Editorial board member of *World Journal of Gastroenterology*, Kazuaki Inoue, MD, PhD, Professor, Departemnt of Gastroenterology, International University Health and Welfare Narita Hospital, 852 Hatakeda Narita, Chiba 286-8520, Japan. kazuaki-inoue@iuhw.ac.jp

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJG* as 4.3; IF without journal self cites: 4.1; 5-year IF: 5.3; Journal Citation Indicator: 0.82; Ranking: 32 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.3 and Scopus CiteScore rank 2022: Gastroenterology is 22/149.

Abstract

Glycogen storage diseases (GSDs), also referred to as glycogenoses, are inherited metabolic disorders of glycogen metabolism caused by deficiency of enzymes or transporters involved in the synthesis or degradation of glycogen leading to aberrant storage and/or utilization. The overall estimated GSD incidence is 1 case per 20000-43000 live births. There are over 20 types of GSD including the subtypes. This heterogeneous group of rare diseases represents inborn errors of carbohydrate metabolism and are classified based on the deficient enzyme and affected tissues. GSDs primarily affect liver or muscle or both as glycogen is particularly abundant in these tissues. However, besides liver and skeletal muscle, depending on the affected enzyme and its expression in various tissues, multiorgan involvement including heart, kidney and/or brain may be seen. Although GSDs share similar clinical features to some extent, there is a wide spectrum of clinical phenotypes. Currently, the goal of treatment is to maintain glucose homeostasis by dietary management and the use of uncooked cornstarch. In addition to nutritional interventions, pharmacological treatment, physical and supportive therapies, enzyme replacement therapy (ERT) and organ transplantation are other treatment approaches for both disease manifestations and long-term complications. The lack of a specific therapy for GSDs has prompted efforts to develop new treatment strategies like gene therapy. Since early diagnosis and aggressive treatment are related to better prognosis, physicians should be aware of these conditions and include GSDs in the differential diagnosis of patients with relevant manifestations including fasting hypoglycemia, hepatomegaly, hypertransaminasemia, hyperlipidemia, exercise intolerance, muscle cramps/pain, rhabdomyolysis, and muscle weakness. Here, we aim to provide a comprehensive review of GSDs. This review provides general characteristics of all types of GSDs with a focus on those with liver involvement.

Key Words: Glycogen storage disease; Liver; Muscle; Hypoglycemia

Core Tip: Glycogen storage diseases are multisystemic diseases that can present at any age. Primarily affected organs are liver and skeletal muscle, but heart, central nervous system, kidneys, intestines, and other organs may also be affected. As the initial presenting symptoms can occur in adulthood, it is a group of rare diseases that should be recognized and managed by not only pediatricians but also physicians taking care of adults.

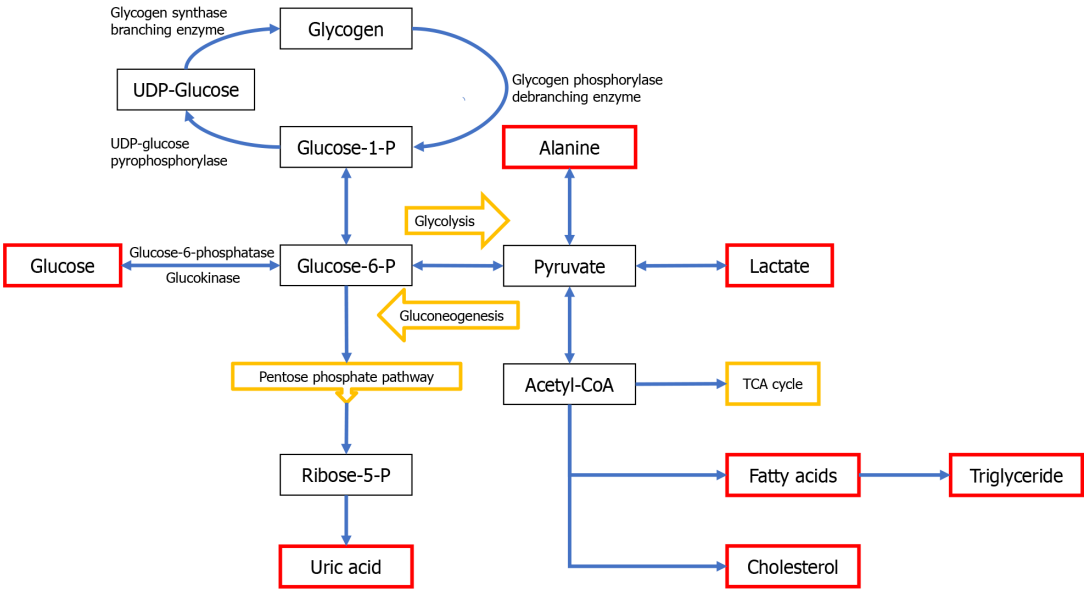
INTRODUCTION

Glycogen storage diseases (GSDs), also referred to as glycogenoses, are inherited metabolic disorders of glycogen metabolism caused by deficiency of enzymes or transporters involved in the synthesis or degradation of glycogen[1]. Disturbances in glycogen metabolism result in aberrant storage and/or utilization of glycogen. Both glycogen formation and breakdown involve several enzymatic reactions and are strictly dependent on hormone regulation (Figure 1)[2]. After a meal, insulin stimulates glycogen storage in muscle and liver by simultaneously promoting glycogen synthesis and inhibiting glycogen breakdown. During exercise or between meals, glucagon and cathecolamines inhibit glycogen synthesis while promoting glycogen breakdown[3]. Hepatic glycogen serves as a depot source of glucose to maintain euglycemia during fasting periods while glycogen in muscle provides glucose to produce necessary energy during high-intensity exertion.

GSDs are multisystemic diseases that can present at any age from the neonatal period to adulthood. The overall GSD incidence is approximately 1 case per 20000-43000 live births and 80% of hepatic GSDs are caused by types I, III, and IX[4,5]. This heterogeneous group of rare diseases represents inborn errors of carbohydrate metabolism and are classified based on the deficient enzyme and affected tissues (Table 1). GSDs primarily affect liver or muscle or both as glycogen is particularly abundant in these tissues. However, besides liver and skeletal muscle, depending on the affected enzyme and its expression in various tissues, multiorgan involvement including heart, kidney and/or brain may be seen[6]. Although GSDs share similar clinical features to some extent, there is a wide spectrum of clinical phenotypes. Hypoglycemia is the hallmark of hepatic GSDs. Hepatomegaly is also a cardinal manifestation of GSDs with liver involvement except for GSD-0. Muscle GSDs, on the other hand, may present with exercise intolerance, muscle cramps/pain, rhabdomyolysis, and muscle weakness and in the case of cardiac involvement, cardiomyopathy[7]. Since the initial presenting symptoms can occur in adulthood, it is a group of rare diseases that should be recognized and managed by not only pediatricians but also physicians taking care of adults. Being multisystemic diseases, GSDs are best managed by a cross-disciplinary approach to achieve good metabolic control, improve the quality of life of patients, and reduce morbidity and mortality[7]. It is recommended that a medical professional with expertise in treating such conditions (*e.g.*, a metabolic disorders specialist, a biochemical geneticist, an endocrinologist, or a hepatologist) should lead and coordinate the patient's care together with a metabolic dietician. Nephrologists, hematologists, genetic counselors, cardiologists, gastroenterologists, neurologists, physical therapists, social workers, and transplant specialists may also be required in the management of a GSD depending on the specific manifestations, complications, and type of the disease. In this article, we aim to update the review published in 2007[1] based on new data and provide a comprehensive review of GSDs. This review provides general characteristics of all types of GSDs with a focus on those with liver involvement.

GSDS INVOLVING LIVER

GSD-0; glycogen synthase deficiency



There are two types of glycogen synthase (GYS) encoded at different genetic loci; muscle GYS (*GYS1*; 19q13.33) and liver GYS (*GYS2*; 12p12.1)[8]. In 1963, GSD-0 was initially reported as glycogen synthetase deficiency in the liver[9]. GSD-0 is distinct from other hepatic GSDs due to the marked decrease in liver glycogen content, thereby making its classification questionable as a genuine GSD. However, since the disease exhibits a phenotype like that of the classic glycogenoses due to unavailability of glycogen during periods of fasting, it is classified as a GSD. GSD-0 is an autosomal recessive genetic disease[10]. The disease is caused by homozygous or compound heterozygous mutations in the *GYS2* gene which was mapped to 12p12.2 in 1994[11]. Liver GYS, the hepatic isoform, is responsible for catalyzing the

Table 1 Overview of glycogen storage diseases

GSD type (eponym)	OMIM#	Defective enzyme or transporter	Gene/inheritance	Gene location	Primary tissue involvement	Distinctive features
GSD-0	GSD-0a: 240600	Liver glycogen synthase	GYS2/AR	12p12.1	Liver	No hepatomegaly. Postprandial hyperglycemia, glycosuria, and hyperlactatemia. Extremely low amount of glycogen in liver tissue
	GSD-0b: 611556	Muscle glycogen synthase	GYS1/AR	19q13.33	Muscle	Cardiac involvement, risk of sudden cardiac arrest
GSD-I (von Gierke)	GSD-Ia: 232200	Glucose-6-phosphatase	G6PC/AR	17q.21	Liver	Coagulopathy, anemia, osteopenia, osteoporosis, renal dysfunction, HA, HCC
	GSD-Ib: 232220	Glucose-6-phosphatase transporter	SLC37A4/AR	11q23.3	Liver	Neutropenia, neutrophil dysfunction, recurrent infections, oral and intestinal mucosal ulcers, IBD, autoimmunity
GSD-II (Pompe)	232300	Acid α-glucosidase	GAA/AR	17q25.3	Muscle	Cardiomyopathy, infantile-onset form. Muscle weakness, late-onset form
Danon disease (formerly GSD-IIb)	300257	Lysosome-associated membrane protein-2	LAMP2/XLD	Xq24	Muscle	Skeletal and cardiac myopathy, arrhythmia, intellectual disability
GSD of heart	600858	AMP-activated protein kinase, γ-2 regulatory subunit	PRKAG2/AD	7q36.1	Muscle	Severe ventricular hypertrophy. Electrocardiographic preexcitation and conduction system disease. Premature sudden cardiac death (< 40 yr)
GSD of heart, lethal congenital	261740	AMP-activated protein kinase, γ-2 noncatalytic subunit	PRKAG2/AD	7q36.1	Muscle	Some mutations (R531Q, R384T) cause more severe phenotype. Fetal onset, extreme cardiomegaly, death in infancy
GSD-III (Cori/Forbes)	IIIa/IIIb: 232400	Glycogen debrancher enzyme	AGL/AR	1p21.2	IIIa: Liver + muscle; IIIb: Liver	Liver fibrosis, cirrhosis, HA, HCC (as a complication of cirrhosis). IIIa: Elevated CK, motor developmental delay, myopathy, cardiomyopathy
GSD-IV (Andersen)	232500	Glycogen branching enzyme	GBE1/AR	3p12.2	Liver	Classical hepatic form (rapidly progressive liver disease, HSM, cirrhosis, HCC). Non-progressive hepatic form. Neuromuscular presentation (perinatal, congenital, childhood and adult forms). Myopathy, cardiomyopathy, neuropathy, CNS involvement, APBD. Amylopectin aggregations in liver
GSD-V (McArdle)	232600	Muscle glycogen phosphorylase	PYGM/AR	11q13.1	Muscle	Exercise intolerance, muscle cramps, rhabdomyolysis, myoglobinuria, "second wind" phenomenon
GSD-VI (Hers)	232700	Liver glycogen phosphorylase	PYGL/AR	14q22.1	Liver	Phenotypic variability (overlap with GSD-IX). Severe hepatic involvement reported. Mild hypotonia and cardiopathy reported. Excessive glycogen accumulation with structurally normal glycogen in liver tissue. Enzyme deficiency in erythrocytes, leukocytes
GSD-VII (Tarui)	232800	Muscle phosphofructokinase	PFKM/AR	12q13.11	Muscle	Exertional myopathy, exercise intolerance, muscle cramps, hemolytic anemia. Rapidly progressive infantile form (multisystem involvement, seizures, cardiomyopathy)
GSD-IX	GSD-IXa1 (XLG-1): 306000	Phosphorylase kinase, α-subunit, liver	PHKA2/XLR	Xp22.13	Liver	The most common subtype. Symptomatic female carriers due to X chromosome inactivation. Clinical symptoms and laboratory abnormalities gradually disappear with age. Severe phenotypes reported
	GSD-IXb: 261750	Phosphorylase kinase, β-subunit	PHKB/AR	16q12.1	Liver	Marked accumulation of glycogen in both liver and muscle. Muscle symptoms are generally mild or absent
	GSD-IXc: 613027	Phosphorylase kinase, γ-subunit	PHKG2/AR	16p11.2	Liver	More severe phenotype with increased risk for liver fibrosis and cirrhosis
	GSD-IXd: 300559	Phosphorylase kinase, α-subunit, muscle	PHKA1/XLR	Xq13.1	Muscle	Muscle weakness and muscle cramps during exercise. Mostly in adults

GSD-X	261670	Muscle phosphoglycerate mutase	PGAM2/AR	7p13	Muscle	Exercise intolerance, muscle cramps and pain, rhabdomyolysis, myoglobinuria
Fanconi-Bickel syndrome (formerly GSD-XI)	227810	Glucose transporter 2	SLC2A2/AR	3q26.2	Liver	Hepatorenal involvement. Proximal renal tubular dysfunction. Osteoporosis/rickets. Different patterns of dysglycemia. Postprandial hyperglycemia and hypergalactosemia
GSD-XI	612933	Lactate dehydrogenase A	LDHA/AR	11p15.1	Muscle	Exertional myoglobinuria, easy fatigability, exercise induced myalgia, erythematosquamous skin lesions on the extensor surfaces of the extremities
GSD-XII	611881	Fructose-1,6-bisphosphate aldolase A	ALDOA/AR	16p11.2	Muscle	Rhabdomyolysis induced by fever and/or exercise, hemolytic anemia with or without myopathy or cognitive dysfunction
GSD-XIII	612932	Enolase 3 (β-enolase)	ENO3/AR	17p13.2	Muscle	Exercise intolerance, exercise induced myalgia, muscle weakness
GSD-XV	613507	Glycogenin-1	GYG1/AR	3q24	Muscle	Ventricular arrhythmogenic cardiomyopathy, progressive muscle weakness

GSD: Glycogen storage disease; HA: Hepatic adenoma; HCC: Hepatocellular carcinoma; AR: Autosomal recessive; XLR: X-linked recessive; XLD: X-linked dominant; CK: Creatinine kinase; CNS: Central nervous system; APBD: Adult polyglucosan body disease: IBD: Inflammatory bowel disease.

Figure 1 Simplified pathway of glycogen synthesis and degradation in hepatocytes. Glucose and glycogen convert into one another *via* synthesis or degradation (glycogenolysis) through various steps. The liver plays a central role in maintaining normoglycemia. During the fasting state, the liver maintains glucose homeostasis *via* a metabolic shift from synthesizing glycogen to endogenous glucose production by glycogenolysis and gluconeogenesis. Specific enzyme or transporter defects in these pathways are associated with clinical and biochemical manifestations including hepatomegaly, hypoglycemia, hyperlipidemia, hypertriglyceridemia, hyperlactatemia, and hyperuricemia. GSD: Glycogen storage disease; UDP-Glucose: Uridine diphosphate glucose; Glucose-1-P: Glucose 1-phosphate; Glucose-6-P: Glucose-6-phosphate; Acetyl-CoA: Acetyl coenzyme A; TCA: Tricarboxylic acid.

rate-limiting step in hepatic glycogen synthesis. GYS deficiency in liver leads to a marked reduction in hepatic glycogen stores. The inability to synthase glycogen inevitably leads to conversion of dietary carbohydrate to lactate rather than being stored as glycogen in the liver. Postprandial hyperglycemia, glycosuria, and lactic acidemia are replaced by ketotic hypoglycemia during fasting[12]. There is often ketosis after a routine overnight fast.

There are wide phenotypical variations[13]. Fasting hypoglycemia usually manifests in late infancy when overnight feedings are discontinued. Hypoglycemia typically occurs early in the morning prior to having breakfast. Hypoglycemia is responsible for the symptoms observed in GSD-0, which encompasses lethargy, pallor, nausea, vomiting, and, in some cases, seizures. Although some children may display developmental delay, most are neurologically normal. Some patients may remain asymptomatic or experience only mild symptoms[14]. Notably, liver enlargement is not a feature of GSD-0. GSD-0 is the only hepatic GSD that is not typically associated with hepatomegaly[15]. Short

stature and osteopenia are frequently observed in GSD-0, but other long-term complications commonly seen in other GSDs have not been documented[16]. Hyperglycemia and glycosuria are rare presentations in GSD-0 but may pose diagnostic difficulties when observed[17]. Postprandial hyperglycemia and glycosuria when taken together with a normal sized liver may mistakenly indicate early stages of diabetes. GSD-0 is underdiagnosed due to the lack of physical findings and milder phenotype[16,18].

Symptoms in GSD-0 are rapidly alleviated by frequent intake of protein-rich meals and bedtime consumption of uncooked cornstarch (UCCS), a slow-release glucose source. The preservation of gluconeogenesis and fatty acid oxidation pathways explains the less severe clinical course of GSD-0 compared to other types of hepatic GSDs. Increased protein intake during meals provides necessary substrates for gluconeogenesis and shows a protective effect against overweight/obesity and insulin resistance[19]. Extended periods of fasting can result in severe hyperketonemia and elevated plasma free fatty acid levels, which in turn leads to the inhibition of alanine release from skeletal muscle causing a reduction in the availability of gluconeogenic substrates, thereby exacerbating hypoglycemia [16]. While fasting is associated with hypoglycemia, hyperketonemia, and low alanine concentrations, feeding causes hyperglycemia and hyperlactatemia. Simple carbohydrates should be limited, and low-glycemic-index complex carbohydrates should be included in the diet to minimize postprandial hyperglycemia and hyperlactatemia. Patients are generally fed more frequently during the daytime to prevent hypoglycemia.

The administration of glucose or galactose to patients with GSD-0 results in elevated levels of serum lactate and lipids and can be used as a diagnostic test[2,17]. Traditional methods of diagnosis, such as liver biopsy to confirm extremely low hepatic glycogen levels and low to absent GYS activity, have been replaced by non-invasive mutation analysis of the *GYS2* gene.

Browner *et al*[20] discovered that muscle GYS, which is distinct from liver GYS, is expressed in both muscle and heart. The defect may be inherited or acquired. Enzyme activity is decreased in patients with type 2 diabetes. Muscle GYS deficiency causes cardiomyopathy and exercise intolerance in affected patients[8]. Histologic examination of muscle shows lack of glycogen and mitochondrial proliferation.

GSD-I; von Gierke disease; hepatorenal glycogenosis

The disease was first described by Gierke[21] in 1929 based on autopsy results showing excessive glycogen storage in the livers and kidneys of two patients. In 1952, Cori and Cori[22] discovered the deficiency of glucose-6-phosphatase (G6Pase) as the causative defect in patients with similar disease phenotype. After more than two decades, in 1978, Narisawa *et al*[23] described the deficiency of glucose-6-phosphate translocase (G6PT), the transporter protein of G6Pase complex (G6PC).

The deficiency of either G6Pase or G6PT activity causes GSD type I (GSD-I). The G6PT/G6PC functions as a multicomponent system and is responsible for glucose production by catalyzing the terminal step of both the glycogenolysis and gluconeogenesis pathways[24]. G6PT translocates G6P into the endoplasmic reticulum, wherein G6Pase converts G6P into free glucose and inorganic phosphate [25]. Two major subtypes of GSD-I are defined according to which part of the complex is defective. Deficiency of the catalytic subunit of G6Pase causes GSD-Ia while deficiency of G6PT activity results in GSD-Ib. Approximately 80% of cases with GSD-I are type Ia while the remaining 20% are type Ib. The presence of further subtypes (GSD-Ic and GSD-Id) is controversial. The majority, if not all, of typical cases of GSD-I are attributed to mutations in the genes encoding G6Pase and G6PT. Additionally, it has been noted that only two subtypes of GSD-I (namely, GSD-Ia and GSD-Ib) have been confirmed in clinical practice, and the existence of other forms of GSD-I requires further substantiation. Because both glycogenolysis and gluconeogenesis are affected due to inability in converting G6P to free glucose the main metabolic derangement of both subtypes is fasting hypoglycemia.

GSD-I is inherited in an autosomal recessive manner. The overall incidence of the disease is approximately 1:100000[26]. The estimated carrier rate in the general population is 1:150. The disease may be more prevalent in people of Ashkenazi Jewish (c.247C>T), Mexican-Hispanic (c.379_380dupTA) and Japanese heritage (c.648G>T) due to the increased frequency of mentioned pathogenic variants. The carrier frequency for the c.247C>T variant among Ashkenazi Jews has been reported to be as high as 1:63[27].

GSD-Ia; G6Pase deficiency

In 1952, Cori and Cori[22] identified the first specific enzyme deficiency associated with an inherited disorder through demonstration of G6Pase deficiency. Subsequently, in 1995, the gene that encodes the catalytic subunit of the G6PC was identified on chromosome 17q21[28]. Later, its molecular and biochemical characteristics were described in detail[29].

While some neonates may exhibit severe hypoglycemia and lactic acidosis, infants who do not receive any treatment typically present between 3-6 mo of age (at a median age of 6 mo) coinciding with prolonged feeding intervals, increased sleeping time through the night or onset of an intercurrent illness disrupting normal patterns of feeding[30]. The onset of symptoms can be soon after birth, and episodes typically remain unresponsive to glucagon therapy. Symptoms mainly include difficulties with feeding, tremors, pallor, excessive sweating, hyperventilation, cyanosis, apnea, irritability, seizures, somnolence, and cerebral edema/dysfunction, with exacerbations typically occurring in the morning or prior to feedings. Severe episodes of ketotic hypoglycemia, if untreated, may eventually lead to coma and

sudden infant death[31]. Older infants may exhibit certain physical characteristics, such as doll-like facies with full cheeks and relatively thin extremities along with frequent lethargy, difficulty in waking from sleep, tremors, an insatiable appetite, growth retardation, and a prominent abdomen resulting from pronounced enlargement of the liver and kidneys. In some cases, xanthomas may appear on extensor surfaces, such as the elbows, knees, or buttocks. During an infection, symptoms of severe hypoglycemia are more prevalent owing to diminished appetite and/or gastrointestinal symptoms (*e.g.*, vomiting and diarrhea) both preventing adequate oral intake. Delayed motor development can be seen but cognitive development is generally normal unless there is cerebral damage due to prolonged or recurrent neuroglycopenia[1,32].

Impaired platelet function, especially in individuals with inadequate metabolic control predisposes patients to nose bleeding[33]. Diminished glucose uptake into platelets due to chronic hypoglycemia and subsequent intracellular ATP deficiency have been proposed as potential causes of platelet dysfunction in GSD-Ia[34]. Additionally, decreased plasma concentration of von Willebrand factor antigen indicating an acquired von Willebrand disease was reported for patients with GSD-Ia[35]. In addition, epistaxis, easy bruising, menorrhagia, intrahepatic adenoma hemorrhage, and excessive bleeding during surgical procedures can also occur[36,37].

Patients with GSD-I have hypovitaminosis D despite adequate supplementation[38]. Low bone mineral density is a long-term complication of GSD-I particularly in those with poor metabolic control [39,40]. Osteoporosis may arise as a consequence of poor nutrition, chronic lactic acidosis and hypogonadism[41]. Anemia is a common complication in both subtypes of GSD-I with a reported prevalence ranging from 17% to 60% across different age groups[30]. The etiology of anemia in GSD-I is complex and involves various factors, including the restrictive nature of the diet, altered iron absorption due to excessive intake of UCCS, chronic lactic acidosis, chronic kidney disease, bleeding diathesis, chronic illness, suboptimal metabolic control, hepatic adenomas, and inflammatory bowel disease. The prevalence and pathophysiology appear to differ in individuals with GSD-Ia and those with GSD-Ib. A multicenter study involving 202 subjects with GSD-I (Ia/Ib: 163/39 subjects) showed that anemia is more common in patients with GSD-Ib compared to GSD-Ia (71.8% *vs* 41.7%, respectively). In addition, the prevalence of severe anemia is also increased in GSD-Ib in comparison to patients with GSD-Ia (41% *vs* 4.9%, respectively)[42]. Severe anemia in GSD-Ia appears to be related to large hepatic adenomas, while in GSD-Ib it is often associated with enterocolitis[42]. Development of severe anemia during the course of the disease warrants further evaluation for hepatic adenomas and inflammatory bowel disease in GSD-Ia and GSD-Ib, respectively.

Patients diagnosed with GSD-Ia or GSD-Ib may experience intermittent diarrhea which seems to deteriorate with age[43]. Diarrhea was reported in 35% of the GSD-Ia and in 55% of the GSD-Ib patients [30]. However, the cause of diarrhea remains unknown. Intolerance to UCCS and inflammatory bowel disease are possible causes of diarrhea in this population. Inflammatory bowel disease is a well characterized feature in individuals with GSD-Ib. Neutropenia and impaired neutrophil function are the underlying causes of inflammatory bowel disease in GSD-Ib[44]. However, inflammatory bowel disease was also recently reported in adult patients with GSD-Ia as a new, long-term complication of the disease [45]. The prevalence of symptomatic inflammatory bowel disease in adults with GSD-Ia also seems to be higher than the general population[45]. The authors speculated that inflammatory bowel disease in GSD-Ia may be caused by chronic UCCS therapy, which could be altering the microbiota of the gastrointestinal tract leading to inflammation. More recently, very early onset inflammatory bowel disease was reported in a child with GSD-Ia at the age of 42 mo[46].

A notable finding among the majority of patients with this condition during childhood is growth retardation, while short stature is commonly observed in affected adults[5,47,48]. In the absence of effective treatment, a range of long-term complications may arise in individuals with GSD-I, including delayed puberty, liver adenomas, hepatocellular carcinoma, renal dysfunction, chronic kidney disease, chronic renal failure, urolithiasis, arterial and pulmonary hypertension, osteopenia/osteoporosis, polycystic ovary syndrome, and gout. Cognitive delay and epilepsy due to repeated or severe hypoglycemic events may occur[31]. Hyperlipidemia may cause xanthomas, pancreatitis, and cholelithiasis[30,49]. Acute pancreatitis may develop secondary to very high serum triglycerides in GSD-I and necessitate plasmapheresis[50].

Systemic metabolic perturbations and glycogen deposition in the kidneys result in glomerular and proximal and distal renal tubular injury. Renal manifestations may occur in childhood but often are not noticed without proper diagnostic work-up. The prevalence of renal involvement tends to rise as patients age[51]. Glomerular hyperfiltration, whose underlying mechanism is not yet fully understood, is typically the initial manifestation of renal involvement. Possible etiologies have been suggested including activation of the renin-angiotensin system, persistent oxidative stress, profibrotic cytokines such as transforming growth factor-β, and changes in energy reserves of renal tubular epithelial cells[52-54]. Glomerular hyperfiltration then progresses to microalbuminuria, proteinuria, glomerular scarring and interstitial fibrosis, and end-stage renal disease in adult patients[48,55]. Hypercalciuria and hypocitraturia due to proximal and distal tubular dysfunction cause nephrocalcinosis and/or urolithiasis[56,57]. This may increase the risk of urinary tract infections causing further renal parenchymal damage. Hypertension and hematuria are other findings[55,56]. Systemic hypertension may develop early in childhood but is seen more often in adults with GSD-I[58]. Renal cysts have also been described in

individuals with GSD-I[59]. Gout can develop due to persistent hyperuricemia as gouty attacks, gouty tophi, and kidney stones.

In GSD-Ia patients, various types of liver lesions, including hepatic adenoma, hepatocellular carcinoma, hepatoblastoma, focal fatty infiltration, focal fatty sparing, peliosis hepatis, and focal nodular hyperplasia have been reported, with hepatic adenomas being the most prevalent among them[37]. The prevalence of hepatic adenomas was reported to vary between 22% to 75%, and they usually manifest during or after puberty, particularly in the second or third decade of life. The median age of adenoma presentation is 15 years[30]. Although the prevalence of hepatic adenomas increases with age in GSD-I, they may be seen in younger children[60]. Progression in size and/or number of hepatic adenomas occurs in half of patients[30]. Inadequate metabolic control appears to play a central role in hepatic adenoma formation. The degree of hyperlipidemia is associated with development of hepatic adenomas [61]. However, the pathophysiological mechanisms are yet to be fully understood and factors other than metabolic control may also be responsible for adenoma formation. In a recent study by Cho *et al*[62], in addition to mitochondrial dysfunction and metabolic alterations caused by G6Pase deficiency, persistent autophagy impairment and activation of multiple tumor-promoting pathways were reported as contributing factors to hepatic adenoma/hepatocellular carcinoma development in GSD-I. Chromosomal and genetic alterations may also play a role in hepatocellular carcinoma associated with GSD-I[63]. Hepatic adenomas have the potential to transform into hepatocellular carcinoma over an extended period, with reports of malignant transformation occurring as long as 28 years after initial diagnosis[64,65]. A rapid increase in size or number of adenomas is associated with an increased risk of adenoma to hepatocellular carcinoma transformation and should be evaluated carefully.

The link between GSD-I and risk for cardiovascular disease is controversial. Although GSD-Ia patients have elevated levels of triglycerides, very low density lipoprotein and low density lipoprotein, the occurrence of endothelial vascular dysfunction and atherosclerosis is uncommon. It has been suggested that the increased serum levels of apoE may offset the elevated risk of atherosclerosis associated with dyslipidemia[66]. Moreover, the reduced von Willebrand factor antigen and density of individual oligomers found in 60% of GSD-Ia patients may also contribute to protection against vascular complications[35]. In addition, an increase in serum levels of antioxidative factors may contribute as a protective mechanism[67,68]. There are conflicting data regarding whether patients with GSD-I are at increased risk for atherosclerosis[69,70]. Pulmonary hypertension is a rare long-term complication of GSD-I with few cases reported. Patients with a concomitant predisposing condition for pulmonary arterial hypertension are at increased risk[37].

The main neurological impact of GSD is related to hypoglycemia. Patients with GSD-I may suffer from brain damage, which may be caused by recurrent severe hypoglycemia[71]. Studies have found a significant correlation between the frequency of hospital admissions for hypoglycemia and abnormalities in both performance ability tests and brainstem auditory evoked potentials. In addition, electroencephalography abnormalities were found to be correlated with dietary compliance. The magnetic resonance imaging abnormalities observed in GSD-I patients were the dilatation of occipital horns and/or hyperintensity of subcortical white matter in the occipital lobes[71]. Brain imaging abnormalities were more frequent among GSD-I patients with early symptom onset, frequent and longer hospital admissions, and poor metabolic control including elevated levels of uric acid, lactate, and triglyceride[32,72].

Some females may have polycystic ovaries and irregular menstrual cycles with normal fertility[73]. Women with GSD-Ia may have pregnancies and deliveries without complications[74]. In consideration of the risk of development of hepatic adenomas in GSD-I patients, estrogen-containing contraceptives should be avoided whenever possible[75]. In addition to hypoglycemia, the most prominent laboratory abnormalities observed in patients with GSD-I include lactic acidosis, hyperlipidemia (especially hypertriglyceridemia but also hypercholesterolemia), and hyperuricemia (Figure 1). Mild elevation in transaminase levels is usually detected[30]. Ultrasonographic examination may reveal enlarged kidneys in affected patients of all ages. Serum biotinidase activity is increased in GSD-Ia patients[76-79]. Biotinidase activity was reported to be positively correlated with hypertriglyceridemia in subjects with GSD-I while severe fibrosis and cirrhosis were related to reduced enzyme activity[80]. There may also be hypercalciuria[5]. There is little or no increase in blood glucose concentration in response to administration of glucagon and this may even lead to worsening of the metabolic acidosis. Histopathological examination of the liver in patients with GSD-Ia typically reveals a mosaic pattern with pale-staining and swollen hepatocytes. Other observed features include steatosis and nuclear hyperglycogenation. Periodic acid-Schiff (PAS)-positive and diastase sensitive glycogen is evenly dispersed throughout the cytoplasm. Glycogen accumulation may be within the normal range or exhibit only a mild increase. While fibrosis is not as prominent in GSD-I as in GSD types III, IV, and VI, it may still be present in some affected individuals[5,81-83]. GSD-Ia is usually suspected based on a set of clinical (*e.g.*, hepatomegaly) and biochemical features (*e.g.*, hypoglycemia, lactic acidosis, hypercholesterolemia, hypertriglyceridemia, and hyperuricemia). The definitive diagnosis is confirmed by a mutation analysis or a liver biopsy and an enzyme assay. If a liver biopsy is performed, diagnosis can be confirmed by measuring G6Pase enzyme activity on a liver biopsy specimen; however, it should be kept in mind that measurement of G6Pase enzyme activity will not detect GSD-Ib. When the specific mutation in the index case is known, prenatal diagnosis *via* chorionic villus sampling can be performed for GSD-I[84].

The mainstay of treatment is to prevent hypoglycemia by avoiding prolonged fasting[85]. Continuously providing a dietary supply of glucose during the day and night by frequent feedings, frequent ingestion of UCCS or nocturnal enteral tube feeding are possible feeding strategies. Infants and children should be fed frequently, not allowing fasting periods longer than 3-4 h. In adolescents and adults, fasting more than 5-6 h should be avoided. Small, frequent meals with balanced macronutrient content and use of UCCS are recommended. Continuous intragastric feeding through a nasogastric or gastrostomy tube can be used overnight allowing the patients to sleep through the night[37]. To ensure adequate glucose supply, a glucose infusion rate of 8-10 mg/kg/min should be maintained for infants, while a rate of 4-8 mg/kg/min is recommended for older children. UCCS can be introduced as early as 6-12 mo of age. For the administration of UCCS in GSD-I patients, the recommended dose is 1-1.5 g of UCCS per kilogram of ideal body weight every 3-4 h for young children and 1.5-2 g of UCCS per kilogram of body weight every 4-5 h for older children, adolescents, and adults[85]. Digestion of UCCS is slow, enabling a sustained release of glucose, thereby achieving a more stable glycemic profile over an extended duration, in contrast to other carbohydrate sources. The administration of UCCS has been shown to achieve adequate glycemia for a median duration of 4.25 h (ranging between 2.5-6 h)[86]. Glycosade®, a modified, waxy maize extended-release cornstarch, is available as a single-dose overnight treatment[87].

In GSD-I, intake of fructose and galactose, which cannot be metabolized to glucose *via* G6P, further contributes to the metabolic derangement. Lactose (galactose and glucose), fructose and sucrose (fructose and glucose) should be restricted in all age groups. Restricting the intake of fruits, vegetables, juices, and dairy products renders the diet inadequate. Micronutrients, vitamins, and minerals should be supplemented to avoid nutritional deficiencies. The recommended dietary plan is to provide 60%-70% of calories from complex carbohydrates, such as whole-grain breads, pastas, legumes, and rice, with a portion of the carbohydrates coming from cornstarch. Additionally, 10%-15% of calories should come from protein and 25%-30% from fat. Effective dietary management is essential to minimize the metabolic derangement associated with GSD-I and to reduce the development of long-term complications[37,85]. However, caution must be exercised to avoid overtreatment. Overtreatment with UCCS has many consequences including obesity, increased glycogen storage in the liver, worsening lactic acidosis, increased gastrointestinal disturbances, hyperinsulinemia, and insulin resistance[88].

If there is anemia, the causes must be evaluated (*e.g.*, nutritional deficiencies, liver adenomas, enterocolitis, menorrhagia in females, and occult blood loss from the gastrointestinal tract) and appropriate treatment should be started. In the case of severe anemia, hepatic adenomas in GSD-Ia and enterocolitis in GSD-Ib should be investigated[42]. To prevent gout in the presence of hyperuricemia, allopurinol is typically administered at a dosage of 10 mg/kg/d, divided into three doses. If acidosis is present, indicated by a blood base excess of less than -5 mmol/L or a blood bicarbonate level below 20 mmol/L, bicarbonate or potassium citrate should be prescribed, with a recommended dose of 1 to 2 mmol/kg/d divided into four doses and 5 to 10 mEq every 8-12 h, respectively[85]. Angiotensin converting enzyme inhibitors or angiotensin receptor blockers should be used to delay the progression of renal damage[53,89-91]. Evidence of hyperfiltration (sustained estimated glomerular filtration rate > 140 mL/min/1.73 m^2), persistent microalbuminuria and frank proteinuria should prompt initiation of angiotensin converting enzyme inhibitors or angiotensin receptor blockers[37]. If serum triglyceride levels remain high despite optimizing dietary treatment, the administration of lipid-lowering drugs, such as 3-hydroxy-3-methylglutaryl-coenzyme A reductase inhibitors and fibrates, may be necessary to decrease the risk of atherosclerosis, cholelithiasis, and pancreatitis. For adults with persistently elevated cholesterol levels, statins may be considered as a treatment option[85]. The positive effect of medium-chain triglycerides on lowering serum cholesterol and triglyceride levels has been reported[92,93].

Recommendations regarding perioperative management of patients with GSD-I are available[37,94]. Close monitoring of blood glucose, electrolytes, and lactate levels is crucial during the peri-operative period. The patient should be admitted to the hospital 24 h before the surgery, continuous intravenous supply with 10% dextrose should be provided and continued until oral feeding is re-established. The administration of Ringer lactate solution should be avoided in GSD-I patients, as it may exacerbate lactic acidosis and worsen metabolic decompensation[37]. Bleeding time must be normalized before elective surgical interventions by 24-h continuous gastric drip feeding for one week or by intravenous glucose infusion over 24 to 48 h[85].

GSD-Ib; G6PT deficiency

In 1968, after realizing that *in vitro* G6Pase activity was normal despite glucose not being released from G6P *in vivo*, a second subtype of GSD-I was identified[95]. In 1975, it was elucidated that a transport system specific to G6P exists and is responsible for transporting G6P from the cytoplasm to the endoplasmic reticulum[96]. The responsible gene, *SLC37A4* (the solute carrier family 37 member 4), has been cloned and located on chromosome 11q23[97,98].

GSD-Ib is characterized by distinctive features such as recurrent infections, neutropenia, and neutrophil dysfunction, in addition to the clinical symptoms and findings observed in GSD-Ia. While not all GSD-Ib patients have neutropenia and neutrophil dysfunction, these conditions are common and predispose patients to severe infections and inflammatory bowel disease[44]. Patients with GSD-Ib may have normal neutrophil counts in the first year of life. *G6PT* gene, unlike *G6Pase*, is also expressed in

hematopoietic progenitor cells, which may be responsible for neutropenia and recurrent infections in GSD-Ib[99]. The neutrophil dysfunction in GSD-Ib includes both impaired motility and respiratory burst[100,101]. Impaired glucose transport across the cell membrane of polymorphonuclear leukocytes may be responsible for neutrophil dysfunction in GSD-Ib. Microsomal transport of G6P has a potential role in the antioxidant protection of neutrophils. Dysfunction of this transporter due to genetic defects in *G6PT* may impair cellular functions and induce apoptosis, contributing to the neutrophil dysfunction seen in GSD-Ib[102]. Some individuals with GSD-Ib do not develop neutropenia. It has been suggested that this could be due to residual transporter activity of some *G6PT* mutations[103]. GSD-Ib patients with neutropenia and neutrophil/monocyte dysfunction are at an increased risk for severe infectious complications due to impaired immune function. Young children with GSD-Ib may experience frequent otitis, gingivitis, periodontal disease, dental caries, and skin abscesses. Oral and genital ulcerations and intestinal mucosal ulcers may occur[43,104]. Individuals with GSD-Ib may experience recurrent episodes of diarrhea. The underlying cause of this symptom appears to be inflammation of the intestinal mucosa, as evidenced by elevated fecal α1-antitrypsin excretion and colonic inflammation in colonoscopic biopsies[44]. There is no established association between the specific genetic mutations causing GSD-Ib and the occurrence of neutropenia, bacterial infections, and other systemic complications in affected individuals[105]. Patients with GSD-Ib may require liver transplantation. Although hypoglycemia, lactic acidosis and dyslipidemia improve after liver transplantation, neutropenia generally continues to be present as it is primarily attributable to an intrinsic defect in the neutrophils [106-108].

Another characteristic clinical finding of GSD-Ib is the occurrence of Crohn disease-like colitis[109, 110]. The enterocolitis observed in GSD-Ib patients has been found to have histological features similar to those seen in inflammatory bowel disease/Crohn disease, characterized by transmural inflammatory changes and the formation of granulomas[111]. Accompanying findings and symptoms include fever, diarrhea, and perioral and anal ulcers. Interestingly, the severity of the primary disorder does not appear to be correlated with the occurrence or severity of intestinal symptoms[109,110]. Manifestations of inflammatory bowel disease may improve with granulocyte colony-stimulating factor (G-CSF) treatment[112]. Enteral nutrition with a polymeric formula enriched in the anti-inflammatory cytokine transforming growth factor-β is recommended as a first-line treatment of digestive complications in GSD-Ib[113]. Inflammatory bowel disease may require treatment with anti-inflammatory and immunosuppressive medications[113]. Successful treatment of inflammatory bowel disease with biologics including infliximab and adalimumab in GSD-Ib patients refractory to conventional treatment has been reported[114,115].

GSD-Ib is characterized by an increased risk for developing autoimmune disorders like thyroid autoimmunity and myasthenia gravis[116]. GSD-Ib patients have a higher likelihood of developing thyroid autoimmunity and hypothyroidism, while GSD-Ia patients show little indication of thyroid pathologies[117,118]. Based on the slightly elevated levels of thyrotropin, even in patients with overt hypothyroidism, it could be postulated that there is concomitant damage occurring at the hypothalamus or pituitary gland[118]. Recently, predisposition to autoimmunity in GSD-Ib patients was linked with a profound defect in conventional T cells and regulatory T cells caused by defective engagement of glycolysis in T cells due to G6PT deficiency[119]. Although a rare outcome of GSD-Ib, patients may develop terminal kidney disease, which may necessitate kidney transplantation[106].

Nutritional management of GSD-Ib is similar to that of GSD-Ia. Neutropenic patients with GSD-Ib should be treated with G-CSF. G-CSF therapy may normalize the number of neutrophils and restore myeloid functions[120-122]. The implementation of a combined therapeutic approach including both dietary management and G-CSF treatment improves the prognosis of patients by significantly mitigating metabolic and myeloid abnormalities. G-CSF administration is associated with not only an elevation of peripheral neutrophil counts, but also a reduction in the incidence of febrile episodes and infections, as well as improvement in enterocolitis in patients with GSD-Ib[123]. In conjunction with other therapies (aminosalicylates, mesalamine, and corticosteroids), G-CSF ameliorates inflammatory bowel disease symptoms[124]. To prevent complications such as splenomegaly, hypersplenism, hepatomegaly, and bone pain, it is recommended that the lowest effective dose of G-CSF is used. Caution must be exercised regarding the development of splenomegaly and myeloid malignancy[124,125]. Vitamin E has been reported to be effective in reducing the frequency of infections and improving neutropenia [126].

Liver transplantation is the ultimate therapy for hepatic metabolic disease related to GSD-I. There is no possibility of the recurrence of GSD-I within the allograft. Liver transplantation is warranted in various situations, such as hepatic adenomas with a high risk of malignant transformation, rapid progression in size and/or number of hepatic adenomas, development of hepatocellular carcinoma, poor metabolic control despite medical therapy, and growth failure[127]. Liver transplantation corrects all liver related biochemical abnormalities including hypoglycemia, lactic acidosis, hyperuricemia, and hyperlipidemia, but its potential to reverse and/or prevent renal disease remains uncertain[107,128-130]. Recently, an unusual post-transplant finding of two siblings with persistent hyperuricemia requiring allopurinol treatment has been reported[131]. Moreover, chronic renal failure is a well-known complication that may arise as a consequence of liver transplantation in individuals with GSD-Ia, and progression to renal failure within a few years of transplantation was reported[128]. It is uncertain

whether post-transplantation renal failure is related to disease progression, toxicity from immunosuppressants used after liver transplantation, a secondary reaction to poor metabolic control, or a combination of these factors. Renal transplantation in GSD-I, on the other hand, corrects only renal abnormalities[132]. Conflicting results have been reported in different studies regarding whether catch-up growth is achieved or not following liver transplantation in children with GSD-I[133,134].

Despite improved survival and growth, long-term complications of GSD-I like progressive renal failure and development of hepatic adenomas do not respond completely to dietary treatment. Although liver transplantation corrects metabolic derangement and improves the quality of life of these patients, it is not without complications[128]. These findings suggest that novel therapeutic approaches with higher success and lower complication rates are warranted. A recent advance in the treatment of neutropenia and neutrophil dysfunction in individuals with GSD-Ib is repurposing empagliflozin, a sodium-glucose co-transporter-2 (SGLT2) inhibitor that is approved to treat type 2 diabetes in adults, to improve neutrophil number and function. A study conducted by Veiga-Da-Cunha *et al*[135] revealed the crucial function of glucose-6-phosphate transporter in neutrophils, which clarifies the pathophysiology of neutropenia in GSD-Ib patients. In addition to G6P, G6PT transports the G6P structural analog 1,5-anhydroglucitol-6-phosphate (1,5AG6P). Neutrophils lacking G6PT activity cannot transport 1,5AG6P from the cytosol into the endoplasmic reticulum, where it is normally dephosphorylated by G6PC3, a phosphatase in the membrane of the endoplasmic reticulum. Cytosolic accumulation of 1,5AG6P inhibits glucose phosphorylation by hexokinases that catalyzes the first step of glycolysis. As glycolysis is the sole energy source for mature neutrophils, depletion of intracellular G6P leads to a deficit in energy production which in turn results in neutrophil dysfunction and subsequent apoptosis. Empagliflozin inhibits renal SGLT2 leading to increased urinary excretion of 1,5AG. This leads to a reduction in the concentration of 1,5AG in the blood, thereby decreasing the cellular accumulation of toxic 1,5AG6P in neutrophils[136]. Following the first report of successful repurposing of empagliflozin to treat neutropenia and neutrophil dysfunction in 4 patients with GSD-Ib, several case reports and case series have shown beneficial effects of this treatment approach on neutrophil number and function, inflammatory bowel disease, recurrent infections[137-139], oral and urogenital mucosal lesions, skin abscesses, anemia, wound healing, and dose reduction or even cessation of G-CSF therapy in GSD-Ib patients[140-144]. A recent international multicenter study examining the clinical experience of 112 patients with GSD-Ib treated with empagliflozin reported improvements in neutrophil counts in the majority of patients, leading to the cessation of regular G-CSF injections in 55% of the participants[145]. Despite a favorable safety profile in patients with GSD-Ib, there is a risk of hypoglycemia with SGLT2 inhibitors. A low dose at treatment initiation with careful titration to optimal dosing is recommended [141]. Growing evidence suggests that empagliflozin is a candidate for first-line treatment of neutropenia and neutrophil dysfunction related symptoms in GSD-Ib patients.

Another promising novel therapeutic strategy is gene therapy by using recombinant adeno-associated virus vectors. The use of a viral vector to administer G6Pase and hepatocyte transplantation are being investigated as potential treatments for GSD-I. Various animal models have shown an increase in hepatic G6Pase and G6PT activity, as well as improvements in metabolic parameters[146-150]. Multiple approaches have been explored for the integration of the G6Pase transgene into the host genome[151, 152]. The successful correction of metabolic imbalances in animal models through gene therapy shows promising potential for future applications of gene therapy in humans. A phase I/II clinical trial using a recombinant adeno-associated virus vector expressing a codon-optimized human G6Pase-α or G6PC for treatment of human GSD-Ia (NCT 03517085) has just been completed and the results are pending.

GSD-III; Cori disease; Forbes disease; limit dextrinosis; amylo-1,6-glucosidase deficiency; glycogen debrancher deficiency

Glycogen debrancher enzyme has two independent catalytic activities; alpha-glucanotransferase and amylo-1,6-glucosidase, with the two catalytic sites being separated on the same polypeptide. Both catalytic activities are required for complete debranching enzyme activity[153]. Deficient activity of these catalytic sites results in accumulation of glycogen with short outer chains, previously defined as limit-dextrins. Deficiency in glycogen debranching enzyme due to biallelic pathogenic variants in the *AGL* gene results in the harmful accumulation of abnormal glycogen in hepatocytes. The *AGL* gene was mapped to the chromosomal locus 1p21, and its nucleotide sequence was determined, revealing the existence of multiple tissue-specific isoforms[154,155]. GSD-III is inherited in an autosomal recessive manner.

GSD-III makes up about 24% of all GSDs, and its estimated incidence is approximately 1 case per 83000 live births in Europe, and 1 in 100000 live births in North America[156]. Certain populations have an increased prevalence due to a founder effect. The highest known GSD-III prevalence occurs in Inuit population in Nunavik (about 1:2500, c.4456delT variant), the Faroese population of the Faroe Islands (about 1:3600, c.1222C>T variant) and North African Jews from Israel (about 1:5400, c.4456delT variant) [156-158]. There is currently limited evidence supporting a correlation between disease severity and pathogenic variants in the *AGL* gene, except for specific exon 3 variants (c.18_19delGA and c.16C>T) which have been found to be associated with GSD-IIIb (liver involvement only). It was suggested that in muscle isoforms of the *AGL* gene, alternative exon or translation initiation may not require exon 3,

thereby resulting in normal enzyme activity in the muscle tissues of patients with GSD-IIIb who harbor an exon 3 deletion[159,160]. Recent evidence suggests that the presence of frameshift, nonsense, and splice site variants may lead to severe phenotypes. Differences in tissue expression of the deficient enzyme is responsible for the phenotypic variability observed in GSD-III patients[153].

GSD-III is characterized by heterogeneous involvement of the liver, skeletal muscle, and cardiac muscle, leading to variable clinical presentations. Various subtypes are defined by the extent of tissue involvement. Two major subtypes of GSD-III have been identified. GSD-IIIa affects both the liver and the muscle (skeletal and cardiac) and is the most prevalent subtype accounting for approximately 85% of cases. Meanwhile, GSD-IIIb primarily affects only the liver and comprises approximately 15% of all GSD-III cases[48,159]. In a limited number of cases, it has been demonstrated that there is a selective loss of either glucosidase activity (resulting in muscle involvement, referred to as GSD-IIIc) or transferase activity (resulting in both muscle and liver involvement, referred to as GSD-IIId)[161,162].

Hepatomegaly, ketotic hypoglycemia, growth retardation and dyslipidemia (hypertriglyceridemia) are the dominant features of hepatic involvement in infancy and childhood. As gluconeogenesis is intact in GSD-III, fasting hypoglycemia tends to be milder than that seen in GSD-I. During infancy, serum hepatic transaminases are markedly elevated. Uric acid and lactate concentrations are relatively normal [163]. Symptoms and laboratory findings related with liver involvement often improve with age and usually disappear after puberty[164,165]. However, liver disease can also be progressive resulting in liver fibrosis, cirrhosis, hepatic failure, and end-stage liver disease[107,165]. Hepatic fibrosis may occur as early as 1 year of age[166]. Overt liver cirrhosis is not common and occurs rarely[153,165]. Hepatocellular carcinoma can develop as a long-term complication of liver cirrhosis, rather than transformation of an adenoma to carcinoma, as seen in GSD-I[167,168]. The prevalence of hepatic adenomas has been reported to range from 4% to as high as 25%[169]. A recent descriptive, retrospective, international, multi-center cohort study revealed that the overall prevalence of severe hepatic complications (hepatic cirrhosis, hepatic adenomas and/or hepatocellular carcinoma) was 11%[170]. Liver transplantation for cirrhosis and/or hepatocellular carcinoma have been reported[107,168]. Children with failure to thrive often catch-up in height in adulthood with optimized, individualized dietary management.

Muscle symptoms associated with GSD-III can manifest concurrently with liver disease or long after hepatic disorders or even after the resolution of hepatic symptoms during childhood. An elevation in creatine kinase (CK) level is observed in 81% to 94% of cases with muscle involvement, serving as a useful indicator of muscle pathology[171]. Nonetheless, a normal CK level does not entirely exclude the possibility of an underlying muscular disease[172,173]. The median age of onset of CK elevation was reported to be 10 years[170]. Although muscle involvement becomes clinically more obvious later in life, mild muscle weakness on physical examination, motor developmental delay (delayed sitting, delayed standing upright, delayed onset of walking), exercise intolerance, and hypotonia were reported in the majority of pediatric patients with GSD-III[174-176]. Muscle weakness and wasting may slowly progress and become severe by the third or fourth decade of life[165,173].

In a subset of adult patients with GSD-III, muscle symptoms can present in the absence of any clinical or previous evidence of liver dysfunction[165,177]. Muscle weakness, although minimal during childhood, is slowly progressive in nature and may become the predominant feature with significant permanent muscle weakness in adults with type IIIa disease[171]. Although myopathy generally progresses slowly and is not severely debilitating, some patients may have severe muscle involvement leading to loss of ambulation[170]. Myopathy can be proximal, distal, or more generalized. Exercise intolerance with muscle fatigue, cramps and pain are evident in more than half of patients[170,174,175]. Bulbar or respiratory dysfunctions are rarely seen in GSD-III patients while no clinical involvement of facial or ocular muscles has been described in the literature[178].

Cardiac involvement in GSD-III is variable. Cardiac involvement is present in most patients, with varying degrees of severity ranging from ventricular hypertrophy detected on electrocardiography to clinically apparent cardiomegaly[179]. Left ventricular hypertrophy, right ventricular hypertrophy, interventricular septal hypertrophy, QT prolongation, sinus tachycardia, and pulmonary hypertension were among electrocardiographic and/or echocardiographic findings of cardiac involvement[170,180]. According to International Study on Glycogen Storage Disease data presented by Sentner *et al*[170], 58% of patients with GSD-IIIa showed cardiac hypertrophy mostly presented by electrocardiographic and/or echocardiographic signs of left ventricular hypertrophy. In the same cohort, only 15% of all patients developed hypertrophic cardiomyopathy. Mogahed *et al*[175] reported that cardiac muscle involvement is less common and mostly subclinical in the pediatric age group. However, a more recent study reported that 91% of patients showed cardiac involvement at a median age of 2.6 years, 86% of cases being under 2 years of age[181]. Moreover, 56% of the patients presented with a symptomatic cardiomyopathy at some point during the follow-up period indicating a more severe cardiac phenotype especially in those on a diet with insufficient caloric and protein intake and suboptimal UCCS treatment [181]. Cardiomyopathy usually presents with asymptomatic left ventricular hypertrophy but can progress to hypertrophic cardiomyopathy with decreased left ventricular function and/or arrhythmias, severe cardiac dysfunction, or congestive heart failure[181,182]. Sudden death has occasionally been reported[183].

Patients with GSD-III may exhibit facial abnormalities such as indistinct philtral pillars, bow-shaped lips with a thin vermillion border, a depressed nasal bridge and a broad upturned nasal tip, and deep-set eyes, particularly in younger patients[184]. Some individuals with GSD-III may have an increased risk of developing osteoporosis with reduced bone mineral density which, in part, may be due to suboptimal nutrition, the effects of metabolic abnormalities and muscle weakness[41,185,186]. Bone fractures due to osteopenia and osteoporosis were reported in patients with GSD-III[170]. Polycystic ovary disease has been reported in women with GSD-III with no significant effect on fertility[187]. Type 2 diabetes may occur during the course of the disease in adulthood[188]. Michon *et al*[189] reported global cognitive impairment in adult GSD-III patients as an underlying cause of psychological and attention deficits seen in this patient group.

Liver histology shows uniform distension of hepatocytes secondary to glycogen accumulation. There is often septal formation, periportal and reticular fibrosis, fine microsteatosis, and less frequently, micronodular cirrhosis without inflammation or interface hepatitis. Skeletal muscle shows subsarcolemmal glycogen accumulation[12]. The diagnosis of GSD-III is made by identification of biallelic *AGL* pathogenic variants on molecular genetic testing. If the diagnosis cannot be established by genetic analysis, demonstrating enzyme deficiency in peripheral leukocytes or erythrocytes, cultured skin fibroblasts or in the liver or muscle tissue samples is necessary.

A practice guideline was published by the American College of Medical Genetics and Genomics in 2010 providing recommendations on the diagnosis and management of the complications of GSD-III [176]. The mainstay of GSD-III treatment is dietary intervention, which aims to maintain normal blood glucose levels while balancing macronutrient and total caloric intake. This is achieved by the avoidance of fasting, frequent meals enriched in complex carbohydrates and use of UCCS. Continuous enteral feeding may be needed in some cases. Sucrose, fructose, and lactose are not contraindicated unlike GSD-I. UCCS can be used as early as the first year of life to prevent hypoglycemia. As an alternative, Glycosade®, an extended-release cornstarch, can also be used[87]. Caution must be exercised to avoid overtreating with cornstarch or carbohydrates, which may lead to excessive storage of glycogen in the liver and weight gain. In patients with myopathy, along with managing hypoglycemia, a high-protein diet is recommended as it prevents muscle protein breakdown during glucose deprivation, thereby preserving skeletal and cardiac muscle[176]. A ketogenic diet (alone or in combination with high protein and ketone bodies) was also shown to ameliorate cardiomyopathy[190,191]. It has been shown that a high-fat, low-calorie and high-protein diet can reduce cardiomyopathy in individuals with GSD-III[192, 193]. The beneficial effects on cardiac or skeletal muscle function of these ketogenic or high-fat diets are possibly related to the increased ketone bodies or fats as fuel sources, or reduced glycogen accumulation through decreased carbohydrate intake. Whether long-term muscular, cardiac, or even liver complications can be prevented by these dietary approaches warrants further studies[194].

Liver transplantation corrects all liver related biochemical abnormalities but does not correct myopathy or cardiomyopathy[107,133,195]. Cirrhosis, liver dysfunction, and/or hepatocellular carcinoma are the main indications for liver transplantation. Detailed information about surveillance recommendations on hepatic, metabolic, musculoskeletal, cardiac, nutritional, and endocrine aspects of the disease can be found elsewhere[176]. Gene therapy and gene-based therapeutic approaches are in development.

GSD-IV; Andersen disease; brancher deficiency; amylopectinosis; glycogen branching enzyme deficiency

The disease was described by Andersen[196] in 1956 as "familial cirrhosis of the liver with storage of abnormal glycogen" and, in 1966, amylo-1,4 to 1,6-transglucosidase [glycogen branching enzyme (GBE)] deficiency was reported[197]. Branching of the chains is essential to pack a very large number of glycosyl units into a relatively soluble spherical molecule. Without GBE, abnormal glycogen with fewer branching points and longer outer chains resembling an amylopectin-like structure (polyglucosan) accumulates in various tissues including hepatocytes and myocytes[198]. The mapping of the *GBE1* gene to chromosome 3p12.2 was first accomplished in 1993[199]. Notably, mutations in the same gene are also responsible for adult polyglucosan body disease. GSD-IV accounts for only 0.3% of all GSDs and follows an autosomal recessive inheritance pattern[200]. This rare disorder has a prevalence of 1:600000 to 1:800000[201].

GSD-IV exhibits significant clinical heterogeneity and phenotypic variability, partly due to variations in tissue involvement, which may be influenced by the presence of tissue-specific isozymes[198,200]. The liver is the primary organ affected, with the classical hepatic form appearing normal at birth but progressing rapidly to cirrhosis in early life, leading to liver failure and death between 3 to 5 years of age[196]. Children with GSD-IV experience growth failure, hepatomegaly and/or splenomegaly, and cirrhosis within the first 18 mo of life. Besides the complications of progressive cirrhosis including portal hypertension, ascites and esophageal varices, the development of hepatocellular carcinoma was also reported[202]. In rare cases, the hepatic disease in GSD-IV may not progress or progress slowly[203]. Patients with the non-progressive hepatic form may present with hepatosplenomegaly and mildly elevated liver transaminases, and experience normal growth. Liver size and transaminase levels may return to normal[203]. Patients with the non-progressive hepatic form usually survive into adulthood.

GSD-IV can present with multiple system involvement, with the enzyme deficiency in both liver and muscle[204]. This form of the disease can manifest as peripheral myopathy with or without cardiomyopathy, neuropathy, and liver cirrhosis. Onset of the disease can be from the neonatal period to adulthood[205]. The neuromuscular presentation can be divided into four groups based on age at onset [206]. In the perinatal (fetal) form, which can lead to hydrops fetalis and polyhydramnios, arthrogryposis develops due to akinesia[207]. Detection of cervical cystic hygroma during pregnancy may indicate the disease[200]. Prenatal diagnosis can be performed by determining enzyme activity in cultured amniocytes or chorionic villi samples. Genetic studies can complement uncertain enzyme activity studies, such as equivocal results in prenatal fetal samples and in patients with higher levels of residual enzyme activity that overlap heterozygote levels[208]. Mortality is unavoidable in the neonatal period. Liver cirrhosis or liver failure has not been reported. Severe hypotonia, hyporeflexia, cardiomyopathy, depressed respiration, and neuronal involvement are features of the congenital form of the disease[198,209-211]. Liver disease is not severe, and the child dies in early infancy due to other reasons. The childhood neuromuscular form may start at any age with either myopathy or cardiomyopathy[206, 212]. Presenting symptoms mainly include exercise intolerance, exertional dyspnea, and congestive heart failure in advanced stages. The disease can be confined to muscular tissue and serum CK level can be within the normal range. In the adult form, there is isolated myopathy or a multisystemic disease called adult polyglucosan body disease. Onset of symptoms can occur at any age during adulthood, usually after the age of 50, and may exhibit a resemblance to muscular dystrophies. Symptomatology includes progressive gait difficulty and proximal muscle weakness, which is more pronounced in the arms as compared to the legs. Both upper and lower motor neurons are affected in the disorder. The disease may manifest as pyramidal tetraparesis, peripheral neuropathy, early onset of neurogenic bladder, extrapyramidal symptoms, seizures, and cognitive dysfunction leading to dementia[210]. The diagnosis can be established by enzyme activity assay in erythrocytes[213]. Amylopectin-like inclusions are detected through ultrastructural examination of the central nervous system and skeletal muscle. These inclusions are intensely PAS-positive and diastase-resistant, both in neurons and muscular fibers [214]. Magnetic resonance imaging shows white matter abnormalities[215].

Liver biopsy can be diagnostic in patients with hepatic involvement[216]. The histopathological evaluation of the liver reveals abnormal hepatocellular glycogen deposits in the form of PAS-positive, diastase-resistant inclusions. Ultrastructural examination with electron microscopy reveals accumulation of fibrillar aggregations that are typical of amylopectin. Typically, enzyme deficiency can be documented through diagnostic assays performed on hepatocytes, leukocytes, erythrocytes, and fibroblasts. However, patients with cardioskeletal myopathy may exhibit normal leukocyte enzyme activity[198]. The diagnosis of GSD-IV can be confirmed through histopathological examination, detection of enzyme deficiency, and mutation analysis of the *GBE1* gene. Genetic confirmation is recommended whenever possible in patients with suspected GSD-IV to provide more data for genotype-phenotype correlations in this extremely rare disease. The genotype-phenotype correlation remains unclear for GSD-IV and the same genetic defect may cause different clinical presentations in unrelated patients[217]. Mutation analysis can also provide crucial diagnostic information in cases with equivocal results of biochemical analyses[218]. Mutations with significant preservation of enzyme activity may be related with milder (*e.g.*, non-progressive hepatic form) and late-onset (*e.g.*, adult polyglucosan body disease) phenotypes of the disease.

Hypoglycemia has traditionally been considered a late manifestation and generally develops due to hepatocellular dysfunction caused by progressive cirrhosis. At this stage of the disease, the biochemical profile of the patients is representative of what is observed in other causes of liver cirrhosis. However, a recent study has reported that fasting intolerance, as indicated by a thorough medical history, along with the presence of hypoglycemia and/or ketosis, can be observed in patients even in the absence of detectable liver injury or dysfunction based on biochemical or radiological assessment[201].

No specific dietary and pharmacological treatments are available for GSD-IV. There is a lack of established guidelines based on either evidence or expert consensus for the dietary management of GSD-IV. Improvement in clinical, anthropometric, and laboratory parameters was reported with a high-protein and low-carbohydrate diet[219,220]. Derks *et al*[201] recently reported improved clinical and biochemical outcomes after dietary interventions including a late evening meal, continuous nocturnal intragastric drip feeding, restriction of mono- and disaccharides, the addition of UCCS, and protein enrichment in patients with GSD-IV. Individual dietary plans should also aim to avoid hyperglycemia to minimize glycogen accumulation in the liver.

At present, there is no effective therapeutic approach other than liver transplantation for GSD-IV patients who are affected by progressive liver disease. However, anecdotal reports indicate that liver transplantation may not alter the extrahepatic progression of GSD-IV[217]. The presence of extrahepatic involvement, especially amylopectin storage in the myocardium, may lead to fatal complications following liver transplantation[221-223]. Careful assessment of cardiac function even in the absence of clinical decompensation or consideration of combined liver-heart transplantation is warranted for patients with GSD-IV[224]. Liver transplantation may provide beneficial effects not only for patients with liver disease but also for those affected by muscular involvement in GSD-IV[107,225,226]. This may be explained by systemic microchimerism (donor cells presenting in various tissues of the liver recipient) after liver allotransplantation and amelioration of pancellular enzyme deficiencies resulting in

a decrease in amylopectin in other organ systems[12]. It has been suggested that the donor cells can transfer enzyme to the native enzyme-deficient cells[226].

In recent years, animal studies have been conducted to prevent glycogen and polyglucosan body accumulation in GSD-IV patients, and GYS inhibitor guaiacol and 144DG11 are promising in this regard [227,228]. The molecular target of 144DG11 is the lysosomal membrane protein lysosome-associated membrane protein 1 (LAMP1), which enhances autolysosomal degradation of glycogen and lysosomal acidification. In the adult polyglucosan body disease mouse model, 144DG11 reduced polyglucosan and glycogen in brain, liver, heart, and peripheral nerve[228].

GSD-VI; Hers disease; liver glycogen phosphorylase deficiency

GSD-VI was first reported by Hers[229] in three patients with hepatomegaly, mild hypoglycemia, an increased glycogen content and deficient activity of glycogen phosphorylase in the liver in 1959. GSD-VI is a rare autosomal recessive genetic disease caused by deficiency of hepatic glycogen phosphorylase. At least three human glycogen phosphorylases exist including muscle, liver, and brain isoforms[230]. In response to hypoglycemia, liver glycogen phosphorylase catalyzes the cleavage of glucosyl units from glycogen which results in the release of glucose-1-phosphate. The glucose-1-phosphate is subsequently converted to glucose-6-phosphate. The *PYGL* gene is currently the only known genetic locus associated with the development of GSD-VI and was mapped to chromosome 14q21-q22 in 1987[231]. Incidence of the disease is estimated to be 1:100000 and believed to be underestimated due to nonspecific and variable phenotypes, and a paucity of cases confirmed by genetic testing[232]. GSD-VI is more prevalent among the Mennonite community, with a prevalence of 1 in 1000, representing the only known population at higher risk for the disease[232].

GSD-VI is a disorder with broad clinical heterogeneity[232]. Infants with liver phosphorylase deficiency mainly present with hepatomegaly and growth retardation. The condition typically has a benign course, and symptoms tend to improve as the child grows[229]. Hepatomegaly usually normalizes by the second decade of life[233]. The child shows mild to moderate ketotic hypoglycemia related to prolonged fasting, illness, or stressful conditions[232]. As gluconeogenesis is intact in GSD-VI, hypoglycemia is usually mild. Despite gross hepatomegaly, the patient may be largely asymptomatic without hypoglycemia. However, there is a range of clinical severity in GSD-VI, with some patients experiencing severe and potentially life-threatening hypoglycemia. There is generally mild ketosis, growth retardation, abdominal distension due to marked hepatomegaly and mildly elevated levels of serum transaminases, triglycerides, and cholesterol. However, in patients with high residual enzyme activity, biochemical investigations may be normal[234,235]. Hypertriglyceridemia may persist despite treatment[108]. A few patients showing mild muscular hypotonia, muscle weakness or developmental impairment were observed, but otherwise, no neurological symptoms were reported in the literature [232]. Sleep difficulties and overnight irritability are common[236]. In contrast to GSD-I, serum levels of lactic acid and uric acid are generally within the normal range[15]. However, in a recent clinical study including 56 GSD-VI patients, hyperuricemia was reported as a complication in adolescent and adult patients with GSD-VI, which indicates the need for long-term monitoring of uric acid in older GSD-VI patients[237]. CK concentration is usually normal. In some patients, severe and recurrent hypoglycemia, pronounced hepatomegaly, and postprandial lactic acidosis have been reported[238]. Recently, children with GSD-VI have been reported to present with only ketotic hypoglycemia as the sole manifestation of the disease, without the characteristic hepatomegaly[239]. Mild cardiopathy has also been described for GSD-VI[233].

The clinical picture of GSD-VI virtually overlaps with phosphorylase kinase (PHK) deficiency (GSD-IX) and the differential diagnosis includes other forms of GSDs associated with hepatomegaly and hypoglycemia, especially GSD-I and GSD-III[236]. It is not possible to distinguish between GSD-VI and GSD-IX based on clinical or laboratory findings alone[232].

Mutation analysis is the suggested method for the diagnosis of GSD-VI. A liver biopsy is not recommended to establish the diagnosis to avoid an invasive procedure. Excessive glycogen accumulation with structurally normal glycogen in the liver biopsy is consistent with GSD-VI. Fibrosis, mild steatosis, lobular inflammatory activity and periportal copper binding protein staining have also been reported in GSD-VI patients. Although it is possible to document glycogen phosphorylase deficiency in frozen liver biopsy tissue or blood cells including leukocytes and erythrocytes, normal *in vitro* residual enzyme activity may be seen and prevents establishment of a definitive diagnosis by an enzyme assay alone in some patients[234,235].

In GSD-VI, nutrition therapy aims to improve metabolic control and prevent primary manifestations such as hypoglycemia, ketosis, and hepatomegaly, as well as secondary complications including delayed puberty, short stature, and cirrhosis. Frequent meals, a high-protein diet providing 2-3 g protein/kg body weight/d, limitation but not prohibition of simple sugars such as sucrose, fructose, lactose, a late evening meal and use of UCCS are the main recommendations in GSD-VI patients[236]. The aim of the therapeutic approach is to achieve euglycemia and normoketosis by administration of the appropriate doses of cornstarch. The target level for blood glucose should be within 70-100 mg/dL, while the optimal range for blood ketones is 0.0-0.2 mmol/L[236]. An extended-release corn starch derived from waxy maize, marketed as Glycosade®, has been found to have a positive impact in delaying overnight hypoglycemia in children over 5 years of age and adults[87]. Some individuals with

GSD-VI may not require any treatment.

GSD-VI usually has a benign disease course. However, focal nodular hyperplasia, fibrosis, cirrhosis, and a degeneration to hepatocellular carcinoma have been reported in some patients[240-242]. Cirrhosis has been reported in patients as young as preschool age, even within the second year of life[242]. Based on these findings, aggressive treatment of GSD-VI has recently been suggested to maintain optimal metabolic control and prevent long-term complications[243]. Long-term monitoring of hepatic function is also recommended[236].

