First, all CCA tissues and CCA cell lines used in the study were derived from *O. viverrini*-associated CCA patients. As different molecular backgrounds of CCA in different areas have been noted [48,49], the current findings may be needed to verify in CCA from the non-endemic areas of liver fluke. Noteworthy, the

Figure 6 Schematic summary of the effects of high glucose on γ-aminobutyric acid B2 receptor expression and the effects of baclofen on cholangiocarcinoma cells. High glucose induces the expression of γ-aminobutyric acid B2 receptor (GABBR2) in cholangiocarcinoma (CCA) cells. The treatment of baclofen, a GABBR2 agonist, to CCA cells inhibits phosphorylation of glycogen synthase kinase 3, resulting in the activation of the kinase activity which further phosphorylates β-catenin. Phosphorylated β-catenin is subjected to degradation preventing its function on promoting cell proliferation *via* c-Myc and cyclin D1 expression. On the other hand, activated GABBR2 by baclofen also inhibits phosphorylation of signal transducer and activator of transcription 3 (STAT3). The inhibition of STAT3 phosphorylation also suppresses its functions as a transcription factor for c-Myc and cyclin D1 expression. Activating GABBR2 by baclofen, thus, suppresses the proliferation of CCA cells. GABBR2: γ-aminobutyric acid B2 receptor; GSK3: Glycogen synthase kinase 3; STAT3: Signal transducer and activator of transcription 3.

correlations between GABBR2 and STAT3, GSK3B, and CTNNB1, were not observed in the analysis using a dataset from The Cancer Genome Atlas which included non-liver fluke-associated CCA[50].

Second, although the *in vivo* effect of natural GABA on CCA growth has been reported in several studies, the treatment of GABA receptor agonists in the animal model remains limited. A further *in vivo* study of GABA-B receptor agonists at an optimal therapeutic dosage in animal models should be certified. Third, the association of GABBR2 expression and nuclear localization of its downstream transcription factor, namely, β-catenin, needs further proof in clinical samples using appropriate techniques. Lastly, a combination of several modalities as the therapeutic regimen for CCA is recommended. The study of combining GABA-B receptor agonists with another standard or alternative modality will help translate these findings to clinical practice, especially in the treatment of CCA patients with DM who are likely suffering from a poor prognosis.

CONCLUSION

GABBR2 is upregulated by HG in both CCA cell lines and tumor tissues from patients. Targeting GABBR2 with GABA-B receptor agonists shows the potential of using GABBR2 as a therapeutic target and repurposing GABA-B receptor agonists for CCA treatment, especially for those patients with DM and hyperglycemia.

ARTICLE HIGHLIGHTS

Research background

The association between diabetes mellitus (DM) and cholangiocarcinoma (CCA) progression has been established with unclear mechanisms. Our previous study showed that γ-aminobutyric acid B2 receptor (GABBR2) is among the top 5 upregulated genes in CCA cells cultured in high glucose (HG). Thus, GABBR2 is highly potential for a repurposing aim in CCA treatment.

Research motivation

Approximately 60% of Thai patients with CCA had fasting blood glucose in a range of pre-diabetes or DM. Targeting the molecules underlying hyperglycemia-induced aggressiveness of CCA cells might improve the prognosis of CCA patients with DM.

Research objectives

This study aimed to investigate the effects of hyperglycemia on GABBR2 expression and the potential use of GABBR2 as a CCA therapeutic target.

Research methods

CCA cells cultured in normal glucose or HG conditions were used as models of *in vitro* euglycemia and hyperglycemia, respectively. Baclofen, a GABBR2 agonist, was used to study the functional roles of CCA cells. Western blot, immunocytofluorescence, and immunohistochemistry were used to study molecular mechanisms.

Research results

HG induced GABBR2 expression in both cell lines and in patients' CCA tissues. Baclofen treatment significantly suppressed CCA cell growth, while cells cultured in HG showed a significantly higher sensitivity. The effects of baclofen on CCA cell growth were achieved by the suppression of the signal transducer and activator of transcription 3 and glycogen synthase kinase 3/β-catenin pathways.

Research conclusions

The expression of GABBR2 in CCA is induced in hyperglycemic conditions. Baclofen significantly suppresses the growth of CCA cells and thus holds a high promise as a repurposing drug for CCA treatment.

Research perspectives

Investigating baclofen's effects at an optimal therapeutic dosage in *in vivo* models would verify the present work and facilitate the translation for clinical study in CCA cases.

ACKNOWLEDGEMENTS

We would like to thank Mr. Chitsakul Phuyao, Cholangiocarcinoma Research Institute, Khon Kaen University, for his technical help in histological sections. This manuscript has been edited for English presentation by Prof. James A. Will, University of Wisconsin, USA, *via* KKU Publication Clinic, Khon Kaen University.

FOOTNOTES

Author contributions: Saengboonmee C, Seubwai W, Gingras MC, and Wongkham S conceptualized the research; Saengboonmee C, Sorin S, Sangkhamanon S, Indramanee S, Chomphoo S, and Thithuan K designed and performed the experiments; Saengboonmee C, Sorin S, Sangkhamanon S, Chomphoo S, Seubwai W, Chiu CF, Okada S, Gingras MC, and Wongkham S analyzed the data; Okada S and Gingras MC contributed research resources and analysis tools; Saengbonmee C and Sorin S wrote the manuscript draft; Saengboonmee C, Chiu CF, Okada S, Gingras MC, and Wongkham S reviewed and edited the manuscript; and all authors read and approved the final version of the manuscript.

Supported by the Research Grant for Young Talented Scholars, National Research Council of Thailand, No. N41A640108.

Institutional review board statement: The protocol of this study has been reviewed and approved by the Khon Kaen University Ethics Committee for Human Research (approval No. HE641441), based on the Declaration of Helsinki and the ICH-Good Clinical Practice Guidelines.

Informed consent statement: Written informed consent was obtained from all participants.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.

Data sharing statement: No additional data are available.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. Abstract

BACKGROUND

Non-alcoholic fatty liver disease (NAFLD) is a major health burden with an increasing global incidence. Unfortunately, the unavailability of knowledge underlying NAFLD pathogenesis inhibits effective preventive and therapeutic measures.

AIM

To explore the molecular mechanism of NAFLD.

METHODS

Whole genome sequencing (WGS) analysis was performed on liver tissues from patients with NAFLD (n = 6) and patients with normal metabolic conditions (n = 6) to identify the target genes. A NAFLD C57BL6/J mouse model induced by 16 wk of high-fat diet feeding and a hepatocyte-specific F-box only protein 2 (FBXO2) overexpression mouse model were used for *in vivo* studies. Plasmid transfection, co-immunoprecipitation-based mass spectrometry assays, and ubiquitination in HepG2 cells and HEK293T cells were used for *in vitro* studies.

RESULTS

A total of 30982 genes were detected in WGS analysis, with 649 up-regulated and 178 down-regulated. Expression of FBXO2, an E3 ligase, was upregulated in the liver tissues of patients with NAFLD. Hepatocyte-specific FBXO2 overexpression facilitated NAFLD-associated phenotypes in mice. Overexpression of FBXO2

aggravated odium oleate (OA)-induced lipid accumulation in HepG2 cells, resulting in an abnormal expression of genes related to lipid metabolism, such as fatty acid synthase, peroxisome proliferator-activated receptor alpha, and so on. In contrast, knocking down FBXO2 in HepG2 cells significantly alleviated the OA-induced lipid accumulation and aberrant expression of lipid metabolism genes. The hydroxyl CoA dehydrogenase alpha subunit (HADHA), a protein involved in oxidative stress, was a target of FBXO2-mediated ubiquitination. FBXO2 directly bound to HADHA and facilitated its proteasomal degradation in HepG2 and HEK293T cells. Supplementation with HADHA alleviated lipid accumulation caused by FBXO2 overexpression in HepG2 cells.

CONCLUSION

FBXO2 exacerbates lipid accumulation by targeting HADHA and is a potential therapeutic target for NAFLD.

Key Words: F-box only protein 2; Nonalcoholic fatty liver disease; The hydroxyl CoA dehydrogenase alpha subunit; Liver steatosis; Ubiquitination; Lipid accumulation

Core Tip: This study involves an assessment of the role of F-box only protein 2 (FBXO2) in non-alcoholic fatty liver disease (NAFLD). First, based on the whole genome sequencing analysis results of liver tissues from normal controls and patients with NAFLD, the expression of FBXO2 was found to be increased during NAFLD. Hepatocyte-specific FBXO2 overexpression facilitated NAFLD-associated phenotypes in mice. In contrast, the knockdown of FBXO2 expression of HepG2 cells significantly alleviated oleate-induced lipid accumulation. Mechanistically, the hydroxyl CoA dehydrogenase alpha subunit, a protein with known role in oxidative stress reaction, is one of the protein substrates of FBXO2-mediated ubiquitination.

INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD), a clinicopathologic syndrome, is characterised by an excessive deposition of fat in hepatocytes [triglyceride (TG) content exceeding 5% of the liver weight] excluding alcohol and other liver-damaging factors[1-3]. With an increase in the incidence of obesity and its associated metabolic syndrome, more than one-third of adults are affected by NAFLD globally[4-6]. NAFLD includes simple fatty liver, non-alcoholic steatohepatitis, and related cirrhosis, which can eventually develop into decompensated cirrhosis and hepatocellular carcinoma[7,8]. The key issues affecting the treatment of patients with NAFLD are atherosclerotic cardio-cerebrovascular diseases, cirrhosis, and malignant tumours associated with the metabolic syndrome[9-11]. Since the pathogenesis of NAFLD remains unclear [12], a clinically effective drug to treat NAFLD is unavailable. A healthy diet and moderate exercise remain the main measures to treat NAFLD clinically[13].

The hydroxyl CoA dehydrogenase alpha subunit (HADHA), a fatty acid β-oxidation enzyme, has been identified as a key pathogenic regulator of metabolism-related diseases, such as NAFLD, obesity, and diabetes[14-16]. Previous studies have confirmed that the expression of HADHA is decreased in L02 cells treated with free fatty acids (FFA) and in mice fed with a high-fat diet (HFD). Knocking out HADHA aggravated liver steatosis, inflammation, and oxidative stress in FFA-treated L02 cells. In addition, oxidative stress and liver damage in NAFLD mice are alleviated by the up-regulation of HADHA[17]. Meanwhile, HADHA can be affected by the ubiquitin-proteasome system (UPS), which mediates important regulatory modifications. Ubiquitination and the degradation of HADHA were reported to be mediated by ubiquitin-conjugating enzyme E2 O, thereby modulating lipid metabolism[18]. However, it remains unclear if there is another regulatory factor that could control and mediate the ubiquitination of HADHA, thus affecting the pathogenesis of HADHA-mediated NAFLD. Therefore, confirming the regulatory signaling pathway in NAFLD that inhibits or activates HADHA is necessary.

The UPS comprises an evolutionarily conserved protein degradation mechanism, including ubiquitin activation (E1), ubiquitin coupling (E2), and ubiquitin ligase (E3) enzymes[19,20]. F-box only protein 2 (FBXO2), a well-known E3 ligase, plays an indispensable role in the UPS[21] and has unique functions in various pathological processes. For example, FBXO2 regulates signal transducer and activator of transcription 3 signaling responsible for modulating the proliferation and tumorigenicity of osteosarcoma cells[22], targets glycosylated SAD1/UNC84 domain protein-2 for ubiquitination and degradation to promote the development of ovarian cancer[21] and mediates the clearance of damaged lysosomes and alters the neurodegeneration phenotype of the brain in Niemann-Pick C disease[23]. In addition, the abnormal expression of FBXO2 in obese mice disrupts glucose homeostasis through ubiquitin-mediated insulin receptor degradation[24]. However, the role of FBXO2 in NAFLD pathology remains unclear.

In this study, we found that expression of FBXO2 was upregulated in the liver tissues of patients with NAFLD when compared with those in liver tissues of normal controls *via* the whole genome sequencing (WGS) analysis. These findings urged us to explore whether FBXO2 can promote the progression of NAFLD and its mechanism. Our findings can clarify whether FBXO2 is a feasible therapeutic target for NAFLD and related metabolism disorders.

MATERIALS AND METHODS

Human liver tissue samples

Liver tissue samples were collected from 10 patients with NAFLD, who underwent sleeve gastrectomy with liver biopsy at the Qilu Hospital of Shandong University, Shandong, China. Control liver tissue samples were obtained from 10 patients with normal metabolic conditions who underwent hepatic hemangioma resection at the same hospital.

The inclusion criteria were: Physical examination, laboratory investigation, ultrasound echography, and a liver biopsy consistent with the diagnosis of NAFLD, according to the Brunt criteria. Exclusion criteria were: Excess alcohol consumption (≥ 20 g/d for women and ≥ 30 g/d for men), the presence of hepatitis B virus surface antigen or hepatitis C virus antibodies in the absence of a history of vaccination, use of drugs linked to NAFLD, evidence of other specific liver diseases, such as autoimmune liver disease, and hemochromatosis[25].

A liver biopsy during surgery was performed to provide foundation to non-alcoholic steatohepatitis (NASH) score. Clinical data of the normal controls and patients with NAFLD are shown in Table 1. Written informed consent was obtained from the patients and their families. All procedures involving human liver samples were approved by the Ethics Committee of the Qilu Hospital and adhered to the principles of the Declaration of Helsinki (approval No. KYLL-2017-073).

WGS and result analysis

RNA extraction and whole genome library sequencing were performed in 12 liver tissues (NAFLD, $n = 6$; normal, $n = 6$) by LC-BIO TECHNOLOGIES (Hangzhou, China) CO. Kyoto Encyclopedia of Genes and Genomes (KEGG) and Gene Ontology (GO) enrichment analyses of the mRNA sequencing part were performed using the DAVID programme (https://david.ncifcrf.gov/). Bar, scatter, and Gene Set Enrichment Analysis result plots were drawn using the LC-BIO Technologies platform (https://www.omicstudio.cn/).

Animals

Eight-week-old pathogen-free C57BL/6J male mice (RRID:IMSR_JAX:000664) were purchased from SPF Biotechnology Co. (Beijing, China). Five mice were placed in each cage at a temperature of 23-26 °C with a 12 h light/dark cycle. Animals had free access to food and water. Rodent food was purchased from Xiao Shu You Tai Biotechnology (Beijing, China). The mice used in this investigation were divided randomly.

To induce NAFLD, 10 mice were fed an HFD (#D12492; Research Diets, New Brunswick, NJ, United States) for 16 wk. Control mice were fed with a standard normal chow diet (ND). After 16 wk of feeding an HFD, the weight of the mice in the HFD group exceeded that of mice in the ND group by 20%, and obvious lipid accumulation was observed in the liver. Serum intracellular TG and total cholesterol (T-Cho) levels also increased significantly in the HFD group ($P < 0.001$, Supplementary Table 1). Finally, eight mice met the experimental criteria. One underweight mouse and one mouse with no significant lipid deposition in the liver were excluded from any analysis.

To establish a liver-specific FBXO2 overexpression model, six mice were injected with adeno-associated virus serotype 8 (AAV8)-His-FBXO2 through the tail vein (100 μL of virus containing 5×10^{11} vg of vectors) after 6 wk of HFD feeding. An empty vector (AAV-His-vector) was injected into the corresponding control mice ($n = 6$). The virus-infected mice were fed with HFD for an another 16 wk. The AAV used in this study was purchased from WZ Biosciences Inc. (Shandong, China). The study was approved by the Institutional Animal Care and Use Committee of Shandong Provincial Qian Foshan Hospital (approval No. S453) in accordance with internationally accepted principles for the use of laboratory animals.

Cell lines and cell culture

Human hepatoma cells (HepG2, ATCC; HB-8065 BCRC, #CL-0103) and human embryonic kidney 293 cells (HEK293T, ATCC; CRL-3216 DSMZ, #CL-0005) were cultured in Dulbecco's Modified Eagle Medium, containing 10% foetal bovine serum and 1% penicillin-streptomycin, in a humidified chamber at 37 °C with 5% CO_2. HepG2 cells were exposed to odium oleate (OA) dissolved in 0.5% fatty acid-free bovine serum albumin (BSA) at a final concentration of 0.3 mmol/L for 24 h to establish an *in vitro* cell lipid deposition model. All cells were purchased from Procell Life Science & Technology Co., Ltd. (Wuhan, China). All cell lines were authenticated *via* STR identification.

Plasmid construction and transfection

FBXO2 or HADHA overexpression was achieved by transfecting cells with His-FBXO2 plasmid (#NM_012168CH895916, WZ Bioscience Inc., Shandong, China) or Myc-HADHA plasmids (#BC009235HG15019-NM, Sino Biological, Beijing, China), respectively, as per the respective manufacturer's instructions. His-vector (#66005-1-Ig, Proteintech) and Myc-vector plasmids (#16286-1-AP, Proteintech) were used as controls. FBXO2 knockdown was achieved by transfecting cells with Sh-FBXO2 plasmid (WZ Bioscience Inc). Sh-NC plasmids were used as a control. The DNA sequences of the plasmids used are shown in Supplementary material.

T-Cho, mmol/L	3.97 ± 0.52	4.47 ± 0.77	1.700	0.106
HDL, mmol/L	1.31 ± 0.20	0.97 ± 0.14	4.486	< 0.001
LDL, mmol/L	2.19 ± 0.37	2.83 ± 0.62	2.824	0.011
sdLDL, mmol/L	0.34 ± 0.14	1.11 ± 0.51	4.580	< 0.001
TG, mmol/L	0.62 ± 0.20	2.05 ± 0.67	6.483	< 0.001
NEFA, μmol/L	44.41 ± 29.72	55.20 ± 15.05	1.024	0.319
FPG, mmol/L	4.82 ± 0.33	4.81 ± 1.09	0.014	0.989
NASH score	0	5.10 ± 1.30	-	-

Data are presented as the mean ± SD. $P < 0.05$ was considered statistically significant. ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; BP: Blood pressure; FPG: Fasting plasma glucose; HDL: High-density lipoprotein; LDL: Low-density lipoprotein; NEFA: Nonesterified fatty acid; NAFLD: Non-alcoholic fatty liver disease; NASH: Non-alcoholic steatohepatitis; sdLDL: Small and dense low-density lipoproteins; TG: Triglycerides; T-Cho: Total cholesterol.

Western blotting, co-immunoprecipitation, and mass spectrometry assays

Briefly, liver tissues and HepG2 cells were lysed with RIPA lysis buffer containing protease inhibitors. Western blotting was performed using standard procedures[26,27]. The primary antibodies used are listed in Supplementary Table 2. Image J (RRID:SCR_003070) and GraphPad Prism software (RRID:SCR_002798) were used to analyze the western blotting results.

For the co-immunoprecipitation (co-IP) assay, HepG2 cell protein lysate was prepared. The cracking solution was then washed with 1 mL of cracking buffer (containing 100 μL of protein A/G agarose beads) and the lysate was incubated overnight with the appropriate antibodies. Next, the beads were washed thrice with cracking buffer and then re-suspended in 2 × sodium dodecyl sulfate (SDS) loading buffer. The beads were incubated at 95 °C for 5 min to elute immunoprecipitated proteins. Finally, the proteins were separated using SDS-PAGE and immunoblotted for detection. Mass spectrometry (MS)-based proteomic analysis was performed by the Jinjie Bio company (Hangzhou, China).

Quantitative reverse transcription polymerase chain reaction

Total RNA was extracted from the liver tissues and HepG2 cells using TRIzol reagent (Invitrogen, #12183555). Complementary DNA (cDNA) was synthesised from the isolated RNA using a cDNA synthesis kit (Takara, #RR047A). Subsequently, SYBR Green Master Mix (Vazyme, Q111-02) and a quantitative reverse transcription polymerase chain reaction (qRT-PCR) system (LightCycle 480 II, Roche, Japan) were used to perform qRT-PCR and analyse the results. The primer sequences used in the study are listed in Supplementary Table 3.

Homeostasis model assessment of insulin resistance (HOMA-IR), oral glucose tolerance test (OGTT) and insulin tolerance test (ITT). Blood glucose levels were measured using a Glucometer Elite monitor (ACCU-CHEK, Roche, Germany) and serum insulin was measured using an insulin ELISA kit (D721159-0048, Sangon Biotech). The HOMA-IR index was calculated based on the fasting serum glucose and insulin levels. OGTT was performed *via* the administration of glucose (2 mg/g) after an overnight fast. ITTs were performed following the *i.p.* injection of 1 U/kg insulin after 4 h of fasting. OGTT and ITT were performed at 16 wk post adenovirus injection.

Mouse serum and cell cytosol lipid analysis

Blood was collected from the tail vein of mice. Serum was obtained after the blood was centrifuged at 8000 × g for 20 min at 4 °C. HepG2 cells were lysed using an ultrasonic crusher (SCINTZ-650E; Ningbo Scientz Biotechnology Co., Ningbo, China). Serum TG and T-Cho levels were measured using commercially available assay kits (Nanjing Jiancheng Bioengineering Institute, Nanjing, China).

Histological analysis

Hematoxylin and eosin (H&E) staining was done to demonstrate the pattern of lipid accumulation. Oil Red-O staining was done to show the accumulation of fat droplets in the liver.

Immunohistochemical staining and immunofluorescence

For immunohistochemistry, paraffin sections of paired human or mouse livers were deparaffinized and rehydrated. Antigens were retrieved using sodium citrate buffer. After blocking with 1% BSA for 1 h at 25 °C, the sections were sequentially incubated with anti-FBXO2 (Proteintech Cat# 14590-1-AP, RRID:AB_2104394) and the corresponding secondary antibodies. The antibodies used in the study are listed in Supplementary Table 2.

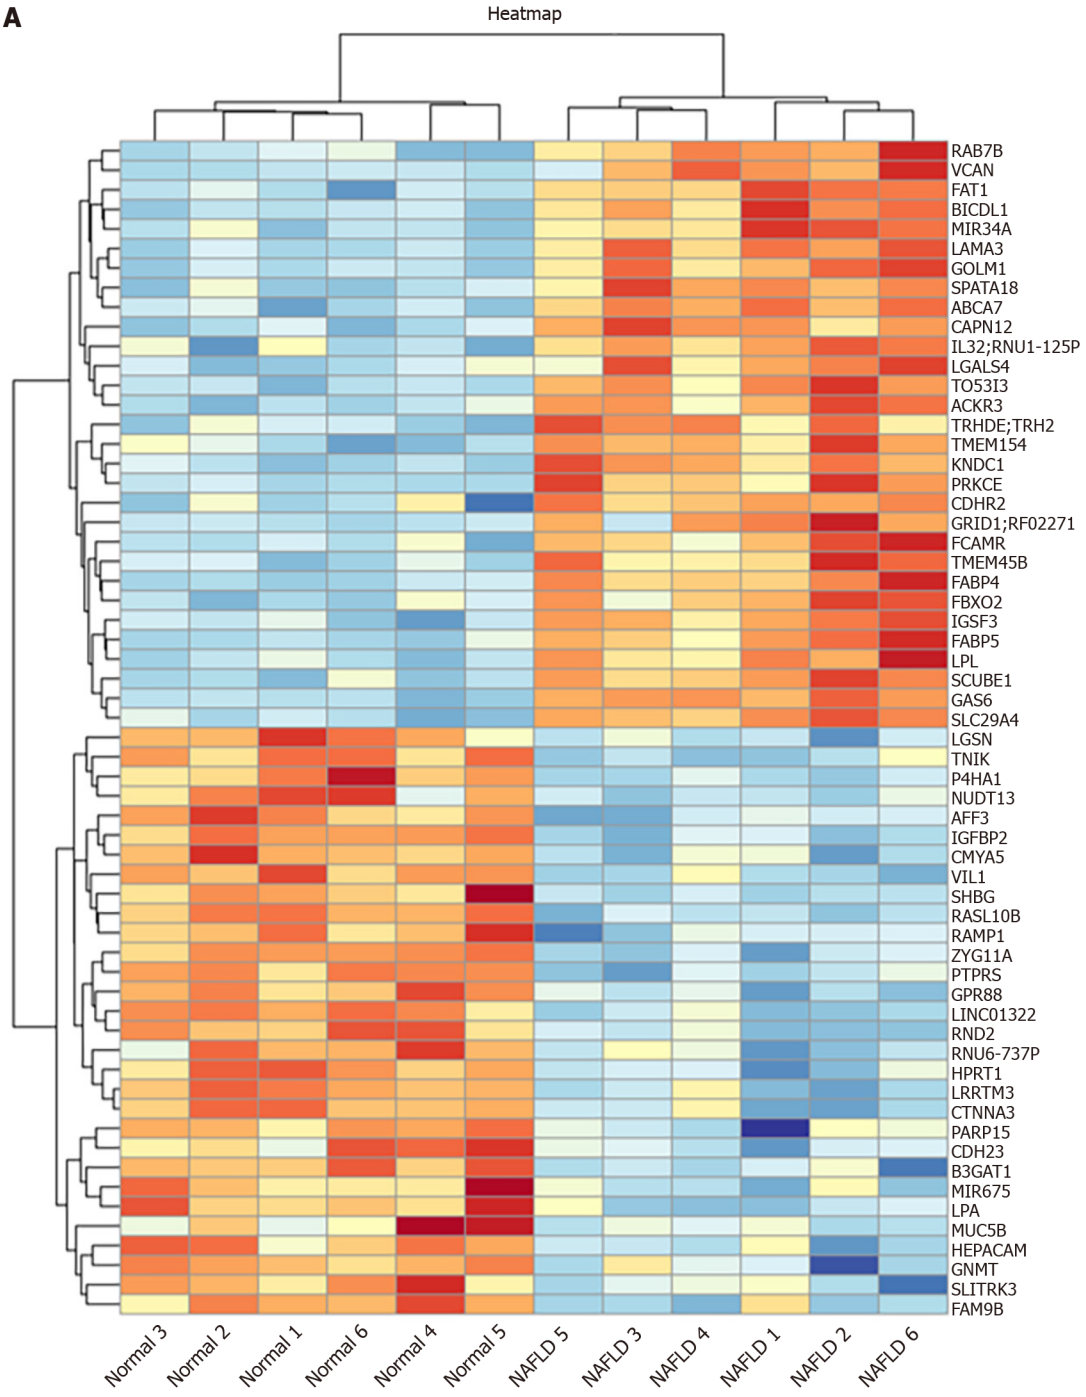
For immunofluorescence staining, cells were fixed with 4% paraformaldehyde for 25 min at 25 °C. Cells were then washed thrice with phosphate-buffered saline (PBS) and lysed with 0.1% Triton X-100 in PBS for 20 min. After washing the cells with PBS three times, the cells were incubated in 1% BSA at 37 °C for 1.5 h followed by overnight incubation at 4 °C with rabbit anti-FBXO2 and anti-HADHA antibodies (Proteintech Cat#10758-1-AP, RRID:AB_2115593). After washing thrice with PBS, the cells were incubated with the appropriate secondary antibodies for 1 h at 37 °C. Finally, the cells were stained with 4′,6-diamidino-2-phenylindole. Images were captured using a confocal microscope (IX-73, Olympus, Japan).

Ubiquitination assay

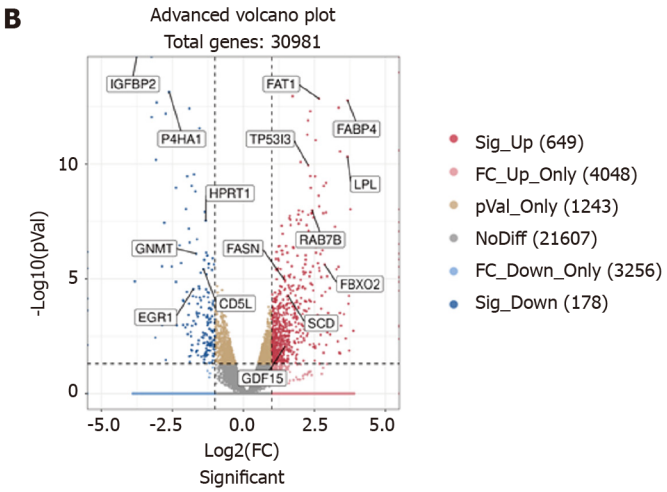
The HADHA ubiquitination assay was performed by transfecting HEK293T cells with FBXO2, HADHA, HA-ubiquitin, or empty vectors using Lipofectamine 2000 (#11668, Invitrogen, United States). After 24 h, the cells were washed twice with PBS and lysed in RIPA lysis buffer. The lysates were then centrifuged to obtain cytoplasmic proteins. The obtained proteins were incubated overnight with anti-HADHA antibody followed by incubation with protein A/G agarose beads at 4 °C for an additional 4 h. After washing the beads three times with lysis buffer, the beads were boiled in 2 × SDS loading buffer, separated *via* the SDS-PAGE, and immunoblotted. All experiments were repeated three times independently.

Statistical analyses

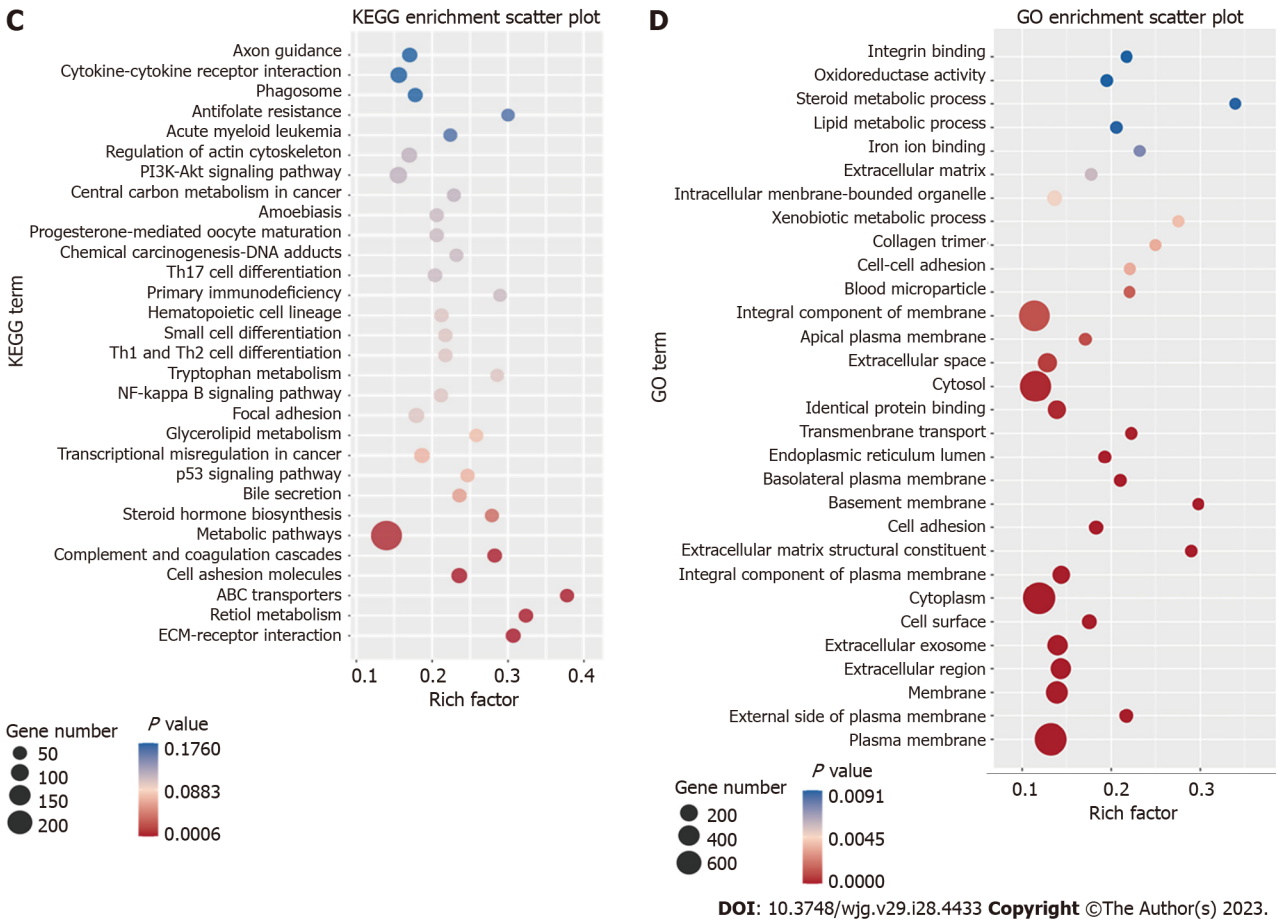
The *t*-test was performed for comparisons between two groups. Statistical significance was set at $P < 0.05$.



RESULTS



FBXO2 expression is upregulated in livers with hepatic steatosis



WGS was performed on the liver tissues of six patients with NAFLD and six normal controls. A total of 30982 genes were detected in the WGS analysis, of which 649 were up-regulated and 178 were down-regulated. The heat map in Figure 1A shows the 60 most significantly up- or down-regulated genes. The volcano plot in Figure 1B depicted an overview of the gene sequencing results [log2 (fold change) > 1; $P < 0.05$]. Some genes marked in our sequencing analysis were closely related to NAFLD[26,28-30], such as fatty acid synthase (FASN), growth differentiation factor 15 and insulin-like growth factor binding protein 2 (Figure 1B). GO and KEGG analyses were also performed (Figures 1C and D, Supplementary Figures 1A and B). GO-biological process analysis indicated that the differential genes were mainly involved in 'signal transduction', 'lipid metabolic process', and 'positive regulation of GTPase activity'. GO-cellular component analysis indicated that the differential genes were mainly associated with the cytoplasm, cytosol, and integral component of the membrane. GO-molecular function analysis indicated that the differential genes were mainly associated with protein binding, identical protein binding, and ATP binding processes. KEGG enrichment results revealed that the differential genes are largely enriched in 'metabolic pathways'.

Among the upregulated genes, the mRNA level of FBXO2 was significantly upregulated among patients with NAFLD. According to previous studies, the abnormal expression of FBXO2 in obese mice disrupts glucose homeostasis through ubiquitin-mediated insulin receptor degradation. We also found that sleeve gastrectomy could downregulate FBXO2 and activate in the phosphatidylinositol 3-kinase-protein kinase B (PI3K-AKT) pathway[31]. In our GO and KEGG analysis, some differential genes were enriched in the PI3K-AKT pathway. Hence, we speculated that FBXO2 may play a role in regulating lipid metabolism in NAFLD.

To investigate whether FBXO2 is involved in the occurrence and development of NAFLD, we analyzed its expression in liver tissues isolated from patients with NAFLD (Table 1, Figures 2A and B). We found that the mRNA and protein levels of FBXO2 were significantly higher in liver tissues of patients with NAFLD compared to that in control liver tissues *via* qRT-PCR analysis (Figure 2D, $P < 0.0001$), western blot analysis (Figure 2C, $P < 0.0001$), and immunohistochemical staining (Figure 2E). Moreover, we established a NAFLD mouse model by feeding C57BL6/J mice an HFD for 16 wk (Figures 2F and G, Supplementary Table 1). Similarly, we also found significantly higher FBXO2 mRNA and protein levels in liver samples obtained from HFD mice compared to ND mice *via* qRT-PCR (Figure 2I, $P < 0.0001$), western blot (Figure 2H, $P < 0.01$), and immunohistochemical staining (Figure 2J) analyses. Based on these results, we confirmed that

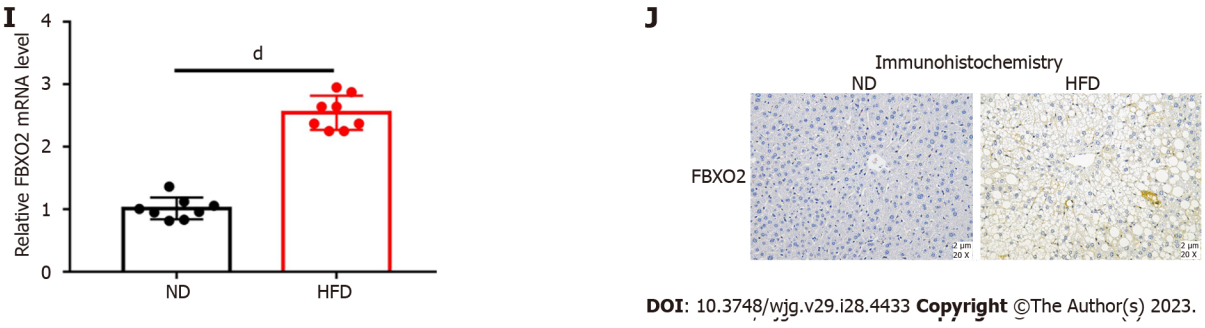
FBXO2 levels in the liver of patients with NAFLD and the HFD-fed mouse model were significantly increased compared to those in non-steatosis samples.



FBXO2 overexpression aggravates hepatic steatosis

Given the close correlation between FBXO2 expression and a fatty liver, we constructed a hepatocyte-specific FBXO2-overexpressing mouse model (Supplementary Figures 2A and B) to investigate the role of FBXO2 in exacerbating the HFD-induced liver steatosis, insulin resistance, and abnormal glucose metabolism. As expected, AAV-His-FBXO2-treated mice exhibited a significant increase in body weight (Supplementary Figure 2C), liver weight (Figure 3D), and the ratio of liver weight to body weight (Figure 3E) compared to AAV-His-vector-treated mice. The deposition of lipids in the liver was noticeably enhanced in AAV-His-FBXO2 mice, as determined by liver observations (Figure 3A), H&E staining (Figure 3B), Oil Red O staining (Figure 3C), and TG and T-Cho levels (Figures 3F and G). The overexpression of FBXO2 in the livers of AAV-His-FBXO2-treated mice significantly promoted the expression of lipogenesis genes [FASN and peroxisome proliferator-activated receptor gamma (PPARγ)] and fatty acid uptake genes [cluster of differentiation 36 (CD36) and fatty acid binding protein-1 (FABP1)] and suppressed the expression of fatty acid β-oxidation-related genes [acyl-CoA oxidase 1 (ACOX1), enoyl coenzyme A hydratase 1 (ECH1), medium-chain acyl-coenzyme A dehydrogenase (MCAD), and PPARα] (Figure 3H).

NAFLD is often accompanied by glucose metabolic disorders and insulin resistance. Unsurprisingly, FBXO2 overexpression significantly increased fasting blood glucose and insulin levels (Figures 3I and J). The HOMA-IR index was also increased accordingly (Figure 3K). Notably, there was no significant difference in food intake between AAV-His-FBXO2 mice and AAV-His-vector mice (Supplementary Figure 2D). In addition, the AAV-His-FBXO2 mice exhibited significantly higher blood glucose levels than AAV-His-vector mice, as determined from the OGTT and ITT data (Figures 3L-N).

We also investigated the effects of FBXO2 overexpression on lipid metabolic disorders *in vitro*. HepG2 cells were treated with OA to simulate the NAFLD phenotype. An increase in the mRNA and protein levels of FBXO2 was observed after 24 h of OA administration (Figures 4D and E). Oil Red O staining revealed that the intracellular lipid deposition (Figure 4A) and TG and T-Cho levels in HepG2 cells (Figures 4B and C) increased after OA treatment. Next, the His-FBXO2 plasmid was transfected into HepG2 cells. qRT-PCR and western blotting revealed increased FBXO2 expression (Supplementary Figures 3A and B). The effect of FBXO2 overexpression on lipid deposition was also observed in OA-

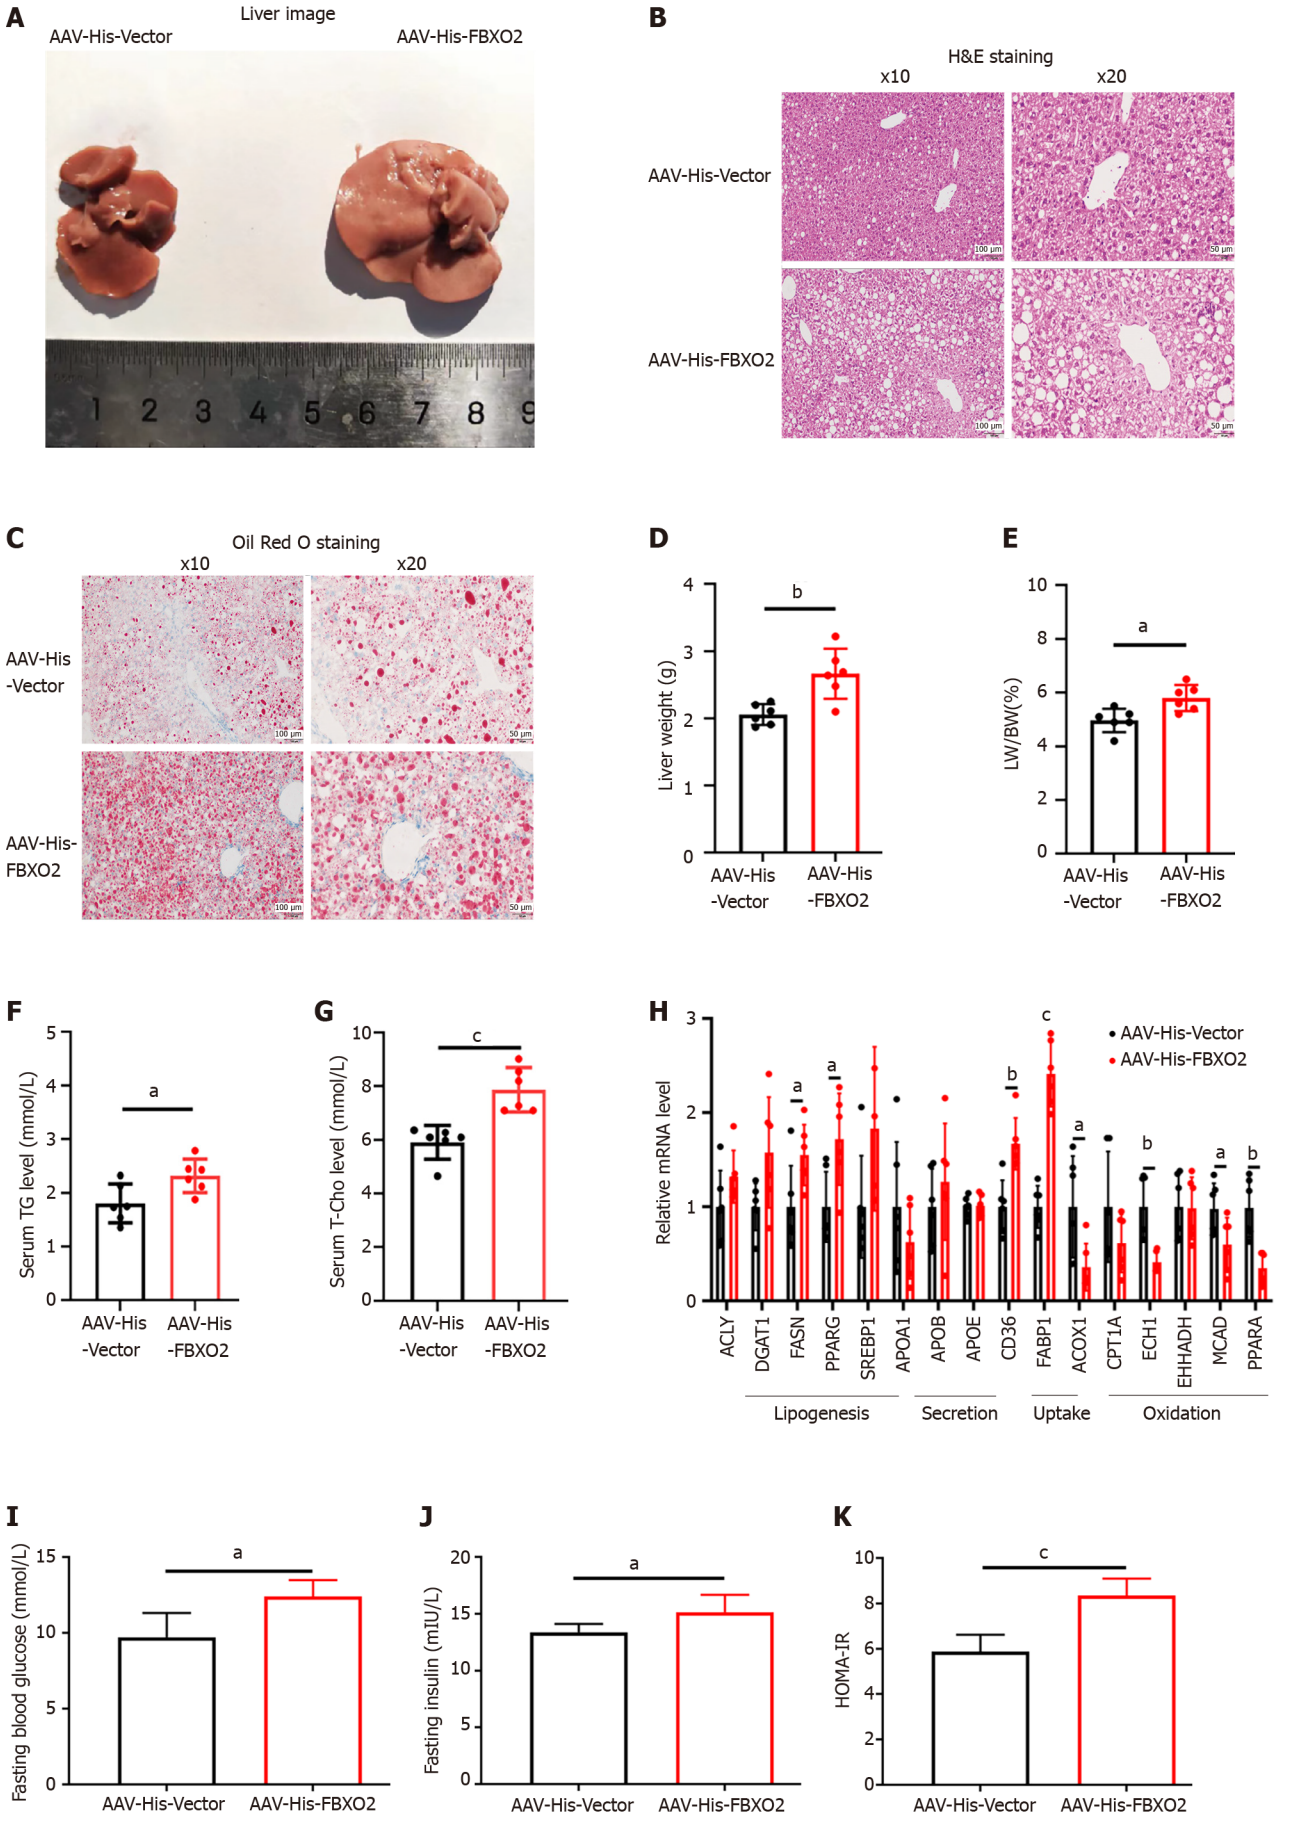
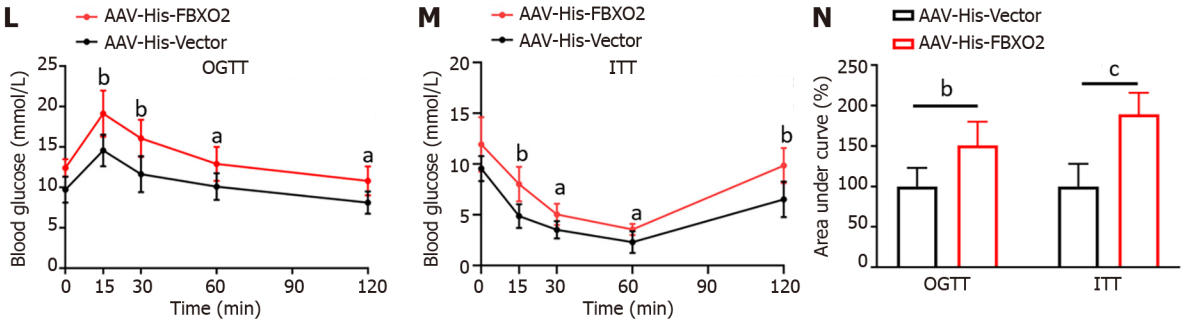
treated HepG2 cells. Specifically, FBXO2 overexpression after transfecting His-FBXO2 plasmids into HepG2 cells, greatly increased OA-induced lipid deposition (Figure 4F). FBXO2 overexpression also increased OA-induced cellular TG and T-Cho levels (Figures 4G and H). The overexpression of FBXO2 in OA-treated HepG2 cells also promoted the expression of FASN, PPARG, CD36, and FABP1 and suppressed the expression of ACOX1, ECH1, MCAD, and PPARα (Figure 4I). These data suggest that the up-regulation of FBXO2 expression in the liver exacerbated liver steatosis, HFD-triggered insulin resistance, and abnormal glucose metabolism.



FBXO2 knockdown ameliorates lipid accumulation in hepatocytes



After confirming that the overexpression of FBXO2 exacerbated liver steatosis, we examined the effect of FBXO2 knockdown on lipid metabolic disorder in hepatocytes. To achieve this, the Sh-FBXO2 plasmid was transfected into HepG2 cells. Both qRT-PCR and western blot results indicated that FBXO2 expression levels decreased after transfection, confirming successful FBXO2 knockdown (Supplementary Figures 3C and D). FBXO2 knockdown decreased the OA-induced lipid deposition (Figure 4J) and regulated OA-induced TG and T-Cho secretion (Figures 4K and L). The knockdown of FBXO2 in OA-treated HepG2 cells inhibited the expression of lipogenesis genes (FASN and PPARγ) and fatty acid uptake genes (CD36 and FABP1) and promoted the expression of fatty acid β-oxidation related genes (ACOX1, ECH1, MCAD, and PPARα) (Figure 4M). Consistent with these data, *in vitro* gene therapy using Sh-FBXO2 plasmids further demonstrated that the knockdown of FBXO2 could significantly alleviate OA-induced lipid accumulation in hepatocytes (hepatic steatosis).

The up-regulation of FBXO2 expression promotes HADHA ubiquitination and degradation in HepG2 cells

We used a co-IP-based MS method to identify which proteins interact with endogenous FBXO2 in HepG2 cells. Based on peptide spectra matching protein score, HADHA was identified as a potential binding protein for FBXO2 in HepG2 cells (Figure 5A). *In vitro* interaction studies suggested that both exogenous and endogenous FBXO2 could bind directly to HADHA and vice versa. Additionally, the interaction between FBXO2 and HADHA was determined *via* a co-IP assay in HEK293T (Figures 5C and D) and HepG2 cells (Figures 5E and F). *In vitro* interaction tests suggested that both exogenous and endogenous FBXO2 could directly bind to HADHA and vice versa. Immunofluorescence staining also revealed the co-localization of FBXO2 and HADHA after the HEK293T cells were transfected with His-FBXO2 and Myc-HADHA plasmids (Figure 5B).

Next, we tested whether FBXO2 could activate the ubiquitination of HADHA. The expression of FBXO2 and HA-Ub together significantly enhanced the ubiquitination of HADHA in HEK293T cells, compared to control cells transfected with vectors expressing FBXO2 and HA-Ub alone (Figure 6A). Consistent with the results of the ubiquitination assays, gene expression analysis supported the reduction of HADHA protein levels in HepG2 cells and HFD-fed mouse models overexpressing FBXO2 (Figures 6B and D). Further, HADHA degradation was reduced after co-treatment with the proteasome inhibitor MG132 (SML1135; Sigma, United States) in HepG2 cells (Figure 6E). Moreover, FBXO2 knockdown increased the level protein of HADHA in HepG2 cells (Figure 6C). Notably, the mRNA levels of HADHA were not affected by FBXO2 overexpression or knockdown (Supplementary Figures 4A-C). Additionally, we analysed whether FBXO2 decreased the half-life of the HADHA protein. We transfected HepG2 cells with His-Vector or His-FBXO2 plasmids and treated them with the protein synthesis inhibitor cycloheximide (CHX) at different time points. The half-life of the HADHA protein was drastically reduced in FBXO2-overexpressing cells compared to the control cells (Figure 6F). These findings indicated that FBXO2 facilitates the degradation of HADHA *via* the ubiquitination machinery.

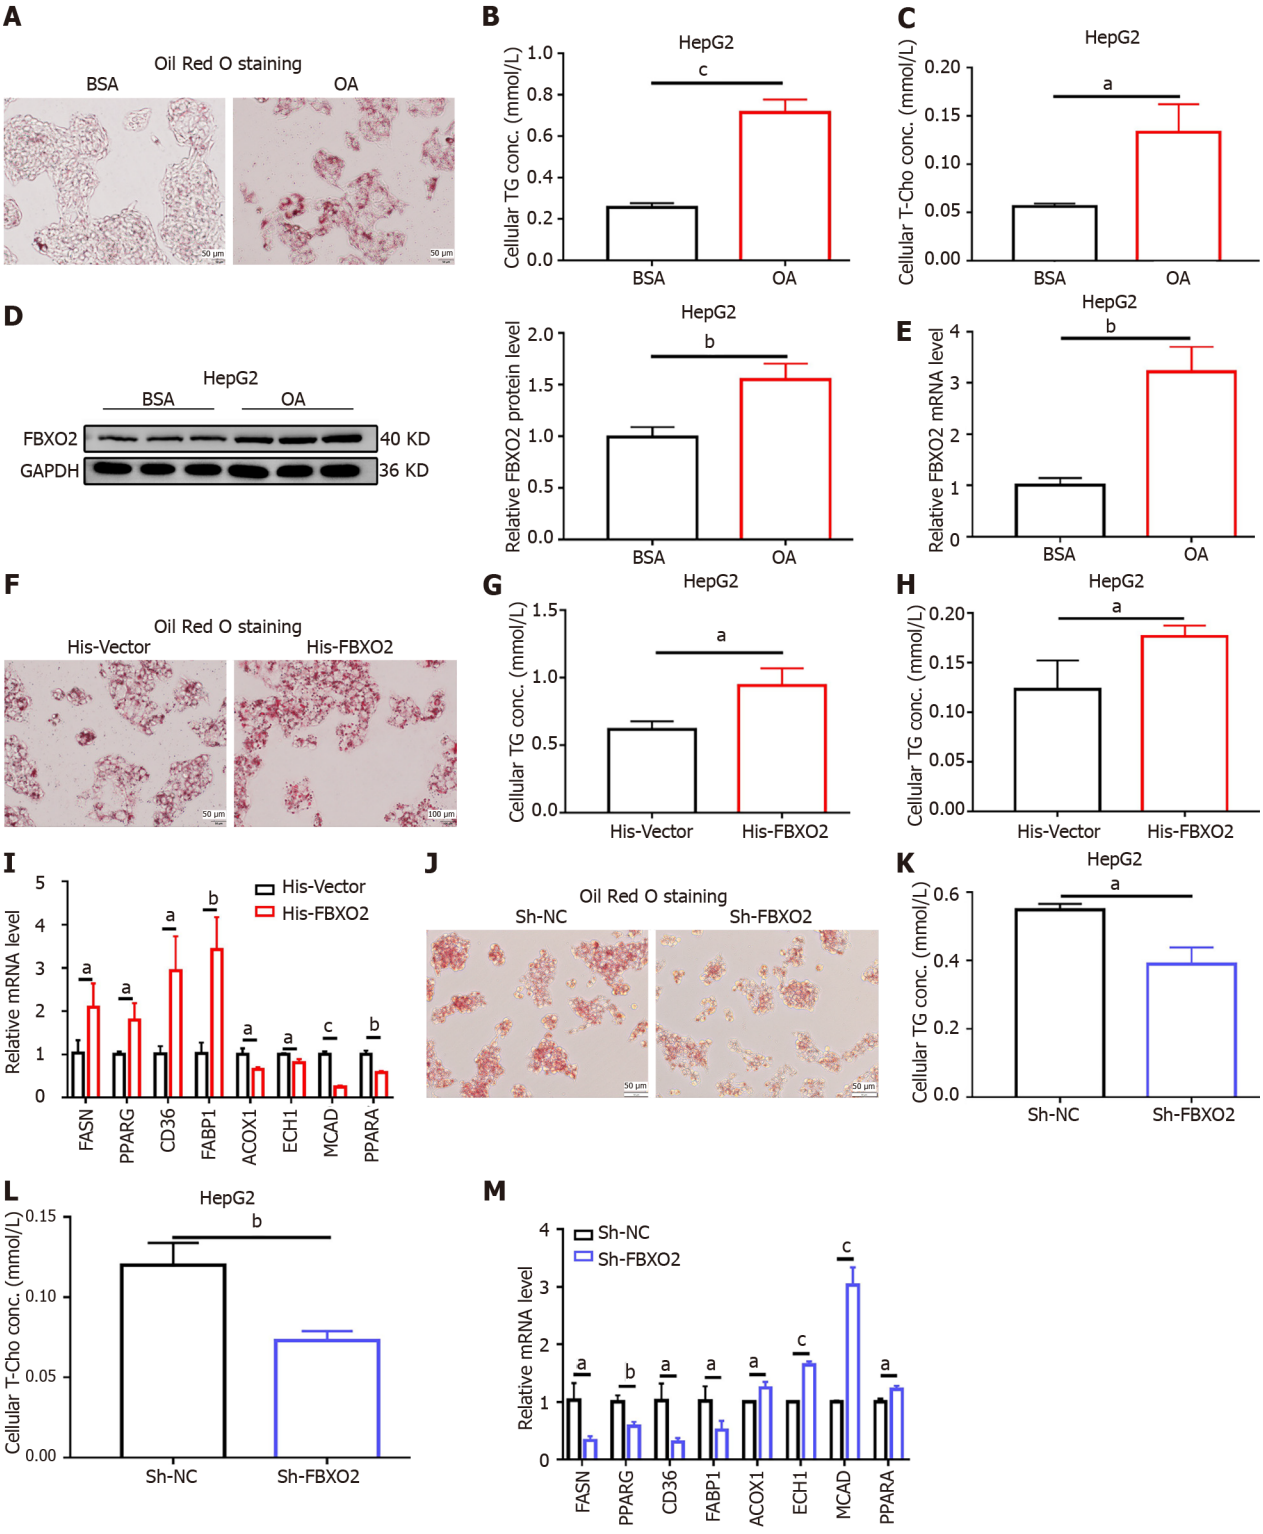

Figure 3 Overexpression of F-box only protein 2 exacerbated high-fat diet-induced liver steatosis, insulin-resistance, and abnormal glucose metabolism. A: Representative images indicating histological changes in the livers of adeno-associated virus (AAV)-His-vector and AAV-His-F-box only protein 2 (FBXO2) mice after 16 wk of administering an high-fat diet (HFD); B and C: Representative images of hematoxylin and eosin and Oil Red O staining of liver tissue obtained from AAV-His-vector and AAV-His-FBXO2 mice after 16 wk of HFD. Scale bars, 50 μm and 100 μm; D-G: The liver weight, ratio of liver weight/body weight, serum triglyceride and total cholesterol levels in AAV-His-vector and AAV-His-FBXO2 mice after 16 wk of administering an HFD (n = 6 per group); H: quantitative reverse transcription polymerase chain reaction analysis of the expression of genes associated with lipogenesis, fatty acid secretion and uptake, and oxidation in AAV-His-vector and AAV-His-FBXO2 mice after 16 wk of administering an HFD (n = 6 per group); I: Fasting blood glucose levels; J: Fasting serum insulin levels; K: The homeostatic model assessment of insulin resistance; L: Oral glucose tolerance test (OGTT) scores; M: Insulin tolerance test (ITT); N: Calculated area under curve of OGTT and ITT in the AAV-His-vector mice and AAV-His-FBXO2 mice after 16 wk of HFD (n = 6 per group). $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$. AAV: Adeno-associated virus; FBXO2: F-box only protein 2; H&E: Hematoxylin and eosin; ITT: Insulin tolerance test; OGTT: Oral glucose tolerance test; LW: Liver weight; BW: Body weight; TG: Triglyceride; T-Cho: Total cholesterol; HOMA-IR: Homeostatic model assessment of insulin resistance; FASN: Fatty acid synthase; PPAR: Peroxisome proliferator-activated receptor; CD36: Cluster of differentiation 36; ACOX1: Acyl-CoA oxidase 1; ECH1: Enoyl coenzyme A hydratase 1; MCAD: Medium-chain acyl-coenzyme A dehydrogenase.

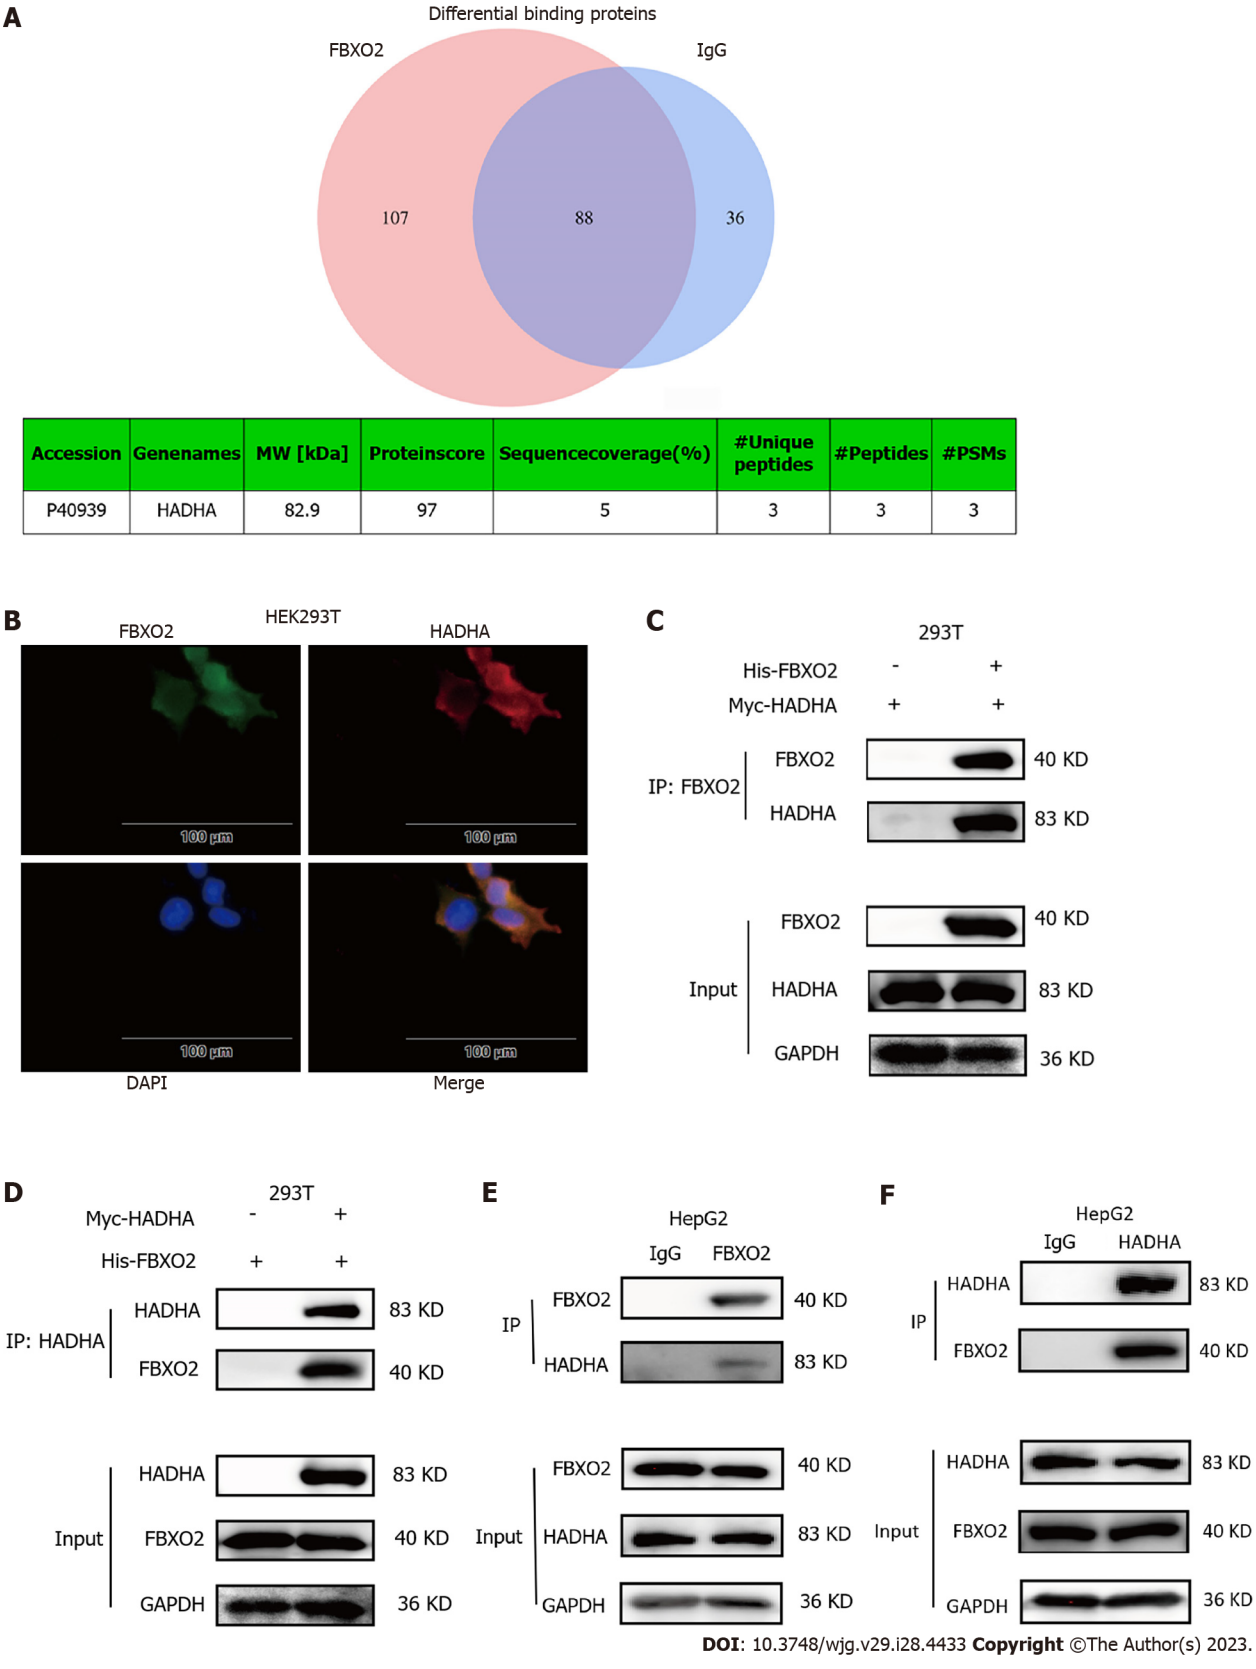
The above finding led us to determine whether HADHA alterations mediate the effect of FBXO2 on lipid accumulation in hepatocytes. First, FBXO2 overexpression increased OA-induced lipid deposition and TG and T-Cho secretion. Moreover, the overexpression of FBXO2 in OA- treated HepG2 cells enhanced the expression of FASN, PPARγ, CD36, and FABP1 and inhibited the expression of ACOX1, ECH1, MCAD, and PPARα. However, these effects were reversed after HepG2 cells were transfected with the Myc-HADHA plasmid to overexpress HADHA as indicated by the changes in lipid deposition (Figure 6G), TG and T-Cho secretion (Figures 6H and I), and mRNA expression of lipid metabolism-related genes (Figure 6J). FBXO2 and HADHA overexpression efficiency was also confirmed *via* western blot (Supplementary Figure 3E). Collectively, these indicated that the up-regulation of FBXO2 exacerbated OA-induced lipid accumulation by promoting the ubiquitination and degradation of HADHA in HepG2 cells.

DISCUSSION



FBXO2 is an E3 ligase that can regulate protein stability through ubiquitin-mediated protein-protein interaction and plays an indispensable role in the cell cycle regulation of the UPS[21]. It regulates cell proliferation, transcription, and apoptosis through the ubiquitination and degradation of target proteins, thereby affecting the occurrence and development of various diseases, such as malignant tumours, neuronal diseases, and inflammation[22,24,32,33]. However, the status of FBXO2 expression in NAFLD and its relationship with clinicopathological parameters has not been clarified. In the present study, we found that FBXO2 levels were significantly up-regulated in NAFLD liver tissues. Subsequently, we simulated NAFLD in HFD mice and OA-treated HepG2 cells, and the results were consistent with those obtained in human liver tissue. Our sequencing results of NAFLD liver tissue samples revealed changes in multiple metabolic pathways, for example the PI3K-AKT pathway. Recent studies conducted by our team found that the expression level of FBXO2 in NAFLD mouse models was downregulated after sleeve gastrectomy. Upregulation of FBXO2 could activate the PI3K-AKT pathway[31]. Based on the above results, we speculate that FBXO2 upregulation is related to NAFLD occurrence and development.

Next, we constructed a hepatocyte-specific FBXO2-overexpressing mouse model to further explore the relationship between FBXO2 and NAFLD. Lipid accumulation in the liver is a clinical feature of NAFLD and is caused by an imbalance between lipid input and output[34]. This imbalance is regulated by four pathways: Lipid lipogenesis, lipid uptake, lipid secretion, and fatty acid oxidation[27,35]. In the present study, we found that the deposition of liver lipids was visibly enhanced in hepatocyte-specific FBXO2-overexpressing mice models. FBXO2 overexpression in the liver significantly promoted the expression of lipogenesis genes (FASN and PPARγ) and fatty acid uptake genes (CD36 and FABP1) and inhibited the expression of fatty acid β-oxidation-related genes (ACOX1, ECH1, MCAD and PPARα) in AAV-His-FBXO2 mice. In contrast, FBXO2 knockdown in OA-treated HepG2 cells had the opposite effect on the expression of lipid accumulation and the expression of lipid metabolism-related genes. The alleviative effect of FBXO2 knockdown on lipid metabolism suggests its effect in treating NAFLD. In addition, combined with the effect of the overexpression and knockdown of FBXO2 on lipid metabolism, it is worth considering that FBXO2 may promote the ubiquitination of one or more proteins that can mediate lipid metabolism. In other words, the overexpression of FBXO2 can accelerate protein

degradation, thus aggravating NAFLD. On the contrary, the knockdown of FBXO2 protects lipid metabolising enzymes from degradation, thus maintaining normal lipid metabolism.

To further explore the mechanism through which FBXO2 affects NAFLD, we screened the proteins that could interact with endogenous FBXO2 in HepG2 cells using a co-IP-based MS method. The mitochondrial trifunctional enzyme subunit-alpha (HADHA) was identified as a potential binding protein for FBXO2. HADHA, a mitochondrial β-oxidation-associated enzyme, encodes the α-subunit of the mitochondrial trifunctional protein (hydroxyacyl-CoA dehydrogenase/3-ketoacyl-CoA thiolase/enoyl-CoA hydratase). This enzyme complex catalyses the three steps of the β-oxidation of fatty acids in the mitochondria[14]. HADHA deficiency in mice has been reported to aggravate NAFLD[36-38]. Further, HADHA knockout can lead to hyperglycemia and consequently induce liver lipid deposition[18,39]. *In vitro* interaction tests in the present study suggested that both exogenous and endogenous FBXO2 could directly bind to HADHA and vice versa. In addition, the results of our ubiquitination assays showed that FBXO2 facilitates the degradation of HADHA *via* the ubiquitination machinery. We further confirmed the interaction between FBXO2 and HADHA in hepatocytes using MG132 and CHX. We also found that FBXO2 overexpression during OA-induced liver steatosis was reversed after Myc-HADHA plasmids were transfected into HepG2 cells to overexpress HADHA.

Another interesting observation is that in addition to the exacerbation of steatosis, the targeted upregulation of FBXO2 expression in HFD-fed mouse livers led to a significant exacerbation of hyperglycemia and insulin resistance, which could be caused by various reasons. Previous studies have shown that FBXO2 targets insulin receptors to achieve ubiquitin-dependent degradation, thus regulating insulin signaling integrity[24]. The overexpression of FBXO2 can stimulate severe insulin resistance in the liver and inhibit its normal function, promoting adipogenesis. Therefore, increased insulin resistance leads to excessive lipid accumulation in the liver[34]. Recent studies have shown that HADHA knockdown augments the glucagon response[14]. This study speculates that a decrease in HADHA levels might induce an increase in blood glucose levels after the overexpression of FBXO2. In addition, the increased expression of lipogenesis- and fatty acid uptake-associated genes and decreased expression of fatty acid β-oxidation-related genes might also contribute to the observed effects on glycemic control[40-44].

CONCLUSION

Liver FBXO2 expression is upregulated in NAFLD and FBXO2 is correlated with metabolic disorders. Moreover, upregulation of FBXO2 exacerbates liver steatosis by promoting the degradation of HADHA. Finally, our findings suggest that FBXO2 can be used as a feasible therapeutic target for NAFLD.

ARTICLE HIGHLIGHTS

Research background

Non-alcoholic fatty liver disease (NAFLD) is a major health burden with an increasing global incidence. Unfortunately, the unavailability of knowledge underlying NAFLD pathogenesis inhibits effective preventive and therapeutic measures. The key issues affecting the treatment of patients with NAFLD are atherosclerotic cardio-cerebrovascular diseases, cirrhosis, and malignant tumors associated with the metabolic syndrome. The abnormal expression of F-box only protein 2 (FBXO2), an E3 ligase, in obese mice disrupts glucose homeostasis through ubiquitin-mediated insulin receptor degradation, however, the role of FBXO2 in NAFLD pathology remains unclear.

Research motivation

Recent studies conducted by our team found that the expression level of FBXO2 in NAFLD mouse models was downregulated after sleeve gastrectomy.

Research objectives

This study aimed to explore the molecular mechanism of NAFLD.

Research methods

Whole genome sequencing (WGS) analysis was performed on liver tissues from patients with NAFLD (n = 6) and patients with normal metabolic conditions (n = 6) to identify the target genes. A NAFLD C57BL6/J mouse model induced by 16 wk of high-fat diet (HFD) feeding and a hepatocyte-specific FBXO2 overexpression mouse model were used for *in vivo* studies. Plasmid transfection, co-immunoprecipitation-based mass spectrometry assays, and ubiquitination in HepG2 cells and HEK293T cells were used for *in vitro* studies.

Research results

A total of 30982 genes were detected in WGS analysis, with 649 up-regulated and 178 down-regulated. Expression of FBXO2 was upregulated in the liver tissues of patients with NAFLD. Hepatocyte-specific FBXO2 overexpression facilitated NAFLD-associated phenotypes in mice. Overexpression of FBXO2 aggravated odium oleate (OA)-induced lipid accumulation in HepG2 cells, resulting in an abnormal expression of genes related to lipid metabolism, such as fatty acid synthase, peroxisome proliferator-activated receptor alpha, and so on. In contrast, knocking down FBXO2 in HepG2 cells significantly alleviated the oleate-induced lipid accumulation and aberrant expression of lipid metabolism genes. The hydroxyl CoA dehydrogenase alpha subunit (HADHA), a protein involved in oxidative stress, was a target of FBXO2-mediated ubiquitination. FBXO2 directly bound to HADHA and facilitated its proteasomal degradation in HepG2 and HEK293T cells. Supplementation with HADHA alleviated lipid accumulation caused by FBXO2 overexpression in HepG2 cells.

Research conclusions

FBXO2 exacerbates lipid accumulation by targeting HADHA.

Research perspectives

Our results shed light on the role of FBXO2 not only in NAFLD but also in other metabolic diseases involving lipid accumulation, supporting further investigation of the therapeutic potential of this molecule in further studies.

Abstract

BACKGROUND

Probiotics have shown promise in alleviating symptoms of diarrhea-predominant irritable bowel syndrome (IBS-D); however, the certainty of evidence is low. Well-powered randomized controlled dose-ranging trials are warranted on promising single-strain candidates.

AIM

To investigate the clinical efficacy of *Lactiplantibacillus plantarum* (*L. plantarum*) Lpla33 (DSM34428) in adults with IBS-D.

METHODS

This is a randomized, double-blind, placebo-controlled, multi-center, and dose-ranging study. Three hundred and seven adults, 18-70 years of age, with IBS-D, according to Rome IV criteria, were allocated (1:1:1) to receive placebo or *L. plantarum* Lpla33 at 1×10^9 (1B) or 1×10^{10} (10B) colony-forming units/d over an 8-wk intervention period. The primary outcome was the change in IBS severity scoring system (IBS-SSS) total score after 8 wk, while secondary and exploratory outcomes included abdominal pain severity, IBS related quality of life, stool and microbial profile, and perceived stress.

RESULTS

IBS-SSS was significantly reduced, after 8 wk, in participants receiving *L. plantarum* 1B (-128.45 ± 83.30; $P < 0.001$) and *L. plantarum* 10B (-156.77 ± 99.06; $P < 0.001$), compared to placebo (-58.82 ± 74.75). Further, a dose-ranging effect was observed, with a greater absolute reduction in the *L. plantarum* 10B group ($P <$

0.05). A reduction in sub-scores related to abdominal pain, abdominal distension, bowel habits, and quality of life was observed in both *L. plantarum* groups compared to placebo ($P < 0.001$). Further, 62.5% and 88.4% of participants administered *L. plantarum* 1B and 10B, respectively, were classified as stool consistency responders based on a reduction in diarrheal stool form, as compared to 26.3% in the placebo group ($P < 0.001$). In contrast, no significant shifts were observed in microbial diversity.

CONCLUSION

L. plantarum Lpla33 (DSM34428) is well tolerated and improves IBS symptom severity with a dose-ranging effect and a corresponding normalization of bowel habits in adults with IBS-D.

Key Words: Randomized clinical trial; Diarrhea-predominant irritable bowel syndrome; Microbiome; Probiotic; *Lactiplantibacillus plantarum*

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The current study is unique in its dose-ranging assessment of a *Lactiplantibacillus plantarum* (*L. plantarum*) probiotic strain in a well-powered multi-center randomized controlled trial in adults with diarrhea-predominant irritable bowel syndrome (IBS-D). *L. plantarum* Lpla33 (DSM34428) was well tolerated and significantly improved global IBS symptom scores as compared to placebo, both at an absolute level and in the number of clinically relevant responders. Further, a dose-ranging effect was observed in global IBS symptom scores, abdominal pain severity, quality of life, and normalization of diarrheal stool type.

INTRODUCTION

Irritable bowel syndrome (IBS) is a chronic disorder of gut-brain interaction, characterized by abdominal pain in association with altered bowel habits[1]. Current estimates report a global prevalence of 4% to 9%, based on Rome IV or Rome III diagnostic criteria, respectively[2]. IBS is further classified according to the predominant stool pattern, with diarrhea predominant subtype (IBS-D) reported to be the most common, affecting approximately 40% of adults with IBS [3]. Pathophysiology is multi-factorial and may include altered gastrointestinal (GI) microbiota, motility or barrier function, immune activation, neurotransmitter imbalance, or visceral hypersensitivity[4,5]. In addition to GI symptoms, IBS significantly impacts quality of life (QoL) and is associated with work absenteeism and avoidance of daily activities [6].

IBS-D treatment options include United States Food and Drug Administration approved pharmacologic therapies such as rifaximin, eluxadoline, and alosetron[4]. However, clinical management is challenging due to chronic daily administration, safety concerns, and the heterogeneity of symptoms to address. Increasing evidence supports a link between psychological processes and IBS symptomology *via* altered gut-brain interaction, and there is a growing application of psychological interventions for IBS[7]. Within the gut, dysbiosis, including reduced abundance of lactobacilli and *Bifidobacterium*[8,9], has been reported and is linked to features of IBS-D such as intestinal permeability and low-grade inflammation[6,10]. There are conflicting reports regarding the efficacy of fecal microbiota transplantation in IBS, with enriched lactobacilli, *Streptococcus, Dorea*, and *Ruminococcaceae* reported as favorable bacterial profiles for donors[11].

Probiotics are defined as live microorganisms that, when administered in adequate amounts, confer a health benefit to the host[12]. Select strains are hypothesized to alleviate symptoms of IBS by promoting intestinal barrier function, modulating markers of inflammation, regulating immune cell balance, preventing pathogen adherence, or producing bioactive molecules such as short chain fatty acids (SCFAs), neurotransmitters, or their precursors[5]. A recent meta-analysis of probiotics for adults with IBS-D assessed ten randomized controlled trials evaluating 943 participants[13]. Probiotics were deemed safe and superior to placebo regarding global IBS-D symptoms, abdominal pain, and abdominal distension, but had no beneficial effect on QoL, stool frequency, or flatulence[13]. Additionally, the certainty of evidence was very low to low, due to heterogeneity between studies, and differences in study population, strain selection, dose, dosage form, and duration of intervention[13]. Another recent systematic review and meta-analysis accounted for probiotic strain-specific efficacy in IBS and included 42 randomized controlled trials evaluating 3856 participants[14]. The meta-analysis highlighted single-strains and combinations showing efficacy in at least one IBS outcome measure; however, most studies did not assess outcomes by IBS subtype[14]. As a result, there is a need for well-powered randomized controlled trials on promising single strain candidates with an IBS-D focus.

The present study investigated a *Lactiplantibacillus plantarum* (*L. plantarum*) strain with several relevant attributes, including GI persistence, maintenance of intestinal barrier function, and anti-pathogenic, anti-inflammatory, and bile salt hydrolase activity (Chr. Hansen internal data). The objective was to assess the efficacy and tolerability of *L. plantarum* Lpla33 (DSM34428), with respect to IBS symptomology in a randomized, double-blind, placebo-controlled, multi-center, dose-ranging study in adults with IBS-D.

MATERIALS AND METHODS

Study population and setting

Females and males, ages 18 to 70 years, meeting Rome IV diagnostic criteria for IBS-D were recruited from 12 gastroenterology specialized centers across India. As per Rome IV, included participants had recurrent abdominal pain, at least once a week for the last 3 mo, with onset of symptoms for at least 6 mo, and with at least two of the following criteria: Pain related to defecation or associated with change in stool frequency or stool form. Participants also had a history of abnormal bowel movements wherein diarrhea (type 6 or 7) was the predominant (> 25%) stool pattern on the Bristol stool scale (BSS). Further, an electronic diary was used during a 14-d placebo run-in period, wherein it was re-confirmed that predominant stool type was type 6 or 7 on the BSS. Additionally, participants had an abdominal pain severity-numeric rating score (APS-NRS) of ≥ 4 (on an 11-point scale) and an IBS severity scoring system (IBS-SSS) total score of > 175 (on a 500-point scale) prior to and after a 14-d placebo run-in period. Dietary preferences of all participants included non-vegetarian options.

The exclusion criteria included a history of organic gastrointestinal disease, including inflammatory bowel disease or ischemic colitis, a history of surgical resection of the GI tract, acute gastroenteritis or complications from infectious enteritis, a recent diagnosis of *Helicobacter pylori* infection, a history of gluten or lactose intolerance, a history of malignant tumors, or a history of neurological or psychiatric conditions. A current or recent history (*i.e.*, past 2 years) of smoking as well as heavy drinking, defined as more than 14 or 7 units per week, for males and females, respectively, was also an exclusion criterion. Additionally, individuals with type I or II diabetes, or uncontrolled hypertension were excluded, as well as individuals with abnormal thyroid-stimulating hormone (< 0.35 mIU/L or > 4.94 mIU/L) or hemoglobin (< 6.21 mmol/L) at screening. The use of probiotic/prebiotic supplements or herbal medicines for gut health, was not permitted within 4 wk prior to screening or during the study. Prohibited medications during the study period included antibiotics, antidiarrheals, or other medications affecting gastric motility and anti-depressants, among others. Lastly, participants who were pregnant or intended to get pregnant or breastfeeding were excluded. All participants provided their voluntary, written, informed consent prior to their inclusion.

Study design and procedures

The study was conducted in accordance with the ethical principles that have their origins in the current version of the Declaration of Helsinki, the International Council on Harmonization E6 Good Clinical Practice, and all applicable local regulatory requirements. The study was approved and monitored by an independent ethics committee (Approval No: VED/P-20/22/JUL/2021; Address: ACEAS, Ahmedabad, Gujarat, India). The trial was prospectively registered on clinicaltrials.gov under study number NCT04950296.

This is a prospective, randomized, double-blind, placebo-controlled, multi-center, and parallel-arm study, including two doses of the probiotic product and one placebo arm. The study population was recruited from physician databases of individuals with IBS symptoms within the gastroenterology specialized centers. Participants visited the clinical sites for screening at least 14 d prior to planned randomization. At screening, the study was explained to participants in their local language, following which written informed consent was obtained. Participants were assessed for inclusion-exclusion criteria; a clinical examination was performed, and medical history, concomitant medication, demographic details, and vitals were recorded. Participants meeting the screening criteria underwent a 2-wk placebo run-in period to observe pre-study symptomology and to identify placebo responders, defined as a decrease of more than 25% in APS-NRS. Participants not meeting the placebo responder criteria were eligible for randomization (day 0) and subsequent visits at day 28 ± 2 and day 56 ± 2 over an 8-wk intervention period.

Participants were randomized (1:1:1), without stratification, to receive either placebo, *L. plantarum* (1B), or *L. plantarum* (10B). Block randomization (block size of six) was performed using Stats Direct software (Version 3.1.17), generating distinct alphanumeric codes, with every block containing two of each arm in random sequence. The study sites were allocated randomization codes in series, and the sites dispensed blinded product and corresponding randomization code, in sequential order of participant qualification. The randomization codes were concealed from site investigators, as well as site and study teams involved in study conduct and evaluation, with blinding codes secured in tamper-evident sealed envelopes.

Study products

Placebo and *L. plantarum* capsules were prepared in compliance with standard operating and quality control procedures at Chr. Hansen Inc. (Wausau, WI, United States). Microbiological analyses were confirmed following production. *L. plantarum* 1B and 10B capsules were formulated with the lyophilized strain and microcrystalline cellulose and contained a potency of not less than (NLT) 1×10^9 colony-forming units (CFU)/capsule or 1×10^{10} CFU/capsule, respectively. Placebo capsules were formulated with microcrystalline cellulose. All capsules were size 1 hypromellose, contained minimal but identical quantities of magnesium stearate and silica as flow aids, were identical in mass, appearance, and taste, and were bottled in identical sealed 112 mL CSP bottles (Aptar CSP Technologies Inc., Auburn, AL, United States) containing 35

capsules per bottle. Participants took the allotted study product orally, one capsule daily before lunch, with a glass of water. Compliance was assessed *via* participants' investigational product diary and confirmed by examining unused study product at each visit.

Outcome measures

On days 0, 28, and 56 visits, study outcomes were assessed, a clinical examination was conducted, study product was dispensed or collected, and concomitant medication usage was recorded. Metronidazole (400 mg/d) was provided as a rescue medication in the case of severe pain and/or frequent loose stool, as it has been shown to provide symptom relief in IBS without affecting rectosigmoid motility[15]. Study product compliance was assessed *via* participants' investigational product diary and confirmed by examining unused study product at each visit. A dietary diary was completed by participants over the 14 d prior to each study visit, recording dietary intake for two weekdays and one weekend day. Dietary information was processed *via* HealthifyMe software[16] for average daily intake of calories and macronutrients over the study period.

The pre-specified ranking of primary and secondary outcomes is listed in Supplementary Table 1. The primary outcome was the change in IBS symptom severity, assessed *via* the IBS-SSS total score[17] from baseline to day 56. Scores on the IBS-SSS range from 0 to 500, with five domains related to abdominal pain severity and frequency, abdominal distention, dissatisfaction with bowel habits, and interference with QoL. A decrease of 95 points has been associated with clinically meaningful improvement[18], and was used for classification of IBS-SSS responders.

Among secondary outcomes, abdominal pain severity was assessed *via* an 11-point numeric rating scale (APS-NRS) [18], with 10 representing most severe pain and 0 representing no pain. Post-screening APS-NRS scores were submitted using a digital diary on a weekly basis. An average of the prior weeks' score was considered as the score for the corresponding visit.

Stool consistency was assessed *via* the BSS, a validated ordinal scale of stool types[19] ranging from 1 through 7, with types 6-7 being indicative of diarrhea. Stool consistency responders were defined as a decrease of 50% or more *vs* baseline in the number of days per week with at least one types 6-7 bowel movement[20].

IBS related QoL was assessed *via* the IBS-QoL, a 34-item questionnaire wherein the individual responses are summed and transformed to a 0-100 scale, with increasing scores indicating improved IBS specific QoL[21]. Lastly, mental stress was assessed using the perceived stress scale (PSS), consisting of 10 items and a total score ranging from 0-40, with higher scores indicating higher perceived stress[22].

Microbial profiling

Participants collected fecal samples, as close as possible but prior to the day 0 and day 56 visits, inside a biome collector device and ultimately a barcoded stool collection tube with preservation buffer. Stool collection tubes were stored at the individual sites, with regular shipments to a central laboratory, wherein they were shipped approximately every 8 wk to CosmosID (Germantown, MD, United States) for analysis. Cold chain (2-8 °C) was maintained during the entire process with data loggers used to confirm temperature variations during shipment.

Sample DNA isolation and quantification, library preparation, and shotgun sequencing of fecal samples were performed by CosmosID. DNA from samples was isolated using the QIAGEN DNeasy PowerSoil Pro Kit, according to the manufacturer's protocol. DNA samples were quantified using the GloMax Plate Reader System (Promega) using the QuantiFluor® dsDNA System (Promega) chemistry. DNA libraries were prepared using the Nextera XT DNA Library Preparation Kit (Illumina) and IDT Unique Dual Indexes with total DNA input of 1 ng. Genomic DNA was fragmented using a proportional amount of Illumina Nextera XT fragmentation enzyme. Unique dual indexes were added to each sample followed by 12 cycles of PCR to construct libraries. DNA libraries were purified using AMpure magnetic beads (Beckman Coulter) and eluted in QIAGEN EB buffer. DNA libraries were quantified using Qubit 4 fluorometer and Qubit dsDNA HS Assay Kit. Libraries were then sequenced on an Illumina NextSeq 2000 platform (2 × 150 bp).

Statistical analysis

The sample size calculation was based on the primary outcome. A reduction in IBS-SSS score of at least 15% in the *L. plantarum* 1B group as compared to placebo, was considered a relevant treatment effect[23]. The standard deviation of the primary outcome was estimated at 30%. A placebo effect was estimated at 20%-25%. Assuming a 90% study power and a two-sided statistical significance level of 5%, the sample size was estimated to be approximately 86 participants per group. With an estimated 15% drop-out rate, 100 participants per group were planned to be randomized.

The primary and secondary outcomes (Supplementary Table 1) were assessed on the intention-to-treat (ITT) population. Descriptive statistics are presented as the mean (SD) for continuous variables or as a percentage for qualitative variables. Data normality was assessed using the Shapiro-Wilk test. Differences between groups for demographic and clinical characteristics at baseline were analyzed using one-way ANOVA for continuous variables or Pearson chi-square test for categorical variables. An analysis of covariance (ANCOVA) was assessed for continuous outcomes on the absolute change from baseline to subsequent visit. Dunnett's test for multiple comparisons was applied to assess statistical significance for each *L. plantarum* dose group as compared to placebo. A two-sample *t*-test was used to compare the difference between the two *L. plantarum* dose groups. Categorical outcomes were assessed *via* a Pearson chi-square test. The associations between efficacy parameters were assessed *via* Pearson correlation coefficients. Descriptive and inferential statistics were performed using Statistical Package for the Social Sciences (SPSS, IBM®) Python 3.0 (Armonk, NY, United States).

Microbial profile stacked bar figures were generated using the R package ggpubr. Linear Discriminant Analysis Effect Size (LEfSe) was calculated with a Kruskal-Wallis alpha value of 0.05, a Wilcoxon alpha value of 0.05, and a logarithmic

LDA score threshold of 2.0.

RESULTS

Study parameters

A total of 333 screened participants were assessed for eligibility and 314 participants were randomized in the study (Figure 1). Enrolment and intervention occurred continuously from September 2021 through May 2022. Seven participants were incorrectly enrolled, without meeting entry criteria, and were excluded. Three hundred and seven participants were randomized as part of the ITT population, with 104, 104, and 99 allocated to the placebo, *L. plantarum* 1B, and *L. plantarum* 10B groups, respectively. A total of 298 participants completed the first follow-up visit, while nine participants were lost to follow-up with no post-baseline efficacy data. Study attrition rates over the intervention period were 5 (4.8%), 2 (1.9%), and 4 (4.0%) for the placebo, *L. plantarum* 1B, and *L. plantarum* 10B groups, respectively. A total of 294 participants completed the study per protocol.

Baseline characteristics

The screening and baseline characteristics of the ITT population are presented in Table 1. The three groups had similar demographic and clinical characteristics with no differences between groups ($P > 0.05$). The mean ages of participants were 39.5, 38.7, and 40.5 years across the three groups with a nearly even distribution of females and males. Participants met Rome IV criteria for IBS-D and demonstrated similar baseline mean IBS-SSS scores of 308.7, 315.2, and 302.9 for the placebo, *L. plantarum* 1B, and *L. plantarum* 10B groups, respectively ($P > 0.05$). At baseline, 43.4%, 41.4%, and 47.4% of participants in the placebo, *L. plantarum* 1B, and *L. plantarum* 10B groups, respectively, had moderate (175-300) IBS-SSS profiles, while 56.6%, 58.7%, and 52.6% of participants in the placebo, *L. plantarum* 1B, and *L. plantarum* 10B groups, respectively, had severe (> 300) IBS-SSS profiles.

IBS symptom severity

A significant between-group difference was observed in the primary outcome, change in IBS-SSS total score after 56 d, for both *L. plantarum* groups when compared to placebo (Table 2). On day 56, a greater reduction in IBS-SSS total score was observed in the *L. plantarum* 1B (-128.45 ± 83.30) and *L. plantarum* 10B (-156.77 ± 99.06) groups, as compared to placebo (-58.82 ± 74.75) ($P < 0.001$). Similarly, a greater reduction in IBS-SSS total score was observed on day 28 in the *L. plantarum* 1B (-66.37 ± 72.27) and *L. plantarum* 10B (-85.80 ± 89.53) groups, as compared to placebo (-35.68 ± 60.81) ($P < 0.01$). Comparing the two dose groups, the *L. plantarum* 10B group demonstrated a significantly greater reduction in IBS-SSS total score at day 56 ($P < 0.05$). End-of-study IBS-SSS profiles were considered either in remission or mild (< 175) in 48.1% and 72.6% of participants in the *L. plantarum* 1B and *L. plantarum* 10B groups, respectively. as compared to 11.1% in the placebo group ($P < 0.001$).

Participants receiving *L. plantarum* 1B capsules reported significant reductions in the scores of IBS-SSS individual domains over the intervention period, as compared to placebo, including abdominal pain severity (-28.91 ± 20.36), abdominal pain duration (-15.29 ± 13.72), abdominal distension (-29.33 ± 21.64), bowel habits (-27.73 ± 19.54) and QoL (-27.19 ± 19.19) ($P < 0.001$). Similarly, participants receiving *L. plantarum* 10B capsules reported significant reductions in IBS-SSS domain specific scores, as compared to placebo, including abdominal pain severity (-36.52 ± 24.39), abdominal pain duration (-19.68 ± 14.91), abdominal distension (-35.45 ± 24.00), bowel habits (-32.31 ± 25.12), and QoL (-32.81 ± 23.66) ($P < 0.001$). Comparing the two dose groups, the *L. plantarum* 10B group demonstrated a greater reduction in abdominal pain severity and duration scores over the intervention period ($P < 0.05$).

After 56 d, 59.6% and 72.6% of participants met 95-point reduction thresholds[18] in the *L. plantarum* 1B and *L. plantarum* 10B groups, respectively, as compared to 26.3% in the placebo group ($P < 0.001$) (Figure 2A). A post-hoc assessment showed 83.7% and 87.4% of participants met 50-point IBS-SSS reduction thresholds[17] in the *L. plantarum* 1B and *L. plantarum* 10B groups, respectively, as compared to 46.5% in the placebo group ($P < 0.001$). Additionally, 2.9% and 2.1% of participants demonstrated an increase in IBS-SSS score in the *L. plantarum* 1B and *L. plantarum* 10B groups, respectively, as compared to 18.2% in the placebo group ($P < 0.001$).

Abdominal pain severity, quality of life, and perceived stress

Baseline APS-NRS scores were 7.14 ± 0.69, 7.14 ± 0.77, and 7.17 ± 0.86 for the placebo, *L. plantarum* 1B, and *L. plantarum* 10B groups, respectively ($P > 0.05$). On day 56, a greater reduction in APS-NRS score (Table 3) was observed in the *L. plantarum* 1B (-1.83 ± 1.38) and *L. plantarum* 10B (-2.39 ± 1.47) groups, as compared to placebo (-0.94 ± 1.36) ($P < 0.001$). The mean reduction in the *L. plantarum* 10B group exceeded a clinically meaningful threshold of 30%[20] over the intervention period.

On day 56, a significant increase in IBS-Qol score (Table 3) was observed in the *L. plantarum* 1B (17.47 ± 19.54) and *L. plantarum* 10B (28.78 ± 23.64) groups, as compared to placebo (4.90 ± 14.29) ($P < 0.001$). Similarly, a greater improvement in total IBS-QoL score was demonstrated on day 28 in the *L. plantarum* 1B (8.82 ± 17.38) and *L. plantarum* 10B (17.65 ± 19.47) groups, as compared to placebo (4.20 ± 14.19) ($P < 0.01$). Comparing the two dose groups, the *L. plantarum* 10B group demonstrated a greater improvement in IBS-QoL at both timepoints ($P < 0.001$).

Perceived stress, assessed *via* the PSS, was similarly improved in the *L. plantarum* 1B and *L. plantarum* 10B groups, as compared to placebo on both day 28 and day 56 (Table 3). On day 56, a significant reduction in PSS score was observed in the *L. plantarum* 1B (-4.33 ± 6.51) and *L. plantarum* 10B (-5.59 ± 6.43) groups, as compared to placebo (-0.46 ± 4.14) ($P <$

BMI: Body mass index; BP: Blood pressure; IBS-SSS: Irritable bowel syndrome-severity scoring system; APS-NRS: Abdominal pain severity-numeric rating scale; IBS-QoL: Irritable bowel syndrome-quality of life; PSS: Perceived stress scale; *L. plantarum*: *Lactiplantibacillus plantarum*.

0.001). No significant differences were observed between the dose groups in PSS. Further, a post-hoc analysis showed PSS response to be moderately but significantly correlated to IBS-SSS (r = 0.326, P < 0.001) and APS-NRS scores (r = 0.355, P < 0.001) over the intervention period.

Stool consistency

Figure 2B shows the percent of participants considered IBS-D stool consistency responders, based on a decrease of 50% or more in the number of days per week with at least one types 6-7 bowel movement, as compared to baseline[20]. On day 56, 62.5% and 88.4% of study participants met the criteria of IBS-D stool consistency responders in the *L. plantarum* 1B and *L. plantarum* 10B groups, respectively, as compared to 26.3% in the placebo group. Additionally, a greater number of responders were observed in the *L. plantarum* 10B group as compared to the *L. plantarum* 1B group (P < 0.001). A significant number of responders were also observed in the *L. plantarum* 1B (30.8%; P < 0.05 *vs* placebo) and *L. plantarum* 10B (48.4%; P < 0.001 *vs* placebo) groups after day 28.

Microbial profiling

There were no significant differences in alpha (Shannon) diversity or beta diversity between groups over the study period, suggesting no major shifts in microbiome composition. Figure 3 shows the proportional family (A) and genus (B) level abundance in participants receiving placebo, *L. plantarum* 1B, and *L. plantarum* 10B, respectively. The most abundant taxa at the phylum level, Firmicutes, Bacteroidetes, and Actinobacteria, did not differ significantly over time in the three groups. Similarly, the most abundant taxa at the family level, *Lachnospiraceae*, *Prevotellaceae*, *Ruminococcaceae*, and *Bifidobacteriaceae* were stable within group over the intervention period, with the exception of a significant reduction in *Ruminococcaceae* and *Bifidobacteriaceae* within the placebo group (LEfSe logarithmic LDA score < -3.0) that was not observed in the *L. plantarum* groups. Similarly, the placebo group demonstrated a significant reduction in *Bifidobacterium*, *Faecalibacterium,* and *F. prausnitzii* (LEfSe logarithmic LDA score < -3.0) over the study period that was not observed in the *L. plantarum* groups. LEfSe identified more taxa enriched in the higher dose *L. plantarum* group at the end of study visit as compared to placebo, including both *Lactiplantibacillus* and *L. plantarum* abundance (LEfSe logarithmic LDA score > 2.0).

Safety, compliance, and dietary profile

A total of 37 adverse events (AEs) were reported during the study, with seven reported during the run-in phase and 30 reported during the intervention phase. Of the 30 AEs reported post-randomization, 12, 13, and 5 were in the placebo, *L. plantarum* 1B, and *L. plantarum* 10B groups, respectively. A total of four AEs were suspected to be related to the study product with one AE (nausea and vomiting) in the *L. plantarum* 1B group and three AEs (heartburn and hyperacidity) in the placebo group. All AEs reported in the study were considered mild and resolved without complications. Vital signs, including systolic and diastolic blood pressure and pulse rate, were within clinically acceptable ranges over the intervention period with no significant differences between groups (Supplementary Table 2). Overall mean compliance over the study period was 98.7%, 98.4%, and 98.5% for the placebo, *L. plantarum* 1B, and *L. plantarum* 10B groups,

respectively, with no differences between groups ($P > 0.05$). Additionally, total caloric and macronutrient intake, including protein, carbohydrates, fat, and fiber, were stable over the intervention period with no significant differences between groups ($P > 0.05$) (Supplementary Table 3).

DISCUSSION

The present study was a randomized, double-blind, placebo-controlled trial to assess the efficacy of *L. plantarum* Lpla33 (DSM34428) in adults with IBS-D. The study is unique in its dose-ranging design in a well-powered study across 12 clinical sites. Enrolled participants were primarily 30 to 50 years of age, with a body mass index ranging from normal to borderline overweight and an IBS symptom score of at least moderate severity.

The study had a roughly equal allocation of females and males, which is in line with prevalence rates for the IBS-D subtype globally[24,25], as well as prior IBS studies in Asia[26-28], and in contrast with a significantly greater female prevalence among constipation-predominant (IBS-C) cohorts[2]. Within South Asia, chronic gut infections, gut microbial dysbiosis, altered intestinal permeability, and inflammation are suggested as contributing factors to IBS and IBS-D[26]. Dietary practices may also play a role, with a generally high consumption of short chain carbohydrates[29].

In the present study, *L. plantarum* Lpla33, at daily doses of 1×10^9 or 1×10^{10} CFU, reduced IBS-SSS by more than twice the magnitude of the placebo group after 56 d, thus achieving the primary outcome while surpassing a clinically

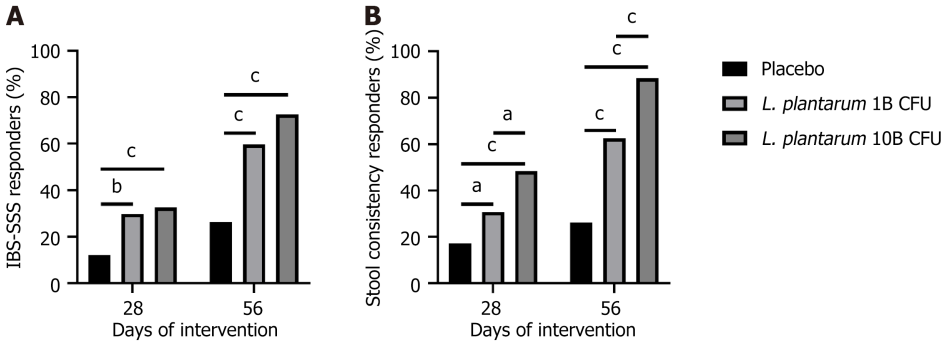
meaningful response[18]. Further, the higher dose *L. plantarum* group demonstrated a greater effect size than the lower dose *L. plantarum* group. Previously, an *L. acidophilus* strain, administered at daily doses of 1×10^9 and 1×10^{10} CFU for 12 wk, exhibited a treatment effect in a post-hoc analysis of IBS participants with elevated abdominal pain levels[30]. However, no dose-response was observed. Similarly, a meta-analysis reported a similar improvement in IBS symptoms when comparing probiotic regimens greater than or less than 1×10^{10} CFU daily[30]. In contrast, a *L. gasseri* strain resulted in a reduction in abdominal pain severity *vs* placebo at a daily dose of 1×10^{10} CFU, but had no effect in groups receiving 2×10^8 or 2×10^9 CFU daily[31]. Another meta-analysis looked at 14 different probiotic products over a total of 45 intervention arms, of which 36%, 51%, and 11% used a daily dose of 10^6-10^9, 10^{10}, and 10^{11} CFU, respectively[14]. Of these, a dose response was noted for a 4-strain probiotic combination at 10^{10} CFU daily[32,33], as well as a *B. infantis* strain, which demonstrated efficacy at a dose of 10^8 CFU daily but not at doses of 10^6 or 10^{10} CFU daily[34].

Both *L. plantarum* dose groups displayed a significant number of IBS-SSS responders using either 95-point[18] or 50-point[17] reduction thresholds, which have independently been correlated with clinically relevant responses. Further, the high responder rates across participants with heterogeneous baseline symptoms[35] may also be applicable to the general healthy population experiencing GI discomfort with less frequency or severity[36].



Abdominal pain severity, assessed *via* the APS-NRS, was also significantly reduced with *L. plantarum* supplementation, with the higher dose group achieving a clinically relevant reduction of over 30%[20]. It should be noted that the placebo response of approximately 20% in the current study was less than those in prior IBS-D studies, which ranged from 32% to 44%[37-39]. This may have been due, in part, to the placebo run-in period as well as geographic, cultural, or dietary differences. Additionally, the higher-dose *L. plantarum* group exhibited a mean increase in IBS related QoL of 28.8 points, above the clinically meaningful threshold of 10 points[40]. This is of note given the lower reported QoL in IBS-D as compared to IBS-C[41], in part due to unpredictable defecation habits that limit daily activity. In addition, perceived stress in the *L. plantarum* groups was reduced compared to placebo. Of note, moderate but significant correlations were observed between reduced IBS symptomology, abdominal pain, and stress levels, with effects possibly linked to a more normalized gut-brain signaling or barrier function.

Rome Foundation reports have supported the concept that the intestinal microbiota is perturbed in IBS[42,43], and both incidence and symptom severity have been inversely associated with microbiome diversity[44,45]. Further, reports have linked IBS pathogenesis to dysbiosis of the microbiota[9,46], which may in turn impact pathogen binding and mucosal barrier integrity. However, there remain no uniform characteristics of an IBS-related gut microbiota[47]. The current study demonstrated a significant reduction in type 6 or 7 stool form *via* stool consistency responder analysis[20], including a dose effect among the *L. plantarum* groups. In contrast, no significant shifts in fecal microbial diversity were observed, in line with systematic reviews of probiotic studies showing no effects on alpha diversity, richness, or evenness, as well as composition[48]. *Lactiplantibacillus* and *L. plantarum* abundances were enriched at the end of study visit in the higher dose group as compared to placebo. Further, *Ruminococcaceae, Bifidobacterium,* and *F. prausnitzii* significantly decreased over the study period in the placebo group. Multi-omics studies have implicated *F. prausnitzii*, *Ruminococcus* spp., and *Bifidobacterium* in IBS treatment response[47], but it is unclear if this played a role here. Overall, the most abundant taxa did not significantly change over time. However, the site of action of *L. plantarum* Lpla33 is postulated to

Figure 2 Responder profile over the intervention period. A: Percentage of irritable bowel syndrome-severity scoring system (IBS-SSS) responders, as defined by a decrease of 95 points or more in the IBS-SSS total score from baseline, in participants receiving placebo or *Lactiplantibacillus plantarum* (*L. plantarum*) (1B or 10B CFU) capsules; B: Percentage of stool consistency responders, as defined by a decrease of at least 50% in the number of days per week with at least one stool that has a consistency of type 6 or 7 compared with baseline, in participants receiving placebo or *L. plantarum* (1B or 10B CFU) capsules. Between group comparison *via* Pearson chi-square test. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$. *L. plantarum*: *Lactiplantibacillus plantarum*.

be proximal to the colon, and fecal samples may not accurately reflect the small intestinal profile or corresponding changes in mucosal inflammation or epithelial function[6].

L. plantarum is a well-documented species, with several prior studies demonstrating efficacy in managing IBS symptomology, albeit with strain specific differences[49-53]. Recent studies with *L. plantarum* strains have also reported improved QoL and defecation frequency in IBS-D[50,52]. In rodent models, *L. plantarum* strains have been shown to

Figure 3 Fecal microbial profile over the intervention period. A: Proportional family level abundance in participants receiving placebo or *Lactiplantibacillus plantarum* (*L. plantarum*) (1B or 10B CFU) capsules; B: Proportional genus level abundance in participants receiving placebo or *L. plantarum* (1B or 10B CFU) capsules.

relieve diarrhea through inflammation modulation and increased SCFAs[54], as well as upregulate the expression of brain-derived neurotrophic factor, serotonin transporter, and intestinal serotonin levels[55]. SCFAs play a critical role in gut homeostasis *via* mucus production, protection from inflammation, and immunomodulation[56]. Further, SCFA-producing microorganisms can also affect neurotransmitter levels and therefore gut-brain signaling, as well as activate and directly act on intestinal vagal terminals[57]. Additionally, SCFAs, particularly butyrate, may help promote intestinal barrier function[58], a feature of several *L. plantarum* strains[59]. Bile acid (BA) metabolism may also be implicated, as *L. plantarum* Lpla33 possesses significant bile salt hydrolase activity. Of note, diarrhea and visceral hypersensitivity have been associated with decreased 7α-dehydroxylation of primary BAs to secondary BAs[60]. Additionally, the ability of *L. plantarum* Lpla33 to modulate intestinal barrier function, inhibit key pathogens, and moderate inflammatory markers may have played a role in the observed effects.

Limitations of the study include the absence of biomarkers assessing immunity, inflammation, and intestinal barrier function, in part due to the large enrollment across several sites. Additionally, the study assessed fecal samples but not proximal sites of interest or corresponding changes in mucosal profile, inflammation, or epithelial function. Further, the study did not incorporate metabolite profiles in serum, feces, or urine to assess changes in immune or inflammation-related pathways[47]. Additionally, while macronutrient intake was shown to be stable over the study period, the association of diet with the microbial community or metabolite profiles would have been of interest to explore in more detail. Going forward, multi-omics studies should play an important role in further understanding therapeutic mechanisms of probiotic and diet-based interventions in IBS-D. Nevertheless, the study was well-powered to evaluate its primary outcome, incorporated 12 clinical sites and multiple doses, and integrated IBS trial design considerations[61].

CONCLUSION

The present randomized controlled trial demonstrates that *L. plantarum* Lpla33 (DSM34428) at a dose of 1×10^9 and 1×10^{10} CFU/day was well tolerated and met the primary outcome (reduction in IBS-SSS total score at day 56) in both dose groups compared to placebo. The study also met the first secondary outcome (reduction in IBS-SSS score at day 28) as well as outcomes related to abdominal pain severity, stool normalization, QoL, and perceived stress, when compared to placebo over the intervention period. Lastly, a *L. plantarum* Lpla33 dose response was observed in several key outcomes in females and males with IBS-D.

ARTICLE HIGHLIGHTS

Research background

Irritable bowel syndrome (IBS) is a disorder of gut-brain interaction characterized by abdominal pain in association with altered bowel habits and further classified by the predominant stool pattern. Global prevalence is high, with diarrhea predominant subtype (IBS-D) considered the most common. IBS-D has a significant impact on quality of life, and clinical management remains challenging due to the variety of symptoms to address.

Research motivation

A recent meta-analysis showed probiotics to be safe and superior to placebo for alleviating global IBS-D symptoms. However, the certainty of evidence is low, due in part to significant heterogeneity between studies. There is therefore a need for well-powered randomized controlled trials on promising probiotic candidates for IBS-D.

Research objectives

To assess the efficacy of a probiotic candidate strain, *Lactiplantibacillus plantarum* (*L. plantarum*) Lpla33 (DSM34428), in adults with IBS-D. The primary outcome was the change in the IBS severity scoring system (IBS-SSS) total score after 8 wk. Additional outcomes included the change in abdominal pain severity, IBS-related quality of life, stool and microbial profile, and perceived stress.

Research methods

Adults meeting Rome IV diagnostic criteria for IBS-D were recruited from 12 gastroenterology specialized centers across India. In this randomized, double-blind, placebo-controlled, multi-center, parallel-arm, and dose-ranging study, a total of 307 adults meeting the inclusion criteria were allocated (1:1:1) to receive placebo or *L. plantarum* Lpla33 at one of two doses [1×10^9 colony-forming units (CFU)/d (1B) or 1×10^{10} CFU/d (10B)] over 8 wk.

Research results

The primary outcome, IBS-SSS total score, was significantly reduced after 8 wk in participants receiving *L. plantarum* compared to placebo ($P < 0.001$), with a dose-ranging effect when comparing the two *L. plantarum* groups ($P < 0.05$). In total, 59.6% and 72.6% of participants in the *L. plantarum* 1B and *L. plantarum* 10B groups, respectively, were considered significant responders based on a 95-point reduction threshold, as compared to 26.3% in the placebo group ($P < 0.001$). Additionally, 62.5% and 88.4% of participants administered *L. plantarum* 1B and 10B, respectively, demonstrated a significant reduction in diarrheal stool form as compared to 26.3% in the placebo group ($P < 0.001$).

Research conclusions

L. plantarum Lpla33 is well tolerated and demonstrates dose-ranging efficacy in alleviating IBS symptom severity with a corresponding normalization of bowel habits in adults with IBS-D.

Research perspectives

Future research should incorporate multi-omics analyses and associated biomarkers to better understand the mechanisms of action involved.

ACKNOWLEDGEMENTS

The authors thank the site investigators (Dr. R. Dargad, Dr. S. Deshpande, Dr. J. Patel, Dr. S. Narang, Dr. P. Rahate, Dr. S. Kulkarni, Dr. A. Khanna, Dr. S. Khanna, Dr. A. Jangid, Dr. A. Pandit, Dr. R. Kushwaha, and Dr. N. Jillawar) for enabling the study, and monitors for overseeing the conduct of the study. We thank the Vedic Lifesciences team, including project, quality assurance, and data managers, as well as the consulting statistician, for professional management of the study. We thank the CosmosID team for their microbial profiling analysis and expertise. Lastly, we are thankful to J. Jensen and team for overseeing the production and quality control of the study products.

Abstract

BACKGROUND

Hemodynamic instability and shock are associated with untoward outcomes in gastrointestinal bleeding. However, there are no studies in the existing literature on the proportion of patients who developed these outcomes after gastrointestinal bleeding.

AIM

To determine the pooled event rates in the available literature and specify them based on the bleeding source.

METHODS

The protocol was registered on PROSPERO in advance (CRD42021283258). A systematic search was performed in three databases (PubMed, EMBASE, and CENTRAL) on 14th October 2021. Pooled proportions with 95%CI were calculated with a random-effects model. A subgroup analysis was carried out based on the time of assessment (on admission or during hospital stay). Heterogeneity was assessed by Higgins and Thompson's I^2 statistics. The Joanna Briggs Institute

Prevalence Critical Appraisal Tool was used for the risk of bias assessment. The Reference Citation Analysis (https://www.referencecitationanalysis.com/) tool was applied to obtain the latest highlight articles.

RESULTS

We identified 11589 records, of which 220 studies were eligible for data extraction. The overall proportion of shock and hemodynamic instability in general gastrointestinal bleeding patients was 0.25 (95%CI: 0.17-0.36, I^2 = 100%). In non-variceal bleeding, the proportion was 0.22 (95%CI: 0.14-0.31, I^2 = 100%), whereas it was 0.25 (95%CI: 0.19-0.32, I^2 = 100%) in variceal bleeding. The proportion of patients with colonic diverticular bleeding who developed shock or hemodynamic instability was 0.12 (95%CI: 0.06-0.22, I^2 = 90%). The risk of bias was low, and heterogeneity was high in all analyses.

CONCLUSION

One in five, one in four, and one in eight patients develops shock or hemodynamic instability on admission or during hospitalization in the case of non-variceal, variceal, and colonic diverticular bleeding, respectively.

Key Words: Gastrointestinal bleeding; Hemodynamic instability; Shock; Meta-analysis; Statistics; Review

Core Tip: Gastrointestinal bleeding is one of the most common gastrointestinal emergencies with estimated mortality up to 10%. It is associated with significant morbidity, additional burden, and health care costs. It is documented that hemodynamic instability and shock are highly associated with untoward outcomes; they lead to a higher mortality rate, rebleeding risk, prehospital transfusion, and sedation complications. Our study provides clear evidence that hemodynamic instability and shock are common presentations and complications in gastrointestinal bleeding and gives insight into some possible predictor factors.

INTRODUCTION

The annual incidence of gastrointestinal bleeding (GIB) is 100 per 100000 population, and it is one of the most common gastroenterological emergencies with an estimated mortality rate in the range of 2%-10%, primarily due to complications related to the admission state and individual patient factors[1-3]. It is associated with significant morbidity, additional burden, and health care costs[4,5]. The mortality rate of upper GIB has not considerably decreased over the past decades, despite the improvement in the diagnosis and endoscopic treatment[6]. We contemplate that pre-endoscopic assessment and post-endoscopic care may contribute effectively to better outcomes.

Several studies showed that hemodynamic instability (HI) and shock in GIB are highly associated with untoward outcomes; they can lead to higher mortality rates, prehospital transfusion, rebleeding risk, and endoscopic sedation might be complicated with unfavorable hemodynamics if the patient presents with massive bleeding[7-9]. Furthermore, the hospital mortality rate of bleeding with shock can be 10 times higher than without shock[10].

Early intensive resuscitation of HI decreases complications in patients with upper GIB[11]. However, there are not enough details in the guidelines regarding the management of hemodynamically unstable patients; there are still some uncertainties about the optimal fluid rate and the ideal type of fluid to be used in treating those patients[12-15].

At the time of our systematic search, there were no published systematic reviews assessing the proportion of hemodynamically unstable and shocked patients in GIB. There are large variations in the proportions of these outcomes. Some studies in variceal and non-variceal bleeding resulted in proportions of 10% or lower[16-19], whereas others exceeded 60%[20-22]. Therefore, we aimed to highlight the importance of recognizing those patients by quantifying the pooled event rates based on the bleeding source. Additionally, we did a subgroup analysis based on the assessment time of these outcomes (on admission or during hospital stay).

MATERIALS AND METHODS

Our systematic review and meta-analysis was conducted following the recommendation of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) 2020 guideline[23]. The recommendations of the Cochrane

Handbook were also followed[24]. The study protocol was registered on PROSPERO (CRD42021283258), and we fully adhered to it[25]. In addition, we applied the Reference Citation Analysis (RCA) tool, which is based on artificial intelligence technology. This tool allowed us to access a comprehensive database of citations across multiple disciplines, aiding us in identifying the most recent and significant articles for our research.

Eligibility criteria

We applied the CoCoPop (condition, context, and population) framework to establish the eligibility criteria[26]; the condition was hemodynamic instability and/or shock, gastrointestinal bleeding as a context, and our population was adult patients. All definitions of hemodynamic instability and shock were accepted.

Randomized Controlled Trials (RCTs), cohorts, and case-control studies were included. Cross-sectional studies were included only if the hemodynamic parameters were assessed on admission. We included studies only if the primary cause of hospital admission was gastrointestinal bleeding and excluded articles that assessed our investigated outcomes after specific interventions. Articles that could not be found were sought for retrieval by contacting the journals and the authors. In the case of studies with overlapping populations, we kept the ones with larger sample sizes.

Information sources

Our systematic search was conducted in three main databases: MEDLINE (*via* PubMed), EMBASE, and Cochrane Central Register of Controlled Trials (CENTRAL) from the inception to 14th October 2021. No language or other restrictions were applied.

Search strategy

Our search key contained two main concepts: All types of bleeding sources and hemodynamic instability or shock. For the detailed search strategy, see Supplementary Table 1.

Screening and selection

Following the systematic search, the yielded articles were imported into a reference management program (EndNote 20.1). Duplicate articles were eliminated automatically and manually with overlapping publication years, authors, and titles. The screening and selection were performed by two independent reviewers (Obeidat M and Tari E) first by title and abstract, and then by full text (considering the eligibility criteria). Cohen's kappa coefficient (κ) was calculated at both levels of selection to measure the inter-reviewer reliability. In case of any disagreement, a consensus was reached after a discussion with the corresponding author (Erőss B).

Data extraction

The relevant data from the eligible studies were extracted independently by two authors (Obeidat M and Rancz A). Disagreements were resolved by involving the corresponding author (Erőss B). All data were manually collected and introduced into an Excel spreadsheet (Office 365, Microsoft, Redmond, WA, United States) for analysis. The following data were extracted: First author, the year of publication, Digital Object Identifier, geographical location, study period and design, number of centers, basic demographics, source of bleeding, the total number of GIB patients and those who developed HI or shock, definitions of the investigated outcomes, and the time of detection (on admission or during hospital stay).

Risk of bias assessment and quality of evidence

Two independent authors (Obeidat M and Tari E) performed the risk of bias assessment using the 'Joanna Briggs Institute Prevalence Critical Appraisal Tool'[26]. A third reviewer resolved potential disagreements (Rancz A). The tool contains nine items regarding the target population and study settings. Each item was rated as 'yes', 'no', 'unclear', or 'not applicable' according to information provided in each study, with a maximum score of nine points. The higher the score, the lower the risk of bias.

We followed the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach[27] to evaluate the quality of evidence of our results, and the GRADEpro tool (software) was used. Study design, risk of bias, inconsistency, indirectness, and imprecision were the determinant factors.

Statistical synthesis

The statistical analysis of the data was conducted by the R programming language using the meta package. We used forest plots to summarize the findings of the studies and show the pooled result. Pooled event rates were calculated with 95%CIs. The random-effect model was anticipated as applied in all analyses as considerable between-study heterogeneity. The random intercept logistic regression model method was used for pooling method as recommended by Schwarzer *et al*[28]. To estimate the heterogeneity variance measure τ^2, the maximum likelihood method was used. For the outcomes where the study number was at least five, a Hartung-Knapp adjustment was used[29,30]. Below five studies, we applied the adjustment if it was more conservative than without the adjustment. Statistical heterogeneity was assessed by Higgins and Thompson's I^2[31].

Egger's test with the Peter's modification and funnel plots were applied to report and visualize publication bias if at least 10 studies were involved in the analysis[32]; $P < 0.1$ indicates potential publication bias. We also performed an influential sensitivity analysis with leave-one-out method to evaluate whether a single study could have a marked influence on the overall proportional rate or heterogeneity.

A subgroup analysis was carried out based on the time of assessment (on admission or during hospitalization) of HI or shock. Studies where there were no data about the time when the patients were assessed, were considered (during hospitalization). We used a fixed-effects "plural" model. We assumed that subgroups had different τ^2 values as we anticipated differences in the between-study heterogeneity in the subgroups, although a common τ^2 assumption was used for practical reasons if the subgroup size was maximum five. To assess the difference between the subgroups, a Cochrane Q test was used between subgroups[33]. We did not calculate the overall effect and heterogeneity for subgroups where less than three studies were included. We calculated the prediction intervals for our outcomes to assess the probability that future studies would have the same result in a similar setting[34]. The statistical methods of this study were reviewed by Veres DS who is a verified biostatistician from the Centre for Translational Medicine, Semmelweis University.

RESULTS

Search and selection

Altogether, 11589 studies were identified by our search key through three main databases, 8129 in EMBASE, 3134 in Medline (*via* PubMed), and 326 in CENTRAL. Of them, 9192 records remained for title and abstract selection after duplicate removal. A total of 601 studies were sought for full-text selection, out of which 164 records were not found. We managed to retrieve 29, but 135 records were still inaccessible. In total, 466 studies were assessed for full-text eligibility, of which 246 were excluded (Supplementary Table 2). Eleven studies were removed for overlapping populations (Supplementary Table 3). Details of search and selection are illustrated in the PRISMA 2020 flow chart (Figure 1).

Basic characteristics of included studies

Most of the included studies were cohort studies. We also included 28 RCTs, 6 case-control, and 4 cross-sectional studies. Eighty records were from Asia, 66 from Europe, 25 from North America, and 13 from Africa. In total, more than six million patients were included in the analysis. However, the study with the largest sample size included 6411838 patients with different bleeding sources from a 12-year national analysis in the United States[10]. The main characteristics of the enrolled studies are detailed in Supplementary Table 4.

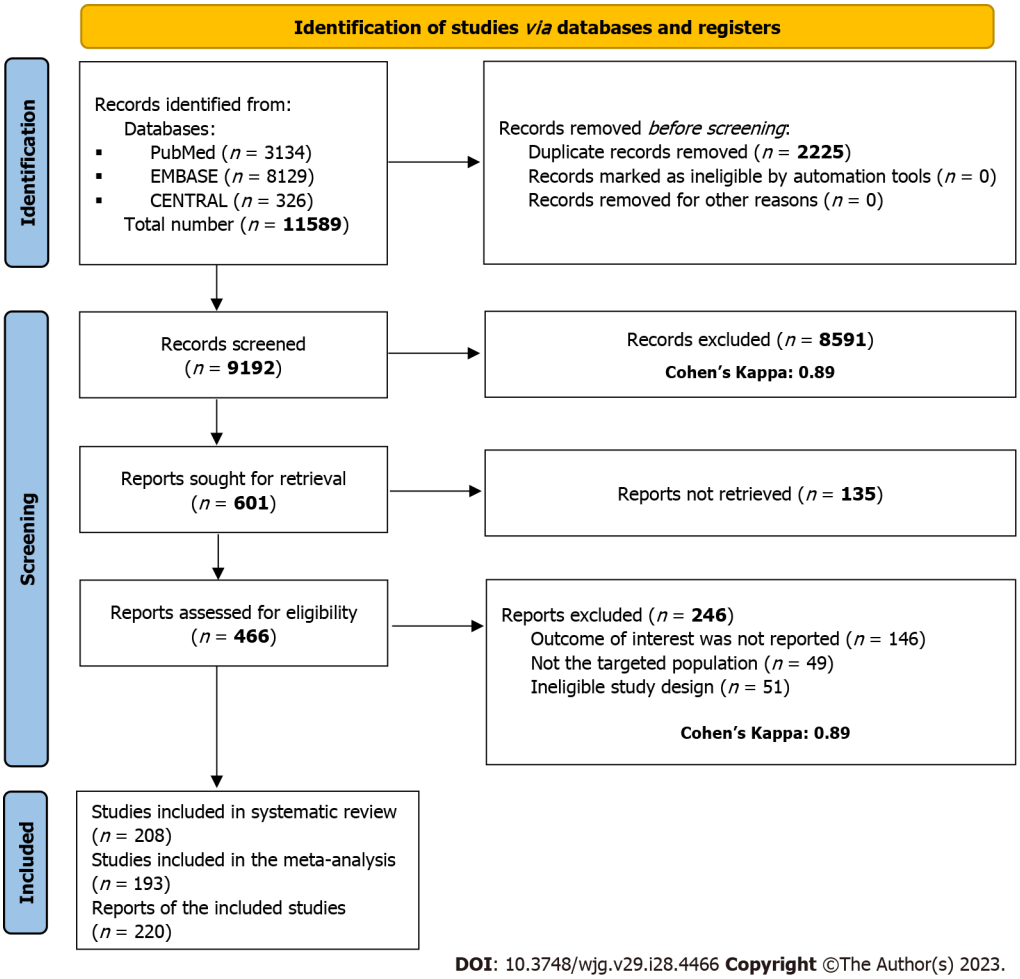
Hemodynamic instability and shock in general gastrointestinal bleeding sources

We included all studies with unspecified bleeding sources[8,10,35-50]. HI was assessed on admission and during hospital stay with pooled event rates of 0.29 (95%CI: 0.12-0.56, I^2 = 87%) and 0.34 (95%CI: 0.11-0.68, I^2 = 93%), respectively. Shock on admission was 0.27 (95%CI: 0.08-0.60, I^2 = 92%), whereas during hospital stay it was 0.15 (95%CI: 0.05-0.36, I^2 = 99%). One in four patients with GIB developed HI or shock; 0.25 (95%CI: 0.17-0.36, I^2 = 100%) (Figure 2).

Hemodynamic instability and shock in non-variceal upper GIB

In the case of non-variceal bleeding, more than three million patients were included in the analysis from 25 studies[10,17,20,21,51-71]. The proportion of hemodynamically unstable patients on admission was 0.21 (95%CI: 0.12-0.36, I^2 = 97%). Two studies assessed HI during hospitalization, Hwang *et al*[58] and Kwon *et al*[60] where the event rate was 0.10 (95%CI: 0.08-0.11) and 0.57 (95%CI: 0.42-0.70), respectively. Moreover, shock on admission was the highest at 0.36 (95%CI: 0.21-0.53, I^2 = 98%), with a noticeable difference from those who developed shock during hospitalization with a rate of 0.07 (95%CI: 0.02-0.18, I^2 = 100%). Altogether, 0.22 (95%CI: 0.14-0.31, I^2 = 100%) of non-variceal bleeders developed shock or HI on admission or during the hospital stay (Figure 3).

Hemodynamic instability and shock in variceal upper GIB



In total, 34 studies were included in this analysis[10,16,20,21,61,65,70,72-98]. The rate of patients with variceal bleeding who presented with HI on admission was 0.38 (95%CI: 0.12-0.73, I^2 = 98%). Two studies assessed HI during hospitalization, Farooqi and Farooqi[96] and Choi *et al*[75] where the event rate was 0.21 (95%CI: 0.14-0.29) and 0.52 (95%CI: 0.40-0.63), respectively. The shock rate on admission was 0.26 (95%CI: 0.18-0.36, I^2 = 100%), whereas it was 0.18 (95%CI: 0.10-0.30, I^2 = 99%) during the hospital stay. In total, one in four patients with variceal bleeding developed shock or HI at presentation or during hospital stay 0.25 (95%CI: 0.19-0.32, I^2 = 100%) (Figure 4).

Hemodynamic instability and shock in peptic ulcer bleeding

Peptic ulcer bleeding (PUB) was the most reported source of bleeding among the included studies. Sixty-seven studies were involved in the subgroups. On admission, 0.22 (95%CI: 0.09-0.44, I^2 = 96%) of the patients were hemodynamically unstable, whereas during the hospital stay, it was 0.41 (95%CI: 0.12-0.78, I^2 = 89%). The rate of shock on admission was 0.25 (95%CI: 0.19-0.32, I^2 = 98%), whereas 0.24 (95%CI: 0.17-0.33, I^2 = 97%) developed shock during hospitalization. As an overall effect, one in four PUB patients was affected by HI or shock on admission or during hospital stay; 0.25 (95%CI: 0.21-0.30, I^2 = 98%) (Supplementary Figure 1).

Hemodynamic instability and shock in upper GIB

The studies included in this plot contain various upper GIB sources. All the studies that reported HI were assessed on admission, with a rate of 0.33 (95%CI: 0.21-0.48, I^2 = 97%). Seventeen studies were included in the shock on admission subgroup with a rate of 0.15 (95%CI: 0.09-0.25, I^2 = 99%), whereas 18 studies evaluated shock during hospitalization with a rate of 0.20 (95%CI: 0.12-0.32, I^2 = 100%). In total, one in five patients with upper GIB developed shock or HI; 0.20

DOI: 10.3748/wjg.v29.i28.4466 **Copyright** ©The Author(s) 2023.

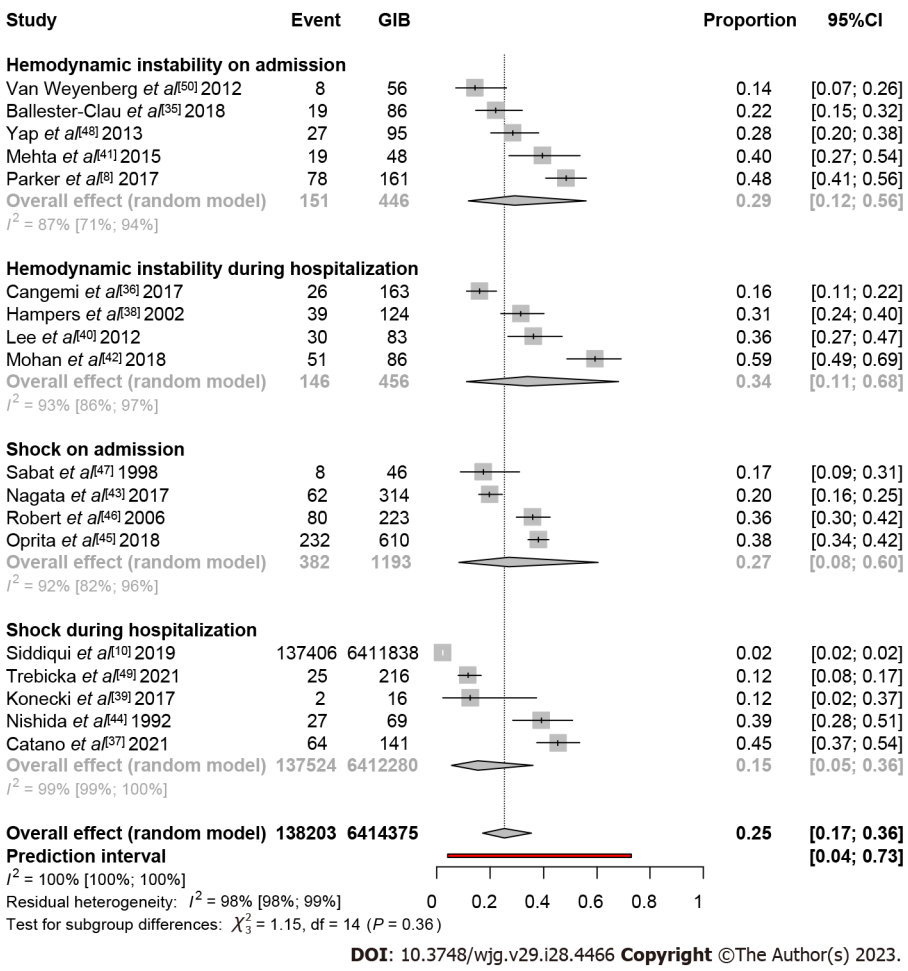
Figure 1 PRISMA 2020 flow chart of the screening and selection process of the studies.

(95%CI: 0.15-0.27, I^2 = 100%) (Supplementary Figure 2).

Hemodynamic instability and shock in lower GIB

In total, 17 studies were included in this analysis[10,48,99-113]. Thirteen studies evaluated HI in lower GIB population: Three studies on admission with a rate of 0.14 (95%CI: 0.01-0.81, I^2 = 83%), and 10 studies during hospitalization with a rate of 0.49 (95%CI: 0.27-0.71, I^2 = 94%). Two studies assessed shock on admission, Oakland *et al*[109] and Li *et al*[105] where the pooled event rates were 0.02 (95%CI: 0.02-0.03) and 0.03 (95%CI: 0.03-0.03), respectively. Another two studies assessed shock during hospital stay. In the study by Siddiqui *et al*[10] the shock rate was 0.02 (95%CI: 0.02-0.02). The study by Lv and Gu[106], which involved patients with life-threatening bleeding, resulted in the highest pooled event rate of shock with a rate of 0.68 (95%CI: 0.50-0.82). In total, of the general lower GIB population, 0.27 (95%CI: 0.13-0-49, I^2 = 100%) developed shock or HI (Figure 5).

Hemodynamic instability and shock in colonic diverticular bleeding



All studies assessed the investigated outcomes on admission only. Six studies evaluated shock in colonic diverticular bleeding (CDB) with a rate of 0.12 (95%CI: 0.05-0.26, I^2 = 91%). Only two studies reported HI, that of Gilshtein *et al*[114] reported a rate of 0.05 (95%CI: 0.02-0.11), and Ichiba *et al*[115] a rate of 0.21 (95%CI: 0.17-0.26). As an overall effect, the proportion of shock and HI in CDB was 0.12 (95%CI: 0.06-0.22, I^2 = 90%) (Supplementary Figure 3).

Risk of bias assessment

Most of the studies received a score of 6 or higher, indicating a moderate to low risk of bias. Only 10 studies were rated with a score less than six. The sample size was not adequate in 33 studies. The results of the risk of bias assessment are presented in Supplementary Table 5.

Heterogeneity and publication bias

Serious heterogeneity (with more than 80%) was observed in all our analyses. The large number of included studies with heterogeneous populations regarding age and sex could explain this. The definitions of HI and shock in the studies were not the same resulting in considerable heterogeneity, too.

DOI: 10.3748/wjg.v29.i28.4466 **Copyright** ©The Author(s) 2023.

Figure 2 Forest plot demonstrating the proportion rates for hemodynamic instability and shock in general gastrointestinal bleeding sources. GIB: Gastrointestinal bleeding.

All of our meta-analytical calculations that included 10 or more studies were investigated for publication bias. CDB was an exception where only eight studies were included. We found potential publication bias in all of our analyses except for non-variceal bleeding based on Egger's test. This result could be explained by the very large heterogeneity of the study estimates. Additionally, a highly influential large study by Siddiqui *et al*[10] led to a false positive result for Egger's test.

Leave-one-out sensitivity analysis showed some variability for some potential outliers. The proportion of our outcomes changed from 0.25 (95%CI: 017-0.36, I^2 = 100%) to 0.29 (95%CI: 0.22-0.37, I^2 = 90%) if Siddiqui *et al*[10] study was eliminated from the GIB analysis. This study did not only include a large sample size compared to other studies but also used the National Inpatient Sample database using International Classification of Diseases (ICD-9) codes to analyze patient data, which might have failed to identify some affected patients. Results of Egger's test, funnel plots, and leave-one-out analysis are found in Supplementary Figures 4-16.

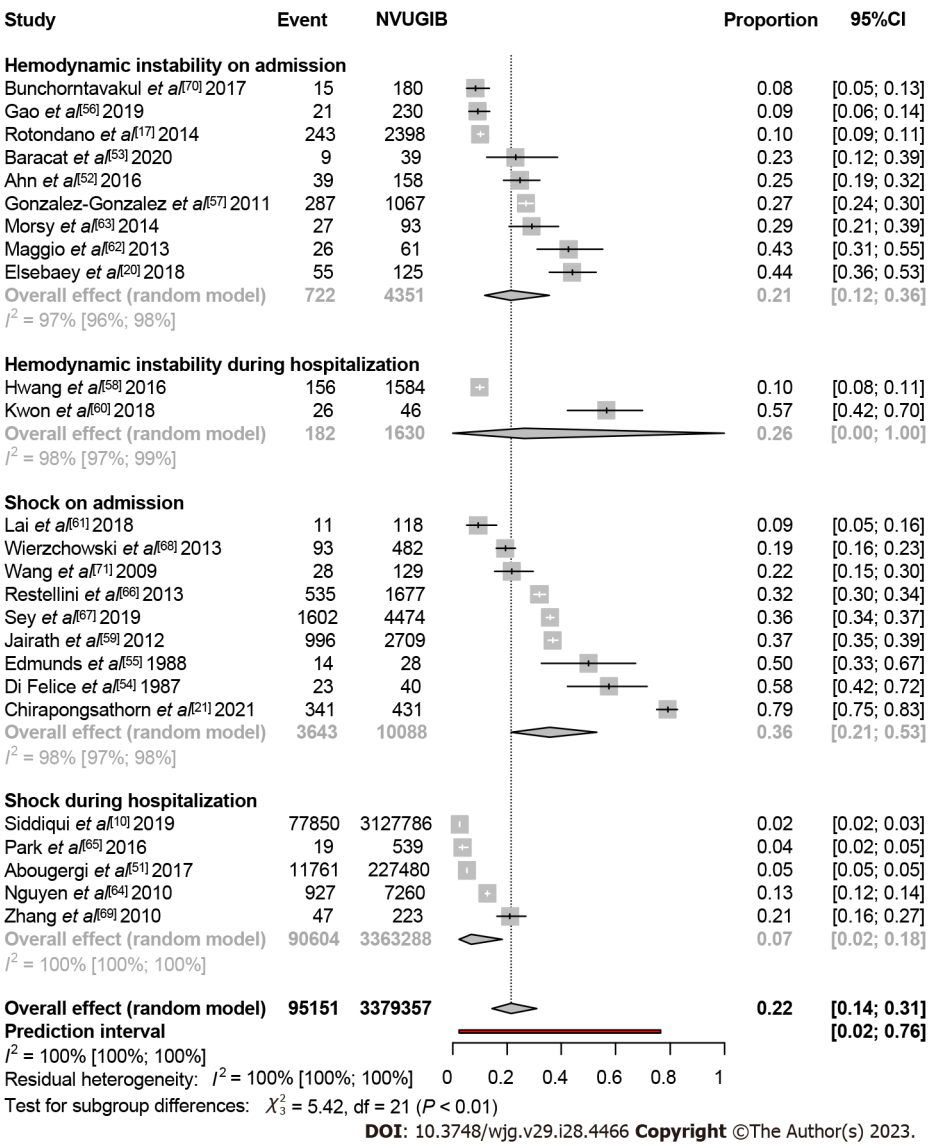
Certainty of evidence

Based on the results and the careful evaluation of the evidence level, the certainty levels were low or very low for each outcome. The very high heterogeneity in almost all analyses was the main reason for that. In addition, all the included studies were considered observational studies, which contributes to the low level of evidence. (Supplementary Tables 6-12).

DISCUSSION

Our study found that HI and shock are common complications of GIB. Either shock or HI affects one in every four patients; even the lowest proportion, one in eight colonic diverticular bleeders, is still a significant portion of patients.

Variceal bleeding resulted in the highest HI on admission, with a rate of (38%) among various bleeding sources. In contrast, the highest HI rates during hospitalization were observed in PUB (41%) and LGIB (49%). The rate of shock on admission was generally the highest among different non-variceal bleeding sources (36%), whereas PUB specifically led to the highest rate of shock during hospitalization (24%).



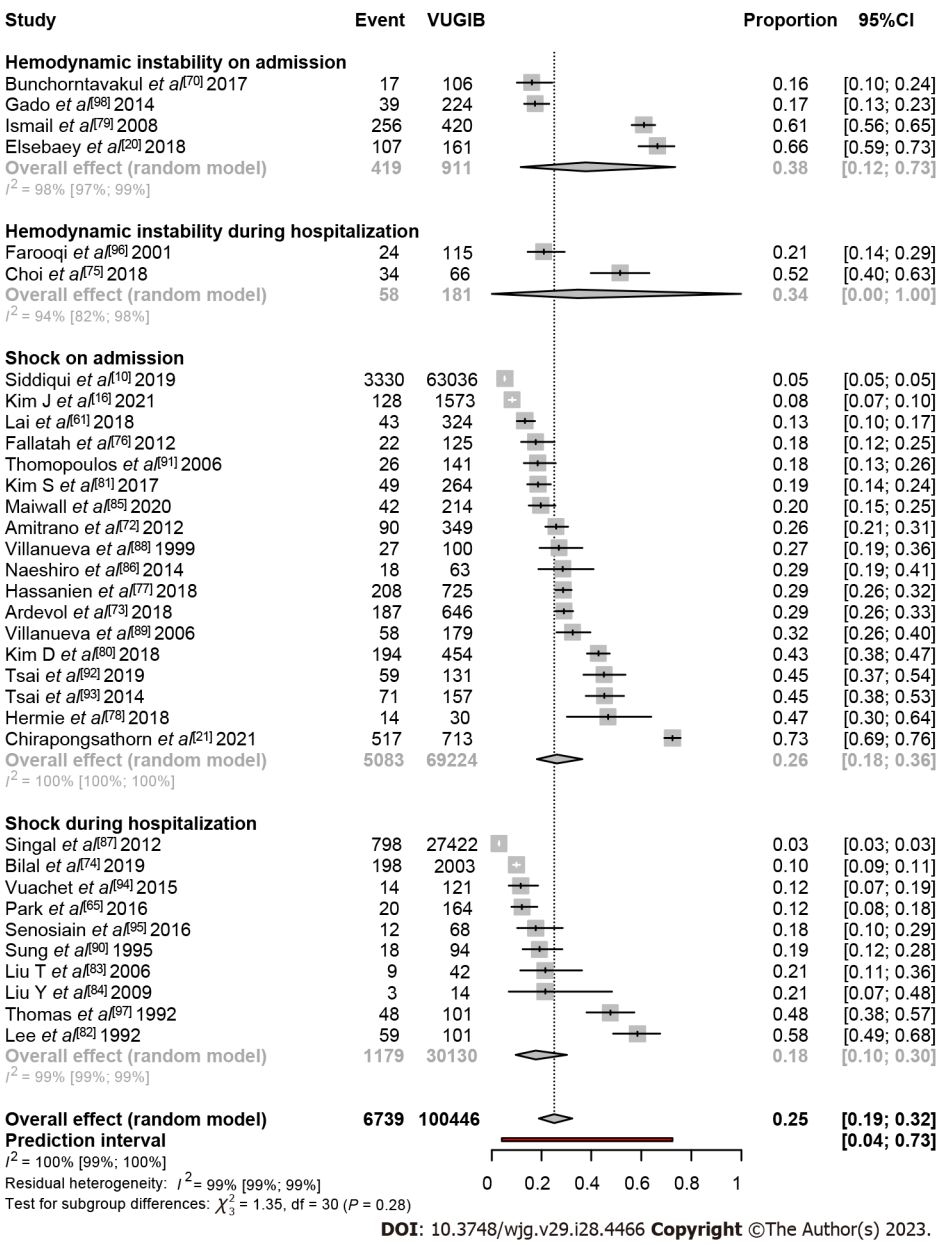


Figure 3 Forest plot demonstrating the proportion rates for hemodynamic instability and shock in non-variceal bleeding. NVUGIB: Non-variceal upper gastrointestinal bleeding.

Our results about unspecified GIB sources, non-variceal, and PUB showed higher rates of HI during hospitalization than on admission and higher rates of shock on admission than during hospitalization. In contrast, variceal bleeding showed higher rates of HI and shock on admission than during hospitalization. Lower GIB, on the other hand, showed higher rates of these outcomes during hospitalization than on admission.

Blood loss leads to HI characterized by a decrease in systolic blood pressure (BP) and an increase in heart rate (HR). Eventually, it can lead to a more severe state of shock, which is caused by a rapid reduction of intravascular blood volume resulting in decreasing hemoglobin levels, thereby decreasing the oxygen delivery capacity of the heart. HI is not just a sign; it is the starting point of a chain of events leading to hypoxemia and hypoperfusion. If it is not appropriately treated as soon as possible, it will lead to multiple organ failures. Therefore, health care providers must emphasize continuous monitoring and efficient stabilization for those patients[11].

Serious heterogeneity was observed in all our analyses. The reason for this lies in the large number of included articles. The population had different geographical locations, ethnicities, several comorbidities, age ranges, and access to different qualities of health care systems. Thus, there was even a variation in the definitions; most of the included studies defined HI as a decrease of systolic BP < 100 mmHg and/or an increase in HR > 100 bpm[6]. However, some definitions included syncope, orthostatic changes[115], or signs of organ hypoperfusion[52]. All these factors contributed noticeably, resulting in a very serious heterogeneity. All definitions of HI and shock can be found in Supplementary Tables 13 and 14, respectively.

Possible predictors were observed that resulted in higher rates of our investigated outcomes. We observed some outliers in different sources of bleeding; in variceal bleeding, intensive care unit admission[79,82,97], elderly population [20], and severe uncontrolled bleeding[75] were possible predictors for higher rates of shock and HI. In non-variceal bleeding, elderly patients > 60 years[20] and those who underwent embolization[60] accounted for the highest rate of HI on admission and during hospitalization, respectively. As for upper GIB in general, the study by Chirapongsathorn *et al*

Figure 4 Forest plot demonstrating the proportion rates for hemodynamic instability and shock in variceal bleeding. VUGIB: Variceal upper gastrointestinal bleeding.

[21] included variceal and non-variceal bleeders, where they defined shock as mean arterial pressure lower than 50 mmHg, which results in a very high rate of shock (75%).

Lower GIB is three times less common than upper GIB and has not been the focus of much attention yet. Mortality rises to 20%-40% in the case of massive lower GIB complicated by unstable hemodynamics[116]. Super-selective patients who underwent arterial embolization[104], angiography[112], or were diagnosed with acute severe bleeding[103] showed higher rates of the investigated outcomes.

Strengths and Limitations

This is the first comprehensive overview to assess the proportion of patients affected by HI and shock in GIB and specify it according to the bleeding source. Our study included many studies with an extensive sample size. Additionally, subgroup analysis, which was based on the time of assessment, whether on admission or during hospital stay, provided a more precise overview. This study also gives an insight into some of the possible predictors that result in higher rates of our investigated outcomes.

Considering the limitations of this work, the definitions of HI and shock were different among the included studies or even missing. Different characteristics of the included population led to high heterogeneity in almost all analyses. The presence of low certainty of evidence in some domains is another limitation.

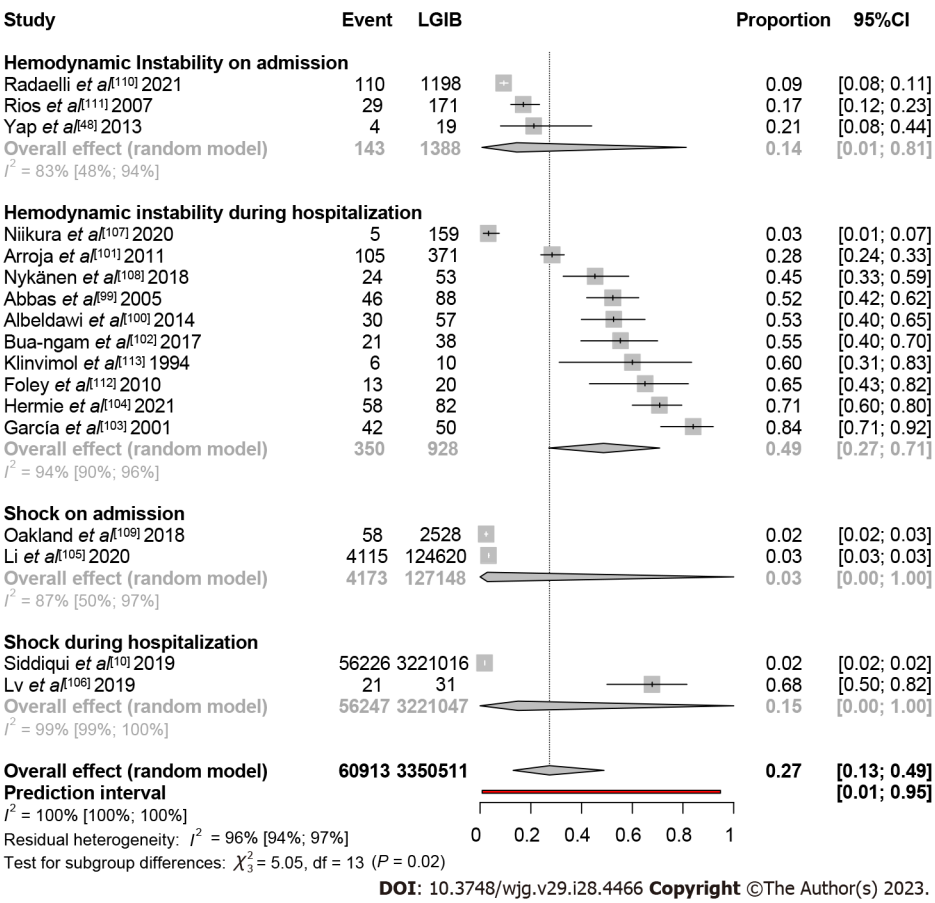

Figure 5 Forest plot demonstrating the proportion rates for hemodynamic instability and shock in lower gastrointestinal bleeding sources. LGIB: Lower gastrointestinal bleeding.

Implications for practice and research

Based on our results, we suggest standardizing the definition of HI and shock, and establishing a protocol to proactively screen and monitor the affected patients in routine management. Physicians involved in the treatment of the affected patients should focus more on early and rapid correction of hemodynamics because it significantly decreases mortality [11]. Therefore, a careful pre-endoscopic assessment and strong adherence to risk stratification scores need to be highlighted. Furthermore, cautious care and continuous monitoring of the affected patients should be emphasized, especially for high-risk patients.

CONCLUSION

Our study has provided clear evidence that hemodynamic instability and shock are common presentations and complications of GIB. On the basis of our findings, a high majority of patients are affected; one in five, one in four and one in eight patients develops shock or hemodynamic instability on admission or during the hospital stay in the case of non-variceal, variceal, and colonic diverticular bleeding, respectively. Patients need a more proactive treatment strategy and require continuous monitoring to prevent untoward outcomes.

ARTICLE HIGHLIGHTS

Research background

Hemodynamic instability (HI) and shock are associated with unfavorable outcomes in gastrointestinal bleeding (GIB). Understanding the proportion of these outcomes is essential for several reasons. Firstly, it provides valuable insight into the severity and potential risks associated with the condition. Knowing the proportion of patients who develop shock or HI helps healthcare providers anticipate the need for immediate interventions and allocate appropriate resources accordingly.

Research motivation

At the time of our systematic search, there was no data in the current literature describing these proportions in GIB based on the bleeding source. Additionally, monitoring changes in these patients over time can serve as an indicator of the effectiveness of medical interventions and guide future treatment strategies to improve patient outcomes.

Research objectives

Our aim is to quantify the pooled event rates of HI and shock in GIB. This will help in risk stratification and determining the overall severity of the condition. By understanding how frequently these outcomes occur, healthcare providers can identify high-risk patients who require immediate and intensive management.

Research methods

We conducted a systematic review with meta-analysis to determine the proportions of HI and shock in different GIB sources. The R programming language, using the meta package, was employed to perform statistical analysis on the data. Forest plots were utilized to summarize the study findings and present the results. Pooled event rates with 95%CIs, were computed to provide a measure of the overall outcomes.

Research results

The overall proportion of HI and shock was found to be 25% across all sources of GIB, 22% in non-variceal bleeding, 25% in variceal bleeding, and 12% in colonic diverticular bleeding. However, our findings also revealed a high degree of heterogeneity, highlighting the significance of our study. This heterogeneity suggests a lack of consensus in the guidelines in this field, as evidenced by the varied definitions of our included outcomes.

Research conclusions

Our study provides compelling evidence that HI and shock are frequently observed complications and presentations in GIB. One in four patients with GIB develops shock or HI on admission or during the hospital stay.

Research perspectives

Given our findings, we recommend the establishment of a standardized definition for HI and shock in GIB. Additionally, implementing a protocol for proactive screening and continuous monitoring of affected patients should be considered as part of routine management. Emphasizing a thorough pre-endoscopic assessment and strict adherence to risk stratification scores is crucial. Furthermore, rigorous care and attentive monitoring should be emphasized, particularly for high-risk patients.

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJG* as 4.3; IF without journal self cites: 4.1; 5-year IF: 5.3; Journal Citation Indicator: 0.82; Ranking: 33 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.3 and Scopus CiteScore rank 2022: Gastroenterology is 22/149.

Abstract

Tumor necrosis factor-α (TNF-α) antagonists, the first biologics approved for treating patients with inflammatory bowel disease (IBD), are effective for the induction and maintenance of remission and significantly improving prognosis. However, up to one-third of treated patients show primary nonresponse (PNR) to anti-TNF-α therapies, and 23%-50% of IBD patients experience loss of response (LOR) to these biologics during subsequent treatment. There is still no recognized predictor for evaluating the efficacy of anti-TNF drugs. This review summarizes the existing predictors of PNR and LOR to anti-TNF in IBD patients. Most predictors remain controversial, and only previous surgical history, disease manifestations, drug concentrations, antidrug antibodies, serum albumin, some biologic markers, and some genetic markers may be potentially predictive. In addition, we also discuss the next steps of treatment for patients with PNR or LOR to TNF antagonists. Therapeutic drug monitoring plays an important role in treatment selection. Dose escalation, combination therapy, switching to a different anti-TNF drug, or switching to a biologic with a different mechanism of action can be selected based on the concentration of the drug and/or antidrug antibodies.

Key Words: Predictor; Management; Tumor necrosis factor antagonist; Primary nonresponse; Secondary nonresponse; Inflammatory bowel disease

Core Tip: Tumor necrosis factor-α (TNF-α) antagonists play an essential role in the management of inflammatory bowel disease (IBD). However, a significant number of patients experience primary or secondary nonresponse to these drugs. Here, we summarize relevant predictors of anti-TNF nonresponse in IBD and discuss the next steps for treating patients with primary or secondary nonresponse to anti-TNF agents.

INTRODUCTION

Inflammatory bowel disease (IBD), an immune-mediated inflammation of the gastrointestinal tract characterized by repeated remission and relapse, comprises Crohn's disease (CD) and ulcerative colitis (UC). Traditionally, IBD has been considered a disease of the Western world, but the newly industrialized countries of Asia, Africa, and South America are experiencing a rapid increase in incidence[1-3]; therefore, IBD has become a global disease[4,5].

IBD is a lifelong disease and is incurable. Currently, medical therapy for IBD mainly includes traditional therapeutics such as 5-aminosalicylates, thiopurines, and steroids, biologics such as antitumor necrosis factor (anti-TNF) therapy, vedolizumab and ustekinumab, and novel small-molecule drugs such as Janus kinase (JAK) inhibitors.

Anti-TNF therapies, the first biologics approved for the treatment of patients with IBD, are effective for the induction and maintenance of remission and significantly improve prognosis[6-8]. The development of anti-TNF therapies revolutionized the treatment of IBD and was a landmark event. Anti-TNF drugs are still the most commonly used biological agents in IBD at present[6]. Four TNF antagonists have been used in the treatment of IBD: infliximab, adalimumab, certolizumab, and golimumab[9]. However, up to one-third of treated patients show no primary response to anti-TNF-α therapies[10], and 23%-50% of IBD patients experience loss of response (LOR) to these biologics during subsequent treatment[11,12]. These patients not only fail to benefit from anti-TNF therapies but also suffer from the side effects of anti-TNF drugs, including increased susceptibility to infection, autoimmune diseases, and malignant tumors[13,14]. In addition, they face a serious financial burden. A retrospective study reported that direct healthcare expenditures increased significantly after the initiation of anti-TNF therapy and remained higher than preinitiation costs for up to 5 years[15].

Hence, it is important to assess the therapeutic response to anti-TNF agents in IBD before initiating treatment. In this review, we conducted a comprehensive search of studies to summarize relevant predictors of anti-TNF nonresponse in IBD and discuss the next steps of treatment for patients with primary or secondary nonresponse (SNR) to anti-TNF agents.

LITERATURE SEARCH STRATEGY

We conducted a search on PubMed and Web of Science. Keywords used include “inflammatory bowel disease”, “Crohn's disease”, “Ulcerative colitis”, “Tumor necrosis factor antagonists”, “anti-TNF”, “infliximab”, “adalimumab”, “certolizumab”, “golimumab”, “primary nonresponse”, “secondary nonresponse”, and “loss of response”. This review included articles, reviews and guidelines that investigated predictors of failure of TNF antagonists in IBD or optimized treatment (Supplementary Figure 1).

DEFINITION

Primary nonresponse

There is no consensus on the definition of primary nonresponse (PNR) in IBD patients as definitions vary across studies. Papamichael *et al*[11] defined PNR as a lack of objectively assessed improvement in baseline inflammatory signs after induction treatment in the presence of adequate concentrations of the drug and in the absence of antidrug antibodies (ADAs). In a cohort study, PNR was classified as treatment failure or use of corticosteroids (new prescription or previous dose not discontinued) or failure to reduce C-reactive protein (CRP) to 3 mg/L or less or to decrease by 50% or more from baseline and failure to decrease Harvey-Bradshaw Index score to 4 or less or by 3 or more from baseline before week 14 [16]. In general, PNR refers to the absence of improvement in clinical symptoms or objective measures during the induction phase[17-19]. The incidence of PNR has been reported to range from 13%-40%[7,20,21].

Secondary nonresponse

SNR, also named LOR, describes the clinical phenomenon of patients who have an initial response to biologics but then subsequently lose this response[22]. Notably, the two features of the SNR are that the patient's symptoms improved

during the initial treatment and that the recurrence of symptoms can only be due to the inflammatory response of IBD and not due to concurrent infection, fibrous stenosis, *etc*.[23]. SNR eventually occurs in 20%-50% of patients[12,24,25]. A recent meta-analysis found that the mean percentages of patients with SNR to infliximab, adalimumab, and certolizumab were 37.8%, 35.4%, and 43.3%, respectively[26].

PREDICTORS OF PNR

Clinical features

Age: Real-world data suggest that elderly individuals with CD benefit less from infliximab and adalimumab at 12 wk [27]. In the precision-3 study, CD patients treated with certolizumab had a reduced probability of achieving a primary response as they aged[28]. However, several other studies have reported no correlation between age and PNR to anti-TNF in CD[21,29]. In UC patients, Arias *et al*[30] found that the benefit was greater when the baseline age was less than 40 years, whereas other studies did not show the impact of age on the efficacy[31,32]. Differences between the results may have originated from variations in designs and how outcomes were defined.

Gender: A single-center study in Britain involving CD patients reported that men were significantly less likely to PNR to infliximab[21]. Another Korean study showed that among CD patients, men benefited from clinical remission at week 14 more than women[29]. However, many researchers have not found an association between sex and PNR to anti-TNF therapy in CD[33-35]. Similarly, the influence of gender on anti-TNF therapy cannot be clearly defined in UC patients. Sandborn *et al*[36] reported that women responded better when assessing the efficacy of golimumab at week 6. Other studies did not report that sex could predict TNF antagonists response in UC[30,37].

Smoking: Smoking is an environmental risk factor for CD[38] and appears to be associated with nonresponse to anti-TNF therapy in CD patients. Analysis from the precision-3 study suggested that nonsmokers are more likely to achieve early clinical remission than smokers[28]. Zorzi *et al*[39] identified a positive association between smoking and anti-TNF nonresponse in CD patients by Cox proportional hazards regression. In addition, a meta-analysis published in 2021 revealed that when smoking status was defined smoking was significantly associated with a reduction in response to infliximab or adalimumab in patients with CD[40]. However, the negative effect of smoking on response was not found in another earlier meta-analysis[41]. Studies of UC have also reported inconsistent results. One Italian study found a significantly lower response to infliximab in ex-smokers[42], while others did not reach this conclusion[37,43]. The conflicting findings may be due to different definitions of smoking among the studies. In summary, smoking cessation is recommended for current smokers diagnosed with IBD[44].

Previous surgery: Although treatment strategies for IBD have changed, 17.4%-25% of patients with CD still require surgery[45-47]. Macaluso *et al*[27] used a logistic regression model to identify a history of previous surgery as an independent risk factor for PNR in CD patients. Another group reported similar results, showing that CD patients without previous surgery had a greater chance of achieving initial remission than patients with previous surgery, with a hazard ratio of 1.387[28]. CD patients with previous surgery had a lower response rate[48]. A study involving 201 CD patients also demonstrated that previous surgery was an independent predictor of PNR[34].

Disease duration: The analysis of pooled data from CD studies indicates that CD with a shorter disease duration is associated with a superior early response[49]. In the MODIFY study, patients who received early adalimumab achieved a higher clinical response and remission rate at week 26 than those who received delayed treatment[50]. This correlation has also been confirmed by a recent meta-analysis[51]. Studies have reported that among UC patients, a shorter disease duration is associated with a better response to anti-TNF drugs[32,52]. However, in general, authors did not find a positive association between long disease duration and anti-TNF nonresponse[31,48,53]. Although the current studies available cannot explain the underlying reasons for poorer response to anti-TNF in IBD with a longer disease duration, it is intuitive that a longer disease duration may contribute to the development of fibrosis, making earlier treatment attractive to patients[54].

Phenotype: The disease phenotype seems to be related to anti-TNF treatment response. In CD patients, isolated ileitis was inversely associated with the anti-TNF response, whereas the opposite was true for isolated colitis[29,48].

Pharmacokinetic

The pharmacokinetic (PK) of anti-TNF consists of four processes: absorption, distribution, metabolism, and elimination [55]. PK failures are characterized by undetectable or subtherapeutic drug concentrations associated with rapid nonimmune clearance or immunogenicity as well as the development of ADAs[56].

Drug concentration and antidrug antibodies: Several studies have demonstrated that subtherapeutic drug concentration is a predictor of PNR, with drug concentrations lower in IBD patients who failed to respond to anti-TNF therapy than in responders[16,57]. Post hoc analysis of data from the MUSIC trial data showed that CD patients with higher levels of certolizumab were more likely to achieve endoscopic response and remission at week 10[58]. Ding *et al*[17] suggested that low anti-TNF levels and the formation of ADAs could predict PNR in CD patients. The same results were reported in another study involving patients with UC[59].

Weight: Weight is a predictor of anti-TNF nonresponse. In a multicenter cohort study, high body mass index (BMI) at baseline in CD patients was associated with an increased risk of PNR[16]. Similar results were reported in another study [60]. In UC patients, Kurnool *et al*[61] reported that an increase in BMI had a negative impact on the response to anti-TNF drug therapy. The reason may be that, on the one hand, obesity induces a proinflammatory state[62], and on the other hand, the proteolytic clearance of immunoglobulins is usually related to weight, that is, the higher the weight is, the faster the clearance[63,64].

Serum albumin: Serum albumin levels predict the PK of anti-TNF therapy. A recent prospective study noted that low albumin levels at baseline in IBD patients predicted low infliximab concentrations at week 14[16]. Several other studies have reached similar conclusions[57,63]. One study of patients with UC found significantly higher serum albumin in responders than in primary nonresponders[65]. This effect occurs because albumin is the main transporter of drugs in blood, and serum albumin binds anti-TNF drugs to protect against degradation[66].

Fcγ receptor type IIIA: Single nucleotide substitutions within the Fcγ receptor type IIIA (FCGR3A) gene result in allelic variations, one valine (V) or one phenylalanine (F) at amino acid position 158. Functional polymorphisms in FCGR3A are significantly associated with response to anti-TNF therapy in CD patients[67]. Bek *et al*[67] used mono-compartmental population modeling to describe the PK of infliximab and found that the FCGR3A-158V/V genotype was associated with increased elimination of infliximab[67]. Further studies identified the FCGR3A VV phenotype as an independent predictor of ADAs generation and associated with a reduced clinical response in IBD patients at the end of induction[68].

Pharmacodynamic

Pharmacodynamic (PD) failure is associated with underlying non-TNF-driven inflammation characterized by no improvement in symptoms even at sufficient concentrations and without ADAs[56].

Pharmacokinetic/pharmacodynamic modeling: Kimura *et al*[69] developed Pharmacokinetic/pharmacodynamic (PK/PD) modeling to predict IBD response to infliximab during induction therapy. Another team of researchers in Japan developed a PK/PD model to calculate the $K^{anti\text{-}TNF\alpha}{}_0/K^{else}$ ratio to predict the PNR to TNF in IBD patients at the second administration[70]. The validity of this model remains to be tested in larger populations.

Biologic markers

C-reactive protein: Several studies have investigated the relationship between CRP levels and anti-TNF responses. A multicenter retrospective study in Korea demonstrated that UC patients with CRP ≥ 3 mg/dL were more likely to achieve clinical remission at week 8[71]. This was also observed in CD treated with certolizumab[72]. However, opposite results were reported in another retrospective study of CD patients[73]. Presumably, high baseline CRP will exclude some patients with noninflammatory functional symptoms and predict a higher response, but it may also reflect a higher inflammatory load with increased drug loss[74].

Antineutrophil cytoplasmic antibody and anti-*Saccharomyces cerevisiae* antibody: In a cohort study involving 90 UC patients, a greater proportion of antineutrophil cytoplasmic antibody (ANCA)-negative patients achieved clinical response during infliximab induction than ANCA-positive patients[75]. Another study in CD patients found that positive perinuclear ANCN (pANCA) is a predictor of anti-TNF nonresponse[76]. In a meta-analysis, pooled results showed that pANCA-negative patients with IBD had a nearly twofold higher response to anti-TNF therapy than pANCA -positive patients[77]. A single-center study evaluating pANCA and anti-*Saccharomyces cerevisiae* antibody (ASCA) simultaneously found that pANCA+/ASCA- serotypes significantly reduced early clinical response to infliximab in CD patients[78].

Fecal calprotectin: Fecal calprotectin (FC) is an indicator of gut inflammation and disease burden in IBD. Beltrán *et al*[79] noted that FC was higher in PNR patients with CD than in responders at weeks 0, 6, and 14, with a statistically significant difference only at week 0. Another study in UC patients also showed that early high FC was predictive of infliximab nonresponse[52]. Pavlidis *et al*[80] suggested that a decrease in FC of less than 70% after induction with anti-TNF drugs could predict PNR in patients with CD. However, some authors have not shown a relationship between FC and anti-TNF PNR in UC patients[81,82].

Fecal lactoferrin: Fecal lactoferrin (FL) can be used to monitor intestinal inflammation in IBD[83]. A retrospective study involving IBD demonstrated that dynamic monitoring of FL could distinguish responders from primary nonresponders, with two sustained drops in FL observed in responders during induction therapy[84].

Genetic markers

TNF and TNF-receptor superfamily genes: Genetic polymorphisms associated with TNF and TNF receptors have been widely studied for their ability to predict the response to anti-TNF therapy. In a clinical trial studying CD, patients homozygous for the TNF/Lymphotoxin alpha (LTA) polymorphism, the LTA NcoI-TNFc-aa13L-aa26 haplotype 1-1-1-1, showed early nonresponse to infliximab[76]. Another study demonstrated that TNF-308 (rs1800629) was associated with response to anti-TNF therapy, and the presence of the minor allele (A) was associated with increased odds of nonresponse to anti-TNF therapy in IBD[85]. For TNF-receptor superfamilies (TNFRSF), Steenholdt *et al*[86] found that CD patients carrying the TNFRSF1B minor allele rs1061622 had a better response to infliximab induction therapy. In a Japanese study, TNFRSF1A (rs767455_G) and TNFRSF1B (rs1061624_A-rs3397_T) were associated with poor response in CD patients[87] and these results were replicated in another Spanish study[88]. Additionally, a meta-analysis indicated

that TNFRSF1A (rs4149570) significantly improved anti-TNF responses in IBD[67].