GSD-IX; PHK deficiency

Glucagon and epinephrine play a critical role in the regulation of glycogenolysis by activation of adenylate cyclase which leads to an increase in the cytosolic concentration of cyclic adenosine monophosphate (cAMP). The increased level of cAMP activates cAMP-dependent protein kinase which activates PHK. In the next step, PHK, a serine/threonine-specific protein kinase, functionally activates glycogen phosphorylase in the liver. PHK is a heterotetramer composed of 4 different subunits (α, β, γ, and δ). Each subunit is encoded by different genes that are located on different chromosomes and differentially expressed in a variety of tissues[244]. α and β subunits have regulatory functions, the γ subunit contains the catalytic site, and δ is a calmodulin protein[245]. PHK has a wide tissue distribution with multiple tissue-specific isoforms.

The α subunit has two isoforms, a muscle isoform, and a liver isoform, which are encoded by two different genes (*PHKA1* and *PHKA2*, respectively) on the X chromosome[244]. The genetic loci of other subunits are mapped to autosomal chromosomes. The γ subunit also has muscle and liver isoforms, each of which is encoded by a distinct gene (*PHKG1* and *PHKG2*, respectively). There is only one gene encoding the β-subunit (*PHKB*). However, *PHKB* is expressed in both muscle and liver[246,247].

Liver PHK deficiency (liver GSD-IX) can be classified according to the involved gene, the X-linked form (GSD-IXa, X-linked glycogenosis) and autosomal recessive forms (GSD-IXb and GSD-IXc). GSD-IXa (*PHKA2*-related GSD-IX) is caused by pathogenic variants in the *PHKA2* gene on X chromosome. GSD-IXb (*PHKB*-related GSD-IX) and GSD-IXc (*PHKG2*-related GSD-IX) are inherited in an autosomal recessive manner and caused by mutations in *PHKB* and *PHKG2* genes, respectively (Table 1). GSD-IXa is further classified into subtypes XLG-I (formerly GSD-VIII) with no enzyme activity in liver or erythrocytes, and XLG-II with no enzyme activity in liver, but normal activity in erythrocytes[248,249].

GSD-IX is one of the most common forms of GSDs. Approximately 25% of all GSDs can be attributed to PHK deficiency[249]. The frequency of liver PHK deficiency was estimated to be 1:100000[15]. GSD-IXa, the most common subtype of liver PHK deficiency, accounts for 75% of all GSD-IX cases. On the X chromosome, there are two enzyme loci; one for the alpha subunit of muscle PHK, and one for the alpha subunit of liver PHK. In 1992, the liver PHK gene was located to Xp22.2-p22.1[244]. GSD-IXa is more common in males due to the X-linked inheritance pattern. Female carriers may become symptomatic due to X chromosome inactivation[250].

Hepatomegaly, growth retardation, delayed motor development, mild hypotonia, significantly elevated serum transaminase levels, hyperlipidemia, fasting hyperketosis, and hypoglycemia are the main symptoms and findings[251-254]. Rarely described clinical features include splenomegaly, liver cirrhosis, doll-like facies, osteoporosis, neurologic involvement, high serum lactate levels, metabolic acidosis, and renal tubular acidosis[233]. With increasing age, there is a gradual resolution of both clinical symptoms and laboratory abnormalities. Although puberty may be delayed, eventual attainment of normal height and complete sexual development is still possible[253]. Most adult patients are asymptomatic[252]. Unusual presentations including asymptomatic hepatomegaly and isolated ketotic hypoglycemia without hepatomegaly have been reported in affected male children underscoring the importance of screening for GSD-IXa in male patients who are suspected of having GSD with atypical features[239,255]. More severe phenotypes including severe recurrent hypoglycemia and liver cirrhosis have also been reported[243,256,257]. Recent findings suggest that GSD-IXa is not a benign condition as is often reported in the literature and patients may have fibrosis even at the time of diagnosis[258].

GSD-IXc is caused by autosomal recessive mutations in the *PHKG2* gene. There are two isoforms, encoded by different genes, for the gamma subunit: The muscle form (*PHKG1* gene) and the testis/liver form (*PHKG2* gene)[259]. The genetic locus of the liver form was located to 16p12.1-p11.2. The presence of *PHKG2* mutations has been linked to more severe clinical and biochemical abnormalities, such as an elevated risk for liver fibrosis and cirrhosis[260-262]. Liver cirrhosis can develop in infancy[263]. Cirrhosis related esophageal varices and splenomegaly, liver adenomas, renal tubulopathy and significant hypocalcemia were other reported clinical findings[236]. Patients with this condition commonly present with severe hypoglycemia requiring overnight feeding, show very low PHK activity in the liver, and exhibit highly elevated serum transaminase levels. A wide range of clinical symptoms can be observed, including hypoglycemia during fasting, hepatomegaly, elevated levels of transaminases, hepatic fibrosis, cirrhosis, muscle weakness, hypotonia, delayed motor development, growth retardation, and fatigue[264].

The genetic cause of GSD-IXb is attributed to mutations in the *PHKB* gene, which is located on 16q12-q13 and encodes the beta subunit of PHK[265]. The main features of the disease include marked hepatomegaly, increased glycogen content in both liver and muscle, and the development of hypoglycemic

symptoms after physical activity or several hours of fasting[265]. Patients with liver fibrosis, adenoma-like mass, mild cardiopathy and interventricular septal hypertrophy were reported[233]. The muscle symptoms are generally mild or absent, affecting virtually only the liver. Distinction between GSD-IXb and individuals with pathogenic variants in *PHKA2* or *PHKG2* cannot be carried out based on clinical findings alone.

Genetic analysis is the preferred first-line diagnostic test in suspected patients. An approach using next-generation sequencing panels is advised due to the involvement of multiple genes. Liver biopsy can be a valuable diagnostic tool for confirming the diagnosis in cases where there are variants of unknown significance. Histopathological assessment of liver involvement is superior to biochemical parameters[266]. It is important to keep in mind that PHK enzyme activity can be normal in blood cells and even in liver tissue of affected patients. On the other hand, a reduction in PHK enzyme activity can also occur secondary to other metabolic defects such as pathogenic variants in *GLUT2* in Fanconi-Bickel syndrome (FBS), PRKAG2 cardiomyopathy syndrome, or mitochondrial complex 1 deficiency[236].

In patients with GSD-IX, close monitoring of long-term liver and cardiac complications is recommended[233]. Aggressive structured dietary treatment with UCCS and relatively high protein intake was associated with considerable improvement in growth velocity, energy, biochemical abnormalities, hepatomegaly, and overall well-being of patients with GSD-IX. Radiographic features of fibrosis were also reported to be improved with early and aggressive dietary management[243]. General nutritional recommendations for GSD-IX are similar to those for GSD-VI and have recently been published[236].

FBS (formerly GSD-XI)

The primary defect in FBS is deficiency of glucose transporter 2 (GLUT2), a monosaccharide carrier that is responsible for the transport of both glucose and galactose across the membranes in hepatocytes, pancreatic β-cells, enterocytes, and renal tubular cells. Utilization of both glucose and galactose is impaired in FBS[267]. Hepatorenal glycogen accumulation and proximal renal tubular dysfunction are the characteristic features of this rare disease[268,269]. FBS follows an autosomal recessive inheritance pattern. The responsible gene, *GLUT2* gene (solute carrier family 2 member 2, *SLC2A2*), was localized to 3q26.1-q26.3 in 1988[270,271]. Since the first patient reported by Fanconi and Bickel in 1949, over 100 cases of FBS with various *SLC2A2* mutations including missense, nonsense, frameshift/insertion-deletion, intronic, and compound heterozygous mutations have been reported[272].

Infants with FBS typically present between the ages of 3 to 10 mo. In addition to hepatorenal glycogen accumulation and proximal renal tubular dysfunction, FBS is characterized by fasting hypoglycemia, postprandial hyperglycemia and hypergalactosemia, rickets and marked growth retardation. Patients have entirely normal mental development. In older patients, dwarfism is the most notable finding. Puberty is significantly delayed, with other remarkable observations including a distended abdomen caused by hepatomegaly, deposition of fat on the abdomen and shoulders, and a moon-shaped face [273]. Some patients may not exhibit hepatomegaly during the early stages of the disease[269,274]. Hyperlipidemia and hypercholesterolemia are prominent and may cause acute pancreatitis. The development of generalized osteopenia occurs early and may result in fractures. Hypophosphatemic rickets and osteoporosis are characteristics of the disease that emerge later in life[275]. Tubular nephropathy is characterized by excessive glucosuria, moderate hyperphosphaturia along with persistent hypophosphatemia, hyperuricemia, hyperaminoaciduria, and intermittent albuminuria, collectively referred to as renal Fanconi syndrome[267,268]. Hypercalciuria is also evident. Due to increased renal losses, there is a frequent tendency towards hyponatremia and hypokalemia. Polyuria may develop due to high urinary osmotic load[276]. Progression to renal failure is not the case. Nephrocalcinosis was also reported in one third of the patients in a recent retrospective study[277]. There may be mild metabolic hyperchloremic acidosis with normal anion gap due to renal loss of bicarbonate[267]. Cataracts, a frequently documented consequence of hypergalactosemia, are only present in a small number of patients[278].

Laboratory findings include fasting hypoglycemia and ketonuria, hyperglycemia and hypergalactosemia in the postabsorptive state, hypercholesterolemia, hyperlipidemia, moderately elevated alkaline phosphatase, mildly elevated transaminases, normal hepatic synthetic function, hypophosphatemia, hyperaminoaciduria, glucosuria, galactosuria, proteinuria, normal activity of enzymes involved in galactose and glycogen metabolism, normal fructose metabolism, and normal endocrinologic results[267]. FBS patients develop different patterns of dysglycemia, ranging from fasting hypoglycemia, postprandial hyperglycemia, glucose intolerance, to transient neonatal diabetes to gestational diabetes and frank diabetes mellitus[279]. The exact molecular mechanisms underlying the occurrence of dysglycemia in individuals with FBS are not yet fully understood. Sharari *et al*[272] recently suggested that *SLC2A2* mutations cause dysglycemia either by a direct effect on *GLUT2* expression and/or activity or, indirectly, by the dysregulated expression of microRNAs implicated in glucose homeostasis. Impaired renal glucose reabsorption, as well as the accumulation of glucose within the hepatocytes, which stimulates glycogen synthesis and inhibits gluconeogenesis and glycogenolysis, result in fasting ketotic hypoglycemia and hepatic glycogen deposition. Postprandial findings of hyperglycemia and hypergalactosemia are caused by impaired hepatic uptake and diminished insulin response[279]. Glycated hemoglobin A1c is usually within the normal range due to recurrent

hypoglycemia episodes[280]. Accumulation of glycogen and free glucose in renal tubular cells leads to general impairment in proximal renal tubular function. Histological evaluation of liver biopsy indicates an excessive buildup of glycogen along with steatosis. Due to the presence of galactose intolerance, newborn screening for galactosemia can sometimes identify patients with FBS[281]. The diagnosis is ultimately confirmed by genetic analysis of *SLC2A2* gene.

The management of symptoms involves measures to stabilize glucose homeostasis and compensate for the renal loss of water and various solutes. Patients typically require replacement of water, electrolytes, and vitamin D, while also restricting galactose intake and adhering to a diabetes mellitus-like diet. Frequent small meals with adequate caloric intake and administration of UCCS are important components of symptomatic treatment. In cases of renal tubular acidosis, it may be required to administer alkali to maintain acid-base balance. Catch-up growth was reported to be induced by UCCS [282]. Continuous nocturnal gastric drip feeding may be indicated in some cases with growth failure [283]. With these measures, the prognosis is good. However, a recent retrospective study reported poor outcome despite adequate metabolic management emphasizing the importance of early genetic diagnosis and facilitating prompt nutritional interventions[277].

GSDS INVOLVING MUSCLE

GSD-II; Pompe disease; acid alpha-glucosidase deficiency; acid maltase deficiency; alpha-1,4-glucosidase deficiency

Pompe disease is a typical example of a lysosomal storage disease. The clinical manifestations of Pompe disease are variable, predominantly due to the varying amounts of residual acid alpha-glucosidase (GAA) activity linked with distinct mutations in the causative gene (*GAA*). *GAA* gene is mapped to chromosome 17q25.2-q25.3[284]. Enzyme deficiency results in intra-lysosomal storage of glycogen especially in skeletal and cardiac muscles. There is no genotype-phenotype correlation, but DD genotype in the angiotensin converting enzyme gene and XX genotype in the alpha actinin 3 gene are significantly associated with an earlier age of onset of the disease[285].

There are mainly two types of GSD-II according to age of onset: Infantile-onset and late-onset Pompe disease. Patients with disease onset before the age of 12 mo without cardiomyopathy and all patients with disease onset after 12 mo of age are included in the late-onset form[286]. The combined frequency of infantile onset and late onset GSD-II varies between 1:14000 and 1:100000 depending on ethnicity and geographic region. In the infantile-onset form, cardiomyopathy and muscular hypotonia are the cardinal features and patients die around 1 year of age. The enzyme activity is less than 1% of normal controls, and the enzyme is deficient in all tissues. Patients also have feeding difficulties, macroglossia, failure to thrive, hearing impairment and respiratory distress due to muscle weakness. The liver is rarely enlarged unless there is heart failure. Hypoglycemia and acidosis do not occur[286]. In the late-onset form, involvement of skeletal muscles dominates the clinical picture, and cardiac involvement is generally clinically insignificant depending on the age of onset. Enzyme activity is partially deficient (2% to 40% of normal controls)[286]. Glycogen accumulation in vascular smooth muscle may cause the formation and subsequent rupture of an aneurysm[287]. Both severe infantile and asymptomatic adult forms of the disease were observed in two generations of the same family[288]. Although women with GSD-II do not have an increased risk of pregnancy or delivery complications, pregnancy may worsen muscle weakness and respiratory complications[289]. As a rule, there is an inverse correlation between the age at disease onset and the severity of clinical manifestations with the level of residual enzyme activity[286].

Laboratory testing reveals nonspecific elevations in CK, aldolase, aminotransferases, and lactate dehydrogenase. Elevated urinary tetrasaccharide is highly sensitive but not specific. To establish the final diagnosis, the measurement of enzyme activity in skin fibroblasts or muscle tissue or the demonstration of the responsible mutation is required[286].

Although it is not curative, ERT has changed the course of Pompe disease since its first use in 2001 [290]. Alglucosidase alfa, a lysosomal glycogen-specific recombinant enzyme, was approved by the European Medicines Agency (EMA) in 2006 in the European Union and by the Food and Drug Administration (FDA) in 2010 in the United States. The indication criteria were as follows: ≥ 8 years and absence of cardiac hypertrophy (https://www.accessdata.fda.gov/drugsatfda_docs/Label/2010/125291Lbl.pdf; accessed on November 5, 2022). Based on data from later studies, treatment initiation was shifted to the neonatal period. The recommended dosage is 20 mg/kg body weight every two weeks by intravenous administration. A new formulation of GAA enzyme, avalglucosidase alfa, improves the delivery of the enzyme to target cells and has 15 times higher cellular uptake when compared with alglucosidase alfa. The FDA and EMA approved avalglucosidase in 2021 and in 2022, respectively, for the treatment of patients who are one year of age and older with late-onset Pompe disease[291]. Ongoing studies show that avalglucosidase is generally well tolerated in patients with infantile-onset Pompe disease[291]. The recommended dose is 5 to 20 mg/kg every 2 wk[291]. Criteria for starting and stopping ERT in adult patients with GSD-II are similar in different countries. While a confirmed diagnosis and being symptomatic are general criteria for starting ERT, patient wish, severe infusion

associated reactions, noncompliance with treatment, and lack of effect are criteria for stopping ERT [292]. Another way to increase the effectiveness of ERT is to use antibodies as an intracellular delivery vehicle. The 3E10 anti-nuclear antibody, that penetrates cells and localizes to the cell nucleus, has been used for this purpose. VAL-1221 is a fusion protein consisting of 3E10 antibody and GAA complex. The presence of 3E10 increases the delivery of GAA to both lysosomal and extra-lysosomal storage of glycogen within cells[293]. The earlier ERT is started, the better its effectiveness. Therefore, it is recommended that ERT is started before irreversible clinical symptoms begin. This concept has led to the development of screening programs for Pompe disease[294]. Recently, it has been shown that in utero alglucosidase alfa treatment, which was started at 24 wk 5 d of gestation and given 6 times at 2-wk intervals through the umbilical vein, was successful[295].

Although antibodies against the enzyme may develop, a recent study showed that the development of antibodies did not affect the clinical course[296]. Whether additional treatments such as oral supplementation of L-alanine is beneficial is being investigated[297]. As an alternative to ERT, studies on gene therapy have also commenced[298].

Danon disease

Although Danon disease was previously classified as a variant of GSD-II with normal alpha-glucosidase activity, it is still controversial whether it is a real GSD. A lysosomal structural protein, LAMP2, is deficient in Danon disease. LAMP2 is involved in autophagosome maturation. Disruption of autophagy leads to accumulation of glycogen granules and autophagic vacuoles[299]. It is an X-linked (Xq24) dominant hereditary disease affecting both skeletal and cardiac muscles, and characterized by skeletal and cardiac myopathy, proximal muscle weakness and intellectual disability. Female patients have a milder disease predominantly involving cardiac muscle[300]. There is currently no treatment for Danon disease. There are ongoing studies evaluating the efficacy and safety of gene therapy[300].

AMP-activated protein kinase deficiency

Another glycogen storage cardiomyopathy results from *PRKAG2* (the gene encoding gamma-2 non-catalytic subunit of adenosine monophosphate-activated protein kinase) mutations on chromosome 7q36.1. The disease is characterized by left ventricular hypertrophy due to altered glycogen metabolism and glycogen storage in cardiac muscle, similar to Danon disease[301-303]. It is inherited in an autosomal dominant pattern. *PRKAG2* gene variants cause a syndrome characterized by cardiomyopathy, conduction disease, and ventricular pre-excitation[302]. It may cause atrial fibrillation/flutter or conduction abnormalities that may cause sudden cardiac death and severe heart failure typically in the third and fourth decade[301,302]. Mutations in the gamma-2 non-catalytic subunit of AMP-activated protein kinase may cause lethal congenital storage disease of the heart, and death in the first year of life [303]. It is important to differentiate the clinical picture related to *PRKAG2* mutations from Danon disease, as management and prognosis are different.

GSD-V; McArdle disease; myophospharylase deficiency; muscle glycogen phosphorylase deficiency

GSD-V is caused by mutations in *PYGM* gene which is the gene encoding the muscle isoform of glycogen phosphorylase. The *PYGM* gene is located on 11q13.1[304]. In a recently published European registry for patients with muscle glycogenosis, 95% of all patients had GSD-V[305]. The clinical manifestations generally occur during early adulthood with physical activity intolerance and muscle cramps characterized by muscle fatigue and pain, contracture, tachypnea, tachycardia, ptosis, and retinal dystrophy. Most of the patients are symptomatic at pediatric age (< 18 years)[306]. An improvement of exercise induced symptoms, named the "second wind phenomenon", characterized by the improvement of exercise tolerance after 8 to 10 min of aerobic exercise, is observed[306,307]. Exercise induced rhabdomyolysis can cause transient myoglobinuria, leading to acute renal failure. Hyperuricemia, gout development and thyroid dysfunction are not uncommon[306]. Many patients are diagnosed with an incidental finding of abnormal serum CK levels[307].

Echaniz-Laguna *et al*[308] studied a family of 13 affected members with adult-onset muscle weakness, and reported a phenotype caused by a dominant myophosphorylase gene mutation (p.Asp639His). The first signs of the disease occurred after 40 years of age with proximal leg weakness, followed by proximal arm weakness. In contrast to McArdle disease, the patients did not have exercise intolerance, second wind phenomenon, markedly increased CK levels, or rhabdomyolysis. The authors concluded that specific *PYGM* mutations can cause either dominant or recessive GSDs[308].

GSD-VII; Tarui disease; muscle phosphofructokinase deficiency; GSD of muscle

The responsible gene is located on chromosome 12q13.3[309]. Exercise induced muscle cramps and myoglobinuria are the main characteristics of GSD-VII. Neurological examination does not reveal any abnormalities at rest. Muscle weakness and stiffness invariably occur in muscle groups that are subjected to intense or prolonged exertion. The ischemic exercise test is characterized by the absence of an increase in venous lactate level. Myoglobinuria may develop following exercise. Nausea and vomiting, icterus, elevated CK, hyperuricemia and reticulosis may also be observed[307]. In contrast to GSD-V, glucose intake prior to exercise worsens exercise capacity due to blocked use of both muscle

glycogen and blood glucose[307].

GSD-IXd; X-linked muscle PHK alpha-1 subunit deficiency

The gene is located on chromosome Xq13.1, and the disease is inherited recessively[310]. In most patients, clinical findings appear in adulthood and are characterized by muscle weakness and muscle cramps during exercise. Elevated serum CK level and myopathic findings on electromyography may guide the diagnosis[311].

GSD-X; muscle phosphoglycerate mutase deficiency

The last steps of glycogenolysis are abnormal. The disease is inherited in an autosomal recessive manner and characterized by exercise induced muscle cramps, myalgia, rhabdomyolysis and myoglobinuria. Serum CK level is increased between episodes[312].

GSD-XI; lactate dehydrogenase a deficiency

GSD-XI was first described by Kanno *et al*[313] in 1980 and characterized by easy fatigue, increase in serum CK, myoglobin, lactate, and pyruvate levels immediately after ischemic work. The gene locus is on chromosome 11p15.1[314].

GSD-XII; aldolase deficiency

GSD-XII is a very rare disease resulting from aldolase A deficiency and characterized by muscle glycogen accumulation, crisis of rhabdomyolysis induced by fever and/or exercise and hemolytic anemia with or without myopathy or cognitive dysfunction[315]. It is an autosomal recessive disorder, and the gene is located on chromosome 16p11.2[316].

GSD-XIII; muscle enolase 3 deficiency

GSD-XIII was first described by Comi *et al*[317] in 2001 in a 47-year-old man with severe deficiency of muscle enolase activity. The patient had recurrent exercise induced myalgia without cramps. Serum CK concentration was elevated while serum lactate level was normal following ischemic forearm exercise. The related gene is located on chromosome 17p13.2[317].

GSD-XV; glycogenin deficiency

Similar to Danon disease and *PRKAG2* variants, glycogenin deficiency may cause left ventricular arrhythmogenic cardiomyopathy. Patients present with chest pain, progressive weakness, and vague presyncope spells[318].

CONCLUSION

There have been significant changes and improvements in the classification, diagnosis, and treatment of GSDs in recent years. We are now more aware that many GSDs, which were previously identified as childhood diseases, may present first in adulthood. Diagnosis can be challenging, especially for GSDs with milder phenotypes and those with only skeletal and/or cardiac muscle involvement. As early diagnosis and aggressive treatment is related to better prognosis, physicians should be aware of these conditions and include GSDs in the differential diagnosis of pediatric and adult patients with not only liver related manifestations but also skeletal and/or cardiac muscle, central nervous system, and multisystemic involvement.

Abstract

The estimated world prevalence of hepatitis B virus (HBV) infection is 316 million. HBV infection was identified in 1963 and nowadays is a major cause of cirrhosis and hepatocellular carcinoma (HCC) despite universal vaccination programs, and effective antiviral therapy. Long-term administration of nucleos(t)ide analogues (NA) has been the treatment of choice for chronic hepatitis B during the last decades. The NA has shown a good safety profile and high efficacy in controlling viral replication, improving histology, and decreasing the HCC incidence, decompensation, and mortality. However, the low probability of HBV surface antigen seroclearance made necessary an indefinite treatment. The knowledge, in recent years, about the different phases of the viral cycle, and the new insights into the role of the immune system have yielded an increase in new therapeutic approaches. Consequently, several clinical trials evaluating combinations of new drugs with different mechanisms of action are ongoing with promising results. This integrative literature review aims to assess the knowledge and major advances from the past of hepatitis B, the present of NA treatment and withdrawal, and the future perspectives with combined molecules to achieve a functional cure.

Key Words: Hepatitis B; Therapy; Antigen; Functional cure; Antiviral agents; Drug development

Core Tip: Treatment for chronic hepatitis B has been used for decades, showing a good safety profile and high virological and clinical efficacy, decreasing hepatocellular carcinoma, clinical decompensation, and mortality. However, the low probability of hepatitis B virus surface antigen seroclearance with therapy made necessary indefinite treatment in a majority of patients. With the new insights about the immune system role in hepatitis B virus infection and the knowledge of the viral cycle phases, there has been in recent years increased activity in new therapeutic approaches. This review focuses on the past, present, and future of chronic hepatitis B therapy.

INTRODUCTION

The hepatitis B virus (HBV) was identified in 1963 when the modern research history of viral hepatitis began. The Nobel Prize winner Baruch S. Blumberg (1925-2011) discovered, 60 years ago, an enigmatic serum protein named "Australia" antigen (AuAg)[1]. Some years later, the recognition of the HBV surface antigen (HBsAg) allowed for the first-time screening of blood donors. The HBsAg was the first marker assessed by a highly sensitive immune analysis, the HBV genome the first identified by deoxyribonucleic acid (DNA), the antibody against HBV core (anti-HBc) the first evaluated by the anti-μ capture technique, and the HBV vaccine the first produced by gene technology[2].

Infection by HBV may lead to acute or chronic hepatitis. Chronic hepatitis B (CHB) infection is defined as HBsAg serum detection for at least six months. The estimated world prevalence of CHB was 316 million in 2019, a major cause of cirrhosis and hepatocellular carcinoma (HCC)[3]. The treatment of choice during the last decades has been the long-term administration of nucleos(t)ide analogues (NA) with a high barrier to resistance. However, the low probability of HBsAg seroclearance made necessary an indefinite therapy.

This integrative literature review aims to review the major advances from the past of hepatitis B, the present of NA treatment and withdrawal, and the future perspectives for the new combined molecules to achieve a functional cure.

PAST

Virus detection: The "Australia" antigen and "Dane" particle

In the 1960s, virology was a young science, and techniques for the diagnosis of most viral diseases were complicated and suboptimal. The most often used method was the complement fixation reaction, which required four complex biological component mixtures from four different animal species. The first hint came from the American physician and geneticist Baruch S. Blumberg who used an immunological approach in 1967[1]. Blumberg's co-worker, Harvey J. Alter, discovered a new antigen in Australian aborigines named the AuAg.

Dane *et al*[4] were inspecting AuAg immune complexes under the electron microscope and identified virus-like particles of 42 nm in size. In 1971, Almeida *et al*[5] were able to free the core particles from the "Dane" particle and showed that patients formed, against this core antigen (HBcAg), antibodies (anti-HBc) suggesting that the Dane particle was the cause of hepatitis B, and the AuAg was the surface antigen of the HBV envelope (HBsAg)[5].

Many scientists, including Blumberg, recognized that the HBsAg did not allow to assess the severity of the disease. Magnius *et al*[6] discovered an additional marker when looking for HBsAg subtypes, the HB e antigen (HBeAg), which helped to distinguish highly infectious from less infectious HBV carriers. However, direct detection of the nucleic acid within HBV was not possible at that time since the HBV still could not be grown in cell cultures, and patient sera contained a few nanograms of Dane particles/mL. It was in 1974 when Robinson *et al*[7] identified the polymerase activity, and the HBV-DNA. The nucleic acid of HBV was a small circular double-stranded DNA but not covalently closed such as the polyoma- or papillomaviruses. Therefore, the ability of the HBV-DNA polymerase to transcribe both RNA and DNA was similar to retroviruses[2,8].

After more than half a century, current international guidelines have recommended using these three viral markers, HBsAg, HBeAg, and HBV-DNA for characterizing HBV infection[9-11].

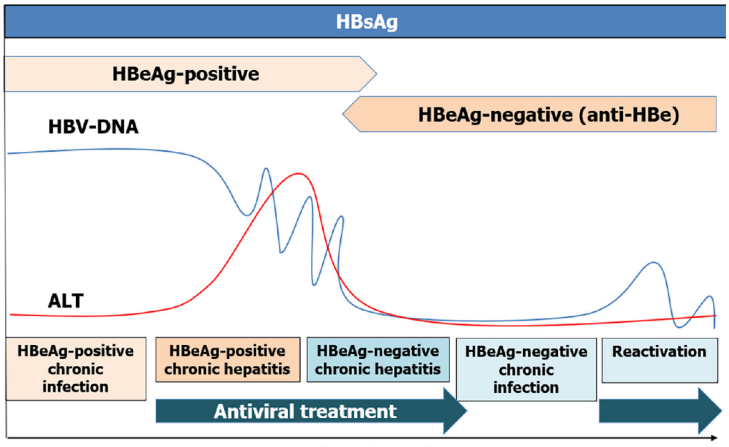
Hepadnaviral life cycle: The journey of Dane particle

HBV is a partially double-stranded virus that belongs to the *Hepadnaviridae* family[12]. The virus replicates in the host's hepatocytes. The first step is viral cell entry *via* the bile acid transporter sodium taurocholate cotransporting polypeptide (NTCP)[13,14]. The HBV is transported to the nucleus to release the relaxed circular DNA (rcDNA) genome[15] and becomes a covalently closed circular DNA (cccDNA) that uses the host-cell DNA repair mechanism and can serve as a template for all viral transcripts that are translated into viral proteins. The HBV genome can be integrated into the host genome with the risk of hepatocyte transformation and carcinogenesis[16]. The pre-genomic RNA (pgRNA) is packaged and reversely transcribed to begin replication. The pgRNA is also enveloped and secreted. The HBV-integrated DNA encodes three HBsAg proteins: Large (L), middle (M), and small (S) HBs which are especially important in HBeAg-negative patients[17]. The viral capsids will be enveloped with the HBsAg and released as infectious virions, non-infectious sub-viral spherical or filamentous particles[18], empty virions (HBsAg and core proteins), and RNA virions[19]. The role of subviral particles in the pathogenesis of chronic HBV infection is not fully understood, but they could act as an immune evasion mechanism by blocking the host's neutralizing antibodies (anti-HBs) and promoting the spread and persistence of the infection[20,21].

Pathogenesis and phases of HBV infection

The first step in HBV infection is a highly replicative phase before immune recognition begins, after weeks or months of delay. A vigorous cellular immune response suppresses viral replication and eliminates most of the HBV-infected hepatocytes resulting in acute hepatitis. During acute hepatitis B, HBsAg disappears within six months. If HBsAg persist longer than this period, is considered a CHB infection. CHB is a dynamic interaction between HBV and the host's immune system.

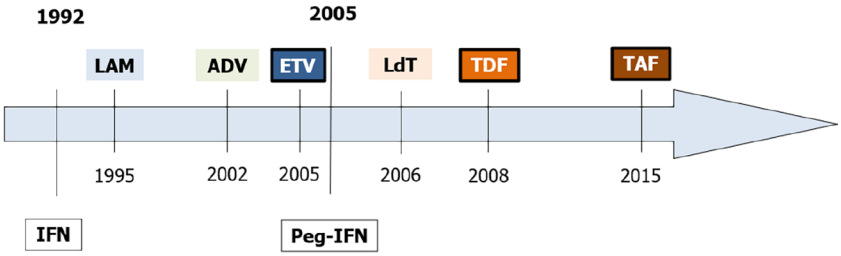
Infection of newborns or infants results in a persistent infection because of an ineffective immune response. After a long anergic phase, immune defense emerges and leads to the selection of escape mutants. The cellular immune responses against HBcAg appear and HBeAg loses its immunomodulatory function. Therefore, the HBeAg-positive chronic infection usually occurs in younger patients during the first years. Patients have a high viral load with normal liver function tests. The HBeAg-negative chronic infection is characterized by low levels of HBV-DNA with normal liver function and without significant fibrosis. Generally, treatment is not recommended in these two phases, but guidelines advocate treating older than 30-40 years HBeAg-positive patients[9-11]. Chronic hepatitis, defined by the elevation of transaminases and high viral load, induces liver fibrosis progression to cirrhosis and risk of developing HCC, being antiviral treatment recommended in these phases (Figure 1).



Antiviral treatments: Interferon and nucleos(t)ide analogues

In 1976, William Robinson and Thomas Merigan reported that interferon alpha suppressed HBV replication and cured some patients suffering from CHB[22]. However, further clinical studies showed that only a minority of the patients achieved the clearance of HBsAg while the majority showed a viral breakthrough under treatment or a relapse after the end of therapy (EoT). Conventional interferon alpha was approved in 1992 and one year later Wong *et al*[23] demonstrated an HBeAg loss rate of 33%. Efficacy in HBeAg-negative patients was very limited and only 15% to 25% showed a sustained biochemical response after 12 mo of treatment[24]. In 2005, pegylated interferon (Peg-IFN) replaced the standard form due to its improved pharmacokinetics and prolonged half-life. In HBeAg-positive patients, 12 mo of therapy achieved the sustained response (HBeAg loss with HBV-DNA < 2000 IU/mL, 6 mo after therapy) in 20% to 30% and the HBsAg loss in 3% to 7%[25]. The Peg-IFN therapy has important disadvantages, its high variability of response and its unfavorable safety profile with a significant number of patients ineligible or unwilling.

In 1995, Benhamou *et al*[26] reported that HIV-co-infected patients with HBV who received the HIV drug named lamivudine (LAM) lost their HBV-DNA and improved their hepatitis (Figure 2). The same year Jules Dienstag showed the efficacy and safety of LAM in HBV-mono-infected patients[27]. LAM was well tolerated, but resistance soon developed in cases with high replication. After 5 years of therapy, 75% of the LAM-treated patients developed resistant HBV variants. The acyclic nucleotide analog adefovir (ADV) was approved in 2002 for LAM-resistant CHB patients. Unfortunately, its activity was relatively low and was rapidly replaced by the newer drug named tenofovir (TDF). This very similar drug was approved in 2001 for HIV and in 2008 for HBV[28]. The guanosine analog entecavir (ETV) was originally developed against the herpes simplex virus. In 1997, ETV showed its strong activity against HBV in the HepG2.2.15 cell line. In 2001, showed its efficacy in LAM-resistant CHB patients, and in 2005, it was approved over LAM[29]. In 2006, a synthetic thymidine nucleoside analogue named telbivudine (LdT) was approved but its activity was relatively low and was rapidly replaced. In 2015, the prodrug of TDF, tenofovir alafenamide (TAF), was approved for older patients with lower eGFR or lower bone mineral density[30,31].



Safety of long-term treatments

The safety profile of NA is very good even in HBV-infected patients with decompensated liver disease,

Figure 1 Phases of hepatitis B virus infection. The persistence of hepatitis B virus surface antigen longer than six months is considered a marker for chronic hepatitis B infection. The HB e antigen (HBeAg)-positive chronic infection occurs in younger patients with high viral load and normal liver function tests. In contrast, HBeAg-negative chronic infection is characterized by low levels of hepatitis B virus-DNA with normal liver function and without fibrosis. Generally, treatment is not recommended in these two phases. Chronic hepatitis is defined by the presence of transaminases and high viral load that can induce liver fibrosis and risk of developing hepatocellular carcinoma, being antiviral treatment recommended[9-11]. HBV: Hepatitis B virus; HBeAg: Hepatitis B e antigen; ALT: Alanine aminotransferase.

liver transplants, extrahepatic manifestations, acute hepatitis, or severe exacerbation[32,33]. However, NA inhibits the HBV polymerase activity only during the time of administration. Long-term therapy with NA can produce a decline in bone mineral density and renal tubular dysfunction[34].

TDF and ETV have renal metabolism and must be adjusted if patients have an estimated glomerular filtration rate (eGFR) of less than 50 mL/min per 1.73 m^2. A multicenter retrospective study including 6189 CHB patients treated with TDF (n = 2482) or ETV (n = 3707) showed that TDF was associated with a higher risk of worsening renal function (adjusted HR 1.26, 95%CI 1.11-1.43)[35]. A systematic review and meta-analysis showed that TDF and ETV can affect renal function and patients with cirrhosis under TDF had a higher risk of renal damage and hypophosphatemia[36]. The effects of TDF on bone mineral density are suspected to be related to an increased tubular phosphate metabolism, but with few clinical implications as they appear to be reversible after withdrawal[34]. Recently, it has been shown an improvement in bone density and renal function in patients previously treated with TDF after switching to TAF[37]. However, TAF is not approved in very low eGFR (below 15 mL/min per 1.73 m^2).

Even if side effects of NA are scarce, CHB patients usually start treatment at young ages, and with NA treatment, they may be treated for decades. Therefore, questions on NA treatment duration and withdrawal have been gaining interest in recent years.

PRESENT

Monitoring HBV infection: Quantification of HBsAg levels

Classically, three viral markers have been used to characterize HBV infection: (1) The qualitative HBsAg; (2) the HBeAg; and (3) the HBV-DNA. However, most patients under NA treatment have

undetectable HBV-DNA and normal alanine aminotransferase (ALT). Therefore, other biomarkers are needed to monitor antiviral activity. The quantified HBsAg is one of the most extensively studied biomarkers because HBsAg negativization, spontaneously or with treatment, has been related to a good prognosis[38]. It has been shown that the decline in HBsAg levels during NA therapy is very slow (around 0.1 Log IU/mL per year)[39-41] suggesting that it would take decades, even long life, to achieve the HBsAg loss[42,43]. Importantly, some patients have shown a faster and larger HBsAg decline during NA therapy achieving low HBsAg levels[41,43]. Importantly, low HBsAg levels after NA withdrawal (below 1000 in Caucasian and below 100 in Asian patients) can be predictors of HBsAg seroclearance[44-47].

Efficacy of long-term antiviral therapy

The NA can be classified as low (LAM, ADV, and LdT) or high (ETV, TDF, and TAF) barrier of resistance. Current international guidelines recommend the use of NA with a high barrier of resistance to prevent the progression of liver disease, decompensation of cirrhosis, the need for liver transplantation, the development of HCC and to improve survival[9-11].

The suppression of HBV-DNA to undetectable levels (virological response) is normally associated with a normalization of transaminases (biochemical response) and an improvement in survival. In the presence of cirrhosis, all patients with detectable HBV-DNA should be treated[9-11]. Indications for HBeAg-positive and HBeAg-negative CHB patients' treatment are generally based on the combination of three main criteria: Liver disease severity, HBV-DNA units, and ALT levels[9-11].

In HBeAg-positive CHB patients, long-term NA therapy can induce HBeAg loss and seroconversion, leading to a low replicative phase with partial immune control[9-11]. In these patients, antiviral treatment with ETV has demonstrated a 5 years cumulative probability with a virological response of 99%, HBeAg loss of 53%, but HBsAg loss of only 1.4%[48]. Similarly, TDF for 10 years has demonstrated an HBeAg loss of 52% but only a 4.9% of HBsAg loss[33].

In HBeAg-negative patients, the 5-year cumulative probability with ETV of virological response was 96%, although HBsAg loss was only achieved in 4.6%[32]. In the TDF registry study with patients treated for 10 years, 100% achieved a virological response, and 83% biochemical response, but only 3.4% succeeded in the HBsAg loss[33].

Similar rates of virological response have been described for TAF in HBeAg-positive[30] and HBeAg-negative patients[31].

This high efficacy in controlling viral replication causes histological and elastographic improvement. The long-term treatment with NA has shown a significant regression of liver fibrosis and even cirrhosis. A study with paired liver biopsies, after a median time of 6 years, in 57 patients receiving ETV[49] showed histological improvement (decrease ≥ 2 points in the Knodell necroinflammatory score) in 96% of patients, and fibrosis improvement (decrease ≥ 1 point in the Ishak fibrosis score) in 88% of them. In a trial with TDF[50], including 348 patients with paired liver biopsies (at baseline and week 240), 87% showed histological improvement and 51% fibrosis regression (decrease ≥ 1 point in the Ishak fibrosis score). Among the 96 patients with cirrhosis at baseline, 74% achieved some degree of fibrosis regression.

A decrease in liver stiffness measurement (LSM) after long-term treatment with NA has been described[51]. After treatment initiation, the LSM decline is faster mainly related to the improvement in necroinflammatory activity. After 6 mo of therapy, the following LSM decrease is slower and could be associated with a true improvement of fibrosis[52,53].

The most important outcome of antiviral therapy is to improve survival. Studies comparing untreated and ETV-treated patients demonstrated that antiviral therapy reduced the incidence of liver-related complications, HCC, and mortality[54,55]. Similarly, a multicenter study in TDF-treated patients with cirrhosis showed a reduced risk of developing, clinical decompensation, HCC or liver transplantation, and death compared to untreated patients[56]. However, patients treated with NA, are still in danger of developing HCC, and high-risk patients stratified by risk scores such as REACH-B or PAGE-B, should continue HCC surveillance[57].

In recent years there has been a debate about the effect of the two main NA on HCC risk. Some data suggest that TDF is associated with significantly lower HCC risk compared to ETV in Asian patients [58]. A Chinese study including 29350 patients, showed a reduced HCC incidence in patients receiving TDF. However, there were differences in HCC risk factors between groups: TDF-treated patients were younger, and more frequently HBeAg-positive, females, without cirrhosis, and without diabetes. Thus, only 1% of patients with cirrhosis had received TDF[59]. Similarly, a recent meta-analysis of individual data including 42939 patients receiving TDF (n = 6979) or ETV (n = 35960) monotherapy, showed a lower risk of HCC with TDF, especially in patients older ≥ than 50, males, HBeAg-positive, and non-diabetic subgroups[60]. In contrast, other studies have failed to demonstrate this association[61,62]. A large study including 1935 Caucasian patients from the PAGE-B cohort did not find differences in 5-year cumulative HCC incidence between ETV (5.4%) or TDF (6.0%) after a median follow-up of 7.5 years[62].

Benefits of functional cure

The "functional" cure defined as the HBsAg loss, with or without seroconversion of antibody against HBsAg (anti-HBs), is considered the optimal goal for antiviral treatments[10,38]. However, even if third-

generation NA are drugs with a high barrier to HBV resistance, and high efficacy, achieving in most patients a virological and biochemical response, the HBsAg seroclearance is anecdotic[63,64]. Table 1 summarizes the efficacy of available treatments to achieve the HBsAg loss.

In patients without advanced fibrosis, the HBsAg loss is associated with an improvement in survival, and minimal risk of developing cirrhosis, decompensation, or HCC[38]. A recent study of 1972 patients with HBsAg loss, showed an HCC annual incidence of 0.38 per 100 person-years (median follow-up of 5.6 years). The study did not show differences between patients who achieved the functional cure spontaneously or with NA[65]. A systematic review showed lower HCC incidence in patients with functional cure (1.86%) compared to those who did not achieve it (6.56%) ($P < 0.001$). Cirrhosis, age ≥ 50, and male gender were the major risks for developing HCC after HBsAg seroclearance[66]. However, the 10-year HBsAg loss rate described in a large multicenter cohort ($n = 4769$) treated with ETV or TDF was only 2.1% with an annual incidence of 0.22%[64].

Rules to consider before treatment withdrawal

International guidelines of the main scientific societies recommend different treatment duration with NA. In non-cirrhotic HBeAg-positive CHB patients, NA treatment can be discontinued when HBeAg seroconversion is achieved and after one year of consolidation[9-11]. However, in non-cirrhotic HBeAg-negative patients, the NA treatment duration has been a matter of debate in recent years[39-43,67].

In 2008 the APASL guideline suggested the possibility of discontinuing NA therapy in HBeAg-negative patients after at least 2 years with undetectable HBV-DNA documented on three separate occasions 6 mo apart[68]. This approach in Asian patients was mostly driven by economics and reimbursement policies. Despite this, in 2012, Hadziyannis *et al*[69] reported in 33 Caucasian patients a high rate of HBsAg seroclearance after stopping ADV (39% at 5.5 years after withdrawal). In 2017, the first randomized controlled trial, the FINITE study, confirmed that the strategy of stopping therapy increased the HBsAg loss rate compared to continuing treatment (19% *vs* 0%)[70]. Based on these studies, in 2017 EASL guideline introduced the possibility of treatment withdrawal in non-cirrhotic HBeAg-negative CHB patients after 3 years of viral suppression[10]. In the last years, several studies have evaluated this strategy with different results (Table 1). Studies in Asian patients have shown a lower HBsAg loss rate compared to Caucasians. The different distribution of HBV-genotypes (especially genotype D), the inclusion or not of patients with advanced liver disease, and the different retreatment rules could explain these dissimilar results[45,71-73].

One of the important points to be considered before stopping treatment is the selection of the best candidates. The initial stopping rules proposed were based on the duration of treatment and virological suppression[9,10]. It has been suggested that NA withdrawal can be successful, only if the transcriptional activity of cccDNA has been silenced during treatment[74]. Additionally, it has been reported that long-term suppression of HBV-DNA can improve CD8 + T cell functions and restore the capacity of immune control by decreasing NK cell killing of HBV-specific T cells and increasing serum cytokines[44,75-77]. This immune restoration can exert control of viral replication after treatment discontinuation, and a large proportion of patients remain as inactive carriers. Moreover, the recurrence of HBV replication after NA discontinuation can represent a trigger for the immune response[78] that can induce an accelerated HBsAg decline and may be beneficial to eradicate residual cccDNA-containing hepatocytes. Our group has recently observed that HBsAg decline was faster during the first year after NA cessation compared to the on-treatment decline[46].

HBsAg and hepatitis B core-related antigen (HBcrAg) levels have been evaluated as surrogate markers to select the patients with a better outcome after NA cessation. It has been shown that not only HBsAg levels at the EoT but also on-treatment HBsAg kinetics are good predictors of HBsAg loss[79,80]. In a study performed by our group, we showed that on-treatment HBsAg kinetics had a high accuracy to predict the HBsAg loss one year after withdrawal[46]. Patients with an HBsAg decline > 1 Log IU/mL during treatment had a probability of 50% of achieving HBsAg loss one year after discontinuation. A large multicenter multiethnic study ($n = 1552$), the RETRACT-B study, showed different cut-offs of HBsAg at EoT in Asian and Caucasian patients. HBsAg levels at EoT < 100 IU/mL in Asian and < 1000 IU/mL in Caucasian patients were associated with a 4-year HBsAg loss probability of 33% and 41%, respectively[47]. Regarding levels of HBcrAg, the CREATE study, including 572 patients with NA discontinuation, showed lower HBcrAg levels at EoT in those with a virological response and HBsAg loss. Patients with undetectable HBcrAg (< 2 Log U/mL) at EoT showed a higher virological response and HBsAg loss rates one year after withdrawal (65% and 12%, respectively). The same group confirmed in 1216 patients that non-Asian ethnicity, HBsAg levels < 100 IU/mL, and undetectable HBcrAg were associated with the highest HBsAg loss rate[81].

Another important point is to define standardized re-treatment criteria. Some authors recommend delaying retreatment, to allow patients with a "beneficial" flare to achieve a functional cure[82]. However, other authors suggested that re-treatment should be initiated in response to significant increases in serum HBV-DNA, regardless of other liver parameters as cases of fulminant hepatitis have been reported[83]. Table 1 summarizes the efficacy of NA withdrawal to achieve the HBsAg loss[84-93].

Table 1 Efficacy of available antiviral treatments and nucleos(t)ide analogues withdrawal to achieve hepatitis B virus surface antigen loss

Ref.	Treatment (duration)	HBeAg	Ethnicity	Follow-up	HBsAg loss (%)

Hirode *et al*[47], 2022	3.0 yr	-	Mixed	17 mo	15.0

Only studies with more than 100 patients have been included. HBsAg: Hepatitis B virus surface antigen; HBeAg: Hepatitis B e antigen; Peg-IFN: Pegylated interferon; LAM: Lamivudine; ADV: Adefovir; TDF: Tenofovir; ETV: Entecavir; TAF: Tenofovir alafenamide.

Risks of treatment withdrawal

The safety of treatment withdrawal is under discussion because on one hand hepatitis flare after NA cessation can induce hepatic decompensation but on the other hand early initiation of NA retreatment can inhibit the beneficial effect of flare-associated immune activation[47,72,94,95]. A study from Taiwan including 691 patients (44.6% with cirrhosis) showed a clinical relapse in 60.6% (7 developed a hepatic decompensation and 3 died)[72]. Similarly, the RETRACT-B study showed hepatic decompensation in only 1.22% (4.3% in patients with cirrhosis and 0.8% in those without cirrhosis; $P < 0.01$)[47]. In this study, 7 patients died (0.45%) by hepatic decompensation and 4 (0.25%) due to hepatitis B-associated flare.

Another important issue is the risk of developing HCC. The study of Jeng *et al*[72] included patients with (n = 308) and without cirrhosis (n = 383). The HCC incidence at 1, and 3 years after treatment discontinuation (0.15% and 1.00% for non-cirrhotic *vs* 1.30% and 4.00% for patients with cirrhosis) was similar to those during NA therapy (0.08% and 0.30% for non-cirrhotic *vs* 1.50% and 3.40% for patients with cirrhosis). Similarly, in the RETRACT-B study, the HCC incidence at 48 mo after NA withdrawal was 2.2% in patients with cirrhosis and 0.7% in those without cirrhosis[47]. Therefore, NA withdrawal does not seem to increase HCC rates. However, the tolerable level of circulating HBV DNA during long-term follow-up post-NA withdrawal has not been yet elucidated.

The evidence of increased HBsAg loss rates after NA cessation in some HBeAg-negative CHB patients must be balanced with safety. NA withdrawal should be performed only in centers with expertise in CHB management and in adherent patients willing stricter control after carefully discussing the pros and cons[74,96,97].

FUTURE

The need of expanding antiviral treatment criteria

Some recent studies have evaluated, with contradictory results, the use of NA in patients who do not meet strict criteria for treatment. On one hand, two retrospective studies in HBeAg-positive HBV-infected patients from Korea showed a lower risk of HCC and cirrhosis in those treated compared to untreated controls, suggesting a benefit of starting NA treatment at earlier phases[98,99]. Similarly, another Asian study including "minimally active" carriers showed a high risk of HCC (HR 9.9; 95%CI, 1.239-76.923; P = 0.031) when compared to inactive carriers[100]. But, the study included HBeAg-positive patients and those with a LSM > 9 kPa[101].

On the other hand, some European studies have not demonstrated significant benefits. A study from Italy, including patients without treatment with normal ALT and DNA < 20000 IU/mL, showed a benign course during a follow-up longer than 4 years[102]. Another study including Caucasian patients with HBeAg-negative chronic infection showed a high rate of HBsAg loss (15%) and low transition to CHB (6.3%) in patients with normal ALT and DNA < 2000 IU/mL or in the "grey zone" (HBV-DNA < 2000 IU/mL and ALT 40-80 U/L or, HBV-DNA 2000-20000 IU/mL and ALT < 40 U/L or ALT 40-80 U/L) after a median follow-up of 8.2 years[103]. However, a recent study from the United States has shown that patients without treatment indications, according to AASLD guidelines, had twice the risk of developing cirrhosis and/or HCC when compared to treated patients[104].

Simplifying indications for treatment initiation could be cost-effective and associated with survival improvement[105]. Therefore, it is plausible that antiviral treatment criteria will be expanded in the coming years to achieve the Global Hepatitis Elimination Goals, especially when new therapies with higher HBsAg loss rates will be available[106].

New HBV biomarkers to monitor antiviral therapy

The persistence of the cccDNA in the hepatocytes perpetuates HBV infection. So, detection and measurement of cccDNA levels would be the most precise tool to recognize HBV eradication. However, cccDNA can only be measured in liver biopsy samples by non-standardized or semi-automated techniques[107]. In recent years, there has been an effort to identify new biomarkers that could serve as cccDNA transcriptional activity surrogate markers.

The hepatitis B virus core-related antigen (HBcrAg) is an interesting biomarker composed of the hepatitis B core antigen (HBcAg), the HBeAg, and the 22-KDa pre-core protein (p22cr)[108]. These protein components are translated from cccDNA transcripts reflecting the cccDNA transcriptional activity. The HBcrAg is detected by automated chemiluminescence techniques using specific monoclonal antibodies with a limited sensitivity of 3.0 Log U/mL. The HBcrAg kinetics has been analyzed during NA therapy in a cohort of 222 CHB patients (132 HBeAg-negative and 90 HBeAg-positive) receiving ETV[109]. The decline of HBcrAg levels was 0.244 Log U/mL per year. HBcrAg levels were lower in HBeAg-negative patients compared to HBeAg-positive, but no differences were found between TDF or ETV[109,110]. On the other hand, the persistence of detectable HBcrAg at EoT has been related to severe aminotransferase flares after NA treatment cessation[111]. The main limitations of HBcrAg are its low sensitivity and its low levels after a long-treatment period in HBeAg-negative patients. Therefore, a great proportion of treated HBeAg-negative patients can show undetectable HBcrAg[112]. Recently, a new ultrasensitive assay has been described to improve the HBcrAg sensitivity, but further studies are needed to consider it in clinical practice[113].

The HBV-RNA is a newer marker under evaluation. The pgRNA is packaged in nucleocapsids and serves as the template for reverse transcription to HBV-DNA. In patients not receiving antiviral therapy, serum HBV-RNA levels are much lower than serum HBV-DNA levels. It can be detected in serum samples as pgRNA and spliced pgRNA variants produced by transcription of cccDNA as a marker of intrahepatic cccDNA transcriptional activity[114]. However, serum HBV-RNA is usually quantified by in-house assays and there are no commercial tests available for routine clinical practice. During NA therapy, reverse transcription of pgRNA to HBV-DNA is blocked, but cccDNA transcription to pgRNA persists, and HBV-RNA may be detected in the serum of patients with undetectable HBV-DNA. Therefore, the HBV-RNA could be useful to monitor NA-treated patients[115,116]. Recently, it has been shown that serum HBV-RNA reduced after treatment initiation from 1.46 Logs at week 48 to 1.77 Logs at week 96[117]. On one hand, serum pgRNA levels at wk 4 after NA initiation were correlated with low HBsAg levels (≤ 100 IU/mL) and seroclearance during follow-up[118]. On the other hand, high levels of pgRNA have been associated with viral relapse after NA withdrawal[119].

The recognition of HBsAg composition could be an interesting tool for following CHB patients because it changes across the stages of HBV infection. The main HBsAg component is S-HBs. The L-HBs and M-HBs proportion is lower in the inactive carrier stage compared to those in HBeAg-negative or HBeAg-positive CHB patients[120,121]. Interestingly, L-HBs and M-HBs proportions decrease prior to total HBsAg loss in patients receiving antiviral treatment[122].

Nowadays, the quantitative HBsAg is the most used and widely available biomarker as a consequence of its standardized and commercial tests. It includes the HBsAg produced not only from cccDNA but also by the integrated DNA that is the main source of the HBsAg in HBeAg-negative CHB patients, being more representative of the transcriptional activity. Moreover, quantitative HBsAg has shown a better predictive capacity compared to HBrcAg and HBV-RNA[123].

However, despite the potential utility of these new biomarkers for monitoring NA treatment, their usefulness should still be established for monitoring the new treatment strategies.

New drugs in development

After several years without major advances in novel therapies for CHB, currently, a multitude of new molecules are emerging, individually or in combination, as future treatment strategies. The last part of this review summarizes the main groups of evolving molecules evaluated in clinical trials (Table 2) and the combinations that are showing higher rates of sustained HBsAg loss (Table 3).

Several drugs are being evaluated in phase II clinical trials. These new molecules can be classified into two main groups according to their mechanism of action: (1) Molecules targeting different steps in the HBV life cycle; and (2) those acting as immunomodulators.

Molecules targeting HBV life cycle

Molecules targeting different steps in the HBV life cycle are summarized according to their treatment class, mechanism of action, and type in Table 2[124-143].

HBV entry inhibitors

HBV entry inhibitors protect naïve hepatocytes from infection. However, they do not directly target cccDNA. The recent identification of liver-specific bile acid transporter, the NTCP, has allowed exploring new therapeutics to block viral entry and reduce viral spread[144]. Bulevirtide consists of the preS1 domain of the large surface protein, which inhibits NTCP and prevents viral entry. In the phase 2 study, Bulevirtide monotherapy was evaluated in patients with CHB co-infected with the hepatitis D virus (HDV)[124]. HBV-DNA declined by > 1 Log in 32% of patients, although HBsAg was not affected. Its low effect on HBsAg levels made most studies focus on long-term treatment for HBV/HDV co-infected patients.

Capsid assembly modulators

The primary mechanism of action of nucleocapsid assembly modulators (CAMs) is to drive the nucleocapsid misassemble. These molecules interfere with capsid formation and disrupt the encapsidation of pgRNA. They have been classified into two main families (Class I and Class II). These agents have been shown to decrease serum HBV-DNA and RNA levels, although declines in HBsAg levels are negligible. Moreover, it has been shown HBV-RNA and HBcrAg rebounded after discontinuation of treatment [126]. Due to these limitations, to date, the role of CAMs in future treatments for CHB must be defined.

Post-transcriptional control inhibitors (small interfering RNA and antisense oligonucleotides)

RNA molecules, both pgRNA, and mRNAs encoding viral proteins, are essential for HBV replication. Small interfering RNA (SiRNA) is a specific post-transcriptional gene silencing mechanism that can inhibit the translation of viral proteins needed for cccDNA formation. SiRNA is 21-23 nucleotide duplexes processed from large double-stranded RNAs[145]. Chemically synthesized short RNA duplexes were shown to be capable of gene silencing *in vitro* without inducing an interferon response [146]. Different anti-HBV siRNA are being tested in clinical trials. Available clinical data are promising and show that siRNAs are safe and well-tolerated[127]. A study of siRNA therapy that targeted the common 3′ ends of all HBV transcripts showed that while the treatment markedly reduced HBsAg levels in HBeAg-positive patients, it had minimal effects in HBeAg-negative patients[128].

Antisense nucleotides (ASOs) are single-stranded DNAs (8-10 nucleotides) that target HBV mRNA sequences, forming a DNA-RNA hybrid that is rapidly degraded by cytoplasmic ribonuclease-H[147]. Early results of ASOs, alone or in combination, have shown a profound HBsAg decline[130]. The B-Clear Study, a phase 2b clinical trial evaluating bepirovirsen 300 mg subcutaneously once weekly for 24 wk, showed undetectable HBsAg in 9% of patients who received bepirovirsen plus NA and in 10% who received bepirovirsen alone[131].

HBsAg release inhibitors: Nucleic acid polymers

HBsAg plays a major role in HBV infection and is the most abundant HBV antigen. Therefore, blocking its release could potentially prevent the release of new virions, decline the number of subviral particles and restore the HBV-specific immune response[148]. Nucleic acid polymers (NAPs) are amphipathic

Table 2 Mechanisms of action of the new drugs under development

Treatment class	Mechanism of action	Types
Drugs targeting HBV life cycle		
Entry inhibitors	Blockage of liver-specific bile acid transporter (NTCP)	Inhibitors of NTCP[124]; NMAb[125]
Capsid assembly modulators	Interfere with capsid formation and disrupt the encapsidation of pgRNA	CAMs[126]
Post-transcriptional control inhibitors	Post-transcriptional gene silencing by inhibition of the translation of viral proteins	SiRNA[127-129]; ASOs[130,131]
HBsAg release inhibitors	Intracellular degradation of HBsAg *via* proteasomal and lysosomal degradation	NAPs[132,133]
Immunomodulators		
Innate immune activator	Stimulation of innate immunity through TLRs and RIG-I	TLRs agonist[134-137]; RIG-I agonists[138, 139]
Adaptive immune activator	Blocking the PD-1/PD-L1 pathway to reverse T-cell exhaustion; stimulation of host's immune response to generate CD4 and CD8 HBV-specific T cells	Checkpoint inhibitors[140,141]; therapeutic vaccines[142,143]

HBV: Hepatitis B virus; NTCP: Sodium taurocholate co-transporting polypeptide; NMAb: Neutralizing monoclonal antibodies; CAMs: Nucleocapsid assembly modulators; SiRNA: Small interfering RNA; ASO: Antisense oligonucleotides; NAP: Nucleic acid polymers; TLRs: Toll-like receptors; RIG-I: Retinoic acid-inducible gene-1; PD-1: Programmed death receptor 1; PD-L1: Programmed cell death ligand 1; HBsAg: Hepatitis B virus surface antigen; HBeAg: Hepatitis B e antigen.

phosphorothioate oligonucleotides. The antiviral effect of NAPs against HBV infection is the inhibition of HBsAg release, although the exact mechanism is unknown, resulting in rapid clearance of HBsAg [132]. In clinical studies, NAP monotherapy was accompanied by rapid HBsAg decline and seroconversion. Recently, NAP-based combination therapy with TDF and Peg-IFN achieved a functional cure in 35% of patients[133] Interestingly, in HBeAg-negative patients, HBsAg produced by integrated DNA was lost. However, more than 90% of patients experienced immune-mediated transaminase flares during therapy[132].

Immunomodulators

Immunomodulator molecules are summarized according to their treatment class, mechanism of action, and type in Table 2.

Immunomodulatory targets including therapeutic vaccines

The impaired immune response is one of the main barriers to eliminating HBV. T cell immune exhaustion due to the presence of high amounts of HBsAg and a defective response of the innate immune response has a role in HBV persistence. Thus, treatment strategies to restore HBV-specific immune responses with immunomodulatory therapies have been evaluated to achieve viral clearance.

Pegylated interferon: A "second life" for an old friend

Interferon was the first drug approved for CHB treatment. Despite the long use of this treatment, the exact mechanism of action is still unclear. It has been suggested that Peg-IFN has two main effects, acting on the transcriptional activity of cccDNA and also an immunomodulatory effect, enhancing both innate and adaptive immunity[149,150]. Due to its hypothetical immunomodulatory effects, the synergistic effects of combination with NA and Peg-IFN have been evaluated.

A recent meta-analysis found that NA and Peg-IFN combination improved HBsAg seroclearance rates (RR: 4.52, 95%CI: 1.95-10.47 for adding-on and RR: 12.15, 95%CI 3.99-37.01 for switching-to) compared to NA monotherapy. One of the strongest predictors of HBsAg seroclearance was the HBsAg level at the start of IFN therapy[151]. Our group also showed that the addition of Peg-IFN to NA produced a faster and larger decrease in HBsAg levels compared to NA monotherapy, especially in those patients with IL28CC polymorphism[112]. A better Peg-IFN response in patients with IL28CC polymorphism has been described especially in those infected with genotype D[152,153]. More recently, a Chinese real-world study (n = 3988), the Everest Project (NCT04035837), has reported that the addition of Peg-IFN alpha 2b to NA in HBeAg-negative patients achieved a 4-year HBsAg loss rate of 33%[89].

The main concerns on the use of Peg-IFN are side effects, poor tolerability, and major contraindication such as decompensated cirrhosis. These explain the preference to use NA in routine clinical practice. However, in selected patients with good tolerance, the adding-on or switching-to strategy may improve the HBsAg seroclearance. Indeed, some of the phase 2 trials evaluating new antivirals, have included concomitant treatment with Peg-IFN and have shown better outcomes.

Table 3 Efficacy of drug combinations to achieve sustained hepatitis B virus surface antigen loss

Drug class	Drug	Patients	Time therapy (wk)	Efficacy	Safety
NA +/- CAM	NA *vs* NA + JNJ-6379 (bersacapavir)	232	24-48	HBsAg decline 0.25 log IU/mL *vs* 0.41 log IU/mL	No major AE
SiRNA +/- NA	AB-729 *vs* NA + AB-729	43	8	HBsAg decline 2.03 log IU/mL monotherapy *vs* 2.16 log IU/mL combination	Injection site reactions; ALT flares
ASO + NA	ASO-GSK3228836 (bepirovirsen) ± NA	457	12-24	HBsAg < LoQ in 28%-29% and HBsAg loss in 9%-10% after 24 wk of EoT	Injection site reactions; few cases of grade 3-4 ALT flares
Inhibitor of NTCP + Peg-IFN	Bulevirtide + Peg-IFN in HDV-HBV co-infection	90	48	HBsAg loss 26.7% in one arm *vs* 0% in the other	Related to Peg-IFN; injection site reactions
NA + TLR agonists	NA + TLR7 agonist (vesatolimod, GS-9620)	162	24	No changes in HBsAg	Some grade 3 AE with higher doses (few treatment discontinuations)
NA + TLR agonists	NA + TLR8 agonist (selgantolimod)	48	24	HBsAg loss 5% at week 48	Mild and transient gastrointestinal AE
NA + checkpoint inhibitors	NA + PD-1 inhibitor (nivolumab)	12	1 dose (24 follow-up)	HBsAg reduction 0.48 log IU/mL (HBsAg loss in 5%)	No major AE
NA + checkpoint inhibitors	NA + PD-L1 inhibitor (ASC22, Menvafolimab)	48	24	HBsAg decline 0.38 log IU/mL (HBsAg loss in 19%)	Grade 1 and 2 ALT flares
NA + SiRNA +/- CAM	NA + JNJ-3989 (siRNA) + NA ± JNJ-6379 (CAM)	117	48	HBsAg decline 2.1 log IU/mL in double *vs* 1.8 log IU/mL in triple combination	No major AE
NAP + NA + Peg-IFN	REP2139 or REP 2165 + NA + Peg-IFN	40	48	HBsAg loss in 35% and HBsAg < 100 IU/mL in 75%	Related to Peg-IFN
SiRNA + NA +/- Peg-IFN	VIR 2218 (siRNA) + NA +/- Peg-IFN	80	24	HBsAg decline 2.03 log IU/mL in dual arm *vs* 2.55 log IU/mL in triple arm (HBsAg < 100 IU/mL in 95% and HBsAg < 10 IU/mL in 55%)	Related to Peg-IFN

CAM: Nucleocapsid assembly modulator; HBV: Hepatitis B virus; SiRNA: Small interfering RNA; NTCP: Sodium taurocholate co-transporting polypeptide; ASO: Antisense oligonucleotides; NAP: Nucleic acid polymers; TLRs: Toll-like receptors; RIG-I: Retinoic acid-inducible gene-1; PD-1: Programmed death receptor 1; PD-L1: Programmed cell death ligand 1; HBsAg: Hepatitis B virus surface antigen; HBeAg: Hepatitis B e antigen; ALT: Alanine aminotransferase; LoQ: Limit of quantification; EoT: End of therapy; AE: Adverse events.

Toll-like receptor and retinoic acid-inducible gene-1 agonists

HBV can be recognized by receptors such as toll-like receptors (TLRs)[154] and retinoic acid-inducible gene-1 (RIG-1)[155] TLRs are receptors that initiated intracellular pathways and induce antiviral molecules such as interferons, and cytokines. It has been reported that the activation of TLR-mediated pathways results in the suppression of HBV replication. An oral TLR 7 (TLR7) agonist, GS9620, has shown a decrease in serum HBV-DNA and HBsAg in chimpanzees[134]. However, a phase IIb trial in humans, showed a minimal decrease in HBsAg levels, despite the increase in cytokines and NK cell activity[135,136]. A more recent trial has shown that the combination of selgantolimod, a TLR8 agonist, with a NA resulted in a minimal reduction of HBsAg levels[137]. RIG-I constitutes an intracytoplasmic receptor that interacts with RNA viruses. Once activated, it leads to signal transduction through protein kinase complexes and activation of transcription factors that migrate to the nucleus and activate interferon-stimulable genes leading to the production of IFN[138]. Inarigivir activates the RIG-I pathway. Although early studies reported a reduction in HBV-DNA levels, there were cases of severe hepatotoxicity, with multiple cases of acute liver failure and one death, that lead to its discontinuation [139].

Checkpoint inhibitors

The immune system of HBV-infected patients shows high levels of programmed death receptor 1 (PD-1)-expressing CD8 T cells and high levels of programmed cell death ligand 1 (PD-L1) expression. This suggests that PD-L1 blockade could be a suitable strategy to treat chronic HBV infection. Furthermore, anti-PD-L1 blockade increases the number of IFN-γ-producing T-cells and the amount of IFN-γ produced per cell[156]. Checkpoint inhibitors against PD-1 and PD-L1 have been shown to be effective in several malignancies by reversing T-cell exhaustion and restoring immunity. However, the efficacy to achieve HBsAg clearance has been disappointing. In the CheckMate 040 trial, nivolumab increased

HBV-DNA 1 Log from baseline in 10% of HBsAg-positive patients[140]. PD-1 blockade showed limited antiviral activity, and no patient exhibited HBsAg seroconversion[141].

Monoclonal antibodies

HBV entry can be interrupted by small compounds such as neutralizing monoclonal antibodies (NMAb). In a phase 2 study, it has been evaluated the combination of NMAb VIR-3434 with small interfering RNA (SiRNA) VIR-2218 for up to 20 wk. Combination treatment was generally well tolerated with no serious adverse events. The majority of patients achieved low levels of HBsAg (< 10 IU/mL) but any patient lost the HBsAg during the study[125].

Therapeutic vaccines

These immunogenic molecules are developed to stimulate the host immune response generating CD4 and CD8 HBV-specific T cells to suppress viral replication and HBsAg loss. Early studies in humans showed a small decline in HBsAg[142]. However, several new therapeutic vaccines are in development probably to be used in combination with other drugs such as SiRNA[143].

Other immunomodulatory approaches

In recent years, a better understanding of the immune response to HBV has emerged with new therapeutic possibilities. T cell receptor (TCR)- redirected T cell and chimeric antigen receptor (CAR) T cell involve genetic engineering to confer specificity in front of HBV. CAR-T cells are transduced with an antibody-like receptor to recognize HBsAg on the surface of infected hepatocytes whereas TCR-redirected T cells respond to HBV peptides[157]. However, the investigation in this field is still under development and is being tested in Phase I studies evaluating HBV-infected patients with HCC[158, 159].

Combinations of drugs in development

None of the new previously described molecules can achieve significant sustained HBsAg loss if used alone. Therefore, the most advisable strategy seems to be the combination of molecules with different mechanisms of action[160]. Table 3 summarizes the efficacy of the evolving combinations to achieve sustained HBsAg loss.

CONCLUSION

Long-term treatment for CHB has been used for decades, showing a good safety profile and high efficacy in controlling viral replication, improving histology, and decreasing the incidence of HCC, clinical decompensation, and mortality. However, the persistence of cccDNA and the low probability of HBsAg seroclearance with NA therapy made necessary indefinite treatment in a vast majority of patients. With the new insights into the role of the immune system in HBV infection persistence and the knowledge of the different viral cycle phases, there has been an increase in new therapeutic approaches in recent years. Moreover, several clinical trials evaluating new drugs with different mechanisms of action are ongoing with promising results. It is expected that in the coming years, there will be a paradigm shift in the treatment of CHB, as we have already seen in chronic hepatitis C, and functional cure in an important number of patients seems closer than ever. Meanwhile, an effort to improve diagnostic rates, and to assure access to treatment for all patients who need it must be urgently done.

Abstract

The gut microbiome plays an important role in the variation of pharmacologic response. This aspect is especially important in the era of precision medicine, where understanding how and to what extent the gut microbiome interacts with drugs and their actions will be key to individualizing therapy. The impact of the composition of the gut microbiome on the efficacy of newer cancer therapies such as immune checkpoint inhibitors and chimeric antigen receptor T-cell treatment has become an active area of research. Pancreatic adenocarcinoma (PAC) has a poor prognosis even in those with potentially resectable disease, and treatment options are very limited. Newer studies have concluded that there is a synergistic effect for immunotherapy in combination with cytotoxic drugs, in the treatment of PAC. A variety of commensal microbiota can affect the efficacy of conventional chemotherapy and immunotherapy by modulating the tumor microenvironment in the treatment of PAC. This review will provide newer insights on the impact that alterations made in the gut microbial system have in the development and treatment of PAC.