Autophagy-related 16 like 1: Autophagy-related 16 like 1 (ATG16L1) is a risk factor for CD[89]. Koder *et al*[90] found a strong association between ATG16L1 (rs10210302) and response to adalimumab treatment in the CD population, with the TT genotype showing a better response after 12 wk of adalimumab treatment. Future studies on the relationship between ATG16L1 and the anti-TNF response are necessary to clarify these effects.

Apoptosis genes: Infliximab and adalimumab induce apoptosis by binding to membrane-bound TNF-α, which is the main mechanism of their efficacy[54]. An earlier study observed the strongest association between the Fas ligand -843 TT genotype and nonresponse to infliximab in CD patients[91]. Furthermore, Hlavaty *et al*[92] developed a novel apoptotic pharmacogenetic index based on three single nucleotide polymorphisms (Fas ligand-843 C/T, Fas-670 G/A, and Caspase9 93 C/T), with a higher score indicating a better response to anti-TNF therapy.

Nucleotide-binding oligomerization domain 2: Nucleotide-binding oligomerization domain 2 (NOD2) mutations predict an increased risk of complications related to CD[93]. Further studies showed that NOD2 mutations were less responsive to anti-TNF therapy than wild-type NOD2 in CD patients[94]. Another study demonstrated that CD patients with either NOD2 variants alone or in combination with ATG16L1 variants were more likely to receive intensive biologic therapy, which may indicate that NOD2 variants have a negative impact on response to biologic therapy[95]. However, this effect was not observed in another trial[96].

Cytokines

Interleukin: One study conducted in CD patients found that primary nonresponders had significantly higher interleukin-8 (IL-8) concentrations at baseline[97]. In addition, the level of IL-6 in responders was significantly lower than that in primary nonresponders at week 2 and week 6[97]. Another study of CD noted that IL17A and IL1B expression was significantly upregulated in anti-TNF refractory patients during anti-TNF therapy[98]. Oncostatin M (OSM), a member of the IL-6 cytokine family, has been shown to disrupt epithelial barrier function and drive intestinal inflammation[99]. An analysis of more than 200 IBD patients treated with anti-TNF therapy found higher baseline levels of OSM expression in those who failed anti-TNF therapy[100]. A cross-sectional study suggested that higher levels of OSM in the colon were associated with PNR to anti-TNF in patients with IBD[101].

Triggering receptor expressed on myeloid cells 1: Triggering receptor expressed on myeloid cells 1 (TREM1) expression has been proposed as a potential marker for predicting response to anti-TNF therapy in IBD patients. Gaujoux *et al*[102] demonstrated that TREM1 can be an ex-ante predictor of the anti-TNF response and that TREM1 Levels were downregulated in nonresponders, with a prediction accuracy of 94%. This phenomenon is also found in the inflamed mucosa.

Gut microbes

Several studies have shown that gut microbes predict nonresponse to anti-TNF treatment in IBD. Magnusson *et al*[103] found that responders had lower dysbiosis indexes, a higher abundance of *Faecalibacterium prausnitzii* (*F. prausnitzii*) at baseline, and an increase in the abundance of *F. prausnitzii* during induction therapy compared with nonresponders. Another study found that high abundances of the genera *Blautia*, *Faecalibacterium*, *Roseburia*, and *Negativibacillus* at baseline were inversely associated with responsiveness to infliximab in CD[104]. In the same study, a high abundance of *Sutterella*, *Roseburia*, and *Intenstinibacter* appeared to predict response to infliximab in UC patients[104]. Alatawi *et al*[105] detected a reduction in the abundance of short-chain fatty acid-producing bacteria, including *Anaerostipes*, *Coprococcus*, *Lachnospira*, *Roseburia*, and *Ruminococcus,* in IBD patients unresponsive to anti-TNF therapy[105]. Nevertheless, a European multicenter study found no differences in the microbiota of anti-TNF therapy responders *vs* nonresponders in IBD[106]. Indicators that predict PNR to anti-TNF agents in patients with IBD are listed in Table 1.

PREDICTORS OF SECONDARY NONRESPONSE

Clinical features

Gender: A retrospective study identified that women were more likely to develop SNR to anti-TNF[107]. Another multicenter retrospective study found a similar result in the CD subgroup[108]. An earlier systematic review noted the male sex was a predictor of LOR in CD[109]. A single-center study demonstrated a significantly higher likelihood of SNR in men with UC[110]. However, no association has been reported between gender and SNR in most studies[21,30,31,37].

Smoking: Sandborn *et al*[28] found that current smoking was associated with LOR in individuals diagnosed with CD. This result was also validated in another single-center study[39]. Chaparro *et al*[111] reported that smoking was associated with the occurrence of LOR in CD.

Previous surgery: A Sicilian study of CD reported that previous surgery was associated with a low rate of clinical remission at 1 year[27]. However, many studies have not demonstrated a relationship between previous surgical history and SNR to anti-TNF therapy in CD[16,112].

Disease duration: Panaccione *et al*[49] showed that patients with CD whose duration was less than 1 year benefited more in maintaining remission. A retrospective cohort study reported that CD patients with a disease duration of more than 2 years had a significantly higher rate of SNR[113]. A subgroup analysis of the placebo-controlled CHARM trial also

Table 1 Predictors of primary nonresponse in Crohn's disease and ulcerative colitis

Predictor	Crohn's disease	Ulcerative colitis
Clinical features		
Age	Yes: Older[27,28]; No[21,29]	Yes: Older[30]; No[31,32]

TREM1	Yes: Low[102]	Yes: Low[102]
Gut microbes	Yes: Abundance of short-chain fatty acid-producing bacteria (decreased)[105]	Yes: Dysbiosis indexes (high)[103]; Abundance of short-chain fatty acid-producing bacteria(decreased)[105]

FCGR3A: Fcγ receptor type IIIA; PK/PD model: Pharmacokinetic/pharmacodynamic modeling; CRP: C-reactive protein; ANCA: Antineutrophil cytoplasmic antibody; ASCA: Anti-*Saccharomyces cerevisiae* antibody; pANCA: Perinuclear anti-neutrophil cytoplasmic antibody; TNF: Tumor necrosis factor; TNFRSF: TNF-receptor superfamily; ATG16L1: Autophagy-related 16 like 1; NOD2: Nucleotide-binding oligomerization domain 2; OSM: Oncostatin M; TREM1: Triggering receptor expressed on myeloid cells 1.

obtained a similar conclusion[114].

Phenotype: A recent study reported that accumulation of the upper digestive tract and the presence of fistulas at baseline were associated with SNR to adalimumab and infliximab in CD patients[27]. Another study involving 93 individuals verified that nonstructuring nonpenetrating CD was associated with sustained remission[39]. CD with concurrent fistula or stenosis had a lower clinical remission rate[115].

Pharmacokinetic

Drug concentration and antidrug antibodies: A multicenter cohort study confirmed that concentrations of infliximab < 7 mg/L and adalimumab < 12 mg/L were independently associated with SNR in CD patients[16]. A prospective study indicated that the trough level (TL) of infliximab < 5.5 μg/mL in patients with IBD was the best threshold to predict LOR [116]. Alternatively, the generation of ADAs, which in combination with circulating drugs also leads to a reduction in drug concentration, is associated with anti-TNF LOR in IBD[117].

Weight: Kennedy *et al*[16] found that obesity at baseline was associated with adalimumab treatment failure at week 54 in patients with CD. Another study also reported that IBD patients with a high BMI displayed a high rate of LOR[118]. In IBD patients treated with adalimumab, SNR was increased in those with BMI ≥ 30 kg/m^2 compared with those with BMI < 30 kg/m^2[119].

Serum albumin: In CD patients treated with certolizumab, low albumin predicted SNR[28]. Higher albumin levels were associated with lower LOR in IBD patients treated with infliximab[119]. A prospective study found that IBD patients with low albumin serum concentrations at baseline had a significantly increased risk for SNR to anti-TNF and that normalization of albumin levels during treatment did not reduce this risk[120].

Serum γ-globulin: A German study from IBD found a positive association between elevated serum γ-globulin concentrations and the risk of SNR to anti-TNF therapy[120]. Higher γ-globulin concentrations imply increased B-cell activity, resulting in increased ADAs production[120].

Matrix metalloproteinase 3: Matrix metalloproteinase 3 (MMP3) expression is significantly upregulated in inflamed colonic segments of IBD patients, suggesting the possible involvement of this enzyme in the inflammatory process[121, 122]. A retrospective study from Italy showed that in IBD patients, MMP3 levels were significantly lower in responders (11.48 ng/mL) than in nonresponders (25.96 ng/mL) at week 52[123]. In the same study, MMP3 levels tended to be higher in patients without ADAs than in those with ADAs[123]. According to a previous report, MMP3 cleaved infliximab and adalimumab which may result in reduced drug efficacy[124].

Fcγ receptor type IIIA: A Spanish team found higher serum concentration levels of both infliximab and adalimumab in FCGR3A FF carriers than in FCGR3A VV carriers during maintenance therapy in IBD and found that the proportion of VV patients who developed ADAs was significantly higher than that of FF patients diagnosed with IBD[125].

Human leukocyte antigen: The value of human leukocyte antigen-DQA1*05 (HLA-DQA1*05) in predicting anti-TNF-ADAs production has been reported in several studies. A genome-wide analysis of 1240 subjects in the PANTS cohort revealed that approximately 40% of Europeans carried HLA-DQA1*05 and significantly increased rates of ADAs production[126]. Wilson *et al*[127], using genotypic analysis, showed that HLADQA1*05 was independently associated with LOR to infliximab and increased ADAs in IBD.

Biologic markers

C-reactive protein: Post hoc analysis of ACCENT I, indicated that high levels of CRP before treatment predicted an increased likelihood of maintaining remission[128]. A study of IBD found that CRP > 5 mg/L was an independent predictor of SNR[116]. However, a Hungarian study reported that low levels of CRP at week 12 were associated with clinical remission at week 52 in CD patients on adalimumab[129]. Additionally, Angelison *et al*[82] did not find an association between CRP and SNR to anti-TNF agents in UC.

Antinuclear antibody: Among patients with IBD, those with positive antinuclear antibody (ANA) at baseline had higher odds of LOR to anti-TNF[130]. More studies are needed to investigate the relationship between ANA and response to anti-TNF therapy in the future.

Fecal calprotectin: Analyses from the 7-year PRECiSE 3 study revealed that an increase in FC implies an increased risk of LOR to anti-TNF[28]. However, Deshpande *et al*[131] reported that FC levels at week 14 could not predict the recurrence of CD one year later. Differences in the timing of FC measurement and sample size may have contributed to this discrepancy.

Fecal lactoferrin: Sorrentino *et al*[132] found that FL levels before and after anti-TNF treatment could be used to distinguish responders, partial responders, and nonresponders in IBD patients with suspected LOR[132]. In the same study, they proposed that responders had normal FL both before and after administration, partial responders had elevated FL before administration, partial FL decreased after administration but remained well above the normal threshold, and FL increased after LOR administration[132].

Genetic markers

TNF and TNF-receptor superfamily genes: Currently, only a retrospective cohort study of CD has demonstrated that carrying the TNFRSF1B minor allele rs976881 was associated with LOR to infliximab[86]. More studies are urgently needed to explore the relationship between TNF and TNFRSF genes and SNR to anti-TNF therapy.

Cytokines

Interleukin: Higher baseline OSM in IBD patients with SNR to infliximab was found in a UK study[100]. Bertani *et al*[133]

demonstrated that in CD patients treated with infliximab, those with low OSM levels at baseline and week 14 were more likely to achieve clinical remission at week 54[133]. Moreover, the level of OSM in patients with mucosal healing was significantly lower than that in patients without mucosal healing at week 54[133]. We summarize the predictors of SNR in Table 2.

OPTIMAL MANAGEMENT OF ANTI-TNF NONRESPONSE

Assessment

PNR or SNR to anti-TNF therapy was determined according to clinical symptoms, laboratory tests, endoscopy, imaging examinations, *etc.* It is worth noting that conditions such as poor adherence[134], improper drug storage medication storage[135], and co-infection[23] need to be excluded during assessment.

Therapeutic drug monitoring

The British Society of Gastroenterology consensus defines therapeutic drug monitoring (TDM) as, the measurement of the drug (± ADAs) levels to assess compliance, drug metabolism, and immunogenicity with a view to guide dose adjustments or switch off therapy[136]. TDM can be used reactively or proactively. The American Gastroenterological Association recommends reactive TDM for adults who fail to respond to anti-TNF therapy[9]. A target TL of at least 5 μg/mL, 7.5 μg/mL, and 20.0 μg/mL for infliximab, adalimumab, and certolizumab, respectively, is suggested[9]. Papamichael *et al*[137] recommend a minimum drug concentration of at least 2.5 μg/mL at week 6 and a trough concentration of at least 1 μg/mL of golimumab during maintenance therapy. Several recent reviews showed that TDM was more beneficial than empirical strategies in terms of cost-effectiveness[138-140]. TDM plays an important role in optimizing anti-TNF therapy.

Management of PNR

There is no consensus on the optimal management of PNR to TNF antagonists. A review proposed that the management of IBD patients with PNR to anti-TNF therapy consists of three major steps: prediction, prevention, and therapeutic intervention[11]. Clinical features, pharmacokinetics, genetic phenotypes, *etc*., can predict the development of PNR. Preventive measures to avoid PNR to anti-TNF include counseling patients to quit smoking, weight intervention, *etc*.[11, 17]. For IBD patients with PNR, empirical intervention can be performed, switching to another TNF antagonist, or switching to a biological agent of a different mechanism, is desirable[141]. Ding *et al*[17] suggested that a second TNF antagonist be administered when the patient is PNR to the first TNF antagonist. If the treatment fails again, switching out of class should be considered.

Some scholars have also proposed that the medication of primary nonresponders can be adjusted according to TDM. With the help of TDM, rational and optimal treatment can be provided[136]. If patients have low TLs and no or low titer ADAs formation, dose optimization or the addition of an immunomodulator is recommended. When TLs are low and high-titer ADAs are detected, switching to another TNF antagonist or biologic agent with a different mechanism may be considered. For patients with therapeutic concentrations, switching out of class is suggested (Figure 1).

Management of secondary nonresponse

The detection of TNF antagonist and ADAs concentration is helpful to guide the next treatment of SNR (Figure 2).

Dose escalation: Dose intensification can reverse nonresponse to anti-TNF in IBD patients with subtherapeutic concentrations and no or low concentrations of ADAs. A meta-analysis reported a 34% need for anti-TNF dose escalation in CD at a median follow-up of 1 year, with pooled rates of 38%, 32%, and 2% for infliximab, adalimumab, and certolizumab, respectively[26]. A multicenter cohort study in Belgium found that 34% of CD patients treated with adalimumab required an increased dose to maintain clinical response, and clinical response was induced again in 67% of these patients[142]. Billioud *et al*[109] concluded that among CD patients who experienced LOR to adalimumab, 71.4% regained response and 39.9% achieved remission after dose optimization. Interestingly, a post hoc analysis of the TAXIT trial showed a significantly higher rate of clinical response with dose intensification, regardless of the presence of ADAs[143]. Meanwhile, Bodini *et al*[144] have suggested that, based on clinical need, anti-TNF doses can be increased, even in older patients of patients receiving combination therapy, with little risk of adverse reactions occurring.

Addition of an immunomodulator: The addition of an immunomodulator is a good option for IBD patients receiving anti-TNF therapy in whom subtherapeutic and no or low concentrations of ADAs are detected. For example, van Schaik *et al*[145] observed a significant increase in mean trough concentrations and a significant decrease in the incidence of ADAs in the infliximab combined with azathioprine group compared with infliximab alone in patients with IBD, whereas no differences were observed in the adalimumab combination *vs* monotherapy groups[145]. Another study involving patients with CD reported that, for both infliximab and adalimumab, combined immunomodulators reduced the risk of ADAs formation[16]. In the SONIC trial, the response rate in corticosteroid-free clinical remission at week 50 was significantly higher with infliximab adding immunomodulator than with monotherapy (55.6% *vs* 39.6%)[146]. In the UC-SUCCESS trial, infliximab plus an immunomodulator was also superior in achieving corticosteroid-free clinical remission [147]. In a 2-year cohort study of 46 patients with IBD, the addition of a low-dose immunomodulator, either azathioprine, methotrexate, or mycophenolate mofetil, reversed clinical response in approximately 50% of IBD patients who had failed to respond to anti-TNF monotherapy[148]. With regard to when to discontinue immunomodulators, Drobne *et al*[149]

Table 2 Predictors of secondary nonresponse in Crohn's disease and ulcerative colitis

Predictor	Crohn's disease	Ulcerative colitis
Clinical features		
Gender	Yes: Female[107,108], male[109]; No[21]	Yes: Female[107], male[110]; No[31,37]

Genetic markers		
TNFRSF	Yes: TNFRSF1B (rs976881)[86]	
Cytokines		
Interleukin	Yes: OSM (high)[100,133]	Yes: OSM (high)[100]

MMP3: Matrix metalloproteinase 3; FCGR3A: Fcγ receptor type IIIA; HLA: Human leukocyte antigen; CRP: C-reactive protein; ANA: Antinuclear antibody; TNFRSF: Tumor necrosis factor receptor superfamily; OSM: Oncostatin M.

suggest that at least 6 mo of combination therapy is required. Mahmoud *et al*[150] compared different durations of combination therapy in relation to LOR and found no significant difference between durations of combination therapy (< 0.5 years, 0.5-1 year, 1-2 years, and > 2 years); however, durations of combination therapy longer than 2 years were associated with a lower risk of ADAs formation.

Switch within class: In the case of subtherapeutic concentrations with high titers of ADAs, switching within class to another anti-TNF agent should be considered. A retrospective study of IBD showed that when ADA titers of infliximab and adalimumab were > 9 μg/mL and 4 μg/mL, respectively, switching within class achieved a longer duration of response compared with dose intensification[151]. In another study of IBD, switching patients positive for ADAs to another anti-TNF agent achieved a response rate of 92%, whereas dose optimization achieved a response rate of 17%[152]. In cases where the first anti-TNF drug failed, switching to another drug achieved remission in approximately 50% of patients, an effect that has been reported in several other studies[153,154]. Moreover, a systematic review reported that switching to a second anti-TNF agent led to successful induction of remission in 46% of patients with IBD who had failed the first anti-TNF agent[155]. Of note, the previous generation of anti-TNF antibodies increases the risk of the generation of a second anti-TNF antibody in IBD[156]. Therefore, when switching to another anti-TNF agent, a combination of immunosuppressive agents is appropriate[136,157].

Switch out of class: If TL is sufficient with high ADAs, it is recommended that the patient switches to a drug that exerts its effects through another mechanism of action, considering that TNF-α is not the primary pathogenesis. Alternatively, for low TLs with high titers of ADAs, switching out of class is also effective. Subgroup analyses of trials investigating vedolizumab[158], ustekinumab[159,160], and tofacitinib[161] all showed that patients who had failed anti-TNF therapy

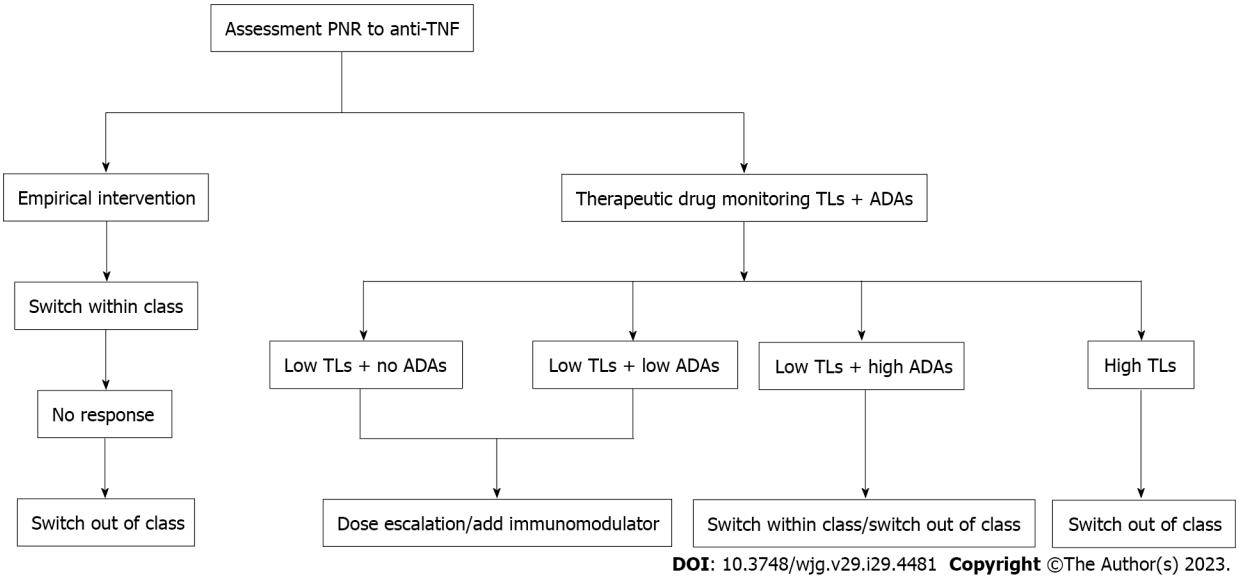

Figure 1 Flow diagram for management of primary nonresponse to tumor necrosis factor antagonists. PNR: Primary nonresponse; TNF: Tumor necrosis factor; TL: Trough level; ADA: Antidrug antibody.

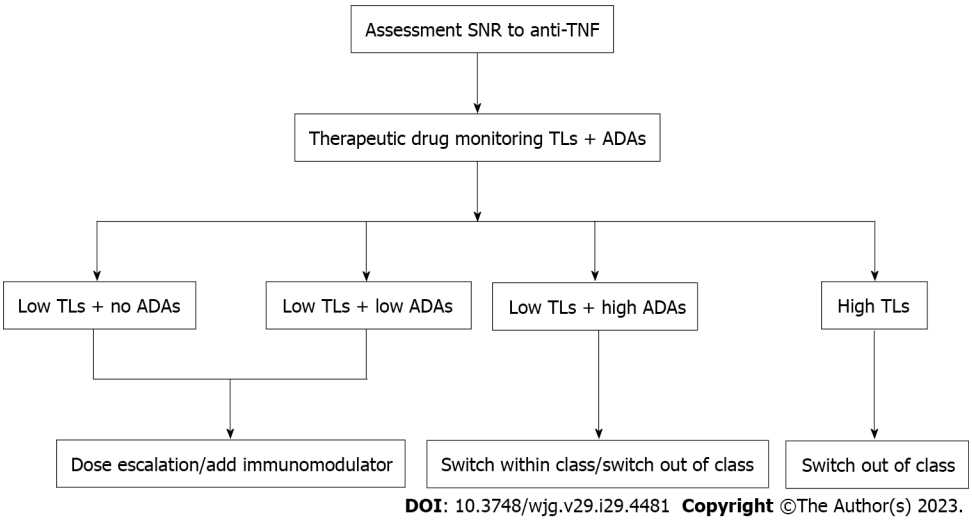

Figure 2 Flow diagram for management of secondary nonresponse to tumor necrosis factor antagonists. SNR: Secondary nonresponse; TNF: Tumor necrosis factor; TL: Trough level; ADA: Antidrug antibody.

benefited from treatment with a novel agent. One study involving 128 CD patients who had failed previous anti-TNF therapy reported that the corticosteroid-free clinical response rates of vedolizumab and ustekinumab treatment at weeks 12, 24, and 52 were 22.7%, 29.7%, 26.8% and 27.1%, 42.4%, 45.9% respectively[162]. Furthermore, propensity score matching concluded that patients who failed anti-TNF therapy benefited more from ustekinumab than vedolizumab[162].

CONCLUSION

IBD is incurable, and anti-TNF therapy plays an important role in IBD. Although existing studies have found that previous surgical history, disease manifestations, drug concentrations, ADAs, serum albumin, ANCA, p-ANCA, ANA, *etc.* have potential predictive effects, to date, there are no practically available indicators that can predict response to TNF antagonists in patients with IBD. Further research is needed to verify the accuracy of existing predictors or discover new biomarkers to achieve personalized treatment for patients with IBD.

TDM forms the core of an optimal strategy for treating IBD. It is recommended to optimize the dose or add immunomodulators when patients with low TLs and no or low titer ADAs. For nonresponders with low TLs and high titer ADAs, switching to another TNF antagonist or biologic agent with a different mechanism can be suggested. When TLs are sufficient, patients can consider switching to another biological agent. In the future, more large randomized

controlled trials are needed to investigate the efficacy of different next-step therapies for IBD patients who do not respond to anti-TNF.

Abstract

Cancer cells exhibit metabolic reprogramming and bioenergetic alteration, utilizing glucose fermentation for energy production, known as the Warburg effect. However, there are a lack of comprehensive reviews summarizing the metabolic reprogramming, bioenergetic alteration, and their oncogenetic links in gastrointestinal (GI) cancers. Furthermore, the efficacy and treatment potential of emerging anticancer drugs targeting these alterations in GI cancers require further evaluation. This review highlights the interplay between aerobic glycolysis, the tricarboxylic acid (TCA) cycle, and oxidative phosphorylation (OXPHOS) in cancer cells, as well as hypotheses on the molecular mechanisms that trigger this alteration. The role of hypoxia-inducible transcription factors, tumor suppressors, and the oncogenetic link between hypoxia-related enzymes, bioenergetic changes, and GI cancer are also discussed. This review emphasizes the potential of targeting bioenergetic regulators for anti-cancer therapy, particularly for GI cancers. Emphasizing the potential of targeting bioenergetic regulators for GI cancer therapy, the review categorizes these regulators into aerobic glycolysis/ lactate biosynthesis/transportation and TCA cycle/coupled OXPHOS. We also detail various anti-cancer drugs and strategies that have produced pre-clinical and/or clinical evidence in treating GI cancers, as well as the challenges posed by these drugs. Here we highlight that understanding dysregulated cancer cell bioenergetics is critical for effective treatments, although the diverse metabolic patterns

present challenges for targeted therapies. Further research is needed to comprehend the specific mechanisms of inhibiting bioenergetic enzymes, address side effects, and leverage high-throughput multi-omics and spatial omics to gain insights into cancer cell heterogeneity for targeted bioenergetic therapies.

Key Words: Energy metabolism; Mitochondria; Hypoxia; Oxidative phosphorylation; Glycolysis; Gastrointestinal neoplasms

Core Tip: This review discusses the bioenergetic alteration and metabolic reprogramming in gastrointestinal (GI) cancers, including the interplay between aerobic glycolysis, tricarboxylic acid cycle, and oxidative phosphorylation. The review also highlights potential strategies for targeting bioenergetic regulators for anti-cancer therapy in GI cancers, summarizing the efficacy and challenges of several drugs.

INTRODUCTION

Cells require energy to carry out their functions, and the most common form of cellular energy is adenosine triphosphate (ATP). This energy is typically produced by oxidative phosphorylation (OXPHOS) in the mitochondria of normal cells[1]. However, in cancer cells, there is a shift in the way energy is generated. Instead of using OXPHOS, cancer cells use glycolysis, a process that results in increased uptake of glucose and secretion of lactate[2]. This phenomenon is known as the Warburg effect and is observed in many types of cancer[3,4]. By understanding the altered energy metabolism in cancer cells, researchers can gain new insights into cancer cell biology and identify potential targets for cancer therapy.

Glycolysis is the process by which glucose is broken down to produce ATP, and it does not require oxygen (Figure 1). Glucose enters cells through glucose transporters and is converted to glucose-6-phosphate (G6P) by hexokinase (HK). Glucose-6-phosphate isomerase (G6PI) converts G6P to fructose-6-phosphate (F6P), which is used in both the glycolytic pathway to generate pyruvate or lactate and the pentose phosphate pathway (PPP) to produce nucleotides and nicotinamide adenine dinucleotide phosphate (NADPH). Phosphofructokinase-1 (PFK1) converts F6P and fructose-2,6-bisphosphate (F2,6BP), a metabolite from a branch driven by fructose-2,6-biphosphatase 3 (PFKBP3), to fructose-1,6-bisphosphate (F1,6BP), which is further processed by aldolase to generate glyceraldehyde-3-phosphate (G3P) and dihydroxyacetone phosphate (DHAP). G3P is converted by glyceraldehyde 3-phosphate dehydrogenase (GAPDH) to 1,3-bisphosphoglycerate (1,3BPG), which is further converted to 3-phosphoglycerate (3PG) by phosphoglycerate kinase (PGK1). The 3PG is subsequently converted by phosphoglycerate mutase (PGAM) to 2-phosphoglycerate (2PG). The 2PG then serves as a substrate for enolase (ENO) to convert to phosphoenolpyruvate (PEP). Pyruvate kinase isozyme M1/M2 (PKM1/2) catalyzes the conversion of PEP to pyruvate, which can be converted to acetyl-CoA or lactate. This process generates NAD+ from NADH, which is important for the continuation of the glycolysis process. Although glycolysis itself does not require oxygen, the fate of the pyruvate produced by glycolysis depends on the availability of oxygen, and the overall efficiency of ATP production is much higher when oxygen is present[5].

Pyruvate, a product of glycolysis, enters the mitochondria where it is converted to acetyl-CoA. The resulting acetyl-CoA can then enter the tricarboxylic acid (TCA) cycle, also known as the Krebs cycle, which plays a pivotal role in generating ATP through the electron transport chain (ETC). The TCA cycle completes the breakdown of glucose by breaking down acetyl-CoA into carbon dioxide (CO_2) and water, releasing energy in the form of NADH and flavin adenine dinucleotide (FADH2). NADH and FADH2 donate their electrons to the ETC at Complex I and II, respectively. The ETC, specifically Complexes I-IV, transfers electrons from NADH and FADH2 to generate a proton gradient across the inner mitochondrial membrane. This gradient is then used by ATP synthase to produce ATP. Complex I, also known as NADH dehydrogenase or NADH ubiquinone oxidoreductase, is the largest of the five mitochondrial complexes and marks the initiation of the ETC[6]. Electrons are transferred from Complex I to coenzyme Q (CoQ) across the inner mitochondrial membrane and then from CoQ to Complex III, although an alternative pathway exists *via* Complex II, succinate dehydrogenase (SDH)[7,8]. Following reduction of succinate by Complex II, electrons are transported to CoQ and then transferred to Complex III. Complex III and cytochrome c transfer electrons to Complex IV, cytochrome c oxidase (COX). The ETC complexes act as proton pumps, creating an electrochemical gradient across the inner mitochondrial membrane, and this energy is harnessed by Complex V, ATP synthase, which generates ATP by using the energy from the movement of protons down their electrochemical gradient. This whole process is known as OXPHOS and is a time-consuming process compared to glycolysis, but is the most efficient way to generate ATP in the cell, producing up to 36-38 ATP molecules per glucose molecule. Complexes I-IV are known as the ETC, while Complex V (ATP synthase) does not (Figure 1). Except for Complex II, all OXPHOS-related complexes are partially encoded by mitochondrial DNA (mtDNA)[9]. Unfortunately, OXPHOS also produces reactive oxygen species (ROS) as a byproduct,

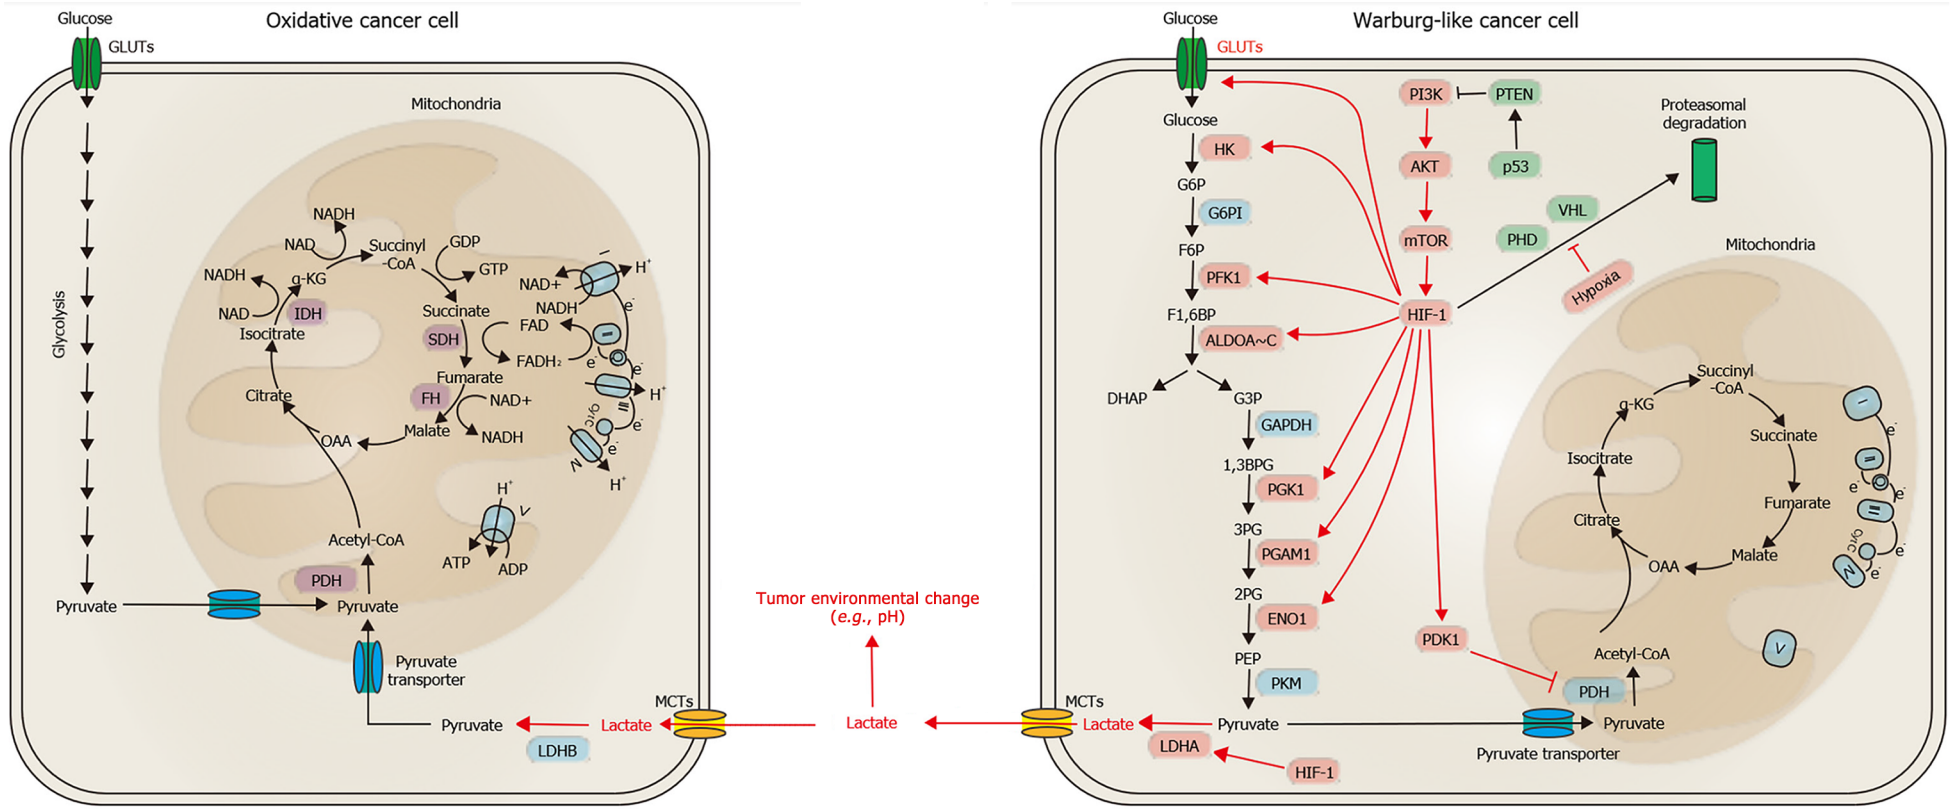
which can cause damage to mitochondrial or nuclear DNA and activate oncogenic signaling pathways, potentially leading to diseases and carcinogenesis[10-12]. Mutations in mtDNA are also implicated in cancer[13]. Overall, the process of OXPHOS is vital for cellular energy production, but careful regulation is necessary to prevent the damaging effects of ROS production.

In cancer cells, certain enzymes and molecules involved in the conversion of glucose to energy are upregulated, which provides an attractive target for anti-cancer therapies[14]. Disrupting this process could prevent cancer cells from producing energy and lead to their death. In addition to the upregulation of these enzymes, alterations in certain mitochondrial enzymes and oncometabolites have been identified in cancer cells. Oncometabolites are small molecules that are produced in cancer cells and contribute to their growth and proliferation[15]. These alterations can be caused by genetic and epigenetic changes in the genes involved in energy production[13,16]. Recent research has focused on understanding these bioenergetic alterations in gastrointestinal (GI) cancers, such as esophageal cancer (ESCA), gastric cancer (GC), hepatocellular carcinoma (HCC), cholangiocarcinoma (CCA), pancreatic cancer (PAC), and colorectal cancer (CRC). Understanding these specific metabolic changes in cancer cells can provide insight into developing more effective targeted therapies for GI cancers. In addition to the potential for targeted therapy, these metabolic changes could also serve as biomarkers for cancer diagnosis and prognosis. By identifying alterations in the genes and molecules involved in energy production, clinicians may be able to more accurately diagnose and predict the course of the disease. Overall, understanding the bioenergetic alterations in cancer cells is a promising avenue for developing new therapies and improving cancer diagnosis and treatment. In this review, we summarize the latest findings on bioenergetic alterations in

various GI cancers, and discuss the potential therapeutic strategies that target these alterations. Such strategies may include inhibitors of specific enzymes or molecules involved in energy production, as well as interventions aimed at modulating the metabolic environment of cancer cells. Further research in this area could lead to new and more effective treatments for GI cancers.

BIOENERGETIC ALTERATION AND THE WARBURG EFFECT

The process of bioenergetic alteration in cancer involves changes in the way cancer cells generate energy. One well-known component of bioenergetic alteration is the Warburg effect. This phenomenon describes how cancer cells prefer to use glucose fermentation to produce energy even in the presence of oxygen[2]. This process, called aerobic glycolysis, is less efficient than mitochondrial OXPHOS in terms of ATP production[17,18]. However, it has been noted that respiration alone can maintain tumor viability, suggesting that glucose and oxygen must be eliminated to kill cancer cells by depriving them of energy[2]. The underlying mechanisms of the Warburg effect have been investigated for decades. Otto Warburg originally proposed that mitochondrial dysfunction could be responsible for aerobic glycolysis[19]. This theory was later confirmed and explored by another group that demonstrated the Warburg effect could be caused by an imbalance of intracellular pH and mitochondrial ATPase dysfunction[20]. Moreover, it was observed that aerobic glycolysis could be controlled by cascade signaling mediated by growth factors and oncogenes, questioning whether the Warburg effect was a mere bystander in the pathogenesis of cancer[21-24]. It was not until later that the Warburg effect was discovered to be crucial for tumor growth in genetic and pharmacological studies[25,26].



Scientists have been trying to understand why cancer cells prefer aerobic glycolysis to mitochondrial OXPHOS for decades, given that the ATP generated by aerobic glycolysis is much lower than that produced by mitochondrial OXPHOS[27-29]. Recent studies have shed light on this phenomenon. For example, when changes in the cellular environment increase ATP demand through alteration of ATP-dependent membrane activity, aerobic glycolysis increases rapidly and OXPHOS remains unchanged[30]. Another study showed high aerobic glycolysis as a metabolic strategy which cancer cells use to optimally respond to fluctuating energy availability[31]. Together, this literature suggests that the Warburg effect is a metabolic strategy that allows flexibility among cancer cells under an unpredictable tumor microenvironment.

THE DYNAMIC INTERPLAY BETWEEN OXPHOS AND AEROBIC GLYCOLYSIS

Not all pyruvate produced during glycolysis is converted to lactate. Indeed, a significant amount of pyruvate can enter the TCA cycle for oxidation and further metabolism. The intermediates generated during the TCA cycle, such as NAD+/NADH and NADP+/NADPH, can continue to enter the OXPHOS pathway, which can further generate bioenergy[32,33]. Although the role of the Warburg effect in cancers remains controversial, interfering with tumor metabolism and targeting both aerobic glycolysis and mitochondrial OXPHOS pathways have been shown to be necessary[34-37]. It is evident from current literature that there exists crosstalk between aerobic glycolysis, the TCA cycle, and coupled OXPHOS, suggesting cooperative and competitive roles in cancer. Interestingly, some studies suggest that targeting mitochondrial metabolism alone may not be sufficient to inhibit tumor growth, as cancer cells can redirect their metabolism to rely on other energy sources. In such cases, blocking both the glycolytic and mitochondrial pathways may be necessary to prevent cancer cell growth[34-37]. Therefore, a better understanding of the metabolic pathways in cancer cells and their interactions is required to develop effective cancer therapies.

Although the exact molecular mechanism that triggers the Warburg effect in cancer remains unclear, multiple hypotheses have been proposed, including the involvement of tumor suppressors (*e.g.*, p53) and oncogenes (*e.g.*, PI3K, AKT, mTOR), all of which appear to converge on the role of hypoxia-inducible transcription factors (HIFs), particularly HIF-1. HIF-1 is a transcription factor that regulates cellular responses to oxygen deprivation, and it was initially identified as a protein that is present only under hypoxic conditions[38-41]. However, it was later discovered that HIF-1 can also be stabilized under normoxia in a microenvironment with high lactate concentration[42,43]. Under normal conditions, HIF-1 α, a subunit of HIF-1, is targeted for degradation by prolyl hydroxylases (PHDs), which utilize molecular oxygen to hydroxylate HIF-1α, leading to its recognition by the von Hippel-Lindau tumor suppressor (VHL), and degradation *via* proteasome-mediated pathways[44-47].

HIF-1 regulates the expression of several key glycolytic enzymes, such as glucose transporter-1 (GLUT1), GLUT3, HK, aldolase A (ALDOA), PGK1, PKM1/2, ENO1, pyruvate dehydrogenase kinase (PDKs), and lactate dehydrogenase subunit A (LDHA), by directly promoting their expression[48-54]. This leads to an increased level of pyruvate, the final product of glycolysis. However, it is important to note that cancer cells with high glycolytic activity are not guaranteed to catabolize all pyruvate to lactate, as significant amounts of pyruvate can enter the TCA cycle for oxidation and metabolism. In cancer cells, it is suggested that the HIF-1 induced increased expression of PDKs can inhibit the function of pyruvate dehydrogenase (PDH), which blocks pyruvate entry into the TCA cycle and promotes lactate production. Since HIF-1 also promotes the expression of LDHA, an important subunit of LDH necessary for lactate biosynthesis from pyruvate, it is thought to be crucial in cancers affecting terminal lactate levels[55] (Figure 2). Therefore, HIF-1 plays a significant role in the Warburg effect, which may have implications for cancer diagnosis and treatment. While the precise molecular mechanism behind the Warburg effect remains to be elucidated, the involvement of HIF-1 is clear. Understanding the interplay between HIF-1, glycolysis, and OXPHOS in cancer cells may lead to the development of novel cancer therapies that target both pathways.

Figure 2 The complex interplay between glycolysis and oxidative phosphorylation in cancer cells. This figure highlights the signaling networks and metabolic regulation in both Warburg-like and oxidative cancer cells. p53 induces PTEN and represses PI3K activity, which inhibits glycolysis and opposes the Warburg effect. Hypoxia and the subsequent activation of hypoxia-inducible factor 1 (HIF-1) play a crucial role in modulating various aspects of cancer cell metabolism, including glycolysis, lactate production, and the tricarboxylic acid (TCA) cycle. Hypoxia counteracts the degradation of HIF-1 by prolyl hydroxylases and von Hippel-Lindau, which stabilizes and activates HIF-1. HIF-1 then transcriptionally activates genes such as hexokinase, phosphofructokinase-1, aldolase A, PGK1, PGAM1, ENO1, and LDHA, as indicated by the red arrows. During glycolysis, excessive lactate can be exported to the extracellular environment, leading to microenvironmental changes such as a lower pH. Intracellular lactate can also be transferred to adjacent cells and re-converted to pyruvate, which can enter the TCA cycle and drive oxidative phosphorylation in oxidative cancer cells. The concept of lactate as a metabolic waste product has been revised with the latest findings in lactate metabolism and transport. It is now known that lactate can serve as an alternative fuel for certain types of cells, including cancer cells[56,57]. In cancer, the excess lactate is transported between the intracellular and extracellular matrix by the monocarboxylate transporter family (MCT1-4), which depends on the gradients of the protons and monocarboxylate ions[58,59]. Imported extracellular lactate can be converted to pyruvate *via* LDH primarily composed by the LDHB subunit[60,61]. In oxidative cancer cells with a functional TCA cycle and OXPHOS, pyruvate can be further converted to acetyl-CoA through PDH, thus linking aerobic glycolysis and OXPHOS[62,63]. It has been demonstrated that HIF-1 and downstream oncometabolite lactate play causal roles in these regulatory events. Therefore, current findings provide a possible explanation for the Warburg effect and crosstalk of bioenergetic homeostatic transition between aerobic glycolysis and OXPHOS observed in cancer. The importance of lactate in cancer metabolism and its potential as a therapeutic target have been recognized by others in the field. Thus, a better understanding of the metabolic pathways and their interactions could lead to the development of new strategies for cancer treatment.

THE LINK BETWEEN HYPOXIA-RELATED ENZYMES, BIOENERGETIC CHANGES, AND GI CANCER: A GENETIC AND EPIGENETIC PERSPECTIVE

Cancer cells often undergo a metabolic shift characterized by increased glycolysis and decreased mitochondrial respiration, a phenomenon known as the Warburg effect. This metabolic reprogramming has been linked to the activity of HIF-1 under low-oxygen conditions[64,65]. Genetic and epigenetic alterations in HIF-1 regulatory genes contribute to the development of the Warburg effect in cancer. Methylation-induced epigenetic changes can drive transcriptional changes, leading to impaired expression of key enzymes involved in bioenergetic homeostasis. Additionally, mutations in nuclear and mitochondrial genomes may cause a loss of function or decreased expression of glycolytic/OXPHOS enzymes. Therefore, mutations, transcriptional changes, or epigenetic alterations that enhance HIF-1 stability or activity can lead to increased aerobic glycolysis, resembling the Warburg effect (Table 1).

Studies have found that alterations in PHD enzymes, which target HIF-1 for degradation, contribute to cancer development and progression. Reduced expression or loss-of-function due to PHD2 mutations lead to constitutive activation of HIF-1 and have been found to stimulate HCC and CC development and progression in mouse models[66,67]. In contrast, decreased PHD1-3 expression correlates with increased HIF-1 and vascular endothelial growth factor (VEGF) levels, invasive tumor behavior, and poor prognosis in certain GI cancers such as HCC[68], GC[69-71], and CRC[72]. Interestingly, the opposite effect has been observed in patients with PAC[73]. Another protein involved in HIF-1 stabilization, VHL, also plays a role in GI cancers. Mutations or promoter methylation within the *VHL* gene lead to increased cytoplasmic HIF-1 levels and an unfavorable prognosis in patients with PAC and CRC[74,75]. However, the general status of VHL protein expression in GI cancers remains unclear, with the exception of HCC, whose levels have been shown to decrease, and low levels correlate with poor prognosis[76]. Further investigation is needed to determine the impact of mutations, genetic, or epigenetic alterations in these hypoxia-associated enzymes on bioenergetic alterations in GI cancers, since understanding the mechanisms behind the Warburg effect and the role of HIF-1 regulatory genes could potentially provide new therapeutic targets for treating GI cancers.

THE LINK BETWEEN MITOCHONDRIAL AND NUCLEAR GENE EXPRESSION, BIOENERGETIC HOMEOSTASIS, AND THE PROGRESSION OF GI CANCERS

Cancer development and progression are often accompanied by changes in cellular metabolism that contribute to tumor growth and survival. In addition to genetic and epigenetic alterations in hypoxia-associated regulatory enzymes that promote aerobic glycolysis, emerging evidence suggests that changes in nuclear-encoded genes for enzymes and subunits involved in OXPHOS and the TCA cycle may also play a role in driving the switch to glycolysis and altering bioenergetic homeostasis in cancer. Studies have shown that changes in the expression of key enzymes involved in OXPHOS, such as cytochrome *c* oxidase (COX) and ATP synthase, as well as the TCA cycle enzymes isocitrate dehydrogenase (IDH), fumarate hydratase (FH), and succinate dehydrogenase (SDH), may contribute to glycolysis transition and cancer progression[77-80]. Furthermore, mutations and copy number alterations in mtDNA have also been identified as important factors in the development and progression of GI cancer by altering bioenergetic homeostasis[81]. These emerging factors and their potential contribution to the complex mechanisms underlying the progression of GI cancer are discussed in more detail in the following sections.

ROLE OF MITOCHONDRIAL-NUCLEAR ENCODED COX SUBUNITS IN BIOENERGETIC CHANGES AND PROGRESSION OF GI CANCERS

The COX complex, also known as respiratory chain complex IV, is a multi-subunit enzyme complex, consisting of 14 subunits, and a vital component of the final step in the mitochondrial ETC responsible for catalyzing the transfer of electrons from cytochrome c to oxygen, a crucial step in the process of OXPHOS[82]. Recent studies have shown that alterations in the expression of both mtDNA-encoded and nuclear-encoded COX subunits are associated with tumori-

Table 1 Genetic and epigenetic alterations in hypoxia-related enzymes correlated with the development and progression of gastrointestinal cancers

Cancer type	Gene	Type of change	Consequence	Model	Ref.
HCC and CCA	PHD2	Haplo-deficiency	Stabilized HIF-1 and promoted carcinogenesis and progression of HCC/CCA	Mice	[66, 67]
HCC	PHD3	Reduced tumor level	Correlated with elevated levels of HIF-1, aggressive tumor behavior, and a poor prognosis in HCC patients	HCC patient	[68]
GC	PHD3	Reduced tumor level	Correlated negatively with tumor size and stage, as well as HIF-1 and VEGF expression	GC patient	[69, 70]
GC	PHD2	Reduced tumor level	Correlated with shortened overall survival	GC patient	[71]
CRC	PHD1-3	Reduced tumor level	Although not correlated with HIF-1 expression, PHD2 was the only factor found to be associated with unfavorable overall survival	CRC patient	[72]
PAC	PHD1-3	Increased tumor level	PHD1-3 expression was elevated, and specifically PHD3 expression was found to be associated with unfavorable overall disease-specific survival	PAC patient	[73]
PAC	VHL	Promoter methylation or deletion of VHL	Correlated with decreased VHL expression and poor prognosis	PAC patient	[74]
CRC	VHL	*VHL* mutation	Elevated cytoplasmic expression of HIF-1 in tumors	CRC patient	[75]
HCC	VHL	Reduced tumor level	Negative VHL expression was correlated with an unfavorable prognosis	HCC patient	[76]

genesis, cancer progression, and bioenergetic homeostasis in cancer. In GI cancers, alterations in the expression of the mitochondrial-nuclear encoded subunits of the COX complex have been implicated in driving disease progression. Studies have shown that the overall levels of the COX complex are increased in GI cancers, and higher levels have been associated with poor clinical outcomes[83,84]. Of the three mtDNA-encoded core subunits essential for the basic functions of the COX complex, including MTCO1, MTCO2, and MTCO3[85], MTCO1 is the most frequently investigated in GI cancers (Table 2). In ESCA, MTCO1 expression was found to be elevated but did not correlate with clinicopathological variables or survival[86]. On the other hand, elevated levels of MTCO1 were associated with diffuse GC types, suggesting a link between MTCO1 expression and GC carcinogenesis, de-differentiation, and distant metastasis[87,88]. In contrast, defective MTCO1 expression was observed in patients with HCC and CCA, while MTCO1 levels have been shown to predict postoperative survival in patients with HCC[89,90]. Elevated MTCO3 levels have been observed only in HCC, especially among patients with hepatitis B virus (HBV)-related HCC. This is likely due to the ability of the HBV X protein (HBx) to interact and increase MTCO3 expression[91,92]. Additionally, genetic variants identified within MTCO1 and MTCO3 are associated with increased carcinogenic risk in CRC[93,94], GC[95], and HCC[96], possibly due to reduced COX activity leading to intrinsic proton leak and a reduction in overall bioenergetic production efficiency[93,94]. However, studies on the expression or genetic variation of MTCO2 in GI cancers are relatively few and need further investigation.

While the three core mtDNA-encoded COX subunits have been extensively studied, 11 nuclear-encoded protein subunits are also required for the full functionality of the COX complex[97]. Of these 11 subunits, six can be replaced by isoforms, leading to heterogeneity in the composition and activity of this large complex[98]. In GI cancers, altered expression of nuclear-encoded COX subunits has been shown to play a crucial role in the switch to glycolysis and the promotion of tumor growth and progression (Table 2). For example, in ESCA, the silencing of COX4I1 and COX5B has been shown to promote bioenergetic changes and increased aggressiveness of ESCA cells *in vitro*[99]. In HCC and CRC, COX5B levels were found to correlate with prognosis, and changes in COX5B expression were associated with alterations in bioenergetics, cell proliferation, tumor growth, migration, and chemosensitivity. HCC and CRC, however, showed different COX5B expression patterns[100-102]. Similarly in CRC, increased COX4I2 has been shown to promote cell proliferation, migration, tumorigenesis, and angiogenesis[103]. COX6C and COX6B2 were also found to be increased in PAC, with changes in expression levels of COX6C affecting COX activity and cell growth *in vitro*. Meanwhile, COX6B2 levels were associated with prognosis, metastatic potential in PAC cells, and altered bioenergetic homeostasis[104,105].

The roles of remaining subunits in GI cancer are currently unknown, and studies focusing on the level of nuclear-encoded COX subunit in GI cancer largely suggest that altered expression leads to decreased OXPHOS activity in a Warburg effect-like phenotype. Increased GI cancer growth and/or progression is also suggested. Together, these findings highlight the crucial role COX subunits play in GI cancer progression and underscore the need for continued research. The identification of altered COX subunit expression and function may lead to the development of novel therapeutic targets for the treatment of GI cancers. Therefore, further research on the COX complex and its subunits is

Table 2 Defects in cytochrome c oxidase subunits correlated with bioenergetic alterations and the growth or progression of gastrointestinal cancers

Type	Gene	Type of defect	Consequence	Model	Ref.
GC	Full COX complex	Increased expression	Correlated with poor prognosis	GC patient	[83]
CRC	Full COX complex	Increased expression	May be involved in the initiation of carcinogenesis, but not in cancer progression	CRC patient	[84]
ESCA	MTCO1	Increased expression	There is no correlation with clinical variables or survival	ESCA patient	[86]
GC	MTCO1	Increased expression	Correlated with gastric tumorigenesis, dedifferentiation, and distant metastasis, but showed no significant correlation with prognosis	GC patient	[87,88]
HCC	MTCO1	Reduced expression	Correlated with postoperative prognosis	HCC patient	[89]
CCA	MTCO1	Reduced expression	Reduced MTCO1 correlates with increased VDAC1 expression but not with other clinicopathological factors	CCA patient	[90]
HCC	MTCO3	Increased expression	HBx interacted with MTCO3, leading to an increase in MTCO3 expression levels and an enhancement in OXPHOS activity	Cell line	[91,92]
CRC	MTCO1	Genetic variation	The Gly125Asp substitution in MTCO1 correlated with an increased risk of CRC and caused proton leak in COX	CRC patient	[93,94]
GC	MTCO3	Genetic variation	Polymorphisms at mtDNA positions 9540 and 9548 correlated with an increased risk of GC	GC patient	[95]
HCC	MTCO3	Genetic variation	Polymorphisms at mtDNA position 9545 correlated with an increased risk of HCC	HCC patient	[96]
ESCA	COX4I1	Expression silenced	Promotes alterations in cellular bioenergetics and increases cancer cell aggressiveness	ESCA Cell line	[99]
ESCA	COX5B	Expression silenced	Promotes alterations in cellular bioenergetics and increases cancer cell aggressiveness	ESCA Cell line	[99]
HCC	COX5B	Increased in tumor	Correlated with prognosis, regulated bioenergetic alterations, and influenced cell proliferation, tumor growth, and migration	HCC patient, cell line, mouse model	[100]
CRC	COX5B	Reduced in tumor	Correlated with prognosis, modulated COX activity, and controlled cell proliferation, apoptosis, and response to chemotherapy	CRC patient and cell line	[101,102]
CRC	COX4I2	Increased in tumor	Promoted cell proliferation, migration, tumorigenesis, and angiogenesis	CRC patient and cell line	[103]
PAC	COX6C	Increased expression	Modulated COX activity and cell proliferation	PAC cell line	[104]
PAC	COX6B2	Increased in tumor	Correlated with prognosis, and modulated cancer cell metastatic potential, and altered bioenergetic homeostasis	PCA patient and cell line	[105]

needed to fully elucidate their role in GI cancer.

THE ROLE OF ATP SYNTHASE SUBUNITS IN DRIVING BIOENERGETIC CHANGES AND GI CANCER PROGRESSION

ATP synthase, also known as Complex V, is a crucial mitochondrial protein complex that plays a vital role in cellular ATP synthesis. The F1 beta-catalytic subunit (ATP5F1B) is a critical component that has been extensively studied to find a significant reduction in various cancer types, including GI cancers[106] (Table 3). However, the expression patterns of ATP5F1B in patients with GC remain controversial. While one study reported increased ATP5F1B expression in tumors,

Table 3 Implications of defects in adenosine triphosphate synthase subunits on bioenergetic alterations and the development or progression of gastrointestinal cancer

Type	Gene	Type of defect	Consequence	Model	Ref.
GC	ATP5F1B	Increased in tumor	Higher ATP5B expression correlated with poor prognosis. Over-expression of ATP5F1B increased intracellular and extracellular ATP levels, cell proliferation, migration, and invasion	GC patient, cell line, and xeno-transplantation mouse model	[107]
GC	ATP5F1B	Reduced in tumor	Reduced ATP5F1B expression correlated with elevated glycolytic enzyme levels	GC patient	[108]
HCC	ATP5F1B	Reduced in tumor	Reduced ATP5F1B expression correlated with impaired OXPHOS	HCC patient	[109, 110]
ESCA	ATP5F1B	Reduced in tumor	Reduced ATP5F1B expression correlated with elevated glycolytic enzyme levels	ESCA patient	[108]
CRC	ATP5F1B	Reduced in tumor	Reduced ATP5F1B expression correlated with poor prognosis in CRC patients	CRC patient	[109]
PAC	ATP5F1B	Reduced in tumor	Unknown	PAC patient and cell line	[111]
CRC	ATP5F1A	Increased in liver metastasized tumor	Silencing of ATP5F1A inhibited cell invasion and reduced cell proliferation in CRC cancer cells	CRC patient and cell line	[112]
CRC	ATP5F1E	Increased in tumor	Higher ATP5E levels correlated with poor prognosis. Silencing of ATP5F1E inhibited cancer cell migration and invasion *in vitro*, and distal metastasis *in vivo*	CRC patient, cell line, and tail vein injected mouse model	[113]
CRC	ATP5F1D	Increased in liver metastasized tumor	Higher ATP5F1D expression correlated with poor prognosis, and silencing of ATP5F1D inhibited cell invasion	CRC patient and cell line	[112]

correlating with poor prognosis[107], consistent findings from other GI cancer studies indicate that decreased ATP5F1B expression results in reduced ATP production efficiency from OXPHOS and a subsequent shift towards the glycolysis-dependent Warburg effect phenotype[108-111]. These findings highlight the critical role of ATP synthase in GI cancer progression, suggesting that mitochondrial defects in ATP synthesis may contribute to the bioenergetic alterations observed in these cancers.

Apart from the F1 beta-subunit, other subunits of the ATP synthase F1 region have been implicated as crucial to CRC carcinogenesis/progression. Interestingly, in contrast to the finding that ATP5F1B generally decreases in tumors, ATP5F1A, ATP5F1E, and ATP5F1D were found to be increased in patients with CRC. Moreover, higher levels correlated with poorer prognosis as well as increased risk of CRC liver metastasis[112,113]. Currently, there are no reports on the expression patterns or role of ATP synthase subunits in CCA. The mechanisms underlying opposing expression patterns in ATP synthase subunits are thus unknown pending further investigation.

To provide more insight into the development of novel therapeutic targets for the treatment of GI cancers, further research on ATP synthase expression and function is necessary. In this regard, potential avenues of research may focus on clarifying the controversial findings regarding ATP5F1B expression patterns in GC and elucidating the mechanisms underlying these opposing expression patterns seen in differing ATP synthase subunits in CRC. Such research may uncover novel therapeutic targets, leading to improved treatment outcomes.

LINKING IDH, FH, AND SDH TO BIOENERGETICS AND GI CANCER PROGRESSION

Fumarate and succinate are critical metabolites that are produced during the TCA cycle, which is an essential process for energy production in cells. While these metabolites are important for normal cellular function, they have been shown to act as oncometabolites in various types of cancer by inducing pseudohypoxia[114]. Specifically, aberrant fumarate and succinate accumulation resulting from mutations or abnormal expression in FH and SDH, respectively, can impede the production of α-ketoglutarate in the TCA cycle, which is a key substrate in tumor suppression pathways. Similarly, mutations in IDH enzymes, which are responsible for α-ketoglutarate synthesis, can directly reduce the levels of α-ketoglutarate. This reduction in α-ketoglutarate can limit the availability of substrate for the hydroxylation of HIF-1 by PHDs for subsequent degradation by the proteasome. Consequently, stabilized HIFs activate the transcription of genes involved in cancer-related processes such as angiogenesis, glucose metabolism, and cell proliferation, thereby promoting cancer development and progression[114].

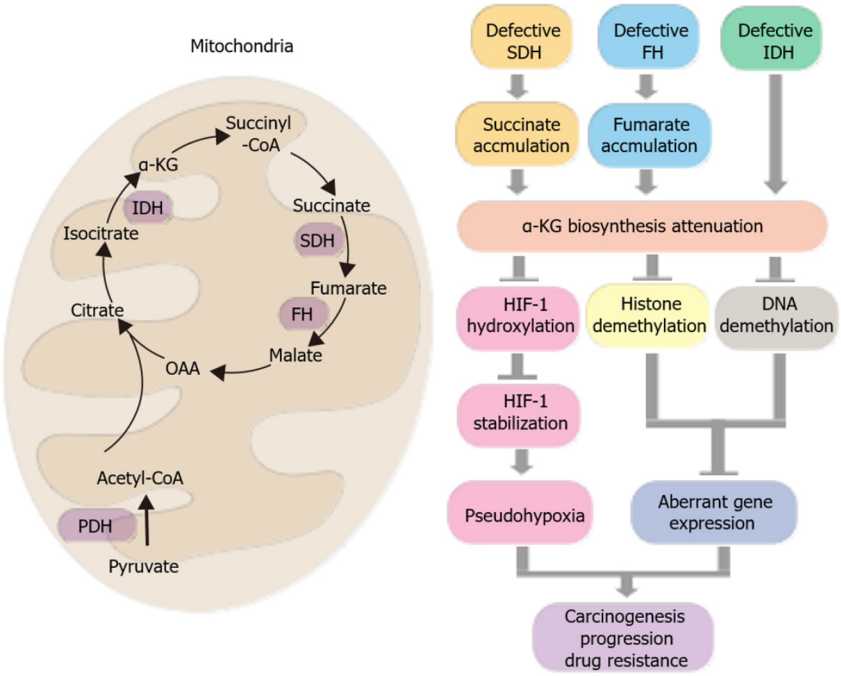
In addition to their effects on HIFs, high levels of fumarate and succinate have been shown to cause abnormal methylation of DNA and histones, leading to dysregulation of gene expression and cell function. This is due to

attenuation of enzymes responsible for DNA and histone demethylation such as tet-eleven translocation methyl-cytosine dioxygenase (TET) and lysine demethylase (KDM, also known as the Jumonji C domain-containing histone demethylase, JHDM)). Dysregulation of gene expression, increased carcinogenicity, and cancer progression can result from decreased α -ketoglutarate under high fumarate and succinate levels[115,116] (Figure 3).

The FH and SDH enzymes responsible for the catabolism of fumarate and succinate have been implicated as tumor suppressors[117]. Genetic variants in FH or SDH complex subunits, including SDHA, SDHB, SDHC, and SDHD, have been associated with increased risk of certain cancers such as hereditary leiomyomatosis and renal cell cancer (HLRCC) [118,119] as well as paraganglioma and pheochromocytoma[120-123]. Although there is limited evidence involving genetic mutants of FH or SDH complex subunit genes in GI cancer, an unusual mutation of the FH gene was found to be associated with the development of gastric leiomyoma following cutaneous and uterine leiomyomatosis[124]. Except for loss-of-function mutations, some researchers have revealed FH and SDH complex subunit gene single nucleotide polymorphisms (SNP) in patients with HCC and CRC[125,126]. Interestingly, FH was found to be downregulated in HCC patients with portal vein thrombosis due to currently unknown underlying mechanisms[127]. However, the role of FH and SDH in GI cancer remains largely unknown. Further investigation is thus necessary.

Understanding the role of oncometabolites in GI cancer could provide valuable insights into the development of novel therapeutic targets for the treatment of these cancers. Further research should be conducted to investigate the potential roles of FH and SDH in the development and progression of GI cancer and explore the possible therapeutic targets associated with the regulation of these enzymes. By gaining a better understanding of oncometabolites in GI cancer, we may be able to develop more effective therapies and improve patient outcome.

EXPLORING BIOENERGETIC REGULATORS AS TARGETS FOR GI CANCER THERAPY



Our current understanding of metabolic reprogramming and bioenergetic alterations in cancer has led to the emergence of several potential drugs that target the bioenergetics of cancer cells, offering a promising avenue for anti-cancer therapy. These drugs can be classified into two main categories based on their mode of action: targeting aerobic glycolysis/lactate biosynthesis and transportation, or targeting the TCA cycle and coupled OXPHOS (Figure 4).

To target aerobic glycolysis, several strategies have been developed including blocking glucose import by targeting GLUT1, reducing glycolysis activity by targeting hexokinase 2 (HK2), PKMFB3, and PKM2, inhibiting lactate biosynthesis by targeting LDHA and PDK, and blocking lactate transportation through targeting MCT1/2. Targeting the TCA cycle and OXPHOS involves PDH and mitochondrial complex inhibitors. Several bioenergetic-targeted drugs have provided pre-clinical or clinical evidence in treating GI cancers. Table 4 provides a summary of these drugs. In the following sections, we will discuss the details of such strategies and the drugs used to target bioenergetic regulators during GI cancer therapy.

UNLOCKING THE POTENTIAL OF GLUCOSE METABOLISM TARGETS IN GI CANCER THERAPY

Cancer cells typically rely on increased glucose uptake, a phenomenon known as the Warburg effect, to meet energy requirements, making glucose uptake a promising target for anti-cancer therapy. As a result, GLUT1 has been identified as a potential drug target for blocking glucose uptake. Several GLUT1 inhibitors, including genistein, apigenin, fasentin, WZB117, WZB27, WZB115, STF-31, and BAY-876 have shown an ability to block glucose uptake[14]. Genistein and apigenin are natural compounds belonging to the flavonoid group, and they have been shown to inhibit hypoxia-inducible factor 1A (HIF1A) mRNA and protein expression, which leads to inactivation of downstream genes such as GLUT1 and HK2, thereby attenuating glycolysis activity[128-130]. In GI cancers, these compounds have demonstrated the ability to inhibit cancer cell proliferation, cell cycle progression, colony formation, migration, invasion, angiogenesis, stemness, spheroid formation, EMT, and to enhance cell death[131-146]. Although the majority of evidence pertaining to efficacy comes from *in vitro* cell-based assays, genistein and apigenin have entered clinical trials as a combination anti-cancer therapy for patients with CRC (NCT10985763 and NCT00609310) and PAC (NCT02336087, NCT00376948 and NCT00882765). Moreover, dietary supplementation with apigenin has been shown to significantly prevent CRC recurrence in a prospective study[147]. Fasentin, WZB117, WZB27, WZB115, STF-31, and BAY-876 are synthetic chemicals with selective activity on GLUT1 inhibition. Fasentin, WZB27, and WZB115 have shown anti-cancer potential in other pre-clinical cancer models, although there is currently little to no research on GI cancers. WZB117 has been shown to reduce glucose uptake, inhibit cell proliferation/invasion, and enhance chemosensitivity in GI cancer cell lines, as well as in xenograft models[148-151]. STF-31 has been implicated in reducing cancer stem cell stemness, cell proliferation, viability, and tumor growth in PAC and CRC cell lines, as well as in xenograft models[152,153]. BAY-876 has been found to inhibit cell proliferation, tumor growth, glucose uptake, and promote chemosensitivity in ESCA, PCA, and CRC cell lines, and in xenograft mouse models[154-156]. Although these findings are promising, WZB117, STF-31, and BAY-876 are not currently in clinical trials for GI cancer. Thus, their safety, dosage, and therapeutic response in GI cancer patients remain to be determined in future studies.

Another strategy to block glycolysis is by targeting glycolytic enzymes or attenuating glycolytic activity. A well-studied example of this strategy is the use of 2-deoxy-D-glucose (2-DG), a glucose molecule with a 2-hydroxyl group replaced by hydrogen. 2-DG is taken up by cells with high glucose uptake ability, such as cancer cells, where it serves as a competitive inhibitor of glucose[157]. Once inside the cell, 2-DG enters the glycolytic pathway and is phosphorylated by HK2 to become 2-DG-6-phosphate (2-DG-6-P), which cannot be further processed by G6P isomerase and therefore

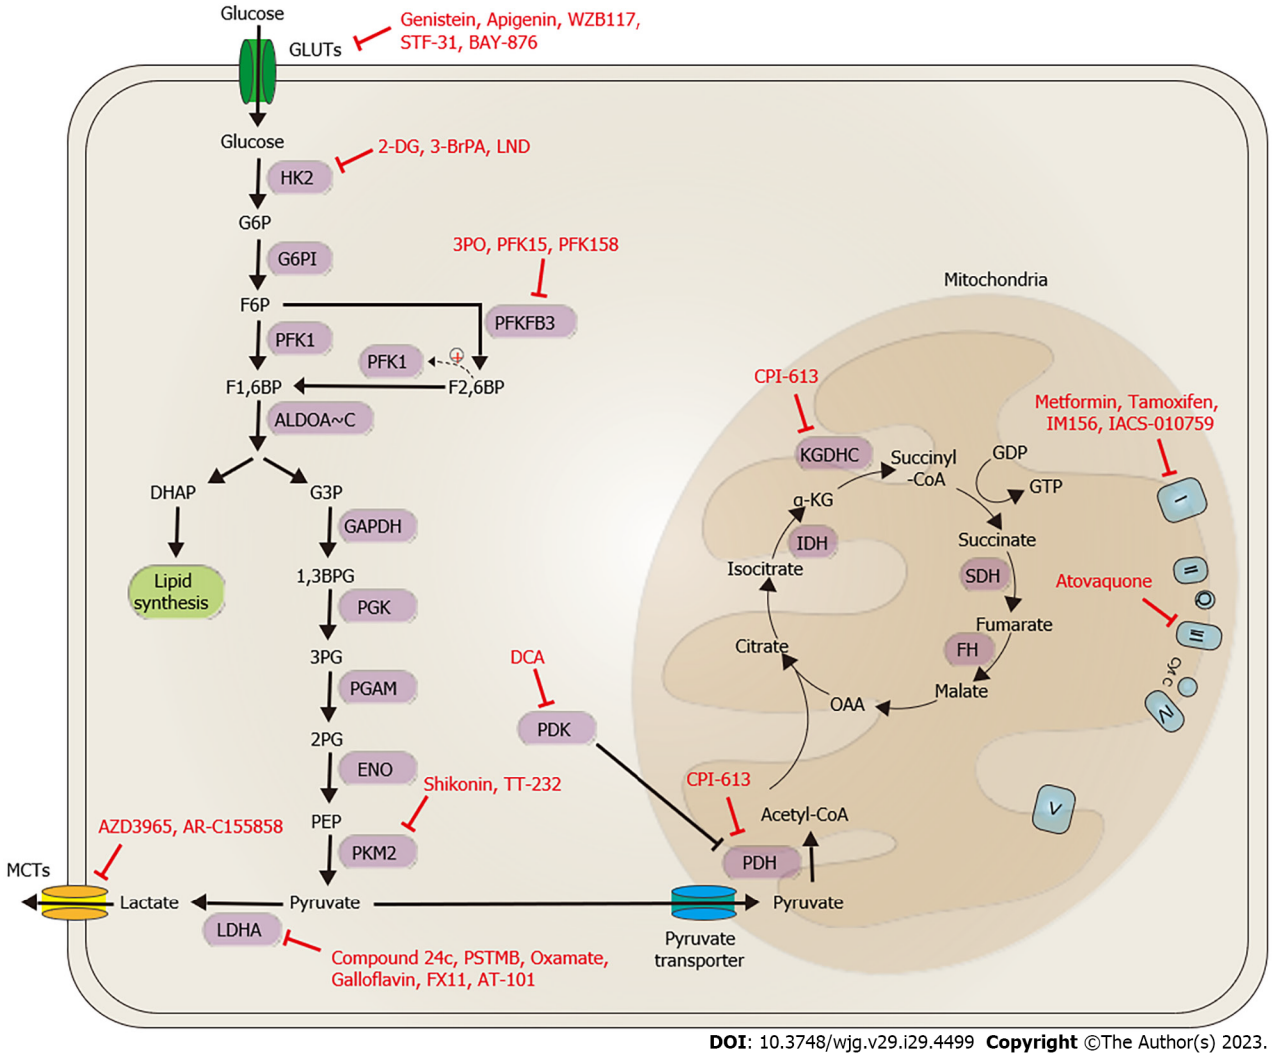

Figure 3 Tricarboxylic acid cycle dysfunction in cancer and its role in carcinogenesis, progression, and anti-cancer drug resistance. The left panel depicts the tricarboxylic acid cycle, with succinate dehydrogenase and fumarate hydratase as key regulatory enzymes responsible for the formation of oncometabolites succinate and fumarate. The isocitrate dehydrogenase enzyme synthesizes α-ketoglutarate, which serves as a substrate for tumor suppressor pathways, such as hypoxia-inducible factor 1 hydroxylation for degradation, as well as histone and DNA demethylation. These processes can lead to pseudohypoxia and aberrant gene expression, promoting carcinogenesis, progression, and anti-cancer drug resistance. The right panel provides a summary of these relationships. OAA: Oxaloacetate; SDH: Succinate dehydrogenase; FH: Fumarate hydratase; PDH: Pyruvate dehydrogenase; IDH: Isocitrate dehydrogenase; α-KG: α-ketoglutarate; HIF-1: Hypoxia-inducible factor 1.

accumulates. Accumulated 2-DG-6-P reversely negatively inhibits HK2 activity, leading to a reduction in glycolytic activity. A derivative of 2-DG, fluorodeoxyglucose (18F-FDG), has been extensively employed in positron emission tomography (PET) to visualize the location and status of certain types of cancers[158]. In pre-clinical studies using GI cancer cell lines, as well as xenograft models and rat HCC and hamster PAC models, 2-DG has been shown to inhibit cell proliferation, tumor growth, and promote chemosensitivity[159-165]. Although 2-DG has entered clinical trials for other cancer types, only a phase I trial (NCT00096707) was conducted for patients with PAC, and the safety, dose, and efficacy of 2-DG in treating patients with other GI cancers are unknown.

Several other chemical drugs have been claimed to inhibit HK2 function, but their roles in GI cancers are unclear, with the exception of 3-bromopyruvate (3-BrPA) and lonidamine (LND). 3-BrPA is an analog of both lactate and pyruvate and shows an inhibitory effect on HK2, possibly due to its ability to induce protein alkylation[166,167]. In pre-clinical studies of GI cancers, 3-BrPA has shown its ability to inhibit cellular ATP generation, cell proliferation, tumor growth, induce mitochondrial depolarization, reduce animal serum VEGF levels, and promote cell death and chemosensitivity in GC, HCC, PAC, and CRC cell lines, as well as rabbit, transgenic mice, and xenograft mouse models[167-171]. Therapeutic efficacy and safety were only evaluated in a case report study, providing a safe and tolerable dose of 3-BrPA in patients with fibrolamellar HCC[172].

LND is an indazole derivative that was previously utilized as an anti-spermatogenic agent. In drug re-purposing studies, LND was found to have anti-cancer activity by affecting bioenergetic homeostasis, including the glycolytic pathway, through targeting HK2 *via* currently unclear mechanisms[173]. LND showed promising therapeutic efficacy by inhibiting cell proliferation, migration, invasion, cell cycle progression, and increasing chemosensitivity in HCC, CCA, and CRC cell lines, as well as in a hamster CCA model[174-179]. Encouraging results were observed in a clinical trial recruiting patients with GC, showing improved overall response rate and duration of disease progression[174]. Reversely, it was reported that administration of LND was ineffective and toxic in clinical trials recruiting patients with CRC[178, 179].

Targeting PFKFB3 is another approach to block cancer glycolysis, as it is considered an oncogene in cancers due to its high expression and role in glycolysis[180]. PFKFB3 is activated by multiple cancer-associated stimuli, including cytokines, chemokines, growth factors, and hypoxia, and then participates in glycolysis through catalyzing fructose-6-P to become F2,6BP, which can further positively enhance PFK1 activity and thus accelerate glycolysis[180]. Accordingly, PFKFB3 drugs have been identified and tested in pre-clinical and clinical studies. Among the list of candidate drugs that target PFKFB3, 3-(3-pyridinyl)-1-(4-pyridinyl)-2-propen-1-one (3PO), 1-(4-pyridinyl)-3-(2-quinolinyl)-2-propen-1-one (PFK15), and 1-pyridin-4-yl-3-[7-(trifluoromethyl)-quinolin-2-yl]-prop-2-en-1-one (PFK158) have drawn more attention than others[181]. It was found that 3PO and PFK15 inhibit cell proliferation, reduce tumor growth, attenuate angiogenesis, prevent fibrogenesis, and increase cell death in pre-clinical studies using GI cancer cell lines, transgenic mice,

Figure 4 Potent bioenergetic-targeting drugs for gastrointestinal cancers. Promising bioenergetic drugs for gastrointestinal cancers can be classified into two main categories based on their mode of action. The first category involves targeting aerobic glycolysis and lactate biosynthesis/transportation, while the second category involves targeting the tricarboxylic acid (TCA) cycle and oxidative phosphorylation (OXPHOS). Strategies to target aerobic glycolysis include blocking glucose importation through the targeting of glucose transporter 1 with compounds such as genistein, apigenin, WZB117, STF-31, and BAY-876, reducing glycolysis activity by targeting HK2 with compounds such as 2-DG, 3-BrPA, and LND, and targeting PKMFB3 and PKM2 with compounds such as 3PO, PFK15, PFK158, shikonin, and TT-232. Lactate biosynthesis can be inhibited by targeting LDHA with compounds such as compound 24c, PSTMB, oxamate, galloflavin, FX11, and AT-101, and PDK with DCA. Lactate transportation can be blocked by targeting MCT1/2 with compounds such as AZD3965 and AR-C155858. Targeting the TCA cycle and OXPHOS involves using inhibitors of pyruvate dehydrogenase, such as CPI-613, and mitochondrial complex I with metformin, tamoxifen, IM156, IACS-010759, and complex III with atovaquone. GLUT: Glucose transporter; HK: Hexokinase; G6P: Glucose-6-phosphate; G6PI: Glucose-6-phosphate isomerase; F6P: Fructose-6-phosphate; NADPH: Nicotinamide adenine dinucleotide phosphate; PFK1: Phosphofructokinase-1; F2,6BP: Fructose-2,6-bisphosphate; PFKBP3: Fructose-2,6-biphosphatase 3; F1,6BP: Fructose-1,6-bisphosphate; G3P: Glyceraldehyde-3-phosphate; DHAP: Dihydroxyacetone phosphate; GAPDH: Glyceraldehyde 3-phosphate dehydrogenase; 1,3BPG: 1,3-bisphosphoglycerate; 3PG: 3-phosphoglycerate; PGK: Phosphoglycerate kinase; PGAM: Phosphoglycerate mutase; 2PG: 2-phosphoglycerate; ENO: Enolase; PEP: Phosphoenolpyruvate; PKM1/2: Pyruvate kinase isozyme M1/M2; LDH: Lactate dehydrogenase; MCT: Monocarboxylate transporter family; PDH: Pyruvate dehydrogenase; IDH: Isocitrate dehydrogenase; α-KG: α-ketoglutarate; OAA: Oxaloacetate; SDH: Succinate dehydrogenase; FH: Fumarate hydratase; I: Mitochondrial complex I; II: Mitochondrial complex II; III: Mitochondrial complex III; IV: Mitochondrial complex IV; V: Mitochondrial complex V; Q: Co-enzyme Q; cyto C: Cytochrome *c*; KGDHC: α-ketoglutarate dehydrogenase complex.

xenograft mouse models, and HCC rat models[182-189]. Intriguingly, it was also found that 3PO suppresses glucose uptake *via* a 14C-2-DG tracing system[184]. Although there is no pre-clinical evidence of efficacy in GI cancers, the safety, tolerated dose, and therapeutic efficacy of PKF158 have been evaluated in a Phase I clinical trial (NCT02044861) that involved patients with solid tumors[190].

One strategy proposed to inhibit glycolysis activity is to target the last enzyme in the glycolytic pathway –PKM2. PKM2 targeting is based on its glycolysis role as well as aberrant expression in cancer-associated events[191]. While many drugs have shown the ability to inhibit PKM activity, only two, TT-232 and Shikonin, have been confirmed efficacious in pre-clinical studies. Both TT-232 and Shikonin have been found to inhibit GI cancer cell proliferation, migration, invasion, cell cycle progression, and tumor growth, as well as enhance cell death[192-200]. However, the efficacy of these drugs in treating GI cancers is still unclear and requires further investigation. Both drugs have entered clinical trials for specific cancers, showing promise as cancer therapy targets.

Table 4 Promising novel bioenergetics targeting drugs for gastrointestinal cancer therapy

Inhibitor	Target	GI model	Consequence	Clinical trial	Ref.
Targeting glucose transportation					
Genistein	HIF1A, GLUT1 and HK2	GC, ESCA, HCC, CCA, PCA, and CRC cell lines	Inhibited cancer cell proliferation, cell cycle progression, migration, invasion, angiogenesis, stemness, spheroid formation, EMT, and promoted apoptosis	CRC patient, phase I/II (NCT10985763), and PAC patient, phase I/II (NCT02336087, NCT00376948 and NCT00882765)	[131-140]
Apigenin	HIF1A, GLUT1 and HK2	GC, ESCA, HCC, CCA, PCA, and CRC cell lines	Inhibited cancer cell proliferation, colony-forming, cell cycle progression, migration, invasion, angiogenesis, and induced apoptosis	CRC patient, phase II (NCT00609310)	[141-146]
WZB117	GLUT1	HCC, CCA, PAC, and CRC cell lines, and xenograft models	Reduced glucose uptake, inhibits cell proliferation, and invasion, and enhanced chemosensitivity	None in GI cancers	[148-151]
STF-31	GLUT1	PAC and CRC cell lines, and xenograft model	Reduced cancer stem cell properties, such as stemness, and inhibits cell proliferation, viability, and tumor growth	None in GI cancers	[152, 153]
BAY-876	GLUT1	ESCA, PCA, and CRC cell lines, and xenograft mouse models	Reduced cancer cell proliferation, tumor growth, and glucose uptake, while also increased chemosensitivity	None in GI cancers	[154-156]
Targeting glucose metabolism					
2-Deoxy-D-glucose (2-DG)	HK2	GC, ESCA, HCC, PAC and CRC cell lines, xenograft models, and rat HCC and hamster PAC models	Inhibited cell proliferation, tumor growth, and promoted chemosensitivity	PAC patient, phase I (NCT00096707)	[159-165]
3-Bromopyruvate (3-BrPA)	HK2	GC, HCC, PCA, and CRC cell lines, and rabbit, transgenic mouse and xenograft mouse models	Inhibited cellular ATP generation, cell proliferation, and tumor growth. Also induced mitochondrial depolarization, reduced animal serum VEGF levels, and promoted cell death and chemosensitivity	HCC patient, case report[170]	[167-170]
Lonidamine (LND)	HK2	HCC, CCA, and CRC cell lines, hamster CCA model, and GC and CRC patients	Inhibited cell proliferation, migration, invasion, and cell cycle progression. Increased chemosensitivity, patient overall response rate, and duration of disease progression in GC patients. However, was ineffective and toxic in advanced CRC patients	GC patient, phase II[172], CRC patients, phase II[176,177]	[174-179]
3-(3-pyridinyl)-1-(4-pyridinyl)-2-propen-1-one (3PO)	PFKFB3	HCC, PAC, and CRC cell lines, and transgenic and xenograft mouse models	Inhibited glucose uptake, cell proliferation, tumor growth, angiogenesis, fibrogenesis, and promoted cell death	None in GI cancers	[182-184]
1-(4-pyridinyl)-3-(2-quinolinyl)-2-propen-1-one (PFK15)	PFKFB3	GC, HCC, PAC, and CRC cell lines, xenograft models, and HCC rat model	Inhibited cell proliferation, migration, invasion, cell cycle progression, tumor growth, and enhanced cell death	None in GI cancers	[185-189]
1-pyridin-4-yl-3-[7-(trifluoromethyl)-quinolin-2-yl]-prop-2-en-1-one (PFK158)	PFKFB3	None in GI cancers	None in GI cancers	Solid tumor patients, phase I (NCT02044861)	[190]
Shikonin	PKM2	GC, ESCA, HCC, CCA, PCA, and CRC cell lines, and xenograft mouse models	Inhibited cell proliferation, migration, invasion, cell cycle progression, tumor growth, and enhanced cell death	None in GI cancers	[192-197]
TT-232	PKM2	HCC, PAC, and CRC cell lines,	Inhibited cell proliferation, tumor growth, and enhanced cell death	None in GI cancers	[198-200]

		and xenograft mouse models			
Targeting lactate biosynthesis					
Dichloroacetate (DCA)	PDK	GC, ESCA, HCC, PAC, and CRC cell lines, xenograft models, and B6C3F1 mice	Reduced lactate production, cell proliferation, migration, and increased chemosensitivity. Showed synergistic anticancer effects in HCC. However, promoted hepatocarcinogenesis in B6C3F1 mice	CRC patient, phase I (NCT00566410)	[203-207]
Compound 24c	LDHA	PAC cell lines, and xenograft model	Suppressed cell proliferation, colony formation, enhanced cell apoptosis, arrested cell at G2 phase, repressed xenograft growth, and re-programmed cancer metabolism, with minimal impact on mouse weight	None in GI cancers	[210]
1-(Phenylseleno)-4-(Trifluoromethyl) Benzene (PSTMB)	LDHA	HCC and CRC cell lines	Inhibited cell proliferation, reduced cell viability, attenuated LDHA activity, lowered lactate levels, and induced mitochondria-mediated apoptosis	None in GI cancers	[211]
Oxamate	LDHA	GC, ESCA, HCC, PCA, and CRC cell lines	Suppressed LDHA activity, lactate production, cell proliferation, migration, MMP9 expression, pro-inflammatory cytokines, EMT transition, and AKT/ERK/mTOR signaling pathways, while enhanced apoptosis, senescence, protective autophagy, and metabolic rewiring	None in GI cancers	[212-218]
Galloflavin	LDHA	HCC, PCA, and CRC cell lines	Reduced ATPase activity and expression levels of heat shock proteins, inhibited cell proliferation, lactate production, pro-inflammatory cytokines, and EMT transition, while promoting apoptosis and senescence	None in GI cancers	[215, 218-220]
FX11	LDHA	HCC, PCA, and CRC cell lines, and xenograft mouse models	FX11 reduced lactate production and ATP levels, suppressed cell proliferation, migration, invasion, and xenograft tumor growth, while enhancing apoptosis. However, in a PCA patient-derived mouse xenograft model, FX11 was only effective in attenuating tumor growth in the presence of mutant TP53	None in GI cancers	[221-225]
Gossypol (AT-101) or its derivatives	LDHA	GC, ESCA, HCC, PAC and CRC cell lines, GC and xenograft mouse models, and ESCA patient	Reduced cell viability, suppressed cell proliferation, migration, and tumor growth, down-regulated cancer stem cell markers CD133, Nanog, LC3, and YAP-1, enhanced apoptosis, protective autophagy. and complete response rate/prognosis	ESCA patient, phase I/II (NCT00561197)	[226-240]
Targeting lactate transportation					
AZD3965	MCT1/2	GC, ESCA, HCC, CRC cell lines	Inhibited cell proliferation and tumor growth, while increasing intracellular lactate concentration, TCA-related metabolites, mitochondrial metabolism, and chemosensitivity. Also decreased intracellular pH	None in GI cancers	[242-246]
AR-C155858	MCT1/2	GC, PAC, and CRC cell lines, and xenograft mouse models	Inhibited cell proliferation, spheroid forming ability, and tumor growth, while decreased glycolysis and increased intracellular lactate concentration, TCA-related metabolites, mitochondrial metabolism, and chemosensitivity	None in GI cancers	[247-249]
Targeting mitochondrial OXPHOS					
Metformin	Mitochondrial complex I	GC, ESCA, HCC, CCA, PAC, and CRC cell lines, xenograft models, and ESCA, HCC, CCA, PCA and CRC patients	Suppressed cell proliferation, migration, cell cycle progression, and tumor growth while increasing chemosensitivity and cell death. Also re-programmed the tumor immune microenvironment in ESCA patients	ESCA patient, phase II (ChiCTR-ICR-15005940), HCC patient, phase I (CTRI/2018/07/014865), CCA patient, phase Ib (NCT0249674), PCA patient, phase II (NCT01210911 and NCT01167738), and CRC patient, phase II (NCT01312467, NCT03047837, and NCT01941953)	[252-265]

Tamoxifen	Mitochondrial complex I	GC, ESCA, HCC, CCA, PAC and CRC cell lines, CRC murine model, and ESCA, HCC and PAC patients	Inhibited cell proliferation, tumor growth, metastasis, and increased chemosensitivity. However, no prolonged survival benefits have been observed in HCC patients, and in some cases, there may even be a higher risk of death	ESCA patient, phase I (NCT02513849), PAC patient, phase II[272-274], and HCC patient, phase III (NCT00003424)	[267-273, 277]
IM156	Mitochondrial complex I	GC and CRC patients	Considered tolerable in human subjects, with stable disease being the most common response. Combinatorial therapy may be necessary for improved efficacy	GC and CRC patients, phase I (NCT03272256), and PAC patient, phase Ib (NCT05497778)	[278]
IACS-010759	Mitochondrial complex I	PAC cell lines, and CCA, PAC, and CRC patients	Reduced cell viability and generally well tolerated, but may induce neurotoxicity, peripheral neuropathy, and behavioral/physiological changes in mice. Increased blood lactate levels	CCA, PAC, and CRC patient, phase I (NCT03291938)	[279, 280]
Atovaquone	Mitochondrial complex III	GC, HCC, PAC and CRC cell lines, and xenograft models	Reduced OXPHOS, oxygen consumption rate, cell viability, cell proliferation, and cell cycle progression. Inhibited tumor growth and enhanced cell death	None in GI cancers	[283-285]
Targeting TCA cycle					
CPI-613	PDH and KGDHC	GC, ESCA, PAC and CRC cell lines, xenograft mouse models, and GC mouse model	Inhibited cell proliferation, cell viability, tumor growth, and metastasis, while increased cell death and chemosensitivity. In PAC patients, also increased the overall response rate	PAC patient, phase I (NCT01835041) and III (NCT03504423), HCC and CCA patients, phase I/II (NCT01766219), and CRC patients, phase I (NCT05070104 and NCT02232152)	[287-291]

GI: Gastrointestinal; ESCA: Esophageal cancer; GC: Gastric cancer; HCC: Hepatocellular carcinoma; CCA: Cholangiocarcinoma; PAC: Pancreatic cancer; CRC: Colorectal cancer; LDHA: Lactate dehydrogenase subunit A; MCT1/2: Monocarboxylate transporter family 1/2; HIF1A: Hypoxia inducible factor 1A; GLUT1: Glucose transporter 1; HK2: Hexokinase 2; PFKFB3: Fructose-2,6-biphosphatase 3; PKM2: Pyruvate kinase isozyme M2; PDK: Pyruvate dehydrogenase kinase; PDH: Pyruvate dehydrogenase; KGDHC: Alpha-ketoglutarate dehydrogenase complex; EMT: Epithelial-mesenchymal transition; OXPHOS: Oxidative phosphorylation.

EXPLORING LACTATE BIOSYNTHESIS AND TRANSPORT AS A POTENTIAL STRATEGY FOR GI CANCER THERAPY

As mentioned above, the Warburg effect is a common phenomenon in many cancers for which glycolysis is upregulated even in the presence of oxygen. This results in the accumulation of lactate, which is the last product of glycolysis. The PDK class of enzymes play a key role in deciding whether pyruvate is converted to lactate or enters the TCA cycle. Under hypoxia, PDKs are transcriptionally upregulated by HIF1A in cancers, promoting the inactivation of PDH through PDK-mediated phosphorylation. This leads to elevated lactate biosynthesis, resulting in excessive lactate levels that can promote carcinogenesis or progression[201]. Therefore, targeting PDKs is a potential strategy to inhibit lactate synthesis. Although several candidate drugs that target PDKs have been proposed, dichloroacetate (DCA) has been the most convincing inactivator of PDKs[202]. DCA has been shown in numerous pre-clinical studies on GI cancer to reduce lactate production, cell proliferation, migration, and increase chemosensitivity[203-207]. It has also shown synergistic anti-cancer activity in HCC despite concerns that it may promote hepatic carcinogenesis in B6C3F1 mice[205,208]. Despite promising pre-clinical results, clinical studies are still necessary to determine the efficacy and safety of DCA during cancer therapy. A clinical trial recruiting patients with CRC has been conducted to evaluate DCA as a potential anti-cancer drug (NCT00566410).

In previous studies on lactic acid inhibitors for anti-cancer therapy, the focus has been on inhibiting the enzymes responsible for lactate biosynthesis, namely LDH. TLDH complex composition has been investigated as a crucial factor in determining the fate of lactate biosynthesis or catabolism, and LDHA homo-tetramer (LDH5 or A4) has been considered the most effective complex for lactate biosynthesis. Accordingly, the currently established strategy is to identify LDH inhibitors with high selectivity against LDHA[209]. Although many candidates exist, including small peptides, small interfering RNAs (siRNAs), small chemical molecules, and natural compounds, only a few have progressed towards clinical use in anti-cancer therapy. Compound 24c and 1-(Phenylseleno)-4-(Trifluoromethyl) Benzene (PSTMB) are small compounds that have recently been identified as capable of selectively inhibiting LDHA, suppressing cancer cell aggressiveness, and enhancing cell death in both PCA cells and xenograft mouse models[210] as well as HCC and CRC cells [211]. Notably, Compound 24c has little effect on mouse weight, perhaps due to its relatively strong activity to reprogram metabolic profiling[210]. In contrast, oxamate, galloflavin, and FX11 have a longer history than Compound 24c and PSTMB in targeting LDHA. Pre-clinical evidence shows promise in suppressing GI cancer cell aggressiveness by targeting LDHA and other cancer-associated signaling pathways, suggesting possible treatment of GI cancers[212-225]. Despite this evidence, there is still a lack of clinical results to support the safety and efficacy of these LDHA-targeting drugs in GI cancer patients. An early natural compound, gossypol (AT-101), derived from the cotton plant, is one exception. Gossypol

and its derivatives have proven potent inhibitors of LDHA[226]. Gossypol not only reduces the aggressiveness of GI and other cancers, but also has a strong cytotoxic effect on cancer cells[226-240]. Most importantly, gossypol has entered a phase I/II clinical trial (NCT00561197) to evaluate its safety and efficacy in treating patients with esophageal cancer, showing significant improvement in complete response and survival rates[231]. Therefore, gossypol may be the most promising clinical drug targeting LDHA to date for use in GI cancers.

Excessive intracellular accumulation of lactate is a hallmark of many cancer types, which necessitates MCTs in transporting lactate from highly glycolytic cancer cells. Secretory lactate can acidify the extracellular microenvironment, which can impact the tumor microenvironment[241]. While secretory lactate was initially considered a waste product of cancer cells, recent evidence has suggested that it serves as an alternative fuel for oxidative cancer cells, leading to enhanced aggressiveness[56]. Therefore, MCT targets have emerged as an alternative strategy for anti-cancer therapy [241]. Among the various compounds proposed to target MCTs in cancer, AZD3965 and AR-C155858 have received more attention from researchers. Both drugs have demonstrated potential in targeting MCTs, inhibiting GI cancer cell aggressiveness, and stunting tumor growth both *in vitro* and *in vivo*[242-249]. While AZD3965 has entered the clinical trial phase, further investigation is needed to determine the safety and therapeutic efficacy of these drugs in patients with GI cancer. Notably, the development of MCT inhibitors has faced several challenges, including the presence of MCT isoforms and the need for inhibitors that selectively target cancer cells without affecting normal tissues[58,250]. In this regard, approaches and strategies to develop selective MCT inhibitors are being actively pursued. While MCT inhibitors hold promise as a potential anti-cancer therapy, further research is needed to fully understand their mechanisms of action and optimize their clinical applications.

TARGETING OXPHOS AS A POTENTIAL THERAPEUTIC STRATEGY FOR GI CANCER

Excessive OXPHOS activity has been observed in certain cancers and has been associated with more aggressive phenotypes/unfavorable clinical outcomes, making it a novel target for anti-cancer therapy[251]. Attenuating OXPHOS activity has been proposed as the best strategy to target OXPHOS, leading to the identification of a large number of candidate compounds that target mitochondrial complex I. Metformin, a compound that has long been used to treat diabetes, has been reported to exhibit mitochondrial complex I inhibition activity and can impact cancer cell aggressiveness/tumor growth in both GI cancer cell lines and xenograft models[252-265]. Metformin has advanced to clinical trials in combination with other anti-cancer regimens for patients with GI cancers, such as ESCA patients in Phase II (ChiCTR-ICR-15005940), HCC patients in Phase I (CTRI/2018/07/014865), CCA patients in Phase Ib (NCT0249674), PCA patients in Phase II (NCT01210911 and NCT01167738), and CRC patients in Phase II (NCT01312467, NCT03047837, and NCT01941953). It was found that metformin combination therapy can provide benefit to patients, perhaps through reprogramming the tumor immune microenvironment[258].

Recent studies have proposed several candidates as mitochondrial complex I-targeting compounds in addition to metformin. Among them, tamoxifen, IM156, and IACS-010759 have gained attention as potential anti-cancer agents. Tamoxifen is an anti-estrogen agent that has been clinically used to treat breast cancer patients with positive estrogen-receptor (ER) expression[266]. Interestingly, tamoxifen has also been shown to inhibit cancer cell aggressiveness, tumor growth, metastasis, and increase chemosensitivity in GI cancers[267-273]. This effect is thought to be through an ER-independent anti-cancer pathway[269]. Tamoxifen has been used as a monotherapy or combined therapy in several clinical trials, including an early phase trial in ESCA patients, Phase II trials in PAC patients[274-276], and a Phase III trial in HCC patients (NCT00003424). Tamoxifen has been found to be tolerable, safe, and with manageable adverse effects, while a Phase III trial in HCC patients found that tamoxifen monotherapy either offered no effect or decreased survival in patients with unresectable HCC[277]. This result has slowed the advancement of tamoxifen in GI cancers and requires further investigation.

IM156 and IACS-010759 are two novel mitochondria-targeting drugs that specifically inhibit mitochondrial complex I. While both compounds have shown promising results in pre-clinical studies against certain cancer cell lines, their potential in treating GI cancers involves limited evidence. Interestingly, IM156 has entered Phase I clinical trials in patients with GC, CRC and PCA (NCT03272256 and Janku *et al*[278]), demonstrating tolerability and safety. However, IM156 monotherapy in patients with GC and CRC offered only disease stabilization, indicating the need for further study.

On the other hand, IACS-010759 has shown significant cell viability reduction in PCA cell lines[279], leading to the initiation of a Phase I clinical trial (NCT03291938) to evaluate clinical efficacy and safety in patients with solid tumors due to CCA, PAC, and CRC. However, a recent publication reported that although IACS-010759 was tolerable and safe, it increased blood lactate levels and neurotoxicity while offering only limited anti-cancer efficacy. A reverse translational study using mice also found IACS-010759 to induce behavioral and physiological changes indicative of peripheral neuropathy, minimizing the possibility of combined therapy with specific anti-cancer compounds (*e.g.*, histone deacetylase 6 inhibitor). The development of mitochondrial complex I inhibitors is ongoing[280].

While the mitochondrial complex I inhibitors metformin, tamoxifen, IM156, and IACS-010759 hold promise as potential treatments for GI cancer, further studies are needed to evaluate their efficacy and safety, particularly in combination with other anti-cancer compounds. The development of more selective and potent mitochondrial complex I inhibitors may help overcome side effects and improve efficacy in cancer treatment.

The targeting of mitochondrial complexes other than complex I has also been proposed as a strategy for anti-cancer therapy[281]. One such compound of note is atovaquone, which was identified as a mitochondrial complex III inhibitor during a drug re-purposing study[282]. Pre-clinical studies have evaluated the potential of atovaquone as an anti-cancer agent in GI cancer cell lines and xenograft models, and have shown its ability to reduce OXPHOS, OCR, cell viability, cell

proliferation, cell cycle progression, and tumor growth, while enhancing cell death[283-285]. Despite promising results, atovaquone is currently in clinical trials for patients with non-small cell lung cancer (NCT04648033) and acute myeloid leukemia (NCT03568994) but not for patients with GI cancer. Further studies are needed to determine drug tolerability, safety, and therapeutic efficacy in patients with GI cancer. Nonetheless, the potential benefits of targeting OXPHOS make for a promising strategy in GI cancer therapy. However, the potential toxicity of these inhibitors in normal cells must be carefully evaluated before being considered as viable anti-cancer agents. In addition, the development of resistance to mitochondrial inhibitors, similar to the resistance seen with other anti-cancer agents, highlights the need for combination therapy.

POTENTIAL OF TCA CYCLE TARGETS IN GI CANCER THERAPY

The TCA cycle is a critical metabolic pathway that fuels bioenergetic processes in cells. Targeting the TCA cycle has emerged as a potential strategy for anti-cancer therapy[286]. Various agents have been tested for their anti-cancer efficacy, including AGI-5195, AG-221, AG-881, and CPI-613[286]. Among these compounds, CPI-613 is the only PDH and alpha-ketoglutarate dehydrogenase complex (KGDHC) dual targeting agent that has shown promising anti-cancer properties in GI cancer models both *in vitro* and *in vivo*[287-291]. The tolerability and safety of CPI-613, alone or in combination with other agents, has been evaluated or is currently being studied in patients with HCC, CCA, and CRC (NCT01766219, NCT05070104 and NCT02232152). However, a recent Phase III trial (NCT03504423) evaluating the anti-cancer efficacy of CPI-613 in patients with advanced PAC failed to improve survival rate but improved overall response rate[292]. This outcome is disappointing, combining CPI-613 with other drugs such as gemcitabine or nab-paclitaxel may provide better results.

The TCA cycle is a complex pathway, and there are multiple enzymes and metabolites that could be targeted for anti-cancer therapy. For example, the isocitrate dehydrogenase 1 and 2 (IDH1/2) enzymes play a crucial role in the TCA cycle, and mutations in these enzymes have been observed in several types of cancer, including gliomas and acute myeloid leukemia (AML)[293]. Enasidenib and ivosidenib are two IDH1/2 inhibitors that have been approved for the treatment of relapsed or refractory AML[294,295]. In GI cancers, however, the efficacy of IDH1/2 inhibitors is still under investigation [296]. In addition to IDH1/2 inhibitors, other TCA cycle inhibitors are being explored for anti-cancer therapy. For example, IDH1/2 mutant tumors are sensitive to glutaminase inhibitor CB-839, which targets glutamine metabolism [297]. Another TCA cycle inhibitor, BPTES, has shown anti-cancer efficacy in pre-clinical studies by blocking the activity of the glutaminase enzyme[298]. However, our understanding of these inhibitors in GI cancer treatment is still limited.

Targeting the TCA cycle and associated bioenergetic processes is a promising approach for anti-cancer therapy. While CPI-613 has shown some success in GI cancer models, the failure in Phase III trial underscores the need for continued research and combination therapy. Other TCA cycle inhibitors, such as IDH1/2 and glutaminase inhibitors, are being evaluated for their anti-cancer efficacy in GI cancers, offering hope for future treatments.

DISCUSSION AND FUTURE PERSPECTIVE

Cancer cells undergo significant metabolic changes which involve alteration to the nuclear and mitochondrial genomes as well as cell microenvironment. Understanding the molecular mechanisms behind these alterations is critical for the development of effective cancer therapies. Next-generation technologies such as metabolic profiling, single-cell sequencing, and metabolic tracing can provide insights into the regulation of mitochondrial metabolism in different cancer types. However, developing therapies based on altered metabolism is challenging due to the diverse metabolic patterns observed across different cancer cells.

Simply targeting a single bioenergetic enzyme or pathway may not be enough to effectively inhibit cancer cell growth, as metabolic symbiosis enables cancer cells to adapt to harsh tumor environments. One potential strategy is to treat the metabolic patterns of different cellular subpopulations in the tumor microenvironment to create a homogeneous metabolic population for targeting.

Bioenergetic enzymes have been explored as a way to inhibit cancer cell growth, with some small-molecule inhibitors of glucose metabolism showing significant inhibition in various cancers. However, clinical translation of these inhibitors has been limited by side effects. Other small-molecule inhibitors and natural products that regulate key bioenergy enzymes have also shown promise, but their specific mechanisms and targets require further investigation. Developing anticancer drugs targeting bioenergetic enzymes remains a significant challenge due to the unique metabolic features of cancer cells. Targeted drugs have shown anticancer effects in various tumor models, and combining them with conventional anticancer drugs is a promising strategy.

High-throughput multi-omics and spatial omics can help elucidate the heterogeneity of cancer cells and provide opportunities for therapeutic drugs targeting the bioenergetics of malignant tumors. Unbiased CRISPR-Cas9 synthetic lethality screening of metabolic genes that favor anti-cancer responses, particularly *in vivo*, could provide an avenue towards the identification of bioenergetic targets of interest. The ultimate goal is to develop drugs that simultaneously disable cancer cells while synergizing with targeted therapies.

However, while targeting bioenergetic pathways in cancer cells shows promise, it also has the potential to affect normal cells and tissues that rely on these pathways. Therefore, careful consideration and further research are needed to ensure that therapies targeting bioenergetics in cancer cells are specific and effective while minimizing potential side effects on normal cells and tissues. Additionally, combination therapies that target multiple pathways may be necessary

to achieve optimal therapeutic effects.

CONCLUSION

The metabolic reprogramming and bioenergetic alteration of cancer cells, particularly their utilization of glucose fermentation (the Warburg effect) for energy production, are well-known phenomena. However, comprehensive summaries of these alterations and their oncogenetic links in GI cancers are lacking. This review provides a summary of the interplay between aerobic glycolysis, the TCA cycle, and OXPHOS in cancer cells, including the molecular mechanisms that trigger these alterations. It also explores the role of HIFs, tumor suppressors, and the oncogenetic link between hypoxia-related enzymes, bioenergetic changes, and GI cancer. Additionally, this review details various anti-cancer drugs and strategies for treating GI cancers, along with the challenges associated with them. Understanding dysregulated cancer cell bioenergetics is critical for effective treatments, although the diverse metabolic patterns present challenges for targeted therapies. Further research is needed to comprehensively understand the specific mechanisms of inhibiting bioenergetic enzymes, address side effects, and utilize high-throughput multi-omics and spatial omics for insights into the heterogeneity of GI cancer cells in targeted bioenergetic therapies.

Abstract

BACKGROUND

Obesity plays a vital role in the occurrence and development of non-alcoholic steatohepatitis (NASH). However, the underlining mechanism is still unclear, where adipose tissue (AT) derived exosomes may actively participate. MicroRNAs (miRNAs) are commonly secreted from exosomes for cell communication. Though the regulation of miR-103 on insulin sensitivity has been reported, the specific role of AT-derived exosomes miR-103 in NASH is still vague and further investigation may provide novel therapeutic choices.

AIM

To determine the specific role of AT-derived exosomes miR-103 in developing NASH through various methods.

METHODS

The expression levels of miR-103 in the AT-derived exosomes and livers were detected and compared between NASH mice and control. The effect of miR-103

on NASH progression was also explored by antagonizing miR-103, including steatosis and inflammation degree changes. The interaction between miR-103 and the autophagy-related gene phosphatase and tensin homolog (PTEN) was confirmed by dual-luciferase reporter assay. The role of the interaction between miR-103 and PTEN on autophagy was verified in NASH-like cells. Finally, the effects of miR-103 from adipose-derived exosomes on NASH and autophagy were analyzed through animal experiments.

RESULTS

The expression of miR-103 was increased in NASH mice, compared to the control, and inhibition of miR-103 could alleviate NASH. The results of the dual-luciferase reporter assay showed miR-103 could interact with PTEN. MiR-103-anta decreased p-AMPKa, p-mammalian target of rapamycin (mTOR), and p62 but increased the protein levels of PTEN and LC3-II/I and the number of autophagosomes in NASH mice. Similar results were also observed in NASH-like cells, and further experiments showed PTEN silencing inhibited the effect of miR-103-anta. AT derived-exosome miR-103 aggravated NASH and increased the expressions of p-AMPKa, p-mTOR, and p62 but decreased the protein levels of PTEN and LC3-II/I and the number of autophagosomes in mice.

CONCLUSION

AT derived-exosome increased the levels of miR-103 in the liver, and miR-103 aggravated NASH. Mechanically, miR-103 could interact with PTEN and inhibit autophagy.

Key Words: Non-alcoholic steatohepatitis; Nonalcoholic fatty liver disease; Exosomes; Phosphatase and tensin homolog

Core Tip: Our study confirms the important role of miR-103-phosphatase and tensin homolog-autophagy axis in the pathogenesis of non-alcoholic steatohepatitis (NASH). More importantly, the elevation of miR-103 in the liver of NASH mice is partly due to adipose tissue exosome secretion and integration, which also partially explains the mechanism of obesity leading to NASH.

INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) is recognized as the hepatocellular manifestation of metabolic syndrome, characterized by hepatic lipid accumulation and inflammation, and precluded with secondary causes, such as chronic viral hepatitis, significant alcohol consumption, long-term use of steatogenic medication, and other chronic liver diseases including autoimmune hepatitis, hemochromatosis, Wilson's disease[1]. NAFLD is categorized into NAFL, non-alcoholic steatohepatitis (NASH), fibrosis, and even cirrhosis according to histological changes in different disease stages. Among them, NASH is considered the watershed in NAFLD and is defined as the presence of 5% hepatic steatosis and ensuing hepatocyte injury[1]. According to a previous meta-analysis, the pooled overall global prevalence of NAFLD was estimated to be 25.24% [95% confidence interval (CI): 22.10-28.65], while the pooled overall NASH prevalence among biopsied NAFLD patients was 59.10% (95%CI: 47.55-69.73)[2]. Moreover, fibrosis, which is closely related to liver cirrhosis, liver cancer, and other end-stage liver diseases, is more likely to occur in NASH patients than NAFL patients [3]. Those findings support the importance of NASH and suggest that the burden of disease caused by NASH needs to be paid adequate attention. NASH has become one of the leading causes of cirrhosis and the second leading cause of liver transplantation in the United States[4,5].

NAFLD is commonly associated with metabolic comorbidities such as obesity, diabetes mellitus, and dyslipidemia[2,6]. The prevalence of obesity is as high as 51.34% (95%CI: 41.38-61.20) and 81.83% (95%CI: 55.16-94.28) among NAFLD and NASH patients, respectively[2]. The effect of obesity on NAFLD has been intensively explored. On the one hand, the expansion of adipose tissue (AT) in obese people leads to increased circulating free fatty acids (FFAs) and leptin and decreased adiponectin, which leads to intrahepatic fat accumulation. On the other hand, the chronic inflammatory state caused by obesity will further lead to the infiltration of inflammatory cells in the liver, resulting in the progression of NAFLD[7]. Due to the important role of obesity in the occurrence and development of NAFLD, in-depth research on the mechanism of obesity leading to NASH may provide new therapeutic targets.

Exosomes are extracellular vesicles secreted by various cells and serve as an essential means of intercellular communication by delivering microRNAs (miRNAs), bioactive lipids, and regulatory proteins from one cell to another [8]. Previous studies have shown that AT-derived exosomes are essential in regulating insulin sensitivity[9,10], a common

manifestation of metabolic syndrome in patients with NAFLD. Previous studies have also shown that AT-derived exosome miRNAs are involved in the occurrence and development of various metabolic-related diseases[11]. Among them, miR-103 attracted our attention since previous studies have shown that miR-103 is involved in regulating insulin sensitivity[12]. The specific role of AT-derived exosomes in the development of NASH also deserves further study. Therefore, in this study, we focused on the specific role of AT-derived exosomes miR-103 in developing NASH through various methods.

MATERIALS AND METHODS

Ethics statement

This study followed the guidelines for the Care and Use of Laboratory Animals of the National Institute of Health. The animal protocol was approved by the institutional review board of the Tab of Animal Experimental Ethical Inspection of the First Affiliated Hospital of Zhejiang University. The Reference Number is 2020-1407.

The successful construction of NASH animal and cell models

C57BL/6 mice were routinely fed a high-fat diet for 12 wk to establish the NASH animal model. According to different treatments, they were initially divided into the control group (12% kcal fat, 66% kcal carbohydrate, 22% kcal protein) and the model group (60% kcal fat, 20% kcal carbohydrate, 20% kcal protein)[13]. Starting from the 13th wk, 40 mg/kg miR-negative control (NC)-anta and miR-103-anta were injected into the mice from the model group (dissolved in 0.2 mL normal saline) through the tail vein every 2 d thrice to construct miR-NC-anta model group and miR-103-anta model group. The control and model groups were injected with blank normal saline thrice (n = 10 in each group). Finally, the mice were sacrificed, where liver tissue, abdominal AT, and serum were collected and stored in a cryostorage tube at -80 °C for further analysis.

NASH-like cell model was constructed by conventional oleic acid (OA)-palmitic acid (PA) mixture culture (OA:PA = 2:1)[14]. Firstly, 128.2 mg PA (molecular weight: 256.42) was sequentially retrieved on a precision balance, 1 mL 1 M OA was added, vortex dissolved, and mixed in a small whirlpool, and then completely dissolved in a water bath at 55 °C-65 °C to obtain 1.5 M FFA mixture. After that, 1.5 M FFA with DMSO was dissolved into 0.1 M working solution. In the model group, Alpha mouse liver 12 (AML-12) cells were added with 400 μM FFA and cultured for 24 h, followed by transfection with miR-103-anta and its sh-phosphatase and tensin homolog (PTEN) and their relative controls. All further *in vitro* experiments were performed on those cells.

Exosome isolation and confirmation

Exosomes were extracted from the filtrate according to the manufacturer's instructions[15]. The diluted exosomes were subjected to NanoFCM (China) for transmission electron microscopy (TEM) and size distribution analysis for further confirmation.

Quantitative real-time polymerase chain reaction, ELISA, and western blotting

Total RNA was isolated using Trizol (Invitrogen, United States) and reverse-transcribed into cDNA using the First Strand cDNA Synthesis Kit (TransGen, China) following the manufacturer's instructions. Quantitative real-time polymerase chain reaction (qRT-PCR) was routinely performed using the SYBR Premix Ex Taq qPCR kit (TaKaRa, Japan). The alanine aminotransferase (ALT), aspartate aminotransferase (AST), total triglycerides (TG), total cholesterol (CHOL), superoxide dismutase (SOD), malondialdehyde (MDA), and H_2O_2 concentrations were detected using test kits according to the manufacturer's instructions. Total protein was isolated using radioimmune precipitation assay buffer (TaKaRa, Japan) supplemented with a protease inhibitor (Roche, Switzerland). After quantification using the BCA Protein Assay Kit (Thermo, United States), the proteins were separated by sodium-dodecyl sulfate gel electrophoresis and transferred onto polyvinylidene fluoride membranes. The membranes were blocked and incubated overnight with antibodies against PTEN (9188T, CST), p-AMPK (ab32047, Abcam), p-mammalian target of rapamycin (mTOR) (CSB-PA271384, Cusabio), LC3 (12741T, CST), p62 (ab91526, Abcam), and GAPDH (ab245355, Abcam) at 4 °C. The membranes were incubated with HRP-conjugated secondary antibodies (ab205718, Abcam). Finally, the protein bands were detected using enhanced chemiluminescence (ECL) kits (Thermo, United States).

Hematoxylin and eosin staining and oil red staining

The hematoxylin and eosin (HE) staining was performed using the HE staining kit (C0105S, Beyotime) according to the manufacturer's instructions. Oil red staining was performed using an oil red staining solution (G 1262, Solarbio; C0157S, Beyotime). Briefly, 5-10 μm thick fresh frozen tissue was placed on the slide and dried at room temperature for 30-60 min. The sections were fixed with 10% paraformaldehyde for 10 min, washed thrice with distilled water, and dried for several minutes. After that, the oil red was diluted with deionized water in a 3:2 ratio, with impurities removed by filter paper, and left for 10 min at room temperature. Preheated oil red was used for tissue dye in a 6 °C temperature box for 8-10 min. After the 85% propylene glycol solution was differentiated for 2-5 min, it was washed twice with distilled water and restained with hematoxylin for 30 s. After rinsing with running water for 3 min, the tablets can be sealed with glycerine gelatin.

Luciferase reporter assay and TEM

The luciferase reporter assay was performed according to the manufacturer's instructions of Pierce™ Cypridina-Firefly Luciferase Dual Assay Kit (16184, Thermo). Briefly, AML-12 cells were co-transfected with a 10 nM miR-103 or NC control, a 2 ng pRL-CMV, and a 20 ng firefly luciferase reporter plasmid containing PTEN of the wild-type or mutant 30-untranslated region. Then, 48 h after transfection, the cell lysates were determined by luciferase to observe the interaction between miR-103 and PTEN. The liver tissues with the size of 1 mm × 1 mm × 1 mm were fixed, dehydrated, impregnated, and embedded to make ultrathin sections (50-70 nm) and then stained with uranium acetate and lead citrate successively and dried for observation under TEM.

Immunofluorescence

The frozen slices of 5-10 μm thick liver tissue were dried at room temperature for 30-60 min. They were sequentially fixed with 10% paraformaldehyde for 10 min, rinsed thrice with distilled water, and dried for several minutes. After that, the antigen was repaired by microwave at 92 °C-96 °C for 10-15 min, cooled to room temperature naturally, and sealed with 5% BSA at 37 °C for 60 min. After pouring the excess serum, LC3-II/I antibody was diluted at 1:100, added into samples, and incubated at 4 °C overnight. Rinsed with phosphate buffered saline (PBS) the next day, samples were added to the mixture of the fluorescent secondary antibody and 4',6-diamidino-2-phenylindole at a ratio of 1:200 and incubated for 60 min at room temperature. After washing with PBS, laser confocal scanning for immunofluorescence was performed.

Transwell analysis

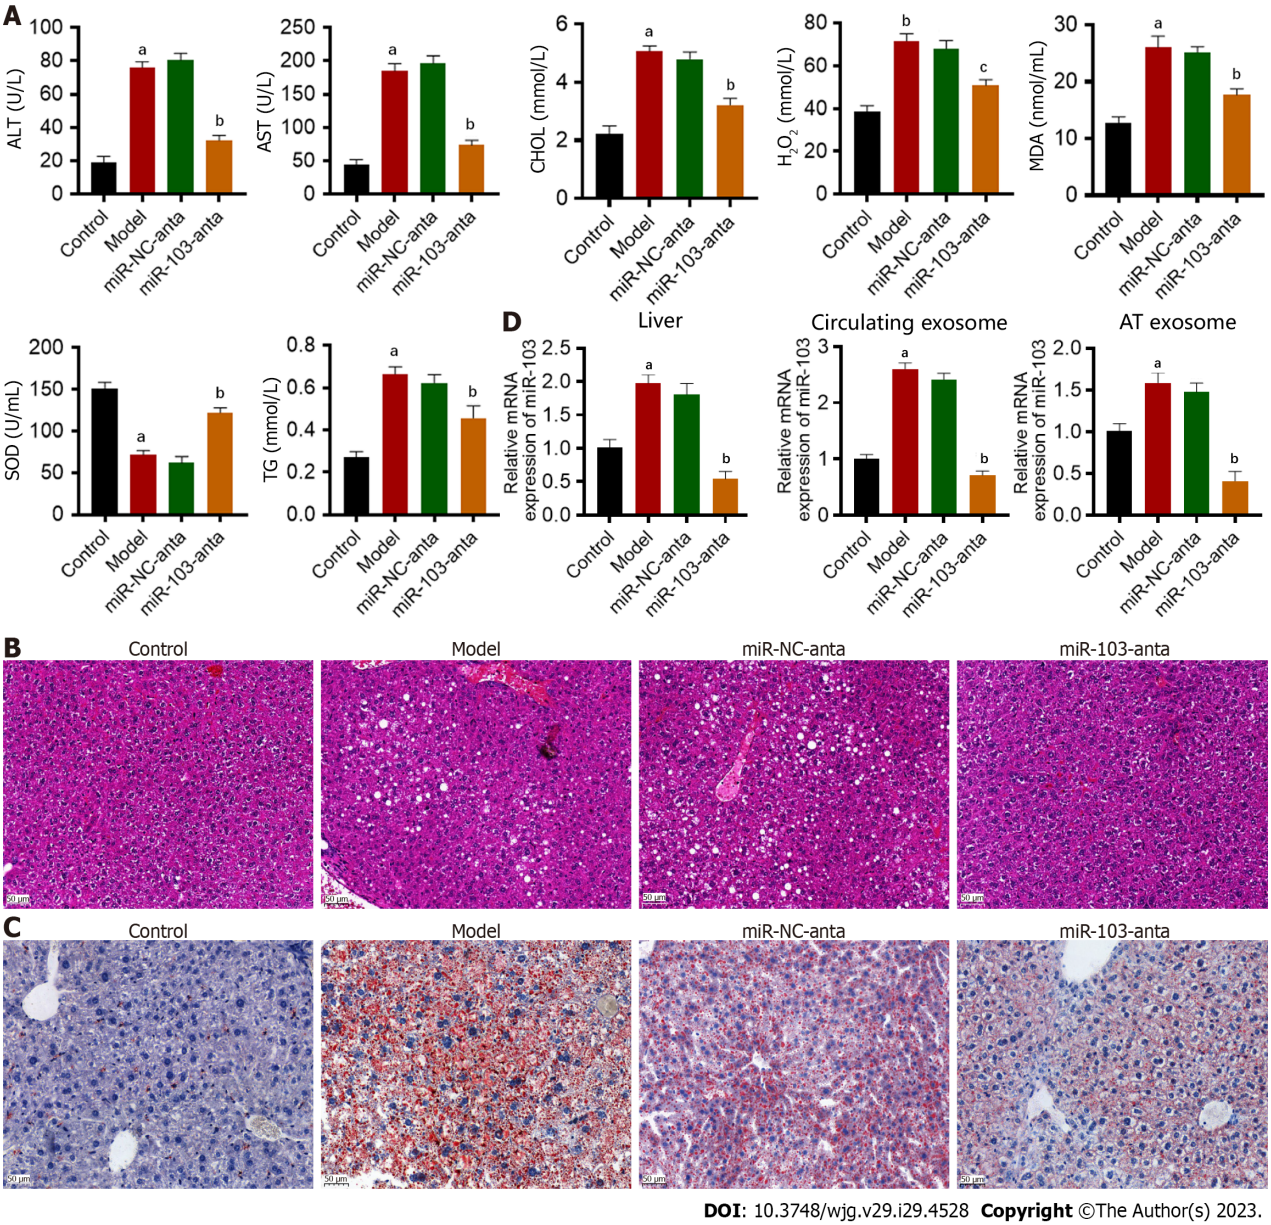
3T3-L1 cells were first routinely induced to differentiate into adipocytes to identify the transfer of miR-103 from adipocytes to AML-12 cells. After that, Cy3-labeled miR-103 was transfected and then co-cultured with the underlying AML-12 cells through a transwell chamber. AML-12 cells were then isolated, and immunofluorescence determined the red fluorescence value.

Cell transfection

Cells for transfection were incubated into a 6-well plate. 5-10 μL miR-NC-anta and miR-103-anta were absorbed and diluted into 250 μL Opti-MEMI reduced serum medium, mixed gently, and incubated at room temperature for 5 min. Then, 3-6 μL Lipofectamine® 2000 Reagent was diluted to 250 μL of Opti-MempI reduced-serum medium, lightly mixed, and incubated at room temperature for 5 min. Diluted miR-NC-anta, miR-103-anta, and diluted Lipofectamine® 2000 Reagent were carefully mixed, gently blended, and incubated at room temperature for 20 min to form the reagent complex. After that, cells were washed with 2 mL serum-free medium, added with 2 mL of Opti-MEMI low serum medium to each well, and then added to 500 μL of miR-NC-anta and miR-103-anta-Lipofectamine® 2000 Reagent complex. These reagents were gently mixed and prepared for use.

Statistical analysis

All data are presented as mean ± SD. Differences between the two groups were analyzed using the student's *t*-test for categorical data and the chi-square method for numerical data. All statistical analyses were performed using GraphPad 9.0.2 software. Statistical significance between groups was set at $P < 0.05$.



RESULTS

The expression of miR-103 was increased in NASH mice, and inhibition of miR-103 could alleviate NASH

First, we successfully constructed animal models of NASH. Compared with the control, ALT, AST, TG, and CHOL were increased in NASH mice (Figure 1A). Hepatocyte ballooning, inflammatory cell infiltration, and hepatic lipid accumulation were observed in the livers of NASH mice (Figures 1B and C). Furthermore, we successfully extracted and confirmed AT-derived and circulating exosomes (Supplementary Figure 1). Subsequently, the expression of miR-103 in the livers, AT-derived exosomes, and circulating exosomes was detected by qRT-PCR. MiR-103 expression levels in the livers, AT-derived exosomes, and circulating exosomes were significantly increased in the NASH model group compared with the control group. Antagonizing miR-103 decreased miR-103 expression in NASH mice, but miR-NC-anta had no significant effect in NASH mice (Figure 1D). In addition, compared with miR-NC-anta and the model group, miR-103-anta treatment significantly reduced serum ALT and AST, decreased serum CHOL and TG, and alleviated oxidative stress (Figure 1A). Histologically, HE and oil red staining of the liver also indicated that inhibition of miR-103 alleviated hepatocyte ballooning, inflammatory cell infiltration, and hepatic lipid accumulation. (Figures 1B and C). Our above results indicate that the miR-103 level is elevated in NASH model mice, and reducing the expression of miR-103 can alleviate NASH, suggesting the potential involvement of miR-103.

The interaction between miR-103 and PTEN is involved in the process of autophagy

To further investigate the regulatory mechanism of miR-103 on NASH, we used *TargetScan* to predict its downstream targets[16]. The predicted results showed that PTEN, a gene that plays an essential role in autophagy, might interact with miR-103. Therefore, we used a dual-luciferase reporting experiment to further confirm their interaction (Figure 2A). The wild-type PTEN could interact with miR-103, while the mutant PTEN could not. Next, the protein content of PTEN and autophagy-related proteins such as p-AMPKa, p-mTOR, LC3-II/I, and p62 were determined by western blot. The results showed that compared with the control group, the expressions of p-AMPKa, p-mTOR, and p62 were significantly

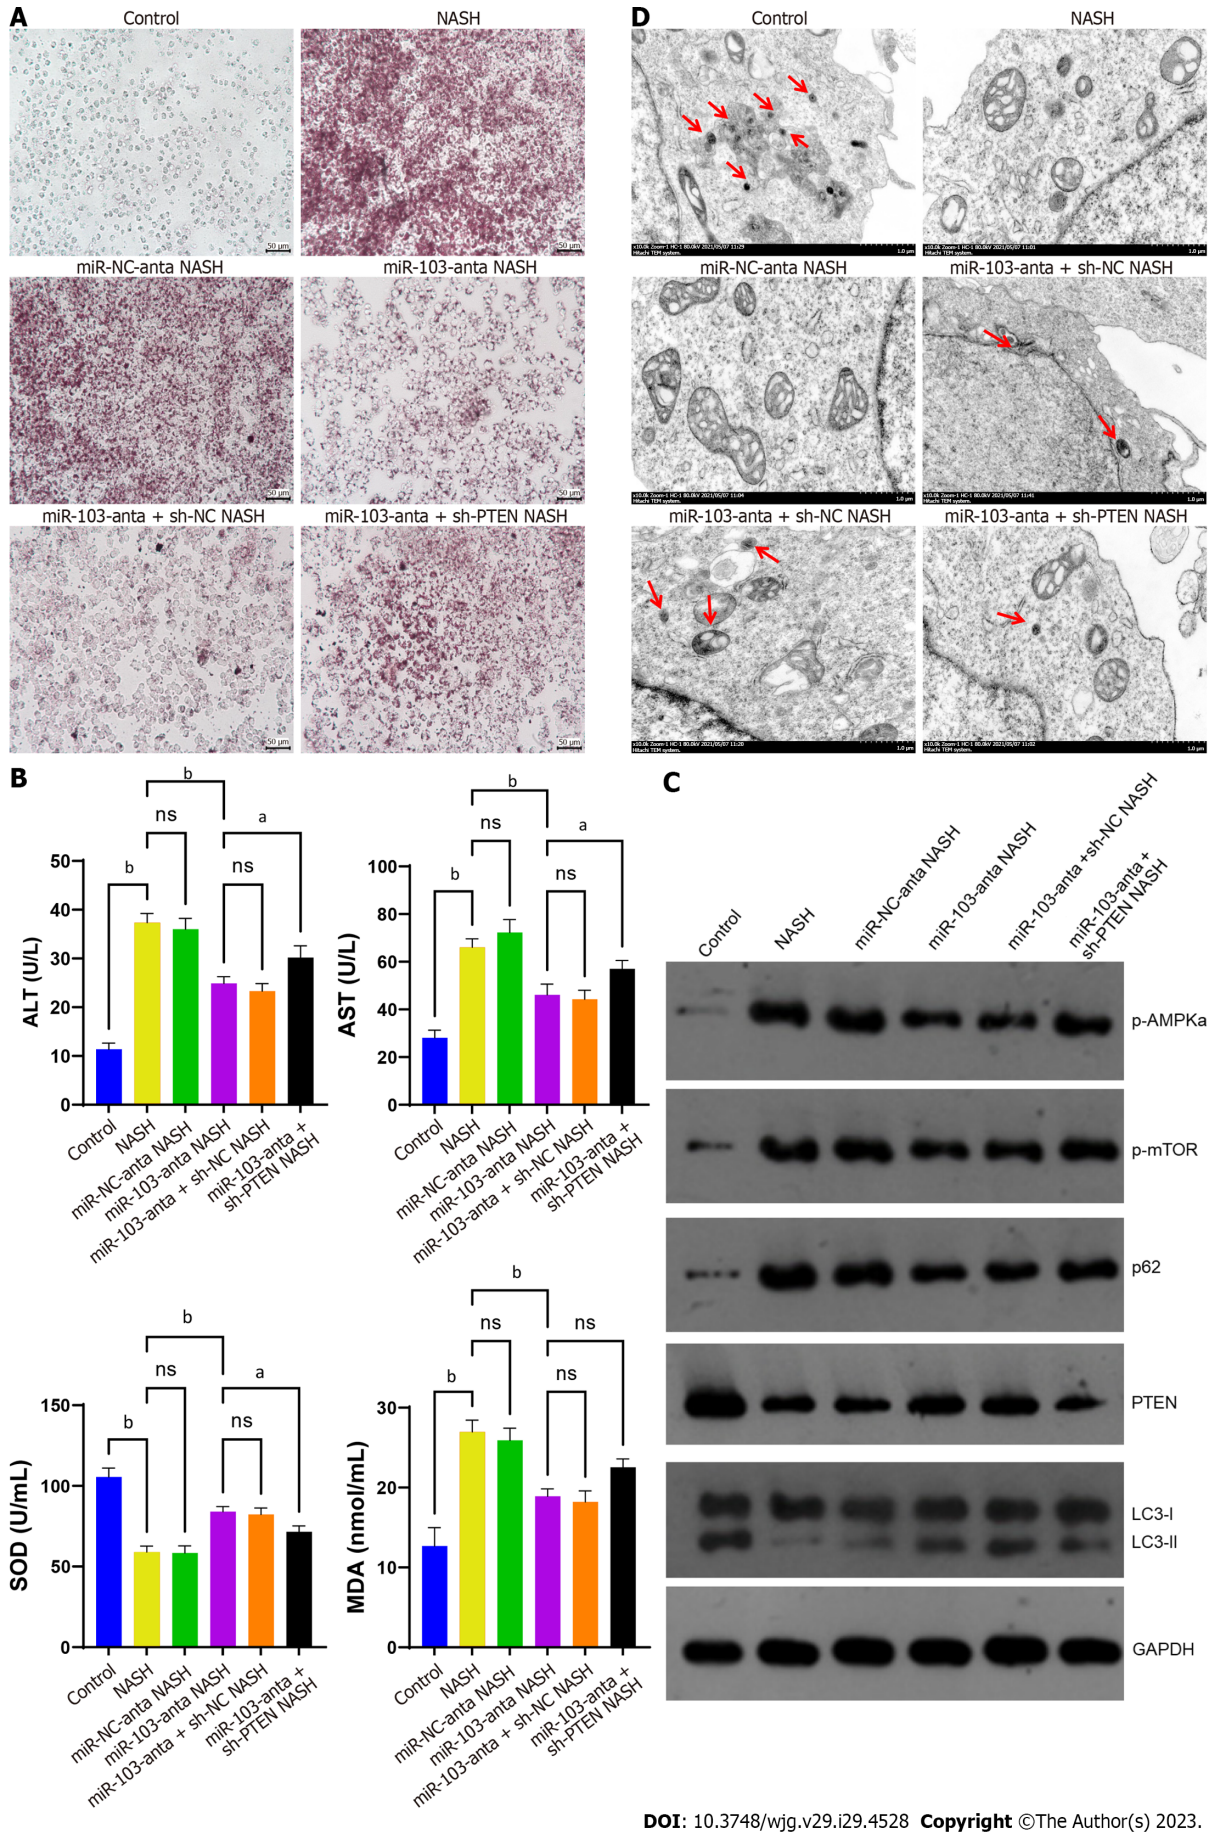
increased in the model group, while the protein levels of PTEN and LC3-II/I were decreased (Figure 2B). In addition, TEM and immunofluorescence staining showed that the number of autophagosomes in the liver of NASH model mice was significantly reduced compared with control mice (Figures 2C and D). However, compared with the model and miR-NC-anta groups, p-AMPKa, p-mTOR, p62, and the number of autophagosomes were significantly decreased in the miR-103-anta group. Similarly, the protein levels of PTEN and LC3-II/I was increased (Figures 2C and D). All these results indicate that autophagy is inhibited in the development of NASH, while miR-103-anta treatment could antagonize those changes. These results indicate that miR-103 interacts with PTEN and interferes with the downstream autophagy process, suggesting that the inhibition of autophagy in NASH may be attributed to the increased expression of miR-103.



MiR-103 participates in the development of NASH by inhibiting autophagy via interacting with PTEN

We then conducted *in vitro* experiments to further confirm our hypothesis. The results showed that inhibition of miR-103 expression could reduce the accumulation of lipids in NASH model cells, decrease the release of ALT and AST, and relieve oxidative stress. However, the effect of miR-103-anta was partially eliminated by silencing PTEN (Figures 3A and B). The above results indicate that miR-103 is involved in NASH formation partially through its interaction with PTEN. In addition, we detected the expression of autophagy-related proteins. We found that the expression of p-AMPKa, p-mTOR, and p62 was increased in NASH cells, while the expression of PTEN and LC3-II/I was decreased. Treatment with miR-

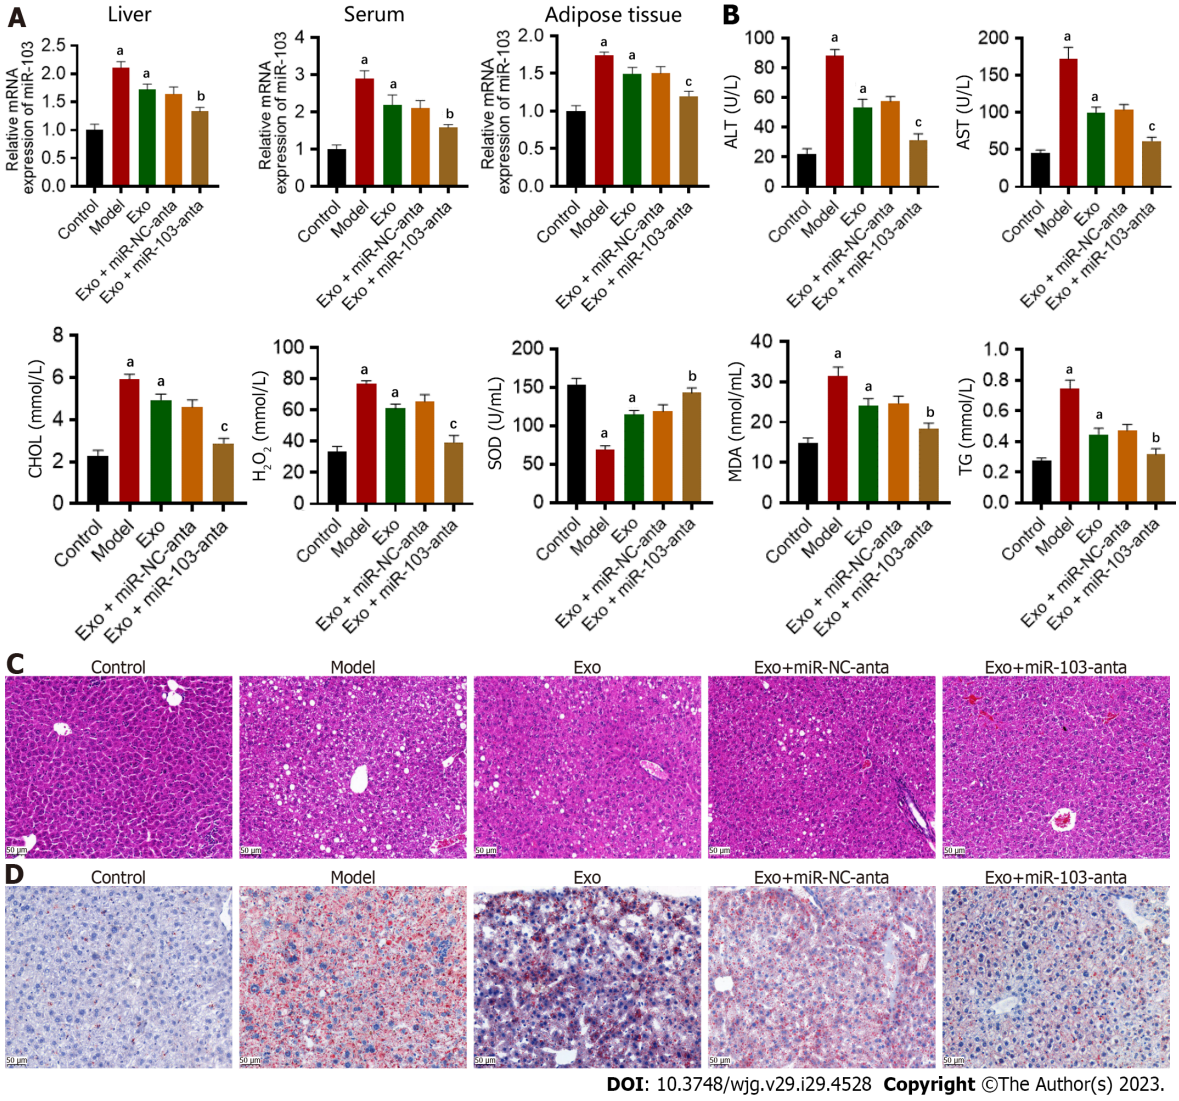
103-anta elevated the expression of PTEN and LC3-II/I and reduced the expression of p-AMPKa, p-mTOR, and p62 in NASH cells, while PTEN silencing inhibited the effect of miR-103-anta (Figure 3C). Finally, we also found that the number of autophagosomes decreased in NASH cells, and such declination was partially antagonized after the inhibition of miR-103. Similarly, PTEN silencing inhibited the effect of miR-103-anta (Figure 3D). To sum up, we confirmed the role of the miR-103-PTEN-autophagy axis in NASH through *in vitro* experiments.

Hepatocyte absorption of AT-derived exosome miR-103



To confirm that AT-derived exosomes can encapsulate miR-103 and target the liver, we conducted *in vivo* and *in vitro* experiments. In the *in vivo* experiment, AT and circulating exosomes of mice were extracted. The exo-DIR complex collected by centrifugation was injected into the tail vein of mice, and the PBS group was used as a control. The fluorescence of liver tissue was observed after mice scarification. There was no fluorescence in the PBS group but observed in AT-exo-DIR and cir-exo-DIR groups, with similar fluorescence intensity (Figure 4A). In the part of the *in vitro* experiment, the AT exosomes and circulating exosomes were detected by the FISH probe to migrate into AML-12 cells (Figures 4B and C). Further transewell assay showed that Cy3-labeled miR-103 could be transferred from adipocytes to AML-12 cells (Figure 4D).

Role of AT-derived exosome miR-103 in NASH

To verify the role of AT-derived exosome miR-103 in NASH through *in vivo* experiments, we extracted exosomes from mouse AT. We injected the extracted exosomes without other treatments and with miR-103-anta or miR-NC-anta into mice through the tail vein. Firstly, we found that injection of AT-derived exosomes increased the level of miR-103 in the liver, serum, and AT compared with the control group (Figure 5A). In addition, compared with the control group, treating AT-derived exosomes can increase serum ALT, AST, CHOL, and TG levels and aggravate oxidative stress (Figure 5B). Histologically, HE and oil red staining of the liver showed that treating AT-derived exosomes could aggravate hepatocyte ballooning, inflammatory cell infiltration, and intrahepatic lipid accumulation (Figures 5C and D). However, miR-103-anta treatment could partially eliminate such an effect while miR-NC-anta treatment could not, suggesting that AT-derived exosome aggravates NASH, and this effect is partly dependent on its encapsulated miR-103.

AT derived-exosome miR-103 inhibits autophagy in hepatocytes

To further verify *in vivo* that miR-103 in AT-derived exosomes is involved in NASH formation by influencing autophagy, we detected the expression of autophagy-related proteins in the liver of mice in each group. We found that compared with the control group, the expression of p-AMPKa, p-mTOR, and p62 in the livers of AT exosome-treated group was increased, while the expression of PTEN and LC3-II/I was decreased. Further miR-103-anta treatment increased the

expression level of PTEN and LC3-II/I and reduced the expression level of p-AMPKa, p-mTOR, and p62, while miR-NC-anta had no similar effect (Figures 6A and B). Finally, through TEM and immunofluorescence, we found that the number of autophagosomes in the livers of mice treated with AT-derived exosomes was decreased, while miR-103-anta could partially antagonize such effect (Figures 6C and D).

DISCUSSION

NASH is considered the watershed in the progress of NAFLD, which is more closely related to the occurrence of liver cirrhosis and other complications. The prevalence of NASH has been increasing in recent years, resulting in a big challenge in disease burden and patient suffering. For instance, the lifetime cost of care for patients with NASH was around US $222 billion in 2017 in the United States[17]. More intriguingly, many NASH patients are obese and tend to have higher healthcare costs than non-obese NASH patients[18], but the etiology is still vague. Therefore, it is necessary to study the role and underlying mechanisms of obesity on NASH and further provide possible therapeutic targets. In this study, we confirmed the important role of AT-derived exosomes miR-103 in NASH and preliminary revealed its regulation on hepatocyte autophagy through targeting PTEN, which might partially provide the mechanisms by which obesity affects NASH.

MiRNA belongs to the family of non-coding RNA, which generally consists of 22 nucleotides[19] and regulates the mRNA levels of target genes[20]. Previous studies have identified a variety of miRNAs involved in metabolism-related diseases[21]. For example, miR-200 and miR-29 families play an important role in maintaining the balance between the

proliferation and differentiation of pancreatic β cells[22,23]. MiR-33a and miR-33b are involved in cholesterol and lipid metabolism[24,25]. Furthermore, several miRNAs are also targeting the liver to regulate metabolic processes. For instance, miR-122, one of the most abundant miRNAs in the liver, is involved in hepatic cholesterol and lipid metabolism [26,27]. Besides, miR-103, the focus of our study, has also been confirmed to be closely related to hepatic insulin sensitivity and the regulation of glucose homeostasis in previous studies[12]. Since NAFLD is the hepatic manifestation of metabolic syndrome, it is theoretically possible that miR-103 participates in NAFLD, but related research is still lacking. NASH was linked to menopause[28], and miR-103 was found to be linked to G protein-coupled estrogen receptor 1[29]. Therefore, the estrogen signaling pathway is the potential mechanism where miR-103 promotes NASH. However, in this study, for the first time, we showed that the miR-103 level in the liver of NASH mice was significantly increased while inhibiting miR-103 expression could alleviate NASH, suggesting that miR-103 is one of the potential targets for NASH

Figure 7 The hypothesis of obesity-induced non-alcoholic steatohepatitis. The increased adipocyte tissue will secret more adipose tissue (AT)-derived exosomes, which include various contents, and miR-103 is our focus. The increased AT-derived exosomes miR-103 could be absorbed by hepatocytes and further regulate non-alcoholic steatohepatitis progression by affecting the autophagy process by targeting phosphatase and tensin homolog gene. AT: Adipose tissue; NASH: Non-alcoholic steatohepatitis; Exo: Exosomes; PTEN: Phosphatase and tensin homolog.

treatment.

We further identified the AT-derived exosomes as the source of miR-103 upregulation in the NASH mouse model. There have been many studies on the role of AT-derived exosomes in the development of NAFLD in obese people[30]. For instance, Fuchs *et al*[31] showed that the concentration of free exosomes is significantly higher in obese with NAFLD (OB-NAFLD) patients compared with lean with normal intrahepatic triglyceride content (LEAN) and obese with normal intrahepatic triglyceride content (OB-NL) populations and that these exosomes are at least partially derived from AT. Compared with exosomes derived from the LEAN and OB-NL groups, plasma and AT-derived exosomes from the OB-NAFLD group caused insulin resistance in both myotubes and hepatocytes, demonstrated by impaired insulin signaling. However, the underlying mechanism of the above effects of AT-derived exosomes in NAFLD patients has not been further explored. Our results complement this by revealing the effect of AT-derived exosomes through the miR-103-PTEN pathway, which broadens our understanding of NASH pathogenesis from the angle of trans-cellular crosstalk.

We also confirmed that autophagy is the downstream of the action of miR-103 through *in vivo* and *in vitro* experiments. Autophagy is an evolutionarily conserved cellular degradation process that delivers some intracellular components to lysosomes for degradation[32]. Current studies suggest that autophagy includes three subtypes: Macroautophagy, microautophagy, and chaperon-mediated autophagy[33]. Autophagy plays a vital role in the liver. It involves many basic liver functions, such as glycogenolysis, gluconeogenesis, and β-oxidation[34]. Previous studies have also shown that autophagy is hampered in NAFLD patients. Our previous study also revealed that autophagy inhibition plays an important role in NASH development[35]. Furthermore, restoring autophagy through certain drugs (trehalose, rapamycin, carbamazepine, or other pharmaceutical agents) or gene targets (overexpression of Atg7 or TFEB) can also alleviate NAFLD[36]. In addition, thyroxine[37] and caffeine[38] were also identified to reduce NAFLD by regulating liver autophagy. Therefore, miR-103 is expected to be one of the therapeutic targets for its autophagy regulation capacity and needs further clinical investigation in the future.

Some limitations in this study should be acknowledged. Firstly, AT-derived exosomes contain many non-coding RNAs, and we did not detect changes in the expression of other non-coding RNAs. Moreover, inhibition of miR-103 only partially inhibited the effect of AT-derived exosomes. Therefore, the above results suggest that AT-derived exosomes promote the development of NASH in multiple ways, and miR-103 is only one of them. Further research is needed on other reasons why AT-derived exosomes promote the development of NASH. Secondly, we did not design *in vivo* experiments to verify whether inhibition of autophagy could abolish the role of miR-103 in NASH. Therefore, in future studies, we may improve this part of the experiment and further explore the mechanism of miR-103 affecting autophagy. Finally, the preliminary data on the hepatocyte absorption of AT-derived exosome miR-103 needs further verification.

CONCLUSION

To sum up, our study confirms the important role of miR-103-PTEN - autophagy axis in NASH, and the elevation of miR-103 in the liver of the NASH model is partly due to hepatocyte absorption of AT derived-exosomes, which also partially explains the underlining mechanism of obesity leading to NASH (Figure 7).

ARTICLE HIGHLIGHTS

Research background

Non-alcoholic steatohepatitis (NASH) has become one of the leading causes of cirrhosis and the second leading cause of liver transplantation. miR-103 is involved in regulating insulin sensitivity, a common manifestation of metabolic syndrome in patients with NASH.

Research motivation

The specific role of miR-103 in the development of NASH also deserves further study.

Research objectives

To explore the specific role of miR-103 in the development of NASH and provide new therapeutic targets for NASH.

Research methods

The expression levels of miR-103 were detected and compared between NASH mice and control. The effect of miR-103 on NASH progression was explored by miR-103 antagonizing, including both changes of steatosis and inflammation degree. The interaction between miR-103 and the autophagy-related gene phosphatase and tensin homolog (PTEN) was confirmed by dual-luciferase reporter assay. The role of the interaction between miR-103 and PTEN on autophagy was verified in NASH cells. Finally, the effects of miR-103 from adipose tissue (AT)-derived exosomes on NASH and autophagy were analyzed through animal experiments.

Research results

The expression of miR-103 was increased in NASH mice, compared with the control, and inhibition of miR-103 could alleviate NASH. MiR-103 could interact with PTEN. MiR-103-anta inhibited autophagy in NASH mice. Further experiments showed PTEN silencing inhibited the effect of miR-103-anta. AT-derived exosome miR-103 aggravated NASH and inhibited autophagy in mice.

Research conclusions

AT derived-exosome increased the levels of miR-103 in the liver, and miR-103 aggravated NASH. Mechanically speaking, miR-103 could interact with PTEN and inhibit autophagy.

Research perspectives

MiR-103 may be a potential target for NASH treatment in the future.

Abstract

BACKGROUND

Gastric carcinoma (GC) is the third most frequent cause of cancer-related death, highlighting the pressing need for novel clinical treatment options. In this regard, microRNAs (miRNAs) have emerged as a promising therapeutic strategy. Studies have shown that miRNAs can regulate related signaling pathways, acting as tumor suppressors or tumor promoters.

AIM

To explore the effect of miR-204-3p on GC cells.

METHODS

We measured the expression levels of miR-204-3p in GC cells using quantitative real-time polymerase chain reaction, followed by the delivery of miR-204-3p overexpression and miR-204-3p knockdown vectors into GC cells. CCK-8 was used to detect the effect of miR-204-3p on the proliferation of GC cells, and the colony formation ability of GC cells was detected by the clonal formation assay.

The effects of miR-204-3p on GC cell cycle and apoptosis were detected by flow cytometry. The BABL/c nude mouse subcutaneous tumor model using MKN-45 cells was constructed to verify the effect of miR-204-3p on the tumorigenicity of GC cells. Furthermore, the study investigated the effects of miR-204-3p on various proteins related to the MAPK signaling pathway, necroptosis signaling pathway and apoptosis signaling pathway on GC cells using Western blot techniques.

RESULTS

Firstly, we found that the expression of miR-204-3p in GC was low. When treated with the lentivirus overexpression vector, miR-204-3p expression significantly increased, but the lentivirus knockout vector had no significant effect on miR-204-3p. *In vitro* experiments confirmed that miR-204-3p overexpression inhibited GC cell viability, promoted cell apoptosis, blocked the cell cycle, and inhibited colony formation ability. *In vivo* animal experiments confirmed that miR-204-3p overexpression inhibited subcutaneous tumorigenesis ability in BABL/c nude mice. Simultaneously, our results verified that miR-204-3p overexpression can inhibit GC cell proliferation by inhibiting protein expression levels of KRAS and p-ERK1/2 in the MAPK pathway, as well as inhibiting protein expression levels of p-RIP1 and p-MLK1 in the necroptosis pathway to promote the BCL-2/BAX/Caspase-3 apoptosis pathway.

CONCLUSION

MiR-204-3p overexpression inhibited GC cell proliferation by inhibiting the MAPK pathway and necroptosis pathway to promote apoptosis of GC cells. Thus, miR-204-3p may represent a new potential therapeutic target for GC.

Key Words: miR-204-3p; Gastric carcinoma; MAPK signaling pathway; Apoptosis; Necroptosis

Core Tip: Gastric carcinoma (GC) is a global health problem that seriously endangers human life; therefore, it is important to identify effective treatment targets. In this regard, microRNAs (miRNAs) have emerged as a promising therapeutic strategy. Studies have shown that miRNAs regulated signaling pathways, acting as tumor suppressors or tumor promoters. In this study, we first verified the inhibitory effect of miR-204-3p overexpression on GC cells through *in vitro* and *in vivo* experiments. Simultaneously, miR-204-3p overexpression induced GC cell apoptosis by inhibiting the MAPK pathway and the necroptosis pathway. Thus, miR-204-3p may represent a new potential therapeutic target for GC.

INTRODUCTION

Gastric carcinoma (GC) is a gastrointestinal tumor and the third major cause of cancer-related death[1,2]. Early clinical symptoms are mild or asymptomatic, resulting in difficult diagnosis and a low patient survival rate[3,4]. Currently, the clinical therapy of GC primarily consists of radiotherapy, chemotherapy, and surgical excision, but the therapeutic effect is unsatisfactory[5,6]. Therefore, feasible targeted therapies are particularly important for GC patients. As research has progressed, molecular targets have been found to have a role in the occurrence and development of GC.

MicroRNAs (miRNAs) are small non-coding RNAs that regulate gene expression by binding to the 3'-untranslated region of target mRNA[7]. With further study in genetic engineering, it has been confirmed that miRNAs regulate different signaling pathways to take part in important cellular processes[8]. miRNAs can act as tumor promoters or inhibitors to target mRNA to regulate GC proliferation, metastasis, angiogenesis, and drug resistance[9-11]. Consequently, it is necessary to strengthen miRNA research for the diagnosis and clinical treatment of GC.

MiR-204-3p has demonstrated efficacy in treating various pathologies, including retinopathy, diabetes, and cancer[12-15]. Crucially, miR-204-3p is underexpressed in melanoma, thyroid carcinoma, glioma and bladder carcinoma, and is related to patient prognosis[16-19]. However, the mechanism of miR-204-3p in GC remains unclear.

Our team's previous research confirmed that the expression of miR-204-3p in GC tissue is low and is associated with poor prognosis in GC patients. In addition, we also verified that KRAS is its direct target[20]. However, the anti-GC effect of miR-204-3p still requires further research to support the possibility of miR-204-3p becoming a new target for the treatment of GC. In this study, we focused on determining the impact of miR-204-3p on GC cells phenotype and its anti-GC molecular mechanism, to provide theoretical support for the treatment of GC by miR-204-3p.

Table 1 Primer sequences

Primer	Forward sequence (5'-3')	Reverse sequence (5'-3')
KRAS	TGTGGACGAATATGATCCAACA	GCAAATACACAAAGAAAGCCCT
ERK1	ATGTCATCGGCATCCGAGAC	GGATCTGGTAGAGGAAGTAGCA
ERK2	TACACCAACCTCTCGTACATCG	ATGTCTGAAGCGCAGTAAGATT
GAPDH	CACCCACTCCTCCACCTTTGA	TCTCTCTTCCTCTTGTGCTCTCTTGC
miR-204-3p	CAAGTCGCTGGGAAGGCAA	CAGTGCAGGGTCCGAGGT
U6	CTCGCTTCGGCAGCACA	AACGCTTCACGAATTTGCGT

MATERIALS AND METHODS

Cell culture and cell transfection

A normal human gastric epithelial cell line (GES-1) and three GC cell lines (HGC-27, AGS and MKN-45) were acquired from BNCC (Beijing, China). MKN-45 and HGC-27 cells were cultured in RPIM-1640 medium, AGS cells in DMEM/F-12 medium and GES-1 cells in DMEM medium. All culture media were purchased from Gibco (United States), and were supplemented with 1% penicillin-streptomycin and 10% fetal bovine serum. Genechem (Shanghai, China) provided the green fluorescent protein-labeled miR-204-3p overexpression lentiviral vector (OE group), miR-204-3p knockdown lentiviral vector (KD group) and empty lentiviral vector (NC group), which were then transfected into HGC-27, MKN-45 and AGS cells using the tool virus user manual as a guide.

CCK-8 assay

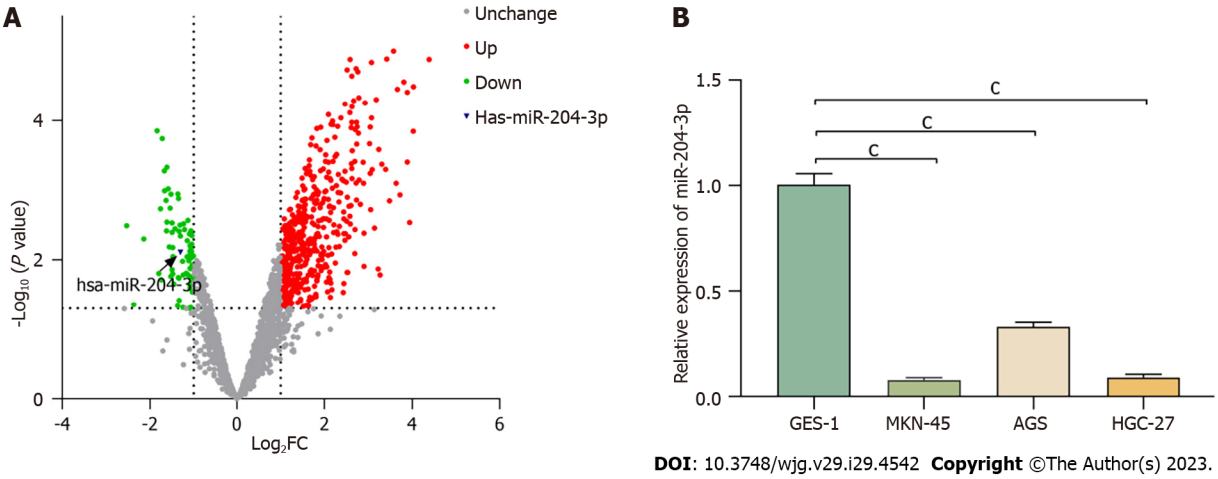
Cell viability was evaluated using the CCK-8 assay. Specifically, lentivirus-transfected AGS and HGC-27 cells were seeded into 96-well plates (5000 cells/well) and cultured for 24 h, 48 h and 72 h, respectively. Following this step, each well was treated with 10 μL CCK-8 reagent (MedChemExpress, United States), and a microplate reader was used to measure the value at 450 nm following incubation for 2 h at 37°C.

Colony formation assay

Lentivirus-transfected AGS and HGC-27 cells were inoculated into 6-well plates (500 cells/well), and fixed with 4% paraformaldehyde for 30 min after 2 wk of continuous culture. Next, the fixing solution was washed off and the cells were stained using 0.5% crystal violet for 10 min. Finally, the cell clones were photographed and statistically analyzed based on clone sizes (diameter > 1 mm).

Flow cytometric analysis

Cell cycle was confirmed using the cell cycle kit (KeyGEN BioTECH, China). Lentivirus-transfected HGC-27 and AGS cells were collected at 1 × 10^6 cells/mL, and then fixed overnight at 37°C with 4% paraformaldehyde. On the second day, the fixing solution was washed off with PBS and 500 μL cell cycle detection working solution (Rnase A:PI = 1:9) was added. The distribution of various groups of cells in the cell cycle was detected after they had reacted for 30 min.



The Annexin V-APC/7-AAD double staining kit (KeyGEN BioTECH, China) was used to confirm apoptosis (early apoptosis and late apoptosis) in each group. Lentivirus-transfected AGS and HGC-27 cells were collected, and 500 μL Binding Buffer, 5 μL Annexin V-APC and 5 μL 7-AAD were added sequentially and gently mixed. Apoptosis was observed after the cells had reacted for 10 min.

Western blot

The expression of related proteins in lentivirus-transfected AGS and HGC-27 cells was detected. Firstly, total protein was extracted with RIPA (Epizyme Biotech, China) from GC cells and their content was confirmed using the BCA assay (Epizyme Biotech, China). Next, the proteins were isolated and transferred onto a polyvinylidene fluoride membrane, which was sealed with 5% skim milk powder, soaked in primary antibody and incubated overnight. On the second day, it was washed with TBST and soaked in HRP-linked secondary antibody (1:1000, 7074/7076, CST, United States) for 1 h. Finally, protein bands were visualized with ECL reagent (KeyGEN BioTECH, China), and the gray values of the protein bands were analyzed using Image J. GAPDH or β-tubulin was used as an internal control to standardize target proteins. p-ERK1/2 (1:5000, 4370), ERK1/2 (1:5000, 9102), RIP1 (1:1000, 3493), p-RIP1 (1:1000, 65746), MLK1 (1:1000, 5029) and p-MLK1 (1:1000, 91689) antibodies were purchased from CST. BAX (1:2000, ab32503), Caspase-3 (1:1000, ab13847), BCL-2 (1:5000, ab182858) and KRAS (1:1000, ab275876) antibodies were purchased from Abcam.

Quantitative real-time polymerase chain reaction

The related genes expressed in each group of GC cells were determined using quantitative real-time polymerase chain reaction (qRT-PCR). Briefly, total RNA was extracted from GC cells using TRIzol reagent (Invitrogen, United States), then cDNA was synthesized (Takara Bio, Japan) and gene expression levels were measured (Takara Bio, Japan). The primer sequences are shown in Table 1. U6 or GAPDH was used as a housekeeping gene, and target genes were calculated using

the $2^{-\Delta\Delta Ct}$ method.

Tumor xenograft experiment

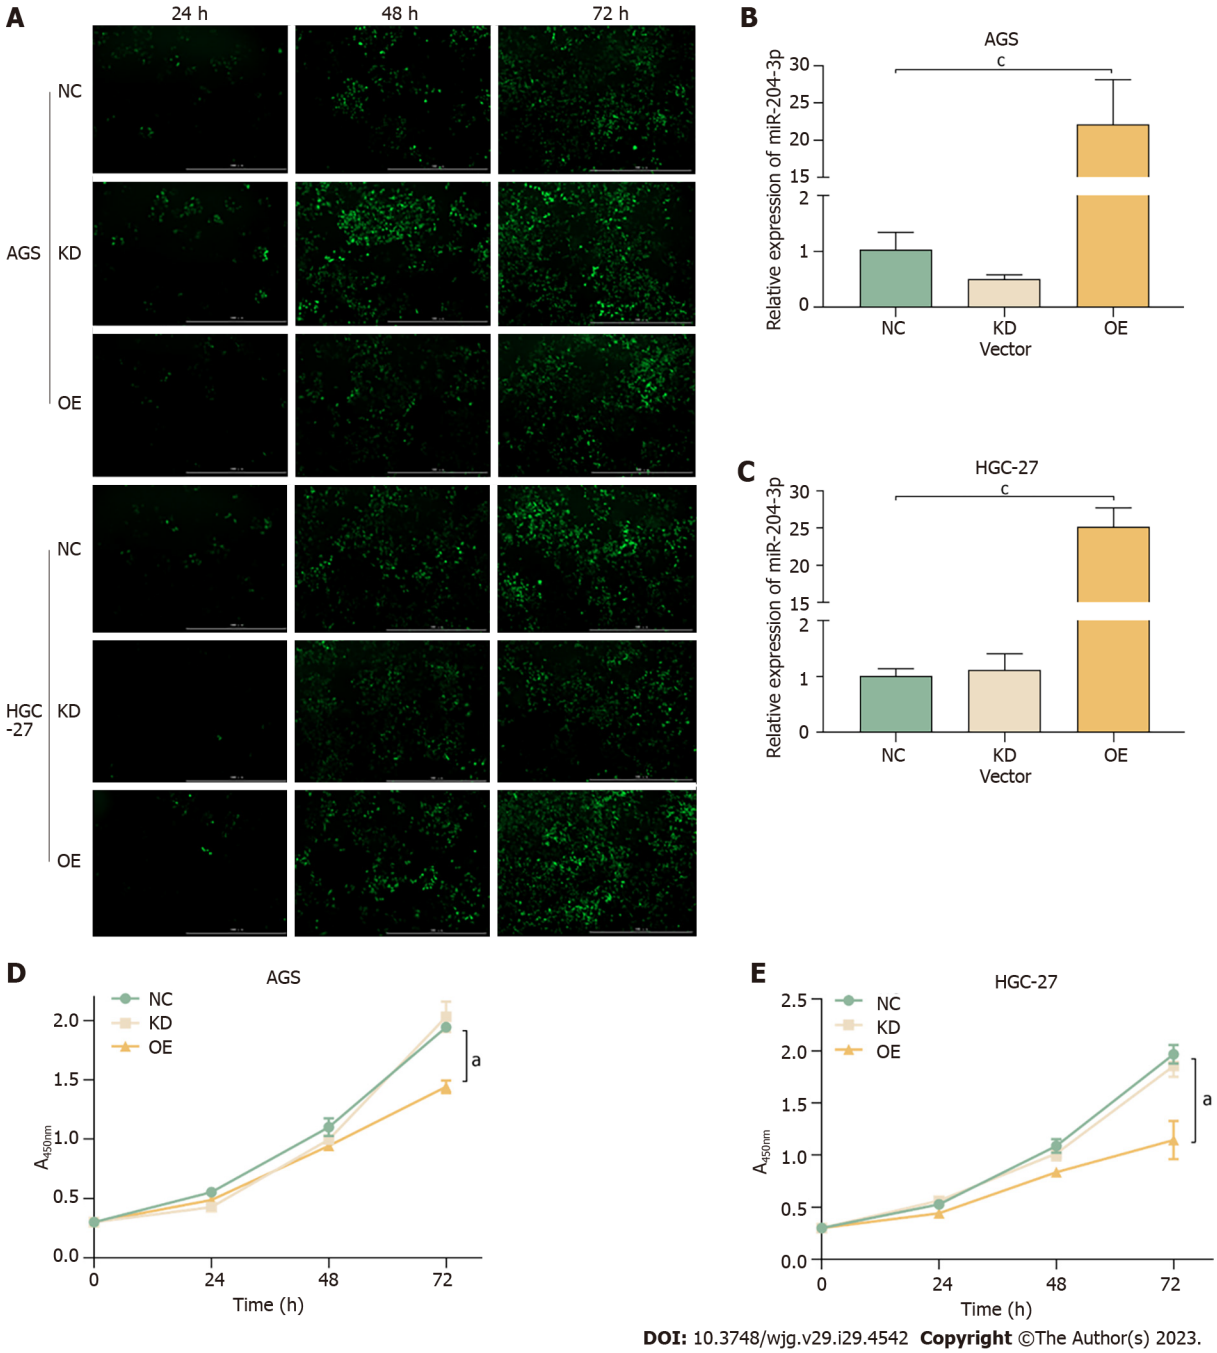
BABL/c nude mice (male, 4 wk, SPF) were provided by the Animal Laboratory Center of Ningxia Medical University. The animal protocol (IACUC-NYLAC-2022-251) was approved by the Institutional Animal Care and Use Committee of Ningxia Medical University. Following 7 d of adaptive feeding in BALB/c nude mice, lentivirus-transfected MKN-45 cells were cultured, and the cell concentration adjusted to 5×10^7 cells/mL. A suspension containing 100 μL cells was slowly subcutaneously injected into the back of nude mice, which were then returned to their cage for feeding. Growth of the subcutaneous tumor and mouse body weight were observed daily. The tumor volume (V) was calculated by $V = (W^2 \times L)/2$ (long diameter: L; short diameter: W). When the tumor on the back grew to an appropriate size and conformed to animal ethics, the animals were killed by CO_2 and photographed.

Differential expression analysis of miRNAs

We used the GEO database (https://www.ncbi.nlm.nih.gov/geo/) to screen differentially expressed miRNAs. We searched the keywords " miRNAs" and "gastric carcinoma, and downloaded Differential expression microarrays of miRNAs (series: GES79973). Then adjusted for $P < 0.05$, $|\log_2 (\text{fold change})| > 1$, and analyzed significant miRNAs.

Statistical analysis

The statistical methods used in this study were reviewed by Li-Qun Wang from the Department of Epidemiology, Department of Medical Statistics, Institute of Public Health and Management, Ningxia Medical University. All data represent the mean ± SD of at least three independent samples. Statistical analysis was conducted using SPSS 27.0 and GraphPad Prism 8.0. One-way analysis of variance was used to analyze the differences between groups. $P < 0.05$ indicated a statistically significant difference.



RESULTS

MiR-204-3p was underexpressed in GC

In our previous study, we analyzed 40 pairs of tissue samples and discovered that miR-204-3p expression was lower in GC tissues compared to normal tissues[20]. To further validate this finding, we utilized the GEO database to identify differentially expressed miRNAs in GC tissues and paracancerous tissues, which confirmed the downregulation of miR-204-3p in GC tissues (Figure 1A). Subsequently, we investigated miR-204-3p expression between GC cell lines (AGS, MKN-45 and HGC-27) and the normal gastric epithelial cell line GES-1. The results revealed that miR-204-3p was underexpressed in MKN-45, AGS, and HGC-27 cells compared to GES-1 cells (Figure 1B).

MiR-204-3p inhibited GC cell viability

Lentivirus transfection caused miR-204-3p overexpression and miR-204-3p knockdown in AGS and HGC-27 cells. The transfection rate was found to be approximately 90% after 72 h, indicating high transfection efficiency (Figure 2A). The qRT-PCR results demonstrated that the miR-204-3p overexpression lentivirus significantly upregulated its expression compared to the NC group in AGS and HGC-27 cells, but the miR-204-3p knockdown lentivirus did not result in downregulation of its expression (Figure 2B and C). These findings indicated that miR-204-3p overexpression in GC cells was highly satisfactory, while miR-204-3p knockdown does not yield meaningful outcomes. Subsequently, the cell viability assay showed that miR-204-3p overexpression significantly inhibited GC cell viability (Figure 2D and E).

NC: Empty lentiviral vector; KD: miR-204-3p knockdown lentiviral vector; OE: miR-204-3p overexpression lentiviral vector.

MiR-204-3p inhibited the colony forming ability of GC cells

The impact of miR-204-3p on the colony forming ability of GC cells was evaluated. The crystal violet positive staining in the miR-204-3p overexpression group decreased (Figure 3A and B), and simultaneously, the number of clones formed in AGS and HGC-27 cells was distinctly reduced compared to the NC group (Figure 3C and D). This indicated that miR-204-3p overexpression inhibited the colony forming ability of GC cells.

MiR-204-3p promoted GC cell apoptosis

We evaluated apoptosis by collecting cells from each group (Figure 4). The apoptosis rates of AGS cells were 2.53 ± 0.12%, 3.73 ± 0.83% and 10.6 ± 0.70% in the NC, KD and OE groups, respectively (Figure 4A and C). Among HGC-27 cells, the apoptosis rates were 9.47 ± 0.58%, 7.87 ± 1.63% and 18.40 ± 1.27% in the NC, KD and OE groups, respectively (Figure 4B and D). The findings revealed that HGC-27 and AGS cells with miR-204-3p overexpression had a notably higher apoptosis rate, which indicated that miR-204-3p overexpression stimulated GC cell apoptosis.

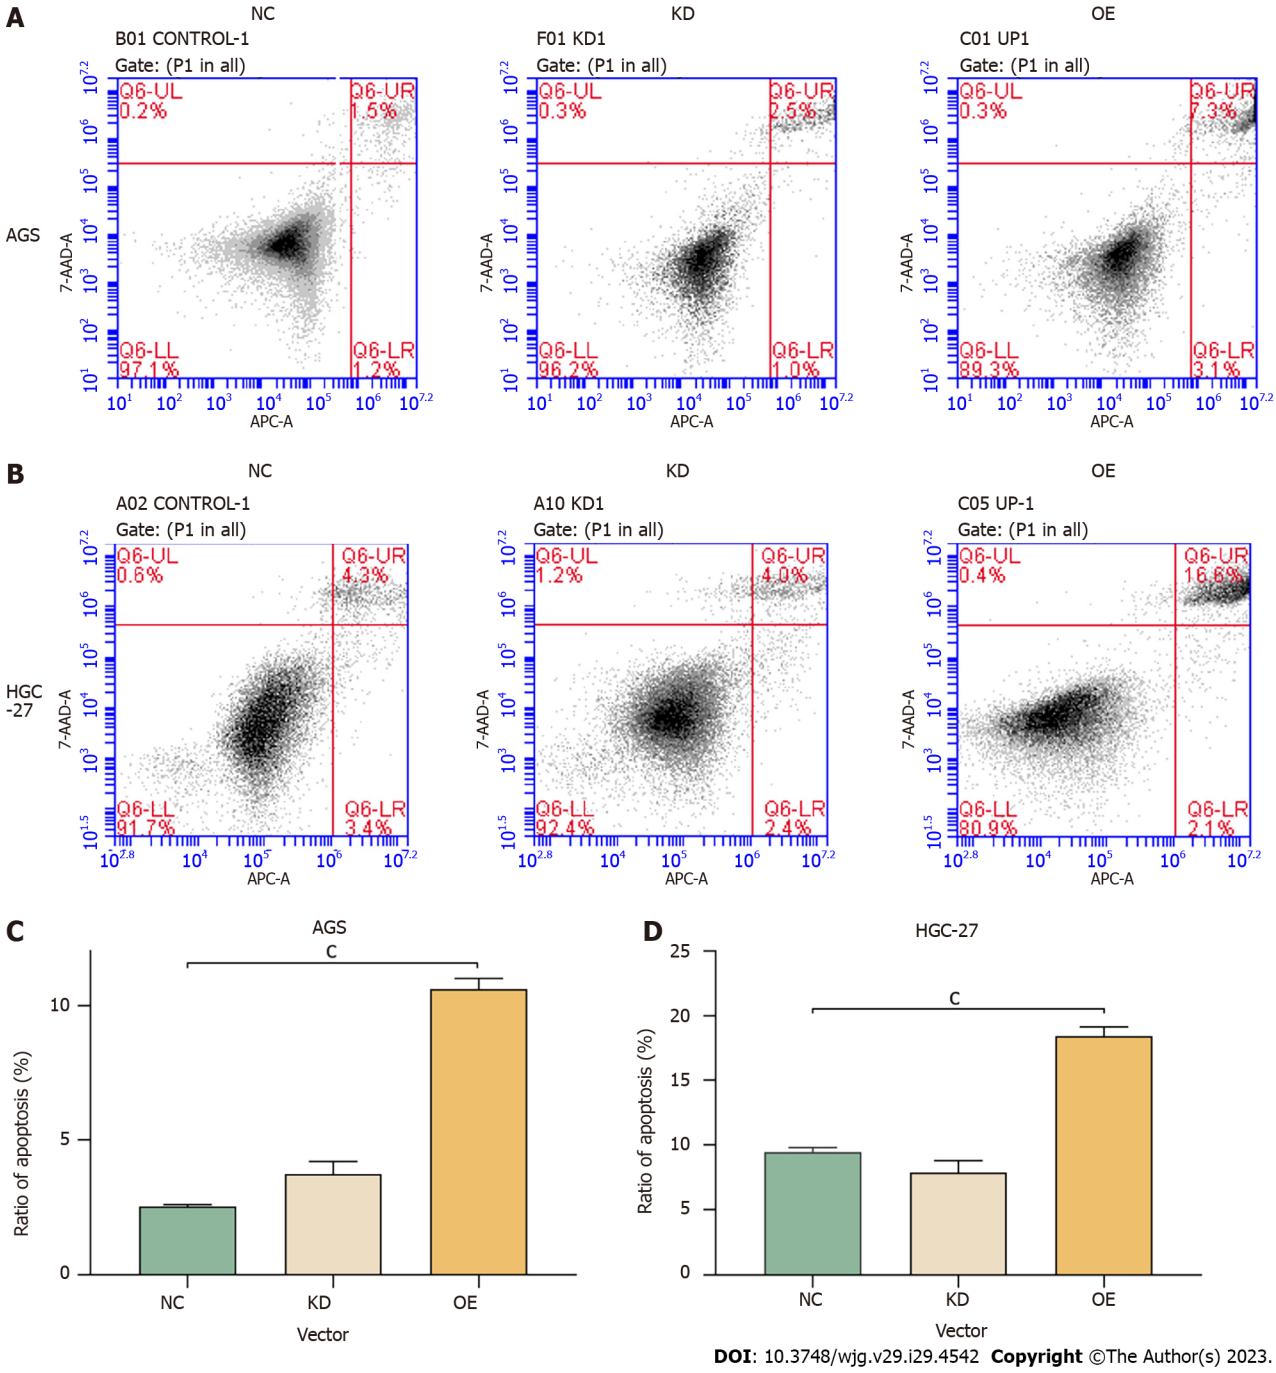
MiR-204-3p retarded GC cell cycle



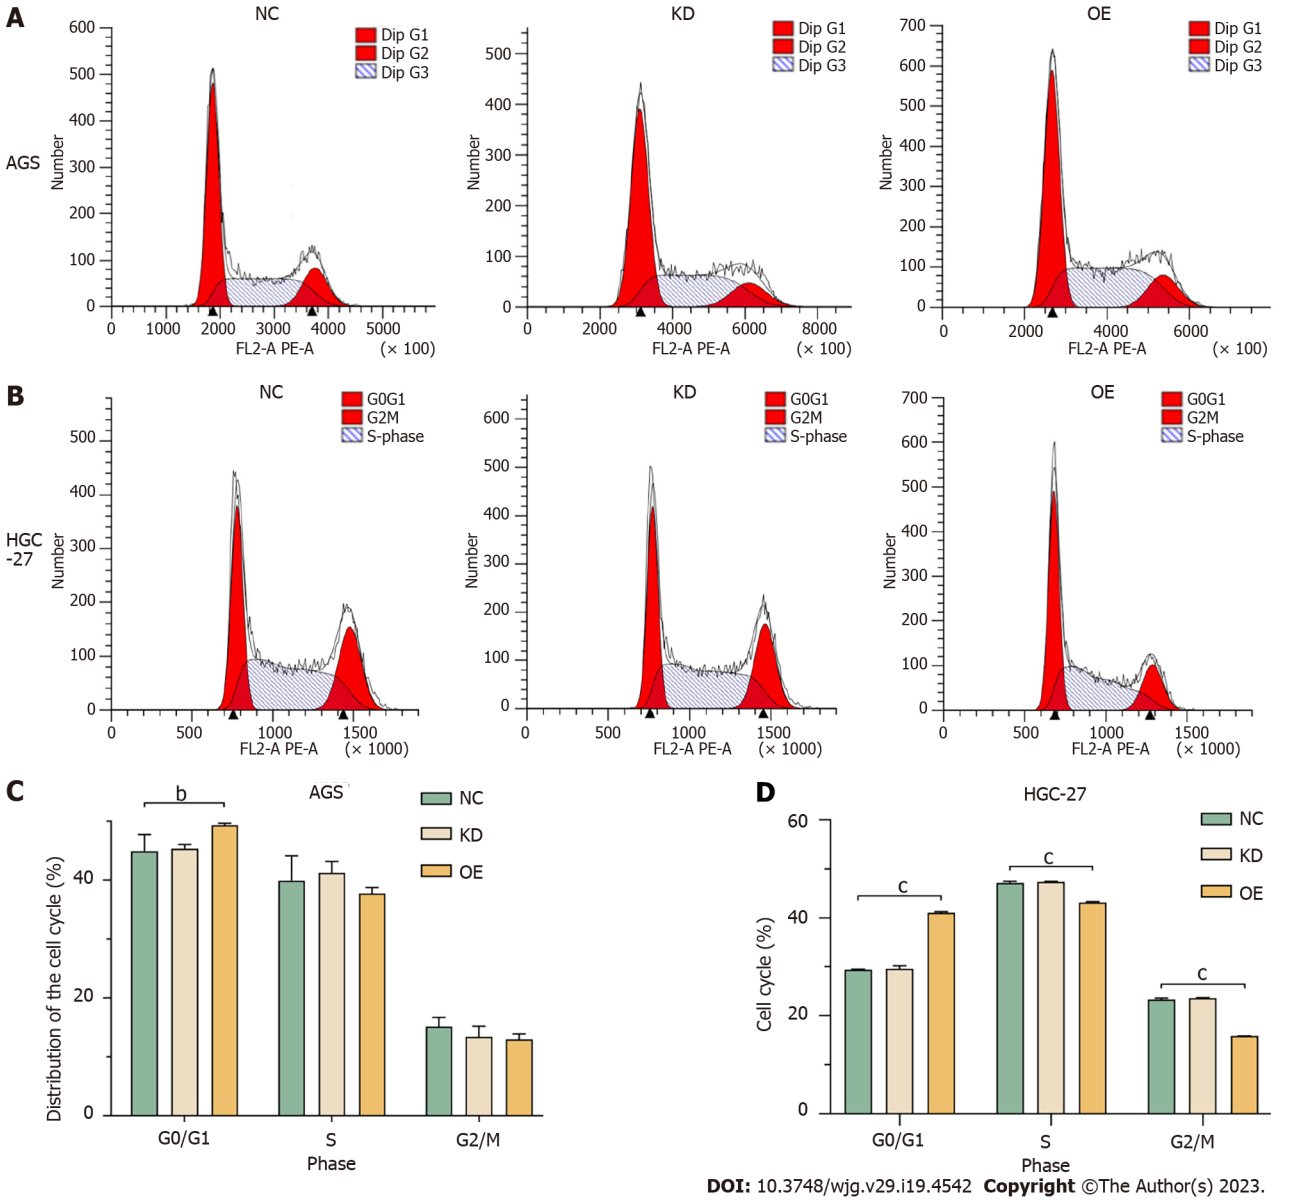
We analyzed cell cycle distribution to investigate whether miR-204-3p inhibited GC cell proliferation by mediating the cell cycle (Figure 5). Among AGS cells, the G0/G1 phase percentages were 44.91 ± 1.15%, 45.36 ± 0.70% and 49.30 ± 0.41% in the NC, KD and OE groups, respectively (Figure 5A and C). Among HGC-27 cells, the G0/G1 phase percentages were 29.36 ± 0.29%, 29.57 ± 1.11% and 41.03 ± 0.47% in the NC, KD and OE groups, respectively (Figure 5B and D). These results revealed that AGS and HGC-27 cells with miR-204-3p overexpression had a notably higher number of cells in G0/G1 phase, which indicated that miR-204-3p overexpression blocked GC cell cycle in the G0/G1 phase.

MiR-204-3p inhibited the formation of subcutaneous tumor in BABL/c nude mice

A subcutaneous tumor formation experiment was conducted in BABL/c nude mice using lentivirus-transfected MKN-45 cells to observe the changes in tumor size and body weight. The results revealed that the OE group had smaller tumors compared to the NC group (Figure 6A and B). According to tumor growth data, it was found that back tumor growth was notably slower in the OE group compared to the NC group (Figure 6C). Additionally, the weight of BABL/c nude mice in the OE group increased significantly (Figure 6D), which indicated that miR-204-3p overexpression suppressed subcutaneous tumorigenesis in BABL/c nude mice.

Effect of miR-204-3p on the MAPK signaling pathway

We investigated the effect of miR-204-3p on the MAPK signaling pathway. Firstly, the impact of miR-204-3p on the



DOI: 10.3748/wjg.v29.i29.4542 **Copyright** ©The Author(s) 2023.

Figure 4 Effects of miR-204-3p on apoptosis in AGS and HGC-27 cells. mRNA levels of *KRAS*, *ERK1* and *ERK2* was detected using qRT-PCR. The results revealed that miR-204-3p overexpression resulted in a significant decrease in *KRAS*, *ERK1* and *ERK2* in AGS and HGC-27 cells (Figure 7A and B). We further investigated the impact of miR-204-3p on the MAPK signaling pathway-related proteins, including KRAS, ERK1/2, and p-ERK1/2. The results showed that in HGC-27 and AGS cells, miR-204-3p overexpression caused noteworthy lower levels of KRAS and p-ERK1/2, but no significant difference was observed in ERK1/2 (Figure 7C-F). These findings indicated that miR-204-3p overexpression effectively inhibited GC cell proliferation, and this effect was achieved through the inhibition of KRAS, which subsequently prevented the phosphorylation of downstream effector protein ERK1/2 in the MAPK signaling pathway.

Effects of miR-204-3p on apoptosis-related proteins

The effect of miR-204-3p on apoptosis-related proteins in GC cells was investigated. The results indicated a reduction in BCL-2 and the BCL-2/BAX ratio, as well as an increase in Caspase-3 in the OE group (Figure 8A-D), which confirmed that miR-204-3p overexpression stimulated GC cell apoptosis *via* the BCL-2/BAX signaling pathway.

Effect of miR-204-3p on necroptosis-related proteins

We examined the protein changes in RIP1, p-RIP1, MLK1 and p-MLK1 during necroptosis and investigated the impact of miR-204-3p on GC cells necroptosis. The results revealed that miR-204-3p overexpression significantly inhibited the protein expression levels of p-RIP1 and p-MLK1 (Figure 8E-H), which confirmed that miR-204-3p overexpression inhibited GC cells necroptosis *via* the RIP1/MLK1 signaling pathway.

DISCUSSION

MiR-204-3p plays a crucial role in various diseases. Some studies have confirmed that miR-204-3p upregulation can be targeted to inhibit Nox4 to reduce memory deficits[21]. Moreover, its overexpression inhibited high glucose induced lens epithelial cells migration and epithelial-mesenchymal transition (EMT), and inhibited high glucose induced podocytes apoptosis and dysfunction[13,15]. Notably, miR-204-3p upregulation inhibited malignant melanoma migration, invasion and EMT progression by targeting inhibition of PAX2[19], its upregulation also inhibited hepatocellular carcinoma cell proliferation by targeting inhibition of FN1[22]. MiR-204-3p was found to be underexpressed in bladder cancer tissues and was related to poor prognosis, it regulated bladder cancer cell proliferation by targeting LDHA mediated glycolysis [16]. Apoptosis of glioma cells is induced by miR-204-3p targeting IGFBP2[23]. Furthermore, LINC00963 was overexpressed in osteosarcoma tissues and was related to poor prognosis, miR-204-3p reversed LINC00963 in promoted

NC: Empty lentiviral vector; KD: miR-204-3p knockdown lentiviral vector; OE: miR-204-3p overexpression lentiviral vector.

osteosarcoma cell proliferation and inhibited migration and invasion[24]. LINC00514 was upregulated in GC tissues, its overexpression stimulated GC cell growth and inhibited EMT by sponging miR-204-3p/KRAS[20]. These results suggest that miR-204-3p may be a new target for cancer therapy.

Firstly, we found that the expression of miR-204-3p was low in GC cells, and its overexpression resulted in the inhibition of cell proliferation, colony formation ability, and the cell cycle, while promoting apoptosis. *In vivo* tumor formation experiments in 4-week-old BABL/c nude mice verified that miR-204-3p overexpression inhibited subcutaneous tumor growth. Thus, both *in vitro* and *in vivo* experiments demonstrated the inhibitory influence of miR-204-3p overexpression on GC cells.

Apoptosis, a programmed cell death, is a natural barrier against tumorigenesis. However, in cancer, abnormal expression of anti-apoptotic or pro-apoptotic proteins causes inhibition of apoptotic pathways[25]. For instance, BCL-2 functions as an anti-apoptotic protein, preventing cytochrome C liberation from mitochondria, thereby inhibiting apoptosis. On the other hand, BAX is a common pro-apoptotic protein that can form homodimers or bind to BCL-2 to form heterodimers that activate Caspase-3 to promote apoptosis[26]. The BCL-2/BAX ratio is closely related to tumor progression, and a lower ratio indicates a stronger apoptosis effect. Therefore, most anti-cancer drugs rely on the BCL-2/BAX mechanism to kill cancer cells[27]. This study verified that miR-204-3p overexpression led to the upregulation of Caspase-3 in GC cells, while downregulating BCL-2 and the BCL-2/BAX ratio. These findings provide evidence that miR-204-3p overexpression can stimulate apoptosis and inhibit GC cell proliferation through the BCL-2/BAX/Caspase-3 apoptosis pathway.

In tumors, the MAPK pathway is frequently activated to control apoptosis, cell growth, and cell division[28]. Signal transmission of the MAPK signaling pathway follows a three-step enzyme-linked reaction. KRAS, as an upstream

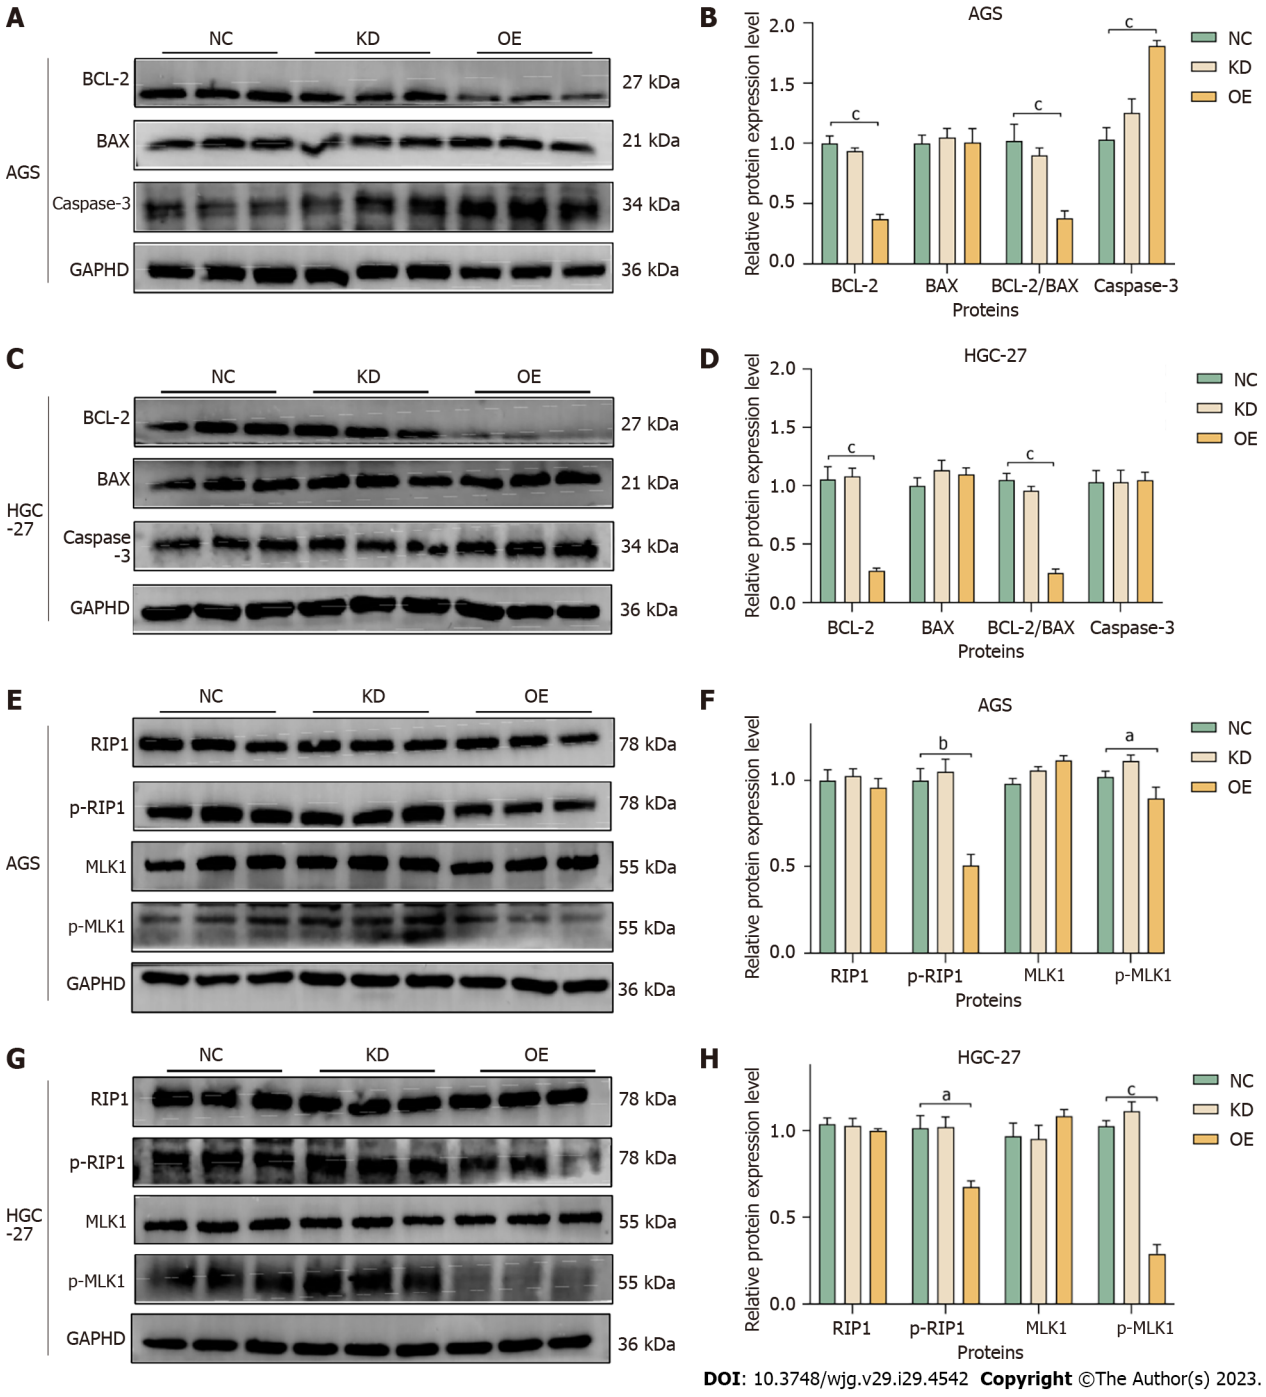
NC: Empty lentiviral vector; KD: miR-204-3p knockdown lentiviral vector; OE: miR-204-3p overexpression lentiviral vector.

activation protein, is activated when bound to GTP. This change causes the recruitment of KRAS to RAF on the cell membrane and promotes RAF activation. Activated RAF phosphorylates and activates MEK, while MEK phosphorylates and further activates ERK, which is located at the end of the signaling pathway and can transfer into the nucleus and bind to transcription factors, thereby regulating transcription programs and mediating cell growth, migration and differentiation[29-31]. Previously, we established that miR-204-3p targeted KRAS[20]. The current study confirmed that miR-204-3p upregulation can inhibit KRAS and p-ERK1/2, which suggested that miR-204-3p overexpression could inhibit the MAPK signaling pathway.

Necroptosis is a newly discovered mechanism of programmed cell death that has the potential to regulate tumorigenesis[32]. This process is primarily regulated by three proteins: RIP1, RIP3 and MLK1. Specifically, RIP1 is activated through phosphorylation, which then recruits RIP3[33]. Once activated, phosphorylated RIP3 can oligomerize MLK1 and transfer it to the plasma membrane, ultimately resulting in necroptosis characterized by cell swelling and organelle damage[34,35]. Interestingly, necroptosis has been found to both promote and inhibit cancer growth. As a form of cell death, necroptosis inhibits the development of tumors, yet it may also incite an inflammatory reaction that encourages cancer metastasis and immunosuppression. Research has revealed that glioblastoma, pancreatic cancer, and lung cancer can be impacted by the upregulation of RIP1, RIP3, and MLK1[36-38]. It was found that downregulation of MLK1 inhibited tumor cell growth and increased sensitivity to radiotherapy in both GC and ovarian cancer[39,40]. We detected necroptosis-related proteins and discovered that miR-204-3p overexpression decreased p-RIP1 and p-MLK1. These findings suggest that miR-204-3p overexpression can inhibit necroptosis through the RIP1/MLK1 pathway, ultimately inhibiting GC cell proliferation.

To sum up, our study verified that miR-204-3p is underexpressed in GC, and that its overexpression inhibits GC cell proliferation, promotes apoptosis, arrests the cell cycle in the G0/G1 phase, inhibits cell colony formation and the formation of subcutaneous tumors. Necroptosis is typically initiated by tumor necrosis factor (TNF) stimulation[41]. RIP1 binds to FADD, which then recruits caspase-8. The activation of caspase-8 promotes the process of RIP1-dependent



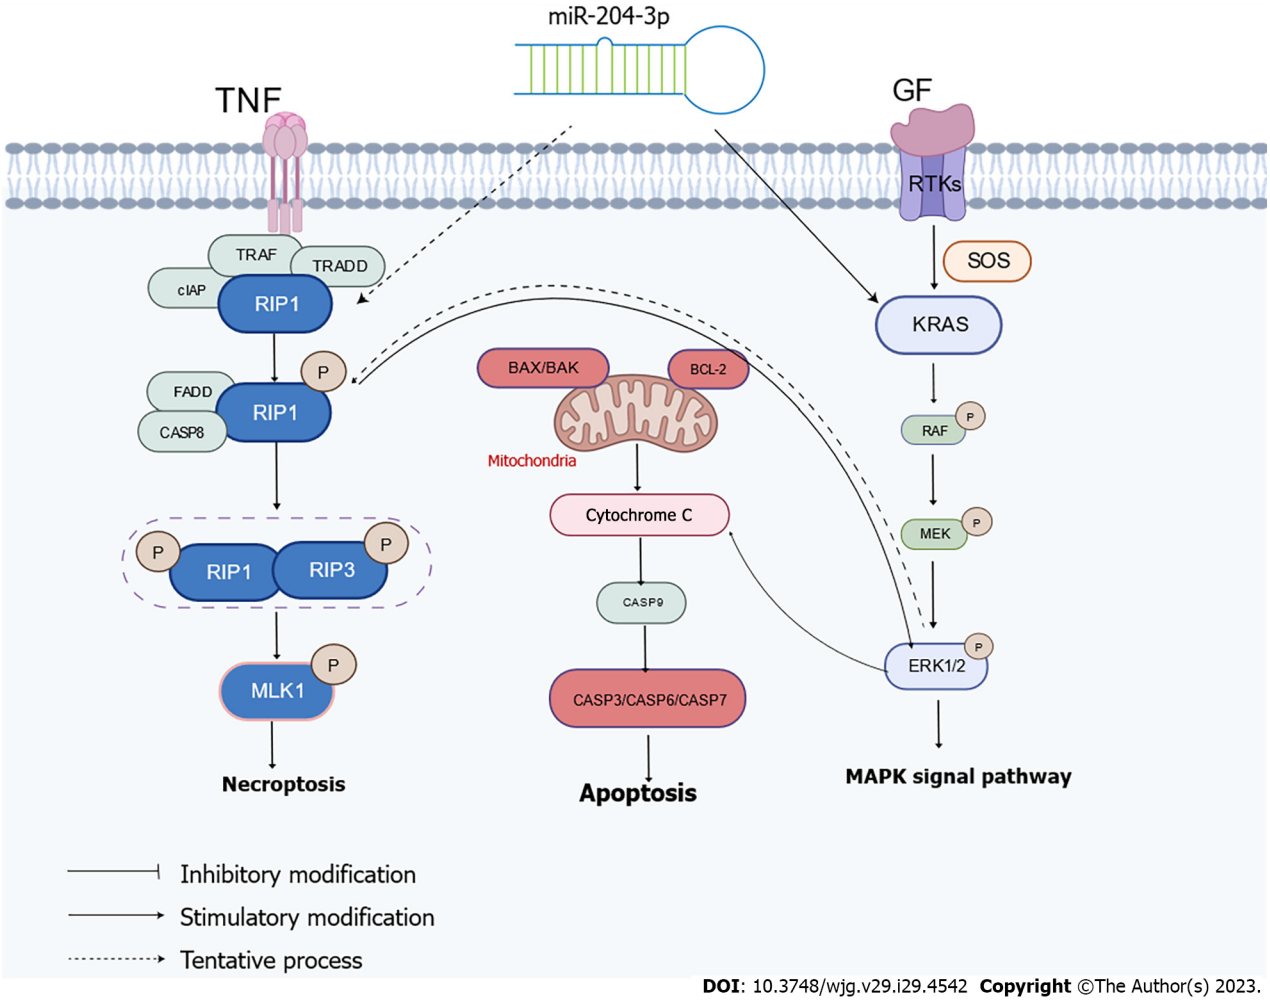


Figure 8 Effects of miR-204-3p on apoptosis-related proteins and necroptosis-related proteins in AGS and HGC-27 cells. NC: Empty lentiviral vector; KD: miR-204-3p knockdown lentiviral vector; OE: miR-204-3p overexpression lentiviral vector.

apoptosis[32]. Additionally, RIP1 activates ERK to regulate the MAPK signaling pathway[42-44]. In the MAPK signaling pathway, phosphorylation of ERK can activate BCL-2, which in turn stimulates the apoptosis pathway and accelerates the process of apoptosis[45,46]. We verified that miR-204-3p overexpression can inhibit GC cell proliferation by inhibiting the MAPK signaling pathway and inhibiting the RIP1/MLK1 necroptosis pathway to promote the BCL-2/BAX/Caspase-3 apoptosis pathway (Figure 9).

CONCLUSION

MiR-204-3p overexpression inhibited GC cell proliferation by inhibiting the MAPK pathway and necroptosis pathway to

Figure 9 Mechanism of the effect of miR-204-3p on the MAPK signaling pathway, apoptosis and necroptosis. TNF: Tumor necrosis factor; GF: Germ-free.

promote GC cell apoptosis. Thus, miR-204-3p may represent a new potential therapeutic target for GC.

ARTICLE HIGHLIGHTS

Research background

Gastric carcinoma (GC) is a common gastrointestinal malignancy worldwide. Based on the cancer-related mortality, the current prevention and treatment strategies for GC still show poor clinical results. Therefore, it is important to find effective treatment targets.

Research motivation

At present, the main treatment for GC is surgery, chemotherapy and radiotherapy, but the therapeutic effect is not ideal.

Research objectives

To explore the effect of miR-204-3p on GC cells.

Research methods

We determined the expression level of miR-204-3p in GC, and then used an miR-204-3p overexpression vector and an miR-204-3p knockdown vector in GC cells. The influence of miR-204-3p on the changes in cell phenotype and tumorigenicity *in vivo* was assessed. Furthermore, the effects of miR-204-3p on various proteins related to the MAPK signaling pathway, necroptosis signaling pathway and apoptosis signaling pathway in GC cells were investigated.

Research results

It was found that miR-204-3p was underexpressed in GC, and miR-204-3p overexpression inhibited GC cell viability, promoted cell apoptosis, blocked the cell cycle, inhibited colony formation ability and inhibited tumorigenicity *in vivo*. It

was also verified that miR-204-3p overexpression can promote apoptosis by inhibiting the MAPK pathway and the necroptosis pathway, thus inhibiting GC cell proliferation.

Research conclusions

MiR-204-3p overexpression inhibited GC cell proliferation by inhibiting the MAPK pathway and the necroptosis pathway to promote GC cell apoptosis.

Research perspectives

MiR-204-3p can be used for targeted therapy of GC, and can also be used as a new biomarker for GC.

Abstract

BACKGROUND

Hydrogen sulfide (H_2S) is a recently discovered gaseous neurotransmitter in the nervous and gastrointestinal systems. It exerts its effects through multiple signaling pathways, impacting various physiological activities. The nucleus tractus solitarius (NTS), a vital nucleus involved in visceral sensation, was investigated in this study to understand the role of H_2S in regulating gastric function in rats.

AIM

To examine whether H_2S affects the nuclear factor kappa-B (NF-κB) and transient receptor potential vanilloid 1 pathways and the neurokinin 1 (NK1) receptor in the NTS.

METHODS

Immunohistochemical and fluorescent double-labeling techniques were employed to identify cystathionine beta-synthase (CBS) and c-Fos co-expressed positive neurons in the NTS during rat stress. Gastric motility curves were recorded by inserting a pressure-sensing balloon into the pylorus through the stomach fundus. Changes in gastric motility were observed before and after injecting different doses of NaHS (4 nmol and 8 nmol), physiological saline, Capsazepine (4 nmol) + NaHS (4 nmol), pyrrolidine dithiocarbamate (PDTC, 4 nmol) + NaHS (4 nmol), and L703606 (4 nmol) + NaHS (4 nmol).

RESULTS

We identified a significant increase in the co-expression of c-Fos and CBS positive neurons in the NTS after 1 h and 3 h of restraint water-immersion stress compared to the expressions observed in the control group. Intra-NTS injection of NaHS at different doses significantly inhibited gastric motility in rats ($P < 0.01$). However, injection of saline, first injection NF-κB inhibitor PDTC or transient receptor potential vanilloid 1 (TRPV1) antagonist Capsazepine or NK1 receptor blockers

L703606 and then injection NaHS did not produce significant changes ($P > 0.05$).

CONCLUSION

NTS contains neurons co-expressing CBS and c-Fos, and the injection of NaHS into the NTS can suppress gastric motility in rats. This effect may be mediated by activating TRPV1 and NK1 receptors *via* the NF-κB channel.

Key Words: Nucleus tractus solitarius; Hydrogen sulfide; Gastric motility; Nuclear factor kappa-B; Transient receptor potential vanilloid 1

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This study revealed a significant inhibitory effect of exogenous hydrogen sulfide on gastric motility in rats. This effect appeared to involve the release of substance P, potentially activating the transient receptor potential vanilloid 1 pathway mediated by nuclear factor kappa-B channels.

INTRODUCTION

The number of patients with stress-induced gastric ulcers has increased dramatically[1], and stress is highly associated with several functional gastrointestinal disorders, such as functional dyspepsia and irritable bowel syndrome[2]. The nucleus tractus solitarius (NTS) is a relay nucleus for visceral primary afferent neural signaling. It receives sensory afferents from visceral organs and projects to the spinal cord to regulate respiratory and cardiovascular activity. The NTS is also closely connected with various brain nuclei[3]. Recent studies have demonstrated the role of the NTS in cardiovascular and respiratory regulation and the reflex regulation of intragastric pressure. Synapses mediate the vagal-dependent gastric reflex between vagal afferent fibers and NTS neurons, and through the vagal preganglionic parasympathetic neurons in the dorsal vagal complex[4]. Neuronal firing studies in the NTS have shown that H_2S increases NTS-evoked postsynaptic currents by enhancing presynaptic glutamate release and affects the membrane potential of NTS neurons in a concentration-dependent manner[5].

Vagal afferent transmission primarily terminates in the NTS[6], which may act as a relay activator to inhibit spinal neuronal activity. Vagal-mediated glutamate release can regulate homeostasis by activating NTS neurons and metabotropic glutamate receptors, contributing to homeostatic regulation. Injection of oxytocin in the NTS has been observed to inhibit gastric smooth muscle diastole in rats, possibly through the cAMP-PKA signaling pathway[7]. The microinjection of monosodium glutamate in the NTS and the activation of NTS opioid receptors inhibit gastric motility and significant c-Fos expression in the dorsal motor nucleus of the vagus (DMV) neurons[8].

However, hydrogen sulfide (H_2S) is a recently discovered gas transmitter endogenously produced in the human and animal brain and organ tissues. Cystathionine beta-synthase (CBS) mainly synthesizes H_2S in the central nervous system and plays a significant physiological role[9] and has a protective role in neurodegenerative diseases such as Parkinson's disease[10] and Alzheimer's disease[11]. CBS is present in neurons and glial cells of the NTS, exerting excitatory effects and modulating synaptic neuronal activity[12]. Blocking CBS attenuates synaptic transmission in NTS neurons. Applying the H_2S donor NaHS also enhances synaptic transmission in NTS neurons. H_2S in the NTS plays an equally important role as a gaseous neuromodulator in maintaining or modulating autonomicand other systems[13]. In vitro experiments have shown that H_2S relaxes gastrointestinal smooth muscles, inhibiting spontaneous movements and responses to chemical or electrical stimuli[14]. H_2S also plays a role in other types of smooth muscle relaxation *via* K^+-ATP channels[15], suggesting that endogenous H_2S has a regulatory role in the gastrointestinal tract's motor function.

The nuclear factor kappa-B (NF-κB) pathway is activated by various factors and plays a crucial role in the immune response and inflammation. A study found that NaHS administration in the rat intraperitoneal *via* sulfhydration caused NF-κB activation and lung inflammation, a significant increase in p65 protein levels, vascular congestion, and neutrophil infiltration. Also, slight neuronal degeneration was observed in the rat heart, liver, and brain, suggesting that H_2S acts on NF-κB channels for messaging[16]. H_2S also interacts with nitric oxide to cause vasodilation, down-regulates NF-kB pathway-induced inflammation, fibrosis and damage from prolonged or intense oxidative stress; protects tissues from ischemia- and reperfusion-induced injury; and reduces immune rejection by reducing oxygen free radicals produced *in vivo*[17]. Additionally, H_2S demonstrates antioxidant and anti-apoptotic effects on neurons and glial cells[18].

Transient receptor potential vanilloid type 1 (TRPV1) is a non-selective calcium channel associated with nociceptive sensations in peripheral nerves. Its activation can lead to neurokinin 1 (NK1) receptor activation, pain, local neurogenic inflammation, and systemic anti-inflammatory/analgesic effects, and enhanced transmitter release in the NTS. TRPV1 involves various physiological and pathological processes[19,20]. Electrophysiological studies have shown that the

activation of TRPV1 by capsaicin enhances glutamate release to visceral sensory neurons, affecting NTS preganglionic neurons[21]. H_2S can cause peripheral inflammation and synaptic enhancement of glutamatergic signaling in the spinal cord by activating TRPV1 channels, thus stimulating other receptors at the terminals of capsaicin-sensitive neurons[22]. TRPV1 activation also leads to the release of substance P (SP), while NK1 receptors are responsible for neurally mediated digestive secretion and contributes to brain homeostasis and sensory neuronal transmission associated with depression, stress, anxiety and vomiting[23]. H_2S causes gastric juice secretion by stimulating TRPV1 receptors on primary afferent nerve fibers and modulates cholinergic neurons by releasing SP to act on NK1, NK2, or NK3 receptors[24]. Therefore, we speculate that TRPV1 channels may be involved in the effect of H_2S donors on gastric emptying.

SP is a neuroactive peptide involved in pain and inflammation[25]. It is widely present in the mammalian organism in the central, peripheral, and gastrointestinal nervous systems[26] and other tissues, participating in various physiopathological processes, including stress, emotional anxiety, and immune regulation. NK1 receptors are the primary receptors for SP and are widely expressed in the brain, contributing to stress and emotional anxiety[27]. SP is widely expressed in the NTS, mainly in the primary sensory neurons in the peripheral nervous system, and intrinsic neurons of the gastrointestinal tract. It has been shown to have neurotransmitter effects in the central and peripheral nervous systems and is associated with immune and inflammatory diseases of the respiratory and gastrointestinal systems[28].

Herein, we investigated the regulatory effects of H_2S in the NTS on rat gastric function and explore whether these effects were mediated by SP release *via* NF-κB channel-dependent activation of the TRPV1 pathway.

MATERIALS AND METHODS

Animal

The animals used in this experiment were 240-280 g adult male Wistar rats purchased from Jinan Panyue Experimental Animal Breeding Co and housed in separate cages at a constant temperature (22 °C ± 2 °C) given appropriate food and water based on their body weight. To allow them to acclimate to their surroundings, the rats were exposed to natural rhythmic light for one week before the start of the experiment.

Before the experiment, the rats underwent a 24-h fasting period, during which they were allowed to freely drink. The other environmental conditions remained consistent throughout the experiment. The Experimental Animal Ethics Committee of Qilu Normal University approved the experiment. All experiments complied with internationally accepted ethical standards. The study also adhered to the guidelines set by the International Association for the Study of Pain[29].

Chemicals

NaHS, L703606, PDTC, Capsazepine, and protamine sky blue were purchased from Sigma-Aldrich (St. Louis, MO, United States). NaHS was dissolved in 0.9% saline, while the other chemicals were dissolved in dimethyl sulfoxide and reconstituted in saline. For the immunohistochemical fluorescence double labeling, the following reagents were purchased from Servicebio (Wuhan, China): Goat serum, anti-CBS rabbit pAb, FITC-conjugated goat anti-rabbit IgG, Cy3-conjugated goat anti-mouse IgG, and anti-c-Fos mouse pAb.

Immunohistochemical fluorescence double labeling

We used the restraint water immersion stress model to investigate acute stress-induced gastric mucosal injury in rats. This acute compound stress model causes changes in gastric function in rats under stress through enhanced parasympathetic activity in the innervated stomach[30]. Once anesthetized, the rats were swiftly removed from the bottle and secured to a wooden board using medical tape to immobilize their limbs and teeth. When awake, the rats were then immersed in cold water (21 °C ± 1 °C) with the sternal process aligned with the water level. To minimize experimental error, consistent time points were selected for each experiment.

The rats were randomly divided into three groups (n = 6) based on the duration of restraint water-immersion stress (RWIS) (0 h, 1 h, or 3 h). Cardiac perfusion was performed using 500 mL of prepared 0.01 mol/L phosphate-buffered saline (PBS) followed by 500 mL of 4% 0.1 mol/L paraformaldehyde (PFA). After administering an overdose of isoflurane to sacrifice the rat, the thoracic cavity was opened along the sternal process, and the heart was exposed. The infuser needle was inserted into the heart's left ventricle, securing the heart, while the right auricle was incised to allow blood to drain. The rat's liver was flushed with 0.01 mol/L PBS buffer until it turned white, followed by perfusion with 4% PFA solution using a "fast and then slow" principle, gradually reducing the flow rate when the rat's limbs twitched.

Upon completion of perfusion, the rat's head was severed, and the brain was extracted. The brain was placed in a small wide-mouth flask containing 4% PFA and kept at 4 °C for 24 h. Subsequently, the fixed rat brain was transferred to a 0.1 mol/L 30% sucrose solution for dehydration. The frozen target nuclei region was then sectioned into 30 μm thick coronal sections using a sectioning machine and stored in 0.01 mol/L PBS.

Next, each well of a multi-well plate was filled with 500 μL of 0.01 mol/L PBS buffer to clean the brain slices and remove impurities. A methanolic solution of 3% H_2O_2 was added to block endogenous peroxidase activity. The wells were then incubated with a goat serum closure solution for 1 h to enhance cell membrane permeability. Subsequently, 500 μL of each primary antibody working solution was added, consisting of mouse anti-c-Fos (diluted at 1:500) and rabbit anti-CBS (diluted at 1:500), and incubated overnight at 4 °C.

Finally, 500 μL of each fluorescent secondary antibody working solution was added for 1 h. Any residual fluorescent secondary antibody was washed off with PBST. Previously treated with chromium-vanadium gelatin, the brain slides were placed on glass slides and allowed to dry naturally. The slides were sealed with an anti-fluorescence quencher, ensuring the removal of air bubbles using a vacuum. Finally, the sealed fluorescent glass slide was placed under an

Olympus Fluorescence confocal microscopy to observe and compare the brain atlas to determine the position of the NTS, observe the CBS and c-Fos-positive neurons number, and take pictures. The expression of c-Fos and CBS in the NTS was counted using Image Pro-Plus 6.0 software (Number/0.01 mm^2).

Experimental grouping

We evaluated the following subgroups to investigate the regulatory effects of NaHS in the NTS on gastric function and its underlying mechanisms. The chosen doses were based on pre-experiments and relevant literature[31]: (1) The effect of microinjection of NaHS (0.1 μL, 4 nmol; n = 6) in NTS on gastric motility; (2) the effect of microinjection of NaHS (0.1 μL, 8 nmol; n = 6) in NTS on gastric motility; (3) the effect of microinjection of saline (0.1 μL; n = 6) in NTS on gastric motility as a control group; (4) the effect of microinjection of NaHS (0.1 μL, 4 nmol) + PDTC (0.1 μL; n = 6) in NTS on gastric motility; (5) microinjection of NaHS (0.1 μL, 4 nmol) + Capsazepine (0.1 μL, 4 nmol; n = 6) in NTS on gastric motility; and (6) microinjection of NaHS (0.1 μL, 4 nmol) + L703606 (0.1 μL, 4 nmol; n = 6) in NTS on gastric motility.

Microinjection

Before conducting the experiments, the rats were anesthetized with 4% chloral hydrate at (400 mg/kg body weight) by intraperitoneal injection until the eyelids and corneal reflexes disappeared, the muscles were relaxed, and the breathing was uniform. The anesthetized rat head was fixed on a brain stereotaxic apparatus (Stoelting 68002, Shenzhen Ruiwode Company, China).

Next, the animal was fixed according to the rat brain stereotaxic atlas (Paxinos and Watson, 2007) using the three points of the animal's bilateral inner ear holes and incisors. With the left and right ear rods reading the same, fontanelle and bregma were kept at the same level with an error of no more than 0.3 mm.

The head hair was removed with hair clippers to expose the scalp and disinfected with 75% alcohol. Then, the scalp was cut along the sagittal suture of the skull with ophthalmic clippers to expose the skull, the excess connective tissue around the skull was cut away, and the surface of the skull was gently wiped with saline until the fontanelle and herringbone suture were exposed. The three-dimensional coordinates of fontanelle were used as the zero point. A small hole of approximately 2 mm in diameter was drilled in the skull ipsilateral to the coordinates of the NTS center point (13.3 mm posterior to fontanelle, 0.8 mm paracentral opening, 7.9 mm subdural) in the atlas using an electric cranial drill. A glass microelectrode with a tip of approximately 30 μm was placed into the brain at the depth of the coordinates.

Recording gastric motility

The anesthetized rats were placed abdomen side up, and a small incision was made in the fundus of the stomach to clean the gastric residue. A 5 mm diameter balloon filled with warm water was inserted into the pylorus of the gastric sinus and kept at a constant baseline pressure. The balloon inserted into the rat's stomach was connected to the pressure transducer and BL-420 (Biological Function Experimental System; Chengdu Taimeng Company, China) *via* a polyethylene plastic tube. The stimulation parameters of the transducer were adjusted to 25 mm/min speed, 0.5 mV/cm sensitivity, and 10 Hz filter. Once the gastric motility curve was stabilized, the drug's microinjections and contaminate sky blue were administered. A heat lamp was used throughout the experiment to maintain a constant ambient temperature, and gastric motility was recorded.

Histological identification of the microinjection site

After gastric motility recording, 2% pontamine sky blue (0.1 μL) was injected into the NTS, the rats were executed with an excess of sodium pentobarbital, and the thorax was opened for cardiac perfusion. After perfusion, the heads of the rats were cut off, and the brain tissues were removed and placed in a 4% formaldehyde solution for fixation.

Subsequently, the brain tissues were frozen at -16 °C for 30 min and sectioned into successive coronal sections with a thickness of 16 μm. The brainstem sections were stained, allowing for the identification of injection sites. The brain slices on slides were treated with a neutral red stain and dehydrated to achieve transparency. The sections were observed and photographed using a microscope (Nikon Optiphot, Nikon, Shanghai, China) and photographed with a digital camera (Magnafire; Optronics, Goleta, CA, United States) connected to a computer. The blue dot marking the precise location of the NTS was identified for further statistical analysis.

Data analysis and statistics

The gastric motility of the rats was assessed by counting the number of contractions before and 5 min after injection were counted respectively. The total duration of contraction waves (T.D.C.W) within 5 min, the total amplitude of contraction waves (T.A.C.W) within 5 min and the gastric motility index (the product of amplitude and duration) before and after the 5-min microinjection were evaluated statistically. To calculate the inhibition rate of gastric motility, the following formula was used: Inhibition rate (%) = (pre-injection value-post-injection value) × 100%/pre-injection value. The height between the highest point of the contraction curve and the baseline is the amplitude of the contraction wave. The time duration between the starting point and the ending point of the contraction wave is the time duration of the contraction wave.

Statistical analysis was performed using SPSS v25.0 (IBM SPSS Inc., Chicago, IL, United States) using Student's t-test or one-way ANOVA, followed by a posthoc test using the Student-Newman-Keuls test. All data are presented as mean ± SE. A P value less than 0.05 was considered statistically significant.

RESULTS

Observation of c-Fos and CBS expression in NTS at different times in RWIS

In this experiment, the number of CBS and c-Fos co-expressing neurons in the NTS (Figure 1, n = 6) was revealed by immunohistochemical fluorescence double-labeling. The expression of c-Fos protein in the NTS showed varying degrees of increase at 1 h (7.00 ± 0.37) and 3 h (4.83 ± 0.31) after RWIS compared to the control group at 0 h (1.83 ± 0.30) (P < 0.01). This finding indicates that CBS neurons in the NTS of rats were activated during the RWIS procedure.

NTS injection site identification

Following neutral red staining, the brain slices were examined under a light microscope to determine the localization of the injected blue spots and drugs within the NTS. The observed data regarding the gastric motility of rats in the correct position were analyzed. Figure 2 presents the diagram for identifying the degree of tissue localization.

NaHS inhibits gastrointestinal motility within NTS

The microinjection of physiological saline (PS) (0.1 μL, n = 6) under the same conditions did not produce a significant change in gastric motility (Figure 3A). In contrast, the microinjection of NaHS at different concentrations (4 nmol and 8 nmol, 0.1 μL, n = 6) into the rat NTS resulted in significant inhibition of gastric motility (Figure 3B and C).

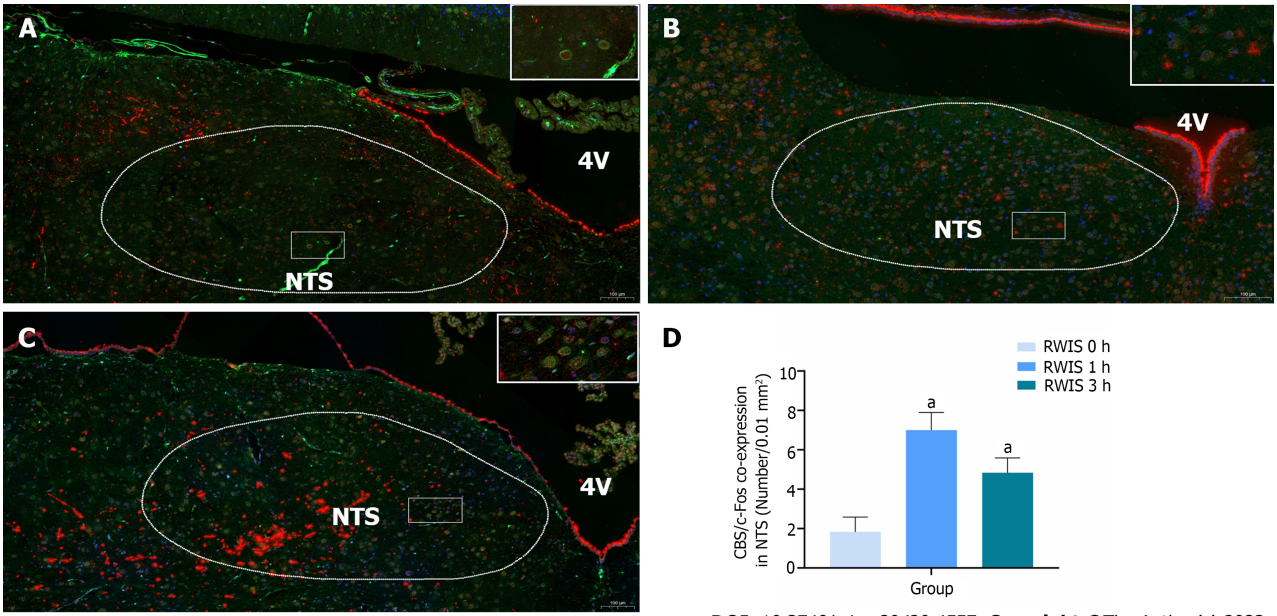
We compared gastric motility curves measured before and 5 min after the drug injection and after 4 nmol NaHS injection in the NTS. The T.A.C.W. decreased from 553.08 mm 5 min^{-1} ± 9.59 mm 5 min^{-1} to 421.30 mm 5 min^{-1} ± 10.58 mm 5 min^{-1} (P < 0.01). The T.D.C.W. decreased from 179.79 s 5 min^{-1} ± 13.33 s 5 min^{-1} to 132.56 s 5 min^{-1} ± 6.67 s 5 min^{-1} (P < 0.01), and the gastric motility index (G.M.I.) decreased from 5219.88 ± 182.11 to 4250.28 ± 159.03 (P < 0.01). At a NTS microinjection dose of 8 nmol NaHS, the T.A.C.W. decreased from 587.62 mm 5 min^{-1} ± 9.58 mm 5 min^{-1} to 407.44 mm 5 min^{-1} ± 10.61 mm 5 min^{-1} (P < 0.01) and the T.D.C.W. decreased from 234.11 s 5 min^{-1} ± 11.74 s 5 min^{-1} to 145.13 s 5 min^{-1} ± 3.93 s 5 min^{-1} (P < 0.01) and the G.M.I. decreased from 5906.07 ± 181.71 to 4105.60 ± 49.35. After PS injection in the NTS, the T.A.C.W. decreased from 468.72 mm 5 min^{-1} ± 6.42 mm 5 min^{-1} to 467.34 mm 5 min^{-1} ± 5.04 mm 5 min^{-1} (P > 0.05), the T.D.C.W. from 236.96 s 5 min^{-1} ± 8.51 s 5 min^{-1} to 232.38 s 5 min^{-1} ± 16.31 s 5 min^{-1} (P > 0.05), and the G.M.I. from 5797.17 ± 141.87 to 5778.08 ± 125.32 (P > 0.05) (Figure 4A-C).

The inhibition rates of the T.A.C.W. in the 4 nmol NaHS, 8 nmol NaHS, and saline groups were 23.83%, 30.69%, and 0.27%, respectively. The inhibition rates of T.D.C.W. in the 4 nmol NaHS, 8 nmol NaHS, and saline groups were 26.21%, 37.43%, and 2.06%, respectively. The inhibition rates of G.M.I. in the 4 nmol NaHS, 8 nmol NaHS, and saline groups were 18.55%, 30.17%, and 0.30%, respectively (Figure 4D). The data indicated that the inhibition rates of T.A.C.W., T.D.C.W., and G.M.I. were significantly higher in the 8 nmol NaHS group compared to the 4 nmol NaHS group. These findings suggest a dose-dependent inhibitory effect of NTS injection of NaHS on gastric motility.

PDTC eliminates the inhibitory effect of NaHS on gastric motility

Injection of PDTC followed by NaHS into the NTS eliminated the inhibitory effect of NaHS on gastric motility (Figure 5A, n = 6). The T.A.C.W. changed from 500.15 mm 5 min^{-1} ± 7.56 mm 5 min^{-1} to 491.06 mm 5 min^{-1} ± 17.19 mm 5 min^{-1} (P > 0.05), the T.D.C.W. changed from 169.84 s 5 min^{-1} ± 3.40 s 5 min^{-1} (P > 0.05), and the G.M.I. changed from 5494.78 ± 140.32 to 5490.60 ± 88.80 after PDTC followed by NaHS injection (P > 0.05) (Figure 5B-D). These data suggest that NaHS can regulate gastric motility through the NF-κB signaling pathway.

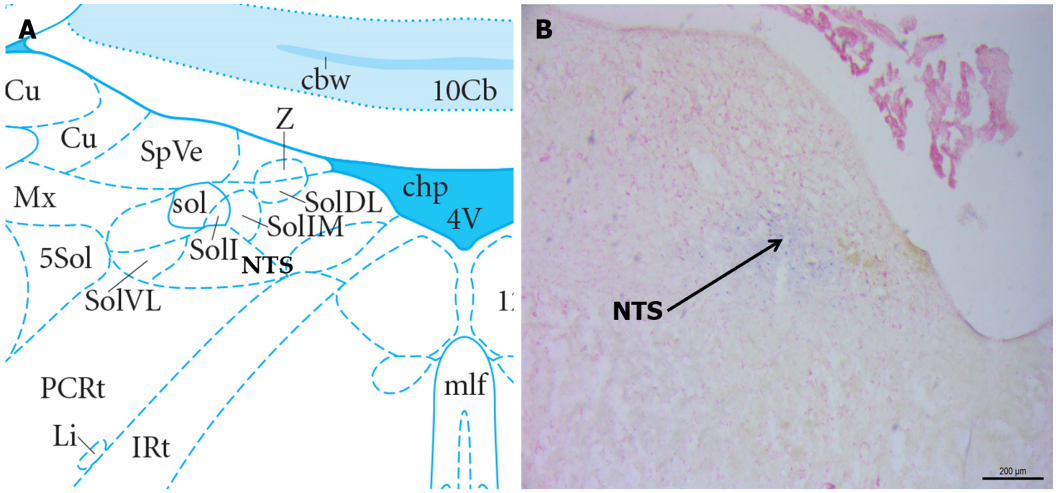
Capsazepine eliminates the inhibitory effect of NaHS on gastric motility



Injection of Capsazepine followed by NaHS into the NTS eliminated the inhibitory effect of NaHS on gastric motility (Figure 6A, n = 6). As a result, the T.A.C.W. changed from 514.46 mm 5 min^{-1} ± 6.56 mm 5 min^{-1} to 523.87 mm 5 min^{-1} ± 9.21 mm 5 min^{-1} (P > 0.05), the T.D.C.W. changed from 175.90 s 5 min^{-1} ± 4.22 s 5 min^{-1} to 172.13 s 5 min^{-1} ± 4.68 s 5 min^{-1} (P > 0.05), and the G.M.I. changed from 5932.97 ± 104.93 to 5946.45 ± 184.14 (P > 0.05) (Figure 6B-D). These data suggest that NaHS can regulate gastric motility through TRPV1 channels.

L703606 eliminates the inhibitory effect of NaHS on gastric motility

Injection of L703606 followed by NaHS into the NTS eliminated the inhibitory effect of NaHS on gastric motility (Figure 7A, n = 6). The T.A.C.W. changed from 494.46 mm 5 min^{-1} ± 11.86 mm 5 min^{-1} to 490.53 mm 5 min^{-1} ± 14.00 mm 5 min^{-1} (P > 0.05), the T.D.C.W. changed from 164.10 s 5 min^{-1} ± 5.53 s 5 min^{-1} to 158.39 s 5 min^{-1} ± 10.64 s 5 min^{-1} (P > 0.05), and the G.M.I. changed from 5827.59 ± 133.74 to 5762.80 ± 114.34 (P > 0.05) (Figure 7B-D). These data suggest that NaHS can act on NK1 receptors to regulate gastric motility.



DISCUSSION

Endogenous H_2S concentrations in the brain range between 10 nM and 160 nM[32], and approximately 33% of H_2S is produced by volatilization in NaHS solutions when measurements are made in a closed environment. H_2S (10 mmol/L) in NTS neurons can maintain excitatory postsynaptic potential excitation for 10 minutes, which is equivalent to the time it takes for a microinjection NaHS to work[33]. Moreover, H_2S can cross the cell membrane by free diffusion to modulate cellular properties[34]. We selected NaHS as an exogenous H_2S rapid drug-delivery donor.

H_2S, an emerging gaseous signaling molecule, plays an important role in regulating digestion and the nervous system [35]. Placing coronal NTS slices into NaHS solution was found to cause rapid concentration-dependent depolarization of neurons at NTS sites, with H_2S increasing the postsynaptic currents in NTS neurons by promoting presynaptic glutamate release[36]. Herein, we observed a significant increase in the co-expression of neurons between CBS and c-Fos in rat NTS after RWIS, indicating that H_2S in the NTS is involved in gastrointestinal regulation and stress.

In this experiment, we found that the amplitude and duration of gastric motility and the index of gastric motility were significantly lower in the NTS than in the control group, in a dose-dependent manner, after the injection of different concentrations of NaHS in rats. Sensory information from the upper gastrointestinal tract is transmitted to the NTS *via* vagal afferent fibers, and c-Fos-positive neurons are significantly increased in the NTS following stressful processes. Glutamate release from vagal afferent fibers activates NTS neurons, which can regulate gastrointestinal activity by inhibiting the vagal excitatory cholinergic efferent pathway *via* the inhibitory neurotransmitter GABA or by exciting the vagal inhibitory non-adrenergic non-cholinergic (NANC) efferent pathway[37]. In addition, vagal afferent nerves from the gastrointestinal tract can activate the NANC efferent pathway leading to gastric smooth muscle relaxation. Vagal

PS: Physiological saline.

efferent fibers activate the noradrenergic neurons in the NTS, which in turn activate the NANC pathway neurons in the DMV. These NANC-DMV neurons transmit to the gastrointestinal plexus to activate postganglionic cholinergic neurons, thus causing gastric relaxation[38].

In vivo studies found that the microinjection of D-glucose into the NTS resulted in decreased gastric motility and increased intragastric pressure in rats *via* K^+-ATP channel relaxation of the smooth muscles and increased firing of GABAergic neurons[39]. Injection of cholecystokinin in the rat NTS modulates the gastrointestinal motility and secretory function in the upper gastrointestinal tract by activating postganglionic cholinergic excitatory or NANC inhibitory pathways[40]. Increased glutamate content within the NTS directly activates excitatory postsynaptic potentials in NTS neurons, which in turn stimulates local circuit GABAergic and glutamatergic neurons. GABAergic signals at the NTS determine the state of the gastric tone and contraction and mediate changes in gastric mechanical function at the onset of the vagal-vagal reflex[41,42]. The intra-NTS injection of GLP-1 reduces the gastric tone by activating NANC and delays gastric emptying in a dose-dependent manner[43]. Therefore, NaHS injection in the rat NTS may inhibit gastric motility by releasing inhibitory neurotransmitters such as GABA from preganglionic cholinergic neurons.

The activation of TRPV1 leads to the release of various pro-inflammatory cytokines, which can activate NF-kB translocation to the nucleus. Our experiments revealed that the injection of the NF-κB pathway blocker PDTC followed by NaHS eliminated the modulation of gastric function by NaHS. H_2S is mainly synthesized in the brain by the CBS enzyme, andwe found that NaHS injection in both the ambiguous and paraventricular nuclei inhibited gastric motility in rats *via* the NF-κB pathway[44,45], that the injection of NaHS to the brain blocked inflammation-associated apoptosis, and that treatment with NaHS reduced the expression of inflammatory factors in astrocytes and microglia due to Alzheimer's disease[46]. H_2S reduces the levels of phosphorylated p38 MAPK and phosphorylated p65 NF-κB *in vivo*. NaHS also reduces LPS-induced inflammation by inhibiting p38 MAPK and p65 NF-κB in rat cells[47]. SP is the main presynaptically released excitatory transmitter from injured primary afferent fibers. It binds to NK1 receptors on the postsynaptic membrane to activate NF-kB-induced inflammatory factor synthesis. NF-κB is reportedly involved in the transcriptional regulation of various response-related genes, including gastrointestinal mucosal damage, and that the downregulation of NF-κB signaling can inhibit stress-induced local inflammatory responses in the gastric mucosa and can repair local lesions in the gastric mucosa[48,49]. Therefore, physiological concentrations of H_2S can modulate the inflam-

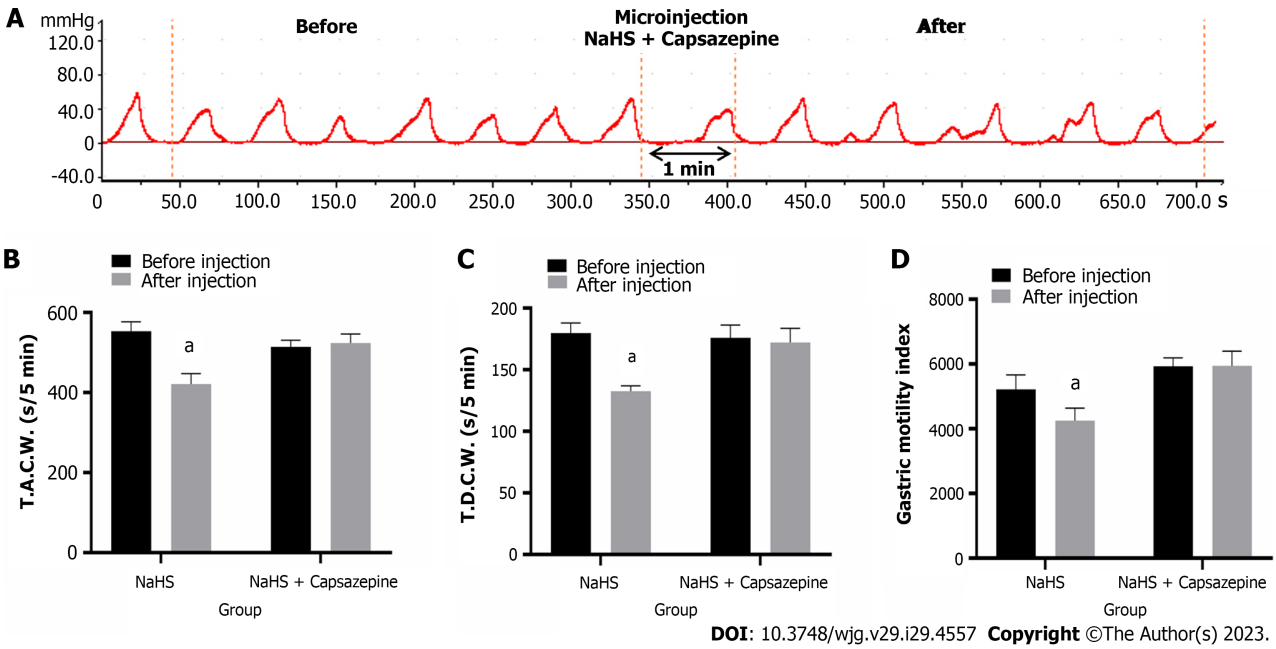
matory process and regulate gastric dysfunction by down-regulating the inflammatory response.



To investigate the signaling pathways involved in H_2S regulation, we focused on the TRPV1-SP-NF-kB pathway[50]. TRPV1 activation, enhanced pro-inflammatory cytokine expression, and oxidative stress *via* the NF-kB pathway led to reduced phosphorylation of the ERK signaling pathway, activation of PAG involved in the ERK-NF-kB pathway, and production of SP, which in turn regulated TRPV1-mediated neurogenic inflammation[51]. Our experiments showed that the administration of the TRPV1 blocker Capsazepine followed by NaHS eliminated the modulation of gastric function by NaHS. TRPV1 is widely expressed in spinal and vagal afferent neurons. It innervates the gastrointestinal tract, and its upregulated sensitivity may be associated with the pathophysiological functions of diseases such as visceral pain, irritable bowel syndrome, inflammatory bowel disease and pancreatitis[52]. TRPV1 presents two sides to inflammation. There are even studies showing the alternating effects of TRPV1 on inflammation[53]. Capsaicin induces inflammation in the stomach by activating TRPV1, damages the gastrointestinal mucosa, causes structural changes in the intestinal barrier and further leads to other gastrointestinal symptoms[54-56]. It also decreases the expression of anti-inflammatory cytokines in the stomach and intestine and promotes the release of gastrointestinal neuropeptide SP, which is closely associated with gastrointestinal visceral pain[57]. The findings suggest that the TRPV1 receptor antagonist caspofungin abrogates H_2S donor-induced enhancement of gastric emptying and that TRPV1-dependent pathways have been shown to produce modulation of vagally mediated muscle contractions in the gastrointestinal tract[58]. Capsaicin also activates the enterocholinergic neurons in guinea pig's small intestine and induces contractile effects and inhibition of gastric emptying, thus inducing the relaxation of smooth muscles of the fundus[59]. Capsazepine was also found to inhibit NaHS-induced pyloric smooth muscle relaxation, indicating that the effect of H_2S donors on enhancing gastric emptying and inducing pyloric sphincter relaxation is mediated by the activation of TRPV1 receptors. Although there are many mechanisms by which this effect can be manifested, our data support the theory of smooth muscle relaxation induced by afferent neuronal TRPV1 receptor activation[45,60].

TRPV1 receptors may act as molecular sensors involved in processing cardiac injury information in spinal neurons. Harmful environmental stimuli can activate TRPV1 to produce pro-inflammatory mediators in the epithelial cells, thus triggering neurogenic inflammatory responses. TRPV1 antagonists reportedly inhibited H_2S-induced neuropeptide release and bronchoconstriction in vitro, whereas H_2S induced the release of an endogenous tachykinin, SP, by stimulating sensory nerve endings, and that NaHS-induced SP release is significantly reduced when the TRPV1 blocker Capsazepine is applied[61]. Capsaicin also slows down gastric motility through TRPV1-induced excitation of gastric sensory nerve fibers[62]. A possible role of capsaicin-sensitive vagal afferent nerves in gastric mucosal injury and prevention has been demonstrated and is associated with the release of SP[31].

We eliminated the inhibitory effect of NaHS on gastric motility in our experiments by injecting the NK1 receptor blocker L703606 followed by NaHS. SP is a brain-gut peptide abundant in mammals that acts as a neurotransmitter for specific receptors to mediate NANC expression in the autonomic nervous system. Numerous studies have shown its role in stress and nociceptive transmission[63]. Injection of exogenous SP into the NTS resulted in the reduction of gastric motility. In contrast, injection of NK1 blockers enhanced the gastric motility. Therefore, SP in the NTS may play a

predominantly inhibitory role in gastrointestinal regulation. Administration of NK1 receptor antagonists also prevented H_2S-induced contractile responses, indicating that SP released from sensory nerve endings is the ultimate mediator of H_2S-induced excitation of smooth muscle in rats, possibly leading to altered gastric motility and the formation of gastric ulcers[64]. Injection of glutamate and SP in the NTS modulates gastric motility and emptying, and leads to a dose-dependent decrease in tonic gastric pressure and inhibition of gastric motility[65,66]. It has been shown that glutamate, acting through N-methyl-D-aspartic acid receptors with glutamate ion channels, and tachykinin, acting through NK1 and NK2 receptors, act synergistically in the transmission of acid stimuli from the gastric mucosa to the NTS[67]. SP regulates gastric smooth muscle contraction by both inhibition and enhancement mechanisms. Studies have found that SP microinjections in the brain have inhibitory effects on gastric motility. Furthermore, microinjections of SP in the rat DMV inhibited gastric EMG fast waves and gastric motility. These effects could be abolished by SP receptor antagonists and by severing the vagus nerve, respectively[68]. SP in the brain plays a role in stress-induced physiological and behavioral activity. The effects of NK1 can be blocked using injectable drugs or knockout methods[69-71]. Moreover, c-Fos expression can be downregulated, with the nucleus involved in stress in the brain and pain, causing pain through increased SP release in the hypothalamic and spinal cord tissue. This results in a sterile inflammatory response, with persistent pain leading to increased levels of SP receptors in the posterior horn of the spinal cord[72]. SP also plays a role in transmitting injurious information, with low doses given ventrally to produce analgesia, acting in a neuroendocrine manner on various immune cells involved in immune regulation and enhancing immune function[73]. We, therefore, consider that H_2S enhances the inhibitory effect of SP on gastric motility by excitation of NTS neurons which are then transmitted to the DMV.

CONCLUSION

Our experiments revealed that CBSergic neurons affecting gastric function were present in the NTS and were activated by stress. Furthermore, exogenous H_2S in the NTS significantly inhibited gastric motility in rats, possibly by activating the TRPV1 pathway through NF-κB channels to release SP. This is the first study to report that H_2S in the NTS may regulate gastric function. It provides an important experimental basis for the clinical prevention and treatment of gastric ulcers.

ARTICLE HIGHLIGHTS

Research background

Recent studies have revealed that hydrogen sulfide is the third class of gas signaling molecules after nitric oxide (NO) and carbon monoxide (CO). The high level of endogenous hydrogen sulfide found in the brain, which is mainly produced by cystathionine beta-synthase, suggests that it may have a physiological function, and the nucleus tractus solitarius is important nucleus that regulates the function of internal organs, so we want to elucidate the role of hydrogen sulfide in the NTS in regulating gastric function in rats.

Research motivation

To investigate whether hydrogen sulfide in the nucleus tractus solitarius is involved in the regulation of gastric dysfunction by restraint water-immersion stress, this study will examine the role of hydrogen sulfide in the nucleus tractus solitarius in the regulation of gastric motility.

Research objectives

It is the first time to propose that hydrogen sulfide in the nucleus tractus solitarius has a regulatory effect on the gastric motility caused by restraint water-immersion stress, and to investigate its mechanism of action, which can not only elucidate the mechanism of regulation of gastric dysfunction by hydrogen sulfide in the nucleus tractus solitarius, and also provide an important experimental basis for the prevention and treatment of stress gastric ulcer from the central aspect in clinical practice.

Research methods

We used immunohistochemical, fluorescent double-labeling technique and restraint water-immersion stress model to confirm the involvement of hydrogen sulfide-producing cystathionine beta-synthase neurons in the nucleus tractus solitarius in the regulation of gastric function, and physiological methods to record changes in gastric motility before and after their brain injection.

Research results

After restraint water-immersion stress, cystathionine beta-synthase neurons containing c-Fos were significantly increased and gastric motility was inhibited in rats after nucleus tractus solitarius injection of NaHS, and this inhibitory effect was eliminated after pre-injection of transient receptor potential vanilloid 1 channels, NF-κB channel blockers, and NK1 receptor antagonists followed by NaHS injection.

Research conclusions

Injection NaHS into the nucleus tractus solitarius can inhibit gastric motility in rats and this effect may be mediated by TRPV1 and NK1 receptors *via* NF-κB channel-dependent activation.

Research perspectives

Our next step will be to continue our work on the effects of endogenous hydrogen sulfide in the nucleus tractus solitarius on gastric function.

Abstract

BACKGROUND

Prophylactic enterostomy surgery is a common surgical approach used to reduce the risk of anastomotic leakage in patients who have undergone partial intestinal resection due to trauma or tumors. However, the traditional interrupted suturing technique used in enterostomy closure surgery has several issues, including longer surgical incisions and higher incision tension, which can increase the risk of postoperative complications. To address these issues, scholars have proposed the use of a "gunsight suture" technique. This technique involves using a gunsight incision instead of a traditional linear incision, leaving a gap in the center for the drainage of blood and fluid to reduce the risk of infection. Building on this technique, we propose an improved gunsight suture technique. A drainage tube is placed at the lowest point of the incision and close the gap in the center of the gunsight suture, which theoretically facilitates early postoperative mobility and reduces the burden of dressing changes, thereby reducing the risk of postoperative complications.

AIM

To compare the effectiveness of improved gunsight suture technique with traditional interrupted suture in closing intestinal stomas.

METHODS

In this study, a retrospective, single-center case analysis was conducted on 270

patients who underwent prophylactic ileostomy closure surgery at the Department of Colorectal Surgery of Qilu Hospital from April 2017 to December 2021. The patients were divided into two groups: 135 patients received sutures using the improved gunsight method, while the remaining 135 patients were sutured with the traditional interrupted suture method. We collected data on a variety of parameters, such as operation time, postoperative pain score, body temperature, length of hospital stays, laboratory indicators, incidence of incisional complications, number of wound dressing changes, and hospitalization costs. Non-parametric tests and chi-square tests were utilized for data analysis.

RESULTS

There were no statistically significant differences in general patient information between the two groups, including the interval between the first surgery and the stoma closure [132 (105, 184) d *vs* 134 (109, 181) d, $P = 0.63$], gender ratio (0.64 *vs* 0.69, $P = 0.44$), age [62 (52, 68) years *vs* 60 (52, 68) years, $P = 0.33$], preoperative body mass index (BMI) [23.83 (21.60, 25.95) kg/m² *vs* 23.12 (20.94, 25.06) kg/m², $P = 0.17$]. The incidence of incision infection in the improved gunsight suture group tended to be lower than that in the traditional interrupted suture group [($n = 2/135$, 1.4%) *vs* ($n = 10/135$, 7.4%), $P < 0.05$], and the postoperative hospital stay in the improved gunsight suture group was significantly shorter than that in the traditional interrupted suture group [5 (4, 7) d *vs* 7 (6, 8) d, $P < 0.05$]. Additionally, the surgical cost in the modified gunsight suture group was slightly lower than that in the traditional suture group [4840 (4330, 5138) yuan *vs* 4980 (4726, 5221) yuan, $P > 0.05$], but there was no significant difference in the total hospitalization cost between the two groups.

CONCLUSION

In stoma closure surgery, the improved gunsight technique can reduce the incision infection rate, shorten the postoperative hospital stay, reduce wound tension, and provide better wound cosmetic effects compared to traditional interrupted suture.

Key Words: Enterostomy; Abdominal wound closure technique; Suture techniques; Surgical wound infection; Hospital costs; Hospital stay

Core Tip: Based on the gunsight technique, we proposed an improved gunsight closure method for enterostomy surgery in this study. This closure method can reduce the incision tension, lower the risk of incision infection, decrease the length of hospital stay, and reduce hospitalization costs. Additionally, it requires less postoperative wound care and provides a better cosmetic outcome.

INTRODUCTION

Patients with colon cancer, inflammatory bowel disease, or intestinal trauma may require partial bowel resection. However, a simple one-stage surgery may result in complications such as anastomotic leakage, significantly affecting patient health and increasing the economic burden. To reduce this risk, a prophylactic intestinal stoma is often performed in patients at high risk for anastomotic leakage during routine surgery[1,2]. After 2-3 mo, the patient's condition was evaluated and a second-stage anastomosis was performed to restore gastrointestinal continuity[3]. Although prophylactic intestinal stoma can reduce complications such as anastomotic leakage[4], second-stage anastomotic surgery also has its own risks, including incision infection, intestinal obstruction, and incisional hernia[5-8]. Unlike Class II incisions in other gastrointestinal surgeries, the skin around the colostomy site is continuously exposed to feces, classifying it as a Class III incision. Incision infections are particularly common, with an incidence of up to 41% reported[9]. Due to factors, such as contamination of the intestinal contents, preventing incision infections may be challenging.

According to guidelines published by different countries, surgical site infection increases hospital stay and the risk of death by 2-11 times[10-13]. To address this issue, researchers have proposed improved surgical methods, such as placing drainage tubes at the incision site, selecting special suture materials, and modifying the suture technique[14-19]. Some special antimicrobial suture materials and techniques are highly regarded; however, there is currently no recognized surgical procedure to reduce the incidence of incision infections. Studies have shown that compared with traditional interrupted sutures, the purse-string suture technique can effectively drain subcutaneous fluid and significantly reduce the incidence of incision infections. However, owing to the high tension at the center of the incision[20-22], the healing

process of the abdominal incision after closure may take up to 3 wk.

In 2010, Lim *et al*[23] proposed a suture technique called "gunsight suture" that can reduce tension at the incision site and leave a smaller drainage gap at the center of the incision. This technique can effectively drain subcutaneous blood and fluid, reduce infection rate, and provide good cosmetic results with minimal scarring[20,24,25]. However, it is difficult to drain all the subcutaneous blood and fluid by placing a drainage tube or strip at an angle in the central gap. In addition, the vertical placement of the drainage tube significantly affects the postoperative activity range, and frequent dressing changes are required owing to leakage at the center of the incision, which can cause serious psychological and economic burdens on patients. Moreover, fixing the drainage tube in the central gap of the gunsight suture incision is challenging; therefore, drainage strips are often used, resulting in a shorter drainage time and a slightly inferior drainage effect.

Therefore, in our hospital, we reserve a smaller gap (approximately 0.2 cm) at the center and place a drainage tube through the entire subcutaneous gap in a small incision next to the incision. The catheter was left in place for approximately 14 d and removed after the incision healed (Figure 1). This design effectively drained the subcutaneous fluid and reduced the local tension at the incision site (Figure 1C). Theoretically, it can reduce the incidence of incision infection, shorten the postoperative hospital stay, provide better cosmetic results, and reduce hospitalization costs. To verify the significance of the improved gunsight suture method in clinical practice, data were collected from 270 patients who underwent ileostomy closure surgery between April 2017 and December 2022. Our findings are reported below.

MATERIALS AND METHODS

Study design

This retrospective case-control study was conducted between April 2017 and December 2022 to evaluate the effectiveness of a modified surgical technique for ileostomy closure and lateral ileal anastomosis. This study was approved by the Ethics Committee of Qilu Hospital, Shandong University (Approval No: KYLL-2020-120).

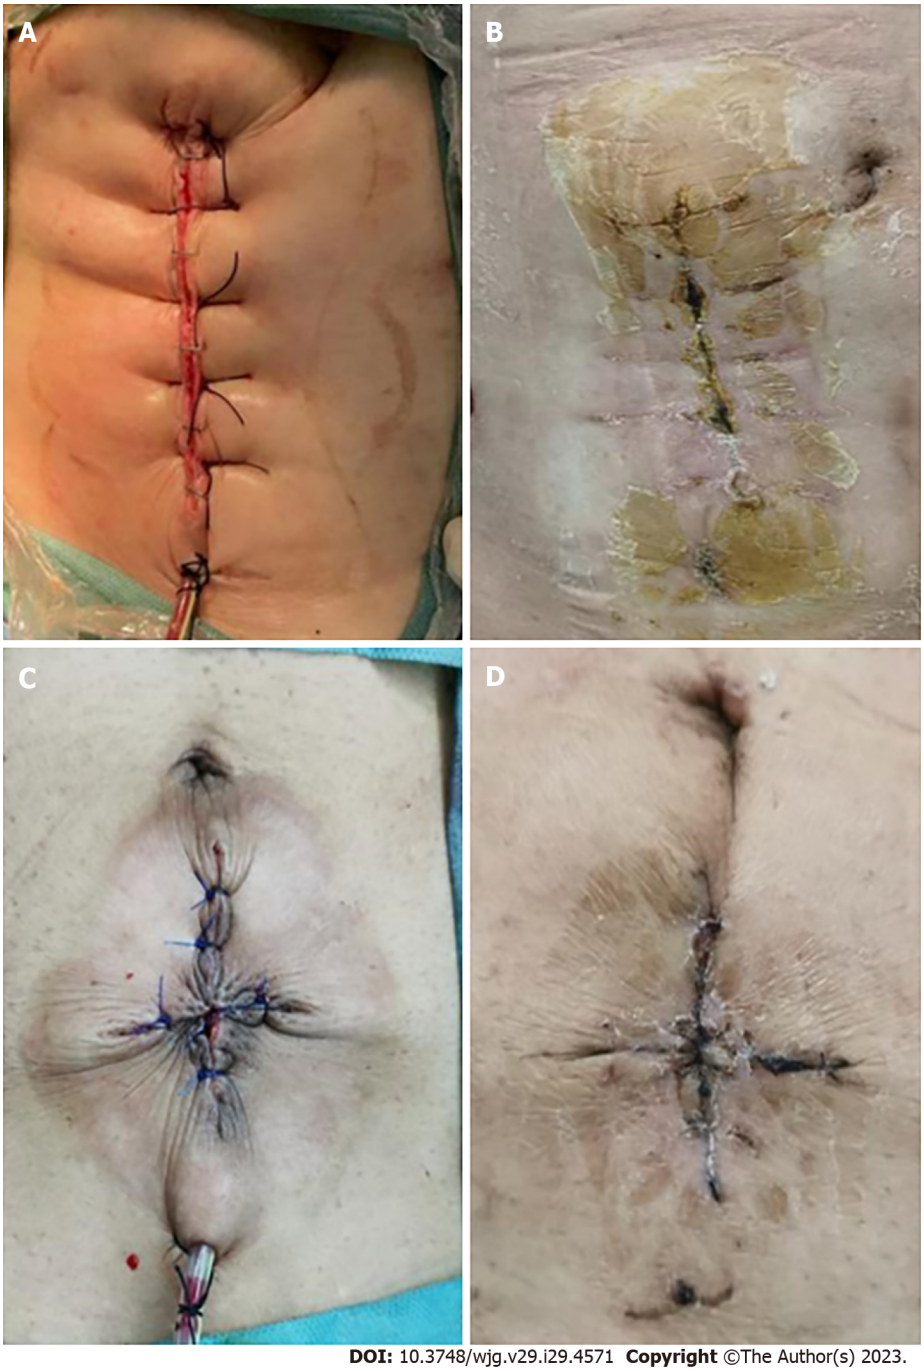
Participants

A total of 270 patients who underwent ileostomy closure and ileo-ileal lateral anastomosis surgery at the Department of Colorectal Surgery at Qilu Hospital were included in this study.

Inclusion criteria: Age > 18 years, patients who underwent ileostomy closure and ileo-ileal lateral anastomosis surgery, no stenosis of the intestinal lumen near the stoma on preoperative colonoscopy, and no concomitant colitis.

Exclusion criteria: Patients who required hernia repair due to concomitant incisional hernia, patients with mental dysfunction, and patients with other tumors, serious illnesses, or severe abdominal adhesions.

Preoperative preparation



The day before surgery, the patient underwent mechanical bowel preparation with polyethylene glycol and rectal cleansing enema. This procedure improved the patient's general condition, eliminated distant obstruction, and controlled the inflammation around the stoma. Prophylactic antibiotics were administered 30 min before surgery to prevent infection.

Surgical procedure

After the patients were fully anesthetized, they were placed in the supine position. First, a 2-0 silk suture was used to close the ileostomy and prevent intestinal contents from spilling out during the reduction process. After re-disinfecting, an appropriate stoma incision was made using the suturing method. The tissues surrounding the stoma were separated layer by layer to avoid damage to the intestinal wall. The freed intestine was then separated in all directions, and the direction with less adhesion was chosen to cut open the peritoneum and enter the abdominal cavity where the adhesions were loosened. The two ends of the freed intestinal tube were pulled out of the abdominal wall by > 5 cm, and a linear cutting closure device was used to perform a side-to-side anastomosis of the proximal and distal ends of the ileum to restore intestinal continuity. The 4-0 absorbable suture (Vycrl, Ethicon) was used to intermittently suture and reinforce the ileal muscularis layers. The bowel is returned to the abdominal cavity without placement of an abdominal drainage tube. Subsequently, a continuous suture is performed using 2-0 absorbable antibacterial sutures (VCP-603) to close the peritoneum and rectal sheath, leaving a subcutaneous drainage tube in place. The appropriate skin closure method is chosen based on the group.

Simple interrupted suture group (A, B): No or only minimal trimming is required at the site of repositioning. A 2-0 suture is used for full-thickness vertical mattress suturing, with a needle margin of 1 cm, a stitch spacing of 2 cm, and avoiding residual ineffective cavities. Reinforcement sutures can be placed between every two stitches, with a needle margin of 0.5 cm. This approach can better support skin closure and reduce tension on the surgical incision. After disinfection, sterile auxiliary materials are used for compression and bandaging.

Modified gunsight suture group (C, D): The incision was marked at the 3, 6, 9, and 12 o'clock positions, and the skin tissue between the marked points was triangularly excised to form a gunsight incision. A 2-0 silk suture was used to suture the subcutaneous tissue at the four marked points, and the skin was tightened and knotted after closure. The central part of the incision was brought together as closely as possible without leaving or leaving a gap of approximately

0.2 cm. Finally, a 2-0 silk suture was used to suture the midpoints of the four edges of the gunsight incision to complete the reinforcement. After disinfection, sterile auxiliary materials were applied for compression and bandaging.

Observation indicators

The patients' baseline data included age, sex, surgery time, postoperative pain score, postoperative temperature changes, hospitalization time, postoperative laboratory indicators, incision infection rate, and hospitalization costs. The temperature was recorded for 3 d after surgery. The Numeric Rating Scale (NRS) was used to assess the pain scores.

Statistical analysis

Data analysis was performed using the SPSS 26 statistical software. Normally distributed metric data were expressed as mean ± SD and intergroup comparisons were performed using independent sample *t*-tests. Non-normally distributed quantitative data were expressed as median (interquartile range) [M (IQR)], and intergroup comparisons were performed using the Mann-Whitney *U* test. Categorical variables were expressed as frequencies, and intergroup comparisons were

performed using Chi-squared test or Fisher's exact test. Statistical significance was set at $P < 0.05$.

RESULTS

The study included 270 patients who underwent stoma closure surgery at Qilu Hospital. All the patients completed the procedure without anastomotic leakage. Among them, 135 patients received modified Gunsight sutures, and 135 received traditional simple interrupted sutures. Statistical comparisons showed no significant differences in sex ratio, age, preoperative BMI, or the proportion of patients with diabetes between the two groups (Table 1).

Laboratory indicators included the systemic immune inflammation index (SII), red blood cell count, and hemoglobin levels. The SII was calculated as the platelet count multiplied by the ratio of neutrophils to lymphocytes and was used as a simple and effective evaluation index to assess the immune and inflammatory status and prognosis of patients before and after colorectal surgery. Previous studies have shown that the SII is an independent risk factor for the prognosis of colorectal cancer patients. There were no statistically significant differences in the laboratory indicators between the two groups[26-28].

According to the comparison of the main observation indicators (Table 2), the incidence of surgical site infection (SSI) in the modified gunsight suture group was lower than that in the traditional simple interrupted suture group [(n = 2/135, 1.4%) *vs* (n = 10/135, 7.4%), $P < 0.05$], and the length of hospital stay and the number of dressing changes were also significantly better than those in the traditional simple interrupted suture group. However, there were no significant differences in the postoperative body temperature, pain score, or postoperative first bowel gas passage time between the two groups ($P > 0.05$). In addition, we compared the surgical and hospitalization costs between the two groups and found that the surgical cost in the modified Gunsight suture group was slightly lower than that in the traditional suture group [4840 (4330, 5138) yuan *vs* 4980 (4726, 5221) yuan, $P > 0.05$], but there was no significant difference in the total hospitalization cost between the two groups. Furthermore, scar formation after incision healing was significantly lower in the modified Gunsight suture group than in the control group (Figure 1B and D).

DISCUSSION

During stoma closure surgery in patients who undergo preventive ostomy, there is a high incidence of incisional infections due to environmental contamination, subcutaneous fluid accumulation, and other reasons, with reported rates ranging from 3% to 41%[29]. This delay in wound healing can severely affect patients' quality of life. To reduce the risk of postoperative incisional infections, many clinicians have proposed improvements in the suture method of the incision [20], among which the modified Gunsight suture technique has shown promise.

Reid *et al*[30] conducted a randomized controlled clinical trial involving 61 patients to compare postoperative complications of the purse-string suture technique with those of the traditional simple interrupted suture technique. They found that purse-string sutures had fewer surgical site infections than conventional sutures, with two out of 30 patients experiencing infections compared to 12 out of 31 patients in the conventional suture group[30]. In a multicenter prospective study by Han *et al*[20], the effectiveness of the gunsight and purse-string suture techniques in closing skin incisions was compared. This study found that the gunsight suture technique has a lower incision infection rate, similar to that of the purse-string suture technique. Additionally, patients in the Gunsight suture group had shorter incision healing times and higher patient satisfaction[20]. In a case-review study of 233 patients, Li *et al*[31] compared the clinical characteristics between patients with traditional simple interrupted sutures and those with gunsight sutures. The incidence of surgical site infections was significantly lower in the Gunsight suture group than in the traditional simple interrupted suture group. Gunsight sutures were identified as an independent protective risk factor for surgical site infections, with a dominance ratio of 0.212 and a P value of 0.048.

This study showed that our modified Gunsight suture technique is associated with a lower incidence of surgical site infection when compared with the traditional simple interrupted suture technique. Specifically, 10 patients in the traditional simple interrupted suture group experienced postoperative incisional infections, with three of these patients requiring a second surgical intervention and wound resuturing after failed conservative treatment. In contrast, only two patients in the modified gunsight suture group developed postoperative incisional infections, which resolved after conservative treatment. These findings provide evidence supporting the effectiveness of the modified Gunsight suture technique in reducing the risk of incisional infection.

In addition to the reduced incidence of SSI, patients in the modified Gunsight suture group also experienced shorter postoperative hospitalization days than those in the simple interrupted suture group. This difference in hospitalization time may be due to an increased risk of incision infection and the need for more frequent and longer wound care, such as wet alcohol dressing, in the simple interrupted suture group.

Furthermore, the surgical costs for patients in the gunsight suture group were slightly lower than those in the traditional suture group, and there was no significant difference in total hospitalization costs between the two groups. Furthermore, there were no significant differences between the two groups in terms of postoperative pain scores, exhaust time, and related laboratory indicators. Postoperative pain scores were evaluated using the NRS, with most patients scoring between 1 and 3 indicating mild pain. This may explain the lack of significant differences between the two groups. Additionally, the postoperative exhaust time and laboratory test results were not significantly associated with wound closure.

Table 1 General information

Group	Gunsight suture	Traditional suture	Statistical quantity	*P* value
Case number	135	135	-	-
Male (%)	86 (63.7)	92 (68.1)	$\chi^2 = 0.59$	0.440
Age in yr (IQR)	62 (52, 68)	60 (52, 68)	$Z = -0.97$	0.332
BMI (IQR)	23.83 (21.60, 25.95)	23.12 (20.94, 25.06)	$Z = -1.377$	0.169
DM (%)	17 (12.6)	23 (17.0)	$\chi^2 = 1.06$	0.300
Length of time between two surgeries, d (IQR)	132 (105, 184)	134 (109, 181)	$Z = -0.489$	0.625

BMI: Body mass index [a commonly used index to assess the relationship between weight and height, usually expressed in units of kilograms per square meter (kg/m²)]; DM: Diabetes mellitus (a chronic metabolic disease characterized by prolonged high blood sugar levels); IQR: Interquartile range [a statistical measure used to describe the spread of a dataset, it represents the span of the middle 50% of the data and is calculated as the difference between the first quartile (Q1) and the third quartile (Q3)].

Table 2 Patient observation indicators

Group		Gunsight suture (IQR)	Traditional suture (IQR)	Statistical quantity	*P* value
SII (postoperative/preoperative)		3.24 (2.16, 4.78)	3.14 (2.10, 5.47)	$Z = -0.592$	0.554
Red blood cell (postoperative/preoperative)		0.90 (0.84, 0.95)	0.91 (0.87, 9.96)	$Z = -1.445$	0.148
Haemoglobin (postoperative/postoperative)		0.91 (0.85, 0.97)	0.92 (0.88, 0.96)	$Z = -1.231$	0.218
SSI (%)		2 (1.4)	10 (7.4)	$\chi^2 = -5.580$	0.018
Postoperative intestinal exhaust time (d)		3 (2, 3)	3 (2, 3)	$Z = -1.171$	0.242
Total cost of hospitalization (Yuan)		33569 (30545, 36757)	32782 (29134, 36199)	$Z = -1.199$	0.230
Cost of surgery (Yuan)		4840 (4330, 5138)	4980 (4726, 5221)	$Z = -2.745$	0.006
Number of dressing changes for surgical incision		2 (1, 3)	4 (3, 6)	$Z = -2.460$	< 0.001
Operation time		80 (70, 90)	80 (70, 85)	$Z = -1.210$	0.220
Early postoperative pain score (NRS)	DAY1	3 (3, 3)	3 (3, 3)	$Z = -1.145$	0.252
	DAY2	2 (2, 2)	2 (2, 2)	$Z = -0.044$	0.965
	DAY3	2.0 (1.5, 2.0)	1.5 (1.5, 2.0)	$Z = -0.603$	0.547
Early postoperative body temperature (°C)	DAY1	36.7 (36.4, 36.9)	36.7 (36.4, 36.9)	$Z = -0.476$	0.634
	DAY2	37.4 (37.1, 37.9)	37.6 (37.1, 38.1)	$Z = -1.769$	0.077
	DAY3	37.1 (36.9, 37.4)	37.20 (36.85, 37.50)	$Z = -1.385$	0.166
	DAY4	36.9 (36.7, 37.1)	36.9 (36.7, 37.3)	$Z = -1.315$	0.189
Postoperative hospital stay (d)		5 (4, 7)	7 (6, 8)	$Z = -5.181$	< 0.001

SII: Systemic immune inflammation index (a composite index based on peripheral blood neutrophil, lymphocyte, and platelet counts, used to reflect the systemic inflammatory response in patients with various diseases); SSI: Surgical site infection (an infection that occurs after surgery in the part of the body where the surgery took place); Postoperative Pain Score (NRS): Numeric Rating Scale (a commonly used tool to assess the intensity of postoperative pain. It consists of a scale from 0 to 10, where 0 represents no pain and 10 represents the worst possible pain).

CONCLUSION

The modified Gunsight suture technique is an effective method for reducing the risk of surgical site infection and shortening postoperative hospitalization. Although this technique may require additional surgical steps, the reduced incidence of SSI and lower surgical costs make it a viable option for wound closure. Further research is needed to investigate the potential benefits of this technique in larger patient populations and evaluate its long-term effectiveness.

ARTICLE HIGHLIGHTS

Research background

In the traditional intestinal stoma closure surgery, the interrupted suturing technique used has some issues, such as longer incisions and higher tension on the incision, which may increase the risk of postoperative complications. To address these concerns, scholars have proposed the use of the "gunsight suture" technique. This method involves using a gun-shaped incision instead of the conventional linear incision, leaving a gap in the center for drainage of blood and fluids to reduce the risk of infection. Building on this, we have proposed an improved gunsight suture technique.

Research motivation

Motivated by the need to enhance patient outcomes, this study focuses on developing an improved prophylactic stoma reversal abdominal closure suturing technique. Our goal is to reduce incision infection rates and alleviate patient burden, improving a key issue in stoma closure methods. We strive to contribute to the advancement of surgical research and help shape safer and more effective surgical practices in the future.

Research objectives

To compare the outcomes of the improved gunsight suture technique with traditional interrupted suture techniques in enterostomy closure. The objective is to minimize complications and related burdens following prophylactic ileostomy closure.

Research methods

This study analyzed 270 patients who underwent prophylactic ileostomy closure surgery at Qilu Hospital from April 2017 to December 2021. The patients were divided into two groups, one group received sutures using the improved gunsight method while the other group was sutured with the traditional interrupted suture method, and data on various parameters such as operation time, postoperative pain score, and hospitalization costs were collected. Non-parametric tests and chi-square tests were used for data analysis.

Research results

This retrospective study compared two suture methods for prophylactic ileostomy closure surgery in 270 patients. The modified gunsight suture group had better outcomes, including lower incidence of surgical site infections, shorter hospital stays, and fewer dressing changes than the traditional simple interrupted suture group. Laboratory parameters, postoperative temperature, pain scores, and time to first bowel gas passage did not differ significantly. The modified gunsight suture group had slightly lower surgical costs and significantly lower scar formation after incision healing.

Research conclusions

The modified Gunsight suture technique reduces the risk of surgical site infection and shortens postoperative hospitalization. Despite requiring additional surgical steps, the technique lowers surgical costs and is a viable option for wound closure.

Research perspectives

Despite the study's retrospective design and challenges in obtaining accurate data on bowel obstruction incidence and long-term complications like incisional hernias, it provides valuable insights. However, the single-center data source may introduce bias during data collection and analysis. Further research on larger patient populations is needed to evaluate the technique's long-term effectiveness and potential benefits.

Abstract

BACKGROUND

Osteoporosis is an extrahepatic complication of primary biliary cholangitis (PBC) that increases the risk of fractures and mortality. However, Epidemiological studies of osteoporosis in patients with PBC in China and the Asia-Pacific region is lack.

AIM

To assess the prevalence and clinical characteristics of osteoporosis in Chinese patients with PBC.

METHODS

This retrospective analysis included consecutive patients with PBC from a tertiary care center in China who underwent bone mineral density (BMD) assessment using dual-energy X-ray absorptiometry between January 2013 and December 2021. We defined subjects with T-scores ≤ -2.5 in any sites (L1 to L4, femoral neck, or total hip) as having osteoporosis. Demographic, serological, clinical, and histological data were collected. Independent risk factors for osteoporosis were identified by multivariate logistic regression analysis.

RESULTS

A total of 268 patients with PBC [236 women (88.1%); mean age, 56.7 ± 10.6 years; 163 liver biopsies (60.8%)] were included. The overall prevalence of osteoporosis in patients with PBC was 45.5% (122/268), with the prevalence of osteoporosis in women and men being 47.0% and 34.4%, respectively. The prevalence of osteoporosis in postmenopausal women was significantly higher than that in premenopausal women (56.3% *vs* 21.0%, $P < 0.001$). Osteoporosis in patients with PBC is associated with age, fatigue, menopausal status, previous steroid therapy, body mass index (BMI), splenomegaly, gastroesophageal varices, ascites, Mayo

risk score, histological stage, alanine aminotransferase, albumin, bilirubin, platelet and prothrombin activity. Multivariate regression analysis identified that older age, lower BMI, previous steroid therapy, higher Mayo risk score, and advanced histological stage as the main independent risk factors for osteoporosis in PBC.

CONCLUSION

Osteoporosis is very common in Chinese patients with PBC, allowing for prior screening of BMD in those PBC patients with older age, lower BMI, previous steroid therapy and advanced liver disease.

Key Words: Primary biliary cholangitis; Osteoporosis; Bone mineral density; Dual-energy X-ray absorptiometry; Prevalence; Chinese

Core Tip: In this paper, we reported for the first large-sample study to explore the prevalence and potential risk factors for osteoporosis in Chinese patients with primary biliary cholangitis (PBC). The prevalence of osteoporosis in Chinese patients with PBC was 45.5%. Osteoporosis in PBC is strongly associated with older age, lower body mass index, previous steroid use, the severity of liver disease, and advanced histological stage. This study provides reference information for future PBC-related guideline development and public policy formulation in China and the Asia-Pacific region.

INTRODUCTION

Primary biliary cholangitis (PBC, also known as primary biliary cirrhosis) is a chronic immune-mediated, progressive cholestatic liver disease characterized by nonsuppurative destructive intrahepatic cholangitis focused on the small bile ducts, which mainly affects middle-aged women over 40 years old, typically manifested as fatigue, pruritus and even metabolic bone disease[1,2]. Currently, ursodeoxycholic acid (UDCA) is its first-line treatment drug, and untreated PBC may eventually lead to cirrhosis and liver failure, requiring liver transplantation[3]. Moreover, PBC affects all races and ethnicities with significant regional differences[1,4]. It is estimated that at least 1 in 1000 women older than 40 years globally has PBC[5], and the prevalence and incidence of PBC in Europe and the United States are higher than that in the Asia-Pacific region[6]. However, the prevalence of PBC in China ranks second only to Japan in the Asia-Pacific region and is increasing[6].

Osteoporosis is a disease characterized by decreased bone density or bone loss, leading to an increased risk of fracture [7]. The prevalence of osteoporosis in patients with PBC is at least three times that of age- or sex-matched controls[8,9]. Thus, osteoporosis is considered an extrahepatic complication of PBC[10]. Unlike increased bone resorption in postmenopausal osteoporosis, osteoporosis in PBC is mainly caused by decreased bone formation[11]. Moreover, recently, a large cohort study indicated that the risk of fracture and post-fracture mortality of PBC patients were significantly higher than those of the control group in the general population[12]. Prevention and timely diagnosis of osteoporosis are key to reducing the associated complications for patients with PBC. With the increasing prevalence of PBC, most likely due to the improvement of diagnosis and awareness, it is likely that the incidence and prevalence of PBC-related osteoporosis will also increase[11]. According to previous studies from Europe, Africa and North America, the prevalence of osteoporosis in patients with PBC is approximately 30% (range 20%-52%) and higher in postmenopause or advanced stages of liver disease[8,9,13-18], and up to 44% of patients waiting for liver transplantation[16]. However, to our knowledge, in China and other Asia–Pacific regions, the prevalence and clinical features of osteoporosis in patients with PBC, including men and women, have not been well defined.

Therefore, this study aimed to investigate the prevalence and clinical features of osteoporosis and independent risk factors associated with osteoporosis using bone mineral density (BMD) detected by dual-energy X-ray absorptiometry (DEXA) in a large series of Chinese patients with PBC.

MATERIALS AND METHODS

Study design

We carried out a retrospective observational study of all consecutive PBC patients between January 2013 and December 2021 from Beijing Ditan Hospital, China. The baseline date was the first admission with a diagnosis of PBC and completion of a BMD examination in the hospital. The study protocol was approved by the Ethics Committee of Beijing

Ditan Hospital, Beijing, China (No. DTEC-KT2022-010-01).

The inclusion criteria were as follows: (1) Age greater than 18 years old; (2) at least two of the following: Elevated γ-glutamyl transpeptidase (GGT) or alkaline phosphatase (ALP), positive antimitochondrial antibody (AMA) or gp210, sp100, and pathological features of non-suppurative cholangitis or small bile duct destruction[19]; and (3) complete BMD examination using DEXA method at baseline. The exclusion criteria were as follows: (1) Alcoholic liver disease, non-alcoholic fatty liver disease, viral hepatitis, drug-induced liver injury, or inherited liver disease; (2) liver transplantation, liver cancer, or other malignant lesions; (3) evidence of intrahepatic or extrahepatic biliary obstruction; (4) severe cardiac or renal insufficiency; (5) previous or current hormone replacement therapy; and (6) pregnancy or breast-feeding.

Data collection

A history of UDCA or steroid treatment, prior fractures, and comorbidities were recorded. Symptoms of chronic cholestasis, such as fatigue and pruritus, and physical signs of liver disease, such as splenomegaly, hepatomegaly, edema and ascites, were collected. Blood was collected for hematological, biochemical and immunological tests after an overnight fast and tested at the Laboratory of Beijing Ditan Hospital using standard methods. These laboratory parameters include serum bilirubin, albumin, ALP, GGT, calcium, phosphorus, creatinine, 25-hydroxyvitamin D, aspartate aminotransferase, alanine aminotransferase (ALT), prothrombin activity (PTA), platelet count (PLT), immunoglobulin G, serum immunoglobulin M, and autoantibodies [AMA, antinuclear antibody (ANA), anti-centromere antibody (ACA), gp210, and sp100] were measured at the time of the first BMD examination. Age, smoking status, body mass index (BMI), menopausal status, duration of PBC, histological stage, and cirrhosis status were recorded. Esophagogastroscopy and abdominal ultrasonography were also evaluated. The Mayo risk score (MRS) was calculated using the previous algorithm[20]. The liver histological stage was determined according to Ludwig's criteria[21].

BMD measurement

Certified technicians measured BMD at the lumbar spine (L1 to L4), femoral neck, and total hip using a DEXA scanner (Lunar, GE Healthcare, United States). The diagnoses of osteopenia and osteoporosis were based on the World Health Organization thresholds: T-score is between -1.0 and -2.5 and ≤ -2.5, respectively[22]. T-score were presented as absolute values (g/cm^2) and the number of SD lower than the average peak value of young sex-matched normal individuals. Z-score are also presented as the number of SD from normal values corrected for sex and age. We defined patients with T-scores ≤ -2.5 in any sites (L1 to L4, femoral neck, or total hip) as having osteoporosis[23].

Statistical analysis

All statistical analyses were performed using SPSS 20.0 (SPSS Inc., Chicago, IL, United States). Quantitative data are expressed as mean ± SD or median and interquartile range, and categorical data are expressed as frequencies with percentages. Student *t*-test or Mann-Whitney U test was used to analyse differences in continuous variables. Chi-squared or Fisher's exact tests were used for categorical variables. The independent risk factor of significant variable associated with osteoporosis with (P value < 0.05) in univariate analyses was determined using multivariate logistic regression with the backward stepwise selection method (the criteria for entering and removing variables were P < 0.05 and > 0.10, respectively). Statistical significance was defined as a two-tailed P value < 0.05.

RESULTS

Demographic and clinical characteristics

From January 2013 to December 2021, we retrospectively enrolled 268 subjects in the final analysis who had undergone BMD examination by DEXA scanner from 1272 patients with PBC. Figure 1 summarizes the enrolment process. The demographic, clinical, serological, histological, and BMD characteristics of all patients with PBC are shown in Table 1. The mean age of the overall patients was 56.7 ± 10.6 years (range 29-94 years). The ratio of women:men was 7.38:1. Liver biopsies were performed in 60.8% of patients. Among the women, 73.7% were postmenopausal. Prior fractures had occurred in 11 patients, including six vertebral fractures and five peripheral fractures. Compared with women, men PBC patients had more smoker, UDCA-treated patients, fewer ACA positive, lower serum calcium, and higher serum creatinine as well as BMD absolute value (all P < 0.05). However, there was no difference between men and women in the T- and Z-score (P > 0.05).

Prevalence of osteoporosis

There were significant differences in the BMD value, T-score, and Z-score at any sites (L1 to L4, femoral neck, or total hip) in patients with osteoporosis compared to those without (all P < 0.001) (Supplementary Table 1). The prevalence of osteoporosis and osteopenia in the lumbar spine (L1 to L4), femoral neck and total hip were 40.3% and 35.8%, 29.1% and 45.9%, 16.8% and 47.4%, respectively (Table 1). Overall, the prevalence of osteoporosis was 45.5% (122/268) in all PBC patients, considering the lowest BMD values at the lumbar spine, femoral neck and total hip (Table 1 and Supplementary Table 2). The prevalence of osteoporosis 47.0% (111/236) was higher among women than among men 34.4% (11/32), but it was not statistically significant (P = 0.177) (Supplementary Table 2 and Figure 2). The prevalence of osteoporosis in postmenopausal women was significantly higher than that in premenopausal women (56.3% *vs* 21.0%, P < 0.001) (Supplementary Table 2 and Figure 2). The prevalence of osteoporosis was assessed according to age, cirrhosis status, histological stage and BMI. Regardless of overall patients or only women patients, the prevalence of osteoporosis

Figure 2 Prevalence of osteoporosis in different subgroups for overall patients with primary biliary cholangitis (*n* = 268). A: Sex; B: Age; C: Cirrhosis status; D: Histological stage; E: Body mass index.

Risk factors of osteoporosis

Table 2 shows the results of univariate analysis of the association between osteoporosis and potential risk factors in patients with PBC. In the univariate analysis, osteoporosis was correlated with older age, fatigue, postmenopausal status, previous steroids use, splenomegaly, gastroesophageal varices, ascites, advanced histological stage (III or IV), higher MRS and bilirubin levels, and lower BMI, ALT, albumin, PTA, and PLT regardless of overall or women patients (all $P < 0.05$). However, there was no association between osteoporosis and other biochemical parameters or immunological indicators such as immunoglobulin, gp210, sp100, ACA, PBC-autoimmune hepatitis (AIH) overlap syndrome, or extrahepatic autoimmune diseases.

In multivariate analysis, older age [odds ratio (OR), 1.80; 95%CI (confidence interval): 1.33-2.44, $P < 0.001$] per 10 years, gastroesophageal varices (OR, 2.11; 95%CI: 1.14-3.92, $P = 0.018$), lower BMI (OR, 0.85; 95%CI: 0.77-0.93, $P < 0.001$), previous steroid use (OR, 4.19; 95%CI: 1.66-10.56, $P = 0.002$), higher MRS (OR, 1.36; 95%CI: 1.08-1.71, $P = 0.009$) were the independent risk factors associated with the presence of osteoporosis in all patients with PBC (Table 3). In addition, when the histological stage was included in the multivariate analysis, higher bilirubin (OR, 1.20; 95%CI: 1.0-1.42, $P = 0.044$) and advanced histological stage (OR, 3.74; 95%CI: 1.60-8.77, $P = 0.002$) gained statistical significance, but the effects of gastroesophageal varices, previous steroid use, and higher MRS were removed. When menopausal status was included in the multivariate analysis (only for female patients), the splenomegaly (OR, 2.62; 95%CI: 1.18-5.80, $P = 0.018$) and postmenopausal (OR, 2.92; 95%CI: 1.02-8.38, $P = 0.046$) gained statistical significance. When both menopausal status and histological stage were included in the multivariate analysis, advanced histological stage, older age, lower BMI, previous

DISCUSSION

To our knowledge, this observational study is the largest population study on BMD in PBC among currently published studies, whether in China, the Asia-Pacific region, or globally. Moreover, this is the first large-sample study to explore the prevalence and potential risk factors for osteoporosis in Asian patients with PBC. PBC patients with advanced stage (Ludwig III/IV) had more than 2-fold increased risk of osteoporosis compared to patients with early stage (Ludwig I/II). The main independent risk factors identified for osteoporosis include older age, lower BMI, previous steroid use, liver disease severity determined by the MRS, and advanced histological stage. These factors are consistent with those of previous studies in Europe and the United States[8,9].

A recent meta-analysis indicated that the risk of osteoporosis increased by 1.8 times in PBC patients compared with non-PBC participants[24]. Similar to this result, our study indicated a 2.3-time increased risk of osteoporosis in PBC patients aged 40 years or older, accounting for 95% of the total patients, compared to age-matched controls in China[23]. However, by searching the literature, we found that since 2001, the prevalence of PBC osteoporosis evaluated by DEXA has been verified in European, African, and American populations but not in Asian populations (Supplementary Table 3). As is well known, genetic factors play a crucial role in the pathogenesis of PBC[1], it is imperative to explore the prevalence of PBC osteoporosis in Asian populations. The findings of our study fill the gap in the epidemiological data on PBC-related osteoporosis in China and Asia. Notably, in our study, the prevalence of osteoporosis (45.5%) in PBC patients was higher than that of PBC patients in Europe and America (approximately 30%). The reason for this difference may be ethnic differences or a high proportion of patients with cirrhosis (60.1%) or decompensated cirrhosis (40.3%) in our study. However, the prevalence of osteoporosis in noncirrhotic PBC patients (23.4%) in our study was similar to that reported in Europe and the United States.

It has been recognized that glucocorticoid administration can significantly increase the risk of osteoporosis and bone fragility[25]. Consistently, our study found that the osteoporosis rate of PBC patients previously treated with steroid was significantly higher than that of patients without steroid treatment (71.9% *vs* 41.0%, $P = 0.001$). However, although many patients in our study were treated with UDCA (64%), it had no effect on the prevalence of osteoporosis. Previous studies have also shown that the treatment of PBC itself has not been shown to improve BMD[10]. In addition, PBC-related osteoporosis is strongly correlated with the severity of liver disease[8,9,14]. Our study results also showed that the more severe liver disease determined by MRS and histological stage in PBC, the more prone the individual is to osteoporosis. Moreover, the univariate analysis in this study demonstrated that osteoporosis in PBC was related to fatigue, higher bilirubin, lower albumin, PTA, and features of portal hypertension, including splenomegaly, gastroesophageal varices, ascites and thrombocytopenia, which are also common clinical indicators of liver disease severity. Moreover, although the pathogenesis of hepatic osteodystrophy has not been clarified, it is generally believed that chronic cholestasis itself may lead to bone loss in PBC patients[14]. Bilirubin inhibits the function of osteoblasts in vitro, which may be related to the low bone formation rate of PBC patients[26]. In our study, bilirubin levels were also statistically significant when the histological stage was considered as a variable in multivariate analysis. Similarly, Menon *et al*[9] found that higher baseline bilirubin level rather than the histological stage was the only variable independently related to bone loss rate

after 3 years of follow up[9].

In addition, lower BMI and older age are recognized risk factors for osteoporosis in postmenopausal women as well as in the general population[27]. Our study also verified the association between lower BMI and older age in PBC and osteoporosis, thus further proving that this may be associated with similar pathogenesis in the general population. However, although the menopausal status was not statistically significant when including histological stage in our multivariate analysis, it was selected as an independent indicator of osteoporosis when excluding histological stage from the model, indicating that histological stage captured the impact of menopausal status when the two variables competed in the model. Interestingly, lower ALT levels were also found to be related to a higher osteoporosis rate in the current univariate analysis, which is similar to our previous study that indicated that the biochemical response rate of PBC patients with lower ALT levels at baseline were worse than that of patients with higher ALT levels[28]. However, the ALT level was not an independent factor of osteoporosis in multivariate analysis.

In addition, one advantage of our study was that it explored the correlation between immune indicators and PBC osteoporosis, which has not been discussed in previous studies. Anti-gp210 and sp100 antibodies are two specific ANAs for PBC diagnosis[2]. Previous studies showed that gp210-positive is associated with poor prognosis in PBC patients[29]. Meanwhile, PBC is an immune-mediated cholangitis with complex pathogenesis, which often occurs concomitantly with PBC-AIH overlap syndrome and other extrahepatic autoimmune diseases such as sicca syndrome, rheumatoid arthritis, and Hashimoto's thyroiditis[2,30]. However, our study showed that osteoporosis in PBC patients was not related to these immunological features.

Up to now, the pathogenesis of PBC osteoporosis is still unclear. Most experts believed that it seems to be mainly caused by reduced bone formation, although increased bone resorption may play a role in certain situations, such as in post-menopausal women and patients with hypogonadism[10]. Osteoblast mediated bone formation and osteoclast dependent bone resorption are two opposite processes that affect bone mass: when absorption exceeds formation, bone mass will inevitably decrease, and this negative balance will lead to bone loss and osteoporosis[31]. Several studies assessing bone histomorphometry have shown that most of the osteoporosis patients with PBC had reduced tetracycline double labeling, bone formation rate, osteoblasts numbers, and reduced serum osteocalcin level, all of which indicate that osteoblast dysfunction and bone formation deficiency are the core of the pathogenesis of PBC-related osteoporosis[32-34]. In addition, other changes, increased levels of bilirubin and bile salts, and production of fibronectin may also reduce bone formation by inhibiting the proliferation and survival of osteoblasts in PBC or cholestasis[26,35]. Other conditions of PBC patients, including increased formation of osteoclast, low vitamin D levels, calcium malabsorption and sarcopenia, may be contributing factors to the panorama of PBC osteopathy[31,33,36,37].

Nevertheless, our study has several limitations. First, despite being the largest DEXA-based BMD measurement cohort of PBC to date, the sample size was relatively small, especially for men. Thus, it would be interesting and necessary to explore the same objective for larger sample size with a fairly balanced number of women and men. Second, this was a single-center, retrospective study. As a tertiary care center in China, our patients come from different regions of China and may not be representative of those at primary or secondary medical institutions. Prospective studies in Chinese populations may validate our findings. Third, a history of use of anti-osteoporosis treatments such as bisphosphonate, Vitamin D, and calcium supplementation was not included in this study for the analysis of the factors influencing osteoporosis. However, data on osteoporosis therapies related to PBC are insufficient and controversial, and the overall quality of evidence is low[11]. Therefore, we do not think that receiving anti-osteoporosis treatments in the past affected our results. In the future, it is necessary to conduct high-quality research and explore PBC specific therapies focused on improving bone formation.

CONCLUSION

In summary, we found a significantly higher prevalence of osteoporosis in Chinese patients with PBC. Osteoporosis in PBC is strongly associated with older age, lower BMI, previous steroid use, the severity of liver disease, and advanced histological stage. Thus, this study contributes to identifying PBC patients who require early screening for BMD, and potential interventions to diminish the risk of osteoporosis and fractures. This study may help to provide reference information for the development and formulation of future PBC-related guideline and public health policy in China and the Asia-Pacific region.

ARTICLE HIGHLIGHTS

Research background

Primary biliary cholangitis (PBC) is a chronic immune-mediated, progressive cholestatic liver disease. Osteoporosis is an extrahepatic complication of PBC that increases the risk of fractures and mortality.

Research motivation

Although the prevalence of osteoporosis in PBC is high in Europe and North America, relevant epidemiological studies of osteoporosis in patients with PBC in China and the Asia-Pacific region is lack.

Research objectives
To assess the prevalence and clinical characteristics of osteoporosis in Chinese patients with PBC.

Research methods
We performed a retrospective observational study to evaluation the prevalence and risk factors of osteoporosis in Chinese patients with PBC from a tertiary care center who underwent bone mineral density (BMD) assessment using dual-energy X-ray absorptiometry between January 2013 and December 2021. Demographic, serological, clinical, and histological data were collected. Independent risk factors for osteoporosis were identified by multivariate logistic regression analysis.

Research results
The prevalence of osteoporosis in Chinese patients with PBC was 45.5%. Osteoporosis in PBC is strongly associated with older age, lower body mass index (BMI), previous steroid use, the severity of liver disease, and advanced histological stage.

Research conclusions
Osteoporosis is very common in Chinese patients with PBC, allowing for prior screening of BMD in those PBC patients with older age, lower BMI, previous steroid therapy, and advanced liver disease.

Research perspectives
This study provides reference information for future PBC-related guideline development and public policy formulation in China and the Asia-Pacific region.

Abstract

BACKGROUND

Several scoring systems are used to assess fecal incontinence (FI), among which, the most commonly used are Wexner and Vaizey's scoring systems. However, there are significant lacunae in these scoring systems, due to which they are neither accurate nor comprehensive.

AIM

To develop a new scoring system for FI that is accurate, comprehensive, and easy to use.

METHODS

A pro forma was made in which six types of FI were included: solid, liquid, flatus, mucous, stress, and urge. The weight for each FI was determined by asking a group of patients and laypersons to give a disability score to each type of FI from 0 to 100 (0- least, 100- maximum disability). The disability was assessed on a modified EQ-5D+ (EuroQol) description system, 4D3L (4 dimensions and 3 levels) for each FI. The average score of each FI was calculated, divided by 10, and rounded off to determine the weight of each FI type. The scores for the three levels of frequency of each FI were assigned as never = 0 (No episode of FI ever),

occasional = 1 (≤ 1 episode of FI/ wk), and common = 2 (> 1 episode of FI/ wk), and was termed as frequency score. The score for each FI would be derived by multiplying the frequency score and the weight for that FI type. In the second phase of the study, a group of colorectal surgeons was asked to rank the six FI types in order of severity, and their ranking was compared with the patient and laypersons' rankings.

RESULTS

Fifty patients and 50 laypersons participated in the study. The weight was assigned to each FI (solid-8, liquid-8, urge-7, flatus-6, mucus-6, and stress-5), and an new scoring system was formulated. The maximum possible score was 80 (total incontinence), and the least 0 (no incontinence). The surgeons' ranking of FI severity did not correlate well with patients' and laypersons' rankings of FI, highlighting that surgeons and patients may perceive the severity of FI differently.

CONCLUSION

A new scoring system for FI was formulated, which was simple, logical, comprehensive, and easy to use, and eliminated previous shortcomings. Patients' and surgeons' perceptions of FI severity of FI did not correlate well.

Key Words: Feal incontinence; Scoring system; Urge; Stress; Flatus

Core tip: There are several scoring systems to assess fecal incontinence (FI), among which, the most commonly used are Wexner's, Vaizey's, and FI Severity Index scoring systems. However, there are major lacunae and shortcomings in these scoring systems, due to which, they are neither accurate and scientific nor comprehensive. We have developed a new scoring system to assess FI, which is better and more accurate than the existing scoring systems. The new system is more comprehensive and simple and easy to use, and most shortcomings of previous scoring systems have been addressed.

INTRODUCTION

Fecal incontinence (FI) is defined as the accidental leakage of stools, flatus, or mucus and is a common gastrointestinal disorder. It affects between 1% and 16% of the population[1-7]. FI drastically impacts the quality of life, and cause embarrassment, anxiety, fear, or reluctance to go out, often leading to social isolation and the need to carry clothes or wear incontinence pads regularly[1,3,8-13]. The sensitive nature of FI makes it a taboo subject, and many people are reluctant to discuss these with family members or even doctors[2,9,14-16].

There are three scoring systems commonly used to assess FI: Cleveland Clinic or Wexner[17] (Table 1), St. Marks Hospital or Vaizey's[18] (Table 2), and FI Severity Index (FISI)[19] (Table 3). The Wexner and Vaizey scores are the most commonly used[20]. However, there are major lacunae in these scoring systems, due to which they are not an accurate reflection of incontinence level and its correlation with the quality of life.

First, the existing scoring systems are not comprehensive. Wexner scores evaluate only three parameters: solid, liquid, and flatus (gas) FI[17], and Vaizey scores include only four parameters: solid, gas, flatus, and urge (lack of ability to defer defecation for 15 min due to sudden need to defecate)[18]. FISI scores include mucus FI (leakage) as the fifth parameter to evaluate FI but do not include urge FI[19]. None of the scoring systems includes stress FI (leakage of fecal matter or flatus on increasing intraabdominal pressure like coughing, lifting weights, *etc.*) as a parameter to evaluate FI.

Stress FI is an essential independent parameter that should be included in a scoring system. The prevention of stress FI primarily depends on the proper functioning of the external anal sphincter (EAS) and intact straining puborectalis reflex [21]. The latter is a coordinated contraction of EAS and puborectalis muscle on coughing or straining. The damage to EAS and puborectalis during surgery or by peripheral neuritis due to any condition (like diabetes, *etc.*) can cause disruption of straining puborectalis reflex and lead to stress FI[22]. Stress FI is prevalent and is independent of other FIs with distinct etiopathogenesis and treatment, and therefore should be separately evaluated in all patients of FI[22].

Second, the different types of FIs are assigned the same weights in Wexner and Vaizey scoring system[17,18]. This implies that uncontrolled passage of flatus is given equal weight to uncontrolled leakage of solid motion. It does not seem logical and scientifically sound to equate and give equal weights to different types of FI. This was perhaps done for the sake of simplicity[20]. Keeping a scoring system simple and easy to use should be a priority, but it is not justified at the cost of accuracy and sacrifice of scientific principles.

Table 1 Wexner scoring

	Never	Rarely	Sometimes	Usually	Always
Solid	0	1	2	3	4
Liquid	0	1	2	3	4
Gas	0	1	2	3	4
Wears a pad	0	1	2	3	4
Lifestyle alteration	0	1	2	3	4

Rarely: < 1/mo; sometimes: < 1/wk to ≥ 1/mo; usually: < 1/d to ≥ 1/wk; always: ≥ 1/d.

Table 2 Vaizey's scoring

	Never	Rarely	Sometimes	Weekly	Daily
Solid stool incontinence	0	1	2	3	4
Liquid stool incontinence	0	1	2	3	4
Gas incontinence	0	1	2	3	4
Alteration in lifestyle	0	1	2	3	4
	No	Yes			
Need to wear a pad or plug	0	2			
Constipating medication	0	2			
Lack of ability to defer defecation for 15 min	0	4			

Never: No episodes in last 4 wk; rarely: 1 episode in last 4 wk; sometimes: ≥ 1 in last 4 wk but < 1/wk; weekly: ≥ 1/wk to < 1/d; always: ≥ 1/d.

Table 3 Fecal incontinence Severity Index scoring

	≥ 2 times/day (patient/surgeon scores)	Once/day (patient/surgeon scores)	≥ 2 times/week (patient/surgeon scores)	Once/week (patient/surgeon)	1-3 times/month (patient/surgeon scores)
Gas	12/9	11/8	8/6	6/4	4/2
Mucous	12/11	10/9	7/7	5/7	3/5
Liquid	19/18	17/16	13/14	10/13	8/10
Solid	18/19	16/17	13/16	10/14	8/11

Third, there are parameters included in the existing scoring systems that are not a direct measure of the degree or severity of FI. This leads to error (confounding bias). The same symptom is scored multiple times due to the inclusion of parameters like "Need to wear a pad"[17,18], "Alteration in lifestyle"[17,18], and "Need to take a constipating medicine"[18] in the Wexner and Vaizey scoring systems. For example, a patient having liquid or stool FI would also wear a pad daily, would have an alteration in lifestyle, and could also be taking constipating medicines to counter the symptom. This way, the patient with liquid or solid FI would be scored four times for the same symptom. These included questions are not independent types of FI but are corrective actions taken to control the symptoms of FI. So, apart from being the indirect measures, they would cause a multiplicity of scoring as the primary direct symptom (liquid or solid FI) would anyway be getting points.

Fourth, the patient perceptions were not taken into consideration while developing these scoring systems. As any FI scoring system is being developed for the patients, the latter's perception is paramount. It would be incorrect to assume that the surgeons' perception of different FIs would be similar to that of the patients. The FISI scoring system is the only one that has compared the surgeons' and patients' perceptions and found them to be different, yet they failed to formulate a simple and clear scoring system that was patient-centric[19]. There were several other discrepancies in the FISI study[23]. The sample size was small (26 surgeons and 34 patients)[19]. The forms were filled by interview as well as through mail. The standard definitions and the disability parameters on the basis of which scoring was made were not used[19]. The lack of proper statistical methods, the scoring system becoming too complex, and no proper weights being

allotted to each FI type were important shortcomings of the FISI system (Table 3). These could be the reasons that the FISI scoring system did not become popular with gastroenterologists and surgeons[19].

Due to these major lacunae in the existing scoring systems (not comprehensive, the different types of FIs were assigned the same weights, parameters included were not a direct measure of the degree or severity of FI, the patient perceptions were not taken into consideration while developing these scoring systems, *etc.*), a need was felt to develop a new scoring system that would be comprehensive, based primarily on patients' and laypersons' perceptions, was scientifically sound, accurate (free of bias or overlapping parameters), faithfully reflected the degree of disability, and yet would be simple and easy to use. Against this background, this study was done in two phases. In the first phase, a new scoring system was developed based on patients' and laypersons' perceptions, and in the second phase, it was analyzed to determine whether patients' perception and surgeons' assessments of the disability of different FIs were similar or not.

MATERIALS AND METHODS

The study was designed in two phases. In the first phase, the assignment of weights to six types of FI and the formulation of a new scoring system based on patients' and laypersons' perceptions were performed. In the second phase, the colorectal surgeons were also interviewed, and their assessment of the severity of different FI types was compared with the rankings of patients and laypersons.

First phase of the study: development of new scoring system

Study group: The first phase of the study comprised the patients and laypersons.

Patients group: (1) Inclusion criteria: the patients were defined as those who knew about FI and could potentially develop it secondary to the treatment of the disease condition they were suffering from. Therefore, patients suffering from anal fistula were included. Since they were experiencing the fear of incontinence, their perception was relevant; and (2) Exclusion criteria: the patients already suffering from any FI were excluded as they would rate their type of incontinence worse than other types.

Laypersons group: The layperson group was included because the patients with FI were expected to be emotionally involved. Therefore, a group that was not directly involved in the disease process was also included. Inclusion criteria: the relatives of the patients suffering from a disease, the treatment of which could potentially cause FI (anal fistula), were included. These persons were aware of the details and the risk of FI in their close relatives but were not actually directly afflicted by the disease. Therefore, they would balance out any extreme response by the patients.

Parameters of FI

The six parameters directly reflecting FI were included: solid, liquid, flatus (gas), urge, stress, and mucus.

Study methodology

Measuring weight for each FI type: The six FI parameters were defined in simple language (English as well as the native language, Hindi), which a patient and layperson could easily understand (Table 4). An interviewer was assigned to interview each person. Both the interviewer and interviewee (study subject) were blinded to the goals or the purpose of the study. The interviewees were shown the proforma, and after they understood the definitions of six FI parameters, they were asked to arrange the six parameters in order of decreasing severity. After this, each parameter was to be assigned numbers (disability score) between 0 and 100. The disability score was the measure of the impact of FI on all aspects of the life of the person. The worst parameter would be assigned a disability score of 100, and all other parameters would be assigned disability scores according to that. The same weight could be assigned to different parameters if the interviewee perceived them as of equal magnitude. In order to guide the interviewee regarding the weight assignment, a modified EQ-5D+ (EuroQol) description system was utilized[24]. EQ-5D+ includes a structured approach in which each health state parameter is described in terms of dimensions and severity levels within each dimension. In the present study, a 4D3L (4 dimensions, 3 levels) description system was used (Table 5). The impact of FI type on four dimensions of daily life, usual routine activity, anxiety/depression, self-esteem, and social life, was assessed, and a maximum of 25 points were assigned to each dimension. Each dimension had three levels, and depending on the severity level of that dimension, the points out of 25 were to be assigned to that dimension (Table 5). For example, an interviewee assessing liquid FI assigns 18 points to usual routine activity (out of 25), 20 points to anxiety/depression (out of 25), 15 points to self-esteem (out of 25), and 22 points to social life dimension (out of 25), then the total disability score assigned to liquid FI would be 75 (out of 100) for that interviewee (Table 5). Similarly, every interviewee would assign disability scores to each of the six types of fecal FIs. The 4D3L system was used to make the procedure objective and also helped the interviewee to fill the proforma easily. The two dimensions, self-esteem and anxiety, are relevant to evaluate the impact of a medical condition and were not given much importance in earlier scoring systems[25,26]. The inclusion of the parameters used as independent parameters in previous scoring systems like "Need to wear a pad"[17,18], "Alteration in lifestyle"[17,18], and "Need to take a constipating medicine"[18], were included as a part of the 4D3L proforma and therefore had an influence on assigning disability score to each type of FI. As discussed above, these parameters are not a type of incontinence, and their independent inclusion in the scoring system would have led to the error.

A pilot study was done before commencing the main study to assess any shortcomings. This was helpful in removing questions that were irrelevant or difficult to comprehend, improving the proforma's content, and making the language

Table 4 Detailed description of different types of incontinence [it was also translated into the local language (Hindi)]

Incontinence	Description
Urge	Whenever there is an urge to pass motion, normally, a person can hold the motion for a few minutes. In urge IC, the person faces difficulty holding the motions whenever there is an urge of passing motions. Although the motion does not come out, the feeling and fear that it will come out force the patient to rush to the toilet
Stress	Whenever there is an increase in pressure inside the tummy like in coughing or lifting weights, a person with normal anal sphincters can tighten his sphincters and hold the motions. A person can hold the motion for a few minutes. In stress IC, on increasing the pressure inside the tummy like in coughing or lifting weights, a little bit of motion or flatus leak from the anus
Mucus	A person with normal anal sphincters has a good anal tone due to which no leakage of mucus (normally present in the rectum as there is saliva in the mouth) occurs. However, in a person with weak sphincters, some mucus may leak out into the area around the anus spontaneously
Flatus	A person with normal anal sphincters has a good anal tone due to which he/she has control over the passage of gas/flatus. The person can hold the gas/flatus for some time. However, in a person with weak sphincters, gas/flatus may leak out of the anus with the person having no control over it
Liquid	A person with normal anal sphincters has a good anal tone due to which no leakage of liquid stool occurs. However, in a person with weak sphincters, some amount of liquid stool may leak out into the area around the anus spontaneously
Solid	A person with normal anal sphincters has a good anal tone due to which no leakage of solid stool occurs. However, in a person with weak sphincters, some amount of solid stool may leak out into the area around the anus spontaneously

Table 5 Four dimensions, 3 levels [modified EQ-5D+ (EuroQol)] description system utilized in the study and assignment of disability score for each fecal incontinence

Dimension	Dimension description	Perception of severity level
Usual routine activity	Performance of usual role activities such as working at a job, housework, child care, volunteer work, *etc.* Need to wear a pad, take a constipating medicine	Minimal problems with performing usual activities (0–5)
		Some problems with performing usual activities and moderate alteration in lifestyle (6–15)
		Unable to perform usual activities and severe alteration in lifestyle (16–25)
Anxiety/depression	Negative psychological states include anxiety, depression, behavioral, emotional control, loneliness, *etc.*	Minimal anxiety or depression (0–5)
		Moderate anxiety or depression (social isolation and loss of appetite) (6–15)
		Extremely anxious or depressed (suicidal ideation) (16–25)
Self-esteem	Perception about self	Minimal loss of self-esteem (0–5)
		Some loss of self-esteem (6–15)
		Marked loss of self-esteem (16–25)
Social life	How frequently the person goes out for socializing, like going to the cinema to watch a movie, going to a party, going out of the station for vacation	Minimal impact on social life (0–5)
		Some loss of social life (6–15)
		Marked curtailment of social life (16–25)

For example, an interviewee assessing liquid fecal incontinence assigns 18 points to Usual routine activity (out of 25), 20 points to anxiety/depression (out of 25), 15 points to self-esteem (out of 25), and 22 points to social life dimension (out of 25), then the total disability score assigned to liquid FI would be 75 (out of 100).

simpler. The subjects in the pilot study were not included in the final study.

Calculating the final weight for each FI type: The data of patients and laypersons were combined. The disability scores for each FI type were tabulated, and the average disability score for each FI type was calculated. Th weight for that FI was calculated by dividing the average disability score by 10 and rounding off the number to the nearest whole number (Table 6). This was done for simplicity, as a numbers with decimals would would have been difficult to use.

Development of a scoring system: Once the weights for each FI type were determined based on patients' and laypersons' perceptions, the three frequencies of each FI type were fixed as never (No episode of FI ever), occasional (≤ 1 episode of FI/ wk) or common (> 1 episode of FI/ wk). These were assigned linear scores of 0, 1 and 2, respectively. The frequency system of never, daily, weekly, monthly or yearly was not used for a few reasons. First, the patients found it difficult to calculate the frequency when there were too many columns. Secondly, the frequency of any FI type could vary in

Table 6 Weight assignment to different types of incontinence by study group

	Solid	Liquid	Flatus	Mucous	Stress	Urge
Patients' (n = 50) average disability score	82.5 ± 19.1	84.8 ± 15.4	58.1 ± 23.6	55.3 ± 21.2	52.0 ± 23.9	68.5 ± 23.5
Laypersons' (n = 50) average disability score	83.0 ± 22.4	81.4 ± 19.2	54.6 ± 21.1	55.2 ± 19.3	48.8 ± 22.0	68.3 ± 22.8
Total average disability score	82.7 ± 20.7	83.1 ± 17.4	56.3 ± 22.3	55.2 ± 20.1	50.4 ± 22.9	68.4 ± 23.0
Division by 10	8.27	8.31	5.63	5.52	5.04	6.84
Final weight (after rounding-off)	8	8	6	6	5	7

frequency over a period of time. Third, increasing the columns would have made the scoring system more cumbersome.

Second phase of the study: comparison of ranking of six types of FI according to severity by patients, laypersons and surgeons

In this phase, the assessment of FI was done by surgeons, and FI ranking in decreasing order of severity was done by three participating groups: patients, laypersons and surgeons. As discussed above, this was not done to assign weights or for formulation of the new scoring system but to check whether there was a correlation between patients, laypersons and colorectal surgeons regarding perception of severity of different types of FI.

Surgeons: Inclusion criteria: colorectal surgeons who had performed at least 30 anal fistula procedures in their surgical career were included. The persons in each group (patients, laypersons and surgeons) were asked to rank the six FI in decreasing order of severity. The most severe FI was given a rank of 6, and the least severe FI was given a rank of 1. The other types of FI were given ranks between 2 and 5, depending on the severity. The average of each FI type in each group was calculated, and the final ranking of FI in the groups was tabulated and compared (Table 7).

Ethics

The study was approved by the Ethics Committee of Adesh Medical College and Hospital, Shahbad, India (reference number AMCH/IEC/2022/02/04).

Statistical analysis

The categorical variables were compared by performing the χ^2 or Fisher's exact test. For normally distributed data, the continuous variables were tested by Student's t test when there were two samples, and analysis of variance (ANOVA) there were three or more samples. For non-normally distributed data, the Wilcoxon signed-rank test was performed for paired samples, and Mann–Whitney U test for unpaired samples. The significant cut-off point was set at $P < 0.05$.

RESULTS

Fifty patients and 50 laypersons were included in the first phase of the study. All the proformas were filled over a period of 1 year by the same interviewer between March 2022 and March 2023. The mean age was 40.7 ± 11.7 years (41.7 ± 12.0 in patients and 39.8 ± 11.4 in laypersons), and 71 were male (44 in patients and 27 in the laypersons groups).

The mean disability scores assigned to solid, liquid, flatus, mucous, stress, and urge FI by the patients were 82.5 ± 19.1, 84.8 ± 15.4, 58.1 ± 23.6, 55.3 ± 21.2, 52.0 ± 23.9, and 68.5 ± 23.5 respectively and by the laypersons were 83.0 ± 22.4, 81.4 ± 19.2, 54.6 ± 21.1, 55.2 ± 19.3, 48.8 ± 22.0, and 68.3 ± 22.8 respectively (Table 6). The overall mean disability scores assigned to solid, liquid, flatus, mucous, stress, and urge FI were 82.7 ± 20.7, 83.1 ± 17.4, 56.3 ± 22.3, 55.2 ± 20.1, 50.4 ± 22.9, and 68.4 ± 23.0 respectively (Table 6). After dividing these by 10 and rounding them off, the final weights assigned to solid, liquid, flatus, mucous, stress, and urge FI were 8, 8, 6, 6, 5, and 7, respectively (Table 6).

The three frequencies fixed for all FIs were never, occasional and common and were assigned points of 0, 1 and 2, respectively (Table 8). Thus, a new scoring system was finalized (Table 8). The maximum possible score was 80, which implied total incontinence, and the minimum score possible was 0, which implied normal continence (no incontinence) (Table 8).

In the second phase of the study, 50 patients and 50 laypersons from the first phase of the study were included, and 33 colorectal surgeons were interviewed to rank the six different types of FI according to severity. The ranking of the surgeons, patients and laypersons was compared. The perception of the patients and the laypersons correlated well, whereas it did not correlate with the surgeons' perception (Tables 7 and 9). The patients rated liquid FI, while the surgeons perceived solid FI as the most severe (Table 7). After solid and liquid FI, the patients and laypersons ranked urge FI as the most severe, whereas the surgeons ranked stress FI at that level (Table 7). The severity perception of the patients and laypersons regarding solid and urge FI was significantly different from the surgeons ($P < 0.00001$, ANOVA) (Table 9).

Table 7 Comparison of ranking of six types of fecal incontinence as per severity perceived by patients, laypersons and surgeons

Ranking	Patients (*n* = 50)		Laypersons (*n* = 50)		Surgeons (*n* = 33)	
Most severe to least severe	Type of FI	Ranking mean ± SD	Type of FI	Ranking mean ± SD	Type of FI	Ranking mean ± SD
6	Liquid	4.73 ± 1.25	Solid	4.80 ± 1.50	Solid	6.0 ± 0.0
5	Solid	4.51 ± 1.50	Liquid	4.64 ± 1.35	Liquid	5.0 ± 0.0
4	Urge	3.65 ± 1.52	Urge	3.70 ± 1.44	Stress	2.90 ± 1.07
3	Flatus	2.87 ± 1.50	Flatus	2.72 ± 1.45	Mucous	2.81 ± 0.91
2	Mucous	2.57 ± 1.38	Mucous	2.70 ± 1.44	Flatus	2.57 ± 1.06
1	Stress	2.53 ± 1.53	Stress	2.46 ± 1.38	Urge	1.69 ± 1.07

The persons in each group (patients, laypersons and surgeons) were asked to rank the six types of fecal incontinence (FI) in decreasing order of severity. The most severe was given 6 points, and the least severe FI was given 1 point. The average of each FI type in each group was calculated, and the final ranking of FI in that group was calculated.

Table 8 New scoring system

Incontinence type	Weight	Frequency			Maximum score
		Never (points)	Occasional (points) (≤ 1 episode/ wk)	Common (points) (> 1 episode/ wk)	
Solid	8	0	1	2	16
Liquid	8	0	1	2	16
Urge	7	0	1	2	14
Flatus	6	0	1	2	12
Mucus	6	0	1	2	12
Stress	5	0	1	2	10
Total					80

Score in a cell = Weight for that incontinence type × frequency points. For example, a person with occasional liquid incontinence would have an 8 × 1 = 8 score. Maximum possible score = 80 (total incontinence), minimum score possible = 0 (no incontinence).

Table 9 Difference in mean ranking six types of fecal incontinence as per severity perceived by patients, laypersons and surgeons

Type of FI	Ranking mean ± SD			Significance
	Patients (*n* = 50)	Laypersons (*n* = 50)	Surgeons (*n* = 33)	(ANOVA)
Solid	4.51 ± 1.50	4.80 ± 1.50	6.00 ± 0.00	$P < 0.00001$
Liquid	4.73 ± 1.25	4.64 ± 1.35	5.00 ± 0.00	$P = 0.35$
Urge	3.65 ± 1.52	3.70 ± 1.44	1.69 ± 1.07	$P < 0.00001$
Flatus	2.87 ± 1.50	2.72 ± 1.45	2.57 ± 1.06	$P = 0.88$
Mucous	2.57 ± 1.38	2.70 ± 1.44	2.81 ± 0.91	$P = 0.90$
Stress	2.53 ± 1.53	2.46 ± 1.38	2.90 ± 1.07	$P = 0.29$

The persons in each group (patients, laypersons, and surgeons) were asked to rank the six fecal incontinence (FI) in decreasing order of severity. The most severe was given 6, and the least severe FI was given 1 point. The average of each FI type in each group was calculated and compared.

DISCUSSION

The objective scoring of FI is an important and necessary tool, especially for gastroenterologists, gastrointestinal and colorectal surgeons, and neurologists. Out of the few scoring systems published, the Wexner and Vaizey scoring systems

are the most popular and commonly used[17,18]. However, as discussed above, there are a few major shortcomings in these scoring systems, due to which they are not accurate, comprehensive, and bias-free. In the present system, it was attempted to remove the lacunae of existing scoring systems (Table 10).

FI missed out in previous scoring systems, such as urge in Wexner, mucous in Wexner and Vaizey, and stress FI in all previous systems, were included in the new scoring system[18]. The new system is the first in which all six types of FI were included: solid, liquid, flatus, mucus, stress, and urge. It is logical to include all these six FI in a scoring system as all of these are distinct, and the presence of any of these indicates a malfunction in the coordinated function of a portion of the sphincter mechanism.

The biggest lacuna in the Wexner and Vaizey scores is that all types of FIs are assigned the same weight (Tables 1 and 2)[17,18]. In fact, no attempt was made to assign differential weights to different types of FI[18]. It is difficult to understand how all types of FI could be assigned exactly the same scores when all six FI types are different. The present study highlighted that weights calculated for different FIs could have significant variations ranging from 5 (urge FI) to 8 (liquid and solid FI) (Tables 6 and 8). Therefore, assigning these FIs equal weight was too simplistic and a source of significant error.

In the past, patients' perceptions were not given due importance, or it was assumed that surgeons' and patients' perceptions would be similar. We were of the opinion that the patients' subjective perception should be the basis of any FI scoring system. If there is any discrepancy between surgeons' and patients' perceptions regarding FI, then the patients' perceptions should be given priority over surgeons' perceptions. Even taking an average of both would be inappropriate. This is because, ultimately, the patients are the sufferers, and before making any decision regarding a treatment/surgery, fellow patients' perceptions would be of more relevance to any patient. Therefore, we did not include surgeons' perceptions in determining the weight of the different types of FI. In the second phase of the study, we compared the severity ranking of different FI according to the patients, laypersons, and surgeons' perceptions. The patients' and layperson's ranking of different FI was similar, but both were significantly different from the surgeons' rankings (Tables 7 and 9).

In the FISI scoring system, as in the present study, the surgeons' and patients' perceptions were different as the surgeons gave more importance to solid than liquid FI (Tables 3, 7, and 9). The reason mentioned in the FISI study was that surgeons viewed solid FI as a reflection of sphincter integrity and the adequacy of surgical repairs[19]. It was further discussed that professionals tended to assign a higher value to more severe elements, whereas patients placed greater importance on more common events[19,27]. In such a scenario where discrepancy arises, the patients' perception should be given priority in formulating a scoring system, and it would be inappropriate to force surgeons' opinions on the patients.

The FISI study also had several lacunae. When compared to the present study, the sample size in the FISI study was smaller (n = 34 *vs* 100 in the present study)[19]. About one-third of patients (12/34) in the FISI study completed the questionnaire through email[19]. Also, their questionnaire was not detailed and contained a single 20-cell table that was to be filled by the patients (Table 3)[19]. Each cell had to be assigned a number between 1 and 20 according to the severity, and no number could be repeated (Table 3)[19]. This step in their methodology could lead to error as two different cells could be perceived to be of similar severity by patients and could have deserved the same number (*e.g.*, mucus leakage once weekly could be perceived as severe as gas leakage once daily by the patient). Also, the present study showed that detailed definitions (Table 4) and the EuroQol descriptive system (Table 5) helped to guide the patients to understand the parameters properly and filling the charts accordingly. In our study, the interviewer took at least 1 h in every case to accurately fill out the chart. It seemed highly improbable that such detailed charts could be filled appropriately *via* email, as was done in the FISI study[19]. The proper statistical methods were also not followed in the FISI study, such as assigning weights to each FI type, linear increase in scores on the increasing frequency of symptoms, *etc.* Therefore, the end result of FISI scoring was haphazard and not amenable to usage (Table 3). This was perhaps the main reason that the FISI scoring system did not become popular and was not widely utilized. All the existing lacunae were removed in the present study, and the latter utilized detailed and sound scientific methods and in a much larger sample than in the FISI study (Table 10).

In the present study, like in the FISI study[19], the surgeons perceived solid FI as the worst, while the patients perceived liquid FI as the worst. Another interesting aspect was that after excluding solid and liquid FI, the surgeons perceived stress FI while patients and laypersons perceived urge FI as the worst (Table 7). On detailed questioning, most surgeons opined that in stress FI, there was actual leakage of fecal matter, while in urge FI, one had to rush to the toilet, and actual leakage could be prevented in most cases. In contrast, the patients and laypersons opined that stress FI would only happen when there was stress (lifting weights, and coughing, *etc.*), and many times, such stressful situations (and hence stress FI) could be avoided (not lifting weights) or curtailed (coughing lightly) but in urge FI, the person had to rush to the toilet every time, and this would hamper the quality of life in a bigger way. It was difficult to ascertain the reason behind this difference in perception between the surgeons and patients.

The parameters included in the existing scoring systems (Wexner and Vaizey) which were not a type of FI and were not a direct measure of the degree of FI like "Need to wear a pad"[17,18], "Alteration in lifestyle"[17,18], and "Need to take a constipating medicine"[18], which led to error, were excluded as parameters in the new scoring system. Rather, these were included in the 4D3L [modified EQ-5D+ (EuroQol)] description system (Table 5), which served as the basis for assigning weights to different types of FI. As discussed above, these parameters are the outcome/side effects of FI, and adding them as separate parameters for scoring was leading to a confounding bias.

It is pertinent that there is an optimal balance between scientific soundness and simplicity of a scoring system. Steps were taken to simplify the new scoring system, such as rounding off the assigned weights to the nearest whole number and decreasing the frequency of FI episodes from 5 (earlier scoring systems) (daily, weekly, monthly, yearly and never) to 3 (common, occasional and never). During the pilot study, it was realized that dividing the symptoms (episodes) into

Table 10 Comparison of existing scoring systems with new scoring system

	Wexner	Vaizey	FISI	NSS
Comprehensive	No	No	No	Yes
FI type included: urge FI	No	Yes	No	Yes
FI type included: mucous FI	No	No	Yes	Yes
Presence of confounding parameters like "Need to wear a pad", "Need to take constipating medicine", and "Alteration of lifestyle"	Yes	Yes	No	No
Assigning weights to each FI by an objective method	No	No	No	Yes
Inclusion of patient perceptions (*n*)	0	0	34	50
Inclusion of laypersons' perceptions (*n*)	0	0	0	50
Simple and easy to use	+++++	+++++	+	+++++
Detailed structured definitions	No	No	No	Yes
In-depth disability scores based on an objective description system	No	No	No	4D3L [modified EQ-5D+ (EuroQol)] used

FI: Fecal incontinence.

daily, weekly or monthly was difficult for the patients as the frequency of FI episodes is not strictly regular or periodic. Therefore, the broad categories of FI episodes as common or occasional made the scoring task easier for the patient while also simplifying the system without significantly impacting the scientific quotient. In contrast, giving equal weight to all types of FI for the sake of simplicity would be inappropriate as that would significantly compromise accuracy.

The subjective evaluation of study subjects could lead to deviation of the results. Therefore, several steps were taken to maximize objectivity while developing the new scoring system. First, in the proforma, the six FI parameters were defined in simple as well as two languages (English and the native language, Hindi), which a patient and layperson could easily understand. Second, both the interviewer and interviewee were blinded to the goals or purpose of the study. Third, all the proformas were filled out by the same interviewer. Fourth, to increase objectivity while filling out the proforma by the study subjects, a modified EQ-5D+ (EuroQol), 4D3L descriptive system was utilized. Scoring (0–25) was also utilized in each dimension to guide study subjects and to increase objectivity.

The study had some limitations. The new scoring system was not tested for inter- and intra-observer variability and test–retest reliability. However, these are planned for the next phase of the study. The validity of the new scoring system could not be checked because there was no gold standard against which it could be validated. The system was based on assigning weights and had more types of FI, due to which it was fundamentally different from the commonly used Wexner and Vaizey scoring systems. Nonetheless, this was a single-center study, and the new scoring system should be validated in a larger sample, preferably in multiple centers.

CONCLUSION

The new scoring system to objectively assess and grade FI clinically is more accurate than the existing scoring systems. It is simple and easy to use, and addresses most of the shortcomings of previous scoring systems. However, further studies are needed to corroborate the results of the present study.

We would like to thank Khushhreet Garg for providing software support and editing the tables.

ARTICLE HIGHLIGHTS

Research background

Fecal incontinence (FI) is a common problem. Its assessment is difficult, and an objective scoring system needs to be developed so that FI can be evaluated uniformly all across the globe.

Research objectives

To develop a new effective, and scientifically sound scoring system in which the shortcomings of the existing scoring

systems are removed.

Research motivation
The existing scoring systems had many lacunae, due to which they were not scientifically accurate.

Research methods
A proforma was made in simple language in which all definitions of FI were included so that the study participants (patients and laypersons) could understand them. The study participants were then assigned disability scores (ranging from 0 to 100) for each type of FI based on a modified EQ-5D+ (EuroQol) descriptive system. The average score of each type of FI was calculated, divided by 10, and rounded off to determine the weight of each type. In the second phase of the study, a group of colorectal surgeons was asked to rank the six FI types in order of severity, and their ranking was compared with that of the patients and laypersons.

Research results
One hundred participants (50 patients and 50 laypersons) were included in the study. A new scoring system was formulated in which the maximum possible score was 80 (total incontinence), and the least 0 (no incontinence). The surgeons' ranking of FI severity differed significantly from the patients' and the laypersons' rankings, highlighting that the surgeons and the patients may perceive the severity of different FIs differently.

Research conclusions
A new scoring system for FI was formulated, which was simple, logical, comprehensive, and easy to use. The perceptions of patients and surgeons regarding the severity of different FIs differed significantly.

Research perspectives
The new scoring system would be useful for clinicians worldwide to objectively assess FI in the clinical setting.

FOOTNOTES

Author contributions: Garg P conceived and designed the study, collected and analyzed the data, revised the data, and finally approved and submitted the manuscript (Guarantor of the study); Sudoł-Szopińska I collected and analyzed the data, revised the data, finally approved and submitted the manuscript; Kołodziejczak M critically analyzed the data, reviewed and edited the manuscript, finally approved and submitted the manuscript; Bhattacharya K analyzed the data, revised the data, finally approved and submitted the manuscript; Kaur G analyzed the data, revised the data, and finally approved and submitted the manuscript.

Institutional review board statement: The study was approved by the Ethics Committee of Adesh Medical College and Hospital (Approval No. AMCH/IEC/2022/02/04).

Informed consent statement: All study participants, or their legal guardian, provided informed written consent prior to study enrollment.

Conflict-of-interest statement: There are no conflicts of interest to report.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Goran Hauser, FEBG, MD, PhD, Professor, Department of Internal Medicine, Division of Gastroenterology, Clinical Hospital Centre, Faculty of Medicine Rijeka-University of Rijeka, Rijeka 51000, Croatia. goran.hauser@medri.uniri.hr

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJG* as 4.3; IF without journal self cites: 4.1; 5-year IF: 5.3; Journal Citation Indicator: 0.82; Ranking: 33 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.3 and Scopus CiteScore rank 2022: Gastroenterology is 22/149.

Abstract

Many studies point to an association between *Helicobacter pylori* (*H. pylori*) infection and inflammatory bowel diseases (IBD). Although controversial, this association indicates that the presence of the bacterium somehow affects the course of IBD. It appears that *H. pylori* infection influences IBD through changes in the diversity of the gut microbiota, and hence in local chemical characteristics, and alteration in the pattern of gut immune response. The gut immune response appears to be modulated by *H. pylori* infection towards a less aggressive inflammatory response and the establishment of a targeted response to tissue repair. Therefore, a T helper 2 (Th2)/macrophage M2 response is stimulated, while the Th1/macrophage M1 response is suppressed. The immunomodulation appears to be associated with intrinsic factors of the bacteria, such as virulence factors - such oncogenic protein cytotoxin-associated antigen A, proteins such *H. pylori* neutrophil-activating protein, but also with microenvironmental changes that favor permanence of *H. pylori* in the stomach. These changes include the increase of gastric mucosal pH by urease activity, and suppression of the stomach immune response promoted by evasion mechanisms of the bacterium. Furthermore, there is a causal relationship between *H. pylori* infection and components of the innate immunity such as the NLR family pyrin domain containing 3 inflammasome that

directs IBD toward a better prognosis.

Key Words: Cytotoxin-associated antigen A oncoprotein; Gut microbiota; *Helicobacter pylori*; *Helicobacter pylori* neutrophil-activating protein; Immunological modulation; Inflammatory bowel disease; NLR family pyrin domain containing 3 inflammasome

Core Tip: *Helicobacter pylori* (*H. pylori*) infection seems to modulate the immune response triggered by inflammatory bowel disease in a way that makes it less aggressive. The virulence factors of *H. pylori*, as well as the mechanisms that allow it to remain in the stomach environment, appear to change the intestinal microenvironment and modulate the local immune response, contributing to a disease with milder symptoms and less tissue damage.

INTRODUCTION

Inflammatory bowel diseases (IBD) are a group of chronic conditions affecting the gastrointestinal tract, characterized by episodes of abdominal pain, diarrhea, bloody stools, and weight loss. The two main types of IBD are Crohn's disease (CD) and ulcerative colitis (UC)[1]. In CD any area of the gastrointestinal tract can be affected, but the most affected regions are the terminal ileum, the cecum, the perianal region, and the colon, while in UC the inflammation is restricted to the colon and rectum[1]. Regarding histology, in CD the intestine presents thickened submucosa, transmural inflammation, ulceration and non-caseating granulomas, while in UC the inflammation is limited to the mucosa, with crypts and abscesses[2].

The pathogenesis of IBD is complex and involves a combination of genetic, environmental, and immunological factors. The gut microbiota is critical to homeostasis in this organ and contributes to the tolerance process, to the development and differentiation of the local and systemic immune system, and may protect the host from pathogenic enteric infections. However, in IBD, luminal bacteria trigger deregulated immune responses, acting as the main environmental factor for the development of these pathologies[3,4].

The loss of tolerance to the commensal microbiota seems to be related to the genetic susceptibility of the individual and to an imbalance in the composition of the microbiota[5]. IBD patients have changes in stool composition, with less bacterial quantity and diversity[6,7].

Genome wide association studies of IBD have identified 99 non-overlapping genetic risk loci including 28 that are shared between CD and UC[8]. These genetic alterations seem to implicate several important pathways, such as intestinal barrier function, regulation of innate and adaptive immunity, reactive oxygen species formation, autophagy, and endoplasmic reticulum stress[9]; associations were identified between polymorphisms in the genes for interleukin (IL)-10, IL-10 receptor alpha, and components of this signaling pathway - signal transducer and activator of transcription 3, tyrosine kinase 2, and JAK2, with the early development of IBD[10].

Dysregulation of the immune component in IBD is marked by abnormal mucus production, failure to repair the epithelial barrier, and excessive and persistent activation of T lymphocytes, B cells, dendritic cells, macrophages, and natural killer cells[11,12].

Naive TCD4+ cells can differentiate into T helper 1 (Th1), Th2, Th9, Th17 and regulatory T (Treg) subpopulations; the main stimulus for differentiation into Th1 cells - secreting interferon (IFN)-γ, tumor necrosis factor (TNF) and IL-2, is the expression of IL-12, while IL-4 leads to differentiation into Th2 cells, whose cytokine pattern is marked by the expression of IL-4, IL-5, IL-13 and IL-25[13]. Classically, CD and UC are described as diseases with a Th1 and Th2 immune pattern, respectively[14-16], since typically CD patients have higher IFN-γ and IL-2 expression than UC patients[17,18], that express more IL-5 and IL-13[19,20]. However, some studies contradict this information, since lower levels of IL-13 were seen in UC patients compared to CD patients[21], and high levels of IFN-γ were found in carriers of both diseases[22]. In line with this, Bernardo *et al*[23] found a mixed cytokine pattern in biopsies from UC patients, associated with low IL-13 levels.

A Th17 pattern response prevails in the gut. The differentiation into Th17 cells leads to the expression of IL-17, IL- 21, IL- 22, and IL-23, which are found in large quantities in the intestine of IBD patients[24]. A study using IL-17 receptor (IL-17R) knockout mice showed that IL-17R deficiency protected the animals from developing trinitrobenzene sulfonic acid (TNBS)-induced colitis[25-27].

Although not conclusive, there is evidence to indicate that two members of this cytokine family have different effects; IL-17A appears to have a protective effect through inhibition of the Th1 response[28], furthermore, other studies indicate that deficiency of this cytokine causes exacerbation of colitis, while IL-17F contributes to and aggravates the inflammatory process[29]. Despite the prevalence of Th17 cells in the gut in the absence of IBD, this response pattern appears to be exacerbated with disease onset leading to increased production of pattern marker cytokines. Perhaps this increase occurs relatively disproportionately, prioritizing the increase in cytokines that induce an inflammatory response, such as IL-17F.

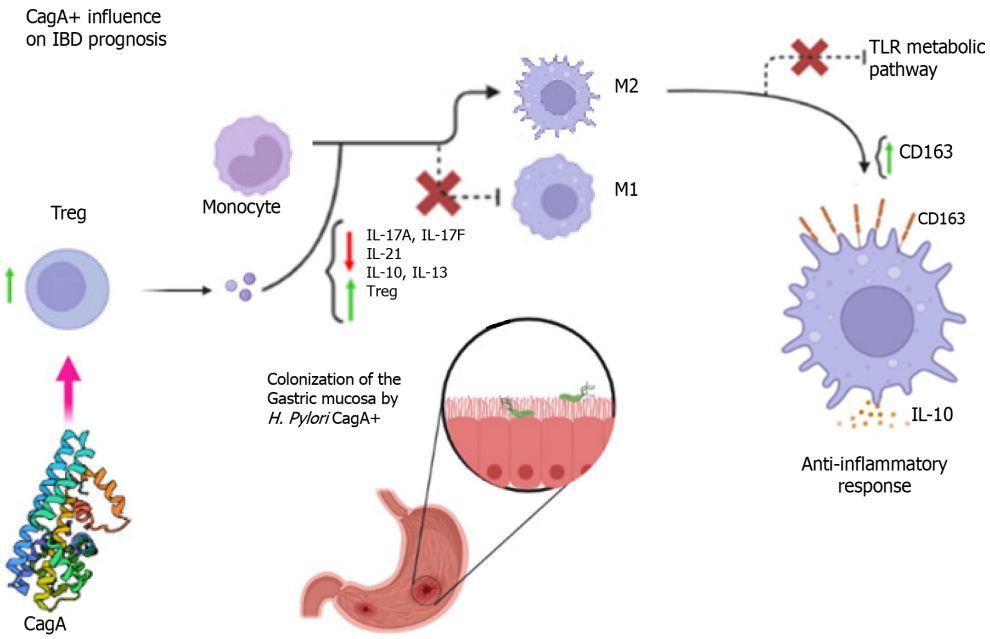
Treg cells which is characterized by constitutive expression of forkhead/winged helix transcriptional factor P3 (FoxP3), CD25 and cytotoxic T lymphocyte-associated protein 4, play a major role in the pathogenesis of IBD[30]. In these diseases, there is a significant dysfunction in the activity of these cells, either by being in low numbers or by having their function suppressed. It has been observed that effector cells from IBD patients exhibit relative resistance to Treg-mediated suppression by expressing high levels of Smad7, an inhibitor of the transforming growth factor (TGF)-β signaling pathway[31,32]. The unbalanced and uncontrolled local immune response against the bacterial microbiota in the IBD occurs when it is poorly controlled by endogenous counter regulatory mechanisms, such as the immunosuppressive cytokine TGF-β. Studies show that the inefficiency in control occurs due to a blockade of TGF-β signaling, caused by a blockade in the phosphorylation of the signaling molecule associated with the TGF-β activated receptor, Smad3. The blockade of Smad3 activity is caused by the upregulation of the Smad7[33].

Individuals with a mutation in the *FOXP3* gene often suffer from intestinal inflammation[34]. Treg cells are able to convert to Th17 cells under inflammatory conditions, and the cytokine IL-1β is key in this process[35]. The balance between the Th17 and Treg response is important, especially in places such as the gut, where there is a commensal microbiota, to prevent deregulated immune responses. IBD patients have a reduced Treg/Th17 ratio in peripheral blood compared to healthy individuals. The installation of the inflammatory process in IBD seems to be fueled by an unbalanced increase in the production of Th17 cytokines, which promote the Th1 pattern. Pro-inflammatory cytokines produced by Th1 cells, such as IL-1β, potentiate the inflammatory process by decreasing the Treg/Th17 ratio, both by proportionally increasing the Th17 response and by reducing the suppression of the inflammatory response by Treg cells. Regarding Th9 cells - capable of exacerbating inflammatory processes by increasing epithelial permeability[36], are at high levels in CD and UC[37,38].

IMMUNOMODULATION OF THE INFLAMMATORY PROCESS AND PATHOGENESIS OF IBD BY *HELICOBACTER PYLORI*

Influence of Helicobacter pylori cytotoxin-associated antigen A+ infection on IBD prognosis

Cytotoxin-associated antigen A (*CagA*) is a gene found in the final portion of the Cag pathogenicity island of the *Helicobacter pylori* (*H. pylori*) genome and encodes the oncogenic protein CagA. Its presence is more frequent in East Asian populations than in those from the West, and determines a number of interactions between the bacterium and the host [39]. Although there is a causal relationship between *H. pylori* CagA+ and the incidence of cancers of the gastrointestinal tract[39,40], when it comes to IBD, especially CD and UC, the presence of the *CagA* gene may positively influence the prognosis of patients[41].



In a first analysis, age, genetic and environmental factors associated with innate and adaptive immunity are key factors in the development of IBD[42,43], thus the presence of *H. pylori* infection becomes yet another variable. Some studies point to several hypotheses for the improved prognosis of IBD in the presence of the *H. pylori CagA* gene, such as the conversion of the M1 macrophage lineage into M2 through modulation of the Th17/Treg immune response, in which there is a decrease in the levels of IL-17F and IL-21 with concomitant increase in the expression of IL-10 and Treg cells[44] due to increased plasma IL-13[45].

Also contributing to the process are increased anti-inflammatory responses through increased expression of CD163 and IL-10, suppression of toll like receptors (TLR) mediated signaling pathways[46], and control of the immune response through activation of pathways mediated by the basic leucine zipper transcription factor ATF-like 2 (BATF2)[47-49] (Figure 1).