Key Words: Pancreatic cancer; Gut microbiome; Chemotherapy; Dysbiosis; Intratumoral microbiome; Gut flora

Core Tip: Pancreatic cancer (PC) remains of on the most dismal in terms of prognosis. Treatment options are limited and even after complete surgical resection, the prognosis remains poor. The gut microbiome has been incriminated in the past for the development of certain cancers. Our review found that observation to be true as well for PC. Furthermore, we also found that it plays a role in efficacy and tolerance of certain regimens used to treat PC.

INTRODUCTION

Pancreatic cancer (PC) usually refers to ductal pancreatic adenocarcinoma (PAC) (including its subtypes), which represents 85 to 90 percent of all pancreatic neoplasms. PC ranks fourth among cancer related mortality in the United States, only behind lung, colorectal, and prostate cancers in males, and lung, breast, and colorectal cancers in females. Although the incidence of PC has been relatively stable over time, the increasing use of imaging techniques such as endoscopic ultrasound and helical (spiral) abdominal computed tomography (CT) scans has revealed an increasing number of incidentally found cases of PC[1,2].

PC can run in some families, and approximately 10 percent of individuals with PC have a family history of the disease[3,4]. There are two broad categories of hereditary risk for PC which are inherited genetic predisposition syndromes associated with PC and familial PC (FPC), which is defined as a family with a pair of affected first-degree relatives who do not meet criteria for a known PC-associated genetic predisposition syndrome[5].

The major gene causing most cases of hereditary PC remains unknown. Pathogenic germline variants (PGVs) in the breast cancer associated (BRCA) 1 and 2 genes are the most commonly associated mutations, occurring in 13 to 19 percent of FPC families[6]. Next generation sequencing helped uncover other genes causing hereditary pancreatic ductal adenocarcinoma: The partner and localizer of BRCA2 (PALB2) gene and the ataxia-telangiectasia mutated (ATM) gene[7,8]. PGVs are especially common in individuals with early onset PC (*i.e.*, developing before age 50)[6]. Cigarette smoking contributes to the risk of PC in patients with hereditary pancreatitis and FPC and is associated with an earlier PC diagnosis by approximately 20 years[9].

In recent years, the role of gut microbiome in the development and treatment of several cancers, including PC, has been an area of active research. *Porphyromonas gingivalis* (*P. gingivalis*), *Aggregatibacter actinomycetemcomitans* (*A. actinomycetemcomitans*) and even *Helicobacter Pylori* (*H. Pylori*) are linked to an increased risk of PC[10,11]. Probiotics have been shown to be effective in reducing pancreaticoduodenectomy complications, by directly suppressing the growth of cancer cells. Postbiotics have been shown to have selective cytotoxicity against tumor cells. Prior literature revealed that fecal microbiota transplantation led to a reduction in tumor size for PC[12].

Carcinoembryonic antigen-related cell adhesion molecule 7 (CEACAM-7), also known as CGM2, is a glycoprotein expressed on the luminal surface of epithelial cells near the mouth of colonic crypts and on pancreatic ductal epithelial cells[13]. Most recently it has been shown that CEACAM7-directed chimeric antigen receptor (CAR) T cells can effectively mediate remission of late-stage patient-derived PAC xenograft tumors[13].

This review will provide a concise and up to date overview of the impact of commensal gut microbiota in the development and management of PAC. Furthermore, we will focus on the pathophysiology and pathogenesis by which the gut flora can gain oncogenetic attributes and to what extent their alteration can affect the treatment and outcome of PAC.

DIAGNOSIS OF PC

Recent advances in imaging techniques have elevated the diagnostic acumen for PC. Abdominal ultrasound (US) is a non-invasive approach, which can detect pancreatic masses with an accuracy of 50%-70%[14]. Although there are no tell-tale characteristic signs of different pancreatic masses, a hypoechoic mass, pancreatic and/or biliary duct dilation could point towards an ominous pathology[14,15]. If a contrast enhanced US is available, the diagnostic accuracy could be significantly enhanced as hypovascularity of a mass point towards PAC whereas endocrine cell tumor is hyper vascularized and any pancreatitis associated mass is usually iso-vascularized[14,16].

CT with contrast is perhaps the most widely used-in detection and staging of PC. Hypovascularity, increased fibrous stroma, and decreased enhancement compared to surrounding tissue points towards PAC[17]. In hypoattenuating lesions and in instances where CT is equivocal, multi-detector row CT can be helpful as it provides three dimensional images and various phases of contrast enhancement-parenchymal, portal venous, and arterial-leading to earlier detection and accurate staging of the cancer [18-20]. Enhanced magnetic resonance imaging (MRI), due to better soft tissue visualization, has been shown to be equal or superior to CT imaging for blood vessel invasion and local extent, however, it is poor in detecting the involvement of portal venous system or duodenum[21-23]. The most accurate and sensitive method for detection of even the smallest tumors with or without vascular invasion is EUS-superior to MRI, CT, or US. It is also an excellent modality for diagnosis when combined with biopsy and has incredibly high sensitivity to detect metastasis to the lymph nodes as well as vascular invasion [24-27]. The biggest challenge in diagnosis is differentiating between chronic pancreatitis and PAC, this is when EUS with biopsy comes in handy.

STAGING OF PC

The staging of PC at the time of diagnosis is pivotal for prognosis and treatment planning as the aggressive or palliative care approach could be applied based on the stage. The role of CT imaging with contrast is pivotal in determining the stage, however, sometimes, sophisticated modalities such as enhanced MRI, EUS, or fluorodeoxyglucose-positron emission tomography could be needed. The tumor size, location in the pancreas, surrounding structures involvement-with or without vascular involvement, and spread to surrounding lymph nodes or metastasis are the components involved in staging for PC.

The T (tumor), N (Node), and M (Metastasis) is the widely accepted staging systems for PC as per The American Joint Committee for Cancer[28]. The T stage is classified based on the tumor size within the pancreas and/or involvement of vascular structures. The N and M stage is classified based on the involvement of regional lymph nodes and sites of metastasis, if any. Subsequently, based on the imaging, cancer is characterized as resectable, borderline resectable, locally advanced, or metastatic disease. Stages I and II do not involve any major blood vessels, stage III is a localized tumor but with involvement of a major blood vessel, whereas Stage IV is metastatic disease[28].

The National Comprehensive Cancer Network stages PC primarily based on tumor extent. This is primarily in the absence of metastatic disease and resection options are localized advanced/unresectable, borderline resectable, and resectable disease. Locally advanced/unresectable disease is predominantly when the tumor involves major vascular structures such as aorta, superior mesenteric or portal vein (unreconstructable), or > 180 degrees of tumor contact with the Superior mesenteric artery or celiac artery. Resectable disease or borderline resectable is defined as no involvement of any vascular structures mentioned above or ≤ 180 degrees of involvement[29].

PC-MODALITIES OF TREATMENT

Depending on the staging of PC, there are various modalities which are employed for the treatment. Surgical resection is always desirable, however, due to the relatively silent clinical course of PC, only 1/5th of patients have resectable tumors at the time of diagnosis[30,31]. The most utilized surgical procedures are total pancreatectomy, distal pancreatectomy, and Whipple's procedure depending on the staging of the cancer[32]. Previously, in patients presenting with jaundice, preoperative biliary stenting was considered if there was a tumor on the head of the pancreas causing biliary obstruction, however, recent studies have shown that this modality is associated with increased time to surgery, increased rates of infection, and complications; preoperative biliary stenting is as a result, no longer recommended for head of the pancreas tumors which have not metastasized and can be easily resected [33,34]. However, preoperative stenting can be considered in patients who are undergoing neoadjuvant chemotherapy, if surgery is postponed by logistical constraints, or have severe jaundice[33,34].

In patients who present with PC s of 'borderline resectability', neoadjuvant therapy prior to surgical resection is a consideration. However, data is conflicting. While there is some evidence on increased survival amongst borderline resectable tumors with neoadjuvant gemcitabine-based chemotherapy, there are also studies which suggest an increased postoperative stay and increased surgical challenges in locally resectable tumor patients who received neoadjuvant chemotherapy[35-37]. Also, it is important to note that histological diagnosis is mandatory prior to starting the chemotherapy, which may further delay the time to surgery.

The overall prognosis of PC is abysmal, even post complete surgical resection. As a result, 5-Fluorouracil (with Leucovorin) or Gemcitabine adjuvant chemotherapy is frequently employed post-surgical resection. Which agent is better though, does remain a topic of discussion. Studies are equivocal with some showing no difference between the two whereas others favor gemcitabine[38]. In patients with metastatic disease, the armamentarium consists of psychosocial support, chemotherapy, treating a

variety of other comorbid conditions, and targeted therapy. As far as chemotherapy is concerned in such a setting, Gemcitabine has been shown to be superior, by far and remains the first line standard of care[39]. Arguably, Conroy *et al*[40] have proven that FOLFIRINOX can super side Gemcitabine, as patients on FOLFIRINOX demonstrated not only a better response rate, but also improved one year, progression free, and overall survival[40]. In patients who are non-tolerant to first line gemcitabine, second line treatment consisting of oxaliplatin with fluoropyrimidines have demonstrated some clinical benefit[41,42]. Furthermore, if FOLFIRINOX was used as the first line, gemcitabine-based therapy should be tried as second line and has some clinical evidence of being beneficial[40].

Newer modalities of treatment include but are not limited to the use of epidermal growth factor receptor (EGFR) inhibitors. Medications like Cetuximab and Erlotinib which target the EGFR have been developed recently for targeted therapy and have been shown to be effective in many clinical trials. A combination of gemcitabine with Erlotinib is shown to increase overall survival rates and decrease the progression of PC[43]. PC cells are notorious to adapt in order to decrease the drug delivery to them by production of desmoplastic stroma and lead to resistance to chemotherapeutic agents[44]. Several therapies have recently been developed to decrease this stromal tissue and improve drug penetration despite the desmoplastic stroma, including nab-paclitaxel[45].

Radiation therapy has a somewhat beneficial role alongside surgery and chemotherapy. Neoadjuvant radiation therapy for PC has been described in prior literature. Pisters *et al*[46] demonstrated that minimal toxicity and a very small recurrence rate can be obtained with preoperative fractionation chemoradiation based on 5-Fluorouracil, Whipple's procedure, and intraoperative radiation[46]. In another study, utilizing a similar strategy for treatment but replacing 5-Fluorouracil with paclitaxel-based chemotherapy, the results were similar, however, the toxicity levels were higher[47].

To improve the patient's overall prognosis, radiation therapy is frequently being utilized for management of PC alongside chemotherapy. In the United States, adjuvant radiation therapy is a common norm after the Gastrointestinal Tumor Study Group's prospective study in 1985. Patients with resectable PC were enrolled in this trial and were found to have a significantly longer and medial survival rate when treated with adjuvant chemoradiation[48]. Owing to this trial, adjuvant chemoradiation, the most commonly used adjuvant treatment for patients with resectable PC, is being practiced to date in the United States.

Novel techniques like stereotactic body radiotherapy have also been developed in recent years for targeted delivery of radiation. However, it has only been shown to slow local progression of the disease but has no effect on overall survival rates as the majority of mortality in PC patients is secondary to systemic and distant metastasis[49-51]. As PC is genetically a heterogeneous malignancy, there have also been baby steps in personalized chemotherapeutic regimen based on the patient's genome to significantly increase the rates of chemotherapeutic efficacy by decreasing the resistance and making the response to chemotherapy consistent across all individuals. However, further research is needed on this novel therapeutic approach.

GUT MICROBIOTA AND PC

Mechanisms via which microbes regulate pancreatic oncogenesis

The gut microbiome, which refers to microbes naturally present in the human mucosal surfaces, has shown, when altered, to lead to oncogenesis and to some extent affect the response to therapy of several cancers, among which PAC[52]. The exact mechanisms by which oral and intestinal microbiota reach the pancreas remains unknown, but the proposed mechanisms involve the translocation *via* biliary/pancreatic ducts or through the blood circulation[52]. A summary can be found in Table 1.

P. gingivalis, which is a bacterium mainly found in the mouth and associated with periodontal diseases, has shown the ability to disseminate and affect immune response. *P. gingivalis* infection has shown an involvement of toll-like receptors (TLRs) including TLR4, involved in protective immunity. TLR signaling, especially TLR4, has been shown to play an important role in human pancreatic tumors [53]. Furthermore, periodontal diseases, such as the ones caused by *P. gingivalis* can lead to an increased production of nitrosamines[54]. Nitrosamines can be metabolized by Cytochrome P450 and produce electrophiles that can effectively interact with the DNA and lead to the formation of DNA adducts that have a carcinogenic potential if not repaired[55]. Porphyromonas Peptidyl Arginine Deaminase (PPAD) is a protein produced by *P. gingivalis* that has been associated with cancer development by the way of P53 activity and KRAS (Kirsten-ras) mutation[52]. P53, which is a tumor suppressor gene, if mutated can lead impairment of cell cycle arrest and decrease of apoptosis increasing the risk of malignancy. KRAS, which is an oncogene with hydrolyzing effect on guanosine triphosphate, can lead uncontrolled and inappropriate cell proliferation, thus increasing the risk of malignancy[52]. P53 is a transcription factor that can activate the transcription of numerous genes, including the Cyclin-dependent kinase (CDK) inhibitor p21.

P53 is rapidly degraded and therefore not detectable within the cell. Mutation of the P53 gene results in a protein that fails to bind DNA effectively. Therefore, expression of the CDK inhibitor P21 gene is decreased, and P21 protein production is decreased. P21 protein is not available to stop the entry of the

Table 1 Gut microbiota associated with Pancreatic oncogenesis

Bacteria	Primary site	Potential mechanism	Subsequent effect	Ref.
Porphyromonas gingivalis	Mouth	TLR signaling disruption; Nitrosamines production; PPAD production	Loss of protective immunity; DNA adducts formation; P53 overactivity (loss of apoptosis); KRAS mutation (cellular overproliferation)	[52-55]
Aggregatibacter actinomycetemcomitans	Mouth	Nitrosamine production; DNA double-strand breaks; CagE production	DNA adducts formation; genome instabilities; dysregulation of DNA methylation expression	[52, 58,59]
Fusobacterium nucleatum	Mouth	FadA production; Fap2 production	activation of the Wnt/β-catenin pathway; suppression of the cytotoxic effects of NK cells and lymphocytes	[59, 61-63]
Helicobacter Pylori	Stomach	cagA, cag PAI and vacA production	Disruption of host intracellular signaling pathways	[64]
Bacteroides fragilis, Bacteroides vulgatus, Listeria monocytogenes, Clostridium, Lactobacillus, Bifidobacterium	Large bowel	Transformation of primary bile acids to secondary bile acids	Reduction of susceptibility to apoptosis, induction of inflammatory mediators, and perturbation of membranes and cellular movement	[76]
Escherichia coli	Large bowel	Polyamines production	Polyamines upregulation	[81-83]

TLR: Toll-like receptor; PPAD: Porphyromonas Peptidyl Arginine Deaminase; CagE: Cytotoxin-associated gene E; NK: Natural killer; PAI: Pathogenicity island; cagA: Cytotoxin-associated gene A.

cell into S phase, again resulting in unregulated cell cycle progression, potentially leading to carcinogenesis[56]. The KRAS gene, an oncogene, is one of the most frequently mutated genes in PC. This gene is the human homolog of a transforming gene isolated from the Kirsten rat sarcoma virus, hence the name KRAS. Mutations in this gene, the vast majority of which are at codon 12, are activating, leading to abnormal activation of the protein product of the gene[57].

A. actinomycetemcomitans is also an oral microbiome that has been incriminated in PAC[52]. Similar to *P. gingivalis*, it can lead to periodontal infections and lead to increased nitrosamine production[54]. *A. actinomycetemcomitan* can also induce DNA double-strand breaks in host cells, independently of apoptosis, and cause the risk of genome instabilities and subsequently increase the risk of carcinogenesis[58]. Furthermore, the bacteria can produce the cytotoxin-associated gene E (CagE). CagE may have helicase activity, and its role in regulating DNA methylation expression is considered as possible mechanisms of tumorigenesis. CagE gene has been widely expressed in various cancer cell lines and cancer tissues including PC[59]. *Fusobacterium nucleatum* (*F. nucleatum*), which is another oral microbiome produces Fusobacterium adhesin A (FadA), that showed capacity of binding to host cells and is also the most characteristic virulence factor of *F. nucleatum*[59]. The host receptors for FadA are members of the cadherin family, mainly E-cadherin and vascular endothelial (VE) cadherin (CDH5) [60]. FadA binds to E-cadherin of epithelial cells, leading to phosphorylation and internalization of E-cadherin on the membrane; afterwards, canonical Wnt pathway is activated, accompanied by decreased phosphorylation of β-catenin, which accumulates in the cytoplasm and translocate to the nucleus[59]. Increase in Wnt signaling activity and subsequent activation of the Wnt/β-catenin pathway, has shown to be essential in the initiation of PC[61,62]. Furthermore, FadA binds VE-cadherin on VE cells, increasing endothelial penetrability[59]. Therefore, FadA not only directly invades host cells but also allows dissemination of itself and other bacteria into blood by increasing endothelial permeability[59]. *F. nucleatum* can produce a protein called familial adenomatous polyposis 2, which binds and interacts to human inhibitory receptor T cell immunoreceptor on natural killer (NK) cells and lymphocytes. Thus, suppressing the cytotoxic effects of NK cells and lymphocytes, leading to protection of tumors from the immune system and fostering a flourishing inflammatory context[63]. By a mechanism similar to *P. gingivalis*, *F. nucleatum* can be involved with the TLRs and lead to carcinogenesis as discussed previously [53].

H. Pylori is notorious for its association with gastric cancer and yields various virulence factors that may disrupt host intracellular signaling pathways and lower the threshold for neoplastic transformation. Of all virulence factors, cytotoxin-associated gene A and its pathogenicity island (cag PAI) and vacuolating cytotoxin A are the major pathogenic factors[64]. Whether *H. Pylori* infection is associated with PAC remains controversial with conflicting data in the literature. A study by Kumar *et al*[65] showed a very low incidence of *H. Pylori* among patients with PAC, whereas studies by Hirabayashi *et al*[66], and Nilsson *et al*[67] found an association.

Several members of the gut microbial community (especially of the large bowel), including *Bacteroides fragilis*, *Bacteroides vulgatus*, *Listeria monocytogenes*, *Clostridium*, *Lactobacillus*, *Bifidobacterium*, and *Escherichia*, are involved in the transformation of primary bile acids to secondary bile acids, either by

deconjugation, oxidation, dehydroxylation, or epimerization[68-70]. Bile acids have multiple nuclear receptors, including farnesoid-X-receptor (FXR), liver-X receptor, CAR, vitamin D receptor (VDR), pregnane X receptor (PXR), and a non-nuclear receptor Takeda G Protein-Coupled Receptor 5/G-protein-coupled bile acid receptor (TGR5), that may impact carcinogenesis[71,72]. Secondary bile acids can behave as both pro- and anti-carcinogens, depending on the cancer concerned and the concentration of the bile acid present[71-73]. Furthermore, bile acids can modulate the composition of the microbiome and facilitate bacterial translocation into tissues, which is a key step in the carcinogenesis of PAC[74]. Bile acid levels have been shown to be elevated in PAC[75]. Bile acids can also affect risk factors for PAC such as pancreatitis and bile acid efflux disorders, type II diabetes, obesity, and hyperlipidemia; and they can reduce susceptibility to apoptosis, induce inflammatory mediators, and may perturb membranes and cellular movement[76]. A secondary bile acid, deoxycholic acid can bind to TGR5 and activate EGFR, mitogen-activated protein kinase, and signal transducer and activator of transcription 3 signaling in PAC cells, inducing cell cycle progression[77]. Other bile acid receptors such as VDR, FXR and PXR are also found to be highly expressed in PAC tissues compared to normal tissues[78-80].

Polyamines can be produced, accumulated, or used by the following gut bacteria *Escherichia coli* (*E. coli*), *Enterococcus faecalis* (*E. faecalis*), Staphylococcus aureus, Haemophilus influenzae, Neisseria flava, Pseudomonas aeruginosa, Campylobacter jejuni, Yersinia pestis, Vibrio cholerae, Bacteroides dorei, Bacteroides thetaiotaomicron, *Bacteroides fragilis*, Bacillus subtilis, and Proteus mirabilis[81,82]. A mouse study revealed that bacterial polyamine biosynthetic capacity was upregulated and aggravated by tumor progression in PAC and there was a correlated elevated serum level of polyamines[83].

As evidence by the work of Riquelme *et al*[84], Fecal Microbiotal Transplant from human subjects to mice, yielded from PC long term murine survivors, showed a significant reduction in tumor growth, however, that effect was lost with the use of antibiotics altering the fecal microbiota[84,85]. Furthermore, it was found that long term survivor mice that did not receive antibiotics were rich in CD8+ T-cell, enhancing the tumor immune cell infiltration. On the other hand, mice that were treated with antibiotics, thus altering the fecal microbiota, showed an increased number of CD4+FOXP3+ T-regs and myeloid derived suppressor cells which are well known to lower the immune system, thus promoting tumor growth[84,85].

NK cells are a group of cells that play an important role by mediating tumor initiation and progression. NK cells are often found in the circulation, preventing tumor cells from metastasizing[86,87]. When a patient is NK cells depleted, tumor escape and growth may ensue[86]. NK cells having the ability to inhibit CD8+ T cell responses during chronic infections, it has been hypothesized that NK cells can facilitate solid tumors infiltration, among which PC[86].

Hepatotropic viruses such as hepatitis B virus (HBV) and hepatitis C virus (HCV) have been incriminated in pancreatic oncogenesis. HBV and HCV have the ability to delay host immune system clearance of the virus by integrating the DNA, modifying tissue viscoelasticity, and modulating the PI3K/AKT signaling pathway, which promotes metabolism, proliferation, cell survival, growth and angiogenesis in response to extracellular signals, *via* the HBV X protein, thus leading to oncogenesis[87].

It has been shown that fungal microbiota including *Candida*, *Saccharomyces*, *Aspergillus* or *Malassezia* spp. are involved in pancreatic oncogenesis. One proposed mechanism is that ligation of mannose-binding lectin, which binds to glycans of the fungal wall may lead to activation of the complement cascade and oncogenic progression[88].

Short-chain fatty acids (SCFA) which are metabolites from the gut microbiota and cathelicidin-related antimicrobial peptides secreted by normal pancreatic β-cells protect against tissue inflammation and control pancreatic bacterial overgrowth[89,90]. It has been shown that patients with PC have an abundance of a higher abundance of lipopolysaccharide-producing bacteria, and a reduction in beneficial microbes, such as butyrate-producing bacteria[91]. Butyrate, which is a SCFA produced by certain bacteria of gut possesses anti-inflammatory and anti-neoplastic properties in regard to PC by the means of "pro-differentiation, anti-proliferation, anti-invasion, pro-apoptosis" and chemo-sensitization effects[91]. Another SCFA from the gastrointestinal (GI) microbiota, acetate, induces insulin secretion *via* the microbiome-brain β-cell axis controlling pancreatic bacterial overgrowth[92,93]. Tryptophan metabolism can serve as an immunomodulatory factor by overexpression of indoleamine2,3-dioxygenase1 which inhibits the maturation of CD11c and dendritic cells, and T-cell proliferation and by high expression of Kyn which leads to induction and activation of the aryl hydrocarbon receptor, leading to upregulation of programmed cell death protein 1 expression; enhancing the efficacy of antitumor adoptive T-cell therapy and reducing the rate of migration and invasion in both tumor-bearing mice and patients with PC[94-96].

IMPACT OF GUT MICROBIOME ALTERATION ON THE TREATMENT OF PC

PAC is only resectable in approximately 15% to 20% of cases at the time of diagnosis, however, surgical resection offers the only chance of cure. PAC carries a dismal prognosis even after surgical resection with negative margins given its high rate of recurrence. Therefore, systemic chemotherapy, radiation therapy, and combined approaches (chemoradiotherapy) have been used both prior to and following

surgical resection in an effort to improve cure rates[97]. More recently, immunotherapy and CAR T-cell therapy have gained favor for use in the treatment of PAC[13]. The gut microbiome has been shown to interact with those treatment modalities and affect their efficacy[13,42]. Furthermore, the gut microbiome has also shown some cytotoxic effect in PAC[42].

E. coli and *Staphylococcus aureus* strains have the potential to produce Cytolysin A (ClyA), which is a pore-forming cytotoxin that possesses anticancer properties[98]. ClyA exerts its cytotoxicity, by creating multimeric pores and imposing cell death in the eukaryotic membrane by the caspase-dependent pathway[99]. *E. coli*, *A. actinomycetemcomitans*, Campylobacter and Helicobacter are known to produce Cytolethal distending toxin (CDT)[100]. CDT is known to have genotoxic attributes by DNase activity which creates DNA double stranded breaks, leading to cell cycle arrest and cytotoxicity[49]. Streptococcus pyogenes secretes streptolysin O which is implicated in cytolysis and apoptosis[101].

Prebiotics are defined as nutrients that are degraded by gut microbiota and may affect not only the intestinal microenvironment but also distant organs. In a mice study by Trivieri *et al*[102] using xenograft mice model confronted with PC gene expression dataset (GSE16515) and investigating the impact of high levels of prebiotic resistant starch diet (RSD) on miRNA expression profiles in tumor tissues, RSD was associated with dysregulation of 19 miRNAs genes expression in comparison to control. subsequent analysis revealed that part of genes participating in the regulation of processes such as the development of carcinoma, inflammatory response, abdominal cancer, metabolic disease, growth, invasion, and metastasis were downregulated in a group of mice fed with RSD in comparison to control. Furthermore, genes participating in the synthesis of carbohydrates, glucose metabolism disorder, and cell death of cancer cell lines were significantly upregulated in mice fed with RSD. Thus, the authors concluded that there is prolonged overall survival and beneficial value of RSD in PAC[103].

Lactobacillus casei is a probiotic that can produce Ferrichrome, which has the potential to suppress the growth of refractory PC cells by inhibiting cancer cells progression and dysregulating cell cycle by activating P53[102,103]. Next-generation probiotics such as *Akkermansia muciniphila* (*A. muciniphila*), are identified using next-generation sequencing and bioinformatics tools. *A. muciniphila* has been shown to inhibit the proliferative activity of INS-1 (rat pancreatic islet cell tumor cells) in a mouse model[104].

FOLFIRINOX, which is a commonly used regimen in PAC is composed of leucovorin calcium (folinic acid), fluorouracil, irinotecan hydrochloride, and oxaliplatin. Oxaliplatin has an immunomodulatory effect as well, potentiating tumoricidal T-cell immunity. In a mice model, a group with a defective TLR signaling pathway, demonstrated no response to oxaliplatin treatment[105]. Agonistic TLR molecules from microbial membranes were reported to help stimulate the immune system and increase reactive oxygen species production, thus enhancing the tumoricidal activity of oxaliplatin[105]. Irinotecan is characterized by common GI side effects limiting the dose and effectiveness of treatment. Those side effects can be modulated by enzymatic activity of the gut microbiome, with some bacteria improving the side effects profile, while others may worsen the side effects. The β-glucuronidase enzyme produced by intestinal bacteria cleaves the active irinotecan metabolite SN-38G into a toxic form that damages the colonic mucosa and causes GI side effects. The literature revealed that antibiotics or modification of gut microbiomes significantly alleviated the GI toxicity in cancer patients[106]. Furthermore, reduced risk of developing irinotecan toxicity has been shown with the use of indigestible fibers, using appropriate probiotics and adequate butyrate intake[107].

Several animal studies showed that mice housed in germ-free conditions and animals treated with broad-spectrum antibiotics showed reduced effects of immunotherapy by a combination of TLR-9 antagonist and anti-interleukin-10 antibody. Furthermore, the ineffectiveness of cancer immunotherapy directed against the major negative regulator of T cell activation cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) was observed when applied to antibiotic-treated animals or germ-free mice[108]. Monoclonal antibodies that neutralize CTLA-4 have been shown to rely on the intestinal microbiota, in particular, Bacteroidales and Burkholderiales[108]. A recent study used a gut microbe-derived metabolite trimethylamine N-oxide (TMAO) that showed enhanced anti-tumor immunity to PAC. TMAO was delivered either intraperitoneally or *via* a dietary choline supplement to orthotopic PAC bearing mice, and lead to reduced tumor growth and associated with an immunostimulatory tumor-associated macrophage phenotype and activated effector T cell response in the tumor microenvironment. The combination of TMAO and immune checkpoint inhibitors (ICI) such as programmed cell death 1, in a mouse model of PAC, proved to be superior in reducing tumor burden and improving survival compared to either therapy alone[109].

CAR T-cell therapy has shown tremendous results in hematologic malignancies. Only recently, it was tried on non-hematologic malignancies with promising preliminary data. CAR T-cell therapy of solid tumors faces a major issue in that commonly targeted tumor antigens are expressed at low levels in normal tissues, leading to on-target off-tumor toxicity. CEACAM7, which has low to undetectable expression in all normal tissues and with strong surface expression on a subset of primary human PAC tumors was identified as a potential target antigen for CAR T-cell therapy of PAC. CAR T-cells targeting CEACAM7 were generated in a study by Raj *et al*[13] and showed significant antitumor activity against patient-derived PAC tumor cultures both *in vitro* and *in vivo*[13]. A brief summary can be found in Table 2.

Oncolytic adenoviruses have been engineered to replicate in cancer cells and controlling tumor progression. Oncolytic adenovirus AdNuPARmE1A with miR-222 binding sites, are made to withdraw

Table 2 Impact of gut microbiota in the treatment of Pancreatic cancer

Bacteria	Primary site	Potential mechanism	Subsequent effect	Ref.
Escherichia coli	Large bowel	Cytolysin A production; Cytolethal distending toxin production	Imposing cell death in the eukaryotic membrane by the caspase-dependent pathway; DNA double stranded breaks, leading to cell cycle arrest and cytotoxicity	[49, 86,87]
Staphylococcus aureus	Variable	Cytolysin A production	Imposing cell death in the eukaryotic membrane by the caspase-dependent pathway	[86]
Streptococcus pyogenes	Variable	Streptolysin O production	Increase in apoptosis and cytolysis	[88]
Aggregatibacter actinomycetem-comitans, Campylobacter and Helico-bacter	Mouth, stomach, large bowel	Cytolethal distending toxin production	DNA double stranded breaks, leading to cell cycle arrest and cytotoxicity	[87]
Lactobacillus casei	Mouth and small intestine	P53 activation	Upregulation of apoptosis	[90]
Bacteroidales, Burkholderiales	Large bowel	CTLA-4 upregulation	Enhancing activity of monoclonal antibody against CTLA-4	[95]

CTLA-4: Cytotoxic T-lymphocyte-associated protein 4.

the miRNA from the cellular environment. AdNuPAR-E-miR222-S mediated-decrease of miR-222 expression in pancreatic cancer cells was shown to strongly improve the viral yield and enhance the adenoviral cytotoxic effects[110].

INTRATUMORAL MICROBIOME IN PANCREATIC CA

Intratumoral microbiome is derived from 3 basic mechanisms; (1) Sloughing of the mucosal barrier; (2) Adjacent normal tissues; and (3) Hematogenous spread[111]. Interestingly, Nejman *et al*[112] demonstrated that amongst the tumors that they studied, every tumor was associated with a completely different microbiome composition[112]. The pancreas is traditionally thought to be a 'bacteria-free' organ. However, bacterial DNA belonging to the Proteobacteria phylum was very abundantly found in pancreatic cancer[112]. Another study which confirmed increased amounts of bacterial DNA in pancreatic cancer *vs* normal pancreatic tissue was the study by Geller *et al*[113]. Bacterial ribosomal DNA was detected *via* FISH technique in 76% of patients with PAC *vs* 15% of patients with normal pancreatic tissue[88]. Similarly, by using the FISH technique, Aykut *et al*[88] demonstrated that *Pseudomonadota*, *Bacillota*, and *Bacteroides* were the most abundant bacteria found intratumorally in pancreatic cancer patients[88]. Interestingly, the fungal mycobiome in pancreatic tissue samples obtained from patients with PAC was also found to be very distinct from healthy individuals with a high prevalence of Malassezia[88].

MICROBIOME IMBALANCE AND PANCREATIC CA

Dysbiosis or imbalance in the microbiome has been shown to impact the inflammatory cascade in a non-physiological way and in turn, contribute to the development of cancer[114]. The known risk factors for pancreatic carcinoma are smoking, advancing age, type 2 diabetes mellitus, chronic pancreatitis, and obesity. Interestingly, many of these risk factors have been recently found to be associated with an imbalance in the microbiome, which may increase the risk of PAC[115-118]. A meta-analysis by Maisonnuevve demonstrated a positive correlation between periodontal disease and PAC[119]. This may be related to an imbalance in the oral microbiome. Oral microbiomes have been shown to be associated with carcinogenesis *via* inducing systemic inflammation, and the most important being Porphyromonas Gingivalis[120-122]. A case control study demonstrated that the risk of PAC was 2-fold higher in patients with a higher level of antibodies against a specific strain of *P. Gingivalis*, whereas higher levels of antibodies against commensal oral microbiome were actually protective against PAC, with an almost 50% lower risk of the cancer in patients who had these antibodies[123]. In-vivo studies have shown that *P. gingivalis* enhances the proliferation of pancreatic tumor cells, regardless of the concentration of TLR-4. Furthermore, the concentration and proliferation of *P. gingivalis* is greatly increased in PAC tissue secondary to hypoxia, which is very prevalent in the cancer microenvironment[124]. Furthermore, bacteria that cause periodontitis are also found to cause K-ras and p53 mutations, and those have in turn been associated with poor prognosis in patients with pancreatic cancer[125]. They also demonstrated that the number of cases of pancreatic cancer were higher in patients who had GI infections from *H.*

Pylori, Enterobacter, and Enterococcus species[125].

This prior literature leads us into sensibly concluding that possibly, an imbalance in the oral microbiome is associated with an increased risk of PAC, however, reverse causation is an important factor that needs to be excluded before exploring this aspect further. One study evaluated this and found that 2 oral bacteria-*P. gingivalis* and Aggregatibacter actinomycetemcomitans are associated with an increased risk whereas *Leptotrichia* genus of *Fusobacterium* species was associated with a reduced risk of PAC. Interestingly, even after excluding patients who developed the cancer within 2 years from the date of sample collection, the risks remained elevated[10]. This significantly reduces the likelihood of reverse causation. Another significant study going in favor of a causality between *E. faecalis*, and pancreatic cancer is the one by Maekawa *et al*[126], wherein the level of antibodies against *E. faecalis* capsular polysaccharide were found to be increased in the serum of pancreatic cancer patients[126]. However, larger cohort studies are needed on the subject to conclusively establish causation.

CONCLUSION

Despite advances in medicine and the discovery of newer anticancer therapies, the prognosis of pancreatic cancer remains dismal. By the way of this review, we found that a prebiotic resistant starch diet has been associated with better overall survival in PAC. We also found that periodontal diseases increase the risk of developing PAC. This is especially important as periodontal diseases should be avoided and promptly treated in patients with a family history of PAC, other risk factors for PAC, and those with known/suspected genetic mutations susceptible for the development of PAC. Furthermore, we found that the use of concomitant antibiotics can positively or negatively affect treatment of PAC. Some gut microbiomes can enhance the effect of therapy and improve tolerance to therapy as well. Thus, neutropenic diet can be avoided in select patients meeting the requirements. Newer therapeutics such as ICI and CAR T-cell therapies can play a major role in the outcome of PAC, however, most promising studies are done in animal models. We hope that in the near future, there will be more clinical trials in human subjects replicating the promising results from animal studies which will possibly offer newer ways to handle this very deadly malignancy.

Abstract

The relationship between metabolic derangements and fatty liver development are undeniable, since more than 75% of patients with type 2 diabetes mellitus present with fatty liver. There is also significant epidemiological association between insulin resistance (IR) and metabolic (dysfunction)-associated fatty liver disease (MAFLD). For little more than 2 years, the nomenclature of fatty liver of non-alcoholic origin has been intended to change to MAFLD by multiple groups. While a myriad of reasons for which MAFLD is thought to be of metabolic origin could be exposed, the bottom line relies on the role of IR as an initiator and perpetuator of this disease. There is a reciprocal role in MAFLD development and IR as well as serum glucose concentrations, where increased circulating glucose and insulin result in increased *de novo* lipogenesis by sterol regulatory element-binding protein-1c induced lipogenic enzyme stimulation; therefore, increased endogenous production of triglycerides. The same effect is achieved through impaired suppression of adipose tissue (AT) lipolysis in insulin-resistant states, increasing fatty acid influx into the liver. The complementary reciprocal situation occurs when liver steatosis alters hepatokine secretion, modifying fatty acid metabolism as well as IR in a variety of tissues, including skeletal muscle, AT, and the liver. The aim of this review is to discuss the importance of IR and AT interactions in metabolic altered states as perhaps the most important factor in MAFLD pathogenesis.

Key Words: Metabolic (dysfunction)-associated fatty liver disease; Insulin resistance; Adipose tissue; Fatty liver; Metabolic syndrome; Adipokine

Core Tip: In this review, we outline the main arguments that support the importance of insulin resistance (IR) in fatty liver pathogenesis, stressing its role in metabolic dysfunction. IR and other genetic and molecular mechanisms play a pivotal role not only in metabolic dysfunction–associated fatty liver disease development but also in some of its complications and comorbidities, such as chronic kidney disease.

INTRODUCTION

The term non-alcoholic fatty liver disease (NAFLD) was initially used by Klatskin and colleagues in 1979[1], while Ludwig coined the term non-alcoholic steatohepatitis after witnessing similar clinical features in patients with liver steatosis[2]. Even though this nomenclature has been used for almost four decades, in 2020 a group of experts suggested a change of nomenclature from NAFLD to metabolic (dysfunction)-associated fatty liver disease (MAFLD) due to the large multifactorial basis for the disease and the fact that non-alcoholic does not accurately describe the disease pathogenesis[3-5]. By contrast, metabolic dysfunction accounts for a great deal of the pathogenesis of fatty liver whenever large alcohol consumption amounts are not present. MAFLD diagnosis is based on the presence of hepatic steatosis in addition to one of the following: obesity or overweight, type 2 diabetes mellitus (T2DM), or metabolic dysregulation. Metabolic dysfunction (in this context) accounts for the following conditions: increased waist circumference, systemic hypertension, dyslipidemia, prediabetes and insulin resistance (IR) (measured through the homeostatic model assessment [HOMA] > 2.5).

The development of MAFLD is linked to dyslipidemia, obesity, and IR. These are also the main features of metabolic syndrome (MetS). MetS constitutes a cluster of metabolic abnormalities which stem from IR and chronic low grade inflammation and on the long run increase the risk for cardiovascular disease (CVD) and T2DM[6]. The criteria for diagnosing MetS have changed since they were first established by the World Health Organization in 1988[7], evolving since the knowledge of the pathogenesis and its implications expanded. The criteria include the presence of visceral adiposity, IR, atherogenic dyslipidemia, and endothelial dysfunction, among others[8].

On a very important note, the change of nomenclature to MAFLD is very well justified by the sole fact that about 90% of NAFLD patients have one or more MetS component[9]. Furthermore, Marchesini *et al*[10] showed that the presence of MetS among patients with hepatic steatosis carry a significantly increased risk of developing steatohepatitis and fibrosis, with odds ratios of 3.2 and 3.5, respectively [10]. Also, MetS is a useful index for the prediction of the severity of obesity-related fatty liver[11].

One way in which we can argue in favor of IR's importance in MAFLD pathogenesis is by analyzing the causes of the established items in the metabolic risk abnormalities checklist. Another way is by refuting the counterarguments for the use of this new term. In this review, we will cover both issues.

One of the most valid points involves the fact that given MAFLD is a heterogeneous and complex disease, considering a single postulation to explain is pathogenesis is absurd. We agree that MAFLD is a multifactorial disease, and similar to diabetes, systemic hypertension and many more involve genetic and environmental mechanisms. In fact, there is progressively more data proving the influence of different environmental factors on fatty liver genesis, including air pollution and cigarette smoke. However, in MAFLD as a multifactorial disease, there is one specific overarching concept that accounts for most of the cases and pathogenesis of MAFLD, which is metabolic dysfunction.

To give an educated opinion on the subject, we must first understand what IR is, how it manifests on different endocrine organs, how it influences triglyceride (TG) metabolism in the liver, and its role in metabolic dysfunction.

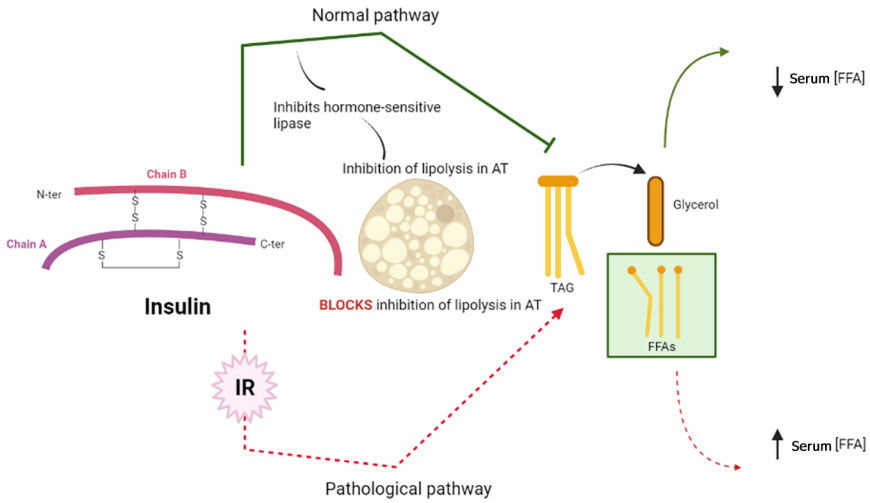
IR: The basis

Insulin is the main anabolic hormone in the body, primordial for glucose homeostasis as well as other functions in tissue growth and development. Glucose homeostasis is maintained by regulating gluconeogenesis and glycogenolysis in the liver, as well as by inducing insulin-mediated glucose uptake in skeletal and cardiac muscle, as well as in adipose tissue (AT)[12]. IR refers to the impaired response of target tissues to insulin stimulation. This abnormality can be a result of altered number of receptors, or malfunction of the existing ones. In reality, there is not a single cause for IR development; instead

multiple factors together lead to this metabolic abnormality. These include the mentioned receptor abnormalities, as well as defects in the insulin signaling cascade, negative regulation of the cascade by inhibitors, or the presence of a proinflammatory internal milieu. There has even been a proposal regarding the induction of IR by fatty acids, which because of their abnormal metabolism lead to lipid accumulation in the muscle and liver. In any given case, whenever there is a decreased sensitivity of a hormonal stimulus, the result is a positive feedback loop that increases the concentration of the effect-lacking hormone (in this case, insulin). Increased insulin serum concentrations have a variety of effects due to its trophic effects on various tissues. Insulin serum concentrations are the basis for determining the presence of IR in an individual, principally through the use of the HOMA.

During the past decade, the "glucocentric" view of IR has shifted to the "lipocentric" view, regarding its pathogenesis and associated mechanisms. We can appreciate how much the focus of IR effect on glucose metabolism prevailed before the year 2000 in any scientific literature, even if we don't look in depth. For instance, IR had been included within a concept denominated the "IR syndrome", which considered the presence of dyslipidemia, hypertension and impaired glucose tolerance as factors leading to increased cardiovascular risk, however, that's the farthest lipids' involvement got[13]. Chronic hyperglycemia leads to glucotoxicity, directly inducing IR and the IR degree is one of the strongest predictors for T2DM onset in populations at risk[14,15]. While all of this is a fact, the role of fatty acid metabolism had been overlooked since in 1965 Randle and colleagues first suggested increased serum free fatty acids (FFAs) as one of the primary causes for decreased glucose oxidation and IR development[16]. The last decade has had an increased body of research supporting this fact, centering the role of lipids, along with that of glucose, in the development of fatty liver.

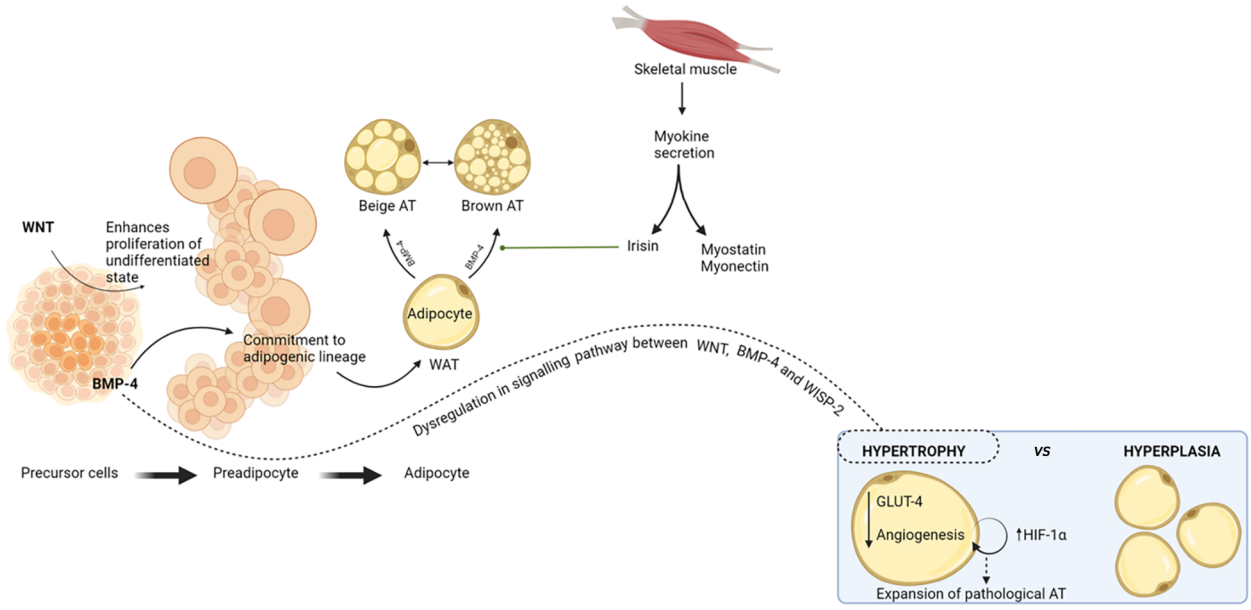
IR is present in a variety of metabolic disorders, such as MetS and T2DM. IR in the liver presents as increased gluconeogenesis and decreased hepatic glycogenesis, resulting in increased glucose production and release[17].



Adipose tissue IR-Which came first: The resistance or the fat?

AT has long been known to be an endocrine organ, both by releasing hormones such as leptin and adiponectin (adipokines), and by regulating proinflammatory mediator secretion and metabolic processes. AT IR refers to the impaired suppression of lipolysis in the presence of high insulin serum levels (Figure 1). One of the key hormones involved in AT-IR is adiponectin, which contributes to the development of obesity-related IR and CVD[18]. While in this case adiponectin levels are lower, other adipokines such as leptin are increased[19], the former one acting as a protective factor for hepatic steatosis development[20].

Whenever IR ensues, there is a disinhibition of lipolysis in the AT, which results in higher breakdown of stored triglycerides in AT and higher release of FFA into the blood. The circulating FFAs lead to activation of the proinflammatory nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) pathway in the liver, ultimately resulting in lipotoxicity. Lipotoxicity, however, is not the end result of a single pathway, but rather the combination of the role of FFAs, TGs, biliary acids (BAs), free cholesterol, ceramides, and lysophosphatidyl cholines[21].



When it comes to metabolic health, AT is the major determinant given the ability of subcutaneous AT (SAT) to store excess fat (through adipocyte *de novo* lipogenesis [DNL] instead of allowing it to deposit in the non-fatty tissues, otherwise known as "ectopic" deposition of fat. Whenever this ability becomes impaired, aberrant adipocyte tissue develops, where the adipocytes undergo hypertrophy along with decreased number of glucose transporter-4 (GLUT-4) receptors. Under physiologic conditions, adipocytes carry out recruitment of adipogenic precursor cells, along with adequate angiogenesis. Dysregulation of the signaling pathway between the wingless-related integration site (WNT) and the bone morphogenetic protein 4 (BMP-4) results in alterations in the recruitment, proliferation and differentiation of the precursors. BMP-4 has also been found to contribute to "browning" of white AT in mice, where brown AT (BAT) tallies to the oxidative phenotype of lipid-storing adipocytes[22]. The alteration in AT expansion means that not only do pathologic adipocytes have decreased number of GLUT-4 receptors but they also have altered blood supply, leading to hypoxia and consequently to activation of hypoxia-inducible factor 1 alpha (HIF-1α). By having a reduced number of GLUT-4 receptors, glucose influx is impaired, which in turn limits DNL. The induction of HIF-1α factor in this pathological AT state increases systemic inflammatory conditions. Transcriptome analysis of AT macrophages in obese mice revealed rewiring of the metabolic pathways within these macrophages with increased glycolysis and oxidative phosphorylation, rendering them as inflammatory macrophages[23]. Macrophage HIF-1α is involved in the formation of crown-like structures, which lead to maintenance of inflammatory processes and inhibition of angiogenesis in preadipocytes, leading to a vicious circle of added hypoxia and expansion of the aberrant AT[24] (Figure 2). Pathologic expansion of AT leads to systemic IR, as mentioned throughout this review.

Briefly expanding upon the importance of BAT, a 2011 paper proved how cold-induced browning of AT in rats controlled TG rich lipoprotein metabolism by boosting their turnover and channeling lipids into AT browning[25]. There has been a number of studies proving that the presence of BAT in adulthood is independently associated with lower probability of developing liver steatosis[26,27], for which multiple mechanisms have been uncovered. For instance, the uncoupling protein 1 (UCP-1) expressed specifically in BAT reverses obesity and also antagonizes liver inflammation and pathology

Figure 1 Effect of insulin resistance on adipose tissue lipolysis. Under normal circumstances, insulin inhibits lipolysis in adipose tissue by inducing the hormone sensitive lipase, thus decreasing the release of excessive free fatty acids (FFAs) into the serum. However, in an insulin resistance state, inhibition of lipolysis is blocked, increasing serum FFAs, which eventually increase the influx of lipids into the liver. All the figures were created using BioRender. AT: Adipose tissue; IR: Insulin resistance.

Figure 2 Adipose tissue dysfunction in metabolic dysfunction–associated fatty liver disease. Adipocyte precursor cells undergo initial proliferation through the wingless-related integration site (WNT) signaling pathway and thereafter commitment to the adipogenic lineage by bone morphogenetic protein 4 (BMP-4) stimulus, until its conversion to preadipocytes and later on to mature adipocytes. White adipose tissue can undergo beiging or browning under the influence of two main stimuli: BMP-4 and irisin. Browning of adipose tissue (AT) implies higher catabolic and oxidation rates, In the case of WNT, BMP-4, and WNT-1 inducible signaling pathway protein 2 pathway dysregulation, there is hypertrophy of AT. Physiologically, hyperplasia through the proliferation process mentioned is the appropriate mechanism for AT expansion. Pathologically, however, hypertrophy of AT leads to decreased levels of intracellular glucose transporter 4 and limited angiogenesis. Limited angiogenesis stimulates the hypoxia inducible factor 1 alpha (HIF-1a), stimulating further AT hypertrophy, creating a vicious cycle in the expansion of pathological AT. WAT: White adipose tissue; WISP-2: WNT-1 inducible signaling pathway protein 2; GLUT-4: Glucose transporter 4.

[28]. Interestingly, uric acid transporters have been seen to influence fatty liver[19]; a study carried out by Tanaka *et al*[29] found that the use of dotinurad (urate reabsorption inhibitor) showed amelioration of IR in rats by reducing liver steatosis and promoting rebrowning of AT[29].

Novel discovery of a group of lipids known as the fatty acid esters of hydroxy fatty acids (FAHFAs) released from the AT when appropriate levels of GLUT-4 and adipogenesis are present shed light to another pathway through which AT, and specially SAT, regulates systemic IR and inflammation[30]. FAHFAs induce metabolic health by stimulating insulin-dependent glucose transport in various tissues, as well as glucagon-like peptide 1 and insulin release from the gut enteroendocrine cells and the

pancreatic β-cells, respectively. Important anti-inflammatory effects have also been shown by studying docosahexaenoic acid (DHA)-derived FAHFAs' effects in cultured human hepatoma-derived cells, finding potent activation of nuclear factor erythroid 2-related factor 2 with tenable antioxidant function [31].

The answer to the question "what came first: the resistance or the fat?" could go both ways, *i.e.* liver fat build-up could be attributed to some degree to IR and hyperinsulinemia or directly from excessive FFA availability, which consequently brings about IR. Amount of AT, hepatic steatosis, and low-grade subacute inflammation are all correlated with the development of IR and MetS[32]. For this reason, the interaction between fat and IR is not causal, but rather reciprocal.

Skeletal muscle IR

Skeletal and cardiac muscle play important roles in glucose metabolism. Studies in humans have shown that it is the principal insulin-stimulated glucose uptake site (about 75% of postprandial serum glucose), whereas AT presents with relatively lower uptake[33]. Similar to hepatic IR, one of the ways skeletal muscle IR develops is by increased FFA supply, which cannot be processed by the tissue.

The association between skeletal muscle dysfunction and the progression of MAFLD has been widely recognized. There are several muscular conditions that are directly related to fatty liver, such as myosteatosis and sarcopenic obesity. We briefly touched upon the fact that AT releases adipokines key to metabolic regulatory systems. However, skeletal muscle also has the capacity to release hormonally active molecules termed myokines, which exert their function in an autocrine, paracrine, or endocrine fashion[34]. There are hundreds of myokines and the specific function of most has not been fully elucidated; however, many have shown effects in a multisystemic manner, including cognition, bone composition, AT "browning," as well as lipid and glucose metabolism. Myostatin, myonectin, irisin and a series of interleukins are among the most important myokines. Myostatin has a negative effect on MAFLD progression, given that it enhances liver inflammation and fibrogenesis by hepatic stellate cell stimulation[35]. Irisin, on the other hand, has the opposite effect by stimulating white AT browning and UCP-1 expression reducing adipose IR. This is key, given that one of the hallmarks of treatment for MAFLD is physical exercise. Irisin, among others, is an exercise-inducible myokine; this represents one of the few pathways through which moderate or rigorous exercise can reduce progression in MAFLD by targeting IR in the liver and AT (Figure 2). An additional feature of irisin is FFA oxidation, which is a method for lipid removal from ectopic tissue; this will later be explained in the intrahepatic triglyceride content section. Lastly, myonectin plays a role in FFA oxidation in the AT and the liver, as well as thermogenesis. Therefore, we already see how different myokines can have both beneficial or detrimental effects on metabolic health depending on the collective organ characteristics. A specific phenotype based on lifestyle characteristics defines the myokines that will be released, *e.g.*, irisin, and therefore the IR in other tissues that affects the development of liver steatosis.

Lean MAFLD

The absence of overt metabolic dysfunction in the lean population with MAFLD does not exclude the presence of metabolic abnormalities at cellular level. An important measurement of our hypothesis would be measuring the presence or absence of overt IR (*e.g.*, as per international criteria, mainly the HOMA) in a follow-up period of the population.

IR causes fatty liver from the inside out and not the other way around. In other words, cellular level alterations can, on their own, cause increased TG accumulation in the liver, even if obesity, acanthosis nigricans or even HOMA are not present or are within out of normal range in the latter case.

Individuals with normal body mass index (BMI) also develop MAFLD, and many studies (mainly in non-Caucasian populations) have shown a lack of IR in patients with MAFLD. A study conducted by Ahmed *et al*[27] studied the presence of NAFLD in patients with different BMI (non-obese, overweight, and obese) and evaluated whether these NAFLD individuals presented with IR. The results showed that a significant number of individuals without IR had NAFLD; however, there was no analysis of whether the NAFLD individuals without IR had non-obese BMI. This small aspect could be quite significant, given that we claim that the two main contributors to MAFLD development are IR and AT dysfunction. Furthermore, regarding lean MAFLD, it is known that IR unrelated to obesity can occur in various hyperglycemic states.

It is important to establish that IR drives DNL in the liver. Fatty liver diagnosis is defined based on the total amount of intrahepatic TG (IHTG). A recent study showed that hepatic DNL is an important regulator of IHTG content, concluded after correcting for the potential confounding contribution of AT in DNL. It was also noted that increases in serum glucose and insulin stimulate hepatic DNL. Glucose and insulin promote DNL by inducing the carbohydrate response element binding protein, as well as the sterol regulatory element binding protein 1c (SREBP 1c) and the acetyl CoA carboxylase, respectively[36]. Increased serum insulin is a compensatory mechanism during IR when there is appropriate endocrine pancreas activity, by having increased insulin release, DNL is stimulated further.

Thus, one of the most important arguments in favor of IR as the base of pathogenesis is the fact that it directly stimulates DNL. The question here would be: can DNL alone be contribution enough to increase IHTG up to MAFLD levels? The answer is no, even though DNL contributes about 26% to total IHTG content, while most of it originates from increased influx of FFA and their esterification in the

liver, accounting for 59% of total lipid content[37]. A smaller percentage, 15%, is attributable to diet TG consumption, as shown by Donnelly *et al*[37].

Mechanisms of IHTG accumulation

Increased lipid content in the liver originates from an imbalance between FFA uptake by the liver, DNL, lipid oxidation, and hepatic very low density lipoprotein (VLDL) export rate[38]. TG synthesis and lysis are the main ways in which the liver regulates the storage of FFA in serum when levels are high, whereas in the case of energy expenditure, it releases VLDL particles containing FFA to the muscle and fat tissue[39]. There was a previous misconception on the role of hepatic TG storage as a cause of lipotoxicity; it is now known that TG storage and secretion of VLDL particles are protective mechanisms against FFA-induced lipotoxicity. An elegant study by Listenberg *et al*[40] proved that through unsaturated fatty acid supplementation in CHO an 25RA cells, a protective effect against lipotoxicity through TG synthesis induction was achieved[40].

TG storage in the liver is carried out through the conversion of FFAs into glycerol-3-phosphate. TGs, along with cholesterol esters are neutral lipid particles which can be stably stored in the liver or can be released as VLDL particles[41]. There are a number of mechanisms involved in FFA oxidation and lipid metabolism. As we briefly touched upon, irisin is one of hundreds of exercise-induced myokines secreted by skeletal muscle, which plays an important role in the AT-muscle-liver axis. It also regulates the adenosine monophosphate-activated protein kinase signaling pathway, thus increasing FFA oxidation in myocytes[42].

Another mechanism that helps keep the balance between the IHTG is fatty acid β-oxidation in the mitochondria or peroxisomes. This process leads to the production of adenosine triphosphate or in the case of excess FFAs, the production of ketone bodies[43]. Alterations in β-oxidation contribute to the development of hepatic steatosis. For instance, downregulation in peroxisome proliferator-activated receptor alpha (PPAR-α), which serves as an FFA sensor, leads to decreased fatty acid catabolism and intrahepatic lipid accumulation. These alterations also determine the severity to which steatosis will develop depending on the nutritional status of an individual[44]. Stimulation of PPAR-α in mice enhances the expression of cytochrome P450 4A and enhances lipid turnover in the liver, decreasing the risk of developing dietary steatohepatitis[45]. Furthermore, PPAR-α activation increases peroxisomal fatty acid β-oxidation by inducing acyl-coenzyme A oxidase (Acox1), the rate-limiting enzyme in the oxidation of very long-chain fatty acids[46,47]. Acox1 is also associated with spontaneous liver damage in humans, as well as spontaneous steatosis, steatohepatitis, and hepatocellular carcinoma development in mice[46]. Despite what we discussed, alterations in PPAR-α are not the only ones leading to hepatic steatosis. Instead, a number of altered function in nuclear receptors such as the pregnane and xenobiotic receptors, the liver X receptor, and the farnesoid X receptor (FXR) contribute to the pathogenesis of MAFLD[48].

What about the comorbidities in MAFLD? Let's not forget CKD: The multiple effects of gene mutations

We have already discussed two primordial concepts in the understanding of MAFLD: AT dysfunction and IR. Even though these attributes explain a great deal of the pathogenic mechanisms involved in MAFLD, saying that overseeing genetic alterations involved is a mistake would hardly be an overstatement.

As it has been already reviewed in multiple studies and around a number of countries, there is a significant amount of genetic mutations that highly predispose populations to MAFLD. Even though there are multiple genetic mutations, the most common involves the gene patatin-like phospholipase domain-containing protein 3 (PNPLA3), which encodes for a protein called adiponutrin that exerts lipolytic action on TGs and reduces DNL within the liver. The PNPLA3 gene is present in many tissues in the body; however, it is most highly expressed in the liver and the kidney.

MAFLD is known for its large range of associated comorbidities; it is not only the hepatic manifestation of MetS but is a rather multisystemic disease on its own. A recent meta-analysis evaluated the risk of having NAFLD (previous nomenclature) and the risk of developing chronic kidney disease (CKD). In total, the data from more than a million patients were analyzed, and the study concluded that pre-existing NAFLD is associated with about a 1.45-fold increased risk of incident CKD stage ≥ 3[49]. The same team carried out a meta-analysis in 2017 showing 40% increased risk of CKD in patients with NAFLD[50]. Another group of researchers reached the same conclusions, showing that the presence and severity of NAFLD are associated with an increased risk and severity of CKD[51]. However, another group concluded that the association was not because of a causal relationship between MAFLD and CKD but was due to shared risk factors between them, namely diabetes, age, hypertension, and hyperuricemia[52]. This recent cross sectional study from The National Health and Nutrition Examination Survey 2017-2018 showed that MAFLD and CKD were not independently related after propensity score matching[52].

We propose an explanation for this, which might account for the high prevalence of CKD in people with MAFLD, and also shed light on the reason why these two diseases, even when highly correlated, are not independently related.

As previously mentioned, the PNPLA3 gene is most highly expressed in two tissues: the liver and kidney. Mutations in the PNPLA3 gene, especially the PNPLA3 I148M variant, leads to CKD in a similar pattern as how the mutation predisposes to MAFLD. Montovani and his team followed this line of thought and by studying 157 patients with T2DM, found that the presence of this mutation (especially in the podocytes on the renal cortex) was associated with lower glomerular filtration rates (GFR) and higher risk of CKD, 63.6% *vs* 24.2% risk in people without homozygous mutation[53]. It is important to establish that the association between the PNPLA3 I148M variant and the risk of lower GFR and CKD development is independent of liver disease severity as well as other factors[53]. This association has also been found among children with MAFLD, where the PNPLA3 G/G genotype leads to decreased kidney function and increased 24-h proteinuria[54].

By having established this, we can understand the multifactorial nature of MAFLD and its comorbidities, as in this case, CKD's. Whether or not MAFLD predisposes to kidney malfunction could be studied in a group of patients who develop both entities but lack mutations in the PNPLA3 gene.

While PNPLA3 gene mutations might be a common factor in the predisposition for both CKD and MAFLD, there are a number of nuclear transcription factors that contribute to the pathogenesis of both diseases. These factors include the peroxisome proliferator-activated receptor (PPAR) family, FXR, and SREBP2, which modify their respective molecular pathways and influence the progression of both CKD and hepatic steatosis[55]. For instance, the downregulation of PPAR-α, PPAR-δ, and PPAR-γ causes a myriad of cellular alterations in the nephron, including increased podocyte apoptosis leading to altered glomerular barrier integrity, increased mesangial cell hypertrophy and enhanced matrix deposition, as well as NF-κB activation with consequent proinflammatory cytokine secretion in the glomerular endothelium[56]. These same factors under physiologic circumstances suppress fibrogenesis by inhibiting the transforming growth factor β in stellate cells, lower the M1/M2 Kupffer cell phenotype ratio (thus decreasing inflammatory stimulus in the liver) and increases catalase activity in hepatocytes, among other functions. It is clear how downregulation of the PPAR family of factors hinders these protective mechanisms in the liver and promotes the development of fatty liver, as well as CKD. The same situation of multiorgan damage comes about with decreased expression of FXR and upregulation of SREBP-2, given that FXR inhibits SREBP-1c-mediated DNL in hepatocytes while decreasing reactive oxygen species formation in mesangial cells and increasing endothelial nitric oxide synthase in the glomerular epithelium[55]. Finally, SREBP-2 upregulation leads to increased cholesterol synthesis and decreased excretion in both liver and renal cells[57,58]. With this brief compilation of the molecular pathway similarities between CKD and fatty liver development, it would be of no surprise to find in the near future novel discoveries on further overlapping mechanisms and genetic predisposition for both diseases.

CONCLUSION

In conclusion, although MAFLD pathogenesis is multifactorial and complex, we consider IR to be the basis for the development of the disease, the abnormal metabolic profile in patients, and disease complications. Further research is required to fully understand and test this hypothesis along with others that may develop. Understanding the basis of the disease and the many variables that play a role in its development will lead to appropriate targeted therapies for MAFLD.

Abstract

Endoscopic full-thickness resection (EFTR) has emerged as a viable technique in the management of mucosal and subepithelial lesions of the gastrointestinal tract (GIT) not amenable to conventional therapeutic approaches. While various devices and techniques have been described for EFTR, a single, combined full-thickness resection and closure device (full-thickness resection device, FTRD system, Ovesco Endoscopy AG, Tuebingen, Germany) has become commercially available in recent years. Initially, the FTRD system was limited to use in the colorectum only. Recently, a modified version of the FTRD has been released for EFTR in the upper GIT as well. This review provides a broad summary of the FTRD, highlighting recent advances and current challenges.

Key Words: Endoscopic full-thickness resection; Full-thickness resection device; Colorectal neoplasm; Subepithelial lesions; Scarred non-lifting polyps

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Endoscopic full-thickness resection (EFTR) is an emerging technique for tissue resection of lesions in the gastrointestinal tract (GIT) not amenable to conventional resection approaches. The novel full-thickness resection device (FTRD) is a combined full-thickness resection and closure device that allows for EFTR of lesions in the GIT. EFTR with FTRD is feasible, safe, and efficacious and should be considered as a viable option for resection of select lesions in the lower and upper GIT.

INTRODUCTION

Traditionally, flexible endoscopic removal of gastrointestinal neoplasms has been accomplished by standard polypectomy, endoscopic mucosal resection (EMR), or endoscopic submucosal dissection (ESD). More recently, endoscopic full-thickness resection (EFTR) has emerged as a complementary resection technique for the removal of colorectal lesions, particularly for lesions that are scarred or non-lifting, early cancers with deeper invasion, and subepithelial lesions, where resection *via* standard endoscopic techniques is difficult or not possible[1,2]. EFTR also has the potential added benefit of decreasing procedural time and providing a minimally-invasive organ-sparing alternative approach, obviating need for surgery. As its name implies, EFTR refers to the technique whereby a lesion is resected endoscopically in its entirety including all layers of the gastrointestinal wall[1]. The two main techniques for EFTR include the "resect and close" method, where the full-thickness resection is performed first exposing the peritoneal cavity, followed by complete closure of the defect, and "close and resect" method, where approximation of the wall layers deep to the lesion is performed first followed by full-thickness resection without exposure and contamination of the peritoneum. Various strategies and devices have been developed to accomplish EFTR, including but not limited to needle-knives, ESD knives, nylon loop accompanied by standard through-the-scope clips, omental patches, endoscopic plicating and suturing devices, and endoscopic staplers[3-9]. These methods will not be covered in this review.

Recently, a single, combined full-thickness resection and closure device referred to as the full-thickness resection device (FTRD system, Ovesco Endoscopy AG, Tuebingen, Germany) has become available and is quickly being adopted across centers worldwide to accomplish EFTR. Its appeal over other strategies includes the ability to perform resection and closure with a single device integrating an over-the-scope clip (OTSC) and electrosurgical snare. It can offer a safe and nonsurgical alternative for removal of lesions that may be challenging to resect with conventional endoscopic methods and might otherwise require surgery. Main indications for the FTRD include non-lifting or scarred polyps, partially resected or residual polyps with submucosal fibrosis, early cancers, subepithelial lesions, and diagnostic EFTR for pathologic assessment of the gut wall. It is approved for use in the colorectum, and recently, received additional approval from the U.S. Food and Drug Administration for use in the upper gastrointestinal tract (GIT)[10].

This review article will provide a summary of the major studies on FTRD, highlighting recent advances and current challenges, in the hopes that practicing endoscopists will be better equipped to understand the role and limitations of, and potentially utilize, this novel and important resection technique.

DEVICE

The FTRD system, a combined full-thickness resection and closure device, was first made available in Europe in 2014[11]. It has since been approved for use in the United States for colorectal EFTR in 2017 and gastroduodenal EFTR in 2020[12].

The FTRD system is based on the principle of "close and resect" for EFTR. It uses the well-established OTSC system (Ovesco Endoscopy AG, Tuebingen, Germany), which allows for full-thickness tissue apposition deeper to the lesion first, followed by full-thickness resection above the clip, thereby performing EFTR without exposure of the peritoneal cavity[13]. The FTRD system (Figure 1) consists of a clear, plastic distal attachment cap that has a mounted ready-for-use 14 mm nickel titanium alloy (Nitinol) clip, integrated 14 mm monofilament snare and thread, thread retriever, endoscope sleeve with fixation tapes, and a hand wheel. Separately, an FTRD Marking Probe (Figure 2A) and FTRD Grasper (Figure 2B) are provided as part of the FTRD set. These individual instruments can be advanced through the working channel for marking and mobilization of the target lesion, respectively. The FTRD system is suitable for use for endoscopes having a diameter of 11.5-13.2 mm and a working channel diameter of 3.2 mm. The cap diameter is 21 mm and the cap depth is 23 mm.

The initial FTRD system was fashioned for use in the colorectum and is now marketed as the colonic FTRD©. With recent advances demonstrating the role of the FTRD in the upper GIT, an additional FTRD system called the gastroduodenal FTRD© has now become available. The gastroduodenal FTRD system is smaller in caliber and additionally comes with an insertion balloon and guide wire to help facilitate passage of the FTRD through the upper esophageal sphincter and pylorus (Figure 2C). A

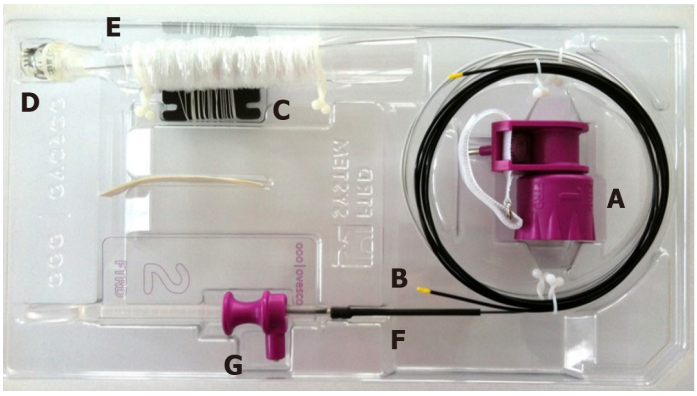

Figure 1 The colonic full-thickness resection device system. A: Hand wheel; B: Thread Retriever; C: Thread; D: Distal attachment cap with affixed over-the-scope-clip; E: Endoscope sleeve; F: Integrated snare; G: Snare lock. Images provided by Ovesco Endoscopy.