The CD163 is a macrophage/monocyte scavenger receptor whose expression is positively regulated by IL-10. The upregulated expression of this receptor is one of the most marked changes in the M2/M1 phenotype switch; therefore, high expression of CD163 is characteristic in inflammatory processes[50,51]. According to studies, the number of CD163- M1 monocytes, as well as CD163+ and CD163+/IL-10+ M2 monocytes are significantly increased in individuals infected with *H. pylori*, in addition to having higher levels of IL-10. IL-10 production is significantly higher by M2 cells from individuals with *H. pylori* infection. In addition, individuals infected with CagA-positive *H. pylori* strains had a significantly higher number of CD163+ and CD163+/IL-10+ monocytes compared to those infected with CagA-negative strains[52].

The TLRs are expressed by cells of the intestinal epithelium, and by cells of the immune system present in the gut, such as leukocytes, dendritic cells, and various polymorphisms of these receptors have been associated with susceptibility to IBD[53,54] and they are involved in signaling pathways leading to the expression of several inflammatory genes[55,56]. BATF2 has unique functions in the regulation of cytokine gene expression by TLR signaling in macrophages[57].

H. pylori has metabolic adaptations for gastric colonization that, in the background, participate in modulating the inflammatory process of IBD. The urease enzyme that confers *H. pylori* resistance to stomach acidity, participates in immunomodulation as it alters particle opsonization, facilitates apoptosis, and by being presented by MHC II increases the expression of pro-inflammatory cytokines[58].

Figure 1 Mechanisms of *Helicobacter pylori* cytotoxin-associated antigen A+ on favorable prognosis of inflammatory bowel diseases. The presence of the cytotoxin-associated antigen A gene at the Cag pathogenicity island induces the modulation of T helper 17/Treg immunological response (1), which reduces levels of interleukin (IL)-17F, IL-17A, and IL-21 and increases the expression of IL-13, IL-10, and Treg (2). These two factors are synergists in the conversion process of the M1 to M2 macrophage lineage (3). Then, M2 macrophages suppress signaling mediated by toll-like receptors (4) and activate metabolic pathways mediated by basic leucine zipper transcription factor ATF-like 2, increasing CD163, a macrophage/monocyte scavenger receptor (5). Finally, the levels of IL-10 expression also increase (6), leading to anti-inflammatory effects (7) and, therefore, to a better prognosis on inflammatory bowel diseases. *H. pylori*: *Helicobacter pylori*; IL: Interleukin; TLR: Toll-like receptor; IBD: Inflammatory bowel disease; CagA: Cytotoxin-associated antigen A; Treg: Regulatory T.

The flagella of *H. pylori*, besides the fundamental importance in its motility for gastric colonization, also induces an inflammatory response. FlaA and FlaB flagellins can promote a humoral response by stimulating the production of specific antibodies[59,60]. Furthermore, studies report that bacteria with increased motility increase IL-8 release and suggest that genes which regulate flagellin production may alter adhesin expression[61-63] facilitating colonization. The chemoattractant effect of IL-8 is all too well known, however, data on the association of IL-8 with *H. pylori* infection are still scarce[64].

Superoxide dismutase from *H. pylori* has also been shown to have a potential immune suppressive effect by inhibiting the production of pro-inflammatory cytokines, through inhibition of pathways activated by the transcription factor nuclear factor kappa B (NF-κB), as well as macrophage inflammatory protein 1-α[65].

Modification of bacterial gut microbiota by H. pylori

The alteration in the pattern of gastric secretion by *H. pylori* is closely related to the modification of the microbiota of the gastrointestinal tract[66]. Hypochlorhydria enables colonization of the distal intestine by acidic pH-sensitive bacteria; this causes people infected with *H. pylori* to have a more diverse alpha intestinal microbiota compared to uninfected people [66-68]. These changes reflect higher percentages of acidophilic bacteria, proteobacteria, bacteria of the genera *Lactobacillus*, *Haemophilus*, *Streptococcus* and *Gemella*; in contrast, there is a decrease in the percentage of pathogenic anaerobic bacteria such as *Clostridium*[69-72].

In addition to the variation in intestinal pH being one of the factors that alter the diversity of the gut bacterial microbiota, it can also be influenced by the virulence factors CagA and VacA of *H. pylori*, which alter the immune response of the infected individual[73-75]. Hormonal factors, influenced by *H. pylori* infection such as an increase of gastrin secretion alter gut metabolism, in addition, leptin has been directly related to an increase of the amount of the probiotic bacteria *Bifidobacterium* and *Lactobacillus*[76].

Indeed, there is an altered composition of the local microbiota of IBD patients[77]. In these diseases an exacerbated immune response against the commensal microbiota occurs in genetically predisposed individuals and, studies suggest that the balance between pathogenic and beneficial bacterial species is altered in these ones[78]. Therefore, the dysbiosis promoted by *H. pylori* infection may help explain the inverse relationship between bacterial infection and IBD in individuals with the two conditions concomitantly, although the underlying molecular mechanisms are not fully understood[79].

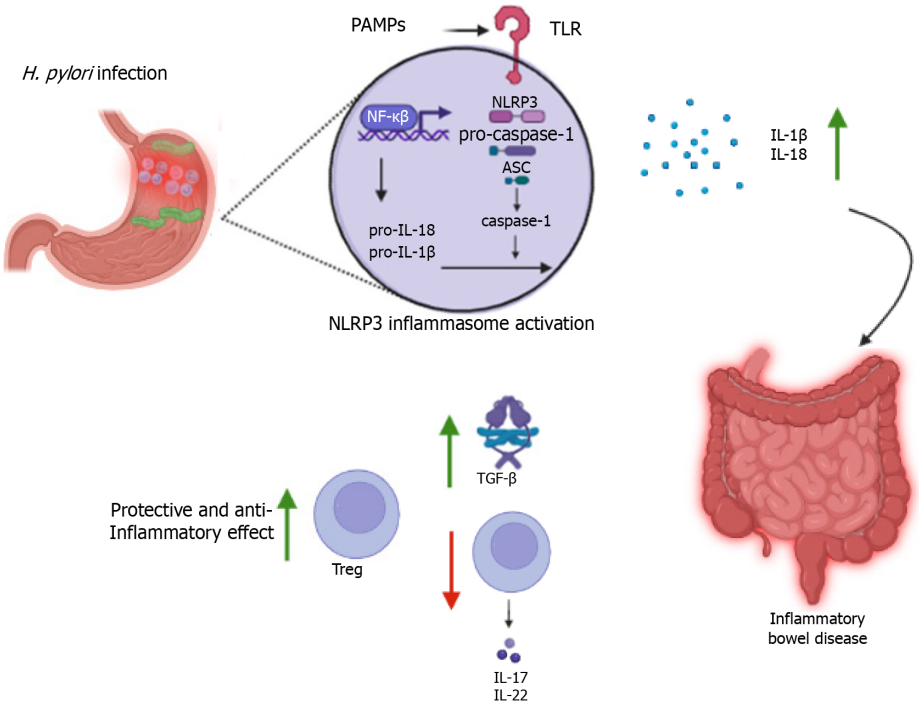
CO-IMMUNOMODULATION OF IBD BY NLR FAMILY PYRIN DOMAIN CONTAINING 3 INFLAMMASOME AND *H. PYLORI* INFECTION

The NLR family pyrin domain containing 3 (NLRP3) inflammasome is a multiprotein complex that plays a crucial role in the innate immune response. The complex is formed by the NLRP3 receptor, the adaptor protein caspase-recruitment domain (ASC) and the enzyme caspase-1 and, appears to play a role in the negative association between IBD and *H. pylori* infection by the IL-1β and IL-18 activity. NLRP3 recognizes a wide variety of stimuli linked to pathogen-associated molecular patterns and damage-associated molecular patterns through pattern recognition receptors such as TLRs and nucleotide-binding oligomerization domain 2. Activation of NLRP3 includes a priming process which components are expressed in greater quantities and depends on several upstream signals such as potassium and chloride efflux, calcium mobilization, lysosomal disruption, and mitochondrial dysfunction with increased reactive oxygen species[80].

Activation of the inflammasome culminates i4n expression of NF-κB and cleavage/activation of caspase-1, responsible for processing pro-IL-1β and pro-IL-18, which are cleaved into their active forms[81,82]. Furthermore, activation of NLRP3 leads to proptosis, a form of programmed cell death mediated by gasdermin D protein. Caspase-1 cleaves gasdermin D, removing its carboxy-terminal portion, which allows its insertion and polymerization into the plasma membrane forming pores. Proptosis also appears to induce the secretion of IL-1β and IL-18[83].

Caspase-1 is highly expressed in the mucosa of the patients infected with *H. pylori*. However, it is observed that together, IL-1β and IL-18 seem to play different roles in controlling the infection and the pathogenicity of the bacterium. While IL-1β presents itself as a potent pro-inflammatory agent, IL-18 has regulatory properties and controls responses mediated by TCD4+ cells. Studies have shown that mice that failed to process IL-18 in the absence of caspase-1 had less bacterial colonization, more robust Th17 responses, and more evident immune pathogenicity compared to control animals[84]. Furthermore, mesenchymal stem cells stimulated by this cytokine promote differentiation of Treg cells into virgin TCD4+ cells, limiting the Th17 response[85], promoting a tolerogenic activity and adjusting chronic inflammation in the gastric mucosa (Figure 2).

The absence of caspase-1 results in an inefficient protective immune response, with a less pronounced Th1 and Th17 pattern[86,87]. There is strong evidence of an association between IL-18 and the prevention and control of allergic diseases such as asthma and rhinitis, through pulmonary infiltration of large amounts of Treg and tolerogenic dendritic cells. This association seems especially beneficial in relation to infection with *H. pylori* CagA+ strains, as observed in a study wherein mice infected with the bacteria in the neonatal period developed specific immunological tolerance and protection against gastric immunopathology resulting from *H. pylori* CagA+ infection[88].



Studies with animal models have shown that NLRP3 activation induced by *H. pylori* infection appears to improve the prognosis of IBD. Engler *et al*[89] observed that mice exposed to the bacterium developed less severe forms of dextran sulfate sodium (DSS)-induced colitis, with significantly milder inflammation and epithelial changes. These positive effects were also observed in animals treated with *H. pylori* extracts. Such beneficial effects are accompanied by positive regulation of TGF-β and the transcription factor caudal-related homeobox transcription factor 2, which regulates the expression of mucins such as mucin 2, a fact that was associated with signaling by NLRP3 and IL-18 production by caspase-1.

Zaki *et al*[90] demonstrated that NLRP3 -/- or ASC -/- mice are more susceptible to DSS-induced colitis and caspase-1 -/- mice are more susceptible to weight loss, diarrhea, rectal bleeding and mortality during the chronic and acute phases of DSS- or TNBS-induced colitis. These findings are related to IL-18 production and its mucosal barrier repair function. Furthermore, IL-18 -/- and IL-18R -/- mice exhibit greater susceptibility to DSS-induced colitis, associated with higher mortality and more severe histopathological changes[91]. Previous studies have reported that the absence of the adaptor protein myeloid differentiation primary response 88 (MyD88), which is involved in the production of IL-18 and IL-1β, increases the severity of inflammatory disease, indicating the importance of MyD88-dependent signaling pathways, such as the TLR4-MyD88 pathway, in blocking the onset and progression of IBD[92-94]. MyD88 is the main signaling adaptor protein of the TLR family. Studies using MyD88-deficient mice suggest a dominant role for TLR/MyD88 signal transduction in preventing intestinal inflammation after acute epithelial injury by promoting epithelial repair[94,95].

Yao *et al*[96] conducted a study with NLRP3R258W mutant mice, a mutation homologous to NLRP3R260W in humans, which causes increased inflammasome activity. The mutant mice developed DSS-induced colitis with milder symptoms compared to wild-type animals, in addition to lower expression of inflammatory mediators, higher expression of IL-18 and IL-1β, and fewer colon tumors. These positive effects were associated with higher activity of Treg cells, positively regulated by IL-1β and fundamental in controlling inflammation. In this study no evidence was found that directly points to IL-18 as an effector molecule in the activation of the inflammasome, but it is believed that this cytokine may be indirectly affected by NLRP3 through secondary effects. However, IL-18 deficiency was shown to override the protective effect of the NLRP3R258W mutation.

IMMUNOMODULATION OF IBD BY NEUTROPHIL-ACTIVATING PROTEIN OF *H. PYLORI*

H. pylori neutrophil-activating protein (HP-NAP) is a virulence factor that plays an important role in immunomodulation. HP-NAP refers to *H. pylori* mini-ferritin, a protein with the ability to activate the production of oxygen radicals by neutrophils promoting their adhesion to the vascular endothelium[97]. Neutrophil adhesion occurs by the positive regulation of β-2-integrin (CD18) expression in a high-affinity state[98,99].

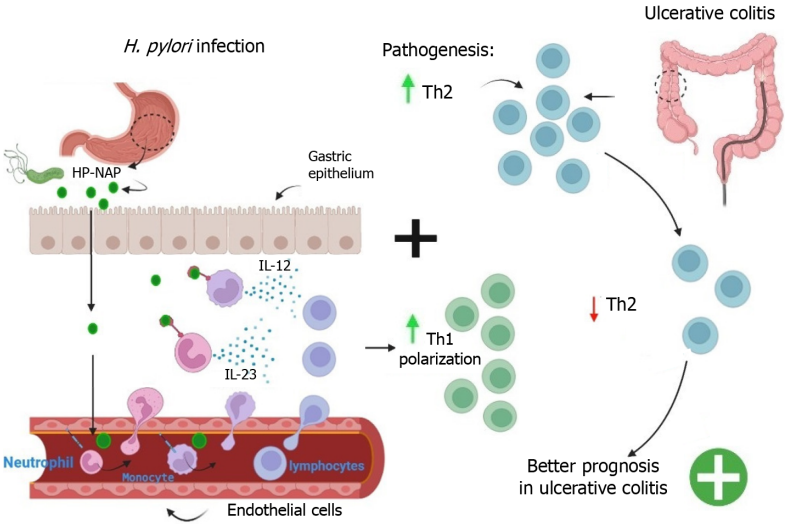
Figure 2 Immunomodulation of the NLR family pyrin domain containing 3 inflammasome and protection against inflammatory bowel diseases. Pathogen-associated molecular patterns from *Helicobacter pylori* are recognized by the NLR family pyrin domain containing 3 (NLRP3) inflammasome toll-like receptors leading to responses that appear to be associated with improved prognosis and an anti-inflammatory effect. Activated NLRP3 is able to increase the expression of caspase-1 which activates the cytokines interleukin (IL)-18 and IL-1β. The positive regulation of these cytokines leads to extragastric immunomodulation by suppressing the T helper 17 subpopulation and increasing regulatory T, transforming growth factor-β and mucins. *H. pylori*: *Helicobacter pylori*; IL: Interleukin; PAMPs: Pathogen-associated molecular patterns; TLR: Toll-like receptor; TGF: Transforming growth factor; NLRP3: NLR family pyrin domain containing 3; Treg: Regulatory T.

The mini-ferritins have the ability to influence host immune cells in addition to protecting bacterial DNA from oxidizing radicals[100]. HP-NAP is released by *H. pylori* near the gastric epithelial monolayer, thus activating macrophages/monocytes and mast cells, with the release of pro-inflammatory cytokines TNF-α, IL-6, IL-12 and IL-23[101,102]. Similar to the chemokine CXCL8, HP-NAP directly promotes leukocyte recruitment; after HP-NAP transcytosis by endothelial cells, part of these proteins remain bound to the luminal portion of the endothelium, increasing the expression of β-2-integrin and changing the local spatial conformation, a fact that culminates in the extravasation of immune cells[99,103].



The IL-8 secretion by neutrophils present at the site of inflammation enables the recruitment of more neutrophils and other immune cells. IL-8 secretion is promoted by HP-NAP and mediated through interactions with TLR2 receptors and pertussis toxin-sensitive G proteins[104]. HP-NAP also induces mast cells and basophils to secrete TNF-α, IL-6, IL-8, IL-12 and IL-23, and stimulates mast cells to release histamine and IL-6[101,102,105]. Besides influencing innate immunity, HP-NAP modulates adaptive immunity by promoting the release of IL-12 and IL-23 by neutrophils and monocytes, thereby causing a Th1 polarization, and directing the maturation of monocytes to mature dendritic cells[102].

The mature dendritic cells are stimulated by HP-NAP to express MHCII and release Th1 pattern cytokines such as IL-12[102,106]. The increased secretion of IL-12 in the gastrointestinal microenvironment, promoted by HP-NAP, causes gastric specific T lymphocyte subpopulations to be able to produce large amounts of IFN-γ and TNF-α and, to exhibit cytotoxic activity[102]. Increased Th1 pattern and cytotoxic response, induced by *H. pylori* infection, may be beneficial in pathologies which the Th2 response is the detrimental mechanism (Figure 3). The ability of HP-NAP to reduce Th2 activity due to the polarization towards Th1 was proven in experiments using mice with atopic dermatitis[107]. Therefore, HP-NAP may have a therapeutic effect in situations which there is a predominance of Th2 response, as was observed in HP-NAP inoculation assays in mice with allergic asthma, which significantly reduced serum immunoglobulin E levels with concomitant increase in IL-2, thus decreasing eosinophil infiltration[108].

Thus, the Th1-directed polarization promoted by HP-NAP, may be a possible explanation for the improvement of IBD symptoms, whose pathogenesis may be the result of a dysregulated Th2 response, as occurs in UC, in which there is a predominance of a Th2 response and inhibition of the Th1 response, in individuals infected with *H. pylori*[109-112].

CONCLUSION

Although significant progress has been made over the last few years in defining the mechanisms that *H. pylori* use to influence on IBD evolution, there is clearly much that remains to be elucidated and many questions persist. In this review

Figure 3 Hypothesis on correlation between concomitant infection with *Helicobacter pylori* and the presence of ulcerative colitis (inflammatory bowel disease), which has a pathological pattern of exacerbated T helper 2 response. The schematic shows HP-NAP being secreted into the gastric mucosa by *Helicobacter pylori* (*H. pylori*). Then, HP-NAP undergoes a process of transcytosis by endothelial cells, binding to the luminal side of the blood vessel. With this, there is an alteration in the expression of β-2-integrin, with the recruitment of neutrophils and monocytes, which carry out diapedesis. The recruited leukocytes secrete cytokines [interleukin (IL)-12 and IL-23], which promote a polarization of the circulating lymphocytes to a T helper 1 (Th1) pattern. The Th1 polarization causes a reduction in the Th2 response, this could explain the improvement of ulcerative colitis symptoms in patients infected with *H. pylori*. *H. pylori*: *Helicobacter pylori*; IL: Interleukin; Th: T helper; HP-NAP: *Helicobacter pylori* neutrophil-activating protein.

we emphasize the role of *H. pylori* CagA+ and HP-NAP on favorable prognosis of IBD. The pathogenesis of IBD is complex and involves a combination of genetic, environmental, and immunological factors. Classically, CD and UC are described as diseases with a Th1 and Th2 immune pattern, but the prevalence of type response remains under study.

Regarding the cellular pattern, Th17 cells have been demonstrated at the site of inflammation, but the levels of total cytokine markers of these patterns remain variable on models' diversity. Treg cells play a major role in the pathogenesis of IBD by suppression of Smad3 and consequently overexpression Smad7, an inhibitor of the TGF-β signaling pathway. Moreover, Th9 cells - capable of exacerbating inflammatory processes by increasing epithelial permeability, are at high levels in CD and UC.

In summary, targeting NLRP3 inflammasome by *H. pylori* infection allows the exacerbation of IL-1β and IL-18 that culminates in high levels of TGF-β and low levels of IL-17 and IL-22 on IBD. The patients with *CagA* gene can induce the Treg cells which contributes to the polarization of the M1 macrophage into M2 macrophage lineage through concomitant increase of the expression of IL-10 and more Treg cells. At the same time, HP-NAP has an important role in immunomodulation by reactive oxygen species production neutrophil-induced. The ability of HP-NAP to reduce Th2 activity due to the polarization towards Th1 response may be a possible explanation for the improvement of IBD symptoms, in which there is a predominance of a Th2 response and inhibition of the Th1 response like occurs in individuals infected with *H. pylori*.

Regarding the capacity of CagA+ and HP-NAP to control inflammation and autoimmunity, and their implication in preventing IBD evolution, it seems probable that a clear understanding of how CagA+ and HP-NAP work on Treg cells, cytokines and macrophages-induced will present definitive opportunities for therapeutic intervention.

Abstract

After being ingested and entering the human stomach, *Helicobacter pylori* (*H. pylori*) adopts several effective strategies to adhere to and colonize the gastric mucosa and move to different regions of the stomach to obtain more nutrients and escape from the harsher environments of the stomach, leading to acute infection and chronic gastritis, which is the basis of malignant gastric tumors. The endoscopic manifestations and pathological features of *H. pylori* infection are diverse and vary with the duration of infection. In this review, we describe the endoscopic manifestations of each stage of *H. pylori* gastritis and then reveal the potential mechanisms of bacterial intragastric colonization and migration from the perspective of endoscopists to provide direction for future research on the effective therapy and management of *H. pylori* infection.

Key Words: *Helicobacter pylori*; Colonization; Endoscopy; Gastritis; Infection

INTRODUCTION

More than half of the world's population is estimated to be infected by the gram-negative, flagellated, spiral-shaped bacterium *Helicobacter pylori* (*H. pylori*)[1]. The bacterium has received intensive attention because *H. pylori* infection is closely associated with the development of peptic ulcers, mucosa-associated lymphoid tissue lymphoma and gastric cancer (GC), resulting in at least 500000 deaths per year[2-4]. The slow carcinogenic process is known as Correa's cascade [5]: At first, gastritis occurs in all infected individuals[2], and then a series of intermediate stages (characterized by precancerous lesions), including atrophy, intestinal metaplasia (IM) and dysplasia, may slowly develop, and eventually, 1%-3% of infected patients develop gastric malignant tumors[6].

All gastric mucosal lesions that occur after *H. pylori* infection can be observed by skilled endoscopists through upper gastrointestinal endoscopy. Based on the Kyoto classification of gastritis, endoscopic features, such as nodularity, diffuse redness, spotty redness, mucosal swelling, enlarged folds, xanthoma, atrophy and IM, are helpful in diagnosing *H. pylori* gastritis[7]. Atrophy can be endoscopically identified with high confidence by applying the Kimura-Takemoto classification[8], while IM and dysplasia can be diagnosed more accurately with advanced image-enhanced endoscopy (IEE) [9].

The highly motile pathogen *H. pylori* usually infects young children[3] and initiates acute infection that lasts for only a few weeks[10,11] and chronic inflammation that can last for the lifetime of the host[12]. Its ability to swim in the gastric mucus and colonize the stomach enables it to survive in the hostile gastric environment[13] and leads to various endoscopic and histological features as gastric mucosal lesions progress[14]. Many articles and reviews have reported the underlying mechanisms, but few have linked endoscopic features to mechanisms. Therefore, in the following sections, we describe the endoscopic manifestations of each stage of *H. pylori* gastritis and summarize the process and potential mechanisms of intragastric colonization by *H. pylori* and its migration.

ACUTE INFECTION

Acute *H. pylori* infection only lasts for a few weeks[10,11] and has been rarely observed or reported in recent decades. The endoscopic manifestation of gastric erythema and a gaping pylorus[10,11] is always featureless. Although the gastric mucosa does not appear damaged at this stage, initial colonization of the mucosa is the basis of a series of lesions, such as atrophic gastritis, peptic ulcer and even gastric carcinoma.

The prevalence of *H. pylori* infection is high, but colonization by this microbe is not easy. Multiple spontaneous eradication events may occur before colonization, leading to acute infection[15]. Sophisticated strategies have been adopted by *H. pylori* that have enabled it to adapt to and survive in the hostile gastric environment.

When *H. pylori* is ingested by adults, it is almost completely destroyed in the gastric acid, while it is easier to survive in the stomach of children younger than the age of five, both in developing and developed countries[3]. Bucker *et al*[3] simulated the pH changes of the postprandial stage in babies, young children and adults and suggested that the bacteria were easiest to reach the mucus layer in young children, whose feature of postprandial gastric condition is moderate food-induced pH elevation and slow reacidification.

During the process of slow reacidification, the urease enzyme is believed to play a key role in bacterial survival and adhesion. Urea is degraded by the urease enzyme, which buffers the cytoplasm and periplasm[16]. This confers many benefits. First, *H. pylori* prefers to live in an environment with elevated pH. A recent study[17] showed that *H. pylori* does not escape from phosphate buffer solutions of pH 6.6 and 7.0. Second, intracellular urease could also increase membrane potential, thereby allowing protein synthesis at a low pH[18]. Third, mucosal viscosity highly depends on acidity[19]. At a less acidic pH, the mucus is less gel-like, which enables *H. pylori* to more easily move through the mucus layer[20]. Fourth, trefoil factor 1 (TFF1) is a member of the trefoil peptide family of proteins and is coexpressed with Mucin-5AC (MUC5AC), a gel-forming mucin that is predominantly secreted and expressed by gastric surface epithelial cells in the stomach[21]. The optimum pH for bacterial binding to TFF1, which thereby promotes colonization, was found to be 5.0-6.0[22]. In addition, urea and bicarbonate were considered to have a chemotactic effect on *H. pylori in vitro*[23], but research by Schreiber *et al*[13] shows that neither the urea/ammonium gradient nor the bicarbonate/CO_2 gradient are essential for the orientation of *H. pylori in vivo*.

However, this does not mean that a neutral or alkaline environment is suitable for *H. pylori*. Previous studies have shown that *H. pylori* is sensitive to alkaline conditions[24], and its growth is limited at neutral pH[25]. To prevent lethal alkalinization of the cytoplasm, *H. pylori* utilizes a proton-gated channel, UreI, which regulates the uptake of urea[26] and only functions in conditions of an acidic pH; thus, the transport of urea into the bacterial cell does not occur at a neutral pH[24]. Therefore, *H. pylori* prefers a weakly acidic environment.

The epithelial surface of the stomach is covered with an approximately 300 μm thick layer of secreted mucus, which mainly consists of mucins Mucin 6 (MUC6) and MUC5AC[27]. MUC6 exists in each layer of the mucus gel, while MUC5AC is mainly present on the surface and bottom. The increase in the viscosity of gastric mucus gel is due to this natural stratification of mucins[28]. While protecting gastric epithelial cells, the mucus layer also plays an important role in the colonization process. The pH is approximately neutral at the epithelium and very acidic (pH 1-2) close to the lumen [21], resulting in a mucus pH gradient that can be used by *H. pylori* for precise spatial orientation[13]. The membrane-bound chemoreceptor TlpA of *H. pylori* detects and mediates repulsion from environments with a lower pH, and the cytoplasmic chemoreceptor TlpD mediates both attraction to higher pH environments and repulsion from lower pH environments[17,29]. Under this chemotactic effect, *H. pylori* penetrates the gastric mucus quickly and reaches the narrow region within 25 μm of the gastric epithelial surface with the help of its two to six sheathed unipolar flagella and helical shape[30,31].

After approaching the lower mucus layer, the majority of *H. pylori* swim in gastric mucus, while others directly adhere to epithelial cells[13,31]. Although it is considered a noninvasive gastric pathogen to date[19], *H. pylori* can indeed bind to, invade, be internalized into and proliferate in gastric epithelial cells[27,32]. The invasiveness of *H. pylori* may partially depend on the strain. Research by Camorlinga-Ponce *et al*[33] showed that CagA-negative bacteria adhered to the surface of the apical epithelium, while CagA-positive bacteria were identified in the intercellular spaces or the immediate vicinity of epithelial cells. Sigal *et al*[34] found a subgroup of *H. pylori* associated with cells deep in the antral glands. These microbes can promote gland hyperplasia by inducing stem cell proliferation and expansion and altering gene expression of stem cells[34].

H. pylori adheres to epithelial cells mainly by outer membrane proteins (OMPs). Blood group antigen-binding adhesion (BabA) and sialic acid-binding adhesion (SabA) are important OMPs[19,27]. Lewis antigens are common in normal, infected and inflamed gastric mucosa[35,36]. BabA can identify and bind to Lewis b antigen[35], while SabA can bind to the antigens Lewis a and Lewis X[36], and its expression can quickly respond to the changes in the stomach or different areas of the stomach, enabling the bacteria to adapt to host's immune responses and varied microenvironments to maintain long-term colonization and infection[37]. In addition to BabA and SabA, other surface proteins, such as AlpA, AlpB, DupA, outer inflammatory protein A (OipA) and HopZ, are considered related to adhesion, but none of them has been shown to be essential to adhesive mechanisms[38]. After *H. pylori* adheres to epithelial cells, the Cag type IV secretion system (T4SS) promotes CagA translocation into host cells, resulting in changes in cell shape, disruption of cell□cell junctions, altered cell polarity and cell adhesion, increased cell motility and cell migration, increased cell proliferation, β-catenin activation, and epithelial-mesenchymal transition[39]. Some bacteria are internalized into the cytoplasm of gastric epithelial cells through endocytosis within 45 minutes of bacterial attachment to the cell surface[32]. *H. pylori* can replicate and proliferate in epithelial cells[40], escape the immune response, and exit cells to colonize and infect cells again when the external environment is suitable for survival[27].

In an artificial ingestion study[10], histological examination during the acute phase of *H. pylori* infection showed many polymorphonuclear neutrophil leucocytes (PMNs) in the lamina propria and on the surface of the mucosa and an absence of intracellular mucus. Spiral bacilli adhered to the surface and glandular epithelium as well as among PMNs in the mucus[10]. Zhao *et al*[41] proposed a novel staging strategy according to the depth and degree of gastric mucosal injury induced by *H. pylori* infection and the progression of lesions. Stage I means the bacteria were present in the mucus layer, stage IIA refers to the specific adhesion to and selective destruction of gastric epithelial cells, and stage IIB refers to the degeneration and shedding of surface mucus cells[41]. It seems that stages I and II are consistent with the pathological characteristics of acute *H. pylori* infection.

CHRONIC GASTRITIS

Cases of *H. pylori* gastritis that are observed by doctors usually involve chronic gastritis that has lasted for years[42]. Chronic gastritis has various endoscopic findings, among which nodularity, diffuse redness, spotty redness, xanthoma, mucosal swelling, enlarged folds, atrophy, and IM are common in *H. pylori*-infected gastric mucosa[43,44] (Figure 1). Considering the severity and progression of chronic *H. pylori* gastritis, we discuss endoscopic manifestations and potential mechanisms from the following three aspects: (1) Early stage of *H. pylori* infection; (2) corpus inflammation; and (3) atrophy and intestinal metaplasia, which are summarized in Table 1.

Early stage of H. pylori infection

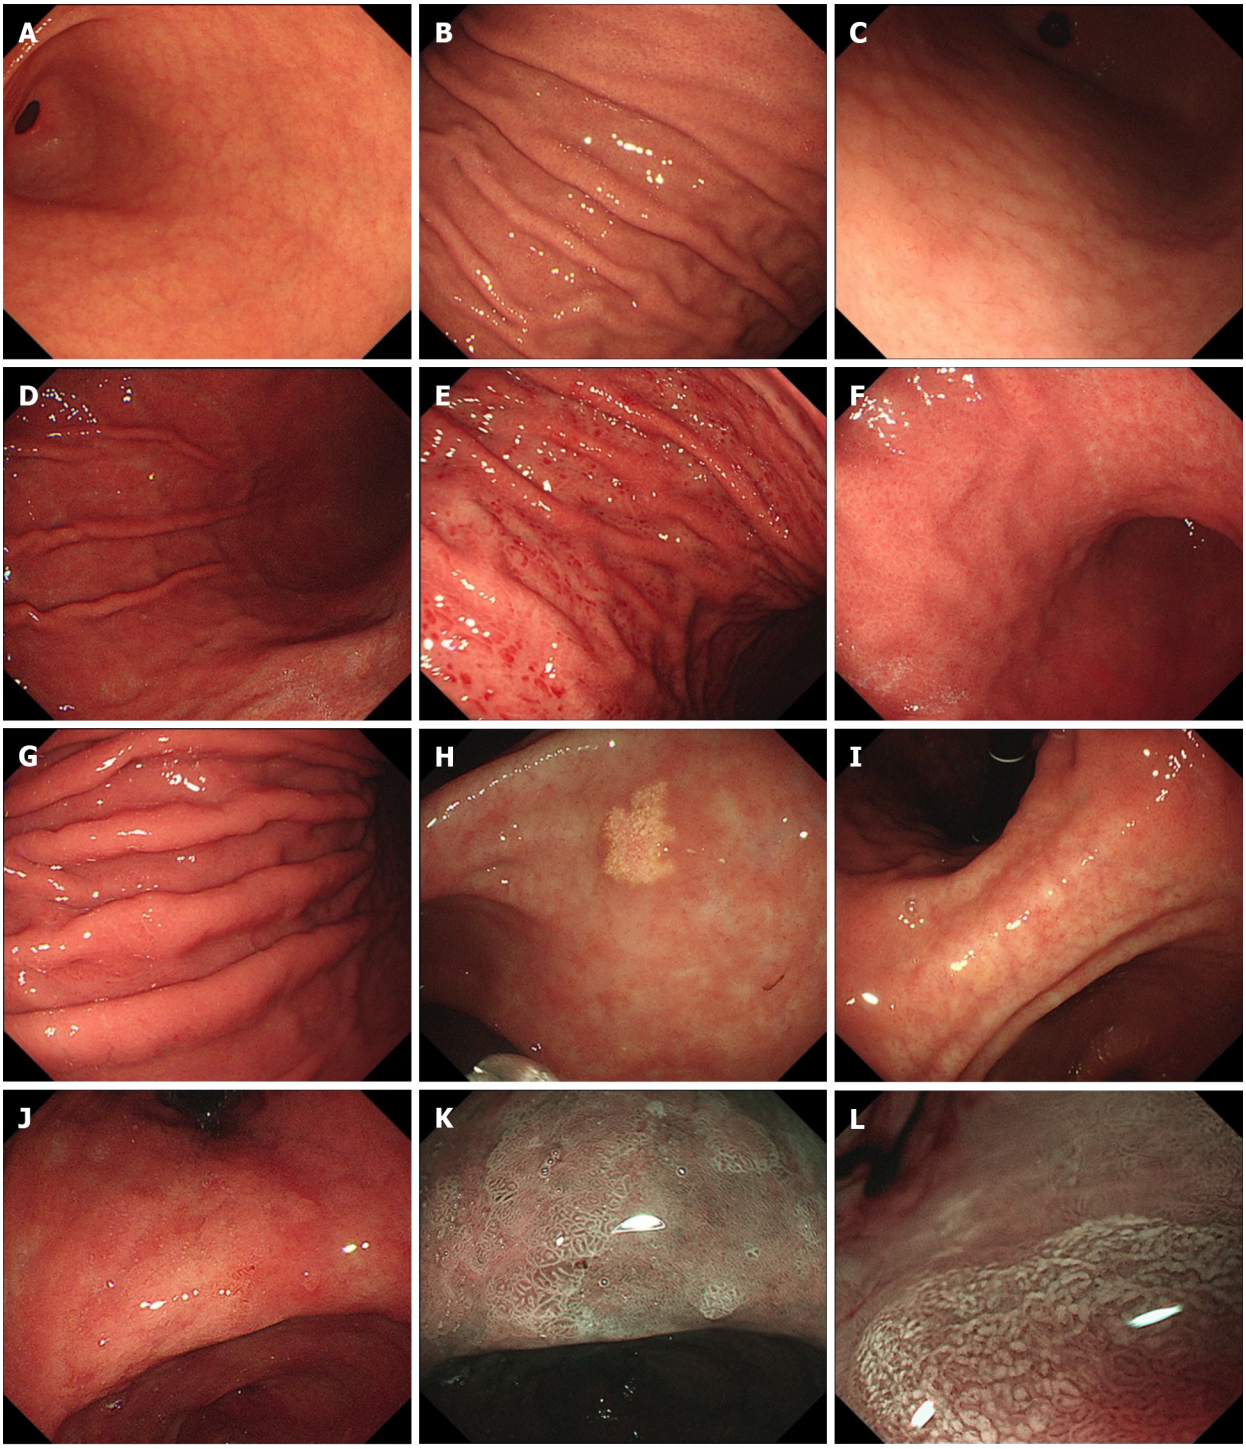
Nodular gastritis is considered a feature of an early stage of *H. pylori* infection in adults and is more common in children, with an incidence of 32.9% to 85%[45,46]. It appears more frequently in the antral mucosa than in the corpus mucosa[47]. Nodularity is characterized by a miliary pattern resembling "gooseflesh" in the gastric mucosa on endoscopy[46] and follicular lymphoid hyperplasia with intraepithelial lymphocytosis on histological examination[47]. Okamura *et al*[48] further demonstrated that superficially located, enlarged hyperplastic lymphoid follicles corresponded to nodular and/or granular lesions, and the percentage of MECA-79 high endothelial venule (HEV)-like vessels was greater in areas with gooseflesh-like lesions in nodules than in normal gastric mucosa. The pathogenesis of nodular gastritis may involve a Th2

Table 1 The mechanisms of common endoscopic features

Endoscopic features	Mechanisms
Nodularity	Follicular lymphoid hyperplasia with intraepithelial lymphocytosis[47]; Superficially located, enlarged hyperplastic lymphoid follicles [48]; Increased numbers of MECA-79 HEV-like vessels[48]; Th2 immune response[49]
Diffuse redness	Infiltration of neutrophils and monocytes[44,58]
Spotty redness	Unclear
Mucosal swelling	Infiltration by neutrophils and monocytes[44]
Enlarged folds	Tumor necrosis factor-alpha gene polymorphism[64]; Genome wide hypomethylation and regional hypermethylation[65,66]; Stimulation of epithelial cell proliferation and inhibition of acid secretion induced by interleukin 1 beta and hepatocyte growth factor [61,62]; Inhibition of acid secretion caused by morphological changes in parietal cells[63]
Xanthoma	Unclear
Atrophy	Cellular injury inflicted by *Helicobacter pylori* or mediated by inflammation or apoptosis[77]; Th1 immune response[78]; C-X-C motif chemokine receptor 2-mediated cellular senescence[79]
Intestinal metaplasia	Death of parietal cells and reprograming of chief cells[82]

immune response, which is more likely to occur in children[49,50].

Early colonization usually occurs in the gastric antrum, and early inflammation is always more serious in the gastric antrum, which is consistent with endoscopic findings. Animal research suggested that the wild-type *H. pylori* strain mostly colonized the antrum and the transition zone between the antrum and corpus rather than the corpus[31,34]. Rolig *et al*[51] demonstrated that inflammation was worse in the antrum than in the corpus in mice infected with wild-type *H. pylori* strains. This may be associated with the particularity of antral glands and chemotaxis of the bacterium.



It is well known that the corpus is populated by oxyntic glands containing many acid-secreting parietal cells that promote acidic conditions in the stomach. In contrast, the antrum, which is defined by the presence of gastrin-expressing G cells, mainly comprises the pyloric or antral glands containing MUC6-expressing deep mucous cells, G cells, D cells, enterochromaffin cells and foveolar surface mucous cells[52]. Interestingly, oxyntic glands also exist in the human gastric antrum, but the proportion of parietal cells and chief parietal cells is significantly less than that in corpus glands[53]. The effects of parietal cells in the antrum on *H. pylori* colonization remains unclear. However, generally, the weaker acidic environment of the antrum provides the bacteria with more opportunities to survive and colonize.

The chemotaxis system of *H. pylori* includes three membrane-bound chemoreceptors, including TlpA, TlpB, and TlpC; one cytoplasmic chemoreceptor, TlpD[29]; three core signaling complex proteins, including CheW, CheA and CheY[54,55]; and auxiliary chemotaxis proteins containing CheV-type coupling proteins (CheV1, CheV2, and CheV3), CheZ phosphatase and ChePep[56]. The role of pH sensing in chemotaxis has been mentioned above. In addition, a study by Rolig *et al*[51] shows that chemotaxis is required for *H. pylori* to swim to and achieve normal bacterial loads in the antrum and transition zone. The number of nonchemotactic mutant (Che-) *H. pylori* strains at this site was found to increase more slowly than that of the wild-type strains. TlpD plays a major role in this process. Therefore, chemotaxis may be necessary for *H. pylori* to locate or to maintain colonization of the antrum.

Corpus inflammation

Previous clinical studies focused on the relationship between endoscopic findings and *H. pylori* infection and demonstrated that diffuse redness, spotty redness, mucosal swelling and enlarged folds under endoscopy are associated with *H. pylori* infection[14,46]. Diffuse redness, defined as uniform redness with continuous expansion involving the nonatrophic mucosa in the region of fundic gland, and mucosal swelling, defined as swollen gastric mucosa in the region of fundic gland or thick, uneven mucosa in the region of pyloric gland, correlate predominantly with the degree of neutrophilic and mononuclear cell infiltration caused by *H. pylori* infection[44,57-59]. Spotty redness comprises multiple spotted small flat erythema, commonly observed in the upper corpus and fornix[44], but its mechanism remains unclear. An enlarged fold is defined as a fold with a width of 5 mm or more in the gastric greater curvature, which is not or only partially flattened by air insufflation[60]. Stimulation of epithelial cell proliferation, inhibition of acid secretion, tumor necrosis factor-alpha gene polymorphism, genome-wide hypomethylation and regional hypermethylation may play a role in the generation of enlarged folds caused by bacterial infection[61-66]. We describe another perspective: these endoscopic features that are mainly observed in the corpus indicate the existence of corpus inflammation, the development of gastric mucosal lesions, and a later stage of *H. pylori* infection that differs from the early stage and mainly manifests as antral inflammation.

H. pylori can survive in and colonize the harsh conditions of the corpus that are promoted by oxyntic glands. This has been indicated by previous studies. *H. pylori* was identified in the corpus in 83% of patients with a previous diagnosis of intestinal metaplasia and known *H. pylori* infection[67]. Biopsies taken from the corpus are conducive to an accurate histologic diagnosis and assessment of *H. pylori* infection[68,69]. Combined antrum and corpus biopsies can lead to a significantly better success rate of *H. pylori* culture than single antrum biopsy[4].

Figure 1 Endoscopic features without and with *Helicobacter pylori* infection. A: Antrum without *Helicobacter pylori* infection; B: Corpus without *Helicobacter pylori* infection; C: Nodularity; D: Diffuse redness; E: Spotty redness; F: Mucosal swelling; G: Enlarged folds; H: Xanthoma; I: Atrophy; J: Intestinal metaplasia; K: Light-blue crest; L: White opaque substance.

H. pylori also reaches the corpus under the guidance of chemotaxis, but afterward, chemotaxis is not needed for *H. pylori* populations to increase[51]. It is likely that the spontaneous eradication of the bacteria is almost impossible at this stage. However, to live, proliferate and induce chronic infection, bacteria need to acquire nutrients and escape immune reactions in addition to adapting to acidic environments, as mentioned above. Due to the low permeability of the mucosal layer, essential nutrients (for example, Fe^{3+}) for ingested microorganisms are scarce in the stomach[70]. Following the successful colonization of gastric epithelial cells, *H. pylori* induces immune cells that cause cell damage to shed nutrients onto the surface of the gastric mucosa for survival[71]. However, *H. pylori* needs to take measures to protect itself from host immunity. Sophisticated mechanisms participate in the response to innate immunity; these mechanisms include: (1) The induction of mitochondrial-dependent apoptosis in macrophages; (2) the defense against NO products available in the gastric microniche through production of peroxiredoxin by the AhpC gene; and (3) the reduction of NO or O_2^- radicals

by arginase due to substrate competition; responses to adaptive immunity, which have been elaborated in a previous review, include: (1) The binding of the VacA toxin to an unknown surface ligand in T cells, which results in actin rearrangement and then inhibition of cell proliferation; (2) The promotion of vacuoles in host cells, which leads to apoptosis by an anion-selective channel formed by the VacA toxin; and (3) VacA binding to mitochondria, which activates the associated apoptotic pathway[19]. In addition, *H. pylori* can be internalized into epithelial cells through endocytosis[32]. Long-term exposure to VacA during chronic infection causes the formation of immature autophagosomes, resulting in a failure to clear the bacteria[72].

In the novel pathological staging strategy mentioned above[41], stage III, the laminar lesion stage, may be consistent with the early stage of gastric antrum and corpus inflammation. Stage III is subdivided into: (1) Stage IIIA: Infiltration of inflammatory cells and vacuolar-like degeneration; (2) stage IIIB: The development of mucous neck cell hyperplasia, glandular hyperplasia and heteroplasia, and serrated structures; (3) stage IIIC: Mucosal ulcers develop; and (4) stage IIID: Histologically diffuse lymphocyte proliferation occurs, and many lymphatic follicles of varying sizes are present.

Atrophy and intestinal metaplasia

In the absence of treatment, the inflammation and immune response caused by *H. pylori* infection may lead to atrophic gastritis[73], which is defined as the loss of gastric glands, with or without metaplasia[74]. This process takes several years in humans[75]. Early *H. pylori* eradication should be considered for preventing GC development prior to the appearance of atrophy or metaplasia because the benefits of *H. pylori* eradication diminish after the gastric IM stage is reached, which is referred to as the "point of no return"[76].

Gastric gland replacement by connective tissue or inflammatory cells is referred to as atrophy[73,74]. Previous studies have reported that atrophy may be related to the Th1 immune response and cellular injury, which is directly inflicted by the bacteria or mediated by inflammation or apoptosis[77,78]. A recent study showed a new mechanism of *H. pylori* –induced atrophy through C-X-C motif chemokine receptor 2 (CXCR2)-mediated cellular senescence[79]. However, in general, the pathogenetic mechanisms that trigger atrophy are still debated.

Color changes (yellowish pale) in the mucosa, mucosal thinning and visible vascular patterns are typical endoscopic atrophic features[80]. In 1966, Kimura and Takemoto described the appearance of an "atrophic transitional zone" in patients with gastritis for the first time, which was subsequently known as the endoscopic atrophic border[8]. The differences in mucosal color and the visibility of capillary networks are remarkable between the two sides of the endoscopic atrophic border[81]. The degree of atrophy can be divided into 6 types based on the location of the endoscopic atrophic border. Endoscopic atrophic findings that are only visible in the antrum are referred to as closed type C-1. In closed types C-2 and C-3, atrophy can be observed in the angulus and the lesser curvature of the corpus. In open type O-1, the atrophic border lies between the lesser curvature and the anterior wall; in type O-2, it lies within the anterior wall; and in type O-3, the endoscopic atrophic area is widely spread within the border between the anterior wall and the greater curvature[81].

When deep damage to the gastric mucosa occurs, acid-secreting parietal cells die, and pepsin-secreting chief cells are reprogrammed into mucin-secreting, wound-healing cells to reduce endogenous production of caustic substances; this response to injury is known as metaplasia[82]. Pathologically, metaplasia refers to gland replacement by a different type of epithelium in a tissue where it is not normally found[74,83]. The characteristics of mucus secretion were used to discriminate metaplastic lineages[83]. Pseudopyloric metaplasia is defined as the presence of MUC6- and trefoil factor 2 (TFF2)-expressing cells at the base of corpus glands with a morphology more characteristic of mucus-producing deep antral glands[84]. IM refers to the presence of Mucin2 (MUC2)/trefoil factor 3 (TFF3)-expressing intestinal-type goblet cells in the stomach[85]. IM can be divided into two types: (1) Incomplete IM, which may be found in either the superficial or foveolar epithelium and in the glands and is characterized by secretive columnar cells that secrete mucin into the apical cytoplasm and the presence of goblet cells; and (2) complete IM, which is characterized by columnar absorptive cells without mucin secretion and the presence of goblet cells[86]. Both incomplete and complete IM can be subdivided into small intestinal type and colonic type (Table 2).

An ash-colored flat nodular change has been considered a typical endoscopic finding of IM since the last century[80]. With the development of endoscopic technology, advanced IEE, including narrow band imaging (NBI) endoscopy, has been used as a more accurate IM diagnostic tool than traditional white light endoscopy[9]. Various markers are related to gastric IM[87]. Light-blue crest (LBC) (Figure 1K), a light blue line observed on the surface of gastric mucosal epithelium, is the earliest mentioned IEE finding[88]. Combining the findings of white opaque substance (WOS) (Figure 1L), white mucosal epithelium observed under IEE, and LBC improves the sensitivity of diagnosing IM[89]. Through systematic review and meta-analysis, the diagnostic sensitivity and specificity of LBC were found to be 0.79 [95% confidence interval (CI): 0.76-0.81] and 0.95 (95%CI: 0.94-0.96), respectively. The sensitivities of the groove type (GT) and marginal turbid band (MTB) were 0.49 (95%CI: 0.43-0.54) and 0.47 (95%CI: 0.40-0.53), respectively, and the specificities were 0.92 (95%CI, 0.89-0.94) and 0.92 (95%CI: 0.89-0.95)[87], respectively. In addition, researchers derived a classification for endoscopic grading of gastric IM (EGGIM) using IEE, which permits immediate grading of intestinal metaplasia without biopsies and is beneficial for GC risk stratification[90].

In addition, gastric xanthoma is a common endoscopic finding in patients with *H. pylori* infection and may serve as a warning endoscopic sign for advanced atrophic gastritis, intestinal metaplasia and GC[91-93]. It is a small yellowish or yellowish-white plaque-like or nodular lesion characterized by the accumulation of lipids, containing cholesterol, low-density oxidized lipoprotein, low-density lipoprotein and neutral fat, in histiocytic foam cells[93,94]. However, the etiopathogenesis is also unclear.

Table 2 Intestinal metaplasia with different mucin secretion

Cells	Incomplete intestinal metaplasia		Complete intestinal metaplasia	
	Small intestinal type	Colonic type	Small intestinal type	Colonic type
Columnar cells	Neutral and scanty sialomucins	Sulpho- and scanty sialomucins	No mucin secretion	No mucin secretion
Goblet cells	Sialomucins	sialomucins	Neutral and sialomucins	Sulpho- and sialomucins

INTRAGASTRIC MIGRATION

H. pylori has shared a coevolutionary history with humans for more than 60000 years[41,95]. Human migration has led to the global distribution of the bacterium from East Africa to other continents[19]. In addition to geographical migration, *H. pylori* has the ability to move between different regions of the stomach.

The motility of *H. pylori* provided by its flagella and helical shape is the basis of intragastric migration. The bacterium possesses two to six sheathed unipolar flagella[96]. The sheath, which consists of both proteins and lipopolysaccharide, protects the flagellar filaments from gastric acid[97]. Expression of the two major flagellar proteins, FlaA and FlaB, is required for full motility of the bacteria[21]. An efficient screw-like movement resulting from the characteristic helical shape of *H. pylori* also provides an advantage for penetrating the gastric mucus layer[98]. Any mutation in the genes associated with bacterial morphology, such as Ccrp89, Ccrp58, Ccrp1142 and Ccrp1143, can lead to a deficiency in bacterial shape and motility[99].

The chemotaxis system of *H. pylori* is necessary for intragastric migration. Chemotactic signals sensed by chemoreceptors are transmitted to the histidine kinase CheA through the coupling protein CheW or CheV1[100]. Repellents activate CheA autophosphorylation, and CheY is subsequently phosphorylated *via* histidine-to-aspartate phosphorelay [101]. Phosphorylated CheY interacts with the flagellar motor, causing it to rotate clockwise and the bacteria to reverse or change direction[56]. Alternatively, the bacteria swim straight because chemicals perceived as attractants squelch CheA autophosphorylation[56]. As described above, the ability of chemoreceptors to sense pH guides the bacteria to the surface of the gastric epithelium. It has been suggested that different regions of the stomach contain unique chemotactic signals [51]. The gastric antrum is usually the first colonized area because of its weaker acidic environment but not due to chemotaxis. The chemotactic signals produced by the antrum or transition zone play an important role in the increase in *H. pylori* numbers that occurs from 14 h to 1 wk after colonization[51]. Chemotaxis is also required when *H. pylori* migrates to the corpus from the antrum but is not needed for the increase in bacterial populations after the initial colonization of the corpus[27]. In addition, *H. pylori* can swim toward injured epithelia[102].

H. pylori can simultaneously survive in the antrum and the corpus in general. However, when atrophy occurs, an environment that is unfavorable to the growth of *H. pylori* develops, and the bacteria can only be found in a small percentage of endoscopic biopsy specimens[103]. Research has revealed that atrophy in the corpus manifests as a continuous sheet of pseudopyloric metaplasia and forms an advancing histologically atrophic front, the presence of which is similar to the spread of antral mucosa toward the corpus and is faster in the lesser curvature[104]. This pattern is the same as the endoscopic atrophic border described by Kimura and Takemoto[8]. This may indicate that the suitable region in which *H. pylori* survives shrinks as the atrophic front advances and is well discriminated by the endoscopic atrophic border.

In addition, *H. pylori* can migrate to the duodenum and colonize the duodenal gastric metaplasia (DGM) with a bacterial density 100-fold lower than that in the antrum[105,106]. DGM is characterized by the metaplastic replacement of normal duodenal epithelial cells with cells displaying a phenotype similar to that of mucus-secreting cells of the gastric mucosa[107]. It is frequently found in patients with duodenal ulcers with a prevalence of 72 to 90% and is associated with the chronicity and recurrence of duodenal ulcer disease[108-110]. The exact pathogenesis of DGM remains unclear. It is speculated that a high acid burden in the duodenum caused by increased gastrin secretion and the inflammatory damage to duodenal mucosa induced by bacterial cytotoxin may lead to the development of DGM in patients with *H. pylori* infection[109]. Liu and Wright[111] considered that metaplastic cells originate from Brunner's gland duct epithelium or basal buds growing out of the crypts of Lieberkühn and migrate in straight lines. However, Shaoul *et al*[112] suggested that DGM develops from goblet cells that simultaneously express gastric antigens, MUC5AC and TFF1, and intestinal antigen, MUC2 core antigen, migrate upward and transform to foveolar-like cells at the site of early metaplastic patches. Published results about the association between *H. pylori* infection and DGM are also conflicting. Some studies reported that *H. pylori* infection was one of the independent risk factors for DGM[113], the amount of *H. pylori* in the duodenal bulb might be related to the extent of gastric metaplasia in the duodenal bulb[114], and the presence of DGM significantly decreased after *H. pylori* eradication[109]. However, some researchers have suggested that DGM is associated with high acid output in the stomach rather than gastric *H. pylori* infection[115-117].

CARDIA

The endoscopic characteristics of the cardia have received little attention in previous studies. In recent years, cardiac nodularity, which involves the appearance of miliary nodules or scattered small whitish circular colorations within 2 cm of the esophagogastric junction, has been proposed by researchers[46,118].

Cardia glands lack chief cells and parietal cells, and have similar characteristics to the pyloric glands[53]. The cardiac and pyloric glands secrete mucus and bicarbonate and are involved in the defense of the gastric epithelium[46]. In addition, both of them secrete MUC6 and pepsinogen II rather than pepsinogen I[46]. Unlike the fundic glands, the similarity of the cardiac and pyloric glands may lead to the appearance of cardiac nodularity.

Nodularity can be observed more frequently in the stomach of children and improves gradually with age[119,120]. Reportedly, the eradication of *H. pylori* in patients with antral nodularity could effectively prevent diffuse-type GC[119]. A study by Nishikawa *et al*[119] suggested that compared with patients without cardiac nodularity, patients with cardiac nodularity were significantly younger and had lower IM scores. Therefore, cardiac nodularity may also be a feature of the early stage of *H. pylori* infection, but further research is needed to analyze its clinicopathological importance.

CONCLUSION

H. pylori infection has received worldwide attention for decades. In this review, we described the process of intragastric colonization by *H. pylori* and its migration and tried to identify a link between endoscopic manifestations and potential mechanisms. Upper gastrointestinal endoscopy and pathological examination of biopsy specimens are useful tools for diagnosing *H. pylori*-induced gastritis and estimating the risk of *H. pylori*-induced GC. In addition to animal models, exploring the mechanisms of *H. pylori* infection requires biopsy sampling. However, extensive study is needed to evaluate the association between endoscopic manifestations and mechanisms.

Abstract

One of the most prevalent malignancies in the world is esophageal cancer (EC). The 5-year survival rate of EC remains pitiful despite treatment advancements. Neoadjuvant chemoradiotherapy in conjunction with esophagectomy is the standard of care for patients with resectable disease. The pathological complete response rate, however, is not acceptable. A distant metastasis or a locoregional recurrence will occur in about half of the patients. To increase the clinical effectiveness of therapy, it is consequently vital to investigate cutting-edge and potent therapeutic modalities. The approach to the management of resectable EC using immunotherapy has been considerably altered by immune checkpoint inhibitors. Systemic immunotherapy has recently been shown to have the potential to increase the survival of patients with resectable EC, according to growing clinical data. A combination of chemotherapy, radiation, and immunotherapy may have a synergistic antitumor impact because, according to mounting evidence, these treatments can stimulate the immune system *via* a number of different pathways. In light of this, it makes sense to consider the value of neoadjuvant immunotherapy for patients with surgically treatable EC. In this review, we clarify the rationale for neoadjuvant immunotherapy in resectable EC patients, recap the clinical outcomes of these approaches, go through the upcoming and ongoing investigations, and emphasize the difficulties and unmet research requirements.

Key Words: Systemic treatment; Resectable carcinoma of the esophagus; Personalized medicine; Biomarkers; Chemotherapy; Chemoradiotherapy; Immunotherapy; Immune checkpoint inhibitors

Core Tip: Despite improvements in neoadjuvant and adjuvant treatment approaches in recent years, the average life expectancy of patients with resectable esophageal cancer (EC) still falls below 5 years. Immunotherapy has been effectively used as a first-line therapy for many oncological diseases at advanced stages for over ten years. Immunotherapy drugs are also making great progress in resectable situations, while it is still debatable whether this treatment should be limited to a certain patient subgroup based on biomarker selection. In order to treat resectable EC, immunotherapy, in particular immune checkpoint inhibitors, has made significant strides. This review also provides a brief overview of potential ongoing clinical studies.

INTRODUCTION

With over 544000 expected deaths from esophageal cancer (EC) in 2020, EC is the sixth most common cancer-related cause of death globally. In East Asia, esophageal squamous cell carcinoma (ESCC) covers up around 90% of cases of EC, in contrast to Western nations[1-3]. Surgery continues to be the therapy of choice for early-stage EC. Unfortunately, the majority of EC patients are stage 4 or advanced stage at the time of diagnosis, and only surgery has a modest impact, hence a 5-year survival rate is only 25%. Systemic treatment, as opposed to surgery alone, may increase survival for resectable locally advanced EC. As a result, preoperative systemic treatment combined with surgery has become the norm for treating EC patients. Despite this, approximately half of these patients experience local recurrence or distant metastases following surgery[4-6]. To enhance survival, it is therefore vital to investigate innovative and effective therapies. Immune checkpoint inhibitors (ICIs) have recently made substantial advancements in a range of malignancies, including EC, with several trials demonstrating longer overall survival (OS), a higher objective response rate (ORR), and a decreased frequency of grade 3-5 adverse events (AEs) as second-line therapy. According to the most recent findings, treating resectable EC patients as first-line therapy with programmed death 1 (PD-1) inhibitors combined with chemotherapy resulted in considerably longer progression-free survival (PFS) and OS than treatment with only chemotherapy. These findings imply that ICIs have a bright future in EC management. ICI systemic treatment is now being extensively researched for EC patients and has been tested in a number of malignancies[7-10]. The rationale for ICI neoadjuvant treatment in EC, the published findings, the upcoming and ongoing studies, the unanswered questions, and the suggestions for more research will all be included in this review.

ROLE OF DIET AND MICROBIOTA IN EC

Some of the traditional risk factors for EC seem to be linked to changes in the esophagus' natural microbiome. In ESCC patients, drinking alcohol has been connected to changes in the microbiota's diversity. In animal studies, high-fat diets have been related to esophageal dysplasia and changes in the microbiome. Gram-negative organisms, which are present in lesions that are precursors to EC, were shown to be more prevalent in those who consumed less fiber. Changes in the esophagus bacterial population have been linked to smoking and medications like proton pump inhibitors and antibiotics. Firmicutes, Proteobacteria, Bacteriodetes, Actinobacteria, and Fusobacteria make up the majority of the microbiota in a healthy esophagus. In comparison, reduced microbial diversity, which appears to start in the precursor stages of EC, is a characteristic of malignancy of the esophagus. The EC microbiome is distinguished at the taxonomic level by a switch from Gram-positive to Gram-negative bacteria. The genera *Fusobacterium*, *Streptococcus*, *Veilonella*, and *Prevotella* are those that are most often enriched in EC. Although particular changes in the EC microbiome can be detected, a consistent microbiota profile linked with EC has not yet been discovered. The varied technical processes, such as the sampling strategy, the types of samples examined, and the analytic approach used to profile the microbiome, as well as the relatively small number of people participated in each experiment, may be to blame for this discrepancy. Future research should take method standardization into account. To study and integrate the impacts of various exposures, including those of nutrition, with the microbiome and the changes that occur during the carcinogenesis process, multidisciplinary research efforts will be necessary. This is especially true in studies of esophageal carcinogenesis associated with the microbiome. Large, well-characterized prospective cohort studies would be beneficial for dissecting these complicated connections, and they would undoubtedly aid in the development of creative preventive and treatment plans that would lessen the incidence of EC[11].

SYSTEMIC TREATMENT OPTIONS FOR RESECTABLE EC

Squamous cell carcinoma and adenocarcinoma, the two principal histological forms of EC, have very different epidemi-

ologies. To some extent, the therapy choices for these two categories differ. The two main therapeutic options for EC are local and systemic therapies. The tumor's histological type, location, extension, and size can all contribute to guiding therapy selections. Endoscopic and surgical resection are the primary treatments for locally advanced EC. Lymphatic node metastases arise early in EC due to the extensive lymphatic drainage in the esophagus submucosa, and the cancer is frequently detected at an advanced stage[12]. For resectable EC, the main systemic treatment options include neoadjuvant chemotherapy (NCT), neoadjuvant chemoradiotherapy (NCRT), and perioperative chemotherapy (PCT). According to the most recent National Comprehensive Cancer Network guidelines for esophageal and esophagogastric junction cancers, the optimal treatment options for both localized squamous cell carcinoma (SCC) and actinic cheilitis (AC) staged as Tis-T2 (low-risk lesions: < 3 cm, well-differentiated) without lymph node metastases include esophagectomy and endoscopic treatments. Patients with unresectable EC should get definitive chemoradiation. Current clinical research focuses mostly on locally progressed EC between the preferable single surgery and the recommended final chemoradiation. The systemic therapeutic approaches listed encompass NCT, NCRT, and PCT indicating a range between the two histological groups. As an adjuvant therapy, immunotherapy is employed[13].

The most prevalent subtype of EC in the world is ESCC, which manifests in the naturally occurring esophageal epithelium. An estimated 456000 people were diagnosed with EC in 2012, of whom 398000 had ESCC. Around 80% of ESCC cases worldwide were found in Central and Southeast Asia. More than half of all cases globally originated in China alone[14]. For 366 patients with locally advanced resectable esophageal or esophagogastric junctional cancer, NCRT that included carboplatin, paclitaxel, and concurrent 41.4 Gy radiotherapy was compared to surgery alone (178 for NCRT and surgery *vs.* 188 for surgery alone). A minimum projected follow-up term of 10 years was guaranteed by the follow-up period, which ended on December 31, 2018. In the first year, patients visited the outpatient clinic once every three months. In the second year, they visited once every six months, and so on until the fifth year, when they visited once a year. After 5 years of follow-up, patients with symptoms could visit the outpatient clinic. Participants in the chemoradiotherapy-surgery group survived more than those in the surgery arm, with 10-year OS rates of 38% and 25%, respectively. The respective 10-year OS rates in the chemoradiotherapy-surgery and surgery groups for patients with SCC were 46% and 23%, respectively, and 36% and 26% for patients with AC. Participants in the chemoradiotherapy-surgical group died from EC at a lower rate than those in the surgery arm, with 10-year absolute risks of 47% and 64%, respectively. Other causes of death were comparable in the chemoradiotherapy-surgery and surgery arms, with 10-year absolute risks of 15% and 11%, respectively. They concluded that the OS advantage of preoperative NCRT for patients with locally advanced resectable esophageal or junctional carcinoma, according to the ChemoRadiotherapy for Oesophageal cancer followed by Surgery Study (CROSS) study, lasts at least ten years[15].

NEOCRTEC 5010, a phase 3 randomized, open-label, multicenter, clinical trial, supported the findings of ESCC patients from the CROSS study. The NCRT group outperformed the surgery-only group in terms of R0 resection rate (98.4% *vs.* 91.2%), median OS (100.1 mo *vs.* 66.5 mo), and disease-free survival (DFS, 100.1 mos vs. 41.7 mos). According to the long-term efficacy of the NEOCRTEC 5010 research, the OS advantage in patients with locally advanced resectable ESCC who received the NCRT regimen was maintained for at least 10 years[16]. The CROSS trial also discovered that NCRT decreased solitary distant relapse (27% *vs.* 28%) but did not lessen isolated distant relapse (8% *vs.* 18%) or synchronous locoregional and distant relapse (13% *vs.* 22%). Relapse following NCRT is thus a critical obstacle to overcome[15].

Esophageal adenocarcinoma (EAC), also known as gastroesophageal adenocarcinoma or esophagogastric junction cancer, usually develops in the lower third of the esophagus. Obesity is its main risk factor since it mostly affects people with a history of gastroesophageal reflux disease[14]. About two-thirds of the histological categories of EC in high-income nations are AC. It is currently the most common histological type in seven high-income countries, including Canada, Denmark, Norway, Australia, New Zealand, Ireland, and the United Kingdom[17]. The CROSS-study's findings similarly positioned NCRT as the therapy of choice for resectable EAC, although superior NCRT effectiveness was shown in ESCC. As a result, depending on specific circumstances, PCT and NCT are different tactics. In order to successfully treat resectable EAC, PCT is crucial. The landmark-like phase 3 Medical Research Council Adjuvant Gastric Infusion Chemotherapy Study (MAGIC) initially showed the survival advantage of PCT in AC. This study revealed that patients with non-metastatic AC who had PCT with epirubicin, cisplatin, and fluorouracil (FU) had better PFS and OS. The MAGIC trial had more treatment-related AEs (TRAEs) than the CROSS study did[15,18]. The FU plus Leucovorin, Oxaliplatin, and Docetaxel triplet FU plus Leucovorin, Oxaliplatin, and Docetaxel (FLOT) regimen was used in a later, important phase 2/3 trial, the FLOT4 trial, which demonstrated superiority in R0 resection rate (85% *vs.* 78%) and median OS (50 mo *vs.* 35 mo). In recent score-matched research, the therapeutic effects of NCRT and PCT were contrasted. The findings demonstrated no discernible differences in tumor response or survival rates between these two common regimens. After PCT, there were more TRAEs (42/97 *vs.* 30/97)[19]. Another effective therapy for resectable EAC is NCT. Preoperative FU and cisplatin (FC) showed a survival benefit over surgery alone in the Medical Research Council OEO2 study[20,21]. The survival benefit remained at a median follow-up of 6 years [hazard ratio (HR), 0.84; 95% confidence interval (CI), 0.72-0.98; $P = 0.03$], while the cisplatin group had a better OS at 2 years (HR, 0.79; 95% CI, 0.67- 0.93; $P = 0.004$). Another sizable experiment, nevertheless, was unable to show the same result[22]. Triplet chemotherapy (epirubicin, cisplatin, and capecitabine) did not improve OS in the OE05 study. Additionally, it was connected to greater toxicity than FC[23]. NCT is therefore hardly employed.

A few noteworthy clinical studies on neoadjuvant therapy for resectable EC have recently been conducted. As a preoperative treatment for locally advanced ESCC, the NExT study seeks to demonstrate that docetaxel, cisplatin plus 5-FU (DCF), and radiotherapy with cisplatin plus 5-FU are superior than FC in terms of OS. The superior OS and manageable toxicity of DCF indicate a new standard therapeutic strategy for ESCC[24]. In 2021, Wang *et al*[25] conducted a prospective, multicenter, open-label, randomized clinical study on 264 patients with locally advanced ESCC to assess the efficacy and safety of NCRT *vs.* NCT followed by minimally invasive esophagectomy (MIE). The postoperative

morbidity rates of 264 patients, 47.4% in the NCRT group and 42.6% in the NCT group, did not significantly vary between the two groups. Based on the Clavien-Dindo classification, the degree of complications was distributed similarly across the two groups. For the NCRT group and the NCT group, the 90-day perioperative mortality rate was 3.5% and 2.8%, respectively. Patients in the NCRT group, however, showed higher rates of negative lymph nodes (66.1% *vs.* 46.2%) and pathologic complete responses (35.7% *vs.* 3.8%). They came to the conclusion that NCRT followed by MIE was safer and produced better histopathologic results than NCT followed by MIE for the treatment of locally advanced ESCC. According to a recent publication by Tang *et al*[26], among patients with cT3-4aN0-1M0 ESCC, NCRT followed by MIE was not significantly related to a better OS than NCT. The findings highlight the ongoing question of the ideal neoadjuvant therapeutic plan for locally progressing bulky ESCC. In the Neo-AEGIS study, 377 European patients were assigned at random to receive PCT, or CROSS. In the 3-year OS, the first OS analysis did not reveal any statistically significant differences (HR, 1.02; 95% CI, 0.74-1.42). However, the results must be taken seriously because the majority of the evaluable perioperative patients did not get the current standard of care FLOT (epirubicin, cisplatin and FU/epirubicin, cisplatin and capecitabine/epirubicin, oxaliplatin and FU/epirubicin, oxaliplatin and capecitabine prior to 2018, FLOT option 2019-2020, only 15% of chemotherapy arm patients received FLOT)[27].

MOLECULAR MECHANISMS OF ICIS FOR EC TREATMENT

Utilizing one's own immune system to find and eliminate tumor cells is the goal of immunotherapy. Understanding the anti-tumor response and the strategies a malignancy may use to modify or inhibit the immune response has seen significant breakthroughs. This has made it possible for a new field of medicine to flourish, one that has shown considerable promise in treating conditions like EC that previously had a low survival rate. Our knowledge of the tumor microenvironment (TME) is one of the essential components for the creation of novel therapies. The TME is a complicated environment where a variety of immune and stromal cell subtypes interact to either promote or prevent tumor growth [28,29]. A crucial component of the immune response against tumors is the effector T cell. To maintain the immune system's equilibrium, negative regulators are produced on the surface of T cells during the activation process. Immune checkpoints are what they are known as. T cell activation, function, proliferation, and survival may be diminished when these immune checkpoints and their ligands are triggered during T cell receptor (TCR) signaling, which promotes tumor immune evasion. When compared to other solid tumor forms, EC is distinguished by having a significant amount of tumor-infiltrating T cells and monocytes/macrophages. The bulk of the tumor-infiltrating T cells are worn-out cluster of differentiation (CD) 8+ T cells and regulatory T cells (Tregs). Tregs, tumor-associated macrophages (TAMs), myeloid-derived suppressor cells, and cancer-associated fibroblasts all contribute to the immunosuppressive TME of EC through immune checkpoint-related mechanisms. The CD8+ T cells in the EC TME display high quantities of immunological checkpoint molecules such the lymphocyte activation gene-3 (LAG-3), cytotoxic T lymphocyte antigen-4 (CTLA-4), programmed cell death PD-1, and programmed cell death-ligand (PD-L) 1[30,31].

PD-1 and PD-L1

Activated cytotoxic T cells and their primary ligands are the best examples of how PD-1 functions. Cancer cells and antigen-presenting cells (APCs) both have PD-L1 and PD-L2 molecules on their surfaces. T cell immunological fatigue is promoted by intracellular phosphorylation events that occur as a result of PD-1 engagement with its ligands, either through processes that depend on or are independent of TCR-CD28. The phosphoinositide 3-kinase route and the mitogen-activated protein kinase pathway are the two principals downstream signaling pathways involved in the TCR-CD28-dependent process. T cell depression that is not caused by TCR-CD28 is also caused by increased expression of the B-cell activating transcriptional factor[32-34]. CD8+ T cells in EC TME consistently exhibit significant levels of PD-1 expression. The findings of several clinical studies revealed that the objective response to immunotherapy was highly correlated with the high level of PD-L1 expression in EC tumor cells[35-37]. As a result, one of the suggested biomarkers for identifying EC patients who may benefit from ICIs is the degree of PD-L1 expression. Other than tumoral or healthy epithelial cells, TAMs play a significant role in the expression of PD-1 ligands in the EC TME. M2 polarization increases PD-L2 expression in TAMs and leads to immune evasion *via* the PD-1 signaling cascade regulated by the C-C motif chemokine ligand 2-C-C motif chemokine receptor 2 axis[38]. Additionally, TAMs showed PD-1 expression, which may increase PD-L1 expression in tumor cells. Increased CD8+ T cell abundance was seen in the responders in the clinical trials of PD-1 blockade therapy for EC, suggesting that the PD-1 inhibitors were successful in saving the worn-out T cells. To increase anti-tumor activity, these T cells settle on the tumor and fill the EC TME. Additionally, the decrease in the fraction of M2-type TAMs coincided with the rise in CD8+ T cell density, demonstrating that other innate immune cells in the EC TME were highly significant to the effectiveness of PD-1 blockade therapy for EC patients. In addition to the PD-1/PD-L1 pathway, interactions between PD-L1, CD80, and PD-L2-repulsive guidance molecule family member B are necessary for ICIs that target PD-L1 to be efficacious[39,40] (Figure 1).

LAG-3

The precise signaling pathways downstream of LAG-3 are unclear, although it is known that LAG-3 has a distinct signaling route that is not shared by other immunological checkpoints. It is not unexpected that LAG-3 binds to major histocompatibility complex (MHC)-II given that their structures are comparable. However, the affinity of the interaction between LAG-3 and MHC-II is substantially stronger. LAG-3 affects CD8+ T cell activity as well, pointing to the possibility of new LAG-3 ligands. LAG-3 is one of the hallmarks of worn-out CD8+ T cells and is considerably overexpressed in ESCC. Positive LAG-3 expression strongly predicted lower recurrence-free survival and OS in ESCC patients

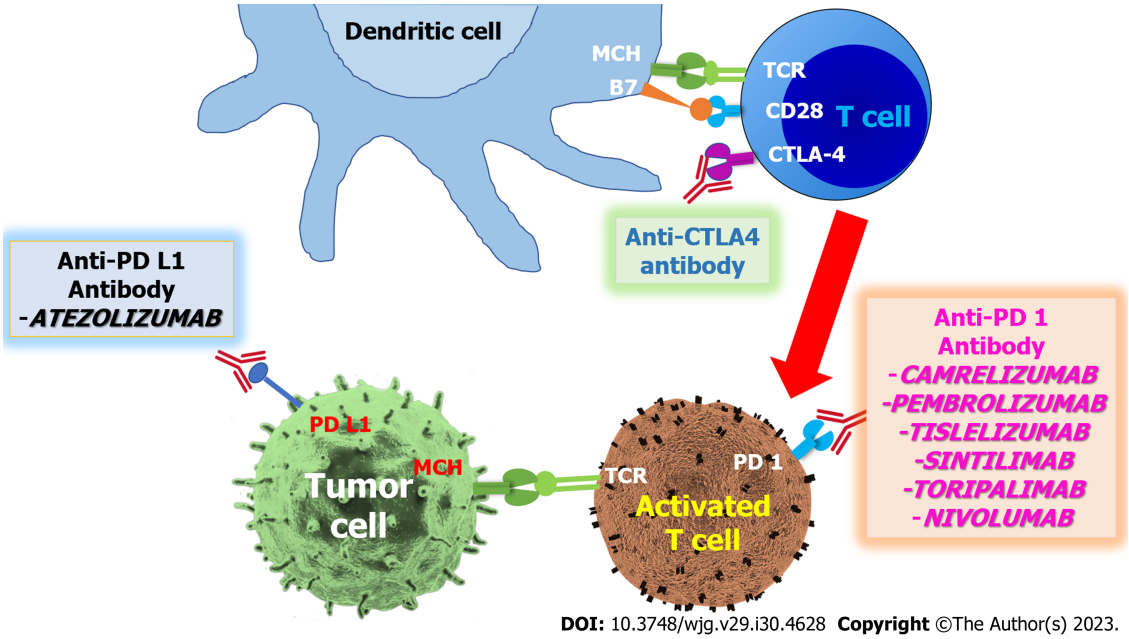

Figure 1 The mechanisms of action of immune checkpoint inhibitors in resectable esophageal cancer immunotherapy. CD28: Cluster of differentiation 28; CTLA-4: Cytotoxic T lymphocyte antigen 4; MHC: Major histocompatibility complex; PD-1: Programmed cell death protein 1; PD-L1: Programmed death-ligand 1; TCR: T cell receptor.

and was significantly correlated with CTLA-4 expression. Strong correlations were found between high levels of CD8+ tumor-infiltrating lymphocytes (TILs) in the EAC TME and high levels of LAG-3 expression. Research on individuals with unresectable EAC found connections between the LAG-3 gene and their response to the combination treatment of nivolumab and ipilimumab. Numerous LAG-3+ CD8+ T cells in the EAC TME are thought to be remnants of a robust anti-tumor immune response that was suppressed by PD-L1 and LAG-3-related mechanisms. The EAC patients who exhibit this TME trait are a good fit for ICIs. As a result, LAG-3 is a novel target for ICI's treatment of EC and is generating a lot of attention[41-44].

CTLA-4

The engagement of the TCR by peptides from the MHC and crucial positive co-stimulatory signals produced by the interaction of CD80 (B7.1) or CD86 (B7.2) on the surface of APCs and CD28 on the surface of T cells are both necessary for T cell activation. This process is damaged by CTLA-4. Intracellularly stored CTLA-4 is transferred onto the surface of T cells during the initial stages of T cell activation, competing with CD80 with a higher affinity and diminishing the signal. *Via* phosphorylation reactions, CTLA-4 attenuates signals downstream of the TCR intrinsically after interacting with CD80. The primary professional APCs whose immunological capabilities are compromised in individuals with EC, along with a reduction in CD80 and CD86 expression, are dendritic cells. The high level of CTLA-4 expression on the surface of Tregs in the EC TME significantly contributes to immunosuppression. Further weakening the anti-tumor immune response, elevated expression of CTLA-4 is found in ESCC tumor cells on both an mRNA and protein level, in addition to effector T cells and Tregs in EC patients. Previous research has shown that ESCC patients with high tumor cell CTLA-4 expression had a poor prognosis, patients with ESCC who exhibited little tumor cell CTLA-4 expression, however, had a longer OS. Additionally, it's been proven that CD80 guards against metaplasia in inflammatory esophageal carcinogenesis, which is linked to EAC. In light of these findings, scientists developed ICIs that specifically target CTLA-4 to enhance EC's anti-tumor immunity. We still don't know how CTLA-4 blocking treatment impacts EC TME and effector T cells[45-47].

ICIS FOR RESECTABLE EC TREATMENT

Neoadjuvant immunotherapy is the main subgroup of the clinical studies on ICI treatment for resectable EC. Camrelizumab, Pembrolizumab, Tremelimumab, Tislelizumab, Sintilimab, Atezolizumab, Nivolumab, Durvalumab, Relatlimab, Toripalimab, and IMC-001 were among the ICIs employed in these research. According to the CROSS-study's protocol, neoadjuvant immunotherapies are frequently used in conjunction with NCRT or NCT.

Camrelizumab

The National Medical Products Administration has authorized the PD-1 inhibitor Camrelizumab as a first-line therapy for unresectable ESCC. The neoadjuvant use of Camrelizumab for resectable locally advanced ESCC has been the focus of a significant number of clinical trials, making it one of the most popular ICIs being studied for its therapeutic efficacy. The

majority of these trials have proven the beneficial effects of combining Camrelizumab with NCT and NCRT. In research done by Wu *et al*[48], 38 patients with resectable ESCC were examined to determine the effectiveness and safety of NCT coupled with immunotherapy. Pembrolizumab (55.26%) and Camrelizumab (31.58%) were the two drugs most often taken by patients. The results of their analysis of 19 individuals revealed that 13 patients (68.42%) had a radiological partial response (PR) on computed tomography scans. 35 patients (92.11%) underwent R0 resection, and postoperative problems occurred in 10 individuals (26.32%). A substantial positive correlation between the pathological remission rate and the regression rate of the sum of lesion diameters was also found. Major pathologic response (MPR) rates were 42.11% in ESCC patients.

In a trial by Liu *et al*[49,50], the primary endpoint was used to assess the safety as well as the efficacy of Camrelizumab with NCT in 60 patients with locally advanced ESCC. Fifty-five (91.7%) of these patients successfully completed the whole two-cycle therapy. Fifty-one patients had surgery, and 50 (98.0%) of them had R0 resection. Twenty patients (39.2%) had pathological complete response (pCR) (ypT0N0), while five patients (9%; ypT0N+) had a full response to the main tumor but persistent illness in the lymph nodes alone. Leukocytopenia (86.7%) was the most prevalent of the 58 TRAEs that affected individuals (96.7%). One patient (1.7% of patients) experienced a grade 5 adverse event, while 34 patients (56.7%) experienced AEs of grade 3 or worse. They stated that chemotherapy and Camrelizumab had strong anticancer effects that had been validated and shown without any unanticipated safety effects. These results demonstrated the efficacy of Camrelizumab with chemotherapy as a neoadjuvant therapy for locally advanced ESCC. It is necessary to conduct a phase 3 randomized controlled study to further illustrate potential survival gains (Table 1).

Pembrolizumab

The United States Food and Drug Administration (FDA) has authorized the PD-1 inhibitor pembrolizumab as a first-line therapy for unresectable ESCC and EAC when combined with chemotherapy. Neoadjuvant immunotherapy has undergone clinical testing to treat both resectable ESCC and EAC. Preoperative Pembrolizumab with concurrent chemoradiotherapy for resectable locally advanced ESCC is being tested in the phase 1b, single-arm PALACE I trial, with safety as the main end measure. Of the 20 participants, 18 (90%) underwent surgery, and 19 (95%) received complete preoperative care. The patient had grade 3 lymphopenia and leukopenia, and she passed away while undergoing surgery, which is why the neoadjuvant therapy was not completed. The disease progression led to the discontinuation of surgery for one participant after full neoadjuvant therapy. All 20 patients experienced the development of TRAEs of any grade during the neoadjuvant therapy phase. The most frequent TRAEs were leukopenia (100%), lymphopenia (100%), anemia (80%), esophagitis (55%), alopecia (55%), and fatigue (55%), the majority of which were grade 1 or 2. With a pCR rate of 56% and a substantial pathological response of 89%, the R0 resection rate was 94%. All of the patients who received radical resection were free of disease recurrence at the median postoperative follow-up of 6.6 mo[51]. The PALACE II multicenter trial is still underway and has a larger sample size (143 participants), with pCR set as the major end measure[52]. Thirty-one eligible patients were included in a phase 1b/2 study to examine the effects of trimodal therapy with Pembrolizumab in the treatment of gastroesophageal junction (GEJ) adenocarcinoma. Twenty-eight individuals got R0 resection, and 29 of the 31 patients received all recommended doses of neoadjuvant Pembrolizumab. All safety criteria were satisfied. The primary efficacy goal was not attained [7/31 (22.6%)]. Individuals with high baseline expression of PD-L1 in the TME [combined positive score (CPS) > 10] had a substantially higher pCR rate than patients with low expression. Additionally, PFS and OS were longer for patients with high PD-L1 expression compared to propensity-score-matched patients. Extracellular vesicles (EV) were investigated to determine whether they may detect additional responders among trial participants with PD-L1 CPS < 10. A greater plasma level of PD-L1-expressing EVs was substantially linked with a higher pCR. They indicated that when Pembrolizumab was added to trimodal treatment, it did not achieve the intended pCR endpoint because of its satisfactory tolerability. Exploratory findings revealed that individuals who are most likely to achieve tumor response may be identified by having high levels of PD-L1 expression in the TME or on EVs[53].

Pembrolizumab in conjunction with chemotherapy and simple chemotherapy were compared for their effectiveness and safety in a trial by Huang *et al*[54], which involved 54 ESCC patients with stages II–IVa (23 in the combination group and 31 in the simple chemotherapy group). After two cycles of neoadjuvant therapy, major surgical intervention was given to all patients. They discovered that the combination group's pCR, ORR, and tumor regression 2 score were all considerably greater than those of the basic chemotherapy group (30.4% *vs.* 9.7% and 80.7% *vs.* 50.0%, respectively). Additionally, there was no statistically significant difference between the two groups' complete esophagectomy and R0/R1 resection rates. They concluded that pembrolizumab with chemotherapy demonstrated encouraging activity with a tolerable safety profile. Additionally, it might present a brand-new neoadjuvant treatment strategy for ESCC patients. In a single-arm study, Duan *et al*[55] evaluated the efficacy and safety of neoadjuvant pembrolizumab with chemotherapy in 18 patients with resectable ESCC. They found that postoperative pathology showed pCR in 6 cases (6/13, 46.2%) and MPR in 9 cases (9/13, 69.2%). Grade 3 or higher: Significant TRAEs occurred in 5 individuals (5/18, 27.8%). The amount of residual viable tumor (RVT) in pretreatment specimens was not substantially correlated with PD-L1 expression. While there was a weak association between postoperative forkhead box P3-positive+ T cells/CD4+ T cell ratios and RVT, there was a substantial correlation between changes in CD68+ macrophage counts between pre- and post-treatment specimens.

Tislelizumab

Another inhibitor of PD-1 is Tislelizumab. Following systemic therapy, ESCCs that cannot be removed, have relapsed, or have spread have been approved for consideration by the FDA. Tislelizumab was combined with NCT in the TD-NICE study, a phase 2, single-arm clinical study. The MPR served as the study's main outcome indicator. Of the 45 patients, 36 had surgery and received comprehensive neoadjuvant care. Eighty percent of R0 resections were successful, with 72% of pCR and 50% of MPR. Leukopenia (73%), anemia (51%), and thrombocytopenia (49%) were the most prevalent TRAEs.

Table 1 The immunotherapies for resectable esophageal cancer patients

Name	Ref.	Number of patients	Treatment regimens	Outcome	Conclusion
Camrelizumab	Wu *et al* [48], 2021	12	Cisplatin + paclitaxel + camrelizumab = 8; carboplatin + paclitaxel + camrelizumab = 4	MPR, 5/7 (71.43%)	Patients with ESCC had an MPR rate of 42.11%; The SLD regression rate has a certain guiding relevance for the impact of immunotherapy, and the adoption of the NACI regimen may not raise the likelihood of problems in neoadjuvant treatment and surgery
Camrelizumab	Liu *et al* [49], 2022	60	Carboplatin + paclitaxel + camrelizumab	Proceeded to surgery, 51/60 (85.00%); R0 resection, 50/51 (98.00%); pCR, 5/20 (39.20%)	Camrelizumab plus weekly chemotherapy as a promising neoadjuvant treatment for locally advanced ESCC, and further phase 3 randomized controlled trial is warranted
Camrelizumab	Liu *et al* [50], 2022	56	Cisplatin + paclitaxel + camrelizumab	Proceeded to surgery, 51/56 (77.40%); pCR, 18/56 (39.20%); MPR, 12/56 (21.43%)	Camrelizumab plus neoadjuvant chemotherapy in resectable ESCC demonstrates promising efficacy with acceptable toxicity, providing a feasible and effective option
Pembrolizumab	Li *et al* [51], 2021	20	Carboplatin + paclitaxel + pembrolizumab + radiotherapy	Proceeded to surgery, 18/20 (90.00%); pCR, 10/18 (55.60%)	PPCT was safe and did not delay surgery in resectable EC
Pembrolizumab	Zhu *et al* [53], 2022	31	Carboplatin + paclitaxel + pembrolizumab + radiotherapy	Proceeded to surgery, 28/29 (96.55%); pCR, 7/31 (22.58%)	Incorporating anti–PD-1 therapy into neoadjuvant chemoradiation and adjuvant treatment of GEJ adenocarcinoma may improve pCR and survival
Pembrolizumab	Huang *et al*[54], 2021	54	Nedaplatin + docetaxel + pembrolizumab = 23 *vs.* nedaplatin + docetaxel = 31	pCR 30.4%/9.7%; ORR 86.9%/95.7%	Pembrolizumab combined with chemotherapy showed promising activity with a manageable safety profile and it could offer a potential new neoadjuvant treatment approach for patients with ESCC
Pembrolizumab	Duan *et al*[55], 2022	18	Nedaplatin + paclitaxel + pembrolizumab = 13 or nedaplatin + docetaxel + pembrolizumab = 5	Proceeded to surgery, 13/18 (72.22%); MPR, 9/13 (69.20%); pCR, 6/13 (46.15%)	The combination of neoadjuvant immunotherapy and chemotherapy for ESCC is associated with a high pathological response and immunologic effects in the tumor microenvironment
Tislelizumab	Yan *et al* [56], 2022	45	Carboplatin + paclitaxel + tislelizumab	Proceeded to surgery, 36/45 (80.00%); MPR (69.20%); pCR (50.00%)	Tislelizumab plus chemotherapy as neoadjuvant therapy demonstrates promising antitumor activity for resectable ESCC with high rates of MPR, pCR, and R0 resection, as well as acceptable tolerability
Sintilimab	Chen *et al* [57], 2023	30	Cisplatin + S1 + paclitaxel + sintilimab	Proceeded to surgery, 30/30 (100.00%); MPR (50.00%); pCR (20.00%)	Neoadjuvant sintilimab plus platinum-based triplet chemotherapy appeared safe and feasible, did not delay surgery and induced a pCR rate of 20.0% in patients with potentially resectable ESCC
Atezolizumab	van den Ende *et al* [58], 2021	40	Carboplatin + Paclitaxel + Atezolizumab + Radiotherapy	Proceeded to surgery, 33/40 (82.50%); MPR (50.00%); pCR, 10/40 (25.00%)	The addition of atezolizumab to conventional nCRT for resectable EC was feasible without compromising surgical outcomes
Toripalimab	Xing *et al* [59], 2021	30	Cisplatin + paclitaxel + toripalimab D3 *vs.* cisplatin + paclitaxel + toripalimab D1	Proceeded to surgery, 11/15 *vs.* 13/15; pCR 4/15 *vs.* 1/15	The study showed that delaying toripalimab to day 3 in chemoimmunotherapy might achieve a higher pCR rate than that on the same day
Toripalimab	He *et al* [60], 2022	20	Carboplatin + paclitaxel + toripalimab	Proceeded to surgery, 16/20; R0 resection, 14/16; MPR, 7/16; pCR, 4/16	The combination of toripalimab plus paclitaxel and carboplatin is safe, feasible, and effective in locally advanced resectable ESCC
Toripalimab	Gao *et al* [61], 2022	20	Cisplatin + docetaxel + toripalimab	ORR, 14/20; MPR, 5/12; pCR, 2/12	Toripalimab combined with docetaxel and cisplatin as a novel neoadjuvant therapy was safe and effective in locally advanced ESCC
Toripalimab	Zhang *et al*[62], 2023	60	S1 + paclitaxel + toripalimab	R0 resection, 55/60; MPR, 27/60; pCR, 16/60	Neoadjuvant therapy with toripalimab, nab-paclitaxel and S1 was less toxic and showed promising antitumor activity in patients with resectable ESCC
Nivolumab	Kelly *et al* [63], 2021	794	Chemoradiotherapy+ nivolumab = 532 *vs.* chemoradiotherapy+ placebo = 262	DFS, 22.4/11.0 mo; distant recurrence, 29/39%; locoregional recurrence, 12/17%	Nivolumab adjuvant treatment significantly increased DFS compared to placebo in patients with resected esophagus or gastroesophageal junction cancer who had received neoadjuvant chemoradiotherapy

DFS: Disease-free survival; EC: Esophageal cancer; ESCC: Esophageal squamous cell carcinoma; GEJ: Gastroesophageal junction; MPR: Major pathological

response; NACI: Neoadjuvant chemotherapy combined with immunotherapy; nCRT: Neoadjuvant chemoradiotherapy; ORR: Objective response rate; pCR: Pathological complete response; PD-1: Programmed cell death protein 1; SLD: Sum of lesion diameter; PPCT: Preoperative pembrolizumab with concurrent chemoradiotherapy.

Nineteen (42.2%) of the 45 patients had TRAEs in grades 3 to 4. Seventy-eight percent of the 36 individuals had postoperative problems. There were no surgical delays or deaths brought on by the therapy. They discovered that Tislelizumab in combination with chemotherapy as neoadjuvant therapy shows encouraging anticancer effectiveness for resectable ESCC with high rates of MPR, pCR, and R0 resection, as well as moderate tolerability[56].

Sintilimab

Sintilimab, another PD-1 inhibitor, has been approved by the FDA for the treatment of certain subtypes of non-small cell lung cancer (NSCLC) and Hodgkin's lymphoma. The primary use of Sintilimab is as a neoadjuvant therapy for ESCC. In 30 patients with possibly resectable ESCC, Chen *et al*[57] performed a single-arm, phase 2, open-label study to evaluate the safety and surgical viability of intravenous Sintilimab preoperatively with triplet chemotherapy (cisplatin, liposomal paclitaxel, and S-1) for a total of two cycles every 3 wk. The MPR and pCR rates were discovered to be 50.0% and 20.0%, respectively. Patients were more likely to react if they had a greater TMB and more clonal mutations. Changes in the circulating tumor DNA high-releaser status and the v-erb-b2 avian erythroblastic leukemia viral oncogene homolog 2 are adversely linked with the response to neoadjuvant ICI. They discovered that neoadjuvant Sintilimab in conjunction with platinum-based triplet chemotherapy was safe and effective, did not delay surgery, and led to a 20.0% pCR rate in patients with ESCC who would be eligible for resection. A total of 36.7% (11/30) of patients experienced TRAEs of grades 3–4. Reduced neutrophil count (73.3%), anemia (76.7%), and reduced white cell count (76.7%) were the most common TRAEs. Hematological toxicities constituted all TRAEs. This confirmed that it was safe to use. To confirm the viability of the suggested approach, more investigation is needed.

Atezolizumab

A PD-L1 inhibitor called Atezolizumab has been given FDA approval for the treatment of melanoma, NSCLC, small cell lung cancer, and some types of urothelial cancer. In the phase 2 feasibility trial PD-L1 Targeting in Resectable EC (PERFECT), NCRT is coupled with Atezolizumab to treat resectable EAC. The major end measure of this trial was feasibility, which was determined as the percentage of Atezolizumab treatments that were completed. Thirty-four (85%) of the 40 patients finished the full course of atezolizumab treatment. Any missed cycles were brought on by autoimmune-related toxicity (n = 3), progression (n = 2), and death (n = 1). The R0 resection rate was 100% with 30% pCR. The PERFECT study had a median OS of 29.7 mo and a median PFS of 19.4 mo[58]. Fatigue (95%), mucositis (60%), nausea (53%), and anorexia (43%) were the most prevalent TRAEs. A grade 3–4 TRAE was encountered by 16 patients (40%). The three most prevalent symptoms were syncope (8%), nausea (8%), and anorexia (10%). The aforementioned TRAEs mostly took place during NCRT in conjunction with ICI. One patient who passed away from a pulmonary embolus had a grade 5 TRAE. Thirteen individuals (33%) had serious TRAEs that resulted in hospitalization or death.

Toripalimab

The FDA authorized Toripalimab, an anti-PD-1 monoclonal antibody, for the treatment of ESCC, nasopharyngeal carcinoma, mucosal melanoma, and sarcoma. In order to assess the efficacy of neoadjuvant chemoimmunotherapy (Toripalimab) in 30 patients with locally advanced ESCC, Xing *et al*[59] conducted an open-label, randomized phase 2 investigation. The patients were divided into two groups: The experimental group, which got chemotherapy on day 1 and Toripalimab on day 3, and the control group, which received chemotherapy and Toripalimab on day 1. The patients were then randomly allocated to either group. Paclitaxel and cisplatin were the components of the chemotherapy regimen. Four to six weeks following the second course of chemoimmunotherapy, surgery was undertaken. They reported that 13 participants in the control group and 11 participants in the experimental group had surgery. In each of these 24 cases, a R0 resection was done. Four patients (36%) in the experimental group and one patient (7%) in the control group both achieved pCR. Statistically non-significantly increased pCR rates were observed in the experimental group. One patient in the control group had a PD-L1 CPS of 10, and pCR was achieved. The other 13 patients all had PD-L1 CPSs of 1, and 11 of the 13 underwent surgery, with two of the 13 patients (in the experimental group) attaining pCR. After one round of chemoimmunotherapy, two patients experienced grade 3 adverse effects, and one patient withdrew out of the research due to immune-related enteritis that was grade 3. After surgery, a second patient passed away from a severe lung infection and elevated troponin. They concluded that postponing Toripalimab until day 3 of chemotherapy could result in a greater pCR rate than that on the same day.

In a study conducted by He *et al*[60], 20 patients with locally advanced resectable ESCC were examined to determine the effectiveness of Toripalimab with paclitaxel and carboplatin as neoadjuvant treatment and the possible prognostic biomarkers. For the 16 patients who underwent surgery without a related delay in treatment, the R0 resection rate was 87.5% (14/16). The pCR rate was 18.8% (3/16), and the MPR rate was 43.8% (7/16) among the 16 patients. Following neoadjuvant treatment, the fraction of M2-type TAMs reduced, and the number of CD8+ T cells rose in surgical tissues. Responders had greater baseline C-X-C motif chemokine 5 gene expression levels and lower baseline chemokine (C-C motif) ligand 19 and uromodulin-like 1 gene expression levels. They concluded that the treatment of locally progressed resectable ESCC with the combination of Toripalimab, paclitaxel, and carboplatin is dependable, doable, and effective, indicating its promise as a neoadjuvant therapy for ESCC. An open-label, non-randomized, single-arm, single-center

phase 2 study also looked at Toripalimab for usage as neoadjuvant treatment in conjunction with Docetaxel and Cisplatin in 20 patients with locally advanced ESCC. The ORR was reported to be 70% (14/20). McKeown's MIE was performed on twelve individuals. Sixteen percent (2/12) of initial tumors achieved pCR, while 41.7% (5/12) of primary tumors achieved MPR. The median time before surgery was 33.2 d, and no patients had surgery delayed as a result of AEs from the medication. The most typical 30-day postoperative consequence (3/12, 25%) was pneumonia. Only 1 patient experienced anastomotic leakage while they were in the hospital. No patients passed away as a result of medical care or surgery. They concluded that Toripalimab was a safe and effective new neoadjuvant treatment for locally progressed ESCC when coupled with Docetaxel and Cisplatin[61]. Toripalimab combined with nab-Paclitaxel and S-1 was evaluated in a phase 2 single-center, open-label, single-arm study in 60 ESCC patients. They discovered that 55 patients (98.21%) had successful R0 resections. In 27 patients (49.09%) with MPR, pCR was attained in 16 individuals (29.09%). There were 37 (61.67%), 21 (35.00%), and 2 (3.33%) patients with PR, stable illness, and progressing disease, respectively. Following therapy, the overall staging, Stooler dysphagia scores, and daily living ability were considerably reduced. Eleven patients (18.3%) had grade 3 AEs. Patients with PD-L1-high levels exhibited a considerably greater PR ratio than those with PD-L1-low levels. In patients who had a PR, the TMB and tumor neoantigen burden considerably decreased with treatment[62].

Nivolumab

The first immunotherapy to be recommended for resectable EC is adjuvant immunotherapy, which is appropriate for both ESCC and EAC with R0 resection following NCRT but staged as ypT-positive and/or N-positive. A PD-1 inhibitor known as Nivolumab is the ICI employed in this treatment plan. With a median follow-up of 24.4 mo, Kelly *et al*[63] conducted the worldwide, randomized, double-blind, placebo-controlled phase 3 study CheckMate 577 to assess Nivolumab as adjuvant treatment in 794 patients with esophageal or GEJ cancer. In contrast to the 262 patients who received a placebo, the authors found that the median DFS for the 532 individuals who received Nivolumab was 22.4 mo, as opposed to 11.0 mo for those who received the placebo (HR for disease recurrence or death, 0.69; 96.4% CI, 0.56 to 0.86; P = 0.001). In the Nivolumab group, 71 of 532 patients (13%), and 15 of 260 (6%) patients in the placebo group, encountered grade 3 or higher AEs. The trial regimen was discontinued in 9% of participants receiving Nivolumab and 3% of patients receiving a placebo owing to adverse drug or placebo-related events. They concluded that DFS was significantly longer in patients with resectable esophageal or GEJ cancer who had received NCRT who got Nivolumab adjuvant treatment than in those who received a placebo.

SUMMARY

Neoadjuvant ICIs are often used to treat ESCC patients, whereas perioperative ICIs are frequently used to treat EAC patients from the perspective of therapeutic models. This could be a result of NCRT having a better pathological outcome for ESCC than for EAC in earlier investigations[64]. A few clinical studies have moved into phase 3, and the majority are still in phase 2. It's important to be aware of phase 2 trial limitations, such as the limited sample size and lack of a control group. Trials investigating the use of ICIs in combination with NCRT, NCT, and PCT for resectable EC are still in their early phases in general. Credibility and generality are insufficient and need to be enhanced going forward. To get over these restrictions, multicenter or international phase 3 studies should be conducted. Very few studies have revealed the specifics of the response evaluation criteria and methodologies used in the various preoperative systemic therapy trials. The full metabolic response was the criterion used in the PALACE I investigation, which made use of the positron emission tomography-computed tomography scan. To help choose the best course of therapy, it is necessary to confirm how to more accurately gauge the reaction and specify the circumstances warranting surgery. TRAEs continue to endanger the safety of ICI therapy regimens, even if an acceptable rate of them has been recorded. All the research mentioned the above-mentioned TRAEs, and in certain situations, TRAE-related surgical delay or mortality happened. The safety of the ICIs is anticipated to drastically increase.

Immunotherapy for resectable EC patients primarily focuses on blocking the PD-1 and PD-L1 pathways, which have demonstrated impressive anti-tumor effects. But for some patients, ICIs treatment was ineffective, and in certain instances, medication resistance developed. PD-L1 expression in ESCC and microsatellite instability-high (MSI-H) or microsatellite instability-deficiency in mismatch repair are two indicators for successful ICIs treatment[65]. Unfortunately, PD-L1-positive ESCC did not significantly improve objective response to ICI treatment in a clinical investigation[66]. Furthermore, only 7% of EAC patients have MSI-H. Their predictive values are constrained. A critical issue that has to be solved is how to more effectively identify the EC patients who will benefit from PD-1 blocking treatment. A number of processes are involved in the PD-1/PD-L1 pathway's signaling process, such as chromosomal changes, mechanisms controlling molecule expression during and after transcription, and post-translational modification of molecules[67,68]. Scientists have identified various immune-related genes and chromosomal alterations unique to EC through the ongoing improvement of gene analysis techniques[69-71]. These are all possible biomarkers for EC patients who react to PD-1/PD-L1 blocking drugs. Furthermore, an immune-related long non-coding RNA signature of this pathway in ESCC was discovered, and it has the potential to be exploited as a stand-alone predictor of ESCC immunotherapy prognosis. PD-L1 expression inside the EC TME is now linked to immune infiltration frequency, which is what makes PD-1/PD-L1 blocking therapy beneficial. The frequencies of TILs, TAMs, CD8+ T cells, and Tregs are among the factors that are connected to clinical outcomes[72].

There aren't many active clinical studies of anti-CTLA-4 immunotherapy for resectable EC, in contrast to PD-1/PD-L1 blocking treatment. Severe TRAEs, the bulk of which were immune-related AEs (irAEs), limited the efficacy of CTLA-4 inhibiting therapy for a number of solid tumors. A deadly autoimmune illness is prevented by the intrinsic immune

checkpoint CTLA-4 on Tregs. Inhibiting CTLA-4 increases anti-cancer immunity but also upregulates auto-immune responses, leading to irAEs. For a safer and more effective immune checkpoint treatment, several scientists concluded that the CTLA-4 checkpoint should be preserved rather than blocked. Some people overcome this obstacle by creating anti-CTLA-4 antibodies that are specific to TMEs. There is an ongoing debate about whether CTLA-4-targeted immunotherapy should be permitted[73,74].

The immunosuppressive mechanism of LAG-3 is a recent area of study that has drawn a lot of interest. According to a recent study, MHC-II-independent fibrinogen-like protein 1 (FGL1) was a significant LAG-3 functional ligand. A poor prognosis and resistance to anti-PD-1 therapy are associated with high levels of FGL1 expression in the plasma of cancer patients, and it has been abundantly produced by human cancer cells[75,76]. The results of the clinical trial employing the Nivolumab and Relatlimab combination treatment for resectable EC may provide some insight into the riddle. Certainly, the positive results of immunotherapy for resectable EC in recent times give reason for optimism, but there are still many shortcomings to be overcome. The ICIs therapy for resectable EC will be ideal with a dependable effect and high safety in the next few days if these problems are promptly addressed.

CONCLUSION

Although systemic immunotherapy has produced encouraging preliminary findings in resectable EC in some clinical studies, and although preoperative immunotherapy may potentially be more beneficial than adjuvant therapy, more confirmation of the feasibility, safety, and effectiveness of neoadjuvant immunotherapy in sizable randomized clinical trials is still needed. Additionally, before neoadjuvant ICI techniques can be extensively used as the standard of treatment, a number of unsolved concerns must be overcome. To choose the right populations, it will be essential to identify predictive biomarkers, and the function of adjuvant treatment must be clearly understood. In order to assess any delayed toxicity and ascertain the long-term consequences, long-term follow-up is also required. Systemic immunotherapy will undoubtedly enter a new phase soon.

Abstract

BACKGROUND

Acute pancreatitis (AP) is a disease featuring acute inflammation of the pancreas and histological destruction of acinar cells. Approximately 20% of AP patients progress to moderately severe or severe pancreatitis, with a case fatality rate of up to 30%. However, a single indicator that can serve as the gold standard for prognostic prediction has not been discovered. Therefore, gaining deeper insights into the underlying mechanism of AP progression and the evolution of the disease and exploring effective biomarkers are important for early diagnosis, progression evaluation, and precise treatment of AP.

AIM

To determine the regulatory mechanisms of tRNA-derived fragments (tRFs) in AP based on small RNA sequencing and experiments.

METHODS

Small RNA sequencing and functional enrichment analyses were performed to identify key tRFs and the potential mechanisms in AP. Reverse transcription quantitative polymerase chain reaction (RT-qPCR) was conducted to determine tRF expression. AP cell and mouse models were created to investigate the role of tRF36 in AP progression. Lipase, amylase, and cytokine levels were assayed to examine AP progression. Ferritin expression, reactive oxygen species, malondialdehyde, and ferric ion levels were assayed to evaluate cellular ferroptosis. RNA pull down assays and methylated RNA immunoprecipitation were performed to explore the molecular mechanisms.

RESULTS

RT-qPCR results showed that tRF36 was significantly upregulated in the serum of AP patients, compared to healthy controls. Functional enrichment analysis indicated that target genes of tRF36 were involved in ferroptosis-related pathways, including the Hippo signaling pathway and ion transport. Moreover, the occurrence of pancreatic cell ferroptosis was detected in AP cells and mouse models. The results of interference experiments and AP cell models suggested that tRF-36 could promote AP progression through the regulation of ferroptosis. Furthermore, ferroptosis gene microarray, database prediction, and immunoprecipitation suggested that tRF-36 accelerated the progression of AP by recruiting insulin-like growth factor 2 mRNA binding protein 3 (IGF2BP3) to the p53 mRNA m6A modification site by binding to IGF2BP3, which enhanced p53 mRNA stability and promoted the ferroptosis of pancreatic follicle cells.

CONCLUSION

In conclusion, regulation of nuclear pre-mRNA domain-containing protein 1B promoted AP development by regulating the ferroptosis of pancreatic cells, thereby acting as a prospective therapeutic target for AP. In addition, this study provided a basis for understanding the regulatory mechanisms of tRFs in AP.

Key Words: Acute pancreatitis; tRNA-derived fragments; tRNA-derived fragments 36; Mouse models; Ferroptosis; Reverse transcription quantitative polymerase chain reaction

Core Tip: Based on reverse transcription quantitative polymerase chain reaction and bioinformatic analysis of small RNA sequencing data extracted from three patients and three healthy controls, and validated by 20 acute pancreatitis (AP) patients and 20 healthy controls, we found that tRNA-derived fragments 36 (tRF36) was significantly upregulated in AP. Furthermore, the results of the cell model of the MCP-83 cell line and knockdown of tRF36 suggested that tRF36 contributed to AP progression by promoting cell death.

INTRODUCTION

As a common acute and critical condition of the digestive system, acute pancreatitis (AP) refers to local inflammation of the pancreas and even organ dysfunction due to self-digestion of the pancreas and surrounding organs after abnormal activation of pancreatic enzymes. The prevalence of AP is rising annually, with a global incidence of 4.9-73.4 per 100000 person-years[1]. Most patients display mild symptoms, recover gradually with treatment and have a good prognosis, however, approximately 20% of patients progress to moderately severe or severe pancreatitis, with a case fatality rate (CFR) of up to 30%[2]. Organ failure and pancreatic infection necrosis are believed to be the common causes of mortality in AP patients, and prompt and effective early intervention can improve the prognosis[3]. Accordingly, the prognosis of AP must be predicted at onset. However, a single indicator that can serve as the gold standard for prognostic prediction has not been discovered. Therefore, gaining deeper insights into the underlying mechanism of AP progression and the evolution of the disease and exploring effective biomarkers are important for early diagnosis, progression evaluation, and precise treatment of AP.

Programmed death of pancreatic acinar cells is the major pathophysiological change in the early stages of AP, with the mode of pancreatic acinar cell death playing a vital role in determining AP advancement and prognosis[4,5]. Ferroptosis is a new type of cell death characterized by intracellular iron-dependent lipid peroxidation. In recent years, excessive cellular ferroptosis has been demonstrated to exert a vital role in the pathogenesis of aseptic inflammatory conditions, such as ischemia-reperfusion injury and nonalcoholic steatohepatitis[6]. According to recent studies using a mouse model of AP with knockout of pancreatic tissue glutathione peroxidase 4 (GPX4), the ferroptosis of pancreatic acinar cells exacerbates pancreatic tissue injury, leading to significantly elevated levels of relevant biomarkers and accelerated AP progression[7,8]. The core proteoglycan released from the cells that have undergone ferroptosis can trigger immune responses and the production of proinflammatory cytokines, thereby exacerbating pancreatic acinar cell death and leading to further exacerbation of AP[9]. As shown above, ferroptosis of pancreatic acinar cells promotes the aggravation of AP; however, the molecular mechanism regulating the ferroptosis of pancreatic acinar cells remains unclear.

Non-coding RNAs (ncRNAs) are gaining increasing interest for AP diagnosis and treatment and are expected to be potential biomarkers and therapeutic targets[10]. tRNA-derived fragments (tRFs) have recently been identified as ncRNAs produced from mature tRNAs or tRNA precursors through a specific mechanism of action[11]. tRFs are widespread in various organisms and are extremely conserved, structurally robust, and tissue specific, participating in

different physiological and pathological processes[12]. A sequencing study revealed that several tRFs were abnormally expressed in AP cell models, among which tRF3-Thr-AGT affected AP progression by regulating trypsinogen activation in pancreatic acini[13]. Subsequently, another study revealed that tRF3-Thr-AGT expression was significantly downregulated in the pancreatic tissues of an AP cell model and an AP animal model, while overexpression of tRF3-Thr-AGT inhibited NACHT, LRR, and PYD domains-containing protein 3 (NLRP3)-mediated pyroptosis and the inflammatory responses of pancreatic acinar cells and alleviated AP progression[14]. Accordingly, tRF3-Thr-AGT may be deployed as a biomarker for AP diagnosis and treatment[14].

In this study, serum RNA extraction for AP patients and healthy controls and small RNA sequencing were performed. Thereafter, candidate tRFs were identified using bioinformatics and validated using reverse transcription quantitative polymerase chain reaction (RT-qPCR). The most significantly differentially expressed tRF36 was selected for subsequent investigation. An AP cell model and an AP mouse model were constructed to probe the role and mechanism of tRF36 in regulating ferroptosis and promoting AP progression and to identify the downstream effector pathways and targets. tRF36 was found to promote AP development and progression by regulating P53 expression and ferroptosis by binding to insulin-like growth factor 2 mRNA binding protein 3 (IGF2BP3). This finding provides a theoretical foundation for gaining further insights into the pathogenesis of AP and identifying new potential therapeutic targets.

MATERIALS AND METHODS

Small RNA sequencing

Serum was collected from three patients with AP and three healthy controls. Total RNA was retrieved utilizing the TRizol method, and libraries were constructed utilizing the Multiplex Small RNA Library Prep Kit for Illumina (NEB, United States). The procedure included: (1) 3′ splice ligation; (2) Reverse primer hybridization; (3) 5′ splice ligation; (4) One-strand cDNA synthesis; (5) PCR enrichment; and (6) 8% sodium dodecyl-sulfate polyacrylamide gel electrophoresis fragment sorting (SDS-PAGE). Thereafter, 2 × 150 bp sequencing was performed on an Illumina platform (Yingbiotech, Shanghai, China). This study was approved by Medical Ethics Committee of Yan'an Hospital Affiliated To Kunming Medical University (Approval No. 2022-024-01).

Identification of the differentially expressed tRFs

The overall quality of the sequencing data was evaluated *via* Fast-QC software (http://www.bioinformatics.babraham.ac.uk/projects/fastqc/). For tRFs, sequences that did not match the miRBase (12-23 bp, 34-43 bp) and piRNAcluster (24-33 bp) were compared to rRNA. After we filtered out sequences that could be matched to rRNA, sequences that could be matched to the GtRNA database were matched to the tRFdb and tRFMINTbase databases to obtain tRF expression profiles. Finally, differential expression analysis of tRFs was performed using the DESeq2.0 algorithm (P value < 0.05 and $|\log_2$ fold change$|$ > 1).

Functional enrichment analysis

The target genes for the tRFs were mined *via* miranda (score > 150, energy < -20) and RNAhybrid (energy < -25), and the ultimate target genes were recognized by intersecting the two algorithms. For Gene Ontology (GO) analysis, the significance level of each GO was calculated depending on the GO database (http://www.geneontology.org/) and Fisher's test. The target genes were also annotated with pathways depending on the Kyoto Encyclopedia of Genes and Genomes (KEGG) database (http://www.genome.jp/kegg/) to obtain all pathways involving the genes. The significance level (P value) of each pathway was calculated using Fisher's test and pathways with P value < 0.05 were deemed significantly enriched.

RT-qPCR

We collected serum from 20 patients with AP and 20 healthy controls. Total RNA was retrieved utilizing TRizol (Invitrogen), and reverse transcribed according to the manufacturer's instructions (Thermo, K1622). qPCR was carried out using 2 × Master Mix (Roche). The following thermocycling program was employed for qPCR: 1 cycle at 95 °C for 10 min, followed by 40 cycles at 95 °C for 15 s, and 60 °C for 60 s. The relative expression level was normalized to that of the endogenous control U6 and calculated using the $2^{-\Delta\Delta Ct}$ method[15].

Establishment of the AP cell model and mouse model

Cerulein is a cholecystokinin analogue that provokes the secretion of digestive enzymes in the pancreas of humans and rodents[16]. Cerulein-induced pancreatitis is one of the best featured animal models of pancreatitis, which was first described in 1977 and is highly reproducible and economical[16-18]. Briefly, 10 nM cerulein (MCE, HY-A0190) was administered to the mouse pancreatic acinar carcinoma cell line MPC-83 (Shanghai Bei Nuo Biotechnology Co., Ltd., China) to develop an AP cell model. Male BALB/C mice (age, 6-8 wk; weight 25 ± 3 g; Beijing SiPeiFu Biotechnology Co., Ltd., China) were intraperitoneally administered cerulein 10 times at 1-h intervals to establish the AP mouse model. This study was approved by Animal Ethics and Welfare Committee of Kunming Yan'an hospital (Approval No. 2022013) in accordance with internationally accepted principles for the use of laboratory animals.

tRF interference

According to the manufacturer's protocols, Lipofectamine™ 2000 Transfection reagent (Invitrogen, United States) was

utilized to transfect the tRF-36 inhibitor into MPC-83 cells to knock down the expression of tRF-36. qRT-PCR was conducted to determine the knockdown efficiency of tRF-36.

Cell Counting Kit-8 assay

The viability of cells was determined *via* Cell Counting Kit-8 (CCK-8) assays (Beyotime, China). Then, we seeded 10^3 cells into a 96-well plate and added 10 μL of CCK-8 per well. The absorbance was measured at 450 nm by an enzyme-linked immunosorbent assay (ELISA) microplate reader (Infinite M1000, Tecan) after 1 h of incubation.

ELISA

The levels of tumor necrosis factor (TNF)-α, interleukin (IL)-6, IL-1β, mouse amylase (AMS), and mouse lipase (R&D Systems, MN, United States) were determined using ELISA kits and the absorbance was measured at 450 nm using a microplate reader (Infinite M1000, Tecan).

Detection of cell death

Cell death was assessed using the TUNEL Kit (Sangon Biotech), as described by the manufacturer. A fluorescent microscope (Nikon, Japan) was utilized to observe the specimens.

Reactive oxygen species and malondialdehyde detection

The oxidative-sensitive fluorescent probe DCFH-DA in the reactive oxygen species (ROS) Assay Kit (Beyotime, China) was utilized to assess the generation of intracellular ROS. A laser confocal microscope (Nikon, Japan) was utilized to observe the green fluorescence intensity. Malondialdehyde (MDA) is a metabolite of lipid oxidation and is widely used as an indicator of lipid oxidation. An MDA detection kit (Beyotime, S0131) was used to measure the MDA level in cells or tissues according to the manufacturer's instructions.

Ferric ion detection

A ferric ion colorimetric assay kit (Pulley's, #E1042) was used to measure ferric ion levels in mouse pancreatic tissue, according to the manufacturer's manuals.

Western blot analysis

Cells were lysed using RIPA lysis buffer, homogenized, and centrifuged. Thereafter, the supernatant was collected. Then, the protein concentration was measured using the bicinchoninic acid assay. The proteins were separated *via* SDS-PAGE and transferred to polyvinylidene fluoride membranes. After that, the membranes were incubated at 4 °C overnight with specific primary antibodies against p53 (Proteintech, 60004-1-Lg) and ferritin (Abcam, ab75973) after blocking with 5% nonfat milk. The membrane was then incubated with secondary antibody for 60 min. After the membrane was washed with TBST solution, it was analyzed using the chemiluminescence method. The relative quantification was performed using scanning software (ImageJ grayscale).

Hematoxylin and eosin staining

The mouse lung and pancreatic tissues were washed with phosphate buffered saline and fixed for 24 h in 4% paraformaldehyde fixative solution. Thereafter, conventional paraffin embedding was conducted, and tissue sections (4 μm) were prepared for hematoxylin and eosin (HE) staining. Finally, the histopathological morphology of the sections was observed under a microscope (Olympus, Tokyo, Japan).

Immunohistochemical staining

The tissue sections were dewaxed, rehydrated with xylene, and washed with an alcohol gradient. After soaking and washing with distilled water, H_2O_2 was used to destroy endogenous peroxidase activity. After incubation with anti-ferritin antibody (Abcam, ab75973), the sections were exposed to secondary antibodies. Instillation with diaminobenzidine for 5 min was then performed. Thereafter, the sections were counterstained with hematoxylin, dehydrated with ethanol, and clarified with xylene. Observation and image capture were performed using a microscope (Olympus, Tokyo, Japan).

RNA pulldown assay

The tRF36 probe labeled by biotin was generated, and a Magnetic RNA-Protein Pull-Down Kit [Sangon Biotech (Shanghai, China)] was utilized to implement the RNA pull-down assay depending on the manufacturer's instructions. First, the tRF36 probe or control probe was incubated with streptavidin magnetic beads for 30 min at room temperature. Thereafter, the cell lysates were incubated with probe-bead complexes for 1 h at 4 °C to enable binding of the proteins to RNAs. The RNA-protein complexes were washed and eluted from beads *via* incubation at 37 °C for 30 min with agitation. The eluted proteins were finally analyzed *via* silver staining. The differential protein bands of immunoglobulin G and tRF36-IP lanes were cut and sent to the mass spectrometry platform for protein profiling.

Methylated RNA immunoprecipitation-qPCR

The methylated RNA immunoprecipitation (MeRIP) experiments were completed *via* the riboMeRIPTM m6A Transcriptome Profiling Kit (Merck Millipore) to capture the RNA modified by m6A. Briefly, the total RNA of AP model cells and control cells was extracted by TRizol (Invitrogen). After fragmentation, RNA was incubated with the magnetic

bead-m6A antibody complex for immunoprecipitation. MeRIPed p53 was then analyzed using qRT-PCR.

Statistical analysis

The experimental data were compared *via* student's *t* test to determine the group difference. If not specified above, a *P* value < 0.05 was considered statistically significant.

RESULTS

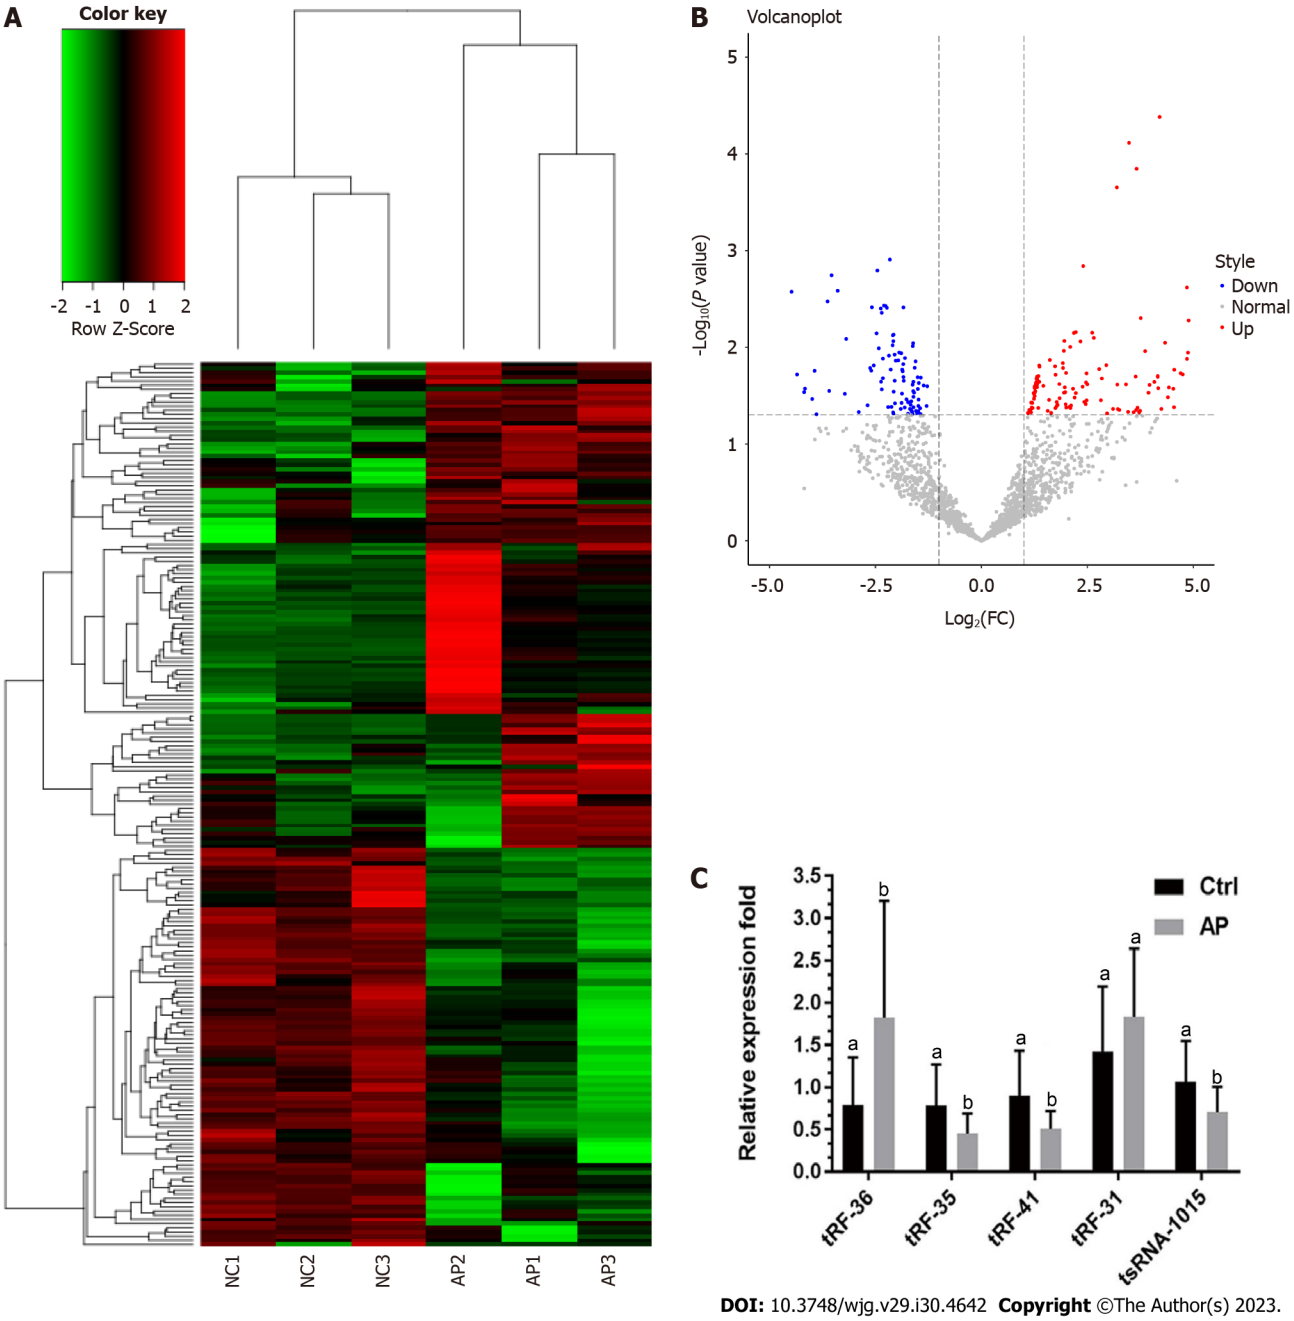
Differentially expressed tRFs in AP

Based on quality control and preprocessing of the raw small RNA sequencing data for three serum samples from three AP patients and three control samples, we found that the sequencing quality met the criteria for subsequent analysis (Supplementary Figure 1). By RNA mapping based on the BWA algorithm, tRF expression data were extracted. A total of 116 upregulated tRFs and 95 downregulated tRFs in AP were screened *via* differential expression analysis (Figures 1A and B, Supplementary Table 1). According to functional enrichment analysis, many biological processes and pathways, including the Wnt signaling pathway, Hippo signaling pathway, and ion transport, were associated with the target genes of these differentially expressed tRFs (DE-tRFs) (Supplementary Figure 2).

tRF36 is upregulated in AP and contributes to AP progression

Due to the uncertainty of high-throughput sequencing, we collected serum from 20 AP patients and 20 healthy controls and verified the five most significant DE-tRFs using RT-qPCR (Figure 1C). As shown in Figure 1C, tRF36 was downregulated in the serum of AP patients, and its differential expression was the most significant ($P < 0.05$, Figure 1C). This finding implied that tRF36 played an important role in AP progression. To test our hypothesis, we generated an AP cell model using the MCP-83 cell line. Figure 2A revealed that the expression of tRF-36 was significantly reduced after the use of inhibitor. It is well known that AMS and lipase have diagnostic value for AP[19], and the inflammatory response is associated with AP-induced injury[20]. Therefore, we measured the expression of AMS and lipase as well as inflammatory factors to determine the feasibility of the model. After MCP-83 cells were treated with cerulein, the levels of AMS and lipase and the inflammatory factors TNF-α, IL-6, and IL-1β in the cell supernatant increased significantly, indicating successful establishment of the AP cell model (Figures 2B-F). After knockdown of tRF36, these markers were further assayed in the cell supernatants. Based on the results, the levels of AMS and lipase and the inflammatory factors TNF-α, IL-6, and IL-1β in the cell supernatant were significantly reduced after knockdown of tRF36 (Figures 2B-F). Cell viability and cell death were measured by CCK-8 and TUNEL assays, respectively. Knockdown of tRF36 was found to significantly increase cell viability, and significantly reduce cell death (Figures 2G and H). These results suggest that tRF36 contributes to AP progression by promoting cell death.

Presence of cell ferroptosis in AP

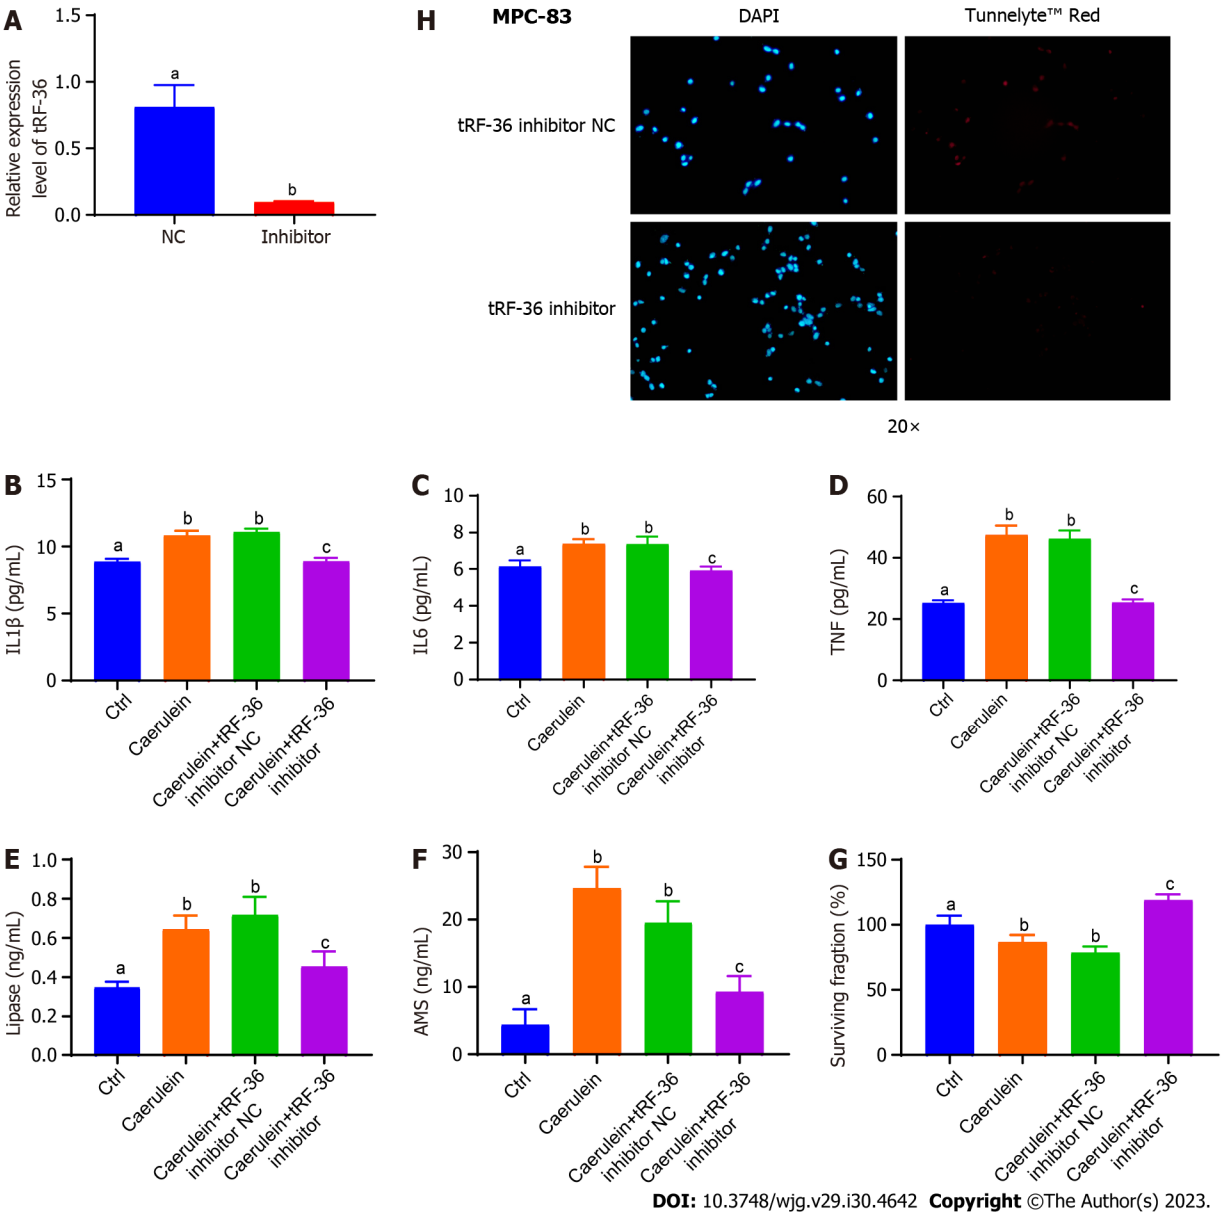


We proceeded to conduct functional enrichment analysis of the target genes of tRF36 (KEGG pathway). The target genes of tRF36 were found to be involved in ferroptosis-related pathways, namely, the P53 signaling pathway and mechanistic target of rapamycin (mTOR) signaling pathway (Figure 3A). To confirm the presence of ferroptosis in AP progression, we constructed an AP mouse model. Based on HE staining of lung and pancreatic tissues, significant changes were observed in pancreatic tissue cell morphology (Figure 3B). Furthermore, the serum levels of lipase and AMS in the AP model mice were significantly higher than those in the controls (Figures 3C and D). The serum levels of the inflammatory factors TNF-α, IL-6, and IL-1β were also significantly increased in the AP model mice (Figures 3E-G). Therefore, the AP mouse model was successfully established. Subsequently, the levels of ferritin expression, ferric ions, and the lipid oxidation metabolite MDA were examined in pancreatic tissue. The expression of ferritin in the pancreatic tissues of the AP model mice was significantly reduced (Figure 3H). Correspondingly, the levels of ferric ion concentration and MDA were significantly increased (Figures 3I and J). These results highlighted the presence of cell ferroptosis in AP.

tRF36 promotes AP progression through the regulation of ferroptosis

Based on the above results, we hypothesized that tRF36 may promote AP progression by regulating cell ferroptosis. Hence, we examined the ROS levels in AP model cells. The ROS levels of cells in the model group were found to be significantly higher than those in the control group (Figure 4A). Similar results were obtained using the AP cell model (*e.g.*, decreased ferritin expression and increased MDA levels) compared to control cells, which were similar to those of the mouse model (Figures 4B and C), suggesting the presence of cell ferroptosis in the AP model. After knockdown of tRF36 in MCP-83 cells, a significant decrease in ROS levels and MDA and a significant increase in ferritin expression levels were found in cells (Figures 4A-C). Therefore, we concluded that tRF36 could promote AP progression through the regulation of ferroptosis.

Exploring the molecular mechanisms by which tRF36 promotes AP progression



To further probe the molecular mechanisms underlying the regulation of ferroptosis by tRF36, we utilized a ferroptosis gene microarray to determine the differentially expressed ferroptosis genes after tRF36 knockdown. The gene expression of p53 was the most significantly downregulated of the genes (Figure 5A). Database analysis revealed that p53 mRNA interacts with several m6A proteins, including METTL3, ALKBH5, IGF2BP3, and others (Figure 5B). The SRAMP database (http://www.cuilab.cn/sramp) predicted that p53 mRNA has m6A modification sites with a very high

probability of modification (Figure 5C). Therefore, we searched for proteins interacting with tRF-36 using an RNA pull down assay and mass spectrometry, which revealed that tRF-36 interacts with the m6A methylation regulator IGF2BP3 (Figures 5D and E, Supplementary Table 2). IGF2BP3 is a unique m6A reader protein that promotes stable mRNA expression and prevents mRNA degradation[21]. MeRIP-qPCR results revealed that the level of m6A modification of p53 was elevated in the AP cell model (Figure 5F). Western blot and qPCR analyses revealed that the knockdown of tRF36 in the AP cell model resulted in a significant reduction in p53 expression (Figures 5G and H). Interestingly, p53 expression was significantly restored after the overexpression of IGF2BP3 in cells with tRF36 knockdown (Figures 5G and H). Therefore, we speculated that tRF36 accelerated the progression of AP by recruiting IGF2BP3 to the p53 mRNA m6A modification site through binding to IGF2BP3, which enhanced p53 mRNA stability and promoted the ferroptosis of pancreatic follicle cells (Figure 6). The p53 expression level after the knockdown of tRF36 was determined by western blot qPCR.

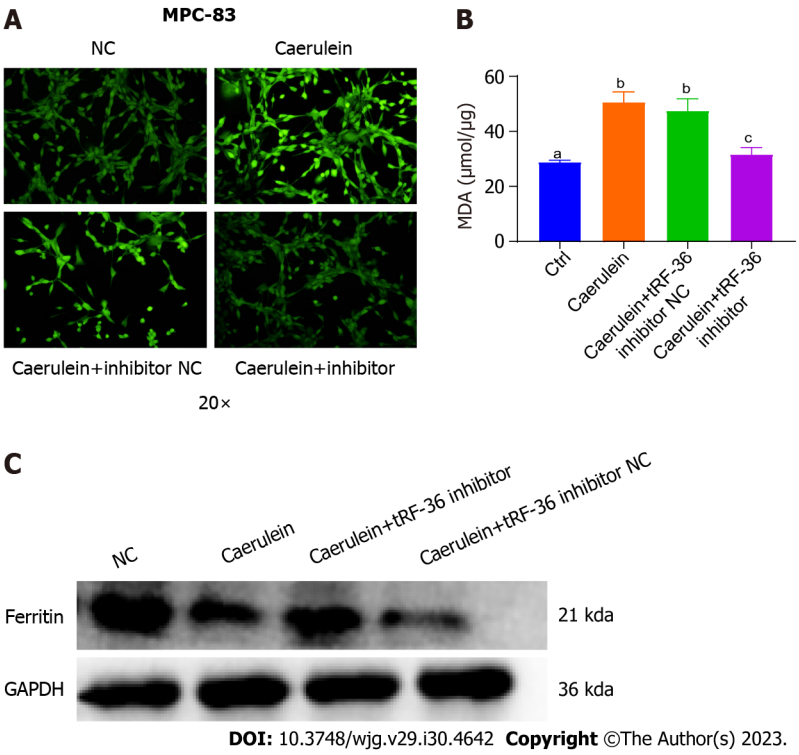
DISCUSSION

The incidence of AP is increasing annually, with a global incidence of 4.9-73.4 per 100000 person-years[1]. Approximately 20% of AP cases will progress to moderate or severe pancreatitis, with a CFR of up to 30%[2]. The pathogenesis of AP is complex, and no effective clinical treatment has been developed to date. Therefore, gaining deeper insights into the underlying mechanism of AP progression and exploring effective biomarkers are important for AP diagnosis and treatment[9]. In this study, tRF36 was discovered to play an important role in AP progression; thus, its regulatory mechanism was explored.

Sequencing and bioinformatics analyses were performed using the small RNAs extracted from the serum samples of AP patients and healthy controls. Validation of tRF36, the most significantly expressed molecule, was performed using qPCR. The downstream target genes of tRF36 were then predicted and analyzed to explore their potential biological functions.



KEGG pathway enrichment analysis revealed that the target genes of tRF36 were mainly enriched in the ferroptosis-related p53 and mTOR signaling pathways. Numerous studies have confirmed that the p53 signaling pathway can regulate ferroptosis. For example, Chen *et al*[22] found that iPLA2 β-mediated lipid detoxification is vital for inhibiting

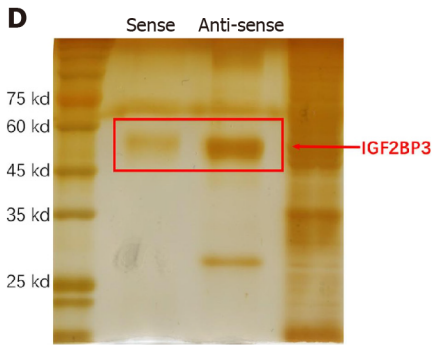
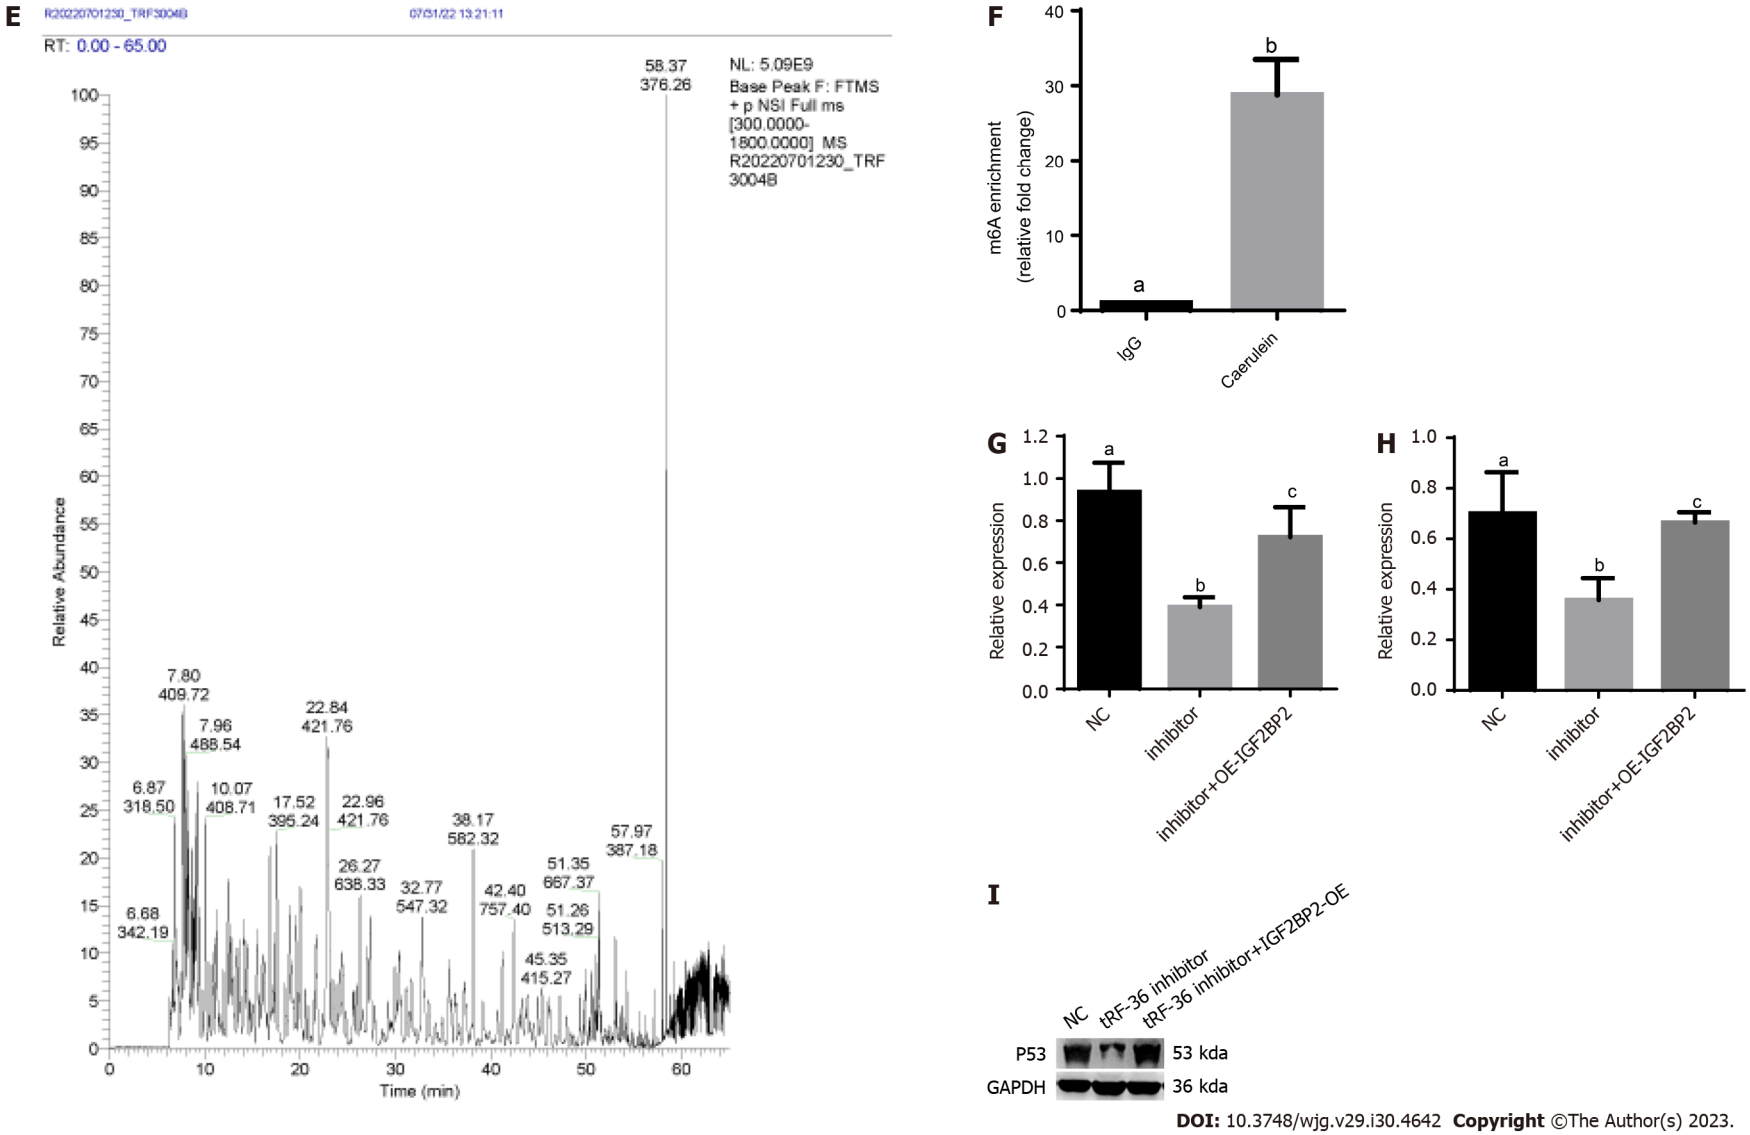
the ROS-induced ferroptosis of cancer cells. Chu *et al*[23] found an ALOX12-mediated, ACSL4-independent ferroptosis pathway that is vital for p53-dependent tumor suppression. Lei *et al*[24] found that radiotherapy (RT)-mediated p53 activation antagonizes RT-induced SLC7A11 expression and inhibits glutathione synthesis, thereby promoting RT-induced lipid peroxidation and ferroptosis. Li *et al*[25] found that ferroptosis contributes to acute lung injury induced by intestinal ischemia/reperfusion and that iASPP treatment partially inhibits ferroptosis *via* nuclear factor E2-related factor 2 (Nrf2). Jiang *et al*[26] found that p53 inhibits cystine uptake and sensitizes cells to ferroptosis by suppressing SLC7A11 expression.



Numerous studies have shown that the mTOR signaling pathway regulates ferroptosis. For example, Conlon *et al*[27] found that acute amino acid deprivation-induced proliferative arrest correlates with protection from ferroptosis in a manner independent of mTOR inhibition and GCN2/ATF4 pathway activation. Sun *et al*[28] not only supported the concept that ferroptosis is autophagy-dependent cell death but also suggested that the combined application of ferroptosis inducers and mTOR inhibitors is a promising approach to improve bladder cancer treatment options. Hsieh *et al*[29] found that ZVI-NP selectively triggered the ferroptosis of cancer cells by inhibiting the Nrf2-mediated cytoprotective program, which was attributed to ZVI-NP-induced disruption of AMPK/mTOR signaling and activation of the GSK3βSK-TrCP-dependent degradation system.



In recent years, the role of ncRNAs in AP has received increasing attention, and ncRNAs are expected to be a potential biomarker and therapeutic target. Owing to the development of sequencing technology, many AP-associated ncRNAs have been identified, such as long ncRNAs, microRNAs, and tRFs[30,31], suggesting that ncRNA dysregulation plays an important role in the development of AP. For example, Li *et al*[32] demonstrated that tRNA-derived small RNAs (tsRNAs) can be used as a potential therapeutic biomarker for bile duct cancer. The sequencing results of Yang *et al*[13] revealed that different tRFs were abnormally expressed in AP cell models, and tRF3-Thr-AGT affected AP progression by regulating trypsinogen activation in pancreatic acini. A later study further showed that tRF3-Thr-AGT expression was significantly downregulated in the pancreatic tissues of an AP cell model and an AP animal model, while overexpression of tRF3-Thr-AGT inhibited the NLRP3-mediated pyroptosis and inflammatory responses of pancreatic acinar cells, thereby alleviating AP progression[14]. However, no existing studies have reported the involvement of tRF36 in regulating the pathogenesis of AP. In the present study, tRF36 expression was upregulated in the serum of AP patients,

and knockdown of tRF36 resulted in a significant decrease in AMS and lipase levels in cell supernatants and a reduction in pancreatic acinar cell death. Therefore, tRF36 exacerbates AP by promoting pancreatic acinar cell death and may be a diagnostic biomarker in clinical treatment.

In AP mouse models in which GPX4 was knocked out in pancreatic tissues, the ferroptosis of pancreatic acinar cells exacerbated pancreatic tissue damage, leading to a significant increase in the levels of relevant biomarkers and accelerated progression of AP[7,8]. The core proteoglycan released from cells that have undergone ferroptosis can trigger immune responses and the production of proinflammatory cytokines, thereby exacerbating pancreatic acinar cell death and leading to further exacerbation of AP[9]. In mice and cell models of AP, the expression of ferritin decreased and MDA level increased. Hou *et al*[33] suggested that ferritin was a major intracellular iron storage protein complex, and its increased expression would limit ferroptosis. On the contrary, there was a low ferritin expression level during ferroptosis. As shown above, ferroptosis of pancreatic acinar cells promotes the aggravation of AP.

In the present study, we constructed an AP cell model in which tRF36 was knocked down in the pancreatic acinar cells. A ferroptosis gene microarray was performed to identify the key genes involved in ferroptosis, among which P53 was demonstrated to exhibit the most significant expression. Database-based prediction revealed that p53 mRNA has an m6A modification site where p53 mRNA interacts with some m6A-reader proteins. Goodarzi *et al*[34] found that tsRNA can inhibit the stability of multiple proto-oncogene transcripts in breast cancer cells by competitively binding to the RNA-binding protein YBX1. Thus, tRFs can regulate the stability of downstream gene transcripts *via* RNA-binding proteins. Accordingly, an RNA pulldown assay combined with mass spectrometry was performed in the present study, which revealed that tRF36 interacted with IGF2BP3. Finally, based on gene interference, overexpression, MeRIP-PCR, RNA pulldown assays, western blotting, and rescue assays, IGF2BP3 was confirmed to regulate the ferroptosis of pancreatic acinar cells by regulating P53 expression by enhancing P53 mRNA stability. Taken together, the above findings suggest that the acceleration of AP progression by tRF36 may involve the process of tRF36 recruiting IGF2BP3 to the m6A modification site of P53 mRNA by binding to IGF2BP3, which enhances P53 mRNA stability, ultimately promoting the ferroptosis of pancreatic acinar cells.

To our knowledge, this is the first study to identify a tRF, tRF36, that promotes AP progression by regulating the ferroptosis of pancreatic acinar cells and to elucidate the molecular mechanism whereby tRF36 is involved in AP progression (*e.g.*, tRF36 regulates the ferroptosis of pancreatic acinar cells by regulating P53 expression through binding to IGF2BP3). The findings fill the knowledge gap by revealing how tRFs are involved in AP progression *via* the regulation of ferroptosis and provide a new direction for further studies on AP development.

The present study had some limitations. The sample size of the study cohort was small. Future studies should employ a larger sample size to further verify the expression of tRF36 in AP. The expression levels of ROS and MDA were determined only by knocking down tRF36. Accordingly, their expression should also be examined by overexpressing tRF36.

Figure 6 A schematic of a putative mechanism of tRNA-derived fragments 36 in the progression of acute pancreatitis. In this model, tRNA-derived fragments 36 might recruit insulin-like growth factor 2 mRNA binding protein 3 (IGF2BP3) to the p53 mRNA m6A modification site by binding to IGF2BP3 to enhance p53 mRNA stability and promote the ferroptosis of pancreatic follicle cells. tRF-36: tRNA-derived fragments 36; IGF2BP3: Insulin-like growth factor 2 mRNA binding protein 3.

CONCLUSION

In this study, the most significantly differentially expressed candidate, tRF36, was identified using bioinformatics and validated using qRT-PCR based on serum RNA extraction and small RNA sequencing data from AP patients and healthy controls. The AP cell model and the AP mouse model were constructed to explore the role and mechanism of tRF36 in regulating ferroptosis and promoting AP progression, indicating that tRF36 might recruit IGF2BP3 to the p53 mRNA m6A modification site by binding to IGF2BP3 to enhance p53 mRNA stability and promote the ferroptosis of pancreatic follicle cells. This finding provides a theoretical basis for gaining further insights into the pathogenesis of AP and identifying new potential therapeutic targets.

ARTICLE HIGHLIGHTS

Research background

Acute pancreatitis (AP), also known as acute inflammation of the pancreas, is an inflammatory injury resulting from the activation of pancreatic enzymes caused by a variety of pathogenic factors, leading to self-digestion of pancreatic tissue.

Research motivation

Difficult treatment, high morbidity, many complications, high cost, and poor prognosis are the current clinical status. Therefore, it is particularly important to investigate the pathogenesis of AP.

Research objectives

Screening for tRNA-derived fragments (tRFs) contribute to AP progression and exploring the molecular mechanism of its action were the main objectives of our study.

Research methods

Firstly, key tRFs and the potential mechanisms of action were explored based on the small RNA sequencing and functional enrichment analyses in AP. The role of tRF36 was investigated by constructing the AP cell and mouse models. Subsequently, the lipase, amylase, and cytokine levels were assayed to examine AP progression. Evaluation of cellular ferroptosis was implemented by analyzing the ferritin expression, reactive oxygen species, malondialdehyde, and ferric ion levels. Finally, RNA pull down assays and methylated RNA immunoprecipitation were performed to explore the

molecular mechanisms.

Research results

In total, 211 differentially expressed tRFs including 116 upregulated and 95 downregulated were identified. According to reverse transcription quantitative polymerase chain reaction, tRF36 was significantly upregulated in the serum of AP patients, compared to healthy controls. Moreover, the occurrence of pancreatic cell ferroptosis was detected in AP cells and mouse models. Furthermore, we hypothesized that tRF36 accelerated AP progression by binding to insulin-like growth factor 2 mRNA binding protein 3, which was recruited to the p53 mRNA m6A modification site, thereby enhancing the stability of p53 mRNA and promoting ferroptosis in pancreatic follicular cells.

Research conclusions

tRF36 promoted AP development by regulating the ferroptosis of pancreatic cells, which would provide a new theoretical basis for understanding the regulatory mechanism of tRF in AP, and also provide new targets for the treatment of AP.

Research perspectives

We will further validate the results of this study and continue to monitor the role of tRF36 in the development process of AP.

Abstract

BACKGROUND

Fecal microbiota transplantation (FMT) has shown promising therapeutic effects on mice with experimental colitis and patients with ulcerative colitis (UC). FMT modulates the Toll-like receptor 4 (TLR4) signaling pathway to treat some other diseases. However, it remains unknown whether this modulation is also involved in the treatment of UC.

AIM

To clarify the necessity of TLR4 signaling pathway in FMT on dextran sodium sulphate (DSS)-induced mice and explain the mechanism of FMT on UC, through association analysis of gut microbiota with colon transcriptome in mice.

METHODS

A mouse colitis model was constructed with wild-type (WT) and TLR4-knockout (KO) mice. Fecal microbiota was transplanted by gavage. Colon inflammation severity was measured by disease activity index (DAI) scoring and hematoxylin and eosin staining. Gut microbiota structure was analyzed through 16S ribosomal RNA sequencing. Gene expression in the mouse colon was obtained by transcriptome sequencing.

RESULTS

The KO (DSS + Water) and KO (DSS + FMT) groups displayed indistinguishable body weight loss, colon length, DAI score, and histology score, which showed that FMT could not inhibit the disease in KO mice. In mice treated with FMT, the relative abundance of *Akkermansia* decreased, and *Lactobacillus* became dominant. In particular, compared with those in WT mice, the scores of DAI and colon histology were clearly decreased in the KO-DSS group. Microbiota structure showed a significant difference between KO and WT mice. *Akkermansia* were the

dominant genus in healthy KO mice. The ineffectiveness of FMT in KO mice was related to the decreased abundance of *Akkermansia*. Gene Ontology enrichment analysis showed that differentially expressed genes between each group were mainly involved in cytoplasmic translation and cellular response to DNA damage stimulus. The top nine genes correlating with *Akkermansia* included Aqp4, Clca4a, Dpm^3, Fau, Mcrip1, Meis3, Nupr1 L, Pank3, and Rps13 ($|R| > 0.9$, $P < 0.01$).

CONCLUSION

FMT may ameliorate DSS-induced colitis by regulating the TLR4 signaling pathway. TLR4 modulates the composition of gut microbiota and the expression of related genes to ameliorate colitis and maintain the stability of the intestinal environment. *Akkermansia* bear great therapeutic potential for colitis.

Core Tip: Recent studies have shown that fecal microbiota transplantation (FMT) has a therapeutic role in patients with inflammatory bowel disease. The Toll-like receptor 4 (TLR4) signaling pathway may play a critical role in intestinal injury and repair. Here, we conducted animal experiments to explore the role of TLR4 in dextran sodium sulphate-induced colitis in mice and the treatment of FMT.

INTRODUCTION

Recent studies support that inflammatory bowel disease (IBD) can be categorized as a "microbial dysbiosis disease," because of its progression synchronizing the dysbacteriosis of gut microbiota[1]. Host physiology such as barrier function, metabolism, immune responses, and homeostasis involves microbiome-induced cell signaling, proliferation, and neurotransmitter biosynthesis[2]. In IBD patients, intestinal bacterial diversity decreases and the bacterial community structure changes[3]. In dextran sodium sulphate (DSS)-induced colitis in mice, some probiotics, including *Lactbacillus* and *Bifidobacterium*, are significantly reduced[4]. New evidence indicates that IBD is not merely a consequence of chronic inflammation, but also of disruption of the gut microbiome and destruction of the intestinal epithelial barrier[5].

Gut microbiota play a role in inflammation-related activities. Fecal microbiota transplantation (FMT) has shown high efficacy and safety in treating ulcerative colitis (UC)[6,7] due to its immunomodulatory and anti-inflammatory functions [8]. Our previous study showed that FMT can counter DSS-induced colitis in mice by increasing the relative abundance of *Lactobacillus*[9]. FMT has also shown therapeutic potential for a range of other diseases, such as hepatic disorders and metabolic syndrome[10]. Recent studies have demonstrated that Toll-like receptor 4 (TLR4) is exploited by FMT in treating many diseases such as spleen deficiency diarrhea[11], Parkinson's disease[12,13], developmental arsenic neurotoxicity[14], fluorosis[15], and acute lung injury[16]. Previous studies have indicated that FMT intervention can inhibit activation of the nuclear factor kappa B (NF-κB) signaling pathway[17], which is downstream of TLR4. However, there have been limited studies investigating the role of TLR4 in FMT for UC.

As a class of transmembrane proteins that recognize invading microbes and activate immune cells, Toll-like receptors (TLRs) regulate gene transcription and the acquired intestinal immune response[18]. In the etiology of IBD, microbes in the intestinal lumen induce abnormal immune responses, along with excessive leakage of bacterial antigens into the mucosa[19]. TLR4, an important immune activator, is highly expressed in the intestinal epithelial cells and lamina propria cells of UC patients[20]. It binds to ligands to activate cytokine signaling, recruit inflammatory cells, and damage intestinal mucosal barrier, all of which aggravate intestinal inflammatory lesions. More importantly, substantial evidence supports a pro-inflammatory role of the TLR4 signaling pathway in UC. Expression levels of TLR4 are positively correlated with disease activity indices (DAIs), endoscopy scores, and histopathological scores[21]. DSS-induced colitis deteriorates in mice with TLR4 overexpression[22,23], but is stably maintained in TLR4-deficient mice[24,25]. Multiple experiments have shown that inhibiting the TLR4 signaling pathway can prevent DSS-induced colitis[26,27]. While TLR4 plays a crucial role in intestinal injury and repair, its role in shaping colonic bacterial homeostasis and microbiota-related immunity remains poorly understood.

Our previous studies confirmed the efficacy FMT on IBD, but the mechanism has not been reported[9]. Therefore, we explored the role of TLR4 in the mechanism by which FMT treats DSS-induced colitis in the mice.

MATERIALS AND METHODS

Animals

Wild-type (WT) C57BL/10J mice and TLR4-knockout (KO) mice on the C57BL/10J background (female; 6 to 8 wk of age; weighing 18-20 g; specific pathogen-free (SPF) grade) were purchased from the Model Animal Research Center of Nanjing University (Nanjing, China). All mice were reared in an SPF condition at the experimental animal center of the Affiliated Huaian No. 1 People's Hospital of Nanjing Medical University. Throughout the acclimatization and study periods, all mice were maintained in a 12 h-light/12 h-dark cycle (21 °C ± 2 °C with a relatively constant humidity of 45% ± 10%) and had access to food and water *ad libitum*. All mice were group-housed and reared in a standard cage, with TLR4 KO mice kept separately from C57BL/10J mice in different cages.

DSS-induced colitis

DSS (36-50 kDa) was purchased from MP Biomedicals LLC (Irvine, CA, United States) and dissolved in distilled water. Experimental colitis was induced as previously described with minor changes[9]. For different groups, the mice were administered 2.5% (w/v) DSS in drinking water for 7 d. Mice in the KO (DSS + FMT) group were fed fecal microbiota from healthy WT mice from day 8 (once every 2 d) until the end of the experiment, while mice in the KO (DSS + water) group were fed normal saline at the same time. The mice were evaluated daily by scoring *via* the disease activity index (DAI)[28]. The DAI score was calculated on a 0-4 scale as previously described[29].

Fecal preparation and transplantation

The process of FMT was performed as previously described[9]. Briefly, feces from donor mice (healthy WT mice) were collected and resuspended in sterile normal saline at 0.125 g/mL. Then 0.2 mL of this suspension was administered to mice once every 2 d by oral gavage. This process lasted 7 d.

Histopathology

Mice were euthanized by cervical dislocation, and their abdominal cavity was opened immediately. The colon tissue was dissected; colons were measured for colon length, and tissues were examined for gross macroscopic appearance and stool consistency. The distal colon segment was placed in 10% neutral buffered formalin for 24 h, embedded in paraffin, and cut into sections 4 μm in thickness. Then the sections were stained with hematoxylin and eosin (H&E). H&E-stained sections were examined for inflammation and tissue damage by an experienced pathologist in a blinded manner. Tissue histology was scored by summing the scores of the following parameters according to a previous study[30]: Extent of inflammation, aberrant crypt foci, lymphocyte infiltration, and aberrant colon wall.

Fecal DNA extraction and 16S ribosomal RNA sequencing

Fecal DNA extraction and 16S ribosomal RNA (rRNA) sequencing were performed as previously reported[9]. The V3-V4 hypervariable region of the bacterial 16S-rRNA gene was amplified with primers 338F (5′-ACTCCTACGGGAG-GCAGCAG-3′) and 806R (5′-GGACTACHVGGGTWTCTAA T-3′) with the ABI GeneAmp® 9700 PCR thermocycler (Applied Biosystems, Foster City, CA, United States)[9]. All PCR products were extracted from a 2% agarose gel and purified using the AxyPrep DNA Gel Extraction Kit (Axygen Biosciences, Union City, CA, United States)[31]. Purified amplicons were sequenced on the Illumina MiSeq PE300 platform (Illumina, San Diego, CA, United States). The raw 16S rRNA gene sequencing reads were demultiplexed, quality-filtered by fastp version 0.20.0, and merged by FLASH version 1.2.7. Operational taxonomic units (OTUs) with 97% similarity cutoff[32] were clustered using UPARSE version 7.1[33], and chimeric sequences were identified and removed. Bacterial alpha-diversity was determined by sampling-based OTU analysis. Analysis of species accumulation curves was performed to assess the rationality and efficiency of the sequencing depth. Principal component analysis (PCA) was implemented in R programming. Using the Wilcoxon rank-sum test, the bacterial taxonomic analysis was performed for comparison at the bacterial phylum, class, order, family, genus levels between two groups. Based on the matrix of normalized relative abundance, bacteria with significantly different abundances between assigned taxa were determined by linear discriminant analysis effect size (LEfSe) with the Kruskal-Wallis rank-sum test ($P < 0.05$). LDA was used to assess the effect size of each feature (LDA score [log10] = 3 as the cut-off value).

Transcriptome analysis

Total RNA was extracted from inflammatory colonic tissue. For sequencing, a 1 cm colon tissue was sampled from the site about 2 cm from the anus, regardless of whether there was visible inflammation. The tissue samples with minimum and maximum histological scores were removed. Then the colon samples from four randomly chosen animals in each group was used for sequencing. Methods for amplifying and sequencing followed those previously published[9,29]. Briefly, 2 μg RNA per sample was used to sequence on the Illumina Hiseq 4000 platform. Differential expression analysis was performed using the DESeq R package (1.10.1) according to the manufacturer's protocol. Then, to explore the potential function of the differentially expressed genes (DEGs), GOseq R package[34] and KOBAS software[35] were used to test the enrichment of DEGs in Gene Ontology (GO) functional annotations[36] and Kyoto Encyclopedia of Genes and Genomes (KEGG) pathways[37].

Correlation analysis for gut microbiota and transcriptome

We used Metastats software to confirm the difference in the relative abundance of microbiota among the samples ($P \leq$

0.05). We used DEG sequencing to carry out transcriptome difference analysis (the threshold was *P*adj < 0.05 & |log2FC| > 1). Finally, R psych software package was used to analyze the Spearman association between the transcriptome and intestinal microflora. Those with $|R| > 0.8$ and $P < 0.05$ (strong correlation) were screened for mapping.

Statistical analysis

Differences were analyzed using the *t*-test with Graphpad Prism 8.0 software (GraphPad Software Inc., La Jolla, CA, United States). Results are shown as the mean ± standard error of the mean. $P < 0.05$ was considered statistically significant.

RESULTS

FMT does not improve acute colitis induced by DSS in TLR4-KO mice

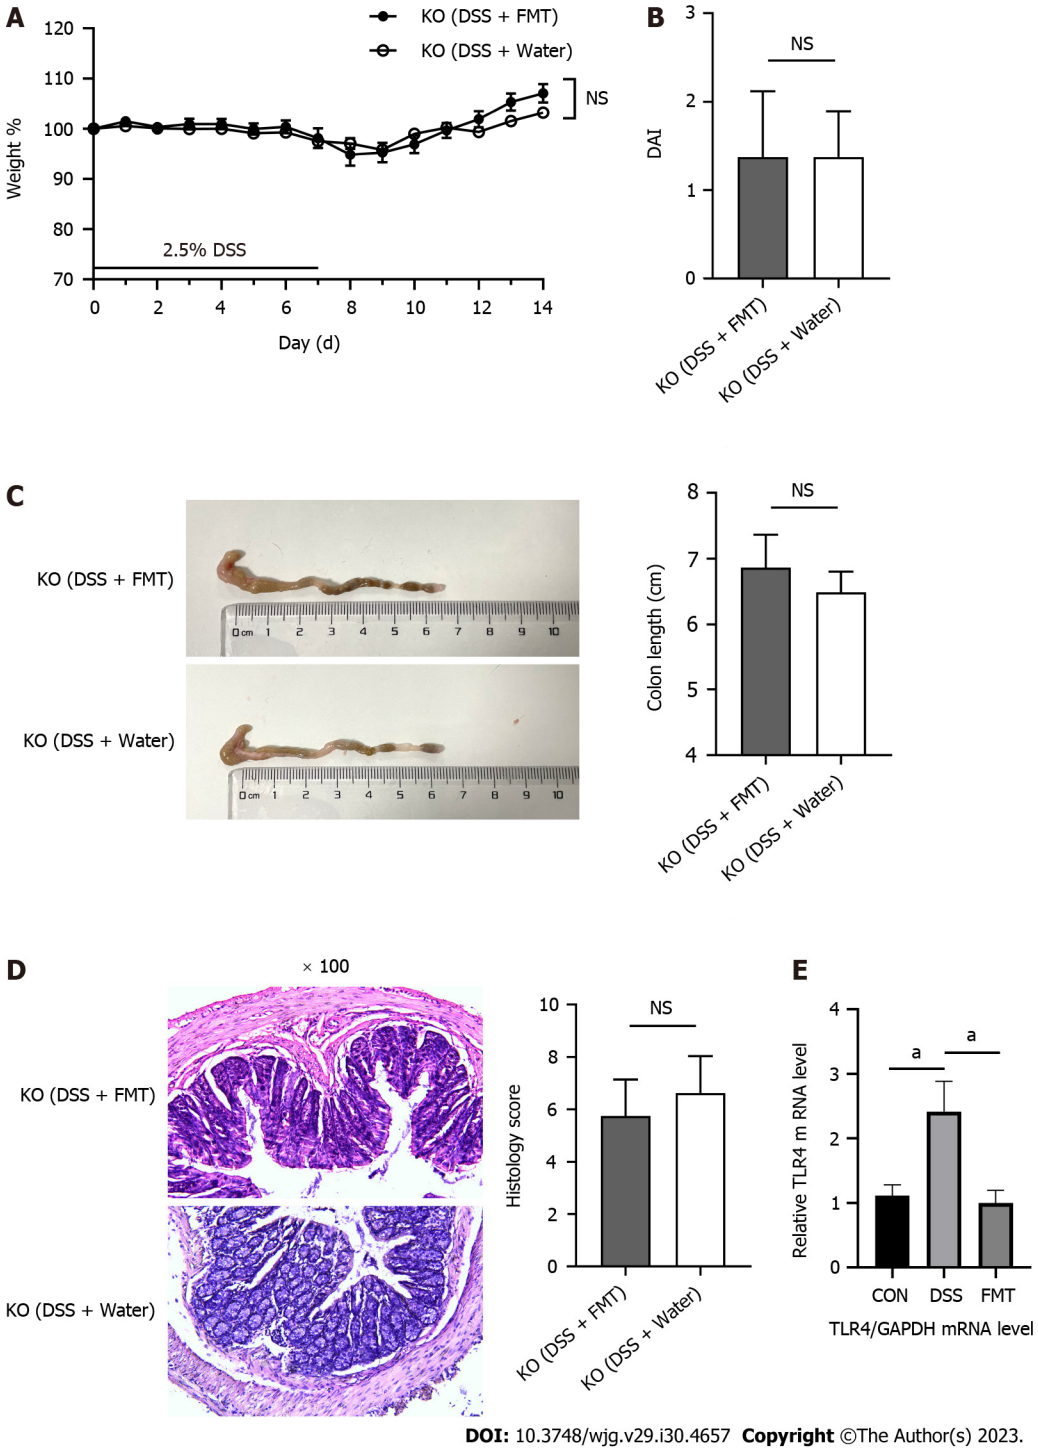
In our previous experiment, we found that FMT is effective to treat colitis[9]. We further explored whether this efficacy is related to the TLR4 pathway. Acute DSS-induced colitis was induced in eight animals per group using 2.5% DSS in the drinking water. After gavage with fecal microbiota from the WT mice, mice in the KO (DSS + water) and KO (DSS + FMT) groups displayed indistinguishable body weight loss, colon length, DAI score, and histology score (Figure 1A-D). Beyond our expectation, FMT had no effect on colonic inflammation in TLR4-KO mice. We compared the expression of TLR4 gene in the intestine of WT mice before and after FMT. The transcriptome sequence data indicated that DSS increased, but FMT effectively decreased the expression of TLR4 (Figure 1E).

FMT changes the intestinal flora of TLR4-KO mice

We investigated whether FMT changed the composition of gut microbiota in the KO (DSS + water) and KO (DSS + FMT) groups. We employed LEfSe to evaluate the bacterial taxa (at genus level) in the two groups (Figure 2A). The dominating taxa in KO (DSS + FMT) group were enriched in *Lactobacillus*, which indicated that we had successfully transplanted the gut microbiota of healthy WT mice. Meanwhile, the KO (DSS + FMT) group had a lower abundance of *Akkermansia*, indicating that FMT could alter the relative abundance of *Akkermansia* in KO mice (Figure 2B).

TLR4 KO alleviates DSS-induced colitis

We used TLR4-deficient mice and WT mice to determine whether TLR4 may protect mice from DSS-induced colitis. Mice in the KO-DSS ($n = 8$) and WT-DSS ($n = 7$) groups were given distilled drinking water containing 2.5% DSS for 7 d (Figure 3A). Compared with WT mice, KO mice showed lower susceptibility to DSS, as manifested by their much smaller body weight loss (Figure 3B), lower DAI (Figure 3C), and longer colons (Figure 3D). Compared to the WT-DSS group, mice in the KO-DSS group exhibited a more intact colon structure, less severe crypt damage, and reduced inflammatory infiltration (Figure 3E). In summary, KO mice showed increased tolerance to DSS-induced colitis.



TLR4 deficiency influences the diversity and composition of gut microbiota

We further investigated whether the protection against DSS-induced colitis was due to TLR4 KO or microbiota re-composition. We detected the gut microbiota of WT and KO mice in the basal and DSS-treated states. We analyzed the beta-diversity of microbiota based on PCA. An evident clustering separation between OTUs revealed the different community structures between each two groups, suggesting that these communities are distinct in terms of their compositional structure (Figure 4A and 5A).

At the phylum level, TLR4 deficiency decreased the abundance of *Bacteroidetes* and increased the abundances of *Actinobacteria* and *Verrucomicrobia* ($P < 0.05$; Figure 4B), compared to those in WT mice. After DSS induction, a significant increase of phylum *Proteobacteria* was observed in the WT-DSS group compared to the KO-DSS group ($P < 0.05$; Figure 5B). *Verrucomicrobia* was the most abundant phylum among those with significant differences ($P < 0.05$). At the genus level, *Akkermansia* abundance was significantly higher in KO mice than in WT mice either healthy or diseased ($P < 0.05$; Figure 4C and 5C). To further investigate the potential effect of microbiota composition on DSS-induced colitis, we used the LEfSe to detect the marked differences in the dominant bacterial communities between the two groups (Figure 4D and 5D). Specifically, *Lactobacillus* and *Peptococcus* were enriched in the WT-CON group (Figure 4D), while *Escherichia Shigella* and *Anaerotruncus* were enriched in the WT-DSS group (Figure 5D). Interestingly, *Akkermansia* and *Bifidobacterium* were enriched either in healthy and diseased KO mice (Figure 4D and 5D). The collective results of our study indicated clear differences in the intestinal microbiome between WT mice and KO mice, both in healthy conditions and during illness. These findings highlight the important role of TLR4 in shaping the composition and diversity of the intestinal microbiota.

TLR4-KO-shaped microbiota affect the transcriptome in the colon of mice

To further explore whether FMT can change the gene expression related to TLR4, we investigated the DEGs between groups. Compared to those in the WT-DSS group, 1436 genes were differentially expressed in the KO-DSS group, and 309 genes in the KO (DSS + FMT) group. Furthermore, 193 DEGs were found among the KO-DSS group, WT-DSS group, and KO (DSS + FMT) group (Figure 6A). GO enrichment analysis showed that these DEGs were mainly involved in cytoplasmic translation and cellular response to DNA damage stimulus (Figure 6B). According to 16S rRNA sequencing analysis, we found that *Akkermansia* was dominant in the KO group. To characterize potential gene-microbe interactions, we computed gene-microbe correlations with Spearman correlation efficients (Figure 6C). The top nine genes correlating

with *Akkermansia* included Aqp4, Clca4a, Dpm^{3}, Fau, Mcrip1, Meis3, Nupr1 L, Pank3, and Rps13 ($|R| > 0.9$, $P < 0.01$).

DISCUSSION

Researchers have found that patients with active UC can benefit from FMT[38]. Moreover, our previous study also verified that FMT can treat colitis in mice. In the present study, the expression of TLR4 was upregulated by DSS, and downregulated after FMT. It therefore stands to reason that, by inhibiting TLR4, a protective effect from intestinal inflam-

mation will be induced. Considering the ubiquitous involvement of the TLR4 signaling pathway in the activities of the mucosa, we designed this animal study to elucidate its interaction with FMT in UC. In this study, TLR4 KO significantly alleviated the clinical and histological manifestations of DSS-induced colitis. Notably, the increased relative abundance of the predominant *Akkermansia* species contributed to the heightened resistance against colon inflammation. Through further investigation, we discovered that genetic KO of TLR4 significantly impacted the structure and composition of the gut microbiota, resulting in a shift towards an anti-inflammatory configuration. This shift plays a crucial role in promoting enhanced resistance and tolerance to colitis.

At the phylum level, DSS changed the relative abundances of *Bacteroidetes*, *Actinobacteria,* and *Verrucomicrobia* in TLR4-KO mice compared to WT mice. Possibly, the high abundance of anti-inflammatory *Akkermansia* in the gut microbiota curbs the aggravation of colitis, despite the absence of TLR4 signaling. *Akkermansia* was the dominant genus in healthy KO mice, while after the treatment of FMT, their level decreased. Compared with that in the WT group, the status of colitis in the KO group was not significantly attenuated by FMT, suggesting that the therapeutic effect of FMT on colitis is closely related to the TLR4 signaling pathway and *Akkermansia*.

In the gut, the expression of TLRs changes with the composition of microbiota[39], as well as the activity of the intestinal epithelium such as inflammation[40]. In the present study, we observed the difference in microbial composition between WT-DSS and KO-DSS groups. At the phylum level, the KO-DSS group had a higher relative abundance of *Actinobacteria* and *Verrucomicrobia*, while WT-DSS had a higher relative abundance of *Proteobacteria*. In addition, *Verrucomicrobia* demonstrated the most significant difference at the phylum level. Lo Sasso *et al*[41] analyzed the composition of gut microbiota in UC patients *via* fecal microbiota whole-genome sequencing, finding increased abundance of *Proteobacteria* and decreased abundance of *Verrucomicrobia*. In addition, one study characterized the mucosal microbiome of pediatric UC patients, noting a significant decrease in the phylum *Verrucomicrobia* at the phylum level[42]. It has been reported that the abundance of *Proteobacteria* increases in UC mice[43]. Moreover, the relative abundance of *Proteobacteria* in DSS-induced mice rises remarkably, compared with that in WT mice, which can be restored to normal after Lizhong therapy[44]. Consistently, this study proves that DSS can raise the abundance of *Proteobacteria* in WT mice, rather than KO mice.

In particular, we found that the abundance of *Akkermansia* increased in the KO-DSS group, but then dropped notably after FMT, indicating its role in the effect of FMT on UC. As previously reported, the abundance of *Akkermansia* decreases in UC patients[45], but it is unclear whether this is a cause or consequence of UC. *Akkermansia* can protect intestinal barrier function and reduce the production of inflammatory cytokines[46]. On the other hand, *Akkermansia* can increase the production of short-chain fatty acids and antioxidant enzymes, indicating that *Akkermansia* may proliferate to alleviate colitis[47]. According to our experiment, the relative abundance of *Akkermansia* was negatively correlated with the severity of colitis in our animal models. *Akkermansia* bear great therapeutic potential for colitis. Studies on human and mice have revealed that the injection of beneficial bacteria such as *Lactobacillus*, *Akkermansia,* and *Bifidobacterium* can alleviate the inflammation in UC patients[48-50]. In a systematic review of three studies, the abundance of *Akkermansia* decreased in all UC patients[51]. A high abundance of *Akkermansia* can modulate host metabolism to prevent seizures [52]. Several *Akkermansia* species have demonstrated the ability to modulate immune responses and protect barrier function[53].

Despite the widely recognized beneficial properties of *Akkermansia* as a potential probiotic, it is crucial to take into account the potential occurrence of adverse effects. Patients with colorectal cancer have a higher abundance of *A. muciniphila*[3]. A prior study demonstrated that the genetic deletion of TLR4 exacerbates the severity of colon inflammation, resulting in the decreased abundance of *Akkermansia*[54]. This conflicting conclusion may be explained by various factors, such as the different mouse species and different experimental models used. When the equilibrium of the gut

FMT: Fecal microbiota transplantation.

microbiota is disturbed, beneficial microbes have the potential to shift towards virulent species, leading to adverse effects on the host. Studies have suggested a potential link between *Akkermansia* and TLR4 signaling. A study demonstrated that the administration of anthocyanins extracted from *Lycium ruthenicum* (ACs) increases the abundance of *Akkermansia*, thus inhibiting the lipopolysaccharide/NF-κB/TLR4 pathway to improve intestinal function[55]. It has also been observed that inhibition of the TLR4 signaling pathway can increase the abundance of *Akkermansia*[56]. *Akkermansia* promotes the integrity of the intestinal barrier and regulates immune homeostasis, potentially by interacting with TLR4[57,58]. In this study, the composition and structure of gut microbiota presented a significant difference between KO-DSS mice and WT-DSS mice. Based on the above results, we advocate that *Akkermansia* can increase resistance to acute colitis in TLR4-KO mice. However, more in-depth investigations are needed to determine if *Akkermansia* negatively associated with TLR4 are a potential target of FMT in treating UC.

TLR4 is differentially expressed in patients with early and advanced UC, indicating a close correlation between TLR4 and UC[59]. Inhibition of TLR4 significantly decreases the expression of cell cycle regulatory genes. Furthermore, TLR4 signaling in colonic epithelial cells promotes the recruitment of inflammatory cells through microRNA 155-mediated posttranscriptional regulation[60]. In the current study, our results showed that FMT downregulated the expression of genes related to the TLR4/myosin light chain kinase signaling pathway in WT mice, highlighting the importance of TLR4 in the effectiveness of FMT. Functional analysis revealed that most DEGs were enriched in cytoplasmic translation and

cellular response to DNA damage stimulus. The top nine DEGs strongly related to *Akkermansia* were primarily associated with cell cycle regulation, transcriptional control, apoptosis, stress responses, and inflammatory responses. Their functions aligned with the main processes identified in GO analysis, indicating their involvement in crucial biological pathways. These functions highlight its potential role in modulating various cellular activities. Aquaporin 4 (AQP4), a water channel protein that facilitates transmembrane water movement, has the strongest correlation[61]. AQPs are widely distributed in mammals' secretory and absorptive epithelial cells and are responsible for transport and trafficking processes. In colonic inflammation, AQP4 is abundantly expressed in the basolateral membrane of colonic epithelial cells in humans and mice. The permeability of cell membranes is positively correlated with AQP4 expression[62]. AQP4 overexpression facilitates the entry of water into cytes, thereby contributing to cytotoxic edema[63-65]. AQP4 deficiency alleviates experimental colitis in the mice[66]. Although we did not use the same mouse KO model in the present study, the effect of AQP4 on colonic inflammation is consistent with that of TLR4. Activating the high mobility group box 1 protein/TLR4/NF-κB pathway can increase the expression of AQP4[67,68]. Furthermore, lipopolysaccharide, a potent TLR4 agonist, significantly increases the mRNA level of AQP4 expression through TLR4 signaling in the cortex and astrocytes[62]. We speculate that TLR4 deficiency can protect against colitis by increasing the abundance of *Akkermansia* and reducing the expression of AQP4. As shown by previous results, FMT can relieve colitis in WT mice[9]. However, in this study, FMT did not exert effects on colonic inflammation in TLR4-KO mice. It was intriguing to determine that the abundance of *Akkermansia*, which was dominant in TLR4-KO mice, was significantly decreased after FMT. This may be related to the decreased relative abundance of *Akkermansia*. While the DEGs mentioned above may have roles in immune regulation, inflammation, or cellular processes that can intersect with TLR4 signaling, their specific relationships with TLR4 are not extensively characterized. Notwithstanding, further studies are needed to determine whether FMT also targets *Akkermansia* to regulate the expression of related DEGs in countering colon inflammation.

In this study, we assessed the microbial diversity and composition in DSS-induced mice. The bacteria inhabited in the mucosa may play major roles in the development of IBD. So it is necessary to explore the function of microbiota in

mucosal tissues in future study. However, animal studies have certain limitations in evaluating the mechanism of TLR4. Therefore, clinical studies should be designed to unveil the interplay among TLR4, gut microbiota, and UC.

CONCLUSION

TLR4 modulates the composition of gut microbiota and regulates the expression of microbiome-related genes to ameliorate colitis and maintain the stability of the intestinal environment. For the first time, we find that FMT may ameliorate DSS-induced colitis by regulating the TLR4 signaling pathway. Our findings will make the treatment of patients more targeted and is worthy of clinical trials in the future.

ARTICLE HIGHLIGHTS

Research background

It is well known that microbiota dysbiosis contributes to the occurrence of inflammatory bowel disease (IBD). Fecal microbiota transplantation (FMT) has shown promising therapeutic effects on both clinical and basic studies of ulcerative colitis (UC). Substantial evidence supports a negative pro-inflammatory role of Toll-like receptor 4 (TLR4) signaling pathway in IBD. However, it remains unknown whether this modulation is also involved in the treatment of FMT on UC.

Research motivation

FMT treats other diseases by regulating the TLR4 signaling pathway. Previous studies have shown that the expression of TLR4 is higher in the intestinal mucosa of patients with effective FMT and lower in patients with poor FMT. We speculate that the TLR4 signaling pathway may be involved in the therapeutic mechanism of FMT on IBD.

Research objectives

To clarify the necessity of TLR4 signaling pathway in FMT on regulating gut microbiota in dextran sodium sulphate (DSS)-induced colitis.

Research methods

Experimental colitis was constructed in wild-type (WT) and TLR4-knockout (KO) mice and fecal microbiota was transplanted by gavage. Colon inflammation severity in mouse model was measured by disease activity index (DAI) score and hematoxylin and eosin (H&E) staining. Gut microbiota alteration was analyzed through 16S ribosomal RNA sequencing. The difference of gene expression in mouse colon was obtained by transcriptome sequencing of colon tissue.

Research results

In KO mice treated with FMT or water, these two groups displayed indistinguishable body weight loss, colon length, DAI score, and histology score, which showed that FMT could hardly alter the disease progress in KO mice. Next, compared with WT mice, the scores of DAI and colon histology clearly decreased in the KO-DSS group. KO mice experienced enhanced resistibility to DSS-induced colitis. There was a significant difference in the microbiota structure between KO and WT mice. *Akkermansia* was the dominant genus in healthy KO mice. But unexpectedly, after treatment with FMT, the relative abundance of *Akkermansia* decreased, while the level of *Lactobacillus* in the intestine of mice was maintained. The ineffectiveness in KO mice after FMT was related to the decrease of *Akkermansia*. GO enrichment analysis showed that DEGs between each group were mainly involved in cytoplasmic translation and cellular response to DNA damage stimulus. Finally, we listed the top nine genes related to *Akkermansia*.

Research conclusions

FMT may ameliorate DSS-induced colitis by regulating the TLR4 signaling pathway.

Research perspectives

This study provides new insights into the underlying mechanisms of FMT as a treatment for UC, which greatly helps to optimize FMT treatment in the future.

Abstract

BACKGROUND

Chronic pancreatitis (CP) is a fibroinflammatory syndrome leading to reduced quality of life and shortened life expectancy. Population-based estimates of the incidence, prevalence, and comorbidities of CP in China are scarce.

AIM

To characterize the incidence, prevalence, and comorbidities of CP in Sichuan Province, China, with population-based data.

METHODS

Data on CP from 2015 to 2021 were obtained from the Health Information Center of Sichuan Province. During the study period, a total of 38090 individuals were diagnosed with CP in Sichuan Province. The yearly incidence rate and point prevalence rate (December 31, 2021) of CP were calculated. The prevalence of comorbid conditions in CP patients was estimated. The annual number of CP-related hospitalizations, hospital length of stay, and hospitalization costs for CP were evaluated. Yearly incidence rates were standardized for age by the direct method using the permanent population of Sichuan Province in the 2020 census as the standard population. An analysis of variance test for the linearity of scaled variables and the Cochran-Armitage trend test for categorical data were performed to investigate the yearly trends, and a two-sided test with $P < 0.05$ was considered statistically significant.

RESULTS

The 38090 CP patients comprised 23280 males and 14810 females. The mean age of patients at CP diagnosis was 57.83 years, with male patients (55.87 years) being younger than female patients (60.11 years) ($P < 0.001$). The mean incidence rate of

CP during the study period was 6.81 per 100000 person-years, and the incidence of CP increased each year, from 4.03 per 100000 person-years in 2015 to 8.27 per 100000 person-years in 2021 ($P < 0.001$). The point prevalence rate of CP in 2021 was 45.52 per 100000 individuals for the total population, with rates of 55.04 per 100000 individuals for men and 35.78 per 100000 individuals for women ($P < 0.001$). Individuals aged 65 years or older had the highest prevalence of CP (113.38 per 100000 individuals) ($P < 0.001$). Diabetes (26.32%) was the most common comorbidity in CP patients. The number of CP-related hospitalizations increased from 3739 in 2015 to 11009 in 2021. The total costs for CP-related hospitalizations for CP patients over the study period were 667.96 million yuan, with an average of 17538 yuan per patient.

CONCLUSION

The yearly incidence of CP is increasing, and the overall CP hospitalization cost has increased by 1.4 times during the last 7 years, indicating that CP remains a heavy health burden.

Key Words: Chronic pancreatitis; Epidemiology; Incidence; Prevalence; Comorbidities; Disease burden

Core Tip: Chronic pancreatitis (CP) remains a heavy health burden worldwide. However, available epidemiological data on CP in China are scarce. We conducted a population-based study on the incidence, prevalence, comorbidities, and disease burden of CP in Sichuan Province, China, from 2015 to 2021. We analyzed a total of 38090 patients, which represents the largest series of CP patients ever reported in China. We observed an increasing incidence and rising costs for CP-related hospitalization. The point prevalence rate of CP was 45.52 per 100000 individuals in 2021. Metabolic-related diseases and pancreatic tumors were among the most common comorbidities among CP patients.

INTRODUCTION

Chronic pancreatitis (CP) is a fibroinflammatory syndrome characterized by chronic upper abdominal pain and exocrine and endocrine pancreatic insufficiency[1]. Although some cases of CP may begin with one or recurrent bouts of pancreatitis, approximately 50% of CP patients have no history of acute pancreatitis[2,3]. Therefore, for a considerable proportion of patients, the development of CP might be attributable to different pathogeneses. As CP progresses, diabetes mellitus, malnutrition, and pancreatic cancer may develop[3,4], leading to reduced quality of life (QoL) and shortened life expectancy. The current strategies for CP include relieving symptoms, preventing disease progression, and managing complications[5]. CP causes a heavy health burden worldwide, consuming many medical resources due to less effective curative treatments for reversing the course of the disease[1,6,7]. Nevertheless, available epidemiological studies on CP are mainly from registry-based analyses and questionnaire-based surveys in European countries and the United States. Reportedly, the prevalence of CP ranges from 13.5 to 163 cases per 100000 individuals, and the incidence of CP ranges from 5 to 31.7 new cases per 100000 person-years[8-14]. The wide CP prevalence and incidence ranges may be related to the differences in case definitions, settings, patient cohorts, and statistical methods. China is one of the most populous countries in the world. However, only two epidemiological studies on CP in the eastern part of China have been conducted[15,16]. These data were mainly based on one or several databases from hospitals with small sample sizes. Population-based epidemiological data from other regions may provide a better picture of the incidence and prevalence of CP in China[1].

In addition, comorbidities, defined as the cooccurrence of two or more chronic medical conditions in one person[17], usually alter the disease management implications. Multiple comorbidities may reduce QoL and increase the risk of death and the consumption of medical resources[18]. Therefore, comorbidities have become an important part of epidemiological studies for chronic diseases[19]. However, data on the comorbidities of CP are still insufficient[20]. This epidemiological study aimed to characterize the incidence, prevalence, and comorbidities of CP in Sichuan Province in Southwest China from 2015 to 2021 with population-based data.

MATERIALS AND METHODS

Study design and population

Data on CP from 2015 to 2021 were obtained from the Health Information Center of Sichuan Province (HIC-SC), which collects electronic hospitalization summary reports (HSRs) from the electronic medical record systems of all hospitals in Sichuan Province. These records contain encrypted patient identification numbers and data on age, sex, admission and discharge dates, International Classification of Diseases, Tenth Revision (ICD-10) codes, and relevant discharge diagnoses. The HIC-SC has provided data for many scientific studies[21-23], verifying the reliability of the database. The data of permanent residents in Sichuan Province over the study years were obtained from the Sichuan Provincial Bureau of Statistics. This study was approved by the biomedical ethics review committee of West China Hospital, Sichuan Univer -sity on February 8, 2022 (IRB approval number: 2022-296), and the requirement for informed consent was waived.

Diagnosis and classification of CP

In China, the definition of CP as a continuing inflammatory disease of the pancreas, characterized by irreversible morphological changes and pain and/or permanent loss of function, has been widely accepted[7,24]. In clinical practice, computed tomography (CT) or magnetic resonance imaging (MRI) are usually recommended as first-line tests for patients with clinical symptoms of an inflammatory disorder of the pancreas (such as a previous episode of acute pancreatitis, characteristic pain, and/or maldigestion) because they are universally available and reproducible. The major imaging characteristics of CP include pancreatic atrophy, fibrosis, duct distortion and strictures, stones in pancreatic ducts or multiple calcifications distributed throughout the entire pancreas, *etc*. Endoscopic ultrasound, because of its invasiveness, is used only if the diagnosis is in question after CT or MRI. The diagnosis of CP in some patients is established by histopathological examination after surgery due to unexplained pancreatic masses. Therefore, patients who had a discharge diagnosis of CP in their HSR provided by the HIC-SC with the following ICD-10 codes were included in this study: K86.102 for CP, K86.852 for pancreatic atrophy, K86.811 for pancreatic calcifications, K86.809 for stones in pancreatic ducts, K86.806/807 for duct distortion and strictures, K86.154 for pancreatic fibrosis, K86.201 for pancreatic cysts, K86.804 for pancreatemphraxis, and K86.901/902 for pancreatic masses. Furthermore, this study classified CP according to the following ICD-10 codes: K86.051 for alcoholic CP, K86.153 for autoimmune pancreatitis (AIP), and K86.151 for biliary pancreatitis. Patients with conflicting information, *i.e.*, different birth dates at each admission, were excluded.

Identification of comorbidities

The comorbidities of CP in this study were selected by referring to previous studies[4,13,25]. Data on comorbidities were extracted from the electronic database by identifying their corresponding ICD-10 codes (Table 1).

Epidemiological outcomes

The major outcomes were the incidence and prevalence of CP. Incident cases were defined as patients with a first-time diagnosis of CP. Patients with a diagnosis of CP before the calculated year were excluded from the incidence estimate calculation. Prevalent cases were defined as patients with a diagnosis at some timepoint before the end of 2021. Crude incidence rates were calculated for each year between 2015 and 2021 as the number of incident CP cases divided by the average permanent population in a year (per 100000 person-years). Yearly incidence rates were standardized for age by the direct method using the permanent population of Sichuan Province in the 2020 census as the standard population. The point prevalence rate (December 31, 2021) was calculated as the number of patients who were diagnosed with CP before the end of 2021 divided by the permanent population of Sichuan Province in 2021. Other outcomes were the number of hospitalizations, the hospital length of stay (LoS), and the hospitalization costs. LoS was defined as the total length of hospital stay of the patient within one year. Costs for hospitalization, including total costs and the mean costs per patient, were calculated. Costs were adjusted by the consumer price index for each year to 2021 costs.

Statistical analysis

Data management and computations were performed using Oracle version 11.2.0 (https://www.oracle.com) and R version 4.1.3 (R Foundation for Statistical Computing; https://www.R-project.org/). Continuous variables are shown as the means ± SD. Since this was a population-based study including the entire permanent population of Sichuan Province during the observation period, no confidence intervals are provided for the estimates of the incidence or prevalence rates. Statistical analysis, such as the student's *t*-test for continuous variables and the chi-squared test for categorical variables, was used for the comparison of statistics between sexes and age groups. To investigate yearly trends, we performed an analysis of variance tests for the linearity of scaled variables and the Cochran-Armitage trend test for categorical data. A two-sided test with $P < 0.05$ was considered statistically significant.

RESULTS

Data collection

There were a total of 61112 electronic records (38296 individuals) with a diagnosis of CP from 2015 to 2021. Among all the records, 3180 records were excluded due to missing encrypted patient identification numbers (1518 records) and conflicting information (1662 records from 206 individuals). The exclusion of the data resulted in the loss of 5.2% of the

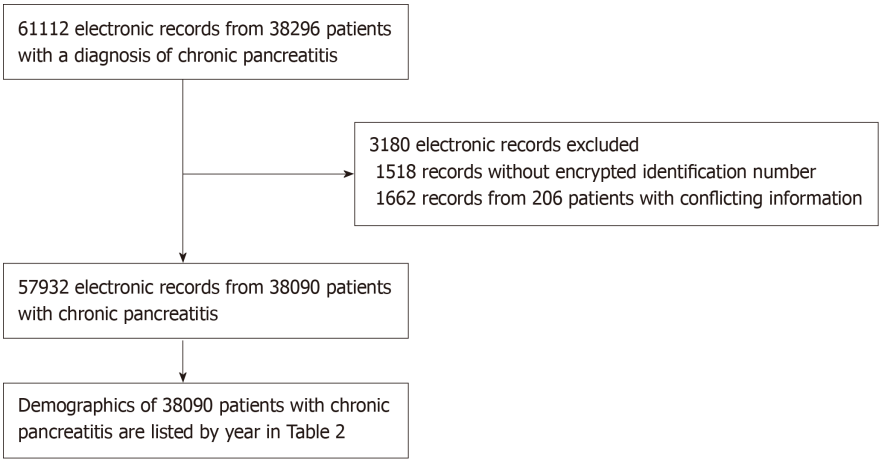
ICD: International Classification of Diseases.



original electronic records and a loss of 0.5% from the original patient cohort. Therefore, 57932 electronic records from 38090 unique patients were ultimately analyzed in this study (Figure 1). Data for 30756 CP patients (80.7% of the cohort) were extracted by the ICD-code K86.102. A total of 3641 CP patients (9.6%) were identified by the ICD-10 code K86.809 (pancreatic calculus). The left 9.7% of the CP patients were included by other ICD-10 codes (K86). Only 397 CP patients (1%) were classified as having alcoholic CP. Sichuan Province is one of the most populous provinces in China, with approximately 83.67 million permanent residents in 2020.

Characteristics of the patients

The demographics of the CP patients with a first diagnosis are presented in Table 2 by calendar year. The number of new cases increased each year from 2015 to 2021, with a significant upward trend ($P < 0.001$). There were 1.56-fold more male patients than female patients. The mean age of the patients at CP diagnosis was 57.83 years, with males (55.87 years) being younger than females (60.11 years) ($P < 0.001$). More than 60% of the patients diagnosed each year were aged 15-64

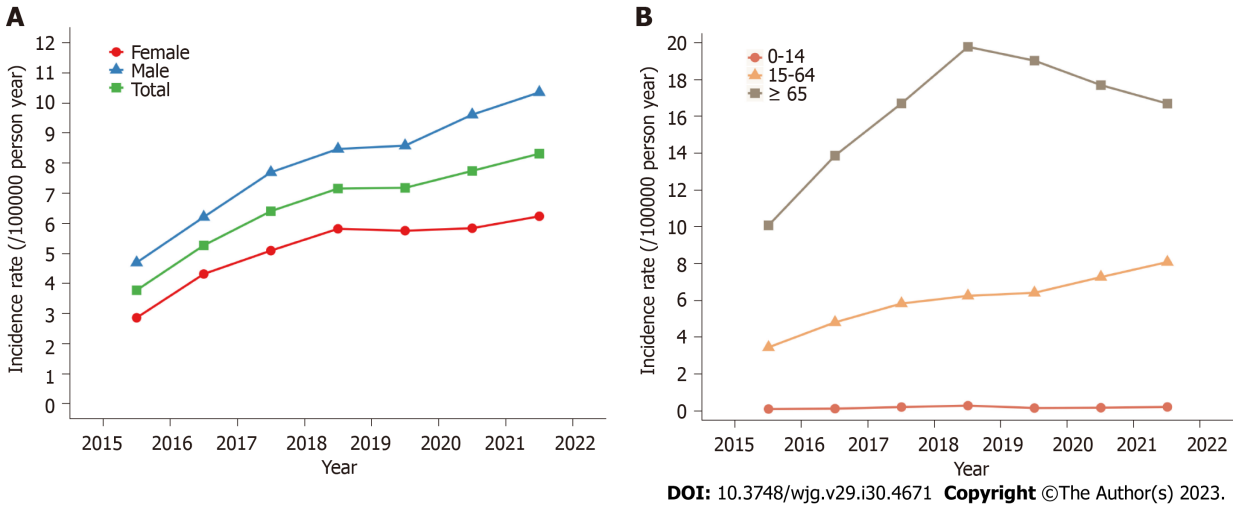
Figure 1 Flowchart of the inclusion and exclusion processes. A total of 61112 electronic records from 38296 patients with a diagnosis of chronic pancreatitis were retrieved from the Health Information Center of Sichuan Province. A total of 3180 records were excluded due to missing encrypted patient identification numbers (1518 records) and conflicting information (1662 records from 206 individuals). A total of 57932 electronic records from 38090 unique patients with chronic pancreatitis were ultimately included in this study.

years, and the proportion of each group remained stable over time (Table 2). Similar to the population ratio, the component ratio of the Han Chinese was the highest (94.92%) in CP patients, although Sichuan is a multiethnic province.



Incidence

The mean standardized incidence of CP was 6.81 per 100000 person-years, and the incidence of CP increased yearly during the study period ($P < 0.001$), from 4.03 per 100000 person-years in 2015 to 8.27 per 100000 person-years in 2021 (Figure 2). The mean incidence of CP in males was 7.95 per 100000 person-years, which was significantly higher than that in females (5.13 per 100000 person-years) ($P < 0.001$). Both sexes presented similar upward trends ($P < 0.001$) (Figure 3A).

Figure 3 Sex- and age-grouped incidence of chronic pancreatitis. A and B: The crude incidence of chronic pancreatitis in the population grouped by sex (A) and age (B) (per 100000 person-years) from 2015 to 2021.

For males, the incidence of CP was 4.70 per 100000 person-years in 2015 and 10.36 per 100000 person-years in 2021; for females, the incidence of CP was 2.86 per 100000 person-years in 2015 and 6.24 per 100000 person-years in 2021. The highest CP incidence (16.27 per 100000 person-years) was observed in patients aged ≥ 65 years, with an upward trend from 10.08 per 100000 person-years in 2015 to 16.70 per 100000 person-years in 2021 ($P < 0.001$) (Figure 3B). Individuals aged 14 years or younger showed the lowest CP incidence (0.17 per 100000 person-years), which remained stable during the 7 years ($P = 0.830$) (Figure 3B). The seven-year mean incidence for the 15-64-year age group was 6.01 per 100000 person-years, with an increase from 3.45 per 100000 person-years in 2015 to 8.08 per 100000 person-years in 2021 ($P < 0.001$) (Figure 3B).

Prevalence

A total of 38090 individuals were diagnosed with CP in Sichuan Province during the study period. The age distribution of the CP patients up to 2021 is shown in Figure 4A. Among all the patients, 23280 (61.12%) were men, and 14810 (38.88%) were women ($P < 0.001$). The point prevalence of CP was 45.52 per 100000 individuals in 2021 for the total population, 55.04 per 100000 individuals for the male population, and 35.78 per 100000 individuals for the female population ($P < 0.001$). The prevalence of CP was 1.53 times higher [95% confidence interval (CI): 1.51-1.57; $P < 0.001$] for men than for women. Individuals aged 65 years or older had the highest prevalence of CP (113.38 per 100000 individuals), with a prevalence of 127.58 per 100000 individuals for men and 100.03 per 100000 individuals for women ($P < 0.001$) (Figure 4B).

DOI: 10.3748/wjg.v29.i30.4671 **Copyright** ©The Author(s) 2023.

Figure 4 The prevalence of chronic pancreatitis. A and B: The age distribution of chronic pancreatitis patients (A) and the prevalence of chronic pancreatitis by sex and age groups (B) in 2021.

For individuals aged between 15 and 64 years, the prevalence of CP was 39.11 per 100000 individuals, with a prevalence of 50.86 per 100000 individuals for men and 27.00 per 100000 individuals for women ($P < 0.001$) (Figure 4B). The prevalence of CP was 2.90 times higher (95%CI: 2.84-2.96; $P < 0.001$) for individuals aged 65 years or older than for individuals aged between 15 and 64 years. Individuals aged 14 years or younger had the lowest prevalence of CP (0.81 per 100000 individuals), with a prevalence of 0.82 per 100000 individuals for boys and 0.80 per 100000 individuals for girls ($P = 1$) (Figure 4B).

Prevalence of comorbid conditions

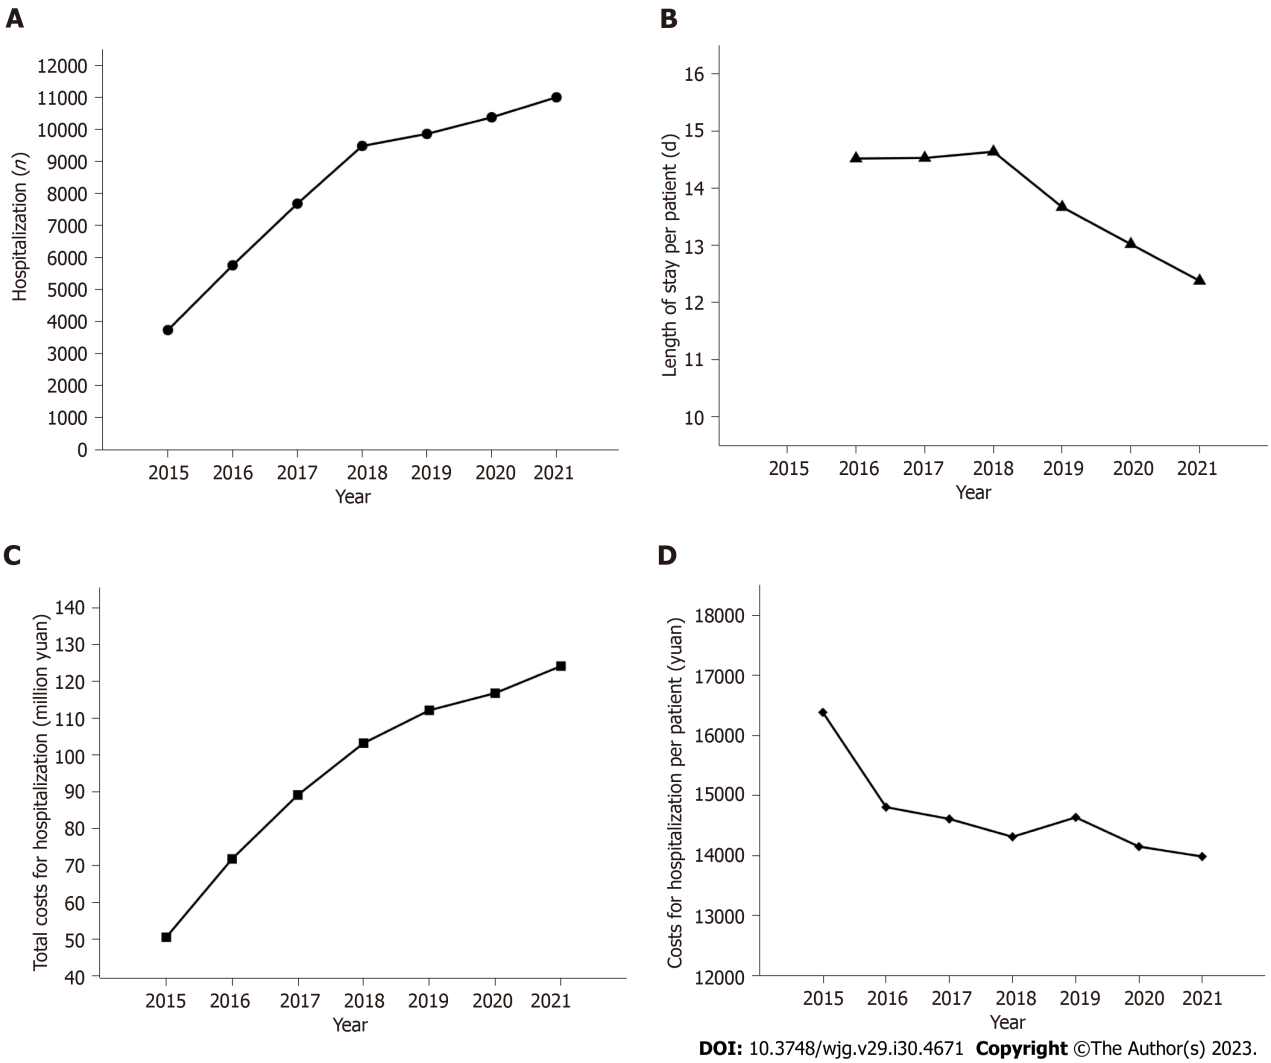
Diabetes (26.32%) was the most common comorbidity in CP patients, and patients with diabetes were similar in age to the overall cohort (Table 3). Metabolic-related diseases, including hypertension (21.51%), cholelithiasis (16.79%), dyslipidemia (16.70%), and fatty liver diseases (12.39%), were also common comorbidities among CP patients. The incidence of acute exacerbations of CP was 5.08% in all CP patients, with an incidence of 6.35% in males and 3.07% in females. A total of 2.65% of the CP patients were also diagnosed with pancreatic tumors, and 2.36% were diagnosed with malignant tumors of the pancreas.

Disease burden of CP

The number of CP-related hospitalizations increased approximately 2-fold, from 3739 in 2015 to 11009 in 2021 ($P < 0.001$) (Figure 5A). The LoS per CP patient decreased from 14.52 d in 2016 to 12.38 d in 2021 ($P = 0.008$) (Figure 5B). The total costs for CP-related hospitalizations for CP patients over the study period were 667.96 million yuan, with an average of 17538 yuan per patient. Total costs for CP-related hospitalizations increased from 50.60 million yuan in 2015 to 124.16 million in 2021 ($P < 0.001$) (Figure 5C), while the costs per patient decreased from 16387 yuan in 2015 to 13986 yuan in 2021 ($P = 0.024$) (Figure 5D).

DISCUSSION

We conducted a population-based study on the epidemiology of CP in Sichuan Province, China, from 2015 to 2021. This study showed that the mean incidence of CP was 6.81 per 100000 person-years in the last 7 years, and the point prevalence of CP was 45.52 per 100000 individuals in 2021 for the total population in Sichuan Province. The incidence and prevalence of CP increased with age and were significantly higher in males than in females over the study years. Metabolic-related diseases, including diabetes (26.32%), hypertension (21.51%), cholelithiasis (16.79%), dyslipidemia (16.70%), and fatty liver disease (12.39%), were common comorbidities in CP patients. In addition, 2.65% of the CP patients were diagnosed with pancreatic tumors. During the 7-year period, CP-related hospitalizations increased approximately 2-fold, and the overall hospitalization cost of CP increased by 1.4-fold. However, the LoS and the costs per CP patient decreased over the study years.



It may be valuable to improve epidemiological data of CP in the southwest area of China due to the rapid economic and societal development of the country. The first population-based epidemiological study of CP reported a mean CP incidence of 6.81 per 100000 person-years in Sichuan Province in the last 7 years. In other words, Sichuan Province has an average of 5652 new cases of CP every year. Thus, although hospitalization costs per patient decreased yearly, overall hospitalization costs still increased year by year. The overall hospitalization cost of CP increased by 1.4 times during the 7-year period. Although this study was analyzed with big data, the incidence rate may be underestimated because the data only covered inpatients with CP, and outpatients with CP were not included. A variety of databases have been used for the epidemiological analysis of CP[8,9,14,26], but it is still difficult to accurately describe the epidemic status of CP

due to the limitations of various databases. There may be many CP outpatients, but if their condition is not severe enough to require hospitalization, the medical costs and the disease burden would be relatively low, and the epidemiological significance may not be very important. Reportedly, the rates of harmful drinking behaviors and smoking, which may be risk factors for CP, have increased in Chinese individuals in the last 10 years[27,28]. In contrast, the incidences of CP remained stable or even decreased yearly in recent years in the United States and Denmark, indicating that the decline in CP incidence might be due to the decrease in tobacco and alcohol consumption in both countries[8,14,29]. However, it was difficult to evaluate the factors related to the increasing incidence of CP in this study because electronic HSRs did not include risk factors associated with CP. CT and MRI have become universally available in hospitals at all levels in Sichuan Province, China. This greatly enhances the detection rate of CP and may partly contribute to the increasing CP incidence rate.

The point prevalence of CP was 45.52 per 100000 individuals in 2021 for the total population in Sichuan Province. The prevalence of CP was 39.11 and 113.38 per 100000 individuals for the population aged between 15 and 64 years and the population aged 65 years or older, respectively. The current results are consistent with those of studies in Minnesota

Figure 5 Disease burden of chronic pancreatitis. A: Annual number of chronic pancreatitis-associated hospitalizations; B: Mean length of stay per patient; C: Total costs for hospitalization; D: Costs for hospitalization per patient. Costs were adjusted by the consumer price index every year to 2021 costs (yuan).

(41.76/100000 individuals), Japan (52.4/100000 individuals), and Spain (49.3/100000 individuals), which were all based on questionnaire-based surveys[10,11,30]. In contrast, the prevalence of CP was considerably higher in register-based studies covering inpatients as well as outpatients[8,9,14]. Based on insurance claims databases, Machicado *et al*[9] and Sellers *et al*[14] reported similar results for the prevalence of CP in adults in America, which was 98.7/100000 individuals (2001-2013) and 91.9/100000 individuals (2007-2014), respectively. Using nationwide health care registries over a long period (1994–2018), Olesen *et al*[8] estimated the prevalence of CP at 153.9/100000 individuals in Denmark. This discrepancy may be explained by differences in study designs or by true differences in the CP prevalence across regions. Compared to the multicenter study in 2003, our current study adds to the prevalence data on CP over the past decades and verifies the upward trend in the prevalence of CP[15]. The increase in the CP prevalence could be explained by the increasing CP incidence and improved prognosis and life expectancy of CP patients[31-33].

Both the incidence and prevalence of CP in males were significantly higher than those in females over the study years. The prevalence for men was 1.53 times higher than that for women. Of all CP patients, 61.12% were men and 38.88% were women. Both the incidence and prevalence of CP were higher among men than women in all age groups, which was consistent with most previous studies[8,11,15,34,35]. This difference may be due to higher alcohol and tobacco exposure and increased genetic susceptibility to alcoholic CP among men[36,37]. The male hemizygous CLDN2 genotype and the female homozygous CLDN2 genotype are known to confer an amplified risk of pancreatitis together with alcohol use, and the frequency of the male hemizygous CLDN2 genotype (0.26) is much higher than that of the female homozygous CLDN2 genotype (0.07); thus, males have a higher genetic susceptibility to alcoholic CP than females[37]. In addition, the prevalence and incidence of CP were the highest among elderly individuals compared with young and middle-aged people in our study. These results are also similar to those of previous studies, suggesting that the incidence and prevalence of CP increases with aging[8,14]. Although the results might represent the prevalence of CP, it is undeniable that there was bias. In terms of the inpatient database, elderly people had the highest rate of hospitalization, which was accompanied by a higher detection rate of CP. In comparison, the detection rates of CP might be lower in other age groups, leading to an underestimation of the incidence and prevalence of CP.

Table 4 Available studies on comorbidities of chronic pancreatitis

Region	Study design	Study period	Total CP patients	Frequent comorbidities compared with controls	Ref.
Denmark	Nationwide retrospective cohort study	1995-2010	11972	Cerebrovascular disease, chronic pulmonary disease, ulcer disease, diabetes, chronic renal disease, and pancreatic cancer	[4]
United States and Denmark	Cross-sectional, multicenter prospective study	Not available	171	Anxiety and depression	[40]
United States	Retrospective cohort study	2015-2020	63230	Hypertension, diabetes, and myocardial Infarction	[41]

China	Population-based cohort study	2000-2011	17778	Deep vein thrombosis and pulmonary embolism	[20]
China	Population-based cohort study	2000-2011	17796	Inflammatory bowel disease	[47]
China	Prospective observational study	2019-2021	720	Anxiety and depression	[48]

As comorbidity, diabetes was reported in 26.32% of CP patients in this study. The prevalence of diabetes in CP patients reported in the previous literature was 15.2%-41.5%[4,13,25]. The high comorbidity of CP with diabetes suggests the importance of the identification of post-pancreatitis diabetes mellitus, which might be greatly different from type 2 diabetes mellitus in its manifestation and treatment. In addition, hypertension (21.51%), cholelithiasis (16.79%), and fatty liver disease (12.39%) were also common comorbidities in CP patients. A cohort study of the United Kingdom Biobank reported an even higher prevalence of gallstones (32.4%), hyperlipidemia (34.7%), and pancreatic cancer (4.7%) in CP patients and a strong association between CP and essential hypertension[13]. In the same cohort (United Kingdom Biobank), a case-control study reported that CP was associated with a significantly higher risk of pancreatic cancer in patients within the first 3 years[38]. These comorbidities may be explained by shared etiologies resulting from general exposure to risk factors such as tobacco use and alcohol consumption among CP patients. However, it is also possible that some of these comorbidities are involved in the pathogenesis of CP development, and some comorbidities may be complications caused by CP. Prospective studies, including longitudinal cohort studies and randomized control trials, may provide more definitive evidence on potential associations with multimorbidity. As shown in Table 4, different comorbidities were reported to be associated with CP in European, American, and East Asian countries. This may be related to different regions, times, and types of research. In addition, the pattern of comorbidities of CP is still under exploration, and the comorbidities reported by the abovementioned studies are similar to our findings. Smaller sample sizes and more accurate and complete diagnoses of diseases in cohort studies as well as different study inclusion criteria could explain the discrepancy between cohort and register-based studies.

AIP represents < 5%-10% of pancreatitis cases and has a smaller prevalence of approximately 1-2/100000 individuals [39]. In the design of this study, AIP was classified as a type of CP. However, data on AIP were not extracted from the electronic HSRs because there is no special ICD-10 code for AIP. Moreover, only 1% of CP patients were classified as having alcoholic CP, which might be underestimated because doctors may not have paid enough attention to alcoholic CP when they filled out the electronic HSRs. This study suggests some improvements for the HIC-SC to enhance the quality of electronic HSR completion.

CONCLUSION

The yearly incidence of CP increased, along with the absolute number of CP patients and associated costs for hospitalization in Sichuan Province over the study period. The current work shows that CP remains a heavy burden on patients and the healthcare system. The implication of the high prevalence of diabetes (26.32%) in CP patients may vary with different people.

ARTICLE HIGHLIGHTS

Research background

Chronic pancreatitis (CP) is a fibroinflammatory syndrome leading to reduced quality of life and shortened life expectancy. Population-based estimates of the prevalence and incidence of CP in China are scarce.

Research motivation

Accurate epidemiological estimates of CP are vital in shaping health resource allocation and medical provider training priorities.

Research objectives

To evaluate the prevalence and time trends of the incidence of CP and describe the comorbidities and disease burden of CP in Sichuan Province, China.

Research methods

Data on CP from 2015 to 2021 were obtained from the Health Information Center of Sichuan Province. During the study period, a total of 38090 individuals were diagnosed with CP in Sichuan Province. The yearly incidence rate and point prevalence rate (December 31, 2021) of CP were calculated. The prevalence of comorbid conditions in CP patients was estimated. The annual number of CP-related hospitalizations, hospital length of stay, and costs for hospitalization for CP were evaluated. Yearly incidence rates were standardized for age by the direct method using the permanent population of Sichuan Province in the 2020 census as the standard population. An analysis of variance test for the linearity of scaled variables and the Cochran-Armitage trend test for categorical data were performed to investigate the yearly trends, and a two-sided test with $P < 0.05$ was considered statistically significant.

Research results

The 38090 CP patients comprised 23280 males and 14810 females. The mean age of patients at CP diagnosis was 57.83 years, with males (55.87 years) being younger than females (60.11 years) ($P < 0.001$). The mean incidence rate of CP during the study period was 6.81 per 100000 person-years, and the incidence of CP increased each year, from 4.03 per 100000 person-years in 2015 to 8.27 per 100000 person-years in 2021 ($P < 0.001$). The point prevalence rate of CP in 2021 was 45.52 per 100000 individuals for the total population, with rates of 55.04 per 100000 individuals for men and 35.78 per 100000 individuals for women ($P < 0.001$). Individuals aged 65 years or older had the highest prevalence of CP (113.38 per 100000 individuals) ($P < 0.001$). Diabetes (26.32%) was the most common comorbidity in CP patients. The number of CP-related hospitalizations increased from 3739 in 2015 to 11009 in 2021. The total costs for CP-related hospitalizations for CP patients over the study period were 667.96 million yuan, with an average of 17538 yuan per patient.

Research conclusions

The yearly incidence of CP increased in Sichuan Province, along with the absolute number of CP patients and associated costs for hospitalization between 2015 and 2021. The point prevalence rate of CP in 2021 was 45.52/100000 individuals for the total population. Diabetes (26.32%), other metabolic-related diseases, and pancreatic cancer are among the common comorbidities in CP patients. The current work shows that CP continues to place a heavy burden on patients and the healthcare system.

Research perspectives

Further studies are needed to identify CP and its comorbidities earlier, triggering potentially preventive mana-gement to relieve the disease burden.

ACKNOWLEDGEMENTS

The authors are grateful to the staff of the Department of Gastroenterology, West China Hospital, Sichuan University, and the Health Information Center of Sichuan Province for their valuable assistance in this work.

Abstract

BACKGROUND

Upper gastrointestinal neoplasia mainly includes esophageal cancer and gastric cancer, both of which have high morbidity and mortality. Lymph node metastasis (LNM), as the most common metastasis mode of both diseases, is an important factor affecting tumor stage, treatment strategy and clinical prognosis. As a new fusion technology, endoscopic ultrasound (EUS) is becoming increasingly used in the diagnosis and treatment of digestive system diseases, but its use in detecting LNM in clinical practice remains limited.

AIM

To evaluate the diagnostic value of conventional EUS for LNM in upper gastrointestinal neoplasia.

METHODS

Using the search mode of "MeSH + Entry Terms" and according to the predetermined inclusion and exclusion criteria, we conducted a comprehensive search and screening of the PubMed, EMBASE and Cochrane Library databases from January 1, 2000 to October 1, 2022. Study data were extracted according to the predetermined data extraction form. The quality of the included studies was assessed using the Quality Assessment of Diagnostic Accuracy Studies tool, and the results of the quality assessment were presented using Review Manager 5.3.5 software. Finally, Stata14.0 software was used for a series of statistical analyses.

RESULTS

A total of 22 studies were included in our study, including 2986 patients. The pooled sensitivity, specificity, positive likelihood ratio, negative likelihood ratio, diagnostic score and diagnostic odds ratio of conventional EUS in the diagnosis of upper gastrointestinal neoplasia LNM were 0.62 [95% confidence interval (CI): 0.50-0.73], 0.80 (95%CI: 0.73-0.86), 3.15 (95%CI: 2.46-4.03), 0.47 (95%CI: 0.36-0.61), 1.90 (95%CI: 1.51-2.29) and 6.67 (95%CI: 4.52-9.84), respectively. The area under the summary receiver operating characteristic curve was 0.80 (95%CI: 0.76-0.83). Sensitivity analysis indicated that the results of the meta-analysis were stable. There was considerable heterogeneity among the included studies, and the threshold effect was an important source of heterogeneity. Univariable meta-regression and subgroup analysis showed that tumor type, sample size and EUS diagnostic criteria were significant sources of heterogeneity in specificity ($P < 0.05$). No significant publication bias was found.

CONCLUSION
Conventional EUS has certain clinical value and can assist in the detection of LNM in upper gastrointestinal neoplasia, but it cannot be used as a confirmatory or exclusionary test.

Key Words: Endosonography; Esophageal neoplasms; Stomach neoplasms; Lymphatic metastasis; Diagnosis; Meta-analysis

Core Tip: This meta-analysis examined the diagnostic value of conventional endoscopic ultrasound (EUS) for lymph node metastasis (LNM) in upper gastrointestinal neoplasia. The pooled analyses of 2986 patients from 22 studies performed herein show that conventional EUS has certain clinical value and can assist in the detection of LNM in upper gastrointestinal neoplasia, but it cannot be used as a confirmatory or exclusionary test. More high-quality studies are needed to further verify the diagnostic value of EUS and determine the best diagnostic criteria.

INTRODUCTION

Upper gastrointestinal neoplasia mainly includes esophageal cancer and gastric cancer, and their morbidity and mortality have long been among the top ten of the global cancer list, bringing great pain and burden to countries all over the world, and they are major global public health problems[1-4]. The onset of esophageal cancer and gastric cancer is hidden, and the best time for treatment has often been passed by the time they are clinically diagnosed. Lymph node metastasis (LNM), as the most common metastasis mode of both diseases, is an important basis for tumor staging, which largely determines the treatment plan and clinical prognosis of patients[5-8]. For patients with early tumor stages and no LNM, we can attempt endoscopic minimally invasive treatment, but for patients with LNM or advanced tumor stages, it is often necessary to consider comprehensive treatment, including radiotherapy, chemotherapy or surgery[9-11]. One study showed that when esophageal cancer has 0, 1-2 or more than 2 malignant lymph nodes, the median patient survival time is 66 mo, 14.5 mo or 6.5 mo, respectively[12]. Therefore, it is very important to accurately predict LNM.

Endoscopic ultrasound (EUS) combines the advantages of endoscopic technology and ultrasound technology; that is, it can evaluate the mucous membrane of the digestive tract with the naked eye, and it can also be used to detect the hierarchical structure and surrounding tissues of the digestive tract wall with ultrasound wave. EUS has the advantages of close observation distance, high resolution, low price and few adverse events. Since the 1980s, EUS has been gradually used in the diagnosis and treatment of many digestive system diseases, including the staging of gastrointestinal tumors, the identification of submucosal tumors, and the study of pancreatic or biliary tract diseases[13,14]. Conventional EUS uses grayscale imaging technology for analysis, which can clearly display the status of lymph nodes near upper gastrointestinal neoplasia and identify the nature of lymph nodes according to the imaging features. When the endosonographic characteristics of lymph nodes are hypoechoic, round in shape, with a clear boundary and a size greater than 1 cm, the accuracy of conventional EUS in predicting malignant lymph nodes is more than 80%[15]. Some studies have shown that the ability of conventional EUS to detect LNM in upper gastrointestinal neoplasia is better than that of computed tomography and positron emission tomography, but some scholars believe that the diagnostic performance of conventional EUS is poor, and study results have varied widely[16-20]. The purpose of this meta-analysis was to explore the diagnostic value of conventional EUS for LNM in upper gastrointestinal neoplasia to guide clinical practice more effectively.

MATERIALS AND METHODS

This meta-analysis was conducted according to the Preferred Reporting Items for Systematic Review and Meta-Analysis statement[21,22]. The study protocol was registered in the PROSPERO database with the number CRD42022372170.

Literature search

We used the "MeSH + Entry Terms" search mode to conduct a comprehensive search of the PubMed, EMBASE and Cochrane Library databases before October 1, 2022. The specific search terms were as follows: ("esophageal neoplasms" OR "stomach neoplasms" OR "duodenal neoplasms") AND ("lymphatic metastasis" OR "lymph nodes") AND "endosonography" AND "diagnostic test search strategy". We also manually searched the references of related studies.

Study selection

We imported all the retrieved articles into EndNote software (Version X9.1; Clarivate Analytics; Philadelphia, United States). Two researchers independently conducted study selection according to the predetermined inclusion and exclusion criteria with the process of identification, screening, eligibility and inclusion. To ensure consistency, we conducted exercises and tests before the formal selection, and the data were verified for internal consistency with the Kappa test during the selection process. If there was any disagreement, the decision was made by the two researchers together through consultation.

The study inclusion criteria were as follows: (1) Patients older than 18 who had recently been diagnosed with upper gastrointestinal neoplasia such as esophageal cancer, gastric cancer, and duodenal cancer; (2) LNM detected by conventional EUS; and (3) Diagnostic testing.

The exclusion criteria were as follows: (1) Studies published before 2000; (2) Case reports, conference abstracts, reviews, comments, letters, meta-analyses and systematic reviews; (3) Animal or *in vitro* models used as the objects of the study; (4) Sample size less than ten cases; (5) Inclusion of only stage cN0 patients; (6) Patients with other malignant tumors; (7) Patients who received or may have received preoperative neoadjuvant therapy; (8) Use of assistive technologies such as fine needle aspiration (FNA); (9) LNM diagnosis not made with postoperative pathological examination as the gold standard or radical surgery not performed for all patients; (10) Per patient not used as the analysis unit; (11) Inability to extract 2 × 2 tables of true positives (TP), false positives (FP), false negatives (FN), and true negatives (TN); (12) Repeated publication of the same data; and (13) Full text of English literature not found.

Data extraction and quality assessment

Two researchers independently extracted the study data using the predetermined data extraction form, and when they faced disagreement, a third researcher was consulted. Extracted data included: (1) Study characteristics such as first author, publication year, study country, study design and participating center; (2) Diagnostic test characteristics such as EUS model, EUS scan type, EUS examination method, EUS scan frequency, EUS diagnostic criteria, type and number of image interpretation experts, blinding, interval between EUS and surgery, gold standard and analysis unit; (3) Patient/tumor characteristics such as tumor type, tumor location, tumor stage, tumor histological type, neoadjuvant therapy, location of metastatic lymph nodes, age, sex and sample size; and (4) Statistical indicators such as TP, FP, FN, and TN. If the data were not reported directly, the sensitivity, specificity, accuracy and other indicators were used for reverse calculation.

Two researchers independently assessed the quality of the included studies using the Quality Assessment of Diagnostic Accuracy Studies (QUADAS-2) tool[23]. Disagreements were resolved through consultation. The results of the quality assessment were presented using Review Manager software (Version 5.3.5; Nordic Cochrane Centre; Copenhagen, Denmark).

Statistical analysis

All data evaluation and picture generation were completed by Stata software (Version 14.0; StataCorp LP; Texas, United States) using the MIDAS module of the bivariable mixed effects model. This model not only considers factors such as heterogeneity between studies, threshold effect and study size but also enables the bivariate nature of the original data to remain unchanged throughout the analysis process, thereby generating reliable statistical indicators. The pooled sensitivity, specificity, positive likelihood ratio (PLR), negative likelihood ratio (NLR), diagnostic score (DS) and diagnostic odds ratio (DOR) were calculated by drawing forest plots. The higher the values of DS and DOR were, the better the diagnostic effect of conventional EUS. The area under the curve (AUC) was obtained by drawing a summary receiver operating characteristic (SROC) curve, and the diagnostic performance was considered low, moderate, and high for AUCs of 0.5-0.7, 0.7-0.9 and 0.9-1.0, respectively. Fagan's nomogram was used to reveal changes in the posttest probabilities. Likelihood ratio scatter diagram was used to evaluate the diagnostic performance of conventional EUS. Sensitivity analysis was used to assess the influence of individual studies on heterogeneity and observe the stability of the summary statistics. The threshold effect was determined according to whether the ROC plane showed a "shoulder-arm" point distribution. The Q statistical test was applied to assess the heterogeneity among the included studies, and heterogeneity was considered statistically significant when $P < 0.05$. The degree of heterogeneity was estimated based on the I^2 statistic, where $I^2 < 25\%$, 25%-50%, 50%-75%, and ≥ 75% were considered low, moderate, substantial, and considerable heterogeneity, respectively. If the heterogeneity was high, meta-regression and subgroup analysis were used to explore the most significant source of heterogeneity. Publication bias was assessed with Deeks' funnel plot, and $P < 0.05$ indicated statistical significance. The statistical methods of this study were reviewed by Professor Yao Zhang from the Department of Epidemiology, College of Preventive Medicine, Army Medical University of China.

RESULTS

Study selection

The study selection process is shown in Figure 1. A total of 729 articles were retrieved from three databases, and 22 articles were included in the manual search. The complete retrieval strategy of each database and manual search literature catalog can be found in Supplementary Table 1. Among them, 99 repeated articles were excluded after checking duplicates with EndNote software, 525 obviously irrelevant articles were excluded after reading the publication year, title and abstract, 8 articles were not published in English, 97 articles that did not meet the requirements were excluded after full-text reading, and 22 articles were included in the analysis according to the screening criteria[24-45]. In addition, the Kappa coefficient of the consistency test of the final selection results of the two researchers was 0.810 (P = 0.000).

Characteristics and quality of the included studies

This meta-analysis included 22 studies with 2986 patients. The basic information of the studies is shown in Table 1, and the detailed information is shown in Supplementary Table 2. Among them, the vast majority of studies were retrospective studies (21/22, 95.5%) and single center studies (20/22, 90.9%); ten studies were conducted in eastern countries, and twelve studies were conducted in western countries; the objects of twelve studies and ten studies were esophageal cancer and gastric cancer, respectively; none of the patients received neoadjuvant therapy before EUS and surgery, and the gold standard for the diagnosis of LNM in all studies was postoperative pathology. The results of the quality assessment based on the QUADAS-2 tool are shown in Figure 2, and detailed quality assessment information is shown in Supplementary Table 3.

Meta-analysis outcomes

Primary outcomes: The pooled sensitivity and specificity of conventional EUS in the diagnosis of upper gastrointestinal neoplasia LNM were 0.62 [95% confidence interval (CI): 0.50-0.73, I^2 = 91.50%] and 0.80 (95%CI: 0.73-0.86, I^2 = 86.10%), respectively, as shown in Figure 3A. According to the SROC curve, the AUC was 0.80 (95%CI: 0.76-0.83), as shown in Figure 4.

Secondary outcomes: The pooled PLR, NLR, DS, and DOR of conventional EUS in the diagnosis of upper gastrointestinal neoplasia LNM were 3.15 (95%CI: 2.46-4.03, I^2 = 61.17%), 0.47 (95%CI: 0.36-0.61, I^2 = 92.21%), 1.90 (95%CI: 1.51-2.29, I^2 = 60.94%) and 6.67 (95%CI: 4.52-9.84, I^2 = 99.99%), respectively, as shown in Figures 3B and C. The likelihood ratio scatter diagram showed that the summary PLR and NLR for the index test were in the fourth quadrant, suggesting that conventional EUS cannot be used as a confirmatory or exclusionary test, as shown in Figure 5. According to Fagan's nomogram, when the EUS results were positive, the probability of diagnosing LNM increased from 50% to 76%; when the EUS results were negative, the probability of diagnosing LNM decreased from 50% to 32%, as shown in Figure 6.

Validation of meta-analysis results

Sensitivity analysis: We conducted sensitivity analysis by eliminating studies one by one, and the results showed that the pooled sensitivity change rate was ≤ 4.84% (I^2 change rate ≤ 2.75%), and the pooled specificity change rate was ≤ 2.50% (I^2 change rate ≤ 5.04%), indicating that the results of the meta-analysis were stable. Detailed data from the sensitivity analysis are shown in Supplementary Table 4.

Heterogeneity: Based on the Q statistical test and I^2 statistic, considerable heterogeneity was observed in the analysis for diagnostic sensitivity and specificity of conventional EUS. The ROC plane showed that the sensitivity was positively correlated with (1 - specificity), resulting in a "shoulder-arm" point distribution and indicating the existence of a threshold effect, as shown in Figure 7. According to the calculations from Stata software, the proportion of heterogeneity likely due to the threshold effect was 0.54. Because of the obvious heterogeneity among studies, we included five covariates: Tumor type (esophageal cancer or gastric cancer), study area (eastern country or western country), publication year (2010-2018 or 2000-2009), sample size (≥ 100 cases or < 100 cases) and EUS diagnostic criteria (criteria 1 or criteria 2). Univariable meta-regression and subgroup analysis were performed to identify the significant sources of heterogeneity. The results showed that tumor type, sample size and EUS diagnostic criteria were significant sources of heterogeneity in specificity (P < 0.05), as shown in Figure 8. The covariable assignment instructions are shown in Supplementary Table 5. The indicators for evaluating the diagnostic value of conventional EUS in each subgroup are shown in Table 2.

Publication bias

Deeks' funnel plot showed that the distribution of all studies was relatively symmetrical; the asymmetry was not statistically significant (P = 0.654), indicating that there was no significant publication bias among the 22 studies, as shown in Figure 9.

DISCUSSION

In this meta-analysis, upper gastrointestinal neoplasia was considered as a whole, and the diagnostic value of conventional EUS for LNM was analysed. To ensure the reliability of the research results, we excluded studies that were old, had incomplete data, had small sample sizes and were published in languages other than English. The effects of incomplete surgical resection, neoadjuvant therapy, animal experiments, assistive technologies and other malignant tumors on the

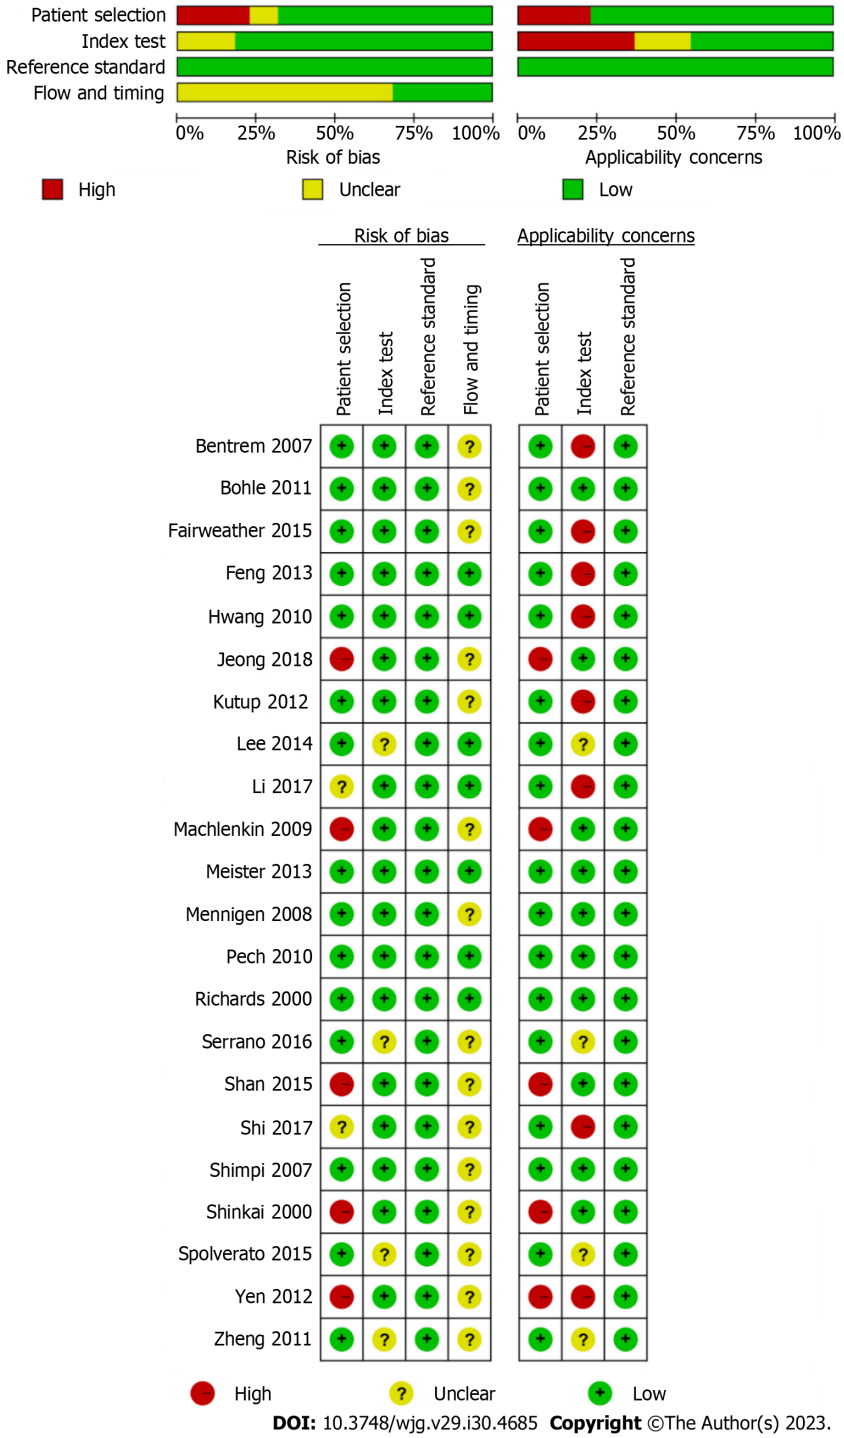
statistical results were excluded (which is also the reason for the small number of studies included in this meta-analysis). The results of conventional EUS were compared with postoperative pathology, and the data of 2986 patients in 22 studies were analyzed in detail.

The results of the quality assessment showed that many studies had a risk of bias, mainly because the proportion of retrospective studies was too high, and selective bias may have been present in the patient inclusion process. Four studies did not clearly describe the diagnostic criteria in the use of EUS, five studies unreasonably excluded some tumor patients (two studies limited the tumor location, two studies defined the location of metastatic lymph nodes, and one study only included esophageal cancer of ≤ pT2 stage), and fifteen studies did not specify the interval between EUS and surgery. However, we believe that since both esophageal cancer and gastric cancer are malignancies, examination and surgery should be arranged as soon as possible after clinical diagnosis. Although many studies did not specify the interval, it should not have had a significant impact on the research results. Regarding concerns regarding applicability, we think that the main reasons were the difference in diagnostic criteria of EUS and bias in patient selection. Therefore, caution should be taken in interpreting the results of the meta-analysis.

Due to the significant heterogeneity among the included studies, we used the bivariate mixed effect model to calculate statistics on various diagnostic evaluation indicators. The results showed that the pooled sensitivity and specificity of conventional EUS in diagnosing LNM in upper gastrointestinal neoplasia were 0.62 and 0.80, respectively, and the AUC of the SROC curve was 0.80, which indicated that the diagnostic value of conventional EUS was moderate. When EUS indicated positive or negative results, the posttest probability could be adjusted from the previous 50% to 76% and 32%, respectively. This result is meaningful for noninvasive examinations, indicating that conventional EUS has certain clinical value. However, it is undeniable that because the PLR < 10 and NLR > 0.1 in conventional EUS diagnosis and the DS and DOR were relatively small, this examination cannot be used to confirm or exclude LNM, which is consistent with the results of previous studies[46-49]. It is not difficult to understand that, as with other imaging examinations, it is difficult for conventional EUS to reach such a high diagnostic level without obtaining lymph node tissue.

We explored the sources of heterogeneity among the included studies. First, we believe that the threshold effect could lead to heterogeneity because the 22 studies adopted a variety of EUS diagnostic criteria, and the "shoulder-arm" point distribution in the ROC plane also confirmed our view; the threshold effect might contribute 54% of the heterogeneity. Then, in view of the differences among the various studies, we included five covariables that could be easily grouped according to the collected data for meta-regression and subgroup analysis. Considering the limited number of studies, it would have been difficult to guarantee the accuracy of the statistical results of the simultaneous inclusion of five covariates, so we included individual covariates one by one for analysis. Although we were unable to identify significant



DOI: 10.3748/wjg.v29.i30.4685 **Copyright** ©The Author(s) 2023.

Figure 1 Flow chart for study selection.

sources of heterogeneity in sensitivity, we found that the significant sources of heterogeneity in specificity included tumor type, sample size, and EUS diagnostic criteria. However, after excluding the influence of the above factors, the heterogeneity within each subgroup was still obvious. Therefore, we have reason to believe that the heterogeneity was caused by a combination of factors. Many unincluded factors may also have been sources of heterogeneity; examples and the reasons they were not analyzed in detail included the study design, participating center and EUS scan type (because of the proportion imbalance within the group), the qualifications of the endoscopists, the EUS model and scan frequency (because of the complexity of the data), and the tumor stage, tumor location and location of metastatic lymph nodes (because these could not be accurately distinguished). We also found that the study area was not a significant source of heterogeneity, indicating that the diagnostic performance of conventional EUS for LNM in patients with upper gastrointestinal neoplasia in eastern and western countries is comparable. Publication year was also not a significant source of heterogeneity, indicating that the diagnostic performance of conventional EUS has not changed significantly in the past 20 years and that there may be technical barriers in conventional EUS that limit opportunities to significantly improve the ability of conventional EUS to identify malignant lymph nodes by relying solely on the diagnostic criteria of size, shape, boundary and echo.

Although the performance of conventional EUS in diagnosing LNM in upper gastrointestinal neoplasia remains nonideal, the diagnostic ability can be greatly improved with the assistance of EUS-guided FNA (EUS-FNA), EUS elastography (EUS-E) and contrast-enhanced EUS (CE-EUS)[50-52]. EUS-FNA uses a slender biopsy needle to perform puncture biopsy for suspicious lesions under the guidance of EUS, which can provide histopathological information and is an accurate method to distinguish between benign and malignant lymph nodes. The sensitivity and accuracy of EUS-FNA in the diagnosis of regional LNM of upper gastrointestinal neoplasia are higher than those of conventional EUS. Chen *et al*[53] included 26 studies with 2753 patients for meta-analysis and found that the pooled sensitivity and specificity of EUS-FNA in differentiating benign and malignant lymph nodes were 87% and 100%, respectively, and the AUC was as high as 0.9912. EUS-E uses different colors to distinguish tissue hardness and displays different color images according to the elastic difference between lymph nodes and surrounding tissues, which can more clearly identify metastatic lymph nodes, improve the diagnostic performance of conventional EUS, and reduce unnecessary biopsies. Xu *et al*[54] included seven studies with 368 patients for meta-analysis and showed that the pooled sensitivity, specificity and AUC of EUS-E in the diagnosis of LNM were 88%, 85% and 0.9456, respectively. CE-EUS obtains enhanced images by using contrast agents, which can provide more information about the lesion tissue and can be used to identify metastatic lymph nodes. Lisotti *et al*[55] included four studies with 336 patients in their meta-analysis and indicated that the pooled sensitivity and specificity of CE-EUS in diagnosing LNM were 82.1% and 90.7%, respectively. However, our study only analyzed the diagnostic value of conventional EUS for LNM of upper gastrointestinal neoplasia, without considering the role of the above assistive technologies, which may underestimate the diagnostic value of EUS and affect the choice of clinicians. Therefore, we can carry out relevant studies in the next stage to evaluate the diagnostic value of various EUS assistive technologies in detail.

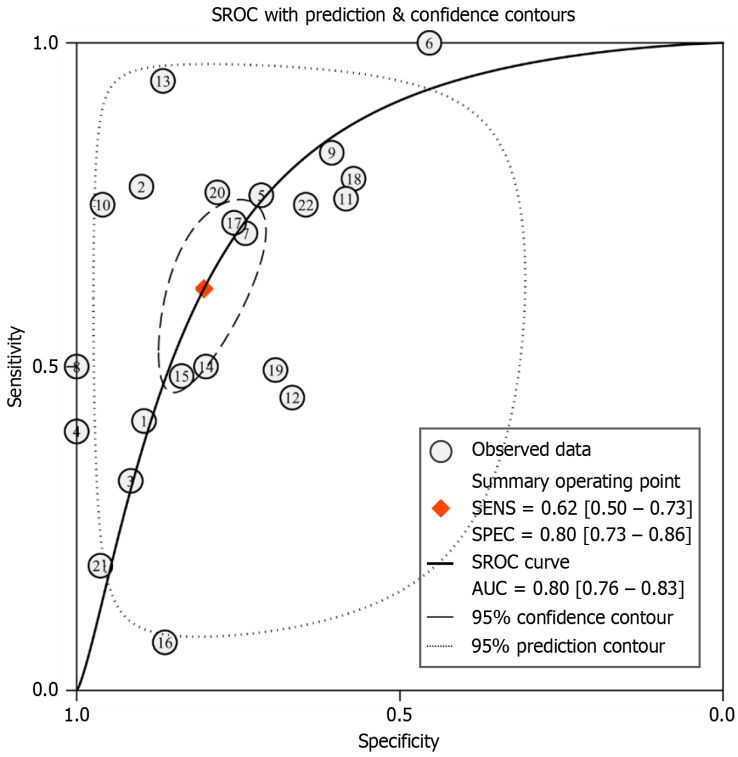
Figure 2 Quality assessment of included studies based on the Quality Assessment of Diagnostic Accuracy Studies tool criteria.

Our study only included patients who underwent radical surgery and did not receive preoperative neoadjuvant therapy, which inevitably led to case selection bias and excluded some patients with early tumors suitable for endoscopic treatment or patients with advanced tumors not suitable for surgical treatment. In addition, because preoperative neoadjuvant chemoradiotherapy can improve the treatment effect and prolong the survival time of some patients with upper gastrointestinal neoplasia, some patients with positive LNM may not have received the best treatment in this study. However, it is difficult to know the exact situation of LNM without obtaining complete pathological tissue, and preoperative neoadjuvant therapy will cause necrosis, fibrosis or inflammation of lymph nodes, which will affect the diagnostic effect of conventional EUS and the manifestations of postoperative histopathology. Therefore, to provide a reliable reference standard, we had to abandon the above cases in the study design stage.



Our study also has the following limitations. First, there were many retrospective studies with a long time span and use of different technologies and tools, which may have led to selection bias. Second, only studies published in English were included, which may have led to information bias. Third, there were differences in the study designs and implementation processes, which may have led to confounding bias. In addition, the significant heterogeneity may have

affected the reliability and repeatability of the analysis results.

CONCLUSION

In conclusion, conventional EUS has certain clinical value and can assist in the detection of LNM in upper gastrointestinal neoplasia, but it cannot be used as a confirmatory or exclusionary test. There was great heterogeneity among the included studies, and more high-quality studies are needed to further verify the diagnostic value of EUS and determine its best diagnostic criteria. However, with the popularization of EUS technology, the use of assistive technologies such as EUS-FNA, EUS-E or CE-EUS, and the training of high-quality endoscopists, we believe that EUS will be increasingly valuable in the diagnosis of LNM in upper gastrointestinal neoplasia.

ARTICLE HIGHLIGHTS

Research background

Upper gastrointestinal neoplasia, mainly including esophageal cancer and gastric cancer, is a common cancer with high mortality. Accurate prediction of lymph node metastasis (LNM) is of great significance for guiding clinical treatment and improving the prognosis of patients. In recent years, endoscopic ultrasound (EUS) has become increasingly used in the diagnosis and treatment of gastrointestinal diseases, but its application in the detection of LNM remains limited.

Research motivation

Although previous studies have reported the diagnostic value of conventional EUS for LNM in upper gastrointestinal neoplasia, the relevant research conclusions were controversial, and the research results have varied widely. Therefore, we intend to further carry out this research through meta-analysis.

Research objectives

This study aimed to systematically search the literature and examine the diagnostic value of conventional EUS for LNM in upper gastrointestinal neoplasia by summarizing and analyzing the data.

Research methods

We conducted a comprehensive search and screening of the PubMed, EMBASE and Cochrane Library databases from January 1, 2000 to October 1, 2022. Then, relevant study data were extracted, and the quality of the included studies was assessed based on the Quality Assessment of Diagnostic Accuracy Studies tool. Afterward, a meta-analysis was performed using the statistical software Stata 14.0.

Research results

A total of 2986 patients in 22 studies were included. The results showed that the pooled sensitivity, specificity and area under the summary receiver operating characteristic curve of conventional EUS in the diagnosis of upper gastrointestinal neoplasia LNM were acceptable, which were 0.62 [95% confidence interval (CI): 0.50-0.73], 0.80 (95%CI: 0.73-0.86) and 0.80 (95%CI: 0.76-0.83), respectively. However, the pooled positive likelihood ratio and negative likelihood ratio were relatively poor, at 3.15 (95%CI: 2.46-4.03) and 0.47 (95%CI: 0.36-0.61), respectively. The pooled diagnostic score and diagnostic odds ratio were relatively small, at 1.90 (95%CI: 1.51-2.29) and 6.67 (95%CI: 4.52-9.84), respectively.

Research conclusions

Conventional EUS has certain clinical value and can assist in the detection of LNM in upper gastrointestinal neoplasia, but it cannot be used as a confirmatory or exclusionary test. More high-quality studies are needed to further verify the diagnostic value of EUS and determine the best diagnostic criteria.

Research perspectives

In the future, further clinical studies should be carried out to evaluate the diagnostic value of various EUS assistive technologies for LNM in upper gastrointestinal neoplasia and to evaluate the influence of neoadjuvant therapy on the diagnostic value of EUS for LNM in upper gastrointestinal neoplasia.

Abstract

Current abdominal surgery has several approaches for biliary reconstruction. However, the creation of functional and clinically applicable bile duct substitutes still represents an unmet need. In the paper by Miyazawa and colleagues, approaches to the creation of bile duct alternatives were summarized, and the reasons for the lack of development in this area were explained. The history of bile duct surgery since the nineteenth century was also traced, leading to the conclusion that the use of bioabsorbable materials holds promise for the creation of bile duct substitutes in the future. We suggest three ideas that may stimulate progress in the field of bile duct substitute creation. First, a systematic analysis of the causative factors leading to failure or success in the creation of bile duct substitutes may help to develop more effective approaches. Second, the regeneration of a bile duct is delicately balanced between epithelialization and subsequent submucosal maturation within limited time frames, which may be more apparent when using quantitative models to estimate outcomes. Third, the utilization of the organism's endogenous regeneration abilities may enhance the creation of bile duct substitutes. We are convinced that an interdisciplinary approach, including quantitative methods, machine learning, and deep retrospective analysis of the causes that led to success and failure in studies on the creation of bile duct substitutes, holds great value. Additionally, more attention should be directed towards the balance of epithelialization and submucosal maturation rates, as well as induced angiogenesis. These ideas deserve further investigation to pave the way for bile duct restoration with physiologically relevant outcomes.

Key Words: Bile duct alternative; Bile duct substitute; Regenerative medicine; Regene-

rative surgery; Theoretical surgery; Quantitative human physiology

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Progress towards the development of clinically applicable bile duct substitutes can be achieved by applying an interdisciplinary approach. This approach should include the utilization of quantitative mathematical methods, principles of cross-tissue interactions for epithelial and submucosal tissues, as well as deep retrospective data analysis of the causes of success and failure in studies on the creation of bile duct substitutes.

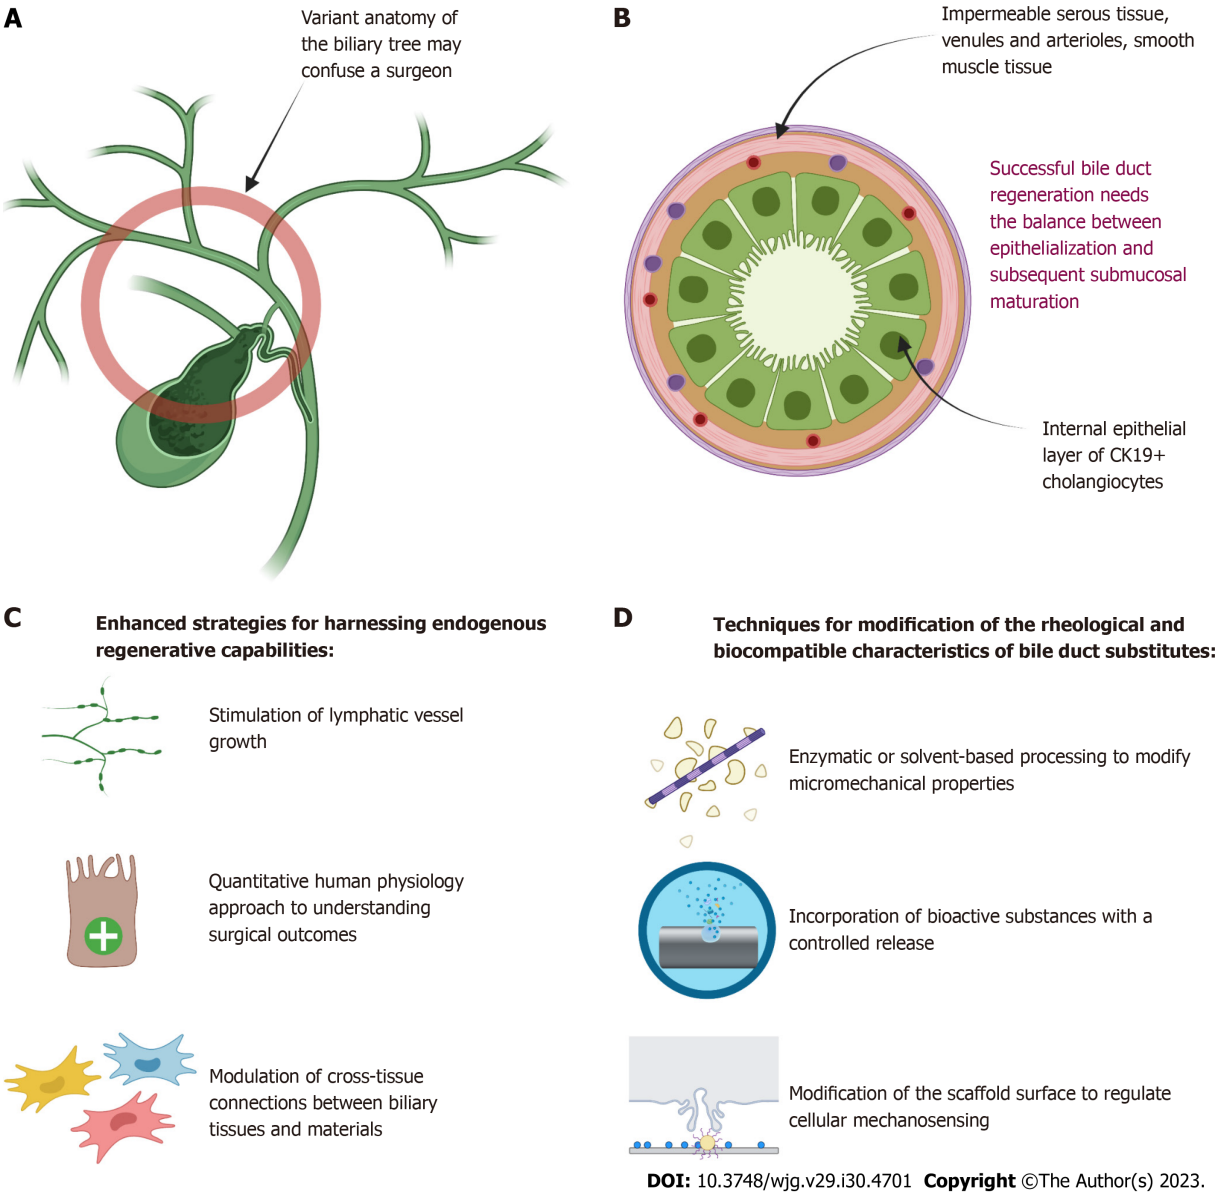
TO THE EDITOR

We read with great interest the paper by Miyazawa *et al*[1], who analyzed the drawbacks and advantages of various alternatives for bile ducts. The authors described the current approaches for substituting the bile duct and acknowledged that a suitable graft has not yet been developed due to limited understanding of the mechanisms involved in the healing and regeneration of bile duct tissue. They are convinced that the use of bioabsorbable materials may facilitate the creation of bile duct substitutes in the future.

The authors have fairly mentioned that there is a 100-year history of attempts to create satisfactory bile duct substitutes [2]. However, despite significant advancements in material and life sciences, the development of engineered bile ducts has not been successful. None of the grafts currently available are reliable enough for use in clinical practice. Additionally, due to the variant anatomy of bile ducts (Figure 1A)[3,4], it is nearly impossible to completely prevent iatrogenic injuries.



One of the most valuable features of the paper by Miyazawa *et al*[1] is the systematization and analysis of the early attempts to create bile duct alternatives, as application of a systematic approach. The authors traced the history of reconstructive hepatobiliary surgery since the 1880s and discussed many intriguing studies. However, we noticed that the causes of negative or positive results are not usually analyzed or systematized in these studies. For example, in the study by Doillon *et al*[5], it was shown that pre-exposure of a venous graft in glycerol improves surgical outcomes, but the fundamental reasons for such improvement were not investigated in this study, as well as in many other papers.

First, we want to emphasize that the analysis of the causes of negative and positive results is just as important as the results themselves. Additionally, studies that describe the unsuccessful use of rubber tubes[6], polyvinyl chloride[7], silastic[8], lyophilized and siliconized dura mater[9] in both humans and animals are valuable as they shed light on the various causes of postoperative surprises. We believe that a systematic analysis of the factors that contribute to failure or success in creating bile duct substitutes could help develop more effective approaches. It is important to note that such a systematic review has never been conducted before.

Secondly, quantitative methods of analysis can also highlight interesting patterns. Specifically, the studies reviewed by the authors revealed the limitations of bile duct epithelialization, which was found to be approximately 3 cm long and not more than 1-2 mm per week[10-12]. Additionally, the required time for submucosal maturation was estimated to be around 6-12 mo[10,13]. These findings provide support for the hypothesis that there are several deterministic mechanisms of bile duct regeneration that have yet to be discovered and completely understood. Furthermore, this suggests that the regeneration of the bile duct is delicately balanced between epithelialization and subsequent submucosal maturation within limited time frames (Figure 1B).

Thirdly, the utilization of the organism's endogenous regeneration abilities may enhance the effectiveness of bile duct substitutes. Cross-tissue interactions play a crucial role in the process of regeneration, as they determine the normal and pathological proliferation and maturation of tissues[14]. Moreover, in interconnected tissues, not only interactions but also division of labor and competition between different tissues become relevant[15]. This phenomenon has gained significant importance, particularly in relation to the biliary microbiota's role in inflammatory diseases of the biliary tract [16]. Therefore, the correct surgical approach with incompatible tissues, or the reconstruction of biliary tissues with incompatible materials, may lead to the development of chronic disorders and require additional supplementation. For example, some methods that have been underestimated include the stimulation of not only blood vessel growth but also lymphatic vessel growth in the interstitium, as well as the specific chemotaxis of mesenchymal stromal cells to the site of injury (Figure 1C).

Miyazawa *et al*[1] have demonstrated a connection between vascularization/angiogenesis and the maturation of biliary glands, as well as the stabilization of inflammation[17]. Considering the recently discovered crucial role played by vascular endothelial growth factor in biliary tree development and cell cycle regulation[18], inducing angiogenesis could be a promising avenue for future research. It is worth noting that the use of grafts may yield varying outcomes, mainly due to differences in their structure, immunogenicity, and vascular density, regardless of whether they are autologous or

allogeneic. Therefore, the mechanical (rheological) and cyto compatible properties of the substitute material are important (Figure 1D).

The functional and biomimetic properties of the bile duct substitute are expected to promote the growth of resident cells and facilitate tissue regeneration[19]. However, significant advancements in regenerative medicine necessitate innovative ideas from interdisciplinary fields. The application of mathematical logic to human physiology has the potential to accelerate progress in tissue engineering[20]. For example, the phase space method, well known in physics, can provide new insights into physiological relevance in bioengineering[21]. This promising and novel concept relies on the application of mathematical logic and machine learning to forecast surgical outcomes, commonly referred to as theoretical surgery[22].

We assume that the views of the surgeon and the biophysicist on the same facts and problems differ, particularly in terms of abstract concepts. This highlights the necessity for collaborative work among specialists from various fields (Table 1). We firmly believe that the integration of quantitative methods and retrospective analysis in bioengineering will open up new avenues for developing models of inter-tissue interaction, ultimately yielding groundbreaking outcomes in bile duct engineering.

Table 1 Differences in understanding of the clinical evidences between a surgeon and a physiologist

Clinical evidences	Understanding of a surgeon	Understanding of a physiologist
There are many negative results of the use of materials for bile duct repair	Materials associated with complications are not suitable for clinical practice	The causes of failure are what we need to determine. Can we cluster these causes to understand the underlying mechanisms? If we only consider successful cases, we will commit survival bias and be unable to determine the reasons for successful outcomes
Bile duct epithelialization never exceed the following limits: About 3 cm long and growth not more than 1-2 mm per week	We must avoid implanting grafts (autografts) longer than 3 cm. This is an interesting fact. My experience supports these values, so I am aware of the potential outcomes that may be achieved after a surgical procedure	The presence of stable values indicates the conservatism of the underlying regenerative mechanisms, which are not dependent on the surgeon's skills or the quality of the materials
The normal human bile is not sterile and contains both living cholangiocytes and normal biliary microbiota	These are interesting facts, but we still lack the necessary tools to support endogenous regeneration in routine clinical practice. The application of cells remains unproven	The presence of living cells in bile may support the existence of unknown ways for the migration of bile duct cells. These methods need to be discovered and applied for bile duct regeneration

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, De-Liang Fu, MD, PhD, Chief Doctor, Professor, Department of Pancreatic Surgery, Pancreatic Disease Institute, Huashan Hospital, Shanghai 200040, China. surgeonfu@163.com

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJG* as 4.3; IF without journal self cites: 4.1; 5-year IF: 5.3; Journal Citation Indicator: 0.82; Ranking: 33 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.3 and Scopus CiteScore rank 2022: Gastroenterology is 22/149.

Abstract

Hepatocellular carcinoma (HCC) is a malignancy with a high incidence and fatality rate worldwide. Hepatitis B virus (HBV) infection is one of the most important risk factors for its occurrence and development. Early detection of HBV-associated HCC (HBV-HCC) can improve clinical decision-making and patient outcomes. Biomarkers are extremely helpful, not only for early diagnosis, but also for the development of therapeutics. MicroRNAs (miRNAs), a subset of non-coding RNAs approximately 22 nucleotides in length, have increasingly attracted scientists' attention due to their potential utility as biomarkers for cancer detection and therapy. HBV profoundly impacts the expression of miRNAs potentially involved in the development of hepatocarcinogenesis. In this review, we summarize the current progress on the role of miRNAs in the diagnosis and treatment of HBV-HCC. From a molecular standpoint, we discuss the mechanism by which HBV regulates miRNAs and investigate the exact effect of miRNAs on the promotion of HCC. In the near future, miRNA-based diagnostic, prognostic,

and therapeutic applications will make their way into the clinical routine.

Key Words: Hepatitis B virus; Hepatocellular carcinoma; MicroRNA; Diagnosis; Prognosis; Biomarker

Core Tip: Hepatocellular carcinoma (HCC) is one of the most common malignancies worldwide. Hepatitis B virus (HBV) infection is one of the predominant risk factors for developing HCC. Early diagnosis and prognosis prediction are pivotal for patients with HBV-associated HCC (HBV-HCC) in their clinical management. MicroRNAs (miRNAs), a subset of non-coding RNAs, play an essential role in human diseases including HBV-HCC. Here, we summarize the role of miRNAs in the diagnosis and prognosis prediction of patients with HBV-HCC. Furthermore, we discuss the underlying mechanism by which HBV dysregulates miRNAs, and the potential role of dysregulated miRNAs in promoting hepatocarcinogenesis, laying the foundation for applying potential therapeutic targets.

INTRODUCTION

According to World Health Organization (WHO) reports, in 2020, primary liver cancer is the sixth most frequently occurring cancer worldwide, with mortality ranking third among all cancers. Hepatocellular carcinoma (HCC) accounted for about 75%-85% of cases. Chronic hepatitis B virus (HBV) infection is one of the major known risk factors[1]. Although the HBV-vaccination program has greatly reduced the incidence of HBV infection, it is estimated that nearly 292 million people are living with chronic hepatitis B (CHB) globally, and approximately 900000 people die annually because of HBV-induced liver cirrhosis and HCC, according to WHO estimates[2]. Liver surgery, including liver resection and liver transplantation, has become an established therapy for HCC and cirrhosis. Early diagnosis is a key factor for liver resection. Biomarkers are widely used for the early diagnosis of several cancers. But HCC biomarkers cannot be clinically useful for early HCC diagnosis due to their low sensitivity[3]. Similarly essential is the construction of prognosis of HBV-associated HCC (HBV-HCC), which can help make treatment decisions[3]. At present, circulating nucleic acid biomarkers, including microRNAs (miRNA), are identified as possible biomarkers for the diagnosis, prognosis, and therapeutics of liver diseases, especially HBV-HCC[4].

miRNA, a subset of non-coding RNAs, possess 19-25 nucleotides in length and play crucial biological roles in the process of gene silencing. Given that up to 60% of human protein-coding genes have conserved miRNA target sites, it is not surprising that dysregulated miRNAs can disrupt homeostasis and cause diseases including cancer[5]. miRNAs play a vital role in different stages of the HBV-HCC continuum, including early HBV infection, chronic inflammation, fibrosis/cirrhosis, and the emergence of HCC[6].

Although most miRNAs are located within cells, circulating miRNAs are present in body fluids and may reflect the pathophysiology of tissues. Several desirable characteristics of circulating miRNAs, such as their high stability in biological samples, non-invasive methods for sampling, and high sensitivity and accuracy, make them suitable as biomarker candidates for cancer diagnosis, prognosis, and therapeutic response prediction[7]. In this review, we summarize the application of miRNAs as diagnostic, prognostic, and therapeutic markers in HBV-HCC. We further discuss the mechanism by which HBV affects miRNA transcription and stability. We also try to understand the mechanisms by which miRNAs participate in the development of HCC. This will provide an in-depth understanding to identify promising biomarkers in HBV-HCC diagnosis, prognosis, and treatment.

DYSREGULATED MIRNAS IN THE DIAGNOSIS OF HBV-HCC

miRNAs are expressed with high tissue and cell selectivity. For example, some miRNAs, such as miR-122-5p, are particularly abundant in the liver, suggesting that certain miRNAs participate in HCC carcinogenesis and progression[8]. After tumor resection in HCC patients, some serum circulating miRNAs exhibit significant changes[9-13], indicating that circulating miRNAs may be specific non-invasive and diagnostic markers for HBV-HCC.

In clinical diagnostic tests, area under the receiver operating characteristic curve (AUC) is widely used to judge the diagnostic accuracy. Generally, an AUC between 0.7 and 0.8 is considered clinically useful, between 0.8 and 0.9 is deemed excellent, and greater than 0.9 is considered outstanding discrimination[14]. Numerous individual miRNAs have shown good diagnostic efficacy, with miR-93-5p[15], miR-122[16], miR-125b[17], miR-150[13], miR-487b[18,19], miR-768-3p[20],

and miR-5193[21] achieving AUC > 0.9 in discriminating HBV-HCC patients from healthy controls (HC) (Table 1), miR-122[22], miR-125b[23], and miR-192[22] in differentiating HBV-HCC from CHB patients (Table 2), and miR-101[24] and miR-125b[17,23] in discriminating HBV-HCC from HBV related liver cirrhosis (HBV-LC) patients (Table 2). Additionally, some HBV dysregulated miRNAs show different expression profiles in the serum or plasma of HBV-HCC patients compared to control populations[25-29], suggesting a potential value of these miRNAs in diagnosing HBV-HCC. In addition, one study reveals that urine miR-93-5p demonstrates diagnostic performance comparable to plasma miR-93-5p for diagnosing early HBV-HCC. Urine sample is non-invasive and simple to perform on humans. Therefore, urine miRNAs may have more clinical application potential than plasma miRNAs[15]. However, individual miRNAs may have limitations in sensitivity and specificity due to HBV-associated chronic liver disease. In addition, despite the fact that numerous miRNAs were highly effective at distinguishing HBV-HCC patients from healthy populations or all control populations, the efficacy used to differentiate HBV-HCC from CHB or HBV-LC is nonspecific. Hence, new methods are required to improve the diagnostic efficacy of miRNAs in diagnosing HBV-HCC patients, particularly in distinguishing them from CHB and LC populations.

Individual miRNAs are altered in different infectious diseases, nonspecific inflammation, and acute lesions in addition to cancer, revealing their lack of specificity. Forming a miRNA panel may help serve as diagnostic biomarkers for HBV-HCC (Table 3). Several miRNA panels, such as miR-21 + miR-122 + miR-192[22], miR-125b + miR-223 + miR-27a + miR-26a[30], and miR-23b + miR-423 + miR-375 + miR-23a + miR-342-3p[31] reach a high value in differentiating HBV-HCC from HC, CHB and HBV-LC patients. However, the good diagnostic efficiency of miRNA profiles does not necessitate the combination of as many miRNAs as feasible to improve diagnostic accuracy, due to the complexity of the method necessary to detect miRNAs and the lengthy timeframes involved. In some cases, the combination of multiple biomarkers showed no additive effect on HBV-HCC diagnosis[32]. Several studies demonstrate that panels with only two miRNAs can also reach a high AUC as panels with more miRNAs, such as miR-10a + miR-125b[31] and miR-15b + miR-130b[9]. Consequently, additional research is required to determine the optimal combination of the fewest possible number of miRNAs and to reduce the cost of diagnosis as much as possible, all while attaining a good diagnostic capacity.

It will be better to combine miRNAs with other biomarkers in HBV-HCC diagnosis (Table 4). The most prevalent combination biomarker is alpha fetoprotein (AFP), a traditional biomarker in HCC. Obviously, the combination of most miRNAs with AFP demonstrates a high AUC and diagnostic accuracy for discriminating HBV-HCC from HC or patients with CHB, HBV-CLD, and HBV-LC, such as miR-24-3p[33], miR-96[34], miR-101[24], miR-122[35], miR-126[32], miR-142-3p[32], miR-205[36] and miR-224[11]. Another study combines miR-122 with AFP and TERT gene promoter mutations in cfDNA. The results show that it reaches a 0.98 and 0.88 AUC in discriminating HBV-HCC patients from CHB and HBV-LC patients, respectively, demonstrating a high diagnostic value in HBV-HCC[35]. Similarly, the combination of miR-122 with AFP and prothrombin induced by vitamin K deficiency or antagonist- II (PIVKA-II) reaches a 0.918 AUC in separating HBV-HCC from HBV-LC patients[37]. Consequently, the combination of single miRNA with other biomarkers may improve the diagnostic accuracy for HBV-HCC from other HBV-related diseases. Moreover, some miRNAs panels show a better diagnostic value than AFP[38], and combination of these miRNA panels with AFP further increased the efficacy[22,30,32]. Therefore, the use of miRNA profiles paired with AFP may be the optimum modality for the diagnosis of HBV-HCC.

In addition, miRNAs may be of particular value in the diagnosis of HBV-HCC with low AFP levels. Despite the fact that AFP is the most often utilized biomarker for HCC worldwide, serum AFP levels stay normal in 15%-30% of advanced HCC. Meanwhile, approximately 30% of early-stage HCC cannot be diagnosed *via* AFP measurement, which delays therapy. Therefore, it is crucial to establish biomarkers capable of identifying HCC patients with negative AFP levels[39]. Different miRNAs and miRNA panels have shown good capacity for separating HBV-HCC patients with negative AFP expression from HC and CHB patients (Table 5), such as miR-125b[23], miR-15b + miR-130b[9] miR-21 + miR-122 + miR-192[22], and miR-125b + miR-223 + miR-27a + miR-26a[30]. A meta-analysis suggests that circulating miRNAs have a relatively high diagnostic accuracy in distinguishing HBV-HCC patients with low AFP levels from non-HCC controls[40]. Therefore, circulating miRNAs may be an ideal potential diagnostic biomarker for HBV-HCC patients with low AFP levels. Notably, these miRNAs or miRNAs panels only show ordinary effects when differentiating HBV-HCC with HBV-LC, and thus, more research is needed to improve the value of miRNA in differentiating HBV-LC and HBV-HCC patients with negative AFP expression.

Overall, miRNAs have great potential for use in the diagnosis of HBV-HCC. Two meta-analyses also show that miRNAs attain a level between moderate and high in terms of diagnostic evaluation criteria, and also demonstrate superior diagnostic performance than AFP[41,42]. According to both studies, miR-125b demonstrates a stronger diagnostic value for HBV-related HCC than other single miRNAs[41,42]. The subgroup analysis further concludes that downregulated miRNAs, miRNA panels, and serum-type miRNAs provide the most accurate diagnostic function for HBV-HCC[42]. Notably, the majority of patients with HCC are frequently diagnosed at an advanced stage, with a 1-year survival rate of less than 50% and a 5-year survival rate of only 10%[43]. This is due to the lack of accurate early diagnostic biomarkers. Several other studies also evaluate the ability of miRNAs to discriminate between early-stage HBV-HCC and controls. In one study, the combination of AFP and miR-125b, miR-223, miR-27a, and miR-26a has the highest diagnostic accuracy for early-stage HBV-HCC[30]. Another study finds that one miRNA panel consisting of seven miRNAs shows significant diagnostic accuracy for HBV-HCC, particularly in patients with early Barcelona Clinic Liver Cancer (BCLC) stages (0/A)[44]. Consequently, these miRNA profiles may serve as possible early diagnostic markers for HBV-HCC.

Notably, in addition to circulating miRNAs, exosome miRNAs may also have diagnostic and prognostic value in HBV-HCC. Exosome miRNAs are miRNAs contained within exosomes and released by various cells. Exosome miRNAs are frequently more stable in bodily fluids than other circulating miRNAs because the exosome membrane protects them from degradation, indicating a higher value as cancer biomarkers[45]. As HBV can impact the production of exosomes

and their cargos to promote HBV replication and diseases progression[46], exosomes derived from HBV-infected cells may be useful biomarkers for HBV-related diseases[47,48]. Several studies have validated and reviewed exosome-encapsulated miRNAs as circulating diagnostic markers for HCC[49,50], which may be beneficial for monitoring CHB progression and for detecting HBV-HCC at an early stage[51,52].

DYSREGULATED MIRNAS IN THE PROGNOSIS OF HBV-HCC

miRNAs, whose expression level is correlated with disease severity and survival rate in HCC patients, have shown good prognostic value for HCC[53]. For HBV-HCC patients, several miRNAs from HCC tissues or blood are found to be significantly correlated with overall survival, diseases-free survival (DFS) and progression-free survival (Table 6). For tissue miRNAs, higher expression of miR-122[54,55], miR-143[55], miR-145[56], miR-193b[57], miR-203a[58], miR-216b [59], miR-375[55,60], and miR-384[61] is associated with a better prognosis, and higher expression of miR-9-3[62], miR-10b [62], miR-21[56], miR-29a-5p[63], miR-31[62], miR-106b[64], miR-224[55], miR-371a-5p[27], miR-519c[62], miR-522[62,65], miR-523[65], miR-3188[28], miR-3682-3p[66], miR-3660[62], miR-4784[62], miR-5188[67], and miR-6883[62] is associated with a significantly poorer long-term prognosis. For circulating miRNAs, higher expression of miR-150[13], miR-223-3p [68], and miR-768-3p[20] is associated with a better prognosis, higher expression of miR-24-3p[33], miR-29a-3p[69], miR-96[34], miR-155[70], miR-192-5p[69], and miR-487b[18,19] is associated with a significantly poorer long-term prognosis. Therefore, tissues or circulating miRNAs can be a promising tool in predicting the prognosis of HBV-HCC patients. Specifically, due to the fact that miRNAs are abundant in serum exosomes, serum exosomal miRNAs can be used to predict the outcome of HCC patients. In addition, tissue miR-21[56], miR-203a[58], miR-375[60], and miR-5188[67], and serum miR-26a[30], miR-27a[30], miR-29a-3p[69], miR-125b[30], miR-150[13], miR-192-5p[69], miR-223[30,68], miR-487b [18,19], and miR-768-3p[20] are independent prognostic factors of HBV-HCC patients.

Researchers also develop different models to predict HBV-HCC survival. One study constructs a multivariate risk model that incorporates BCLC stage, miR-192-5p, and miR-29-3p. This risk model is significantly correlated with patient survival and has a good prognostic value. Consequently, the serum miRNA signature can offer predictive value for the BCLC stage classification. In addition, one random forests model made with miRNAs can predict HBV-HCC survival well[62].

It is worthy of note that miRNAs are also correlated with the probability of HBV-HCC recurrence. Several miRNAs may serve as a potential predictor for early tumor recurrence after HCC resection. For instance, the amount of miR-29a-5p in HCC tissues is strongly linked with early HCC recurrence following surgery, including in early-stage HCCs. Stages 0 and A of BCLC are regarded as the early stages, it implies that these HCC patients may have a better prognosis. However, in clinical practice, some patients still have a bad prognosis. Predicting the prognosis of these individuals is a

HC: Healthy control, CHB: Chronic hepatitis B patient; HBV-LC: Hepatitis B virus-related liver cirrhosis patient; AUC: Area under the receiver operating characteristic curve; miRNAs: MicroRNAs.

huge challenge for clinicians. As miR-29a-5p sensitivity and specificity may reach approximately 70% for HCC patients with BCLC 0/A stage, their miR-29a-5p expression level may provide a visual aid to distinguish them from other early-stage patients[63]. In addition, it has been discovered that the recurrence of HBV-HCC is closely associated with dysregulation of miR-21 and miR-145[56].

In addition, one study reveals that miRNAs are related with the development risk of HCC in CHB. In CHB patients who do not develop HCC, nucleos(t)ide analogue (NA) treatment restores expression of these miRNAs to near-normal levels, whereas the expression profile is not fully restored in individuals who ultimately develop HCC. Therefore, in CHB patients treated with NA, the changes in miRNAs expression may help identify HCC development risks[71].

MECHANISMS OF HBV-INDUCED DYSREGULATION OF MIRNA

In HCC, HBV and its proteins [HBV surface antigen (HBs), HBV core antigen (HBc), HBV envelope antigen (HBe), HBV x

protein (HBx), and HBV polymerase protein (HBp)] dysregulate miRNAs to promote hepatocarcinogenesis. In this part, we summarize the available studies deciphering the way in which HBV regulates the expression profiles of miRNAs through modulating miRNA processing genes and proteins and influencing transcriptional, posttranscriptional, and epigenetic mechanisms, as well as the factors affecting the regulation process, which may help to identify the novel

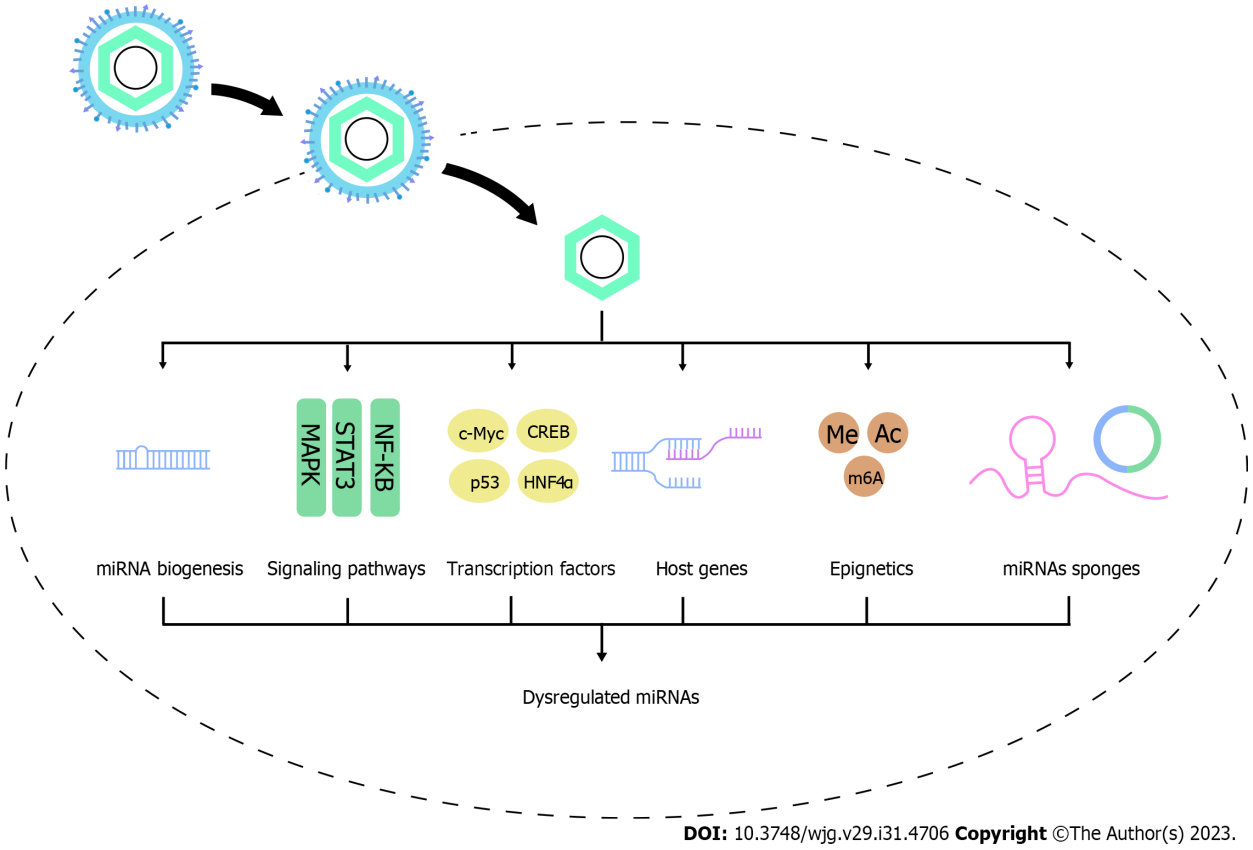
therapeutic pathways (Figure 1).

HBV modulates miRNA processing proteins to affect the biogenesis of miRNAs

It takes a complex process to form mature miRNAs. Firstly, miRNA genes, encoded by introns of noncoding or coding regions, are transcribed to pri-miRNAs by RNA polymerase II (Pol II) in the nucleus. Then, pri-miRNAs are spliced to pre-miRNAs by the Microprocessor complex (composed by the nuclear RNase III Drosha and DGCR8). Depending on the protein exportin 5 (EXP5), pre-miRNAs are exported to the cytosol, and are cleaved to a small RNA duplex by Dicer. The duplex is subsequently sorted and loaded onto Ago proteins, of which the guide strand is selected and preserved to form the RNA-induced silencing complex and silence gene expression[72].



There is evidence that HBV contributes to pre-miRNA production. Rather than pri-miR-18a levels, pre-miR-18a levels are associated with miR-18a elevation in HBV-HCC cases, indicating increased processing of pri- to pre-miR-18a[73]. Another study demonstrates that ectopic expression of HBx stimulates the transcription of pri-miR-1269b and hence induces the expression of pre-miR-1269b in HCC cell lines[74]. Therefore, HBV may affect miRNA expression through modulating its synthesis process.

Studies have verified a strong correlation between HBV and miRNA processing proteins. CHB patients with high HBV loads have lower mRNA and protein levels of Drosha, Dicer and Ago2 compared with patients with low viral loads[75]. In HBV-positive HCC patients, Drosha, DGCR8, Ago1, and Ago2 are significantly overexpressed[76], whereas Dicer and Ago3 are significantly downregulated in HCC tissues than that in adjacent nontumor tissues[76,77].

Figure 1 Mechanisms of hepatitis B virus-induced dysregulation of microRNAs. miRNAs: MicroRNAs.

For Drosha protein, researchers find that HBV inhibits Drosha promoter activity to downregulate its expression. HBx are inferred to interact with SP1 and AP-2a to downregulate Drosha expression[78]. HBV can downregulate DGCR8 expression *via* suppressing its promoter activity through upregulating transcription factor YY-1, in which HBs and HBx may play a role[79]. No study has provided direct evidence that the EXP5 protein is controlled by HBV. PIN1 decreases mature miRNA expression by catalyzing EXP5's conformational change and reducing its ability to export pre-miRNAs from the nucleus to the cytoplasm[80]. It is reported that PIN1 can bind specifically to the HBx to synergistically increase cell proliferation[81], indicating that HBx interacts with PIN1 and may affect pre-miRNAs export. Upon export to the cytoplasm, pre-miRNA is cleaved by Dicer in Drosophila. MiRNAs and siRNAs share a similar step in splicing and partitioning[82]. Considering that HBx can inhibit the Dicer-mediated processing of dsRNAs into siRNAs[75], HBV may also modulate miRNA through inhibiting Dicer and Dicer-mediated splicing of pre-miRNAs. Researchers discover that Ago2 mRNA is repressed by miR-99a in Huh7 and Hep3B cells[83], whereas miR-99a is found to be up-regulated in serum of HBV patients[84], indicating that there may be an HBV/miR-99a/Ago2 regulatory axis.

Overall, there is still no evidence directly indicating that HBV affects miRNA expression by altering miRNA processing proteins. But due to the crucial role of these proteins in miRNA biogenesis, it is reasonable to infer that this is possible. It's worth noting that in a study with non-viral-associated HCC samples, DGCR8, Dicer, Ago3 and Ago4 are also significantly downregulated, in which epigenetic regulation may be implicated[77]. Therefore, the regulatory role and mechanisms of HBV on miRNA machinery components still need further investigation (Figure 2).

HBV alters signaling pathways to modulate miRNAs

Although miRNAs share a common synthesis machinery, specific miRNA is regulated by different transcriptional and posttranscriptional mechanisms. HBV generally leads to a range of aberration of signaling pathways, Sartorius *et al*[6] summarize the miRNAs that are dysregulated by HBV and are involved in regulating these signaling pathways. However, miRNAs are also regulated by these signaling pathways induced by HBV infection (Table 7).

HBV: Hepatitis B virus; HBe: Hepatitis B virus envelope antigen; HBx: Hepatitis B virus x protein, HBc: Hepatitis B virus core antigen; miRNAs: MicroRNAs.

MAPK pathway plays a crucial role during the innate immune response. HBeAg is able to activate ERK, one of the MAP kinases, to induce the expression of phosphorylated CREB, which is able to bind to the promoter of miR-212-3p and subsequently enhance miR-212-3p expression[85]. In addition, several AP-1 components including Fra-1, c-Jun, and JunB are found to be recruited on a miR-21 50-flanking region, thus promoting miR-21 transcription. HBx has been previously shown to activate Ap-1, which is activated predominately by MAPK signaling cascade[86]. Therefore, there is a potential HBx/MAPK/Ap1/miR-21 regulatory pathway[87,88]. Meanwhile, HBV also induces YY1 expression through MAPK signaling, and negatively regulates the expression of miR-335, miR-129-2, and miR-203[89].

STAT3 is crucial for transducing signals and regulating the expression of a wide range of genes to promote tumor progression. Studies have found that HBV, HBc and HBx but not HBs and HBp increase STAT3 phosphorylation[90], suggesting that HBV and its viral proteins underline a role in STAT3 activation. STAT3 has been proved to directly bind to several miRNAs' promotors, increase the promotors activity, and subsequently activate miRNAs transcription. STAT3 mediates upregulation of miR-21[91], miR-328-3p[90] and miR-539[92], which are dysregulated by HBV infection. However, Huang *et al*[93] found that STAT3 mediates HBV-induced miR-204 suppression. HBV also activates STAT3 to induce SALL4 expression, while SALL4 suppresses miR-200c expression through directly binding to miR-200c promoter [94]. In addition, STAT3 may mediate the suppression of miR-34a caused by HBx[95].

NF-κB is a transcription factor with broad roles in gene induction in a variety of cellular responses, particularly throughout the immune system. HBV and its proteins have been shown to increase NF-κB content and facilitate its translocation from the cytoplasm to the nucleus[74,96]. Researches show that multiple miRNAs are dysregulated by HBV through modulating NF-κB signaling. For example, HBx and HBc upregulate miR-146a-5p through activating NF-κB signaling[97]. HBx upregulates miR-143[98,99], miR-146a[100] and miR-1269b[74] by activating NF-κB binding to the

DOI: 10.3748/wjg.v29.i31.4706 **Copyright** ©The Author(s) 2023.

Figure 2 Hepatitis B virus modulates microRNAs processing proteins to affect the biogenesis of microRNAs. miRNAs: MicroRNAs.

miRNAs promotor. Meanwhile, inhibitors of NF-κB and PI3K decrease miR-155 in HBeAg-stimulated macrophages, suggesting NF-κB and PI3K mediate HBeAg-induced miR-155 upregulation in macrophages[101]. In addition, NF-κB subunit p50 but not p65 mediates upregulation of miR-942 by LPS through binding to miR-942 promotor, and miR-942 expression is increased with progression of HBV-mediated liver fibrosis, implying a putative regulation of HBV on miR-942[102]. As a consensus p65-binding sequence (AGGGATTTCC) is located in the miR-23a promoter region, p65 dominantly represses miR-23a promoter activity, and suppresses miR-23a transcription[103]. Therefore, HBV has the potential to upregulate miR-23a by suppressing p65 expression. In addition, nuclear IKKα coordinates the transcriptional activity of NF-κB to mediate the expression of miR-7, miR-21, miR-103, and miR-107 caused by HBx[104]. Intriguingly, HBV induced PPARγ to negatively control NF-κB/p65 protein *via* ubiquitination and degradation. Repressed NF-κB/p65 then reduces the endogenous miR-130a expression[105]. The discrepancy in the NF-κB results may be due to the different HBV viral proteins.

Toll-like receptors (TLRs), the main cellular innate immune cell receptor, play crucial roles in immune responses against viral infections, including HBV. Sarkar *et al*[106] find that TLR7 expression is reduced by HBV infection, while TLR7 is able to induce miR-155 through the NF-κB pathway. Considering that HBV suppresses TLR7 and its subsequent signaling pathway including MAPK/Ap-1, NF-κB, IRF3 and IRF7[107], HBV may impact miRNAs expression through regulating TLR proteins and their signaling pathways. In addition, one study finds that HBV upregulates LEF-1, a key component of the Wnt signaling pathway, to induce miR-371a-5p expression through binding with miR-371a-5p promoter[27].

Membrane-initiated estrogen receptor (ER) and androgen receptor (AR) signaling participate significantly in physiology and disease[108]. HBx enhances AR-responsive gene expression[109], and represses ERα responsive gene transcription[110]. Therefore, HBV has the potential to regulate the miRNAs that act as AR or ERα responsive elements. HBx amplified the transcription of pri-miR-216a which is activated as a result of ligand-stimulated AR binding to the ARE site at the 5′ promoter region. However, when applied to AR-negative cells, HBx failed to stimulate an increase in pri-miR-216a[111].

HBV modulates transcription factors to regulate miRNAs

HBV protein and its RNA can modulate the expression of some transcription factors or other proteins, which in turn regulate miRNAs expression (Table 8).

HBV promotes the expression of oncogenic proteins to regulate miRNAs. c-Myc oncoprotein is a transcription factor that regulates numerous physiological processes. Chang *et al*[112] identify 13 miRNAs which are prominently repressed by c-Myc through binding to miRNA promotors. HBV can directly interact with c-Myc and stimulate its expression, thereby affecting the expression of miRNAs. For example, HBx induces c-Myc, and then c-Myc is recruited to a region of miR-192 promotor, which leads to decreased promotor activity, and subsequently downregulates miR-192-3p expression [113]. Similarly, HBx also downregulates miR-15a/16 expression[114], and suppresses let-7 family through c-Myc[115]. In addition, Jung *et al*[116] find that c-Myc mediates HBV-induced miR-17-92 overexpression. c-Myc also binds to the miR-3682-3p promoter, thus HBx may also induce miR-3682-3p expression *via* c-Myc[66]. CREB is an essential subset of phosphorylation-dependent transcription factors. HBx promotes CREB-mediated activation of miR-3188[28]. Similarly,

Table 8 Dysregulated transcription factors or upstream regulatory elements mediates hepatitis B virus-induced microRNAs dysregulation

HBV: Hepatitis B virus; HBx: Hepatitis B virus x protein; HBp: Hepatitis B virus polymerase protein; miRNAs: MicroRNAs.

HBx promotes miR-520c transcription through CREB1[117]. Meanwhile, HBx, survivin and Sp1 form a complex in the promotor of miR-520b, and the interaction between HBx and survivin or Sp1 is indispensable for the regulation of miR-520b[118]. FOXO3 is a transcriptional factor that promotes oncogenesis, HBp can promote the expression of miR-30b-5p through its interaction with FOXO3[119]. Moreover, HBx and TGF-1 induce JNK-dependent activation of c-Jun, which is then recruited to the miR-199a-3p promoter to stimulate its transcription[120].

HBV inhibits the expression of tumor suppressor proteins to regulate miRNAs. Acting as an important tumor suppressor gene, TP53 is the most frequently mutated gene in HBV-related HCC[121]. HBx can decrease the recruitment of p53 to the miR-216b promoter, and then inhibit miR-216b transcription[59]. Another research indicates that HBx can also repress miR-148a *via* suppressing p53-mediated activation[122]. Hepatocyte nuclear factor 4α (Hnf4α), a liver-enriched transcription factor that activates miR-122 gene transcription by binding to its promotor, is found to be repressed by HBV infection in both mRNA and protein levels[123]. Similarly, Hnf4α mediates HBx induced downregulation of miR-548p, possibly through direct binding to the miR-548p promoter[124].

In addition to these transcription factors, HBV also regulates some other proteins to affect miRNAs expression. URG4/URGCP, up-regulated by HBx, can up-regulate 77 miRNAs and down-regulate 9 miRNAs in HepG2 cells[125]. Yuan *et al* [126] find that HBx-induced miR-148a is dependent on oncogenic URG11. HBx also downregulates DDX3, which upregulates miR-34 expression[127]. Meanwhile, one study also identifies 75 miRNAs by ChIP-Seq whose promotor regions are putatively targeted by HBx protein, some of which have been implicated in hepatocarcinogenesis[128].

HBV affects production of miRNAs from their host genes

As the majority of miRNA genes are encoded in the introns of either noncoding or coding regions, multiple studies have demonstrated that only one-third of intronic miRNAs are transcribed from their own promoters. The coregulation of intronic miRNAs with their host genes can be further illustrated by their tissue- or disease-specific co-expression patterns [129].

Some miRNAs are derived from lncRNA precursors, which have the potential to be affected by HBV. LncRNA H19 has been proved to harbor a miRNA containing hairpin in its exon 1, which serves as the precursor for miRNA-675[130]. HBx upregulates H19 expression, leading to a corresponding increase of miR-675[131,132]. Therefore, HBV may affect the LncRNA-derived miRNAs. However, HBx can positively regulate miR-545/374a cluster in the Ftx lncRNA, but fails to regulate miR-421/374b cluster which is also encoded in Ftx introns. Even though miR-374a and miR-545 are transcribed off the same promoter, their abundances are not always correlated[12].

In addition, intronic miRNAs may be coupled with their host genes. miR-26b gene resides in an intron of CTDSP1. They share the same transcription start sites (TSS). miR-26b is therefore transcribed as part of its host transcription unit [133,134]. HBV downregulates miR-26b expression, partly because of the suppression of CTDSP1 mRNA transcription. Notably, the extent of the decrease in miR-26b level was greater than that of CTDSP1 mRNA, implying the other putative

regulatory pathway[135]. Similarly, HBx promotes miR-106b, miR-93, and miR-25 transcription in HCC cells, whose host gene MCM7 is also co-transcribed and upregulated, suggesting that MCM7 activation may be involved in the regulation of these miRNAs by HBV[64].

Notably, despite the fact that some miRNA genes share the promoter of their host gene, the vast majority of miRNA genes have multiple TSS, and the promoters of intronic miRNAs are sometimes distinct from the promoters of their host genes.

HBV participants in epigenetic regulation of miRNAs

Epigenetic mechanisms mainly include DNA methylation, posttranslational histone modifications, chromatin remodeling, ncRNA interactions and RNA modification. Despite the significant involvement of miRNAs in epigenetic regulation, miRNAs are also regulated by epigenetic modifications and involved in diverse human diseases[136]. HBV can regulate epigenetics of miRNAs, leading to the functional disruption of miRNAs and consequently promoting HCC.

HBx has been found to increase the DNA methyltransferase (DNMT) activities and promote regional hypermethylation of specific tumor suppressor genes (TSG)[137]. It has been elucidated that HBx induces DNA hypermethylation of CpG islands in miR-18b[138], miR-30e[139], miR-132[140], and miR-205 promoter[141] to affect their expression. Shang *et al*[89] identify that miR-335, miR-129-2, and miR-203 are repressed by HBV, but are significantly activated by 5-azacytidine, the DNMT inhibitor, indicating that HBV regulates these miRNAs through DNMT-mediated methylation. Meanwhile, Tsang *et al*[142] find that knockdown of HBV-upregulated YY1[89] significantly decreases DNA methylation levels in the miR-9 Loci, leading to an increased miR-9 in HCC cells. Thus, YY1 may mediate the suppression of miRNAs caused by HBV through inducing DNA methylation. Conversely, although HBx leads to overall hypomethylation, HBx highly interferes methylation levels of -550 CpG site in the miR-125a promoter, and therefore triggers miR-125 expression[143]. Further study is needed to elaborate this phenomenon.

As for the histone modification, Guerrieri *et al*[128] verify that HBx decreases H4 acetylation level in the promoter regions of miR-138-2, miR-224, miR-302e, miR-576-3p and miR-596, which may explain their downregulation. Conversely, HBx increases H4 acetylation at the miR-26b promoter. These imply HBx ability to regulate miRNAs by modulating the histone modification of miRNAs promotors[128]. In addition, H3K27me3 is an epigenetic modification to the DNA packaging protein Histone H3[144]. The genomic regions enriched for H3K27me3 can function as silencers to repress gene expression *via* chromatin interactions[145]. Knockdown of HBV-upregulated YY1 reduced not only global H3K27me3 levels, but also EZH2 and H3K27me3 promoter occupancy, leading to the increased miR-9 in HCC cells. It is also found that HBV-upregulated YY1 Leads to EZH2 recruitment for H3K27me3-mediated silencing of tumor-suppressing miRNAs[142], supporting the idea that HBV may indirectly regulate miRNAs through impacting H3K27me3 Levels mediated by EZH2 and YY1.

PPARγ, a ligand-activated transcription factor, is able to form a heterodimer with RXRα. The complex binds to DR1 and DR2 motifs in the miR-122 gene promoter to enhance miR-122 gene transcription, which will be amplified by 5-Aza-CdR (DNA methylation inhibitor) and PBA (histone deacetylation inhibitor). However, this positive regulation is abrogated by HBx which suppresses PPARγ-mediated transactivation through binding to the PPARγ DNA binding domain[146], indicating HBx may affect miR-122 epigenetics through binding and inhibiting PPARγ.

N6methyladenosine (m6A) modification is the most widespread post-transcriptional modification in mammalian mRNAs. MiRNAs can control the expression of m6A regulator, but they are also frequently modified with m6A[147]. HBV infection enhances the expression of METTL3, promotes miR-146a-5p maturation in an m6A-dependent manner [148]. In addition, Gld2 is a cytoplasmic non-canonical poly(A) RNA polymerase that adds successive AMP monomers to the 3'-end of specific RNAs. It can directly monoadenylate specific miRNAs, including miR-122, to stabilize and prolong the activity of miRNAs[149]. HBx also downregulates Gld2 expression, decreasing miR-122 3’ monoadenylation and ultimately suppressing mature miR-122 expression[150].

A variety of endogenous RNAs are able to bind to miRNAs to reduce the number of free miRNAs. These competitive endogenous RNAs (ceRNAs) mainly include lncRNAs and circRNAs, showing an increasing significance in multiple diseases[151]. HBV has been shown to regulate miRNAs through lncRNAs or circRNAs (Table 9). HBV-induced lncRNA-Unigene56159 directly targets miR-140-5p and suppresses its expression[152]. HBV infection also elevates lncRNA PCNAP1 to target miR-154[153]. HBV also enhances LncRNA n335586 to competitively bind with miR-924[154]. Meanwhile, HBx is found to stimulate lncRNA H19 to directly target to miR-138[131] and miR-22[155] through endogenous competition. HBx upregulates TRERNA1, which functions as a ceRNA sponge for miR-22-3p[156]. Additionally, HBx upregulates lncRNA MALAT1 and downregulates miR-124 expression. Further study indicates that MALAT1 directly binds to miR-124[157]. HBx also upregulates HMMR-AS1 and downregulates miR-627-3p expression. And HMMR-AS1 directly targets miR-627-3p[158]. Conversely, HBx inhibits LINC01352, which functions as a tumor suppressor by sponging miR-135b, through binding to the site where ERα binds[159]. HBx also downregulates lncRNA F11-AS1 expression and elevates expression of miR-211-5p, while lncRNA F11-AS1 is capable of binding to miR-211-5p [160]. In HBV-positive HCC cells, LncRNA XIST[161], LINC01232[162] are markedly increased and TFAP2A-AS1[163] are significantly decreased. Further studies show that XIST targets miR-192[161], LINC01232 targets miR-708-5p[162] and TFAP2A-AS1 targets miR-933[163] in HCC, suggesting HBV may dysregulate these miRNAs through lncRNAs. Similarly, HBV may downregulate LINC00924 expression, while LINC00924 interacts with miR-6755-5p, suggesting a potential HBV/ LINC00924/ miR-6755-5p regulatory axis[164]. HBx also promotes the progression of HCC through translocation and secretion of HMGB1, as a sponge to competitively bind the miR-200 family, *via* calcium dependent cascades[165,166]. Therefore, HBx may affect miR-200 expression through HMGB1.

HBV also regulates circRNAs to affect miRNAs (Table 9). HBx upregulates METTL3 expression to increase the m6A modification of circ-ARL3, and further favors circ-ARL3 reverse splicing and biogenesis. circ-ARL3 binds to miR-1305, antagonizing the inhibitory effects of miR-1305 on target oncogenes[167]. HBV also upregulated Circ-RNF13, as a sponge

for miR-424-5p[168]. HBV upregulates Circ-BACH1, which sponges miR-200a-3p to reduce its expression[169]. Meanwhile, HBV upregulates Circ-ATP5H expression, while Circ-ATP5H directly targets miR-138-5p[170]. In HBV-positive HCC cells compared to HBV-negative HCC cells, circ_0027089 is markedly increased and specifically binds to miR-136-5p[171].

HBV sponges miRNAs to inhibits miRNAs' function

In addition to the lncRNAs and circRNAs, ceRNAs also include viral RNAs and host mRNAs[151]. HBV RNA could function as sponges to directly bind with miRNAs. Studies have implicated that HBV RNA may dysregulate miRNAs by binding to the complementary binding sites of miRNAs and depletion of miRNAs (Table 9).

HBV mRNAs, including pre-C/C (pgRNA), pre-S, S 3'-UTR, and X mRNAs, act as sponges to bind and sequester miR-15a/16-1, subsequently resulting in a depletion of miR-15a/16-1[172,173]. Li *et al*[174] validate that HBV mRNAs (pre-C/C (or pgRNA), pre-S, S 3'-UTR, and X mRNAs) can sponge miR-122 to inhibit its expression and function. Deng *et al*[175] identify that there is a let-7a complementary region in the HBV genome in HBV pre-C/C, pre-S, and S mRNAs. Notably, HBV regulates downstream targets of let-7a in a sequence-dependent manner. In addition, HBV transcripts harboring the preS2 region, such as HBV large S mRNA, can almost entirely interact with let-7g and subsequently promote HCC[176]. Ochi *et al*[177] find that HBx mRNA has complementary sequences with the central region of miR-129-5p, HBx mRNA interacts with the responsive element in the 3' UTR of miR-129-5p and sequesters it from forming a complex with Ago2. It is noted that the abundances of viral RNAs may affect their regulation on miRNAs. Although HCV 5'UTR may be able to

bind miR-122, it fails to change miR-122 expression like HBV mRNAs do. This discrepancy may be due to the fact that HCV mRNAs copy numbers are much less than miR-122, while HBV mRNAs copy numbers are more than miR-122[174]. Besides, HBV RNA copies per cell are much higher than those of let-7a[175], which may be essential for HBV RNA sequestration.

Of note, HBV genome gene is frequently inserted to host genes, which may lead to the transcription of the integrated virus-human chimeric fusion. It is exemplified by the discovery of a novel chimeric HBx-LINE1 RNA, which is generated from a normally silenced region of chromosome 8p11.21 after HBV integration[178]. Functioning as a long noncoding RNA (lncRNA)-like transcript, HBx-LINE1 sequesters cellular miR-122 by directly absorbing it, which ultimately leads to the depletion of miR-122[178,179].

HBV affects miRNAs through autophagy

Autophagy is the major intracellular degradation system and plays a pivotal role in multiple physiological processes [180], some of which have been delineated to function through modulating specific miRNAs. Majority of existing works have shown that HBV is able to induce autophagy. However, Lan *et al*[181] find that HBx transgenesis leads to a lower autophagic level, and miR-224 is preferentially recruited and degraded through autophagic progression. In addition, the selective autophagy receptor NDP52 targets Dicer and Ago2 proteins for the degradation. Autophagy is required for miRNA homeostasis and activity. Moreover, autophagy participates in the posttranscriptional regulation of Dicer mRNA, and chronic autophagy deficits impair miRNA stability after pre-miRNA processing[182]. Therefore, HBV has the potential to affect autophagy to disrupt the homeostasis of miRNAs biogenesis.

C-terminal truncated HBx and HBV integration may affect the ability of HBV in inducing dysregulation of miRNA

Carboxyl-terminal truncated HBx proteins (Ct-HBx, also called HBxΔC or trHBx) are variants transcribed from the mutant HBV X gene whose 3′-end are deleted during HBV genome integration into the host cells. Ct-HBx plays a pivotal role in hepatocarcinogenesis[183,184]. Ct-HBx regulates specific miRNAs more effectively than full-length HBx (HBx-FL). For instance, HBx-D35 enhances miR-21 promoter occupancy and upregulates miR-21 expression compared to HBx-FL [91]. HBxD127 also remarkably increases miR-215 expression relative to HBx[185]. A possible explanation is that C-terminal truncation may affect the binding of HBx to cellular proteins, resulting in altered miRNA gene expression patterns in cells[184]. Notably, Ct-HBx directly binds to some miRNAs promotors, such as miR-26a and miR-29c, resulting in direct transcriptional suppression which HBx-FL is unable to induce. The reason for this discrepancy may be that HBx-FL and Ct-HBx bind to different chromatin binding regions of miRNAs[186]. However, not all miRNAs are under this regulation. miR-23a and miR-27a are concordantly regulated by both HBx-FL and Ct-HBx, and their binding regions are similar[186]. For miR-146a, Ct-HBx does not lead to the same elevation as HBx-FL does[187].

HBV pre-S2 mutant protein may also play a role in the dysregulation of miRNA. HBV pre-S2 mutant induces endoplasmic reticulum stress and the mTOR signal cascade in transgenic livers and HCC tissues[188,189]. Meanwhile, Mdm^2-dependent ubiquitinoylation of Drosha by mTOR activates miRNA synthesis and controls many cancer-related miRNAs[190]. Since PreS/S proteins initiate a cascade of events that lead to malignancy[189], it's worth to investigate whether PreS mutant dysregulates miRNAs.

Considering HBV integration severely disrupts host cellular gene expression, genomic loci containing miRNA sequences inserted by HBV may impact miRNA expression. It has been found that HBV DNA integration into fragile sites may alter the expression of a couple of miRNAs which are located in or near fragile sites, including miR-200a near FRA1A, miR-143, miR-145 and miR-224 near FRA5C, miRNA-17–92 cluster near FRA13D, miR-195 near FRA17A, miR-99b, miR-125a and let-7e near FRA19A, and miR-199a-1 near FRA19B[191-193]. These miRNAs have been documented in HCC[191], and there are still a great many miRNAs that are potentially dysregulated by HBV integration[192].

In addition, Yang *et al*[194] also find miR-602 is upregulated by HBV or HBx, and they speculate that the chromosome 9q34.3 containing miR-602 sequence is commonly integrated by HBV, which may lead to increased miR-602 expression. Similarly, Guo *et al*[195] speculate that HBV-induced chromosome instability caused by HBV integration may play a role in promoting the miRNAs-371-3 gene cluster expression. Further study is needed to support this hypothesis. Therefore, HBV DNA integration may alter miRNA expression, but the underlying mechanism requires additional study.

MECHANISMS OF HBV DYSREGULATED MIRNAS IN PROMOTING HCC

By dysregulating miRNAs, HBV exacerbates its function in the oncogenesis of HCC. Currently, multiple reviews have summarized the essential role of HBV-dysregulated miRNAs in affecting tumor cell cycle, cell proliferation, cell apoptosis, cell migration and invasion, and epithelial-mesenchymal transition (EMT)[6,196-199]. Therefore, we provided an updated supplementary list of miRNAs dysregulated by HBV and involved in these processes (Supplementary Tables 1 and 2), which will not be elaborated here. In this section, we discuss the role of HBV-dysregulated miRNAs in the tumor stemness, metabolic reprogramming, anti-tumor immunity, and tumor drug resistance of HCC, which may shed light on potential treatment approaches (Table 10 and Figure 3).

Dysregulated miRNAs promote tumor stemness

Liver cancer stem cells (CSCs) are a distinct population of HCC cells with stem cell characteristics, defining a hierarchical structure and contributing to treatment resistance and tumor recurrence. HBV is one of the most prominent players in liver CSCs. miRNAs partially mediate the stemness progression[200] (Table 11).

Table 10 Functions of hepatitis B virus-dysregulated microRNAs in promoting hepatocellular carcinoma

miRNA	HBV protein	Expression	Target genes	Abnormal function in HBV-HCC	Ref.
miR-7	HBV, HBx	Up	Mapsin	Conferring HBx-mediated anoikis resistance and doxorubicin resistance	[213]
miR-15a/16	HBV mRNA	Down	-	Inducing etoposide-induced apoptosis	[173]
miR-21	HBV, HBx	Up	Mapsin	Conferring HBx-mediated anoikis resistance and doxorubicin resistance	[213]
miR-23a	HBV	Down	CCL22	Inhibiting Tregs recruitment	[103]
miR-30b-5p	HBp	Up	MINPP1	Promoting tumor growth, enhancing cell proliferation, promoting cell migration and invasion, regulating glycolytic bypass metabolism	[119]
miR-34a	HBV	Down	CCL22	Inhibiting Tregs recruitment	[209]
miR-103	HBV, HBx	Up	Mapsin	Conferring HBx-mediated anoikis resistance and doxorubicin resistance	[213]
miR-107	HBV, HBx	Up	Mapsin	Conferring HBx-mediated anoikis resistance and doxorubicin resistance	[213]
miR-124	HBx	Down	PI3K/Akt	Suppressing CSC differentiation	[157]
miR-135a-5p	HBc	Up	VAMP2	Preventing Doxorubicin hydrochloride-induced apoptosis	[212]
miR-138	HBV	Down	PD-1	Regulating cytokine secretion of T cells and improving T-cell immune responses	[208]
miR-146a	HBV	Up	STAT1	Suppressing IFN-induced anti-HBV effect	[187]
miR-152	HBV	Down	HLA-G	Enhanced NK cytolysis against hepatoma cells	[210]
miR-193b	HBV	Down	Mcl-1	Sensitizing sorafenib-induced apoptosis	[57]
miR-200a/200b/429	HBx	Down	RICTOR	Impairing HCC stem cell properties, regulating glutamine metabolism, sensitizing the response to anti-PD-L1 immuno-therapy	[165, 166]
miR-203a	HBs	Down	BMI1	Sensitizing 5-FU-induced apoptosis, impairing HCC stem cell properties	[58]
miR-205	HBx	Down	ACSL1	May promote lipogenesis	[141] [206]
miR-325-3p	HBV	Down	DPAGT1	Sensitizing the response to Doxorubicin chemotherapy	[201, 202]
miR-329	HBV, HBx	Down	AFP	Sensitizing chemotherapy induced apoptosis	[214]
miR-384	HBV, HBx	Down	PTN/PI3K/AKT/mTORC1	Inhibiting high glucose-induced lipogenesis	[61]
miR-429	HBx	Down	Rab18	Inhibiting dysregulation of lipogenesis	[205]
miR-1236	HBV, HBx	Down	AFP	Sensitizing chemotherapy induced apoptosis	[214]
miR-3682-3p	HBx	Up	FOXO3/PI3K/AKT1/β-catenin/c-Myc	Promoting HCC stemness	[66]
miR-5188	HBx	Up	FOXO1/β-catenin	Resisting the effects of chemotherapy 5-FU, CDDP and EPI, promoting HCC stemness	[67]

HBV: Hepatitis B virus; HBx: Hepatitis B virus x protein; HBp: Hepatitis B virus polymerase protein; HBc: Hepatitis B virus core antigen; HBs: Hepatitis B virus surface antigen; HCC: Hepatocellular carcinoma; miRNAs: MicroRNAs.

In HCC cells, the expression of CD44, CD133, and EpCAM is markedly reduced by miR-124, indicating the pivotal effects of miR-124 in suppressing CSCs differentiation. HBx downregulates miR-124, and may therefore interfere CSCs differentiation[157]. In one research, HBx supports the progression of HCC *via* translocation and secretion of HMGB1, which regulates RICTOR expression in HCC by competitively binding to the miR-200 family[166]. Both HMGB1 and RICTOR mRNAs can augment HCC stemness characteristics in HCC[165]. HBsAg inhibits the expression of miR-203a in HCC cells. miR-203a decreases the proportion of CD133-positive HCC cells but not CD90, and it also significantly lowers

Table 11 Hepatitis B virus-dysregulated microRNAs that play different roles in hepatitis B virus-associated hepatocellular carcinoma

Process	HBV-dysregulated miRNAs
Tumor stemness	miR-124[157], miR-200a/200b/429[165], miR-203[58], miR-325-3p[201], miR-3682-3p[66], miR-5188[67]
Metabolic reprogramming	miR-30b-5p[119], miR-200[165], miR-205[141,206], miR-384[61], miR-429[205]
Anti-tumor immunity	miR-23a[103], miR-34a[209], miR-138[208], miR-146a[187], miR-152[210], miR-200[165,166]

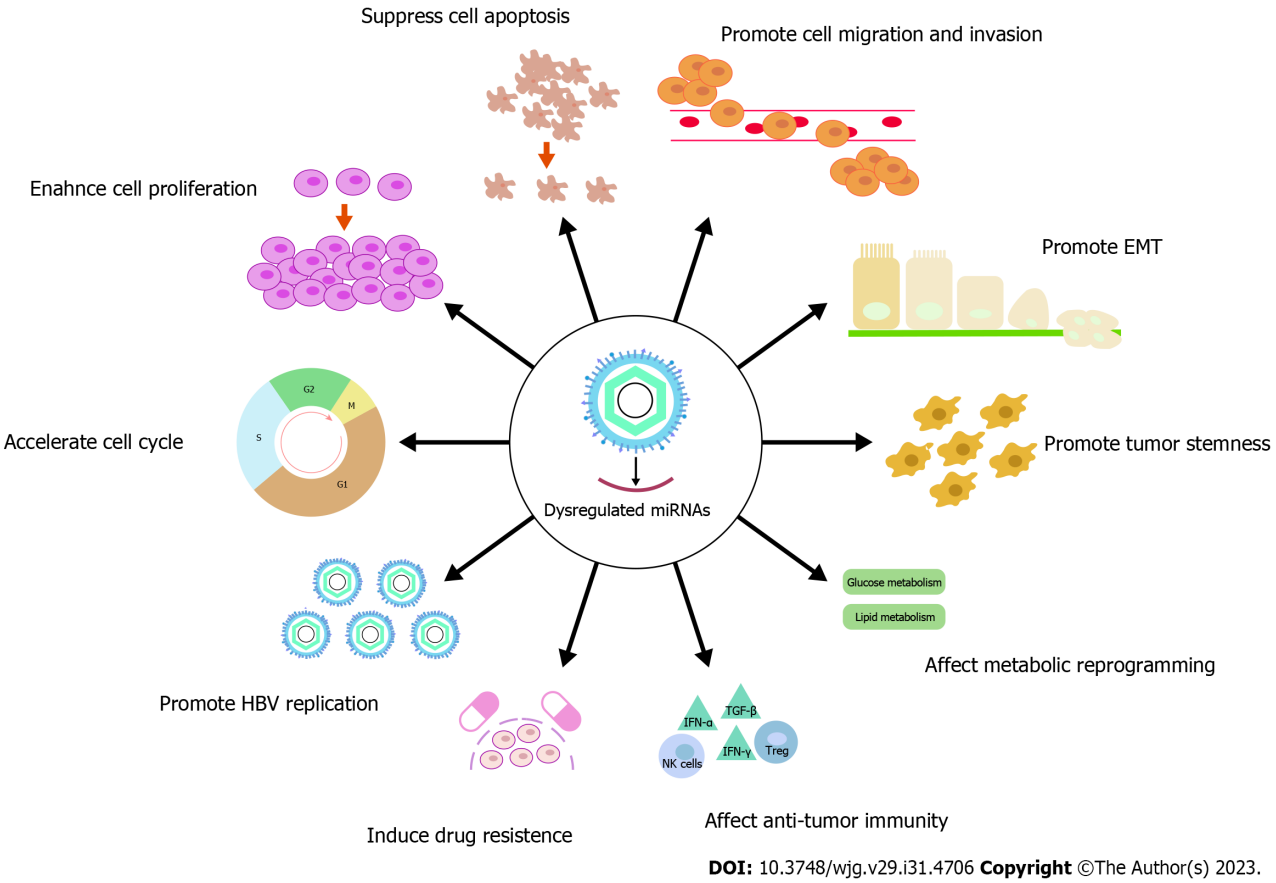

Figure 3 Mechanisms of hepatitis B virus dysregulated microRNAs in promoting hepatocellular carcinoma. miRNAs: MicroRNAs; HBV: Hepatitis B virus; EMT: Epithelial-mesenchymal transition.

the average percentage of ALDH-positive malignant stem cells. Therefore, HBV infection may promote the stemness of HCC *via* regulating miR-203a[58]. HBV also inhibits miR-325-3p[201], which suppresses the expression of critical stemness markers, including SOX-2, Nestin, Notch-1, OCT4, and Nanog. miR-325-3p/DPAGT1 may presumably have a role in HBV-induced HCC stemness[202]. In addition, miR-3682-3p mediates the oncogenic consequences of HBx-induced PI3K/AKT/c-Myc signaling. HBx increases stemness by elevating miR-3682-3p expression[66]. Meanwhile, miR-5188 directly targets FOXO1, which inhibits the nuclear translocation of β-catenin and promotes Wnt signaling activation and downstream tumor stemness. HBx modulates the miR-5188/FOXO1/β-catenin/c-Jun feedback loop to drive Wnt/β-catenin activation, subsequently promoting HCC stemness[67].

Dysregulated miRNAs affect metabolic reprogramming

Metabolic reprogramming plays a crucial role in the initiation and progression of cancer. A few studies have revealed that HBV affects the process of HCC by regulating metabolism (Table 11). Aerobic glycolysis is a distinguishing feature of HCC and is responsible for regulating proliferation, immune evasion, invasion, metastasis, and drug resistance in HCC [203]. The miR-30b-5p/MINPP1 axis is capable of accelerating the conversion of glucose to lactate and 2,3-bisphosphoglycerate (2,3-BPG), as well as regulating the glycolytic bypass to generate more 2-PG for energy supplementation. HBV

protein P (HBp) regulates the miR-30b-5p/MINPP1 axis, contributing to the development of HBV-positive HCC cells *via* glycolytic bypass[119]. RICTOR regulates glutamine metabolism *via* mTOR signaling[165]. HBx stimulates the translocation and secretion of HMGB1[166], which regulates RICTOR expression in HCC by binding competitively to the miR-200 family. Therefore, HBx may affect miR-200 to dysregulate glutamine metabolism. As for lipid metabolism, changes in fatty acid synthesis, β-oxidation, and cellular lipidic composition contribute to hepatocarcinogenesis[204]. HBx inhibits miR-384 and upregulates its target PTN expression, while PTN promotes hepatoma cell lipogenesis[61]. Knockdown of Rab18b decreases the lipogenesis. HBx activates Rab18 through downregulating miR-429. Therefore, HBx could enhance hepatocarcinogenesis by leading to the dysregulation of lipogenesis *via* the miR-429/Rab18 axis[205]. Meanwhile, HBx inhibits miR-205 expression[141], and miR-205 inhibits lipogenesis in hepatoma cells dependent on ACSL1, suggesting that HBx inhibits miR-205 to promote lipogenesis[206].

Dysregulated miRNAs affect anti-tumor immunity

It is widely acknowledged that HBV causes chronic liver damage through aberrant immunological reactions. During chronic HBV infection in humans, adaptive immunity transitions may be immune pathogenic factors for the development of HCC[207]. A number of research have revealed the function of miRNAs in HBV-induced immunological dysregulation (Table 11). HBV infection increases the expression of miR-146a, which impairs the IFN-induced anti-HBV immune response. Additionally, inhibition of miR-146a improves IFN-α-mediated anti-HBV efficacy[187]. In HBV-HCC patients, miR-138 is significantly higher than in asymptomatic carriers. By targeting the 3'-UTR region of PD-1, miR-138 alters its expression directly. miR-138 exerts its regulatory effects on T-cell cytokine production by suppressing PD-1 expression [208].

HBV also represses some miRNAs to affect anti-tumor immunity. One study finds that HBV-elevated CCL22 induction is mediated by transcriptionally repressing miR-23a. It is hypothesized that the axis of p65/miR-23a/CCL22 is present in the HCC cells and may drive tumor progression by recruiting Tregs, particularly when HBV infection was involved[103]. In HBV-expressing HepG2.215 cells, miR-34a is downregulated, while suppressed miR-34a leads to enhanced production of chemokine CCL22, which recruits Tregs to facilitate immune escape[209]. In addition, HLA-G, which inhibits different kinds of immune cells directly, such as NK, is downregulated by miR-152 in hepatoma cells. HBV inhibits miR-152 and increases the expression of its target HLA-G, which may further suppress NK against cancer cells[210]. Additionally, mRNAs of HMGB1 regulated by HBV and RICTOR regulated by HMGB1 mediated by miR-200[166] inhibit the response to anti-PD-L1 immunotherapy in HCC by elevating PD-L1+ exosomes[165].

Dysregulated miRNAs promote tumor drug resistance

Chemoresistance, resulting in cancer relapse and spread, is frequently mentioned as the largest cause of cancer therapeutic failure. In HCC, HBV commonly drives chemoresistance[211]. Accumulating evidence implicates the role of miRNAs in HBV-driven chemoresistance of HCC (Table 11).

HBc upregulates miR-135a-5p to suppress VAMP2 expression, blocking doxorubicin hydrochloride-induced apoptosis in HCC[212]. Similarly, HBV-upregulated miR-5188 Leads to an increase in resistance to the chemotherapy drugs 5-FU, cisplatin, and pharmorubicin[67]. Meanwhile, it is inferred that HBx elevates miR-7, -103, -107, and -21 expression to downregulate their target mapsin. Silencing maspin boosts HCC resistance to doxorubicin and other chemotherapeutic drugs[213]. These miRNAs may contribute to HBV-induced resistance to chemotherapy.

For some anti-tumor miRNAs, HBV suppresses their expression to promote HCC drug resistance. HBV mRNA can directly sponge miR-15a/16 and inhibit the subsequent cascade of etoposide-induced apoptosis in hepatoma cells[173]. miR-193b is downregulated in HBV-positive cells and tissues. Recent research shows that it increases the sensitivity of HCC cells to sorafenib by suppressing the expression of the anti-apoptotic protein Mcl-1[57]. miR-203a reduces HCC cell viability after 5-fluorouracil (5-FU) treatment and also increases the apoptosis rate of HCC cells in response to 5-FU[58]. HBV suppresses miR-203a expression, and subsequently renders HCC cells resistant to chemotherapy drug-induced apoptosis. HBV inhibits miR-325-3p[201], which remarkably increases chemosensitivity to doxorubicin in HCC cells[202]. Similarly, HBV negatively regulates miR-329 and miR-1236 to elevate their target AFP expression, while AFP further attenuates the proapoptotic effect of chemotherapy agents cisplatinum[214].

At present, the research on HBV-dysregulated miRNAs to enhance drug resistance in HCC is in its infancy. It has been discovered that miRNA promotes tumor treatment resistance through targeted regulation of multiple drug-related genes and DNA damage repair-related genes[215]. Therefore, more in-depth studies are needed.

Dysregulated miRNAs promote HBV replication to perpetuate its infection

The majority of HBV-infected patients have strong viral replication. By promoting self-replication, HBV maintains a high titer and promotes hepatocarcinogenesis. The complex relationship between HBV replication and miRNA has been described in a number of reviews[53,199,216]. We have enumerated the currently known miRNAs dysregulated by HBV that regulate HBV replication in the Supplementary Tables 1 and 2. Intriguingly, HBx upregulates miR-125a-5p expression[217], which interferes with expression of HBV surface antigen[218]. HBV may modulate miRNAs to restrict self-replication, therefore maintaining a long period of existence.

Others

DNA hypermethylation is responsible for suppressing TSGs in hepatocarcinogenesis. The inhibition of miR-101 by HBx leads to an increase in DNMT3A expression, while miR-101 inhibition or overexpression drastically affects the mRNA expression of different TSGs, demonstrating that miR-101 operates upstream to enhance TSG expression[219].

During the process of metastasis, cancer cells detaching from extracellular matrix (ECM) acquire the ability to persist in circulation by evading anoikis-induced cell death[220]. It is found that HBx induces miR-7, -103, -107, and -21 to suppress maspin expression, while maspin downregulation conferes HBx-mediated anoikis resistance in HCC cells[213]. Therefore, it can be speculated that these miRNAs may similarly confer HBx-mediated anoikis resistance.

In addition to directly affecting tumor cells, miRNA can indirectly accelerate the development of HCC *via* acting on other liver cells. Exosomal miR-142-3p from HBV-positive cells induces ferroptosis in HBV-infected M1-type macrophages *via* SLC3A2[221]. Similarly, exosomal miR-222 from HBV-infected hepatic cells boosts LX-2 cell activation by suppressing TFRC-induced ferroptosis, which ultimately exacerbates liver fibrosis[222]. Besides that, HBx-elevated P4HA2 enhances the collagen deposition in the liver *in vivo* and *in vitro* by inhibiting miR-30e, leading to liver fibrosis and liver cancer progression[139]. Moreover, HBx and TGF-β1 exposure induces the upregulation of miR-199a-3p, which contributes to the malignant transformation of hepatic progenitor cells (HPCs)[120]. As HPCs have the capacity to generate HCC with the cooperation of HBx and AFB1 in the liver microenvironment, this may provide new insight of HBV promoting HCC[223].

FUTURE PROSPECTS - CHALLENGES AND POTENTIAL CLINICAL USE OF MIRNAS IN DIAGNOSIS AND TREATMENT OF HBV-HCC

Due to the significant changes of miRNA in bodily fluid and tissues of HBV-HCC, its utility as a biomarker for the diagnosis of HCC incidence and prognostic risk has been extensively evaluated. However, since the PLR of miRNAs diagnosing HBV-HCC is less than 10 and the NLR is greater than 0.1[41,42], the clinical use of miRNAs for detecting HBV-HCC may still be limited. Traditional techniques for detecting miRNAs include Northern blotting, quantitative reverse transcription polymerase chain reaction (qRT-PCR), next-generation sequencing, and microarray-based hybridization[7,224]. However, quantifying miRNA in a dependable and robust manner can be challenging, and these methods may involve significant trade-offs between cost, complexity, and efficacy[7,224]. Therefore, using standardized measurements with unified standards will facilitate the collection of trustworthy miRNA data that can be compared across institutions[7]. It is crucial to minimize the influence of confounding factors, such as measurement technical characteristics, when detecting miRNA. Additionally, novel miRNA detection assays, such as miRacles which utilize conformationally responsive DNA nanoswitches, have been proved to be a simple, inexpensive, and accurate method for detecting miRNAs[224]. With the continuous development of new materials, it is anticipated that the miRNAs detection technology will increase in precision and sensitivity while decreasing in cost and operational complexity.

In addition to their use as diagnostics, miRNAs have significant promise for prognostication. Current relevant research has focused on miRNAs to predict the risk of recurrence, OS, and DFS in patients with HBV-HCC. There are few studies and insufficient data on circulating miRNAs. As circulating miRNAs offer numerous advantages, such as being convenient, safe, and noninvasive, their potential as biomarkers can be exploited further. For instance, miRNAs can be used to predict or evaluate the efficacy of neoadjuvant chemotherapy[225], radiotherapy[226], and immunotherapy[227] in cancer patients. Hence, miRNAs have the potential to anticipate therapeutic efficacy in HBV-HCC, which warrants further investigation.

Since HBV-dysregulated miRNAs play a significant role in hepatocarcinogenesis, miRNAs can be used as viable alternative therapeutic targets. Despite the fact that miRNA delivery to specific locations is hampered by many challenges, several techniques, such as conjugation, virus-associated delivery, and nanoparticles, have been researched to improve the efficacy of miRNA delivery[8]. In fact, multiple miRNA-based therapeutics have entered the clinical phase of cancer therapy. The combination of miRNAs therapy with chemotherapy, radiotherapy, and immunotherapy has shown encouraging outcomes against different malignancies[215]. Unfortunately, there is no relevant clinical research on the use of miRNAs in the treatment of HCC. Given that miRNAs play a crucial part in the occurrence and progression of HBV-HCC, the approaches of combining diverse strategies, applying complementary miRNAs together, or inventing new forms of miRNAs may bring considerable clinical benefits for HBV-HCC patients. To reach the ultimate objective of enhancing patient OS and DFS, additional research is required in this area.

CONCLUSION

HBV dysregulates miRNAs in multiple ways, thereby contributing to the occurrence and progression of HCC. Consequently, miRNAs are anticipated to become HBV-HCC biomarkers for diagnosis and prognosis. miRNAs-based therapies may also improve the efficacy of HBV-HCC. More research is required for miRNA clinical transformation.

Abstract

Diabetes is a highly prevalent disease that was initially simplified into three major types: Type 1, type 2 and gestational diabetes. With the global rise in incidence of acute pancreatitis (AP), a lesser-known type of diabetes referred to as diabetes of the exocrine pancreas (DEP) is becoming more recognized. However, there is a poor understanding of the inherent relationship between diabetes and AP. There is established data about certain diseases affecting the exocrine function of the pancreas which can lead to diabetes. More specifically, there are well established guidelines for diagnosis and management of DEP caused be chronic pancreatitis. Conversely, the sequelae of AP leading to diabetes has limited recognition and data. The purpose of this review is to provide a comprehensive summary of the prevalence, epidemiology, pathophysiology and future research aims of AP-related diabetes. In addition, we propose a screening and diagnostic algorithm to aid clinicians in providing better care for their patients.

Key Words: Acute pancreatitis; Type 3c diabetes; Diabetes of the exocrine pancreas; Sequelae of acute pancreatitis; Screening and diagnostic algorithm

Core Tip: Acute pancreatitis (AP)-related diabetes has limited recognition and data. The disease occurs more often than previously recognized and patients are often misdiagnosed with type 2 diabetes. The purpose of this review is to provide a comprehensive summary of the prevalence, epidemiology, pathophysiology and future research aims of AP-related diabetes. In addition, we propose a screening and diagnostic algorithm to aid clinicians in providing better care for their patients.

INTRODUCTION

Acute pancreatitis (AP) is a condition defined by rapid onset pancreatic inflammation that is short-lived and may be associated with local and systemic complications[1]. Alcohol use and gallstones are the most common etiologies, which may explain its standing as one of the leading gastrointestinal diseases requiring hospitalization in the United States[2]. The severity of AP is graded based on the presence or absence of local complications, systemic complications, and persistent organ failure. Patients with mild disease recover with supportive care alone while those with severe disease may experience prolonged hospitalization and require procedural interventions to treat various complications. The severe form of the disease occurs in 20% of all patients with AP and carries a mortality rate as high as 30%-40%[1,3]. Following a single episode of AP, all patients are susceptible to the potential sequela of the injury sustained by the pancreas regardless of the severity of the episode[4]. The complication acquiring interest of late is new-onset diabetes mellitus (DM) after AP.

Diabetes is a term used to classify a group of diseases characterized by persistent hyperglycemia that afflicts 37 million adults in the United States alone. Type I diabetes (T1D) accounts for 5%-10% of the total prevalence of diabetes and is hypothesized to be a consequence of autoimmune destruction of beta cells, resulting in inadequate insulin levels[5]. The most common form of diabetes, type II DM (T2DM), is caused by insufficient insulin secretion by pancreatic beta cells and progressive development of insulin resistance (IR). Persistent impairment in glucose control may also be promoted by diseases of the exocrine pancreas, including AP[6]. This form of diabetes has been referred to as type 3c diabetes or diabetes of the exocrine pancreas (DEP)[6,7].

Hyperglycemia during AP was previously speculated to be a transient event that resolved as the inflammatory process improved[4]. Recent meta-analyses have questioned this notion by showing evidence of a high incidence of AP-related DM[4]. Two meta-analyses found 15%-23% of patients developed new-onset diabetes following a single episode of AP and the remaining patients had greater than a two-fold risk of diabetes over five years[8,9].

The various pancreatic diseases known to potentially cause DEP are often grouped together despite this collection encompassing multiple distinct conditions that should be further investigated on an individual basis. The unique mechanisms in which these conditions cause damage to the pancreas is important to take into consideration as they may allow for specific therapeutic options, change screening recommendations, and affect the length of time to diabetes. AP in particular, the most common disease of the exocrine pancreas, warrants further discussion. The goal of this review is to summarize the prevalence and pathophysiology of DEP after episode(s) of AP, elucidate diagnostic criteria for AP-related DM and identify risk factors of those at highest risk of developing the complication. We will also suggest management and screening recommendations, including the emergence of potential new ways to diagnose AP-related DM and identify areas for further study.

PREVALENCE OF DM AFTER AP

In the United States, AP is estimated to account for approximately 275000 hospital admissions and $2.5 billion in healthcare costs annually[10]. A meta-analysis of the global incidence of AP from 1961 to 2016 found the incidence of AP has been increasing over time. Select populations were noted to have disproportionate rises in incidence especially throughout the majority of countries within the Western world, including North America, Europe, and Oceania[3]. One study aimed at determining the global incidence of AP reported the countries with the greatest incidence of AP in 2019 were India, China, and the United States. Alcohol was found to be an important cause of increased morbidity and mortality. The study also uncovered the existence of significant differences in the burden of AP across geographic regions and differences in outcomes based on socioeconomic factors. For example, patients admitted to smaller hospitals with fewer resources were noted to have a higher risk of pancreatitis-related mortality[10].

The lesser-known sequelae of AP are the development of endocrine and exocrine insufficiency, which in turn can contribute to the development of diabetes. All patients are susceptible to these effects, even those with a mild case of AP and after a first-time episode[11]. In one cohort study, exocrine pancreatic dysfunction was associated with significantly increased risk for new-onset DM, including when the analysis was limited to mild AP[12]. A systematic review and meta-analysis from May 2019 found the incidence of AP-related DM was 23% and new onset insulin dependent DM (IDDM) was 15%. The incidence of DM was higher for severe AP (SAP) compared to mild AP, pancreatic necrosis compared to without, and alcoholic compared to biliary AP. The incidence of IDDM after SAP was 21% and 18% following an episode

of alcohol-related AP. Within five years of the initial episode of AP, the rate of DM and IDDM was 20% and 14%, respectively. The rate of DM and IDDM after AP increased to 37% and 25%, respectively[9]. Another study demonstrated similar findings of the development of endocrine and exocrine insufficiency despite severity of AP, number of or time from episodes of AP, gender, and etiology. However, there was a statistically significant difference in the prevalence of DM when patients with SAP were compared with non-SAP[12].