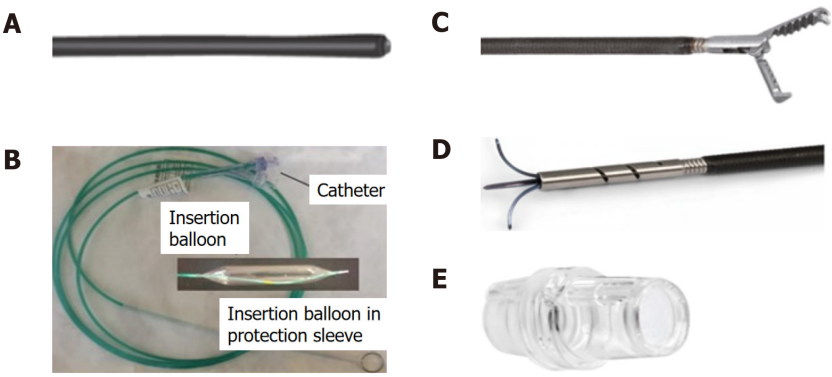

Figure 2 Full-thickness resection device separately included items. A: Marking probe; B: Grasper; C: Guidewire and balloon (diagram) — for gastroduodenal full-thickness resection device (FTRD)®; D: Modified anchor — for gastroduodenal FTRD®; E: prOVE cap. Images courtesy of Ovesco Endoscopy.

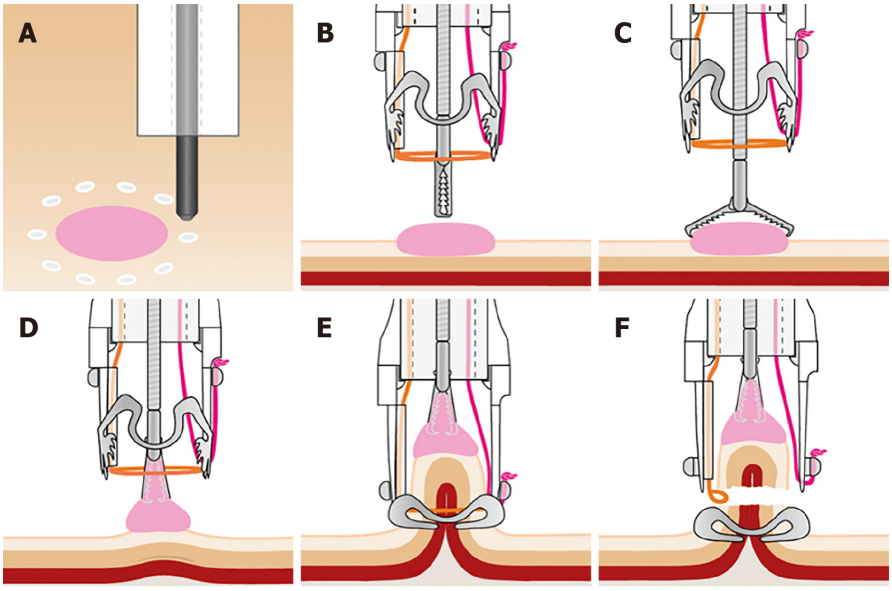
separate modified Anchor (Figure 2D) is also available to allow for better tissue mobilization (*i.e.*, for subepithelial lesions). The gastroduodenal FTRD is suitable for endoscopes having a diameter of 10.5-12.0 mm and a working channel diameter of 3.7 mm. The cap diameter is 19.5 mm and the cap depth is 23 mm.

Recently, a third FTRD system called the diagnostic FTRD© was made available for use in the colorectum for diagnostic resection, or full-thickness biopsy. This system is nearly identical to the colonic FTRD system but is smaller in size allowing for full-thickness resection of lesser tissue volume when desired for diagnostic purposes. The diagnostic FTRD system can also be applied to a pediatric colonoscope allowing for increased flexibility and mobility. The diagnostic FTRD system is suitable for endoscopes having a diameter of 10.5-12.0 mm and a working channel diameter of 3.2 mm. The cap diameter is 19.5 mm and the cap depth is 23 mm.

TECHNIQUE

Once a target lesion in the GIT is identified, its margins are delineated with the FTRD Marking Probe ensuring a margin of normal surrounding tissue (Figure 3A). The endoscope is then withdrawn from the patient. It is often cumbersome to advance the endoscope (with the attached stiff FTRD cap) to the lesion (especially lesions located in the right colon), and sometimes difficult to grasp and bring a scarred lesion into the cap. Hence many endoscopists will first attach a test cap — the FTRD prOVE cap (a "blank" cap similar to the FTRD cap but without the mounted clip or snare; see Figure 2E) — to the endoscope to perform a "test run" without using the FTRD, which may otherwise be wasted if unable to be advanced to the lesion. Once it is confirmed that the endoscope with the attached prOVE cap can be advanced to the lesion and the lesion able to be brought inside the cap, the endoscope is withdrawn and fitted with the "real" FTRD system. The hand wheel (Figure 1A) is first inserted into the working channel of the endoscope. The thread retriever (Figure 1B) is then inserted into the working channel and used to retrieve the thread (Figure 1C) allowing for attachment of the plastic attachment cap (Figure 1D) onto the distal end of the endoscope. The distal attachment cap has a preloaded clip attached to the thread that runs inside the working channel of the endoscope and attaches to the hand wheel, as well as



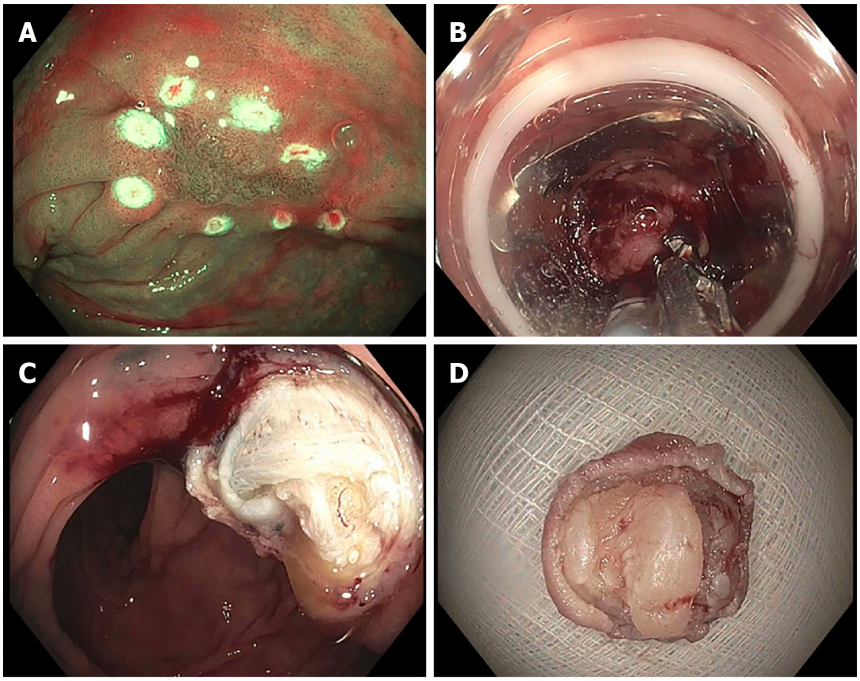


Figure 3 Technique for accomplishing endoscopic full-thickness resection using the full-thickness resection device. A: Borders of target lesion marked using full-thickness resection device (FTRD) Marking Probe; B: FTRD Grasper positioned over target lesion; C: FTRD Grasper opened over target lesion; D: Target lesion grasped and pulled into cap; E: Over-the-scope-clip deployed; F: Specimen resected with electrosurgical snare. Images provided by Ovesco Endoscopy.

a preloaded snare that runs outside of the endoscope. The accompanying endoscope sleeve (Figure 1E) and adhesion tapes help affix the snare (Figure 1F) to the outside of the endoscope and prevent inadvertent twisting of the snare around the endoscope or entrapment of tissue between the snare and the endoscope. Turning of the hand wheel allows for adjusting tension on the thread, and eventually, deployment of the clip. A snare lock (Figure 1G) helps prevent inadvertent snare opening and can be removed to "unlock" the snare once ready for use. The endoscope with the attached FTRD system is then re-inserted into the GIT to the target lesion. Next, with the tip of the cap appropriately positioned over the lesion (Figure 3B), the FTRD Grasper is used to grasp (Figure 3C) and mobilize the lesion completely within the cap (Figure 3D). All markings made by the FTRD Marking Probe should be visible inside the cap. Suction should not be used to draw the lesion into the cap as this may bring in extraluminal structures (*e.g.*, small bowel) into the cap causing significant injury to adjacent organs and structures. Finally, the clip is deployed (Figure 3E) by turning the hand wheel, and the lesion immediately resected with the snare using an electrosurgical current (Figure 3F) while being firmly grasped with the Grasper. It should be noted that once the lesion is brought into the cap, these steps should be performed quickly and sequentially in this specific order to prevent perforation and/or the lesion slipping out of the cap. The resected specimen is retrieved by withdrawing the endoscope with the lesion held by the Grasper. The endoscope without the attached FTRD is then reinserted to inspect the resection site for complete resection and confirm the absence of adverse events (AEs) (Figure 4).

PROOF OF CONCEPT AND PRECLINICAL DATA

Earlier studies established efficacy and safety of the OTSC system for endoscopic closure of gastrointestinal perforations and surgical anastomotic leaks and fistulas[14,15]. Following these data, several observational experiences and case series were described using an OTSC-assisted method for resection of gastrointestinal lesions, whereby the OTSC system was used to deploy the clip deep to a lesion prior to snare resection[16-18]. Based on these experiences, the basis for the FTRD system — a combined device containing an OTSC system plus a preloaded snare — was developed.

An early preclinical study using the FTRD in an animal (porcine) model demonstrated safety and efficacy[11]. The FTRD was used for resection of the colon wall in 11 pigs, and 7 and 28-d follow up study sessions were performed to evaluate the clip application site. Clips were still present in all but one case at 28 d and adherent stool and fibrin were found on the clips. There were mild inflammatory reactions seen histologically at day 7, but no acute inflammation was noted on day 28. The underlying tissue at the clip bed showed no signs of dehiscence or ischemia. Manometric pressure tests demonstrated no leak. Histology assessments revealed successful full-thickness resection (mucosa to serosa) in all cases.

CURRENT APPLICATIONS AND CLINICAL DATA

Study search and inclusion criteria

A summary of the major studies investigating the FTRD are included below. The keywords "endoscopic full thickness resection", "full thickness resection device," and "FTRD" were used for the initial query on PubMed. Studies published within a 10-year period from January 1, 2011-December 31, 2021, were considered for inclusion. To be considered for inclusion in this review, studies had to be original research studies using the Ovesco Endoscopy FTRD (other devices described for EFTR were not included) and be designed as prospective or retrospective studies. Observational studies, case reports, preclinical animal studies and proof of concept studies were not included. Studies that did not report the type of lesion, technical success rates, R0 resection rates, full-thickness resection rates, and rates of AEs were also not included.

Colorectal FTRD

The first clinical experience using the FTRD was published in 2015[19]. In this retrospective, two-center European study, 24 patients who underwent resection of colorectal lesions with the FTRD were identified. Indications included recurrent or incompletely resected adenomas with a non-lifting sign (n = 11), appendiceal adenomas (n = 5), untreated adenomas with a non-lifting sign (n = 2), incomplete resection of T1 carcinoma (n = 2), submucosal tumors (n = 2), adenoma within diverticulum (n = 1), flat adenoma in a coagulopathic patient (n = 1), and diagnostic resection in a patient with suspected Hirschsprung's disease (n = 1). Technical success (complete *en bloc* resection) was achieved in 20/24 (83.3%) patients and R0 resection (histologically complete resection with tumor-free margins) in 18/24 (75.0%) patients. Two patients developed post-polypectomy syndrome and required antibiotics, but there were no other reported AEs including no perforations or major bleeding events.

This study has been followed by numerous retrospective and prospective studies demonstrating safety and efficacy of FTRD in the colon and rectum (see Table 1 for summary of major clinical studies with current applications of FTRD for EFTR)[12,20-27]. In the largest, prospective multicenter study to date, 181 patients were recruited to receive EFTR with the FTRD system[25]. Indications for EFTR included "difficult" adenomas (n = 143), early carcinomas (n = 15), and subepithelial tumors (n = 23). "Difficult" adenomas included adenomas with a non-lifting sign, adenomas at the appendiceal orifice, and adenomas at a diverticulum. Technical success was achieved in 89.5% of cases and R0 resection in 76.9% of cases. AEs were noted in 18/181 (9.9%) patients and included bleeding (4/18), post-polypectomy syndrome (3/18), perforation (6/18), acute appendicitis (3/18), abdominal pain without clear etiology on laboratory and radiographic work-up (1/18), and enterocolonic fistula formation (1/18). All four patients with bleeding were treated conservatively and did not require transfusion of blood

Table 1 Summary of major clinical studies with current applications of full-thickness resection device for endoscopic full-thickness resection

	Ref.	Study type	Total FTRD cases, *n*	Site (s)	Type of lesion	Technical success, %	R0 resection, %	Full-thickness resection, %	Adverse events, %
1	Schmidt *et al* [19]	Retrospective	24	Colon; Rectum	Non-lifting polyps (*n* = 13); Appendiceal polyps (*n* = 5); Diagnostic (*n* = 3); Subepithelial tumor (*n* = 2); Polyp involving diverticulum (*n* = 1)	83.3	75.0	87.5	8.3
2	Schmidt *et al* [25]	Prospective	181	Colon; Rectum	Difficult adenomas (79.0%); Cancer (8.3%); Subepithelial tumor (12.7%)	89.5	76.9	81.0	9.9
3	Meier *et al* [12]	Retrospective	1178	Colon; Rectum	Difficult adenomas (67.1%); Cancer (18.4%); Subepithelial tumor (6.8%); Diagnostic (1.3%)	88.2	80.0	89.9	12.1
4	Boger *et al* [23]	Retrospective	68	Colon; Rectum	Non-lifting polyps (*n* = 29); Cancer (*n* = 13); Subepithelial tumor (*n* = 9); Polyps in appendix or diverticulum (*n* = 17)	88.2	76.8	NA	5.9
5	Hajifathalian *et al*[37]	Retrospective	56	Stomach; Duodenum	Mesenchymal neoplasm including GIST (*n* = 26); Diagnostic (*n* = 10), NET (*n* = 9); Adenomas (*n* = 6); Adenocarcinoma (*n* = 5)	93.0	68.0	NA	21.0
6	Meier *et al* [39]	Prospective	29	Stomach	Subepithelial tumor (*n* = 29)	89.7	76.0	65.5	31.0
7	Ichkhanian *et al*[20]	Retrospective	66	Colon/appendiceal orifice	Polyps involving appendiceal orifice	89.0	93.0	91.0	17.0
8	Zwager *et al* [28]	Prospective	367	Colon; Rectum	Difficult polyps (*n* = 133); T1 cancer (*n* = 71); Incomplete resection (*n* = 150); Subepithelial tumors (*n* = 13)	83.9	82.4	83.2	9.3
9	Zwager *et al* [29]	Retrospective	330	Colon; Rectum	Primary resection of T1 cancer (*n* = 132); Secondary resection of T1 cancer (*n* = 198)	87.0	85.6	NA	2.2

FTRD: Full-thickness resection device; GIST: Gastrointestinal stromal tumors; NA: Not available; NET: Neuroendocrine tumor.

products. Emergency surgery was required in 3/181 (2.2%) patients.

The results of a recent large retrospective analysis using the German colonic FTRD registry (*n* = 1178) reported similar findings, corroborating the previously reported findings of smaller studies[12]. Indications included difficult adenomas, early carcinomas, subepithelial tumors, and diagnostic resection. The technical success rate was 88.2% and R0 resection rate 80.0. The AE rate was 12.1% with 3.1% being major AEs. A similar but smaller retrospective study from the UK FTRD registry (*n* = 68) reported similar outcomes[23] with technical success rate 88.2%, R0 resection rate 76.8%, and AE rate 5.9%. This has since been further replicated in a larger Dutch FTRD registry (*n* = 367) with technical success rate 83.9%, R0 resection rate 82.4%, full-thickness resection rate 83.2%, and AE rate 9.3%[28].

Colorectal FTRD for early cancer, lesions at the appendix, and subepithelial lesions

Studies have reported slight variations (albeit with comparable success) in outcomes for FTRD depending on the indication for EFTR. Regarding FTRD use for early cancer, a recent study of 156 patients with a histologically proven diagnosis of adenocarcinoma showed FTRD to have a technical success rate of 92.3% and R0 resection rate of 71.8%. Serious AEs were reported in 3.9% of patients[24]. In a subgroup analysis from the previously mentioned retrospective study using the German colonic FTRD registry by Meier *et al*[12], 217 cases of FTRD in early cancers were identified. Technical success was reported to be 84.6% and R0 resection in 82.8% of cases. In a separate analysis by Schmidt *et al*[25], 29 cases of FTRD for early carcinomas were identified (14 harbored unsuspected cancer and 15 were known cancers). R0 resection was achieved in 72.4% of cases, but curative resection could only be achieved in 44.8% of cases. Similarly, a study from the Dutch FTRD registry showed overall technical

success, R0 resection, and AE rates of 87.0%, 85.6%, and 2.2%. However, the curative resection rate was only 60.3% with a curative resection rate of 23.7% for primary resection of T1 cancers[29]. Hence, given these low curative resection rates, there is some uncertainty regarding the role of FTRD as primary use for early cancers.

For lesions at the appendiceal orifice, a recent study of 66 patients demonstrated a technical success rate of 89% and R0 resection rate of 79%[20] using FTRD. Of note, 17.2% of patients developed appendicitis and 10.3% of patients (60% of those who developed appendicitis) required surgical appendectomy. Factors associated with risk of appendicitis included male sex (odds ratio: 1.2, $P = 0.03$) and failure to achieve histologic full-thickness resection (odds ratio: 1.5, $P = 0.04$)[20]. The high rates of appendicitis for this indication have raised concerns regarding the use of FTRD for appendiceal lesions. Further highly powered studies are needed to clarify the safety of FTRD for these lesions.

There is a lack of highly powered studies investigating FTRD for subepithelial tumors. A recent study of 40 patients with rectal neuroendocrine tumors (NETs) did report a technical success rate of 100%, R0 resection rate of 100%, and no AEs[21]. While these outcomes should be interpreted cautiously in the setting of a small sample size, the reported success is nonetheless encouraging and in line with the success reported in other FTRD studies[12,22,23,25]. In a subgroup analysis using the German colonic FTRD registry by Meier *et al*[12], 80 cases of FTRD for subepithelial tumors were identified. The technical success rate was 97.3% and R0 resection rate was 97%. R0 resection was significantly higher for subepithelial tumors compared with that for other lesions in the German FTRD registry (77.2% for difficult adenomas, 82.8% for early cancers). Data regarding AE rates within the subgroup analysis were not available. In a separate subgroup analysis from Schmidt *et al*[25], 23 cases of FTRD for indication of subepithelial lesions were identified, with R0 resection rate of 87%. Overall, FTRD for subepithelial lesions seems to be very effective, with greater technical success and R0 resection than FTRD for other lesions.

Subgroup analyses have also been performed in studies to determine whether differences in outcomes may be related to other factors such as lesion location, lesion size, and prior treatment. Findings have varied[12,25], though by and large, there does not appear to be convincing evidence of any significant differences in technical success and other outcomes based on lesion location, size, or prior treatment[12]. Further studies may help better clarify what factors independently predict these outcomes of success.

Similar technical success and R0 resection rates have been reported for EMR and ESD[30,31]. ESD has been associated with greater R0 resection rates than EMR, but is also associated with greater rates of AEs like perforation and major bleeding. Direct comparisons of technical success and R0 resection between EMR/ESD and FTRD are difficult to make, as the majority of indications for FTRD currently are for lesions deemed difficult or challenging to resect *via* EMR or ESD. Few studies have reported on the efficacy of salvage ESD (ESD performed for residual or locally recurrent non-lifting lesions), which would likely be a better comparator group for FTRD, but these few small studies do appear to suggest comparable rates of success[32,33]. Similar AE rates have been reported for ESD and FRTD[31]. However, procedural time for ESD is considerably longer than FTRD[31].

Overall, EFTR with the FTRD system in the colorectum appears to be safe and efficacious. Common indications for FTRD in the lower GIT include select lesions difficult to resect by more conventional approaches (*i.e.*, non-lifting adenomas, adenomas at appendiceal orifice, adenomas at diverticulum), early cancers, subepithelial lesions, and diagnostic resection. Very large lesions > 3 cm may not be appropriate for FTRD.

Gastroduodenal FTRD

Recently, a newer and smaller caliber FTRD, the gastroduodenal FTRD©, has become available for use in the upper GIT.

Prior to the development of the newer gastroduodenal FTRD system, experiences using the traditional FTRD system (now known as the colonic FTRD©) in the upper GIT were reported[34-36]. These were primarily case reports and small case series dating as far back as 2014 (when the FTRD first became available in Europe) reporting safe and successful use of the FTRD in the stomach and duodenum in patients with malignant or large, nonmalignant subepithelial lesions who were deemed unsuitable for surgery[34-36]. Several retrospective analyses have followed demonstrating safety and efficacy of FTRD in the UGIT[37,38]. The largest of these was an international multicenter trial of 56 patients across 13 centers[37]. Common indications included gastrointestinal stromal tumors (GIST), adenomas, hamartomas, and adenocarcinomas. Results showed a technical success rate of 77% and R0 resection rate of 68%. The AE rate was 21%, though none were classified as severe AEs. Common AEs included intraprocedural and delayed bleeding. No perforations were reported.

Recently, a prospective multicenter pilot study (RESET trial) investigated the new gastroduodenal FTRD in the upper GIT[39]. 29 patients underwent EFTR with the gastroduodenal FTRD in this trial for gastric subepithelial tumors, which included leiomyomas, lipomas, schwannomas, ectopic pancreas, GISTs, and NETs. The technical success rate was 89% and the R0 resection rate was 76%. Minor bleeding occurred in 31% of cases and was able to be managed intraprocedurally in all cases. No transfusion of blood products was required nor was any further bleeding observed. No other AEs were reported. The success rates and AE rates reported here are similar to those reported with FTRD in the lower GIT.

To our knowledge, there is only one single report on the use of the FTRD in the esophagus[37]. However, this was reported as part of a larger multicenter study, and it is not evident whether this case was technically successful or associated with any AEs.

Similar to FTRD in the lower GIT, various subgroup analyses have been performed to ascertain whether outcomes of FTRD in the upper GIT are associated with other variables. Thus far, variables such as indication, lesion size, lesion location, prior treatment, participating center, or number of FTRD cases performed by the endoscopist have not been clearly associated with technical success and other success outcomes[37,39]. Further studies are needed to help delineate the impact of these individual factors on gastroduodenal FTRD outcomes.

Overall, early data suggests that FTRD in the upper GIT appears to be feasible, safe, and efficacious. Common indications include gastric and duodenal subepithelial lesions, adenomas, and early cancer. However, given the paucity of data of FTRD in the upper GIT compared to the lower GIT, further studies are needed to further clarify the indications, especially for the indication of early cancer, as well as clarify overall safety and efficacy.

EMERGING APPLICATIONS

Hybrid FTRD

In cases with lesions > 3 cm or where *en bloc* EFTR appears challenging for other reasons, various hybrid techniques have been proposed. These have been referred to by varying names including Hybrid FTRD, EMR + FTRD, and ESD + FTRD. In general, these hybrid techniques refer to using either piecemeal EMR or ESD followed by FTRD of scarred areas or residual abnormal appearing tissue. Hybrid techniques have shown some promise in small case series[40-44]. However, further evaluation in larger scale studies is needed to draw conclusions on their routine use.

TECHNICAL CHALLENGES

Several limitations of the FTRD have been reported. One technical challenge is the difficulty in resecting larger lesions. With a cap diameter of 21 mm and cap depth of 23 mm for the standard colonic FTRD (and smaller for the gastroduodenal FTRD and diagnostic FTRD), it is often difficult to adequately grasp large lesions (> 3 cm) to accomplish *en bloc* resection. In addition, these lesions are often scarred and fixed to the colon wall, and therefore may be difficult to grasp and bring into the cap even if they are smaller than 3 cm. The length and stiffness of the plastic cap can also interfere with visualization and flexibility at the scope tip, thereby making it quite cumbersome to advance the colonoscope with the FTRD across a tortuous sigmoid and especially to the right colon. As described earlier, a proprietary test cap called the FTRD prOVE Cap© is available to help circumvent some of these issues and to determine whether a target lesion can be reached and might be suitable for resection with FTRD. The long plastic sheath that wraps around the scope shaft can increase friction of the device and also make advancement of the scope through tight or tortuous anatomic locations difficult. Some endoscopists leave a guidewire in the colon after the diagnostic colonoscopy is performed. The colonoscope with the attached FTRD is then advanced alongside the guidewire, following the guidewire to the lesion, overcoming the limited visualization and maneuverability with the FTRD cap. Device failure (failure of the clip to fully cinch down or complete malfunction of the clip or snare's opening and closing functions) and premature clip deployment leading to immediate perforation or incomplete resection have been reported[12]. Risk factors for incomplete or partial resection include tissue fibrosis, right-sided colonic lesions, and size > 3 cm[25]. It should be emphasized that clip placement must be immediately followed by prompt snare resection, often requiring good communication and teamwork between the endoscopist and assistants handling the snare and grasper. It is important to have the endoscopist fire the clip and have two separate assistants operate the grasper and snare. Delay in snare resection after clip placement, slippage of the lesion from the grasper, or inadvertently performing snare resection before firing the clip can result in incomplete resection or immediate perforation. As with other endoscopic devices and techniques, EFTR with the FTRD requires adequate training and endoscopic skill. Completion of mandatory training is required prior to the purchase and use of FTRD.

FUTURE DIRECTIONS

Currently, there is a lack of direct comparison between FTRD and other standard resection approaches such as EMR and ESD. Direct comparisons between FTRD and more standard approaches are needed to further clarity the role of FTRD, whether it is merely adjunctive to standard approaches or may be a suitable primary or "standard" approach itself. Cost-effectiveness studies may help further clarify this role as well. Recently, laparoscopic and endoscopic cooperative surgery (LECS) has been described as a

less invasive approach to resecting lesions in the GIT, such as GIST[45]. Prospective studies comparing FTRD with LECS and other similar novel minimally-invasive surgical techniques will help clarify the advantage of FTRD over these novel surgical approaches. Studies investigating longer term outcomes are also needed, especially regarding AEs and the ability to perform adequate endoscopic examination of the full-thickness resection site during follow-up and surveillance. This may be challenging if the FTRD clip is still in place and not fallen off. There are still concerns regarding AEs with EFTR with FTRD, especially for resection of lesions at the appendiceal orifice and with regards to delayed perforation. Long term data are needed on specific outcomes such as the development of an appendiceal mucocele or delayed appendicitis after using FTRD in this location. It is also tempting to consider whether there might be safe applications for the FTRD in the esophagus, particularly in the treatment of early carcinomas or subepithelial lesions. Future studies may help clarify this and other expanded roles of FTRD.

CONCLUSION

EFTR can be successfully and safely accomplished with the FTRD system. The role of FTRD has expanded in recent years and the FTRD is currently available for use in the lower and upper GIT. EFTR with FTRD is a crucial addition to the endoscopic armamentarium for resection of gastrointestinal lesions and reducing need for more invasive surgery. Common indications for its use include resection of lesions difficult to resect with conventional techniques like EMR and ESD, such as scarred or non-lifting polyps, early cancers, subepithelial lesions, and diagnostic resection for evaluation of various neuromuscular or entero-infiltrative conditions (*e.g.*, Hirschsprung disease, gastrointestinal amyloidosis). EFTR with FTRD has a high technical success and R0 resection rate, and AE rates are acceptable, especially when used as a less invasive option for lesions not amenable for standard endoscopic resection. Common AEs include bleeding and perforation, and further long-term data on unique complications such as post-polypectomy syndrome, delayed perforation, acute appendicitis, and enterocolonic fistula are needed. Several technical challenges exist and endoscopists should be adequately trained on the FTRD system prior to use in clinical practice. FTRD, used in its proper context, has the ability to be a major advancement in endoscopic resection for populations felt to be too high risk for traditional resection techniques and surgery (*e.g.*, elderly patients, patients at high risk of bleeding, high risk for anesthesia).

Abstract

Contrast enhanced ultrasound (CEUS) has been widely implemented in clinical practice because of the enormous quantity of information it provides, along with its low cost, reproducibility, minimal invasiveness, and safety of the second-generation ultrasound contrast agents. To overcome the limitation of CEUS given by the subjective evaluation of the contrast enhancement behaviour, quantitative analysis of contrast kinetics with generation of time-intensity curves has been introduced in recent years. The quantification of perfusion parameters [named as dynamic-CEUS (D-CEUS)] has several applications in gastrointestinal neoplastic and inflammatory disorders. However, the limited availability of large studies and the heterogeneity of the technologies employed have precluded the standardisation of D-CEUS, which potentially represents a valuable tool for clinical practice in management of gastrointestinal diseases. In this article, we reviewed the evidence exploring the application of D-CEUS in gastrointestinal diseases, with a special focus on liver, pancreas, and inflammatory bowel diseases.

Key Words: Quantitative perfusion analysis; Gastrointestinal diseases; Time-intensity curve; Multiparametric ultrasound

Core Tip: Contrast-enhanced ultrasound (CEUS) has been widely implemented in clinical practice in recent years. Despite its several advantages, the qualitative evaluation of this exam and the lack of objectivity could lead to variability between different operators and ultrasound equipments. Dynamic-CEUS (D-CEUS) with the measurement of perfusion parameters is aimed at overcoming this important limitation. The purpose of this review is to explore the usefulness of D-CEUS in gastroenterological diseases.

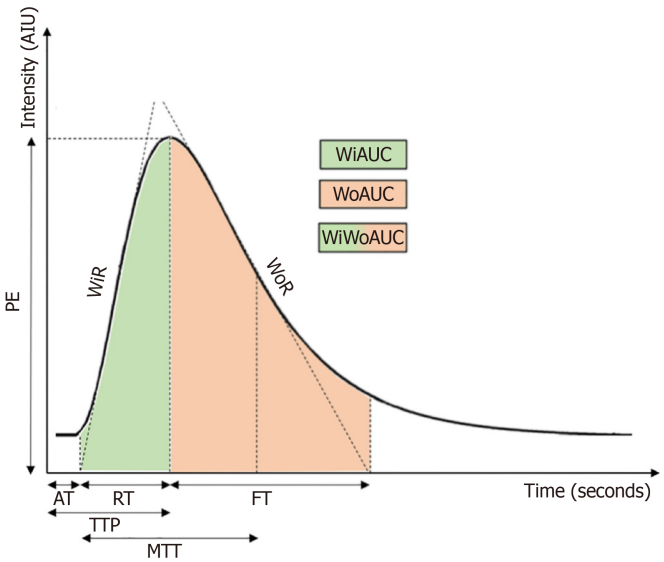
INTRODUCTION

Contrast enhanced ultrasound (CEUS) has been widely implemented in clinical practice as a result of the enormous quantity of information it provides, along with its low cost, reproducibility, minimal invasiveness, and safety of the second-generation ultrasound contrast agents (UCAs)[1-4]. Despite its numerous advantages, one of the most significant limitations of CEUS is the subjective evaluation of contrast enhancement related behaviour of the explored tissues[5]. In recent years, dynamic-CEUS (D-CEUS) has been explored to overcome this limitation.

D-CEUS represents the quantitative analysis of UCA-kinetics in a specific region of interest (ROI)[6]. This technique allows two types of analysis in the examined tissue: Disruption-replenishment analysis and wash-in/wash out analysis[7]. The first analysis consists in the evaluation of microbubbles replacement after destroying them with high mechanical index. Requiring the continuous intravenous infusion over five to twenty minutes of UCA, the disruption-replenishment analysis are infrequently used due of their complex methodology[8]. Consequently, the second form of analysis is more frequently employed in clinical practice. It consists of measuring the average intensity of a ROI following a bolus injection of UCA and generating a time-intensity curve (TIC). Hence, multiple parameters are derived from the TIC to quantitatively characterize the different stages of the wash-in and wash-out phases. The fundamental parameters derived from TIC are summarized in Table 1[9,10] and a schematic representation of TIC is shown in Figure 1. Generally, these parameters are obtained from different softwares and might consequently have varying nomenclature but can be divided into two categories: Amplitude parameters and time parameters. These criteria reflect various vascularization features: Amplitude parameters are mainly related to blood volume in the ROI, while blood flow is mostly correlated with time parameters[11]. Tracking microbubbles circulation provides the spatial representation of blood flow patterns and the derivation of parametric values of tissue perfusion since microbubbles strictly remain within the vasculature compartment[12].

Examining the pros and cons, D-CEUS is a widely accessible, radiation-free, non-nephrotoxic and cost-effective technique that allows objective enhancement quantification, image comparison, real-time evaluation of the microcirculation perfusion by a strictly intravascular blood pool agent. This is crucial after the introduction of updated response evaluation criteria in solid tumor (RECIST) criteria based on tumour perfusion as D-CEUS potentially enables the monitoring of changes in vascularization even shortly after tumor treatment[13,14]. According to current European Federation for Ultrasound in Medicine and Biology recommendations, D-CEUS is useful for quantifying tumor enhancement objectively, to characterize focal lesions and evaluate the therapeutic response[7]. In contrast, D-CEUS should ideally be uniform regardless of the ultrasound equipment, data collecting, and analysis software, as different approaches and technical issues may influence the results' validity. Lastly, the technical limitations of the method must be addressed, particularly in the abdomen, where intestinal, respiratory, and probe motion artefacts could make this exam challenging, as well as the patient's ability to accomplish the instructions based on his mental and physical state[15].

The first D-CEUS examination was performed on oncological renal illness more than two decades ago [16]. Since then, this technique has spread to several medical specialties, especially in the gastroenterological setting and not only for oncological diseases. In this review we summarize the evidence exploring the application of D-CEUS in gastrointestinal diseases.



LIVER DISEASES

In liver diseases, D-CEUS has been explored primarily for its usefulness in characterizing focal liver lesions (FLLs). Several applications of D-CEUS in predicting biological behaviour, differential diagnosis, and prognosis have been explored. These studies are summarized in Table 2, and Figure 2 illustrates the

Table 1 Dynamic contrast-enhanced ultrasound parameters in time-intensity curve

Abbreviation	Parameter	Definition	Unit
AT	Arrival time	Time from administration of UCA to the beginning of the curve	s
AUC or WiWoAUC	Area under the curve or wash-in and wash-out area under the curve		AIU
FT	Fall time	Time from PE to point where tangent of descending curve across x-axis	s
IMAX or MI	Maximum intensity	Maximum intensity of the curve	AIU
MTT	Mean transit time	Mean time taken by contrast to pass through the ROI	s
PE	Peak enhancement	Maximum intensity of the curve	AIU
PI	Peak intensity	Maximum intensity of the curve	AIU
Pw	Slope coefficient of wash-in	Coefficient of the enhancement wash-in slope	AIU × s
RT	Rise time	Time from PE to point where tangent of ascending curve across x-axis	s
TPI or TTP or TP	Time to peak	Time from the beginning of the curve to peak	s
WiAUC	Wash-in area under the curve	AUC from the beginning of the curve to PE	AIU × s
WoAUC	Wash-out area under the curve	AUC from the PE to the end of the curve	AIU × s
WiR	Wash-in rate	Tangent at the ascending part of the curve	AIU × s
WoR	Wash-out rate	Tangent at the descending part of the curve	AIU × s

AIU: Absolute intensity unit; ROI: Region of interest; UCA: Ultrasound contrast agent.

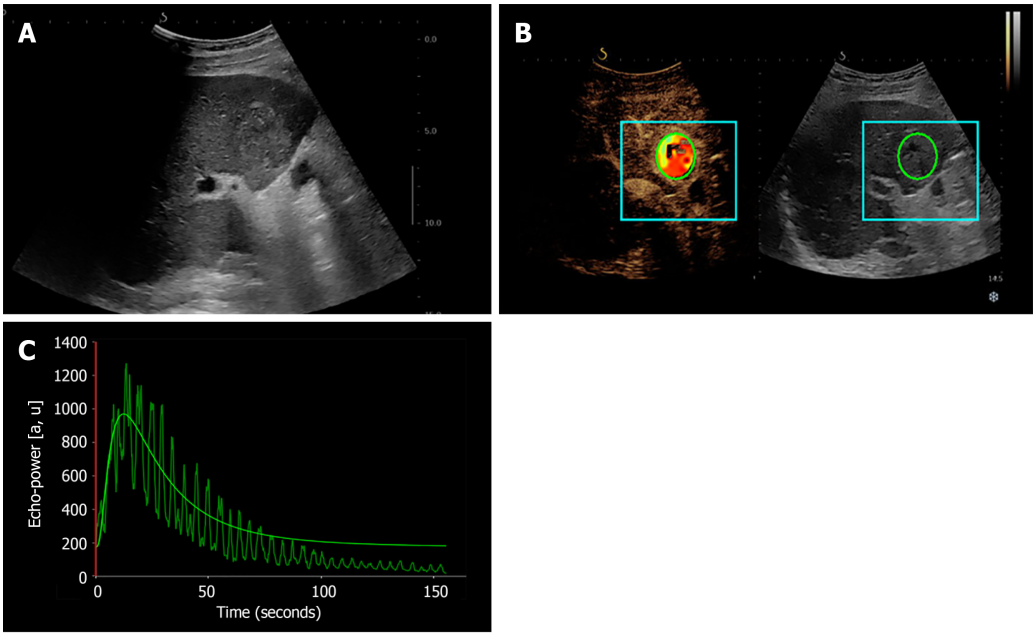
Figure 1 Time-intensity curve and derived parameters. AIU: Absolute intensity unit; AT: Arrival time; FT: Fall time; MTT: Mean transit time; PE: Peak enhancement; s: Second; TTP: Time to peak; WiAUC: Wash-in area under the curve; WiR: Wash-in rate; WiWoAUC: Wash-in and wash-out area under the curve; WoAUC: Wash-out area under the curve; WoR: Wash-out rate; RT: Rise time.



use of D-CEUS to characterize liver lesions.

Table 2 Dynamic contrast-enhanced ultrasound and liver diseases

Ref.	Study design/number of patients	Object of D-CEUS	Population/groups	Machine/UCA/software	Significant results ($P < 0.05$)
Wildner *et al*[31], 2022	Prospective/17	Melanoma liver metastasis	Patients with melanoma liver metastasis treated with sorafenib/Responders' *vs* non-responders	Sequoia 512/SonoVue/Qontrast	Increase of MTT and TTP is associated with response to treatment and prognosis
Gu *et al*[30], 2022	Retrospective/97	HCC	Patients with HCC underwent thermal ablation	Acuson Sequoia, Phillip EpiQ7/SonoVue/VueBox	WiAUC, WoAUC, and WiWoAUC ratios between HCC and surrounding parenchyma before ablation were predictors of survival
Huang *et al*[18], 2022	Prospective/120	HCC	Patients with HCC underwent biopsy/Low-Ki-67 *vs* high-Ki-67	Logiq E9/Sonazoid/NovoUltrasound Kit	PE difference between HCC and distal liver parenchyma was different in the Kupffer phase
Li *et al*[22], 2022	Retrospective/31	HCC	Patients with HCC underwent surgery/MVI-positive *vs* MVI-negative	Phillip EpiQ7/Sonazoid/built-in auto contrast software	None of the D-CEUS parameters was related to MVI
Zocco *et al*[28], 2013	Prospective/46	Liver parenchyma	Cirrhotic patient underwent HVPG/clinically significant portal hypertension *vs* severe portal hypertension	iU22/SonoVue/QLAB	Negative correlation between PI, Pw and HVPG. Positive correlation with MTT. AUROC of 1.00 for PI < 23.3 AIU to predict clinically significant portal hypertension
Dong *et al*[21], 2021	Retrospective/16	HCC	Patients with HCC underwent surgery/MVI-positive *vs* MVI-negative	Acuson Oxana, Logiq E9, Siemens Acuson Sequoia/SonoVue, Lumason/VueBox	WiAUC and WoAUC were higher in MVI positive group
Schwarz *et al*[24], 2021	Retrospective/139	Focal liver lesion	Patients with diagnosed focal liver lesion/malignant versus benign	Acuson Sequoia, S2000 or S3000 and Phillip EpiQ7/SonoVue/VueBox	RT and late phase ratio were different between malignant and benign liver lesion
Xuan *et al*[19], 2021	Retrospective/128	HCC	Patients with HCC underwent biopsy or surgery/highly-differentiated *vs* moderate-differentiated *vs* poorly-differentiated	-/SonoVue/-	RT and MTT increased from poorly- to moderate- to highly-differentiated. Enhancement rates decreased from poorly- to moderate- to highly-differentiated
Amadori *et al*[32], 2018	Prospective/37	CRC Liver metastasis	Patients underwent chemotherapy/chemotherapy *vs* chemotherapy plus bevacizumab	iU22 vision 2008/SonoVue/QLAB	Reduction of PI and AUC and increase of TPI correlated with higher PFS in chemotherapy plus bevacizumab group
Wildner *et al*[25], 2019	Prospective/148	Focal liver lesion	Patients with focal liver lesion and subsequent final diagnosis/HCC, CCC, PCA, CRC, BC, MM, FNH	Sequoia 512/SonoVue/VueBox	Higher PE and WiWoAUC in HCC than CRC. Lower Relative intensity signal for PCA and CRC compared to HCC at 30 and 120 s after PE
Mogensen *et al*[33], 2017	Prospective/12	CRC liver metastasis	Patients underwent chemotherapy/chemotherapy *vs* chemotherapy plus bevacizumab	Logiq E9/SonoVue/VueBox	Early changes of PE correlate with tumor shrinkage at CT scan
Zocco *et al*[28], 2013	Prospective/28	HCC	Patients treated with sorafenib/Responders' *vs* non-responders	iU22/SonoVue/QLAB	PI, Pw and AUC 10% decrease correlate with response to therapy. AUC 10% decrease and increased/unchanged TPI and MTT are associated with longer survival. Decrease of Pw is associated with PFS
Zhan *et al*[20], 2019	Prospective/35	HCC	Patients with HCC underwent microwaves ablation	Acuson Sequia/Sonovue/SonoLiver	Positive correlation between MVD, VEGF and IMAX; negative correlation

					between MVD and TTP. TTP was an independent predictor of OS
Wildner *et al*[26], 2014	Prospective/43	HCC, ICC	Patient with proven HCC and ICC	Acuson Sequoia 512/SonoVue/VueBox	FT and MTT were lower in ICC than HCC. Relative signal intensity was lower in ICC than HCC in all time point after PE
Frampas *et al*[69], 2013	Prospective/19	HCC	Patients with HCC treated with sorafenib or sunitinib/RECIST progressor *vs* non-progressor	Aplio XV/SonoVue/Vascular Recognition Imaging" mode	AUC decrease ≥ 40% correlated with RECIST non-progression
Lassau *et al* [29], 2011	Prospective/42	HCC	Patients with HCC treated with Bevacizumab	Aplio scanner/SonoVue/Contrast Harmonic Imaging-Quantification software	AUC, WiAUC, WoAUC and TPI decrease correlate with tumor response. TPI decrese correlate with PFS. AUC and WoAC decrease correlate with OS

Biological behaviour

The vascular structure of a tumour lesion is closely associated with microscopic features such as the degree of differentiation, the proliferation index and growth rate, the presence of necrosis, the angiogenesis and the vascular invasion[17]. Therefore, the analysis of vascularization parameters could be different according to each of the aforementioned characteristics.

Huang *et al*[18] investigated the correlation between perfusion parameters and Ki-67 in hepatocellular carcinoma (HCC) patients. Prospective analysis of one hundred twenty patients showed that the peak enhancement (PE) difference between HCC and distal liver parenchyma in the Kupffer phase was significantly higher in low Ki-67 (< 10%) group compared to high Ki-67 (≥ 10%) group, probably due to lower concentration of Kupffer cells in poorly differentiated neoplasms[18]. Supporting this, differences in D-CEUS parameters were found among HCC differentiation classes. Specifically, rise time (RT) and time to peak (TTP) demonstrated a significant positive correlation with differentiation degree, whereas

enhancement rate was significantly higher in lesions with less differentiation[19].

Regarding the pure vascular features of tumors, Zhan *et al*[20] demonstrated that histological determined microvessel density and vascular endothelial grow factor stain positively correlated with maximum intensity (MI), while microvessel density negative correlated with TTP[20]. This suggested that D-CEUS parameters could provide a reliable characterization of the microvascular scaffold of lesions. In another study Dong *et al*[21] perform a retrospective analysis of D-CEUS characteristics of HCC to investigate the capability to predict microvascular invasion in a cohort of 16 patients who underwent subsequent surgery. They found that wash-in area under the curve (WiAUC) and wash-out area under the curve (WoAUC) were significantly higher in microvascular invasion positive group ($P < 0.05$), especially when the ROI was positioned in the marginal area of the lesion. This phenomenon is likely to be attributed to the formation of arteriovenous fistulas during vascular invasion, which leads to an increase in blood flow[21]. In contrast, using different UCA, Li *et al*[22] found no correlation between quantitative parameters and microvascular invasion in thirty-one resected HCCs[22]. One of the most significant differences between second-generation UCAs is their resistance to US wave pressure, which could explain this apparent contradiction in results[23].

This evidence suggests that D-CEUS may serve as a biomarker of the biological behaviour and microscopic characteristics of HCC, detecting the abnormal vascularization characteristics that developed as the disease progressed.

Differential diagnosis

Quantitative analysis of perfusion parameters demonstrated a promising potential to distinguish between benign and malignant FLLs. In a retrospective study including one hundred and thirty-nine FLLs of which forty-four benign and ninety-five malignant, benign lesions showed a significantly higher late-phase ratio (ratio between signal intensities of lesion and surrounding tissue in late phase, LPR) compared to malignant counterpart, showing an area under the curve (AUC) of 0.9, with maximal sensitivity (100%) but low specificity (56.8%). Interestingly, the difference in LPR remains significant also comparing hypoechoic haemangiomas to malignant lesions, suggesting the ability to distinguish a real wash-out from other phenomena. Although RT demonstrated a lower AUC (0.58) for distinguishing benign from malignant lesions, it demonstrated outstanding accuracy (AUC: 0.91) when applied to the distinction between haemangioma and malignancy. Furthermore, considering only benign lesions, haemangioma and adenoma displayed longer mean RT values than other benign lesions[24]. This suggests that quantitative analysis could increase the diagnostic accuracy between benign liver lesions and in challenging situations, such as benign lesions with moderate hyperenhancement (*e.g.*, thrombosed haemangioma) or modest hypoenhancement in late phase (*e.g.*, certain subtypes of hepatic adenoma).

D-CEUS might be helpful to differentiate hypervascular tumours like HCC from other malignant liver lesions that are predominantly necrotic and hypovascular. Wildner *et al*[25], analysing D-CEUS parameters in HCC and different secondary liver lesions showed that PE normalized for parenchyma signal and wash-in-wash-out area under the curve (WiWoAUC) were significantly higher in HCC compared to colorectal cancer (CRC) metastasis and relative signal intensity at 30 and 120 s after PE was significantly lower for pancreatic adenocarcinoma and CRC liver metastasis compared to HCC[25]. These results clearly suit to the hypervascular nature of HCC in contrast to the more necrotic and weakly centrally vascularized secondary liver lesions of other primitive cancers. While arterial phase parameters are significantly different between HCC and CRC metastatic liver masses, their applicability to differentiate HCC from other primary intrahepatic malignancies is unfitted. Previously, the same authors had investigated the differences between HCC and intrahepatic cholangiocellular carcinoma (ICC) showing no significant differences in arterial phase parameters while ICC group showed lower values of mean transit time (MTT) and fall time in portal and venous phase. Furthermore, relative signal intensity was significantly lower in ICC compared to HCC in all time points after PE at 40 s, 80 s, 100 s and 120 s[26]. Actually, the main difference between HCC and ICC at CEUS is the early and marked wash-out in portal phase for ICC[4]. Objective quantification of the wash-out phenomenon using D-CEUS could improve the diagnostic accuracy of differentiating lesions with similar portal and late phase hypoenhancement.

Prognosis prediction

One of the most promising applications of D-CEUS is the assessment of liver tumour response to treatment, particularly in HCC where chemotherapy regimens are mostly based on vascular-targeting agents[27]. To this purpose, Zocco *et al*[28] investigated the role of D-CEUS to early detect vascular changes in HCC patients treated with sorafenib and to predict response to therapy and prognosis. The results showed that a decrease in AUC, peak intensity (PI), and slope of wash-in (Pw) between T0 (baseline) and T1 (after fifteen days of therapy) was significantly associated with response to therapy assessed with RECIST criteria after two months of treatment. Furthermore, 10% decrease in AUC was significantly associated with longer survival as increased/unchanged of time to PI (Tp) and MTT, while a Pw reduction was significantly associated with progression-free survival (PFS)[28]. Similar results were obtained by Lassau *et al*[29] considering patients with advanced HCC treated with bevacizumab. D-CEUS was performed before treatment and at days 3, 7, 14, and 60 after treatment; and every 2 mo

thereafter. Interestingly, the results showed that very early changes in D-CEUS characteristics correlated with response to therapy and prognosis. Particularly, the decreases in AUC, AUC during wash in, AUC during washout, and time to PI (TPI) at day 3 were significantly associated with RECIST response at 2 mo. Furthermore, PI, AUC and AUC during washout changes at day 3 were correlated with PFS and overall survival (OS)[29]. These results suggest that effects of antiangiogenetic treatments can be early assessed quantifying the perfusion parameters and could allow for a tempestive intervention when relative prognosis is unfavourable.

D-CEUS could also have a role in predicting the prognosis of HCC patients who received loco-regional treatments. In HCC patients undergoing microwave ablation, TTP evaluated before the procedure was confirmed as an independent predictor of OS[20]. Similarly, the WiAUC, the WoAUC and the WiWoAUC ratio between HCC lesion and surrounding liver parenchyma evaluated before thermal ablation were significantly associated with survival[30]. As a consequence, quantitative perfusion evaluation might provide additional information useful to plan treatment procedures.

Considering non-HCC malignant liver lesions, different studies evaluated D-CEUS modifications to predict early response to therapies. In patients with liver metastasis of melanoma treated with sorafenib, TTP and MTT increased significantly in responders group at 15 and 56 d assessment[31]. Furthermore, CRC-metastatic patients treated with chemotherapy plus bevacizumab showed changes in derived PI, TPI and AUC at day 15 that were significantly correlated with PFS, however these modifications were not related with tumor response or survival[32]. In contrast, Mogensen *et al*[33] observed a significant association between PE early variation and computed tomography (CT) dimensional tumour decrease in patients treated with chemotherapy plus bevacizumab[33]. Variability in these results could be explained by limitations of 2-dimensional imaging techniques used in all the discussed studies. In the future, 3-dimensional D-CEUS might provide a more accurate evaluation of entire tumor features[34].

Non-oncological hepatic application of D-CEUS

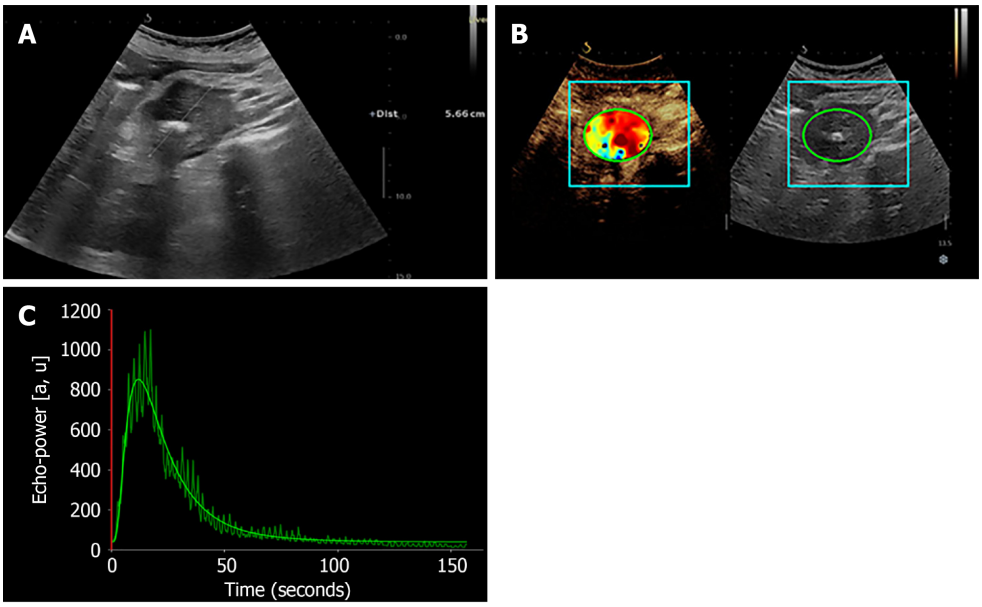
Despite most studies primarily focused on neoplastic liver disease, the application of quantitative analysis of perfusion parameters has also been explored in chronic liver disease. The TICs of the liver parenchyma can provide information's of intrahepatic blood flow and, indirectly, of portal vein pressure, either that could be altered by liver fibrosis.

In the past, different studies evaluated transit time between vessels to estimate the intrahepatic blood flow and to assess liver fibrosis stage. It was showed that hepatic vein transit time decreased as severity of histologically proved chronic hepatopathy increased, thus allowing diagnosis of severe fibrosis with an accuracy of 79%[35,36]. In addition, hepatic vein arrival time and intrahepatic transit time were correlated with hepatic venous pressure gradient (HVPG), with an area under the receiver operating characteristic (AUROC) of 0.97 for HVPG > 10 mmHg and 0.94 for HVPG > 12 mmHg, respectively[37, 38].

Recently, perfusion parameters analysis of liver parenchyma showed a decrease of amplitude-parameters and an increase of time-dependent parameters according to grade of portal pressure assessed with HVPG. Interestingly, PI resulted significantly negative correlated with portal hypertension and showed high accuracy (100% for both specificity and sensitivity) to predict clinical significant portal hypertension using a cut-off of 23.3 dB in patients with liver cirrhosis[39].

PANCREATIC DISEASES

Existing evidence about the usefulness of D-CEUS for pancreatic diseases is very limited and is resumed in Table 3. Characterization and differential diagnosis of benign and malignant pancreatic lesions are the focus of the available research. Figure 3 depicts an example of D-CEUS in pancreatic disease.



One of the first studies regarding the perfusion analysis of pancreatic cancer was conducted by D'Onofrio *et al*[40]. Prospectively, ten patients with suspected pancreatic ductal adenocarcinoma (PDAC) (as confirmed by histology) underwent CEUS with subsequent quantitative perfusion analysis. The results showed a significant difference in PE and ascending curve between PDAC and normal pancreatic parenchyma, providing an objective quantification of enhancement for the assessment of pancreatic lesion[40].

Chronic pancreatitis (CP), localized autoimmune pancreatitis (AIP), and paraduodenal pancreatitis can present CT and magnetic resonance imaging abnormalities identical to PDAC and, vice versa, potentially resectable malignant lesions can be misdiagnosed due to their similarities with benign masses[41]. In such instances, D-CEUS may reveal the pathophysiological differences between highly vascularized inflammatory lesions and essentially necrotic malignant masses, enabling a correct differentiation between benign lesions and cancer. To compare CP to PDAC, Kersting *et al*[42] performed D-CEUS in sixty undetermined pancreatic lesions that were histologically characterized as PDAC (fourty-five) or inflammatory lesion in CP (fifteen). The grouped analysis of TICs showed that TTP and arrival time were significantly prolonged in PDAC compared to CP. On the contrary, no differences were detected in MI and AUC between the two pathological conditions[42]. Regarding AIP, D-CEUS with quantitative analysis has the potential to make pre-operative differential diagnosis between focal-type

Table 3 Dynamic contrast-enhanced ultrasound and pancreatic diseases

AIP and PDAC non-invasively. Vitali *et al*[43] compared D-CEUS parameters of three patients with focal AIP with seventeen PDAC patients. Specifically, the difference between PE of PDAC and circumjacent normal parenchyma was significantly lower as compared to AIP. Significant was also the difference between wash in index perfusion (WiPI = WiAUC/RT) of PC and AIP[43]. In another study, TICs of AIP lesions showed delayed and higher enhancement compared to PDAC. Among all CEUS perfusion parameters, ratio of PE, WiAUC, wash-in rate (WiR), WiPI, WoAUC, WiWoAUC, and wash-out rate (WoR) between pancreatic lesion and surrounding normal pancreatic tissue were significantly higher in AIP lesions than PDAC lesions[44]. In cases of diffuse AIP, quantitative perfusion analysis is not suggested since there is no healthy parenchyma for comparison, which is necessary to enhance the

comparability of the results regardless of exam- or patient-related factors[42].

Similarly to perfusion analysis for malignant liver lesions, D-CEUS could be considered to evaluate the response to therapies in PDAC. Recently, Zhang *et al*[45] investigated the role of D-CEUS to monitor the response to chemoradiotherapy in eleven patients with local advanced pancreatic cancer. They performed D-CEUS at baseline and after four weeks of therapy and analyzed the variation of TICs and related parameters. The rising and falling slope rates of TICs diminished after four weeks, and the percentage of MI decreased significantly compared to the surrounding normal parenchyma[45]. Since MI is related to tumour microvascular density, its reduction is coupled with a decrease in lesion blood perfusion, and the quantification of this consequence might reflect the objective efficacy of chemotherapy.

Lastly, D-CEUS could provide information in other types of pancreatic tumors. It has been proven that pancreatic neuroendocrine tumors (pNETs) with different histopathological grades have differences in tumor microvascular perfusion[46], therefore Yang *et al*[47] analyzed the correlation between perfusion analysis and histopathological grades of pNETs. In forty-two patients, the TICs shape of grade 1 (G1)/grade (G2) lesions were significantly different compared to TICs of grade 3 (G3)/pancreatic neuroendocrine carcinomas (pNECs). Significant differences were revealed at relative RT, relative MTT and relative AUC which were higher in G1/G2 than G3/pNECs. ROC analysis showed that relative AUC had the higher accuracy to distinguish the two groups[47]. The D-CEUS analysis and quantitative parameters have the potential value to non-invasively predict the biological behaviour of pNETs.

INFLAMMATORY BOWEL DISEASES

Table 4 summarizes the evidence regarding the role of D-CEUS in inflammatory bowel diseases, and Figure 4 depicts a TIC derived from intestinal wall examination. These studies are mainly focused on Crohn's disease (CD).

D-CEUS and inflammatory/fibrotic disease

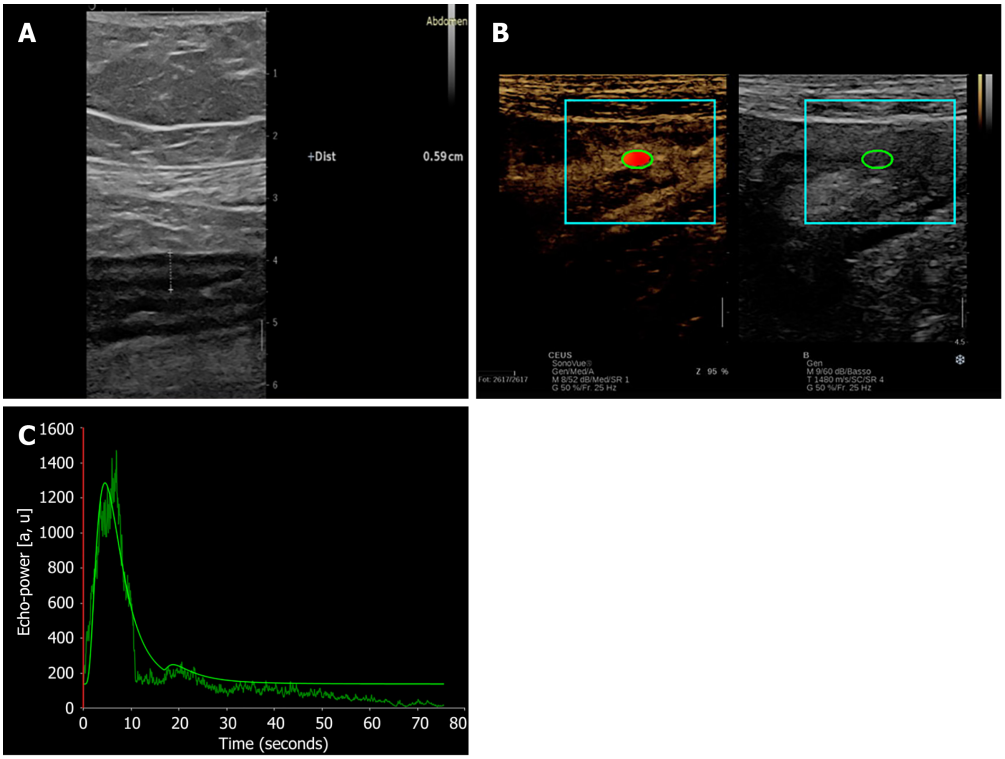
TICs represent the perfusion of a tissue, and we would expect a difference in perfusion parameters not only when comparing fibrosis to inflammation, but also when considering various degrees of inflammation.

Girlich *et al*[48] described for the first time the difference in perfusion parameters between CD and healthy gut. As expected, the differences were substantially with significantly higher PE and regional blood volume, and longer TTP of thickness bowel wall of CD patients[48]. In another study, the same authors investigated the correlation between perfusion parameters and histopathological characteristics of the gut wall in surgically treated CD patients, confirming that TTP was negatively correlated with the histological inflammatory score[49]. Similarly, a higher PE, regional blood flow and regional blood volume, and shorter TTP were significantly correlated with high vascular density defined as the presence of more than two hundred sixty five vessels per field on histological examination[50]. On the contrary, Ripollés *et al*[51] showed a non-significant association of TTP with inflammatory or fibrosis histological score, however they used different histological scores and had longer time between CEUS and surgery (34.5 ± 17.3 *vs* 4.7 ± 4.7 d)[51].

To assess the differences between fibrotic or inflammatory CD, Nylund *et al*[52] compared sixteen patients with fibrotic disease undergoing surgery to seventeen patients with medically treated active inflammatory disease. In inflammatory disease, the blood volume and blood flow were significantly higher compared to fibrotic disease, while MTT was not significantly different between the two groups. Interestingly, blood volume/bowel wall thickness ratio showed a high accuracy to predict surgery[52]. Similarly, Quaia *et al*[53] found a significant difference in blood volume related parameters (PE, AUC, WiAUC, WoAUC, WiR and, WiPI) between fibrotic strictures and inflammatory strictures among patients with CD, with the latter having higher values. However, TTP showed no significant differences between the two groups[53]. These findings imply that D-CEUS can detect the microvascular differences between fibrotic and inflammatory tissue and allows non-invasive differentiation of CD phenotypes.

Regarding ulcerative colitis (UC), only one prospective study investigated the relationship between perfusion parameters and histopathological findings. In this study, TTP/Peak(%) showed a strong negative correlation with histopathological inflammatory activity score[54].

D-CEUS and clinical outcomes



Given the negative correlation with inflammation, Peak% > 40.5% and TTP < 35 seconds had a high positive predictive value (94%) and a high negative predictive value (92.3%) for active disease, respectively[50].

It has also been shown that the evaluation of PE and AUC is a useful tool to assessing the severity of CD when the ultrasound global assessment and colorDoppler imaging criteria are indeterminate. Particularly, PE > 23 dB showed a sensitivity and specificity of 90% and 89.5%, respectively, to distinguish moderate from severe disease[55]. Using this cut-off to identify patients with severe disease, Wilkens *et*

Table 4 Dynamic contrast-enhanced ultrasound and inflammatory bowel diseases

al[56] investigated the clinical outcomes in twenty patients with severe disease in whom they observed an atypical, prolonged intestinal washout due to the stuck bubble phenomenon (AUC > 20000 AIU) compared to patient with severe disease and AUC < 20000 AIU (control group). They found a significative higher rate of surgery and a trend toward more combination therapies in study group. Interestingly, they ascribed the stuck bubbles phenomena to the attachment of microbubbles to active leukocytes on the endothelium; if confirmed, this might be utilized as a tool for targeted therapy[56].

Assessment of perfusion parameters is important for identifying disease status, as well as monitoring and predicting the efficacy of therapies. Indeed, D-CEUS measurements changed significantly between clinical- and endoscopic-assessed responders and non-responders with CD and UC following treatments[57,58]. In a prospective study, Saevik *et al*[59] included fourteen patients with acute CD who started treatment with steroids or tumor necrosis factor-α (TNF-α) inhibitors. CEUS was performed before starting therapy and at one, three and twelve months. At one month, the differences between patients who achieved clinical remission and those who had treatment failure during the follow-up period were significant. Particularly, PE, WiAUC, WiR and WoR was significantly lower in effective treatment group[59]. The reduction in perfusion parameters could be related to a decrease in inflammation and, thus, a treatment response. Recently, it was demonstrated that the reduction in PI, AUC, Pw, and MTT was higher in patients responding to anti-TNF-α therapy after two weeks than in patients who relapsed within six months of treatment initiation, who displayed not only a lower early reduction in perfusion parameters but also an increase in PI after twelve weeks[60]. Changes in quantitative perfusion analysis parameters between baseline and six weeks after therapy initiation distinguished responders from non-responders defined by clinical and endoscopic evaluation at twelve weeks[61]. This highlights the potential for D-CEUS to detect therapy-induced modifications in the pathologic bowel wall and support clinicians in disease management.

OTHER GASTROINTESTINAL DISEASES

The investigation of perfusion parameters with D-CEUS could be an informative tool in the diagnosis and prognosis of other gastrointestinal diseases, such as gastric cancer[62]. In a prospective study including forty-three patients with advanced gastric cancer, Joo *et al*[63] showed a good feasibility of CEUS (88.4%) and a significant difference in PI and AUC according to differentiation status of the tumor. Localization in the upper stomach and an ulcerated phenotype were the limiting variables for D-CEUS feasibility[63]. Regarding the CRC, the difference in AUC was significantly related with tumor

necrosis and T stage[64], suggesting a possible role of D-CEUS in predicting tumor microenvironment characteristics and behavior. Furthermore, dynamic contrast enhanced endoscopic ultrasound (D-CE-EUS) showed a significant correlation between RT and vessel density in patients with left side colonic tumors[65], indicating that perfusion analysis might be useful to predict outcomes of antiangiogenic treatment as Lassau *et al*[66] has showed in a multicentric study including over one thousand D-CEUS evaluations in more than five hundred patients with solid tumor treated with antiangiogenic therapy [66]. In particular, D-CEUS blood volume related parameters showed significant early changes in gastrointestinal stromal tumours treated with masitinib, predicting positron emission tomography-CT outcome[67].

Concerning non-neoplastic bowel diseases, different studies described the CEUS aspects of various inflammatory bowel diseases, including abscesses, acute appendicitis, diverticulitis, vascular bowel disease, such as intestinal ischemia, and graft *vs* host disease[68]. To the best of our knowledge, no specific study employing D-CEUS in the aforementioned conditions has been published yet; however, it would be desirable to investigate the potential usefulness of quantitative perfusion analysis in predicting pathological features and prognosis also in this field.

CONCLUSION

The quantification of perfusion parameters in CEUS has several applications in gastrointestinal neoplastic and inflammatory disorders. Everything that is visible with ultrasound can be measured, and this has allowed D-CEUS to be employed within the pancreas and digestive system in addition to the liver evaluation. The objective assessment of tissue perfusion is crucial for the evaluation of all disorders in which the vascular component plays a key pathophysiological role, such as malignant tumours and inflammatory bowel disease. However, the limited availability of large studies and the heterogeneity of the technologies employed have precluded the standardization of this approach which potentially represents a valuable tool for clinical practice in management of gastrointestinal diseases.

Abstract

The morphological complexity of cells and tissues, whether normal or pathological, is characterized by two primary attributes: Irregularity and self-similarity across different scales. When an object exhibits self-similarity, its shape remains unchanged as the scales of measurement vary because any part of it resembles the whole. On the other hand, the size and geometric characteristics of an irregular object vary as the resolution increases, revealing more intricate details. Despite numerous attempts, a reliable and accurate method for quantifying the morphological features of gastrointestinal organs, tissues, cells, their dynamic changes, and pathological disorders has not yet been established. However, fractal geometry, which studies shapes and patterns that exhibit self-similarity, holds promise in providing a quantitative measure of the irregularly shaped morphologies and their underlying self-similar temporal behaviors. In this context, we explore the fractal nature of the gastrointestinal system and the potential of fractal geometry as a robust descriptor of its complex forms and functions. Additionally, we examine the practical applications of fractal geometry in clinical gastroenterology and hepatology practice.

Key Words: Fractals; Geometry; Gastroenterology; Esophagus; Stomach; Colon; Pancreas;

Liver; Time-series; Shape; Behavior

Core Tip: Utilizing fractal analysis to estimate the fractal dimension is a potent tool for investigating the geometrical properties of the gastrointestinal system. This approach has the potential to improve diagnostic and prognostic rates, leading to better patient care and a deeper understanding of the underlying pathophysiological mechanisms.

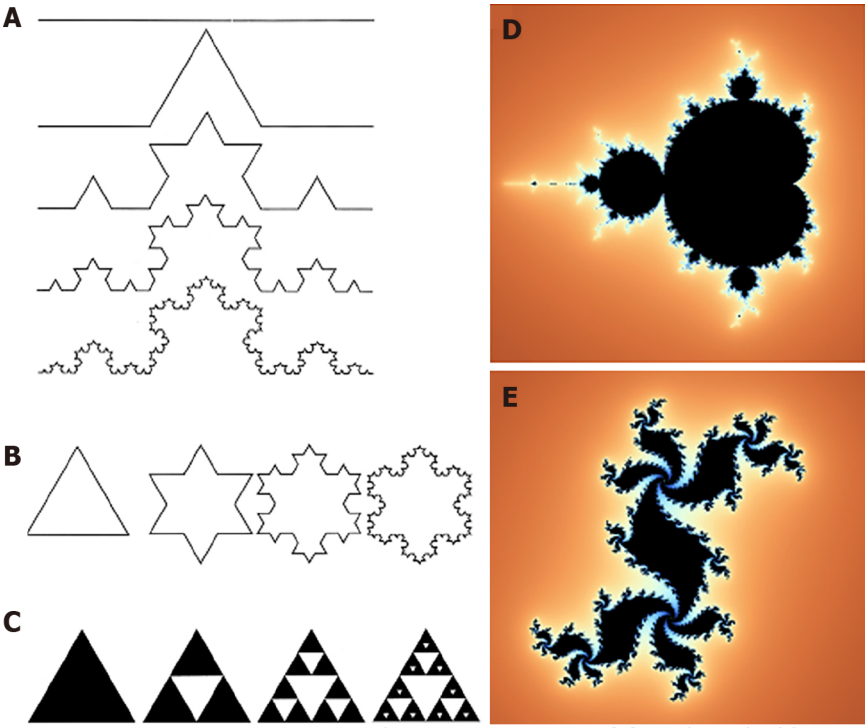
INTRODUCTION

"In One Dimension, did not a moving Point produce a Line with two terminal points? In Two Dimensions, did not a moving Line produce a Square with four terminal points? In Three Dimensions, did not a moving Square produce-did not this eye of mine behold it-that blessed Being, a Cube, with eight terminal points? And in Four Dimensions shall not a moving Cube-alas, for Analogy, and alas for the Progress of Truth, if it be not so-shall not, I say, the motion of a divine Cube result in a still more divine Organization with sixteen terminal points? Behold the infallible confirmation of the Series, 2, 4, 8, and 16 is not this a Geometrical Progression? Is not this-if I might quote my Lord's own words-strictly according to Analogy?" From Flatland: A romance of many dimensions, Edwin A. Abbott.

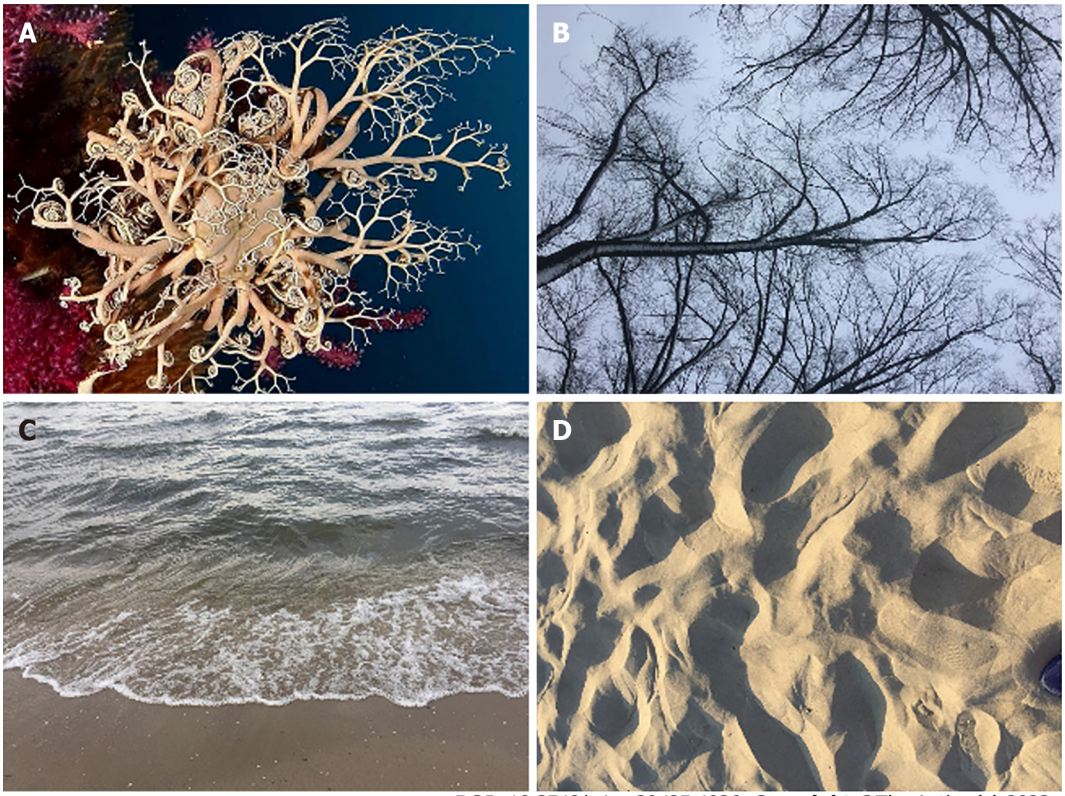
The complexity of nature, characterized by its various degrees of irregularity and diverse physical properties[1], is a challenging topic. The Scottish biologist and mathematician D'Arcy Wentworth Thompson (1860-1948) proposed that the form of an anatomical entity can be identified through its dimensions and contour. However, Euclidean-based morphometric analyses, which involve measurements like area, perimeter, and form factor, fall short in accurately describing natural, including anatomical, entities due to their irregular shapes that cannot be quantified by means of the classical Euclidean geometry, which is only able to describe regular geometrical objects. Mandelbrot[2] (1924-2010) introduced the notion of fractal geometry[3] and coined the term "fractal" to describe spatial or temporal irregular patterns[4,5]. Fractal geometry has been suggested as an instrument to define the geometry of various natural entities, such as mountains, coastlines, clouds, trees, molecular structures, and an array of forms within anatomical systems along with their underlying dynamic processes[6]. The gastrointestinal or digestive system is a complex network of organs including the mouth, pharynx, esophagus, stomach, small and large intestines, rectum, and anus, as well as the salivary glands, liver, gallbladder, and pancreas. The morphological intricacy of the gastrointestinal system, both in its natural state and under pathological conditions, is mainly characterized by its irregularity and self-similarity across varying scales[7]. Classical examples of irregularly-shaped histological entities that defy Euclidean geometric principles include gastric pits, which are indentations in the stomach signifying entrances to tubular gastric glands, and villi, which are finger-like structures that significantly increase the surface area of the small intestine[8]. The human stomach is known to have millions of these pits across the surface of its lining epithelium. The adult small intestine, with an average inner surface area of around 30 m^2[9,10], necessitates such a large surface for effective metabolism and nutrient absorption. This is achieved by forming unique irregularly-shaped structures like villi and microvilli. The functional efficiency of epithelia is enhanced by their fractal organization, which expands the surface area for processes like absorption or sensory reception, thereby enabling more efficient interaction with the external environment[11]. This level of surface area and functional efficiency would be unattainable if the colonic mucosa were to be represented by a two-dimensional Euclidean plane. However, the fractal-like characteristics observed in epithelial tissues, which line organ surfaces and body structures, are not universal but rather specific to certain instances. The liver development, commonly described as a fractal-like phenomenon, involves intricate processes and interactions among various cell types. During embryonic development, a bud-like structure known as the hepatic diverticulum, which emerges from the endodermal layer of the early gut tube, forms the liver. The hepatic diverticulum then undergoes branching morphogenesis, leading to a complex network of interconnected structures that enable liver tissue expansion and development of bile ducts, blood vessels, and functional units like lobes or lobules. Similarly, pancreas development is a regulated process involving growth and branching. While the developing liver and pancreas' branching patterns may superficially resemble fractal structures, it's



crucial to acknowledge that true fractals display self-similarity across multiple scales, a trait not precisely seen in liver development. Fractal geometry has been used to describe pathological entities within the gastrointestinal system as well. The irregularity in the shape of the interface between epithelial and connective tissues is a recognized characteristic of malignant and pre-malignant epithelial lesions. However, efforts to objectively assess this have been sparse. Landini and Rippin[12] have applied fractal geometry as an instrument for evaluating this irregular epithelial-connective tissue interface[13]. Intestinal polyps, characterized by abnormal tissue overgrowth within the intestinal lining, can display varying shapes and structures based on factors like the type of polyp (*i.e.*, adenomatous polyps, hyperplastic polyps), their location, and size. Some polyps, such as villous adenomas, appear to exhibit a self-similar form, hinting at a possible fractal structure within a specific magnification range. The fractal dimension has been leveraged to quantify these polyps, proving to be a more effective discriminator between diagnostic groups than Euclidean measures like area or perimeter length[14]. Several studies suggest that fractal estimation could offer a novel method for examining the nonlinear dynamics of the gastrointestinal system. This approach sheds light on the complexity and unevenness of colonic pressure activity during different periods, providing potential applications for understanding gastrointestinal system functions. As fractal analysis becomes increasingly prevalent in biomedical research, it serves to quantify the irregularities of anatomical entities, their generation patterns, and their physiological and pathological processes. In this context, we delve into the potential of fractal geometry as a tool for understanding the gastrointestinal system and its possible applications in clinical practice.

FRACTAL GEOMETRY: BASIC PRINCIPLES

Fractals, whether anatomical or natural, are characterized by four primary attributes: (1) Irregularity in shape; (2) self-similarity in structure; (3) non-integer or fractal dimension; and (4) scaling. Scaling indicates that the measured features of a fractal depend on the scale at which they are observed[15]. The most significant characteristic of fractal objects is their ability to display similar patterns at different scales, resulting in the component parts having a form that is similar to the whole in all dimensions. Complex curves such as coastline shapes serve as typical examples of this property, where each segment can be regarded as a smaller version of the complete structure in a statistical sense (Figure 1). The term "self-similarity" refers to a property of fractals that can be either geometric or statistical. Geometric self-similarity occurs when every smaller piece of an object is an exact replica of the whole object. For instance, the "snowflake" and the "curve", both described by Swedish mathematician Niels Fabian Helge von Koch (1870-1924) in 1904, are examples of geometrically self-similar figures[16]. Another geometrically self-similar figure is the "Sierpinski triangle", originally described by Polish mathematician Waclaw Sierpinski (1882-1969) in 1915. In contrast, statistical self-similarity pertains to biological objects, including natural objects (Figure 2) and anatomical forms (Figure 3). While small components of anatomical systems are not typically exact replicas of the entire system, they still exhibit self-similarity. For instance, if we examine a segment of a tree branch or vascular vessel, it may not look identical to the entire tree or vessel, but it still displays self-similarity. Many anatomical structures have been identified as statistical self-similar entities, including the circulatory system, the biliary tree of the liver, the dendritic structure of neuronal cells, the ductal system of glands, the cell membrane, and the extracellular matrix (ECM) in cases of chronic liver disease[17].



The concept of "dimension" is a fundamental aspect of fractals and represents a characteristic value of the object. There are two definitions of dimension: the first is the "topological dimension", introduced by Austrian mathematician Karl Menger (1902-1985), which assigns an integer number to each point in three-dimensional Euclidean space (E3). For example, a "point" is assigned a dimension of 0, a "straight line" a dimension of 1, a "plane surface"a dimension of 2, and a "three-dimensional figure" a dimension of 3. The second definition was introduced by Felix Hausdorff (1868-1942) and Abram Besicovitch (1891-1970), who assigned a "real number" between the topological dimension and 3 to every natural object in E3. Mandelbrot designated Menger's dimension with the symbol D_γ and Hausdorff and Besicovitch's dimension with the symbol D. For all Euclidean figures, D_γ and D are equivalent ($D_\gamma = D$). However, this equality does not apply to all fractal natural objects, as the inequality $D > D_\gamma$ is true. Many methods have been proposed to estimate the fractal dimension, with the "box-counting method" being the most widely used in biomedical sciences to estimate the space-filling properties of anatomical objects in two-dimensional and three-dimensional space.

It applies the following formula: $D = \lim \varepsilon \to 0 [\log N(\varepsilon)/\mathrm{Log}(1/\varepsilon)]$, where D is the box-counting fractal dimension of the object, ε is the side length of the box, and N(ε) is the smallest number of boxes of side ε required to cover the outline or the surface of the object completely. Because the zero limit cannot be applied to natural objects, the dimension was estimated by the formula D = d, where d is the slope of the graph of Log N(ε) against Log (1/ε). The linear segments of these graphs were identified using the least-squares method of regression, and the gradients of these segments are assessed using an iterative resistant-line method[15,18-25].

The fractal esophagus

Wax *et al*[26] conducted a quantitative analysis of nuclear morphometry in epithelial cells using an animal model of esophageal carcinogenesis in 2003. They observed changes in the size and texture of cell nuclei caused by neoplastic transformation and chemopreventive action[26]. However, the fractal dimension did not enhance the diagnostic ability of the technique for classifying neoplasia[26]. Instead, the increase in fractal dimension observed in dysplastic tissues corresponded with changes in the texture of cell nuclei observed in histological images, where clumped and grainy cell nuclei are typical of dysplasia. The authors concluded that the increased fractal dimension resulted from alterations in the organization of chromatin and proteins within the nucleus, as demonstrated by the changes in the visual appearance of cell nuclei in histological images[26]. A framework for creating a two-dimensional, globally interconnected map to simulate epithelium dynamics has been proposed by Hosseini and Hashemi Golpayegani[27]. The aim of this model was to facilitate early-stage dysplasia detection using microscopic imagery from endoscopic biopsies. Their findings suggested a potential direct correlation between the system's structural complexity and the unpredictability of its dynamics[27]. Textural analysis of positron emission tomography (PET) and other imaging techniques is gaining interest in measuring intra-tumoral heterogeneity.

Studies have demonstrated that measuring tumor heterogeneity through textural analysis in 18F-fluorodeoxy glucose PET can provide predictive and prognostic information. In a study by Doumou *et al*[28], sixty-four patients with adenocarcinoma of the lower esophagus underwent 18F-FDG PET/CT imaging for clinical staging before surgery. Using in-house software implemented under MATLAB (The MathWorks Inc.) and calculating 57 textural features, including fractal indexes, they discovered that altering the "bin width" produced poor agreement for most second- and high-order features, with less impact on fractal parameters. The authors concluded that fractal analysis features were relatively resistant to changes in smoothing, segmentation, and bin width. In 2005, Gardner *et al*[29] noted that in normal subjects, patients with gastroesophageal reflux disease (GERD), and individuals with GERD treated with a proton pump inhibitor, both esophageal and gastric pH reflect an underlying stochastic process that generates a fractal pattern over time. The authors hypothesized that the fractal pattern of esophageal pH and gastric pH, along with the statistical association of sequential pH values for up to 2 h, encodes information regarding gastric acidity. They proposed that depending on the value of gastric acidity, gastroesophageal reflux causes the esophagus to signal the stomach to alter gastric acidity by influencing gastric secretion of acid or bicarbonate[29]. The authors subsequently confirmed their hypothesis by investigating 26 healthy adults with no history of gastrointestinal disease or symptoms and 27 adult subjects with a history of GERD who experienced heartburn at least four times per week for at least 6 mo[30] Their findings suggest that the esophagus can signal the stomach to alter gastric acidity, depending on the value of gastric pH, and that this ability is impaired in subjects with GERD.

Thus, the self-similar, fractal pattern encodes information about gastric acidity that the esophagus can decode and, when necessary, signal the stomach to reduce gastric pH.

The fractal stomach

In 1994, Demling and Ell[31] conducted a study titled "Fractal stomach ulcer. A new measurement parameter for benign and malignant changes for the future", proposing that fractal geometry could be beneficially applied for the spatial and temporal analysis of the stomach. Abdominal sound analysis is known to aid in the diagnosis of gastrointestinal diseases, and bowel sounds originating from the stomach and intestine are highly variable over time. They are described as loose successions or clusters of sudden bursts. Realistic recordings of abdominal sounds are contaminated with noise and artifacts that must be differentiated from the bowel sounds. More recently, Kölle *et al*[32] suggested a method of intrinsic mode function-fractal dimension filtering based on a multivariate empirical mode decomposition approach. The intrinsic mode function-fractal dimension filtering method has been applied to a realistic, contaminated dataset, with close to 100% of manually labeled bowel sounds correctly identified[32]. In a novel approach, West *et al*[33] analyzed fluctuations in human myoelectric gastric activity noninvasively measured from the surface of the abdomen. They estimated the "scaling index" in 17 healthy individuals and found it to be statistically different from a set of surrogate data. The authors also demonstrated that the dynamical pattern of the gastric rate variability time series was significantly reduced in systemic sclerosis patients compared to healthy individuals, indicating a decrease in complexity of the underlying gastrointestinal control system. In terms of clinical relevance, employing fractal image analysis to model the conduction patterns of slow waves (SWs) through detailed networks of interstitial cells of Cajal can enhance our comprehension of the principles driving gastrointestinal myoelectric activity, as well as the diseases linked to its malfunction[34]. Interstitial cells of cajal (ICC) are specialized pacemaker cells in the gastrointestinal system responsible for generating and propagating SWs of depolarization throughout the muscularis propria. These SWs regulate the motility of the gastrointestinal system tract, which is essential for digestion, nutrient absorption, and waste elimination. By using a combined approach based on image analysis and fractal geometry of detailed ICC networks, researchers have demonstrated that modeling SW conduction patterns can aid in improving our understanding of the mechanisms underlying gastrointestinal system myoelectric activity and the diseases associated with its dysfunction[35,36].

Watanabe *et al*[37] applied fractal analysis to contrast-enhanced computed tomography (CT) images to estimate structural abnormality in gastric tumors and evaluated its biomarker value for predicting survival in surgically treated gastric cancer patients. The authors found that high fractal dimension values of tumors were significantly associated with high T stage and high pathological stage. Moreover, in Kaplan-Meier analysis, patients with higher fractal dimension tumors had significantly worse disease-specific survival, indicating that contrast-enhanced CT fractal analysis could be a useful biomarker for gastric cancer patients, reflecting clinic-pathologic features and survival.

In a study by Liliac *et al*[38], the pattern of E-cadherin at the cell membrane level was analyzed using fractal dimension analysis on fluorescence immunohistochemistry samples labeled with E-cadherin in gastric well/moderate and solid gastric adenocarcinoma from patients without any associated chemotherapeutic treatment or radiotherapy. The images were binarized using a fixed threshold of the E-cadherin fluorescence channel, and the fractal dimension of the binarized image outlines was calculated to assess the ruggedness of the cellular membranes. The study demonstrated that the morphological analysis of a simple marker for the cell membrane can identify and distinguish tumor cells.

The fractal colon

Cross *et al*[14] suggested that colorectal polyps have a self-similar structure that may contain fractal elements, and that the fractal dimension could be a useful morphometric discriminator. The authors estimated the fractal dimensions of images from hematoxylin and eosin-stained sections of 359 colorectal polyps, including 214 tubulovillous adenomas, 41 tubular adenomas, 29 villous adenomas, 68 metaplastic polyps, and 7 inflammatory polyps, and found that colorectal polyps exhibit a fractal structure within a defined range of magnification[14]. They concluded that fractal dimension can provide a new method of estimating polyp shape and serve as a useful morphometric discriminator between diagnostic categories[14].

It is clear that the invasive front of colorectal cancers (CRCs) can vary in complexity, ranging from smooth to highly complex when the front breaks up into small cell clusters or single cancer cells[39]. Currently, the degree of complexity is estimated visually and/or semi-quantitatively. Franzén *et al*[39] compared the visual estimation of CRC invasive front irregularity to different quantitative image analytical techniques and developed a "complexity index" for the invasive margin. They analyzed cytokeratin 8-stained tissue sections from 29 CRCs and found that the fractal dimension and tumor cell clusters provided the best correlation to visual grading using discriminant analysis. Moreover, the fractal dimension separated tumors up to a certain level of complexity, while tumor cell cluster counting distinguished cells above and beyond the fractal dimension when the tumor front fragmented into small cell clusters. These results suggest that the fractal dimension could be a valid index for objectively quantifying the complexity of tumor invasive fronts. In another study, Hahn-Strömberg *et al*[40]

correlated the complexity of colon carcinoma invasive fronts with cell adhesion protein expression and polymorphisms in their genes. They constructed a "complexity index" using computer-assisted morphometry to estimate fractal dimension and tumor cell clusters, followed by tree analysis, for 32 colon carcinomas. Hahn-Strömberg *et al*[40] found that adhesion protein distribution was significantly altered in most carcinomas, but no correlation was observed between the complexity of the invasive border and protein distribution or genetic alterations. These findings indicate that the complexity of CRC invasion is not solely dependent on genetic derangements in adhesion protein genes or protein distribution, but also on aberrations in the function of other proteins related to adhesive proteins.

In their research, Ştefănescu *et al*[41] utilized fractal analysis and neural network modeling of colon mucosa images generated by confocal laser endomicroscopy to develop an automatic diagnosis algorithm for CRCs. They examined 1035 images of normal mucosa and tumor regions, processed using a computer-aided imaging system to achieve an automatic diagnosis. The researchers found that non-malignant colon mucosa has polyhedral crypt structures while malignant colon mucosa has irregular and interrupted crypts. They estimated seven parameters for each image, with only contrast, homogeneity and feature number showing significant differences between natural and cancer images. Their findings suggest that computed aided diagnosis through fractal analysis of glandular structures can be used in combination with traditional histological and minimally invasive imaging methods[41]. Another study by Shaleve *et al*[42] used the fractal dimension to predict clinically significant post-endoscopic bleeding (CSPEB) by analyzing blood vessel morphology within post-colonic endoscopic mucosal resection (EMR) mucosal defects. They introduced the fractal dimension estimate as a measure of the complexity of blood vessel contour, and on multivariate analysis, found that fractal dimension and four other independent variables correlated with CSPEB. This suggests that the morphometric characteristics of blood vessels in post-EMR defects can be used to predict delayed bleeding following colonic EMR. Ren *et al*[43] measured curvature, fractal dimension, and volumetric feature maps to assist radiologists in reducing interpretation time and improving detection results in computed tomographic colonography.

In their study, Mah *et al*[34] investigated the use of fractal dimension to distinguish between healthy and cancerous colon images and to examine the relationship between fractal dimension and traditional texture analysis features. They found a highly significant difference between the groups using fractal analysis. Interestingly, they also reported that micro-architectural analysis of the histologically examined colon mucosa provided unprecedented sensitivity for early detection of CRC[34]. They observed significant alterations in spectral slope, fractal dimension, and principal component 3 in mouse mucosa at the earliest time points, and these alterations increased over time, indicating the micro-architectural underpinnings of subsequent tumorigenesis.

Additionally, these indexes spatially correlated with future adenoma development. The concept of "deformability" has been introduced as a hallmark of the CRC process leading to metastatic spread.

Furthermore, Streba *et al*[44] used fractal analysis to estimate elements obtained from images taken from pathological and immunohistochemical investigations of colonic biopsy fragments in patients who underwent surgery for previously diagnosed CRC. They introduced the concept of "deformability" as a hallmark of the CRC process leading to metastatic spread. The authors performed a fractal analysis using an in-house tool.

Streba *et al*[44] found that the fractal dimensions were significantly different between adenocarcinomas and other types of colonic cancers, but no significant differences were found between most types of CRCs. They also reported a significant statistical difference when comparing well-differentiated tumors with all other stages. The authors concluded that fractal analysis is a novel and interesting tool for determining the pathologic diagnosis of CRCs, and may further improve diagnostic and prognostic rates, thus enhancing patient care.

Several initial studies have suggested that the novel agent polyethylene glycol (PEG) may have the necessary chemopreventive properties for widespread clinical use[45]. Despite reports attesting to its remarkable efficacy, the mechanisms of action of PEG remain largely unexplored. To determine the stage of carcinogenesis that PEG targets, Roy *et al*[45] assessed fractal dimension, one of the earliest markers of neoplastic transformation of the colon, in fresh colonic tissue using four-dimensional elastic light-scattering fingerprinting.

Studies have shown that PEG can suppress morphologic variables and restore micro-architectural organization, as indicated by the fractal dimension estimate. Changes in fractal dimension have been observed prior to the development of aberrant crypt foci in azoxymethane-treated rats and adenomas in mouse models, making fractal dimension a sensitive early marker in cancer prevention. Short-term treatment with PEG has been shown to completely normalize fractal dimension, indicating that PEG can reverse the earliest changes of colon carcinogenesis.

Strauss *et al*[46] assessed the impact of quantitative parameters on the differentiation of primary CRCs from normal colon tissue. They applied compartment and non-compartment modeling to dynamic PET data in 22 patients with CRCs prior to surgery, five of whom also had liver metastases at the time of the PET study. The non-compartment modeling was used to calculate the fractal dimension of the time-activity data. The study found that using quantitative data had the advantage of not being primarily dependent on the individual assessment and experience of the physician visually evaluating the FDG PET data. Additionally, the analysis of dynamic PET data of the corresponding primary tumor

could predict the presence of metastatic lesions.

Strauss *et al*[46] found that the fractal dimension, standardized uptake value, influx, and k3 were the most important single parameters for lesion differentiation[46]. The study also demonstrated that the highest accuracy for lesion differentiation was achieved with the fractal dimension[46]. The use of quantitative data has the advantage that the detection of CRC is not solely dependent on the individual assessment and experience of the physician visually evaluating the FDG-PET data. Quantitative FDG-PET studies provide accurate data for differentiating primary CRCs from natural tissue, and most of these studies conclude that the presence of metastatic lesions can be predicted by analyzing the dynamic PET data of the corresponding primary tumor[46,47].

Studies have found that 18F-FDG kinetics are primarily dependent on the expression of genes associated with glucose transporters and hexokinases, but may also be modulated by other genes. Strauss *et al*[47] investigated the dependency of 18F-FDG kinetics on angiogenesis-related gene expression. They evaluated a series of 25 patients with primary CRCs using PET and 18F-FDG within 2 d before surgery.

During surgery, tissue specimens were obtained from the tumor and adjacent non-tumoral colon, and gene expression was assessed using gene arrays. Strauss *et al*[47] identified 23 angiogenesis-related genes with a tumor-to-normal ratio exceeding 1.50, and found a significant correlation between k1 and vascular endothelial growth factor, as well as between fractal dimension and angiopoietin-2. They also noted a negative correlation between k3 and VEGF-B, and a positive correlation for angiopoietin-like 4 gene. In a recent study, Goh *et al*[48] evaluated the feasibility of using fractal analysis to assess the spatial pattern of CRC perfusion at dynamic contrast-enhanced CT (perfusion CT).

Twenty CRC patients who underwent a 65-second perfusion CT study. A perfusion parametric map was generated using validated commercial software. The tumor was identified by an experienced radiologist, segmented *via* thresholding, and fractal analysis was applied using in-house software. Fractal dimension, abundance, and lacunarity were assessed for the entire outlined tumor, as well as for selected representative areas within the tumor of low and high perfusion.

The study by Goh *et al*[48] concluded that fractal values were higher in cancer than in normal colon, and that fractal values were lower in areas of high perfusion compared to low perfusion areas. Lacunarity curves were shifted to the right for cancer compared to normal colon. The results suggest that CRCs mapped by perfusion CT demonstrate fractal properties, and thus fractal analysis is feasible, potentially providing a quantitative measure of the spatial pattern of tumor perfusion.

Lętowska-Andrzejewicz *et al*[49] have investigated the effects of 5-fluorouracil, interferon, and dexamethasone, on the healing of colon anastomosis by assessing morphometric and fractal parameters of the colonic wall. Lętowska-Andrzejewicz *et al*[49] performed an experimental anastomosis of the ascending colon in 60 male Wistar rats and subsequently randomly assigned them to four groups. On the second to sixth post-operative days, the rats were administered 5-fluorouracil, interferon-α, dexamethasone, or 0.9% NaCl solution as a control. The healing of the anastomosis was assessed through macroscopic, histomorphometric, and microbiological evaluations. The histomorphometric parameter changes were most evident on the seventh and fourteenth post-operative days in all treatment groups. Connective tissue fractal dimension significantly decreased in those animals treated with interferon and dexamethasone. All three pharmaceutical agents impaired healing of the anastomosis and promoted infection in the anastomosis and skin wound sites. Dexamethasone was considered the most detrimental in this study, as it induced both morphometric and macroscopic alterations.

The inability of cytotoxic anticancer therapies to effectively treat tumors may lead to changes in their morphology and increased tissue invasion. This effect is more prominent in cancer cells with strong metastatic capabilities. Researchers, Pasqualato *et al*[50], have established a clear correlation between alterations in cell shape and the development of a more aggressive phenotype in colon cancer cells that are resistant to 5-FU treatment, specifically HCT-8FUres.

The observed changes in cell shape were strongly associated with an increase in the speed of cellular movement. Pasqualato *et al*[50] developed a method to quantitatively measure the shape of both wild-type and chemoresistant HCT-8 cells during a wound healing assay. They assessed various shape descriptors such as the area/perimeter ratio, circularity, roundness, fractal dimension, and solidity to characterize the biological behavior of these two cell lines. Solidity was identified as the most effective parameter for distinguishing between the chemoresistant and wild-type cells. Moreover, this parameter was found to capture the differences in cell shape at each time point of the migration process. Furthermore, a negative correlation was observed between solidity and motility speed.

The fractal pancreas

Studies that attempt to quantitatively analyze the growth and development of pancreatic islets in both normal and pathological conditions have encountered significant challenges in terms of methodology and conceptualization. To address these challenges, Hastings *et al*[51] conducted a study that utilized the "geometry of random fractals" to investigate the regeneration of islets in guinea pigs that had been treated with alloxan.

The authors of the aforementioned study have since demonstrated that the power-law distribution of pancreatic islets is consistent across various mammalian species and is maintained throughout ontogenetic development in guinea pigs[52]. This suggests that islet formation adheres to an iterative or fractal pattern that is common among mammals. The islets of Langerhans, which are responsible for regulating blood glucose levels, are known to be unevenly distributed throughout the pancreas. In fact, it has been reported that there exists a universal power-law that governs the fractal spatial distribution of islets in two-dimensional pancreatic sections[52].

In a study conducted by Jo *et al*[53], the three-dimensional spatial distribution of islets in intact mouse pancreata was examined using optical projection tomography. The results showed a power law distribution with a fractal dimension of 2.1. The authors also analyzed two-dimensional pancreatic sections from human autopsies and found that the distribution of human islets followed a universal power law with a fractal dimension of 1.5 in adult pancreata. This value is consistent with previous findings in smaller mammalian pancreas sections. Finally, the authors developed a growth model to explain the development of islet distribution and suggested that the fractal nature of the spatial islet distribution may be due to self-avoidance in the branching process of vascularization in the pancreas[53].

Pancreatic cancer is a highly aggressive disease with a poor prognosis, despite surgical intervention. To improve patient outcomes and avoid unnecessary laparotomies, it is crucial to identify reliable factors that can predict the resectability of pancreatic tumors. Vasilescu *et al*[54] conducted a study to determine if nuclear morphometry and fractal dimension of pancreatic nuclear features could serve as preoperative indicators for assessing pancreatic resectability. The study involved sixty-one patients diagnosed with pancreatic cancer, who were divided into two groups: those with resectable cancer and those with non-resectable pancreatic cancer. The authors evaluated several morphometric parameters, including nuclear area, length of minor and major axes, and nuclear shape and chromatin distribution of pancreatic tumor cells, which were estimated using fractal dimension analysis. The morphometric analysis conducted by Vasilescu *et al*[54] revealed significant differences in the nuclear area between the resectable and non-resectable groups. The non-resectable group was also found to have a higher value of fractal dimension in both nuclear outlines and chromatin distribution. Based on these findings, the authors suggested that objective measurements should be utilized to enhance risk assessment and treatment decision-making for pancreatic cancer. Additionally, they proposed that the fractal dimension of nuclear shape and chromatin distribution could be a valuable tool for conventional pathological analysis. In another study, fractal analysis was used to demonstrate that ghrelin administration increased structural complexity and tissue disorder in rat exocrine pancreas[55].

The study involved 40 male Wistar rats, where pancreas tissue sections were stained with hematoxylin and eosin and visualized through light microscopy. The average values of tissue fractal dimension, lacunarity, and co-occurrence matrix texture parameters were determined for each animal using computer-aided image analysis. The authors found that regardless of age, administration of ghrelin increased the fractal dimension and textural entropy of the exocrine pancreas, while decreasing its lacunarity. This is the first study to examine the effects of ghrelin on the morphological properties of pancreatic tissue and the first to utilize fractal and textural analysis methods to quantify the architecture of exocrine pancreas tissue.

According to Metze[56], fractal characteristics of chromatin have been identified through light or electron microscopy in the past 20 years. These features can be easily estimated from digitized microscopic images and are useful for cancer diagnosis and prognosis. Studies have shown that an increase in the fractal dimension of stained nuclei occurs during carcinogenesis and tumor progression in various cancers, including pancreatic cancer. Researchers have also reported potential connections between changes in chromatin organization during carcinogenesis and tumor progression and an increase in the fractal dimension of stained chromatin.

The fractal dimension of chromatin in routine histological or cytological preparations has been found to increase during various stages of tumor development, including from pre-neoplastic stages to cancer, and from initial cancer stages to advanced stages. Additionally, higher fractal dimensions are associated with poor prognosis, while lower fractal dimensions are observed in patients with a better prognosis. Al-Mrabeh *et al*[57] conducted a study to determine whether the low volume and irregular border of the pancreas in patients with type-2 diabetes could be normalized following the reversal of diabetes.

The study conducted by Al-Mrabeh *et al*[57] utilized three-dimensional volume-rendering and fractal dimension analysis of MRI-acquired images, along with three-point Dixon imaging to measure fat content. The results indicated no change in pancreas volume six months after diabetes reversal compared to baseline. However, the reversal of diabetes was associated with an increase in the irregularity of pancreas borders between baseline and eight weeks, followed by a decrease at six months. In contrast, no changes in fractal dimension were observed in the non-reversed group. The authors concluded that combining three-dimensional volume segmentation of the pancreas with fractal dimension analysis could provide a promising mathematical definition of the pancreas border morphology.

Fractal dimension analysis revealed a significant increase in pancreas complexity after acute weight loss in the responder group, followed by a significant decrease resulting in a smoother pancreas border by the end of the study. Conversely, no changes in the pancreas border were observed in the non-responder group. Although the effect of insulin on the endocrine pancreas has been extensively studied,

there have been few quantitative morphometric investigations of the exocrine pancreas. Recently, Pajevic *et al*[58] conducted a study to investigate the effect of acute and chronic insulin administration on the morphology of rat pancreas acini. The results showed that acute insulin treatment, regardless of the applied doses, increased the fractal dimension of the pancreas acini while decreasing their lacunarity.

The study showed that chronic low-dose insulin treatment decreased the fractal dimension and increased the lacunarity of pancreas acini, whereas high-dose insulin had the opposite effect. These findings suggest that fractal analysis could be used to detect fine architectural changes in acini, making it a potential alternative or addition to routine stereology.

In recent years, endoscopic ultrasound (EUS) elastography has been demonstrated as a useful technique for characterizing solid pancreatic lesions (SPLs). Carrara *et al*[59] introduced a combined analysis using EUS elastography (strain ratio) and fractal analysis to characterize the morphology of SPLs. A total of 102 SPLs from 100 patients were analyzed, and the results showed that both the parenchymal strain ratio (pSR) and wall strain ratio (wSR) were significantly higher in malignant SPLs than benign ones during elastography.

Fractal analysis revealed a significant difference in mean surface fractal dimensions between malignant lesions and neuroendocrine tumors, suggesting that combining EUS elastography with pSR and fractal-based analysis is a promising method for quantitatively characterizing SPLs[60].

It is widely accepted that the desmoplastic reaction is a hallmark of pancreatic cancer, although its impact on tumor behavior remains debated. Grizzi *et al*[61] recently developed a computer-aided method for quantifying the amount of pancreatic collagenic ECM, its spatial distribution pattern, and its degradation process.

The study conducted by Grizzi *et al*[61] demonstrated a progressive increase in pancreatic collagenic ECM from normal to inflammatory and pancreatic ductal adenocarcinoma. The two-dimensional fractal dimension revealed a significant difference in the spatial complexity of collagenic ECM between normal and inflammatory and pancreatic ductal adenocarcinoma. Moreover, a significant difference was observed when comparing the number of cycles required to degrade pancreatic collagenic ECM in normal *vs* inflammatory and pancreatic ductal adenocarcinoma. The mean velocity of collagenic ECM degradation was also found to be faster in inflammatory and pancreatic ductal adenocarcinoma than in normal. These findings highlight the potential of computer-aided methods and fractal analysis in quantifying the pancreatic ECM and its role in pancreatic diseases.

The study has demonstrated that inflammatory and pancreatic ductal adenocarcinomas are characterized by an increased amount of pancreatic collagenic ECM, as well as changes in its spatial complexity and degradation. These findings define new features of the pancreatic collagenic ECM and provide a basis for further investigations into the clinical behavior of pancreatic ductal adenocarcinoma and the development of therapeutic strategies. Overall, the study highlights the potential of computer-aided methods and fractal analysis in quantifying the pancreatic ECM and its role in pancreatic diseases, ultimately contributing to improved diagnostic and therapeutic approaches for patients with pancreatic cancer.

Recently, researchers investigated the relationship between ductal morphometry and ramification patterns in the submandibular gland and pancreas to confirm their shared fractal dimension[62]. The study found that while the length of the intraglandular submandibular duct and the main pancreatic duct were correlated, other morphometric features of the ducts were not. This suggests a more intricate relationship between the two digestive glands beyond a simple shared fractal dimension.

Fractal analysis offers maps of the FD, which allows for a more dependable and size-independent measurement utilizing gross pathology or multi-parametric MRI as reference standards[63]. This approach quantifies perfusion chaos, the underlying pathophysiological principle, and can differentiate the more chaotic tumor rim from the tumor core and nearby non-tumorous pancreatic tissue.

Abdominal CT biomarkers, both inside and outside the pancreas, have the potential to diagnose type 2 diabetes mellitus. Tallam *et al*[64] conducted a study on a large clinical dataset using fully automated deep learning to investigate abdominal CT biomarkers for type 2 diabetes mellitus. Their findings revealed that the most accurate predictors of type 2 diabetes mellitus include intrapancreatic fat percentage, pancreatic fractal dimension, plaque severity between the L1 and L4 vertebra levels, average liver CT attenuation, and BMI.

The fractal liver

In 1989, Dioguardi[65-67] (1921-2019) proposed the liver as a composite system comprised of a set of operative microunits that receive a continuous flow of matter, energy, and information. The development of mathematical models for non-Euclidean geometry has led to the creation of models for highly complex natural phenomena[68]. In developmental biology, branching morphogenesis has been explained through self-similar iterative branching rules that have helped to elucidate branch patterns observed in various tissue types. However, in solid viscera, the issue of geometry is more complex, as there is no readily available marker for geometry in parenchymal tissue. The mosaic pattern provides such a marker for studying solid viscera.

The patches observed in mosaic liver have been shown to exhibit fractal properties, indicating that the pattern may have arisen from a self-similar process in which small areas are representative of, although not necessarily identical to, the whole object. This observation provides a new analytical approach to the study of biological structure in organogenesis[68]. It is well-established that partial hepatectomy induces compensatory, non-neoplastic growth and regeneration in mammalian liver[69]. Previous experimental evidence has suggested that compensatory liver growth occurs uniformly, without focal centers of proliferation. Given this information, fractal analysis was used to test various hypothesized patterns of regenerative growth in the liver. The results of this analysis indicate that the mosaic pattern does not change significantly during the regenerative process. The area and perimeter of patches (the area occupied by or perimeter around cells of like lineage) increase during compensatory liver growth in chimeric rats without altering the geometric complexity of patch boundaries (the boundaries around cells of like lineage). These tissue findings are consistent with previously reported computer models of growth in which repetitive application of simple decisions assuming uniform growth created complex mosaic patterns.

These findings support the idea that an iterating, self-similar cell division program is sufficient for the regeneration of liver tissue following partial hepatectomy. Such programs are important because they suggest a way in which complex patterns, or morphogenesis, can be efficiently created from a small amount of stored information. In geometrical terms, liver fibrosis is an example of self-similar natural fractal structure[70].

To evaluate the usefulness of a reliable and reproducible mathematical scoring system based on fractal geometry for quantifying the irregular pattern in fibrosis commonly seen in liver biopsy specimens from chronic liver diseases, Dioguardi *et al*[70] investigated 26 liver biopsy sections obtained from patients with chronic hepatitis C virus-related liver disease. The degree of fibrosis in each section was estimated using a quantitative scoring system based on the computer-assisted evaluation of both the fractal and spectral dimensions of deposited collagen. The findings indicated that the fractional dimension of its irregular shape defines fibrosis as a natural fractal structure.

The study by Dioguardi *et al*[70] proposed a method for quantifying irregular patterns in liver tissue using fractal geometry. The method is based on a quantitative scoring system that evaluates the fractal and spectral dimensions of collagen deposited in liver biopsy sections obtained from patients with chronic hepatitis C virus-related liver disease. The results showed that the fractional dimension of the irregular shape of fibrosis defines it as a natural fractal structure, and a single numerical score can be used to quantify the complex distribution of collagenous components. The method is reproducible, rapid, and inexpensive, and eliminates subjectivity and external factors that can influence staging and classification. The method uses a rectified meter implemented in a computer-assisted planar image analysis system to give metric measures of irregular outlines and surfaces, which can be used to produce an index that quantifies the typical wrinkledness of biologic objects[71]. A computer-aided morphometric method employing fractal geometry and Delaunay triangulation was introduced to quantify the necro-inflammatory phase in liver biopsy specimens. The method was applied to two-micrometer thick sections from 78 chronic hepatitis C virus-infected patients, immunohistochemically treated to identify inflammatory cells[62]. An automatic image analysis system was used to define the inflammatory cell network based on Delaunay triangulation, and the cells were categorized geometrically into clusters or irregular distributions within the tissue. This automatic method is fast and objective, producing accurate results represented by scalar numbers and allowing the organ's condition to be represented by Hurst's exponent with an error of no more than 12%. The availability of precise measurements and a reasonably representative assessment of the organ's overall state raises questions about revising the indications for hepatic biopsy, taking into account its invasiveness and subjective interpretation. A computer-aided method utilizing fractal principles was applied to digitized histological biopsy sections from 209 patients with varying degrees of chronic hepatitis C virus-related fibrosis or cirrhosis[72]. This model offers the first metric evaluations of fibrosis's geometric properties and quantitative liver tissue architectural changes[72]. To evaluate the sampling variability of computer-aided, fractal-corrected fibrosis measurements in liver biopsies, Grizzi *et al*[73] examined samples from different liver parts removed from 12 patients with clinically and histologically proven cirrhosis who underwent orthotopic liver transplantation. A computer-aided image analysis system automatically measured fibrosis surface, perimeter, fractal surface and dimensions, wrinkledness, and Hurst coefficient in Sirius red-stained sections. High inter-sample variability was found in fibrosis surface and wrinkledness measurements, while Hurst's exponent variability was low. The study suggests that Hurst's exponent is a valuable histological estimate of fibrosis in the entire organ for clinical use, emphasizing the crucial role biopsy sections play in qualitatively diagnosing chronic hepatitis and quantitatively estimating architectural changes in liver tissue.

A technique for analyzing liver biopsy samples was proposed, which involves the use of the "Dioguardi Histological Metriser" machine to automatically measure various parameters related to liver health, including residual hepatocyte mass, inflammation, fibrosis, and loss of liver tissue tectonics[74]. This technique was validated by analyzing digitized images of liver biopsy sections from 398 patients and comparing the results to a semi-quantitative scoring system. The method provides measurements for the extent of hepatocyte mass, including abnormal lipid accumulation; the size of the inflammation basin and the number of leukocytes within it; the degree of collagen islets, which are classified into three

magnitudes; and the tectonic index, which quantifies the degree of liver tissue organization disorders.

The findings of the proposed technique represent the first standardized method for measuring the geometric properties of liver tissue, including parenchyma, inflammation, fibrosis, and tectonics of biopsy sections. Other authors have also reported on the accuracy and feasibility of using fractal analysis to measure liver fibrosis. A study involving 77 rats, including 10 sham, 46 with fibrosis due to bile duct ligation, and 21 with fibrosis resulting from CCl_4 intoxication, was conducted to investigate various measurements, such as the fractal dimension of Kolmogorov, histologic lesions, the area of fibrosis by image analysis, liver hydroxyproline content, messenger RNA fibronectin, serum hyaluronate level, and portal pressure[75]. The results showed that the fractal dimension of Kolmogorov was correlated with other markers of fibrosis, including the area of fibrosis, hydroxyproline content, serum hyaluronate level, and portal pressure.

The study found that the fractal dimension of Kolmogorov was significantly different between the two fibrosis models, unlike the area of fibrosis, and this relationship was independent of other histologic lesions. These results suggest that fractal analysis is an appropriate technique for analyzing liver fibrosis and has excellent reproducibility. In fact, this method is the only quantitative morphometric approach that can distinguish between different fibrosis models and is sensitive enough to detect pharmacologically-induced changes in liver fibrosis. Meanwhile, Fibroscan is a widely used technique for assessing liver fibrosis in chronic hepatitis C by measuring liver stiffness. However, it remains unclear how liver steatosis, which is a common feature of chronic hepatitis C and other chronic liver diseases, affects the accuracy of liver stiffness evaluation (LSE).

A quantitative morphometric analysis was conducted on 650 patients with chronic hepatitis C who underwent liver biopsy and LSE. The liver specimens were evaluated using both optical analysis (Metavir F and A, steatosis grading) and computerized morphometry to determine the area and fractal dimension of liver fibrosis and steatosis. The precise evaluation of liver histology using computerized morphometry revealed that liver stiffness measured by Fibroscan was associated with liver fibrosis, activity, and steatosis. In cases of high levels of steatosis, Fibroscan measurements may result in misinterpretation of liver fibrosis. Meanwhile, Nielsen *et al*[76] used a polygonization-based method to estimate the fractal dimension and other scalar lacunarity features from digitized transmission electron micrographs of mouse liver cell nuclei.

The aim of Nielsen *et al*[76] was to determine whether a small set of fractal features could differentiate between natural liver samples, hyperplastic nodules, and hepatocellular carcinomas (HCC). They found that several single fractal features estimated from the periphery of the cell nuclei could distinguish between samples from hyperplastic nodules and HCC and those from normal liver tissue. Recent studies suggest that the cellular environment's mechanical influences can have significant effects on gene activity, cell differentiation, and proliferation, in addition to chemical factors[77]. These mechanisms involve a tissue matrix system that includes the ECM, nuclear matrix, and cytoskeleton. As hepatocytes during fetal development are a useful model for studying such variations, Vassy *et al*[77] investigated hepatocyte differentiation from fetal to adult livers using computerized quantitative image analysis of cytokeratin 8 immunofluorescent localization.

Vassy *et al*[77] investigated a set of line features, including the number and length of lines, orientation of lines, and the fractal dimension of the filament network, to analyze hepatocyte differentiation from fetal to adult livers. The study found highly significant differences in the features studied throughout liver development, including an increase in the total amount of cytokeratin filaments, demonstrating the feasibility of objective and quantitative analysis of the differences in the pattern of the cytokeratin filament network. Meanwhile, the organization of the hepatic microvascular network has been widely studied in recent years, particularly in cirrhosis. A quantitative mathematical approach based on fractal and Fourier analyses performed on photomicrographs has been used to recognize the distinctive vascular patterns in cirrhotic livers compared to natural livers[78]. The study found that the natural hepatic sinusoidal network had higher complexity than the cirrhotic network, with more significant morphological changes observed in rats with bile duct-ligation cirrhosis than those with CCl_4-induced cirrhosis. These findings could provide insight into the pathophysiological alterations of the liver and may have diagnostic value in future clinical research. Additionally, aging-related modifications have been shown to cause marked changes in both the structure of the liver sinusoidal endothelial cell and liver perfusion[79]. Fractal and Fourier analyses and micro-CT showed that age did not affect sinusoidal dimensions, sinusoidal density, or dispersion number, but there were changes in the geometry and complexity of the sinusoidal network as determined by fractal dimension and degree of anisotropy.

Small age-related changes in the architecture of the liver sinusoidal network can influence hepatic function and may reflect broader aging changes in the microcirculation. Fractal analysis has been applied to HCC as well[80-83]. The fractal dimension has been investigated as a quantifier of non-Euclidean two-dimensional vascular geometry in a series of paired specimens of primary HCC and surrounding non-tumoral tissue. Blood vessels had a higher fractal dimension in primary tumors compared to liver metastasis, and this approach allowed for differentiation between primary liver tumors with and without neurodifferentiation. Fractal geometry has also been used to investigate alpha-fetoprotein behavior in patients with HCC waiting for liver transplant[84]. Furthermore, it has been shown that the chromatin of mouse hepatocytes exhibits age-related reduction of fractal dimension, suggesting that this index can be a potential indicator of age-associated changes in chromatin structure

[83].

The study of fractal architecture in various organs and structures has expanded the possibilities for determining their functioning and structural arrangement, leading to the development of new approaches to diagnostics and therapeutic interventions. Recently, Azmaiparashvili *et al*[85] investigated the spatial geometry of the biliary tree and assessed the significance of both its fractal and Euclidean characteristics for developing approaches that provide a comprehensive description of intrahepatic biliary tract architecture. This configuration of the biliary bed is essential for ensuring the smooth implementation of the physiological function of the liver and its adaptation to different pathologies accompanied by biliary hypertension. Furthermore, the findings could be considered in the diagnosis and assessment of ductular reaction, biliary regeneration, and/or carcinogenesis.

There is a growing interest among researchers in employing fractal geometry-based algorithms for modeling, monitoring, and treating hepatitis B virus infections, as comprehending the intricate relationships between pathogens, immune systems, and overall liver function is of vital importance[86].

Recently, fractal geometry has been employed to model portal hypertension[87]. Specifically, the model encompasses the entire process of blood flow, starting from the sinusoids and culminating in the portal vein. It can be adjusted to account for the diagnosis of portal hypertension caused by thrombosis and liver cirrhosis. Moreover, this approach offers a novel way to detect portal vein pressure noninvasively from a biomechanical perspective. Furthermore, the combination of qualitative MRI features with fractal analysis has enabled the identification of subtypes of hepatocellular adenomas HCCs in patients with non-cirrhotic livers[88]. This approach also enhances the differentiation of lesions with a high-risk of malignant transformation from those with a low-risk[88]. Liver and tumor segmentation from CT scans plays a critical role in hepatic surgical planning. As manual segmentation is both time-consuming and labor-intensive, a fully automated approach is highly sought after. Chen *et al*[89] introduced an automatic two-step liver and tumor segmentation method. Full-field optical coherence tomography (FF-OCT) has been recognized for its label-free subcellular imaging capabilities. Recently, Zhu *et al*[90] demonstrated the promise of their classifier using FF-OCT images for label-free, quantified tumor detection. This suggests that a fractal dimension-based classifier could potentially assist clinicians in identifying tumor boundaries for surgical resection in the future.

CONCLUSION

Irregularity and self-similarity under scale changes are the main attributes of the morphologic complexity of cells and tissues, either normal or pathologic. Fractal analysis is used in biomedical studies for the exact characterization of the complexity of analyzed structures. Fractal analysis has been demonstrated as a suitable method for quantifying heterogeneity from histological, endoscopic, radiological, and nuclear medicine images under a variety of conditions and in different organs. The application of nontraditional mathematics models to GI tract oncology may represent a comprehensive way to interpret the physical and biological nature of tumors opening new windows in the field of knowledge. Further research is required to exploit physiologically proven fractal behavior in the clinical setting. It is encouraging to see mathematicians, biologists, and clinicians collaborating towards a common quantitative understanding of anatomical complexity. This interdisciplinary approach has the potential to clarify concepts, interpret new and old experimental data, identify alternative experiments, and categorize acquired knowledge based on similarities and shared behaviors of different types of anatomical entities.

ACKNOWLEDGEMENTS

The Authors express their gratitude to Dr. Lorenzo Mottadelli for granting permission to feature his personally photographed Figure 2A as a representative illustration of an underwater natural fractal organism. The Authors are also grateful to Teri Fields for her assistance in editing this manuscript.

Abstract

BACKGROUND

Cholangiocarcinoma (CCA) is a devastating malignancy and has a very poor prognosis if tumors spread outside the liver. Understanding the molecular mechanisms underlying the CCA progression will likely yield therapeutic approaches toward treating this deadly disease.

AIM

To determine the molecular pathogenesis in CCA progression.

METHODS

In silico analysis, *in vitro* cell culture, CCA transgenic animals, histological, and molecular assays were adopted to determine the molecular pathogenesis.

RESULTS

The transcriptomic data of human CCA samples were retrieved from The Cancer Genome Atlas (TGCA, CHOL), European Bioinformatics Institute (EBI, GAD-00001001076), and Gene Expression Omnibus (GEO, GSE107943) databases. Using Gene set enrichment analysis, the cell cycle and Notch related pathways were demonstrated to be significantly activated in CCA in TCGA and GEO datasets. We, through differentially expressed genes, found several cell cycle and notch associated genes were significantly up-regulated in cancer tissues when compared

with the non-cancerous control samples. The associated genes, *via* quantitative real-time PCR and western blotting assays, were further examined in normal human cholangiocytes, CCA cell lines, mouse normal bile ducts, and mouse CCA tumors established by specifically depleting P53 and expressing $Kras^{G12D}$ mutation in the liver. Consistently, we validated that the cell cycle and Notch pathways are up-regulated in CCA cell lines and mouse CCA tumors. Interestingly, targeting cell cycle and notch pathways using small molecules also exhibited significant beneficial effects in controlling tumor malignancy. More importantly, we demonstrated that several cell cycle and Notch associated genes are significantly associated with poor overall survival and disease-free survival using the Log-Rank test.

CONCLUSION

In summary, our study comprehensively analyzed the gene expression pattern of CCA samples using publicly available datasets and identified the cell cycle and Notch pathways are potential therapeutic targets in this deadly disease.

Key Words: Bile duct cancer; Notch; Cell cycle; Liver cancer; Therapeutic target

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Molecular profiling of cholangiocarcinoma (CCA) has been conducted using various cohorts. However, the identified targets vary among different cohorts. In the current study, we combined different cohorts of CCA RNA sequencing datasets and refined the potential therapeutic targets in human CCA malignancy. We validated the findings using human CCA cell lines, the $Kras^{G12D}$ and P53 mutation transgenic mouse model, and human CCA clinical data, thus supporting the potential of targeting the identified pathways in clinical trials.

INTRODUCTION

Cholangiocarcinoma (CCA) is a devastating malignancy with "silent" clinical manifestations, genetically heterogeneous, anatomically distinct, but limited treatment options[1]. CCA can be classified as three subtypes depending on the origin of anatomical site, including intrahepatic (iCCA), perihilar (pCCA) and distal (dCCA) CCA[2]. If CCAs are diagnosed at the early stage, surgical resection may be a treatment option. However, CCA tumors are generally diagnosed at advanced stages due to lack of symptoms. Therefore, it is urgent to develop early detection markers and effective therapies for CCA patients. Understanding the molecular pathogenesis of CCAs may help identify early detection markers and potential therapies for this deadly disease.

Advances in whole-exome and transcriptome sequencing have paved the way for precision medicine in patients with advanced-stage or unresectable lesions[3-5]. Several genetic mutations have been identified in CCA patients[6]. Among them, IDH1 mutations have been well studied and the IDH1 mutation specific inhibitor has been developed for targeting malignant tumors with this mutation. In the ClarIDHy clinical trial, it was found that Ivosidenib-IDH1 mutation inhibitor could improve CCA patient overall survival (OS) and progression free survival[7,8], which eventually led to the FDA approval of Ivosidenib use in CCA patients with IDH1 mutation. Nevertheless, the 5-year survival of these patients treated with Ivosidenib is not significantly improved[7,8]. Besides, there is no effective therapy for those CCA patients with wild-type IDH1, despite that cisplatin and gemcitabine could extend the median OS for 3.6 mo but is not curative. Therefore, there is still an unmet need for identifying effective therapies in CCA patients.

In the current study, we utilized the transcriptomic profiling of CCA to explore the oncogenic driver events, analyzed the relevant genes expression, and identified the feasibility of target therapies with respect to those tumorigenic lesions.

MATERIALS AND METHODS

Human data

A total of 2 archival tissue blocks from patients with eCCA were retrieved from the First Affiliated Hospital of Zhengzhou University (Zhengzhou, Henan Province, China) and the specimens were independently diagnosed by two hepatobiliary pathologists. This study was conducted in accordance with the Declaration of Helsinki, and approved by the Institutional Review Board of the same institution (Approval No. 2022-KY-1514-002). Informed consents were obtained from all patients.

Cell Lines and reagents

Human CCA cell lines, including H1 (OCUCh-LM1-H1)[9], HuCCT1[10], SSP-25[11], and ETK1[12] cell lines were kindly provided by Dr. Jack Wands. TFK-1 and RBE were purchased from RIKEN Cell Bank (Tsukuba, Japan). The non-malignant human bile duct cells hBD was purchased from Celprogen Inc (Torrance, CA, United States, Catalog Number: 36755-12). CCA cell lines were cultured in RPMI-1640 supplemented with 10% fetal bovine serum (FBS; Gibco™, Thermo Scientific, Waltham, MA, United States; Cat# 10099141C), 100 μg/mL streptomycin, and 100 U/mL penicillin (HyClone™, Logan, UT, United States). The hBD cell line was grown in DMEM containing 10% FBS, 100 μg/mL strep. All cell lines were authenticated by STR and were negative for contamination of mycoplasma recently. Arcyriaflavin A, Flavopiridol, Roscovitine, and γ-secretase inhibitor, DAPT (N-[N-(3, 5-difluorophenacetyl)-l-alanyl]-s-phenylglycinet-butyl ester) were all purchased from Cayman Chemical (Ann Arbor, MI, United States).

Data collection

RNA-Seq, DNA methylation, and clinicopathological data of 36 patients with cholangiocarcinoma (liver/normal bile duct = 9, iCCA = 30, pCCA = 4, dCCA = 2) were retrieved from The Cancer Genome Atlas (TCGA) database. The Genomic Data Commons mRNA quantifications were calculated by STAR [13], and then annotated by the reference gene model GENCODE v36. iCCA and the related para-cancerous normal livers from 30 patients, and their survival information were employed (GSE107943) [14]. Fastq files of RNA-Seq from 162 samples of CCA (iCCA = 122, pCCA = 14, dCCA = 26) and the associated survival status of patients were fetched from the European Genome-phenome Archive[15].

Survival analysis

The Kaplan-Meier analysis was performed to evaluate the OS and disease-free survival (DFS) of patients from GEO and EBI cohorts. The optimal cutoff point for two groups was estimated based on maximally selected rank statistics[16], and then significance of survival analysis was calculated using log-rank test between the two groups.

Gene set enrichment analyses

Gene set enrichment analysis (GSEA) was conducted using R package "Pi"[17]. Hallmark (H) and KEGG subset of Canonical Pathways (CP) gene sets were selected for GSEA[18].

Tumor-infiltrating immune cell analysis

Single-sample GSEA was performed to analyze the tumor-infiltrating lymphocytes (TILs) based on the 28 immune cell types[19]. Correlations between the indicated genes expression and each infiltrating immune cells levels were calculated based on Spearman correlation (ρ).

Genetically engineered mouse

All protocols were approved by the Institutional Animal Care and Use Committee (IACUC) at Rhode Island Hospital, and all experiments were conducted in accordance with the guidelines of this IACUC. The specifical $Kras^{G12D}$ (LSL-$Kras^{G12D}$), floxed-p53 (p53L/L), and albumin-Cre mutants strains were purchased from the Jackson Laboratory (Bar Harbor, ME, United States). They were intercrossed to achieve the mutant mice as indicated in the results section. The specific primers and genotyping protocol were performed following the instruction suggested by the Jackson Laboratory. Mice were bred in a pathogen-free environment and provided with free access to food and sterilized water Ad Libitum. Animals within experimental cohorts were monitored until the appearance of illness, including diminished activity, abdominal bloating, and cachexia, followed by full necropsy and the subsequent histopathological analysis.

MTT cell growth assay

Three CCA cell lines, including HuCCT1, H1, RBE, were seeded at 2×10^3 cells/well into 96-well plate in six replicates. And then the above-mentioned cells were treated with small molecular inhibitors targeting cell cycle (Arcyriaflavin a, Flavopiridol, and Roscovitine) and Notch (DAPT) pathways 24 h post-seeding, respectively. The treatments were changed as indicated at days 1, 3, 5, and 7. Cell proliferation was measured using MTT at the following day (day 0 and day 1) and every 48 h after (up to day

7). Absorbance at OD570 nm and 650 nm were read and then normalized to vehicle control (0.1% DMSO or the corresponding medium). The relative cell proliferation rates were calculated as OD570-OD650.

RNA extraction and real-time quantitative PCR

Total RNA was extracted from CCA cell lines using TRIzol™ (Invitrogen, Thermo Scientific; Cat# 15596026) according to the manufacturer's protocol. 1 μg of total RNA was used to reverse transcription using iScript™ Reverse Transcription Supermix (Bio-Rad, Hercules, CA, United States, Cat#1708840). The qRT-PCR was conducted using SYBR® Green Realtime PCR Master Mix (Bio-Rad, Cat#1725270) by QuantStudio™ 5 Real-Time PCR System (Applied Biosystems). The relative mRNA expression was calculated based on $2^{-\Delta\Delta Ct}$ protocol. All primers were listed in Supplementary Table 1.

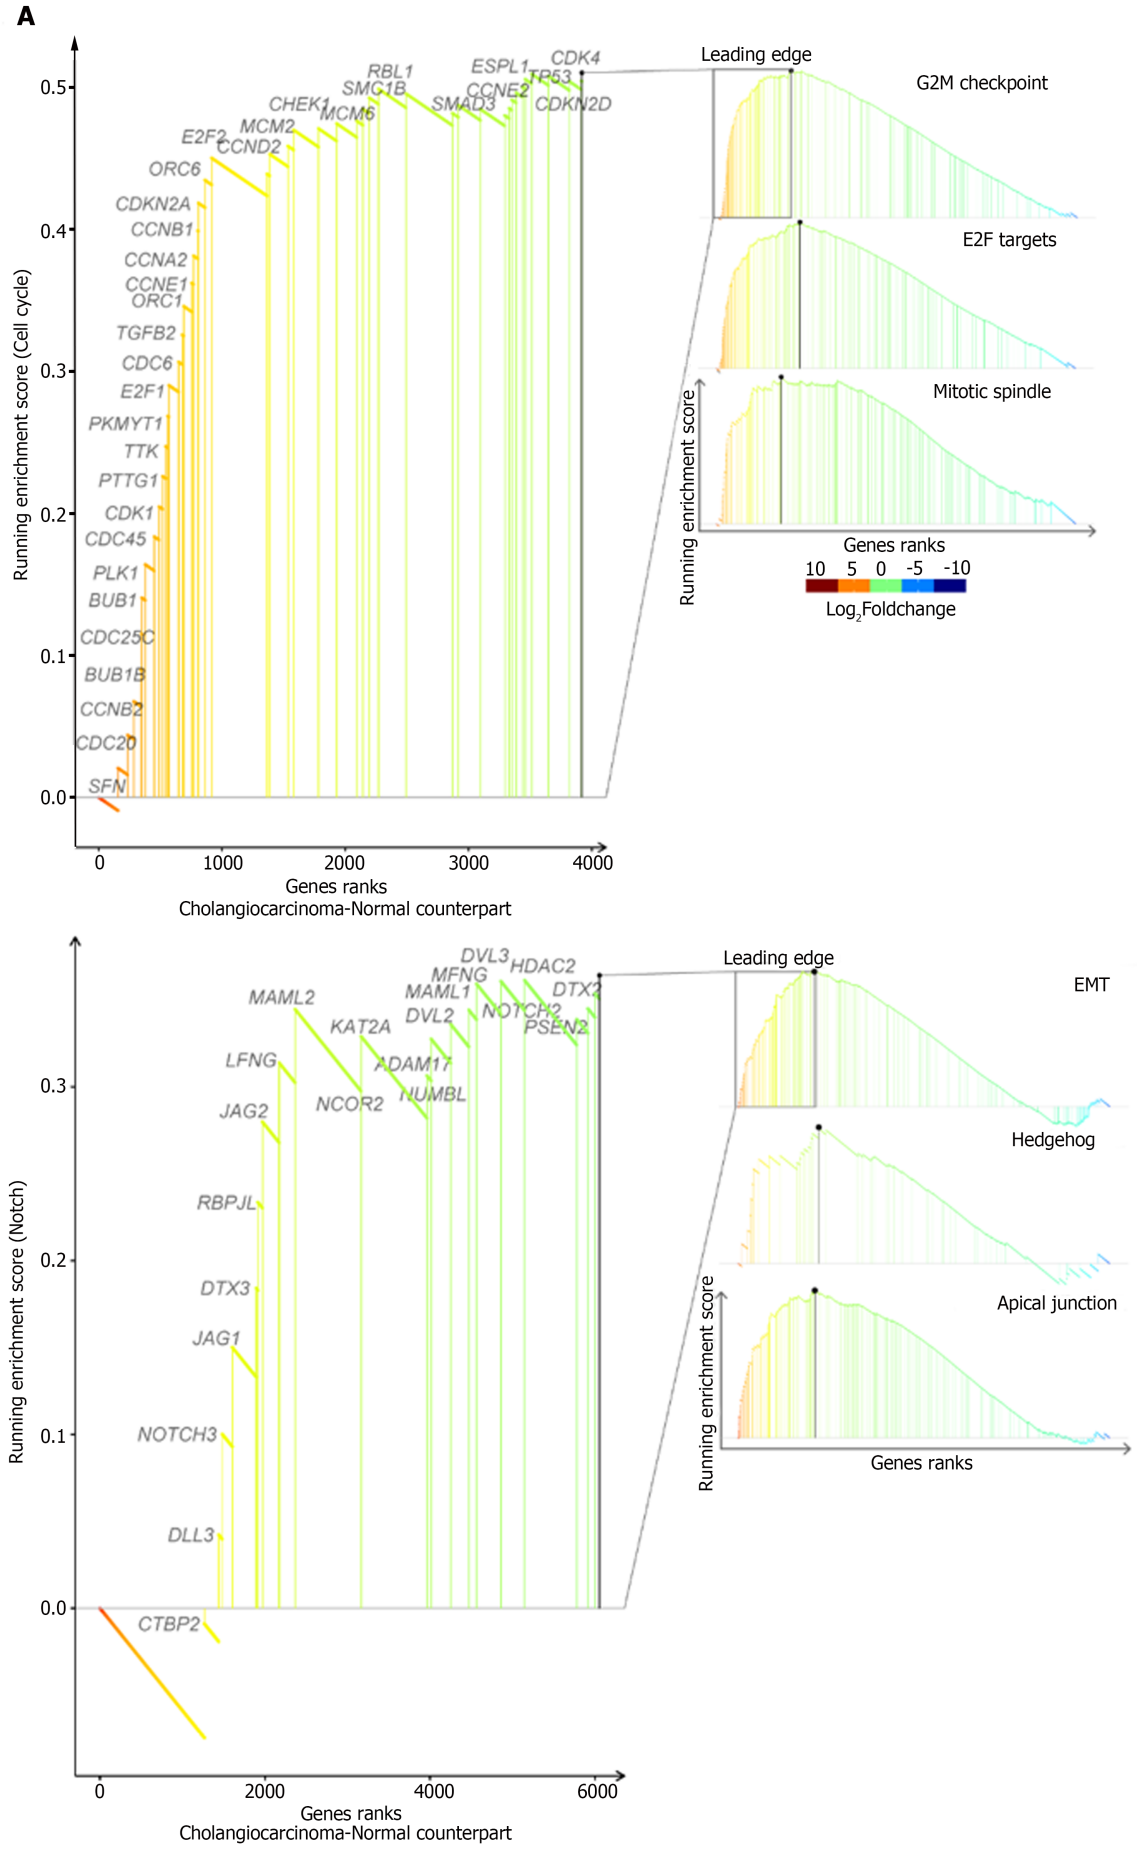
Western blotting

Whole-cell protein extractions was acquired using RIPA Lysis and Extraction Buffer (Thermo Fisher Scientific, Cat# 89901), supplemented with protease inhibitor (Thermo Fisher Scientific, Cat#78430). The concentration of protein was quantified using Pierce BCA Protein Assay Kit (Thermo Fisher Scientific, Cat# J63283.QA) before mixed with protein loading buffer (3×). Then the protein samples were separated by 10% SDS-PAGE, and the detailed procedures conducted as previously described[20].

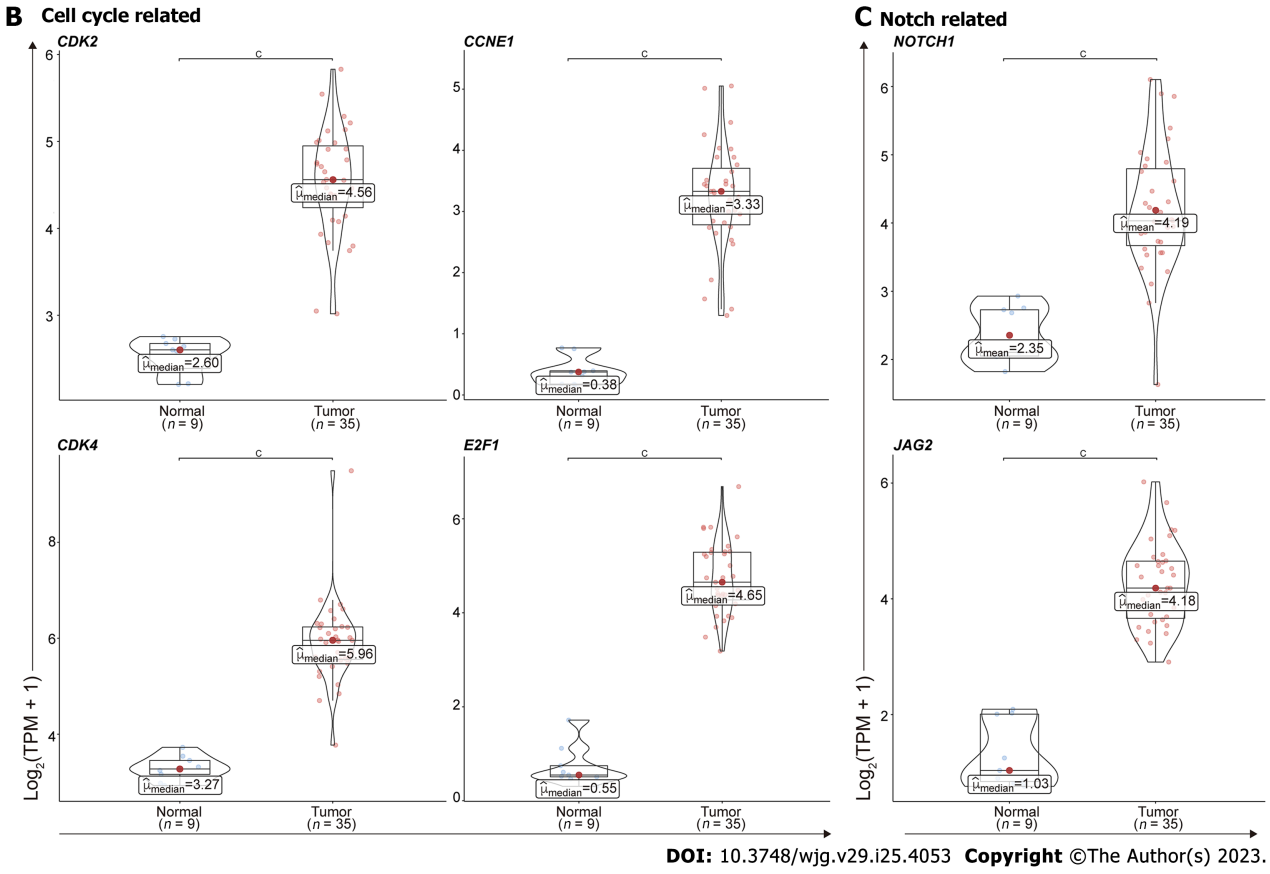
Antibodies including α-Tubulin, GAPDH, Cyclin D1, P21, PCNA, E2F1, CDK2, CDK4, CDK6, RB1, JAG1, JAG2, Caspase 8, BAX, XIAP, BCL-2L12, ATR, ATM, Rad50, Mre11, PIK3C3, LC3A/B, and ULK1 were purchased from Cell Signaling Technology (Danvers, MA, United States) and Santa Cruz Biotechnology (Dallas, TX, United States).

Statistical analysis

Statistical analyses were performed using STATA software 16.0 (StataCorp, College Station, TX, United States) and R software (version 4.2.0). Statistical analysis was performed using unpaired Student's *t* and Mann-Whitney *U* test with respect to Gaussian distribution or not, respectively, unless otherwise indicated. Kruskal-wallis test was performed to compare the expression of genes examined by PCR, and the *post-hoc* tests within two groups were adjusted by Holm's correction. Spearman correlation coefficient (ρ) is used to evaluate the correlations between DNA methylation levels of CpG islands and the associated genes expression. Wilcoxon signed-rank test was utilized to compare the expression level of cell cycle and Notch related genes between iCCA and its corresponding normal tissues. Two-way repeated measures Anova was utilized to compare optical densities of CCA cell lines treated with the serial gradient concentration of drugs, which measured more than once. Then simple effect at day 7 was calculated when there were interaction effects between time and dosages. *P* values were shown as: $^{a}P < 0.05$, $^{b}P < 0.01$, and $^{c}P < 0.001$.