PATHOPHYSIOLOGY

Ongoing investigations have proposed multiple mechanisms believed to contribute to the development of AP-related DM. These mechanisms presumably occur in parallel and it is unknown which mechanism has the greatest impact. Prior to further discussing the theories it is important to understand the roles of the individual cell types of the pancreas and where they reside. This will aid in demonstrating the clinical implications of their malfunction or loss.

The pancreas consists of two tissue types which give rise to the distinct actions of the pancreas, the exocrine and endocrine functions. Exocrine tissue makes up an estimated 95% of the pancreas and produces enzymes necessary for digestion. The remaining tissue is made up of special endocrine cells embedded within the exocrine pancreas that are collectively known as the islets of Langerhans[13]. This collection consists of four cell types that play exclusive roles in regulating glucose levels and pancreatic secretions: Alpha cells, beta cells, pancreatic polypeptide (PP) cells and delta cells. Alpha cells release glucagon and make up 15% of the total islet cell volume in the anterior portions of the pancreas (head, body and tail). Glucagon is important in preventing hypoglycemia through several well-known mechanisms. Insulin-releasing beta cells make up 80% of the islet volume in the anterior pancreas and 20% of the volume in the posterior head. Insulin regulates glucose by promoting uptake and storage of glucose in the liver, muscle and adipose tissue. The hormone also regulates the action of alpha cells through paracrine inhibition. PP cells make up 80% of the islet volume in the posterior head and have a small presence (< 1%) in the anterior portions of the pancreas. They produce PP, which enhances the effect of insulin on the liver. Delta cells have a small overall existence, contributing to < 1% of islet volume in the posterior head and 5% in the anterior pancreas. Nevertheless, they are essential for their release of somatostatin which has multiple functions throughout the body. In the gastrointestinal system, somatostatin is important for regulating the release of glucagon and insulin through paracrine inhibition. The hormone also slows both gastric emptying and nutrient absorption from the intestinal tract[7].

MECHANICAL DESTRUCTION OF THE PANCREAS *VS* LOSS OF ISLET MASS

Unlike T1D and T2DM, DEP is a consequence of damage to the pancreas that affects all of the highly specialized cells of the organ. Based on this observation and previous data showing a higher incidence of DEP in patients suffering from necrotizing pancreatitis compared to those without necrosis, a correlation between the extent of loss of islet cells and the risk of developing AP-related DM has been suggested[9]. This inference has been further substantiated by evidence that patients with T1D and T2DM have decreased pancreatic volume compared to non-diabetics[14]. Nevertheless, emerging evidence indicates the overall pathogenesis is likely more complicated and requires more investigation. One systematic review examining the risk of developing DM after partial pancreatectomy found the incidence of new-onset DM was significantly different between various types of resection. Those who underwent a distal pancreatectomy had the highest incidence of developing DEP followed by patients who underwent a Whipple. Patients who underwent a central pancreatectomy had the smallest incidence[15]. A study by Tu *et al*[16] reports that in comparison to necrosis in the head and body of the pancreas, necrosis in the tail was associated with a greater risk of developing diabetes. Others also report that surgical resection of up to 50% of the pancreas did not necessarily lead to diabetes[14]. These new findings may explain why the severity of AP does not necessarily positively correlate with the risk of developing AP-related DM.

DYSFUNCTION OF THE EXOCRINE PANCREAS

Damage to the exocrine pancreas may contribute to endocrine dysfunction through mechanisms still undergoing analysis. When chronic pancreatic exocrine disease occurs, findings of decreased pancreatic endocrine function including islet function and insulin secretion can be seen. For example, one of the results of chronic pancreatitis is damage to nerve bundles, specifically vagal afferents, which are necessary for PP secretion. Volume loss within the posterior head of the pancreas, in which resides the majority of PP cells, further exacerbates the reduction in insulin secretion. Significant pancreatic endocrine dysfunction can thereby lead to DEP[14].

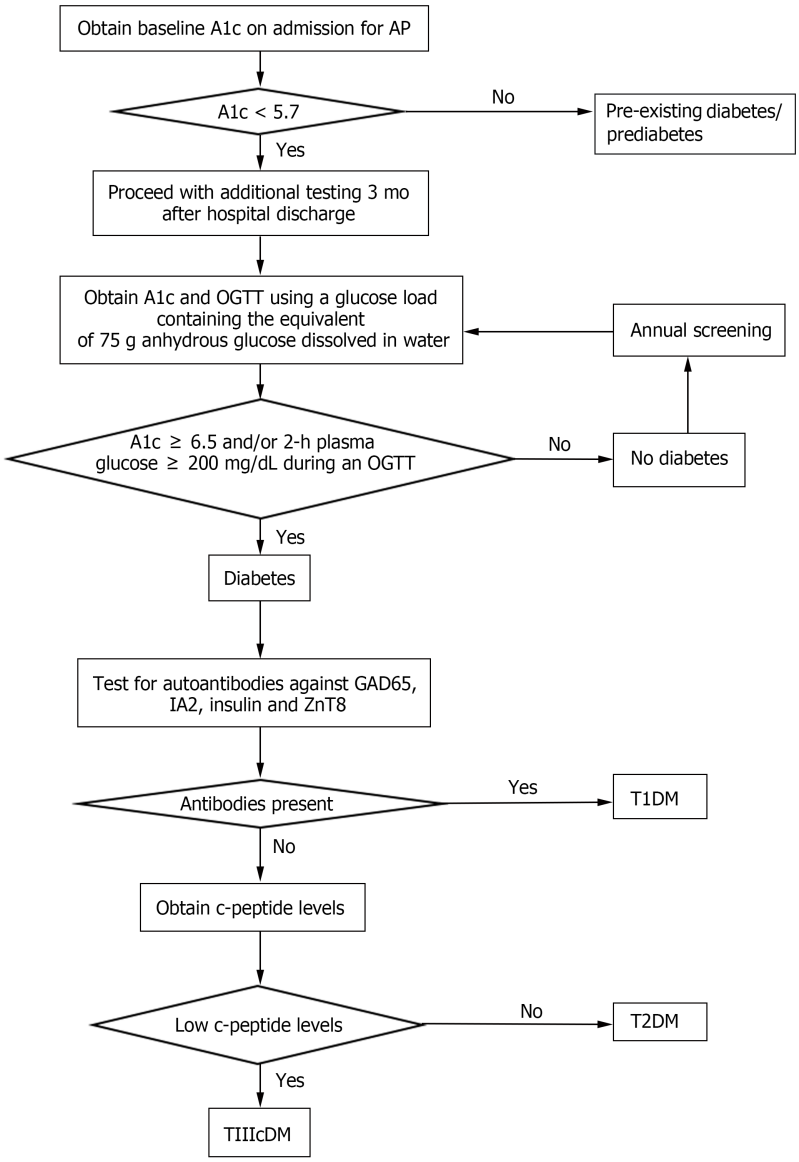
In a recent cohort study, Cho *et al*[12] found that patients with exocrine pancreatic dysfunction requiring pancreatic enzyme replacement therapy (PERT) after their initial attack of pancreatitis were at increased risk of new-onset DM. New-onset DM was defined as diagnostic coding of DM and/or receiving a new oral hypoglycemic medication. This association remained even when the analysis was limited to mild AP. Patients with exocrine dysfunction are prone to deficiencies in fat-soluble vitamins.

In the past, vitamin D was found to play a role in glucose control. Mirhosseini *et al*[17] describe the mechanism in a meta-analysis, reporting that the active form of vitamin D regulates the expression of the insulin receptor gene and facilitates the transport of glucose into muscle cells. The authors conclude that vitamin D supplementation may

significantly reduce serum fasting plasma glucose (FPG) and hemoglobin A1c (HbA1c)[17]. However, study results regarding the association of vitamin D and glucose control have been inconsistent. One randomized placebo-controlled trial found that daily vitamin D and calcium supplementation did not have a significant effect on insulin sensitivity, insulin secretion, or β-cell function in vitamin D deficient individuals at risk of T2DM[18]. An important point to note is that the authors classified patients "at risk of T2DM" based on a diabetes risk questionnaire. In a *post hoc* analysis restricted to patients with clinically diagnosed prediabetes, they found a significant beneficial effect of vitamin D and calcium supplementation on insulin sensitivity. There were no changes in insulin secretion or beta cell function.

In a more recent study, Norbitt *et al*[19] investigated potential connections between the intake of fat- and water-soluble vitamins with markers of glucose metabolism in patients after AP. They found a significant association between three fat-soluble vitamins (α-carotene, β-carotene, and total carotene) and homeostasis model assessment of β-cell function (HOMA-β) in patients with new-onset prediabetes/diabetes after AP[19]. Despite this association, there were no significant associations with FPG or HOMA-IR index. Although more studies are needed to help uncover the role of vitamin deficiencies in oxidative stress-driven disorders, it appears that optimizing the exocrine function of the pancreas plays an important role in glucose control. This may provide a key opportunity for intervention to prevent AP-related DM.

RISK FACTORS



An important component of understanding the etiology of AP-related DM is identifying risk factors linked with heightened endocrine dysfunction after AP. One case-controlled study with multivariable analysis found AP-related DM occurred more often in patients with components of metabolic syndrome such as hypertension, obesity and hyperlipidemia[20]. The potential explanation is that this particular population has an underlying predisposition toward T2DM and the additional insult of AP accelerates the progression to sustained hyperglycemia[21,22]. In another study, Lv *et al* [23] found similar results but also discovered non-alcoholic fatty liver disease (NAFLD) was an additional independent risk factor. Until now, most studies have focused on the effect of the exocrine pancreas on endocrine function yet the liver also plays a critical role in regulating and maintaining glucose levels. Those with NAFLD have underlying IR due to chronic inflammation from the release of inflammatory mediators by adipose tissue. These mediators which include leucine-rich alpha-2-glycoprotein 1 and interleukin-6 have been found to inhibit insulin receptors and the action of insulin through different signaling pathways[23]. The authors suggest chronic inflammation combined with inflammation-induced lipolysis contribute to the process of IR. Investigations to further characterize risk factors for AP-related DM are needed to help identify patients who will benefit from closer follow-up and earlier interventions to control glucose levels following an episode of AP.

DIAGNOSIS

Diagnostic criteria for T1D and T2DM have been well established and have undergone very minor revision over the last decades. The diagnosis of DEP has been more challenging to standardize as it shares clinical features that overlap with T1D and T2DM. The development of standardized criteria is also complicated by the fact that DEP is the result of multiple clinically distinct diseases and/or mechanisms. These individual etiologies lead to variable levels of pancreatic dysfunction and have varying rates of progression to diabetes, making the timing of the initiation of screening difficult to determine[7,24]. Previously, Ewald and Bretzel[25] suggested the following to diagnose DEP: Major criteria (all must be fulfilled): Presence of exocrine pancreatic insufficiency (according to the monoclonal fecal elastase-1 test or direct function tests); pathological pancreatic imaging (endoscopic ultrasound, magnetic resonance imaging, computed tomography); absence of T1DM associated autoimmune markers. Minor criteria: Impaired beta cell function (*e.g.*, HOMA-B, C-peptide/glucose-ratio); no excessive IR (*e.g.*, HOMA-IR); impaired incretin secretion [*e.g.*, glucagon-like peptide 1 (GLP-1), PP]; low serum levels of lipid-soluble vitamins (A, D, E, and K).

Although cited in numerous articles over the years, the criteria were never universally accepted. As we learn more about the underlying mechanisms of each disease process and how they may lead to DEP, most of the above criteria have become invalid. For example, pancreatic insufficiency is not a specific characteristic of any of the diseases of the exocrine pancreas. Pancreatic insufficiency is a risk factor for the development of DEP and therefore should not be considered a defining characteristic. Additionally, pathological pancreatic imaging varies among the different diseases and is not a reliable marker of pancreatic function. Not all patients with imaging findings consistent with necrotizing pancreatitis develop DEP. Patients with mild pancreatitis may lack significant radiographic findings yet are still at risk of developing DEP. Furthermore, patients with pancreatic adenocarcinoma are commonly diagnosed with diabetes prior to developing cancer visible on cross-sectional imaging[26].

Here, we will focus on screening and diagnosis of AP-related diabetes (Figure 1). The first step should be to rule out undiagnosed diabetes/prediabetes by obtaining an HbA1c on admission for AP. We recommend screening for diabetes three months after hospital discharge by obtaining an HbA1c and an oral glucose tolerance test (OGTT). The timing of screening at three months post-hospitalization was selected to limit confounding by stress-related hyperglycemia and to help ensure that the HbA1c is an accurate reflection of changes in glucose levels after AP. Recommendations to use an OGTT are based on several observations. First, studies have shown poor test performance of HbA1c in diagnosing diabetes in patients with cystic fibrosis, another well-known disease affecting the exocrine pancreas. As a result, screening guidelines for cystic fibrosis-related diabetes recommend use of OGTT over HbA1c, and the committee concluded HbA1c

Figure 1 Diagnostic algorithm for acute pancreatitis related diabetes. OGTT: Oral glucose tolerance test; GAD65: Glutamic acid decarboxylase; IA2: Tyrosine phosphatase; ZnT8: Zinc transporter 8; T1DM: Type 1 diabetes mellitus; AP: Acute pancreatitis.

was not sufficiently sensitive for diagnosis of diabetes in this patient population[27]. Similarly, Meier and Giese[28] advocate for the use of OGTT for earlier detection of diabetes in those with pancreatic disease. They found the OGTT diagnosed diabetes when the beta cell area was reduced by 64% compared to a more sizeable beta cell area loss of 89% when diabetes was diagnosed by HbA1c. A more recent study found that fasting glucose and HbA1c underestimate the prevalence of DEP and also recommend use of OGTT[29]. In this study, the diagnosis of over half of the new cases of diabetes after SAP were only possible by using the OGTT.

Once a diagnosis of diabetes is established, the next steps involve ruling out T1D and T2DM. The exclusion of T1D is more straightforward and can be performed by demonstrating the absence of autoantibodies. Duggan *et al*[29] suggest that c-peptide levels may be used to differentiate DEP and T2DM. Levels of c-peptide are typically used to distinguish T1D from T2DM, as levels are low in T1D and high in T2DM. They found that SAP patients with diabetes demonstrated a lower insulin response to glucose ingestion and had lower c-peptide secretion. This suggests the diagnosis of AP-related DM/DEP should be made in the setting of low c-peptide levels and the absence of autoantibodies[29]. More studies are needed to confirm the correlation, but it is a reasonable place to start. As studies showed risk of developing DEP up to five years after a single attack, it would be reasonable to consider continuing annual screening with HbA1c and OGTT *vs* more frequently depending on the presence of other risk factors.

MANAGEMENT

While the overall pathophysiology of DEP is far more complex than the more common types of diabetes, the treatment

algorithms for T2DM are often applied for management of DEP. This may be problematic on several fronts. Studies have shown that patients with CP have an increased risk of developing pancreatic adenocarcinoma through a mechanism potentiated by hyperinsulinemia[2,7,30]. As a result, interventions that reduce ambient insulin levels (*i.e.*, exercise, weight loss, low-carb diet) coupled with the anti-neoplastic properties of Metformin has become the preferred first-line treatment option. If glucose levels remain elevated it is reasonable to consider the addition of oral agents from the thiazolidinedione and/or alpha-glucosidase inhibitor classes. Clinical trials evaluating the safety of sulfonylureas, GLP-1 analogs, and dipeptidyl peptidase-IV inhibitors are lacking and these medications should be avoided due to possible association with pancreatitis[7,30]. All patients should also be counseled on the importance of abstinence from alcohol and tobacco use.

Screening for malabsorption and fat-soluble vitamin deficiencies can help guide the initiation of PERT and vitamin supplementation. The response and release of incretins, such as GLP-1, to fat hydrolysis may even be impaired with subclinical fat-soluble vitamin deficiency and thereby promote post-prandial hyperglycemia. PERT may augment the post-prandial incretin response and has been demonstrated to stabilize glucose levels in patients with alcoholic pancreatitis and cystic fibrosis. Additionally, some believe that PERT may help improve pain associated with pancreatitis.

Every effort should be made to detect AP-related DM before the development of critical insulin deficiency. If insulin therapy is necessary, it is important to remember that DEP may cause enhanced peripheral sensitivity to insulin, increasing the risk of hypoglycemia[7,30]. Dosing calculations similar to those used for T1D should be used rather than those used for T2DM[7]. Additionally, patients with DEP may require more frequent dose adjustments compared to patients with T2DM.

FUTURE RESEARCH

Further investigation should focus on how to use IR and insufficient insulin production to distinguish T2DM from DEP. Although we have proposed a set of diagnostic criteria, further research is needed to confirm whether the absence of autoantibodies in conjunction with low c-peptide levels is enough to diagnose DEP. Additionally, exploration into the possible contribution of PP cell tracking and other biomarkers to characterize DEP is necessary[4].

Improved characterization of alpha cells, beta cells, PP cells and delta cells may also have implications on the diagnosis and treatment of DEP[4]. Methods to do so may include new radiological techniques as well as neural networks. Newer advanced magnetic resonance techniques, including diffusion-weighted imaging, T1 mapping, and T2 mapping, provide quantifiable imaging features to gain additional understanding of underlying irregularities in AP. This goes beyond the traditional magnetic resonance sequences' qualitative imaging features to detect morphological changes in AP[31]. Further, these newer radiological techniques may be able to improve the detection of islet volume changes involved in DEP. Advanced analytic techniques, including radiomics and artificial neural networks, may be able to uncover imaging biomarkers to enable further risk stratification of DEP secondary to AP.

Artificial intelligence (AI) offers risk stratification and prognostication information for AP, including DEP secondary to AP. Machine learning through large data sets may be able to better determine an association between AP disease severity and DEP. An ongoing clinical trial is investigating whether AI machine learning can be used to estimate the disease severity in AP according to the revised Atlanta criteria, which may have implications on DEP[32]. Similarly, while parameters used in handcrafted AP severity prediction scores, such as APACHE II and Ranson, are typically unavailable until 24 to 72 h after hospitalization, the early achievable severity index prediction score which was developed using machine learning, can identify patients at high risk for SAP within 24 h of hospital admission[33]. Early identification of patients at risk of SAP allows for early interventions to decrease mortality, which may also be critical in preventing the development of DEP.

As deficiency of fat-soluble vitamins associated with exocrine pancreatic dysfunction may be linked to new-onset DM, early administration of fat-soluble vitamins needs to be further studied as a possible preventative measure against the development of DEP[12]. Additionally, serum levels of fat-soluble vitamins (vitamin D in particular) may have the potential to be used as markers of risk of AP-related DM, as mentioned by Norbitt *et al*[19]. The connection comes from previous findings that vitamin D levels negatively correlated with AP severity indexes[19,34].

Based on the data mentioned earlier, the incidence of AP continues to rise and we should anticipate an increasing incidence of AP-related DM. This escalates the importance of needing to screen for, monitor, and treat DEP[3]. The next major step in research should also include investigating the reasons for the increased incidence of AP to prevent the disease and DEP by extension.

CONCLUSION

AP is the most common disease of the exocrine pancreas and places a significant strain on healthcare costs as the incidence continues to rise. While many studies have focused on treatment during hospitalization, the sequela of the disease are becoming more important as more patients develop AP and recover from the disease. AP-related diabetes, a type of DEP, is likely more prevalent than initially thought as it is often misclassified as T2DM and treated as such. As new studies emerge, we have learned that the diagnostic criteria for AP-related diabetes needs to be better defined in order to improve management of this unique type of diabetes. Through common knowledge of the pathophysiology of T1D and T2DM and the review of newer studies attempting to find biomarkers to help characterize DEP, we were able to propose a set of diagnostic criteria for AP-related DM. Although studies are needed to test the utility, this may at least provide a starting point. Furthermore, we have identified specific areas in need of further research in hopes that it may

help lead to the development of guidelines for the diagnosis and management of AP-related DM.

Abstract

BACKGROUND

Nonalcoholic fatty liver disease (NAFLD) is a clinicopathological entity characterized by intrahepatic ectopic steatosis. As a consequence of increased consumption of high-calorie diet and adoption of a sedentary lifestyle, the incidence of NAFLD has surpassed that of viral hepatitis, making it the most common cause of chronic liver disease globally. Huangqin decoction (HQD), a Chinese medicinal formulation that has been used clinically for thousands of years, has beneficial outcomes in patients with liver diseases, including NAFLD. However, the role and mechanism of action of HQD in lipid metabolism disorders

and insulin resistance in NAFLD remain poorly understood.

AIM
To evaluate the ameliorative effects of HQD in NAFLD, with a focus on lipid metabolism and insulin resistance, and to elucidate the underlying mechanism of action.

METHODS
High-fat diet-induced NAFLD rats and palmitic acid (PA)-stimulated HepG2 cells were used to investigate the effects of HQD and identify its potential mechanism of action. Phytochemicals in HQD were analyzed by high-performance liquid chromatography (HPLC) to identify the key components.

RESULTS
Ten primary chemical components of HQD were identified by HPLC analysis. *In vivo*, HQD effectively prevented rats from gaining body and liver weight, improved the liver index, ameliorated hepatic histological aberrations, decreased transaminase and lipid profile disorders, and reduced the levels of pro-inflammatory factors and insulin resistance. *In vitro* studies revealed that HQD effectively alleviated PA-induced lipid accumulation, inflammation, and insulin resistance in HepG2 cells. In-depth investigation revealed that HQD triggers Sirt1/NF-κB pathway-modulated lipogenesis and inflammation, contributing to its beneficial actions, which was further corroborated by the addition of the Sirt1 antagonist EX-527 that compromised the favorable effects of HQD.

CONCLUSION
In summary, our study confirmed that HQD mitigates lipid metabolism disorders and insulin resistance in NAFLD by triggering the Sirt1/NF-κB pathway.

Key Words: Nonalcoholic fatty liver disease; Huangqin decoction; Lipid metabolism disorders; Insulin resistance; Sirt1/NF-κB pathway

Core Tip: Huangqin decoction (HQD) has substantial therapeutic effects in liver diseases. We previously showed that HQD mitigates hepatic inflammation in a rat model of High-fat diet (HFD)-induced Nonalcoholic fatty liver disease (NAFLD) by inhibiting the TLR4/NF-κB/NLRP3 pathway. Here, we investigated the effects of HQD on lipid metabolism disorders and insulin resistance in NAFLD. Our results demonstrated that HQD effectively antagonizes hepatocyte steatosis and insulin resistance in HFD-fed rats and palmitic acid-challenged HepG2 cells by triggering Sirt1/NF-κB pathway-modulated lipogenesis and inflammation. These data will significantly promote the clinical application of HQD in the treatment of NAFLD.

INTRODUCTION

As lifestyles have been increasingly shifting to "eat more, move less", overweight and obese cohorts is on a monumental rise. Consequently, the incidence of obesity-related chronic diseases, such as type 2 diabetes, cardiovascular disease, and nonalcoholic fatty liver disease (NAFLD) is on the rise. NAFLD is the most common liver disease characterized by excessive hepatocellular lipid build-up, which is caused by factors other than alcohol intake, drugs, viral infections, and autoimmunity[1]. The initial signs and symptoms of NAFLD are limited to benign steatosis[2]. However, if not managed, approximately 30% of NAFLD cases will progress to nonalcoholic steatohepatitis (NASH). Subsequently approximately 30%–40% of NASH cases will further progress to fibrosis and cirrhosis, and approximately 5%–25% of NASH patients will die from advanced liver diseases within ten years[2-5]. Additionally, epidemiological studies suggest that NAFLD patients are more prone to develop heart disease and die from heart attacks compared to healthy individuals[6]. Currently, NAFLD affects approximately 25% of the general population worldwide, and the associated morbidity in China has increased substantially from 18% to approximately 30% in recent decades[7]. It is estimated that more than 300 million cases of NAFLD will emerge in China by 2030, causing a tremendous strain on its healthcare and economy[8]. Unfortunately, no specific drug has been approved by the Food and Drug Administration for NAFLD; invasive bariatric surgery and lifestyle modifications are thought to be effective strategies[9]. Therefore, there is an urgent need to identify more efficacious agents for NAFLD treatment.

NAFLD is driven by multiple factors and its etiology remains complex and elusive. Several hypotheses have been proposed over the past few decades to explain its pathogenesis. According to the canonical "two-hit" hypothesis originally proposed by Day and James[10], obesity and insulin resistance-evoked excessive intrahepatic lipid accumulation constitutes the "first hit," and ensuing oxidative stress and inflammation constitute the "second hit". Subsequent studies found that hepatocyte regeneration and proliferation were impeded during the progression of NAFLD, which was termed as the "third-hit"[11]. Following further in-depth investigations, a more precise "multiple-hit" hypothesis was proposed that deems that hepatic steatosis increases the susceptibility of the liver to intra- and extrahepatic offenders, such as hepatic oxidative stress and inflammation, gut dysbiosis, and disturbed adipokines, and the multiple insults simultaneously and synergistically induce and advance NAFLD[12]. However, in both the hypotheses, hepatic steatosis is considered to be the paramount driver of NAFLD, and numerous studies have focused on lipid metabolism-associated targets (*e.g.*, Sirt1) in an attempt to reduce intrahepatic fat[9]. Sirt1, a nicotinamide adenine dinucleotide-dependent lysine deacetylase, is a metabolic sensor that is highly expressed in metabolically active organs (*e.g.*, the liver and skeletal muscles) and is extensively involved in glucose and lipid metabolism[9,13,14]. Clinical evidence indicates that patients with NAFLD exhibit defective Sirt1 expression in the liver[15]. Additionally, inhibition of Sirt1 exacerbated high-fat diet (HFD)-induced hepatic steatosis in mice, whereas activation of Sirt1 exerted anti-steatotic effect[16]. Importantly, it was reported that Sirt1 deacetylates lysine residues of NF-κB (RelA/p65 subunit), thereby affecting its transcriptional activity and restricting the expression of pro-inflammatory target genes[17]. Curative effects including anti-steatosis, anti-inflammation, and anti-apoptosis were noted when Sirt1/NF-κB pathway was triggered in methionine-choline-deficient diet-induced NASH mice, indicating the vital role of Sirt1/NF-κB pathway in defense against NAFLD[18]. In addition, recent studies suggest that NF-κB-stimulated pro-inflammatory factors activate hepatic insulin resistance, and thereby aggravate hepatic steatosis[17,19]. Therefore, triggering the Sirt1/NF-κB pathway represents a potential strategy for counteracting insulin resistance and hepatic steatosis in NAFLD.

Huangqin decoction (HQD) is a classical traditional Chinese medicine (TCM) formulation that was first mentioned in "Treatise on Febrile Diseases" by the medical sage Zhong-Jing Zhang. According to records, HQD harbors the efficacy of "clearing away heat and treating dysentery" and "regulating the stomach and relieving pain," and has long been utilized to treat inflammatory diseases. It has a positive reputation as "the ancestral agent for curing dysentery in all ages" and "the first decoction for febrile diseases"[20]. Notably, HQD has been used to treat liver disorders (*e.g.*, NAFLD) at the First Affiliated Hospital of Nanjing University of Chinese Medicine for decades with positive outcomes. HQD is composed of four botanical herbs, *Scutellariae Radix* (Huangqin in Chinese), *Paeoniae Radix Alba* (Baishao in Chinese), *Glycyrrhizae Radix et Rhizome* (Gancao in Chinese), and *Jujubae Fructus* (Dazao in Chinese), which are clinically combined in a 3:2:2:2 ratio. Previous studies reported that these herbs can alleviate NAFLD when used independently[21-23]. More importantly, in our recent study, the anti-hepatitis effects of HQD in HFD-induced NAFLD rats were found to be mediated *via* inhibition of the TLR4/NF-κB/NLRP3 pathway[24]. However, the regulatory mechanisms of HQD in hepatic steatosis and its ameliorative effects in insulin resistance remain undefined.

To address this gap, we used HFD-induced NAFLD rats and palmitic acid (PA)-induced HepG2 cells to investigate the ameliorative effects of HQD in lipid metabolism disorders and insulin resistance, and identify the potential molecular mechanisms by focusing on the Sirt1/NF-κB pathway.

MATERIALS AND METHODS

Plant materials and reagents

Scutellariae Radix, *Paeoniae Radix Alba*, Glycyrrhizae Radix et Rhizome, and *Jujubae Fructus* were obtained from Wansheng Herbal Decoction Pieces Co. Ltd. (Bozhou, China) and authenticated by Professor Sheng-Jin Liu of the Nanjing University of Chinese Medicine (Nanjing, China). All voucher specimens (Voucher No. 220301, 220302, 220303, and 220304) were deposited at the Central Laboratory of Jiangsu Health Vocational College (Nanjing, China). Gallic acid, paeoniflorin, scutellarin, liquiritin, baicalin, scutellarein, wogonoside, baicalein, wogonin, and chrysin (purity ≥ 98%) were purchased from Yuanye Biotechnology Co. Ltd. (Shanghai, China). Fenofibrate (Fen) was obtained from SPGC Sine Pharmaceutical Co. Ltd. (Shanghai, China). Enzyme-linked immunosorbent assay (ELISA) kits for insulin, tumor necrosis factor (TNF)-α, interleukin (IL)-6, and IL-1β were obtained from Solarbio (Beijing, China). Commercial biochemical kits for triacylglycerol (TG), total cholesterol (TC), free fatty acids (FFA), low-density lipoprotein cholesterol (LDL-c), high-density lipoprotein cholesterol (HDL-c), alanine transaminase (ALT), and aspartate transaminase (AST) were obtained from the Nanjing Jiancheng Bioengineering Institute (Nanjing, China). Hematoxylin and eosin (H&E) and Oil Red O staining kits were supplied by Beyotime (Shanghai, China). Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS), bovine serum albumin (BSA), and PA were purchased from Sigma-Aldrich (St. Louis, MO, United States). Penicillin-streptomycin solution was obtained from Thermo Fisher Scientific (Waltham, MA, United States). EX-527 was purchased from Selleck Chemicals (Houston, TX, United States). A colorimetric 2-deoxydglucose (2DG) uptake assay kit and antibodies against IL-1β, sterol regulatory element-binding protein (SREBP)-1, fatty acid synthase (FAS), cluster of differentiation 36 (CD36), Sirt1, NF-κB, p-NF-κB, IRS-2, p-IRS-2, and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) were purchased from Abcam (Cambridge, MA, United Kingdom). All the chemicals used were of analytical grade.

Preparation of HQD

HQD was prepared using established protocols. Briefly, 300 g *Scutellariae Radix*, 200 g *Paeoniae Radix Alba*, 200 g *Glycyrrhizae Radix et Rhizome*, and 200 g *Jujubae Fructus* were combined in 10-fold volume of double-distilled water and extracted in boiling water for 1 h. Following filtration through gauze, the herbal residue was extracted again for 1 h at 100

°C with 8-fold volume of double-distilled water. Subsequently, the two extracts were pooled, concentrated under reduced pressure, and lyophilized to yield 173.1 g of the extract powder. The extract ratio of HQD was 19.23% (w/w). The lyophilized extract powder was stored at -80 °C for subsequent experiments.

High-performance liquid chromatography analysis of HQD

An Agilent 1260 high-performance liquid chromatography (HPLC) separation system (Agilent, Santa Clara, CA, United States) equipped with a diode array detector was used to analyze the chemical composition of HQD. Briefly, the lyophilized powder (0.5 g) was dissolved in 20 mL of ultrapure water using ultrasonication. Following filtration through a 0.22 μm syringe filter, 20 μL of the supernatant was injected into the HPLC system and separated chromatographically through an Agilent ZORBAX SB-C18 column (4.6 mm × 150 mm, 5 μm). The mobile phase comprised of linear gradients of 0.1% (v/v) formic acid in water and acetonitrile. Gradient elution was performed as follows: 0–10 min, 5%–8% acetonitrile; 10–20 min, 8%–16% acetonitrile; 20–40 min, 16%–22% acetonitrile; 40–50 min, 22%–25% acetonitrile; 50–60 min, 25%–40% acetonitrile; 60–70 min, 40%–60% acetonitrile; 70–75 min, 60%–5% acetonitrile; 75–80 min, 5% acetonitrile. Programmable parameters for flow rate, injection volume, and detector wavelength were 1 mL/min, 5 μL, and 270 nm, respectively.

Animals

Male Sprague-Dawley rats (seven weeks old, weighing 180–200 g) were obtained from the Hangzhou Medical College (Hangzhou, China). The rats were housed in a conventional habitat (40%–50% humidity, 25 ± 1 °C, and 12 h light/dark) at the Laboratory Animal Center of the Jiangsu Health Vocational College. The experimental protocols strictly complied with the European Community criteria and were authorized by the Animal Ethics Committee of the Jiangsu Health Vocational College (Permission No. JHVC-IACUC-2022-B007).

Animal grouping and treatment

Following one week of acclimatization, the rats were randomly allocated to five groups (n = 8/group): Normal, HFD, HFD plus Fen (30 mg/kg), and HFD plus HQD (400 and 800 mg/kg). Rats in the normal group were fed a normal chow diet (10% calories from fat), whereas the rats in the other groups were fed a HFD (60% calories from fat) for 16 wk to establish the NAFLD model[25]. Both diets were provided by Jiangsu Xietong Pharmaceutical Bioengineering Co. Ltd. (Nanjing, China). Starting from the 8th week, the rats were orally administered Fen or HQD once daily for intervention, whereas the rats in the normal and HFD groups received an equal volume of 0.5% sodium carboxymethylcellulose (CMC-Na) orally as the control. Body weights of the animals were monitored weekly during the experimental period. At the end of the experiment, the rats were fasted overnight prior to being anesthetized with 1% pentobarbital sodium. To obtain serum, blood samples were collected from the abdominal aorta and centrifuged at 3500 rpm for 15 min. The rat livers were swiftly resected and flushed with phosphate buffered saline. Liver weights were measured and the liver indices (liver weight/body weight) were calculated. Portions of the liver were fixed in 4% paraformaldehyde for histological analysis and the remaining liver specimen was snap-frozen and stored at -80 °C for future molecular biology analyses.

Evaluation of insulin sensitivity

Two days prior to the termination of the experiment, the mice were fasted for 12 h and then orally administered 2 g/kg glucose. Blood was drawn from the tail vein before or at the indicated time points (30, 60, 90, and 120 min) after gavage. Blood glucose levels were measured using a glucometer (Yuwell, Inc., Zhenjiang, China). The oral glucose tolerance test (OGTT) curve and area under the curve (AUC) of the OGTT were drawn and calculated using GraphPad Prism 8.0. At the end of the experiment, fasting blood glucose (FBG) and serum insulin levels were determined using a glucometer and an insulin ELISA kit, respectively. The homeostasis model assessment of insulin resistance (HOMA-IR) was calculated as follows: (FBG × fasting serum insulin)/22.5.

Cell culture and treatment

HepG2 cells were purchased from the Chinese Academy of Cell Resource Center (Shanghai, China) and cultured in DMEM (supplemented with 10% FBS and 1% penicillin-streptomycin) at 37 °C in a humid environment containing 5% CO_2. PA stock solution (5 mmol/L) was dissolved in 5% BSA by incubating at 55 °C for 15 min. Subsequently, the PA-BSA solution was incorporated into the medium at a final concentration of 125 μM. HQD-mediated cytotoxicity was determined using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. For the interventions, HepG2 cells (70% confluent and serum-starved for 12 h) were treated with insulin (1 IU/mL), various doses of HQD (0, 25, 75, or 125 μg/mL) or a combination of HQD (100 μg/mL) and EX-527 (10 μM) under PA (125 μM) challenge for 24 h. HepG2 cells grown in serum-free media with 5% BSA served as the blank control.

MTT assay

HepG2 cells were seeded in 96-well plates (1×10^4 cells/well) and cultured overnight, followed by exposure to different concentrations of HQD (0, 25, 50, 75, 100, 120, 150, 175, and 200 μg/mL) with or without 125 μM PA for 24 h. MTT solution (10 μL of 5 mg/mL) was added to each well and incubated at 37 °C for 4 h. Dimethyl sulfoxide (150 μL) was added to dissolve the formazan crystals with vigorously shaking for 5 min. Finally, a Multiskan MK3 microplate reader (Thermo Fisher Scientific) was used to measure the absorbance at 490 nm. Cell viability (% of control) was calculated using the following formula: [Optical density (OD) 490 (sample-blank)/OD 490 (control-blank)] × 100%.

Glucose uptake assay

HepG2 cells were cultured overnight in 96-well plates (5 × 10^3 cells/well) and then starved for 12 h. The cells were stimulated without or with 1 μM insulin for 20 min to activate the glucose transporters. A colorimetric 2DG uptake test was performed according to the manufacturer's protocol to evaluate glucose absorption by HepG2 cells in response to insulin.

ELISA and biochemical analyses

TNF-β, IL-6, and IL-1β levels in the liver and cell supernatants, as well as serum insulin levels, were measured using the corresponding ELISA kits following the manufacturer's instructions. Biochemical parameters in the serum, liver, and HepG2 cells, including TG, TC, LDL-c, HDL-c, FFA, ALT, and AST were determined using commercial kits following the manufacturer's instructions.

Histological and immunohistochemistrical/immunofluorescent analyses

Fixed liver tissues were embedded in paraffin, cut into 5 μm slices, and stained with H&E according to the standard procedure. Immunohistochemical analyses were performed as described previously[25]. Briefly, primary antibodies against IL-1β, SREBP-1, Sirt1, and p-NF-κB were diluted 200-fold and then incubated with the tissue samples overnight at 4 °C. Following that, 100 μL of secondary antibody (diluted 400-fold) was added dropwise to each section. Horseradish peroxidase (HRP)-conjugated goat anti-rabbit IgG (H + L) was used for IL-1β and SREBP-1. HRP- or Alexa Fluor594-conjugated goat anti-rabbit IgG (H + L) was used for Sirt1 and p-NF-κB. Subsequently, 4',6-diamidino-2-phenylindole (DAPI) or 3,3'-diaminobenzidine substrate solution was sequentially added to each section. Images were captured using either a DM2500 optical microscope (Leica, Wetzlar, Germany) or an LSM 700 confocal laser microscope (Zeiss, Oberkochen, Germany). Finally, the data were quantified using the Image-Pro Plus software (version 6.0; Media Cybernetics, Rockville, MD, United States). For immunofluorescence analysis, HepG2 cells were immobilized in 4% paraformaldehyde solution for 10 min, blocked with 5% BSA, and incubated overnight with primary antibodies against Sirt1 and NF-κB (both diluted 200-fold). Thereafter, the cells were probed with Alexa Fluor 488-conjugated secondary antibodies (diluted 500-fold) and counterstained with DAPI to visualize the nuclei. Fluorescence images were acquired using an LSM 700 confocal laser microscope (Zeiss).

Oil Red O staining

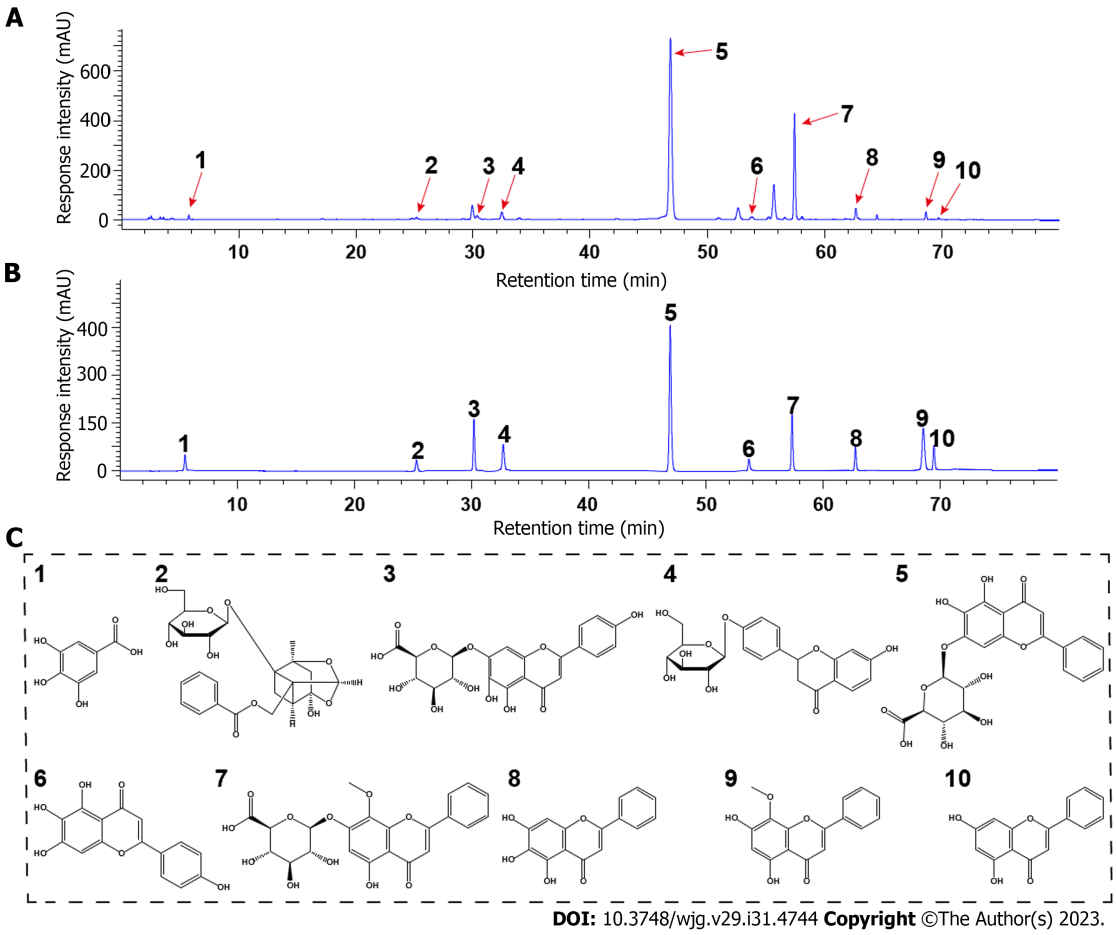
Paraffin-embedded liver tissues were cut into 5 μm sections, followed by staining with Oil Red O dye according to standard procedure. HepG2 cells were fixed in 4% paraformaldehyde for 15 min, rinsed with distilled water, and stained with Oil Red O dye. Images were captured using a DM2500 optical microscope (Leica).

Western blotting

Pre-chilled radio immunoprecipitation assay buffer (containing a protease inhibitor cocktail) was used to lyse liver samples. A commercial bicinchoninic acid assay kit was used to quantify total proteins. Immunoblot analysis was performed as previously described[25]. Specific primary antibodies against SREBP-1c, FAS, CD36, Sirt1, NF-κB, p-NF-κB, IRS-2, p-IRS-2, and GAPDH were used at 1000-fold dilution. The protein bands were visualized and semi-quantified using Azure Biosystems C600 (Azure Biosystems Inc., Dublin, CA, United States) and ImageJ software (NIH, Bethesda, MD, United States), respectively.

Statistical analysis

Data were analyzed using IBM SPSS software (version 21.0; Armonk, NY, United States) and expressed as mean ± SD. One-way analysis of variance followed by a least significant difference test for multiple comparisons was used to assess significant differences among groups. Statistical significance was set at $P \leq 0.05$.



RESULTS

Phytochemical analysis of HQD

The multifaceted effectiveness of TCMs stem from their multi-component trait. First, we sought to identify the primary chemical components of HQD using HPLC analysis. As shown in Figure 1, ten major monomeric components were identified in HQD by comparing the retention times of the standards. Based on the standards, the concentrations of: (1) Gallic acid, (2) paeoniflorin, (3) scutellarin, (4) liquiritin, (5) baicalin, (6) scutellarein, (7) wogonoside, (8) baicalein, (9) wogonin, and (10) chrysin were determined to be 0.709, 2.005, 1.417, 1.626, 60.092, 0.916, 13.471, 1.905, 2.088, and 0.559 mg/g, respectively.

HQD alleviated adiposity and hepatic histological abnormalities in HFD-induced NAFLD rats

Patients with NAFLD frequently present with increased body and liver weight. Fen, a lipid-lowering medication that is clinically used for NAFLD treatment, was chosen as the positive control drug. The experimental scheme is indicated in Figure 2A. As shown in Figure 2B-E, HQD treatment (400 and 800 mg/kg) significantly attenuated HFD-induced increase in body and liver weight, as well as the liver index. As hepatic steatosis is the primary hallmark of NAFLD, we performed histological analysis to assess the effect of HQD on hepatic steatosis. H&E staining indicated that rats in the HFD group presented with severe structural disruption of the hepatic lobules, steatosis, and hepatocellular ballooning degeneration,

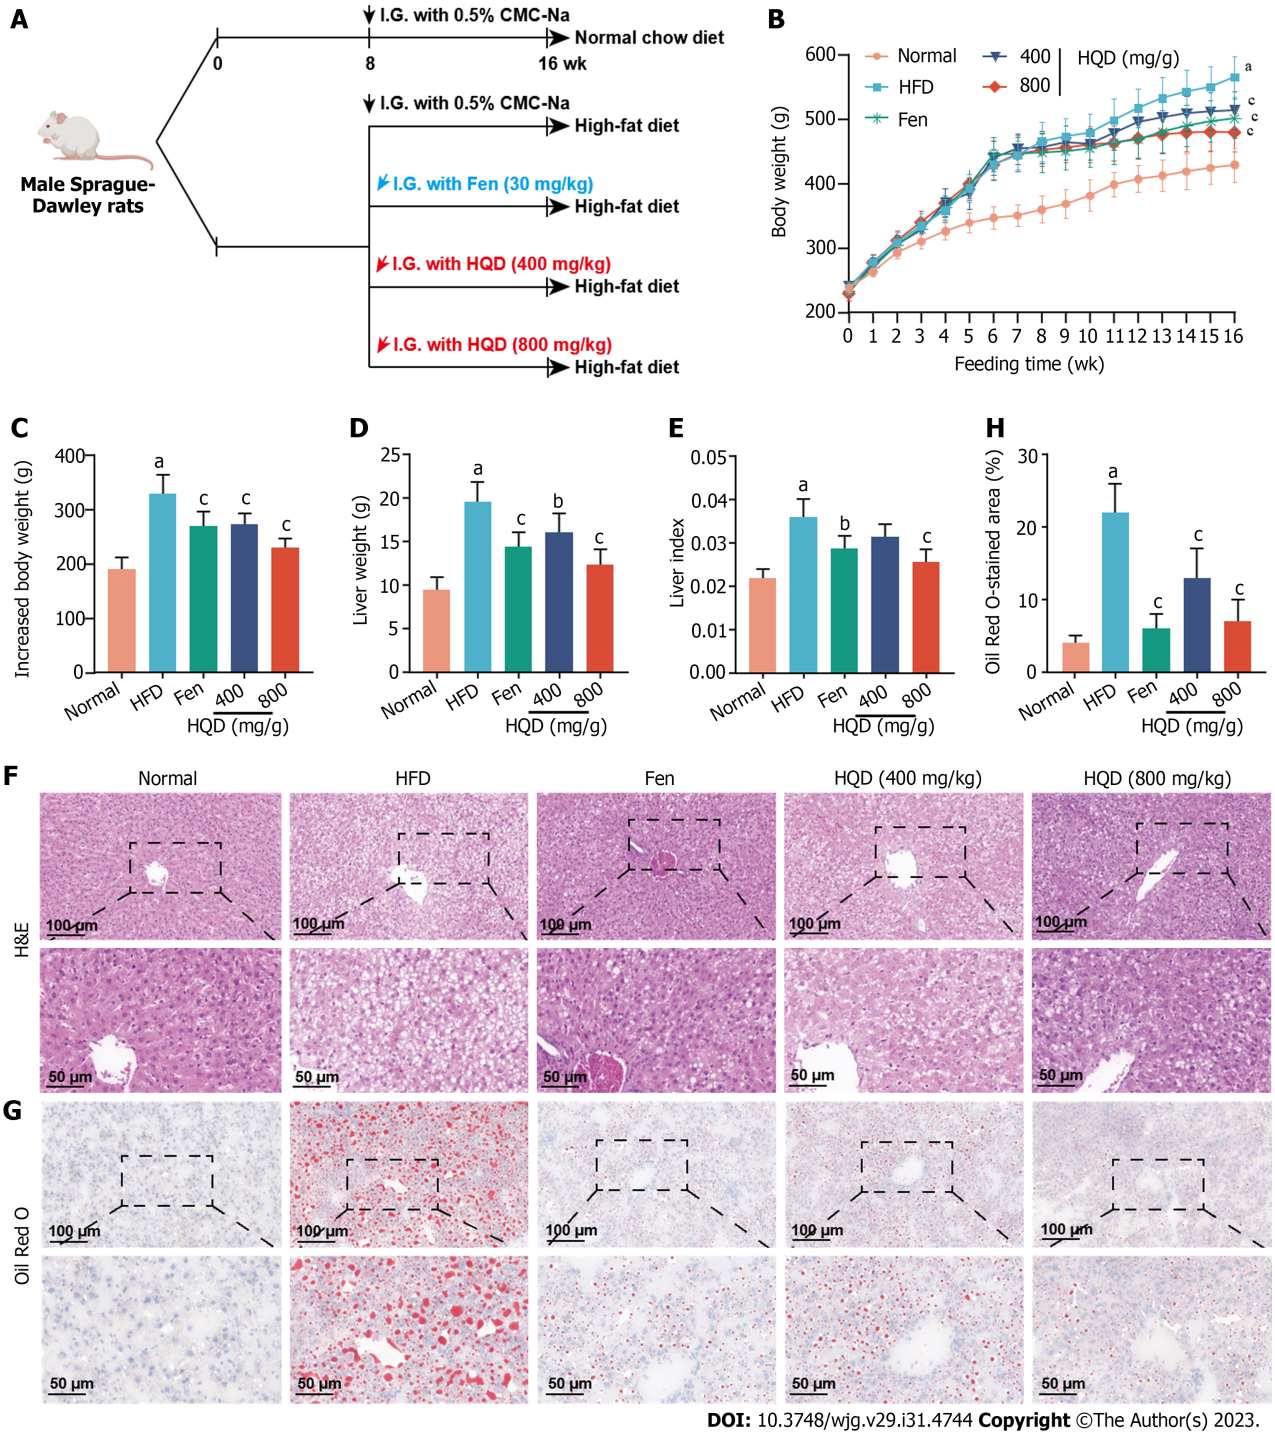
Figure 1 High-performance liquid chromatography fingerprint spectrum of Huangqin decoction and structures of the major phytochemicals in Huangqin decoction. A and B: High-performance liquid chromatography profiles of Huangqin decoction (HQD) and the standard mixture: (1) Gallic acid, (2) paeoniflorin, (3) scutellarin, (4) liquiritin, (5) baicalin, (6) scutellarein, (7) wogonoside, (8) baicalein, (9) wogonin, and (10) chrysin; C: Structures of the major phytochemicals in HQD.



whereas oral administration of HQD mitigated these pathological alterations in a dose-dependent manner, as evidenced by relatively intact hepatic lobules and smaller fat vacuoles (Figure 2F). Additionally, Oil Red O staining showed numerous lipid droplets in the HFD group that reduced significantly following HQD treatment (Figure 2G and H). Notably, high-dose HQD exerted anti-steatosis effects comparable to those of Fen.

HQD mitigated liver damage and lipid metabolism disorders in HFD-induced NAFLD rats

Biochemical parameters of liver damage and lipid metabolism disorders, including ALT, AST, TC, TG, FFA, LDL-c, and HDL-c, are robust diagnostic markers for NAFLD. As shown in Figure 3, serum levels of ALT, AST, TC, TG, FFA, and LDL-c, as well as hepatic TC, TG, and FFA in the HFD group were noticeably higher than those in the control group. These levels were markedly reduced following HQD treatment. In contrast, the HFD-challenged group exhibited lower serum HDL-c level than the normal group, which was markedly restored following HQD treatment. In addition, the therapeutic efficacy of a high dose of HQD was equivalent to that of Fen.

HQD relieved hepatic inflammation and insulin resistance in HFD-induced NAFLD rats

Liver inflammation and insulin resistance are pivotal concomitant factors that facilitate NAFLD progression. Inflammation exacerbates insulin resistance, and both form a vicious cycle with each promoting the other and accelerating NAFLD progression[26]. As shown in Figure 4A and B, IL-1β-positive area in the liver of the HFD group was significantly higher relative to that in the control group, indicating extensive inflammatory response in the liver, which was further supported by markedly elevated levels of IL-6, IL-1β, and TNF-α in the liver (Figure 4C-E). However, all these alterations were reversed following HQD interventions. To ascertain the effect of HQD on glucose tolerance, an OGTT was performed. As shown in Figure 4F and G, higher levels of blood glucose (0–120 min) were noted in the HFD group following intragastric administration of glucose, which was robustly attenuated by HQD treatment. This was quantitatively verified by the AUC of the OGTT. Moreover, the HFD-induced elevation in serum insulin levels also decreased markedly following HQD treatment (Figure 4H). As shown in Figure 4I, the HOMA-IR value in HFD-challenged rats was significantly higher than that in normal rats, and was effectively reduced following HQD intervention. Notably, high-dose HQD showed curative efficacy similar to that of Fen.

HQD triggered the Sirt1/NF-κB pathway in HFD-induced NAFLD rats

Sirt1/NF-κB pathway-modulated insulin resistance and hepatic steatosis play an important role in the progression of NAFLD. Therefore, protein levels of Sirt1, NF-κB, p-NF-κB, and the downstream insulin signal transduction- and lipid metabolism-related proteins (*i.e.*, IRS-2, p-IRS-2, SREBP-1, FAS, and CD36) in the liver were examined. As shown in Figure 5A-G, Sirt1 and p-IRS-2 protein levels were significantly lower in the HFD group relative to that in the normal group, whereas those of p-NF-κB, SREBP-1, FAS, and CD36 were clearly elevated in response to HFD challenge. Oral supplementation with HQD markedly reversed these changes in a dose-dependent manner. To further validate these findings, the levels of Sirt1, p-NF-κB, and SREBP-1 were evaluated immunohistochemically. Consistent with the previous

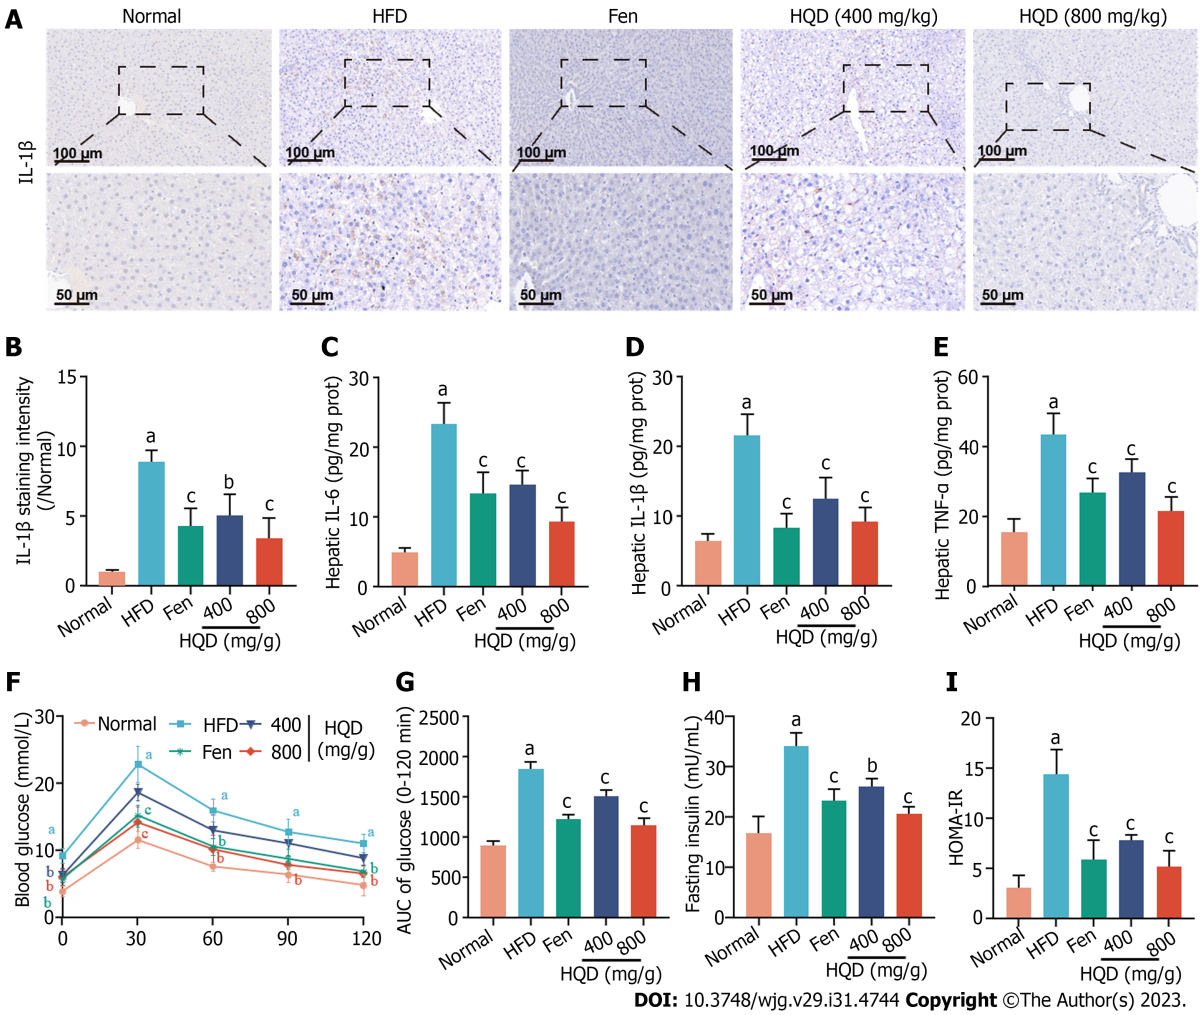
Figure 3 Huangqin decoction alleviates liver damage and lipid metabolism disorders in high-fat diet-induced nonalcoholic fatty liver disease rats. Data are presented as mean ± SD (n = 8). $^{a}P < 0.01$ *vs* the normal group, $^{b}P < 0.05$ and $^{c}P < 0.01$ *vs* high-fat diet group. A-J: Effects of different treatments on levels of alanine transaminase (A); aspartate transaminase (B); total cholesterol (TC) (C); triacylglycerol (TG) (D); free fatty acid (FFA) (E); low-density lipoprotein cholesterol (F); high-density lipoprotein cholesterol (G); TC (H); TG (I); FFA (J) levels in rats are shown. ALT: Alanine transaminase; AST: Aspartate transaminase; Fen: Fenofibrate; FFA: Free fatty acid; HDL-c: High-density lipoprotein cholesterol; HFD: High-fat diet; HQD: Huangqin decoction; LDL-c: Low-density lipoprotein cholesterol; TC: Total cholesterol; TG: Triacylglycerol.



data, mild staining intensity of Sirt1 (brown/fluorescence) and strong staining intensities of p-NF-κB (brown/fluorescence) and SREBP-1 (brown) were observed in the HFD group, indicating the up-regulation of these proteins and activation of Sirt1/NF-κB pathway (Figure 5H-P). However, HQD administration substantially reduced the increased expression noted in immunohistochemical analyses. Overall, these findings suggest that the therapeutic effects of HQD on HFD-induced disorders in insulin signaling and lipid metabolism are closely associated with the Sirt1/NF-κB pathway.

HQD improved steatosis, inflammation, and insulin resistance in PA-induced HepG2 cells

The direct exposure of HepG2 cells to PA is a commonly used approach to mimic the symptoms of NAFLD *in vitro*[27, 28]. PA-induced HepG2 cells were used to investigate the therapeutic effects of HQD in NAFLD *in vitro*. Initially, MTT assay was used to examine the cytotoxicity of HQD in HepG2 cells. As shown in Figure 6A and B, HQD presented no obvious cytotoxic effect in HepG2 cells at doses ≤ 150 μg/mL, and the safe concentration of HQD when co-incubated with PA (125 μM) was determined to be ≤ 125 μg/mL. Accordingly, HQD at doses of 25, 75, and 125 μg/mL were selected for the treatment of PA-induced HepG2 cells in subsequent experiments. As shown in Figure 6C and D, the levels of neutral lipids (TC and TG) in PA-challenged HepG2 cells were noticeably increased relative to that in the control cells, but markedly reduced following HQD intervention. This was further supported by the results of Oil Red O staining, which showed reduced lipid droplets in the HQD-treated groups (Figure 6E). As inflammation is a major cause of NAFLD and is strongly associated with insulin resistance, we examined the effects of HQD on the release of inflammatory factors in PA-challenged HepG2 cells. Figure 6F-H shows that HQD attenuated the PA-induced increase in the levels of IL-6, IL-1β, and TNF-β in a dose-dependent manner. A 2DG assay was performed to assess insulin resistance. The results showed that 2DG uptake was significantly lower in PA-treated HepG2 cells, whereas it increased markedly following HQD treatment (Figure 6I), indicative of the ameliorative effect of HQD on insulin resistance.

HQD exerted hepatocyte protection by triggering Sirt1/NF-κB pathway in PA-induced HepG2 cells

Consistent with the *in vivo* results, we noted that PA-stimulated HepG2 cells showed markedly decreased expression of

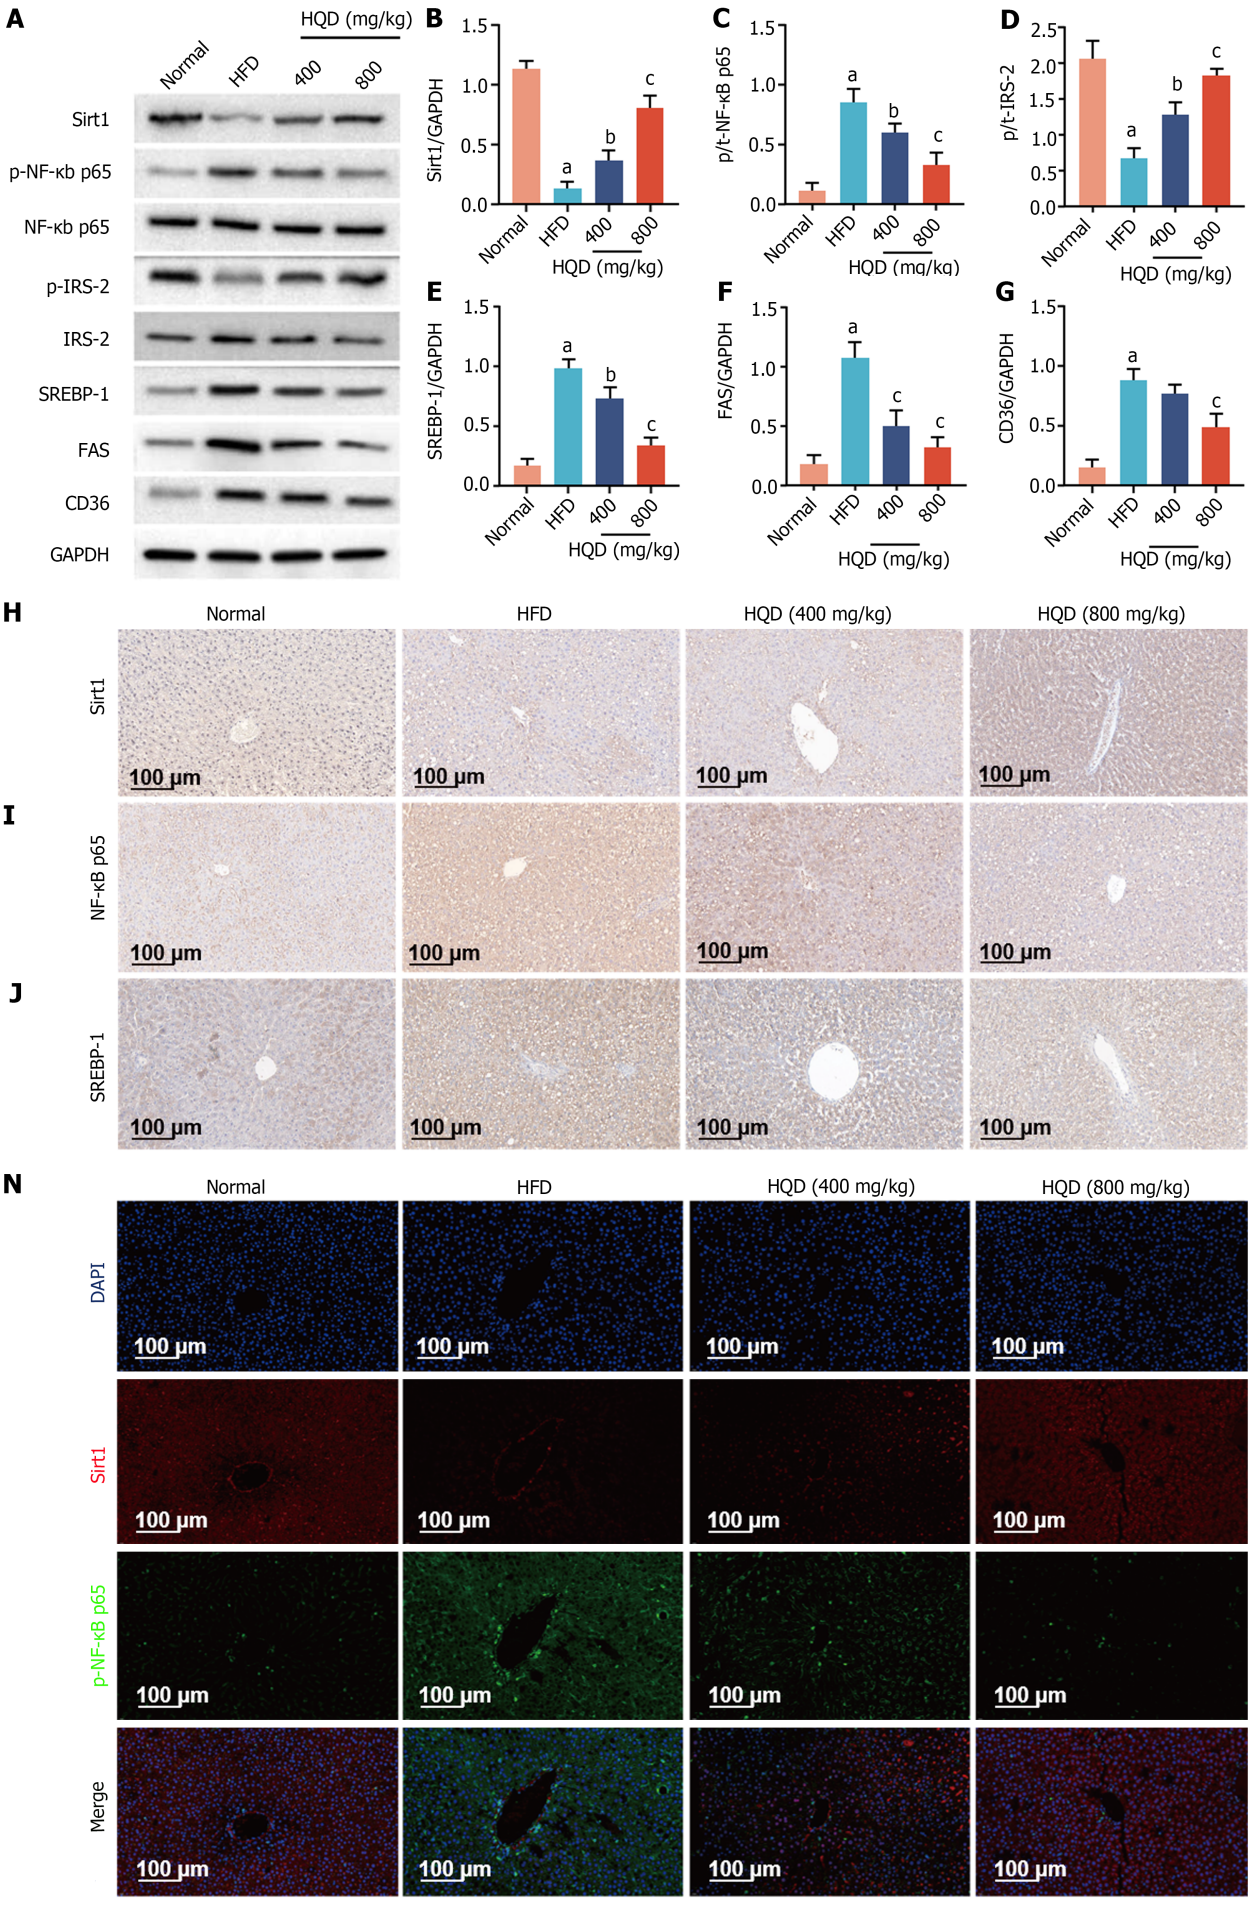

Figure 4 Huangqin decoction suppresses hepatic inflammation and insulin resistance in high-fat diet-induced nonalcoholic fatty liver disease rats. Data are presented as mean ± SD (n = 4–8). $^{a}P < 0.01$ *vs* the normal group, $^{b}P < 0.05$ and $^{c}P < 0.01$ *vs* the high-fat diet (HFD) group. A: Representative images of immunohistochemical staining of interleukin (IL)-1β in liver sections; B: Quantitative analysis of staining intensity of IL-1β; C-E: Levels of IL-6 (C), IL-1β (D), and tumor necrosis factor-α (E) in the liver of HFD-fed rats; F: Oral glucose tolerance test (OGTT); G: Area under the curve from OGTT; H: Level of fasting serum insulin; I: Values of homeostasis model assessment of insulin resistance. AUC: Area under the curve; Fen: Fenofibrate; HFD: High-fat diet; HOMA-IR: Homeostasis model assessment of insulin resistance; HQD: Huangqin decoction; IL: Interleukin; TNF: Tumor necrosis factor.

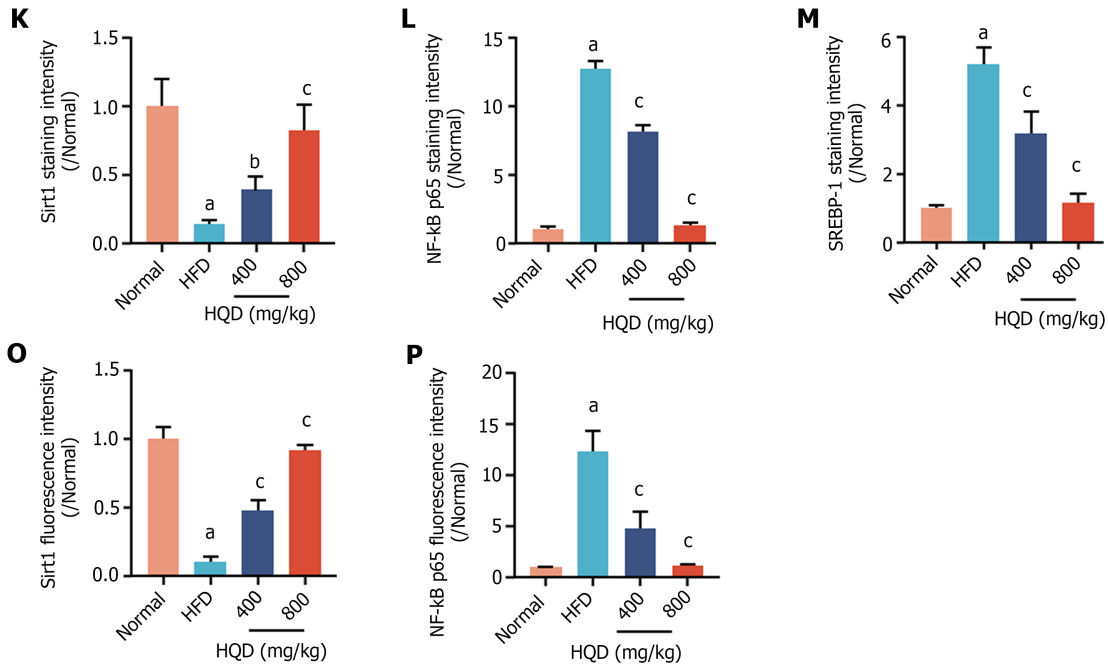

Sirt1 and p-IRS-2, and increased expression of p-NF-κB, SREBP-1, FAS, and CD36 compared with that in the control cells (Figure 7A-G), indicative of inhibition of the Sirt1/NF-B pathway. However, these changes were restored following HQD treatment. To further determine the expression and distribution of Sirt1 and NF-κB, immunofluorescence analyses were performed. Consistently, the intensity of Sirt1 staining in the PA group was clearly lower compared to that in the control group. Furthermore, significantly increased NF-κB nuclear translocation was noted in PA-induced HepG2 cells, which was conspicuously reversed following HQD treatment (Figure 7H). Collectively, these data suggest that HQD protects hepatocytes against PA-induced insults *via* the Sirt1/NF-κB pathway.

To further confirm that the HQD-mediated mitigatory effects on insulin resistance and lipid accumulation occurs *via* the Sirt1/NF-κB pathway, we used a Sirt1 inhibitor, EX-527 to block the pathway. As shown in Figure 8A-G, the ameliorative effects of HQD on lipid accumulation, inflammation, and 2DG uptake were significantly compromised following co-treatment with EX-527. More importantly, EX-527 abolished the regulatory effects of HQD on Sirt1/NF-κB pathway and its downstream-modulated insulin signal transduction- and lipid metabolism-related proteins (Figure 8H-O). In summary, our data indicate that the protective effects of HQD against hepatic lipid accumulation, inflammation, and insulin resistance are mediated through triggering of the Sirt1/NF-κB pathway.

DISCUSSION

NAFLD is the most prevalent chronic liver disease for which no specific effective drug has been approved, making its treatment a top research priority[29]. Unlike synthetic drugs, whose efficacy depends mainly on their action on one target, the efficacy of TCM depends on its holistic effects on multiple targets and pathways. Therefore, TCMs are promising complementary and auxiliary agents for metabolic diseases with multifactorial pathogeneses, such as NAFLD

[30-32]. HQD, a well-known TCM formula, has emerged as a potentially effective modality for the clinical treatment of liver diseases, including NAFLD. In our study, several constituents of HQD, including gallic acid, paeoniflorin, scutellarin, liquiritin, baicalin, scutellarein, wogonoside, baicalein, wogonin, and chrysin were identified by HPLC analysis. The beneficial effects of these compounds in NAFLD have been reported both *in vivo* and *in vitro*[33-36], which provide the basis for the potential application of HQD in NAFLD therapy. In the present study, using both *in vivo* and *in vitro* experiments, we demonstrated that HQD mitigates insulin resistance and hepatic steatosis by modulating the Sirt1/NF-κB pathway.

Overconsumption of HFD, which is associated with a modern lifestyle, plays a role in the progression of NAFLD[37]. Currently, NAFLD murine models are most commonly developed by long-term consumption of an HFD, resulting in symptoms similar to those observed in patients with NAFLD[37]. PA is an essential fatty acid for TG synthesis in the liver and increased concentrations of PA in hepatocytes accelerate the progression[38]. Typically, the exogenous addition of PA induces hepatocellular lipid accumulation to mimic the pathological process of NAFLD *in vitro*. We used HFD-fed rats and PA-treated HepG2 cells to study the therapeutic effects of HQD on NAFLD. Our results showed that the HFD-fed rats had higher body and liver weights. Histological analysis revealed hepatic steatosis and injuries, which were further supported by aberrant levels of TC, TG, ALT, and AST in the serum and liver. Furthermore, abnormal levels of serum FFA, LDL-c, HDL-c, OGTT, insulin, and HOMA-IR were observed in the HFD-fed rats, indicating the onset of dyslipidemia and insulin resistance. Consistent with these findings, PA-stimulated HepG2 cells exhibited a marked increase in lipid accumulation, intracellular TC and TG levels, and glucose uptake. Notably, all the above mentioned NAFLD symptoms were dose-dependently reversed following HQD treatment, indicating that HQD mitigates lipid metabolism disorders and insulin resistance in NAFLD.

Compromised lipid metabolism contributes to hepatic steatosis, thereby triggering the onset of NAFLD[39,40]. Several studies have confirmed that the activation of *de novo* lipogenesis (DNL) promotes FFA generation and esterification into TG, which are crucial driving factors contributing to lipid metabolism dysfunction[41]. A previous clinical trial revealed that individuals with NAFLD had higher nighttime plasma FFA levels and a threefold increase in DNL[42]. SREBP-1c is a key transcription factor that controls hepatic DNL and lipolysis by modulating the activities of lipogenic enzymes (FAS) and fatty acid importer proteins (CD36) as downstream targets[43-45]. The active state of SREBP-1c directly influences FLD progression in fatty liver[43]. In the present study, rats with HFD-induced NAFLD and PA-treated HepG2 cells showed elevated SREBP-1, FAS, and CD36 Levels, indicating increased DNL and fatty acid uptake. However, oral HQD supplementation effectively reversed these changes. Sirt1 plays a critical role in cellular energy metabolism and deacetylates and inhibits SREBP-1c activity in the regulation of hepatic lipid metabolism; however, it is downregulated in patients with NAFLD[15]. In the rat liver and HepG2 cells, we observed deactivation of Sirt1 following exposure to HFD or PA, whereas HQD treatment increased Sirt1 levels, resulting in NAFLD mitigation.

Figure 6 Huangqin decoction improves lipotoxicity, inflammation, and insulin resistance in palmitic acid-induced HepG2 cells. Data are presented as mean ± SD of at least three independent experiments. $^{a}P < 0.01$ *vs* the control group, $^{b}P < 0.05$ and $^{c}P < 0.01$ *vs* the palmitic acid (PA) group. A: Viability of HepG2 cells following incubation with different concentrations of Huangqin decoction (HQD); B: Viability of HepG2 cells following co-culture with PA and different concentrations of HQD; C and D: Levels of triacylglycerol and total cholesterol in HepG2 cells; E: Representative micrographs of Oil Red O staining of HepG2 cells; F–H: Levels of interleukin (IL)-6, IL-1β, and tumor necrosis factor-α in HepG2 cells; I: Level of glucose uptake in HepG2 cells. 2DG: 2-deoxydglucose; HQD, Huangqin decoction; IL: Interleukin; TC: Total cholesterol; TG: Triacylglycerol; TNF: Tumor necrosis factor; PA: Palmitic acid.

Insulin resistance is the initial driver of hepatic steatosis in NAFLD[10,11,46]. Moreover, recent studies have suggested that obesity-induced chronic low-grade inflammation exacerbates insulin resistance[26,47]. Specifically, hypertrophic adipocytes promote macrophage infiltration and secrete pro-inflammatory factors including IL-6, IL-1β, and TNF-α, which downregulate insulin signaling molecules by inhibiting the phosphorylation of IRS-2, ultimately promoting insulin resistance[48-50]. NF-κB acts as an inducible transcription factor and induces the production of pro-inflammatory factors [51]. A previous study reported that FFA-induced insulin resistance is strongly associated with the activation of the pro-inflammatory NF-κB pathway[52]. More importantly, Sirt1 can inactivate NF-κB by deacetylating lysine 310, impeding the expression of pro-inflammatory target genes, whereas patients with NAFLD are more susceptible to inactivation of the Sirt1/NF-κB pathway[17,53]. In both, *in vivo* and *in vitro* NAFLD models, phosphorylation of NF-κB was upregulated and accompanied by increased levels of pro-inflammatory factors (IL-1β, TNF-α, and IL-6), whereas phosphorylation of IRS-2 was downregulated, suggesting that Sirt1/NF-κB pathway-mediated insulin resistance occurred in NAFLD. In contrast, the HQD intervention clearly restored these changes. Furthermore, treatment with the Sirt1 inhibitor, EX-527, abolished all HQD-mediated favorable effects in PA-challenged HepG2 cells, confirming that HQD mitigated hepatic steatosis and insulin resistance *via* the Sirt1/NF-κB pathway.

Fen, a peroxisome proliferator-activated receptor α (PPARα) agonist, offers potential therapeutic efficacy against NAFLD by inducing fatty acid oxidation and inhibiting inflammatory gene expression in the liver[54,55]. Clinical studies have shown that Fen may have positive therapeutic outcomes in NAFLD/NASH[56,57]. Herein, we found that HQD achieved therapeutic effects comparable to those of Fen by activating Sirt1. Several studies have shown that Sirt1, a key regulator of PPARα signaling, can trigger PPARα-mediated fatty acid oxidation in the liver, showing favorable effects in NAFLD[9,58,59]. Although HQD and Fen act on different targets, their therapeutic effects could be interpreted from the upstream and downstream regulatory relationships between Sirt1 and PPARα make.

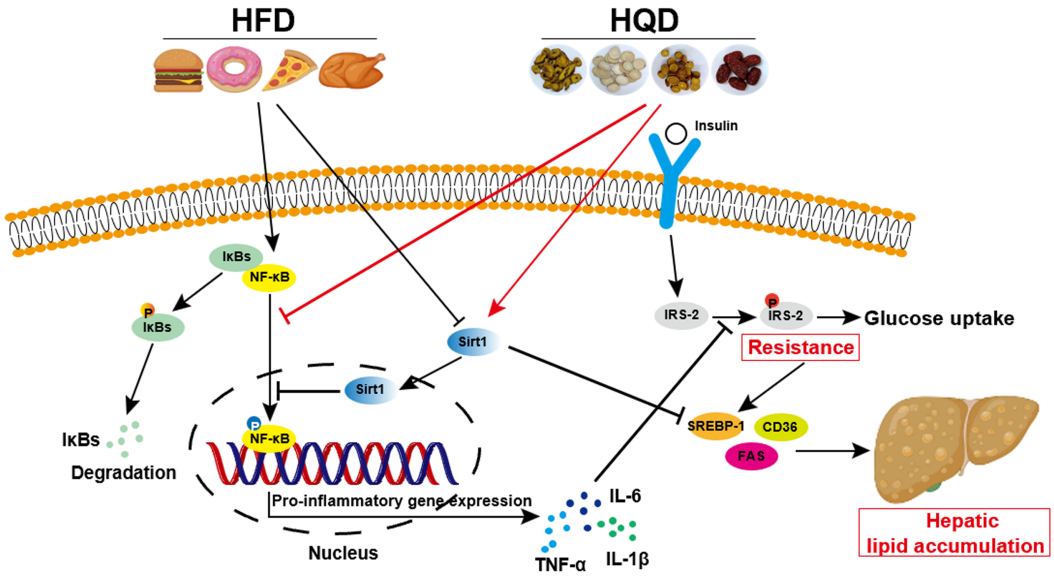
CONCLUSION



In summary, we have demonstrated the mitigating effects of HQD on lipid metabolism disorders and insulin resistance. Our investigations revealed that HQD mediates these beneficial effects by modulating lipogenesis and inflammatory responses which trigger the Sirt1/NF-κB pathway (Figure 9). Our study provides strong evidence supporting HQD as a promising agent for NAFLD treatment.

ARTICLE HIGHLIGHTS

Research background

Non-alcoholic fatty liver disease (NAFLD) is the most common chronic liver disease, for which no effective therapeutic drugs have been approved. Huangqin decoction (HQD), a traditional Chinese medicine, has been widely used to treat liver diseases in clinical practice. Our study confirmed that HQD effectively mitigates high-fat diet (HFD)-induced hepatic inflammation. However, whether HQD has ameliorative effects on lipid metabolism disorders and insulin resistance, as well as the underlying mechanisms, remains unclear.

Research motivation

Convincing evidence for HQD in the clinical treatment of NAFLD is required.

Research objectives

This study aimed to investigate the therapeutic efficacy of HQD on lipid metabolism disorders and insulin resistance and explore the possible molecular mechanisms by focusing on the Sirt1/NF-κB pathway.

Research methods

High-performance liquid chromatography was used to identify the key components of HQD. HFD-induced NAFLD rats and palmitic acid-induced HepG2 cells were treated with HQD to investigate the mitigating effects of HQD on lipid metabolism disorders and insulin resistance. Finally, molecular biology techniques, including western blotting, immunohistochemistry, and immunofluorescence, were applied to explore the protein expression in the Sirt1/NF-κB pathway.

Research results

Ten key components of HQD were identified. The results showed that HQD effectively prevented lipid metabolism disorders in rats and HepG2 cells, inflammatory responses, and insulin resistance. Mechanistic exploration revealed that triggering Sirt1/NF-κB pathway-modulated lipogenesis and inflammation contributed to the favorable effects of HQD, which was further validated by the addition of EX-527 (a Sirt1 antagonist).

Research conclusions

Supported by our previous findings, we strongly believe that HQD is a promising complementary or auxiliary agent for the clinical treatment of NAFLD.

Research perspectives

HQD has been used to treat liver diseases in clinical practice for decades, with positive outcomes. More in-depth and precise research on the molecular mechanisms of HQD could guide and promote the clinical treatment of NAFLD more effectively.

Abstract

BACKGROUND

Gastric cancer (GC) incidence based on the endoscopic Kyoto classification of gastritis has not been systematically investigated using time-to-event analysis.

AIM

To examine GC incidence in an endoscopic surveillance cohort.

METHODS

This study was retrospectively conducted at the Toyoshima Endoscopy Clinic. Patients who underwent two or more esophagogastroduodenoscopies were enrolled. GC incidence was based on Kyoto classification scores, such as atrophy, intestinal metaplasia (IM), enlarged folds (EFs), nodularity, diffuse redness (DR), and total Kyoto scores. Hazard ratios (HRs) adjusted for age and sex were calculated using a Cox hazard model.

RESULTS

A total of 6718 patients were enrolled (median age 54.0 years; men 44.2%). During the follow-up period (max 5.02 years; median 2.56 years), GC developed in 34 patients. The average frequency of GCs per year was 0.19%. Kyoto atrophy scores 1 [HR with score 0 as reference: 3.66, 95% confidence interval (CI): 1.06 to 12.61], 2 (11.60, 3.82-35.27), IM score 2 (9.92, 4.37-22.54), EF score 1 (4.03, 1.63-9.96), DR scores 1 (6.22, 2.65-14.56), and 2 (10.01, 3.73-26.86) were associated with GC incidence, whereas nodularity scores were not. The total Kyoto scores of 4 (HR with total Kyoto scores 0-1 as reference: 6.23, 95%CI: 1.93 to 20.13, $P = 0.002$) and 5-8 (16.45, 6.29-43.03, $P < 0.001$) were more likely to develop GC, whereas the total Kyoto scores 2-3 were not. The HR of the total Kyoto score for developing GC per 1 rank was 1.75 (95%CI: 1.46 to 2.09, $P < 0.001$).

CONCLUSION

A high total Kyoto score (≥ 4) was associated with GC incidence. The endoscopy-based diagnosis of gastritis can stratify GC risk.

Key Words: Gastric cancer; Gastritis; Endoscopy; Atrophy; Intestinal metaplasia; Kyoto classification

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: A high total Kyoto score (≥ 4) was associated with gastric cancer (GC) incidence. Adjusted hazard ratios (HRs) for the total Kyoto scores of 4 and 5-8 were high at 6.23 and 16.45, respectively, compared to the total Kyoto scores of 0-1. The HR of the total Kyoto score for developing GC per 1 rank was 1.75.

INTRODUCTION

Gastric cancer (GC) is a global health problem and the third most common cause of cancer-related deaths worldwide[1]. *Helicobacter pylori* (*H. pylori*) infection is estimated to account for 89% of GC cases, and *H. pylori*-related gastritis is a precursor of GC[2-6]. Evaluation of *H. pylori*-related gastritis is clinically important because it allows for the risk stratification of GC[2,7-9]. Endoscopy detects early GCs and precisely diagnoses gastritis. Periodic endoscopic screening can reduce deaths from GC[10]. Recent advances in endoscopic technology allow for more accurate endoscopic diagnosis of gastritis[11,12].

The endoscopy-based Kyoto classification of gastritis was advocated by the Japan Society for Gastrointestinal Endoscopy in 2013. This classification aims to ensure that the endoscopic diagnosis of gastritis is unified and matched with the histopathology[13]. Recently, the Kyoto classification has been widely used in clinical practice and vigorously studied worldwide[14,15]. To assess GC risk, the Kyoto classification individually scores five *H. pylori*-related gastritis findings, such as atrophy, intestinal metaplasia (IM), enlarged fold (EF), nodularity, and diffuse redness (DR), and defines their sum as the total Kyoto score.

Several investigations have clarified that not only individual Kyoto scores but also the total Kyoto score are associated with *H. pylori* infection and GC risks[14]. For example, the total Kyoto score was associated with *H. pylori* infection, presence of GC[16-19], and GC risk indicators, such as serum pepsinogen titer, serum *H. pylori* antibody titer, histological distribution of neutrophil infiltration in the gastric mucosa, and genotype of the single nucleotide polymorphism. Collectively, total Kyoto scores of 0, ≥ 2, and ≥ 4 indicated a normal stomach, *H. pylori*-infected gastritis, and gastritis at risk for GC, respectively[14].

To date, GC incidence based on the Kyoto classification scores has not been systematically investigated using time-to-event analysis. Therefore, we examined GC incidence according to the five individual Kyoto scores and the total Kyoto score in the endoscopic surveillance cohort and verified the GC risks of endoscopic gastritis in Japan, which is a high GC morbidity area.

MATERIALS AND METHODS

Study design and overview

This cohort study was retrospectively conducted at the Toyoshima Endoscopy Clinic. We obtained data from the Toyoshima Endoscopy Clinic Database. This study was approved by the institutional review board of the Yoyogi Mental Clinic (approval no. RKK227). Written informed consent was obtained from patients at the time of esophagogastroduodenoscopy (EGD) to use their data for research purposes. The study's protocol was published on our institute's website (

www.ichou.com) so that patients could opt out of the study. All clinical investigations were conducted in accordance with the ethical guidelines of the Declaration of Helsinki.

Patients

This study enrolled patients who underwent two or more EGDs at the Toyoshima Endoscopy Clinic, an urban area in Tokyo, Japan, between April 2017 and April 2022. We excluded patients with a previous surgical gastrectomy at baseline and those who underwent the last EGD within one month after the index EGD. The indications for the index EGD included screening, surveillance for gastritis or other upper gastrointestinal diseases, and examination for symptoms or abnormal findings on other tests. *H. pylori* status was determined using serum anti-*H. pylori* antibodies, urea breath test, histology, and/or endoscopy.

Kyoto classification score

In the Kyoto classification, the total Kyoto score was developed as a GC risk score[14]. The total Kyoto score is calculated as the sum of the following five Kyoto scores: Atrophy, IM, EF, nodularity, and DR, and ranges from 0 to 8 (Supplementary Table 1). Atrophy was classified based on the extent of mucosal atrophy using the Kimura-Takemoto classification[20]. Non-atrophy and Closed I, Closed II and III, and Open I to III were scored as atrophy scores of 0, 1, and 2, respectively. The IM commonly appears as a grayish-white, slightly elevated patch. IM scores of 0, 1, and 2 were defined as the absence of IM, IM limited to the antrum, and IM extending into the corpus, respectively. EF was defined as a width of ≥ 5 mm in the greater curvature of the corpus, which was not flattened by stomach insufflation. The absence and presence of EF were scored as 0 and 1, respectively. Nodularity was identified by a miliary pattern resembling "goose flesh", which was typically located in the antrum. The absence and presence of nodularity were scored 0 and 1, respectively. DR indicated uniform redness observed in the non-atrophic mucosa, mainly in the greater curvature of the corpus. The regular arrangement of collecting venules (RAC) in the corpus appears as numerous dots, which are starfish-like shapes in close view. DR scores of 0, 1, and 2 were defined as the absence of DR, mild DR and/or DR with partial RAC, and severe DR without RAC, respectively[14].

EGD

EGDs were performed by gastrointestinal endoscopists using the Olympus' (Tokyo, Japan) endoscopic system (EVIS X1 or LUCERA ELITE) and endoscope (GIF-XZ1200, GIF-1200N, GIF-HQ290, GIF-H290Z, or GIF-XP290N). The T-File System (STS-MEDIC Inc., Tokyo, Japan) was used to file endoscopic images and document endoscopic findings.

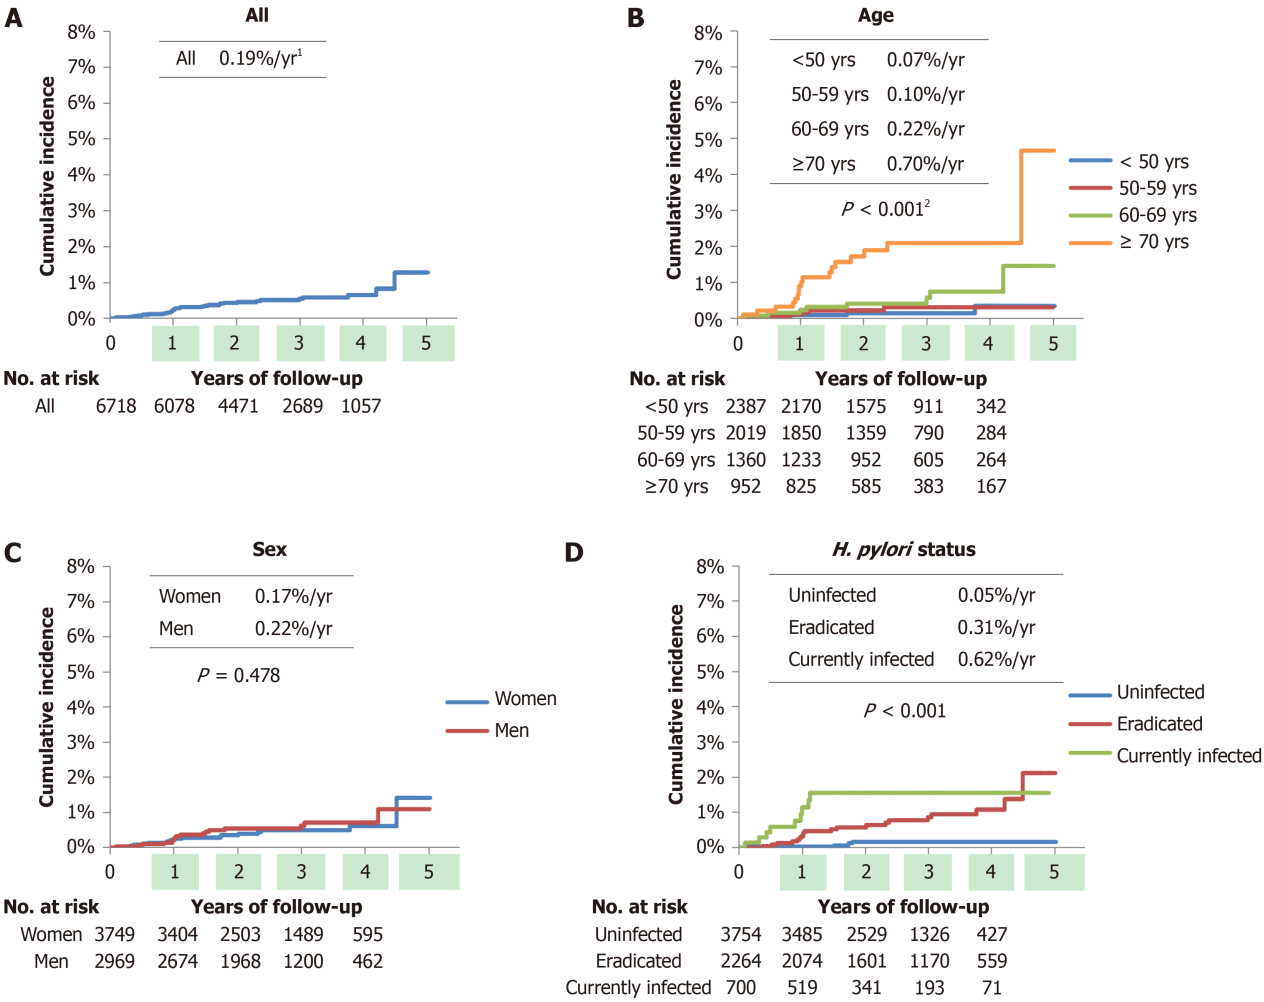
The Kyoto classification scores were assessed using white light imaging without magnification. The endoscopists diagnosed the Kyoto classification scores on-site during EGD, and it was retrospectively reviewed by experienced endoscopists. Endoscopists performed EGDs after learning from textbooks and journal articles on the Kyoto classification of gastritis[14,21].

GC

GC was histologically diagnosed based on biopsy or resected specimens. GC morphology and histology were classified based on the Japanese classification of gastric carcinoma[22] and Lauren's classification[23], respectively.

Outcomes

This cohort study evaluated GC incidence based on patients' age, sex, *H. pylori* status, and endoscopic Kyoto classification scores of gastritis, such as atrophy, IM, EF, nodularity, DR, and total Kyoto scores. The primary outcome was GC incidence according to the total Kyoto score. We performed a time-to-event analysis with the start time as the date of index EGD. Data were censored on the date of the last EGD. The effects of Kyoto classification scores on GC development were estimated. The total Kyoto scores were categorized into 4 (*i.e.*, 0-1, 2-3, 4, and 5-8) based on the frequency of GC increasing stepwise with the total Kyoto scores of 0-1, 2-3, and ≥ 4 in a cross-sectional study[24] and the number of patients in this study. The secondary outcomes were GC incidence according to the Kyoto atrophy, IM, EF, nodularity, and DR scores.



Statistical analysis

Baseline characteristics were compared between GC and non-GC groups using binomial logistic regression model. Kaplan-Meier curves were constructed according to patient age, sex, *H. pylori* status, and Kyoto classification scores (*i.e.*, atrophy, IM, EF, nodularity, DR, and the total Kyoto scores). Statistical differences were estimated using the log-rank tests. The average frequency of GCs per year was calculated by dividing the number of events by the total person-years of observation. Hazard ratios (HRs) with 95% confidence intervals (CIs) for GC development were estimated using the Cox proportional hazards regression model. In multivariate analysis, HRs were adjusted for patient age and sex. A P value < 0.05 (two-sided) was defined as statistically significant. Statistical analysis was conducted using BellCurve for Excel version 4.03 (Social Survey Research Information Co., Ltd., Tokyo, Japan).

RESULTS

Patient enrollment

A total of 30585 EGDs in 16969 patients were performed during the study period. Six thousand seven hundred forty-four

Figure 1 Cumulative incidence of gastric cancer according to patient demographic characteristics. A-D: Kaplan-Meier curves of gastric cancer development for all patients (A), according to age (B), sex (C), and *Helicobacter pylori* status (D). [1]The average frequency of gastric cancer per year. [2]*P* values were calculated using a log-rank test.

patients underwent two or more EGDs. Of these, 19 patients with a previous surgical gastrectomy and 7 with a follow-up period of less than 1 mo were excluded. A total of 6718 patients were enrolled.

The baseline patient characteristics are shown in Table 1. The median age of the patients was 54 years with the interquartile range (IQR) of 46-64 years. Men accounted for 44.2% of the cases. The proportion of patients with *H. pylori* status of uninfected, eradicated, and currently infected was 55.9%, 33.7%, and 10.4%, respectively. Patients were followed up for up to 5.02 years (median 2.56 years, IQR 1.74-3.64 years). The median (IQR) of Kyoto classification scores were 0 (0-1) for atrophy; 0 (0-0) for IM, EF, nodularity, and DR; and 0 (0-2) for total Kyoto. Supplementary Table 2 is shown with the mean and standard deviation. During the follow-up period, 37 GCs occurred in 34 patients. The characteristics of GCs are presented in Table 2. All GCs were superficial and within the submucosal depth. Lauren's intestinal type made up 89.1% of GCs.

GC incidence

Kaplan-Meier curves of GC development according to patient demographic characteristics are shown in Figure 1. In this study, the average frequency of GCs was 0.19%/year. Age and *H. pylori* status were associated with GC incidence (both $P < 0.001$), whereas sex was not.

Figures 2A-E show the cumulative incidence using the Kaplan-Meier method for each Kyoto classification score. Atrophy, IM, EF, and DR scores were associated with GC development (all $P < 0.001$), whereas nodularity was not. The average frequencies of GCs per year were 0.04%, 0.17%, and 0.73% for atrophy scores of 0, 1, and 2; 0.07%, 0.25%, and 1.10% for IM scores of 0, 1, and 2; 0.17% and 0.92% for EF scores of 0 and 1; and 0.06%, 0.55%, and 0.74% for DR scores of 0, 1, and 2, respectively. The total Kyoto score was associated with GC development ($P < 0.001$), as shown in Figure 2F. The average frequencies of GCs were 0.05, 0.07, 0.47, and 1.27% per year for the total Kyoto scores of 0-1, 2-3, 4, and 5-8, respectively.

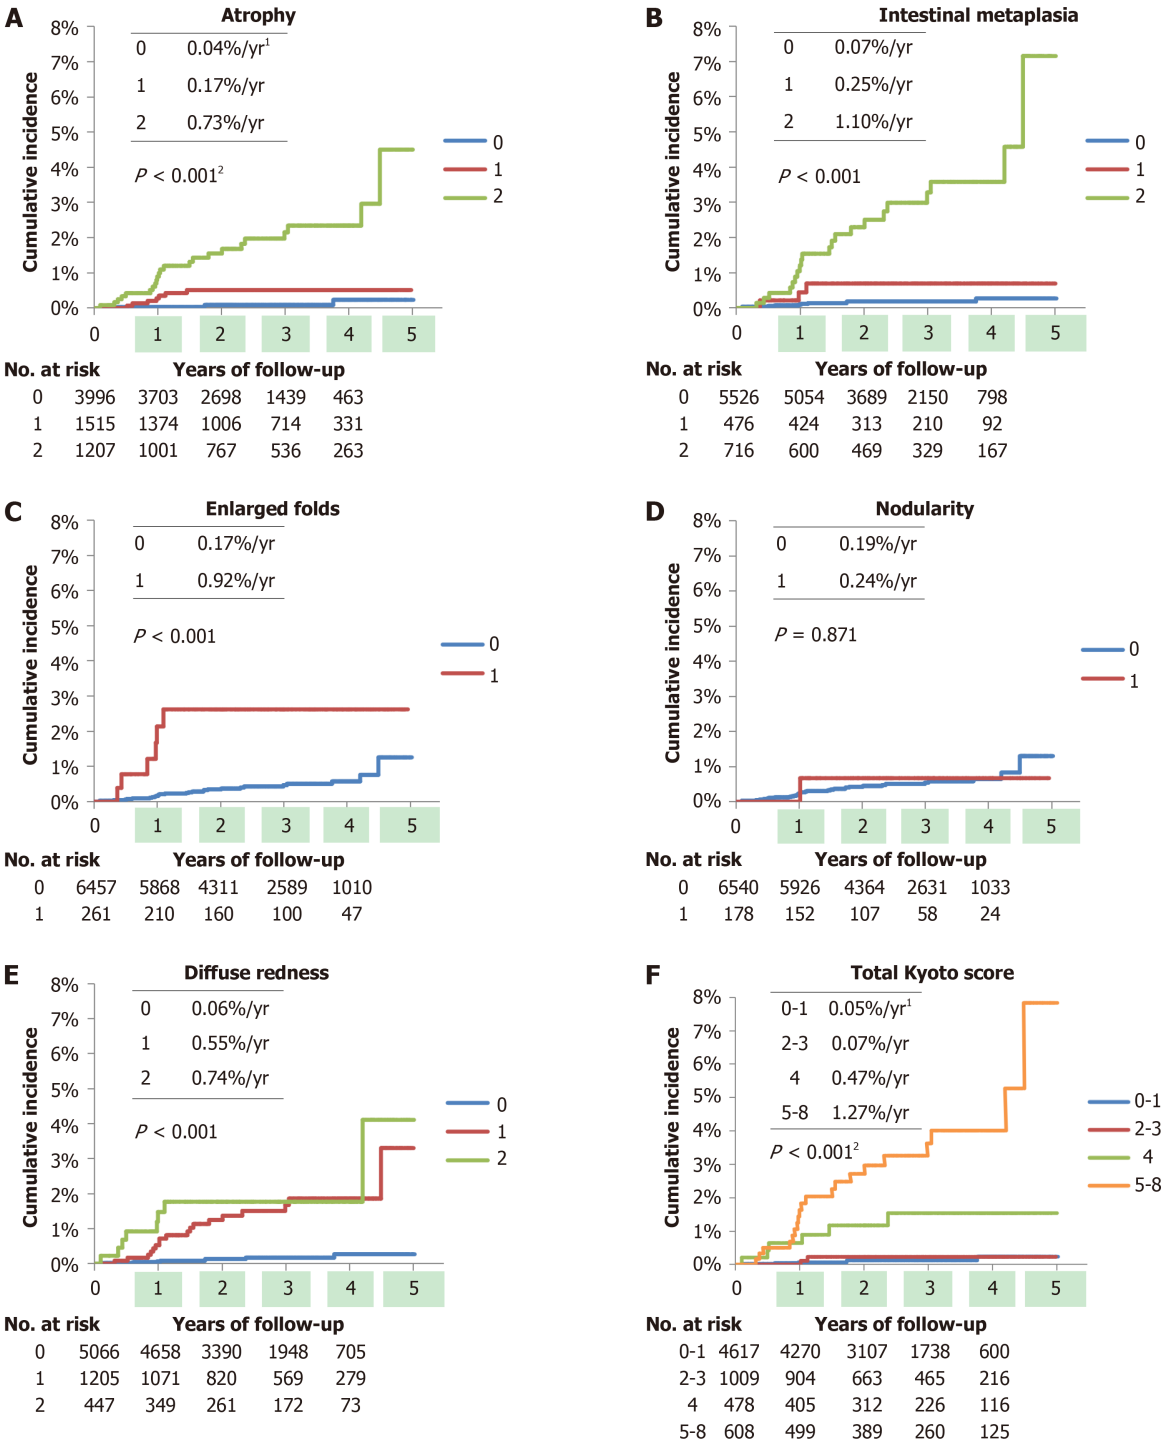
Multivariate analysis of GC incidence

Table 3 provides the crude and adjusted HRs for GC development according to Kyoto classification scores. Multivariate analysis showed that atrophy scores 1 (adjusted HR with score 0 as reference: 3.66, 95%CI: 1.06 to 12.61), 2 (11.60, 3.82-35.27), IM score 2 (9.92, 4.37-22.54), EF score 1 (4.03, 1.63-9.96), DR scores 1 (6.22, 2.65-14.56), and 2 (10.01, 3.73-26.86) were significantly associated with GC incidence, independent of patient age and sex, whereas nodularity score was not.



The total Kyoto scores of 4 (adjusted HR with total Kyoto scores 0-1 as reference: 6.23, 95%CI: 1.93 to 20.13, $P = 0.002$) and 5-8 (16.45, 6.29-43.03, $P < 0.001$) were more likely to develop GC, whereas the total Kyoto scores of 2-3 were not. In

[1]The average frequency of gastric cancer per year. [2]*P* values were calculated using a log-rank test.

DISCUSSION

We found that high total Kyoto scores, especially ≥ 4, were associated with GC incidence. The adjusted HR of the total Kyoto score for GC development was 1.75 per 1 rank analysis. Additionally, adjusted HRs for the total Kyoto scores of 4 and 5-8 were high at 6.23 and 16.45, respectively, compared to the total Kyoto scores of 0-1. The total Kyoto score was associated with the cumulative incidence of GC ($P < 0.001$). The average frequencies of GCs per year increased with the total Kyoto score (0.05%, 0.07%, 0.47%, and 1.27% for the total Kyoto scores of 0-1, 2-3, 4, and 5-8, respectively). This is the first report that shows that high total Kyoto scores represent GC risks in a time-to-event analysis. This finding is consistent with those of several previous studies. In cross-sectional studies, we and Lin *et al*[19] reported that the odds

ratios of the total Kyoto score for GC were 1.6 and 1.5 per 1 rank, respectively[18]. Liu *et al*[24] indicated an increased trend of GC frequency in patients with total Kyoto scores of 0-1, 2-3, and ≥ 4. Some investigators showed that the mean total Kyoto scores of the patients with GC, *H. pylori*-infected GC, and *H. pylori*-eradicated GC were 4.0-4.6, 4.8-5.6, and 4.2, respectively[18,25,26]. Taken together, a total Kyoto score ≥ 4 was available for determining GC risks.

This cohort study demonstrated that patients with endoscopy-based atrophy, IM, EF, and DR are more likely to develop GC. In contrast, nodularity was not associated with GC incidence. Endoscopic atrophy has been shown to be a predictor of GC development. Shichijo *et al*[27] described a significantly higher adjusted HR of severe atrophy for developing GC as 9.3, while we identified significantly higher adjusted HRs of Kyoto atrophy scores 1 and 2 as 3.7 and 11.6, respectively. Several cohort studies have shown that severe endoscopic atrophy is associated with a high incidence of GC, especially in patients who have undergone *H. pylori* eradication[9,27,28]. These studies revealed that the average frequencies of GCs per year for non-to-mild, moderate, and severe atrophy were 0.06%-0.15%, 0.12%-0.34%, and 0.31%-1.60%, respectively. Similarly, our study showed that the average frequencies of GCs per year for total Kyoto scores of 0, 1, and 2 were 0.04%, 0.17%, and 0.73%, respectively. Since more than half of the study patients were uninfected with *H. pylori*, our study may present a lower GC incidence in patients with a Kyoto atrophy score of 0. Two meta-analyses also showed that a high Kyoto atrophy score provided a high-risk ratio of 2.8-8.0[29,30]. Thus, our study results are in line with those of previous studies.

Although the risk of GC in histological IM has been well studied[2,8,27,31,32], few studies have examined GC risks associated with endoscopic IM. A high Kyoto IM score has been identified as a risk factor for GC, especially multiple GC [14,18]. This study revealed that endoscopic corpus IM was associated with GC development (adjusted HR: 9.92), which is supported by Sakitani *et al*[33], who clarified histological corpus IM as a predictor of GC. The consistency of IM between endoscopy and histology has been demonstrated[13]; we successfully verified endoscopic IM as a risk factor for GC using event history analysis.

Watanabe *et al*[34] provided an adjusted HR of EF for GC development as high as 43.3, whereas our study's adjusted HR was 4.03. These results are similar; however, the difference in HRs between them may be attributed to the inclusion of many *H. pylori*-uninfected individuals in the study population. However, whether nodularity is a risk factor for GC remains controversial. Nodularity has been reported to be a juvenile and histologically diffuse-type GC risk[35,36], whereas we have shown in a cross-sectional study that the odds ratio for GC of nodularity is low at 0.5[18]. After adjusting for age and sex, no association between nodularity and GC was observed. Although nodularity decreases with age[37], the risk of intestinal-type GC increases with age. Furthermore, intestinal-type cancers are more common than diffuse-type cancers. Therefore, age offsets the association of nodularity with GC, especially in older generations, although nodularity is associated with diffuse-type GC in the young generation[35]. As the association between nodularity and the risk of developing GC is still debated, nodularity might be listed separately. For example, the total Kyoto classification score for atrophy 1, IM 0, EF 1, nodularity 1, and DR 1 might be reported as 3 + 1 instead of 4.

Several studies have reported that DR is strongly associated with *H. pylori* infection[15,38-40], but little is known about the association between DR and GC incidence. This study identified Kyoto DR scores of 1 and 2 as indicators of GC incidence (adjusted HRs: 6.22 and 10.01, respectively). Since DR presents inflammatory cell infiltration caused by *H. pylori* [13] and *H. pylori* infection is a definite risk factor for GC[2,3], DR is expressed as a GC risk. Additionally, since the Kyoto DR score includes RAC as a negative factor and RAC is inversely associated with GC development[41], a high Kyoto DR score may be associated with high GC incidence.

This study has some limitations. First, this was a single-center, retrospective cohort study. Although the endoscopy data were well-organized, multi-center, prospective studies are warranted. Second, this study was conducted only in areas with a high GC prevalence in Asia. Therefore, studies in Western countries are warranted. Third, the total Kyoto score has shortcomings in the scoring design, which simply adds five individual Kyoto scores[14]. IM is associated with a high risk of intestinal-type GC but a low risk of diffuse-type GC[18]. In addition, EF and nodularity are high risks for diffuse-type GC but low risks for intestinal-type GC. Therefore, the evaluation of GC risk using a scoring system that individually predicts the risks of intestinal- and diffuse-type GCs is needed.

CONCLUSION

In conclusion, a high total Kyoto score of ≥ 4 was associated with GC incidence in a cohort study. The endoscopy-based diagnosis of gastritis can stratify GC risk.

ARTICLE HIGHLIGHTS

Research background

The Japan Gastroenterological Endoscopy Society advocated the Kyoto classification, a new grading system for endoscopic gastritis in 2013.

Research motivation

Although a high Kyoto score is believed to reflect an increased gastric cancer (GC) risk, it has not been systematically investigated using time-to-event analysis.

Research objectives
We examined GC incidence according to the total Kyoto score in the endoscopic surveillance cohort and verified the GC risks of endoscopic gastritis.

Research methods
Patients who underwent two or more esophagogastroduodenoscopies were enrolled. GC incidence was based on Kyoto classification scores. Hazard ratios (HRs) adjusted for age and sex were calculated using a Cox hazard model.

Research results
A total of 6718 patients were enrolled. The annual incidence rate of GC was 0.19%. The total Kyoto scores of 4 [HR with total Kyoto scores 0-1 as reference: 6.23, 95% confidence interval (CI): 1.93 to 20.13, $P = 0.002$] and 5-8 (16.45, 6.29-43.03, $P < 0.001$) were more likely to develop GC, whereas the total Kyoto scores 2-3 were not. The HR of the total Kyoto score for developing GC per 1 rank was 1.75 (95%CI: 1.46 to 2.09, $P < 0.001$).

Research conclusions
A total Kyoto score ≥ 4 could predict GC risk. The endoscopic Kyoto classification of gastritis can stratify GC risk.

Research perspectives
This was a single-center, retrospective cohort study, and multi-center, prospective studies are warranted.

Abstract

BACKGROUND

Heartburn is identically the key symptom of both, gastroesophageal reflux disease (GERD) and functional heartburn (FHB), making the differential diagnosis resource-intensive. Oral manifestations of GERD can be easily examined; therefore, their exploration might be a cheap, widely available, and useful tool in the differentiation of GERD and FHB.

AIM

To evaluate the prevalence of dental erosions (DE) and periodontal diseases (PD) in patients with heartburn and their association with GERD and FHB.

METHODS

A total of 116 [M/F: 51/65, mean age: 54 (17-80) years] consecutive patients with heartburn were enrolled for detailed esophageal function and orodental examinations.

RESULTS

Dental disorders were detected in 89% (103/116). Patients with PD + DE had significantly more often pathologic reflux (90.0% *vs* 27.8%; $P < 0.05$), higher esophagitis scores (1.8 *vs* 0.9; $P < 0.05$), and a significantly different mean impedance curve ($P = 0.04$) than those without any dental diseases. The opposite approach established that patients with GERD had significantly higher prevalence of DE and PD, especially if both were present (28.9% *vs* 2.0%; $P < 0.01$), more severe PD (1.5 *vs* 1.0; $P < 0.01$), and longer history of heartburn (15 years *vs* 9 years; $P < 0.01$) than those with FHB.

CONCLUSION

The dental evaluation of patients with heartburn seems to be useful in the differential diagnosis of GERD and FHB. Among the studied parameters, the co-appearance of DE and PD seems to be the best predictor of GERD, whereas the absence of dental disorders was mostly observed in FHB.

Key Words: Gastroesophageal reflux disease; Gastric acid; Heartburn; Differential diagnosis; Epidemiology; Oral manifestations; Prevalence; Risk factors; Dental erosion; Periodontal diseases

INTRODUCTION

Heartburn is mostly considered a typical symptom of gastroesophageal reflux disease (GERD) and has a global prevalence of 11.9%. However, it cannot be diagnosed without performing detailed esophageal function tests based on the symptom of patients with functional heartburn (FHB)[1].

According to the Montreal definition, GERD may be associated with supraesophageal manifestations, including oropharyngeal symptoms[2]. Among various oropharyngeal symptoms (salivation, mouth burning, and tongue burning), dental erosion (DE) is considered to have a proven correlation with GERD. The association between DE and GERD was apparently first reported in 1933[3]. By definition, DE is a progressive loss of tough tissues of the teeth due to the action of extrinsic or intrinsic acids. Its median prevalence has been reported to be 24% in all patients with GERD and 32.5% in adult patients with GERD[4]. However, DE can be accompanied by other disorders, such as bulimia, rumination, and the consumption of acidic foods or drinks.

Much less data are available regarding other oral symptoms, especially periodontal diseases (PD), which have recently been suggested to be associated with GERD[5]. PD, which represent a group of oral inflammatory conditions caused by oral pathogens, lead to the destruction of tooth-supporting soft tissues. DE and PD may be considered as cumulative lesions, representing the long-term consequences of gastroesophageal reflux.

To the best of our knowledge, currently, no studies have been performed to assess hard and soft tissue injuries (DE and PD), and their relationship has never been investigated from dental and gastroenterological perspectives. Moreover, there are no studies about the possibility to distinguish GERD from FHB on the basis of oral manifestations.

Therefore, we aimed to obtain data on the prevalence of DE and PD in patients with heartburn and evaluate their association with GERD.

MATERIALS AND METHODS

One-hundred and sixteen consecutive patients (M/F: 51/65, mean age: 54.00 years ± 15.62 years) with heartburn were enrolled in our tertiary center for detailed esophageal function testing, including upper gastrointestinal endoscopy, high-resolution esophageal manometry [medical measurement systems (MMS) solar with a 22-channel, water-perfused catheter], and 24-h multi-channel intra-esophageal pH-impedance monitoring (MMS Ohmega®, with a pHersaflex Z61A pH probe). Any medications with any effect on gastrointestinal motility or gastric secretion were suspended one month before the esophageal testing. For gastroscopy, Olympus GIF-Q165 endoscopes were used, and the procedure was carried out under local, topical anesthesia. The presence of esophageal manifestations was recorded. Esophagitis was classified per the Los Angeles criteria[6]. On this basis, the following scoring system (no erosion = 0, LA-A = 1, LA-B = 2, LA-C = 3, LA-D = 4) was applied for quantitative comparison of the degree of esophagitis. Esophagogastric junction outflow obstruction and other major motility disorders were excluded *via* high-resolution esophageal manometry according to the Chicago classification 3.0[7]. During pH-impedance monitoring, the pH sensor was placed 5 cm above the lower esophageal sphincter as determined *via* manometry.

The significance of GERD was judged by the Lyon consensus[8]. The diagnosis of FHB was established according to the Rome IV criteria[9], including < 4% acid exposure time in the esophagus and the independence of symptoms of acidic and non-acidic reflux episodes. The occurrence of reflux hypersensitivity was also evaluated, but none of the studied patients fulfilled the accepted Rome IV criteria of this disease. Moreover, baseline impedance values were above 2000 Ω in this patient group[10]. We also calculated the mean 24-h impedance in all channels, the impedance values of the six channels during the 24-h measurement were exported to a .csv file and averaged.

Before dental examinations, general personal data, social and dental habits, and the presence, frequency, and appearance of typical and atypical reflux symptoms were assessed using standardized questionnaires that were collected by an interviewer (medical doctor and student). Among the enrolled subjects, 116 patients [M/F: 51/65, mean age: 56 (22-82) years] with heartburn were participating in further oral and dental examinations. Oral evaluations were carried out by a dentist who was blinded to the results of the esophageal function tests. The tooth wear index was evaluated and scored using the Smith and Knight's criteria, while the clinical staging of periodontitis was performed according to some study[11,12]. To quantitatively compare the severity of periodontitis, the following score system was used: No sign = 0, mild = 1, moderate = 2, severe = 3). The plaque index was calculated *via* percentage of plaque area in relation to total area.

Based on the presence of DE and/or PD, subgroups were formed.

Statistical analyses (one-way analysis of variance, chi-squared test, and unpaired *t*-test) were performed using R program; the significance level was set at $P = 0.05$. Data are expressed using the mean ± SD. This study was approved by the Regional Human Research Ethics Committee of the University of Szeged (Ethical approval No. 4564).

RESULTS

Detailed esophageal testing identified 66 patients with GERD (56.9%) and 50 patients with FHB (43.1%) among the 116 enrolled patients. Dental disorders were detected in 89% (103/116) of the enrolled patients with heartburn. The global prevalence of DE among the enrolled patients was 23.3%. In the group of subjects with GERD, the mean DeMeester score (DMS) was 29.84 ± 27.06. In contrast, in the other group, the mean DMS was 3.34 ± 2.94. Fourteen subjects were diagnosed with Barrett's esophagus. Among patients with GERD, LA-A in 12 (18.2%), LA-B in 15 (22.7%), LA-C in 20 (30.3%), and LA-D in 4 cases (6.1%) were detected, and 15 (22.7%) of them had no sign of esophagitis. In the group with FHB, there was no esophagitis on gastroscopy. Based on the results of pH-impedance monitoring, proximal reflux was found in 41 cases. Dental erosions were significantly more common among patients with GERD (66/116) than among those with FHB (21/66, 31.8% *vs* 6/50, 12.0%; $P = 0.0312$). The mean body mass index (BMI) in the GERD group was 27.8 kg/m^2 ± 4.45 kg/m^2 while that in the FHB group was 26.2 kg/m^2 ± 4.53 kg/m^2 ($P = 0.0192$). Eleven patients were toothless. Furthermore, we established significantly more severe periodontal problems in patients with GERD ($P = 0.0253$). However, instead of the fact that neither only DE nor only PD was significantly more common in any of the study groups, PD and DE together were significantly more prevalent among patients with GERD ($P = 0.00008$). DEs alone were less common among patients with GERD (3/8, 37.5%) than among those with FHB (5/8, 62.5%). Moreover, more patients were toothless in the GERD group (8/11, 72.7%). However, the most prominent difference is the presence of DE and PD together: 19/20 (95%) in the group of patients with GERD and 1/20 (5%) in the control group. The mean plaque index was 52 (0-100) in both groups. Fewer teeth were detected in the GERD group; however, the difference was not statistically significant (18 *vs* 21; $P = 0.098$). Patients with GERD had a longer history of symptoms than those with FHB (15 years *vs* 9 years, $P = 0.0041$) (Table 1).

Mean impedance values were compared between the two study groups and found to be significantly lower among patients with GERD than among those with FHB, and a characteristic tendency of GERD was detected (Figure 1).

In the entire study population, the periodontal examination was possible in only 105 patients because 11 of them were toothless. Among the examined subjects, 17/105 (16.2%) had DE alone, 24/105 (22.9%) had PD alone, 10/105 (9.5%) had both, and 54/105 (51.4%) had neither. Patients with DE alone had no more pathologic reflux than those with intact teeth (41.2% *vs* 27.8%). Among patients with both PD and DE, pathologic reflux was significantly more prevalent (27.8% and 90.0%; $P = 0.03$) than among patients without DE and PD. Furthermore, patients with PD and DE had higher esophagitis scores (1.8 *vs* 0.9; $P = 0.05$) than those without any dental diseases, and there was a tendency for more proximal reflux ($P = 0.08$). The presence of PD causing tooth loss was more common than the presence of DE or both (18 *vs* 22 and 24, $P = 0.11$) On the other hand, the mean plaque index was significantly higher among patients with PD than among patients without PD and/or DE (72 *vs* 49, $P < 0.0001$; Table 2). Other oral, atypical symptoms were not significant in the studied group, such as burning sensation of the mouth and tongue, sore throat, bad breath, sour taste, and ageusia.

Evaluating the mean impedance values, the tendency in patients with DE and PD was similar to that in patients with GERD (Figure 2).

Besides the abovementioned risk factors, no other ones were detected in the study. Furthermore, there was no difference between the four groups in terms of smoking ($P = 0.36$), alcohol consumption ($P = 0.59$), and coffee consumption ($P = 0.86$). There was also no significant difference in different habits resulting in DEs, such as drinking carbonated drinks ($P = 0.58$), teeth grinding ($P = 0.71$), and eating sour foods ($P = 0.23$).

DISCUSSION

The complete symptom similarity of GERD and FHB makes the differential diagnosis of heartburn complicated and resource-intensive. According to the Rome IV classification, it is not possible to differentiate the role of acid and

Table 1 Comparison of parameters between patients with gastroesophageal reflux disease and those with functional heartburn

		GERD (*n* = 66)	FHB (*n* = 50)	*P* value
Gender (male/female)		32 (48.5%)/34 (51.5%)	19 (38%)/31 (62%)	NS

GERD: Gastroesophageal reflux disease; FHB: Functional heartburn; BMI: Body mass index; DMS: DeMeester score; PD: Periodontal disease; DE: Dental erosion; DE all: All the patients who had DE, and some of them have associated PD as well; DE only: Such patients have only DE and have not PD; PD all: All the patients who had PD, and some of them have associated DE as well; PD only: Such patients have only PD and have not DE; SD: Standard deviation; NS: Not significant.

hypersensitivity in the development of heartburn on the basis of the frequency and subjective severity of heartburn symptom. To confirm the diagnosis, detailed esophageal examinations are mandatory. That is why the necessity of comparative studies was also raised in the latest Rome IV criteria[13]; however, such studies had not been carried out. To the best of our knowledge, this study attempted the first differentiation between FHB and GERD based on oral manifestations. The rationale behind the use of oral evaluation is based on its low cost, wide availability, and the fact that the suggested parameters are not temporary symptoms but long-term consequences of GERD.

In the literature, there are many studies on the association between GERD and DE or PD. However, to the best of our knowledge, studies assessing the hard and soft tissue injuries, namely DE and PD, together have not been conducted yet. Furthermore, none of the previous studies examined their relations from both dental and gastroenterological perspectives.

Several studies discussed and concluded a clear but variable relationship between DE and GERD[14,15]. The proposed pathogenesis of DEs is attributed the direct contact of acid and the enamel, resulting in dissolution of the enamel crystals and destruction of the interprismatic matrix and subsequently, the dentin[16-19].

As a result of our research, 41.2% of those with DE had reflux, which did not prove to be a significant result. However, this result differed from the findings recorded in the literature. Pace *et al*[4] published a recent systematic review involving 17 eligible studies, mainly observational and case-control studies on GERD and DE, in which they reported a strong association between the two conditions. The median prevalence of DE among all patients with GERD was 24%, and the median prevalence of GERD among adults with DEs was 32.5% (21.0%-83.0%) However, in this population, there were wide percentage ranges and degrees of tooth tissue loss, and not all studies and evaluations of patients included esophageal endoscopy and/or 24 h esophageal pH-metry[4].

Table 2 Comparison of parameters between patients with or without dental erosion and periodontal disease

		DE (*n* = 17)	PD (*n* = 24)	Both (*n* = 10)	Neither (*n* = 54)	*P* value

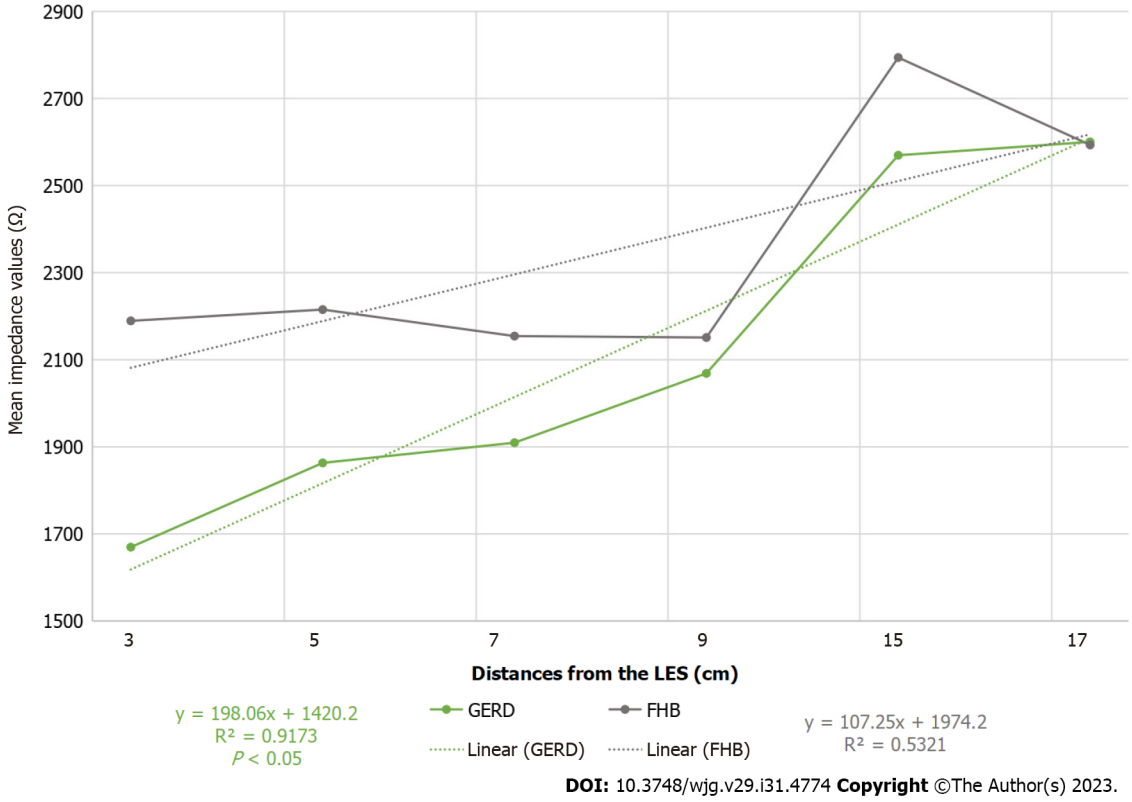
PD: Periodontal disease; DE: Dental erosion; BMI: Body mass index; DMS: DeMeester score; SD: Standard deviation; NS: Not significant.

Another systematic review was carried out and used different references since 2007. From a total of 273 articles, the mean prevalence values of DE were 48.8% in GERD patients and 20.5% in non-GERD controls. The prevalence of DE among adults with GERD was 38.9%, compared to 98.1% among children with GERD[20].



The total prevalence of DE (23.3%) in all subjects was less than the known global prevalence of DE. It can be stated that in the patient group we examined, the prevalence of DEs was found to be significantly higher among patients with GERD (33.1%) than among patients with FHB (12.0%) ($P < 0.01$). Our findings differ from those of studies conducted in different parts of the world.

A recent study conducted in China in 2016, reported a 60.8% presence of DE among patients diagnosed with GERD [21]. Another study carried out in Italy could not establish a significant co-appearance in the association between GERD and DE[22].

Previous studies have confirmed the association between DE and GERD. However, other manifestations (xerostomia, halitosis, oral burning, altered taste, bruxism, and soft tissue injuries, such as mucositis/stomatitis, aphthous-like ulcerations, gingivitis, and periodontal disease) are less likely to be investigated. The relationship between these diseases and GERD could either be direct or indirect[23].

In the literature, the presence of extrinsic factors resulting in DE was uncertain. According to a cross-sectional study, there was a clear relationship between DE and extrinsic dietary factors in patients with GERD[24]. This result was supported by a systematic review that highlighted the etiological complexity of DE (dietary habits, lifestyle, abrasion, bruxism, *etc*.), and the importance of taking a detailed medical history[25]. In contrast, based on an Indian cross-sectional study, extrinsic factors were not related to DE in GERD. In our study, there was no significant difference between the different habits resulting in DE ($P = 0.23$)[26].

In contrast to Song *et al*[27], our results could not confirm a close association between GERD and such manifestations except PD. The mechanism by which PD develops in GERD is mainly attributed to the direct action of acid on the mucosa, although hyposalivation is also suggested to play a role[28,29]. Watanabe *et al*[30] reported significant presence of soft tissue symptoms (stinging, bad breath, and burning sensation), oral cavity symptoms (sour/sour taste sensation),

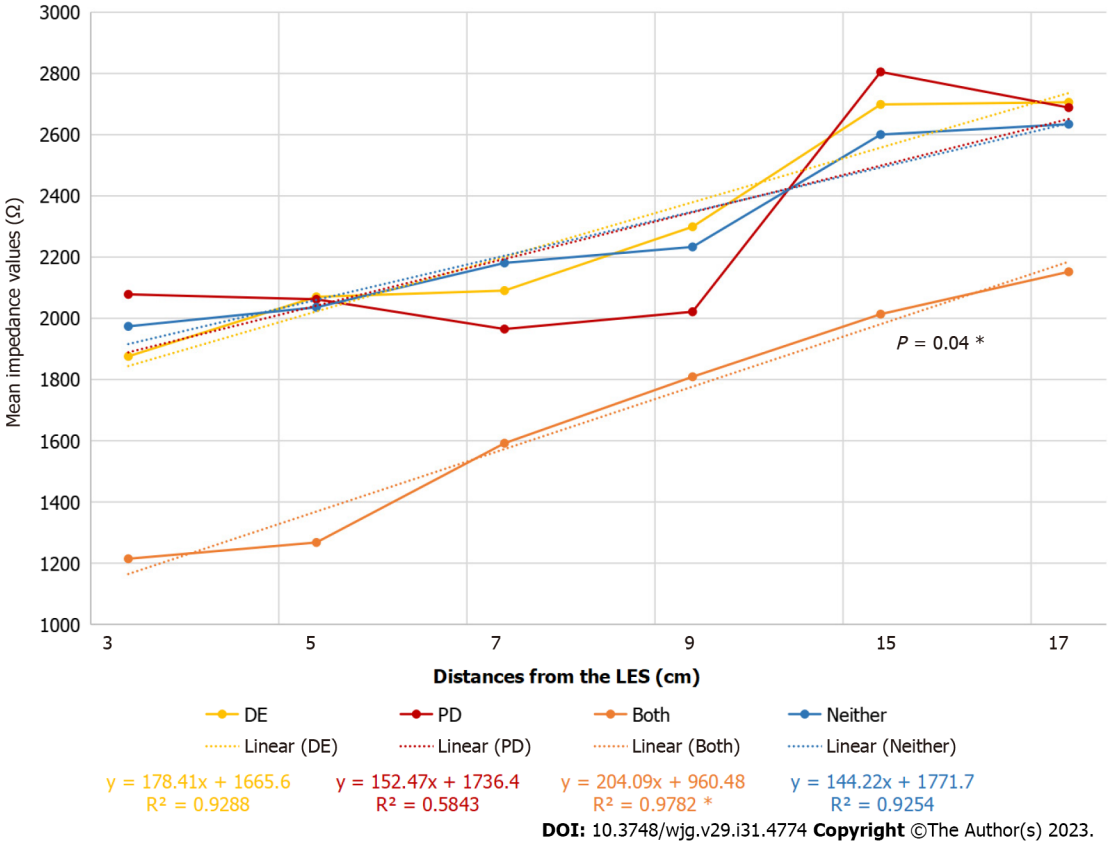
Figure 1 Mean impedance values in patients with gastroesophageal reflux disease and those with functional heartburn. GERD: Gastroesophageal reflux disease; FHB: Functional heartburn; LES: Lower esophageal sphincter.

and the presence of GERD.

Di Fede *et al*[22] assessed the occurrence of oral pathological changes and symptoms in patients with GERD. Two hundred patients with GERD and 100 matched healthy controls were enrolled and studied. Univariate analyses revealed that xerostomia, oral burning sensation, subjective halitosis, and soft, hard palate mucosa, and uvula erythema were more common among patients with GERD than among matched controls ($P < 0.05$). The main outcome of this study was that no significant association between GERD and DEs was found, whereas some other symptoms or objective oral mucosal changes were found to be significantly associated with GERD[22]. In contrast, based on the responses of the patients we interviewed and examined, we did not find any data indicating a significant occurrence of oral complaints (such as the mouth and tongue burning, unpleasant breath, taste perception problems, inflammation of the mucous membrane, hypersensitivity, and sensations of sour taste).



A Chinese study found that periodontal factors were significantly associated with the risk of GERD in the studied 50183 patients. Severe periodontitis (OR = 1.40, $P < 0.001$) and lower frequency of tooth brushing (OR = 2.01, $P < 0.001$) were significantly associated with GERD[31].

In our study, neither DE nor PD alone was predictive of the presence of pathological reflux. There is not significantly more reflux in these cases. However, if both are present, the simultaneous presence of pathological reflux is more likely, as evidenced by the characteristic impedance deviations following the reflux pattern.

Increased BMI is commonly mentioned as a predictor of GERD. In their population-based study, Locke *et al*[31] found a significant relationship between higher BMI and the presence of GERD compared to subjects without reflux disease. Conversely, Watanabe *et al*[30] failed to establish a significant correlation between an increase in BMI and the presence of GERD. Our results seem to support the suggested association because our patients with GERD had significantly higher BMI than those with FHB. However, the observed difference is not significant enough to allow the prediction of GERD on the basis of this parameter alone.

In our study, higher esophagitis scores were detected in patients with DE and PD together than those without any dental diseases. This result suggests that there is more severe esophagitis in case of DE and PD than in the other groups. The correlation between the degree of DE and the severity of esophagitis was barely studied. A study conducted among the Mexican population found that 3/4 of the patients with mild grade DE had normal esophageal mucosa or LA-A esophagitis, whereas patients with severe DE were associated with a higher frequency of esophagitis LA-C and -D ($P = 0.021$)[32].

There are limitations to our study: First, the study was carried out in a single tertiary referral center; therefore, the prevalence of GERD phenotypes is different from the values of the general population. Second, during the process of pH-MII, inpatients were examined under standard conditions that do not correspond to their everyday conditions at home. DEs could be considered as cumulative lesions, representing the long-term consequences of reflux. Therefore, the dental status does not necessarily correlate with the current reflux state, since the bolus exposure time is not always the same, and it may significantly vary day by day, especially in the proximal part of the esophagus.

Figure 2 Mean impedance values in patients with or without dental erosion and periodontal disease. The asterisk (*) the curve of "Both" group is significantly different from the others, and similar to the one in patients with gastroesophageal reflux disease. PD: Periodontal disease; DE: Dental erosion; LES: Lower esophageal sphincter.

CONCLUSION

The dental evaluation of patients with heartburn seems to be useful in the differential diagnosis of GERD and FHB. The co-appearance of dental erosions and periodontal diseases was present mostly in patients with GERD, whereas DE or PD (especially its mild forms) alone were not predictive for the disease. In contrast, the absence of dental disorders in patients with heartburn was predictive of FHB.

ARTICLE HIGHLIGHTS

Research background

Heartburn is a typical symptom of gastroesophageal reflux disease (GERD) and other functional gastrointestinal diseases. To diagnose them, detailed esophageal function tests are required. Oral manifestations are also common in patients with GERD. The dental evaluation is cheap and widely available.

Research motivation

This study raised the hypothesis that dental evaluation (dental erosions, periodontal diseases) in patients with heartburn may be useful in the differential diagnosis of GERD and functional heartburn (FHB).

Research objectives

To evaluate the prevalence of oral manifestations in patients with heartburn and their association with GERD and FHB.

Research methods

We enrolled 116 [M/F: 51/65, mean age: 54 (17-80) years] consecutive patients with heartburn for detailed esophageal function tests and dental evaluation.

Research results

The prevalence of dental diseases in patients with heartburn was about 89%. Compared with heartburn patients without any dental diseases, heartburn patients with both DE and PD had more significant pathological reflux, higher grade of

esophagitis, and significantly different mean impedance curves. Compared to FHB, GERD had a higher prevalence of DE and PD, especially when they coexisted. When evaluating the mean impedance curve, the trend of patients with both PD and DE was similar to those with GERD. The results of the study confirmed the abovementioned hypothesis experimentally.

Research conclusions

The co-existence of PD and DE is more likely to have pathological reflux, and the severity of esophagitis is higher than that of other groups. This study provides a new, inexpensive, widely available, and useful method for the differential diagnosis of GERD and FHB.

Research perspectives

On the one hand, our aim is to expand the study multicentrally in the direction of patients with heartburn presenting in primary care, and thereby reach a larger number of cases. On the other hand, this would probably also enable the inclusion of patients with reflux hypersensitivity, which is defined as a special borderline area between GERD and FHB in the Rome IV criteria system, which may help to decide whether this group of patients is more similar to patients GERD or FHB based on the oral status.

Abstract

BACKGROUND

Bioinformatics analysis showed that the expression of the poly(A)-specific ribonuclease (PARN) gene in gastric cancer, head and neck squamous cell carcinoma, melanoma, cervical cancer and lung squamous cell carcinoma tissues was significantly higher than that in normal tissues and was associated with high stage and poor prognosis. The expression of the PARN gene in esophageal cancer (EC) tissue is also significantly higher than that in normal tissues, but the effect of PARN on the proliferation, migration and invasion of EC cells remains unclear.

AIM

To investigate the relationship between PARN and the proliferation, migration and invasion of EC cells.

METHODS

The EC tissues of 91 patients after EC surgery and 63 paired precancerous healthy tissues were collected. PARN mRNA levels were measured using a tissue microarray, and the PARN expression level was evaluated using immunohistochemistry to analyze the relationship between PARN expression and clinicopathologic features as well as the survival and prognosis of patients. In addition, the effects of PARN gene knockout on tumor cell proliferation, invasion and migration were studied by using shRNA during the *in vitro* culture of EC cell lines Eca-109 and TE-1, and the effects of the PARN gene on tumor growth *in vivo* were verified by a xenotransplantation nude mice model.

RESULTS

The expression of PARN in EC tissues was higher than that in adjacent normal tissues, and the level of PARN expression was significantly positively correlated with lymphatic metastasis. Patients with high PARN levels had poor overall survival. BIM, IGFBP-5 and p21 levels were significantly increased in the PARN knockout group, while the expression levels of the antiapoptotic proteins Survivin and sTNF-R1 were significantly decreased in the apoptotic antibody array data. In addition, the expression levels of Akt, p-Akt, PIK3CA and CCND1 in the downstream signaling pathway regulating EC progression were significantly decreased. The culture of EC cell lines confirmed that the apoptosis rate of EC cells was significantly increased, the growth and proliferation of tumor cells were significantly inhibited, and the invasion and migration ability of tumor cells were significantly decreased after PARN gene knockout. *In vivo* experiments of BALB/c nude mice transfected with Eca-109 cells expressing control shRNA (sh-NC) and PARN shRNA (sh-PARN) showed that the tumor volume and weight of nude mice treated with sh-PARN were significantly decreased compared with those of nude mice treated with sh-NC, indicating that PARN knockdown significantly inhibited tumor growth *in vivo*.

CONCLUSION

PARN has antiapoptotic effects on EC cells and promotes their proliferation, invasion and migration, which is associated with the development of EC and poor patient prognosis. PARN may become a potential target for the diagnosis, prognosis prediction and treatment of EC.

INTRODUCTION

Esophageal cancer (EC) is one of the most common malignancies in the world and the sixth leading cause of cancer-related mortality worldwide[1]. The main pathological types of esophageal carcinoma include esophageal squamous cell carcinoma (ESCC) and esophageal adenocarcinoma. In contrast to Europe and America, Asia has the most ESCC cases, which account for the vast majority of EC cases[2,3]. Currently, the main treatments for EC include surgery, radiotherapy and chemotherapy[4]. Since the clinical symptoms of early EC are not obvious, more than half of patients are in the advanced stage at the time of detection, and only 20% of patients with EC can be treated with surgery. Inoperable EC patients can only use radiotherapy, chemotherapy and other comprehensive treatments. Since it is highly invasive and has a high recurrence and metastasis rate, the prognosis for ESCC patients remains poor despite the use of multidisciplinary therapies[5]. The overall 5-year survival rate for ESCC patients is only 30%-40%. Patients with advanced or metastatic EC have a worse prognosis, with a 5-year overall survival of less than 15 years[2,4,5].

Increasing evidence shows that the resistance of some ECs to radiotherapy and chemotherapy is the cause of relapse and metastasis. Obviously, it is necessary to study the molecular mechanism of EC progression through genomics and proteomics and explore effective cancer biomarkers to predict treatment efficacy and EC patient prognosis.

Bioinformatics analysis from The Cancer Genome Atlas (TCGA) database showed that the expression of the PARN gene in breast cancer, head and neck squamous cell carcinoma, skin cancer, testicular cancer, thymic carcinoma and lung cancer tissues was significantly higher than that in normal tissues and was positively correlated with high stage and poor prognosis. In addition, the expression of the PARN gene in EC tissues in the TCGA database was also significantly higher than that in adjacent tissues. However, the effect of PARN on the proliferation, migration and invasion of EC cells is not clear and is worth further discussion.

Poly(A)-specific ribonuclease (PARN) is a deadenylase enzyme that is present in mammalian cells[6,7]. As a deadenylase, PARN interacts with the cap and the poly(A) tail of mRNA to control the length of the poly(A) tail and regulate gene expression. Therefore, it plays a role in mRNA degradation in the nucleus and cytoplasm[8,9]. Interference

in RNA stability is closely related to tumorigenesis and tumor development, and factors that affect RNA stability may become new targets for the treatment of malignant tumors[10]. Recent studies have shown that RNA-degrading enzymes, called RNases, are involved in the development of malignant tumors, so the regulation of mRNA turnover is a promising mechanism[11].

However, the biological function of PARN and its basic molecular mechanism in the carcinogenesis of the esophagus are still unclear and are worthy of further investigation. In the present study, EC tissues and adjacent normal tissues were immunohistochemically stained and analyzed to detect PARN expression. Moreover, we also investigated the clinicopathological characteristics of PARN and explored the value of PARN expression in predicting prognosis. In addition, we investigated the role of PARN knockdown in the biological characteristics of EC cells *in vitro* and *in vivo*.

MATERIALS AND METHODS

Online databases used in this study

Data on PARN expression in EC cell lines were obtained from the Cancer Cell Line Encyclopedia (CCLE) (www.broadinstitute.org/ccle). Mutation data were obtained from cBioPortal (https://www.cbioportal.org/). The mRNA expression level data of EC patients were downloaded from TCGA Portal (https://tcga-data.nci.nih.gov/tcga/).

Clinical samples

Ninety-one EC tissues and 63 healthy mucosa tissues were taken from EC patients who underwent resection at the Second Affiliated Hospital of Guangxi Medical University and the Affiliated Zhujiang Hospital of Southern Medical University from 2017 to 2018. The study ethics were approved by the Research Ethics Committee of the Second Affiliated Hospital of Guangxi Medical University and Zhujiang Hospital Affiliated to Southern Medical University, and written patient consent was obtained from all patients.

Immunohistochemistry

Immunohistochemistry (IHC) was conducted as previously described[12]. Briefly, the unstained tissue sections were deparaffinized by xylene and then rehydrated with a graded alcohol series. The sections were placed in EDTA buffer (pH = 8.0) buffer at 95-100 °C for 20 min to retrieve antigens. Then, the sections were incubated with rabbit anti-human PARN primary antibodies at 4 °C (1:100; Abcam, ab188333) overnight and then incubated with secondary antibodies for 1 h at room temperature.

Tissue microarray

The mRNA transcription levels of PARN in tumor tissues and adjacent normal mucosal tissues were measured using a tissue microarray (TMA).

Construction of a protein-protein interaction network and enrichment of functions and pathways

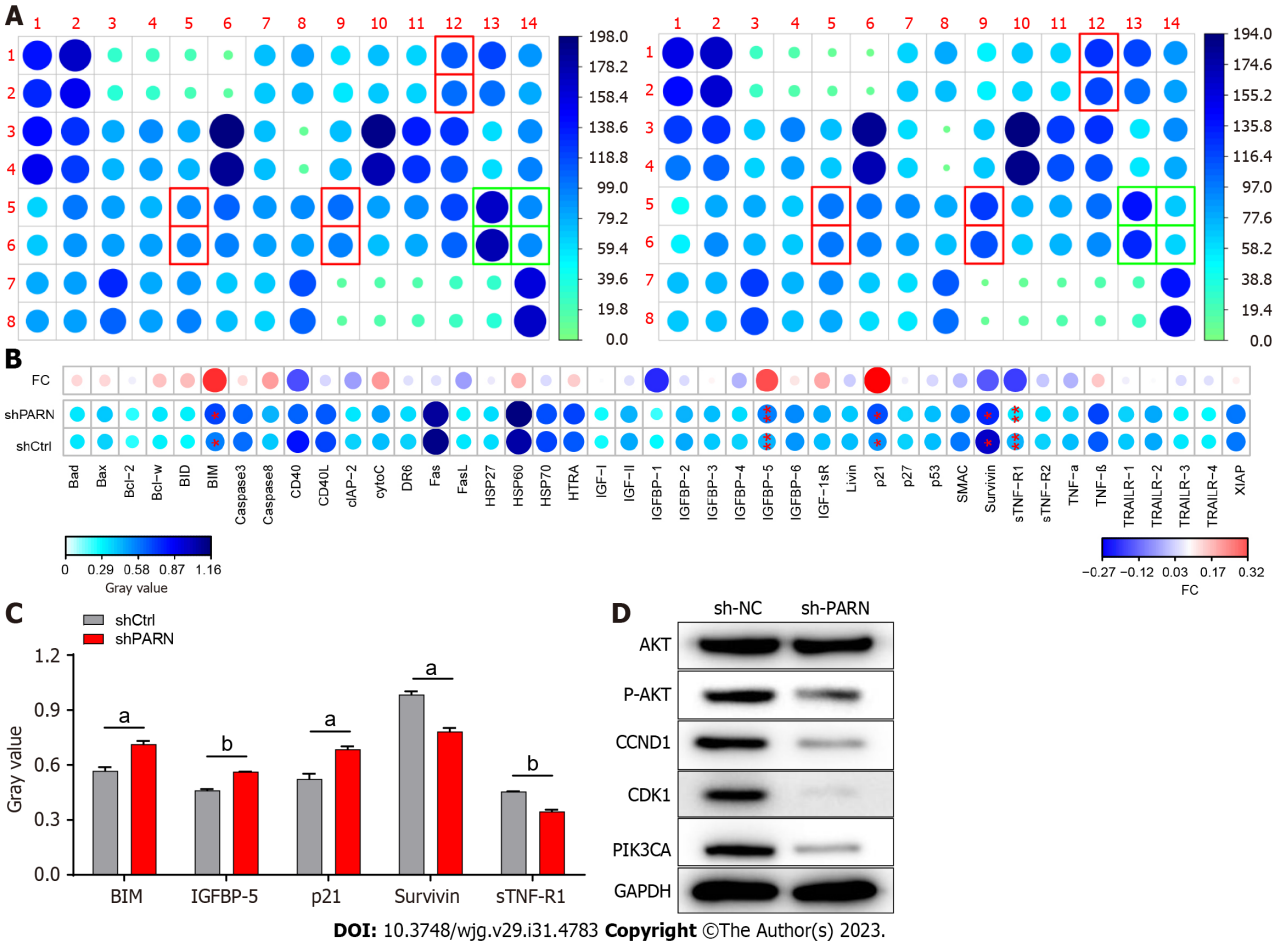
In this research, we obtained the protein-protein interaction by using an online tool, the String Database (STRING, https://string-db.org/). Then, the protein-protein interaction (PPI) we obtained was analyzed by using the software CytoScape (https://cytoscape.org/) and its plug-ins ClueGO and CluePedia. Then, Gene Ontology and Kyoto Encyclopedia of Genes and Genomes analyses were performed. The results of the PPI network and functional and pathway enrichment analyses are shown in Figures 1A and B.

Human apoptosis antibody array

The *Homo sapiens* apoptosis antibody array kit was purchased from Abcam (ab134001). Total protein samples were prepared as described above and incubated with the array according to the kit instructions. After the addition of chemiluminescence detection reagent, a signal proportional to the protein binding amount was detected. After RNA interference with the PARN gene in Eca-109 cells, the expression levels of apoptosis signaling pathway-related genes and proteins BIM, IGFBP-5 and p21 were evaluated.

Cell culture and transfection

We purchased human EC cell lines (Eca-109 and TE-1) from the Chinese Academy of Sciences Cell Bank (Shanghai, China). We cultured all cells in RPMI 1640 (Gibco, Grand Island, NY, United States) supplemented with 10% fetal bovine serum and maintained all cells in a humidified chamber at 37 °C with 5% CO_2. Control shRNA, shPARN-1, shPARN-2, and shPARN-3 were constructed by our group (the list of shRNA sequences is shown in Table 1). Viral transduction and selection of stable transfectants were carried out as mentioned above.



Western blot assay and antibodies

We collected cells and lysed them in RIPA lysis buffer. Aliquots of protein were then loaded and separated on SDS-PAGE gels and transferred to a polyvinylidene difluoride membrane. After blocking, the membrane was incubated with the appropriate primary antibody, followed by incubation with the corresponding secondary antibody. The primary antibodies and dilution factors were as follows: Rabbit anti-PARN (ab1883331, 1:1000 dilution; Abcam, United States), rabbit anti-CDK1 (ab133327, 1:3000 dilution, Abcam, United States), rabbit anti-PIK3CA (ab40776, 1:1000 dilution, Abcam, United States), rabbit anti-AKT [4685, 1:1000 dilution, Cell Signaling Technology (CST), United States], rabbit anti-

CCND1 (2978, 1:1000 dilution, CST, United States), rabbit anti-P-AKT (AF887-sp, 1:500 dilution, R&D Systems, United States), and rabbit anti-GAPDH (AP0063, 1:3000 dilution, Bioworld, United States).

Quantitative real-time polymerase chain reaction

Total RNA was isolated using TRIzol (Sigma-Aldrich, T9424-100 m), and cDNA was obtained with HiScript Q RT SuperMix for quantitative real-time polymerase chain reaction qRT-PCR (+gDNA wiper) (Vazyme, R123-01). PCRs were performed on an ABI 7500 qRT-PCR machine. GAPDH was used as an endogenous control. We assessed the qualified expression by employing the $2^{-\Delta\Delta Ct}$ formula, while statistical analysis was conducted by using the fold change. All primer sequences used in this research are available in Table 2.

Cell viability assay

The cell viability of the TE-1 and Eca-109 cell lines was calculated using the Celigo cell counting assay after transfection. Logarithmic-phase transfected cells were collected, and cell suspensions were obtained by trypsin digestion. Then, we

seeded the cell suspensions (2000 cells/well) into 96-well plates and cultured them for 5 d. The cell number was recorded, and the cell growth curve was plotted.

Apoptosis and cell cycle assay

Apoptosis and cell cycle analyses were performed by flow cytometry. As mentioned above, transfected TE-1 and Eca-109 cells were cultured in 6-well plates and then collected, washed with D-Hanks buffer and incubated with 1 × binding buffer. The cells were centrifuged and resuspended in 200 μL 1 × binding buffer, and an additional 10 μL Annexin V from the Annexin V Apoptosis Detection kit APC (cat. no. 88-8007; eBioscience; Thermo Fisher Scientific, Inc.) was added. Then, the cells were incubated in the dark for 15 min. The cell cycle distribution phases were detected based on propidium iodide (PI; Sigma, P4170) staining. The samples were analyzed on an easy Cyte HT flow cytometer (Merck Millipore).

Wound healing assay

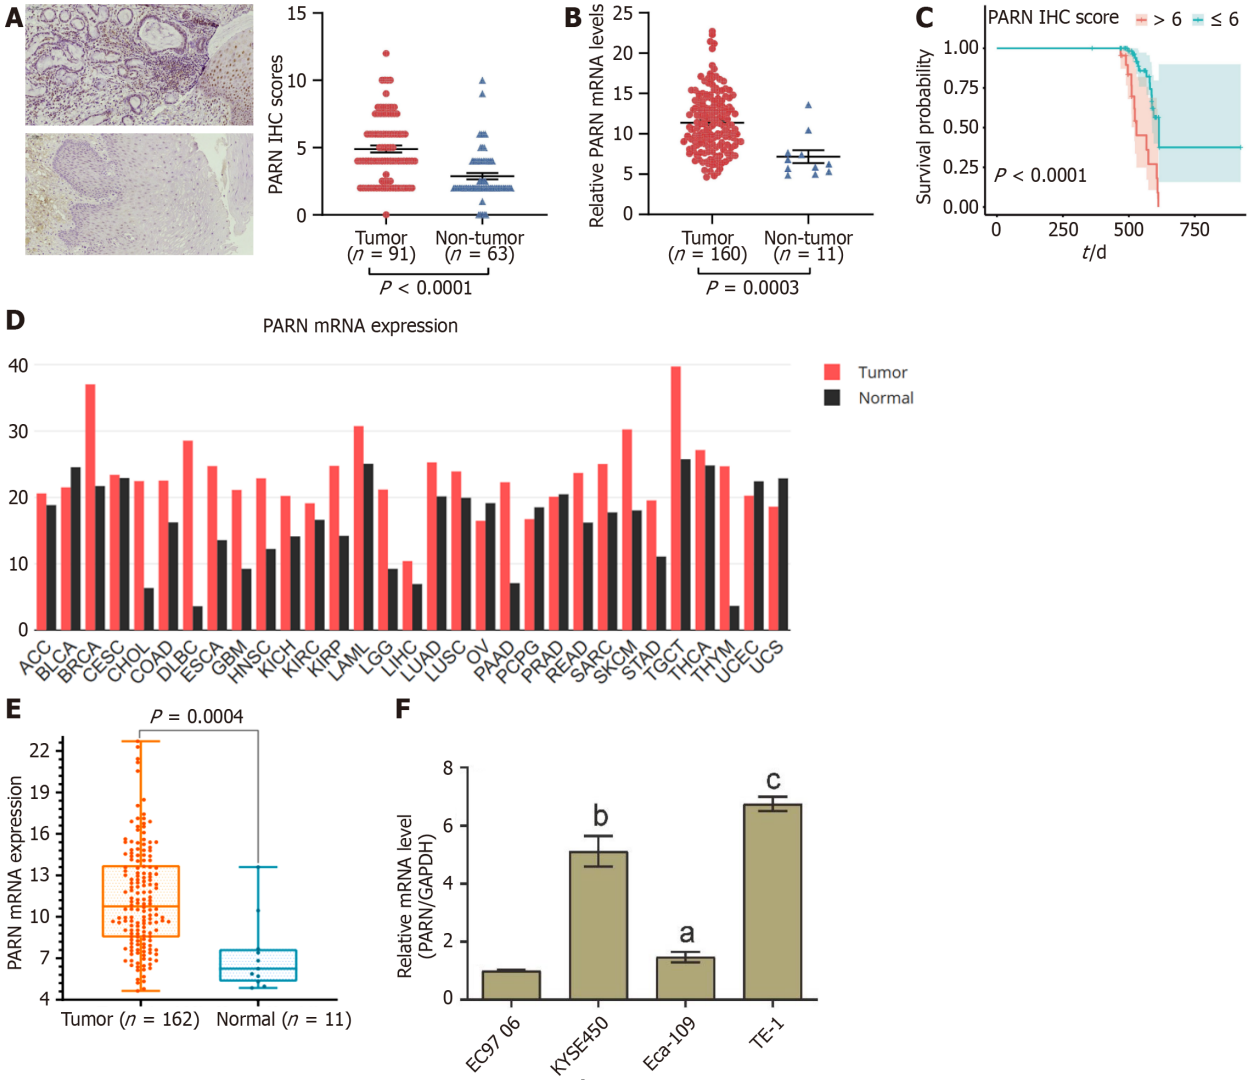
In this study, we detected cell migratory abilities by using a wound healing assay. Cells were seeded into 96-well plates (5.0×10^4) and cultured to 90% confluence. Confluent monolayer cells were scratched gently with a 96 Wounding Replicator (VP scientific, VP408FH), and images were captured using a Cellomics ArrayScan VTI (Thermo Scientific) at 0 h, 4 h, 8 h, 24 h and 72 h. The wound area was quantified using a Cellomics ArrayScan HCS Reader (Thermo Scientific).

Migration assay

Transwell plates (Corning, 3422) were used for migration assays, which were carried out according to the manufacturer's protocol. Cells were seeded in transwell inserts (100 μL, 6.0×10^4/inserts), and RPMI 1640 medium with 30% foetal bovine serum (600 μL) was added to the bottom chamber. Following incubation for 24 h, the inserts were removed and stained with crystal violet. Photos were obtained using an inverted microscope (Olympus I × 73) and analyzed by ImageJ software.

BALB/c nude mouse xenograft model

This study was approved by the Guangxi Medical University Ethics Committee. All BALB/c nude mice (male; 4 wk old) were purchased from Charles River (Beijing, China). All BALB/c nude mice (male; 4 wk old) were maintained in a specific-pathogen-free environment. Cells were collected and suspended in D-Hanks solution (1×10^7 cells/mL) and then subcutaneously injected into the right front limb of 20 nude mice (n = 10 for each group). After injection, the size of the tumor was measured with calipers every 4 d for 23 d. On day 23 after injection, the mice were deeply anesthetized with isoflurane gas, and tumor growth and metastases were visualized and analyzed using a whole-body fluorescence imaging system (Berthold Technologies, LB983). After the live imaging experiment, mice were sacrificed by cervical dislocation under anesthesia. Additionally, the tumors were isolated, weighed and photographed. Tumor tissues were saved for further experimentation.



Statistical analysis

In this study, data are reported as the mean ± SD, and statistical analysis was carried out using GraphPad Prism 8.3 and SPSS 23.0. The Kaplan-Meier log rank test was used for survival curve analysis. Unpaired student's t test was used to assess statistically significant differences between two groups, and one-way ANOVA with Dunnett's posttest was used to compare the differences among three or more groups. P values < 0.05 represented a statistically significant difference.

RESULTS

Cancer data and bioinformatics analysis

Analysis of EC datasets from TCGA demonstrated that PARN mRNA levels were significantly increased in EC tissues compared with adjacent nontumor tissues (Figure 2B). Then, we extended the detailed annotation process of the preclinical human cancer model by compiling CCLE data and proved that PARN was abnormally upregulated in EC cell lines (Figures 2D and E). We found that PARN expression was upregulated in various EC cell lines, including Eca-109,

Figure 2 Poly(A)-specific ribonuclease protein expression was upregulated in both esophageal cancer tissue and cell lines and correlated with poor prognosis in esophageal cancer patients. A: Left panel: Representative immunohistochemistry (IHC) staining images of poly(A)-specific ribonuclease (PARN) in esophageal cancer tissue specimens (magnification × 400, bar = 50 μm). Right panel: Summary of IHC staining of PARN in esophageal cancer tissues (n = 91) and adjacent normal tissues (n = 63) in an esophageal tissue microarray; B: PARN mRNA levels were significantly increased in esophageal cancer tissue (n = 160) compared with adjacent normal tissues (n = 11). The data were obtained from The Cancer Genome Atlas; C: Kaplan-Meier survival analysis showed that high expression of PARN was correlated with poor prognosis in esophageal cancer patients (the PARN IHC score criteria: Table 5); D and E: Exploration of PARN gene expression in various malignant tumors using TCGA database, and the expression of PARN gene in EC was significantly higher than that in adjacent tissues in the TCGA database, P = 0.0004; F: PARN mRNA levels in esophageal cancer cell lines. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$, mean ± SD is shown. PARN: Poly(A)-specific ribonuclease; IHC: Immunohistochemistry.

KYSE450 and TE-1 cells (Figure 2F). In this study, we observed PARN mutations in < 2% of EC patients based on the cBioportal datasets, suggesting that gene mutation is not a major mechanism contributing to the frequent upregulation of PARN in EC patients (Supplementary Figure 1).

IHC and TMA of clinical samples

The IHC staining and the TMA assay results indicated that PARN protein expression is exceedingly upregulated in EC tissues compared with nontumor tissues (Figure 2A). Additionally, to assess the clinical significance of PARN expression in EC, we investigated the relationship between PARN expression and clinicopathologic data in 91 EC patients (Table 3). After statistical analysis, we found that PARN expression was correlated with lymphatic metastasis (P = 0.028). The expression of PARN was positively correlated with tumor lymph node metastasis (N value). With increasing tumor malignancy, the expression levels of PARN increased (Table 4). However, PARN expression was not correlated with tumor size (P = 0.110), T cell infiltration (P = 0.680) or stage (P = 0.336). To determine the relationship between PARN expression and EC patient clinical prognosis, we performed survival analysis using the survival data of 91 EC patients. The Kaplan-Meier analysis results indicated that high PARN levels were linked with poor survival (Figure 2C and Table 5). In summary, the above results demonstrated that high PARN expression may be implicated in the progression and metastasis of EC and that high PARN expression may predict a worse prognosis.