RESULTS



CCA oncogenesis is highly associated with elevated cell cycle and Notch associated pathways

To determine what molecular events are up-regulated in cholangiocarcinogenesis, we downloaded the transcriptomic data of CHOL from the TCGA database. We performed the GSEA and found that cell cycle associated pathways were preferentially activated in tumors compared with the normal samples, such as genes involved in G2M checkpoint, E2F Targets, and Mitotic spindle (Figure 1A, upper). Besides, the pathways related with Notch were also induced in tumors, *e.g.*, genes implicated in epithelial mesenchymal transition (EMT), Hedgehog, and Apical Junction (Figure 1A, lower). We retrieved the leading edge gene sets from those pathways, which drive the enrichment score and dominate the tumorigenicity of those pathways. Consistently, the genes from those leading edges are distinctly up-regulated in tumors compared with the normal samples, in line with the oncogenic properties (Figure 1B and C). Together, through the analysis of GSEA and differentially expressed genes, we found cell cycle and Notch pathways are up-regulated in CCA patients compared to non-malignant patient controls.

Cell cycle and Notch associated pathways were found upregulated in CCA cell lines compared to normal biliary epithelial cells

To facilitate the application of identified genes in preclinical studies, we must validate if these findings are reproducible in established normal biliary epithelial cells and CCA cells. In this case, we would be able to evaluate whether these pathways can be targeted using the *in vitro* cell culture system. Thus, we examined several leading-edge genes associated with these pathways in normal biliary epithelial cells and several CCA cell lines. The results suggest that several cell cycles associated genes were up-regulated in CCA cancer lines, including *PCNA*, *E2F1*, *CDK2*, *CDK4*, and *CDK6* (Figure 2A). Besides, *JAG1* and *JAG2* which serve as the Notch ligand also substantially increased in CCA cell lines when compared with normal biliary epithelial cells (Figure 2B). We also examined several genes involved in autophagy, cell death, and DNA damage pathways since we wanted to illustrate if cell cycle associated

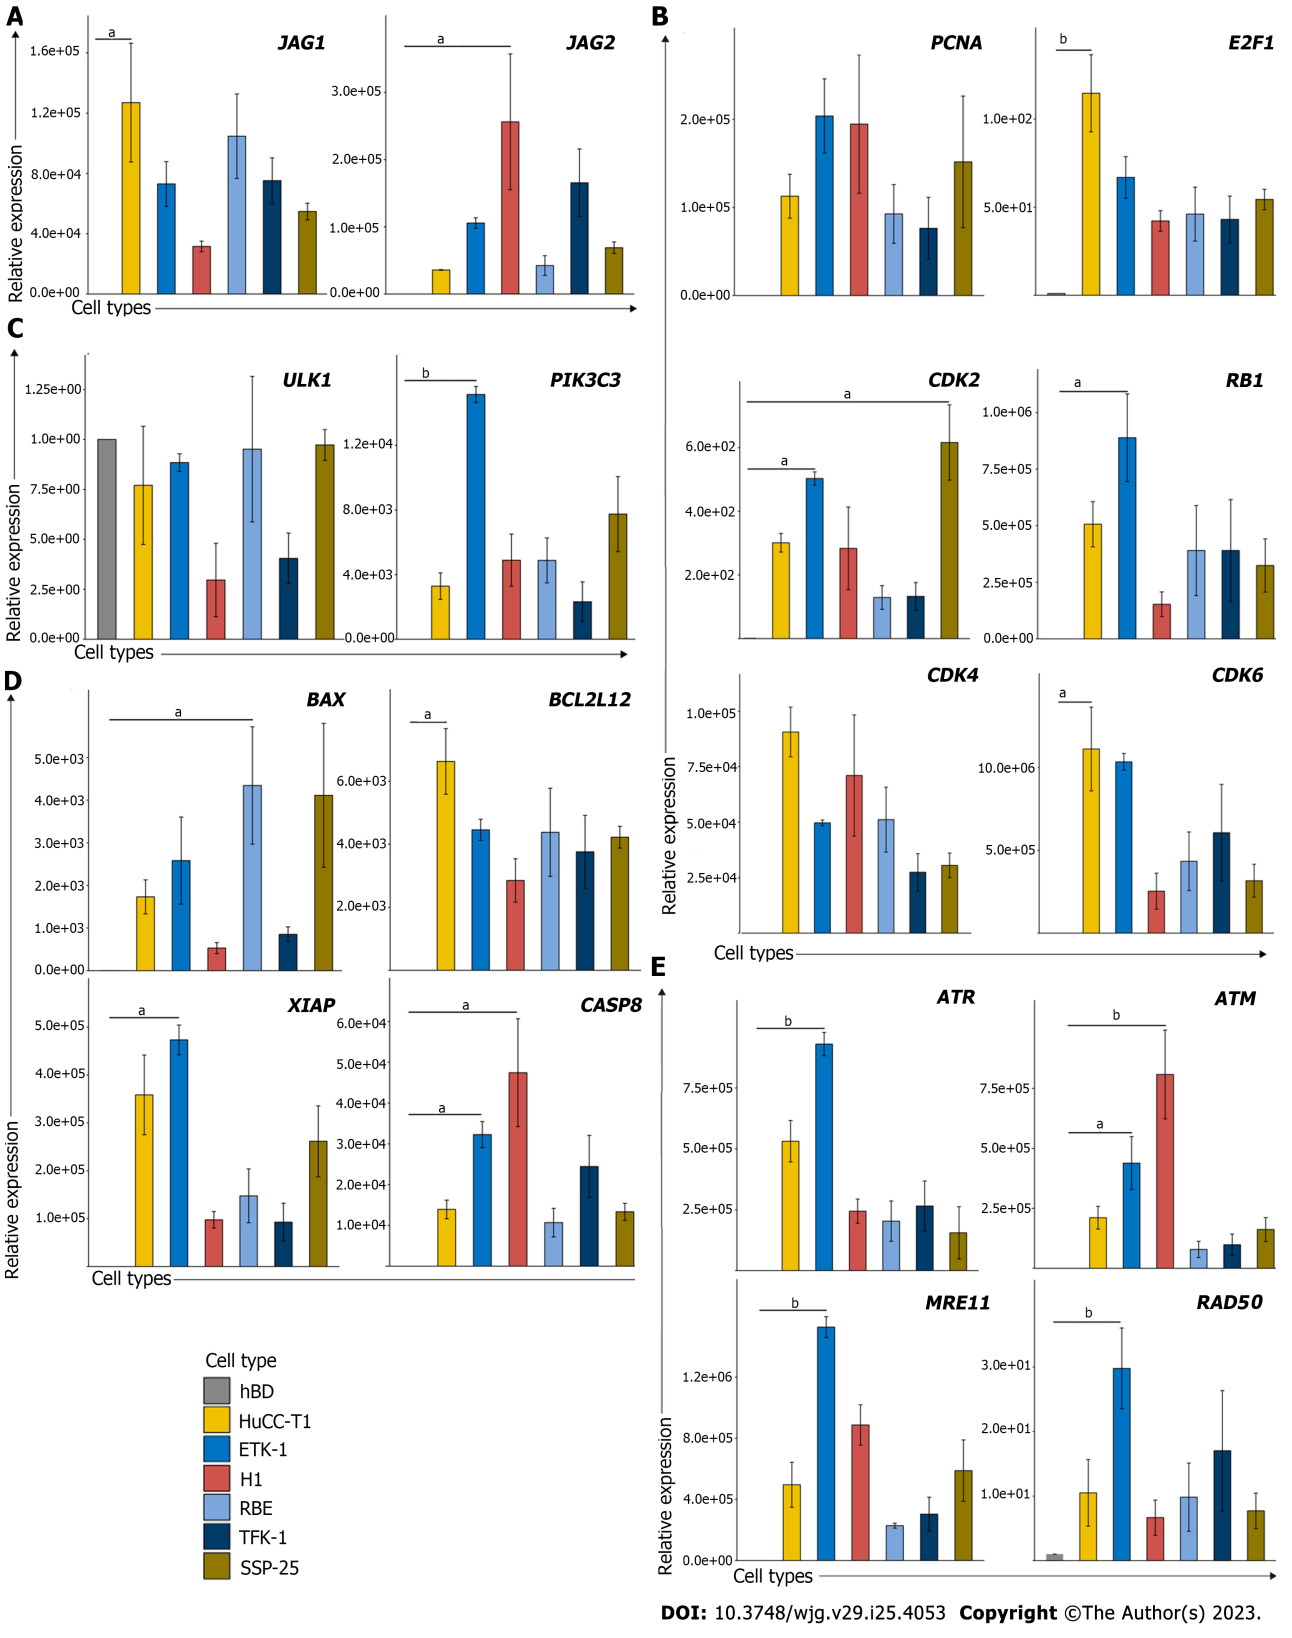
Figure 1 Cholangiocarcinogenesis driven by cell cycle and Notch associated pathways. A: Rank-based gene set enrichment analysis of genes preferentially activated in tumors identified the tumorigenic pathways, cell cycle and Notch from Hallmark gene sets, in CHOL transcriptome from TCGA database. Upper: Cell cycle associated pathways, including G2M checkpoint, E2F Targets, and Mitotic spindle gene sets; Lower: Notch associated pathways, including epithelial mesenchymal transition, Hedgehog, and apical junction gene sets. The mRNA expression levels from the leading edges of cell cycle (B) and Notch (C) associated pathways were analyzed in human normal bile ducts (n = 9) and CCA samples (n = 35) using TCGA database, suggesting up-regulation of cell cycle and Notch associated genes in CCA samples. TPM: Transcripts per kilobase million; Red: Cholangiocarcinoma (iCCA/eCCA), Blue: Normal bile ducts and/or para-cancerous liver; EMT: Rpithelial mesenchymal transition. $^{c}P < 0.001$ when compared with the normal control.

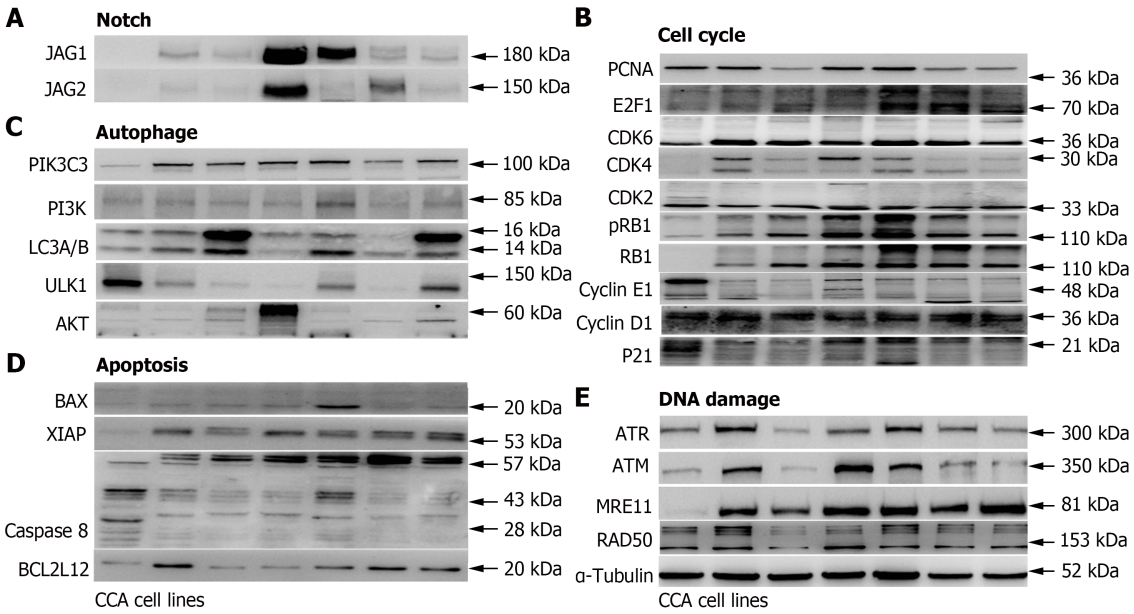


pathways play a dominant role or cell death pathways dominate the CCA tumorigenesis. Interestingly, we found several up-regulated genes that are associated with DNA damage and cell death pathways, but not autophagy (Figure 2C-E). Moreover, the negative correlations between the methylation status (β value) and its expression of those genes suggested that the aberrant expression might be attributed to the hyper- or hypomethylation (Supplementary Figure 1).

Up-regulated cell cycle and Notch associated gene expression levels were correlated with protein expression profiles in CCA cell lines

To determine if the identified genes have increased protein expression levels or promote other protein expression levels of the same pathway in CCA cell lines compared with the control biliary epithelial cells, we decided to examine protein expression of several major representative genes in each pathway (Figure 3, Supplementary Figure 2). As shown, several cell cycles associated genes were up-regulated in CCA cell lines when compared with the control biliary epithelial cells, including CDK2, CDK4, CDK6, and E2F1. Unexpectedly, several cyclins which include cyclin D1 and cyclin E1 were found decreased (Figure 3A). When we examined Notch ligands which include JAG1 and JAG2, we found JAG1 and JAG2 were all significantly increased in CCA cell lines compared to the biliary epithelial cells (Figure 3B). We further examined autophagy associated proteins and found no significant difference in autophagy between normal and malignant cells based on the autophagy definition (Figure 3C)[21]. In line with the mRNA change data, several apoptosis and DNA damage associated genes that were identified elevated in CCA cell lines were found increased as well (Figure 3D and E). Together, the mRNA and protein profile data demonstrated that it is feasible to identify potential target genes through mining public datasets and validating through *in vitro* human CCA cell lines.

Validation of the identified genes in a triple transgenic CCA mouse model



It has been well characterized that *KRAS* and *P53* are two of the most mutant genes in human CCA tumor samples[22]. Thus, a previous study has established the CCA transgenic mouse model by

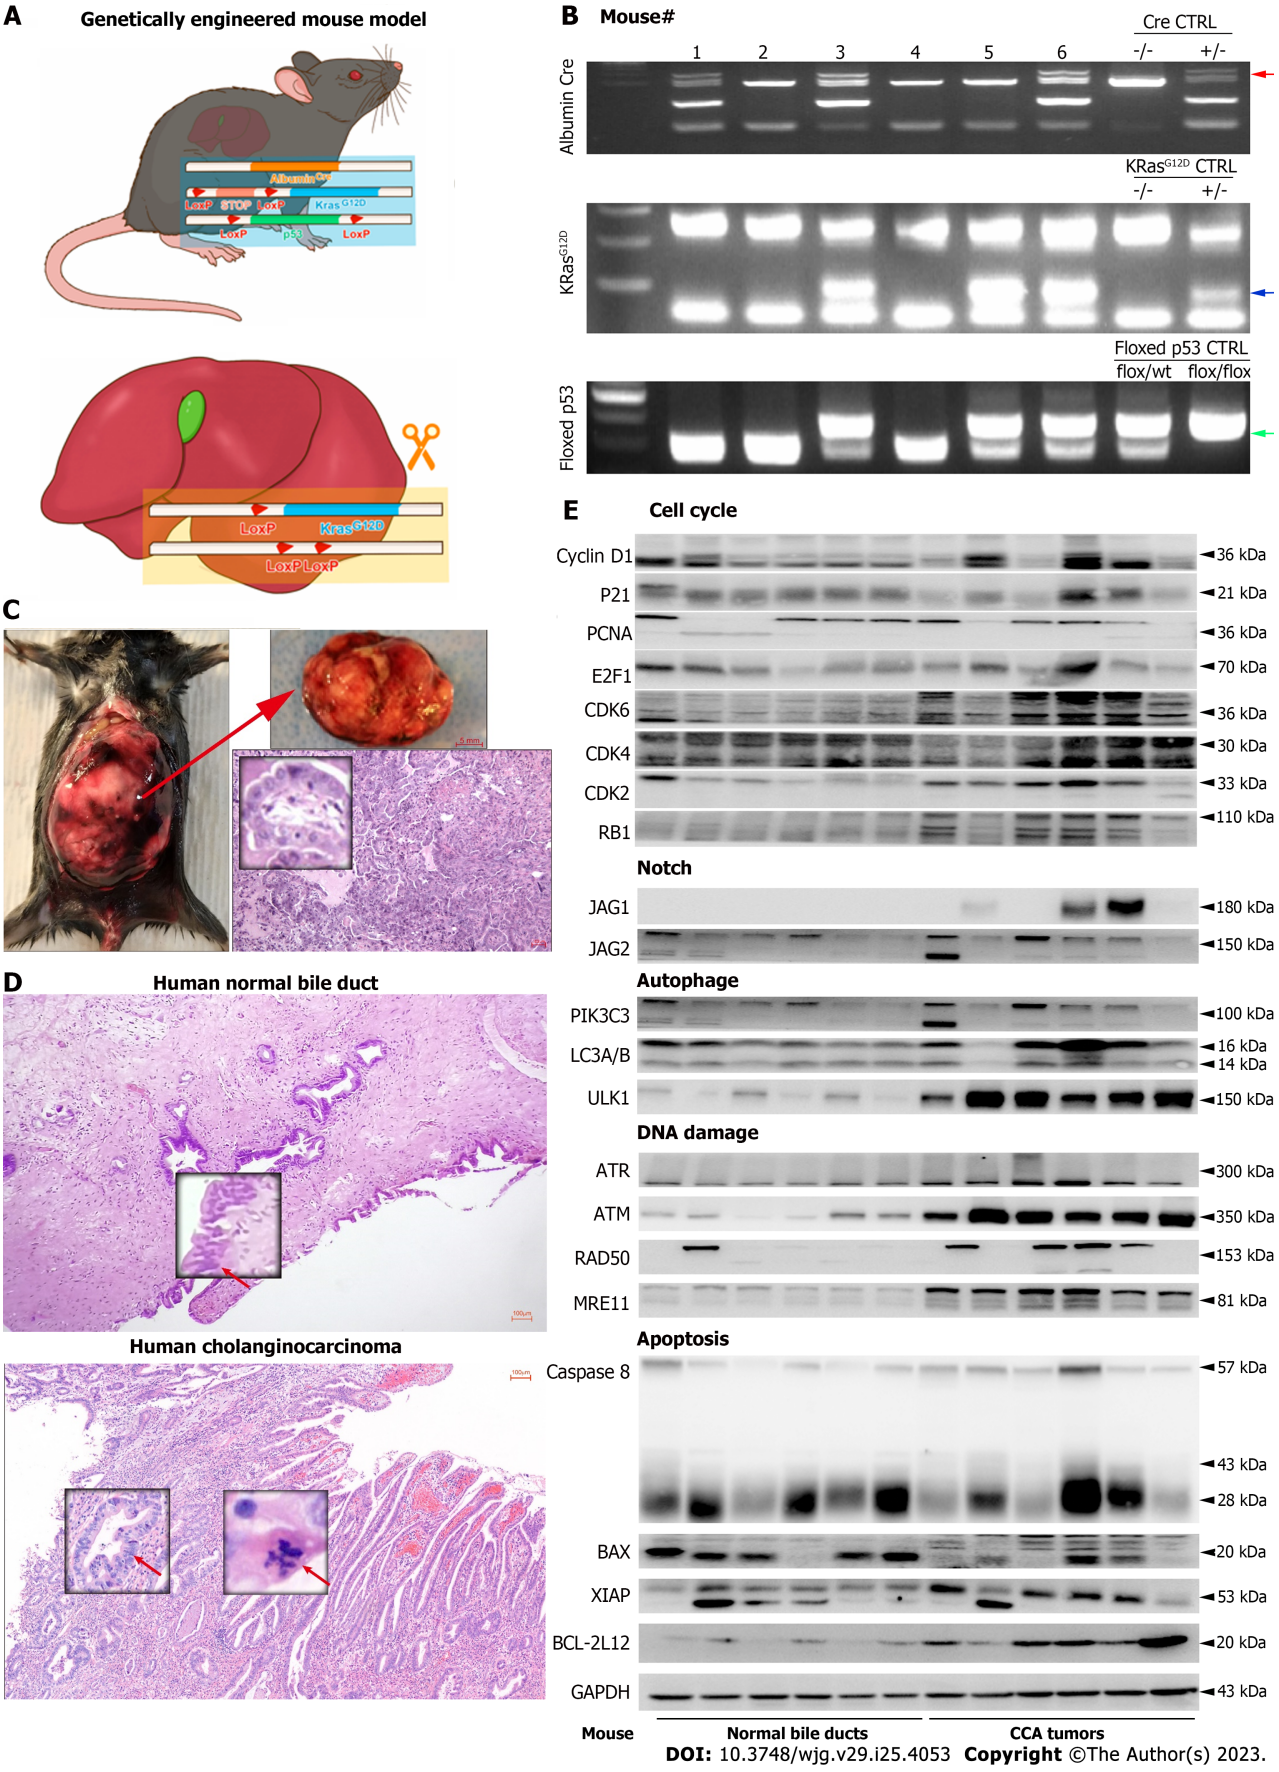
Figure 3 The cell cycle and Notch pathway associated protein expression levels are up-regulated in cholangiocarcinoma cell lines compared to the normal human bile duct cells. The protein expression levels of leading-edge genes from (A) Notch, (B) cell cycle, (C) autophagy, (D) cell death, and (E) DNA damage were determined in cholangiocarcinoma (CCA) cell lines compared to hBD. Several cell cycle and Notch associated genes, including CDK4, CDK6, E2F1, JAG1, and JAG2, were up-regulated in CCA cell lines. CCA tumor cell lines including HuCCT1, ETK-1, H1, RBE, TFK-1 and SSP25. α-Tubulin served as the loading control.



tumor were showed (Figure 4C). When comparing with human non-malignant bile duct and CCA tumor samples, the mouse CCA tumors present almost identical CCA histology to human CCA tumor samples (Figure 4C and D). To further determine whether mouse CCA and human CCA tumors have similar molecular profiles, we examined the genes that we identified using public human CCA dataset and validated using normal biliary epithelial cells and human CCA cell lines. Intriguingly, mouse and human CCA both have highly elevated genes associated with cell cycles and Notch, including CDK2, CDK4, CDK6, JAG1, and JAG2 (Figure 4E and Supplementary Figure 3). In line with CCA cell line data, several DNA damage genes, including RAD50 and MRE11, were found increased in mouse CCA tumor samples as well (Figure 4E). Given all these facts, our data demonstrated that the CCA tumors derived from the CCA transgenic mouse model have very high similarity to human CCA tissues and cell lines. Besides, the results of CCA transgenic mouse tumor data further demonstrated that refining the public human RNA sequencing data would help identify dysregulated pathways which may be druggable.

Targeting cell cycle and Notch pathways inhibited cell growth of human CCA cell lines

As we have found that cell cycle and Notch associated pathways are highly elevated in human CCA tumor samples and validated these findings in CCA cell lines, we proposed to determine whether targeting these pathways using small molecular inhibitors could achieve therapeutic potential in CCA cell lines, including H1, HuCCT1 (Kras and P53 mutations), and RBE (IDH1 mutation). It was found that the D1-dependent CDK4 inhibitor Arcyriaflavin a significantly suppressed cell growth in HuCCT1 and RBE CCA cell lines, but to a less extent in H1 (Figure 5A). The pan-CDK inhibitor Flavopiridol and the selected CDK inhibitor Roscovitine, which targets multiple CDKs, both displayed substantial growth inhibition in H1, HuCCT1, and RBE CCA cell lines (Figure 5B and C). It was noted that RBE CCA cells with IDH1 mutation are very vulnerable upon the treatments of CDK inhibitors (Figure 5A-C). Regarding the treatment using a Notch inhibitor, a γ-secretase inhibitor-DAPT was used to challenge these CCA cell lines. Although the Notch inhibitor could exert anti-tumor effects in CCA cell lines, the suppressive effects are not as strong as CDK inhibitors. Furthermore, the close relationships between the levels of TILs and those genes expressed indicated that cell cycle related pathways are associated with immune check point therapies (Supplementary Figure 4). Taken together, our results suggested that targeting cell cycle and/or Notch pathways could be considered as alternative modalities for patients with CCA.

Validation of identified cell cycle and Notch related pathways in other datasets

It is essential to verify whether our findings are applicable to other datasets. Thus, we utilized another dataset (GSE107943) to validate the oncogenic traits of cell cycle and Notch related pathways in CCA. Consistently, the leading edge of GSEA showed pathways pertaining to cell cycle (Figure 6A, upper) and Notch (Figure 6A, lower) were significantly activated in tumors compared with the normal

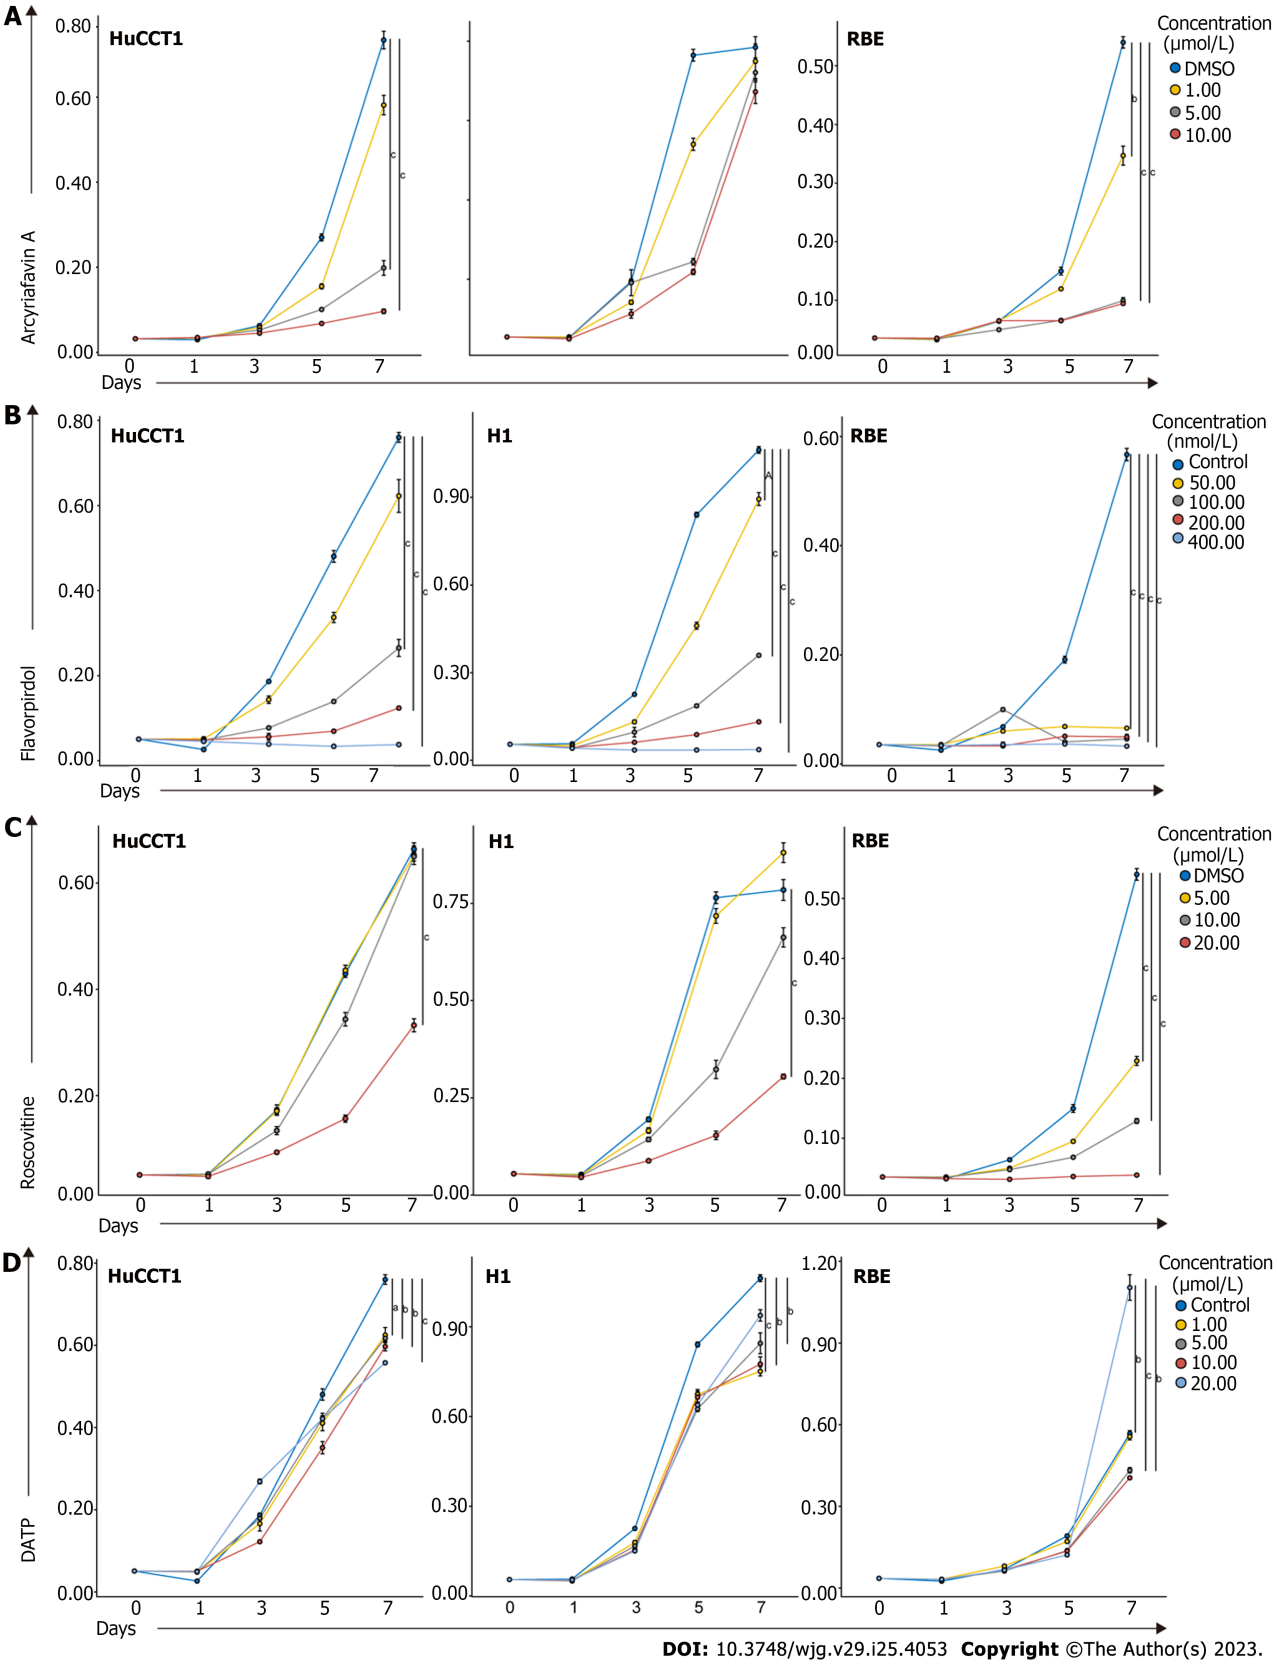
B: The genotyping data presenting positive Cre (red triangle),

KrasG12D (blue triangle), and homozygous floxed P53 genes (green triangle). C: The gross image of representative tumor (upper right, scale bar = 5 mm), and the corresponding histopathology (lower right, scale bar = 100 μm) with inset showing glandular appearance (arrow, scale bar = 20 μm). D: Histology of human bile duct (upper, scale bar = 100 μm) with inset showing biliary epithelium (arrow, scale bar = 20 μm), and cholangiocarcinoma (lower, scale bar = 100 μm) with inset showing mitotic figure (arrowhead, scale bar = 20 μm) and glandular appearance (arrow, scale bar = 20 μm). E: The protein expression levels of leading-edge genes from cell cycle and Notch associated pathways, and genes involved in autophagy, cell death and DNA damage in CCA tumor tissues from the GEM (50 wk) compared to the normal bile ducts of control mice (50 wk). GAPDH was used as the loading control.

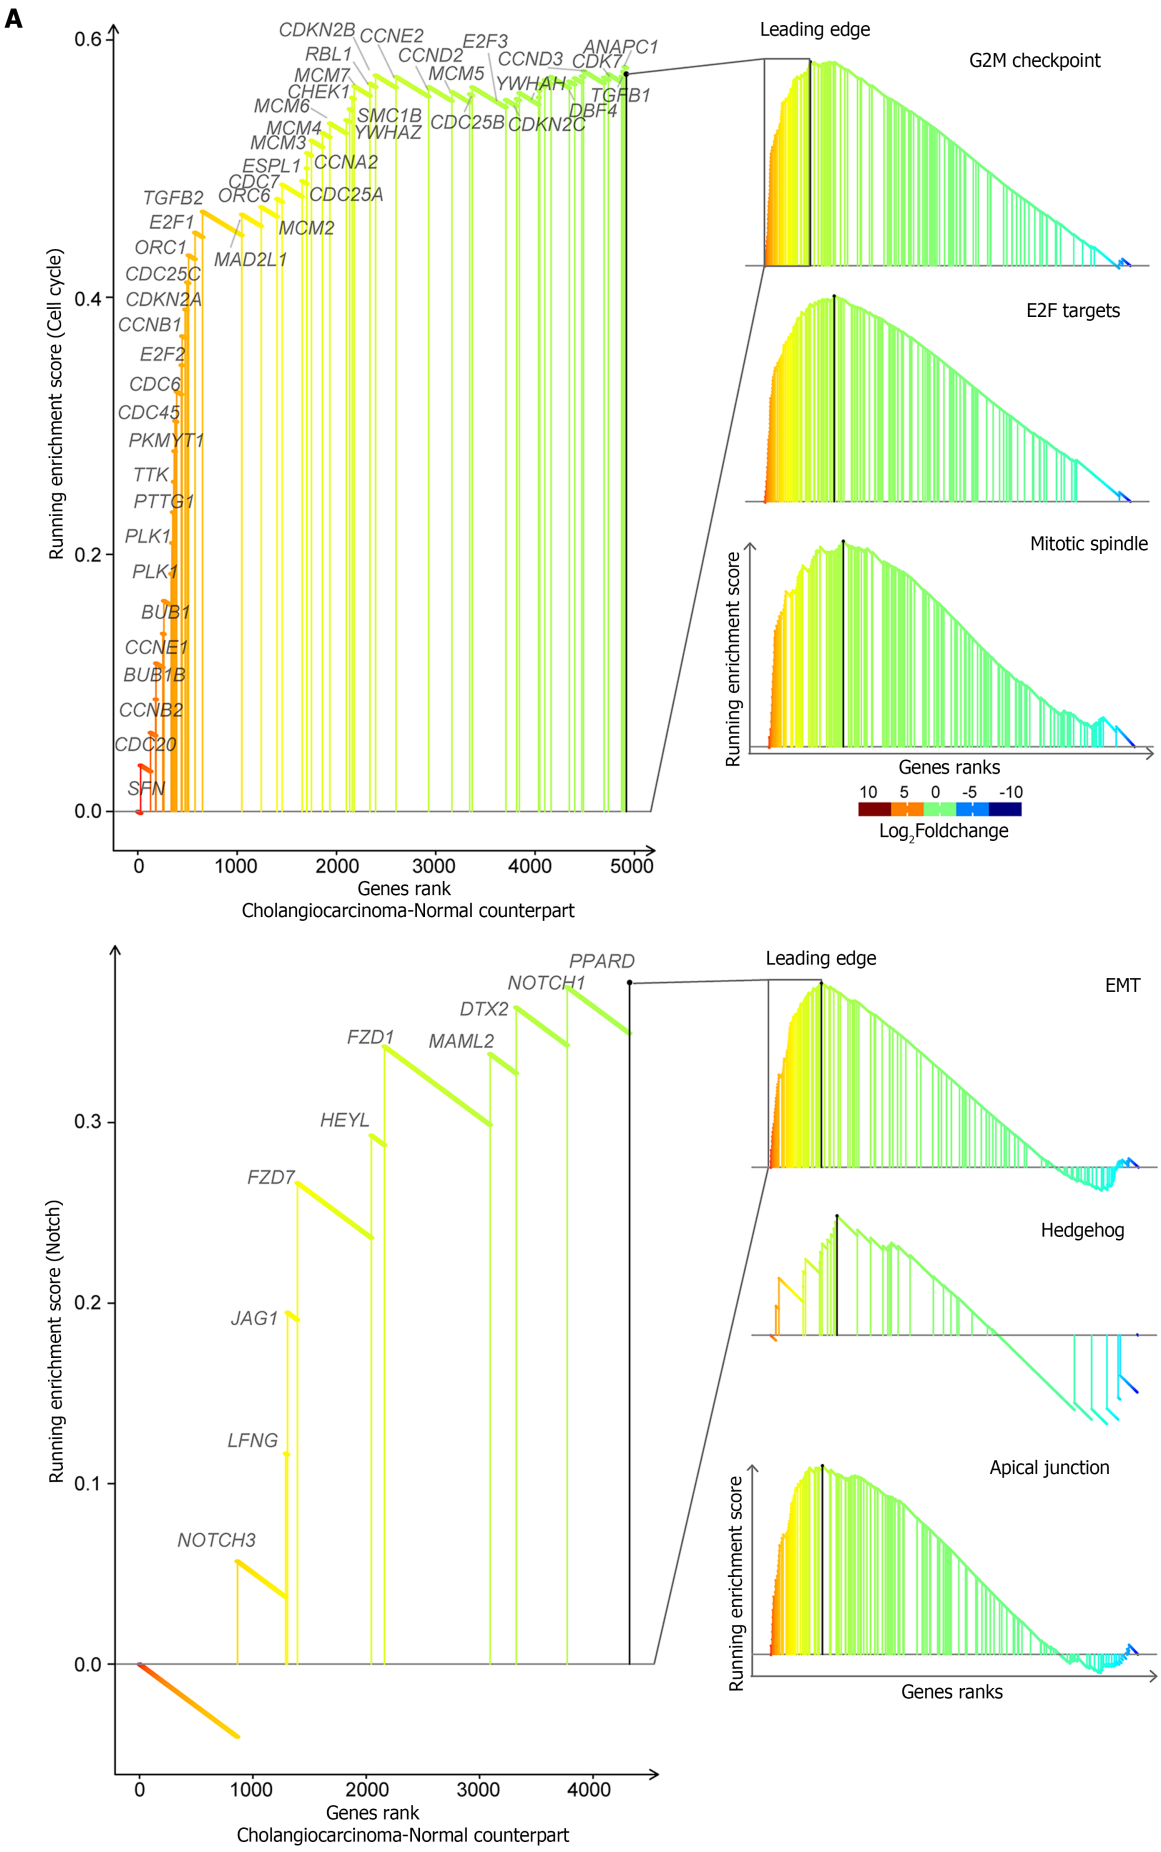
samples. Besides, the analysis of differentially expressed genes also revealed that upregulation of cell cycle related genes, including *CDK2*, *CDK4*, *CCNE1*, and *E2F1*, were observed in human CCA tumor samples compared with the adjacent normal liver tissues. Similarly, several Notch associated genes, including *NOTCH1* and *JAG2*, were found up-regulated in CCA tumor samples as well (Figure 6C). Together, with the validation data derived from another dataset, it is therefore suggested that our findings are applicable to other clinical human CCA tumor samples.



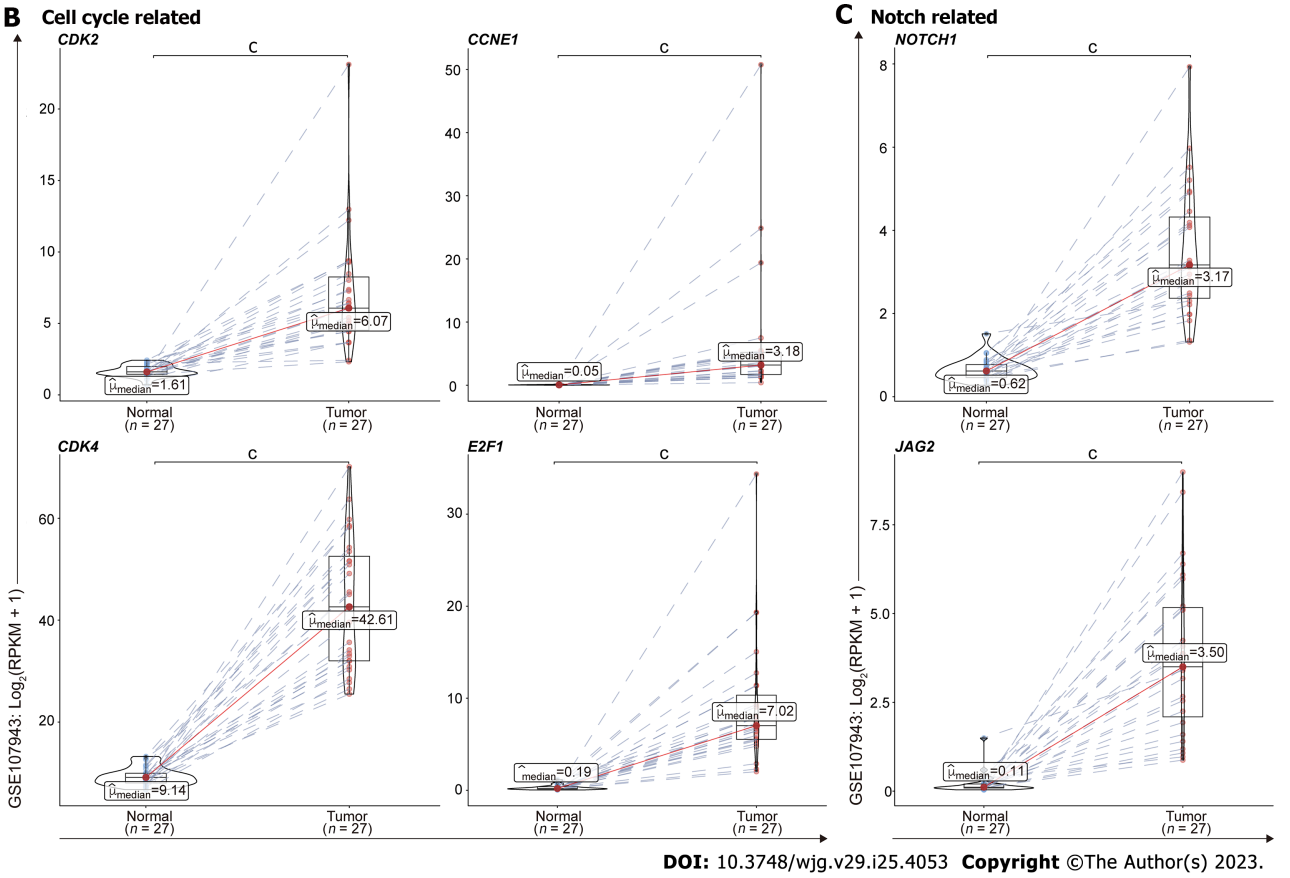
Cell cycle and Notch associated genes were correlated with poor prognosis in CCA patients

The cell cycle and Notch pathways were refined from the analysis of GSEA. These genes were found up-regulated in CCA tumor samples as well when compared with adjacent normal liver tissues. As we have found that targeting these pathways significantly suppressed CCA cell growth *in vitro*, we speculated that high expression of these genes may correlate with poor prognosis. To determine the correlation of these genes and CCA patient prognosis, we conducted the Kaplan-Meier survival analysis using the cell cycle and Notch pathways associated genes in CCA patients derived from two datasets, including GSE107943 and EBI (EGAD00001001076). It was found that high expression of cell cycle genes, including *CDK2*, *CDK6*, *CCNE1*, and *E2F1*, were negatively correlated with OS of CCA patients derived from the EBI database (EGAD00001001076) (Figure 7A). Similarly, high expression of Notch related genes, including *NOTCH1* and *JAG2*, were associated with poor prognosis in these patients (Figure 7B). These findings were further validated using the GSE107943 database. Consistently, high *CDK2*, *CDK4*, *CCNE1*, and *E2F1* were correlated with poor OS of CCA patients (Figure 7C). High *NOTCH1* expression was associated with poor OS and DFS in these patients as well (Figure 7D). Collectively, these data demonstrated that refining the signaling pathways associated with tumorigenesis of human CCA using bioinformatics approach could identify potential therapeutic targets for patients with this deadly disease (Figure 8).

DISCUSSION



The current study demonstrated that cell cycle and notch associated pathways are elevated in human CCA patients compared with adjacent normal tissues. These findings were verified using human biliary epithelial cells and CCA cell lines. Consistently, cell cycle and Notch associated genes were found increased in CCA cell lines compared with non-malignant human biliary epithelial cells. As it has not been investigated if the cell cycle and Notch associated pathways are up-regulated in the CCA transgenic mice, our studies therefore disclose the similar but novel findings in the transgenic CCA mouse model. Cell cycle and Notch associated genes were up-regulated in mouse CCA tumors when compared with age-matched mouse normal bile ducts. Besides, we demonstrated that targeting cell cycle and Notch pathways could inhibit cell growth in human CCA cell lines. Furthermore, we validated the GSEA findings using another dataset. Most importantly, we demonstrated that high expression of several cell cycle and Notch associated genes are highly associated with poor prognosis in human CCA patients in two databases.



Refining RNA sequencing results have been well studied in liver malignancy, including hepatocellular carcinoma and CCA[3,4,24,25]. By combining whole genomic sequencing and RNA sequencing data, it was previously suggested that intrahepatic CCA could be classified as inflammation and proliferation groups which have different clinical outcomes, specifically worse prognosis in the proliferation group[26]. Recently, it was also suggested that extrahepatic CCA could be classified as immune, mesenchymal, metabolic, and proliferation groups. Further analysis revealed specific potential therapeutic targets correspondent to different groups, *i.e.*, PD1/PD-L1 inhibitors were suggested to be potential therapies for the immune group of extrahepatic CCA patients[4]. Nevertheless, these potential therapeutic approaches have not been evaluated in preclinical models due to the possible reasons that no preclinical models could represent the individual group specifically. However, the recent study investigated the microenvironment-based classification of intrahepatic CCA and identified the inflammatory stroma class of intrahepatic CCA with T cell exhaustion and KRas mutation. Thus, they evaluated if the combination of KRas inhibitor and PD1 antibody could inhibit the malignant progression of CCA tumors established by using tail vein hydrodynamic injection of SB13 transposase, CRISPR/Cas9-sg-p19, pCaggs-KrasG12D. The model has high similarity to the inflammatory stroma intrahepatic CCA group. Their findings demonstrated that Kras inhibitor and PD1 antibody could

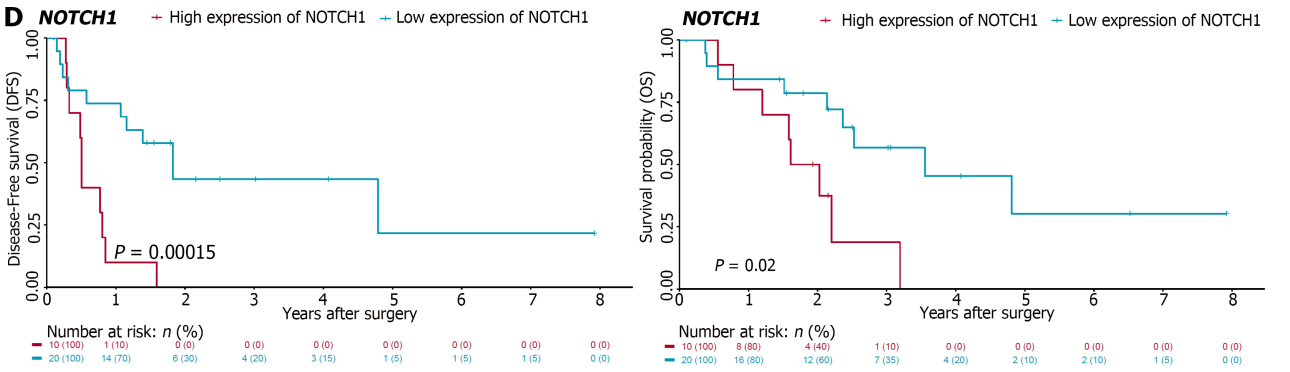

Figure 6 The generalizable oncogenic traits of cell cycle and Notch associated pathways in cholangiocarcinoma. GSEA identified cell cycle and Notch associated pathways significantly activated in tumors compared to the corresponding adjacent normal livers from GEO database (GSE107943) (A). Upper: Cell cycle associated pathways, including G2M checkpoint, E2F Targets, and Mitotic spindle gene sets; lower: Notch associated pathways, including epithelial mesenchymal transition, Hedgehog, and apical junction gene sets. The mRNA expression levels from the leading edges of cell cycle (B) and Notch (C) associated pathways were analyzed in CCA samples compared to the corresponding adjacent normal livers (pairs = 27). RPKM: Reads per kilobase million; Red: Intrahepatic cholangiocarcinoma; Blue: Para-cancerous normal liver; $^{c}P < 0.001$ when compared with the relevant normal control.

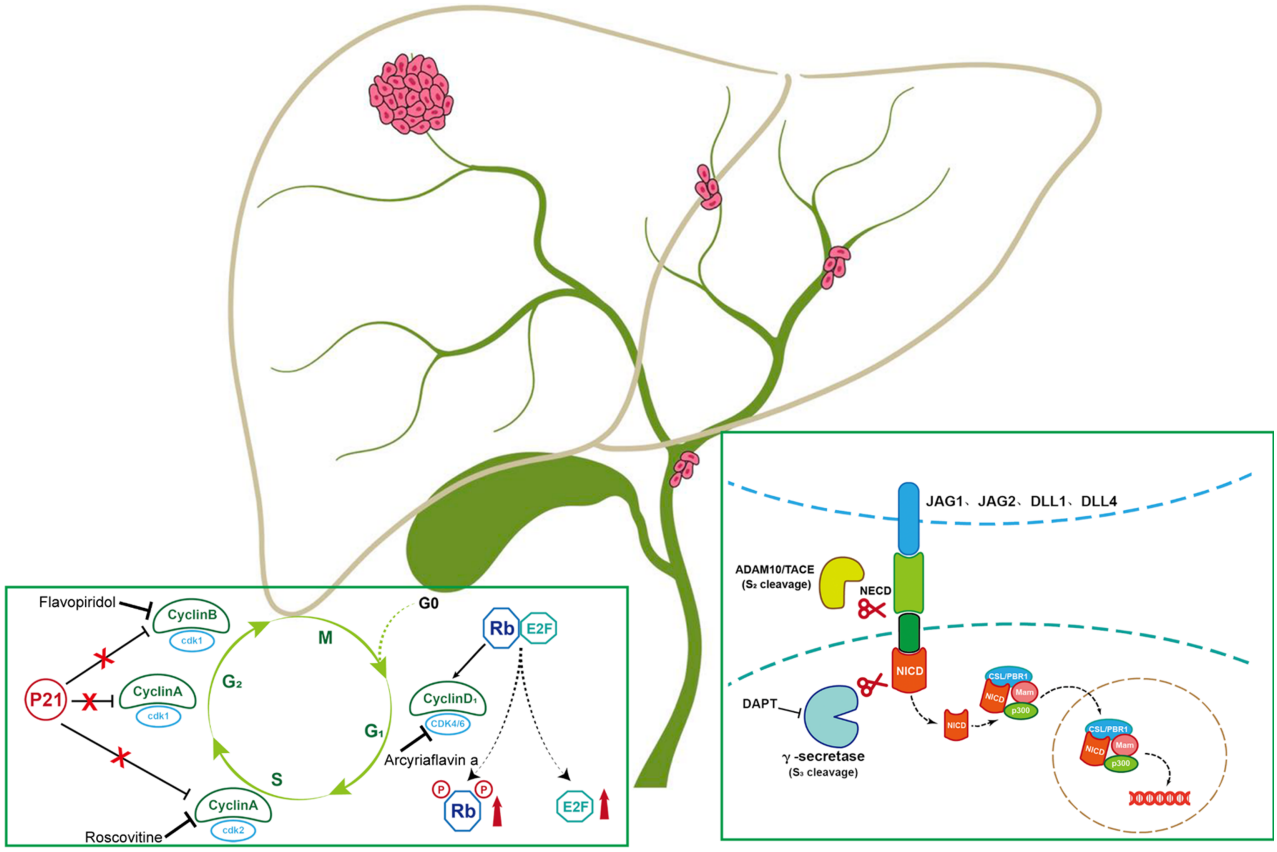
substantially inhibit tumor malignant progression[3]. Taken together, it is very likely to identify potential therapeutic targets by refining publicly available RNA sequencing datasets.

By using this approach, we found that Notch and cell cycle associated pathways are potential therapeutic targets in CCA tumors. It has been previously demonstrated that specific overexpression of intracellular domain of Notch 1 could lead to CCA development possibly through cyclin E1[27]. The Notch1 Ligand, JAG1 could activate Notch1 signaling cascade to initiate cyclin D1 transcriptional expression[28]. Both JAG1 and Notch1 contain the epidermal growth factor like domain[29] which could be hydroxylated by aspartate beta-hydroxylase[30-32]. Indeed, previous studies have demonstrated that aspartate beta-hydroxylase could promote CCA progression through the Notch1-mediated cyclin D1 pathway[33]. Cell cycle is tightly controlled by the tumor suppressor retinoblastoma protein (RB1)[34]. Although RB1 mutation is not a common event in CCA patients[35], dysregulated cell cycle regulating genes are often found in these patients. Dysregulated cell cycle control would lead to cancer cell proliferation. As discussed, intrahepatic CCA patients could be classified as proliferative and inflammatory groups[26]. Previous studies also demonstrated the therapeutic potential of targeting CCA tumors by using the specific inhibitor targeting cyclin dependent kinases 4 and 6[36,37] which are important mediator controlling RB1 phosphorylation. Phosphorylation of RB1 prevents its binding from the E2F1 transcriptional factor, which finely modulates cell cycle regulating genes[38]. Thus, phosphorylation of RB1 would lead to inactivation of RB1 tumor suppressor function, in turn promoting cell cycle progression. It was previously reported that aspartate beta-hydroxylase could promote RB1 phosphorylation to disrupt cell cycle regulation in CCA tumors[39]. Interestingly, aspartate beta-hydroxylase was reported to be highly expressed in CCA but barely detectable in normal bile duct tissues[39], suggesting the linkage of identified Notch1 and cell cycle associated pathways to aspartate beta-hydroxylase.



The current study has several limitations. (1) We did not evaluate if targeting Notch1 and cell cycle pathways could inhibit CCA progression using preclinical models. Actually, the previous studies have demonstrated that Notch1 inhibitor could be a potential therapeutic approach[27] and that targeting cell cycle with CDK4/6 inhibitors could suppress CCA progression[36,37]. Figure 8 The summary of dysregulated cell cycle and Notch pathways in cholangiocarcinoma progression. The cholangiocarcinogenesis driven by aberrant cell cycle and Notch pathways, which may be targeted by small molecular inhibitors.

initiated from a different angle by using transcriptomic analysis, it ended up with similar findings that Notch1 and cell cycle pathways could be potential targets in CCA patients; (2) We did not separate intrahepatic and extrahepatic CCA patients. We pooled the available data by combining intrahepatic and extrahepatic transcriptomic datasets due to the limited datasets publicly available; and (3) our studies did not investigate if elevation of cell cycle and Notch associated pathways may be used as early detection markers. Future studies will be needed to further determine potential therapeutic approaches specifically for intrahepatic and extrahepatic CCA patients, respectively.

CONCLUSION

In conclusion, our data, through mRNA and protein profiling, identified very high similarity between CCA tumors derived from the CCA transgenic mice and human CCA tumors, thus providing a potential preclinical CCA model for investigating the CCA tumorigenesis. Besides, our data suggested that cell cycle and Notch associated pathways could be potential therapeutic targets in CCA patients.

ARTICLE HIGHLIGHTS

Research background

The molecular pathogenesis of cholangiocarcinoma (CCA) remains largely unknown. Investigating the molecular mechanisms underlying CCA progression will potentially yield results toward identifying therapeutic targets.

Research motivation

Several mRNA sequencing (Seq) datasets in CCA samples are publicly available, but it remains unclear if the data can be validated in CCA cell lines, the transgenic CCA mouse model, and human CCA samples.

Research objectives

To summarize the mRNA Seq results and validate the findings in CCA cell lines, the transgenic CCA mouse model, and human CCA samples.

Research methods

Bioinformatic analysis, cell culture studies, transgenic mouse model, human CCA samples, and molecular strategies were used to determine molecular pathogenesis of CCA.

Research results

Through bioinformatic analysis, we found that cell cycle and Notch associated pathways are up-regulated in human CCA samples, compared to the non-tumor controls. We validated the findings in human CCA cell lines and the transgenic CCA mouse model.

Research conclusions

Our data, through mRNA and protein profiling, identified very high similarity between CCA tumors derived from the CCA transgenic mice and human CCA tumors, thus providing a potential preclinical CCA model for investigating CCA tumorigenesis. Besides, our data suggested that cell cycle and Notch associated pathways could be potential therapeutic targets in CCA patients.

Research perspectives

Systemic chemotherapy, gemcitabine and cisplatin, is recommended for CCA patients. However, the 5-year survival of CCA patients has not been significantly improved, suggesting an urgent need to develop novel therapeutic approaches.

Abstract

BACKGROUND

Acute bleeding due to esophageal varices (EVs) is a life-threatening complication in patients with cirrhosis. The diagnosis of EVs is mainly through upper gastrointestinal endoscopy, but the discomfort, contraindications and complications of gastrointestinal endoscopic screening reduce patient compliance. According to the bleeding risk of EVs, the Baveno VI consensus divides varices into high bleeding risk EVs (HEVs) and low bleeding risk EVs (LEVs). We sought to identify a non-invasive prediction model based on spleen stiffness measurement (SSM) and liver stiffness measurement (LSM) as an alternative to EVs screening.

AIM

To develop a safe, simple and non-invasive model to predict HEVs in patients with viral cirrhosis and identify patients who can be exempted from upper gastrointestinal endoscopy.

METHODS

Data from 200 patients with viral cirrhosis were included in this study, with 140 patients as the modelling group and 60 patients as the external validation group, and the EVs types of patients were determined by upper gastrointestinal endoscopy and the Baveno VI consensus. Those patients were divided into the HEVs group (66 patients) and the LEVs group (74 patients). The effect of each parameter on HEVs was analyzed by univariate and multivariate analyses, and a non-invasive prediction model was established. Finally, the discrimination ability,

calibration ability and clinical efficacy of the new model were verified in the modelling group and the external validation group.

RESULTS

Univariate and multivariate analyses showed that SSM and LSM were associated with the occurrence of HEVs in patients with viral cirrhosis. On this basis, logistic regression analysis was used to construct a prediction model: Ln [P/(1-P)] = -8.184 -0.228 × SSM + 0.642 × LSM. The area under the curve of the new model was 0.965. When the cut-off value was 0.27, the sensitivity, specificity, positive predictive value and negative predictive value of the model for predicting HEVs were 100.00%, 82.43%, 83.52%, and 100%, respectively. Compared with the four prediction models of liver stiffness-spleen diameter to platelet ratio score, variceal risk index, aspartate aminotransferase to alanine aminotransferase ratio, and Baveno VI, the established model can better predict HEVs in patients with viral cirrhosis.

CONCLUSION

Based on the SSM and LSM measured by transient elastography, we established a non-invasive prediction model for HEVs. The new model is reliable in predicting HEVs and can be used as an alternative to routine upper gastrointestinal endoscopy screening, which is helpful for clinical decision making.

Key Words: Cirrhosis; High-risk esophageal varices; Non-invasive prediction model; Spleen stiffness measurement; Liver stiffness measurement; Upper gastrointestinal endoscopy

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The non-invasive prediction model for predicting high risk esophageal varices (HEVs) in patients with viral cirrhosis was successfully established based on the spleen stiffness measurement and liver stiffness measurement. It is a novel model that has not been reported. The model was shown to be better than previous prediction models. The new model is reliable in predicting HEVs and can be used as an alternative to routine upper gastrointestinal endoscopy screening, which is helpful for clinical decision making.

INTRODUCTION

Liver cirrhosis is the end stage of chronic liver disease. When hepatic venous pressure gradient (HVPG) ≥ 10 mmHg is defined as clinically significant portal hypertension (CSPH), the patients who meet this criteria may suffer from complications such as esophageal variceal bleeding, ascites, hepatic encephalopathy, and jaundice due to portal hypertension and liver insufficiency[1,2]. Rupture of esophageal varices (EVs) is a common and life-threatening complication in patients with liver cirrhosis. The incidence of EVs bleeding is approximately 5%-15% per year, the re-bleeding rate within 6 wk after EVs rupture bleeding is 30% to 40%, and the mortality rate is 15%-25%[3-5]. The severity of liver cirrhosis, the size of EVs and the presence or absence of the red sign (RS) are related indicators of EVs bleeding [6]. For routine assessment of the above indicators, the Baveno VI consensus recommends that patients with cirrhosis need to undergo regular screening upper gastrointestinal endoscopy so that appropriate preventive treatment can be administered to prevent variceal bleeding events[7]. To date, HPVG and upper gastrointestinal endoscopy are considered the gold standards for the assessment of PH and EVs, respectively[6]. However, the prevalence of varicose veins requiring treatment (VNT), as defined by the Baveno VI guidelines, is very low in Compensated advanced chronic liver disease (cACLD) patients who are detected at an early stage[8]. HPVG and EGD are invasive procedures and expensive, and the patient compliance associated with them is poor[9,10]. Therefore, in clinical practice, it is necessary to develop a safe, non-invasive and patient-acceptable prediction model that can not only prevent frequent HPVG or gastrointestinal endoscopy examinations but also better predict HEVs in patients with viral cirrhosis. With the development of transient elastography (TE), studies have shown that liver stiffness

(LS) and spleen stiffness (SS) detected by TE are associated with liver fibrosis, significant portal hypertension, and EVs. SS is increased in patients with viral hepatitis, and SS is positively correlated with HVPG, which has good predictive performance for CSPH and EVs in patients with cACLD[11-13].

At present, in addition to ultrasound, CT, MRI, and other imaging methods, there are also several common prediction models[14,15]. The LS-spleen diameter to platelet (PLT) ratio score (LSPS), variceal risk index (VRI), aspartate aminotransferase (AST) to alanine aminotransferase (ALT) ratio (AAR) and Baveno VI model have all achieved good clinical effects in predicting HEVs[16-19]. In addition, the Baveno VI consensus states that LS measurement (LSM) combined with PLT helps to exclude HEVs[8, 19,20]. To initially predict HEVs in patients with viral cirrhosis, the aim of this study is to establish a non-invasive prediction model that can predict HEVs based on SS measurement (SSM) and LSM and to evaluate the accuracy of the new model in identifying HEVs in patients with viral cirrhosis who can be exempted from upper gastrointestinal endoscopy.

MATERIALS AND METHODS

Patients and study design

The study was authorized by the Ethics Committee of the Second Affiliated Hospital of Xi'an Jiaotong University (Xi'an, Shaanxi Province, China). As a retrospective study; therefore, the Ethics Committee waived the informed consent. This study retrospectively analyzed the data of patients with viral cirrhosis who were admitted to the Second Affiliated Hospital of Xi'an Jiaotong University and underwent upper abdominal computed tomography (CT) examination from March 2020 to November 2022. The inclusion criteria were: (1) Age > 18 years old; (2) patients with hepatitis B and hepatitis C cirrhosis; (3) patients who underwent endoscopy, upper abdominal CT, and laboratory examinations with complete results; and (4) the interval between two examinations was not more than 3 mo. Exclusion criteria: (1) Other liver injury factors, such as alcoholic liver disease, autoimmunity, metabolic liver disease, occult liver cirrhosis, *etc*; (2) suspicious liver tumor; (3) history of liver resection, liver transplantation or splenectomy; (4) frequent use of proton pump inhibitors; (5) other diseases that may impact the haemodynamics of the splenic vein or portal vein, such as cavernous degeneration, thrombosis, embolism; (6) cirrhotic patients with moderate or massive ascites; (7) previous treatment of portal hypertension, such as splenectomy, transjugular intrahepatic portosystemic shunt, endoscopic therapy, and nonselective β-blocker therapy; (8) diseases may affect the liver or spleen size, such as cysts, leukaemia, thrombocytopenic purpura, haemolytic anaemia, multiple myeloma, *etc*; (9) patients with a history of esophageal bleeding undergoing endoscopic or surgical treatment; (10) severe malnutrition or weight loss; (11) unreliable LSM: Quartile range/median > 0.3, success rate < 60%, or the number of effective measurements < 10; or (12) other conditions affecting LSM, such as body mass index > 35 kg/m^2.

A total of 140 patients who met the inclusion criteria were selected as the modelling group. According to the results of upper gastrointestinal endoscopy and the Baveno VI criteria, the patients were divided into the HEVs group and the LEVs group; 66 patients were HEVs patients, and 74 patients were LEVs patients. In addition, 60 patients who met the inclusion criteria were used as the validation group. The patient's data were collected when the model was established, and the data collection procedure and the model application did not interfere with each other.

Definition of EVs

Patients with liver cirrhosis were graded and scored using the Child-Pugh scoring system[21]. According to Baveno VI criteria, HEVs were defined as EVs with a diameter ≥ 5 mm, EVs with a diameter ≤ 5 mm and a positive RS, EVs in patients with Child grade C, and EVs that did not meet these criteria were LEVs with a low risk of bleeding[22,23].

CT scan-based liver and spleen volume measurement

The CT examinations were conducted by a multislice spiral CT scanner (GE 128-slice spiral CT scanner; Linux Medical System, United States) with a 5 mm reconstructed layer thickness, and the time interval was 5 s.

Actual liver volume measured by CT (CTLV), actual spleen volume measured by CT (CTSV), portal vein diameter (PVD) and spleen long diameter (SLD) were simultaneously measured by experienced radiologists who did not know the basic information of the patients. CTLV and CTSV were obtained by manually tracing the surface area of the liver and spleen at each level and multiplying by the layer thickness. The entire measurement process requires active avoidance of large blood vessels, gallbladder, and fissure. The SLD was defined as the length of the superior pole to the inferior line of the spleen at the plane of maximum surface area. The PVD needs to be measured at the midpoint between the portal vein bifurcation site and the vein confluence site[24].

Laboratory examination

For each patient, data on age, sex, height, weight, medical history, medication use, the presence or absence of ascites, and Child-Pugh score were collected. The white blood cell count, red blood cell count, PLT, ALT, AST, total bilirubin (TBil), alkaline phosphatase (ALP), glutamine transferase (GGT), albumin (ALB), total cholesterol (TCHO), prothrombin time (PT), international prothrombin ratio (INR), and prothrombin activity (PTA) of all patients included in the study were collected. The blood test was tested by an XN-9000 analyser (Xisen Meikang Medical Electronics Co. Ltd., Shanghai, China), and the coagulation function was tested by a Sysmex CO-CS-1500 system (SYSMEX Co., Ltd, Kobe, Japan) and the liver function test was performed using a Cobas 8000 analyser (Roche Diagnostics, Mannheim, Germany).

Liver and SS measurements by TE

LSM and SSM were measured in all patients using FibroScan (Echosens, Paris, France) and FibroTouch (Hai's Medical Technology Center, Beijing, China). The LSM was assessed by a trained and experienced operator after at least 4 h of fasting, and the SSM was performed on the same day as the LSM assessment. All measurements were obtained by experienced operators who had performed at least 300 tests in patients with chronic liver disease. The TE results of the patients were collected retrospectively, and the obtained results were expressed in kilopascals (kPa). The interquartile range (IQR) was defined as the intrinsic variation index between the 25th and 75th percentiles of the LS results containing 50% of the valid measurements. Therefore, LSM and SSM values were considered to be reliable when at least 10 valid measurements were obtained and the results were reliable, with an overall success rate of more than 60% and IQR/median ≤ 0.3[25,26].

Upper gastrointestinal endoscopy

Upper gastrointestinal endoscopy was performed by an endoscopic operator who was experienced in the assessment of patients with cirrhosis (with a minimum of 500 endoscopic procedures). Endoscopic examinations were performed to determine whether the patients had EVs, and if so, the EVs were graded according to the location (L), shape and size (F), colour (C), and presence or absence of RS of the lesion.

Non-invasive score of EVs

The non-invasive prediction models we choose to compare were as shown blow: LSPS = [LSM (KPa) × SLD (cm)]/PLT (× 10^9/L)[16]; VRI = -4.364 + 0.538 × SLD-0.049 × PLT-0.044 × LSM + 0.001 × (LSM × PLT)[17]; AAR = AST/ALT[18] and the Baveno VI criteria proposed by the consensus conference. The Baveno VI criteria were defined as LSM < 20 kPa and platelet count > 150 × 10^9/L. The extended Baveno VI criteria were defined as LSM < 25 kPa and platelet count > 110 × 10^9/L[8,27]. The results of upper gastrointestinal endoscopy were used as the gold standard. The receiver operating characteristic (ROC) curves of LSPS, VRI, AAR and Baveno VI were drawn, and the area under the ROC curve (AUC), sensitivity, specificity and Youden index were calculated to evaluate the performance of the new model and the previous four models in identifying HEVs. The point with the largest sum of sensitivity and specificity was selected as the best cut-off value for the diagnosis of HEVs.

EVs saluation of new prediction models

The discrimination ability of the new model was assessed by the ROC curves in the modelling group and the external validation group. The *Z* test was used to evaluate differences in ROC curves. If there was no significant difference in the ROC between the two groups and AUC > 0.7, the model was considered to have good discrimination ability. The calibration ability of the prediction model was evaluated by the Hosmer-Lemeshow test and the two sets of calibration scatter plots. Decision curve analysis (DCA) was performed to evaluate the clinical efficacy of the new model.

Statistical analysis

SPSS 26.0 and R software (IBM SPSS, Chicago, IL, United States) were used for statistical analysis. Data are presented as the mean ± SD. The chi-square test was used to compare the measurement data between the HEVs group and the LEVs group. The Mann-Whitney *U* test was used for univariate analysis of continuous variable measurement data, and WALD backwards regression analysis was used for multivariate analysis. SPSS 26.0 software was used to draw the ROC curve and calculate the AUC to evaluate the diagnostic performance of the model. The maximum corresponding point of the Youden index was selected as the best cut-off value, and a positive prediction result was defined as equal to or greater than the best cut-off value. The best discrimination probability threshold, sensitivity, specificity and predictive value were calculated, and the diagnostic accuracy was compared. The higher the Youden index (1% or 100%), the more effective the correlation. Hosmer-Lemeshow test results, calibration charts and DCA were obtained using R software. All statistical tests were two-sided, with an alpha value of 0.05 and a statistical significance threshold of $P < 0.05$.

RESULTS

Baseline characteristics of the patients

Tables 1 and 2 List the baseline characteristics of the modelling group and the external validation group, respectively. In the LEVs group, the mean age was 50.88 years ± 11.6 years, 43 (58.1%) were male, and 61 (82.4%) had hepatitis B. The age of the HEVs patients was 55.36 years ± 11.1 years old, 37 (56.1%) were male, and 53 (80.3%) had hepatitis B. In the modelling group, there was a significant difference in age between the HEVs group and the LEVs group ($P < 0.05$) but no significant difference in sex or hepatitis type ($P > 0.05$), and the two groups were comparable. In the external validation group, there was no significant difference in sex, age or hepatitis type ($P > 0.05$).

Univariate analysis of HEVs

T tests and non-parametric rank sum tests were used for the univariate analysis. The summarized results are shown in Table 3. There were significant differences in SSM, PLT, LSM, ALT, AST, GGT, SLD, PT, INR, PTA, PVD, CTLV, and CTSV between the HEVs group and the LEVs group ($P < 0.05$). There were no significant differences in ALP, TBil, and TCHO between the two groups ($P > 0.05$).

Multivariate analysis of HEVs

The parameters shown in Table 3 with statistically significant differences between the HEVs and LEVs groups were analyzed by multivariate analysis using backwards WALD regression analysis. As shown in Table 4, the SSM and LSM between the HEVs group and LEVs group were significantly different ($P < 0.05$). There were no significant differences in PLT, ALT, AST, GGT, SLD, PT, INR, PTA, PVD, CTLV, and CTSV ($P > 0.05$).

Establishment of a non-invasive prediction model

Based on the results of the multivariate analysis, the parameters with no statistically significant difference between the two groups were excluded, and the parameters with statistically significant differences, including SSM and LSM, were used to establish a non-invasive prediction model. The logistic regression analysis showed that SSM and LSM were independent factors affecting the occurrence of HEVs and were statistically significant ($P < 0.05$). As shown in Table 5, the model was as follows: Ln [P/(1-P)] = -8.184 - 0.228 × SSM + 0.642 × LSM. HEVs in patients with viral cirrhosis were negatively correlated with SSM and positively correlated with LSM.

Comparison of non-invasive prediction models

The new model was compared with other models reported to predict EVs in patients with liver cirrhosis, namely, the LSPS, VRI, AAR, and Baveno VI models. The sensitivity, specificity and AUC of the new model based on the SSM and LSM and LSPS, VRI, AAR and Baveno VI models were calculated. The cut-off value of the model was defined as the maximum value of the sum of the specificity and sensitivity. Patients were considered to have HEVs when the P value calculated by the established formula was greater than the cut-off value. As shown in Figure 1A and Table 6, the AUC of this model was 0.965, while the AUCs of LSPS, VRI, AAR and Baveno VI were 0.835, 0.744, 0.641, and 0.675, respectively. The AUC > 0.7 indicated the good discrimination power of the model. The higher the AUC is, the better the discriminative power of the model, so the new model has good discriminative power.

Diagnostic accuracy of non-invasive tests for predicting HEVs

The accuracy, positive predictive value and negative predictive value of LSPS, VRI, ARR, Baveno VI, and the new model of 140 patients in the modelling group were calculated according to the calculation formula. As shown in Table 7, the non-invasive prediction model shown in this study had an accuracy of 89.30% and a positive predictive value of 83.52%. The accuracy and positive predictive values suggest the likelihood that the new model can correctly diagnose HEVs, with higher values indicating a more correct diagnosis.

Discriminating ability edicting HEVs

Evaluation of the ability of the non-invasive model was performed by drawing the ROC curve of the established new model in the external validation group and using the Z test to compare the AUC curve between the modelling group and the external validation group and to evaluate the discriminative power of the new model. The AUC of the new model for predicting HEVs in the modelling group was 0.965, which was higher than that of the LSPS, VRI, AAR, and Baveno VI models. The AUC of the new model in the external validation group was 1. The Z test result was 0.896, and the *P* value was 0.37, indicating that there was no significant difference between the modelling group and the external validation group. The ROC curve of the external validation group is shown in Figure 1B.

EVs saluation of the calibration ability of the new model

The Hosmer-Lemeshow test was used to calculate the χ^2 value of the modelling group and the external

LSPS: Liver stiffness-spleen diameter to platelet ratio score; VRI: Variceal risk index; AAR: Aspartate aminotransferase/alanine aminotransferase ratio; BavenoVI: Baveno VI criteria were defined as liver stiffness measurement < 20 kPa and platelet count > 150 × 10^9 /L; CI: Confidence interval.

validation group to evaluate the calibration ability of the new model. The results showed that χ^2 was -10.39 in the modelling group and 0.03 in the external validation group. The P values were 0.999 and 1.000, respectively. Both the groups' P value were greater than 0.05, indicating that the model could predict HEVs accurately. The calibration scatter plots of the two groups were shown in Figure 2. As seen from the figure, all scatter points fluctuated around the baseline without significant deviation because the *P* values of both groups were greater than 0.05 and the difference between the groups was not statistically significant. The results showed that the HEVs patients who were predicted to have viral

Table 7 Comparison of various parameters of each model

	Sensitivity	Specificity	Accuracy, %	Positive predictive value, %	Negative predictive value, %	Cutoff value

cirrhosis by using the new model were in good agreement with the actual HEVs patients.

EVs salvation of the clinical efficacy of the new model

DCA was plotted against the probability of actual HEVs occurrence by predicting the probability of the modelling group and the external validation group by the new model. The DCA of the two groups is shown in Figure 3. In the DSA curve, the two dashed lines represent the two extreme cases, and the black line indicates that the new model predicts there was no HEVs, and a net clinical benefit of zero. The other grey line with a negative slope indicates that the new model predicts HEVs in all patients with viral cirrhosis, and the net clinical benefit is a back-slope with a negative slope[28]. The red line is the new model's DCA. As the DCA curve shown, the red line was higher than the black and grey lines, indicating that when the new model was applied to the modelling group and the external validation group, both groups of patients could benefit, so the new model had certain clinical efficacy.

Figure 3 Adjusted decision curve analysis of data of patients. A: Modelling group; B: External validation group. The black line indicates that in extreme cases, the new model predicted that there were no high-risk esophageal varices in all patients with viral cirrhosis, and the clinical net benefit was 0. The gray curve indicates that in extreme cases, the new model predicts there are high-risk esophageal varices in all patients with viral cirrhosis, the clinical net benefit is the negative slope. The red line indicates that the new model has a clinical net benefit. The red line is higher than the black and gray lines, indicating that patients in the modelling group can benefit from the new model.

DISCUSSION

Long-term chronic viral hepatitis can lead to liver cirrhosis and is associated with high morbidity and mortality; therefore, it is a public health concern that deserves attention[29-31]. EVs rupture and bleeding are common causes of death in patients with liver cirrhosis. Clinical guidelines recommend the use of upper gastrointestinal endoscopy in screening and periodic reexamination of patients with cirrhosis regardless of the disease cause[9]. According to the results of upper gastrointestinal endoscopy and the Baveno VI criteria, EVs were divided by the low bleeding risk EVs (LEVs) and the high bleeding risk EVs (HEVs). For patients with HEVs, early precation measures can significantly reduce the esophageal variceal bleeding risk[22,32]. However, the invasiveness of upper gastrointestinal endoscopy, the high price, and the risk of anaesthesia make the compliance of patients to upper gastrointestinal endoscopy very low[9,10]. Considering that many patients do not have EVs in the early stage of liver cirrhosis, there is a need for non-invasive, simple, and safe means to identify liver cirrhosis patients with HEVs. In addition to upper gastrointestinal endoscopy, a variety of imaging methods, such as ultrasound, CT, and MRI, can be used to predict HEVs. However, these three methods cannot visually observe EVs, and the accuracy of identifying HEVs is poor[33]. A number of non-invasive models have been developed to predict HEVs, and several studies have shown that the LSPS, VRI, AAR, and Baveno VI models have achieved good results in predicting HEVs. Measurement of LS and SS by TE (using FibroScan) is a fast, non-invasive, easy to perform and reproducible procedure for predicting the presence of clinically significant EVs and PH, so LS and SS were measured by TE in this study[34]. In this study, to ensure the homogeneity of aetiology, we included patients with cirrhosis and HBV/HCV infection. Our study showed that LSM and SSM were two independent variables associated with the presence of HEVs. The results of our study are similar to those of several studies. LSM is associated with PH, and LSM combined with other indicators can predict HEVs[35,36]. Splenomegaly is common in patients with chronic viral cirrhosis, and splenic blood flow enters the portal vein system through the splenic vein. Therefore, SSM can simultaneously reflect static resistance fibrosis of the liver (LSM can also reflect) and dynamically capture PH-related visceral hypoperfusion, changes in spleen results, changes in blood flow, and PH-induced splenic fibrosis[37].

In this study, we constructed a non-invasive prediction model including LSM and SSM. The AUC of the new model was 0.965, the accuracy was 89.30%, which was better than that of the LSPS, VRI, AAR, and Baveno VI models, and the new model showed good diagnostic performance. When the optimal cut-off value was 0.27, the sensitivity and negative predictive value (NPV) of the new model in the modelling group were both 100%, and due to the Baveno VI criteria and other models, the new model could best identify non-HEVs patients so that these patients could be spared from undergoing upper gastrointestinal endoscopy. Morishita *et al*[38] used a similar approach in 135 patients with HCV-related cirrhosis to predict the presence of HEVs in patients with viral cirrhosis using a single indicator of LSM, and their results showed that the AUC of LSM for predicting the presence of HEVs was 0.868. The sensitivity, specificity, positive predictive value and negative predictive value were 81%, 82%, 69%, and 89%, respectively[38]. Similarly, in another study, Stefanescu *et al*[5] used a single-indicator SSM to assess the presence of HEVs, selecting an SSM@50 Hz with a 95% sensitivity for the best cut-off value [5]. Moreover, many studies have shown that when the HVPG value is ≥ 12 mmHg, LSM alone cannot reliably diagnose or exclude the risk grade of varices because of the poor correlation of extrahepatic factors. However, SSM can evaluate the severity of PH, the presence of EVs and the risk of bleeding but cannot predict the grade of EVs[39]. Therefore, this study developed and validated whether a non-invasive prediction model based on the combination of SSM and LSM indicators can be used as a useful tool to assess the severity of EVs and the risk of upper gastrointestinal bleeding (UGIB). These results of our study suggest that in the majority of patients with viral cirrhosis evaluated, the new model can

accurately exclude patients with HEVs, thereby allowing these patients to avoid endoscopy or prophylactic therapy. Furthermore, the higher NPV and sensitivity, regardless of the cirrhosis severity, suggest that use of the new model may be more cost-effective, as endoscopic screening of patients with both compensated and decompensated cirrhosis proved to be cost-effective[40]. In addition, a second independent dataset was used to externally validate the clinical utility of the new model, and the results showed that the new model had high discrimination power. In addition, DCA was cited to illustrate the clinical benefit of the new model, and both the modelling group and the external validation group could benefit from the new model. In addition, the included indicators in the new model can be obtained by TE and B-ultrasound, which are non-invasive, inexpensive, do not require radiation, are highly feasible in clinical practice, and are easy to popularize in clinical work.

Generally speaking, we have successfully developed a non-invasive prediction model using LSM and SSM indicators to predict the presence of HEVs in patients with viral cirrhosis, which has not been reported in the literature. Compared with other models LSPS, VRI, AAR, and Baveno VI, the new model has a good diagnostic performance, a high discrimination ability, calibration ability and a clinical application value. In addition, we enrolled patients with viral cirrhosis, which provided good consistency while minimizing bias in the results. However, this retrospective study has limitations. First, the sample size of this study is relatively small, and more data need to be collected for evaluation. Second, the patients in this study were all Chinese, and it is unclear whether this model can be applied in other ethnic groups. Additionally, because the patients in this study were all patients with viral cirrhosis and because changes in liver and spleen volume can vary with cirrhosis from different causes, it is unclear whether the new model can be applied to cirrhosis from other causes.

In conclusion, the new model based on SSM and LSM indicators, ln [P/(1-P)] = -8.184 - 0.228 × SSM + 0.642 × LSM, can effectively rule out the presence of HEVs in patients with viral cirrhosis, and this model needs to be further verified in prospective trials. This model helps physicians recognize the presence of HEVs in patients with viral cirrhosis, make more informed decisions, and provide appropriate preventive treatment.

CONCLUSION

The new model can effectively rule out the presence of HEVs in patients with viral cirrhosis and can be used as an alternative to routine upper gastrointestinal endoscopy screening.

ARTICLE HIGHLIGHTS

Research background

Acute bleeding due to esophageal varices (EVs) is a life-threatening complication in patients with cirrhosis. The diagnosis of EVs is mainly through upper gastrointestinal endoscopy, but the discomfort, contraindications and complications of gastrointestinal endoscopic screening reduce patient compliance.

Research motivation

To develop a safe, simple and non-invasive model to predict high risk EVs (HEVs) in patients with viral cirrhosis and identify patients who can be exempted from upper gastrointestinal endoscopy.

Research objectives

To establish a non-invasive prediction model based on spleen stiffness measurement (SSM) and live stiffness measurement (LSM) as an alternative to EVs screening.

Research methods

Two hundred Chinese adults, from March 2020 to November 2022, were included at the Second Affiliated Hospital of Xi'an Jiaotong University. Required data were collected by the medical records, and the EVs types of patients were determined by upper gastrointestinal endoscopy and the Baveno VI consensus. The effect of each parameter on HEVs was analyzed by univariate and multivariate analyses, and a non-invasive prediction model was established, and then the effect of each parameter on HEVs was analyzed by univariate and multivariate analyses, and a non-invasive prediction model was established.

Research results

After univariate and multivariate analyses, SSM and LSM were used to established a prediction model. The new non-invasive model was better than other four models to predict HEVs in patients with viral cirrhosis.

Research conclusions

The new model is reliable in predicting HEVs and can be used as an alternative to routine upper gastrointestinal endoscopy screening, which is helpful for clinical decision making.

Research perspectives

In the future, we will try to apply the new model to predict HEVs in patients with viral cirrhosis.

ACKNOWLEDGEMENTS

We thank all the participants in this study.

Abstract

BACKGROUND

It is estimated that 58 million people worldwide are infected with the hepatitis C virus (HCV). Patients with severe psychiatric disorders could not be treated with previously available interferon-based therapies due to their unfavorable side effect profile. This has changed with the introduction of direct-acting antivirals (DAA), although their real-life tolerance and effectiveness in patients with different psychiatric disorders remain to be demonstrated.

AIM

To evaluate the effectiveness and safety of DAA in patients with various mental illnesses.

METHODS

This was a retrospective observational study encompassing 14272 patients treated with DAA for chronic hepatitis C in 22 Polish hepatology centers, including 942 individuals diagnosed with a mental disorder (anxiety disorder, bipolar affective disorder, depression, anxiety-depressive disorder, personality disorder, schizophrenia, sleep disorder, substance abuse disorder, and mental illness without a specific diagnosis). The safety and effectiveness of DAA in this group were compared to those in a group without psychiatric illness (n = 13330). Antiviral therapy was considered successful if serum ribonucleic acid (RNA) of HCV was undetectable 12 wk after its completion [sustained virologic response (SVR)]. Safety data, including the incidence of adverse events (AEs), serious AEs (SAEs), and deaths, and the frequency of treatment modification and discontinuation, were collected during therapy and up to 12 wk after treatment completion. The entire study population was included in the intent-to-treat (ITT) analysis. Per-protocol (PP) analysis concerned patients who underwent HCV RNA evaluation 12 wk after completing treatment.

RESULTS

Among patients with mental illness, there was a significantly higher percentage of men, treatment-naive patients, obese, human immunodeficiency virus and hepatitis B virus-coinfected, patients with cirrhosis, and those infected with genotype 3 (GT3) while infection with GT1b was more frequent in the population without psychiatric disorders. The cure rate calculated PP was not significantly different in the two groups analyzed, with a SVR of 96.9% and 97.7%, respectively. Although patients with bipolar disorder achieved a significantly lower SVR, the multivariate analysis excluded it as an independent predictor of treatment non-response. Male sex, GT3 infection, cirrhosis, and failure of previous therapy were identified as independent negative predictors. The percentage of patients who completed the planned therapy did not differ between groups with and without mental disorders. In six patients, symptoms of mental illness (depression, schizophrenia) worsened, of which two discontinued treatments for this reason. New episodes of sleep disorders occurred significantly more often in patients with mental disorders. Patients with mental illness were more frequently lost to follow-up (4.2% *vs* 2.5%).

CONCLUSION

DAA treatment is safe and effective in HCV-infected patients with mental disorders. No specific

psychiatric diagnosis lowered the chance of successful antiviral treatment.

Key Words: Hepatitis C; Mental disorders; Direct-acting antivirals

Core Tip: In the population of patients with mental illness, the prevalence of hepatitis C virus infection is many times higher than in the general population. In the era of interferon-based therapy, these patients had minimal access to antiviral treatment due to contraindications to interferon with the risk of exacerbation of psychiatric diseases. Their situation has improved with the introduction of direct-acting antivirals, but data from real-world studies are scarce. This retrospective analysis carried out in clinical practice confirmed that the good safety profile and treatment effectiveness are not inferior to those obtained in a population without mental disorders.

INTRODUCTION

Hepatitis C virus (HCV) infection, currently affecting approximately 58 million individuals worldwide, still poses a severe global issue[1]. It remains a major cause of chronic liver disease worldwide, liable to progress to cirrhosis and hepatocellular carcinoma, and can lead to various extrahepatic manifestations [2]. The prevalence of HCV infection is significantly increased (3-fold to 20-fold) in individuals with mental disorders compared to the general population. This includes patients with depression, bipolar disorder, schizophrenia, and personality disorders. In patients with substance abuse, particularly with intravenous drug use, the reported percentage of HCV infection is as high as 60%-70%[3,4]. In addition, preexisting mental illness may complicate HCV treatment by adversely affecting treatment adherence[5-7]. Moreover, HCV infection itself can further exacerbate or accelerate psychiatric symptoms[6,8].

In the past, treatment of patients with severe psychiatric disorders infected with HCV was highly challenging due to neuropsychiatric side effects (*e.g.*, anxiety, affective, cognitive, and psychotic symptoms) of previously used interferon (IFN)-based therapies[9]. Their situation has improved with the introduction of direct-acting antivirals (DAA), which are well tolerated and easier to dose[10]. Whether they are also effective in different mental disorders requires further studies. Observations from the IFN-era period indicate that these disorders were not necessarily associated with a worse sustained viral response (SVR) rate[11-13]. However, the observations encompassing the period when DAA were introduced are scarce, include small study groups, only particular diseases (*e.g.*, depression), or treat them collectively as mental disorders[14-17]. The results of one multicenter study evaluating a single DAA regimen among psychiatric patients by type of mental disorder have recently been published, but evidence is still needed from large populations of real-world experience that discriminate between individual psychiatric diseases treated with different DAA options and compare the results to the group without mental disorders while controlling for confounding variables[18].

To this end, the present study aimed to evaluate the effectiveness and safety of DAA in patients with various mental illnesses: Anxiety, anxiety-depressive disorder, bipolar disorder, depression, personality disorder, schizophrenia, sleep disorder, substance abuse, and mental illness without a specific diagnosis. In order to achieve this goal, a retrospective, real-world analysis of the Polish population of HCV-infected patients treated with DAA between 2015 and 2022 was conducted.

MATERIALS AND METHODS

Data collection

The data of 14272 patients treated with DAA for chronic hepatitis C (CHC) from 1 July 2015 to 30 December 2022, included in the EpiTer-2 observational study database, were analyzed. This study was conducted under the auspices of the Polish Association of Epidemiologists and Infectiologists and

included data from 22 Polish hepatology centers on treating CHC in everyday practice. The choice of CHC therapy was at the physician's discretion and followed the existing recommendations of the Polish Group of Experts for HCV and the recommendations of the National Health Fund. The data were collected retrospectively and included age, sex, body mass index, the severity of liver disease, HCV genotype (GT), human immunodeficiency virus (HIV) and/or hepatitis B virus (HBV) coinfection, previous and current CHC treatment, presence of hepatocellular carcinoma, HCV viral load, alanine transaminase activity, albumin, hemoglobin, creatinine, and platelets level.

Assessment of mental disorders

The patients were divided into two groups: 942 patients with concomitant mental illness (group A) and 13330 without psychiatric disorders (group B). Mentally ill patients were under the care of psychiatrists, who diagnosed their mental illness, prescribed and monitored psychiatric treatment.

Assessment of liver disease severity

The severity of liver disease was assessed using non-invasive methods of fibrosis assessment: Transient elastography or shear-wave elastography with an Aixplorer device (SuperSonic Imagine, Aix-en-Provence, France) or transient FibroScan. Based on the METAVIR score, according to the guidelines of the European Association for the Study of the Liver, the cutoff value of 13 kPa was used to predict individuals considered to be cirrhotic[19]. These patients were evaluated for the presence of decompensation of liver function (in the past and at the beginning of antiviral therapy) and were assessed on the Child-Pugh (CP) scale. Patients scored as B or C on the CP scale were considered to be decompensated. Data were also collected on the past diagnosis of HCC and liver transplantation.

Effectiveness assessment

Antiviral therapy was considered successful if ribonucleic acid of the virus (HCV RNA) in serum was undetectable 12 wk after its completion, meaning that the patient achieved a sustained virologic response (SVR). Patients with detectable viral load at this time point were considered virologic failures, while those lost to follow-up without HCV RNA evaluation 12 wk after the end of therapy were recognized as non-virological failures and not included in the PP analysis.

Safety assessment

An analysis of potential drug-drug interactions was carried out before the start of DAA therapy using an online tool on the University of Liverpool website[20]. The results of this analysis influenced the choice of DAA regimen or modification of psychiatric therapy. Safety data, including the incidence of adverse events (AEs), serious AEs (SEAs), and deaths, as well as the frequency of treatment modification and discontinuation, were collected during therapy and up to 12 wk after treatment completion.

Ethics

The data were originally collected not for scientific purposes but to evaluate the effectiveness and safety of real-world treatment with registered drugs. Patients were not exposed to any experimental interventions. According to local law (Law of 6 September 2001, Pharmaceutical Law, Article 37al), non-interventional studies do not require ethics committee approval. Due to the retrospective design of the analysis, the requirement for patient consent was not necessary. Patient data were collected and analyzed in accordance with applicable data protection rules.

Statistical analysis

Statistical analyses were performed using Statistica v. 13 (StatSoft, Tulsa, OK, United States) and MedCalc v. 15.8 (MedCalc Software Ltd, Ostend, Belgium). The entire study population was included in the ITT analysis. The PP analysis concerned patients who underwent HCV RNA evaluation 12 wk after completing treatment. Differences in frequencies of events between groups with and without mental disorders were assessed with χ^2 Pearson's test or Fisher exact test (when the number of observations was < 10). The differences in data expressed on the interval scale were evaluated with a non-parametric Mann-Whitney U test because they did not meet the Gaussian assumption (Shapiro-Wilk's test, $P < 0.05$). Multiple logistic regression was used to predict the odds of no response to HCV treatment for mental disorders (for which a lower frequency of SVR was observed) while controlling for known factors affecting the chance of SVR in the IFN and IFN-free era: male sex, obesity, GT3, cirrhosis, history of HCV treatment failure, HIV coinfection, HBV coinfection, and three antiviral combinations: asunaprevir (ASV) and daclatasvir (DCV), sofosbuvir (SOF) and velpatasvir (VEL), and SOF/VEL with ribavirin (RBV)[21-24]. A P value below 0.05 was deemed statistically significant.

RESULTS

Characteristics of the studied groups

The demographic characteristics of the groups are summarized in Table 1. Group A included 503 patients who had depression (55.6%), 121 with schizophrenia (12.8%), 36 with mental illness without a specific diagnosis (3.8%), 26 with anxiety-depressive disorders (2.8%), 24 with bipolar affective disorder (2.6%), 21 with anxiety disorders (2.2%), 16 with personality disorders (1.7%), and 6 with sleep disorders (0.6%). Substance abuse disorder was diagnosed in 159 cases (16.9%). Moreover, in 30 patients (3.2%), substance abuse and other mental illness coexisted: Depression in 21 patients (2.2%), personality disorders in 4 (0.4%), schizophrenia in 2 (0.2%), anxiety disorders in 2 (0.2%), and an anxiety-depressive disorder in 1 patient (0.1%).

The mean age of patients in both groups was comparable. Group A included a higher percentage of men, obese individuals, patients with more advanced liver fibrosis, and a higher percentage of CP class B and C patients. Similar to group B, the GT1b prevailed, although its frequency was lower, while the higher percentage of HCV-infections with GTs 3 and 4 were noted. Coinfections with HIV and/or HBV were also more common in the group of patients with mental disorders (Table 2).

This group was also characterized by a higher baseline HCV viral load. Most patients in group A (80.6%) were treatment-naïve, while 16.7% (n = 157) of the cases had previously been treated with IFN. Of these, 34 patients discontinued IFN-based therapy due to AEs. During current therapy, 12/34 (35%) had mild AEs, the most common of which was headache (n = 3), and one patient in this group experienced increased insomnia. All patients in this group completed therapy as planned, 31 achieved SVR, and 1 patient was lost to follow-up. Patients with mental illnesses were more often treated with pangenotypic therapy for CHC (Table 3).

Treatment effectiveness

There were no statistically significant differences in the achievement of SVR in groups A and B in both the ITT (92.8% *vs* 95.3%, respectively) and PP (96.9% *vs* 97.7%) analyses (Figure 1A). A significantly lower percentage of SVR was observed in patients with bipolar disorder (Figure 1B). In multivariate analyses, a lower chance of SVR was associated with male sex, GT3, cirrhosis, history of previous HCV-treatment failure, and two DAA regimens: ASV + DCV and SOF + VEL + RBV (Table 4).

Treatment safety

Patients with mental illness more often belonged to the group lost to follow-up (4.2% *vs* 2.5%). In six patients symptoms of mental illness (depression - 5, schizophrenia - 1) worsened during antiviral therapy, of which two permanently discontinued treatment for this reason. New episodes of sleep disorders occurred significantly more often in group A during DAA therapy. In group B, one patient experienced an episode of schizophrenia, and six were diagnosed with depression. In both groups, a similar percentage of patients completed the planned treatment. There were no statistically significant differences in discontinued and modified treatments (Table 5).

Modification of therapy concerned only a change in the dose of RBV. Possible drug interactions were analyzed prior to antiviral therapy. Patients in group A were treated with neuroleptics, anticonvulsants, antidepressants, sedatives, anxiolytics, and methadone. Only carbamazepine could have clinically relevant interactions. This drug was used in 3 patients in group A and in 12 patients in group B. All patients with mental diseases using carbamazepine completed the treatment as planned without AEs, and all achieved SVR.

DISCUSSION

By documenting the high rate of SVR in patients with mental diseases, our study proves that this patient population does not differ in their response to DAA treatment from those with CHC not affected by psychiatric conditions supporting the findings of a recently published multicenter analysis[18]. Thus, there is no rationale for considering these patients as a difficult-to-treat population in terms of virologic response to therapy, as they were previously recognized in the era of IFN-based regimens. Antiviral therapy for mentally ill patients has been a challenge due to contraindications to the use of IFN and the side effects of this cytokine[9,25]. Neuropsychiatric disorders of various caliber during IFN therapy have been widely reported[26-28]. Most were mild in severity and transient in nature, but severe psychosis and suicide attempts have also been described as a reason for discontinuing therapy. Such side effects of therapy have been described even in patients with no prior mental disorders[29]. Due to the risk of exacerbating psychiatric conditions, many patients with a diagnosed mental illness were not eligible for treatment. The mental state of those included in therapy had to be closely monitored, requiring cooperation with the patient's attending psychiatrist[30]. This was the only way to keep the patient in therapy and in the event of exacerbation of mental disorders, to react swiftly and to modify or discontinue antiviral treatment, if necessary for safety reasons[5,31]. At the same time, this was a population of patients in whom successful antiviral therapy offered a chance for mental improvement

The reported *P* value relates to Pearson's chi-square test (or Fisher's exact test if the number of observations in a category was less than 10) or the Mann-Whitney *U* test. BMI: Body mass index; ALT: Alanine transaminase; HCC: Hepatocellular carcinoma; IQR: Interquartile range; HCV: Hepatitis C virus; RNA: Ribonucleic acid.

[32]. In addition to causing liver disease, HCV can potentially induce extrahepatic manifestations, *i.e.*, disorders of other organs and systems that are pathogenetically associated with infection[33]. One of them is the central nervous system, whose involvement results in neurological and psychiatric disorders [6,7,34]. The mechanism of the virus's impact on the nervous system is complex and includes both a direct cytopathic effect related to the infection of nerve cells, as well as the impact of the immune response triggered by the HCV and the effects of psychogenic stressors[8,34,35].

The frequent co-occurrence of CHC and psychiatric disorders was confirmed by numerous studies analyzing this issue in Real World Evidence (RWE) populations[36,37]. The estimated frequency of active mental illness in patients with CHC assessed in the large cohort of American Veterans was as high as one-third, while in our analysis, the percentage of patients was 6.6%[38]. Among them, depression, addiction, and schizophrenia were the most common. On the other hand, the pooled prevalence of HCV infection among patients with severe psychiatric diseases evaluated in a meta-analysis that included papers from 1989-2020 was 8%, which is several times higher compared to the general population[38,39]. However, the fact that patients with mental illnesses are disproportionately affected by HCV is also influenced by other factors beyond the pathogenetic relationship. One that seems to be historical is exposure to infection through frequent contact with healthcare facilities, and it cannot be overlooked that hospitalizations for mental illness are very long. Another factor contributing to the higher prevalence of HCV infections in this population, the importance of which persists to the present day, is that persons diagnosed with mental disorders are much more likely to abuse substances, including injection drugs and needle sharing used for intravenous drug administration is the most common route of HCV transmission[17]. This was also documented in our analysis. Moreover, the population of HCV-infected patients with mental diseases, which was underserved in the era of IFN, has gained its opportunity in the time of DAA therapy. The much shorter course of treatment and the lack of contraindications to the drugs has enabled patients with psychiatric disorders to access therapy on the same principles as for other HCV-infected individuals and has provided a basis for predicting HCV microelimination in this population[18]. In the current analysis, we found no statistically significant differences in the course of treatment in mentally ill patients compared to others. The percentage of those who had their therapy modified or discontinued was comparable; the modification

in both groups concerned only RBV dose reduction according to the label. The safety profile was also comparable with the percentage of patients experiencing SEAs and deaths. Similar conclusions on the good tolerability of DAA can be drawn from the observations of other researchers in RWE cohorts[40,41]. When analyzing psychiatric complications occurring during therapy, we found a significantly higher percentage of sleep disorders in patients with psychiatric diseases than in those without mental conditions. Other researchers evaluating the quality of sleep in patients with mental disorders did not find any significant differences during DAA therapy compared to the baseline, demonstrating that DAA regimens are free of mental side effects regardless of current and/or past psychiatric history[14,15].

In our analysis, however, in six patients, the underlying disease (five cases of depression and one of schizophrenia) worsened during antiviral therapy, which in 2 cases was the reason for discontinuing treatment. However, we cannot exclude the potential influence of other factors. It should be noted that the cited analyses were prospective, while ours is a retrospective study with limitations in data collection. Interestingly, another prospective study reported some degree of neuropsychiatric impairment associated with IFN-free treatment in 10 cirrhotic patients, suggesting their susceptibility to mild DAA neurotoxicity[42].

Despite the significant change in access to treatment, there are still some challenges for a group of patients with mental illness. These are related to potential drug interactions. For this reason, this is carefully reviewed before therapy, and if there are contraindications to combining medications, psychiatric drugs are modified to allow the patient to receive antiviral treatment. This is not always possible; in our study, three patients were on carbamazepine, which could not be discontinued as it was the only drug that stabilized their mental state. Although this drug is not recommended in combination with DAA because it can reduce their levels below therapeutic levels, all patients completed the

treatment as planned without AEs and achieved SVR. It should be emphasized that a possible modification in psychiatric treatment in case of expected drug interactions, as well as monitoring the mental state of the patient, requires the cooperation of a hepatologist and a psychiatrist. However, the scope of supervision is significantly smaller than in the case of IFN-based therapy[17,43]. The issue we highlighted in our analysis was the significantly higher percentage of patients lost to follow-up without SVR evaluation in the population of patients with mental illness compared to those without mental disorders, 4.2% *vs* 2.5%, respectively. The problem with adherence, concerning not only the use of drugs which was not evaluated in our study but, as in this case, keeping the dates of follow-up visits, is also raised by other authors[18]. However, some analyses did not report the difference in adherence between mentally ill patients (including those with substance abuse disorder) and the general HCV-infected population[3,40,44].

In patients with available SVR, we did not observe significant differences in the effectiveness of DAA therapy depending on the diagnosis of mental illness, which is consistent with reports from other RWE cohorts[40,45]. A 96.9% cure rate was achieved in the mentally affected group compared to 97.7% in the patients without psychiatric disorders, despite a higher proportion of men, those with liver cirrhosis, and a higher prevalence of GT3 infection in this population, which are considered negative predictors of SVR in HCV-infected patients treated with DAA[21]. Significantly lower SVR rates have been documented in patients with bipolar disorder, which is consistent with the results of the analysis by Wedemeyer *et al*[18]. However, this multicenter study did not control for potential confounders, while in our research, the multivariate analysis clearly excluded bipolar disorder as an independent predictor of non-response to treatment. The identified independent negative predictors included the presence of liver cirrhosis, GT3 infection, history of prior therapy failure, and male gender, which is in line with available data concerning the general HCV-infected population[21,46]. However, apart from the abovementioned factors, administration of the ASV + DCV regimen or SOF/(VEL + RBV) combination was also associated with a lower chance of SVR. The ASV + DCV option was registered only for patients with GT1b infection and used until 2018. Due to its cumulative efficacy of 85%, evaluated in a meta-analysis of 9 clinical trials, it was considered suboptimal[23]. The SOF/(VEL + RBV) regimen is

registered in patients with decompensated cirrhosis, and its efficacy in a randomized clinical trial was 83%[47]. In our analysis, 23/26 (88.5%) patients with mental disorders responded to this type of treatment. There are no papers evaluating this regimen exclusively in patients with mental illness, so we cannot relate our results to another study.

Figure 1 The sustained virological response rate in the group with mental disorders compared to the control group in intention-to-treat and per protocol analyses and calculated per protocol analysis in the population with mental disorders. A: The sustained virological response rate (SVR) in the group with mental disorders (n = 942) compared to the control group (n = 13330) in intention-to-treat and per protocol analyses; B: SVR calculated per protocol analysis in the population with mental disorders considering the type of the psychiatric illness in comparison to the control group. All statistical comparisons were performed with Pearson's chi-square or Fisher's exact test. ITT: Intention-to-treat; PP: Per protocol.

Our study has some limitations which we wish to stress. This is a retrospective study with all its consequences, such as incomplete data, including information on side effects, data entry errors, and possible bias. The database includes information from baseline to 12 wk after the end of therapy, and there are no data on the number of patients who had their psychiatric treatment modified before treatment, as well as the nature of these modifications. Additionally, no data were collected on the adjustment of psychiatric treatment during DAA therapy. Another limitation is the lack of systematic monitoring of the patient's mental state, such as with appropriate questionnaires. The main strength of the current study is the large group of patients from different centers in our country treated in routine clinical practice, which affects the quality of the results and the possibility of generalizing conclusions. To the best of our knowledge, this is the first study to address the problem of treating CHC with various DAA regimens in patients with mental disorders, highlighting the differences in specific psychiatric illnesses.

CONCLUSION

This study provides real-world evidence for the effectiveness and safety of DAA treatment of HCV infection in patients with preexisting psychiatric disorders. As shown, most of these patients achieve SVR. No specific psychiatric diagnosis lowered the chance of successful DAA treatment. Negative predictors of virologic response do not differ for these patients compared to the general HCV-infected population and include cirrhosis, GT3 infection, male gender, and failure of previous therapy.

ARTICLE HIGHLIGHTS

Research background

In the era of interferon (IFN)-based therapies, patients with psychiatric disorders had limited access to therapy due to their unfavorable safety profile. This changed with the introduction of direct-acting antiviral (DAA) drugs.

Research motivation

We aimed to evaluate the tolerability and effectiveness of IFN-free therapies in patients with various psychiatric disorders and to identify predictors of virologic response in this patient population.

Research objectives

Data of 14272 patients treated with IFN-free regimens for chronic hepatitis C included in the EpiTer-2 database were analyzed. The patients were divided into two groups: 942 patients with mental disorders and 13330 without psychiatric diseases.

Research methods

The effectiveness and safety of antiviral treatment were compared between both populations. Effectiveness was assessed by the percentage of patients with sustained virologic response (SVR). Multiple logistic regression was used to predict the odds of no SVR in patients with mental illness. Safety data were collected through the treatment period and 12 wk of follow-up.

Research results

The cure rate was not significantly different in the two groups analyzed, with an SVR of 96.9% in patients with psychiatric disorders and 97.7% without psychiatric disorders. Patients with bipolar disorder achieved a lower SVR (90.5%), but multivariate analysis excluded it as an independent predictor of treatment non-response. Male gender, genotype 3 infection, cirrhosis and failure of previous therapy were identified as independent negative predictors. The percentage of patients who completed the planned therapy did not differ between the groups with and without mental disorders. In six patients, symptoms of mental illness (depression, schizophrenia) worsened, of which two discontinued treatment for this reason. New episodes of sleep disorders occurred significantly more often in patients with mental disorders. Patients with mental illness were more frequently lost to follow-up (4.2% *vs* 2.5%).

Research conclusions

DAA treatment is safe and effective in hepatitis C virus (HCV)-infected patients with mental disorders. No specific psychiatric diagnosis lowered the chance of successful antiviral treatment.

Research perspectives

The data obtained provide real-world evidence of the effectiveness and safety of DAA for HCV infection in patients with mental disorders, indicating that there are no differences compared with the general HCV-infected population.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Zoltán Rakonczay Jr, DSc, MD, PhD, Professor, Department of Pathophysiology, University of Szeged, Szeged 6701, Hungary. rakonczay.zoltan@med.u-szeged.hu

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports, Index Medicus, MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJG* as 4.3; IF without journal self cites: 4.1; 5-year IF: 5.3; Journal Citation Indicator: 0.82; Ranking: 33 among 93 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.3 and Scopus CiteScore rank 2022: Gastroenterology is 22/149.

Abstract

Coronavirus disease 2019 (COVID-19) has several extrapulmonary symptoms. Gastrointestinal (GI) symptoms are among the most frequent clinical manifestations of COVID-19, with severe consequences reported in elderly patients. Furthermore, the impact of COVID-19 on patients with pre-existing digestive diseases still needs to be fully elucidated, particularly in the older population. This review aimed to investigate the impact of COVID-19 on the GI tract, liver, and pancreas in individuals with and without previous digestive diseases, with a particular focus on the elderly, highlighting the distinctive characteristics observed in this population. Finally, the effectiveness and adverse events of the anti-COVID-19 vaccination in patients with digestive disorders and the peculiarities found in the elderly are discussed.

Key Words: COVID-19; Elderly; Inflammatory bowel disease; Liver disease; Cirrhosis; Pancreatic disease

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Gastrointestinal symptoms are frequent in coronavirus disease 2019 (COVID-19), with more severe consequences reported in elderly patients. Patients with pre-existing liver disease are at an increased risk for worse outcomes, while no definitive conclusions can be drawn regarding patients with inflammatory bowel disease or pancreatic diseases. Elderly patients with digestive disorders, although the available data are limited, have no worse COVID-19 outcomes than those without these diseases.

INTRODUCTION

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is responsible for the ongoing pandemic of coronavirus disease 2019 (COVID-19). Since its first report in December 2019 in Wuhan, China[1], COVID-19 has quickly spread worldwide with 635229101 confirmed cases, including 6602552 deaths according to the World Health Organization (WHO) at the moment of writing[2]. Although symptomatic COVID-19 patients exhibit various signs and symptoms, the typical clinical presentation has been predominantly respiratory[3]. The most common symptoms include cough (60%-86%), shortness of breath (53%-80%), and taste and smell alteration (64%-80%)[4-6]. However, as caseloads rise, many extrapulmonary effects have been observed, affecting the cardiovascular, neurologic, gastrointestinal (GI), and dermatologic systems. Liver and pancreatic impairment may also occur, especially in critically ill patients[7]. Although their exact prevalence is still the subject of debate, GI symptoms are more and more frequently reported[8]. However, it is impossible to exclude a bias thriving from the increased awareness of GI manifestations[9]. Some authors reported a prevalence of GI involvement of around 31.9%[10,11], while others up to 61%[12]. Regarding the impact of SARS-CoV-2 infection on older age, more severe outcomes are described [13,14]. The reason is the various age-related changes and the higher number of comorbidities typical of these patients. However, increasing evidence suggests that age is the most significant risk factor for worse outcomes[15]. Immunosenescence, the age-associated decline of immune system function, is the primary reason for the increased susceptibility to viral infection[16,17].

Methods

Considering a broad topic such as SARS-CoV-2 infection, this narrative review aimed to provide an overview of current knowledge of its impact on the GI tract, liver, and pancreas, with a particular interest in the elderly population. First, we created a list of keywords related to our research question. Articles were searched in the PubMed, Scopus, and EMBASE databases using the following search terms: "COVID-19", "SARS-CoV2 infection", "Elderly people", "Elderly population", "Old people", "Gerontal population", "Extrapulmonary manifestations", "Gastrointestinal symptoms", "Gastrointestinal bleeding (GIB)", "Inflammatory bowel disease (IBD) ", "Liver injury", "Liver dysfunction", "Chronic liver disease", "Drug liver injury", "Pancreatic involvement", "Acute pancreatitis" and "COVID-19 vaccination". We then synthesized, analyzed, and critically evaluated the related data to identify trends and patterns, in theory, debates, conflicts, and, most of all, persistent gaps in the existing knowledge.

Mechanisms of GI involvement in COVID-19

It is well known that SARS-CoV-2 enters cells using angiotensin-converting enzyme 2 (ACE2)[8,18]. In addition to the respiratory tract, ACE2 has also been found in the GI tract, especially in the tongue, esophageal, gastric, and rectal mucosa[19]. Mechanisms underlying the probable pathological effect of SARS-CoV-2 are varied. First, the virus's entry into cells may lead to a direct cytopathic effect[20]. SARS-CoV-2 infection emphasizes inflammatory pathways determining the "cytokine storm", which is characterized by the overproduction of mediators such as interleukin-2 (IL-2), IL-7, tumor necrosis factor (TNF) and granulocyte monocyte colony-stimulating factors[21]. This condition could generate diarrhea due to the alteration of gut motility and GI flora[22]. Notably, gut microbiota alterations have been found in these patients, probably due to factors such as exposition to antimicrobial agents or expression of viral proinflammatory mediators. Moreover, ACE2 seems to be involved in the antimicrobial peptide secretion through target of rapamycin activity; an aberrant functioning of this pathway has been described during COVID-19[23]. In addition to this mechanism, disorders of the gut-lung axis may be involved in the pathophysiology of GI symptoms. For example, it has been reported that lung flora alteration can correlate with intestinal microbiota modifications, probably due to increased recruitment of lung-derived CCR9+CD4+T cells into the bowel[24,25]. Regarding nausea and vomiting, these symptoms are likely

related to SARS-CoV-2 infection of the vagus nerve and a cytokine-mediated stimulation of the central and autonomic nervous systems[26]. Moreover, anorexia might be related to nausea and vomiting or associated with acute viral prodrome and cytokine storm[27]. Some studies have identified a lower prevalence of GI symptoms in the elderly population. This finding could be related to differences in gene expression of the ACE2, which seems to be directly correlated with age[9,28,29]. Older patients showed higher intestinal ACE2 mRNA expression, which could modify susceptibility to GI symptoms by influencing intestinal immunity and microbiota composition[29,30]. However, studies on this relation are few and with uncertain results.

GI symptoms in patients with COVID-19

In one-third of patients with COVID, GI symptoms occur as the first presentation. Nausea and vomiting may be present in up to two-thirds, diarrhea in up to 50%, loss of appetite in approximately 40%, and less than 10% present abdominal pain[7]. Moreover, extreme cases, such as the autoptic finding of segmental dilatation and stenosis of the small intestine in an 85-year-old man with COVID-19, have been reported in the literature[31]. However, the causal role of SARS-CoV-2 has yet to be established.

GI manifestations in elderly patients with COVID-19

Anorexia and diarrhea were the most frequent symptoms reported in the elderly, with variable frequencies depending on the study. In a large Brazilian cohort of 9807 patients, low frequencies of GI symptoms were reported, with diarrhea being registered only in 2% of patients[32]. Marziliano *et al*[33] reported a prevalence of GI symptoms of near 9% in a population of older adults (65 years and older). Ramos-Rincon *et al*[34] reported that very old patients (age > 80 years old) had higher frequencies of GI symptoms, with diarrhea presenting in 14% and vomiting in 5%, and anorexia in nearly 21% of patients. In the studies mentioned above, GI symptomatology did not impact mortality. Other studies pointed out an inverse correlation between age and the prevalence of GI symptoms[9,28]. Aroniadis *et al*[9] reported that older COVID-19 patients were less likely to exhibit digestive symptoms. A lower prevalence of GI symptoms was reported in 70 and older patients compared with those < 70 years (32% *vs* 41%). This potential age-related protective effect is found in a dysregulation of the immune system activation and a different expression of the ACE2 receptor in the digestive system [28]. Surprisingly, some studies highlighted a possible protective role of GI symptoms in COVID-19. Belgian research observed a prevalence of 30% of GI symptoms in frail older patients (aged over 80 years) and a positive correlation between their presence and patients' survival[35]. These results were also aligned with those of Vrillon *et al*[36], who described a positive outcome in older people presenting with GI symptoms, whereas younger adults with digestive symptoms had a higher prevalence of complications. On the contrary, Atalla *et al*[37] in their retrospective study, revealed a higher incidence of loss of appetite (83.3% *vs* 44.4%) and diarrhea (50% *vs* 28.6%) in the deceased patients than in those who survived. However, the onset of diarrhea during hospitalization was not necessarily related to SARS-CoV-2 infection, and the etiological analyses are not presented in the article[37]. Patients with SARS-CoV-2 infection are also at risk of other potential causes of diarrhea, such as Clostridium difficile infection and antibiotic-associated diarrhea due to frequent antimicrobic therapy and hospitalization. These could be confounding factors that alter the analysis of GI symptoms during SARS-Cov-2 infection, especially when they appear during infection and not at onset[18,24]. GI bleeding (GIB) in COVID-19 patients can represent a fatal complication. In the literature, a rate of GIB between 1.1% and 13% during SARS-CoV-2 infection has been reported[38]. However, the actual incidence and prevalence of GIB in COVID-19 patients are extremely difficult to assess. The underlying mechanisms for GI hemorrhage in COVID-19 patients could involve conditions that increase the risk of thromboembolism, such as dehydration, which may follow fever or diarrhea[39]. Anticoagulation drugs prescribed for preventing thrombotic events should be considered additional risk factors[40]. Although Ion *et al*[41] sustained that the use of anticoagulation or antiplatelet agents was not a risk factor for GIB, at least in hospitalized COVID-19 patients. Stress ulcers may be another major cause of bleeding unrelated to SARS-COV-2[41]. Furthermore, assisted ventilation techniques could cause stress ulceration and generate GIB[42]. However, rates of thrombosis and bleeding related to COVID-19 were congruent to those reported in hospitalized patients with comparable grades of critical illness. Except for case reports, no elective studies on the elderly population are available in the literature[43]. An overview of the analyzed studies is shown in Table 1.

COVID-19 in inflammatory bowel disease patients

Due to the immunosuppressive therapies, malnutrition, and chronic inflammation, patients affected by inflammatory bowel disease (IBD) are potentially at augmented risk for SARS-CoV-2 infections and complications due to the immunosuppressive therapies, malnutrition, and chronic inflammation[44,45]. However, various studies have investigated the incidence of COVID-19 in IBD patients, concluding that it is not increased compared to the general population [46-48]. Interestingly, COVID-19 in IBD patients has a clinical presentation similar to the general population. A recent meta-analysis found that the most common symptoms in these patients are extraintestinal, such as fever and cough[49]. However, GI manifestations appear more common than in the general population. Diarrhea can occur in 27.2% of patients, followed by abdominal pain, nausea, and vomiting, with a pooled prevalence rate of 13%, 10%, and 8.8%, respectively, and sporadically GI symptoms can be the only clinical presentation, which could be challenging to differentiate from IBD reactivation[49]. The prognosis of COVID-19 patients affected by IBD is not different from that of the general population. A recent meta-analysis observed that IBD was not correlated with augmented risk of death, intensive care unit (ICU) admission, or hospitalization related to COVID-19, and the pooled odds ratios were 0.67 [95% confidence interval (CI): 0.32-1.42], 1.09 (95%CI: 0.27-4.47), and 0.58 (95%CI: 0.28-1.18), respectively[50]. On the other hand, another meta-analysis found that in IBD patients affected by COVID-19, the risk ratio (RR) of adverse outcomes was increased (RR = 1.32; 95%CI: 1.06-1.66) compared to patients without IBD[51]. The risk factors for worse outcomes of COVID-19,

Table 1 Overview of studies evaluating the course of gastrointestinal symptoms during severe acute respiratory syndrome coronavirus 2 infection in the elderly population

Zhan *et al*[23]	39	Age > 75	36%	-	-	-	-	No association
Vrillon *et al* [36]	76	90 median (IQR: 86-92)	22%	-	-	-	-	Digestive symptoms were associated with a favorable outcome

The sample's age was expressed either by the mean or the median in the studies analyzed. For some non-specific studies performed on older people, only the characteristics of the population mentioned above have been shown in the table. However, some of these have yet to express a category-specific significant trend measure. For example, the relationship between the course of the infection and the outcome was reported in the last column. SD: Standard deviation; IQR: Interquartile range; GI: Gastrointestinal.

such as age, male sex, and comorbidities, are the same as observed in the general population. In IBD patients with COVID-19, an active disease was considered a risk factor for poor outcome[52,53], and in a cohort of 79 patients with IBD and COVID-19, active IBD, especially in elderly patients, was correlated with worse outcomes such as pneumonia, hospitalization, respiratory support, and death[52]. Another study reported that the correlation between IBD activity and the risk of severe COVID-19 appears to vary with age and is more relevant in younger patients[53]. The impact of IBD medications on the course of COVID-19 is still under investigation. A meta-analysis by Tripathi *et al*[54] has shown that the therapy with TNF-α antagonists is associated with favorable hospitalization and mortality outcomes, while the use of mesalamine was correlated with worse outcomes in terms of hospitalization, ICU admissions, and death. Another recent study, including 6144 patients, found that systemic corticosteroids were associated with severe COVID-19, while mesalamine and sulfasalazine were not associated with adverse outcomes[55]. In addition, combination therapy with TNF-α antagonists plus thiopurines was correlated with an augmented risk of hospitalization or death, but not the combination with methotrexate. Moreover, biologics were not associated with worse COVID-19 outcomes and could have a protective effect without differences when comparing biologic classes such as TNF-α, IL-12/23, or integrin antagonists [56]. Therefore, the correct management of IBD therapy is relevant because SARS-CoV-2 is not correlated with the risk of IBD relapse. Conversely, the discontinuation or delay of the IBD therapy, regardless of SARS-CoV-2 infection, is significantly associated with the disease activity[55,56] (Table 2).

COVID-19 in elderly patients with IBD

Elderly-onset IBD is defined as onset at 60 years or older[57], and up to 30% of the IBD population is older than 60 years, while 15% of IBD patients have been diagnosed after age 65. It has been observed that in elderly-onset IBD, there is a different natural history and disease phenotype. The disease outcomes are less influenced by genetics, while frailty, immunosenescence, and dysbiosis have a more significant role[58]. In IBD patients, as in the general population, age and comorbidities increase the risk of severe COVID-19 and disease-related mortality[45,59]. A prospective observational study that included 482 patients confirmed that age over 60 years was correlated with severe COVID-19 [odds ratio (OR) = 4.59, 95%CI: 1.3-15.9] and was an independent risk factor related to death (OR = 7.1, 95%CI: 1.8-27.4), as to have two or more comorbidities (OR = 3.9, 95%CI: 1.3-11.6)[60]. Wetwittayakhlang *et al*[61] examined a cohort of 3516 IBD patients, of whom 82 were diagnosed with COVID-19 infection, and they observed that age over 55 years was an independent risk factor for developing severe COVID-19. The study by Brenner *et al*[59], through an extensive international registry, corroborates these observations, finding that advanced age [adjusted OR (aOR) = 1.04; 95%CI: 1.01-1.06] and having at

Table 2 Risk of severe coronavirus disease 2019 in elderly inflammatory bowel disease patients

least two comorbidities (categorized into lung disease, cardiovascular disease, hypertension, history of stroke, cancer, liver disease, kidney disease, and diabetes) (aOR = 2.9; 95%CI: 1.1-7.8) were positively associated with severe COVID-19.

Regarding the risk of SARS-CoV-2 infection, a study by Gubatan *et al*[62] observed that IBD patients older than 66 years have an augmented risk of acquiring SARS-CoV-2 infection compared to younger patients. On the other hand, a retrospective cohort study by Calafat *et al*[63] that included 418 IBD patients over 65 years of age, of whom 32 were diagnosed with COVID-19, found that the incidence of COVID-19 in elderly IBD patients is similar to that reported in the age-adjusted general population. Furthermore, the incidence of COVID-19 was not influenced by the use of immunosuppressants, but the authors observed a worse prognosis among the patients who did not use immunosuppressants. Medication use in older patients with IBD differs from younger ones since they are treated less often with biological agents and immunosuppressants. However, corticosteroid use is similar[63,64], and it is possible to hypothesize that these differences could have a role in the course of SARS-CoV-2 infection. Overall, in the elderly population, IBD does not seem to increase the risk of SARS-CoV-2 infection or severe COVID-19[65] (Table 2).

LIVER MANIFESTATIONS ASSOCIATED WITH COVID-19

Introduction

Among the extrapulmonary manifestations of SARS-CoV-2, abnormal liver function reflecting hepatocellular and cholangiocellular injury is often reported[12,66]. COVID-19-associated liver injury includes any liver abnormality due to the disease course or the treatment. Indeed, it is not always possible to determine whether the liver injury is due to the infection or other concomitant conditions, such as the co-administration of hepatotoxic agents or ischemic hepatitis from severe and prolonged hypotension. Moreover, the cytokines storm observed in the severe forms of COVID-19 and caused by systemic hyper-inflammation may result in multiple severe organs injury and, in turn, it represents another cause of liver damage[67]. However, the frequency of liver dysfunction in COVID-19 infection has not yet been well understood [68].

Liver test abnormalities

Among abnormal liver function, liver test abnormalities have often been described. The incidence of elevated liver transaminases, alanine transaminase (ALT), and aspartate aminotransferase (AST) in COVID-19 patients range from 2.5% to 76.3%[69]. A systemic review pointed out that elevated liver chemistries occurred in 23.1% of adult patients with COVID-19 at initial presentation[66]. In comparison, 24.4% develop elevated liver chemistries during the illness, and up to 10.7% have severe liver injury[66]. In detail, the pooled incidence of AST and ALT elevation at initial presentation of COVID-19 was 22.5% and 17.9%, respectively[66]. The incidence of hyperbilirubinemia at the onset of symptoms was 13.4%, while the incidence of alkaline phosphatase (ALP) and gamma-glutamyltransferase (gamma-gt) was 6.1% and 21.1%, respectively[66]. In addition, hypoalbuminemia ranged from 1.1% to 45.8% in non-severely infected patients, reaching 72.9% in those severely infected[66].

The cause of the elevated liver enzymes in COVID-19 patients without pre-existent liver diseases still needs to be well elucidated. In the study of Kulkarni *et al*[66], only 3.6% of the analyzed patients had underlying chronic liver disease (CLD), suggesting that liver damage might be directly caused by the viral infection of liver cells. It is believed that SARS-CoV-2 could penetrate the liver cells thanks to the ACE2 receptor, which is expressed in the liver and bile duct cells[70]. Recent data show that ACE2 is expressed in 2.6% of hepatocytes and 59.7% of cholangiocytes. The level of ACE2 expression in cholangiocytes was similar to type 2 alveolar cells of the lungs. Therefore, liver dysfunction may result from SARS-CoV-2 attachment to ACE2 on cholangiocytes[71]. Of note, studies on both mice and humans reveal an increased ACE2 expression in hepatocytes when liver fibrotic/cirrhotic conditions are present[69]. This finding leads us to believe that preexisting liver injury could exacerbate SARS-CoV-2 hepatic tropism. Although COVID-19 may contribute to liver dysfunction directly through an inflammatory response, postmortem pathological findings of the liver suggest that COVID-19-related liver dysfunction may be mainly caused by secondary liver damage by respiratory distress syndrome-induced hypoxia, multiple organ failure, and the use of potentially hepatotoxic drugs[72]. Microscopically, the most

significant findings in postmortem hepatic tissue of patients with COVID-19 were microvesicular steatosis and mild lobular inflammation[73]. Zhao *et al*[72] presented unique findings, such as platelet-fibrin microthrombi in hepatic sinusoids, central vein or portal vein, histolytic hyperplasia in portal tracts, and megakaryocytic in sinusoids.

Liver test abnormalities and COVID-19 outcomes

Liver test abnormalities can predict the severity of COVID-19 disease[74]. Patients with abnormal liver tests at admission or during hospitalization, classified as hepatocyte type or mixed type, had significantly higher risks of progressing to severe COVID-19 and mortality when compared to patients with normal liver tests[66,75]. Elevated liver enzyme levels are linked to adverse manifestations such as shock, admission to an ICU, and mechanical ventilation. Although, Săbiescu *et al*[76] proved that only elevation over five times the upper limit is strongly correlated with high mortality risk. Also, hypoalbuminemia is a strong predictor of severe COVID-19 course and, in combination with AST or total bilirubin (TBIL), has a remarkable association with mortality[77], even in patients without chronic illness[78]. Furthermore, Da *et al*[79] reported a correlation between ALT levels and levels of inflammatory markers such as C-reactive protein, D-dimers, ferritin, and IL-6.

It appears evident that liver injury in COVID-19 patients is linked to the severity of the hyperinflammatory response, thus, reinforcing the hypothesis that the entity of liver damage is related to the severe forms of SARS-CoV-2 infection. Pazgan-Simon *et al*[80] reported that liver injury in patients with COVID-19 with no underlying liver disease did not correlate with higher mortality. On the other hand, patients with preexisting liver disease, particularly those with cirrhosis, have a higher risk of death than those without any known liver pathology[81].

Impact of SARS-CoV-2 infection on patients with CLD

Wang *et al*[82] showed an increased risk of COVID-19 infection in patients with a recent diagnosis of CLD. A multicentric retrospective study revealed that nearly one-fifth of hospitalized COVID-19 patients had CLD[82]. However, the elevated aminotransferases on admission were higher in patients with CLD than those without CLD. On the contrary, during hospitalization, the aminotransferase level did not differ between patients with or without CLD. Iavarone *et al*[83] described the impact of SARS-CoV-2 infection on ALT levels in cirrhotic patients, revealing that acute liver injury was observed in almost 50% of patients with previously average ALT values. However, more data are necessary to clarify the impact of an ALT increase on the natural history of cirrhosis and COVID-19. It has been described that CLD can negatively influence the clinical outcomes of patients with COVID-19[84,85]. The overall mortality rate of COVID-19 is estimated at 0%-2% in these patients[86]. However, currently, there is no convincing evidence that patients with stable CLD without advanced fibrosis/cirrhosis, primary biliary cholangitis, or primary sclerosing cholangitis have increased susceptibility to severe COVID-19 infection[87]. Contradictory data exist on the risk of developing severe illnesses of non-alcoholic fatty liver disease (NAFLD)[88]. Patients with NAFLD often suffer from metabolic comorbidities such as diabetes, hypertension, and obesity and, for this reason, present an increased risk of a severe course of COVID-19[89]. However, Sachdeva *et al*[90] affirmed that NAFLD might represent a predictor of severe COVID-19, even after adjusting to the presence of confounding factors. The risk of a worse prognosis of COVID-19 is directly related to the severity of the liver disease, and cirrhosis may appear independently associated with an increased risk of death in patients hospitalized with COVID-19[91]. A large multinational cohort study determined that baseline liver disease severity is the primary determinant of SARS-CoV-2 infection outcome[92]. This study resulted in a mortality of 32% in patients with cirrhosis compared to only 8% of those with CLD without cirrhosis. In addition, patients with CLD without cirrhosis appear to have a similar risk of SARS-CoV-2 infection-related mortality compared to patients without liver disease. Furthermore, since only 19% of cirrhosis patients' mortality was related to liver complications, the leading cause of death remained COVID-19-related lung injury. Patients with cirrhosis may also have underlying complications such as hepato-pulmonary syndrome, porto-pulmonary hypertension, or hepatic hydrothorax, which can increase the risk of respiratory failure[93]. On the contrary, a Korean cohort study showed no significant association between developing severe complications from COVID-19, including mortality, or the presence of liver cirrhosis[94]. A possible explanation could be attributed to the different etiologies of cirrhosis in the patients analyzed. In particular, chronic hepatitis B is responsible for more than 70% of cirrhosis cases in Korea[95], and NAFLD and alcoholic liver disease are the most common etiologies of liver cirrhosis in Europe and North America. Consequently, the different etiologies of cirrhosis may play a critical role in developing severe complications from COVID-19. For example, a United States multicentric study pointed out that, among patients with CLD, those with decompensated cirrhosis, alcohol-related liver disease, and hepatocellular carcinoma (HCC) were more vulnerable to adverse outcomes from COVID-19. These patients also had a higher risk for all-cause mortality from COVID-19[96] (Table 3).

Drug-induced liver injury caused by COVID-19 treatment

Liver injury can be caused by several medications used in the treatment of COVID-19. Drug metabolites can cause cellular stress that can lead to apoptosis or necrosis of liver cells[97]. Since most of these drugs cause an elevation of liver enzymes alone, it is important to correctly define acute liver injury to avoid withdrawing this medication improperly[98]. Drug-induced liver injury (DILI) is defined as an increased level of ALT ≥ 5-times upper limit of normal (ULN), or increased level of ALP ≥ 2-times ULN (in the absence of bone pathology), or a simultaneous increase of ALT ≥ 3-times ULN and TBIL concentration > 2-times ULN. While analyzing the different medications used for COVID-19 infection, liver-related adverse effects were more common in patients who used hydroxychloroquine and azithromycin and those who did not receive any targeted therapy[99]. In contrast, drugs, including lopinavir/ritonavir (LPV/v), were associated with 4 × higher odds of liver injury[75]. According to another study, no apparent side effects were found in the LPV/r group, except for transient ALT elevation (< 125 U/L)[96]. A meta-analysis revealed that the incidence of DILI in patients treated

Table 3 Summary of studies on the relationship between liver disease and coronavirus disease 2019 in elderly patients

Ref.	Outcome considered	Results
Khateri *et al* [108]	Incidence of acute liver injury in patients affected by COVID-19	Acute liver injury has no relationship with age
Metawea *et al* [110]	Mortality of patients with hepatocellular carcinoma infected with COVID-19	Age is associated with poorer outcomes and higher mortality
Ji *et al*[111]	Severe COVID-19 in patients affected by NAFLD	Associated in patients older than 60 yr
Zhou *et al* [112]	Severe COVID-19 in patients affected by NAFLD	Associated in patients younger than 60 yr
Hartl *et al* [113]	Liver-related death due to COVID-19 between different age groups	More frequent in the 40-69 years old group than in the over 70 years old group (6.5% *vs* 2.2%)
Ioannou *et al* [115]	Predictors of mortality among patients with cirrhosis and SARS-CoV-2 infection	Advanced age was one of the main risk factors for mortality among patients with cirrhosis and SARS-CoV-2 infection
Brozat *et al* [116]	The case fatality rate in patients with cirrhosis and SARS-CoV-2 infection	The case fatality rate in cirrhotic patients and SARS-CoV-2 infection aged 65 yr and older was nearly three times that in patients younger than 65 yr (43.6% *vs* 16.1%)

SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2; COVID-19: Coronavirus disease 2019; NAFLD: Non-alcoholic fatty liver disease.

with remdesivir was 15.2%, while the incidence of DILI in patients treated with LPV/v was 37.2%[66]. Although some extensive reviews concluded that remdesivir does not affect liver function[100], AST and ALT elevations have been described in a cohort of patients treated with remdesivir. However, in most cases, elevated levels of AST and ALT do not progress to severe liver injury[101]. Hepatotoxicity is documented among the possible Tocilizumab-related side effects. In registration trials, serum aminotransferase elevations occurred in up to 40% of patients receiving tocilizumab. After its licensure, it has been linked to several instances of clinically apparent liver injury with jaundice. Also, liver failure and transplantation may occur in patients treated with tocilizumab[102]. Interestingly, the median age of COVID-19 patients with DILI ranged from 54.3 to 56 years; therefore, age does not appear to significantly influence the risk of developing DILI[103]. Although animal studies have demonstrated changes in hepatic physiology that affect drug metabolism in the aging liver, there is no evidence that this leads to any appreciable deterioration of liver function in healthy elder patients. Moreover, several large international DILI registries do not support elder age as an independent risk factor for developing hepatic injury[104]. On the contrary, it has been described that age does affect the incidence rates of liver injury in COVID-19 patients. Older patients have a higher incidence of liver injury. In addition, impaired liver function in the elderly increases the drug concentrations in their livers. The decline in liver function also explains the higher incidence of DILI in the elderly[105]. Therefore, intensive liver function monitoring should be considered for patients treated with drugs such as remdesivir, LPV/v, and tocilizumab.

COVID-19 liver manifestations in elderly patients

It has been debated if age may represent a risk factor in developing severe complications of SARS-CoV-2 infection in patients with CLD. Several studies demonstrated that older patients are more susceptible to developing severe COVID-19 [106] but are also more likely to develop liver function abnormalities[68]. However, advanced age as a risk factor for more severe forms of COVID-19 has not yet been well assessed. Older patients with COVID-19 have a higher risk of liver injury [107]. Indeed, Khateri *et al*[108] have revealed that the prevalence of acute liver injury has no relationship with age. Spearman *et al*[109] have pointed out that age represents one of the main risk factors for adverse outcomes in individuals with CLD and COVID-19. In patients with HCC infected with COVID-19, age is considered one of the factors responsible for poorer outcomes and higher mortality[109,110]. In a Chinese retrospective study of patients with COVID-19, NAFLD and age over 60 years were associated with a more severe course of COVID-19[111]. On the contrary, Zhou *et al*[112] demonstrated that the association between metabolic-associated fatty liver disease and the development of severe COVID-19 was significant in patients aged less than 60 years. The higher prevalence of severe COVID-19 in patients aged under 60 years with NAFLD compared to those without NAFLD may be attributed to hepatic and systemic immune responses caused by NAFLD, which may increase the severity of the cytokine storm in younger patients with COVID-19. Hartl *et al*[113] analyzed the frequency and the predictive role of abnormal liver chemistries in different age groups. Interestingly, the study revealed that patients aged 40-69 years had a significant risk for COVID-19-associated liver injury. The median levels of hepatocellular injury were highest in patients aged between 40 and 69 years, while cholestatic liver injury was similar within both groups (40-69 years and > 70 years). However, the patients aged over 70 had the highest risk of COVID-19-related mortality; liver-related death due to COVID-19 occurred significantly more often in 40-69-year-old patients than those aged over 70 years (6.5% *vs* 2.2%)[113]. Moreover, this study revealed that increased AST levels were linked to a shorter survival time in patients older than 70, while elevated AST seems to predict a severe course of COVID-19 in all age strata[113]. Of all patients with liver-related death, only 1.7% had no preexisting liver disease. Another study pointed out that among patients with CLD, the highest risk of death was found in their eighth decade of life[92]. Age was associated with higher 30-d mortality in patients with cirrhosis and SARS-CoV-2 infection compared with patients without SARS-CoV-2 infection[114]. Ioannou *et al*[115] also highlighted that higher age, decompensation,

and high model for end-stage liver disease scores were mortality predictors. Also, a more recent study pointed out that older age > 65 and Child-Pugh class C were associated with a high mortality rate[116]. In contrast, Marjot *et al*[92] revealed that mortality in patients with cirrhosis was more evenly distributed across age categories, including a high mortality rate under age 40. A multicentric retrospective Italian study confirmed that the outcomes of cirrhosis patients with COVID-19 were poor. According to a previous study, cirrhotic patients had a higher mortality rate and lower age at death[83].

In summary, COVID-19 is frequently associated with liver function abnormality. However, liver dysfunction may predict a severe form of COVID-19. Therefore, special attention should be paid to older patients, especially those with preexisting CLD and after using hepatotoxic agents. Lastly, cirrhotic patients deserve special attention because they have a high risk of liver function deterioration and mortality with COVID-19 infection, regardless of age (Table 3).

Pancreatic manifestations associated with COVID-19 in elderly patients

The pancreatic involvement of COVID-19, both in terms of clinical implications and underlying mechanisms, is highly manifold and individual-specific[97]. Clinical presentations may range from asymptomatic increases in pancreatic enzyme levels to episodes of acute pancreatitis (AP) and its related complications included pseudocyst formation, peripancreatic fluid collection, pancreatic necrosis, and walled-off necrosis[97,117-119]. Several studies also reported the impact of COVID-19 on metabolic and endocrinologic pancreatic function; manifestations include the development of glucose intolerance and the exacerbation of hyperglycemia, both leading to the development of new-onset diabetes[120, 121].

COVID-19 and AP: Examining the causality

The mechanisms underlying COVID-induced pancreatic damage can be direct, due to the cytopathic effect of local SARS-CoV-2 replication, or indirect, caused by the infection's systemic inflammatory and immune response. Moreover, drug-induced pancreatic injury resulting from antipyretics, anti-inflammatories, and corticosteroids, should also be considered as an additional risk factor[122,123]. However, despite several proposed explanations, no comprehensive theory of COVID-induced pancreatic impairment is universally accepted. The most accredited theory views the engagement of several complexes and interrelated processes. For example, whether the pancreatic injury is caused by SARS-CoV-2 or is just an epiphenomenon is often unclear.

Incidence of COVID-induced pancreatic impairment

From an analysis of the present literature, it can be inferred that the range of incidence of COVID-19-caused pancreatic damage is susceptible to the definition of pancreatic impairment itself. Studies accounting for amylase or lipase serum level increases as an index of pancreatic involvement report an incidence level of 8.5%-17.3%[122,124]. When the more stringent Atlanta criteria are considered, lower incidence values of 1.7%-1.8% are reported[125-127]. An example of this can be found in McNabb-Baltar *et al*[128]'s work; who pointed out that despite mild hyperlipasemia being observed in 9 out of 71 patients (12.1%), only 2 of those (2.8%) had levels more than three times higher than the ULN and that none of them showed any characteristic imaging findings of AP. Similar conclusions are supported by the works of Bansal *et al* [129], Rasch *et al*[130], Barlass *et al*[131], and Bacaksiz *et al*[132], all of which call out for caution when addressing the interrelation between the alteration of pancreatic enzymes and COVID-induced pancreatic impairment. Despite the increase in pancreatic biomarkers typical of COVID-19 patients, no direct correlation to pancreatic impairment is established, as these imbalances could result from concurrent clinical conditions[86,133].