Construction of a PPI network, enrichment analyses and human apoptosis antibody array results

Functional and pathway enrichment and differential gene analysis showed that PARN plays a role in tumor apoptosis. To further identify the potential mechanism by which PARN induces apoptosis, a Human Apoptosis Antibody Array kit (ab134001), including 43 human apoptosis-related proteins, was used to investigate the mechanisms of PARN knockdown treatment-induced apoptosis. Among all detected proteins, BIM, IGFBP-5 and p21 were found to be significantly

Table 4 Relationship between poly(A)-specific ribonuclease expression and tumor characteristics (lymphatic metastasis) in patients with esophageal cancer (Spearman's correlation coefficient for ranked data)

		PARN

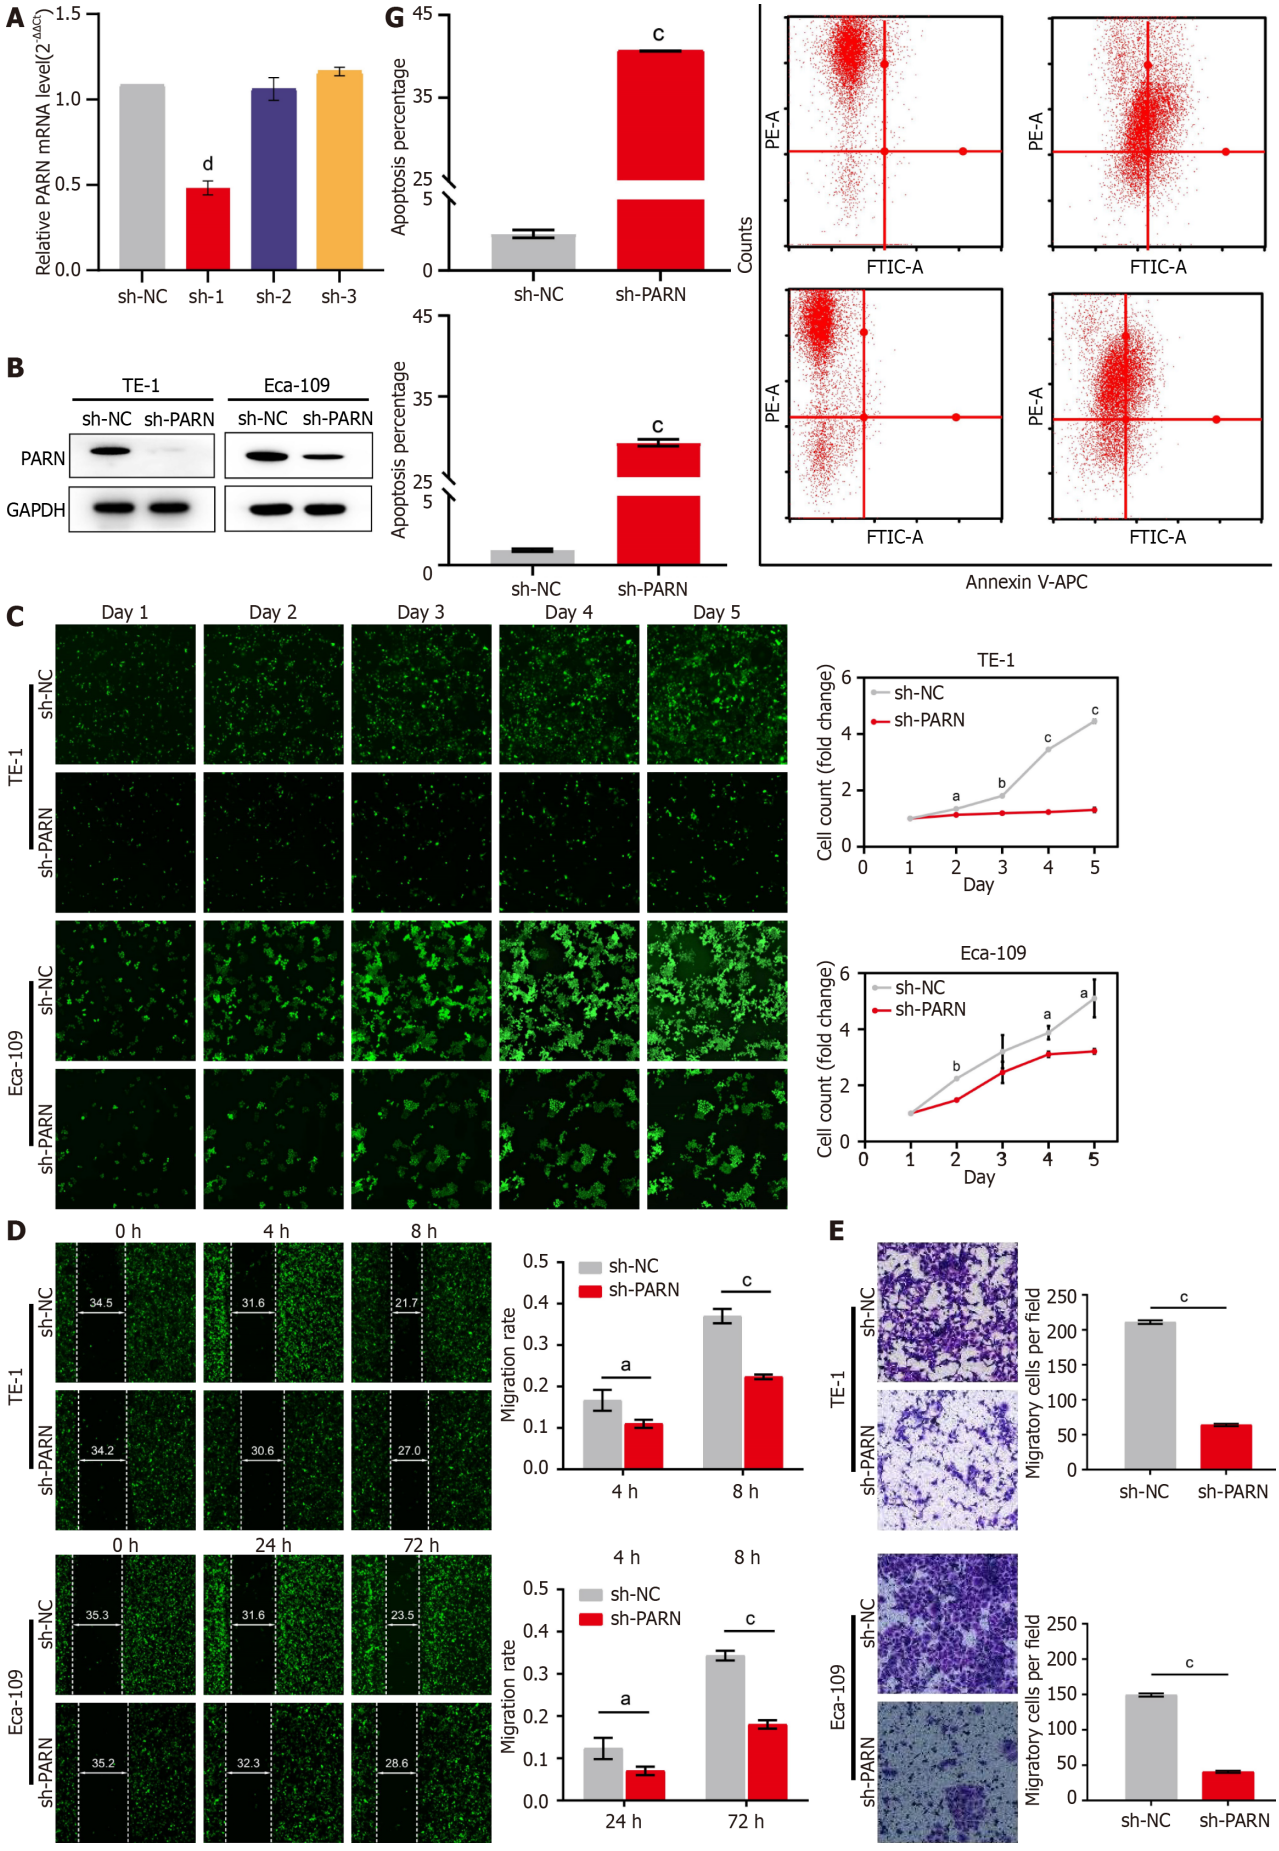
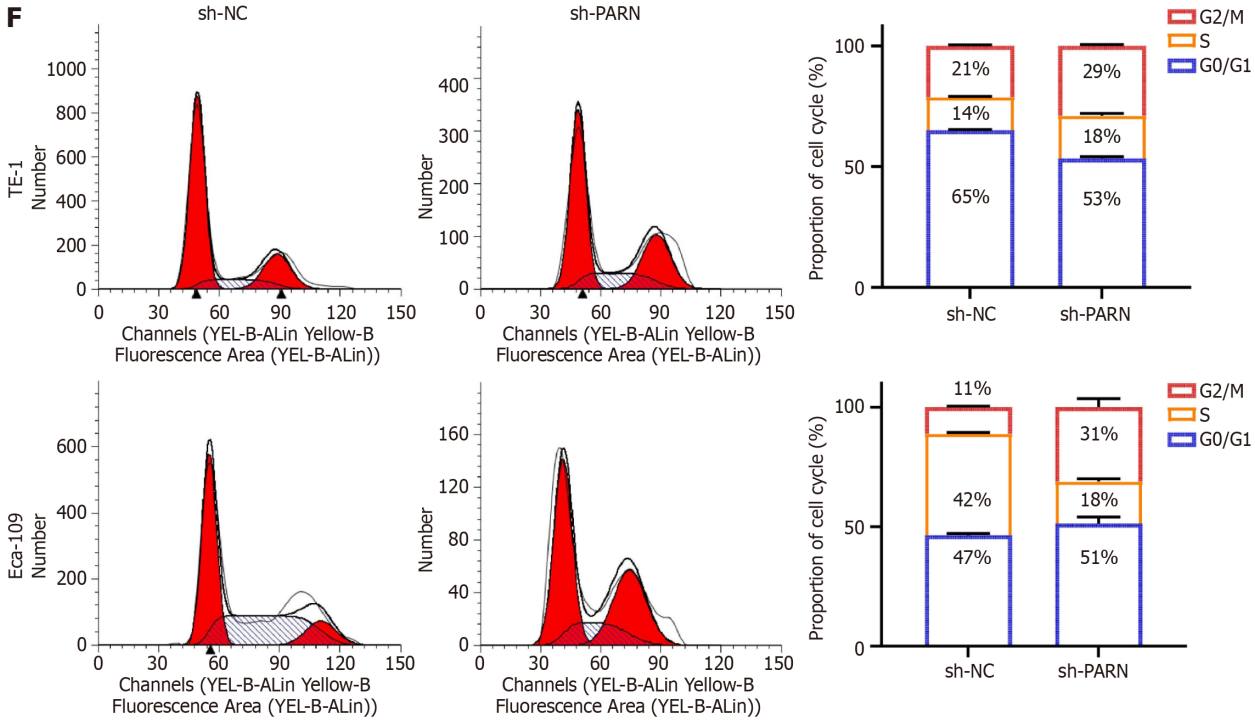
Table 5 Immunohistochemistry scoring criteria

Score type	Score point	Score
Positive cell score	No positive signal	0 (negative)
	0% < the proportion of positive cells < 25%	1
	25% ≤ the proportion of positive cells < 50%	2
	50% ≤ the proportion of positive cells < 75%	3
	75% ≤ the proportion of positive cells	4
Staining intensity score (the staining intensity of cytoplasm, membrane or nucleus)	No signal color	0 (negative)
	Pale yellow	1
	Brown yellow	2
	Dark brown	3

The positive cell score × staining color intensity score was used to judge the immunohistochemistry results, and the higher the score, the higher the antibody expression (score 0: Negative, score 1-4: Positive, score 5-8: Positive ++, score 9-12: Positive +++).



upregulated in the PARN knockdown group, while knockdown of PARN significantly downregulated the expression of the antiapoptotic proteins Surviving and sTNF-R1 (Figures 1A-C). Changes in apoptosis-associated proteins strongly demonstrated that PARN is involved in preventing apoptosis of EC cells by regulating these apoptotic proteins. The original figures of the Human Apoptosis Antibody Array in this study are provided (Supplementary Figure 2). Furthermore, the expression of Akt, p-Akt, CCND1, CDK1 and PIK3CA was downregulated in the sh-PARN group compared with the sh-NC group (Figure 1D).



Effects of PARN on the proliferation, apoptosis and cell cycle of tumor cells in vitro

To investigate the effect of PARN on the biological characteristics of esophageal tumor cells, TE-1 and Eca-109 cells were transfected with sh-NC, shPARN-1, shPARN-2, and shPARN-3. The knockdown efficiency of PARN was validated by RT-qPCR. The results showed that shPARN-1 achieved the most efficient knockdown of PARN (Figure 3A), and thereafter, it was used to represent PARN knockdown in all follow-up experiments. The knockdown efficiency was verified at the protein level by western blotting (Figure 3B). The potential effect of PARN on the proliferation of Eca-109 and TE-1 cells was evaluated using the Celigo cell counting method. The results showed that the proliferation rate of Eca-109 and TE-1 cells infected with sh-PARN was significantly reduced compared with that of control cells (Figure 3C). It was confirmed that PARN knockout could significantly inhibit the proliferation of tumor cells. Apoptosis was analyzed by flow cytometry with Annexin V staining and showed a significantly increased percentage of apoptotic cells in sh-PARN-infected TE-1 and Eca-109 cells compared to sh-NC cells (Figure 3G). These results suggest that PARN knockout inhibits cell proliferation by inducing apoptosis. It was also found that compared with the sh-NC group, the sh-PARN group exhibited a significantly increased percentage of cells in the G2/M phase (Figure 3F), suggesting that PARN affects the proliferation of TE-1 and Eca-109 cells by regulating the cell cycle. Together, these findings confirm that PARN promotes EC cell proliferation by blocking cell cycle arrest and apoptosis.

Wound healing assay and transwell invasion assay

In the wound healing assay, the migration rates were significantly decreased in the sh-PARN group compared to the sh-NC group after lentivirus transfection. The migration abilities of Eca-109 cells in the sh-PARN group (72 h) were 47% lower than those in the sh-NC group ($P < 0.001$). In TE-1 cells, migration abilities in the sh-PARN group (8 h) were reduced by 40% ($P < 0.001$). (Figures 3D and E). Transwell invasion assays showed that after lentivirus transfection, the invasion ability of Eca-109 cells in the sh-PARN group was reduced by 73% compared with that in the sh-NC group ($P <$

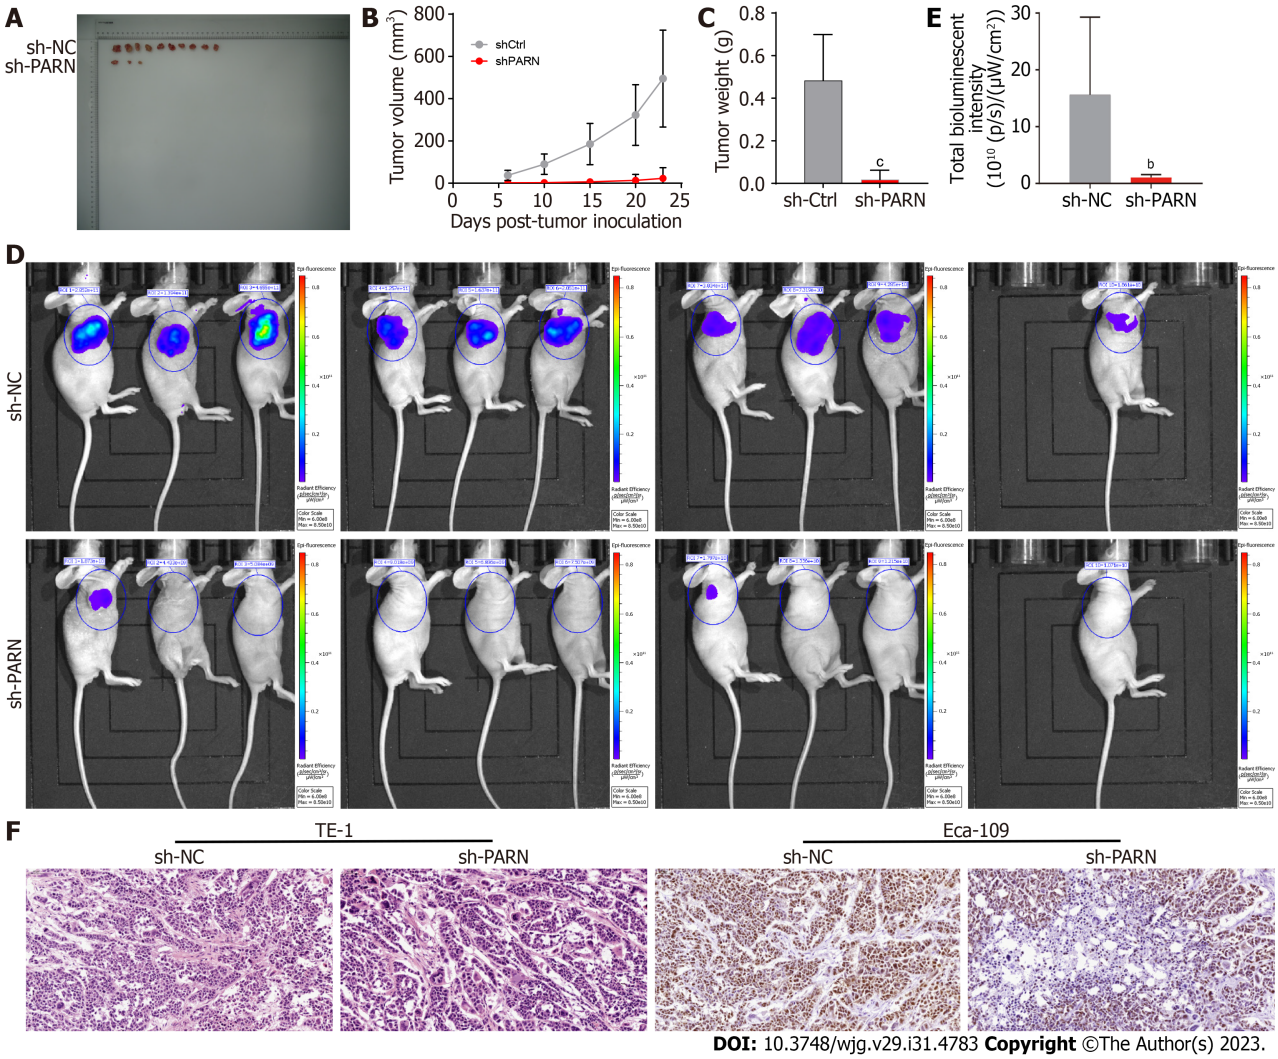
Figure 3 Effect of poly(A)-specific ribonuclease on esophageal cancer cell proliferation, migration and invasion, cell cycle, and cell apoptosis *in vitro*. A and B: The interference efficiency of poly(A)-specific ribonuclease (PARN) *via* shRNA; C: Representative images of the Celigo cell count assay (magnification, × 100) and cumulative data of cell numbers in TE-1 and Eca-109 cells transfected with control shRNA or PARN shRNA; D: Representative images and statistical analysis of the wound healing assay; E: Representative images and statistical analysis of the transwell assay; F and G: Representative images and statistical analysis of flow cytometry analysis of TE-1 and Eca-109 cells after transfection. Cell cycle analysis revealed that PARN affected TE-1 and Eca-109 cell proliferation (F), and cell apoptosis analysis showed that PARN affected the apoptosis of TE-1 and Eca-109 cells (G). $^{a}P < 0.05$, $^{b}P < 0.01$, $^{a}P < 0.0001$, $^{c}P < 0.001$, means ± SDs are shown. sh PARN: Poly(A)-specific ribonuclease shRNA; sh-NC: Control shRNA.

0.001). In TE-1 cells, cell invasion was 70% lower in the sh-PARN group than in the sh-NC group ($P < 0.001$).

PARN facilitates tumor growth in vivo



The above results showed that knockdown of PARN inhibits cell proliferation and promotes cell apoptosis *in vitro*. We next wanted to examine the tumor suppression effects of PARN *in vivo*. To establish the xenograft tumor model, Eca-109 cells that were stably transfected with sh-NC and sh-PARN were subcutaneously implanted into BALB/c nude mice. Tumor weight and volume in the shPARN group were significantly reduced compared with those in the sh-NC-treated group (Figures 4A-C). Additionally, bioluminescence imaging suggested that tumor growth in the sh-PARN group was substantially suppressed (Figures 4D and E), which was similar to the results presented above. The sh-PARN group exhibited significantly repressed tumor development *in vivo*, suggesting that the tumor-forming capacity of Eca-109 cells in nude mice was significantly accelerated by PARN downregulation. Additionally, Ki67 staining was used to examine the proliferative cells in tumors. IHC data of tumor tissue showed that the number of Ki-67-positive tumor cells in the sh-PARN group markedly declined in comparison to that in the sh-NC group (Figure 4F). These *in vivo* results confirmed the *in vitro* results and showed that PARN significantly accelerated EC formation in nude mice.

DISCUSSION

Tumor progression is a complicated process, and increasing the degradation rate of homologous mRNAs affects the expression of dominant oncogenes, dysfunctional trans-acting factors and/or destruction of specific tumor suppressor genes. Therefore, precise control of mRNA levels is important for the regulation of gene expression[13,14].

As an RNA-processing enzymes, PARN may have an important role in tumor development and progression[15-17]. Currently, there is little evidence indicating a correlation between PARN expression and EC. Our study found that PARN expression levels in EC tissues are clearly higher than those in adjacent normal tissues and are significantly correlated with lymph node metastasis and poor patient survival. Since PARN expression has potential clinical implications in EC, the investigation of its regulatory mechanisms attracted our attention.

The main function of PARN is to cut the mRNA poly(A) tail and produce AMP in the process. The shortening of the eukaryotic poly(A) mRNA tail inhibits mRNA translation and induces transcript renewal; the deregulation of this process is common in cancer. A shortened poly(A) tail destabilizes mRNA and induces degradation. Thus, PARN is considered to be one of the important posttranscriptional regulators in cells. Previous studies have reported that the poly(A) tail of

Figure 4 Poly(A)-specific ribonuclease promotes tumor growth *in vivo*. A: Representative image of tumors separated from nude mice; B and C: Tumor volume and weight were measured in nude mice; D and E: Representative bioluminescence imaging (BLI) images and quantification of BLI in the tumor regions of nude mice; F: Representative images of Ki-67 staining in tumors isolated from the nude mice. Scale bars are indicated in the upper left corner of the picture (Bar = 50 μm). Assays were conducted in triplicate. °$P < 0.001$, mean ± SD is shown. sh PARN: Poly(A)-specific ribonuclease shRNA; sh-NC: Control shRNA.

mRNA transcripts is removed by 3′ to 5′ exonucleases (deadenylases), and this process is referred to as the rate-limiting step of mRNA degradation[9,18-21]. After mRNA transcript degradation, the protein expression levels also change accordingly. The levels of these mRNAs are low under normal conditions due to deadenylase activity[22-24].

In our study, compared with normal tissues, EC tissues exhibited significantly increased mRNA levels of PARN, and we also observed this trend in EC cell lines. Interestingly, we found that high PARN expression predicted a poor prognosis in EC patients.

Furthermore, compared with the those of the respective control cell lines, the growth and proliferation of EC cells were significantly inhibited after PARN knockdown. In contrast, it was confirmed that high PARN levels can promote the growth and proliferation of EC cells.

In addition, it was also found that compared with the sh-NC group, the sh-PARN group exhibited a significantly increased percentage of cells in the G2/M phase, suggesting that PARN affects the proliferation of carcinoma cells by regulating the cell cycle.

Escape from apoptosis is beneficial for malignant cell survival and thus could be one of the important mechanisms in cancer pathogenesis[25,26]. Apoptosis involves many biochemical processes that are induced by multiple signaling pathways[27,28]. In our study, PARN knockdown significantly downregulated multiple apoptosis-related proteins (for example, the antiapoptotic proteins Surviving and sTNF-R1) and promoted apoptosis. Therefore, knockdown of the PARN gene promotes apoptosis by regulating apoptotic proteins. In addition, PARN knockdown not only affects the apoptosis rate but also regulates a wide range of downstream signaling factors, including Akt, p-Akt, PIK3CA and CCND1. There has been much evidence suggesting that the PI3K/Akt pathway is one of the most important signaling pathways for cell proliferation, survival, apoptosis and malignant transformation[29,30]. These results suggest that PARN may inhibit tumor cell apoptosis and promote tumor proliferation through the PI3K/Akt pathway in EC. Subsequent wound healing tests and transwell invasion tests confirmed the promoting effect of PARN on the migration and invasion of EC cells. In a BALB/c nude mouse xenograft model, the apoptosis ratio of Eca-109 and TE-1 cells was significantly

increased after PARN knockout, and the cell proliferation rate was significantly decreased, as well as the percentage of cells in G2/M phase arrest. It has been confirmed that PARN promotes tumor cell proliferation by blocking cell cycle arrest and apoptosis in EC.

CONCLUSION

Our study preliminarily concluded that PARN may inhibit in EC cell apoptosis and cell cycle arrest through the PI3K/Akt pathway, thus promoting tumor proliferation, invasion and migration and further accelerating the progression of EC. Therefore, PARN can be used as a prognostic marker and therapeutic target for the diagnosis and treatment of EC.

ARTICLE HIGHLIGHTS

Research background

Esophageal cancer (EC) is a common malignant cancer type and the sixth leading cause of cancer-related mortality worldwide. The main treatment options for esophageal squamous cell carcinoma (ESCC) include surgery, radiotherapy, and chemotherapy. Due to its high invasiveness and high recurrence and metastasis rates, the prognosis of ESCC patients remains poor despite the use of multidisciplinary treatment. The 5-year overall survival rate of ESCC patients is only 30%-40%. However, the prognosis of patients with advanced or metastatic EC is even worse, with a 5-year overall survival rate of less than 15%.

Research motivation

Poly(A)-specific ribonuclease (PARN) is a multifunctional enzyme that plays a crucial role in the occurrence and development of a variety of cancer types. The aim of this study was to explore the relationship between PARN and the proliferation, metastasis and invasion of EC cells to evaluate whether PARN could be a potential biomarker and drug target for the treatment of EC.

Research objectives

The objects of this study are as follows: (1) EC tissues and paired adjacent normal tissues were obtained from 91 patients with EC after surgery; (2) EC lines Eca-109 and TE-1; and (3) Nude mice.

Research methods

The expression of PARN mRNA was measured using a tissue microarray, and the expression of PARN was also detected using immunohistochemistry. The relationship between PARN expression and clinicopathological features and the survival prognosis of patients was analyzed. The effect of PARN on the proliferation, invasion and migration of Eca-109 and TE-1 EC cells was investigated *in vitro* by knocking down PARN using shRNA. The effect of PARN on tumor growth *in vivo* was verified by a nude mouse xenograft model.

Research results

Our study found that PARN expression in EC tissues is clearly higher than that in adjacent healthy tissues and is significantly correlated with lymph node metastasis and poor survival. It was confirmed that PARN can promote the growth and proliferation of EC cells. Compared with the control shRNA group, the PARN shRNA group exhibited a significantly increased percentage of cells in the G2/M phase, suggesting that PARN affects the proliferation of carcinoma cells by regulating their cell cycle. Knockdown of the PARN gene promoted apoptosis by regulating apoptotic proteins. Wound healing tests and transwell invasion tests confirmed the promoting effect of PARN on the migration and invasion of EC cells. In the BALB/c nude mouse xenograft model, the apoptosis ratio of Eca-109 and TE-1 cells was significantly increased after PARN knockout, and the cell proliferation rate was significantly decreased, as well as the percentage of cells in G2/M phase arrest.

Research conclusions

Our study preliminarily concluded that PARN may inhibit EC cell apoptosis and cell cycle arrest through the PI3K/Akt pathway, thus promoting tumor cell proliferation, invasion and migration and further accelerating the progression of EC.

Research perspectives

PARN can be used as a prognostic marker and therapeutic target for the diagnosis and treatment of EC.

Abstract

BACKGROUND

The relationship between copeptin and the severity of circulatory dysfunction and systemic stress response in patients with chronic liver disease (CLD) has been established. Nevertheless, the potential of serum copeptin levels to predict the prognosis of CLD patients remains unclear.

AIM

To conduct a systematic review and meta-analysis to investigate the correlation between serum copeptin and transplant-free survival (TFS) in this population.

METHODS

To achieve the objective of the meta-analysis, PubMed, Embase, the Cochrane Library, and the Web of Science were searched to identify observational studies with longitudinal follow-up. The Cochrane *Q* test was utilized to assess between-study heterogeneity, and the I^2 statistic was estimated. Random-effects models were employed to combine the outcomes, taking into account the potential influence of heterogeneity.

RESULTS

Ten datasets including 3133 patients were involved. The follow-up durations were 1 to 48 mo (mean: 12.5 mo). Overall, it was shown that a high level of serum copeptin was associated with a poor TFS [risk ratio (RR): 1.82, 95% confidence interval: 1.52-2.19, $P < 0.001$; $I^2 = 0\%$]. In addition, sensitivity analysis by omitting one dataset at a time showed consistent results (RR: 1.73-2.00, $P < 0.05$). Finally, subgroup analyses according to study country, study design, patient diagnosis,

cutoff of copeptin, follow-up duration, and study quality score also showed similar results (*P* for subgroup difference all > 0.05).

CONCLUSION
Patients with CLD who have high serum copeptin concentrations may be associated with a poor clinical prognosis.

Key Words: Chronic liver disease; Liver cirrhosis; Copeptin; Prognosis; Mortality; Meta-analysis

Core Tip: Serum copeptin has been related to the severity of circulatory dysfunction and systemic stress response in patients with chronic liver disease (CLD). However, little is known about the relationship between serum copeptin and the prognosis of patients with CLD. In this systematic review and meta-analysis, evidence from ten datasets including 3133 patients were integrated. The results showed that a high level of serum copeptin was associated with a poor transplant-free survival in these patients. These findings support the use of serum copeptin as a prognostic biomarker for patients with CLD.

INTRODUCTION

Chronic liver disease (CLD) patients are more likely to develop complications associated with the progression of the disease, such as portal hypertension, ascites, spontaneous bacterial peritonitis, gastroesophageal varices, and hepatic encephalopathy[1,2]. For those with advanced CLD (ACLD), the clinical prognosis is generally poor, which has become a substantial cause of morbidity and mortality worldwide[3,4]. Accumulating evidence suggests that patients with ACLD may have multiple features of circulatory dysfunction, such as incremental intrahepatic vascular resistance, decrease of portal blood flow, and a reduced systemic vascular resistance[5,6], all of which could subsequently activate the neurohormonal system for counter regulation, including the upregulated systemic arginine vasopressin (AVP)[7,8]. As a biomarker of disease progression, the AVP increment in patients with CLD has been hypothesized as a predictor of poor prognosis[9]. However, as a small peptide of nine amino acids, the blood level of AVP is difficult to quantitatively analyze due to its short half-life[10]. Copeptin is a 39-amino-acid glycopeptide which contains the C-terminus of AVP precursor, making it an effective surrogate marker for AVP release[11,12]. As a result of osmotic stress and osmotic stimulation, a high level of copeptin has been demonstrated in patients with ACLD[13,14]. However, it remains unknown whether the serum level of copeptin may predict the prognosis of patients with CLD. Therefore, in this study, we conducted a systematic review and meta-analysis to investigate the potential association between serum copeptin and clinical outcomes in this patient population.

MATERIALS AND METHODS

Throughout the process of planning, conducting, and reporting the study, the Preferred Reporting Items for Systematic Reviews and Meta-Analyses statement[15,16] and Cochrane Handbook[17] were followed.

Search of databases

We searched electronic databases including PubMed, Embase, the Cochrane Library, and Web of Science, starting from inception and ending April 21st, 2023, for studies that had been published up to that date. The search was performed with terms related to our study including: (1) "Copeptin" OR "C-terminal provasopressin"; and (2) "cirrhosis" OR "cirrhotic" OR "liver" OR "hepatic" OR "hepatitis". There was no limitation on the language of the publication in the search for human studies. As part of our manual screening process, references from relevant original and review articles were screened for possible relevant studies.

Inclusion and exclusion criteria of studies

Inclusion criteria were developed in accordance with PICOS recommendations and according to the aim of the meta-analysis.

P (patients): Adult patients (18 years or older) with a confirmed diagnosis of CLD; I (exposure): Patients with a high serum concentration of copeptin at baseline. Methods for measuring serum copeptin and cutoffs for defining high serum copeptin were consistent with those of the original studies; C (control): Patients with a low serum concentration of

copeptin at baseline; O (outcomes): Incidence of transplant-free survival (TFS) compared between CLD patients with high *vs* low serum levels of copeptin at baseline. S (study design): Studies with longitudinal follow-up, including cohort and case-control studies, as well as post-hoc analyses of clinical trials.

Excluded from the meta-analysis were reviews, editorials, preclinical studies, and studies that did not involve patients with CLD, failed to measure serum copeptin, or did not report the relevant outcome. In instances where there was a patient population overlap, the study with the greatest sample size was incorporated into the meta-analysis.

Data extraction and quality evaluation

Two of the authors conducted literature searches, data collection, and assessments of study quality independently. In instances where discrepancies arose, a third author was consulted for discussion, and a consensus was reached. The analysis of studies included the collection of information pertaining to study information, design characteristics, patient diagnosis, demographic factors, measuring methods, serum copeptin cutoffs, follow-up durations, and adjusted variables for the evaluation of the association between serum copeptin levels and TFS in patients with CLD. In terms of quality, the study was scored using the Newcastle-Ottawa Scale[18] based on the criteria for participant selection, the comparability of the groups, and the validity of the outcomes. There were nine stars on the scale, with a larger number of stars representing a higher quality study.

Statistics

Risk ratios (RRs) and corresponding 95% confidence interval (CI) were used as the variables to indicate the association between serum concentration of copeptin and the survival of patients with CLD. A logarithmical transformation was performed on the RR and its corresponding standard error from each study to stabilize and normalize its variance[19]. In order to estimate between-study heterogeneity, the Cochrane Q test and the I^2 statistic[20] were used. An $I^2 > 50\%$ indicates that there is significant heterogeneity between studies. The utilization of a random-effects model was employed to amalgamate the findings, as it has been acknowledged to encompass the impact of potential heterogeneity[17]. In order to assess the impact of individual studies on the meta-analysis outcomes, sensitivity analyses were conducted by eliminating one dataset at a time[21]. To ascertain the effect of study characteristics on the outcome, subgroup analyses were executed based on the study country, design, patient diagnosis, cutoffs of copeptin, follow-up duration, and study quality scores. The subgroups were defined based on the medians of continuous variables. A funnel plot was used to estimate publication bias based on visual judgments of symmetry, along with Egger's regression asymmetry test[22]. The statistical analyses were carried out with RevMan (Version 5.1; Cochrane Collaboration, Oxford, United Kingdom) and Stata software (version 12.0; Stata Corporation, College Station, TX, United States).

RESULTS

Database search and study retrieval

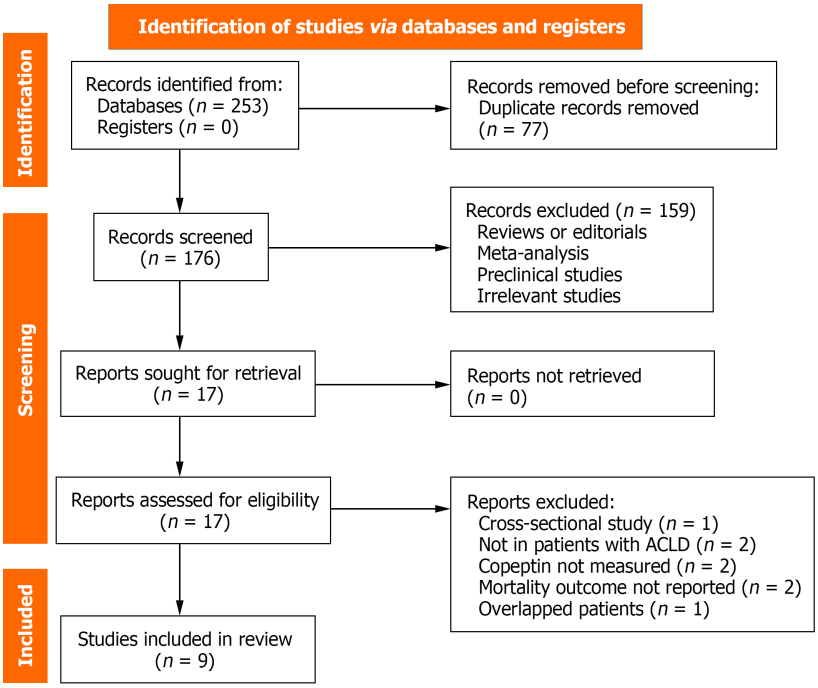

Figure 1 shows the process of the literature search and study retrieval. Initially, 253 records were obtained from the database, and 77 duplicate entries were removed. After screening the titles and abstracts, a further 159 studies were removed as they did not fit the meta-analysis' objectives. Following full-text reviews of 17 studies, eight were excluded because of the reasons listed in Figure 1. Accordingly, 9 studies were obtained for subsequent meta-analysis[23-31].

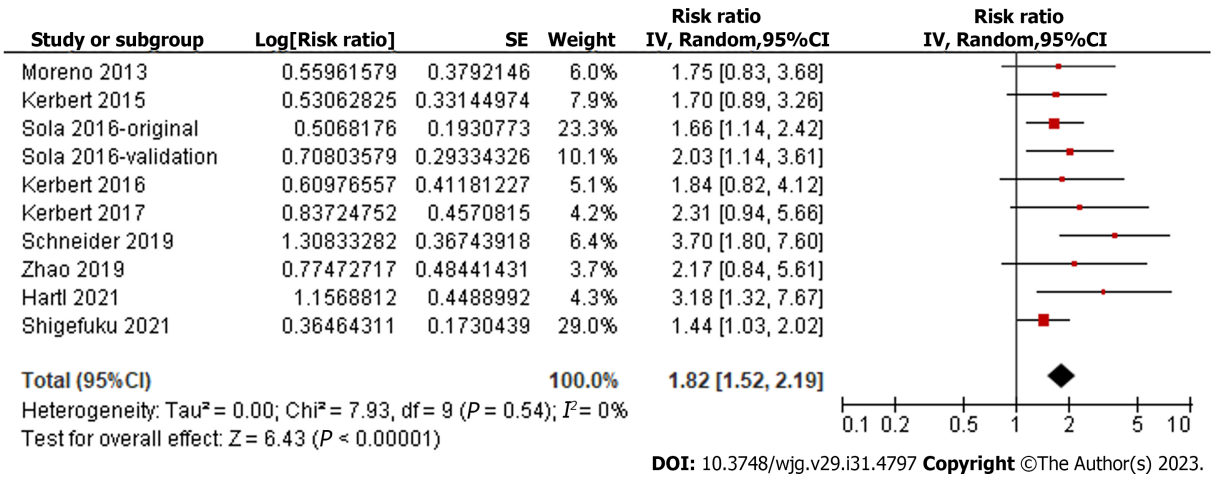
Study characteristics

One of the studies reported two datasets from two cohort studies[26], and these datasets were independently incorporated into the meta-analysis. Overall, ten datasets from nine cohort studies[23-31], which included 3133 patients with CLD, were used for the meta-analysis. The characteristics of the included studies are summarized in Table 1. These studies were published between 2013 and 2021, and performed in European and Asian countries. As for the study design, four cohorts were prospective[23,25,26,29], and six were retrospective[24,26-28,30,31]. Patients with cirrhosis were included in six cohorts of the included studies[23-27], while patients with various CLD were included in the other four cohorts[28-31]. The mean ages of the patients were 49.0 years to 67.3 years, and the proportions of men were 58.2% to 83.4%. Serum copeptin was measured with the Kryptor immunoassay in eight cohorts[23-28,30], while other methods such as enzyme-linked immunosorbent assay and the automated copeptin immunofluorescent assay were used in the other two studies[29,31]. A high serum level of copeptin was defined according to receiver operating characteristic analysis in four cohorts[24,25,27,31], medians in three cohorts[26,29], tertiles in two cohorts[23,28], and the upper limit of normal level in one cohort[30]. The follow-up durations were 1 mo to 48 mo (mean: 12.5 mo). Multivariate regression analyses were applied in all of the included studies when the association between serum copeptin and TFS of patients with CLD were estimated, and factors including age, sex, and scores for hepatic dysfunction were adjusted, such as the Child-Pugh score, the Model for End-Stage Liver Disease score, and the albumin-bilirubin score. Among the included studies, all had quality scores between seven and nine stars, indicating that they were of good quality (Table 2).



Meta-analysis results

Overall, pooled results of ten datasets from nine cohort studies showed that a high level of serum copeptin at baseline was associated with a poor TFS (RR: 1.82, 95%CI: 1.52-2.19, $P < 0.001$; Figure 2) with no evidence of significant heterogeneity (P for Cochrane Q test = 0.54, $I^2 = 0\%$). In addition, sensitivity analysis by omitting one dataset at a time showed consistent results (RR: 1.73-2.00, $P < 0.05$). Finally, subgroup analyses showed that the association between serum

Figure 2 Forest plots for the overall meta-analyses regarding the association between serum copeptin and transplant-free survival of patients with chronic liver diseases. 95%CI: 95% confidence interval.

copeptin and poor TFS was consistent between European and Asian studies (*P* for subgroup difference = 0.16, Figure 3A), between prospective and retrospective cohorts (*P* for subgroup difference = 0.48, Figure 3B), between studies of patients with cirrhosis and all CLD (*P* for subgroup difference = 0.42, Figure 4A), between studies with cutoffs for copeptin < and ≥ 15 pmol/L (P for subgroup difference = 0.17, Figure 4B), between studies with mean follow-up durations < and ≥ 1 year (*P* for subgroup difference = 0.29, Figure 5A), and between studies with different quality scores (*P* for subgroup difference = 0.14, Figure 5B).

Publication bias

The funnel plots for the meta-analysis of the association between copeptin and TFS in patients with CLD are shown in Figure 6. Based on visual examination, the plots are symmetrical, suggesting that publication bias is low. Additionally, Egger's regression tests indicated a low likelihood of publication bias (*P* = 0.47).

DISCUSSION

This systematic review and meta-analysis synthesized data from ten cohort studies to investigate the association between serum copeptin concentration and poor TFS in patients with CLD. Our findings indicate that patients with a high serum copeptin level at baseline are at a greater risk of experiencing poor TFS during follow-up, compared to those with a low serum copeptin concentration. The robustness of our results was confirmed through sensitivity analyses that excluded

individual datasets and subgroup analyses based on various study characteristics, including country, design, patient diagnosis, copeptin cutoffs, follow-up duration, and study quality scores. These findings demonstrate that a high serum copeptin level may be a useful index which is associated with poor prognosis for patients with CLD.

To the best of our knowledge, this is the first meta-analysis investigating the potential role of serum copeptin concentration as a prognostic factor of patients with CLD. Several advantages in meta-analysis methodologies deserve to be noticed. For example, we performed a comprehensive literature search in four commonly used databases, which could provide current evidence regarding the relationship of serum copeptin and TFS of patients with CLD. Furthermore, it is noteworthy that all of the studies incorporated in this analysis were cohort studies, implying a potential longitudinal correlation between elevated serum copeptin levels and diminished transplant-free survival among individuals with

CLD. Additionally, the utilization of multivariate regression analysis in all of the studies included in this review indicates that the relationship between heightened serum copeptin levels and reduced TFS in this population may be autonomous of potential confounding factors, such as age, gender, and hepatic dysfunction scores. Ultimately, multiple sensitivity and subgroup analyses were executed, and the uniform outcomes reinforced the durability and stability of the conclusions. Collectively, these conclusions substantiate that elevated serum levels of copeptin in individuals with CLD may serve as an indicator of unfavorable prognosis.

There may be multiple mechanisms underlying the relationship between a high serum copeptin level and a poor survival outcome in patients with CLD. Previous studies have shown that a high copeptin level in patients with cirrhosis was correlated to the risk of various complications that may lead to a poor prognosis of these patients, such as gastrointestinal hemorrhage due to portal hypertension, hepatorenal syndrome, hepatic encephalopathy, and larger amounts of ascites[32,33]. Pathophysiologically, as a surrogate marker of AVP, increased copeptin may reflect the enhanced systemic release of AVP in these patients[34]. A high AVP in patients with cirrhosis may deteriorate the status of vasoconstriction, water retention, and hyponatremia, which have all been recognized as key risk factors for poor survival of these patients[35]. The role of copeptin in the pathogenesis and progression of CLD should be further investigated, either as a simple biomarker or an active participant in the disease.

This study is subject to certain limitations. Firstly, the meta-analysis results were predominantly influenced by studies involving patients with ACLD, including those with decompensated cirrhosis and other end-stage liver diseases. The efficacy of copeptin as a prognostic factor in patients with early CLD requires further validation in future research. Additionally, despite the utilization of multivariate regression analyses across all the studies included, the potential for residual factors to confound the association between copeptin and TFS cannot be entirely ruled out. For example, serum copeptin may predict the response to tolvaptan in patients with decompensated cirrhosis[36]. Accordingly, use of treatments such as tolvaptan may confound the association between copeptin and TFS. Furthermore, the determination of an optimal serum copeptin cutoff for predicting the survival of patients with CLD remains elusive, necessitating further investigation. Moreover, the absence of a causal association between elevated copeptin levels and unfavorable TFS in CLD patients is attributable to the reliance on observational studies in the meta-analysis.

A: Subgroup analysis according to the diagnosis of the patients; B: Subgroup analysis according to the cutoffs of serum copeptin. 95%CI: 95% confidence interval.

CONCLUSION

The findings of the meta-analysis indicate that an elevated serum copeptin concentration in individuals with CLD is linked to unfavorable TFS. The assessment of serum copeptin levels may hold significance in the stratification of risk among CLD patients. Furthermore, it is imperative to investigate whether the reduction of copeptin levels in these patients is correlated with a better clinical outcome, particularly in those with ACLD.

ARTICLE HIGHLIGHTS

Research background

Patients with chronic liver disease (CLD) will develop various complications with the progression of the disease. Upregulated systemic arginine vasopressin (AVP) has been observed in patients with advanced CLD. However, measuring AVP is clinically challenging due to the short half-life. Copeptin is a C-terminus of AVP precursor, which may be of importance for prognostic prediction in patients with CLD.

Research motivation

Identifying biomarkers that predict the prognosis of patients with CLD is clinically important. Although there are pilot studies aiming to correlate copeptin with survival of patients with CLD, the results are not always consistent. In this regard, a systematic review with meta-analysis is particularly useful.

Research objectives

To investigate the correlation between serum copeptin and transplant-free survival (TFS) in patients with CLD with a systematic review and meta-analysis.

Research methods

Studies were obtained by search of PubMed, Embase, the Cochrane Library, and Web of Science. Two authors independently screened the studies, assessed the study quality with Newcastle-Ottawa Scale, and extracted the data. Risk ratios and corresponding 95% confidence intervals were used as the variables to indicate the association between serum concentration of copeptin and the survival of patients with CLD. The RevMan and Stata software were used for the statistical analyses.

Research results

This meta-analysis enrolled ten datasets involving 3133 patients, who were followed for 1 to 48 mo (mean: 12.5 mo). We found that a high level of serum copeptin was associated with a poor TFS, with a risk ratio of 1.82. Additionally, sensitivity analysis retrieved similar results by omitting one dataset at a time. The robustness of the finding was further evidenced by consistent results of subgroup analyses according to study country, study design, patient diagnosis, cutoff of copeptin, follow-up duration, and study quality score.

Research conclusions

High serum concentration of copeptin may be associated with a poor clinical prognosis in patients with CLD. These findings were not significantly affected by either of the included studies and were not influenced by multiple study characteristics within the subgroup analysis.

Research perspectives

In view of the standard methods for the measuring copeptin in clinical practice, as well as the finding of the meta-analysis, evaluating serum copeptin may be considered at the initial management of patients with CLD, which may provide prognostic significance.

Abstract

BACKGROUND

Solitary rectal ulcer syndrome (SRUS) is a rare rectal disease with unknown etiology. Data on the genetic background in SRUS is lacking.

CASE SUMMARY

Here, we report the first case of SRUS in a mother-son relationship. Gene sequencing was conducted on the whole family, which revealed an inherited CHEK2 p.H371Y mutation. The experiment preliminarily revealed that the CHEK2 mutation did not affect the expression of CHEK2 protein, but affected the function of CHEK2, resulting in the expression level changes of downstream genes such as CDC25A.

CONCLUSION

SRUS is a genetic susceptibility disease where CHEK2 p.H371Y mutation may play a crucial role in the development and prognosis of SRUS.

Key Words: Solitary rectal ulcer syndrome; CHEK2 mutation; CDC25A; Genetic background; Gene sequencing; Case report

INTRODUCTION

Solitary rectal ulcer syndrome (SRUS) is a chronic rectal disease characterized by difficulty in defecation, mucous hematochezia, and anal pain, and bulging. SRUS is a rare disease with unknown etiology that was proposed by Rutter in 1975[1]. We have a detailed understanding of the clinical, endoscopy, pathology and images characteristics based on recent reports about SRUS, but data about the etiology, especially the virulence genes and genetic background, are limited[2,3]. Herein, we present the first case that describes a Chinese female patient with SRUS and one of her sons diagnosed with SRUS. Her daughter and the other son demonstrated healthy gastrointestinal tracts. Next-generation sequencing of family inheritance results indicated an inherited CHEK2 p.H371Y mutation may contributes to SRUS.

CASE PRESENTATION

Chief complaints

A 63-year-old female patient was admitted to the Third Affiliated Hospital of Guangzhou Medical University for abdominal pain, anal irritation, and repeated hematochezia. Her 31-year-old son was previously diagnosed with SRUS and underwent an inpatient examination.

History of present illness

Her symptoms started 1 year before the presentation of abdominal pain, anal irritation, and repeated hematochezia. Additionally, her 31-year-old son started to present with repeated diarrhea and intermittent hematochezia at the age of 26. He suffered from chronic diarrhea of up to 30 times a day, with the worst demonstrating fecal incontinence. He was subsequently diagnosed with SRUS 3 years ago and underwent surgical removal. The surgical pathology was consistent with the pathological features of SRUS (Supplementary Figure 1). Hematochezia disappeared postoperatively, but his diarrhea remained. Chronic diarrhea causes his anxiety because his symptoms worsen as his mood changed.

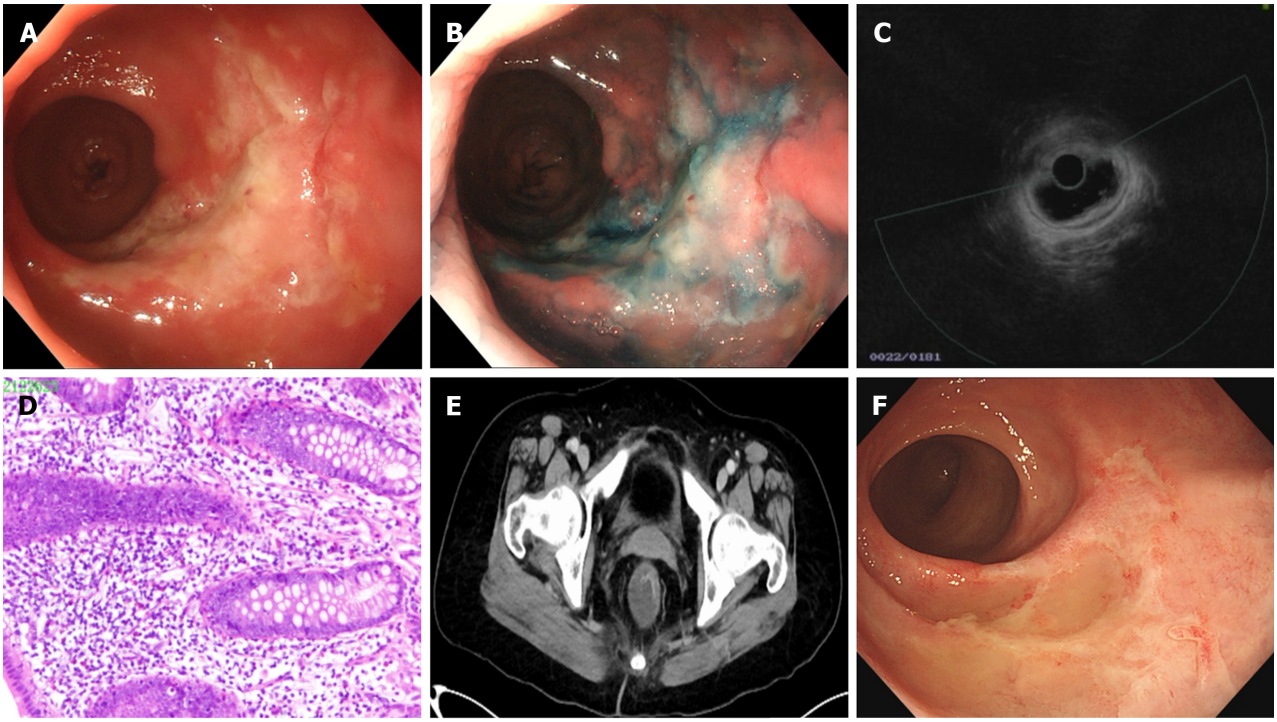
History of past illness

The patients were healthy before the SRUS incidence.

Personal and family history

The patient has two sons and one daughter. Notably, one of her sons was diagnosed with SRUS before her diagnosis and underwent partial rectal resection. The other son was healthy. Additionally, she and her son with SRUS like to eat mixed and coarse grains, and they have high-fiber eating habits and a sedentary lifestyle. Moreover, they are accustomed to squatting for a long time to defecate. Furthermore, they were healthy before the SRUS incidence, but are prone to anxious behaviors in life.

Physical examination



A physical examination upon admission revealed no obvious abnormality in both patients.

Laboratory examinations

Laboratory tests of the female patient revealed high triglyceride (2.11 mmol/L), while others were all within normal ranges. Further, Epstein-Barr virus, and cytomegalovirus were negative. Blood routine, coagulation function and autoimmune tests were within normal ranges. Additionally, laboratory tests of the male patient upon admission revealed no obvious abnormality.

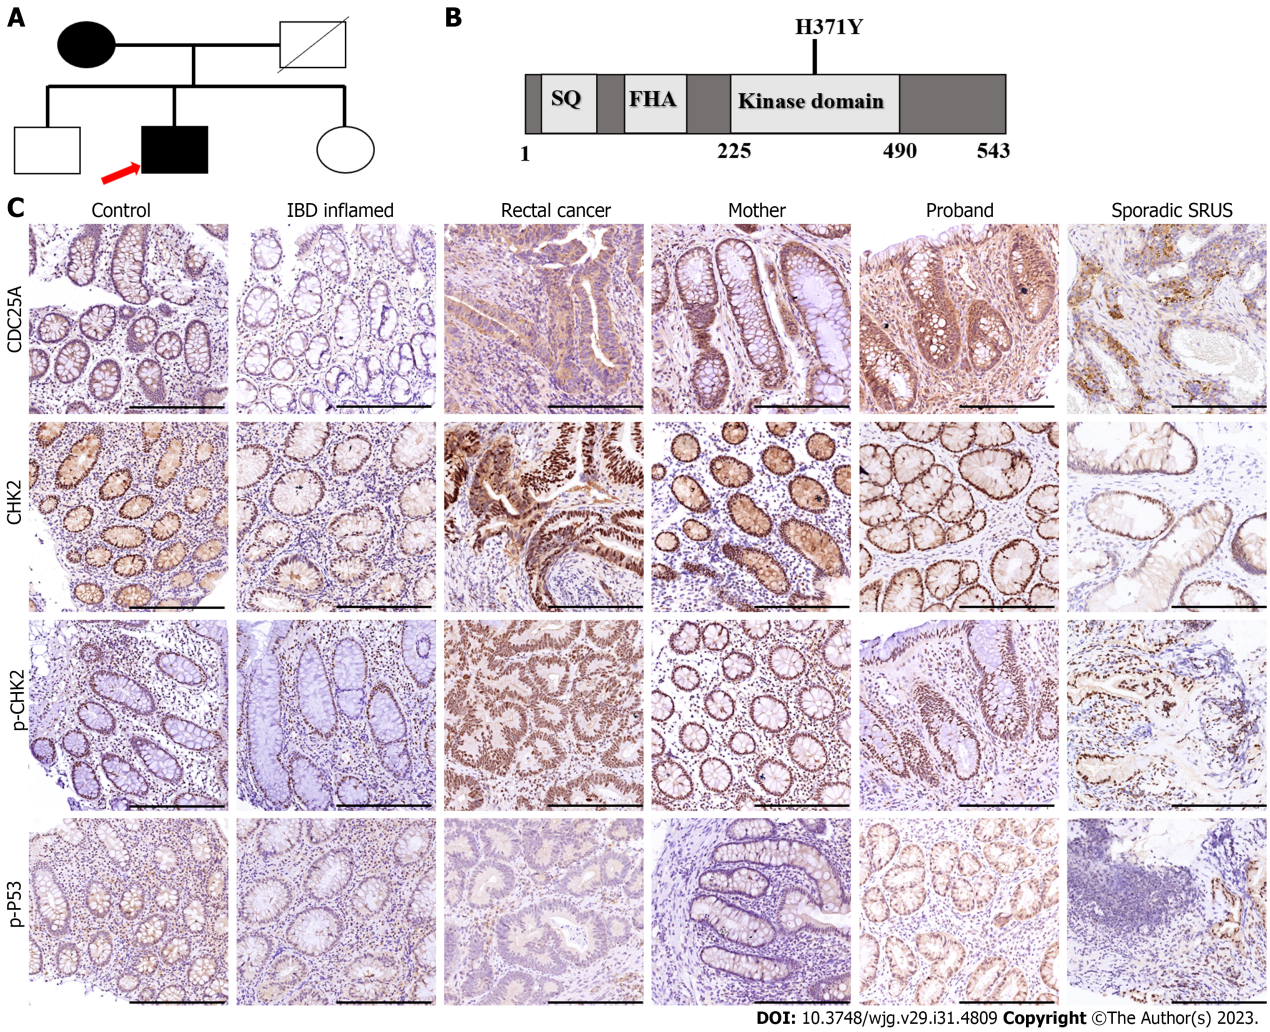
Imaging examinations

Her total digestive tract endoscopy results revealed a rectal solitary ulcer (Figure 1A), the indicarmine dyeing demonstrated a clear boundary (Figure 1B), and pathological results indicated the fibrous tissue hyperplasia in the lamina

DOI: 10.3748/wjg.v29.i31.4809 **Copyright** ©The Author(s) 2023.

Figure 1 Clinical features of the female patient with solitary rectal ulcer syndrome. A: Colonoscopy image upon her admission; B: Chromoendoscopy result upon her admission using the Indicarmine dyeing; C: Ultrasonic endoscopy was used for solitary rectal ulcer observation; D: Pathological results of the solitary rectal ulcer; E: Imaging of the solitary rectal ulcer, using the intestine computed tomography enhancement; F: Colonoscopy image upon her reexamination after therapy.

propria layer as well as glands destruction (Figure 1D). Ultrasonic endoscopy revealed clearly demarcated mucosal layers, missing ulcerative mucosa and submucosa layers, and intact and thickened muscularis propria (Figure 1C). Moreover, the intestinal computed tomography enhancement revealed segmental rectal wall thickening (Figure 1E). The anorectal function test demonstrated a low resting pressure of the anal canal and normal contractile response and anorectal inhibition reflex but with increased anorectal sensitivity. Further, a colonoscopy of the male patient showed that the mucosa of his rectal anastomosis was smooth without any erosion or ulcer (Supplementary Figure 1).



Further diagnostic work-up

Whereas their complicate family history and next-generation sequencing of heritage whole exome sequencing was then conducted with their consent. The results (Figure 2) exhibited a CHEK2 gene (c.1111C>T, p.His371Tyr) missense mutation in the patient and her son with SRUS, but not in the other son and the daughter. The CHEK2 p.H371Y mutation was reported as a kind of pathologic mutation[4]. Then we conduct the immunohistochemical staining (IHC) to analyze the expression and function of CHEK2 (Antibody: CHEK2, CST#3440, 1:1600; p-CHEK2, CST#82263, 1:500; CDC25A, CST#3652, 1:100; p-P53, CST#9287, 1:100), which revealed a normal CHEK2 protein level but an impaired downstream gene protein level. As shown in Figure 2, CHEK2 protein levels and autophosphorylation CHEK2 protein levels showed no significant difference among the healthy control, inflammatory bowel diseases, rectal cancer and SRUS groups (including familial and sporadic cases). In contrast, the downstream gene of CHEK2, such as CDC25A and p-P53 (Ser 20), exhibit differential expression among these groups. CDC25A and p-p53 protein expression levels were the highest and the lowest in the SRUS group, while the differences between the SRUS and rectal cancer groups do not reach significance.

The SRUS groups contain familial patients in our case and non-familial cases (sporadic cases). The IHC results revealed that the CHEK2 mutation did not affect the expression of CHEK2 protein whether in familial SRUS cases or sporadic SRUS cases, but it would affect CHEK2 functions to different degrees. CDC25A expression level variations are more significant in familial SRUS cases, while p-p53 expression level changes are more pronounced in sporadic SRUS cases.

FINAL DIAGNOSIS

Both patients with a mother-son relationship were diagnosed with SRUS based on the above-mentioned results.

DOI: 10.3748/wjg.v29.i31.4809 **Copyright** ©The Author(s) 2023.

IBD: Inflammatory bowel diseases; SRUS: Solitary rectal ulcer syndrome.

TREATMENT

SRUS treatment should be comprehensive and aimed at restoring the patient's normal bowel pattern, including behavior modification, medication, biofeedback, and surgery. Initially, we guided patient's lifestyles and eating habits and advised them to change their sedentary habits and appropriately reduce the amount of dietary fiber in their food. Simultaneously, we guided them to develop good defecation habits, avoid forceful defecation, set defecation time and body position, and artificially limit defecation frequency. Then, we provide psychological care to patients and encourage them to appropriately participate in social activities to vent their bad emotions. Concurrently, biofeedback, which can limit the change of toilet frequency in patients with frequent bowel movements, was recommended as an effective treatment. Biofeedback training can help resolve symptoms, especially in patients who remain symptomatic postoperatively. Finally, we advise patients to use thalidomide and mesalazine for rapid improvement of inflammation, considering the long medical history of the patient, especially frequent diarrhea in the male patients. Mesalazine is a commonly used drug for SRUS and thalidomide is used for anti-inflammation and its side effects of constipation and improved sleeping happen to help patients relieve diarrhea and help them sleep.

OUTCOME AND FOLLOW-UP

Changes in eating and living habits need to be maintained for a long time. Patients are advised to undergo re-examination 3 mo after drug treatment and biofeedback adjuvant therapy. A significant improvement can be maintained for a long time under the condition of monitoring drug side effects. Additionally, the medication regimen was adjusted

following the patient's symptoms during the follow-up. Patients' symptoms were significantly improved under the comprehensive treatment. The reexamination results after 3 mo indicated a significantly relieved mucosa (Figure 1F). Patients remain under regular follow-up and treatment annually.

DISCUSSION

Previous studies have reported the relevance of rectal mucosal prolapse, ischemia, or injury to SRUS pathogens. These main SRUS features include the following clinical manifestations: defecation difficulty with mucous blood stools and lower abdominal pain, normal general physical examination condition, colonoscopy revealing an isolated rectal ulcer, ultrasound colonoscopy showing proliferative mucosal lesions, pathological results demonstrating mucosal myometrium hyperplasia and fibrosis, dynamic examination indicating abnormal rectal and pelvic floor dynamics, normal blood and inflammatory markers, and negative tumor markers[5].

SRUS has no specific clinical manifestation, thus it is frequently misdiagnosed because its clinical diagnosis mainly depends on endoscopy and histopathology. Current SRUS treatment includes medical, surgical treatment, and biofeedback therapy. Drug therapy aims to inhibit inflammatory response and proliferation. Literature reports revealed a similar treatment plan to ulcerative colitis (UC), which can be used orally with mesalazine and locally with rectal administration. This disease has a long treatment period, causing a non-exact therapeutic effect, although biofeedback therapy aims to harmonize and improve pelvic floor muscle function. However, biofeedback therapy may be effective for patients with pelvic floor dysfunction[6]. Surgical treatment is an alternative option, but it is only effective for some patients and has a risk of recurrence postoperatively. Hence, surgical treatment should not be the first therapeutic choice.

To the best of our knowledge, this is the first case of two patients with SRUS in a mother-son relationship. Thus, this is the first study to indicate a possible genetic background for SRUS. The mother in our cases had a very late onset although SRUS was rarely reported in patients over 60 years old. Meanwhile, the symptoms of both patients have commonalities and differences. Her ulcer and symptom significantly improved after medication, while her young son's symptoms did not improve much even with surgery, although a follow-up colonoscopy revealed no further rectal mucosa damage and anastomosis. Concurrently, long-term diarrhea caused psychologically abnormalities, specifically anxiety, in the young male thereby aggravating diarrhea symptoms. Therefore, surgery may be not available for all patients. Most importantly, the psychological symptoms of the disease should also be considered an important treatment scheme aspect.

Genetic data on SRUS is limited. Genes, heritage data, and features need to be explored for a better understanding of the SRUS pathogen and mechanism. Our cases demonstrated that CHEK2 p.H371Y mutation may be relevant to SRUS development and prognosis. CHEK2 is a cell cycle checkpoint regulator, and it plays an essential role in DNA damage repair. Phosphorylation of p53/TP53 at "Ser-20" by CHEK2 is required for the accumulation of active TP53. When activated, the encoded CHEK2 is known to inhibit CDC25A through phosphorylation of CDC25A and cause its degradation[7]. The CHEK2 p.H371Y mutation was reported as a pathogenic mutation causing decreased kinase activity because p.H371Y is located within the activation region of the CHEK2 protein kinase domain. Here, we performed a series of clinical specimens, which revealed no changes in the CHEK2 expression level while the downstream gene expression was significantly modified, exhibiting an impaired CHEK2 protein function. Both familial and sporadic SRUS cases showed weakened function in CHEK2 protein, and familial SRUS cases are mainly characterized by changes in CDC25A of CHEK2 downstream, while sporadic SRUS cases are mainly characterized by variations in p-p53 of CHEK2 downstream. We speculate similarities and differences in the pathogenesis and prognosis between familial SRUS and non-familial SRUS.

Previous studies have revealed that CHEK2 is associated with inflammation and functions through the kinase mechanism to down-regulate the nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) pathway in macrophages to alleviate *Staphylococcus aureus*-induced pneumonia in mice. Additionally, phospho-CHEK2 was associated with high macrophage infiltration in UC[8]. Moreover, SRUS is a manifestation of inflammation and CHEK2 mutation may contribute to the development of SRUS *via* effects on inflammatory pathways, such as the NF-κB pathway [9]. Furthermore, the CHEK2 gene is associated with rectal cancer and inflammatory bowel diseases (IBD). SRUS is closely correlated with rectal cancer and IBD, thus it is difficult to differentiate the diagnosis between SRUS from IBD, especially through UC[10]. Rectal cancer is the most important aspect of SRUS prognostic follow-up, but whether the CHEK2 gene is a pathological gene causing SRUS or a gene for assessing the SRUS prognosis or a potential cause of rectal cancer remains uncertain, as well as the exact role of CHEK2 p.H371Y mutation in familial SRUS.

Limitations related to a small-cohort study and the patient heterogeneity exist. The following possible drawbacks may occur in our study. Firstly, this is a single case report and a retrospective study, and the role of CHEK2 mutation in SRUS pathogenesis needs further investigation. Secondly, this study did not involve the detailed mechanism of CHEK2 mutation causing SRUS. Therefore, subsequent verification of large samples and more detailed experimental verification should be prepared.

CONCLUSION

In summary, this is the first study to report two patients with SRUS in a mother-son relationship with an inherited CHEK2 p.H371Y mutation, which provides insights that SRUS may serve as a genetic susceptibility disease, and CHEK2 p.H371Y mutation may play a crucial role in the development and prognosis of SRUS.

Navadurong H, Thanapirom K, Wejnaruemarn S, Prasoppokakorn T, Chaiteerakij R, Komolmit P, Treeprasertsuk S

4883 Different oncological features of colorectal cancer codon-specific *KRAS* mutations: Not codon 13 but codon 12 have prognostic value

Ahn HM, Kim DW, Oh HJ, Kim HK, Lee HS, Lee TG, Shin HR, Yang IJ, Lee J, Suh JW, Oh HK, Kang SB

4900 Hepatitis B virus infection in patients with Wilson disease: A large retrospective study

Zhou HY, Yang X, Luo KZ, Jiang YF, Wang WL, Liang J, Li MM, Luo HY

CASE REPORT

4912 Drug-induced entero-colitis due to interleukin-17 inhibitor use; capsule endoscopic findings and pathological characteristics: A case report

Saito K, Yoza K, Takeda S, Shimoyama Y, Takeuchi K

ABOUT COVER

Editorial Board of *World Journal of Gastroenterology*, Haruhiko Sugimura, MD, PhD, Director, Sasaki Institute, Sasaki Foundation, Tokyo 101-0062, Japan. hsugimur@po.kyoundo.jp

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJG* as 4.3; IF without journal self cites: 4.1; 5-year IF: 5.3; Journal Citation Indicator: 0.82; Ranking: 33 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.3 and Scopus CiteScore rank 2022: Gastroenterology is 22/149.

Abstract

The robotic liver resection (RLR) has been increasingly applied in recent years and its benefits shown in some aspects owing to the technical advancement of robotic surgical system, however, controversies still exist. Based on the foundation of the previous consensus statement, this new consensus document aimed to update clinical recommendations and provide guidance to improve the outcomes of RLR clinical practice. The guideline steering group and guideline expert group were formed by 29 international experts of liver surgery and evidence-based medicine (EBM). Relevant literature was reviewed and analyzed by the evidence evaluation group. According to the WHO Handbook for Guideline Development, the Guidance Principles of Development and Amendment of the Guidelines for Clinical Diagnosis and Treatment in China 2022, a total of 14 recommendations were generated. Among them were 8 recommendations formulated by the GRADE method, and the remaining 6 recommendations were formulated based on literature review and experts' opinion due to insufficient EBM results. This international experts consensus guideline offered guidance for the safe and effective clinical practice and the research direction of RLR in future.

Key Words: Robotic liver resection; Laparoscopic liver resection; Guidelines; Expert consensus

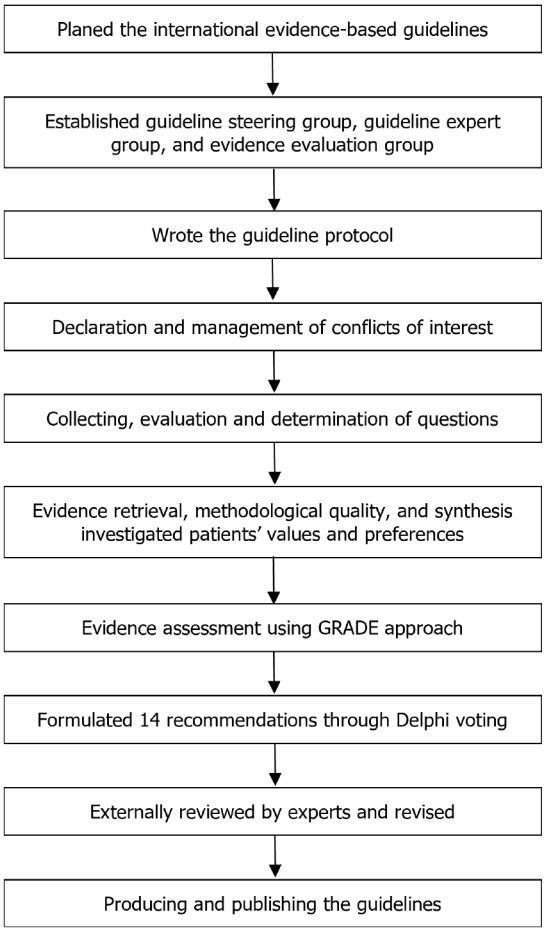
INTRODUCTION

Laparoscopic liver resection (LLR) was first introduced in the 1990s for treatment of benign and malignant tumors[1,2]. Over the past few decades, laparoscopic hepatectomy has developed rapidly and gained widespread acceptance around the world. In 2008, the Louisville Statement indicated the feasibility of laparoscopic hepatectomy[3], and the second international consensus conference in Morioka recommended LLR as a standard practice in specific types of hepatectomy [4]. After that, the Southampton consensus guidelines promoted the safe expansion of LLR and improved patient care after LLR[5]. Since then, laparoscopic techniques have occupied an important place in hepatobiliary surgery. At the same time, with the approval of clinical application and technique developments of robotic surgery systems, robotic hepatectomy has gradually been used in clinical practice. Experience in robotic liver resection (RLR) has been reported in many parts of the world and its feasibility has gradually been identified by clinical studies[6-8]. The robotic system is superior in providing three-dimensional magnified field of vision and robotic arms offer flexibility and tremor filter to surgeons to overcome the shortages of conventional laparoscopic hepatectomy. However, the high cost of the mainstream models and the lack of surgical instruments and experience limit the application of RLR.

With the advent of advanced technique and with experience accumulation, the indications of RLR have been expanded. The robotic system can be used in almost all types of liver resection, including minor hepatectomy, major hepatectomy, donor hepatectomy, and complex liver resections[9-16]. In 2018, an international consensus statement on robotic hepatectomy provided recommendations for RLR based on relevant research and experts' opinions, which contribute to standardization of robotic hepatectomy[17]. However, the recommendation grades were relatively low due to the lack of high-quality evidence. Furthermore, some important issues, like cost-effectiveness of RLR, learning curve of RLR, and outcomes of RLR for difficult liver segments, remain controversial. Available data derive from case series, case-comparative studies, reviews and meta-analyses have been published in recent years, and some new theories also provide new views and perspectives on RLR[18-25].



Based on the foundation of the previous statement, the 2023 international consensus statement on RLR aimed to update clinical recommendations and provide guidance to improve the outcomes of RLR clinical practice. We invited a team of robotic surgeon experts to provide their views related to RLR. Based on the related topics, we searched the online databases for RLR studies and the GRADE system was used to grade the evidence. The final consensus was reached by using a combination of clinical evidence and experts' opinions with the aim to improve the clinical outcome of RLR.

METHODS

This international evidence-based guideline is based on the WHO Handbook for Guideline Development and refers to the Guidance Principles of Development and Amendment of the Guidelines for Clinical Diagnosis and Treatment in China 2022. Reporting of the guideline follows the Appraisal of Guidelines, Research, and Evaluation (AGREE II)[26]. A flow chart describes the process and steps of the guideline development (Figure 1).

The guideline development group included the Steering Committee, Consensus Expert Group, and Evidence Evaluation Group. The Steering Committee and Consensus Expert Group consisted of 29 members from different countries or regions. Literature review, questionnaires, and expert discussions were implemented to initially identify clinical questions. All members of the Steering Committee and Consensus Expert Group were encouraged to submit suggestions and add potential questions. Each question was then evaluated and confirmed by the Steering Committee through meetings or emails. The Evidence Evaluation Group performed a literature search, literature screening, method quality evaluation, and data extraction, and thus formed the body of evidence.

Figure 1 The flow chart illustrates the process of guideline development.

databases were systematically searched from inception to September 5, 2022, to retrieval potential eligible studies. There were no regional and language restrictions, but it was limited to human studies. The Evidence Evaluation Group evaluated titles, abstracts, and full texts to identify the eligible publications based on inclusion and exclusion criteria approved by the Steering Committee. The eligible literature included clinical guidelines, systematic reviews and meta-analyses, randomized controlled trials (RCT), non-RCT, cohort studies, case-comparative studies, and case reports or case series that were considered for inclusion when necessary. Information on the included studies was extracted according to a pre-designed extraction form. A Measure Tool to Assess Systematic Reviews (AMSTAR II) was used to evaluate the methodological quality of the included systematic reviews and meta-analyses[27]. The revised Cochrane Risk of Bias Tool and the Newcastle-Ottawa Scale were performed to assess the methodological quality of their corresponding types of clinical studies[28,29]. All the above processes were completed by two independent terms of the Evidence Evaluation Group. If there are differences, they will be resolved by discussing or consulting third parties.

According to the WHO Handbook for Guideline Development, the Evidence Evaluation Group evaluated the need for an update or rapid development of systematic review[30]. The method of GRADE was used to assess the quality of the evidence[31]. Based on the GRADE approach, clinical outcomes, patients' benefit, and economic evaluation, the Steering Committee and Consensus Expert Group used the GRADE decision form and Delphi voting to formulate the strength of recommendations. The consensus was considered to have been reached when 80% of the experts approved a proposal. Before submitting the manuscript for publication, the final draft was reviewed and approved by all members of the guideline development group. This evidence-based guideline is expected to be updated again in 2026.

RESULTS

Question 1: What are the indications of RLR?

In general, the indications of the RLR are similar to those of LLR and open liver resection (OLR). RLR can be applied for treating various liver diseases, including hepatocellular carcinoma (HCC), intrahepatic cholangiocarcinoma (ICC), colorectal liver metastases (CRLM), benign tumors of liver, and living donor hepatectomy. RLR is associated with the following advantages over OLR and LLR in the majority of the currently available studies: less intraoperative blood loss, shorter postoperative hospital stay, less overall complications, and lower pain intensity after surgery[21,22,32-45].

However, in complex hepatectomies such as large tumor size or proximity of tumor to vital vascular structures, RLR should be performed with caution and by highly experienced surgeons (clinical recommendation: Expert agreement 100%).

In a prospective study using propensity score matching, Zhu *et al*[21] compared the short-term perioperative outcomes and long-term survival outcomes of RLR, LLR, and OLR in patients with BCLC stage 0-A hepatocellular carcinoma. The results showed that there were no significant differences among the three interventions except for a shorter hospital stay in the minimally invasive group (RLR and LLR)[21]. Hu *et al*[33] evaluated the clinical efficacy of robotic, laparoscopic, and open liver resection for giant liver haemangiomas (> 10 cm in diameter). They reported robotic hemihepatectomy to be associated with less intraoperative blood loss, better postoperative recovery and lower pain score than OLR. When compared with laparoscopic hemihepatectomy, robotic hemihepatectomy was associated with significantly less intraoperative blood loss and a shorter operative time[33]. Masetti *et al*[46] analyzed the short-term outcomes of patients with CRLM comparing from a multicenter study who underwent RLR *vs* LLR. The results showed RLR and LLR to be comparable in postoperative overall complication rates, intraoperative blood loss, conversion rates, operation time, and hospital stay, but RLR showed a reduced rate of R1 resection margins compared with LLR. Masetti *et al*[46] found the effect size of RLR to be increased for posterosuperior lesions and difficult procedures, which may be due to RLR being able to offer some technical advantages over conventional laparoscopy to improve the short-term outcomes of these patients.

Question 2: Is RLR safe and effective in patients with HCC?

Recommendation: RLR is safe and feasible for HCC, as it is associated with lower overall complication rates than LLR and OLR and a shorter hospital stay than OLR, although it has a longer operative time than LLR and OLR. Other perioperative outcomes are comparable among the three interventions. Regarding oncologic outcomes, limited evidence suggested there is also no significant difference.

Level of evidence: Low level of recommendation: Weak (Grade 2C). Expert agreement: 96.55%.

Two systematic reviews[47,48] and 15 publications[21,35,37,43,49-59] were included to evaluate the perioperative and oncologic outcomes of robotic *vs* laparoscopic or open hepatectomy for treatment of HCC patients, respectively. When compared with LLR for HCC patients, the pooled results indicated that RLR had a lower overall complications rate (RR = 0.72, 95%CI: 0.57 to 0.90; P = 0.003), lower minor complication (Clavien-Dindo I-II) rate (RR = 0.72, 95%CI: 0.54 to 0.96; P = 0.030), and longer operative time (SMD = 0.66, 95%CI: 0.22 to 1.10; P = 0.003)[21,50,52-57]. When compared with OLR for HCC patients, RLR was associated with a shorter hospital stay (SMD = -0.42, 95%CI: -0.57 to -0.28; P < 0.00001), lower overall complication rate (RR = 0.61, 95%CI: 0.45 to 0.84; P = 0.002), lower minor complication rate (RR = 0.59, 95%CI: 0.42 to 0.84; P = 0.003), and longer operative time (SMD = 0.82, 95%CI: 0.18 to 1.46; P = 0.01)[21,35,37,43,49,51,58,59]. For other outcomes, RLR showed similar results when compared with LLR or OLR, including estimated blood loss, transfusion rate, severe complication (Clavien-Dindo III-IV), and 90-d mortality. Thus, RLR was comparable to OLR and LLR in feasibility and safety for patients with HCC.

Regarding oncologic outcomes, the three interventions showed comparable R0 resection rates and similar short- and long-term oncological outcomes[21,35,37,43,49,51,53-56,58,59]. Also, a recently published study with a large sample size suggested that robotics may be associated with improved overall survival[54]. The study reported that the RLR group had significantly higher 1- , 3- , and 5- year overall survival rates of 92%, 75%, and 63% compared with the LLR group of 86%, 60%, and 45%, respectively (all P < 0.01)[54]. Based on the currently available studies, the implementation of RLR is feasible and safe and is associated with similar oncologic outcomes. Prospective studies are recommended to further evaluate whether the safety and efficacy of RLR can be affected by tumor size, resection complexity, and the quality of the underlying liver parenchyma.

Question 3: Is RLR safe and effective in patients with ICC?

Recommendation: Currently, there is insufficient evidence to compare the safety and feasibility between RLR and LLR for treatment of ICC. Limited evidence suggests that RLR has less intraoperative blood loss, shorter hospital stay, and better overall survival than OLR.

Level of evidence: Very low. Level of recommendation: Weak (Grade 2D). Expert agreement: 86.21%.

Two comparative studies were reported to evaluate the safety and feasibility of robotic *vs* open hepatectomy for ICC [36,60]. The pooled results suggested that RLR had less intraoperative blood loss (SMD = -0.75, 95%CI: -1.46 to -0.05; P = 0.04) and shorter hospital stay (SMD = -0.31, 95%CI: -0.54 to -0.09; P = 0.006) than OLR[36,60]. There were no significant differences in other perioperative outcomes between the two groups. Limited evidence suggests RLR may improve the outcomes of ICC when compared to OLR, but we need to carefully interpret these findings. Shapera *et al*[60] suggested that patients after RLR or OLR had similar resection margins, and median overall survival was similar in patients with any resection margin distance. Hamad *et al*[36] compared short- and long-term outcomes between RLR and OLR for patients with ICC, and they reported that patients who underwent RLR had shorter hospital stays and similar long-term risk of death between the two groups. These results suggested RLR for ICC could shorten hospital stay without compromising oncological outcomes such as negative margins, postoperative mortality, and long-term survival[36]. As there have been few comparative studies focusing on ICC and there is no meta-analysis on the short- and long-term clinical outcomes of RLR *vs* LLR or OLR for ICC, higher levels of evidence are urgently needed to answer this question.

Question 4: Is RLR safe and effective in patients with CRLM?

Recommendation: RLR is safe and feasible for patients with CRLM, since it is associated with a lower conversion rate but

longer hospital stay than that of LLR. Limited evidence suggests no significant difference in all the perioperative outcomes between RLR and OLR in patients with CRLM. Oncologic outcomes with limited evidence suggested there was also no significant difference between RLR *vs* LLR and RLR *vs* OLR.

Level of evidence: Very low. Level of recommendation: Weak (Grade 2D). Expert agreement: 89.66%.

Studies on RLR *vs* LLR or OLR for CRLM have been extensively published in the past three years[45,46,61-63]. The evidence suggested RLR to have a lower conversion rate (RR = 0.42, 95%CI: 0.23 to 0.77; P = 0.005) and longer hospital stays (SMD = 0.19, 95%CI: 0.03 to 0.35; P = 0.020) than LLR for patients with CRLM, and there were no significant difference in operation time, estimated blood loss, intraoperative blood transfusion rates, R0 resection, postoperative morbidity, and overall survival[45,46,61,62]. In addition, limited evidence showed there were no significant differences in operation time, estimated blood loss, R0 resection, hospital stays, overall complications, minor and major complications, postoperative 30-d mortality, and survival outcomes between RLR and OLR for patients with CRLM[61,63]. With appropriate expertise and experience, robotic-assisted surgery can be considered to be an alternative minimally invasive approach to CRLM resections[64,65].

Currently, there is insufficient evidence on patients who underwent simultaneous robotic-assisted resections of CRLM and the primary tumor. A conference abstract on one RCT in comparing RLR and OLR for simultaneous resections suggested a longer operating time in the robotic arm, and patients who underwent RLR had less blood loss, less Clavien-Dindo III-IV complications, a shorter time to pass first flatus, and a shorter hospital stay when compared to open surgery [40]. A recent systematic review reported that all patients who underwent robot-assisted R0 resection had no perioperative deaths[65]. However, when patients who underwent simultaneous major hepatectomy combined with complex colorectal surgery, the operative risks were increased, leading to poorer perioperative outcomes with increased length of stay, morbidity, and mortality, and unfavorable patient recovery due to delay in the initiation of subsequent adjuvant therapy[5,65].

Question 5: Is robot approach safe and feasible for living donor hepatectomy?

Recommendation: Robotic living donor hepatectomy can be a safe and feasible alternative to open and laparoscopic approach. Robotic living donor hepatectomy has a longer operative time than that of OLR and LLR, but a shorter hospital stay compared with OLR. The other donor and recipient outcomes were reported to be comparable among the three interventions.

Level of evidence: Very low. Level of recommendation: Weak (Grade 2D). Expert agreement: 96.55%.

We systematically reviewed 4 studies that investigated the safety and feasibility of robotic and open living donor hepatectomy, with a total of 972 patients being included in the meta-analysis[41,66-68]. The pooled results suggested that RLR had lower postoperative peak serum bilirubin (SMD = -0.59, 95%CI: -0.81 to -0.37; P < 0.0001), shorter postoperative hospital stays (SMD = -0.53, 95%CI: -0.90 to -0.17; P = 0.004) and a longer operative time (SMD = 1.45, 95%CI: 0.66 to 2.25; P = 0.003) compared to the open group[41,66-68]. There were no significant differences in terms of other donor and recipient outcomes. Rho *et al*[41] evaluated the clinical and perioperative outcomes of robotic living donor right hepatectomy from carried out on 52 consecutive cases patients and compared with patients who underwent comparison with open (n = 62) and laparoscopic (n = 118) donor hepatectomy. They reported that although RLR was associated with a longer operation time, the mean estimated blood loss was significantly lower compared with LLR and OLR, and donor satisfaction (body image and cosmetic appearance scores) was higher in RLR than that of LLR[41].

Large incisions resulting in large scars are an ongoing concern for surgeons performing open living donor hepatectomy. For robotic living donor hepatectomy, there is a better body image, improved cosmetic appearance, and fewer wound-related complications[41]. Living donor hepatectomy is considered to be the pinnacle of hepatobiliary surgery, which requires assurance of donor survival, good graft status and minimization of associated complications[66]. Based on the currently available studies, RLR reduced postoperative pain, resulted in rapid donor recovery and with similar postoperative complications[41,66-68]. However, studies comparing RLR with LLR are insufficient[41]. In summary, RLR for living donor hepatectomy is feasible and safe when performed by surgeons with both excellent knowledge of liver anatomy and long experience of open living donor hepatectomy[41,66]. However, biliary complications are a problem that should never be ignored. The combination of robotic-assisted procedures and indocyanine green (ICG) fluoroscopy is recommended for precise division and fine suturing of the divided bile ducts[41,66].

Question 6: Is robotic approach safe and feasible for minor hepatectomy?

Recommendation: For minor hepatectomy, the safety and feasibility of RLR are comparable to that of LLR and OLR. Robotic minor hepatectomy was reported to have a longer operative time than LLR, but there was less overall complication. RLR resulted in a shorten hospital stay and decreased overall morbidity compared to the open approach. The other perioperative outcomes were comparable among the three interventions.

Level of evidence: Low. Level of recommendation: Weak (Grade 2C). Expert agreement: 96.55%.

Minor hepatectomy with fewer than 3 adjacent hepatic segmental resections is the most commonly carried out procedure in RLR. As a minimally invasive surgery, the benefits of the robotic approach for minor hepatectomy have been controversial[36,37,49,51,69-72]. An updated meta-analysis based on new evidence was conducted by the Evidence Evaluation Group on 13 retrospective cohort studies with 735 robotic and 1362 laparoscopic minor hepatectomies[12,22,34,53,73-81]. The results showed that the operative time was significantly longer (SMD = 0.44, 95%CI: 0.19 to 0.69; P = 0.0006) with the robotic approach, but it had less overall complication (RR = 0.76, 95%CI: 0.61 to 0.95; P = 0.01) than LLR. No statistically significant differences were observed in estimated blood loss, conversion rate, blood transfusion rate,

postoperative hospital stays, 90-d mortality, and R0 resection. Based on the currently available studies and expert opinions, RLH was associated with a longer operation time when compared with LLH because of the additional time required to dock and undock the robot, and the large extent to exchange instruments required by the robot-assisted procedures[34,69,70].

We also systematically reviewed 6 studies to investigate the safety and feasibility between RLR and OLR[9,38,71,73,82,83]. The results showed that robotic minor hepatectomy had a shorter postoperative hospital stay (SMD = -0.91, 95%CI: -1.27 to -0.55; P < 0.00001), less overall complications (RR = 0.39, 95%CI: 0.23 to 0.64; P = 0.0002), and less severe complications (RR = 0.28, 95%CI: 0.08 to 0.97; P = 0.04) when compared to open surgery. There were no significant differences in terms of operation time, estimated blood loss, intra-operative blood transfusion rate, and readmission rate, and R0 resection for malignancy between robotic and open minor hepatectomies. Liver resections for difficult-located segments (1, 4a, 7, and 8) are recommended to be defined as technical major hepatectomy.

Question 7: Is robotic approach safe and feasible for major hepatectomy?

Recommendation: For major hepatectomy, robotic hepatectomy is as safe and feasible as laparoscopic and open hepatectomy. Compared with LLR, RLR was significantly better in estimated blood loss and conversion rate. In comparison with OLR, the estimated blood loss and hospital stay of RLR are significantly better than those of OLR, but there is a longer operation time in the RLR group.

Level of evidence: Low. Level of recommendation: Weak (Grade 2C). Expert agreement: 93.10%.

Chong *et al*[32] compared the efficacy and safety of 989 individuals, including 220 who underwent robotic and 769 who underwent laparoscopic right and extended right hepatectomy (RH/ERH). They reported a lower open conversion rate and a shorter postoperative hospital stay for robotic RH/ERH. We systematically reviewed 10 studies that investigated the safety and feasibility of robotic and laparoscopic major hepatectomy[22,32,33,39,84-89]. The results showed that robotic major hepatectomy resulted in less estimated blood loss (SMD = -0.52, 95%CI: -0.88 to -0.16; P = 0.005) and a lower conversion rate (RR = 0.44, 95%CI: 0.29 to 0.67; P = 0.0001) compared to laparoscopic surgery. There were no significant differences between robotic and laparoscopic major hepatectomies in transfusion rate, R0 resection, readmission, mortality within 90 d, overall complications, mild/severe complication, bile leakage and liver failure rates.

Hamad *et al*[36] investigated 1876 patients who underwent open (n = 1804) and robotic assisted (n = 72) resection between 2004 and 2017. The results showed that the patients who underwent RLR had a shorter length of hospital stays yet there was no difference in 30-d readmission or 90-d mortality[36]. Lee *et al*[43] matched 36 patients each in the robotic and open group. They found that operative time was significantly longer but the postoperative hospital stays was significantly shorter in the robotic group[43]. An updated meta-analysis based on the latest evidence was conducted by the Evidence Evaluation Group on 8 retrospective cohort studies. The pooled results suggested the estimated blood loss and hospital stay of the robotic group to be significantly shorter than the open group, but there was a longer operation time in the robotic group[22,33,37,43,49,51,71,72].

We also focused on the safety and feasibility of RLR in technically "major" resections (segment 1, 4a, 7, and 8). Liver resection on segments 1, 4a, 7, and 8 is relatively more technically difficult owing to a large parenchymal transection plane with proximity to critical structures and major vessels[90-92]. RLR on difficult liver segments has been reported to be a safe and feasible procedure, and many experienced surgeons tend to perform robotic resections on these selected patients. In a recent international multicenter retrospective study comparing robotic *vs* laparoscopic right posterior sectionectomy, the author reported RLR to be associated with reduced blood loss and lower open conversion rates than LLR, and suggested that RLR and LLR could be performed in expert centers with good outcomes in well selected patients [93]. A study reported a patient with hepatocellular carcinoma which involved segments 4 and 8 to undergo robotic central bisectionectomy. The outcomes indicated that robotic central bisectionectomy could be performed safely using proper exposure techniques and an appropriate combination of several useful technical tips[16]. A multicenter study reported that robotic right posterior sectionectomy could be performed in expert centers with less blood loss and lower conversion rates in well-selected patients[93,94]. Another study indicated that RLR on segments 1, 4a, 7, and 8 showed similar surgical outcomes, including blood loss, hospital stay, R0 negative margin rate, and morbidity, when compared with laparoscopic liver resection[95]. The application of robotic approach has also been reported for caudate lobectomy, including Spiegelian lobectomy, isolated partial and complete caudate lobectomy[96,97]. However, most studies reported only a few cases with the potential of selection bias, thus limiting the application of the results. It is necessary to conduct high-quality clinical studies in the future to further clarify the impact of robotic hepatectomy on difficult liver segments.

Question 8: Is RLR more cost-effective than LLR and OLR?

Recommendation: As the policy on medical expense and definition of cost are different in the literature, the real cost of three interventions should be calculated and compared based on a standard method in the future. Limited evidence suggests the total cost of RLR to be higher than LLR, but there were no significant differences between RLR and OLR. The cost-effectiveness of the three interventions should be synthetically evaluated based on many factors, including direct and indirect costs, hidden benefits from favorable clinical outcomes and local social and economic situations.

Level of evidence: Very low. Level of recommendation: Weak (Grade 2D). Expert agreement: 89.66%.

The most common concern about cost-effectiveness analysis of RLR is simply on the total cost, hospitalization costs, and readmission costs. One systematic review and meta-analysis and nine additional updated original studies were included to answer this question[9,34,42,84,98-103]. The resynthesized evidence suggests that the total costs (SMD = 1.15, 95%CI: 0.24 to 2.07; P = 0.01) and hospitalization costs (SMD = 0.96, 95%CI: 0.50 to 1.41; P < 0.0001) of RLR is higher compared to LLR[34,42,75,78,104]. However, no statistically significant differences were observed regarding total costs,

hospitalization costs, and readmission costs between RLR and OLR[9,42,44,68,101]. In addition, total costs were assessed for different type of liver resection. For the included studies which investigated RLR *vs* LLR, these studies were more focused on the cost-effectiveness in minor liver resections, and the results showed that RLR had higher total costs than LLR (SMD = 1.22, 95%CI: 0.60 to 1.83; $P < 0.0001$)[34,75,78]. When various types of pathologies in patients were included in the comparison between RLR and OLR, including complex hepatolithiasis, donor right hepatectomy, minor and major resections, these confounders were introduced to become an important reason to decrease the level of evidence[9,44,68,103]. According to the currently available studies, even though the higher total costs of RLR were closely associated with more operating room supplies[34,68,73,79,80,84], the higher total costs were mainly due to longer hospital stays and more treatment of complications in the laparoscopic and open group than the robotic group[9,71,100,105,106]. The favorable perioperative outcomes in RLR should be weighed against the higher operative costs when compared with laparoscopic or open approaches[98].

Robotic surgical systems have evolved rapidly in recent years, and the trends in the total cost and operative cost are worth future investigating. Although the costs of RLR may differ among countries or regions due to differences in medical policy or insurance premium, a serious obstacle to the widespread use of robotic surgical system is the large indirect cost[34,78-80]. Furthermore, a comprehensive evaluation of the cost-effectiveness should also consider the hidden benefits from favorable clinical outcomes associated with robotic hepatectomy to include patient's psychological benefits and social benefits.

Question 9: What is the role of RLR for cirrhotic patients?

In the setting of cirrhotic patients, similar to LLR, RLR could also be performed in to selected patients. Currently, there are insufficient studies focusing on the application of RLR on cirrhotic patients (clinical recommendation: Expert agreement 100%).

The improvement of surgical techniques, perioperative management, and patient selection improved the surgical outcome of patients with cirrhosis, and the overall improvement of surgical techniques as represented by the minimally invasive approach improved the outcomes of perioperative management in patients with cirrhosis[107-109]. Minimally invasive hepatectomy for cirrhotic patients has been reported to be associated with less complications, shorter postoperative hospital stay, and similar outcomes in operative time, estimated blood loss and postoperative complications when compared with non-cirrhotic patients, and laparoscopic surgery may provide potential benefits in reducing the incidence of postoperative ascites and liver failure[5,110]. Only a few patients were included in these studies and the outcome of robotic hepatectomy in patients with cirrhosis were not evaluated separately[47]. It is necessary to conduct more research on RLR for liver cancer patients with cirrhosis to further evaluate the safety and efficacy of the robotic approach.

Question 10: What is the role of RLR for lesions located close to major vascular and biliary structures?

For lesions located close to major vascular and biliary structures, especially for deeply located lesions, parenchyma-sparing liver resection should be performed by using the robotic approach to rely on the delicate dissection offered by the stable and flexible movements of the robotic arms, as an alternative approach to major liver resection. Compared to robotic major liver resection, robotic parenchyma-sparing liver resection could potentially increase resectability of these lesions. However, as this is a technically demanding procedure, it should be performed by experienced surgeons on well-selected patients (clinical recommendation: Expert agreement 100%).

For malignant liver lesion with a small tumor size but in close proximity to important vessels such as the hepatocaval confluence, or the bifurcation of the primary or secondary Glissonean pedicles, the conventional approach is to use major resection to remove the vessel in its entirety along with the liver tissues it supplies or drains. However, in patients with a poor liver function and insufficient liver remnant volume, the safety of major resection is difficult to ensure, resulting in a reduced operative resection rate. Parenchyma-sparing liver resection addresses this dilemma to some extent. Removal of the tumor off the adjacent vascular structures or combined vascular resection and reconstruction could increase the resection rate of the tumor. In contrast to the laparoscopic approach with its intrinsic drawbacks including the fulcrum effect and rigid instruments, the robotic system could offer stable and flexible movements of the instruments, which facilitate the operative procedures to achieve a higher level of difficulty. RLR for treatment of centrally located lesions has been reported and shown to be safe and feasible in small case series[111,112]. In addition, with the help of intraoperative ultrasound, it has been shown that the robotic approach allowed optimal access to all liver segments and facilitated parenchymal-sparing surgery for lesions located in the posterosuperior segments or in contact with main liver vessels, not only for colorectal liver metastasis but also for HCC[113]. Robotic parenchyma-sparing liver resection for lesions located close to major vascular and biliary structures allows for sufficient liver remnant to be retained, thus allowing patients to start their postoperative adjuvant therapy early, which is important in improving patients' survival in today's rapidly evolving of comprehensive treatment.

Question 11: What is the role of robotic approach for associating liver partition and portal vein ligation for staged hepatectomy?

Robotic first- or second-stage associating liver partition and portal vein ligation for staged hepatectomy (ALPPS) is an optional strategy for treatment of primary and metastatic liver cancer in patients with insufficient residual liver volume. Due to the complexity of ALPPS surgery and the high morbidity rate, the benefit of robotic ALPPS is unclear on the curative effect of the initially unresectable liver cancer, as there have been rapidly evolving developments in locoregional and systemic therapies. Robotic ALPPS must be evaluated with caution before operation and should only be performed in highly selected patients (clinical recommendation: Expert agreement 100%).

ALPPS has been introduced to treat patients with advanced liver tumors and insufficient residual liver volumes for more than 10 years. However, there is still a lot of controversies on the value of this approach due to its high mortality rate[114,115]. Minimally invasive approach for ALPPS has been applied for the purpose of reducing mortality and improving recovery of patients. Most of the ALPPS procedures were used for the first-stage[116]. A systematic review of 27 patients who underwent ALPPS reported the potential benefit of using the minimally invasive ALPPS in reducing morbidity and mortality[117]. However, there was selective bias in this study and the sample size was small, which compromised the robustness of the conclusions. Previous studies with small case numbers showed that the robotic approach could be used for the first-stage ALPPS for HCC, CRLM and ICC[118-120]. Complex robotic ALPPS procedures (*e.g.*, robotic ALPPS for patients with portal vein thrombosis, robotic ALPPS with simultaneous left colectomy) have also been reported to be safe and feasible carried out by experienced surgeons[121-124]. After the long period of development of ALPPS and its modified approaches, the role of ALPPS should be revisited due to its complexity in treating patients with advanced stage of malignancy and the high morbidity rate, especially when facing the major developments in locoregional and systemic therapies[125-128]. Although the robotic ALPPS is technically feasible, the oncological and health economic benefits are still unclear. The efficacy of robotic ALPPS still needs to be evaluated through high-quality clinical researches.

Question 12: Could the robotic approach shorten the learning curve of liver resection?

The case number required to surmount the learning curve for RLR has been reported to be lower than that for LLR. The case number required to surmount the learning curve of RLR varied among different studies[12,32,129-134]. The surgeons' experience in LLR could have a significant influence on the learning curve of RLR. About 25 consecutive cases are needed for an experienced surgeon to surmount the learning curve of major RLR and 15 cases for minor RLR (clinical recommendation: Expert agreement 100%).

Because of the enhanced surgical dexterity offered by the robotic system, robotic hepatectomy may have a shorter learning curve compared to laparoscopic hepatectomy. However, the large experience in LLR surgeons had before embarking on robotic liver surgery could have an impact on the learning curve[100,135]. Chua *et al*[136] reviewed the literature reported up to July 2019 pertaining to the learning curves in minimally invasive hepatectomy (MIH) by searching PubMed and Scopus databases. Forty studies were included to explore quantitatively the learning curve for MIH. They reported the case number required to surmount the learning curve for RLR was 25 consecutive cases (range: 16-50)[136].

Liu *et al*[131], by analyzing the learning curve of 100 robotic left and right hemihepatectomy (RLH/RRH) in terms of operative time, reported that the learning process was completed in the RLH group after an initial phase of 35 cases, which was shorter than the RRH group (n = 45). Given that, mobilization and resection of the left liver are easier to perform than the right liver, RLH might be the first choice for beginners.

Question 13: Which difficulty scoring systems should be used for RLR?

Ban and Iwate reported on the difficulty scoring system for LLR which was externally validated for RLR. The two difficulty scoring systems are currently recommended. A difficulty scoring system exclusively for RLR should be established by further studies (clinical recommendation: Expert agreement 100%).

By predicting the complexity of different surgeries, the difficulty scoring system (DSS) can recommend suitable patients to surgeons at their corresponding learning stages. Current DSS scores on the basis of the weighted combination of predicted factors that affect the surgeries' complexity include tumor size, position, number of the tumor, extent of liver resection and liver function[137,138].

However, the scoring system for RLR remains to be designed. Linn *et al*[137] summarized 11 types of DSS for LLR based on previously reported studies and conducted a meta-analysis. The results showed that 5 DSS (including Ban DSS, Iwate DSS, Hasegawa DSS, IMM DSS, and Southampton DSS) could be used for predicting the difficulty of LLR surgeries [138-141]. Though no DSS has significant advantages, Ban and Iwate DSS were externally validated for RLR[137,138].

Question 14: What is the role of intraoperative navigation techniques in RLR?

Intraoperative ultrasonography (IOUS) and indocyanine green (ICG) imaging has been used for tumor locating and surgical margin delineation in RLR. Surgeons are supposed to master these techniques and choose the suitable navigation tools to increase the safety of RLR (clinical recommendation: Expert agreement 100%).

Studies have supported the importance of IOUS in liver operations[142,143]. Based on the experience of IOUS in 110 consecutive patients, Zhu *et al*[144] put forward a standardized 4-step IOUS agreement to ensure the safety of RLR operation. Moreover, when using IOUS to examine all the patients, they found 11 patients (10%) had extra lesions, and 7 of these patients (63.64%) underwent improved surgical strategies[144]. However, IOUS has the limitations to accurately show irregular hepatic segmental demarcation and anatomical structure, while ICG imaging has become a supplementary tool for IOUS due to its ability on real-time 3D recognition of tumor margins and to guide liver transection plane. Wakabayashi *et al*[145] reviewed articles related to ICG imaging in liver resection and showed that the combination of IOUS and ICG imaging can increase the safety of liver resection, but the timing and dose administration of ICG remain uncertain. Furthermore, Liu and his team reported the application of ICG using "four-zone three-phase" fluorescence imaging in robot-assisted anatomical hepatectomy in which the liver was divided into 4 anatomical zones include the "tumor zone", "peritumor zone", "ischemia zone", and "reserved liver zone"[146]. The ICG "four-zone three-phase" fluorescence imaging could accurately locate most tumors, clearly display the liver resection plane in a real-time manner and achieved the precision and standardization of anatomical hepatectomy.

The application of augmented reality (AR) technology can increase the accuracy of tumor positioning and surgical margin delineation. At present, only a few cases have been reported on the application of AR technology in RLR. Further technological advance and studies on evaluation of AR technology in clinical applications remain to be done.

CONCLUSION

This international experts consensus guideline offered guidance for the safe and effective clinical practice and the research direction of RLR in future. This evidence-based guideline is expected to be updated again in 2026 and further randomized controlled trials are needed to validate these recommendations.

ACKNOWLEDGEMENTS

We thank all the external reviewers for giving responses to the consensus; and all Members of the Evidence Evaluation Group: Shao-Ming Song and Lin Zhu (The First School of Clinical Medicine, Lanzhou University, Lanzhou 730000, China), Gui-Neng Zeng and Yue Li (School of Medicine, Nankai University, Tianjin 300300, China), Zhao-Da Deng and Zhi-Yuan Yao (Medical School of Chinese PLA, Beijing 100000, China).

FOOTNOTES

Author contributions: Members of the guideline steering group: Liu R, Abu Hilal M, Wakabayashi G, Fan J, Chen XP, and Lau WY contributed to designing guidelines, identifying problems, and providing comments; Members of the guideline expert group: Han HS, Palanivelu C, Boggi U, Hackert T, Kim HJ, Wang XY, Hu MG, Choi GH, Panaro F, He J, Efanov M, Yin XY, Croner RS, Fong YM, Zhu JY, Wu Z, Sun CD, Lee JH, Marino MV, Ganpati IS, Zhu P, Wang ZZ, and Yang KH provided expert's opinion; and all authors approved the final version of the manuscript.

Conflict-of-interest statement: The authors declare no conflict of interest in the development of consensus guidelines.

REVIEW

Non-alcoholic fatty liver disease: Immunological mechanisms and current treatments

Lucy Petagine, Mohammed Gulrez Zariwala, Vinood B Patel

Specialty type: Gastroenterology and hepatology

Provenance and peer review: Invited article; Externally peer reviewed.

Peer-review model: Single blind

Peer-review report's scientific quality classification

Grade A (Excellent): 0
Grade B (Very good): B
Grade C (Good): C
Grade D (Fair): 0
Grade E (Poor): 0

P-Reviewer: Sun H, China; Zhang Y, China

Received: May 3, 2023

Abstract

Non-alcoholic fatty liver disease (NAFLD) causes significant global disease burden and is a leading cause of mortality. NAFLD induces a myriad of aberrant changes in hepatocytes at both the cellular and molecular level. Although the disease spectrum of NAFLD is widely recognised, the precise triggers for disease progression are still to be fully elucidated. Furthermore, the propagation to cirrhosis is poorly understood. Whilst some progress in terms of treatment options have been explored, an incomplete understanding of the hepatic cellular and molecular alterations limits their clinical utility. We have therefore reviewed some of the key pathways responsible for the pathogenesis of NAFLD such as innate and adaptative immunity, lipotoxicity and fibrogenesis, and highlighted current trials and treatment options for NAFLD patients.

Key Words: Liver; Fat; Inflammation; Mitochondria; Immune system

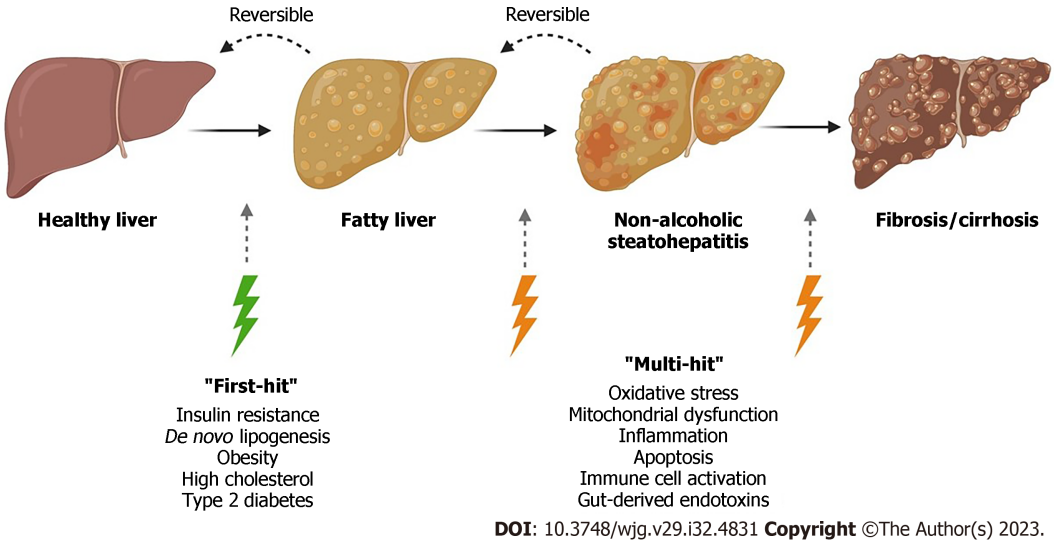
INTRODUCTION

Non-alcoholic fatty liver disease (NAFL) (NAFLD) is the most common cause of liver disease globally which occurs due to an excessive accumulation of fat in the liver in the absence of secondary causes or other liver disease aetiologies[1]. NAFLD encompasses the spectrum of disease from simple NAFL, non-alcoholic steatohepatitis (NASH), fibrosis, cirrhosis, and in many cases hepatocellular carcinoma (HCC)[1]. Due to increasing trends of sedentary lifestyles and dietary choices the prevalence of NAFLD continues to rise[1].

NAFLD has a significant global disease burden (882 million cases in 2017)[2], with cases likely to be higher due to poor screening of high risk asymptomatic populations. Furthermore, inaccurate disease progression predication markers and a lack of available licenced therapeutics hinders the treatment of NAFLD. Management of NAFLD is largely based on lifestyle modifications, but many newer therapies are being evaluated (discussed later). Further understanding into the mechanisms of disease progression, diagnostic biomarkers and therapeutic intervention should help mitigate burden of disease. Finally, liver disease combination therapies are becoming increasingly popular. This review will highlight some of the recent developments in NAFLD and aims to define the pathological features associated with disease progression including the immunological mechanisms as well as the current therapeutic interventions used for NAFLD.

Epidemiology and prevalence

Global reports relating to the epidemiology of NAFLD have estimated a global prevalence of NAFLD between 25% and 35%[3-5], with Europe as high as 30%[6], 35% in South American countries[6,7], and 35% in North America[6]. During the period of 1991 to 2019, trend analysis shown that increasing global prevalence increased yearly by 0.7%, rising from 21.9% in 1991 to 37.3% in 2019[5].



NAFLD has a global impact on health care systems due to its high rates of morbidity and mortality[8]. NASH is a particularly prevalent cause of chronic liver disease which in turn leads to cirrhosis and HCC, whereas NAFLD has been noted as the biggest cause of HCC in the United States, France, and the United Kingdom, with NAFLD-related HCC predicted to increase globally alongside the rise in obesity[3]. In the United States, by 2030, almost 49% of the total population is projected to be obese[3].

Globally, the phenotype of patients with NAFLD appears to be men of a mean age of 51.7 years old, with obesity and/or type 2 diabetes[6]. A linear increase prevalence of NAFLD, diabetes and metabolic disorders have also been documented[9,10], and especially occurs in those with central obesity, diabetes and metabolic syndrome[11,12]. Metabolic comorbidities include hypertension (37%) and metabolic syndrome (40%)[6]. NAFLD prevalence in type-2 diabetes mellitus (T2DM) is as high as 70%[13], and patients with T2DM also have a twofold increased risk of all-cause mortality [4,14]. Prevalence of NAFLD in patients with morbid obesity also rises to 90%[4]. Therefore, prevalence of NAFLD poses a significant global health burden requiring clinical attention.

Histopathology and disease spectrum

NAFLD is the most common cause of liver dysfunction with a high association for obesity and insulin resistance (IR). The spectrum of NAFLD can lead to progressive NASH, fibrosis, and lastly HCC and liver failure. NAFLD is a complex disease which results from environmental causes as well as polygenic background and risk factors (Figure 1). Although the molecular mechanisms underlying disease progression are complex, the histological spectrum of disease has been well described[15].

NAFLD is defined as a disease of the liver which is characterised by macrovesicular fat deposition and storage (> 5% of the hepatocytes) due to dysregulation in the mechanisms of fat synthesis and utilisation by the liver[7,16]. Steatosis is predominantly graded on a four-step scale, from 0 to 3. Grade 0 is defined as a normal liver containing fat in < 5% of hepatocytes[17,18]; grade 1 occurs when fat deposits occur in < 33% of hepatocytes, and grade 2 when fat occurs in 33%-66%[17,18]; grade 3 is the final stage in the spectrum of steatosis which occurs when > 66% hepatocytes contain fat[17,18]. The most important histological feature of NASH is hepatocyte ballooning and lobular inflammation as well as a steatotic liver. Hepatocyte ballooning is the second histological feature of NASH. Hepatocyte ballooning is defined by a clear, flocculent, not vacuolar cytoplasm with a ballooned shape. Inflammation occurs in a lobular pattern in NASH, containing Kupffer cells (KC), aggregates of neutrophils, and Mallory-Denk bodies[15]. NASH is defined as a chronic state of inflammation whereby hepatic stellate cells (HSCs) transform into myofibroblasts[19]. These transformed cells produce extracellular collagen matrix[19]. Normally fibrogenesis is a wound healing process. However, in NAFLD, sustained and progressive insults occurring over many years causes unregulated fibrogenesis[19]. Initially collagen deposits form in the perisinusoidal space. As collagen bundles form, architectural remodelling occurs which can lead to cirrhosis and HCC. Fibrosis stage 1 (F1) occurs when mild perisinusoidal/pericellular fibrosis is documented without septa[20]. Stage two occurs when fibrosis occurs in perisinusoidal/pericellular and portal/periportal regions with few septa (F2)[20]. Stage three (F3) is seen when numerous septa are documented, also known as bridging fibrosis[20]. Lastly, stage four is a cirrhotic liver[20]. An overview of NAFLD progression is shown in Figure 1.

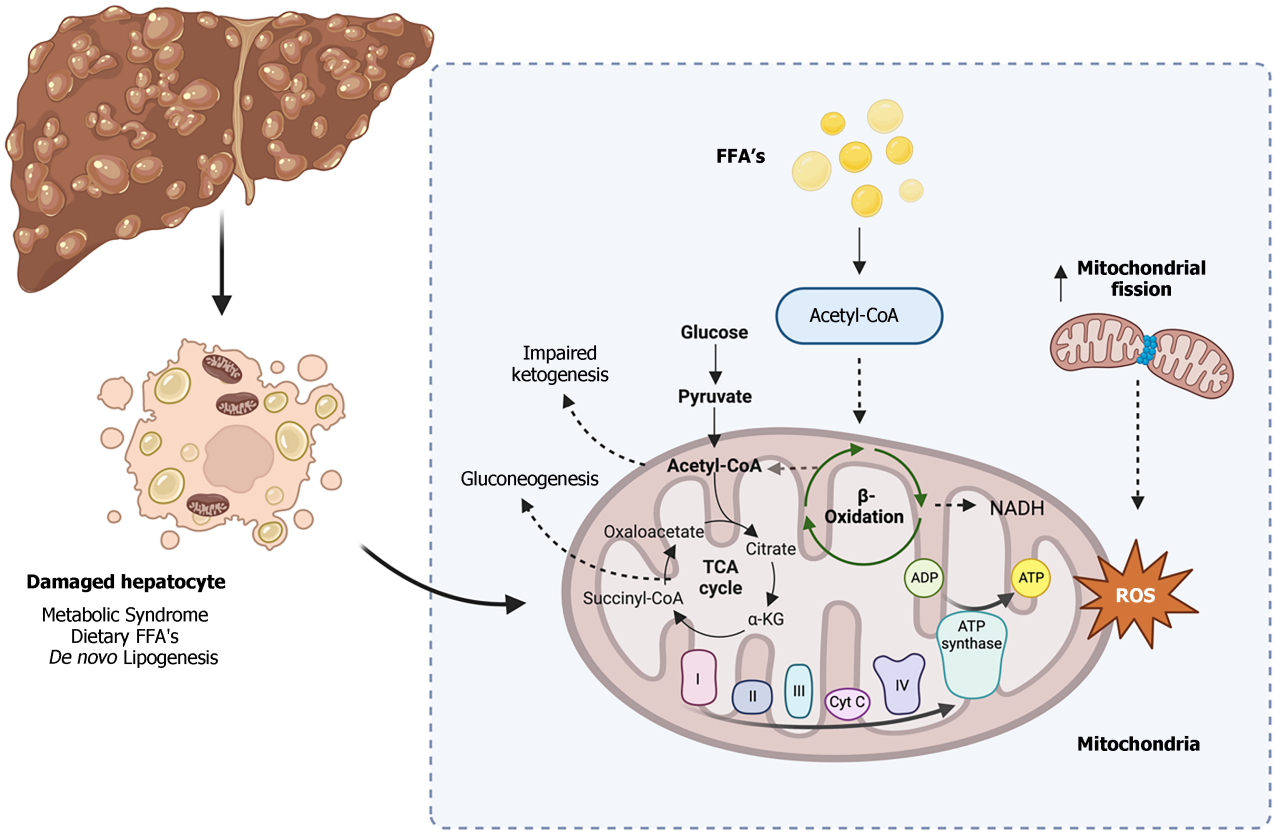

Figure 1 Overview of the current understanding of non-alcoholic fatty liver disease progression. Non-alcoholic fatty liver disease (NAFLD) encompasses a range of liver damage, from simple accumulation of fat in liver cells, named steatosis, to more severe forms of the diseases such as steatohepatitis, involving inflammation which can lead to fibrosis and cirrhosis. In the "multiple-hit" theory of progression, the first cause or "first-hit" in NAFLD is insulin resistance, obesity, type 2 diabetes, and metabolic syndrome. As the first hit occurs, free fatty acids are stored in the liver as triglycerides, resulting in simple steatosis. Disease progresses when multiple factors, or "multi-hits", such as oxidative stress, inflammatory mediators, apoptosis, and mitochondrial dysfunction cause liver damage (created with BioRender.com).

Progression of the fibrosis stage to a cirrhotic scarred liver can vary between individuals, with cirrhosis occurring up to 15 to 20 years after initial diagnosis[19,21]. The median survival rate for patients with compensated cirrhosis is approximately 9 to 12 years, however, patients with decompensated cirrhosis have a significantly lower median survival rate of approximately 2 years[22]. Patients in the compensated stage are frequently asymptomatic, and often remain undiagnosed[22]. Therefore, early detection of cirrhotic patients who are still in the compensated stage is crucial, as early diagnosis could prevent or slow down disease progression. The onset of decompensated cirrhosis occurs when symptoms such as ascites, hepatic encephalopathy, and/or gastroesophageal variceal haemorrhage are found[22]. Histologically, cirrhosis is diagnosed when a disconnection of the hepatocytes from the central vein occurs as well as capillarisation of the liver sinusoids[19]. These modifications that occur to the liver structure and integrity lead to elevated intravascular resistance within the portal system and decreased hepatic perfusion, ultimately causing a loss of liver function[19]. Hence, timely diagnosis and management of cirrhosis is required to improve patient outcomes.

IR in NAFLD

Many studies have shown that metabolic dysfunction and IR play a significant role in the development of NAFLD. Various animal and clinical studies suggest that chronic low grade inflammation may play a role in the development of IR and NAFLD as well as extrahepatic complications such as cardiovascular diseases, T2DM, and renal dysfunction[23]. IR is a complex state by which the skeletal muscle, liver, and adipose tissue become less sensitive to insulin and its metabolic effects[24]. IR is related to obesity, hypertension, hyperglycaemia and metabolic syndrome. During a carbohydrate-rich diet, excess glucose is converted into fatty acids *via* lipogenesis, using acetyl-CoA which is generated from glycolysis-driven pyruvate[25]. These fatty acids are then incorporated into very low-density lipoproteins (VLDL) for transport to white adipose tissue for storage[25]. Accumulation of lipids in adipocytes trigger downstream signalling of pathways including c-Jun N-terminal kinase (JNK) and nuclear factor-kappa B (NF-κB), leading to production of proinflammatory cytokines, such as tumour necrosis factor-alpha (TNF-α) and interleukin (IL)-6[26,27]. JNK regulates the production of proinflammatory cytokines, karyomitosis, and cellular apoptosis, and therefore, contributes to inflammation and IR. Research has proposed activation of JNK also accelerates lipid accumulation, thus, exacerbating liver injury. JNK-1 deficiency in adipose tissue shows protection from development of hepatic steatosis and promotes glucose intolerance, insulin clearance, IR, and hepatic steatosis[24]. Kluwe *et al*[28] also showed that in a mouse model, inhibition of JNK lead to modulation of fibrosis in hepatocytes. In a high fat diet (HFD) model of NAFLD, IR, liver injury and increased autophagy were documented[29]. However, JNK inhibition decreased autophagy and IR[29]. Therefore, JNK signalling plays a significant role in NAFLD progression.

The hormone adiponectin is secreted by adipocytes and is associated with improved insulin sensitivity. Adiponectin-mediated signalling is also able to stimulate fatty acid β-oxidation, glucose utilisation and uptake, as well as suppression of fatty acid synthesis[30]. Adiponectin can also inhibit the glycerol 3 phosphate (G3P) pathway; however, research has shown that during NAFLD serum levels of adiponectin are reduced[30]. Another metabolite of the G3P pathway is fatty acyl-CoA which is involved in mitochondrial β-oxidation. In patients with NAFLD, an increase in mitochondrial β-oxidation can lead to a state of oxidative stress due to increased substrate delivery to the mitochondrial electron transport chain (ETC), increasing reactive oxygen species (ROS) and damaging mitochondrial DNA[30,31]. Although β-oxidation is upregulated, ATP levels are decreased in NAFLD due to reduced activity of ETC complexes I and IV[32], and have been

DOI: 10.3748/wjg.v29.i32.4831 **Copyright** ©The Author(s) 2023.

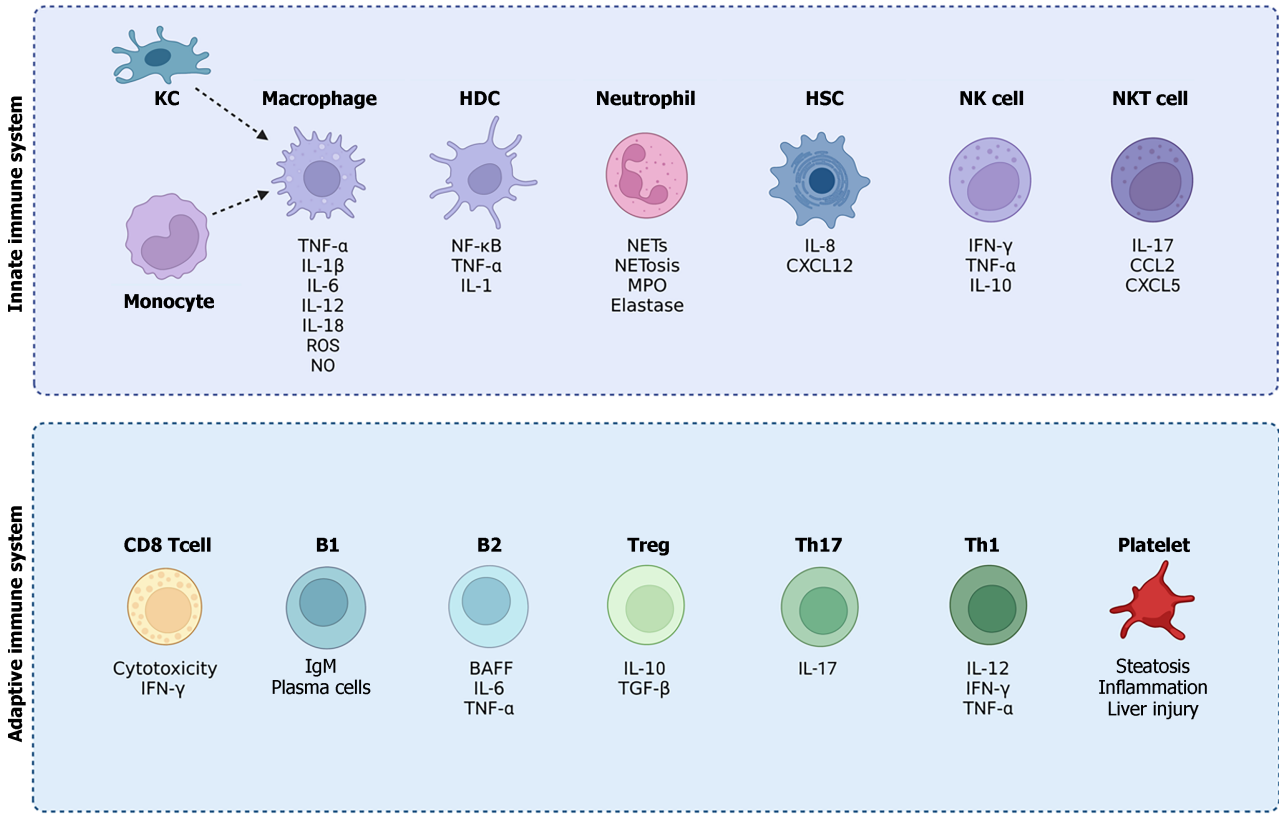

Figure 2 Overview of mitochondrial dynamics in non-alcoholic fatty liver disease. The accumulation of triglycerides and free fatty acids (FFAs) in the liver are converted to fatty acyl-CoA, which is then transported to the mitochondria for β-oxidation, generating acetyl-CoA. However, increased accumulation of FFA can cause insufficient hepatic β-oxidation, triggering inflammation and oxidative stress. Acetyl-CoA enters the mitochondrial tricarboxylic acid cycle allowing continuation of gluconeogenesis. The by-product nicotinamide adenine dinucleotide, produced though β-oxidation are transported to the electron transport chain (ETC) for oxidative phosphorylation. Disruption and dysfunction of the ETC can cause electron leakage and hepatocyte damage leading to reactive oxygen species production and oxidative stress. Accumulation of FFAs can cause mitochondrial damage, resulting in increased mitochondrial fission and degradation *via* mitophagy processes (created with BioRender.com). ROS: Reactive oxygen species; NADH: Nicotinamide adenine dinucleotide; TCA: Tricarboxylic acid; ADP: Adenosine diphosphate; ATP: Adenosine triphosphate.

correlated to levels of disease progression. Therefore, modifications to mitochondrial function can exacerbate disease progression in NAFLD. Hyperinsulinemia alongside increased levels of ROS also leads to an imbalance between mitochondrial fission and fusion proteins such as dynamin-related protein 1 (Drp1) and mitofusin-2 proteins (Mfn2)[33]. It is possible that an excessive mitochondrial fission in the liver plays an important role in NAFLD progression. Increases in the Drp1-to-Mfn2 ratio causes enhanced mitochondrial fission which in turn causes reduced endoplasmic reticulum association, decreases oxidative phosphorylation capacity, and elevated mitochondrial ROS production[33], which can exacerbate disease state. Therefore, it is plausible that a reduction in mitochondrial oxidative capacity as well as the impairment of metabolic fuels provides a plausible relationship between mitochondrial dysfunction, lipotoxicity and IR. Therefore, metabolic health and mitochondrial function are fundamental to progression of NAFLD (Figure 2).

The inflammasome pathway and macrophages are known to play a significant role in the development of IR. Production of IL-1β and IL-18 can be regulated by the inflammasome pathway, which contains complexes including nucleotide-binding oligomerization domain (NOD)-, leucine-rich repeats-and pyrin domain-containing protein 3 (NLRP3) and activation of caspase-1[34]. In NAFLD, inflammasome formation can be activated upon a variety of stress stimuli such as damage-associated molecular patterns, pathogen-associated molecular patterns, for example, lipopolysaccharide (LPS) from the gut-liver axis, mitochondrial ROS, endoplasmic reticulum stress, and ROS[34-36]. Activation of the NLPR3 inflammasome has shown to contribute to disease progression from steatosis to NASH[34,37]. MRNA levels of NLRP3 inflammasome components such as NLRP3, caspase-1, IL-1β, and IL-18 were also found to be significantly upregulated in NAFLD patients[37-39]. Therefore, targeted modulation of the inflammasome will lead to improved insulin signalling and mitochondrial function.

Immunological Mechanisms

In chronic liver disease, the activation of the immune response can both restore tissue function as well as cause tissue injury. Therefore, an amplified immune response may lead to organ dysfunction. The following section describes the involvement of various immune cell types in the pathogenesis of NAFLD (Figure 3).

DOI: 10.3748/wjg.v29.i32.4831 **Copyright** ©The Author(s) 2023.

Figure 3 Overview of innate and adaptive immune cells involved in non-alcoholic fatty liver disease (NAFLD). Activation of immune cells can promote inflammation and liver injury in NAFLD. The innate immune system cells include Kupffer cells, monocytes, and macrophages as well as hepatic dendritic cells, neutrophils and natural killer cells. Natural killer T cells provide a bridge between both the innate and adaptive immune system. The adaptive immune system includes T cells such as CD8 T cells and CD4 T cells (Th1, Th17 and regulatory T cells). The adaptive immune system also comprises of B1 and B2 cells as well as platelets. Although the contribution of immune cells to the development of NAFLD has been explored, the crosstalk between the distinctive immune cell subsets in the pathogenesis of NAFLD requires further investigation (created with BioRender.com). KC: Kupffer cells; TNF-α: Tumour necrosis factor-alpha; IFN-γ: Interferon-γ; IL: Interleukin; ROS: Reactive oxygen species; NO: Nitric oxide; NETs: Neutrophil extracellular traps; NF-κB: Nuclear factor-kappa B; HDC: Hepatic dendritic cells; MPO: Myeloperoxidase; HSC: Hepatic stellate cells ; CXCL: C-X-C motif chemokine ligand; BAFF: B cell activating factor; TGF-β: Transforming growth factor-β; NK: Natural killer; NKT: Natural killer T cells; Treg: Regulatory T cells.

Innate immune system in NAFLD: During NAFLD, the innate immune system is involved in the activation of resident KCs, with recruitment of innate immune cells such as neutrophils, monocytes, natural killer (NK) cells and natural killer T (NKT) cells[40], and inflammation is further exacerbated *via* the production of cytokines, (*e.g.* TNF-α, IL-1β, IL-6, IL-12, IL-18), chemokines, nitric oxide (NO) and ROS[40-42].

Macrophages: The main role of macrophages in the liver is predominantly for immunoregulatory and detoxifying functions, however, alterations in macrophage phenotypes and dynamics have been reported to be involved in the pathogenesis of NAFLD[43,44]. Liver resident KCs are a large population of macrophages as well as other subsets of macrophages such as monocyte-derived macrophages and liver capsular macrophages[45]. M1 macrophages have a pro-inflammatory phenotype and are induced by mediators such as LPS and interferon-γ (IFN-γ) and their activation causes secretion of pro-inflammatory cytokines such as IL-1β, IL-6 and TNF-α[46,47]. On the other hand, M2 macrophages have an anti-inflammatory phenotype and are induced by Th2 cytokines such as IL-4 and IL-13, causing secretion of anti-inflammatory factors such as IL-10 and transforming growth factor-β (TGF-β)[46,47]. M2-type macrophages have also been reported to induce M1-type KCs apoptosis decreasing disease progression[48]. Therefore, the balance between M1 and M2 macrophages is important for homeostasis in the liver.

During NAFLD, macrophages can recognise and respond to stimuli through pattern recognition receptors such as membrane-bound toll-like receptors (TLRs), such as TLR4 and TLR9, and cytoplasmic NOD-like receptors [43,45,49]. LPS translocated from the gut can activate TRL4 and TLR9, and this recognition of stimuli can then result in inflammation *via* secretion of proinflammatory cytokines such as TNF-α, IL-1β, IL-6, IL-12, and IL-18, as well as molecules such as ROS and NO. Activation of TLR9 can induce the release of IL-1β from KCs, which occurs during processes such as lipid accumulation, fibrinogenesis and cell death[50]. In NAFLD patients, TLR4 expression is often correlated with hepatic inflammation and fibrosis[51]. There are also many advantages to the activation of macrophages due to their immunosuppressive effects and secretion of anti-inflammatory cytokines, however, they also have pro-fibrinogenic effects. Activation of M2-type macrophages can release TGF-β1 and IL-13, leading to a fibrotic response of liver remodelling and tissue repair[52].

During IR, circulating free fatty acids (FFA) can also directly activate KCs causing activation of the stress-response kinases (JNK1 and JNK2) producing pro-inflammatory cytokines and extracellular vesicles (EVs), stimulating macrophage activation. EVs have been studied in their contribution to pathobiology of NAFLD, and have been found to mediate inflammation[53,54]. Hepatocytes can release EVs containing cargoes which activate signalling pathways[53,54]. Some EVs can carry mitochondrial DNA, which in mice and humans have been shown to activate macrophages *via* TLR9 [53,54]. Activation of TLR9 then causes inflammation though resultant downstream activation of NF-κB-dependent pro-inflammatory cytokines in macrophages[53,54]. Macrophage activation and inflammation may also occur *via* EV formation in response to lipid-associated toxicity[55]. Therefore, both harmful and beneficial macrophage phenotypes can co-exist during NAFLD, and the balance between these phenotypes must be considered for therapeutic strategies. Both cellular and molecular macrophage targets for therapy may provide a new perspective as well as the adoptive transfer therapies.

Neutrophils: Neutrophil infiltration during NASH has been documented in both patients and in mouse models. In the early stages of NAFLD, recruitment of neutrophils occurs *via* chemokines such as C-X-C motif chemokine ligand (CXCL) 1, IL-8, and CXCL2[56]. Research has shown that various neutrophil specific components are released in NAFLD. Neutrophil elastase is a major inflammatory protease which can be released by neutrophils. In a mouse model of NAFLD, elastase suppression has been shown to improve disease severity[57]. As well as elastase, neutrophil proteinase-3 has also been reported as elevated in NASH and both the levels of proteinase-3 and elastase were correlated with liver fibrosis [58]. Elastase has also been shown to play a role in metabolic dysfunction and IR, and therefore, targeting or improving IR and metabolic disease may improve inflammation in NAFLD. Myeloperoxidase (MPO), a neutrophil derived enzyme has been shown to become increased in NASH. It is thought that both neutrophils and MPO may cause activation of HSCs inducing liver fibrosis and inflammation in NASH[59,60]. Plasma levels of MPO have been found to be correlated with fibrosis in NAFLD patients[61]. More research is required to determine how neutrophils contribute to disease pathogenesis in NAFLD.

NKT cells: NKT cells provide a bridge between the innate and adaptive immune system and express both NK cell and T cell markers[40]. NKT cells become activated upon antigen presentation by CD1d which can be expressed by a variety of cells such as hepatocytes, macrophages, dendritic cells, and B cells[40]. Pro-inflammatory cytokines such as IL-4 and IFN-γ are secreted after NKT activation causing further tissue injury. Although there is conflicting evidence, during steatosis levels of NKT cells become reduced, whereas in NASH and fibrosis they are increased[40]. This has been shown by in vivo studies where NKT cells were elevated in the blood and liver of patients with moderate-to-severe steatosis[62]. During early-stage NAFLD such at fatty liver, the phenotype of NKT cells demonstrate a pro-inflammatory Th1 cytokines profile such as IFN-γ, whereas, in advanced end stage disease, they have a profibrotic role[40].

NK cells: NK cells have a cytotoxic role and can attack cells *via* perforin-mediated pathways or cell-cell interactions, for example Fas. NK cells can also act as regulatory cells by releasing various cytokines and chemokines, such as IFN-γ, TNF-α, and IL-10 as well as growth factors[40]. NK cell-associated cytotoxic ligands, such as TNF-related apoptosis-inducing ligand (TRAIL), NK group 2 member D, and major histocompatibility (MHC) class I chain-related protein A and B mRNAs, have been reported to be elevated in obese NASH patients[63]. NK cells therefore may possibly promote inflammation and hepatocyte apoptosis *via* TRAIL secretion[63], leading to progression of fibrosis.

Dendritic cells**:** Hepatic dendritic cells (HDCs), which highly express MHC-class II molecules and CD45 are important immune cells in the liver which have migratory capabilities as well as production of cytokines such as TNF-α, IFN-γ, IL-2, IL-4, and IL-6[64]. Three distinct subsets of HDCs have been described in experimental models of HDCs: Lymphoid, myeloid and plasmacytoid[64]. They play a crucial role in the progression of metabolic steatohepatitis bridging lipid metabolism and inflammation. HDCs can shift from a tolerant state to an active state, triggering an inflammatory process [65]. In an immune tolerant state, immature HDCs secrete IL-10, and TGF-β, as well as limit T cell expansion[64]. In a tolerant state they supress inflammasome activation, maintaining homeostasis in the liver. This regulatory role of HDC in NASH can therefore restrict inflammation as well as clear apoptotic cells and necrotic debris[65]. Additionally, they are involved in lipid storage within the liver and are important for antigen presentation and induction of inflammatory pathways[64]. Recent studies suggest that HDCs have antifibrogenic effects by activating metalloproteinases, such as matrix metallopeptidase 9 which has been found to be involved in regression of fibrosis as well as remodelling of the extracellular matrix.

On the other hand, in an active state HDCs cause inflammation and liver damage as well as contribute to fibrosis. In an active or inflammatory state, mature recruit macrophages to the liver and can activate the NF-κB pathway as well as produce pro-inflammatory cytokines such as TNF-α and IL-1, contributing to the inflammatory microenvironment[64]. In humans, a subset of HDCs (CD11C + cDC2) have been shown to play an important role in development of fibrosis and have been positively correlated with metabolic steatohepatitis[64]. HDC's in a mouse model of metabolic associated fatty liver disease (MAFLD) have shown that in a matured form they produce more inflammatory cytokines and may be responsible for proinflammatory responses[65]. HDC may therefore play dual roles in both the suppression and progression of disease state.

Adaptive immune system in NAFLD: The adaptive immune system is defined by antigenic specificity and immunological memory and includes predominantly B and T lymphocytes. Experimental research has suggested that sustained immune responses activated by oxidative stress-related antigens can affect the pathogenesis of disease *via* activation of CD4+ T-cells, which, in turn, stimulate macrophage M1 responses and liver CD8+ T- and NKT cell recruitment[66]. Experimental in vitro data as well as in vivo data supports adaptive immunity in NAFLD disease progression.

T cells: Conventional T cells have been well studied in their involvement in the pathogenesis of NAFLD. The main CD4+ T-cell are divided into Th1, Th2, and Th17 populations characterised by production of specific cytokines. Recruitment of CD4+ T-cell in the liver have been reported to be increased in individuals diagnosed with NASH[67-71],

as well as in animal models fed a high calorie diet[72]. Upon presentation to inflammatory stimuli, CD4+ T cells can differentiate into Th17 cells[73], a subset of pro-inflammatory T helper cells defined by their ability to produce IL-17. In animal models of NAFLD, in the liver it has been documented that the Th-17 phenotype was favoured, promoting inflammation[74]. Human studies in obese and overweight patients have also shown an increase in the Th17 population[74]. The IL-17 family of cytokines have been implicated in the progression of fatty liver disease through interference of the insulin signalling pathway[75]. In mouse models, deficiency of IL-17A, IL-17F or IL-17A receptor (IL-17RA) results in increased steatosis but reduced steatohepatitis[76,77]. In HFD mouse model, neutralisation or IL-17RA deficiency as well as treatment with anti-IL-17mAb therapy has shown to protect mice from diet-induced liver injury *via* improvement of lipid accumulation, suppressing KCs activation, decreased pro-inflammatory cytokines levels and inhibition downstream of NF-κB signalling[40,78]. IL-17 has also been shown to activate the signal transducer and activator of transcription 3 pathway in HSCs causing progression of fibrosis in the liver[79]. These studies indicate the involvement of IL-17 in the pathogenesis of NAFLD.

Regulatory T cells (Tregs), a subset of cells which promote immune tolerance and facilitate tissue repair and express the transcription factor forkhead box P3. Although there is limited data available, the number of hepatic Tregs have been documented to be decreased in in animal models of NAFLD[80]. In humans, the levels of Tregs in the liver and the circulation of patients with NAFLD is also reported to be decreased[80]. Also, in a NASH mouse model, induced by a HFD and endotoxin challenge, a decrease in liver Tregs was documented, however, transfer of Tregs into mice showed reduced liver injury and inflammation, through decreased expression of TNF-α[81].

B cells: Until recently, the role of B cells is the pathogenesis of NAFLD was less understood. B cells are highly specific antibody producing cells of the adaptive immune system. B cells contribute to approximately 6% of intrahepatic cells[40,82]. B cells produce the B cell activating factor (BAFF), a cytokine controlling the process of B cell survival and maturation [83,84]. Liver biopsies from patients with NASH have been shown to contain both B and T cells in the inflammatory infiltrates [73,85,86].

In mouse models, B cells have been shown to become activated in NASH, concomitantly with the onset of steatohepatitis and thus, maturing to plasma blasts and plasma cells[73,86]. Another study has also shown that BAFF signalling increased IR in an NAFLD model as well as promoting fatty liver[87]. Whereas, in mice models of NASH, B2 cell responses upregulate BAFF[73]. Levels of BAFF in patients with NASH appear to occur at a higher level than with patients with fatty liver, therefore it has been proposed BAFF levels correlate with severity of steatohepatitis fibrosis[88]. BAFF receptor-deficient mice showed an improvement in HFD-induced obesity and IR, as well as a reduction in the number of B cells and a decrease in serum immunoglobulin G level[40]. The involvement of B cells in the progression of liver disease can also be due to production of pro-inflammatory mediators and antigen-presentation[89,90]. In patients with NASH, MHC class II molecules become upregulated causing inflammatory infiltration and recruitment of CD4+ and CD8+ T cells to the liver[73], whereby Th1 CD4 + T cell activation and IFN-γ production occurs[86]. Therefore, this research suggests B cells and BAFF play an important role in NAFLD pathogenesis and can contribute to pathogenesis of NAFLD *via* autoimmune hepatitis and liver fibrogenesis [87,90,91].

Serum levels of IgA has been found to be associated with patients with NASH and levels of IgA can predict advanced liver disease progression[92]. Patients with HCC have also been documented to have higher serum IgA[93-95]. In both mouse models and human studies, liver resident IgA accumulation in hepatic cells has been associated with chronic inflammation and fibrosis[93]. Regression of HCC has also been documented when IgA is inhibited, causing reactivation of CD8+ T cell function[93,94].

B cell deficiency also has been shown to improve development of NASH. The mechanisms and signalling of B cell activation in NASH is *via* myeloid differentiation early response protein 88[40,96]. Studies have shown that elimination of myeloid differentiation early response protein 88 on B cells reduced hepatic T cell-mediated inflammation and fibrosis, but had no effects on steatosis[40,96]. Therefore, B cells show involvement in the pathogenesis of NAFLD, and manipulation on B cells may provide a therapeutic opportunity for NAFLD treatment. An overview of innate and adaptive immune cells involved in NAFLD is shown in Figure 3.

Diagnostic procedures

Most commonly a combination of clinical history, laboratory findings, biopsies and radiological testing are used in the diagnosis of NAFLD. The clinical diagnosis of NAFLD is usually considered when aminotransferases become elevated or imaging on the liver detects high hepatic fat[97]. Both the American and European guidelines agree that suspicion of fibrosis warrants a confirmatory liver biopsy[98].

Current biomarkers: Liver function tests, particularly alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels, can indicate liver damage in NAFLD/NASH[12,99]. These levels may be elevated by two to four times the normal limit. Mild elevations in aminotransferase levels may be present in lower stages of the disease, but routine tests may appear normal. Alkaline phosphatase and gamma-glutamyl transferase (GGT) levels may be up to three times the upper limit even in the absence of advanced disease[100]. A serum GGT cut-off value of 96.5 can predict advanced fibrosis with a sensitivity of 83% and specificity of 69%[101].

Several different biomarker panels have been described in their use to assess liver fat. These include the liver fat score (LFS) (sensitivity 86%, specificity 71%), hepatic steatosis index (sensitivity 92.5%, specificity 92.4%), fatty liver index (FLI) (sensitivity 87%, specificity 86%) and the steatotest (sensitivity 95.5%, positive predictive value 97.0%)[102]. LFS is calculated using a patients serum AST/ALT ratio, fasting serum AST level, fasting serum insulin level, any presence of metabolic syndrome and diagnosed diabetes mellitus. Studies have shown that a score greater than -0.640 can predict NAFLD with a sensitivity of 86% and specificity of 71%. The FLI uses waist circumference, body mass index (BMI), triglyceride, and GGT and this was initially developed to detect fatty liver in western countries.

Screening tools: The fibrosis-4 scoring system uses a patients age, platelet count, AST, and ALT to determine a liver fibrosis score and can help to predict advanced fibrosis. A score < 1.45 defines a negative predictive value or low probability of advanced liver fibrosis[103]. Scores of A score > 3.25 indicated a higher likelihood and has a positive predictive value of 65%, and specificity of 97% at predicting advanced fibrosis[103]. Recently, a new FAST™ screening tool has been used which compromises a combination of FibroScan® parameters such as liver stiffness measurement and controlled attenuation parameter as well as AST. This screening tool has been shown to have diagnostic accuracy when predicting those at risk of NASH. The FAST™ screening tool may provide a better non-invasive algorithm for diagnosis of NASH. FAST™ performed better than other non-invasive algorithms for the diagnosis of at-risk NASH[104,105]. Results have shown that the FAST score had the highest area under curve for the most high-risk NASH criteria as well as liver stiffness showing a consistently acceptable performance in predicting NASH[106].

Emerging biomarkers: Various non-invasive biomarkers for NAFLD have been developed and validated over the last 20 years, however, there is a need to develop and validate new biomarkers for NAFLD which encompass IR, inflammation and fibrogenesis[107-109].

Cell Death**:** As well as current markers such as cytokeratin 18, necroptosis is a form of cell death which is characterised by changes such as organelle swelling, plasma membrane damage, and release of cellular contents[110]. Proteins such as receptor-interacting protein kinase (RIPK) family members such as RIPK1 and RIPK3, and mixed lineage kinase domain-like (MLKL) are involved in the process[111]. During NAFLD, TLR4 ligands such as LPS cause activation of the TLR4 receptor causing activation of proteins such as RIPK3 and MLKL leading to necroptosis[112]. In patients with MAFLD, necroptosis components such as RIPK3 have been shown to be upregulated, therefore, it may be important to consider markers of necroptosis in NAFLD.

MicroRNAs (miRNAs): miRNAs are non-coding RNAs which play a role in gene expression regulation[113] and have been implicated as potential biomarkers in NAFLD. Research has shown that miRNAS such as miR-21, miR-34a, miR-122, and miR-451 have been found to be upregulated in NAFLD patients[114-117]. Various studies have also shown that profiles of miRNAs in NAFLD patients can differentiate between disease stage. In NAFLD and NASH, miR-122, miR-192, miR-19a, miR-19b, miR-125b, and miR-375 have been found to be increased greater than 2-fold, whereas continuous upregulated expression of miR-122, miR-192, and miR-375 was found in NASH patients[118,119]. Furthermore, higher expression of miR-122 and miR-21 have been reported in people with high fasting blood glucose, obesity and fatty liver infiltrations[119,120]. Therefore, these findings suggest that miRNAs may be promising biomarkers for NAFLD and metabolic disease, in particular miR-122, miR-192, and miR-34a, which have been shown to be correlated with severity of NAFLD.

EVs**:** Growing evidence suggests that EVs play a significant role pathological disease including those associated with obesity and metabolic syndrome. Obesity, IR, T2DM and NAFLD have all been linked to changes in the abundance and phenotype of circulating EVs[121] and therefore circulating EVs and their composition may be a candidate biomarker for NAFLD. EVs contain substances such as genetic material including miRNAs[122]. It has been documented that in humans, the number of AD-EVs is correlated with IR in overweight people[123], as well as visceral AD-EV number correlated with liver injury measured by ALT and AST and metabolic syndrome[124]. Circulating EVs have also been shown to become elevated during the progression of NASH and have reported to be correlated with histological findings [125]. Research has also shown that EVs from a NAFLD model in mice contained miR-122 and miR-192[125]. In cirrhotic patients, plasma hepatocyte-EVs were found to contain elevated levels of CK-18[126]. EVs from visceral adipose tissue can exacerbate disease in NAFLD by causing further inflammation, fibrosis and IR. Both pro- and anti-fibrotic EVs have been documented in the liver and therefore it is plausible to investigate the differences in the pro- and anti-fibrotic phenotypes to track disease progression and likelihood of fibrosis development. Future research should consider the use of EVs in monitoring metabolic dysfunction and IR in NAFLD, with focus on EV phenotypes, cargo and cell specific markers.

Therapeutic interventions

Despite NAFLD being an extremely prevalent liver disease, no specific pharmacological interventions are currently Food and Drug Administration approved for treatment. Some therapeutic agents used as anti-diabetics, antilipidemic and natural bile treatments have previously been evaluated in their ability to treat liver disease, although they have limitations. Predominantly, lifestyle interventions including diet and exercise are most commonly used to treat NAFLD. The current therapeutic interventions used for NAFLD are outlined below including future potential agents such as sirtuins, antioxidants and vitamins.

Lifestyle modifications: A substantial amount of research indicated that changes to lifestyle are a primary approach for the treatment of NAFLD[127]. Diet changes and weight loss can reverse liver disease. Weight loss in the range of 5%-10% can provide beneficial effects to NAFLD patients *via* a reduction in NAFLD activity score (NAS)[128,129]. A weight reduction greater than 10% has also been shown to reduce the severity of fibrosis as well as resolution of NASH[12,129,130].

European Association for the Study of the Liver (EASL), National Institute for Health and Care Excellence and American Association for the Study of Liver Diseases guidelines provide recommendations in terms of diet and physical activity for the management of NAFLD. These bodies recommend caloric restriction with a calorie deficit of 500-1000 kcal a day, as well as limiting the consumption of alcohol, fats and coffee. EASL also favours the Mediterranean diet, with studies indicating a reduction in liver fat in NAFLD patients[131]. Lifestyle modifications in terms of physical exercise can also positively effect liver fat content. Both resistance/weight training, high-intensity interval training and aerobic exercise have all equally been shown to reduce liver fat content; however, in men with NAFLD, high-intensity interval

training was the most effective in restoring hepatic fat, reducing hepatic stiffness and improving Kupffer cell function; key features of NASH[132].

Evidence has suggested that the ketogenic diet (KD) is an effective treatment for NAFLD. Ketogenesis is a metabolic process resulting in the production of ketone bodies, namely acetoacetate, beta-hydroxybutyrate (BHB), and acetone, which act as alternative energy sources[33,133]. The KD has been shown to change hepatic mitochondrial fluxes and redox state as well as significantly reducing liver fat content and hepatic IR[134]. These changes were found to be accompanied by an increase in the net hydrolysis of liver triglycerides, a decrease in endogenous glucose production, and lower serum insulin levels[134]. BHB has also been shown to interact with inflammasomes[135,136] and neutralise ROS [137], leading to a reduction in inflammatory cytokines and oxidative damage *via* its antioxidant capacity. These findings suggest a KD can contribute to the reversal of NAFLD through improvement of IR and cellular redox function.

Bariatric surgery: Bariatric surgery been shown to be an effective treatment for NAFLD improving overall liver health *via* facilitating weight loss, improving insulin sensitivity, and subsiding inflammation[138,139]. Roux-en-Y gastric bypass (RYGB) and laparoscopic sleeve gastrectomy (LSG) are the most prevalent bariatric procedures, which lead to significant weight loss and metabolic health improvements[140].

Several research studies have investigated the impact of bariatric surgery in NAFLD and have shown positive results. Studies have indicated that bariatric surgery resulted in significant improvements in liver enzymes and histology, with a decrease in liver fat and fibrosis. Results from two meta-analyses have shown that treatment of NAFLD using bariatric surgery resulted in a biopsy-confirmed resolution of steatosis (56%-66%), inflammation (45%-50%), ballooning degeneration (49%-76%), and fibrosis (25%-40%), as well as showing a decrease in NAS scoring[140-142]. Bariatric surgery has therefore proven to be effective in ameliorating NAFLD, however, it is important to clarify which type of surgery is most effective. A study by Baldwin *et al*[143] compared RYGB and LSG against its effectiveness at improving AST and ALT concentration, NAS and NAFLD fibrosis score. Overall, both procedures reduce AST and ALT levels, however, LSG showed slightly more favourable results[139]. Another study has shown NAS scoring reduced significantly in patients who underwent both surgery types 12-mo after the surgery[139]. RYGB patients had a more significantly decreased steatosis and superior improvement in plasma lipid profile[144]. Furthermore, bariatric surgery has been demonstrated to lower the risk of liver-related complications and death in individuals with NAFLD. Bariatric surgery can therefore be considered as a promising treatment option for those with NAFLD who are overweight or obese.

Insulin sensitising agents: IR is believed to play an essential role in the development and progression of NAFLD. In recent years, various insulin sensitizers such as biguanides, thiazolidinediones (TZDs), glucagon-like peptide-1 receptor agonists (GLP-1), and dipeptidyl peptidase 4 inhibitors have been investigated as potential therapeutic targets for NAFLD[145]. However, there are safety concerns associated with long-term use of these targets[145].

Biguanides*:* As the development of NAFLD is closely associated with IR, diabetes, hyperglycaemia and hyperlipidaemia, antidiabetic drugs are often utilised in the treatment of NAFLD[145]. Metformin is considered the first-line treatment for T2DM due to its ability to improve insulin sensitivity and promote weight loss without causing hypoglycaemia[145,146]. Although its mechanisms of action are not fully understood, it works by lowering hepatic glucose production[145]. Previous open-label studies have suggested that metformin may have a positive impact on hepatic steatosis and necroinflammation, although excessive weight loss may have confounded these results[30]. However, some studies have shown that metformin does not significantly improve the histological response in NAFLD [30,147], but improves liver function and BMI[148]. In a mouse model, metformin treatment showed improvements to the gut-liver axis *via* attenuation of the loss of tight junction proteins in the small intestine as well as reducing the increase of endotoxin levels in the portal circulation[149].

GLP-1: GLP-1 receptor agonists can alter IR by promoting weight loss *via* suppressing appetite and delaying gastric emptying[150]. In NAFLD patients, research has shown GLP-1 receptor agonists improve hepatic and adipose tissue IR, suppress de novo lipogenesis and oxidative stress as well as increased clearance of VLDL[30,150]. GLP-1 may also modulate the immune system *via* the reprogramming of macrophages to the M2 phenotype. In the exenatide study of cardiovascular event lowering trial, GLP-1 receptor agonists reduced cardiovascular risk[151] and visceral fat, improved glucose tolerance, body fat percentage and resting energy rate (NCT01144338). The trial semaglutide unabated sustainability in treatment of type 2 diabetes (NCT02054897) are a series of phase III clinical trials which suggest treatment with semaglutide has a higher effectiveness than other GLP-1 therapeutics in the reduction of HbA1c in patients with T2DM. In a phase 2 trial with patients diagnosed with NASH receiving semaglutide treatment of 0.1 mg (80 patients), 0.2 mg (78 patients), or 0.4 mg (82 patients), patients resulted in a significantly higher NASH resolution when compared to the placebo (NCT02970942)[152]. Although NASH resolution was significantly improved, no significant difference was shown in the fibrosis stage[152].

Fibroblast growth factor (FGF) based therapeutics: FGF analogs have been proposed to target steps of disease pathogenesis. FGF-21 treatments are currently in clinical development for the treatment of NASH[153,154] and data suggests that FGF21 is anti-fibrotic and has the potential to improve the metabolic syndrome and is effective in treating NASH. The BALANCED trial (NCT03976401) evaluated the effects of efruxifermin, a long-acting Fc-FGF21 fusion protein [155]. In this study, 80 patients were given either placebo (n = 21) or efruxifermin 28 mg (n = 19), efruxifermin 50 mg (n = 20) or efruxifermin 70 mg (n = 20) *via* weekly subcutaneous injection for 16 wk[155]. Treatment with efruxifermin was found to significantly reduced hepatic fat fraction (HFF) in patients with F1-F3 stage NASH[155]. FGF based compounds which are currently in phase II are efruxifermin (FGF-21), pegbelfirmin (FGF-21), aldafermin (FGF-19), pegozafermin (FGF-21) and BFK8588A (FGF-21), which have been shown to achieve a reduction in ALT levels[109].

Thyroid hormone receptor-β (THRβ) 1 agonists: Currently, several different THRβ specific agonists have been shown to produce positive therapeutic effects in both animal models and clinical trials for treatment of NAFLD. Treatment with

TG68, a novel THRβ agonist, has positive effects on resolution of NAFLD *via* reduction in liver weight, hepatic steatosis, serum transaminases, and circulating triglycerides in a NAFLD model[156]. Resmetirom (MGL-3196) has also been found to significantly reduce hepatic lipid content and improve liver enzyme levels and plasma lipid levels in NASH patients [157], however, glucose or insulin levels remained unchanged. Another THRβ agonist, VK2809 has been shown to reduce hepatic steatosis in a mouse model and in a phase II clinical trial reduced liver lipid content[158,159].

Currently there are many ongoing clinical trials studying the effects of THRβ agonists in NAFLD. The VOYAGE study is assessing VK2809 to determine its efficacy in the resolution of biopsy proven NASH (NCT04173065). The DUET study is also assessing the effects of orally administered TERN-501 and TERN-101 in presumed NASH (NCT05415722), whilst the LIFT study is assessing TERN-101 alone in NASH patients (NCT04328077)[160]. In a NASH mouse model, TERN-501 reduced steatosis as well as reducing serum total cholesterol, triglyceride and ALT levels[161].

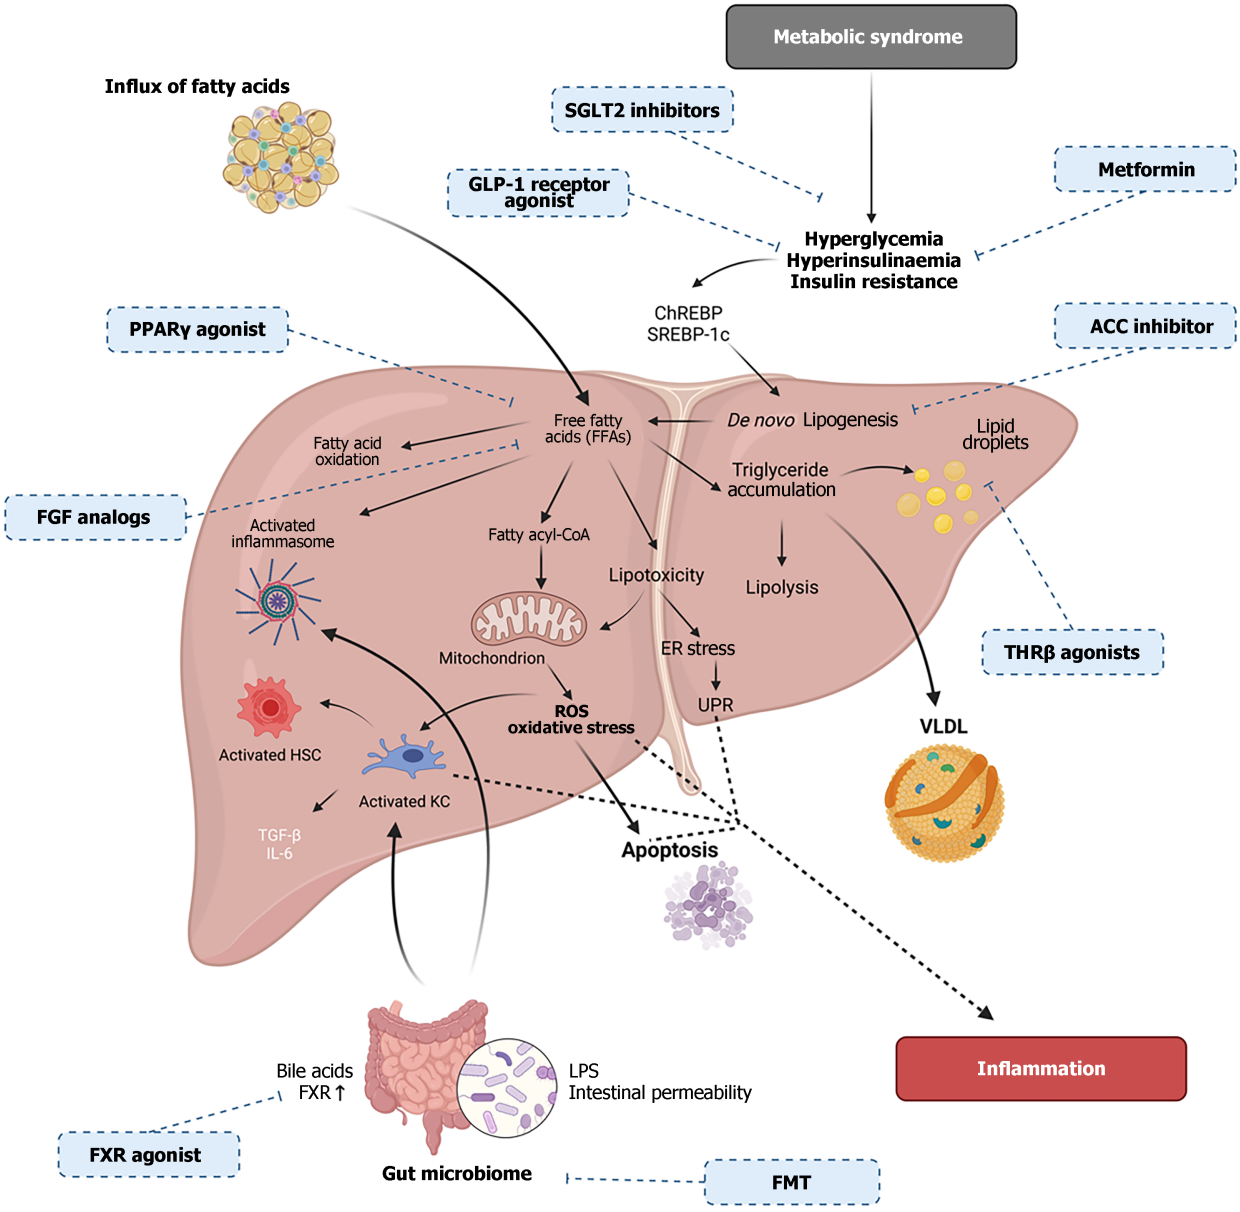
Peroxisome proliferator-activated receptor-γ (PPAR-γ) agonists: PPAR-γ is a ligand-activated nuclear receptor and its activation causes insulin sensitization and enhances glucose metabolism. TZDs are a group of insulin sensitisers used to treat T2DM by action on PPAR-γ. PPAR agonists have been shown to modulate the innate immune response. PPAR-δ can promote anti-inflammatory polarization of macrophages and modulate their activation[162], whilst PPAR-γ ligands can inhibit the activation of macrophages and cytokine production (TNF-α, IL-6, and IL-1β), thus, reducing inflammation [163]. Activated PPARs can also regulate immune cells (macrophages, DCs, T cells, and B cells) as well as decrease inflammatory cytokine production[163].

Pioglitazone, a TZD, has been used for treatment of NASH with its effects improving steatohepatitis, ballooning degeneration and lobular inflammation[164]. Pioglitazone (45 mg/d) for 6 mo has been shown in patients with prediabetes or T2DM to improve the fibrosis stage (NCT00227110)[165]. Elafibranor is a dual PPAR-α/δ agonist. PPAR-δ functions to regulates peroxisomal β-oxidation of FFA as well as improve insulin sensitivity, lipid and glucose homeostasis[30]. Several clinical trials have assessed the effects of elafibronor in improving histology in NASH patients such as RESOLVE-IT (NCT02704403), and the GOLDEN trial[166]. In both trials elafibranor showed no effect.

Sodium glucose cotransporter 2 (SGLT2) Inhibitors: Another class of drugs lower serum glucose levels *via* inhibition of the SGLT2 and promote weight loss. Studies have shown that SGLT2 inhibitors reduce ALT levels correlating with changes in bodyweight and glycaemic control[30], although further studies are required to identify whether SGLT2 inhibitors can prevent progression of NAFLD/NASH.

Current clinical trials are underway to assess the efficacy and effectiveness of SGLT2 inhibitors. A randomised clinical trial aims to compare the effect of the pioglitazone and empagliflozin combination on liver fat mass (NCT04976283). Another trial is investigating dapagliflozin in NASH (NCT05254626).

Farnesoid X receptor (FXR) agonists: The FXR is a nuclear receptor which is activated by bile acids. FXR inhibits the expression sterol regulatory element binding protein-1 and carbohydrate-responsive element-binding protein. FXR also enhances the clearance of high-density lipoprotein and VLDL in the liver and well as promoting hepatic regeneration. However, little is documented regarding the immune modulation in this class of drugs.



Obeticholic acid (OCA) is a synthetic bile acid which acts as a FXR agonist. The use of OCA for NASH is still under investigation, due to reported side effects. The FLINT trial (NCT01265498) was a multicentre, randomized, double-blind, placebo-controlled phase IIb study assessing the effects of 25 mg of OCA for 72 wk. Treatment with OCA was linked with a significant improvement fibrosis stage in the treated group (35% *vs*. 19%; $P = 0.004$), although there was no difference in rates of NASH resolution. A phase III trial (REGENERATE) is currently active to further assess the treatment of OCA in patients with NASH (NCT02548351).

Other FXR agonists, such as tropifexor, have been studied in the treatment of NASH in the FLIGHT-FXR study (NCT02855164). This 48-wk study using tropifexor found sustained decreases in ALT and liver fat content (measured by HFF using magnetic resonance imaging-estimated proton density fat fraction) during the therapy duration[167]. A Phase IIa (LIFT trial) studying TERN-101, a FXR agonist, showed that in a 12-wk controlled trial, significant improvements in cT1, a marker of fibro-inflammation was observed[160].

Other treatment approaches: Modulation of the gut microbiome: Gut dysbiosis is a common feature of NAFLD[168]. Whilst pre- and pro- biotics are being evaluated, faecal microbiota transplant (FMT) may provide an alternative approach. HFD-fed mice which received FMT from healthy donors showed a significant reduction in intracellular hepatic lipid and proinflammatory cytokines concentration (IFN-γ and IL-17)[169]. Small intestinal microbiota transplants from healthy lean individuals to obese individuals have reported improvements in insulin sensitivity in those patients with metabolic syndrome[170]. A phase I pilot study is currently underway to study FMT in patients with NASH (NCT02469272). FMT as a treatment for NASH patients seems to be both a safe and efficient treatment, although, more high quality studies, trials and follow-ups are required to verify its therapeutic potential[168].

Modulation of the immune system: Methods for modulating the immune system as potential therapies for NAFLD are currently under investigation. Various pleiotropic effects of platelets have recently been discovered in liver homeostasis and disease as platelets are also involved in inflammatory regulation. Anti-platelet therapy (APT) has been shown to reduce NASH pathogenesis in rats[171]. Evidence has shown that APT may have a protective effect in patients with NAFLD[172]. In the liver, platelet and neutrophils can interact leading to neutrophil extracellular trap formation[173]. APT has been shown to reduce both NASH and HCC development[174]. It has been observed that APT reduced platelet accumulation in hepatocytes as well as reducing immune cell interaction, which led to decreases in cytokine and chemokine release, thus attenuating macrovesicular steatosis and liver damage[174].

It is well documented that NASH can progress to HCC. Immunotherapy, including programmed cell death 1 (PD-1) treatment, has been approved for the treatment of HCC[175]. PD-1 can interfere with the immune response and contributes to the growth and expansion of cancer. It has been documented that in NASH there is a progressive accumulation of exhausted, unconventionally activated CD8+ PD1 + T cells[175] and data has shown that in HCC, immune

Figure 4 Overview of the metabolic and molecular mechanisms occurring in non-alcoholic fatty liver disease pathogenesis with therapeutic targets. Non-alcoholic fatty liver disease (NAFLD) is a multifactorial disease, including metabolic syndrome, insulin resistance (IR) and gut microbiome changes. IR and metabolic syndrome cause increased free fatty acids (FFAs) which lead to endoplasmic reticulum stress, reactive oxygen species accumulation, oxidative stress, apoptosis, immune cell activation and inflammasome activation. Changes in the gut barrier can cause changes to bile acids and intestinal permeability causing lipopolysaccharides translocation from the gut causing immune activation, thus, inducing inflammation. FFA's can also activate transcription factors such as sterol regulatory binding protein-1c and carbohydrate response element binding protein causing the storage of FFAs as triglycerides in lipid droplets. Accumulated triglycerides can be exported as very low-density lipoprotein or oxidized by mitochondrial β-oxidation. Pharmacologic treatments for NAFLD are identified with corresponding drug mechanism of action (created with BioRender.com). ROS: Reactive oxygen species; LPS: Lipopolysaccharide; UPR: Unfolded protein response; FMT: Faecal microbiota transplant; VLDL: Very low-density lipoproteins; PPAR-γ: Peroxisome proliferator-activated receptor-γ; KC: Kupffer cells; HSC: Hepatic stellate cells; FXR: Farnesoid X Receptor; SGLT2: Sodium-glucose cotransporter 2; SREBP-1c: Sterol regulatory binding protein-1c; ChREBP: Carbohydrate response element binding protein.

surveillance was impaired[175]. Several pharmaceutical agents have been developed to target PD-1 receptors. Pembrolizumab has shown significant enhancement in overall survival and progression-free survival although statistical significance was not met[176]. However, it is also thought that NASH-derived HCC may be less responsive to immune modulated therapy due to NASH-related aberrant T cell activation, causing damage to tissues[175,177,178]. A summary of current clinical trials is shown in Table 1; and an overview of the metabolic and molecular mechanisms occurring in NAFLD pathogenesis with therapeutic targets in Figure 4.

Table 1 Current active and recruiting clinical trials assessing therapeutics for non-alcoholic fatty liver disease

Drug name	Condition	Target	Clinical trial Number	Phase	Status	Primary endpoint
GH509	NASH NAFLD		NCT05784779	Phase Ib/II	Recruiting	Change in liver fat content assessed by MRI-PDFF
LUM-201	NASH NAFLD	Lipid accumulation	NCT05364684	Phase II	Recruiting	Change in intrahepatic lipid content measured by proton magnetic resonance spectroscopy
Choline	NAFLD	Choline deficiency	NCT05200156	N/A	Recruiting	Change in Thiobarbituric acid reactive substances serum level
Dasatinib and quercetin	Fibrosis	Senescence	NCT05506488	Phase I	Recruiting	Improvement of fibrosis NAFLD score based on histology after 21 wk
GSK4532990	NAFLD fibrosis	17 β-HSD	NCT05583344	Phase II	Recruiting	Improvement of fibrosis measured by clinical research network scoring
Lisinopril	NASH HCC	ACE inhibitor	NCT04550481	Phase II	Recruiting	Changes in fibrosis marker PRO-C3
Rencofilstat	NASH Fibrosis NAFLD	Cyclophilin inhibitor	NCT05402371	Phase II	Recruiting	Improvement in fibrosis score CRN or NASH resolution
Lactobacillus reuteri GMNL-263 and GMNL-89 and lactobacillus rhamnosus GMNL-74	NAFLD	Gut microbiome	NCT05402449	N/A	Recruiting	Changes in serum ALT levels
Lubiprostone	NAFLD	Type 2 chloride channel activator	NCT05768334	Phase III	Recruiting	Changes in liver fat by measured by MRI-PDFF
Bacillus coagulans TCI711	NAFLD	Gut microbiome	NCT05635474	N/A	Recruiting	Changes measured by fibroscan
TVB-2640	NAFLD	FASN inhibitor	NCT04906421	Phase III	Active, not recruiting	Improvement in NAS and CRN scoring
ASC41		THRβ agonist	NCT05462353	Phase II	Recruiting	Improvement in NAS score
Ketohexokinase inhibition	NAFLD		NCT05463575	Phase II	Recruiting	Insulin-mediated suppression of endogenous glucose production
PF-06865571/ PF-05221304	NAFLD NASH with fibrosis	DGAT2 inhibitor/ACC inhibitor	NCT04321031	Phase II	Active, not recruiting	Resolution of NASH
ZED1227		TG2 inhibitor	NCT05305599	Phase II	Recruiting	Relative change of serum PRO-C3 levels
MK-3655	NASH	FGF21 agonist	NCT04583423	Phase II	Active, not recruiting	Resolution of NASH
MXP22 (probiotic and antioxidant capsule)	NAFLD	Gut microbiome	NCT05808049	N/A	Recruiting	Changes in steatosis measure by fibroscan
TERN 501/TERN-101	NASH	THRβ agonist/ FXR agonist	NCT05415722	Phase II	Active, not recruiting	Relative change in liver fat content (MRI-PDFF)
MET642	NASH	FXR agonist	NCT04773964	Phase II	Active, not recruiting	Safety study to measure adverse events
VK2809	NASH	THRβ agonist	NCT04173065	Phase II	Recruiting	Relative change in liver fat content (MRI-PDFF)

MRI-PDFF: Magnetic resonance imaging-estimated proton density fat fraction; NASH: Non-alcoholic steatohepatitis; FXR: Farnesoid X receptor; NAFLD: Non-alcoholic fatty liver disease; THRβ: Thyroid hormone receptor-β; NAS: Non-alcoholic fatty liver disease activity score; HCC: Hepatocellular carcinoma; ALT: Alanine aminotransferase; FASN: Fatty acid synthase; HSD: High-salt diet; CRN: Clinical research network; N/A: Not applicable.

CONCLUSION

NAFLD is a prevalent and progressive disease that can lead to liver damage and is strongly associated with obesity, IR,

and metabolic syndrome. Current treatments for NAFLD include lifestyle modifications such as diet and exercise, surgery, as well as medications to sensitise insulin. However, there is a need for effective and safe interventions that can directly target the underlying mechanisms of NASH/NAFLD in relation to IR, the gut microbiome and immunological mechanisms.

There is a growing body of evidence that NAFLD and metabolic syndrome are closely linked, and it is crucial for future research to prospectively evaluate interventions and therapeutics which both target improvement to liver outcomes as well as comorbidities associated with NAFLD (including cardiovascular diseases, T2DM, renal dysfunction). It is also essential to develop more refined and early risk stratification tools and biomarkers to identify individuals at the highest risk for NAFLD, considering that this condition affects a substantial portion of the world. Understanding the implications of metabolic signatures, chronic insulin signalling, mitochondrial dysfunction and cellular redox, is important for accurate prognosis and potential therapeutics.

Significant progress in the field has been made using bioinformatics to integrate intra- and extra-hepatic signals including gut and adipose interactions as well as patient information regarding lifestyle, nutrition, and comorbidities. The interplay between this multitude of factors provides promise for advancing therapeutics targeting immune regulation and mitochondrial function during progression of NAFLD. Advancements to the field should consider multidisciplinary approaches for the prevention, diagnosis, treatment, and care of patients with NAFLD.

Abstract

Marginal zone lymphomas rank as the third most prevalent form of non-Hodgkin B-cell lymphoma, trailing behind diffuse large B-cell lymphoma and follicular lymphoma. Gastric mucosa-associated lymphoid tissue lymphoma (GML) is a low-grade B-cell neoplasia frequently correlated with *Helicobacter pylori* (*H. pylori*)-induced chronic gastritis. On the other hand, a specific subset of individuals diagnosed with GML does not exhibit *H. pylori* infection. In contrast to its *H. pylori*-positive counterpart, it was previously believed that *H. pylori*-negative GML was less likely to respond to antimicrobial therapy. Despite this, surprisingly, increasing evidence supports that a considerable proportion of patients with *H. pylori*-negative GML show complete histopathological remission after bacterial eradication therapy. Nonetheless, the precise mechanisms underlying this treatment responsiveness are not yet fully comprehended. In recent years, there has been growing interest in investigating the role of non-*H. pylori* gastric helicobacters (NHPHs) in the pathogenesis of *H. pylori*-negative GML. However, additional research is required to establish the causal relationship between NHPHs and GML. In this minireview, we examined the current understanding and proposed prospects on the involvement of NHPHs in *H. pylori*-negative GML, as well as their potential response to bacterial eradication therapy.

Key Words: Lymphoma; B cell; Marginal zone; Gastric mucosa-associated lymphoid tissue lymphoma; *Helicobacter pylori*; Non-*Helicobacter pylori* gastric helicobacters; *Helicobacter heilmannii*; *Helicobacter suis*

Core Tip: Gastric mucosa-associated lymphoid tissue lymphoma (GML) is a type of non-hodgkin lymphoma that arises in the stomach. It has been well-established that *Helicobacter pylori* (*H. pylori*) infection plays a crucial role in the development of GML. However, a subset of patients diagnosed with GML are negative for *H. pylori.* In recent years, there has been growing interest in investigating the role of non-*H. pylori* gastric helicobacters (NHPHs) in the pathogenesis of *H. pylori*-negative GML. This minireview aims to explore the current understanding of the involvement of NHPHs in the development of GML and its potential responsiveness to bacterial eradication therapy.

INTRODUCTION

Marginal zone lymphomas (MZLs) rank as the third most prevalent form of non-hodgkin B-cell lymphoma, trailing behind diffuse large B-cell lymphoma and follicular lymphoma[1]. The 5th edition of the World Health Organization Classification of Hematolymphoid Tumors-Lymphoid Neoplasms further categorizes MZL into four subtypes: Extranodal MZL of mucosa-associated lymphoid tissue (MALT), primary cutaneous MZL, nodal MZL, and pediatric MZL[2].

Gastric MALT lymphoma (GML) is a low-grade B-cell neoplasia often correlated with *Helicobacter pylori* (*H. pylori*)-induced chronic gastritis[3]. Although the normal gastric mucosa lacks lymphoid follicles, chronic inflammation can lead to the formation of MALT. Continuous antigenic stimulation fosters the clonal expansion of B cells within the MALT, supported by specific T helper cells, which may lead to malignant transformation[4,5]. As GML progresses, genetic and epigenetic alterations occur in both oncogenes and tumour suppressor genes, resulting in dysregulated cell growth and survival. Common genetic alterations seen in MALT lymphoma include chromosomal translocations involving the *API2-MALT1* gene fusion and mutations in genes such as *TP53* and *MYD88*[5-7].

The current clinical guidelines advocate for the use of *H. pylori* eradication therapy as the primary treatment approach for localized GML[8-10]. In a recent systematic review conducted by our group, including meta-analyses, it was highlighted that bacterial eradication treatment resulted in the disappearance of lymphoma in over 75% of patients with low-grade, *H. pylori*-positive GML[11]. Hence, our results ratified that bacterial eradication is effective as the sole initial therapy for early-stage GML.

On the other hand, a specific subset of individuals diagnosed with GML does not exhibit *H. pylori* infection[12-15]. Consequently, it was assumed that these patients might not respond favorably to bacterial eradication therapy. However, another meta-analysis conducted by Jung *et al*[16] showed that 29.3% (95% confidence interval: 22.2%-37.4%, I^2 = 41.5%) of *H. pylori*-negative GML patients experienced complete histopathological remission after eradication therapy. Nonetheless, the underlying mechanisms for this responsiveness remain unclear[16].

There has been a growing interest in exploring the involvement of species of non-*H. pylori* gastric helicobacters (NHPHs) in the development of *H. pylori*-negative GML and its responsiveness to bacterial eradication therapy[17-20]. NHPHs represent a group of bacterial species that colonize the stomach but differ genetically and phenotypically from *H. pylori*[21-24]. These differences include variances in flagella, urease activity, and other virulence factors[25,26]. While NHPHs have been detected in some patients with gastritis and peptic ulcers, their precise role and contribution to disease progression are not yet fully understood[27].

Some studies have indeed suggested an association between specific NHPH species and the development of GML, particularly in *H. pylori*-negative cases[28]. However, further research is required to establish a definitive causal relationship between NHPHs and GML. This article aims to explore the current understanding and propose prospects on the role of NHPHS in *H. pylori*-negative GML and its potential responsiveness to bacterial eradication therapy.

H. pylori-negative GML

H. pylori-negative GML accounts for around 10% of all GML cases[29-31]. The cause of *H. pylori*-negative GML is not fully understood, and ongoing research aims to uncover the underlying factors contributing to its development. Symptoms of this type of lymphoma, such as abdominal pain, indigestion, bloating, nausea, vomiting, and weight loss, are similar to other gastric lymphomas but are nonspecific and can be caused by various conditions[32]. Diagnosis is made based on morphologic, immunophenotypic, and genetic analysis of biopsy material. Once the diagnosis is confirmed, a staging procedure to evaluate the extent of lymphoma dissemination is imperative[33].

In contrast to its *H. pylori*-positive counterpart, *H. pylori*-negative GML was previously believed to have a reduced likelihood of responding to antimicrobial therapy. In this context, treatment options may involve watchful waiting, radiation therapy (RT), chemotherapy (ChT), and immunotherapy[9]. Watchful waiting is suitable for slow-growing

lymphomas without significant symptoms and with regular monitoring[33]. However, RT is the preferred treatment for localized disease in the management of *H. pylori*-negative GML. Several series have reported excellent disease control using RT alone, highlighting the efficacy of moderate-dose involved-field RT. Typically, a dose of 24-30 Gy is delivered to the stomach and perigastric nodes throughout 3-4 wk. To achieve optimal outcomes in gastric extranodal MZL[34,35]. Systemic treatment with ChT, immunotherapy, or a combination of both (chemoimmunotherapy) is recommended for patients with symptomatic systemic disease, contraindications to RT, treatment failure following antibiotic therapy or local treatments (such as RT or surgery), and those with histological transformation[36].

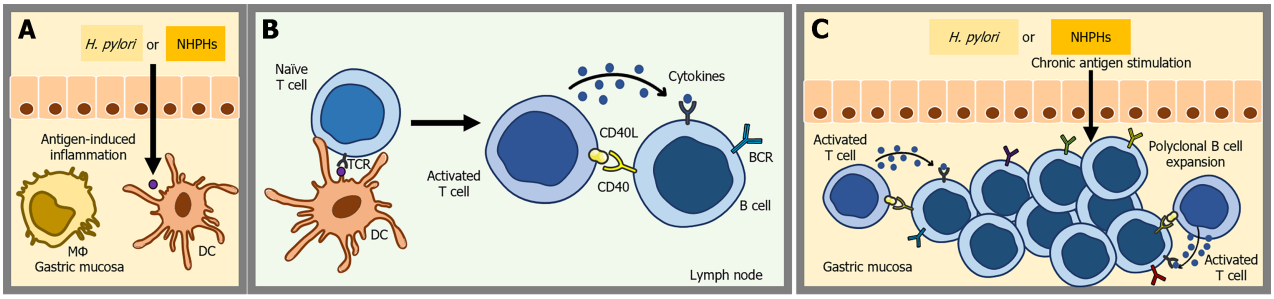
Despite this, surprisingly, increasing evidence supports that a considerable proportion of patients with *H. pylori*-negative GML show complete histopathological remission after bacterial eradication therapy[16,28,37]. Nonetheless, the precise mechanisms underlying this treatment responsiveness are not yet fully comprehended. Initially, it was attributed to false-negative tests for *H. pylori*[8,37]. However, more recently, the infection with other *Helicobacter* species (NHPHs) is acknowledged as a potential explanation for this phenomenon.

NHPHs

The *Helicobacter* genus includes gram-negative, microaerophilic, spiral, helical, curved, or fusiform rod-shaped bacteria that inhabit the gastrointestinal tract of several animals, such as humans, cats, dogs, pigs, and mice[38,39]. Currently, 53 species with validly published names comprise this genus[40], with *H. pylori* being the most prevalent in humans and well-known to be related to the development of chronic gastritis, peptic ulcer, and gastric cancer[41-43]. However, emerging evidence has highlighted the potential role of NHPHs in the progression of these diseases, including GML[24,44-46].

Among the NHPHs, *H. suis*, *H. heilmannii*, *H. felis*, *H. salomonis* and *H. bizzozeronii* are the most common species associated with human infection[47,48]. According to Yakoob *et al*[49], the prevalence of *H. heilmannii* and *H. felis* among patients with dyspepsia was 6% and 4%, respectively. On the other hand, Øverby *et al*[48] revealed a prevalence of gastric NHPH in Japanese patients of 6.1% and within this group, *H. suis* was the most prevalent, followed by *H. heilmannii*. This latter finding agrees with Nakamura *et al*[50], who found a prevalence of NHPHs of 20.8% in gastric mucosal samples of *H. pylori*-negative gastric disease patients, with *H. suis* and *H. heilmannii* also as the most prevalent species. However, it is important to note that the current diagnostic methods available, such as polymerase chain reaction (PCR) and immunohistochemistry, have limited accuracy in detecting NHPHs infections[26]. In a specific study, researchers faced difficulties in identifying the species associated with the infection in approximately 50% of the cases[50]. This challenge can be attributed to several factors, including the high genetic similarity between different NHPH species, significant genetic variation within a single species, limitations imposed by identification methods, and the concurrent presence of multiple NHPH species[51-53]. As a result, there is a concern that the actual prevalence of NHPHs infections among patients with dyspepsia may be underestimated.

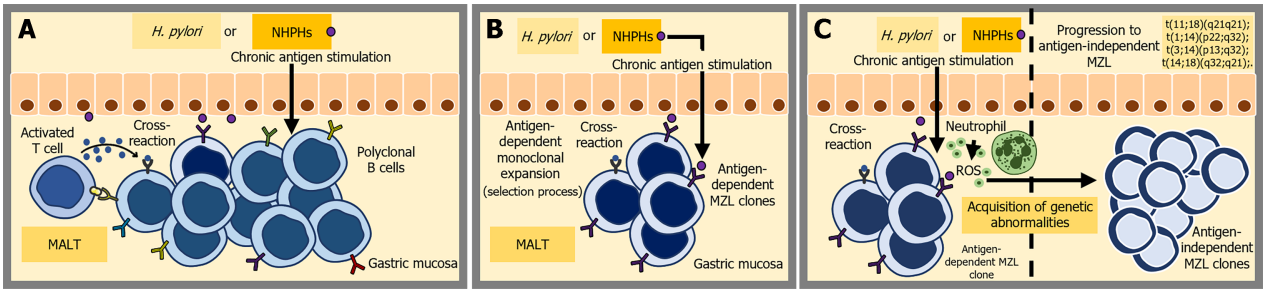
Regarding the association of NHPHs with GML, some studies have evaluated the prevalence of infections by these species and its correlation with the complete remission of *H. pylori*-negative GML through eradication therapy. In this regard, Takigawa *et al*[54] report that the rate of complete remission in NHPH positive group of patients was significantly higher (75%) when compared to the negative cases (23%) of *H. pylori*-negative GML, which suggests a potential role for NHPHs in the pathogenesis of GML and the treatment effectiveness of *H. pylori*-negative GML. Such data are corroborated by Morgner *et al*[17], which advocate that *H. heilmannii* infection might be a causative factor in GML and that the current eradication therapy employed for *H. pylori* (standard antibiotics combined with proton pump inhibitors) is effective and results in complete remission of the lymphoma[17]. Nevertheless, upon confirming the presence of NHPH infection, it is strongly advised to implement a therapeutic approach that is tailored to the susceptibility profile of the individual bacterium.



Pathogenesis of GML

The pathogenesis of GML is a complex event that involves antigen-induced transformation of normal marginal-zone B-cells into malignant cells[55]. In contrast to MALT lymphomas observed in various locations, GML is distinguished by its association with specific microbial species: Primarily, *H. pylori*, and to a lesser extent, *Helicobacter heilmannii*[17,54,56]. Under normal physiological conditions, the stomach does not possess MALT. However, in the presence of chronic antigenic stimulation, gastric mucosal cells produce proinflammatory cytokines (such as lymphotoxin beta) and B-cell homing factors (*e.g.*, bicinchoninic acid-1), leading to the infiltration of lymphoid cells into the gastric tissue. This cascade of events leads to the development of MALT[32,57,58] (Figure 1).

Regarding *H. pylori* infection, it is well-established that certain T helper cells target specific epitopes of the bacterium and support polyclonal B cells[59,60]. These B cells possess receptors that are able recognize autoantigens found in the gastric mucosa due to cross-reactivity. Consequently, the polyclonal B cell population undergoes expansion and a selection process, resulting in the emergence of an antigen-dependent MZL clone[61,62].



Sustained antigenic exposure not only stimulates the proliferation of a diverse array of B cells but also attracts neutrophils to the site of inflammation. The inflammatory process initiates the release of reactive oxygen species, leading to the occurrence of various genetic abnormalities[55,63,64]. Furthermore, the persistent proliferation of B cells during chronic inflammation increases the risk of double-stranded DNA breaks and translocations[5] (Figure 2).

Likewise, the involvement of NHPHs in *H. pylori*-negative GML could also be attributed to the induction of chronic inflammation, resulting in the local aggregation and proliferation of antigen-dependent B cells and T cells. Indeed, the infection of mice with NHPHs species, including *H. felis*, *H. suis* and *H. heilmannii*, also leads to a similar process of chronic gastritis and GML development with similarities to the human disease[65-69]. Possibly, the inflammatory microenvironment associated with NHPH-induced gastritis also facilitates the acquisition of genetic abnormalities by B cell clones. Nevertheless, further studies are required to construct a more comprehensive pathogenesis model.

Figure 1 Antigen-induced acquisition of gastric mucosa-associated lymphoid tissue. A: Antigen-induced inflammation; B: Clonal expansion of B cells supported by specific T helper cells; C: Acquisition of mucosa-associated lymphoid tissue (MALT). In the presence of chronic antigenic stimulation, gastric mucosal cells undergo activation and produce proinflammatory cytokines. These molecular mediators play a crucial role in initiating and perpetuating an immune response within the gastric tissue. As a consequence, lymphoid cells are recruited and infiltrate the gastric tissue. This cascade of events ultimately culminates in the development of MALT. *H. pylori: Helicobacter pylori*; NHPHs: Non-*Helicobacter pylori* gastric helicobacters; DC: Dendritic cell; MΦ: Macrophage; TCR: T cell receptor; CD40: Cluster of differentiation 40; CD40L: Cluster of differentiation 40 Ligand; BCR: B cell receptor.

Figure 2 Simplified scheme of antigen-induced transformation of normal marginal-zone B-cells into malignant cells. A: Polyclonal B cell expansion and a selection process; B: Antigen-dependent monoclonal expansion; C: Acquisition of genetic abnormalities and antigen-independent lymphomagenesis. The proliferation of B cells is primarily induced by the interaction between CD40 and CD40 Ligand, facilitated by antigen-activated reactive T cells. Additionally, cytokines play a role in driving this B-cell proliferation. The persistent proliferative state of these B cells, along with chronic inflammation, triggers additional oncogenic events. Ultimately, these events lead to the development of antigen-independent lymphoproliferation. NHPHs: Non-*Helicobacter pylori* gastric helicobacters; ROS: Reactive oxygen species; MZL: Marginal zone lymphoma; MALT: Mucosa-associated lymphoid tissue; *H. pylori: Helicobacter pylori*.

Irrespective of etiology, progression towards antigen-independent MZL is associated with genetic events, while the role of direct antigenic stimulation gradually decreases in the development of GML[5,70] (Figure 2). Four recurrent chromosomal translocations have been found in MZL: *t* (1; 14) (p22; q32), *t* (11; 18) (q21; q21), *t* (14; 18) (q32; q21), and *t* (3; 14) (p14.1; q32)[71-73]. In GML, the translocation *t* (11; 18) (q21; q21) is the prominent structural chromosomal abnormality, occurring in approximately 10%-50% of cases[74-76]. This translocation results in the activation of NF-kappaB, which is a downstream target of B-cell receptor (BCR) signaling, independent of BCR signaling itself. The activation is mediated by the disruption of a signalosome complex involving CARD11, BCL10, and MALT1. Within this context, the presence of the MALT1 fusion protein is notably linked to more advanced stages of MALT lymphoma[77-80].

Indeed, numerous studies have demonstrated that GMLs harboring the *t* (11; 18) (q21; q21) translocation are frequently resistant to *H. pylori* eradication treatment compared to tumors that do not possess this specific translocation[11,81,82]. The decrease in the rate of complete histopathological remission following eradication therapy was also observed in *H. pylori*-negative GML cases; however, its influence on the treatment of NHPH-positive GML is still unclear[16].

Clinical implications and research prospects

Given the limited regression observed in *H. pylori*-negative GML after antibiotic treatment, clinical guidelines previously advised prompt initiation of targeted anti-lymphoma treatments[8,83]. Currently, the European Society for Medical Oncology Guidelines Committee suggests that a trial of anti-*Helicobacter* therapy may be worthwhile in *H. pylori*-negative early-stage GML (stages I and II_1)[9]. This recommendation presents new opportunities for research in this field. Specifically, future studies could focus on investigating the mechanisms underlying the response to this therapy and further exploring the involvement of other *Helicobacter* species (NHPHs) in the development of *H. pylori*-negative GML. Additionally, it is crucial to investigate the long-term outcomes and assess the effects of early intervention with targeted anti-lymphoma treatments on patient prognosis.

In this context, accurate detection of NHPHs is vital for precise clinical diagnosis and targeted treatment strategies. However, current diagnostic methods primarily focus on *H. pylori*, leaving a gap in the detection of NHPHs infections. Goji *et al*[26] conducted a review of 26 articles and determined that the sensitivities of diagnostic methods for *H. pylori* infection, such as the rapid urease test, urea breath test, blood antibody analysis, immunohistochemical analysis, and

stool antigen analysis, were low for NHPHs. The calculated sensitivities were only 40.0%, 14.8%, 23.1%, 40.0%, and 0%, respectively[26]. Therefore, at present, the most effective diagnostic tools for identifying NHPH infections are histological techniques and genetic diagnosis based on PCR, which hinders the clinical diagnosis of NHPHs infection, both due to the inflated cost and the dependence on laboratory apparatus. To address this, the development of tests that possess sensitivity, specificity, and the ability to detect different strains of NHPHs is crucial. The availability of reliable diagnostic methods for NHPHs will not only enable timely diagnosis and treatment for *H. pylori*-negative GML, but also contribute to a better understanding of their epidemiology and impact on human health.

When it comes to comprehending the pathogenesis of NHPH-positive GML, the significance of molecular and immunological studies cannot be overstated. These investigations should encompass the analysis of gene expression profiles in affected tissues, identification of pertinent genetic mutations, and study of cellular signaling pathways involved in the development and progression of the lymphoma. Additionally, it would also be interesting to analyze cytokine profiles, characterize immune cells infiltrating the affected gastric tissue, and conduct studies on the interaction between NHPHs and the host immune system. This deeper understanding might open doors to the development of targeted therapeutic strategies and hold promise for improved clinical outcomes in patients with NHPH-positive GML.

CONCLUSION

While *H. pylori* remains the primary pathogenic factor in the development of GML, the role of NHPHs in *H. pylori*-negative cases is an emerging area of research. It is crucial to identify these alternative pathogens and understand their mechanisms of pathogenesis to improve diagnostic accuracy and guide appropriate treatment strategies for patients with *H. pylori*-negative GML. Further research is warranted to elucidate the complex interplay between these bacteria, the host immune system, and the gastric microenvironment, which may lead to the development of novel therapeutic interventions and personalized approaches for this subset of patients.

Abstract

BACKGROUND

Resistance to antibiotics is one the main factors constraining the treatment and control of *Helicobacter pylori* (*H. pylori*) infections. Therefore, there is an urgent need to develop new antimicrobial agents to replace antibiotics. Our previous study found that linolenic acid-metronidazole (Lla-Met) has a good antibacterial effect against *H. pylori,* both antibiotic-resistant and sensitive *H. pylori*. Also, *H. pylori* does not develop resistance to Lla-Met. Therefore, it could be used for preparing broad-spectrum antibacterial agents. However, since the antibacterial mechanism of Lla-Met is not well understood, we explored this phenomenon in the present study.

AIM
To understand the antimicrobial effect of Lla-Met and how this could be applied in treating corresponding infections.

METHODS
H. pylori cells were treated with the Lla-Met compound, and the effect of the compound on the cell morphology, cell membrane permeability, and oxidation of the bacteria cell was assessed. Meanwhile, the differently expressed genes in *H. pylori* in response to Lla-Met treatment were identified.

RESULTS
Lla-Met treatment induced several changes in *H. pylori* cells, including roughening and swelling. *In vivo* experiments revealed that Lla-Met induced oxidation, DNA fragmentation, and phosphatidylserine ectropionation in *H. pylori* cells. Inhibiting Lla-Met with L-cysteine abrogated the above phenomena. Transcriptome analysis revealed that Lla-Met treatment up-regulated the expression of superoxide dismutase *SodB* and *MdaB* genes, both anti-oxidation-related genes.

CONCLUSION
Lla-Met kills *H. pylori* mainly by inducing oxidative stress, DNA damage, phosphatidylserine ectropionation, and changes on cell morphology.

Key Words: *Helicobacter pylori*; Oxidation; Superoxide dismutase; *SodB* genes; *MdaB* genes

Core Tip: The clarithromycin resistant *Helicobacter pylori (H. pylori)* is listed by the World Health Organization as the priority bacteria in urgent need of developing new antibiotics. Our previous research found that linolenic acid-metronidazole has a good antibacterial effect on *H. pylori* and is not easy to develop drug resistance. Therefore, we further explored its antibacterial mechanism against *H. pylori*. It was found that it mainly kills *H. pylori* by inducing oxidative stress, DNA damage, phosphatidylserine ectropionation, and changes on cell morphology. This study may provide a theoretical basis for the development and application of new anti *H. pylori* lead compound.

INTRODUCTION

Helicobacter pylori (*H. pylori*) is the main pathogen that causes upper digestive diseases, such as chronic gastritis, peptic ulcer, and gastric cancer[1-4]. At present, the treatment options for *H. pylori* infections include standard triple therapy, bismuth-containing quadruple therapy, and sequential therapy[5,6]. Due to the overuse and misuse of antibiotics, the drug resistance rate of *H. pylori*, including multi-drug resistance, is gradually increasing, negatively impacting the control and treatment of *H. pylori* infections[7-10]. Therefore, there is an urgent need to develop new anti-*H. pylori* agents[11].

Due to the long period and significant investment required for developing new antibiotics, the transformation or modification of the existing drugs is more efficient in shortening the drug research and development cycle. Modifying existing drugs could improve their efficacy while reducing the development of antimicrobial resistance. Zinc linolenic acid and liposome linolenic acid are linolenic acid derivatives effective at increasing the sensitivity of drug-resistant *H. pylori*. Resistance against zinc linolenic acid and liposome linolenic acid is minimal[12,13]. Although metronidazole is a widely used and cost-effective drug, its clinical application for *H. pylori* infection treatment is limited by resistance development.

Our previous study found that the minimum inhibitory concentration (MIC) of linolenic acid-metronidazole (Lla-Met) against six strains of the drug-resistant *H. pylori* was 2-4 μg/mL. Additionally, the *H. pylori* strains did not develop resistance against this compound. Therefore, Lla-Met would serve as promising antibiotics. However, its antibacterial mechanism is poorly understood[14], this study explored this mechanism.

MATERIALS AND METHODS

Materials

H. pylori strain G27 (Courtesy of Prof. Bi Hongkai, Nanjing Medical University), calf serum, a Columbia blood agar base, a brain heart infusion (BHI,OXOID) medium, L-cysteine (L-cys) (AR 99%, MACKLIN), a fluorescence orthomicroscope (OLYMPUS, Tokyo, Japan), reactive oxygen species (ROS) detection kits (Beyotime), cell apoptosis 4',6-diamidino-2-phenylindole (DAPI) detection kits (Beyotime), apoptosis detection kits (Beyotime), reverse transcription kits (Monad), reverse transcription quantitative real-time polymerase chain reaction (RT-qPCR) kits (Monad), a Lightcycler96 fluorescence ration PCR instrument (Roche, Germany), and a scanning electron microscope were used in the present study.

Thawing and culture of H. pylori strain

Standard *H. pylori* strain G27 stored at -80 °C were thawed and centrifuged to remove the preservation solution (Glycerin:BHI:serum = 3:6:1). The bacteria were inoculated on a Columbia agar medium, or a brain heart infusion medium supplemented with 10% calf serum and cultured in a microaerophilic environment.

Cell morphology assay

The effect of the Lla-Met on *H. pylori* morphology was observed by scanning electron microscopy[15-18]. *H. pylori* was treated with 4 and 8 μg/mL of Lla-Met and incubated for 24 h in a three-gas incubator. The bacteria were pelleted by centrifugation and fixed overnight with 2.5% glutaraldehyde. The bacteria suspension was centrifuged to remove glutaraldehyde before dehydration with 30%, 50%, 70%, 90%, and 100% ethanol. The pellet was dried through refrigeration in a vacuum. After that, the *H. pylori* morphology was observed and photographed under a KYKY-EM8100 scanning electron microscope (KYKY, Beijing).

Membrane damage assay

The *H. pylori* cells were stained as previously described by Hwang *et al*[19]. Briefly, the G27 bacterial suspension (1×10^8 CFU/mL) at the logarithmic phase was treated with Lla-Met for 2 h at the rate of 16 μg/mL. The cell suspension was centrifuged at 12000 r/min for 2 min to pellet the cells. The medium was poured out, and the harvested cells were suspended in phosphate buffered saline (PBS). The cells were stained with a propidium iodide solution (PI, 10 μg/mL, Thermo Fisher) at 37 °C protected from light 30 min and thereafter centrifuged at 12000 r for 5 min. The dye unbound to the harvested cells was washed away with sterile PBS. Thereafter, the cells were suspended in PBS and immediately observed under a fluorescence microscope (Olympus Corporation, Tokyo, Japan).

Cell membrane pore size assay

FITC-FD was mainly used to evaluate the degree of *H. pylori* cell membrane damage after treatment with Lla-Met. The process was performed as previously described[20]. Briefly, G27 bacterial suspension (1×10^8 CFU/mL) at the logarithmic phase was incubated with Lla-Met (16 μg/ML) for 2 h, centrifuged, and the pellet was suspended in sterile PBS. The cell suspension was protected from light with FIFC-labeled glucan FD4, about 4.0 kDa, with a diameter of 1.4 nm (Sigma, United States) and FD10, about 10.1 kDa, with a diameter of 2.3 nm (Sigma, United States), both at a final concentration of 100 μg/mL. After 30 min of incubation at 37 °C, the unbound fluorescent dye was washed off with sterile PBS. The cells were suspended in sterile PBS. Finally, the fluorescence influx of FD4 and FD10 was detected at the excitation and emission wavelengths of 495 nm and 520 nm, respectively, by a multimode reader (BioTek, America).

Ion channels assay

The G27 bacterial suspension (1×10^8 CFU/mL) at the logarithmic phase was incubated with Lla-Met (16 μg/mL) for 2 h and centrifuged at 12000 r/min for 2 min. The changes in concentrations of extracellular K^+, Na^+, Cl^-, and Ca^{2+} were determined by ion-selective electrodes. Three biological repeats were performed for each experiment.

Intracellular reactive oxygen assay

The level of intracellular ROS in the *H. pylori* cell was detected by the DC-FDH probe, as described by Akhtar *et al*[21-22]. Briefly, G27 bacterial suspension (1×10^8 CFU/mL) was treated with Lla-Met (8 μg/mL and 16 μg/mL) for 2 h and centrifuged to remove the supernatant. The harvested cells were protected from light DCF-DA (10 μM) for 30 min and centrifuged at 12000 r for 2 min. The excess probe was washed off with sterile PBS. Finally, the cells were resuspended in PBS solution, and the fluorescence intensity was analyzed using a multifunctional microplate reader (BioTek, America) at the excitation and emission wavelengths of 485 nm and 520 nm, respectively. The fluorescence intensity was also analyzed using a fluorescent microscope (OLYMPUS, Tokyo, Japan). PBS and polymyxin were the controls.

Validation of how Lla-Met kills H. pylori

The G27 bacterial suspension was incubated with L-cys, a ROS scavenger, to evaluate the effect of ROS on the viability of G27 bacteria. Briefly, G27 bacterial suspension (1×10^8 CFU/mL) at the logarithmic phase was incubated with or without 40 mmol/L L-cys (which did not affect the viability of G27 cells) for 1 h and thereafter with Lla-Met (16 μg/mL) for 8 h. The optical density values were measured at $OD_{600\ nm}$ using a multifunctional microplate reader (BioTek, America). In addition, the fluorescence intensity was analyzed using fluorescence microscopy (OLYMPUS, Tokyo, Japan). G27 bacterial suspension treated with or without 40 mmol/L L-cys was incubated for 1 h. The suspension was treated with

Lla-Met (16 μg/mL) for 2 h and centrifuged to remove the supernatant. The harvested bacteria were incubated with DCF-DA (10 μM) for 30 min and washed with sterile PBS.

DNA fragmentation assay

When DAPI passes through the intact cell membrane, it binds to bacterial DNA. The bacterial DNA thus stains blue. Damaged DNA appears as dots. Therefore, the fragmentation of *H. pylori* DNA after Lla-Met treatment was detected using the DAPI staining[23]. Briefly, the G27 bacterial suspension (1×10^8 CFU/mL) was incubated with or without 40 mmol/L L-cys for 1 h and thereafter with Lla-Met (16 μg/mL) for 2 h. Thereafter, the suspension was centrifuged to remove the supernatant and treated with DAPI (1 μg/mL) for 30 min. The unbound dye was washed off with PBS, and the cells were resuspended in PBS. Fluorescence intensity was determined at excitation and emission wavelengths of 358 nm and 460 nm, respectively (OLYMPUS, Tokyo, Japan), with PBS as a control.

Phosphatidylserine ectropion assay

Phosphatidylserine (PS) is usually located on the inner side of the cell membrane. At the early stage of apoptosis, PS is translocated to the cell surface. Annexin-V, a $Ca2^+$-dependent phospholipid binding protein, bind to PS with high affinity [24]. The G27 bacterial suspension in the logarithmic phase (1×10^8 CFU/mL) was incubated with or without 40 mmol/L L-cys for 1 h and thereafter with Lla-Met (16 μg/mL) for 2 h. Thereafter, the suspension was centrifuged to remove the supernatant, and the pellet was incubated with Annexin-V and incubated for 30 min. The unbound dye was washed off with PBS, and the cells were resuspended in PBS. The fluorescence intensity was analyzed at excitation and emission wavelengths of 490 nm and 520 nm, respectively, using a multifunctional microplate reader (BioTek, America) and a fluorescence microscope (OLYMPUS, Tokyo, Japan), with PBS as a control.

Transcriptome sequencing

G27 bacterial suspension (1×10^8 CFU/mL) (OD_{600} = 0.3) was incubated with 2, 4, 8, and 10 μg/mL Lla-Met for 0 h, 2 h, and 8 h, and the ODs were measured at 600 nm. Three biological repeats were performed for each experiment. When the OD remained constant (0.3), the bacterial RNA was extracted for transcriptome sequencing, which was performed by Nanjing Fengzi Bio-pharm Technology. Three biological repeats were performed for each experiment.

The sequencing was performed using Illumina PE150 technology. The alignment and transcript assembly were performed using Boetie2 and the Rockhhoper software. All genes were quantitatively analyzed, and the differentially expressed genes (DEGs) were identified. The biological processes and pathways regulated by the DEGs were then identified. Principal component analysis (PCA) demonstrates principal component analysis, analyzing the composition of different samples can respond to the differences and distances between samples, the more similar the sample composition, the closer the distance in the PCA graph.

Validation of differential gene expression

Total bacterial RNA was extracted using a Novizan RNA kit, and the expression of mRNA was analyzed by a real-time fluorescent quantitative PCR instrument (Lightcycler96 fluorescent quantitative PCR instrument, Roche, Germany). The 16s was used as the reference gene. The sequences of primers used in this study are shown Table 1. Three biological repeats were performed for each experiment.

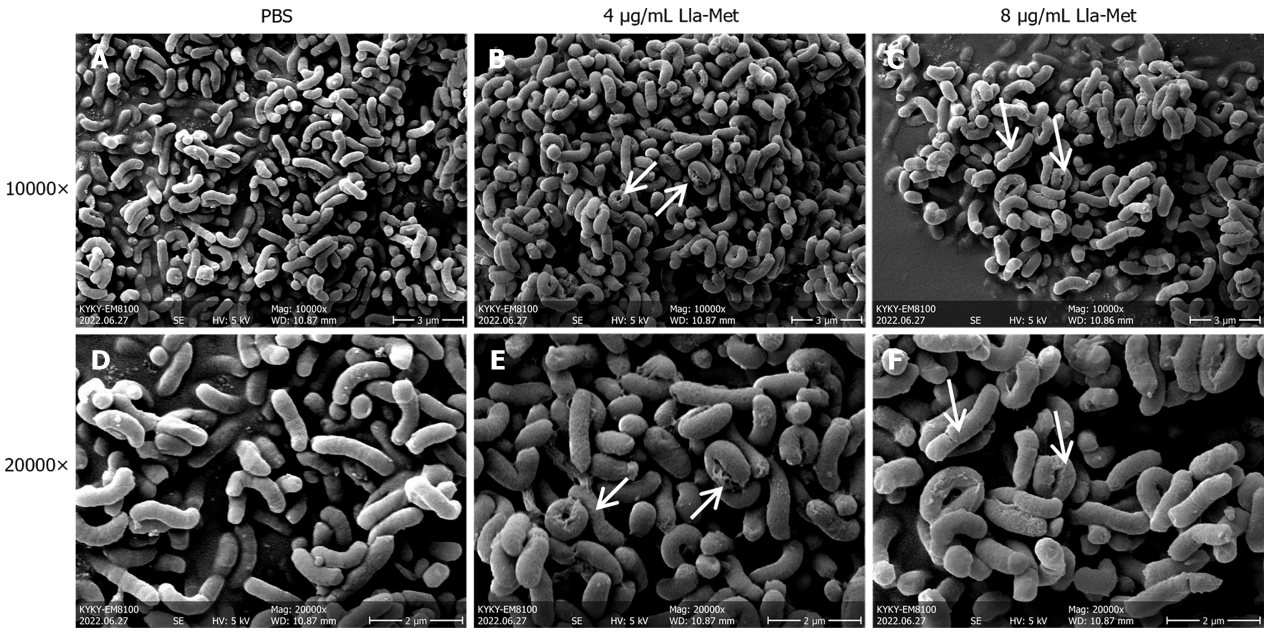
Statistical analysis

Statistical analysis was performed using the SPSS software, Version 26.0. Continuous data were expressed as mean ± SD. Differences between groups were analyzed using the *t*-test, while multiple groups were compared using the single factor variance analysis. $P < 0.05$ was considered statistically significant.

RESULTS

Effect of Lla-Met on H. pylori morphology

The impact of the Lla-Met compound on the morphology of *H. pylori* was observed using scanning electron microscopy. *H. pylori* in the control group was found to have a smooth and homogenous cell surface (Figures 1A and D). The surface of *H. pylori* in the treatment group (4 μg/mL and 8 μg/mL) was rough and swollen, and the cell damage worsened with the Lla-Met concentration (Figures 1B, C, E, and F).



Lla-Met impact of cell membrane integrity

PI penetrates through a damaged cell membrane, where it binds and stains the DNA. Therefore, an influx of intracellular PI represents the integrity of the bacterial cell membrane. The fluorescence intensity of PI in the G27 treatment group (16 μg/mL Lla-Met) was weaker than in the control group, though statistically insignificant (Figure 2A).

FITC-labelled glucans of different pore sizes (FD4 and FD10) were detected using a multifunctional microplate detector to examine damage to the *H. pylori* cell membrane after treatment with Lla-Met. Linolenic acid treatment had no significant effect on the permeability of *H. pylori* cells (Figures 2B and C).

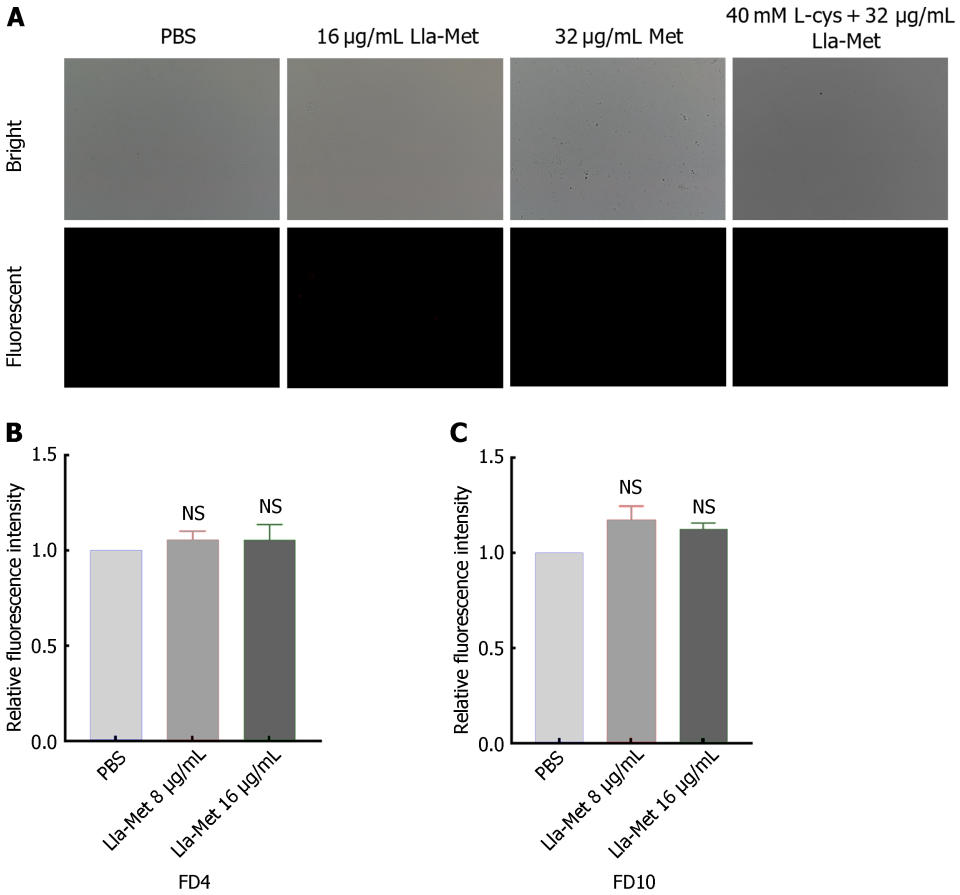
The arrow points to the cell damage. Roughness, swelling, breakages on the cell surface, *etc.*, are shown. PBS: Phosphate buffered saline; Lla-Met: Linolenic acid-metronidazole.

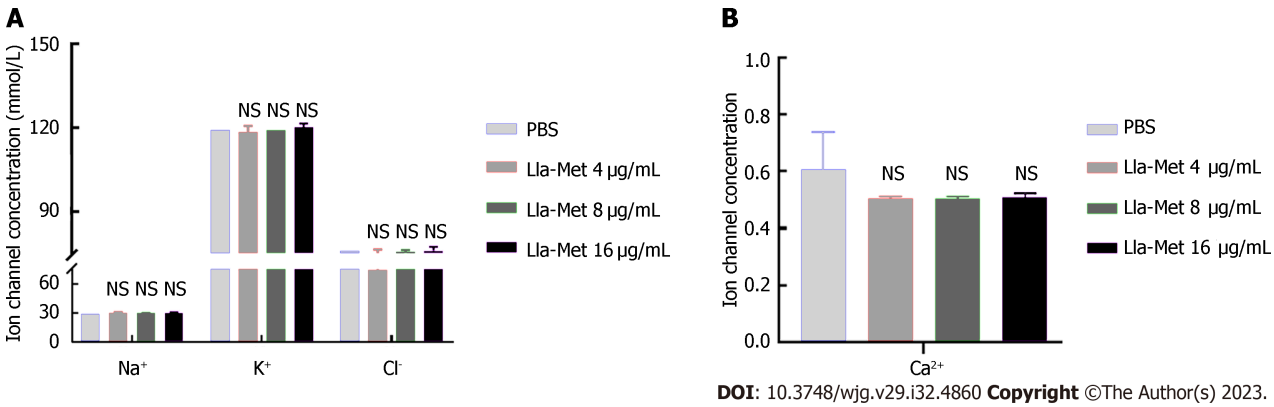
Lla-Met impact on H. pylori ion channels



To further investigate whether Lla-Met compound penetrated the cells *via* ion channels, the concentrations of K^+, Na^+, Cl^-, and Ca^{2+} ions in the supernatant were measured after treating *H. pylori* with Lla-Met. There was no statistically significant difference in the concentrations of the aforementioned ions between the treatment and the control group after G27 was applied with 16 μg/mL compound (Figures 3A and B).

Lla-Met impact on the intracellular ROS

DC-FDA fluorescent probes can be used to detect whether Lla-Met compounds can accelerate intracellular oxidation reactions. Compared with the control group, 8 μg/mL and 16 μg/mL Lla-Met compound increased the intracellular oxidation in *H. pylori* cell. Moreover, 8 μg/mL Lla-Met was more potent than 16 μg/mL metronidazole (Figure 4A); The relative fluorescence intensity of *H. pylori* treated with 16 μg/mL Lla-Met was stronger than that treated with 40 μg/mL polymyxin B ($P < 0.01$, Figure 4D). However, L-cys treatment abrogated the effect of Lla-Met (Figures 4B and D, $P < 0.01$), implying that L-cys abolished ROS generated by Lla-Met in *H. pylori*. In addition, L-cys pretreatment increased the cell viability from 20.5% to 57.7% (Figure 4C).



Lla-Met induced DNA fragmentation and apoptosis

In the early stage of apoptosis, PS translocates to the cell surface, where it could be bound by Ca^{2+}-dependent phospholipid-binding protein. Thus, the phospholipid-binding protein could be used for analyzing cell apoptosis in prokaryotes. In the present study, we found that the fluorescence intensity of *H. pylori* treated with 16 μg/mL Lla-Met was higher than that of the untreated group and the L-cys pretreatment group (Figure 5A). The multifunctional microplate labelling instrument results showed that the relative fluorescence intensity of Lla-Met-compound treatment group was significantly stronger than that of the PBS group and L-cys pretreatment group (Figure 5C, $P < 0.0001$). These results indicated that linolenic-acid-metronidazole caused PS eversion, but L-cys pretreatment inhibited this

phenomenon.

Subsequently, cellular DNA fragmentation serves as a marker of late apoptosis. The DAPI staining evaluated whether Lla-Met compound could cause the fragmentation of *H. pylori* DNA. The results showed that 16 μg/mL Lla-Met caused the fragmentation of bacterial *H. pylori* DNA (Figure 5B red circles represent the fragmented DNA). However, DNA fragmentation was inhibited in the L-cys treatment group (Figure 5D, $P < 0.0001$). These findings suggested that Lla-Met caused the fragmentation of *H. pylori* DNA by inducing the accumulation of ROS.

A_M_3 (Figure 6D). The gene set enrichment analysis and Gene Ontology of the DEGs. The DEGs were divided into three main categories: Those that regulate biological processes, secretion of cellular components, and molecular function. The differential genes between the groups are primarily concentrated in tRedox pathways, metabolic processes and other pathways. Gene set enrichment analysis revealed that the DEGs regulated the REDOX and the metabolism pathway (Figure 6E). Lla-Met is inducing production of ROS in *H. pylori*, and therefore an increased expression of MdaB and SodB, both of which are associated with protection against the oxidative stress (Table 2). RT-qPCR and transcriptome sequence analyses revealed comparable findings (Figure 6F).

Table 2 Gene affected by linolenic acid-metronidazole treatment

Gene	Name	Log_2 fold change	Description	Enrichment pathway

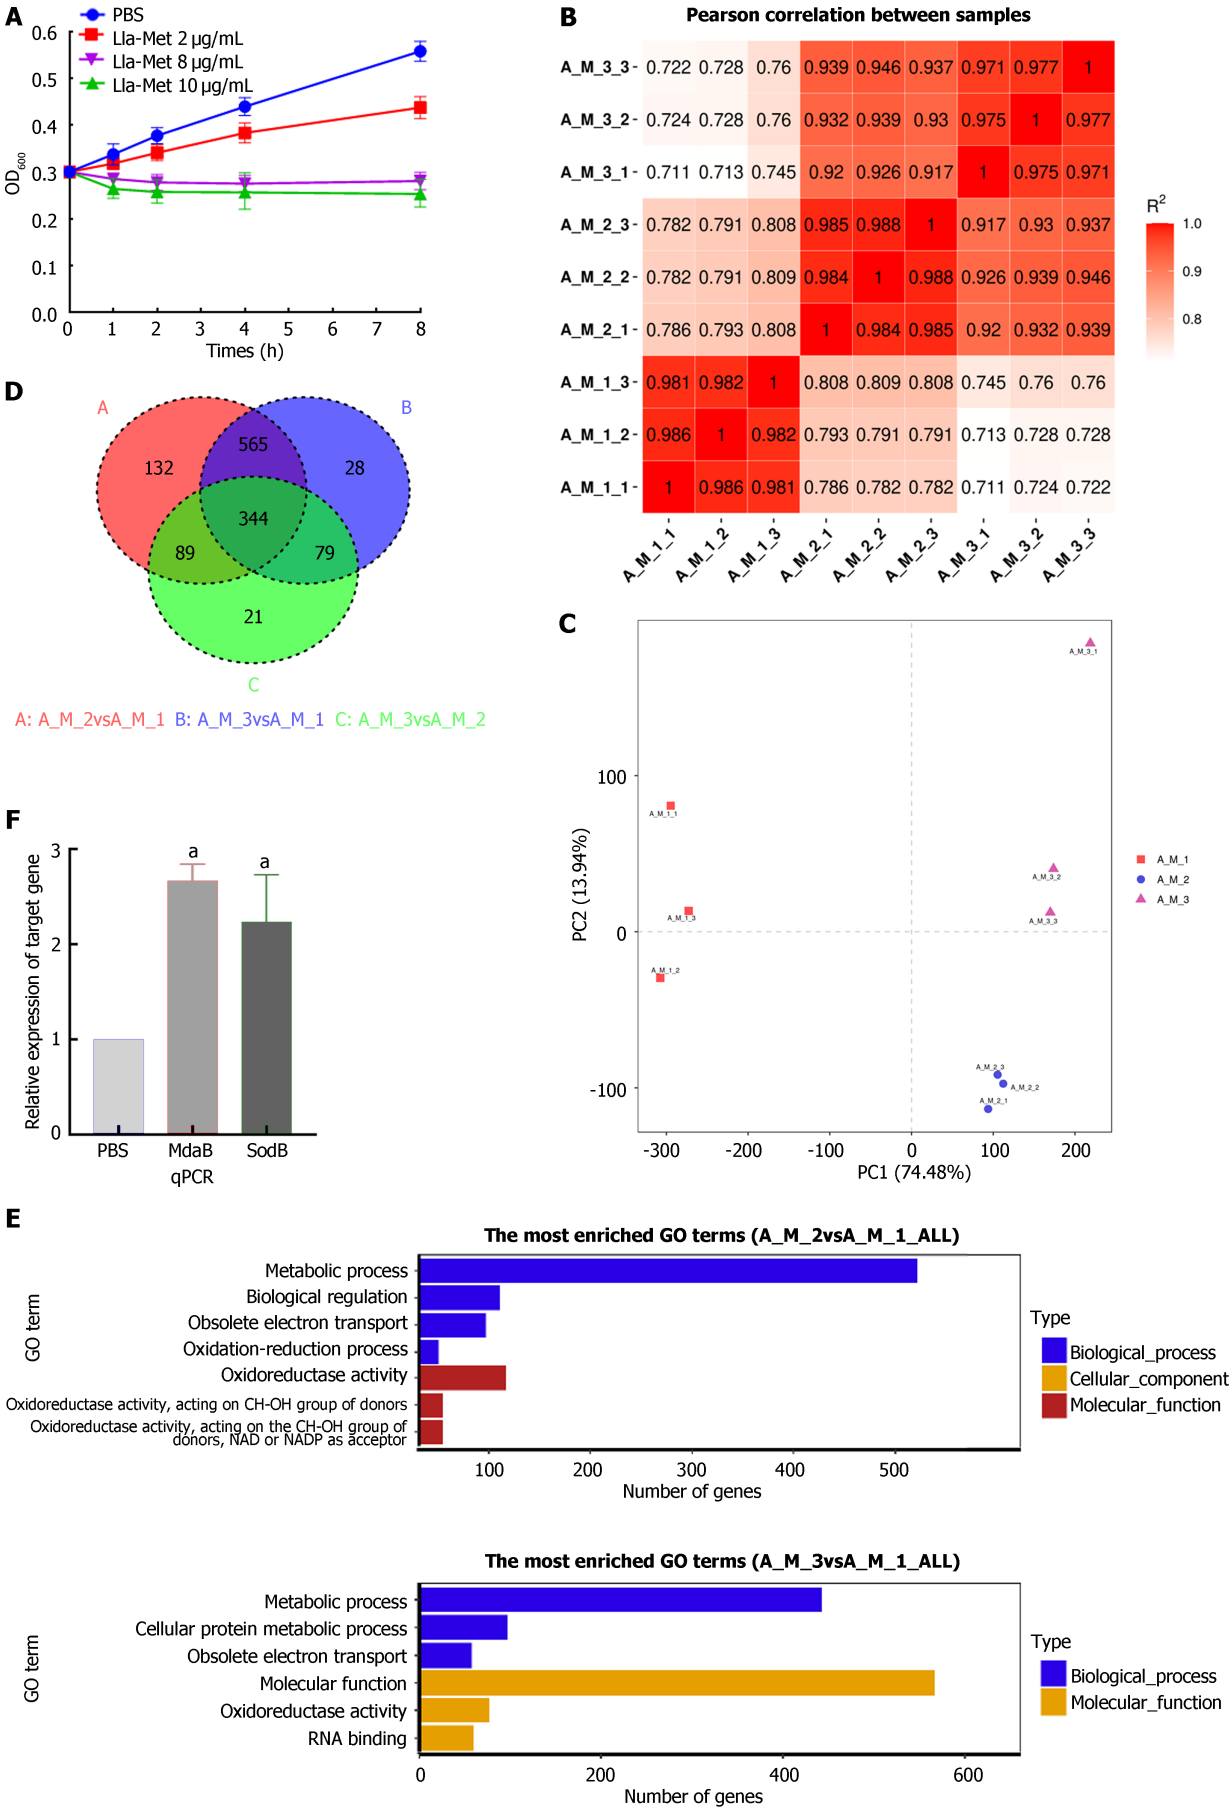
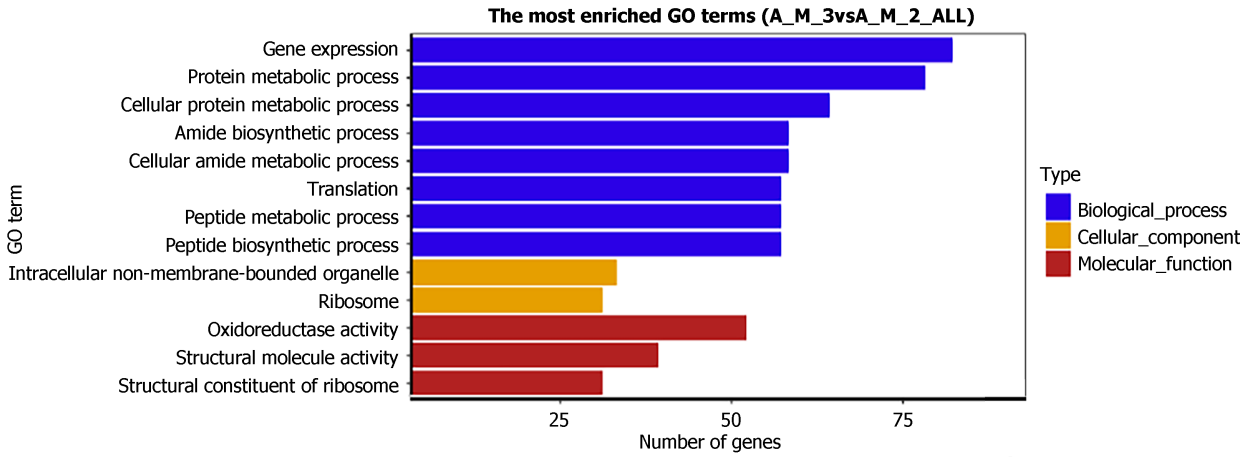
SodB	*HPG27_RS05265*	4.2287	Superoxide dismutase	Oxidoreductase activity

DISCUSSION

Lla-Met compound is synthesized from linolenic acid and metronidazole. Linolenic acid is an essential fatty acid with broad-spectrum antibacterial spectrum and antioxidant activities and capability to overcome *H. pylori* resistance to antibiotic treatment. In addition, with more functional groups, it can react with various substances to form related derivatives, which are widely used in the anti-infection treatment. Obonyo *et al*[25] suggested that the antibacterial mechanism of linolenic acid liposome against *H. pylori* is mainly to cause damage to the bacterial cell membrane. Huang *et al*[26] used linolenic acid and zinc to synthesize zinc linolenic acid with an MIC of 4-8 μg/mL to drug-resistant *H. pylori* strains. Its antibacterial mechanism is mainly to destroy cell membrane and cause accumulation of ROS, which finally leads to the death of bacteria. In this experiment, the damage caused by Lla-Met compound to the cell membrane was detected by PI, FD4, FD10 and lactate dehydrogenase activity determination. There was no change in cell membrane permeability after *H. pylori* was treated with 16 μg/mL Lla-Met compound. This result suggested that Lla-Met compound did not inhibit *H. pylori* by damaging the cell membrane.



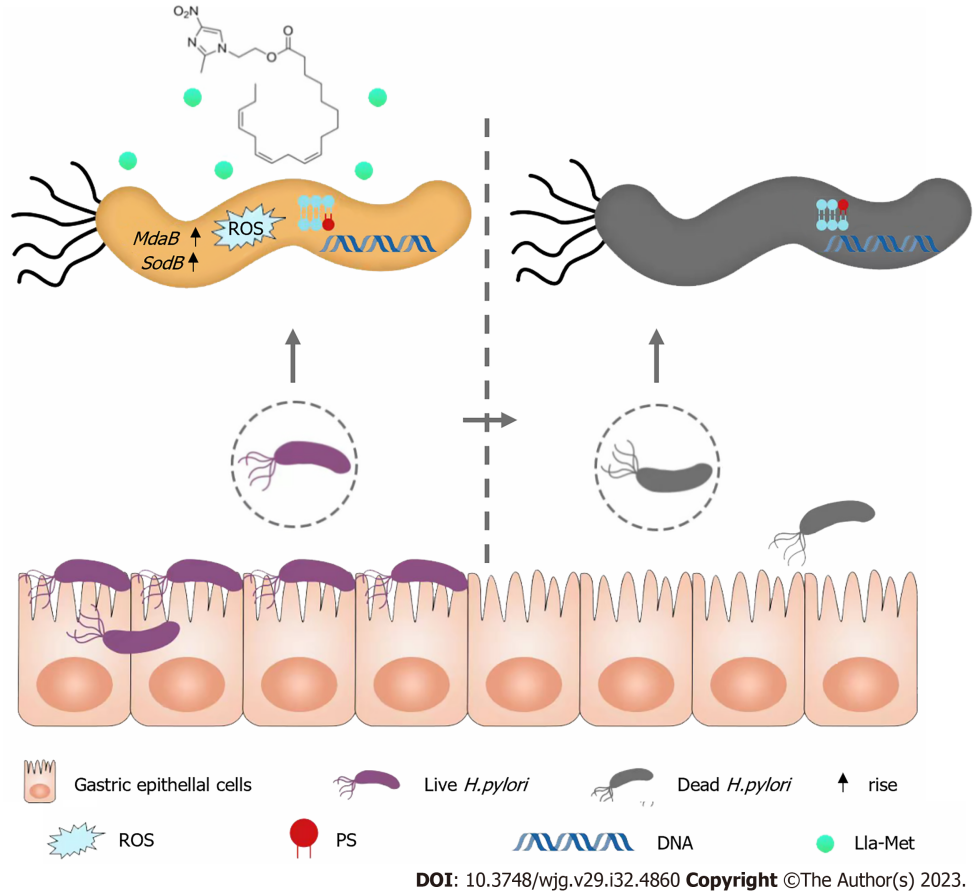
The accumulation of intracellular ROS activates eukaryotic cell apoptosis[27]. This process produces dying cells with typical morphological features, including cell shrinkage, membrane blistering, chromatin condensation, DNA fragmentation, and PS ectropion[28]. Studies have shown that apoptosis also occurs in prokaryotic cells, and is characterized with similar morphological characteristics as those in eukaryotes, such as the destruction of bacterial membrane integrity, DNA fragmentation, and PS ectropion[22,29]. Therefore, in the present study, we investigated whether Lla-Met compound could inhibit *H. pylori* growth by causing oxidative damage. In the experiment, 8 μg/mL Lla-Met compound was found to produce a stronger fluorescence signal compared with the control group. In addition, at a higher dose of 16 μg/mL Lla-Met, *H. pylori* produced a stronger fluorescence signal compared with the positive control group. Indicated that Lla-Met compound could increase accumulation of ROS in *H. pylori* in a dose-and time-dependent manner. This experiment also investigated whether intracellular ROS accumulation could affect *H. pylori* viability. The results showed that excessive accumulation of ROS could affect viability of *H. pylori* by reducing it to 20.5%, which increased to 57.7% when *H. pylori* was treated with 40 mmol/L L-cys. Interestingly, the accumulation of intracellular ROS was also found to significantly decrease after *H. pylori* was treated with L-cys. This result suggested that Lla-Met compound could cause excessive accumulation of intracellular ROS, leading to a decrease in cell viability, and that ROS accumulation could be reversed by L-cys treatment. In addition, after treatment with Lla-Met compound at different concentrations for 24 h, *H. pylori* surface became rough and swollen compared with the control group. As previously demonstrated, Lla-Met compound caused no damage to the cell membrane of *H. pylori*. This suggested that the death of *H. pylori* was due to the accumulation of intracellular ROS caused by Lla-Met compound.



Oxidation can cause both prokaryotic and eukaryotic cell death. In the present study, treatment with 16 μg/mL Lla-Met for 2 h was found to cause *H. pylori* DNA fragmentation and PS ectropion. Meanwhile, these effects were found to be reversed after *H. pylori* was treated with L-cys. DNA damage and membrane depolarization are characteristic changes in eukaryotic cell apoptosis[30]. Our experimental results showed that *H. pylori* cell death is similar to eukaryotic apoptosis, and ROS accumulation could induce prokaryotic cell-like death. However, compared with other studies, significant damage to the cell membrane was not found in the present study. This result indicated that damage to the integrity of the cell membrane might not be as necessary in the apoptosis of prokaryotic cells as slight DNA fragmentation and PS ectropion.

These results indicated that Lla-Met compound can promote intracellular ROS-generation reaction in *H. pylori* and effectively inhibit its growth. However, since several enzymes are involved in ROS-generating reaction, we used RT-qRCR to identify and verify key enzymes involved in this process and detect transcriptome changes. The results revealed that superoxide dismutase *MdaB* and *SodB* genes were found to play an important role. Under normal circumstances, the intracellular oxidative system and antioxidant system are in a dynamic balance. However, after treatment of with linolonic acid-metronidazole compound, superoxide dismutase *MdaB* and *SodB* genes were found to be highly expressed in *H. pylori*, and intracellular ROS was found to accumulate excessively, thereby damaging DNA and causing PS ectropion.

CONCLUSION



In this paper, the mechanism of linoleic-metronidazole compound was demonstrated to involve inhibiting *H. pylori* growth by inducing excessive ROS accumulation, resulting in excessive superoxide dismutase *MdaB* and *SodB* genes expression (Figure 7). Besides, this study further proves the antibacterial effect of Lla-Met on *H. pylori* at the molecular level, providing theoretical support for further research and development of Lla-Met as an anti-*H. pylori* drug to help overcome *H. pylori* resistance to current antibiotic drugs.

ARTICLE HIGHLIGHTS

Research background

Helicobacter pylori (*H. pylori*) is recognized as an important human pathogen associated with superficial gastritis, atrophic gastritis, gastric cancer, *etc.*, each of which has become a serious threat to human health and survival. The rate of drug resistance is increasing due to the wide use of antibiotics and high rates of resistance to clarithromycin, metronidazole, and levofloxacin are associated with the failure of *H. pylori* eradication. At present, the mechanism of antibiotic resistance

of *H. pylori* is not completely understood. It is very difficult to prevent drug resistance and improve the rate of eradication of the target, thus warranting exploration of the mechanism of drug resistance to *H. pylori*, and provision of an experimental basis for the prevention and treatment of drug resistance.

Research motivation

Currently, there is a serious drug resistance situation in *H. pylori* and new antibiotics are urgently needed; however, antibiotic research and development are very difficult. If we can understand the antibacterial mechanism of linolenic acid-metronidazole (Lla-Met), we can better apply it to antimicrobial treatment and solve the problem of antibiotic resistance.

Research objectives

The objectives of this study were to confirm the antibacterial effect of Lla-Met on *H. pylori*, and to provide theoretical support for further research and development of Lla-Met as an anti-*H. pylori* drug, and to help overcome the resistance of *H. pylori* to existing antibiotic drugs.

Research methods

H. pylori cells were treated with the Lla-Met compound, and the effect of the compound on the cell morphology, cell membrane permeability, and oxidation of the bacteria cell was assessed by scanning electron microscope, propidium iodide staining, FIFC-FD, detection of ion channels, detection of intracellular reactive oxygen species, and detection of phosphatidylserine ectropion. Meanwhile, the differently expressed genes in H. pylori in response to Lla-Met treatment were identified by transcriptome sequencing and quantitative real-time polymerase chain reaction.

Research results

The expression of both *SodB* and *MdaB* genes was up-regulated after treatment with Lla-Met, and both genes are associated with antioxidants. Lla-Met inhibits the growth of *H. pylori* through oxidation.

Research conclusions

The mechanism of linoleic-metronidazole compound was demonstrated to involve inhibiting *H. pylori* growth by inducing excessive reactive oxygen species accumulation, resulting in excessive superoxide dismutase *MdaB* and *SodB* genes expression.

Research perspectives

This study proves the antibacterial effect of Lla-Met on *H. pylori* at the molecular level, providing theoretical support for further research and development of Lla-Met as an anti-*H. pylori* drug to help overcome *H. pylori* resistance to current antibiotic drugs.

Abstract

BACKGROUND

The albumin-bilirubin (ALBI) score is an index of liver function recently developed to assess prognosis in patients with hepatocellular carcinoma (HCC). It can detect small changes in liver dysfunction and has been successfully applied to the prediction of survival in patients with non-malignant liver diseases of various etiologies.

AIM

To investigate the ALBI score for identifying decompensation risk at the 3-year follow-up in patients with compensated cirrhosis.

METHODS

One-hundred and twenty-three patients with compensated cirrhosis without HCC in King Chulalongkorn Memorial Hospital diagnosed by imaging were retrospectively enrolled from January 2016 to December 2020. A total of 113 patients (91.9%) had Child A cirrhosis with a median model for end-stage liver disease (MELD) score of less than 9. Baseline clinical and laboratory variables and decompensation events were collected. The ALBI score was calculated and validated to classify decompensation risk into low-, middle-, and high-risk groups using three ALBI grade ranges (ALBI grade 1: ≤ -2.60; grade 2: > -2.60 but ≤ -1.39; grade 3: > -1.39). Decompensation events were defined as ascites development, variceal bleeding, or grade 3 or 4 hepatic encephalopathy.

RESULTS

Among 123 cirrhotic patients enrolled, 13.8% (n = 17) developed decompensating events at a median time of 25 [95% confidence interval (CI): 17-31] mo. Median baseline ALBI score in compensated cirrhosis was significantly lower than that of patients who developed decompensation events [-2.768 (-2.956 to -2.453) *vs* -2.007 (-2.533 to -1.537); P = 0.01]. Analysis of decompensation risk at 3 years showed that ALBI score had a time-dependent area under the curve (tAUC) of 0.86 (95%CI: 0.78-0.92), which was significantly better than that of ALBI-Fibrosis-4 (ALBI-FIB4) score (tAUC = 0.77), MELD score (tAUC = 0.66), Child-Pugh score (tAUC = 0.65), and FIB-4 score (tAUC = 0.48) (P < 0.05 for all). The 3-year cumulative incidence of decompensation was 3.1%, 22.6%, and 50% in the low-, middle-, and high-risk groups, respectively (P < 0.001). The odds ratio for decompensation in patients of the high-risk group was 23.33 (95%CI: 3.88-140.12, P = 0.001).

CONCLUSION

The ALBI score accurately identifies decompensation risk at the 3-year follow-up in patients with compensated cirrhosis. Those cirrhotic patients with a high-risk grade of ALBI score showed a 23 times greater odds of decompensation.

Key Words: Albumin-bilirubin score; Compensated cirrhosis; Hepatic decompensation risk

Core Tip: The albumin-bilirubin (ALBI) score has been successfully applied to the prediction of survival in patients with non-malignant liver diseases of various etiologies. This study demonstrated that the ALBI score can accurately identify decompensation risk at the 3-year follow-up in patients with compensated cirrhosis. The ALBI score is a simple and ready-to-use tool to help clinicians monitor and make appropriate treatment strategies in patients with compensated cirrhosis.

INTRODUCTION

Cirrhosis is the end stage of chronic liver disease which is currently the 11th leading cause of death and 15th leading cause of morbidity across the world, accounting for 2.2% of deaths and 1.5% of disability-adjusted life years worldwide[1]. The disease evolves from an asymptomatic phase as compensated cirrhosis to a symptomatic phase as decompensated cirrhosis[2]. Decompensated cirrhosis is defined by the presence of variceal bleeding, encephalopathy, ascites, hepatorenal syndrome, and/or jaundice[3]. Transition from a compensated to a decompensated stage occurs at a rate of 5%-7% per year[4]. Median survival of patients with compensated cirrhosis is 12 years, while that of decompensated patients is less than 2 years[5]. Once decompensation has occurred, mortality without transplant is as high as 85% over 5 years[4].

For over 60 years, the best predictor of decompensation in cirrhotic patients has been the hepatic venous pressure gradient (HVPG)[6]. HVPG has a greater discriminative ability to predict clinical decompensation in patients with compensated cirrhosis than either the model for end-stage liver disease (MELD) or Child-Pugh score. Research shows that patients with a HVPG < 10 mmHg have a 90% probability of not developing clinical decompensation in a median follow-up of 4 years[6]. However, HVPG measurement is invasive, requires specialized healthcare personnel, and is often unavailable in many healthcare systems. The appearance of noninvasive tests, most notably, transient elastography, has provided a staging tool for prognostic markers of portal hypertension[7]. Recently, Baveno VII criteria were developed using transient elastography for liver stiffness measurements and platelet counts to define clinically significant portal hypertension and prognosis, risk stratification, and indication to start beta-blocker therapy in compensated advanced chronic liver disease and compensated cirrhosis patients[8]. Within a median follow-up of 40 mo, 7.2% of the 1159 compensated advanced chronic liver disease and compensated cirrhosis patients developed an initial decompensation event[8].

Well-known prognostic scoring systems that are currently used such as the MELD score and Child-Pugh score were primarily established to predict mortality in patients with cirrhosis. The Child-Pugh score was originally developed to assess the survival of cirrhotic patients undergoing shunt surgery to relieve portal hypertension in order to treat variceal bleeding[9,10]. The MELD score was developed to more precisely evaluate 3-mo mortality for patients with cirrhosis in order to prioritize liver donor allocation[11]. The MELD score is considered more reproducible than the Child-Pugh score because it does not include subjective variables such as ascites and encephalopathy. However, the MELD score has not been shown to be superior to the Child-Pugh score in terms of predictive accuracy in different cirrhotic populations[12].

Many studies have attempted to evaluate or develop a prognostic scoring system for predicting the risk of decompensation in a patient with compensated cirrhosis based on clinical and laboratory parameters. Well-known scoring systems such as MELD, Child-Pugh, Fibrosis-4 (FIB-4) scores and newly developed scoring system such as albumin-bilirubin FIB-4 (ALBI-FIB4) score which combine the ALBI score and FIB-4 score were evaluated for predicting the risk of decompensation in a patient with compensated cirrhosis. Prior studies show that the ALBI-FIB4 score can identify a high-risk patient more accurately than MELD, Child-Pugh and FIB-4 scores[13-15].

The ALBI score was recently created and validated to specifically assess hepatocellular carcinoma (HCC) liver functional reserve for predicting survival of HCC patients receiving various treatment modalities[16]. The ALBI grade was calculated using albumin and bilirubin levels. Its application has been increasingly expanded to chronic liver disease in general and has proven remarkably accurate in terms of prognosis[17]. Many publications have shown that the ALBI score is highly prognostic in cirrhotic patients and has shown the ability to correlate to HVPG levels[18], predicting the presence of gastroesophageal varices and stratifying bleeding risk[19], and severe portopulmonary hypertension[20].

Since the utility of ALBI score in predicting decompensation risk in patients with compensated cirrhosis has yet been fully investigated, we aimed to evaluate the ALBI score's ability to identify decompensation risk at 3 years follow-up in patients with compensated cirrhosis.

MATERIALS AND METHODS

Patients with compensated cirrhosis receiving care at King Chulalongkorn Memorial Hospital from January 2016 to December 2020 were enrolled retrospectively. The diagnosis of cirrhosis was made by imaging with ultrasonography, multiphasic contrast-enhanced computed tomography, or gadoxetic acid-enhanced magnetic resonance imaging. Patients with missing data, HCC at baseline, or a history of hepatic decompensation at the time of diagnosis were excluded. Baseline characteristics of patients including age, sex, and etiologies of cirrhosis were obtained from medical records. Laboratory data including serum creatinine, albumin, bilirubin, aspartate transaminase (AST), alanine transaminase (ALT), platelets, and international normalized ratio (INR) were collected.

Decompensation events, defined as ascites development, variceal bleeding, or grade 3 or 4 hepatic encephalopathy, were ascertained by clinicians in charge of their care and supported with either endoscopy reports, abdominal imaging, or medical reports. Time to decompensation was calculated from date of study entry until date of first recorded decompensation.

The ALBI score at baseline was calculated using the equation (log10 bilirubin in μmol/L × 0.66) + [albumin in g/L × (-0.085)][16] and validated to categorize decompensation risk into low-, middle-, and high-risk groups classified by ALBI grades 1, 2, and 3. The cut points of ALBI grades were similar to those in HCC patients: ALBI grade 1: ≤ -2.60; grade 2: > -2.60 but ≤ -1.39; grade 3: > -1.39.

Statistical analysis

For baseline characteristics, continuous variables with a normal distribution are presented as the mean ± SD, while those with a non-normal distribution are presented as median and interquartile range (IQR). The Mann-Whitney *U* test was used to compare differences in continuous variables while Fisher's exact test was used to assess for significant differences in binomial variables. Time to decompensation according to baseline ALBI grade and overall survival following the first decompensation were examined by Kaplan-Meier graphs and compared using the log-rank test. Cox proportional hazards analysis was used to identify ALBI score and other potential factors associated with decompensation. Significant factors identified in the univariate analysis were included in the multivariate analysis. The odds ratio (OR) calculated by logistic regression analysis provided estimates of the change in decompensation odds at each ALBI grade at baseline. The time-dependent area under the curve (tAUC) was estimated to evaluate the ability of each prognostic score to predict decompensation. A *P*-value of < 0.05 was considered statistically significant. All statistical analyses were performed using IBM SPSS Statistics version 22.

RESULTS

A total of 123 compensated cirrhotic patients were enrolled in our study. Table 1 summarizes their baseline characteristics. Mean age was 63.9 years (SD: 12.3), and 72 (58.5%) patients were male. Mean body mass index was 24.5 kg/m^2 (SD: 3.7). Viral hepatitis B was the most common etiology of cirrhosis (n = 43, 35%), followed by viral hepatitis C (n = 30, 24.4%), nonalcoholic steatohepatitis (NASH) (n = 29, 23.6%), alcohol liver disease (n = 19, 15.4%), and autoimmune hepatitis (n = 2, 1.6%). All patients with viral hepatitis B or viral hepatitis C received antiviral treatment with a sustained virological response. For patients with NASH, 17 (58.6%) patients had diabetes mellitus and 15 (51.7%) patients were obese. At baseline, 113 (91.9%) patients had Child-Pugh class A with 91 (80.5%) and 22 (19.5%) patients having a Child-Pugh score of 5 and 6, respectively, and 10 (8.1%) had Child-Pugh class B. For ALBI grade at baseline, 64 (52%) patients had ALBI grade 1, 53 (43.1%) had ALBI grade 2, and 6 (4.9%) had ALBI grade 3. Median prognostic scores predicting first decompensation at baseline were: MELD score (8.7; IQR: 7.8-10.1), ALBI score (-2.63; IQR: -2.91 to -2.06), ALBI-FIB4 score (-2.79; IQR: -3.28 to -1.93), and FIB-4 score (3.2; IQR: 1.8-5.3).

Predictors of decompensation in patients with compensated cirrhosis

During a median follow-up of 36 (IQR: 35-36) mo, 17 (13.8%) patients developed an initial decompensation event within 3 years follow-up at a median time of 25 [95% confidence interval (CI): 17-31] mo. Events included variceal bleeding in eight (47%) patients, ascites in five (29.4%), and grade 3 or 4 hepatic encephalopathy in four (23.6%). Among the 17 patients who experienced decompensating events, the most common precipitants of hepatic decompensation were

gastrointestinal bleeding (n = 8, 47%), followed by infection (n = 1, 6%). However, in eight (47%) of the patients who developed decompensating events, no specific cause of decompensation could be identified. The eight patients who experienced variceal bleeding received a combination of endoscopic treatment, intravenous octreotide, and antibiotic prophylaxis. Treatment for ascites in the five affected patients involved a combination of spironolactone and furosemide, with one patient requiring abdominal paracentesis due to tense ascites. All the four patients with grade 3 or 4 hepatic encephalopathy were treated with lactulose. Additionally, the patient who experienced decompensation due to infection received intravenous antibiotic therapy. Overall survival following the first decompensation was 82.4% at 3 years. The median overall survival of patients who developed the first decompensation was 29.9 (95%CI: 23.7-36.0) mo.

In compensated cirrhotic patients who developed an initial decompensation, albumin, bilirubin, ALT, ALBI, MELD, ALBI-FIB4, and Child-Pugh scores were found to be associated with initial decompensation, with an hazard ratio (HR) of 0.10 (95%CI: 0.03-0.26, P < 0.001), 1.21 (95%CI: 1.02-1.43, P = 0.02), 1.01 (95%CI: 1.00-1.02, P = 0.01), 8.31 (95%CI: 3.48-19.85, P < 0.001), 1.11 (95%CI: 1.02-1.21, P = 0.01), 2.30 (95%CI: 1.60-3.31, P < 0.001), and 1.98 (95%CI: 1.15-3.39, P = 0.01), respectively. In the multivariate analysis, ALBI score remained independently associated with initial decompensation with an adjusted HR of 4.18 (95%CI: 1.40-12.53) (P = 0.01) (Table 2).

Performance of each prognostic score for predicting decompensation at 3-year follow-up

An analysis of decompensation risk at the 3-year follow-up demonstrated that ALBI score had an tAUC of 0.86 (95%CI: 0.78-0.92), which performed significantly better than ALBI-FIB4 (tAUC = 0.77), MELD (tAUC = 0.66), Child-Pugh (tAUC = 0.65), or FIB-4 scores (tAUC = 0.48) (P < 0.05 for all) (Table 3 and Figure 1).

Decompensation risk stratification based on ALBI grade

In patients who developed a decompensation event, the majority were in the middle-risk group (n = 12, 70.6%), two in low-risk group (11.8%), and three in high-risk group (17.6%) according to the ALBI grade (Table 4). Median baseline ALBI score in the decompensated cirrhosis group was significantly higher than that of the compensated cirrhosis group [-2.768 (-2.956 to -2.453) *vs* -2.007 (-2.533 to -1.537), P = 0.01]. The cumulative incidence of decompensation at 3 years was 3.1% in the low-risk group, 22.6% in the middle-risk group, and 50% in the high-risk group (P = 0.003 and P < 0.001, respectively) (Table 4). The OR for decompensation in patients in the high-risk and middle-risk groups was 23.33 (95%CI: 3.88-140.12, P = 0.001) and 7.83 (95%CI: 1.75-35.01, P = 0.007), respectively (Table 4). Patients in the high-risk group exhibited a significantly shorter time to the initial decompensation compared to those in both the middle-risk and low-risk groups [26.5 mo (95%CI: 18.5-34.5), 33.2 mo (95%CI: 31.5-35.1), and 35.5 mo (95%CI: 34.7-36.2), respectively (P < 0.001)] (Figure 2).

Regarding the etiology of liver disease within each decompensation risk group, viral hepatitis was found in a significantly higher number of patients within the low-risk group compared to the middle and high-risk groups, with 45 (61%), 24 (32.9%), and 4 (5.5%) patients, respectively (P = 0.02). However, there was no statistically significant difference in the prevalence of NASH, alcohol-related liver disease, or autoimmune hepatitis among the decompensation risk groups.

DISCUSSION

This study validated the ALBI score as an accurate prognostic tool to stratify patients with compensated cirrhosis for the risk of decompensation at the 3-year follow-up. The ALBI grade identified high-risk patients more effectively than either MELD, Child-Pugh, ALBI-FIB4, or FIB-4 score.

Novel scoring systems have been developed for prognostic stratification risk of decompensation among patients with compensated cirrhosis over a medium- or long-term follow-up period. One novel scoring system focusing on liver stiffness and measured by transient elastography, presence of gastroesophageal varices from endoscopic screening, albumin, and platelets, has shown excellent accuracy in predicting risk of decompensation at the 3-year follow-up with a tAUC of 0.89. This performance was significantly higher than that of ALBI-FIB-4, Baveno VII criteria, or MELD score. ALBI grade score maintained a tAUC of over 0.8 throughout the 5-year follow-up period[15]. Other novel scoring systems, which consisted of simple and routinely performed serum marker-based scores such as AST, ALT, albumin, bilirubin, and platelets, have also shown an effective ability to identify high-risk patients for the risk of decompensation. The tAUC ranged from 0.69-0.80 using these scoring systems, which was significantly higher than that of the MELD or Child-Pugh score[14,21].

The ALBI score was recently developed to assess liver functional reserve and prognosis among HCC patients[16]. It offers a simple, evidence-based, objective, and discriminatory method that has been extensively tested with an international cohort and enables more detailed prognostic classification than the Child-Pugh grade[16]. Due to the fact that ALBI is simple to calculate needing only albumin and bilirubin measures, application of ALBI has been increasingly extended to other chronic liver diseases including decompensation for liver cirrhosis[17]. Several studies reported that ALBI might be comparable to MELD for predicting short-term mortality, but better than MELD in predicting longer-term mortality in patients with decompensated cirrhosis[22-25]. Recently, one study that evaluated the correlation between the ALBI score and portal pressure in cirrhotic patients showed that ALBI had a better correlation with HVPG compared to MELD, Child-Pugh, FIB-4, and aminotransferase/platelet ratio index scores with a tAUC of 0.72 (P < 0.001)[18]. This study also showed that ALBI grade 3 was able to predict early mortality in patients with a MELD score lower than 14. Based on the pathophysiology of decompensated cirrhosis, which involves an elevation in portal pressure, it has been observed that when the HVPG surpasses 10 mmHg, it correlates with the occurrence of decompensation[26], Therefore, the ALBI score exhibits potential in predicting decompensation by virtue of its correlation with HVPG. However, this study had a higher

Table 2 Predictors of decompensation in patients with compensated cirrhosis

Variable	Univariate		Multivariate	
	Hazard ratio (95%CI)	*P* value	Adjusted hazard ratio (95%CI)	*P* value

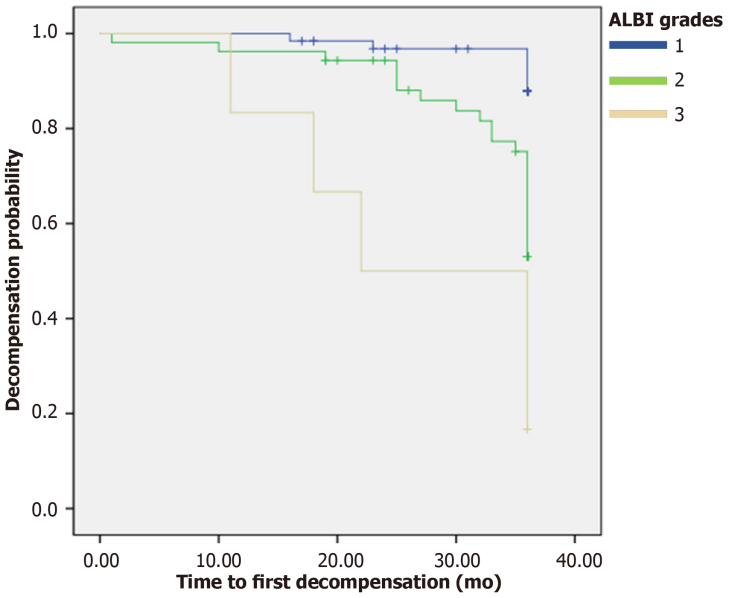
Table 4 Decompensation risk stratification based on albumin-bilirubin grade at baseline

ALBI grade	Decompensation at 3-yr (*n*, %)	*P* value	OR (95%CI)	*P* value
1	2/64 (3.1)	-	1.0 (reference)	-
2	12/53 (22.6)	0.003	7.83 (1.75-35.01)	0.007
3	3/6 (50)	< 0.001	23.33 (3.88-140.12)	0.001

ALBI: Albumin-bilirubin; OR: Odds ratio.



median MELD score at enrollment than our study (13 *vs* 8.7). By using ALBI grade 3 to predict decompensation stemming from increases in portal pressure, our study may need more patients with a higher MELD score at enrollment to evaluate the performance of ALBI to predict decompensation due to an increase in HVPG.

Our study found that the odds of decompensation in patients of the high-risk group was 23.33 times higher compared to patients in the lower risk group. The small sample size of the high-risk group and the high dispersion of ALBI score causes the precision of the OR in our study to be low. Thus, we need a greater number of high-risk patients for quantitative confirmation and to more precisely analyze the predictive performance of the high-risk group.

Figure 2 Time to decompensation using the albumin-bilirubin grade at baseline. ALBI: Albumin-bilirubin.

Although our study cohort was enrolled at a single-centered tertiary care hospital in Thailand, baseline characteristics of our patients were similar to those of cohorts used to validate other newly developed scoring systems in different countries and continents. In a cohort comprised of an Asian population[15], the most common etiology of cirrhosis was viral hepatitis B at 37.1% compared to 35% in our study cohort. Baseline MELD score and Child-Pugh score in our study cohort were similar to those of cohorts used to validate other scoring systems, where 90% of patients had Child-Pugh class A with a median MELD score ranging from 7-9[14,15,21]. The rate of decompensation in our study cohort, at 13.8%, was found to be lower compared to those of other cohorts utilizing different scoring systems, where the decompensation rates ranged between 19.3% and 26.9%[14,15,21]. This discrepancy in decompensation rates could potentially be attributed to a shorter median follow-up time in our cohort, which was 3 years, in contrast to the longer follow-up periods of 4.1 to 4.5 years observed in other cohorts[14,15,21].

Viral hepatitis accounted for 59% of patients in our cohort, all of whom received antiviral treatment resulting in a sustained virological response. Among patients with viral hepatitis, 70.3% were classified as belonging to the low-risk group. We observed a significant increase in the number of patients with viral hepatitis in the low-risk group compared to the middle and high-risk groups (P = 0.02). Consequently, 52% (n = 64) of patients in our cohort were categorized as

belonging to the low-risk group, while only 4.9% (n = 6) were classified as high-risk. This distribution can primarily be attributed to the prevalence of viral hepatitis as the underlying etiology of liver disease in our study population.

The strength of this study was that we provided the first evidence that the ALBI score accurately identified decompensation risk at the 3-year follow-up in patients with compensated cirrhosis. The ALBI score is a useful tool to help select high-risk patients to guide treatment to reduce the risk of decompensation. This study represents the ability of the ALBI score to assess liver function and liver disease progression with the advantage of being simple to calculate using only serum albumin and bilirubin levels.

This study has several limitations. First, the cohort in our study was retrospectively completely only at a single-center tertiary care hospital in Thailand. A large multi-center prospective cohort study is required to validate the ALBI score. Second, most of patients had Child-Pugh class A, suggesting that the number of patients with decompensated cirrhosis is relatively low. Thus, our findings may not be readily applicable to a population predominantly with advanced cirrhosis. Third, comparisons to other novel scoring systems that require predictors besides laboratory variables such as transient elastography and gastroesophageal varices from endoscopic findings, could not be performed due to the lack of this information in our study cohort. Inclusion of patients with prompt predictor variables to validate is required. Finally, additional data of the ALBI score including changes in annual ALBI grading or changing of ALBI grades between compensation and decompensation may give new information for the prediction of a decompensation event.

CONCLUSION

This study has documented the excellent performance of the ALBI score to accurately identify decompensation risk at the 3-year follow-up in patients with compensated cirrhosis. The ALBI score is a simple and ready-to-use tool to help clinicians monitor and make appropriate treatment decisions among patients with compensated cirrhosis.

ARTICLE HIGHLIGHTS

Research background

The albumin-bilirubin (ALBI) score is an index of liver function recently developed to assess prognosis in patients with hepatocellular carcinoma (HCC). It has been successfully applied to the prediction of survival in patients with non-malignant liver diseases of various etiologies.

Research motivation

The utility of ALBI score in predicting decompensation risk in patients with compensated cirrhosis has yet been fully investigated.

Research objectives

The objective of this study was to investigate the ALBI score for identifying decompensation risk at the 3-year follow-up in patients with compensated cirrhosis.

Research methods

One-hundred and twenty-three patients with compensated cirrhosis without HCC in King Chulalongkorn Memorial Hospital diagnosed by imaging were retrospectively enrolled from January 2016 to December 2020. The ALBI score was calculated and validated to classify decompensation risk into low-, middle-, and high-risk groups using three ALBI grade ranges (ALBI grade 1: ≤ -2.60; grade 2: > -2.60 but ≤ -1.39; grade 3: > -1.39). Decompensation events were defined as ascites development, variceal bleeding, or grade 3 or 4 hepatic encephalopathy.

Research results

Among 123 cirrhotic patients enrolled, 13.8% (n = 17) developed decompensating events at a median time of 25 [95% confidence interval (CI): 17-31] mo. Analysis of decompensation risk at 3 years showed that ALBI score had a time-dependent area under the curve (tAUC) of 0.86 (95%CI: 0.78-0.92) which was significantly better than that of ALBI-Fibrosis-4 (ALBI-FIB4) score (tAUC = 0.77), model for end-stage liver disease score (tAUC = 0.66), Child-Pugh score (tAUC = 0.65), or FIB-4 score (tAUC = 0.48) (P < 0.05 for all). The 3-year cumulative incidence of decompensation was 3.1%, 22.6% and 50% in the low-, middle-, and high-risk groups, respectively (P < 0.001). The odds ratio for decompensation in patients of the high-risk group was 23.33 (95%CI: 3.88-140.12, P = 0.001).

Research conclusions

The ALBI score accurately identifies decompensation risk at the 3-year follow-up in patients with compensated cirrhosis. Those patients with a high-risk grade of ALBI score showed a 23 times greater odds of decompensation.

Research perspectives

The ALBI score represents an outstanding non-invasive scoring system, enabling clinicians to make precise decisions regarding the monitoring and guidance of treatment for patients with compensated cirrhosis.

Abstract

BACKGROUND

Approximately 40% of colorectal cancer (CRC) cases are linked to Kirsten rat sarcoma viral oncogene homolog (*KRAS*) mutations. *KRAS* mutations are associated with poor CRC prognosis, especially *KRAS* codon 12 mutation, which is associated with metastasis and poorer survival. However, the clinicopathological characteristics and prognosis of *KRAS* codon 13 mutation in CRC remain unclear.

AIM

To evaluate the clinicopathological characteristics and prognostic value of codon-specific *KRAS* mutations, especially in codon 13.

METHODS

This retrospective, single-center, observational cohort study included patients who underwent surgery for stage I-III CRC between January 2009 and December 2019. Patients with *KRAS* mutation status confirmed by molecular pathology reports were included. The relationships between clinicopathological characteristics and individual codon-specific *KRAS* mutations were analyzed. Survival data were analyzed to identify codon-specific *KRAS* mutations as recurrence-related factors using the Cox proportional hazards regression model.

RESULTS

Among the 2203 patients, the incidence of *KRAS* codons 12, 13, and 61 mutations was 27.7%, 9.1%, and 1.3%, respectively. Both *KARS* codons 12 and 13 mutations showed a tendency to be associated with clinical characteristics, but only codon 12 was associated with pathological features, such as stage of primary tumor (T stage), lymph node involvement (N stage), vascular invasion, perineural invasion, tumor size, and microsatellite instability. *KRAS* codon 13 mutation showed no associations (77.2% *vs* 85.3%, $P = 0.159$), whereas codon 12 was associated with a lower 5-year recurrence-free survival rate (78.9% *vs* 75.5%, $P = 0.025$). In multivariable analysis, along with T and N stages and vascular and perineural invasion, only codon 12 (hazard ratio: 1.399; 95% confidence interval: 1.034-1.894; $P = 0.030$) among *KRAS* mutations was an independent risk factor for recurrence.

CONCLUSION

This study provides evidence that *KRAS* codon 13 mutation is less likely to serve as a prognostic biomarker than codon 12 mutation for CRC in a large-scale cohort.

Core Tip: Based on a large-scale cohort of patients with stage I-III colorectal cancer (CRC), Kirsten rat sarcoma viral oncogene homolog (*KRAS*) codon 13 mutation is less pathogenic and recurrent. Moreover, focusing on the biological effects of codon-specific *KRAS* mutations and minimizing interference with various medical therapies, previous *in vivo* studies demonstrating that *KRAS* codon 13 mutation is less aggressive were translated into clinical outcomes in this study. This may influence many oncologists to consult with patients on their prognosis after surgery. We propose that *KRAS* codon 13 mutation is less likely to serve as a prognostic factor of CRC, compared with codon 12.

INTRODUCTION

Kirsten rat sarcoma viral oncogene homolog (*KRAS*) is one of the downstream molecules of the epidermal growth factor receptor (EGFR) associated with cell proliferation, anti-apoptosis, and survival[1-3]. Abnormal activation of *KRAS*, a well-known oncogene, triggers uncontrolled tumor cell proliferation regardless of the initiating molecular signal from EGFR [4]. Mutations in *KRAS* promote the development of cancer in a variety of organs including the breast, prostate, lung, pancreas, colon, and rectum[1,2]. According to previous reports, approximately 40% of colorectal cancer (CRC) cases are linked to *KRAS* mutations[5-7], which occur more frequently in the proximal rather than in the distal colon[4,8,9]. Clinically, *KRAS* mutations are associated with resistance to anti-EGFR therapy and poor CRC prognosis[10,11].

CRC-related point mutations in *KRAS* occur at different codon locations. In most cases, *KRAS* mutations are detected in codon 12 or 13, whereas mutations in codon 61 or 146 have been reported only in a minority of patients with CRC[12]. Several clinical studies have indicated that *KRAS* codon 12 mutations are associated with metastasis and poor survival in advanced CRC[8,12-14]. *In-vitro* studies comparing cells with *KRAS* codon 12 and 13 mutations have demonstrated stronger transforming activity and resistance to apoptosis in cells with mutations in *KRAS* codon 12 than codon 13[15,16]. Most reports have concluded that *KRAS* codon 12 mutation is a poor prognostic factor following CRC resection. However, the oncological role of *KRAS* codon 13 mutation is controversial. *KRAS* codon 13 mutation has been linked to advanced-stage or lymph node metastasis and has been considered predictive of a higher likelihood of death in several studies[17,18]. In contrast, other investigators have shown no association between *KRAS* codon 13 mutations and tumor progression or CRC prognosis[4,19].

In addition to the controversial prognostic significance of *KRAS* codon 13 mutations, limited information is available regarding the clinical characteristics of codon-specific *KRAS* mutations in CRC. The incidence of codon-specific *KRAS* mutations other than those involving codon 12 (including codon 13) is low. Owing to the infrequency of *KRAS* abnormalities, the pathological features of codon-specific mutations at sites other than codon 12 remain unclear. Owing to the small cohort sizes of previous studies[4,8,12,14,20], the clinical roles of codon-specific *KRAS* mutations in CRC, including codons 12 and 13, are yet to be validated. Moreover, studies on the oncological effects of codon-specific *KRAS* mutations, particularly regarding abnormalities located within minor codons, are limited.

This study was designed to elucidate the clinicopathological characteristics associated with codon-specific *KRAS* mutations in CRC, including codons 12, 13, and 61. The main objective of this study was to determine whether *KRAS* codon 13 mutation could serve as a prognostic biomarker for CRC in a relatively large cohort of individuals.

MATERIALS AND METHODS

Patients

This retrospective observational cohort study was registered at ClinicalTrials.gov (NCT05657210) and reviewed 3144 patients who underwent surgery for CRC between January 2009 and December 2019, with available clinical data on recurrence and survival. All patients underwent routine colon or rectal resection and lymph node dissection according to the tumor location, with or without diverting ileostomies or colostomies. The surgical specimens were submitted to the laboratory for pathological evaluation. Patients with confirmed molecular pathology reports of *KRAS* mutation status were included, whereas those with incomplete data on *KRAS* mutations (n = 368) or microsatellite instability (MSI) status (n = 232) were excluded. Patients with dual or triple *KRAS* mutations (within more than one codon) from pathology reports (n = 2) were excluded. Additionally, to understand the biological importance and minimize the potential influence of systemic therapeutic factors on the prognosis of codon-specific *KRAS* mutations, we excluded patients with stage IV metastatic CRC (n = 339). Finally, data from 2203 eligible patients were collected separately for statistical analysis. This study was approved by the Institutional Review Board (IRB No. B-2203-742-101) of Seoul National University Bundang Hospital and the requirement for informed consent was waived.

Adjuvant/neoadjuvant therapy and follow-ups

All patients who underwent colorectal surgery for curative purposes were recommended adjuvant therapy according to the pathological stage of the cancer. Patients with pathological stage III and high-risk stage II colon cancer are recommended adjuvant chemotherapy. In rectal cancer, patients with pathological stages II and III are treated with adjuvant chemotherapy after surgery. However, in patients with clinical T4 or positive nodes without distant metastasis, preoperative chemoradiation therapy is recommended with long-course radiotherapy (dose of 5040 cGy of radiation over 5 wk; 28 fractions) combined with chemotherapy with 5-fluorouracil/Leucovorin or capecitabine.

According to the cancer monitoring protocol after curative surgery at our facility, patients were evaluated regularly one month after surgery, then every 3 mo for the first 2 years, every 6 mo for the next 3 years, and every 12 mo thereafter for a total of 5 years. Monitoring included measurements of serum carcinoembryonic antigen (CEA) levels every 3 mo; imaging modalities, including computed tomography (CT) (abdomen, pelvis, and chest) every 6 mo; and annual colonoscopy. Cancer recurrence was confirmed histologically or radiologically. The assigned research nurse constantly updated the data on recurrence and death. Information about deaths was double-checked by comparison with the database of the National Health Insurance Service, Korea, which lists the life and death records of Korean people. The registry data were constantly updated and managed by an assigned research nurse in the colorectal surgery department of our hospital.

Data collection

Basic patient clinical information [age, sex, height, weight, and American Society of Anesthesiologists (ASA) score] was collected. Cancer-related clinical characteristics such as primary tumor location, preoperative CEA level, and diverting stoma were included. Data on pathological features were collected based on pathology reports of surgical specimens. The following variables were statistically analyzed: T and N stages, tumor size, lymphatic invasion, vascular invasion, perineural invasion, number of harvested lymph nodes, number of metastatic lymph nodes, MSI status, and *KRAS* mutation status. Codon-specific *KRAS* mutation status was examined for codons 12, 13, and 61.

KRAS mutations were identified from formalin-fixed, paraffin-embedded cancerous tissue obtained from surgical specimens. After deoxyribonucleic acid (DNA) extraction from the tissue, the exons 2 and 3 of the *KRAS* gene were separately amplified by polymerase chain reaction (PCR) using optimized PCR reagents and primers. Codon-specific *KRAS* mutations were identified by pyrosequencing (PyroMark Q24 Mdx, QIAGEN, Hilden, Germany). MSI status was also evaluated using formalin-fixed tissues during surgery. PCR with five markers (*BAT26, BAT25, D5S346, D17S250,* and *D2S123*) followed by fragmentation assay (ABI-3130xl, Thermo Fisher Scientific, MA, United States) was performed to identify the MSI status.

Statistical analysis

Descriptive statistics were used to identify the basic clinicopathological characteristics of the patients, including MSI status frequency and *KRAS* mutations. The differences between wild-type and mutant *KRAS* as well as the mean values of continuous variables, were compared using either the independent *t*-test or the Mann-Whitney *U* test according to the results of the Kolmogorov-Smirnov test. Chi-squared or Fisher's exact tests were used to compare categorical variables. Overall survival (OS) and recurrence-free survival (RFS) were calculated from the date of surgery and compared using the Kaplan-Meier method and the log-rank test. For the analysis of risk factors for tumor recurrence, the Cox proportional hazards regression model was used, with the covariance input criterion set at $P < 0.1$. Patients were subdivided based on the primary tumor location (colon *vs* rectum) and MSI status [microsatellite stable (MSS)/MSI-low *versus* MSI-high]. Each subgroup was analyzed for recurrence-related factors using a Cox proportional hazards regression model. All statistical analyses were performed using the Statistical Package for the Social Sciences (SPSS), version 25.0, for Windows (SPSS, IBM). Descriptive results of continuous variables are expressed as mean ± SD. P value < 0.05 were considered statistically significant.

RESULTS

The present study included 2203 patients who underwent CRC surgery. The clinicopathological characteristics of the patients are shown in Table 1. In terms of MSI status, 1866 patients (84.7%) were identified as MSS, 153 (6.9%) as MSI-low, and 184 (8.4%) as MSI-high (Figure 1A). *KRAS* mutations were detected in 840 patients (38.1%) patients. The incidence of *KRAS* codons 12, 13, and 61 substitutions was 27.7%, 9.1%, and 1.3%, respectively (Figure 1B).

Among the clinical characteristics, female sex, lower ASA score, right-sided colon cancer, higher preoperative CEA levels, and low rates of diverting stoma formation were associated with *KRAS* mutations in codons 12, 13, and 61. Most pathological features, including T stage, N stage, tumor size, lymphatic invasion, perineural invasion, and number of harvested lymph nodes, were associated with *KRAS* mutations, along with molecular features such as MSI status (Table 2).

Analysis of the codon-specific *KRAS* mutational status revealed significant associations of both clinical and pathological characteristics with *KRAS* codon 12 mutations, including female sex, lower ASA score, right-sided colon cancer, preoperative CEA level above the normal range (≥ 5.0 ng/mL), T stage, N stage, MSI status, tumor size, vascular invasion, and perineural invasion. In contrast, only female sex, right-sided colon cancer, high preoperative CEA levels, diverting stoma formation, and no pathological features were significantly correlated with *KRAS* codon 13 mutations. Other than perineural invasion, no clinical characteristics or pathological features were associated with *KRAS* codon 61 mutations (Table 2).

At a mean ± SD follow-up duration of 29.7 mo ± 14.3 mo, and a median of 29 (0-85) months, recurrence within 5 years of curative surgery was observed in 205 (9.3%) among the 2203 patients. Five-year RFS (78.3% *vs* 77.4%, $P = 0.130$) and OS (89.0% *vs* 89.5%, $P = 0.971$) rates did not differ significantly between the wild-type and *KRAS* mutant CRC groups. Notably, the 5-year RFS for all codon-specific *KRAS* mutations was statistically different (wild-type, codon 12, and codon 13 mutations: 78.4%, 75.5%, and 85.3%, respectively; $P = 0.013$; Figure 2A), but the 5-year OS rates were comparable (wild-type, codon 12, and codon 13 mutations: 89.2%, 89.8%, and 86.9%, respectively; $P = 0.805$; Figure 2B). The 5-year RFS rate of the *KRAS* codon 12 mutation group was significantly lower than that of the patients without codon 12 mutations (78.9% *vs* 75.5%, $P = 0.025$; Figure 3A). The 5-year RFS rate of the *KRAS* codon 13 mutation group was higher than that of the patients without codon 13 mutations; however, the difference was not statistically significant (77.2% *vs* 85.3%, $P = 0.159$; Figure 3B). The RFS of the *KRAS* codon 61 mutation group was significantly lower than that of the patients without codon 61 mutations (78.2% *vs* 60.6%, $P = 0.039$; Figure 3C); however, all cases of recurrence occurred within 2 years of surgery.

In the univariate analysis of recurrence-related factors, cancer location (colon or rectum), preoperative CEA level, diverting stoma, T stage, N stage, MSI status, tumor size, lymphatic invasion, vascular invasion, perineural invasion, number of metastatic lymph nodes, and *KRAS* codon 12 mutations were associated with recurrence. In multivariable analysis, most pathological features, including higher T stage [hazard ratio (HR): 2.620; 95% confidence intervals (CI): 1.479-4.641; $P = 0.001$], higher N stage (HR: 2.001; 95%CI: 1.399-2.861; $P < 0.001$), vascular invasion (HR: 1.578; 95%CI: 1.164-2.139; $P = 0.003$), perineural invasion (HR: 1.684; 95%CI: 1.194-2.376; $P = 0.003$), and mutation of *KRAS* codon 12 (HR: 1.399; 95%CI: 1.034-1.894; $P = 0.030$) were identified as independent risk factors of recurrence in multivariable analysis. Among the clinical characteristics, only the presence of a diverting stoma (HR: 1.874; 95%CI: 1.260-2.787; $P = 0.002$) was independently correlated with recurrence (Table 3).

Tumor size (HR: 1.100; 95%CI: 1.011-1.198; $P = 0.027$), vascular invasion (HR: 1.981; 95%CI: 1.362-2.880; $P < 0.001$), perineural invasion (HR: 1.793; 95%CI: 1.200-2.679; $P = 0.004$), the presence of metastatic lymph nodes (HR: 1.048; 95%CI: 1.014-1.083; $P = 0.006$), and *KRAS* codon 12 mutation (HR: 1.496; 95%CI: 1.019-2.196; $P = 0.040$) were determined as independent risk factors for cancer recurrence when the primary tumor location was in the colon. Perineural invasion (HR: 3.358; 95%CI: 1.885-5.983; $P < 0.001$), and the presence of metastatic lymph nodes (HR: 1.095; 95%CI: 1.017-1.178; $P = 0.016$) were independently associated with cancer recurrence when the primary tumor was in the rectum. No codon-specific *KRAS* mutations were associated with recurrent rectal cancer (Table 4).

Among MSS/MSI-low CRC patients, tumor size (HR: 1.117; 95%CI: 1.038-1.202; $P = 0.003$), vascular invasion (HR: 1.740; 95%CI: 1.282-2.363; $P < 0.001$), perineural invasion (HR: 2.335; 95%CI: 1.663-3.279; $P < 0.001$), number of metastatic lymph nodes (HR: 1.050; 95%CI: 1.020-1.081; $P = 0.001$), and *KRAS* codon 12 mutation (HR: 1.467; 95%CI: 1.077-1.998; $P = 0.015$) were independent risk factors for cancer recurrence. In contrast, only a high preoperative CEA level (HR: 8.321; 95%CI: 1.387-49.920; $P = 0.020$) was associated with recurrence in MSI-high CRC. In cases of MSI-high CRC, the *KRAS* codon 12 mutation was statistically irrelevant regarding cancer recurrence, and there were no cases of recurrence during the study period among patients with *KRAS*-mutant CRC involving codons 13 and 61 (Table 5).

DISCUSSION

Among the 2203 patients who underwent curative surgery for stage I-III CRC, the incidence of codon-specific *KRAS* abnormalities was, respectively, 27.7%, 9.1%, and 1.3% for patients with *KRAS* codon 12, 13, and 61 mutations. Only 9.3% (205/2203) recurrences were observed during the 5-year follow-up period. To our knowledge, this study is based on the largest scaled cohort that has ever analyzed not only the oncological impact but also the clinicopathological characteristics of codon-specific *KRAS* mutations in patients with CRC. Most previous studies have reported similar results for *KRAS* codon 12 mutations, but not codon 13, in CRC as a poor oncological factor[4,8,12,14,20]. Despite the minimal oncological effects of minor *KRAS* mutations, such as in codon 61, the data obtained were sufficient to gain statistical power, supporting previous findings that *KRAS* codon 61 mutation is not associated with the clinicopathological features of CRC

[21]. An earlier study in a Japanese cohort also identified *KRAS* codon 12, but not codon 13, as an independent risk factor for tumor recurrence in stage I-III CRC. While their results supported the utility of *KRAS* codon 12 mutation as a poor prognostic factor, the correlation between codon-specific *KRAS* mutations and clinicopathological characteristics could not be validated because of the small sample size[20]. In the present study, we analyzed the largest sample group of patients, which provided not only results complementing earlier studies on *KRAS* mutations in CRC, but also additional information on correlations with clinicopathological characteristics and prognostic factors for individual codon-specific *KRAS* mutations.

In addition to resistance to anti-EGFR therapies, such as cetuximab and panitumumab[22], *KRAS* codon 12 mutation in CRC has been established as a poor prognostic factor of survival associated with aggressive behavior[23]. However, the role of *KRAS* codon 13 mutation in CRC remains unclear. Several studies have suggested that *KRAS* codon 13 mutations are associated with advanced-stage disease and metastasis of CRC and potentially serve as a predictive factor for a higher likelihood of death[17,18]. An earlier meta-analysis reported a lower overall survival in patients with *KRAS* codon 13 mutant CRC with no exposure to anti-EGFR therapy than in those treated with targeted therapy[24]. Other studies have demonstrated that *KRAS* codon 13 mutations are not associated with CRC progression[4,19]. Another meta-analysis of metastatic CRC with mutated *KRAS* codon 13 revealed a more significant response to cetuximab than that in patients with other codon-specific *KRAS* mutations[25]. To ascertain the correlation between codon-specific *KRAS* mutations and clinical oncological outcomes throughout the stages of CRC, therapeutic options such as chemotherapy, radiotherapy, and targeted therapy, along with inevitable resistance mechanisms, should be considered[5,26,27].

The survival analysis showed that CRC recurrence, but not overall survival, was associated with codon-specific *KRAS* mutations. Analysis of individual codons showed that *KRAS* codon 12 mutation is an independent risk factor for recurrence, while *KRAS* codon 13 and 61 mutations appeared to be statistically irrelevant. In earlier *in vivo* molecular biology studies, cells with *KRAS* codon 12 and 13 mutations displayed similar morphological changes, but only codon 12 mutants induced anchorage-independent growth, implying a lower aggressiveness of *KRAS* codon 13 mutations[15]. Another *in vitro* study reported that *KRAS* codon 12 mutant cells were more resistant to apoptosis and exhibited enhanced anti-apoptotic molecular signaling relative to codon 13 mutant cells, consistent with the finding that the codon 13 mutation is less aggressive[16]. These *in vivo* results were translated into the clinical outcomes of our study, demonstrating that *KRAS* codon 13 mutation is less aggressive and less likely to serve as a poor prognostic factor for CRC compared with *KRAS* codon 12 mutation.

Interestingly, the prognosis of *KRAS* codon 12 mutant CRC varied based on the primary tumor location in either the colon or rectum. The majority of experiments on tumor location were stratified into right- or left-sided colorectum based on the splenic flexure[28,29]. Even the definition of 'left-sided' differs among studies according to the involvement of the rectum[30,31]. Thus, in the present study, recurrence-related factors were analyzed by subgrouping the tumors into colon and rectum. In the subgroup of tumors located in the colon, patients with *KRAS* codon 12 mutations were estimated to be at a 1.5-fold higher risk of CRC recurrence than those without codon 12 mutations. In contrast, in the rectum, all codon-specific *KRAS* mutations were not linked to recurrence. To the best of our knowledge, this is the first study to investigate the oncological impact of codon-specific *KRAS* mutations based on tumor location (colon or rectum). Our findings support the theory that *KRAS* codon 12 mutation is a poor prognostic factor for colon cancer, but not for rectal cancer.

Previous studies have shown that the combination of *KRAS* mutations and MSI status is a potential prognostic factor in various stages of CRC [26,32-36]. In addition, since MSI status is associated with chemoresistance[37,38], the MSS/MSI-low and MSI-high subgroups were analyzed separately to eliminate the effect of MSI status on prognosis. Interestingly, in the MSS/MSI-low patient subgroup, only *KRAS* codon 12 mutation was statistically related to recurrence, whereas there was no association between codon-specific *KRAS* mutations and recurrence among MSI-high tumors. It is well known that poor oncological outcomes including disease-free and overall survival were reported within MSS tumors combined with *KRAS* mutation[33-36]. To the best of our knowledge, analysis results of codon-specific *KRAS* mutations in MSS/MSI-low and MSI-high tumors have never been reported. Based on our subgroup analysis, *KRAS* codon 12 mutations may be associated with the location of colon and MSS tumors, and not all CRC patients with *KRAS* codon 12 mutations have poor outcomes.

Clarifying the effects of codon-specific *KRAS* mutations on the prognosis of stage IV CRC is a complex issue[5,26,27,39]. A recent study on *KRAS* mutations in CRC with liver metastasis reported that *KRAS* codon 12 mutations were associated with poorer overall survival, while codon 13 was not; however, they also pointed out the exclusion of perioperative management such as anti-epidermal growth factor receptor agents[12]. Among the patients diagnosed with stage IV CRC who underwent surgery in our hospital during the period of the present study, 48.4% had *KRAS* mutations. However, only about half of them (53.1%) underwent surgery with curative intent, whereas the others underwent

palliative treatment. Additionally, there is a wide range of variations in the metastatic burden and forms of treatment for these patients. Therefore, in the present study, we excluded stage IV disease to focus on the biological importance and prognostic impact of codon-specific *KRAS* mutations in stage I-III CRC.

In two patients in our cohort, *KRAS* mutations were detected at two or more codon sites. The first patient was a 75-year-old male who underwent surgery for descending colon cancer and was pathologically diagnosed with stage III (pT3N1M0) colon cancer with codon 12 and 13 *KRAS* mutations. The second patient was a 60-year-old female who underwent surgery for sigmoid colon cancer diagnosed as stage I (pT1N0M0) with both codon 12 and 61 *KRAS* mutations. Both patients survived for more than 5 years after surgery with no recurrence or metastasis. In a previous

Figure 1 Incidence of microsatellite instability status and Kirsten rat sarcoma viral oncogene homolog mutations. A: Microsatellite instability status; B: Mutations of the Kirsten rat sarcoma viral oncogene homolog (*KRAS*) gene in relation to baseline characteristics. *KRAS*: Kirsten rat sarcoma viral oncogene homolog; MSS: Microsatellite stable; MSI: Microsatellite instability.

study, 12 patients with two or more codon mutations among 505 CRC *KRAS* mutation cases were reported but were eventually excluded from the analysis[21]. For the same reason, these two patients were excluded from the current study despite our intellectual curiosity.

The present study had several limitations. First, *BRAF* mutation, a biomarker related to the prognosis of CRC after surgery, was omitted from our analysis. According to previous studies on CRC biomarkers, both *BRAF* and MSI status have an important prognostic impact on recurrence and survival[34,40]. Unfortunately, a large amount of data was collected without knowledge of the *BRAF* mutation status because of alterations in routine molecular examinations by our facility during the study period. Second, since *KRAS* mutations were evaluated using postoperative specimens for both colon and rectal cancer, it may be audacious to conclude that the *KRAS* codon 12 mutation is a prognostic factor in rectal cancer. In advanced rectal cancer, trimodality therapy comprises chemoradiation followed by surgery, which takes at least 1-2 mo. This delay may affect the oncological outcome; therefore, the prognostic value of codon-specific *KRAS* mutations according to the primary tumor site should be carefully interpreted. Third, uncontacted patients without follow-up could have missing data on recurrence and survival despite constantly updating the clinical data by the

Figure 2 Comparative survival analysis between colorectal cancer samples with wild-type and Kirsten rat sarcoma viral oncogene homolog mutation. Blue lines indicate wild-type Kirsten rat sarcoma viral oncogene homolog (*KRAS*). Other lines represent codon-specific *KRAS* mutations of codon 12 (red), 13 (green), and 61 (orange). A: Recurrence-free survival; B: Overall survival rates were compared using a log-rank test. WT: Wild-type; MT: Mutation.

assigned research nurses in our department. The refusal to revisit after a few follow-ups could have produced missing data in our cohort, and double-checking with the National Health Insurance database might have reduced the error as much as possible. Unfortunately, these efforts could not separate other causes of death from cancer-related ones. Fourth, this study had a retrospective and single-center design, which could have led to selection bias. Despite this, the present study was based on a large-scale cohort with a relatively well-organized CRC registry of patients who underwent surgery, and is the largest cohort study ever that analyzed codon-specific KRAS mutations.

CONCLUSION

Most of the *KRAS* mutations in our study involved *KRAS* codons 12 and 13. Notably, *KRAS* codon 12 mutation was significantly associated with pathological features closely related to cancer recurrence and had a poor prognostic impact

Figure 3 Survival analysis of each codon-specific Kirsten rat sarcoma viral oncogene homolog mutation in colorectal cancer. Colored lines indicate codon-specific Kirsten rat sarcoma viral oncogene homolog (*KRAS*) mutations. A: The red line indicates the recurrence-free survival (RFS) of patients with *KRAS* codon 12 mutations; B: The green line indicates the RFS of patients with *KRAS* codon 13 mutations; C: The orange line indicates the RFS of patients with *KRAS* codon 61 mutations. MT: Mutation.

in patients with MSS tumors, or those located in the colon but not in the rectum. Given its irrelevance to pathological features and recurrence, we propose that *KRAS* codon 13 mutation is less likely to serve as a prognostic factor for CRC.

ARTICLE HIGHLIGHTS

Research background

Abnormal activation of Kirsten rat sarcoma viral oncogene homolog (*KRAS*), a well-known oncogene, triggers uncontrolled tumor cell proliferation. Approximately 40% of colorectal cancer (CRC) are linked to *KRAS* mutations. CRC-related point mutations in *KRAS* occur at different codon locations. *KRAS* codon 12 or 13 mutations are detected in a majority of CRC patients, whereas mutations in codon 61 or 146 have been reported only in a minority.

Research motivation

KRAS mutations are associated with poor CRC prognosis, especially *KRAS* codon 12 mutation, which is associated with metastasis and poorer survival. However, the clinicopathological characteristics and prognosis of *KRAS* codon 13 mutation in CRC remain controversial.

Research objectives

This study aimed to evaluate the clinicopathological characteristics and prognostic value of codon-specific *KRAS* mutations, especially in codon 13.

Research methods

This retrospective, single-center, observational cohort study included patients who underwent surgery for stage I-III CRC. The relationships between clinicopathological characteristics and individual codon-specific *KRAS* mutations were analyzed. By using the Cox proportional hazards regression model, survival analysis were performed to identify codon-specific *KRAS* mutations as recurrence-related factors.

Research results

Both *KARS* codons 12 and 13 mutations showed a tendency to be associated with clinical characteristics, but only codon 12 was associated with pathological features. *KRAS* codon 13 mutation showed no associations, whereas codon 12 was associated with a lower 5-year recurrence-free survival rate. In multivariable analysis, only codon 12 (HR: 1.399; 95% confidence interval: 1.034-1.894; P = 0.030) among *KRAS* mutations was an independent risk factor for recurrence. This may influence many oncologists to consult with patients on their prognosis after surgery.

Research conclusions

KRAS codon 12 mutation was significantly associated with pathological features closely related to cancer recurrence and had a poor prognostic impact in patients with microsatellite stable tumors, or those located in the colon but not in the rectum. On the other hand, *KRAS* codon 13 mutation is irrelevant to pathological features and recurrence, which consider less likely to serve as a prognostic factor for CRC.

Research perspectives

Focusing on the biological effects of codon-specific *KRAS* mutations, *KRAS* codon 13 mutation is less pathogenic and recurrent, Based on a large-scale cohort of patients with stage I-III CRC. This study's results may influence not only the prognosis but also the management of CRC patients individually. Therefore, the therapeutic usage and needs of codon-specific *KRAS* mutation in CRC should be considered in future studies.

ACKNOWLEDGEMENTS

The authors would like to thank the staff involved in the operating room and pathology laboratory of Seoul National University Bundang Hospital. The authors thank the Division of Statistics at the Medical Research Collaborating Center at Seoul National University Bundang Hospital for statistical analyses.

Abstract

BACKGROUND

Wilson disease (WD) is the most common genetic metabolic liver disease. Some studies have shown that comorbidities may have important effects on WD. Data on hepatitis B virus (HBV) infection in patients with WD are limited.

AIM

To investigate the prevalence and clinical impact of HBV infection in patients with WD.

METHODS

The clinical data of patients with WD were analyzed retrospectively, and the data of patients with concurrent WD and HBV infection were compared with those of patients with isolated WD.

RESULTS

Among a total of 915 WD patients recruited, the total prevalence of current and previous HBV infection was 2.1% [95% confidence interval (CI): 1.2%-3.0%] and 9.2% (95%CI: 7.3%-11.1%), respectively. The main finding of this study was the identification of 19 patients with concurrent WD and chronic hepatitis B (CHB) infection. The diagnosis of WD was missed in all but two patients with CHB infection. The mean delay in the diagnosis of WD in patients with concurrent WD and CHB infection was 32.5 mo, which was significantly longer than that in patients with isolated WD (10.5 mo). The rates of severe liver disease and mortality in patients with concurrent WD and CHB infection were significantly higher than those in patients with isolated WD (63.1% *vs* 19.3%, $P = 0.000$ and 36.8% *vs* 4.1%, $P < 0.001$, respectively). Binary logistic regression analysis revealed a significantly higher risk of severe liver disease at the diagnosis of WD in patients

with current HBV infection [odds ratio (OR) = 7.748; 95%CI: 2.890-20.774; *P* = 0.000)] or previous HBV infection (OR = 5.525; 95%CI: 3.159-8.739; *P* = 0.000) than in patients with isolated WD.

CONCLUSION

The total prevalence of current HBV infection in patients with WD was 2.1%. The diagnosis of WD in CHB patients is usually missed. HBV infection is an independent risk factor for severe liver disease in WD patients. The diagnosis of WD should be ruled out in some patients with CHB infection.

Key Words: Wilson disease; Hepatitis B virus; Chronic hepatitis B; Kayser-Fleischer ring; Ceruloplasmin; Concurrent Wilson disease and hepatitis B virus infection

Core Tip: Data on hepatitis B virus (HBV) infection in patients with Wilson disease (WD) are limited. This is the largest investigation of HBV infection in WD patients. The most important finding of this study was the identification of 19 patients with concurrent WD and chronic hepatitis B (CHB) infection. The total prevalence of current HBV infection in patients with WD was 2.1%. The diagnosis of WD in CHB patients is usually missed. HBV infection is an independent risk factor for severe liver disease in WD patients. The diagnosis of WD should be ruled out in some patients with CHB infection.

INTRODUCTION

Wilson disease (WD) is an autosomal recessive disorder of copper metabolism caused by a mutation of the gene coding for copper-transporting P-type ATPase (ATP7B). It is characterized by an excessive accumulation of copper in the liver and brain, and occurs in all ethnic groups with an average prevalence of 1:30000[1,2]. The WD gene was cloned in 1993[3-5], and more than 600 gene mutations have been identified[6]. Disease progression in WD may vary, ranging from fulminant WD to an insidious progression to cirrhosis over 20-30 years. Overall, available data in literature strongly suggest that genotypic variability alone does not explain the surprisingly heterogeneous presentation of WD[7]. Some studies have shown that comorbidities may have important effects on WD[8,9].

Currently, hepatitis B virus (HBV) infection is the common cause of liver disease worldwide, affecting 290 million individuals[10,11]. However, data on the prevalence of HBV infection in WD patients are limited and inconsistent. A study from Italy reported that after monitoring 60 WD patients for 20 years, no active HBV infection was found. Accordingly, they hypothesized that the excessive copper levels caused by WD could prevent HBV infection[12]. Contrarily, a study conducted in Taiwan in 1998 reported that the prevalence of HBV infection in 61 patients with WD was 16%, which was similar to that in the general population[13]. However, this finding is different from the previously published observations of Lau *et al*[14] in Hong Kong. Moreover, these studies were conducted many years ago and in small sample size populations; therefore, more studies involving larger sample size populations are needed. Furthermore, the influence of HBV infection on the diagnosis and clinical aspect of WD remains unclear. Given the paucity of studies in this field, this study was undertaken to investigate the prevalence of HBV infection in patients with WD and to explore the impact of HBV infection on the diagnosis, clinical aspect, treatment and prognosis of WD.

MATERIALS AND METHODS

Design overview, setting, and patients

We retrospectively analyzed the data of WD patients diagnosed between May 2003 and December 2020 at the Department of Infectious Diseases/Institute of Hepatology, the Second Xiangya Hospital, Central South University, China, which is the oldest and largest tertiary referral hospital in the Hunan Province. The Institute of Hepatology of this hospital is one of the first centers to carry out research on WD in China, and it offers services to WD patients in the whole province, neighboring provinces, and all over the country.

Patients with suspected WD underwent slit-lamp examination [to identify Kayser-Fleischer (KF) rings], neurological examination, measurement of serum ceruloplasmin levels, and determination of 24 h urinary copper excretion (before and after a penicillamine challenge). In cases where there were no contraindications, a liver biopsy was performed to confirm the presence of copper deposits, and in some other cases, gene analysis was performed. The diagnosis of WD was made based on a combination of clinical symptoms and laboratory tests, and on the WD scoring system published in 2003

[15,16]. WD was confirmed if the WD score was ≥ 4. The WD phenotypes were classified based on previously published criteria[16]. All WD patients were tested for HBV markers, including hepatitis B surface antigen (HBsAg), anti-HBs, hepatitis B e antigen (HBeAg), anti-HBe, and anti-HBc, at the time of diagnosis. Patients positive for HBsAg underwent further analysis to quantify HBV DNA levels. For each patient, all the data obtained at the time of diagnosis and at each follow-up time point were recorded in a medical record specifically designed for the WD study.

All the patients diagnosed with WD during the study period were eligible for inclusion. We excluded WD patients with other types of viral hepatitis (A, C, or E), autoimmune hepatitis, drug-induced liver disease, a history of alcohol intake > 30 g ethanol/day, and patients whose HBV markers were not tested.

Laboratory methods

Routine laboratory data were obtained using standard methods. HBV markers were tested using commercial diagnostic kits (ELISA; Shanghai Kehua Bioengineering Co. Ltd., Shanghai, China). HBV DNA levels were quantified using a commercial hepatitis B DNA quantitative fluorescence diagnostic kit (Sansure Biotech Inc, Changsha, Hunan Province, China). The lower limits of the HBV DNA quantification were 100 and 10 IU/mL before 2011 and after 2012, respectively. The KF rings were examined under a slit-lamp by an experienced ophthalmologist. Serum ceruloplasmin levels were measured using the nephelometric method (normal range, 210-500 mg/L; Beckman Coulter, Image® Immunochemistry System, Brea, CA, United States). Copper levels in serum, urine, and liver were determined as previously described[17]. Moreover, the ATP7B coding region and exon/intron boundaries were amplified and sequenced, as previously described [18].

Study outcomes

The study outcomes included the following: The proportion of patients with WD who had current HBV infection (positive for HBsAg); the proportion of those with previous HBV infection (negative for HBsAg but positive for anti-HBc, with or without anti-HBs); the rate of severe liver disease {defined as the proportion of WD patients who experienced severe decompensated cirrhosis [Child-Turcotte-Pugh (CTP) score ≥ 10] or acute-on-chronic liver failure (ACLF) in WD patients with HBV infection and those without HBV infection}. The CTP score was determined based on a previously described criterion[19,20]. ACLF was diagnosed according to a combination of consensus recommendations published by the Asian Pacific Association for the Study of the Liver (in 2009) and the guidelines for the diagnosis and treatment liver failure published by the Chinese Society of Hepatology in 2006[21,22]. The criteria were as follows: (1) Acute severe exacerbation of liver disease complicated within 4 wk by clinical ascites and/or encephalopathy, with previously diagnosed or undiagnosed chronic liver disease/cirrhosis; (2) Serum bilirubin ≥ 10 mg/d; and (3) Coagulopathy (international normalized ratio ≥ 1.5 or prothrombin activity < 40%).

Statistical analysis

Continuous data were expressed as mean ± SD and compared using the unpaired *t*-test or Mann-Whitney *U* test. Categorical variables were expressed as proportions and compared using the chi-squared test or Fishers exact test. We used a binary logistic regression model to evaluate the association between HBV infection and the risk of severe liver disease at the time of diagnosis of WD, the results were summarized as odds ratio (OR) with 95% confidence intervals (CI). All statistical analyses were performed using the software Statistical Packages for the Social sciences, SPSS version 20.0 Windows (IBM Corp., Armonk, NY, United States). Statistical significance was set at a two-tailed *P* value < 0.05.

RESULTS

During the study period, 973 patients were diagnosed with WD. Among them, 58 patients were excluded because of concurrent hepatitis E infection (*n* = 3), hepatitis C infection (*n* = 3), thalassemia (*n* = 3), and schistosomiasis japonica (*n* = 2), as well as insufficient length of hospital stay to perform the tests (*n* = 47). The remaining 915 patients with WD (532 men, 383 women; mean age, 20.2 ± 13.1 years; age range, 1-68 years) were included in our analysis. The patients resided in 25 provinces and belonged to 825 families. Moreover, 644 (70.4%), 218 (23.8%), 35 (3.8%), and 18 (2.0%) patients presented with only hepatic disease, neuropsychiatric and hepatic disease, only neuropsychiatric disease, and neither hepatic nor neurological disease, respectively. WD diagnosis was confirmed by a liver copper level ≥ 250 μg/g dry weight, the identification of two disease-causing mutations or homozygosity for a single disease-causing mutation, or both criteria in 320, 378, and 102 patients, respectively. All patients met the criteria of the WD scoring system, with 735 (80.3%), 87, and 93 patients having WD scores ≥ 6, 5, and 4, respectively.

Prevalence of HBV infection among patients with WD

Among the 915 patients with WD, 393 tested negative for all HBV markers (43.0%, 95%CI: 39.8%-46.15%) and 419 (45.8%) tested positive for immunization-related anti-HBs alone (45.8%, 95%CI: 42.5%-49.0%). The total prevalence of current and previous HBV infections were 2.1% (95%CI: 1.2%-3.0%) and 9.2% (95%CI: 7.3%-11.1%), respectively. Table 1 summarizes the prevalence of HBV infection stratified by sex and age. The prevalence of both current and previous HBV infections were significantly lower in women than in men and in patients aged ≤ 10 years than in those aged ≥ 11 years. The prevalence of previous HBV infection increased with age; however, the prevalence of current HBV infection remained low irrespective of age (Table 1).

Table 1 Prevalence of hepatitis B infection in patients with Wilson disease stratified by gender and age

	Number of patients	Negative for HBVM (%)	Anti-HBs(+) alone (%)	Prior HBV infection (%)	Current HBV infection (%)
Total group	915	393 (43.0)	419 (45.8)	84 (9.2)	19 (2.1)
Sex

41-65	85	29 (34.1)	26 (30.6)	28 (32.9)	2 (2.3)

HBVM: Hepatitis B virus markers; HBV: Hepatitis B virus.

Characteristics of WD patients with current HBV infection

During the study period, 19 WD patients with current HBV infection were consecutively diagnosed (men, 13; women, 6; mean age, 25.1 ± 13.3 years; age range, 11-64 years). Among them, six and ten patients were positive for HBeAg and HBV DNA, respectively. Moreover, 16 patients had a 1- to 30-year history of HBV-related liver disease, among whom there were three patients who had undergone splenectomy 3 years earlier and five patients who had been receiving a treatment based on lamivudine or entecavir for 2-24 mo. All patients met the WD criteria. More specifically, WD diagnosis was based on elevated liver copper levels, identification of two disease-causing mutations or homozygosity for a single disease-causing mutation, or both in 10, 6, and 5 patients, respectively. Furthermore, 16 patients had a WD score ≥ 6 (84.2%). However, among the patients, only two were suspected of having WD; 17 were referred to our hospital because of chronic hepatitis B (CHB) and had never been diagnosed of WD before.

There was a high variability in the clinical manifestations in patients with WD and current HBV infection. Five patients (cases 2, 6, 7, 11, and 19) presented with ACLF, characterized by severe jaundice, markedly decreased albumin levels, and prolonged prothrombin time (except for case 6, the remaining four patients among these patients died within 15-30 d following diagnosis). Two and eight patients presented with evidence of compensated and decompensated cirrhosis, respectively. Two patients presented with symptoms and signs of chronic liver disease, including hepatic enlargement or abnormal serum aminotransferases levels. Two patients were entirely asymptomatic, with normal serum aminotransferase and mild hepatomegaly or splenomegaly (Tables 2-4).

Characteristics of WD patients with previous HBV infection

During the study period, 84 patients with WD and previous HBV infection were consecutively diagnosed (men, 52; women, 32; mean age, 33.3 ± 15.9 years; age range, 3-68 years). Among them, 74 patients were positive for anti-HBs and anti-HBc, 10 patients were positive for anti-HBc only, and none of the patients had detectable levels of HBV DNA. The diagnosis of WD was based on elevated liver copper levels, identification of two disease-causing mutations, or both in 16, 47, and 8 patients, respectively. All patients met the criteria of the WD scoring system, with 70 patients having WD scores ≥ 6 (83.3%).

Comparison between patients with isolated WD and those with concurrent WD and HBV infection

There were no differences in sex, WD phenotype, copper metabolism parameters (such as the positivity rates of KF rings, urinary copper excretion, and hepatic copper content), and mean WD score distribution between patients with isolated WD and those with concurrent WD and current or previous HBV infection. Compared with patients with isolated WD, WD patients having HBV infection were significantly older and had significantly more severe liver function damage (including lower serum albumin levels, higher serum total bilirubin levels, and longer prothrombin time). The ACLF rates in WD patients with current and previous HBV infection were 26.3% and 13.1%, respectively, which were significantly higher than the rate in patients with isolated WD (4.5%, $P = 0.000$). The rates of severe decompensated liver cirrhosis in WD patients with current and previous HBV infection were 40.5% and 36.8%, respectively, and these were significantly higher than the rate in patients with isolated WD (14.8%; $P = 0.000$). The mortality rates during the first 60 d of follow-up following diagnosis were 36.8% and 15.5% in WD patients with current and previous HBV infection, respectively; these values were significantly higher than the rate in patients with isolated WD (4.1%, $P = 0.000$) (Table 5). Based on the binary logistic regression analysis model, after accounting for age, sex, and HBV infection and taking as reference the groups of patients with isolated WD, there was a significantly higher risk of severe liver disease at WD diagnosis in WD patients with current (OR = 7.748; 95%CI: 2.890-20.774; $P = 0.000$) or previous HBV infection (OR = 5.525; 95%CI: 3.159-8.739; $P = 0.000$).

Table 2 Characteristics of patients with Wilson disease and chronic hepatitis B: The demographic characteristics and parameters of hepatitis B virus infection

Case	Sex	Age (yr)	History of HBV (yr)	HBsAg	HBeAg	Anti-HBe	HBV DNA
1	Female	16	2	+	-	+	< 100

HBV: Hepatitis B virus; HBsAg: Hepatitis B surface antigen; HBeAg: Hepatitis B e antigen.

Treatment and outcomes of WD patients with current HBV infection

Five patients with concurrent WD and current HBV infection diagnosed before 2007 were treated with a chelator alone. The patients refused liver transplantation for financial reasons, rapidly deteriorated, and died from liver failure 2-4 wk after admission. Eight patients with detectable HBV DNA levels, diagnosed after 2008, were treated with a combination of penicillamine and nucleoside. Among them, two patients (cases 11 and 19) with ACLF rapidly deteriorated and died 1 mo after admission. Two patients (cases 6 and 8) were lost to follow-up. The condition of the remaining four patients gradually improved with treatment; however, one patient (case 5) developed hepatocellular carcinoma and died 7 mo after admission. Six patients with undetectable HBV DNA levels, diagnosed after 2008, were initially treated with a chelator only. Their condition gradually improved. However, three among them experienced HBV replication at 7-12 mo after therapy. Among the latter, there was one patient (case 10) with severe hepatitis reactivation and increased serum alanine aminotransferase (ALT; 930 IU/L), aspartate aminotransferase (AST; 790 IU/L), and HBV DNA (9.2×10^4 IU/mL) levels. This patient was treated with entecavir and penicillamine. However, within 2-3 mo after treatment initiation, HBV DNA levels were undetectable, and the AST and ALT levels normalized. The remaining three patients continued treatment with a chelator only. Currently, nine of the 14 patients diagnosed after 2008 have achieved a stable disease status after therapy and have resume their routine living activities (full-time work or study). WD patients with a previous HBV infection were treated using a chelator only. None of the patients experienced HBV reactivation during the study period.

DISCUSSION

To the best of our knowledge, the prevalence of HBV infection in patients with WD has been reported in only two small studies, and only two case studies involving single cases of concurrent WD and CHB infection have been reported in the English literature[23,24]. This is the largest investigation of HBV infection in WD patients, and it is helpful in understanding the true prevalence of HBV infection in WD patients and the impact of HBV infection on WD.

A national survey conducted in 1992 reported that the overall HBsAg prevalence in the Chinese population was 9.8%, declining to 7.2% in 2006[25,26]. In the present study, the total HBsAg prevalence was 2.1% in WD patients, a figure which is far lower than previously reported national HBsAg rates. However, this does not imply that the prevalence of

WD: Wilson disease; KF rings: Kayser-Fleischer rings; ND: Not done; PC: Penicillamine challenge; N: Negative; P: Positive.

HBV infection in patients with WD is lower than that in the general population. First, since the 1990s, the rate of HBV infection in China has been decreasing annually. The data of WD patients today should not be compared with those of the general population many years ago. Second, the age composition of WD patients is different from that of the general population. Among our patients, 41% were aged below 14 years; however, the HBV infection rate is known to be very low in this age group. Therefore, the average HBsAg positivity rate in WD patients should not be directly compared with that in the general population. To find studies with more comparable data, we conducted a literature search and found a large survey on HBV infection conducted in the Henan Province in 2015. This has been the largest survey on HBV infection in China during the recent years, and it involved a total of 13207 children and 16685 adults[27,28]. The Henan Province is located in the middle of China and is adjacent to Hunan. Its economic development level and HBV infection rate are similar to those in Hunan, making the data from Henan comparable with those from our study. We calculate the HBsAg positivity rates among different age groups of the WD patients, according to the age group divisions used in the Henan study (Table 6). The positivity rates of HBsAg in WD patients aged 1-4, 5-9 and 10-14 years were 0.0%, 0.0%, and 1.6%, respectively, which were similar to those in Henan children of the same age groups (0.5%, 0.7%, and 1.2%, respectively). The positivity rates of HBsAg in the 18-34, 35-54, and 55-74 years age groups of WD patients were 3.0%, 2.5%, and 5.3%, respectively, which were similar to those in the general population of the same age group (3.1%, 4.7%, and 5.1%, respectively). Our study indicates that the prevalence of HBV infection in WD patients is similar to that in the general population, and that WD patients are equally susceptible to HBV infection.

The most important finding of this study was the identification of 19 patients with concurrent WD and CHB infection. It is worth noting regarding the 19 patients that 17 were referred for CHB infection and not WD; thus, the WD was diagnosed at our hospital. There was a significant delay in the diagnosis of WD in these patients (mean delay = 32.5 and 10.5 mo in WD patients with concurrent CHB infection and in patients with isolated WD, respectively). Our results suggest that the diagnosis of WD may be missed in patients with CHB infection. Although a missed diagnosis of WD is not uncommon given the rarity of the disease[29-31], it is worth noting that many patients with CHB infection suffer from undiagnosed WD. The clinical manifestations of patients with concurrent CHB infection and WD are nonspecific and difficult to distinguish from those of patients with isolated CHB infection, unless the clinicians deliberately and diligently examine the patients to rule out WD. Therefore, more attention should be paid regarding the coexistence of WD in patients with CHB infection. WD should be considered and ruled out in some patients with CHB infection, especially in those with cirrhosis, hepatic failure, or poor response to antiviral therapies.

ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ALB: Albumin; TBIL: Total bilirubin; GGT: Gamma-glutamyl transpeptidase; ALP: Alkaline phosphatase; INR: International normalized ratio; ACLF: Acute-on-chronic liver failure; CTP: Child-Turcotte-Pugh.

Compared to patients with isolated WD, patients with concurrent WD and CHB infection had significantly lower serum albumin levels, higher serum total bilirubin levels, and longer prothrombin time. The mortality rates of WD patients with current and previous HBV infection during the first 60 d of follow-up (following diagnosis) were 36.8% and 15.5%, respectively; these rates were significantly higher than those of patients with isolated WD (4.1%, $P = 0.000$). The ACLF rates in WD patients with current and previous HBV infection were 26.3% and 13.1%, respectively, which were significantly higher than those in patients with isolated WD (4.5%, $P = 0.000$). Binary logistic regression analysis revealed that the risk of severe liver disease in WD patients with current and previous HBV infection was 7.7 and 5.3 times (respectively) higher than that in patients with isolated WD. Our findings indicate that HBV infection substantially affects the severity liver disease in patients with WD (Tables 5 and 7). The mechanism through which CHB causes severe liver injury could involve the induction, by viral hepatitis, of hepatic injury and copper accumulation, which could additively or synergistically aggravate WD-induced liver damage. Many studies have shown that HBsAg clearance usually results in good long-term prognosis[32]. However, an unexpected finding was that previous HBV infection also had a significant impact on the severity of liver disease in patients with WD. The reason for this may be that WD patients with a previous HBV infection usually have severe liver injury and cirrhosis (due to the joint action of HBV and WD) that occurred before the HBsAg clearance. After the HBsAg clearance, the severe liver injury and cirrhosis that had been formed usually persist[33,34]. Considering the serious impact of HBV infection on the clinical aspect of WD patients, current and previous HBV infections must be screened when evaluating the clinical aspect and prognosis of WD patients.

The strengths of this study are: (1) Considering the rarity of the disease, the sample size of the WD patient cohort was very large; (2) All patients were diagnosed in our department and met the diagnostic criteria; among them, 80% were confirmed by genetic examination and/or liver copper level determination; and (3) All data were prospectively collected by the authors and therefore were complete and reliable. The limitation of this study is the relatively small number of WD patients with concurrent CHB infection, as this might impede the detection of more significant differences between patients with isolated WD and those with co-existing CHB infection and WD.

In conclusion, our study indicates that the prevalence of HBV infection stratified by sex and age in patients with WD is similar to that in the general population. There was a significant delay in the diagnosis of WD in CHB patients. Furthermore, our findings suggest that HBV infection significantly affects the severity of liver disease in patients with WD. Therefore, more attention should be paid to patients suffering from concurrent WD and CHB infection. Although we found that previous HBV infection is an independent factor in the exacerbation of WD, its mechanism remains unknown.

Table 5 Factors associated with severe liver disease at the Wilson disease diagnosis

Factors (at diagnosis)	OR	95%CI	*P* value
Gender			
Male	1		
Female	1. 945	1.402-2.698	0.000
Age at diagnosis (yr)			
Group 1 (0-10)	1		
Group 2 (11-20)	1.766	1.145-2.723	0.010
Group 3 (21-30)	0.757	0.423-1.352	0.346
Group 4 (31-40)	1.178	0.646-2.148	0.594
Group 5 (41-65)	1.455	0.777-2.724	0.241
HBV infection			
WD alone	1		
WD with previous HBV	5.255	3.159-8.739	0.000
WD with current HBV	7.748	2.890-20.774	0.000

Severe liver disease is defined as patients with acute-on-chronic liver failure or a Child-Turcotte-Pugh score ≥ 10 at the Wilson disease diagnosis, HBV: Hepatitis B virus; WD: Wilson disease; OR: Odds ratio; CI: Confidence interval.

Table 6 Comparison of hepatitis B surface antigen positivity rates among different age groups between patients with Wilson disease and the general population

Age groups (yr)	Wilson disease		General population (Henan)		*P* value
	Number tested	HBsAg(+) (*n*, %)	Number tested	HBsAg(+) (*n*, %)	
1-4	40	0, 0.0	5474	26, 0.5	0.827
5-9	148	0, 0.0	4407	32, 0.7	0.625
10-14	191	3, 1.6	3376	40, 1.2	0.505
15-17	97	3, 3.1	Not done		
18-34	298	9, 3.0	6764	220, 3.1	0.825
35-54	122	3, 2.5	6777	275, 4.7	0.490
55-74	19	1, 5.3	3144	147, 5.1	0.599
Total	915	19, 2.1	29892	740, 2.5	0.510

HBsAg: Hepatitis B surface antigen.

Further research is needed to confirm this finding and to elucidate the mechanisms underlying the associations between WD progression and previous HBV infection or cryptogenic HBV infection.

CONCLUSION

This is the largest investigation of HBV infection in WD patients, and it is helpful in understanding the true prevalence of HBV infection in WD patients and the impact of HBV infection on WD.

Table 7 Comparison between Wilson disease patients alone and Wilson disease patients with hepatitis B virus infection

	WD alone (*n* = 812)	With previous HBV (*n* = 84)	With current HBV (*n* = 19)	P1	P2

ARTICLE HIGHLIGHTS

Research background

Although hepatitis B virus (HBV) infection is the most common cause of liver disease in China, the occurrence of HBV infection in Wilson disease (WD) patients and the clinical manifestations of concurrent WD and HBV infections have rarely been reported.

Research motivation

Our study suggests that both WD and HBV infections may coexist. The clinical symptoms of concurrent WD and HBV infections are difficult to distinguish from those of simple viral hepatitis. Therefore, the existence of WD may be hidden. The study of concurrent WD and HBV infection deserves careful consideration.

Research objectives

To investigate the incidence of HBV infection in patients with WD and to analyse how HBV infection affects WD.

Research methods

The clinical data of patients with WD were analyzed retrospectively, and the data of patients with concurrent WD and HBV infection were compared with those of patients with isolated WD. Considering the rarity of the disease, the sample size of the WD patient cohort was very large.

Research results

Among a total of 915 WD patients recruited, the total prevalence of current and previous HBV infection was 2.1% and 9.2% respectively. The main finding of this study was the identification of 19 patients with concurrent WD and chronic hepatitis B (CHB) infection. The mean delay in the diagnosis of WD in patients with concurrent WD and CHB infection was 32.5 mo, which was significantly longer than that in patients with isolated WD (10.5 mo). The rates of severe liver disease and mortality in patients with concurrent WD and CHB infection were significantly higher than those in patients with isolated WD (63.1% *vs* 19.3%), respectively. Binary logistic regression analysis revealed a significantly higher risk of severe liver disease at the diagnosis of WD in patients with current HBV infection or previous HBV infection than in patients with isolated WD.

Research conclusions

Our study indicates that the prevalence of HBV infection stratified by sex and age in patients with WD is similar to that in the general population. There was a significant delay in the diagnosis of WD in CHB patients. HBV infection is an independent risk factor for severe liver disease in WD patients. WD should be considered and excluded in some patients with CHB infection.

Research perspectives

As we found that previous HBV infection was an independent factor in the exacerbation of WD, the mechanism of which is speculative, future studies could further explore the mechanism by which WD is exacerbated by previous HBV infection and whether it is related to occult HBV infection.

Abstract

BACKGROUND

Interleukin-17 (IL-17) inhibitors are known to cause exacerbation or new onset of inflammatory bowel disease upon administration. However, few reports have described characteristic endoscopic and histopathologic findings, and no small intestinal lesions have been reported so far.

CASE SUMMARY

A woman in her 60s with psoriasis was administered ixekizumab (IXE), an anti-IL-17A antibody, for the treatment of psoriasis. Twenty months after commencing treatment, the patient visited our hospital because of persistent diarrhea. Blood tests performed at the time of the visit revealed severe inflammation, and colonoscopy revealed multiple round ulcers throughout the colon. A tissue biopsy of the ulcer revealed infiltration of inflammatory cells and granuloma-like findings in the submucosal layer. Capsule endoscopy revealed multiple jejunal erosions. After the withdrawal of IXE, the symptoms gradually improved, and ulcer reduction and scarring of the colon were endoscopically confirmed.

CONCLUSION

To the best of our knowledge, 17 reports have documented IL-17 inhibitor-induced entero-colitis with endoscopic images, endoscopic findings, and pathological characteristics, including the present case. Nine of these cases showed diffuse loss of vascular pattern, coarse mucosa/ulcer formation in the left colon, and endoscopic findings similar to those of ulcerative colitis. In the remaining eight cases, discontinuous erosions and ulcerations from the terminal ileum to the rectum were seen, with endoscopic findings similar to those of Crohn's disease. In this case, the findings were confirmed by capsule endoscopy, which has not been previously reported.

Core Tip: While Interleukin-17 (IL-17) inhibitors are effectively used in the treatment of psoriasis, psoriatic arthritis, and ankylosing spondylitis, they are ineffective in patients with Crohn's disease (CD) and can worsen their condition. To the best of our knowledge, we present capsule endoscopic images of IL-17 inhibitor-induced entero-colitis for the first time, suggesting that IL-17-induced inflammatory lesions may be distributed in the proximal small bowel, unlike CD lesions. We also compared the endoscopic and pathological features of IL-17 inhibitor-induced entero-colitis with those previously reported.

INTRODUCTION

Interleukin-17 (IL-17) inhibitors, such as ixekizumab (IXE) and secukinumab, are a class of molecular-targeted therapies used to treat psoriasis, psoriatic arthritis, and ankylosing spondylitis. IL-17 is a type of inflammatory cytokine produced by helper T cells and is known not only to induce local inflammation in the human body but also to be involved in host infection defense against pathogens in the skin and intestinal epithelium[1]. In patients with both psoriasis and Crohn's disease (CD), biopsy specimens of lesions express high levels of IL-17[2,3]. Therefore, IL-17 inhibitors were hypothesized to be effective in treating psoriasis and CD. However, IL-17 inhibitors are only effective in psoriasis; in patients with CD, IL-17 inhibitors are ineffective and exacerbate the disease[4]. Furthermore, in clinical trials of IL-17 inhibitors in inflammatory bowel disease (IBD), rheumatic diseases, and dermatological diseases, exacerbations or new-onset IBD have been reported at a frequency of 0.4%[5]. The mechanism underlying this seemingly contradictory adverse reaction remains unclear.

CASE PRESENTATION

Chief complaints

A woman in her 60s with diarrhea and anorexia.

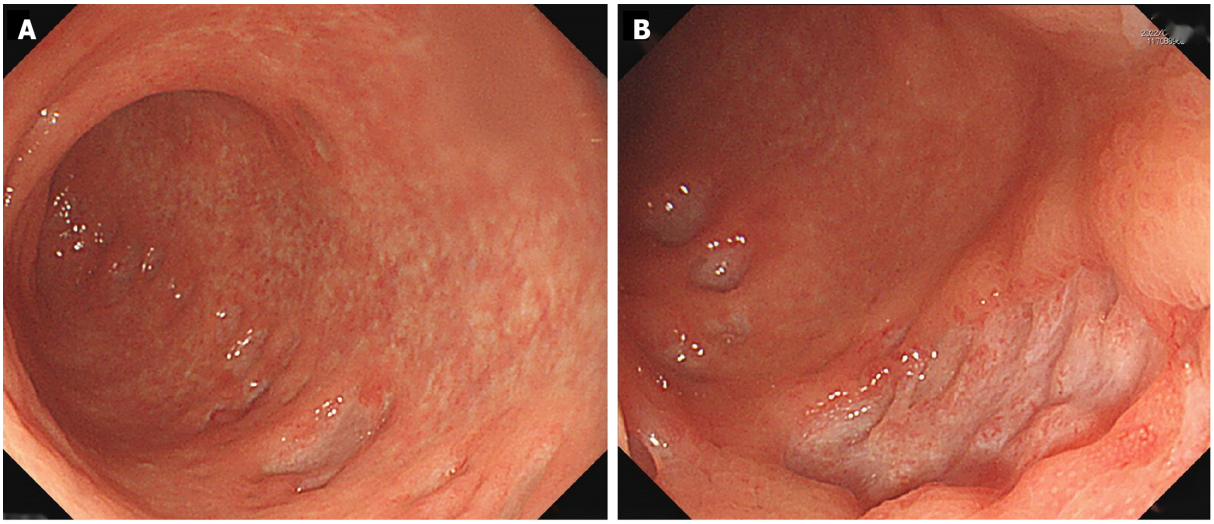
History of present illness

Gastrointestinal symptoms appeared 24 mo after IXE was started for the treatment of psoriasis.

History of past illness

The patient was diagnosed with psoriatic arthritis by her family physician and started on IXE. However, anorexia and diarrhea appeared 20 mo after treatment initiation. After conservative treatment by her family doctor, her symptoms did not improve, and she visited our hospital 24 mo after IXE initiation for a close examination and treatment.

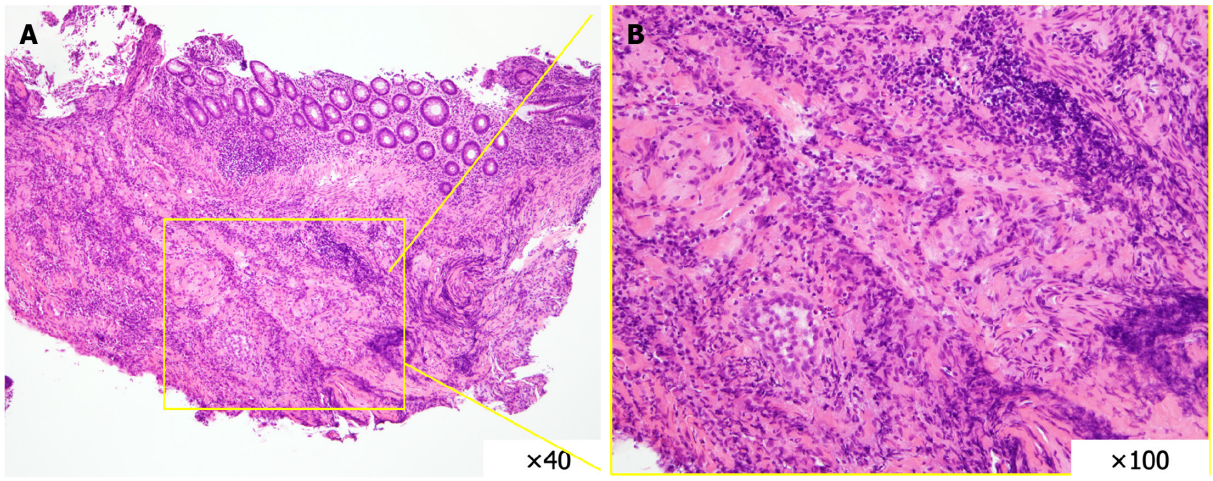
Personal and family history



Her medical history included type 1 diabetes at the age of 35 and hypothyroidism at the age of 50 years, each of which was medically managed by her family physician. No family history of IBD was reported; her father had gastric cancer, and her mother had diabetes. The injectable medications used were insulin and IXE for diabetes and psoriasis, respectively.

Physical examination

The patient was conscious but noticeably emaciated, appeared weakened, and walked with a limp. She had a body temperature of 36.0 ℃ and 114/52 mmHg of blood pressure. The skin of the upper extremities was fragile, with epidermal exfoliation of the right forearm. Multiple scars were observed on the upper arm and mild deformities and swelling of the hand joints.



Laboratory examinations

On admission, blood biochemistry tests showed anemia with a hemoglobin level of 10.4 g/dL and hypoalbuminemia with an albumin level of 2.8 g/dL. She was also dehydrated, with a blood urea nitrogen level of 28.2 mg/dL and

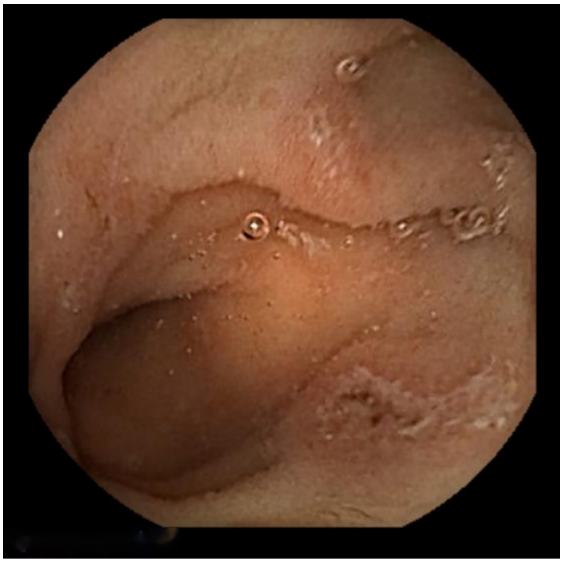
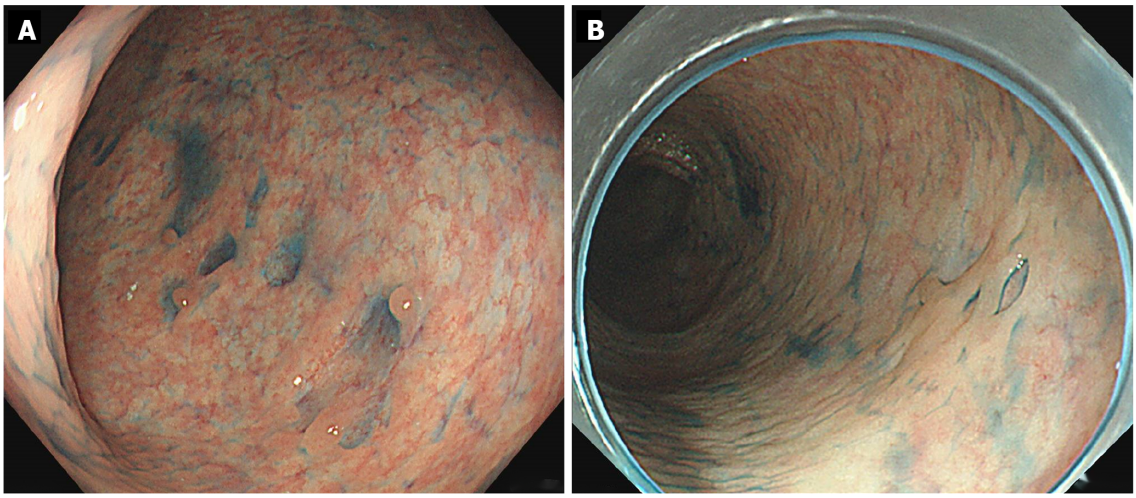
Figure 2 Pathological findings at admission. A: Hematoxylin-eosin (HE) stained specimen at 40 × magnification; B: HE stained specimen at 100 × magnification. The mucosa is erosive and infiltrated with inflammatory cells, predominantly lymphocytes. The submucosa shows granulomatous collagen fibers and fibroblast proliferation.



creatinine of 0.8 mg/dL and had high inflammation with a C-reactive protein level of 15.3 mg/dL. Leucine-rich alpha-2 glycoprotein level was 44.1 μg/mL and fecal calprotectin level was also high at 7357 mg/kg, suggesting strong intestinal inflammation.

Imaging examinations

Computed tomography revealed edematous wall thickening of the intestinal tract, continuous from the ascending colon to the rectum.



Further diagnosis workup

Colonoscopy revealed multiple round, punched-out ulcers with a longitudinal trend from the cecum to the rectum (Figure 1). The intervening mucosa of the ulcer was nearly normal, and the ulcer did not coincide with the mesenteric attachment. A biopsy of the ulcer showed mucosal erosion, lymphocyte-dominated inflammatory cell infiltration, and regenerative epithelial growth (Figure 2). Submucosal fibroblast and collagen fiber proliferation were also present-a granuloma-like finding similar to that of CD. An upper gastrointestinal endoscopy revealed reflux esophagitis and chronic gastritis. The gastric mucosa exhibited scattered erythema and erosions; however, no specific abnormalities were observed in the duodenum. Capsule endoscopy revealed multiple jejunal erosions (Figure 3). The erosions were scattered on the proximal side of the jejunum; each erosion was shallow and < 1 cm in size, and hematin adhesions were visible on the surface. However, stool culture and *Clostridioides difficile* toxin tests were negative, as were cytomegalovirus antigen

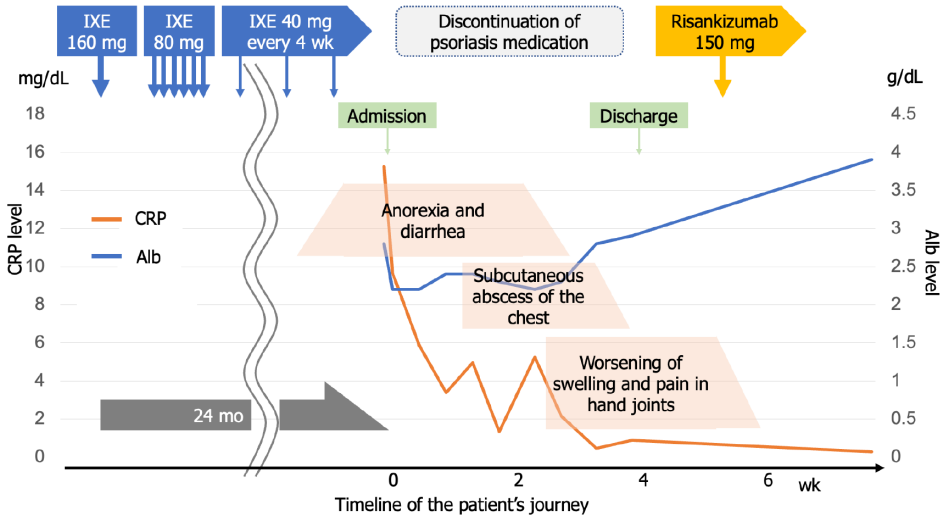
Figure 4 Colonoscopy findings after drug withdrawal. A: At three weeks, there is shrinkage of ulcers; B: At four months, all ulcers have disappeared and scarring is observed.



and polymerase chain reaction tests and interferon-gamma release assays.

FINAL DIAGNOSIS

As no episodes of irradiation or introduction of other new drugs occurred, we suspected drug-induced due to IXE.

TREATMENT

First, we monitored the patients' progress during drug withdrawal and intestinal rest after fasting. Multiple erosions in the upper jejunum were also observed; therefore, the patient commenced on bonoprazan fumarate, a potassium-competitive acid blocker. Due to the lack of improvement in symptoms, steroid administration was considered, and a gradual improvement in abdominal symptoms was observed. Three weeks after withdrawal, endoscopy revealed shrinkage of the ulcer and scarring (Figure 4A). Although her abdominal symptoms resolved, her skin and joint symptoms worsened, and she was started on Risankizumab by her family physician for psoriasis treatment.

DOI: 10.3748/wjg.v29.i32.4912 **Copyright** ©The Author(s) 2023.

Figure 5 Albumin (Alb) and C-reactive protein (CRP) levels plotted against the timeline of the patients' journey. The patient visited our hospital 24 mo after the start of the ixekizumab (IXE) administration. In the graph, CRP is shown on the left vertical axis and Alb on the right vertical axis. Abdominal symptoms gradually improved with IXE withdrawal, but skin and joint symptoms tended to worsen. After 4 wk of hospitalization, the patient was discharged home, as the endoscopy showed that the ulcer had healed and the patient was able to eat adequately. After discharge, risankizumab was introduced to control skin and joint symptoms, and the patients' condition stabilized. IXE: Ixekizumab; CRP: C-reactive protein; Alb: Albumin.

OUTCOME AND FOLLOW-UP

The abdominal, skin, and joint symptoms remained stable, and endoscopy performed 4 mo after IXE withdrawal confirmed the disappearance of all ulcers and scarring (Figure 4B). As abdominal symptoms improved, capsule endoscopy was not performed again due to a lack of patient consent, and bonoprazan fumaric acid was also discontinued. The clinical course from IXE initiation to the present is illustrated in Figure 5.

DISCUSSION

Drug-induced entero-colitis caused by IL-17 inhibitors is well known in the field of dermatology; however, very few reports have described all the endoscopic images, endoscopic features, and pathological characteristics of this condition. To the best of our knowledge, only 16 cases have been reported thus far[5-20]; we reviewed 17 cases, including our own (Table 1). Nine reported cases showed ulcerative colitis (UC)-like findings characterized by circumferential loss of vascular pattern and coarse mucosa/ulceration in the left colon, and eight reported cases with CD-like findings characterized by discontinuous erosion/ulceration from the terminal ileum to the rectum. All patients who presented with CD-like endoscopic findings after IXE administration had granulomas. In almost all the reports, the disease prognosis appeared to be good, with improvement in abdominal symptoms after the administration of steroids or molecularly targeted drugs. Only one patient with UC-like endoscopic findings after IXE administration required surgery because of a lack of improvement with drug administration.

Another case similar to CD with multiple ulcers of a similar round shape, as in the present case, has also been reported. However, in the present case, the ulcers tended to be longitudinally arranged and did not coincide with the mesenteric attachment side, which is atypical of CD. Furthermore, no reports have indicated improvement in abdominal symptoms with drug discontinuation alone, as in this case. In the present case, the various test results allowed us to promptly identify IXE as the suspected drug, and we surmised that excessive therapeutic intervention could be avoided. It should be noted that the introduction of a new drug may be necessary to manage the primary disease after drug withdrawal, and close communication with the dermatologist is important.

The association between psoriasis and IBD should be investigated in future studies. It has been reported that 1%-2% of patients with psoriasis have IBD[21]. Coincidentally-timed events during the initiation or administration of IL-17 inhibitors highlighted that IBD cannot be excluded.

CONCLUSION

At the very least, we should always check for IBD-related symptoms and family history before administering IL-17 inhibitors and suggest a screening colonoscopy if possible. Here, we report, for the first time, the capsule endoscopic findings of IL-17 inhibitor-induced entero-colitis. We also compared the endoscopic and pathological features of IL-17 inhibitor-induced entero-colitis with those previously reported. We believe that these findings will be useful for dermato-

Table 1 Patient background and endoscopic and pathological findings of entero-colitis after interleukin-17 administration

Year	Ref.	Age	Sex	Primary disease	Drug	Time to onset	IBD	Endoscopic findings	Pathological findings	Treatment and course
2017	Shiga *et al* [5]	56	M	Psoriasis	SEC	8 wk	CD	Longitudinal ulcer of the ileum and round ulcer of the esophagus	Nonspecific inflammatory cell infiltration	Improved with prednisolone 40 mg/d
2018	Philipose *et al*[6]	31	M	Psoriasis	IXE	3 mo	UC	Loss of vascular permeability throughout the sigmoid colon, erythematous coarse mucosa, ulcer	Lymphoplasmacytic infiltration	Mesalamine and methylprednisolone did not improve, but IFX administration improved
2018	Wang *et al* [7]	41	F	Psoriasis	SEC	1 wk	UC	Coarse mucosa and deep-burrowing ulceration of the entire sigmoid colon	Cryptitis, erosions, lymhoplasmacytic infiltration	Improved with methylprednisolone 40 mg/d and cyclosporine 2 mg/kg
2018	Ehrlich *et al*[8]	42	M	Ankylosing spondylitis	SEC	6 wk	UC	Deep ulcers and fragile mucosa of the transverse and sigmoid colon	Cryptitis, crypt abscess, loss of crypts	No improvement with solumedrol, improved after introduction of IFX
2019	Smith *et al* [9]	42	M	Psoriasis	IXE	12 wk	CD	Deep rounded punctate ulcers of the transverse and descending colon	Pancolitis with rare granuloma	No improvement with solumedrol, improved after introduction of IFX
2019	Uchida *et al*[10]	41	F	Psoriasis	SEC	4 mo	UC	Easy bleeding edematous mucosa of rectum to sigmoid colon, erosions, ulcers	High degree of inflammatory cell infiltration into the stroma and crypt abscess	Improved with mesalazine 2400 mg/d
2019	Achufusi *et al*[11]	39	M	Psoriasis	SEC	6 mo	UC	Ulceration of the splenic flexure, moderate to severe active colitis, ulceration at 30 cm, and active colitis in the rectum	Atrophy of the crypts, decreased goblet cells, cryptitis, crypt abscess	No improvement with steroids, improved after introduction of IFX
2019	Johnston and Veettil [12]	27	M	Ankylosing spondylitis	SEC	4 mo	UC	Multiple ulcers and moderate inflammation, sigmoid colon	Crypt abscess	No improvement with mesalazine and hydrocortisone, improvement with introduction of IFX
2019	Haidari *et al*[13]	69	M	Psoriatic arthritis	SEC	18 mo	CD	Multiple ulcers of the terminal ileum	Neutrophil infiltration of the epithelium of the crypts, no granuloma	Originally asymptomatic
2020	Nazarian *et al*[14]	48	F	Psoriasis	IXE	12 wk	CD	Mild erythema and punctate ulcerations in the terminal ileum	Active inflammation with the presence of granuloma	Improved with budesonide administration
2020	Varga *et al* [15]	52	M	Psoriasis	SEC	2 wk	UC	Loss of vascular permeability of sigmoid colon, ulcer	Lymphocytic infiltration of lamina propria, cryptitis, crypt abscess	Improved with prednisone 60 mg/d and mesalazine 3200 mg
2020	Gallego *et al*[16]	42	M	Psoriasis	IXE	2 wk	CD	Aphthous erosions and patchy ulcers of the rectum to cecum and terminal ileum	Cryptitis, crypt abscess, non-caseating granuloma	Improved with systemic corticosteroid administration
2021	Ali *et al*[20]	70	F	Psoriasis	SEC	1 mo	UC	Ulcerated and edematous mucosa in sigmoid colon	Acutely and chronically inflamed granulation tissue with extensive plasma cell infiltrate	Intravenous methylprednisolone
2022	Kakizoe *et al*[17]	65	M	Psoriasis	SEC	15 mo	CD	Deep ulcers of the cecum and transverse colon	No description	Hematochezia persisted after drug discontinuation and improved after induction of ADA
2022	Morosanu *et al*[19]	42	F	Psoriasis	IXE	1 wk	UC	Continuous congestive, friable rectal and colonic mucosa, spontan-	Neutrophilic inflammatory infiltrate disposed irregularly, edema and congestion, decrease of the crypts mucose-	Total colectomy with ileostoma and rectum preservation

								eously bleeding, deep and large ulcerations	cretion and crypt's abscesses	
2023	Khouri *et al*[18]	38	F	Psoriatic arthritis	SEC	1 mo	CD	Small ulcerations throughout the entire lumen of the terminal ileum and the cecum	Minimal architecture distortion in the large bowel mucosa, along with focal acute colitis	Initiated with prednisone and SEC was switched to IFX
2022	Our case	69	F	Psoriatic arthritis	IXE	21 mo	CD	Multiple round punctate ulcers throughout the colon. Capsule endoscopy shows multiple erosions in the jejunum	Inflammatory cell infiltrate, predominantly lymphocytes. Granulomatous fibroblasts and collagen fibers in the submucosa	Improvement only with drug discontinuation and fasting bowel rest

CD: Crohn's disease; SEC: Secukinumab; M: Male; F: Female; IBD: Inflammatory bowel disease; IXE: Ixekizumab; UC: Ulcerative colitis; ADA: Adalimumab.

logists and gastroenterologists in clinical practice.

ACKNOWLEDGEMENTS

The authors express their profound gratitude to the doctors, nurses, endoscopy staff, and medical personnel involved in the treatment of this patient.