On the other hand, many authors have recognized and described a significant prognostic role of amylase and lipase levels in poor outcomes in COVID-19. Liu *et al*[125] reported a pancreatic enzyme alteration incidence about nine times higher in patients with severe COVID conditions compared to those with non-severe disease (17.4% *vs* 1.85%). Barlass *et al*[131] showed an association between lipase elevation and worse disease outcomes, especially in terms of the need for intensive care (92.9% in patients with elevated lipase levels *vs* 32.8% in those with lower levels) and rate of intubation (78.6% *vs* 23.5%). Ultimately, the multicenter retrospective cohort study by Singh *et al*[134] played a vital role in strengthening this theory, and if its findings are confirmed, serum lipase can be utilized as a marker of disease severity in patients with COVID-19.

Prevalence and outcomes of acute and chronic pancreatitis in COVID-19

After carefully examining the existing literature, a bidirectional relationship between COVID-19 disease and AP can be inferred, at least in terms of outcomes. As part of their retrospective observational cohort study, Inamdar *et al*[135] reported the point prevalence, risk factors, and outcomes among hospitalized patients with pancreatitis with or without COVID-19. This work illustrated a point prevalence of pancreatitis of 0.27%, a higher need for intensive care (mechanical ventilation), and a longer length of hospital stay (OR = 5.65 and OR = 3.22, respectively) among COVID-19 patients. Comparable data were obtained in the works of Karaali and Topal[136], Dirweesh *et al*[137], and from the COVID PAN collaborative study[138], the last of which reported longer length of hospital-stay, persistent organ failure, and higher 30-d mortality in patients with SARS-CoV-2 co-infection. As clearly described by Ye *et al*[139], COVID-19 patients with comorbidities had worse clinical outcomes and greater risk of adverse events proportionally to the number of comorbidities. Focusing on AP, only two studies have compared outcomes in COVID-19 patients with and without pancreatic impairment. Mirò *et al*[140] found comparable results for these two groups, except for the former, being more frequently in need of hospitalization. Similarly, Akarsu *et al*[141] reported that COVID-19 patients who suffered from pancreatitis were more likely to have higher hospitalization and mortality rates. Gubatan *et al*[62] were the first to evaluate the prevalence and outcomes of COVID-19 among patients with a history of pancreatitis. As thoroughly

described by Huang *et al*[142], preexisting pancreas condition was associated with an increased risk of COVID-19 hospitalization and mortality compared to pancreatitis-free patients. Specifically, the highest hospitalization and ICU admission rates were registered in those with a history of chronic pancreatitis. Multicenter research by Hadi *et al*[143] have confirmed that COVID-19 patients with convalescent plasma (CP) bear higher hospitalization rates despite showing no difference in mortality and critical care need. A plausible explanation looks at the higher pancreatic fibrosis grade and the lower inflammatory state, typical of these patients, as predisposing agents to the burden of comorbidities and worse COVID-19 outcomes (Tables 4 and 5).

Distinctive features of COVID-19-associated AP in elderly patients

Focusing on the elderly population, it seems that AP has some particular clinical features that lead to a clinically severe evolution, systemic complications, and, therefore, higher mortality rates[145]. AP has been increasing globally because of an aging population. However, it is worth noting that even if the WHO's definition of elderly is over > 65 years, the age cut-off used for "elderly" in AP prevalence studies differs. In detail, the highest prevalence was found in subjects between 55 and 65 years of age[145-147]. The non-specific presentation and the last occurrence of the symptoms typical of elderly patients make the clinical assessment more difficult for physicians. For example, the typical abdominal pain radiating to the back is absent or mild in 53.8% of cases[148]. For these reasons and the overlap of coexisting comorbidities, AP is often clinically indistinguishable from other clinical conditions in this population. Márta *et al*[149] reported that aging greatly influenced AP's outcome. Their work demonstrated a direct relationship between age and the mortality rate with mortality increase of 0.08% per year between the ages of 20 and 59 and up to 0.76% per year between 59 and 70[149]. These findings, suggesting the involvement of additional deteriorating factors in the elderly population, led the way to other/further studies. COVID-19-induced AP in the elderly population is increasingly reported. Unfortunately, no studies account for only COVID-19 elderly patients with pancreatic impairment, and the few data available are insufficient to draw general conclusions. In Wang *et al*[122]'s work, which describes the incidence of comorbidities in a COVID-19-affected population, the nine patients with pancreatic damage had an average age of 55 years, ranging from 25 to 71 years. Similar data are reported in Inamdar *et al*[135]'s (average age of 54 years), Bruno *et al*[124]'s (average age of 56), and Bulthuis *et al*[150]'s work (60 years). Moreover, a systematic review of case reports and case series pointed out that COVID-19-associated AP affected primarily females with a median age of 53.5 years[144]. The average age of all these study populations aligns with the definition mentioned above of elderly in AP, but the range does not[145]. Conversely, from what was stated before about geriatric patients solely affected by AP[142], 11 case reports of AP in COVID-19-affected elderly patients showed the typical clinical presentation with all the patients experiencing abdominal pain radiating to the back[151-160]. However, these findings are insufficient to suggest a direct or, most likely, indirect effect of SARS-CoV-2 infection on AP's clinical presentation. Therefore, further studies are necessary to establish a causative role. As previously reported, aging is considered a risk factor for a worse outcome not only in COVID-19 disease[161] but also in pancreatitis[149]. Advancing age is one of the 8 modified Glasgow Imrie severity Criteria for AP [162]. Three or more positive criteria, generally assessed within 48 h from admission, are indicative of severe pancreatitis and may require transfer to an intensive care unit[163]. Three of the 11 case reports had to be excluded from the analysis for insufficient data availability. Half of the remaining reports showed a result equal to or higher than three, suggesting severe pancreatitis. However, it is essential to highlight that due to the intrinsic limitation of retrospective analysis, information about the specific timings of the blood test is missing. To the authors' knowledge, no studies evaluating the isolated impact of age as a risk factor for severe prognosis exist for specific subgroups of patients like COVID-19 and AP. Moreover, in the aforementioned prognostic studies[136-138], the demographic composition of the age of the analyzed groups was so similar that no meaningful information could be inferred on the topic.

Impact of SARS-CoV-2 vaccines on patients with IBD

Initially, SARS-CoV-2 vaccines caused hesitancy in the IBD, mainly due to fear of poor response and safety concerns. IBD represents impaired immune function due to the disease and the therapies used to control this illness[60]. Jena *et al*[164] in a systematic review and meta-analysis, analyzed the response to complete vaccination in IBD patients. They reported positive seroconversion rates (95%), although these rates were slightly lower than non-IBD controls (98%). However, if considering only mRNA vaccines, the seroconversion data overlapped between the two populations. Similar results are reported by Bhurwal *et al*[165], which confirmed the adequate response to vaccination in the IBD population (96%), again showing improved outcomes with mRNA vaccines. Moreover, these two meta-analyses found no significant difference in seroconversion concerning the therapy administered (anti-TNF alone, vedolizumab, ustekinumab, or JAK inhibitors), in contrast to other studies which found lower responses to vaccination during anti-TNF alpha and JAK inhibitors therapy [166,167]. In addition, the analysis of breakthrough infections suggests an overall frequency similar to the general population. Nevertheless, a more rapid decline in antibody titers is described in IBD patients, particularly those treated with anti-TNF, immunomodulators, or a combination of these drugs[164]. Another parameter used to assess the efficacy of vaccination is the T cellular response, which plays an essential role in preventing disease progression[168]. Patients with IBD maintain this response even when receiving immune-targeted therapies, confirming that the immunocompromised state does not necessarily prevent a response to vaccination[169,170]. Interestingly, the T cellular response appears to be increased in patients taking anti-TNF-α due to unclear mechanisms[170]. Regarding the safety of vaccinations, several studies have observed similar side effect frequencies between the IBD population and the general population. However, no worsening or flare-up of the disease following vaccination has been proved. Thus, vaccines are considered a safe and well-tolerated strategy for IBD patients[171,172].

Focusing on the elderly population, it is well known that the response to vaccines may be lower than in young people [173], which may also occur with SARS-CoV-2 vaccines. This is probably the result of immune-senescence phenomena, which leads to quantitative and qualitative alterations in the immune system, including a reduction in naive T

Table 4 Evidence regarding pancreatic involvement in coronavirus disease 2019 patients

Ref.	Study design	No. of patients with pancreatic injury/total no. of patients	Remarks
Wang *et al*[122]	CHS	9/52 (4.68%)	Potential mild pancreatic involvement in patients with COVID-19 pneumonia
Bruno *et al*[124]	CHS	6/70 (8.5%)	Pancreatic involvement in hospitalized patients with documented COVID-19
Liu *et al*[125]	RS	13/121 (10.74%)	Pancreatic enzyme alteration incidence was higher in patients with severe COVID-19-related conditions than those with the non-severe disease. However, only a minority of patients with pancreatic enzyme alteration had a confirmed diagnosis of AP as defined by the AC
Stephens *et al*[126]	RS	158/234 (67.5%)	Raised serum amylase in patients with COVID-19 may not be associated with pancreatitis
Akkus *et al*[127]	RS	127/309 (15.7%)	Pancreatic injuries or AP are frequent during COVID-19 infection, especially in those with pre-existing DM
McNabb-Baltar *et al*[128]	RS	9/71 (12.1%)	Although a mild elevation in serum lipase was observed in some patients with COVID-19, acute clinical pancreatitis was not seen, according to the AC
Bansal *et al*[129]	RS	14/42 (33%), 7/29 patients (24.1%)	Pancreatic injury showed no statistically significant relation to the severity or outcome of COVID-19
Rasch *et al*[130]	CHS	22/38 (57.8%)	Patients with lipasemia needed more extended periods of mechanical ventilation than patients with COVID-19-associated ARDS
Barlass *et al*[131]	CCS	14/83 (16.8%)	Elevated lipase is associated with worse disease outcomes and increased ICU admission and intubation
Bacaksiz *et al*[132]	RS	316/1378 (23%)	Hyperamilasemia was significantly associated with COVID-19 severity
Magro *et al*[86]	Review	NA	Increased amylase or lipase levels might not be associated with AP in COVID-19 and may be a consequence of concurrent clinical conditions
Hunt *et al*[133]	Review	NA	No direct correlation between COVID-19 and pancreatic impairment could be established
Singh *et al*[134]	MS	1406/435731 (0.32%)	Worse clinical outcomes
Inamdar *et al*[135]	MS	189/11.883 (0.01%)	COVID-19 patients with pancreatitis were more likely to require mechanical ventilation and had a more extended hospital stay than patients without COVID-19
Karaali and Topal[136]	RS	189/562 (33.6%)	COVID-19 patients with AP had a higher rate of severe AP and a higher need for ICU admission
Dirweesh *et al*[137]	RS	75/339 (22.1%)	Higher mortality, MOF, and POF rates were registered in patients with AP and coexisting COVID-19
Pandanaboyana *et al*[138]	CHS	149/1777 (8.3%)	SARS-CoV-2 infection in acute pancreatitis increases 30-d mortality and disease severity
Mirò *et al*[140]	MS	45/63.822 (0.0007%)	Higher need for hospitalisation in COVID-19 patients with pancreatitis
Akarsu *et al*[141]	CCS	40/316 (12.6%)	Higher mortality rate and increased need for hospitalisation in COVID-19 patients with pancreatitis
Gubatan *et al*[62]	RS	100% total population 14235	Patients with a history of pancreatitis may be more susceptible to COVID-19
Huang *et al*[142]	RCS	4706/326993 (1.4%)	Pre-existing pancreatitis was associated with an increased risk of COVID-19–related hospitalisation and mortality
Hadi *et al*[143]	CS	2/3 (66.6%)	COVID-19 patients with CP bear higher hospitalisation rates
Georgakopoulou *et al*[144]	RS	100%	COVID-19-associated acute pancreatitis affected primarily females with a median age of 53.5 yr

lymphocytes available to respond to a vaccine, a significant decrease in CD8 T cells, and a reduction in the T helper follicular cell response[174-176]. Unfortunately, there are currently no studies evaluating vaccination efficacy and safety in elderly patients with IBD. However, in many studies, older age has been associated with attenuated responses, with an earlier decline of the antibody title and reduction differences in the overall strength of the T-cell, although in most of

Table 5 Case reports regarding pancreatic involvement in old coronavirus disease 2019 patients

Ref.	Study design	Age (yrs)	Remarks
Meyers *et al* [151]	CR	67	COVID-19 can cause clinical AP. Typical abdominal pain radiating to the back. Increase lipase serum level. Evidence of AP in abdominal CT scan. Glasgow Acute Pancreatitis Score: NA
Karimzadeh *et al*[152]	CR	65	COVID-19 presents as mild AP. Typical abdominal pain radiating to the back. Increase lipase serum level. Negative abdominal CT scan. Glasgow Acute Pancreatitis Score: 1 point
Gadiparthi *et al* [153]	CR	74	AP in a patient with COVID-19 with SARS-CoV-2 as the possible etiological agent. Typical abdominal pain radiating to the back. Increase lipase serum level. Evidence of AP in abdominal CT scan. Glasgow Acute Pancreatitis Score: 1 point
Wifi *et al*[154]	CR	72	Emphasises the importance of measuring serum amylase and lipase in patients with COVID-19. Typical abdominal pain radiating to the back. Increase lipase and amylase serum levels. Negative abdominal CT scan. Glasgow Acute Pancreatitis Score: 3 points
Gonzalo-Voltas *et al*[155]	CR	76	A case of AP that could be related to COVID-19 infection. Typical abdominal pain radiating to the back. Increase amylase serum level. Evidence of AP in abdominal CT scan. Glasgow Acute Pancreatitis Score: NA
Reick-Mitrisin *et al*[156]	CR	71	AP should be considered in differential abdominal pain in patients with active or recent SARS-CoV-2 infection. Typical abdominal pain. Increase lipase serum level. Evidence of AP in abdominal CT scan. Glasgow Acute Pancreatitis Score: 3 points
Brikman *et al* [163]	CR	61	Unresolved abdominal pain occurring late during COVID-19 warrants a thorough workup. Typical abdominal pain. Increase lipase serum level. Evidence of AP in abdominal CT scan. Glasgow Acute Pancreatitis Score: 2 points
Acherjya *et al* [157]	CR	57	Pay attention to the atypical presentations of SARS-CoV-2, including AP. Typical abdominal pain radiating to the back. Increase lipase serum level. Evidence of AP in abdominal CT scan. Glasgow Acute Pancreatitis Score: 4 points
Alves *et al*[158]	CR	56	Physicians should be aware that asymptomatic or mildly gastrointestinal symptomatic patients with COVID-19 require pancreatic enzymes and even abdomen imaging to diagnose pancreatitis. them, the presence of IBD does not influence these findings[169,170,177,178].

In conclusion, most of the studies mentioned above agree on the potential benefit of a further vaccine booster dose in patients with IBD, especially if elderly or on specific immunosuppressive therapies, such as anti-TNF alpha or JAK inhibitors. To date, studies reporting response rates with additional doses of COVID-19 vaccine in IBD are limited; however, current data suggest a significant boost in antibody binding levels from a third vaccine dose, even during immunosuppressive therapies, but patients receiving infliximab or tofacitinib show a lower response than healthy controls[179].

Impact of SARS-CoV-2 vaccines on patients with CLD

As mentioned above, cirrhotic patients are at high risk of severe COVID-19 infection. Therefore, vaccination against SARS-CoV-2 represents a significant protective measure in patients with CLD, which must be administered as early as possible[180,181]. Moreover, due to vaccinations, patients should not discontinue any of their medications for liver disease or delay any local or regional treatments for HCC[182]. Current COVID-19 vaccines are safe, but a rare vaccine-triggered immune-mediated hepatitis is reported after COVID-19 vaccination. These events are described in the literature in association with mRNA platforms, but cases have also been described for vector-based vaccines. These cases of liver injury are sporadic and respond to corticosteroid treatment. Therefore, liver injury after vaccination should not represent a limit to further vaccination[183]. Furthermore, a Chinese multi-centric study analyzed the safety and immunogenicity of inactivated SARS-CoV-2 vaccines in patients with CLDs[184]. These vaccines are safe in patients with CLD, as there was no significant difference in adverse reactions among the non-cirrhotic CLD, compensated cirrhosis, and decompensated cirrhosis subgroups. Pain was the most common local adverse reaction, while fever was the most commonly systematic adverse reaction reported. Among laboratory findings, only three patients of 437 with CLD had significant aminopherase elevation with ALT levels > 5 ULN, all of which had elevated aminopherase at baseline. Only one of the three patients required hospitalization. Nevertheless, it is impossible to attribute his adverse reaction to the vaccine for certainty since this patient had a history of discontinuing anti-hepatitis B virus therapy before the SARS-CoV-2 vaccination. In addition, patients with CLD often present an inadequate immune response, which may cause an incomplete immediate and long-term protective response[185]. Therefore, although these vaccines are safe in patients with CLD, they do not guarantee such patients equal antibody levels if compared to healthy controls. However, the difference in the positive rate of SARS-CoV-2 neutralizing antibodies between patients with CLD and healthy control groups is statistically significant (77.3% *vs*

90.3%) despite the adjustment for age, gender, and body mass index[184]. While there was no significant difference in positive rate between non-cirrhotic CLD patients (76.8%), compensated cirrhosis patients (78.9%), and decompensated cirrhosis patients (76.7%). Chen *et al*[186] confirmed in their study that inactivated SARS-CoV-2 vaccines are safe and well tolerated in patients with severe liver disease (such as cirrhosis or HCC). However, they also stressed the necessity to assign priority to vaccine patients with severe liver disease, which may have worse antibody responses than those with non-severe CLDs. Thuluvath *et al*[187] instead, analyzed the antibody response in CLD patients after administration of 2 doses of mRNA vaccines or a single dose of viral vector vaccine. This study revealed that only 24% of patients with CLDs had poor antibody responses. More in detail, 15.8% of patients who received the vector vaccine Johnson & Johnson had a good response, and the mRNA Moderna vaccine showed a better response than the mRNA Pfizer vaccine (76.4% *vs* 64.4%). Moreover, analyzing patients' characteristics, it emerged that those with undetectable antibodies (< 0.4 U/mL) had the highest mean age (64.8 years). In line with Thuluvath *et al*[187], Bakasis *et al*[188] highlighted that CLD was not associated with mRNA vaccine hypo-responsiveness. Only 4% of patients with CLD did not respond to SARS-CoV-2 vaccination, with statistically significant differences between cirrhotic and non-cirrhotic patients. The presence of liver disease showed no correlation with antibody titers or neutralizing activity, while age was negatively correlated with neutralizing activity. According to Willuweit *et al*[189], up to 96% of patients with liver cirrhosis presented an antibody response after receiving two doses of the mRNA-based vaccine. Unfortunately, antibody titers remained relatively stable in the control group while showing a rapid and significant decrease in patients with liver cirrhosis, with any differences stratifying cirrhotic patients according to age. The studies mentioned above do not focus on the differences between safety and efficacy among age (patients under 65 and over 65 years old or following stratification of groups according to age). Moreover, the studies conducted to evaluate the safety and efficacy of SARS-CoV-2 vaccination include a limited number of older adults[190]. Therefore, considering that older adults are more inclined to develop vaccine-related adverse events[191] and the lack of older adults in specific SARS-CoV-2 vaccination studies, further research is recommended to evaluate the safety and efficacy of COVID-19 vaccines in older people.

COVID-19 vaccines and pancreatic involvement

To the best of our knowledge, no published work evaluates the COVID-19 vaccination response in older adults suffering from pancreatic diseases. On the other hand, according to Pfizer's data, only 2 cases of AP as an adverse reaction (among 38000 participants) were reported during the clinical trial of the COVID-19 mRNA vaccine[192]. Since the Pfizer-BioNTech mRNA vaccine was approved for COVID-19 infection, AP has been reported in a few case reports[193-201]. Data inferred from United Kingdom databases (up to November 2022) for the same vaccine report 21 cases of pancreatitis, 19 cases of AP, and 3 cases of necrotizing pancreatitis[202]. The National Agency for the Safety of Medicines and Health Products reports 164 cases of pancreatitis up to February 10, 2022[203]. Data released from VigiBase, the WHO's global database, show 1093 cases of pancreatitis[204]. Currently, there is no evidence supporting a direct relationship between the vaccine and AP; even assuming the existence of vaccine-related pancreatic injury, its mechanism would still be unclear[194]. Moreover, considering the high rate of idiopathic pancreatitis[205], the available data are even more challenging to analyze. Considering the higher vaccination prevalence, fewer cases of AP following vaccination may suggest the involvement of different mechanisms in developing a vaccine-related pancreatic injury[196]. The benefits of vaccination against COVID-19 are unquestionable and not disputed in this paper. However, by reporting this evidence, we aim to make all healthcare workers aware of these possible adverse effects and to highlight the importance of not underestimating any abdominal pain after vaccination. As far as we know, the current literature does not include studies evaluating the safety and efficacy of SARS-CoV-2 vaccines in patients with CP. As mentioned above[142,143], CP may be associated with an increased risk of complications from COVID-19 infection leading to worse outcomes. Thus, reducing that risk by having the vaccine would be advisable.

CONCLUSION

Literature data confirm that the digestive manifestations of COVID-19 are frequent and often impact the clinical course of affected patients. In particular, patients with pre-existing liver disease, including cirrhosis or HCC, are at increased risk for worse outcomes. On the contrary, no definitive conclusions can be drawn for patients with IBD or pancreatic diseases. As for elderly patients with digestive disorders, although the available data are limited and extrapolated from studies not designed for this specific issue, there seems to be no evidence of worse COVID-19 outcomes than those without digestive diseases. As expected, this review confirms that age represents one of the main risk factors for poorer outcomes and higher mortality for COVID-19. Moreover, considering the under-representation of older adults in SARS-CoV-2 vaccination studies, further studies are necessary to evaluate better the safety and efficacy of COVID-19 vaccines, especially in frail older people with chronic digestive diseases.

Abstract

Irritable bowel syndrome (IBS) is a common chronic gastrointestinal disease with a significant impact on patients' quality of life and a high socioeconomic burden. And the understanding of IBS has changed since the release of the Rome IV diagnosis in 2016. With the upcoming Rome V revision, it is necessary to review the results of IBS research in recent years. In this review of IBS, we can highlight future concerns by reviewing the results of IBS research on epidemiology, overlap disorders, pathophysiology, and treatment over the past decade and summarizing the latest research.

Key Words: Irritable bowel syndrome; Overlap; Pathophysiology; Treatment

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Irritable bowel syndrome (IBS) is a physical and mental illness that is becoming more prevalent, and its impact on society is expanding. Understanding of IBS has changed since the release of the Rome IV diagnosis in 2016, and this paper reviews the literature from the past decade to find that research around the brain-gut axis, diet, and gut microbiota are at the forefront of IBS. Moreover, as the research on the physiopathology of IBS has advanced, the treatment model has become more refined, which has important clinical implications.

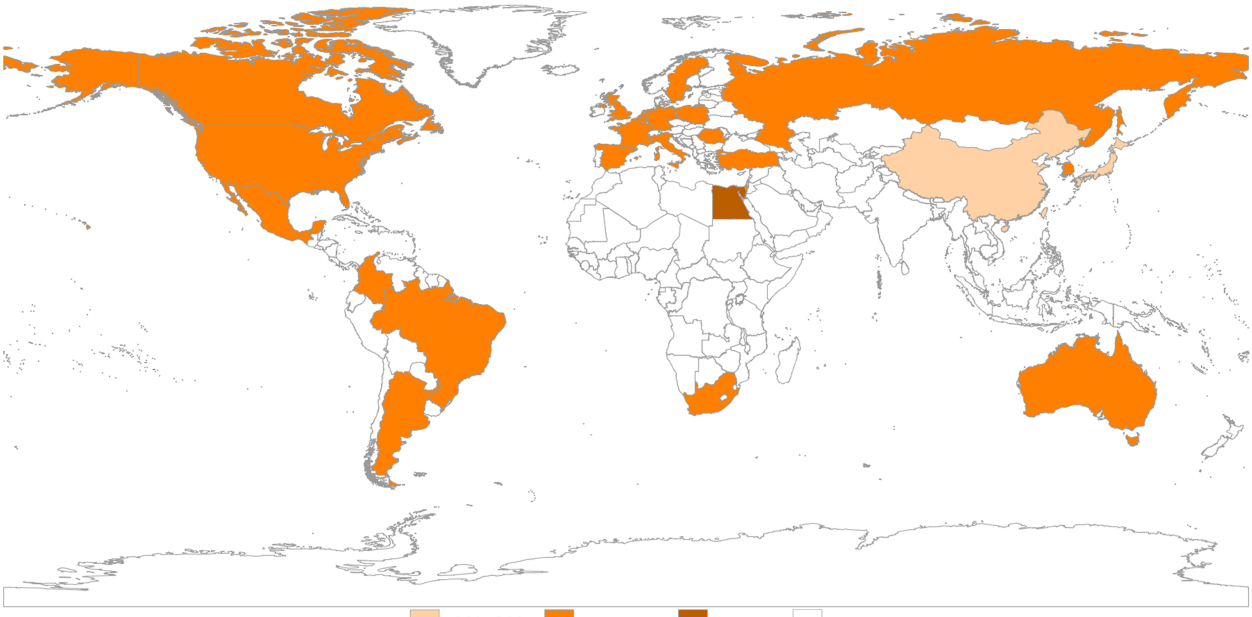
INTRODUCTION

Irritable bowel syndrome (IBS) is a chronic functional disease, and the changes that it causes in bowel function and abdominal pain seriously affect the patient's normal life and work. It mainly affects young and female individuals, and it tends to overlap with other functional gastrointestinal diseases (FGIDs) and cause a huge burden to life and society's economy[1,2]. Prevalence varies greatly between countries because of differences in food, culture, and diagnosis. The Rome Foundation Global Study[3] coverage across the country reported that the overall prevalence of IBS was 3.8% in Rome IV and 10.1% in Rome III. The Rome IV criteria, based on symptoms that have undergone a change in dynasty, suggest that the pathogenesis of IBS is associated with gut-brain interactions, which may be an overlapping pathogenesis between FGIDs. Based on the results of Rome IV, many studies have been performed, so it is necessary to summarize their findings. The aim of this study is to summarize IBS from the perspectives of epidemiology, disease overlap, pathological mechanisms, diagnosis, and treatment, focusing on disease overlap, pathological mechanisms, and treatment.

REGIONALIZATION SHOULD BE EMPHASIZED IN EPIDEMIOLOGY

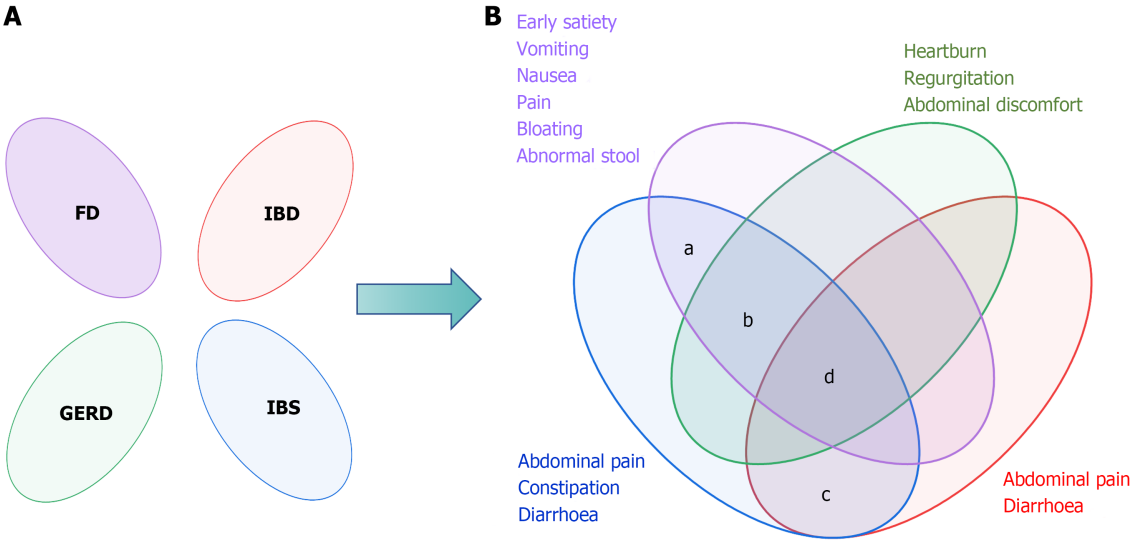
The prevalence of IBS varies widely between different countries. In 2017, the Rome Foundation working group reviewed related work and showed that the prevalence of IBS varied from 1.1% (France and Iran) to 35.5% (Mexico), and the prevalence in Asia is also uneven[4-6]. It might be that many previous surveys did not use uniform diagnostic criteria or the same methodology, with geography, culture, and population being the reasons for different prevalences, and thus the included studies were heterogeneous. The goal of determining the global prevalence of IBS is still inaccurate[7]. Therefore, we discuss the epidemiology of IBS in different continents in recent years.



The Rome Foundation Global Epidemiological Study organized a study using Rome IV in 33 countries and Our analysis discovered that the prevalence rates in Europe and the United States were comparable, while those in Asia and Australia were marginally lower[7] (Figure 1). Egypt had the highest prevalence rate of internet surveyed countries[8]. As well as that, representative researches have also been carried out in various countries in recent years and reported that the prevalence of IBS was 5.2% (Rome IV), 5.9% (Rome III), and 6.98% (Rome IV) in Gibraltar, the United Kingdom[9], Hangzhou, China[10] and Latin America[11], respectively. Based on population survey data in the United States, Canada, and the United Kingdom, the results revealed the Rome III IBS rate was roughly twice as high as the Rome IV rate[12]. Overall, there is a clear predominance in the prevalence in Africa, and the prevalence based on Rome IV diagnosis is similar in the United States and Europe. However, prevalence varies widely between Europe and Asia, especially in Asian countries surveyed by using the internet and questionnaires. In the past, most studies have shown a higher prevalence of IBS in women[13]. Interestingly, IBS is equally common in men and women in Asia[14-16]. The highest prevalence was observed in the educated, the wealthy, students and younger individuals[17]. It also declined with age[1,18,19]. Through years of research and analysis, it was determined that estimating a pooled global prevalence of IBS was unlikely to be feasible, so regionalization should be emphasized in future research.

NEW INSIGHTS INTO THE OVERLAP OF IBS

Rome criteria for IBS based on symptoms were the most recognized, and the overlap of FGIDs was gradually valued by Roman criteria over time (Figure 2). Now, Rome IV suggests that the pathologies exist in the gastrointestinal tract on a continuum instead of as separate disorders, and overlap may be a natural clinical symptom of FGIDs[20]. Likewise, 54127 adults from 26 countries participated in an internet survey and discovered that 68.3% had symptom overlap in both gastrointestinal regions and 2.3% had esophageal, gastroduodenal, bowel, and anorectal overlap[21]. Overall, by reviewing the overlap of IBS and other diseases, it was found that there was obvious overlap between IBS and FGIDs, and anxiety and depression were their common characteristics, which verified the vital position of the central nervous system and brain-gut axis in the pathological mechanism of FGIDs. Therefore, the overlapping pattern and pathology of FGIDs are something that should be studied in depth.



Functional dyspepsia

Functional dyspepsia (FD) and IBS are the most prevalent FGIDs, postprandial fullness, early satiation, epigastric pain, and epigastric burning are the main symptoms of FD. The global prevalence of FD varies from 10%-20%[22]. Clinical studies have identified not only overlap between FD and IBS[23-25], but also the most common overlapping characteristics. In the overlap between FD and IBS-D (diarrhea), abdominal pain, bloating, and diarrhea are prominent. However, in the overlap between FD and IBS-C (constipation), abdominal fullness and constipation are prominent.

Figure 2 The Rome Foundation's views on the overlap of functional gastrointestinal diseases. A: Rome I considered the functional bowel disorders to be independent diseases; B: Rome II and Rome III recognized there was overlap between functional gastrointestinal diseases. a: The prevalence of overlap between irritable bowel syndrome (IBS) and functional dyspepsia was 55.3%; b: The overlap between IBS and gastroesophageal reflux disease ranged from 3%-79% in the questionnaire and 10%-74% when diagnosed by endoscopy; c: A 2020 meta-analysis showed that the pooled prevalence of IBS-type symptoms was 32.5%; d: Only 2.3% had esophageal, gastroduodenal, bowel, and anorectal overlap. FD: Functional dyspepsia; IBD: Inflammatory bowel diseases; GERD: Gastroesophageal reflux disease; IBS: Irritable bowel syndrome.

In a longitudinal follow-up study published in 2022, 807 individuals (Rome IV) were included, 446 (55.3%) of whom had overlapping IBS and FD, which showed that patients with overlapping IBS and FD had more severe symptoms and were more likely to have depression and anxiety[26,27]. Furthermore, a prospective study in South Korea in 2019-2020 reported the same conclusion; moreover, women with overlap of IBS and FD experienced more severe gastrointestinal and depression symptoms than men. Interestingly, an Australian study showed no relationship between gender and overlap[25,28]. There seems to be a distinct overlap between IBS, FD, and gastroesophageal reflux disease (GERD), in which it is easier to merge psychological morbidity and sleep disturbance[29]. Although age, gender, and IBS subtype were not correlated with overlap[25], the pathogenesis analysis of IBS and FD indicates that psychological factors are linked to the overlap of IBS and FD. Therefore, the diagnosis of IBS or FD should be considered in terms of each other,

especially when encountering some anxious, severe symptoms.

GERD

GERD is a condition in which stomach contents reflux and cause uncomfortable symptoms[30], which present with regurgitation, heartburn, or being asymptomatic. Then, GERD is divided into three phenotypic presentations: Nonerosive reflux disease, erosive esophagitis (RE), and Barrett's esophagus (BE), with prevalence rates of 60%-70%, 30%, and 6%-8%, respectively[31]. Before Rome IV, a small number of studies had shown overlap between GERD and FGIDs[32], and IBS is a risk factor for GERD[33]. But now, the Rome Foundation considers overlap between FGIDs to be a trend. In patients with overlapping GERD and IBS, acid reflux and heartburn may present with abdominal pain or discomfort, and visceral hypersensitivity and gastrointestinal motility disorders may be coexisting mechanisms. However, the prevalence of patients with GERD and IBS (different criteria) varies greatly, and the overlap between IBS and GERD ranges from 3% to 79% based on the questionnaire and 10% to 74% when diagnosed by endoscopy[34]. In 2016, an Italian study with 697 heartburn patients found that cases of IBS overlapping with GERD/hypersensitive esophagus (HE) and overlapping functional heartburn (FH) were 147/454 (33%) and 187/243 (77%), respectively[35]. Besides, there is a higher risk of possible overlap between FGIDs.

Inflammatory bowel disease

Crohn's disease (CD) and ulcerative colitis (UC) are common inflammatory bowel diseases (IBDs). CD is characterized by chronic or nocturnal diarrhea, abdominal pain, and weight loss, whereas UC is characterized by bloody diarrhea with rectal urgency and tenesmus[36,37]. Although some biomarkers are used to distinguish between IBS and IBD, there is also overlap between them. Patients with overlapping IBD and IBS are prone to diarrhea and abdominal pain, which can be serious. Besides, a 2020 meta-analysis showed that the pooled prevalence of IBS-type symptoms among patients with IBD was 32.5%[38]. IBS-D is related to gut infections, and the gut microbiome and the intestinal barrier are bridges that connect them. Thus, IBS-D is a common diagnosis in patients with chronic diarrhea following chronic infection[39,40]. Overall, IBD and IBS can be different stages of the same disease. Therefore, the overlapping disease characteristics of IBS and IBD should not be ignored when the patient has a history of intestinal infection. At the same time, it is necessary to prevent IBS when diagnosing IBD.

Other

A follow-up study in the US performed an analysis of data from 655 adults to compare the degree of overlap between chronic overlapping pain conditions (COPCs). Surprisingly, IBS is the most common COPC other than headache. Furthermore, 63% of IBS cases have one or more COPCs, and 53% of IBS cases reported pain in ≥ 3 non abdominal areas [41]. Therefore, when there is chronic physical and abdominal pain, IBS overlap should not be ignored[42]. It was observed that IBS and nonceliac gluten sensitivity had significant symptom overlap, and their physiology and pathology were not clear[43]. Moreover, there is overlap between adolescents with endometriosis and IBS[44], and the overlap between IBS and endometriosis may have the same pathogenesis; specific mechanisms need to be further explored.

PATHOPHYSIOLOGY

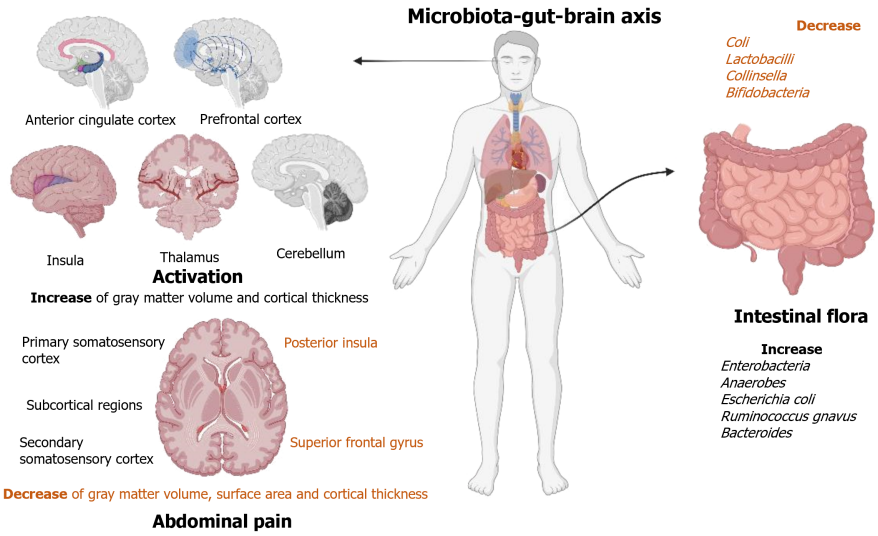
In the past, IBS was thought to be a functional disorder that could not be explained by organic disease or a clear etiology [45]. With the increasing research on IBS and the update of the Rome criteria, the view on the pathophysiological mechanisms of IBS has changed from functional to brain-gut interaction. The aim of this article is to review the pathophysiology from clinical studies and basic research on IBS after Rome IV.

Clinical studies

Recurrent abdominal discomfort, abdominal pain, and altered bowel habits are the core clinical symptoms of patients with IBS, and clinical studies on pathogenesis show that the microbiome, gastrointestinal endocrine cells, visceral hypersensitivity, and gastrointestinal motility disorders , are observed in IBS patients and are the direct causes of abdominal discomfort, abdominal pain, or diarrhea. It was discovered through experiments that the levels of colonic mucosal Takeda G protein-coupled receptor 5 protein expression, short-chain fatty acid (SCFA), fecal bile acids (FBA)[46, 47], tryptophan (aryl hydrocarbon receptor kynurenine pathways), and methane gas production[47,48] were higher in patients with IBS than in healthy control (HC), and metabolites such as SCFA and bile acids are mainly associated with gastrointestinal malabsorption; there are differences between IBS subtypes, and neurotransmitters cause abdominal pain through the brain-gut axis and center. DuPont *et al*[49], recorded intestinal transport in 46 patients with IBS using a wireless pH/pressure recording capsule and found a delayed gastric emptying time in 35/46 (76%) IBS patients. And abnormal colonic transit and disorders of evacuation are important physiopathologies in patients with IBS, leading to constipation, bloating, and abdominal pain. Furthermore, abnormal oroanal transit time (OATT) was associated with hydrogen and methane concentrations, and more rapid OATT was associated with a higher severity of abdominal discomfort, rumbling, and nausea[48]. In addition, gut endocrine cells are scattered throughout the gastrointestinal tract and have sensory microvilli that sense gut pressure and gut contents[50-52], and when the gut lumen is stimulated by food[53], and microbial metabolism, the cells release hormones into the lamina propria to act mainly through paracrine and afferent and efferent synaptic transmission[54-56]. And studies found that histamine, 5-HT, glutamate, and noradrenalin strengthen visceral pain, and γ-aminobutyric acid reduces gastrointestinal motility.

Abdominal pain in IBS patients has been shown to be associated with structural features of the brain. Rectal stimulation seems to activate the anterior cingulate cortex, prefrontal cortex, insula, thalamus, and cerebellum, and is higher in patients with IBS[57]. A study[58] of female IBS patients included 216 female IBS patients and 138 women serving as HC. In comparison to HC, patients with IBS had an increase in gray matter volume and cortical thickness in the primary and secondary somatosensory cortex and subcortical regions; however, the volume, surface, and cortical thickness of the gray matter in the posterior insula and superior frontal gyrus were reduced. Moreover, abdominal pain caused by rectal dilation is linked to the thicker left primary somatosensory cortex (Figure 3).

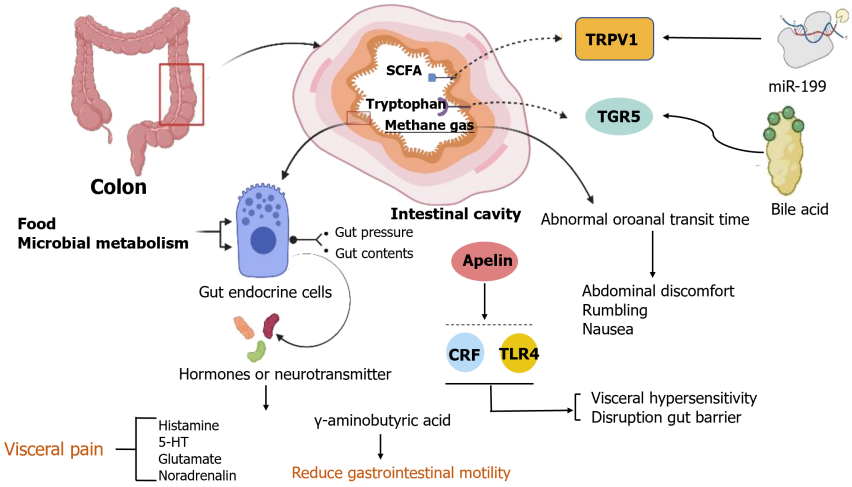
Animal experiments



Visceral hypersensitivity and gut barrier disruption have been shown to be mediated *via* corticotropin-releasing factor (CRF)-Toll-like receptor 4 (TLR4)-proinflammatory cytokine signaling in animal experiments[59,60]. In addition, Nozu *et al*[61] conducted experiments based on IBS model rats and discovered that apelin activates CRF and TLR4, which may create a vicious cycle of proinflammatory cytokine signaling, which is a key pathway for the pathological mechanism of IBS. Then, the disruption of the gut barrier leads to an increase in lipopolysaccharides (LPS) and proinflammatory cytokines, which is a vital pathological mechanism that causes abdominal pain in patients with IBS[62]. And there are some new developments, such as a study using NanoString mRNA measurement of colonic neuroimmune gene expression and founding that the expression of the gene Trpv1 was higher in Gnotobiotic mice from patients with IBS and comorbid anxiety; moreover, it was associated with visceral hypersensitivity and anxiety[63]. Besides, decreasing miR-199 caused visceral hypersensitivity and augmented visceral pain in patients with IBS through translational upregulation of TRPV1[64]. Both activating BDNF-TrkB-PKMζ signaling in the thoracolumbar spinal cord of rats to increase synaptic activity and activating TLR4 trigger the release of pro-inflammatory cytokine afferent nerves and can cause visceral hypersensitivity[65,66]. Moreover, recent studies have shown that abnormal mast cell structure or function is a potential mechanism for visceral hypersensitivity in IBS[67], and post-IBS with gut microbial disorders leading to IBS and signaling pathways are also associated with visceral hypersensitivity[67,68]. In addition, an excellent review by Tozlu *et al*[69]. indicated that the number of mucosal eosinophils increased substantially more in patients with post-IBD IBS-D than in patients with active IBD, there was a reaction to the removal of allergic foods during treatment, and intestinal inflammation in patients with IBS was associated with food allergic reactions. Peptide YY (PYY) is localized in endocrine cells and regulates gut motility and visceral sensitivity by releasing and modulating serotonin[70] (Figure 4).

Microbiome

Koloski *et al*[71,72] discovered that higher baseline levels of anxiety and depression were significant predictors of developing IBS, and two prospective studies found that functional gastrointestinal symptoms preceded the mood disorder in two-thirds of patients. Dinan *et al*[73,74] have suggested that disturbances in the gut microbiota can affect brain function, behavior, and cognition, and the theory has developed into the microbiota-gut-brain axis, which is an important basis for the influence of gut microbes as well as neurotransmitters on IBS. The microbial diversity and abundance of stool in patients with IBS were altered compared to those in HC, with a decrease in *Coli*, *Lactobacilli*, *Collinsella*, and *Bifidobacteria* and an increase in *Enterobacteria*, *Coli*, anaerobes, *Escherichia coli*, *Ruminococcus gnavus*, and Bacteroides in patients with IBS. And a higher proportion of Bacteroides and *Allisonella* in patients with IBS-M[75,76]. In addition a study[77] used 16S rRNA metagenomic sequencing and performed phylogenetic investigation of communities by reconstruction of unobserved states to analyze fecal samples from control (n = 12) and IBS-D patients (n = 7) and reported that in patients with IBS, the abundances of *Sutterellaceae*, *Acidaminococcaceae,* and *Desulfovibrionaceae* were significantly increased, and those of *Clostridiaceae, Leuconostocaceae, Enterococcaceae, Peptostreptococcaceae*, and *Lachnospiraceae* were significantly decreased; moreover, secondary bile acid biosynthesis was decreased, and the citrate cycle was increased. Moreover, a study[78] used proton nuclear magnetic resonance spectroscopy and shotgun metagenomic sequencing to analyze fecal metabolites and the gut microbiome (IBS patients =142 and HC =120). It reported that the gut microbial diversity of IBS (Simpson's evenness metric) was drastically lower than that of HC, and metabolomics found that the mechanism of IBS was related to 5-HT.



TREATMENTS

The diagnosis of IBS is based on symptoms ranging from the Manning criteria to the Rome criteria, and the most widely used diagnostic criteria are the Rome IV[79]. Research around Rome IV has revealed that there are many important biomarkers that guide the differential diagnosis and symptomatic treatment of IBS that may be taken into account. According to Vijayvargiya *et al*[80], FBA and fecal fat are potential biomarkers for IBS-D and IBS-C. Total FBA, chenodeoxycholic acid (CDCA), cholic acid (CA), and primary bile acids were significantly higher in patients with IBS-D than in healthy patients or patients with IBS-C. In contrast, deoxycholic acid (DCA) and combined DCA and CDCA (secretory) bile acids were significantly lower in patients with IBS-C than in HC and patients with IBS-D. Combining fasting serum 7α-hydroxy-4-cholesten-3-one and primary bile acids or fecal bile acid concentrations in stool samples is a simple, low-cost diagnostic for bile acid diarrhea (BAD). Circulating resolvin D1 (RvD1) and c-reactive protein (CRP) are inflammatory markers in patients with IBS-C; patients with IBS-C have higher CRP and lower RvD1 concentrations than HC[81]. Furthermore, radiopaque markers and scintigraphy can be used to assess transit function, and rectal sensation to balloon distension can be used to assess visceral hypersensitivity[82]. All of the ancillary tests listed above can be used to further identify the cause and guide medication use if the first-line medication is ineffective.

Figure 3 Research progresses on the mechanism of action of the microbiota-gut-brain axis. Brain changes in patients with irritable bowel syndrome (IBS) are associated with abdominal pain. They have higher activation of the anterior cingulate cortex, prefrontal cortex, insula, thalamus, and cerebellum. They also mainly showed an increase of gray matter volume and cortical thickness in the primary somatosensory cortex, secondary somatic sensory cortex, and subcortical regions and a decrease of gray matter volume, surface area, and cortical thickness in the posterior insula and superior frontal gyrus. Specific changes in the intestinal flora of patients with IBS. The number of *Coli*, *Lactobacilli*, *Collinsella*, and *Bifidobacteria* in IBS patients decreased, while the number of *Enterobacteria*, *Anaerobes*, *Escherichia coli*, *Ruminococcus gnavus*, and *Bacteroides* increased.

Figure 4 Pathology of irritable bowel syndrome in the intestinal. Food and microbial metabolism stimulate the gut's endocrine cells to release hormones and neurotransmitters, leading to visceral pain and reducing gastrointestinal motility. Apelin, corticotropin-releasing factor, and Toll-like receptor 4-proinflammatory cytokine signaling lead to visceral hypersensitivity and disruption of the gut barrier. The concentrations of hydrogen and methane are related to abnormal oroanal transit time (OATT), and a more rapid OATT was associated with a higher severity of abdominal discomfort, rumbling, and nausea. Decreasing miR-199 caused visceral hypersensitivity and augmented visceral pain in patients with irritable bowel syndrome (IBS) through translational upregulation of TRPV1. Colonic mucosal protein expression and faecal bile acids were correlated with the symptom severity of IBS-D patients. CRF: Corticotropin-releasing factor; TLR4: Toll-like receptor 4.

Patients with mild IBS first choose education, diet, and lifestyle interventions as prerequisites, combined with first-line therapeutic drugs. If first-line treatment is ineffective, clinical judgment combined with ancillary tests is required to select appropriate second-line drugs and non-pharmacological interventions (Figure 5). Furthermore, patients with psychological problems can be assessed using psychological questionnaires, emphasizing doctor-patient communication for emotional relief, and using tricyclic antidepressant (TCA) or selective serotonin reuptake inhibitor (SSRI) medications.

Lifestyle intervention therapy

Stress reduction, appropriate exercise, and a special diet are the main non-pharmacological treatments for preventing induction; likewise, the publication of the British Gastroenterological Society guidelines[83] in 2021 and the updated guidelines from the American College of Gastroenterology (ACG) in 2022 emphasized that dietary counseling should be regarded as a first-line treatment option. A low-FODMAP (fermentable oligosaccharides, disaccharides, monosac-

Figure 5 The conventional treatment and further treatment of irritable bowel syndrome patients. TCM: Traditional Chinese treatment; CBT: Cognitive behavioral treatment; HAD: Hospital Anxiety and Depression scale; IBS-QOL: Irritable Bowel Syndrome-Quality of Life Questionnaire; PAC-QOL: Patient Assessment of Constipation-Quality of Life Questionnaire; PAC-SYM: PAC-Symptoms Questionnaire; 7αC4: 7α-hydroxy-4-cholesten-3-one; 75-SeHCAT: 75-selenium homocholic acid taurine; TCA: Tricyclic Antidepressants; SSRI: Selective Serotonin Reuptake Inhibitors; IBS: Irritable bowel syndrome; IBS-C: IBS-constipation; IBS-D: IBS-diarrhea.

charides, and polyols, LFD) diet is currently the most recommended and effective diet for IBS intervention[84]. And FODMAP induces symptom generation in IBS based on the gut-brain axis[85]. The ACG suggests that the LFD diet be implemented in three steps: (1) A period of strict restriction (lasting no longer than 4-6 wk); (2) reintroduction of FODMAP foods; and (3) personalization based on reintroduction results[86]. The short-term efficacy and safety of LFD compared to a Western diet and conventional diet in relieving IBS patients are definite[87]; of course, a regular diet is the foundation. Gluten-free foods and dietary fiber are other currently approved diets for patients with IBS[88,89]. IBS-D patients benefit more from LFD than IBS-C patients, while fiber diets such as psyllium fiber are more effective in IBS-C patients[90]. Garg[91], professor, proposed the "FEED" method, in which ample daily psyllium fiber (25 g) and sufficient water (500 mL), along with elevation of the feet and exercises of the abdominal muscles while sitting on the toilet, can help IBS-D symptoms. In contrast, lactose, sorbitol, fructose, xylitol, mannitol, fat, alcohol, insoluble fibers, and fizzy drinks increase pain and flatulence and should be avoided by patients with IBS[92-94].

Cognitive behavioral treatment

Since IBS is a gastrointestinal physical disorder that often fluctuates with stress, the Rome working team strongly recommends brain-gut axis behavior therapies as part of the treatment of DGBI disorders such as IBS[95]. Including hypnotherapy, dynamic psychotherapy, and relaxation therapy[96] can improve abdominal pain, standard of living, and psychological symptoms in patients with IBS and can reduce health care costs. Although some patients are unable to

receive psychotherapy, recent studies have shown that cognitive behavioral treatment (CBT) of hypnotherapy is a potential and affordable treatment. A study included 436 patients with IBS (Rome III) who were followed up at 2 wk and 3, 6, 9 and 12 mo after the end of specific CBT treatment, and the results showed that not only did CBT improve symptoms, but the improvement usually extended up to 12 mo after treatment[97,98]. Additionally, gut-directed hypnotherapy (GHT) can also improve the symptoms of IBS by affecting gastrointestinal motility and visceral sensitivity [99,100]. Overall, most views support the ideal that it works because it is based on the brain-gut axis. GHT is beneficial in directly reducing the discomfort of IBS and refractory IBS as well as improving quality of life and health, and the efficacy is sustained. Moreover, it can reduce anxiety and depression, but its mechanism is largely unclear[101]. The mechanism of hypnotherapy is related to the brain-gut axis, but current research on the microbiome has not provided definitive results[102]. What is certain is that hypnotherapy works by regulating the autonomic nervous system (ANS). The vagus nerve is related to the brain-gut axis and can coordinate gastrointestinal functions, and there seems to be potential in studying the role of the vagus nerve[102,103].

Pharmacological treatment

IBS-D: The ACG published guidelines for IBS-D conditional recommendations in 2022[104] include the three drugs eluxadoline, rifaximin, and alosetron (moderate certainty), which can relieve or assist abdominal pain and stools, but there are adverse effects and contraindications. Loperamide (very low certainty) can relieve diarrhea, but there is no evidence that it improves abdominal discomfort. TCA and antispasmodics have low certainty. Moreover, SSRIs are recommended against use (low certainty) (Table 1).

IBS-C: The first-line therapy for IBS-C are bulking agents and osmotic laxatives. The ACG published guidelines for IBS-C [105] and recommended them in 2022, including a strong recommendation for linaclotide (high certainty) and conditional recommendations for tenapanor, plecanatide, tegaserod, and lubiprostone (moderate certainty); polyethylene glycol laxatives, TCA, and antispasmodics have low certainty. The panel made a conditional recommendation against the use of SSRIs (low certainty). Chloride channel activators and guanylate cyclase activators are recommended for global IBS with constipation symptoms[106]. However, adverse effects of diarrhea may occur (Table 1).

Pain: Antispasmodics, including anticholinergic and calcium-blocking drugs, which can relieve pain and improve bowel movements, remain the first choice for abdominal pain in IBS[107]. Such as cimetropium/dicyclomine, peppermint oil, pinaverium, and trimebutine have clear benefits on abdominal pain and symptom scores[108]. By reviewing relevant RCTs[109-112], it was shown that most samples were small and of moderate quality. Overall, limited to short-term treatment Antidepressants can improve pain through central nervous system action, but clinical trials are scarce and the limitation of adverse events is uncertain. Although pinaverium was the most commonly used drug for the treatment of abdominal pain with a rapid onset of action and the improvement in abdominal pain was greater than that of bowel movements, its efficacy was less significant than that of placebo after one week. Whereas otilonium bromide (OB) significantly has a longer onset of action than pinaverium but is more suitable for patients with diarrhea. Moreover, drotaverine has a slow onset of action and is more suitable for the later stages of IBS. Although peppermint oil has been shown to be effective, it has many adverse events (heartburn or GERD symptoms, belching, headache, *etc.*). Finally, TCA and SSRIs have been shown to be effective, but SSRI adverse events are more numerous, and TCA is recommended for patients with significant anxiety or abdominal pain[113,114] (Table 1).

Traditional Chinese treatment

Traditional Chinese treatment: Traditional Chinese treatment (TCM) prescriptions Traditional Chinese medicine treatments, including prescriptions, acupuncture, and moxibustion, are the main treatments for IBS, although they are still complementary treatments that have been found to have great potential through research. Its possible mechanisms of action are mainly through regulating the enteric nervous system, improving gastrointestinal motility, reducing visceral hypersensitivity, regulating intestinal flora, and regulating the immune system to alleviate IBS[115].

A RCT designed in China, enrolling 216 patients with IBS who were assigned to the control group that took the Chang'an I Recipe or placebo group, reported that the Chang'an I Recipe outperformed the placebo in the treatment of IBS-D with no major side effects[116]. Furthermore, 60 IBS patients were enrolling in a study and were divided into the control group (n = 20) and the treatment group (n = 40), which were given oral pinaverium bromide tablets and Tongxie Yaofang decoction on the basis of conventional treatment, respectively. And the results reported that the flavored Tongxie Yaofang had a significant effect on the symptoms of patients with IBS-D[117], and improving the gut microbiome, alleviating visceral hypersensitivity, regulating 5-HT level in patients, and inhibiting colonic contraction are mechanisms for the treatment of IBS[118-120]. Moreover, Tongxie Anchang Decoction improves IBS by reducing visceral hypersensitivity, reversing mast cell infiltration, and regulating 5-HT[118,121]. And Xiang Sha Liu Jun Zi Decoction reduced the mean diarrhea score of IBS patients[122]. Finally, the Fuzi-Lizhong pill can impact bacterial diversity in the gut and regulate inflammation and immune system to treat IBS-D[123].

Acupuncture and moxibustion: The therapeutic effects of acupuncture are recognized worldwide, although its mechanisms of action are still being further explored. Acupuncture has a bright future in IBS and FGIDs, yet there remain controversies that need to be further explored. A randomized trial of 344 patients with IBS in the acupuncture group and 175 in the pinaverium bromide group reported that the acupuncture group was more effective than the control group, and the effect lasted up to 12 wk[124]. Besides, 126 patients with IBS-D (liver stagnation and spleen deficiency) were randomly assigned to one of three groups: A herb-separated moxibustion group (n = 42, applied to Jinsuo (GV 8)-eight-diagram points), a Western medication group (n = 42), and a Chinese herbal medication group (n = 42), and the results

Table 1 Summary of irritable bowel syndrome medications

Type	Mechanism of action	Example	Appearing dose	Efficient	
IBS-D					
Opioid agents	Inhibits secretion, transit	Loperamide	4 mg tid	Unknown for IBS; effective for diarrhea	First-line
		Eluxadoline	75 mg or 100 mg bid	Effective for FDA composite: 100 mg: OR, 0.87 (95%CI: 0.83-0.91); 75 mg: OR, 0.89 (95%CI: 0.84-0.94). RCTs: Effective for diarrhea and composite diarrhea + pain; not pain alone	
Bile acid sequestrants	Bind to bile acids	Cholestyramine	4 g bid	Unknown: effective in open-label studies; ineffective in 1, single-center RCT	
		Colestipol	-		
		Colesevelam	32 mg bid		
Antibiotic	Anti-inflammatory	Rifaximin	550 mg tid	Effective: In 2012 SRMA: Global: OR 1.57 (1.22 to 2.01); Bloating: OR 1.55 (1.23 to 1.96); In 2020 SRMA: FDA composite: OR: 0.92 (0.86 to 0.98) Global OR: 0.91 (0.77, 1.07)	Second-line
5-HT3 Receptor antagonists	Delays colonic transit and reduces visceral pain	Alosetron	0.5-1 mg qd or 1 mg bid	Effective: Global RR 1.60 (1.49 to 1.72); Pain RR 1.30 (1.22 to 1.39); FDA composite: OR 0.69 (0.60 to 0.80)	Third-line
		Ramosetron	2.5 μg qd		
IBS-C					
Osmotic	Osmotic secretion	PEG3350	-	Effective: improves SBMs, CSBMs, consistency straining but not pain, bloating or incomplete evacuation	First-line
Secretory	Increased Cl- and water secretion	Lubiprostone	8 μg bid	Effective: Lubiprostone 8 μg RR: 0.85 (0.78 to 0.96) for FDA endpoint	Second-line
		Linaclotide	290 mg qd	Effective: Adequate relief IBS: RR 1.95 (1.3 to 2.9); Abdo pain: RR 1.58 (1.02 to 2.46) RR 0.81 (0.76 to 0.86) for 290 μg for FDA endpoint	
		Plecanatide	3 mg/6 mg qd	Effective: Using FDA endpoint 6 mg: RR 0.87 (0.81 to 0.94); 3 mg RR 0.88 (0.82 to 0.94)	
Anti-absorptive	NHE3 inhibitor stimulates Na+, water secretion	Tenapanor	15mg bid	Effective at 50 mg 2/d; NNT, 7-9 for complete SBM and combined complete SBM ≥ 30% pain reduction; 11 for abdominal pain reduction > 30% alone	Third-line
Pain					
Anti-spasmodics	Inhibition of muscarinic Ach receptors or block Ca++ channels, relaxation of GI smooth muscle	Pinaverium	50 mg tid	May be effective: OR, 0.68 (95%CI: 0.57-0.71); overall NNT, 5	First-line
		Otilonium	20/40/80 mg tid		
		Hyoscine	-		
		Peppermint Oil	182 mg	Effective: OR, 0.43 (95%CI: 0.32-0.59); Global: RR 2.23 (95%CI: 1.78-2.81); overall NNT, 2.5; RCT of sustained release formulation: decrease pain, bloat, urgency but not total IBS scores	
Antidepressants	Psychological, acting on the CNS	TCA	-	Effective: OR, 0.67 (95%CI: 0.58-0.77); for global: OR, 0.62 (95%CI: 0.43-0.88); NNT, 4 for abdominal pain	Second-line
		SSRI	-		

Adapted from Camilleri *et al*[82]. Ach: Acetylcholine; 5-HT3: Serotonin type 3; IBS: Irritable bowel syndrome; IBS-C: Constipation; IBS-D: Diarrhea; IBS-M: Mixed symptoms; NHE3: Sodium-hydrogen exchanger 3; OR: Odds ratio; PEG 3350: Polyethylene glycol 3350; RCT: Randomized clinical trial; RR: Relative risk; Rx: Prescription; SSRI: Selective serotonin reuptake inhibitor; SBM: Spontaneous bowel movement; SRMA: Systematic review and meta-analysis; TCA: Tricyclic antidepressant.

showed that the TCM symptom score, gastrointestinal symptom score, and IBS-SSS score were significantly reduced in the moxibustion group[125]. Overall, Pishu (BL 20), Zhongwan (RN 12), and Zusanli (ST 36) are acupuncture points commonly used in clinical practice, and acupuncture and moxibustion have few side effects[93].

Microbial therapy

Probiotics: Probiotics can relieve bloating, intestinal gas, and IBS symptoms, and in addition, studies have shown that probiotics (*Lactobacillus*, *Bifidobacterium*, *Escherichia coli*, and *Streptococcus*) can significantly relieve the overall symptoms of diarrhea and IBS-D[126,127]. However, the role of probiotics is controversial; a small number of studies have discovered that probiotics have no effect on bloating or abdominal pain[128,129]. A RCT included 389 patients with IBS. The control group was treated with oral probiotics for 6 wk. The final results showed that the treatment effect of probiotics was not superior to placebo when all IBS subtypes were included, but the analysis found a higher percentage of sustained responders in the probiotic group than in the placebo group in IBS-D[130]. Although there is a contradiction in the current evidence, analyzing it objectively resolved the contradictions and also demonstrated that probiotics have great potential for the treatment of IBS, especially in patients with IBS-D[131].

Prebiotics and synbiotics: Prebiotics and synbiotics, the collaboration of prebiotics and probiotics, become synbiotics, which have beneficial effects on the gastrointestinal tract by regulating the diversity and activity of intestinal microorganisms and protecting the integrity of the intestinal mucosa[132,133]. A RCT reported, that compared to placebo, synbiotics treatment over an 8-wk period (*Lactobacillus* and *Bifidobacterium* probiotic strains and short-chain fructooligosaccharides; colony-forming units (CFU) per sachet was five billion, bid) significantly improved overall symptoms of IBS, flatulence (P = 0.028), and bowel habits (P = 0.028). It is recommended to try probiotics for 12 wk and observe the efficacy[83], have benefits in improving IBS-D.

Fecal microbiota transplantation: Fecal microbiota transplantation (FMT) for *Clostridium difficile* infection has shown good efficacy in improving intestinal flora[134], and although studies on FMT for IBS are scarce and results remain controversial, the overall results suggest a positive trend for FMT for IBS. A RCT included 135 IBS patients randomly assigned to receive their own stool, 30 g FMT, or 60 g FMT, with response rates of 23.6%, 76.9%, and 89.1%, respectively [135]. Moreover, a recent study has found that FMT not only improves the symptoms of IBS patients but also improves depression and anxiety[93]. However, the studies of Madsen, A.M.A. *et al*[136] and Browne *et al*[137] reported that FMT capsules have no clinical benefit on abdominal pain, stool frequency, or stool form in IBS patients and have no benefit. Therefore, the clinical practice and clinical effect of FMT in the field of gut microbiomes and IBS need to be further verified and explored.

CONCLUSION

IBS-related studies have shown a downward trend in IBS dysfunction, and the brain-gut axis is gradually becoming more prominent in IBS research by reviewing the related research of the last decade. With the help of convenient laboratory tests, a new diagnosis and treatment model was formed based on the complex etiology and clinical combination of IBS, and the above has positive implications for a new understanding of IBS.

It is concluded that a pooled global prevalence of IBS is unlikely to be meaningful and that future research should focus more on regionalization. The definition of IBS has been updated with the discovery of overlapping symptoms and advances in research on IBS pathogenesis, and its definition tends to suggest that FGIDs are a group of disorders with the same pathogenesis, such as the brain-gut axis and visceral hypersensitivity. Therefore, in the future, we should pay more attention to the influence of the brain-gut axis and the central nervous system on the entire gastrointestinal tract and understand FGIDs as a whole. IBS is a dysfunctional disease, but in the absence of simple and inexpensive screening tests for many biological markers, patients such as those with BAD are still included in IBS-D. These technologies still need further validation and dissemination. It is possible that an updated Rome criteria will exclude them from the IBS diagnosis as technology advances. Furthermore, studies of IBS-related dietary interventions, such as LFD, special diets for IBS-C, and foods with gastrointestinal allergies, as well as the gut microenvironment and the brain-gut axis, are the hot spots of research on gut inflammation and the gut barrier.

Long-term treatment brings economic pressure and psychological burden, and for patients for whom conventional treatment is ineffective, further search for etiology should be done with the help of adjuvant examinations, and appropriate second-line treatment or psychotherapy should be chosen. In recent years, non-pharmacological treatment and Chinese medicine have been favored by IBS patients, but the current treatment should be further improved in order to facilitate the development of alternative medicine, with lifestyle, diet, and acupressure as routine interventions. It is important to note that lifestyle and CBT only relieve the symptoms and frequency of IBS; they do not improve the quality of life. Moreover, the involvement of microbiota in the brain-gut axis is widely recognized and studied, and RCTs related to intestinal flora have yielded encouraging results. However, current studies of microbiota are mostly related to IBS-D and have limitations. Let's look forward to more clarity on the treatment and management of IBS.

Abstract

The world is experiencing reflections of the intersection of two pandemics: Obesity and coronavirus disease 2019. The prevalence of obesity has tripled since 1975 worldwide, representing substantial public health costs due to its comorbidities. The adipose tissue is the initial site of obesity impairments. During excessive energy intake, it undergoes hyperplasia and hypertrophy until overt inflammation and insulin resistance turn adipocytes into dysfunctional cells that send lipotoxic signals to other organs. The pancreas is one of the organs most affected by obesity. Once lipotoxicity becomes chronic, there is an increase in insulin secretion by pancreatic beta cells, a surrogate for type 2 diabetes mellitus (T2DM). These alterations threaten the survival of the pancreatic islets, which tend to become dysfunctional, reaching exhaustion in the long term. As for the liver, lipotoxicity favors lipogenesis and impairs beta-oxidation, resulting in hepatic steatosis. This silent disease affects around 30% of the worldwide population and can evolve into end-stage liver disease. Although therapy for hepatic steatosis remains to be defined, peroxisome proliferator-activated receptors (PPARs) activation copes with T2DM management. Peroxisome PPARs are transcription factors found at the intersection of several metabolic pathways, leading to insulin resistance relief, improved thermogenesis, and expressive hepatic steatosis mitigation by increasing mitochondrial beta-oxidation. This review aimed to update the potential of PPAR agonists as targets to treat meta-

bolic diseases, focusing on adipose tissue plasticity and hepatic and pancreatic remodeling.

Key Words: Obesity; Insulin resistance; Peroxisome proliferator-activated receptors; Pancreas; Hepatic steatosis; Adipose tissue

Core Tip: The world faces a pandemic of obesity and metabolic diseases. Peroxisome proliferator-activated receptors' (PPARs') target genes regulate several metabolic pathways, alleviating obesity and its metabolic impairments. PPARα exerts relevant anti-inflammatory, anti-steatotic, and pro-thermogenic effects, collaborating with weight loss and insulin resistance alleviation. PPARγ is useful for glycemic management, albeit with caution due to side effects after its total activation. PPAR β/δ is not clinically used owing to a pro-tumorigenic profile. However, Pan-PPAR or dual-PPAR agonists can retain PPARβ /δ or partial PPARγ activation benefits and configure promising approaches to treat metabolic diseases alone or in combination with other drug classes.

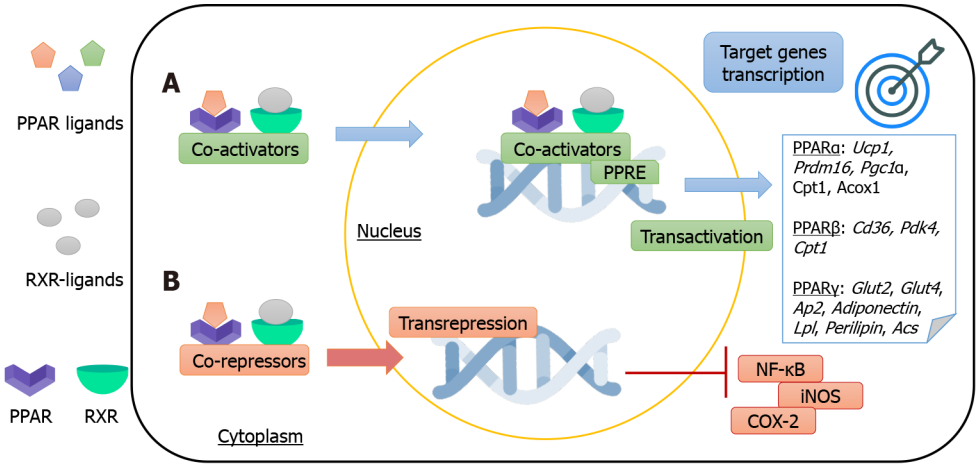
INTRODUCTION

The unprecedented obesity rates have become an immense public health problem due to increased costs to treat comorbidities like diabetes, cancer, osteoarticular diseases, and cardiovascular events[1]. Most obesity cases stem from a chronic positive energy balance, where surplus energy intake surpasses the energy expenditure (EE), sending excessive energy to the adipose tissue[2,3].

The white adipose tissue (WAT) is a buffer against excess energy from the diet and first undergoes hyperplasia and hypertrophy and preserves its different types of cell composition[4,5]. As this process continues, preadipocytes become rare, and hypertrophy predominates until the adipocyte reaches its maximal capacity to enlarge, parallel to a rarefaction of vascularization and the high amount of proinflammatory immune cells within the stromal vascular fraction of the WAT[6,7]. At this stage, inflammation and insulin resistance activates lipolysis to allow the storage of the continuing excessive energy from the diet at the expense of diverting the non-esterified fatty acids (NEFAs) from lipolysis to organs not specialized to store lipids like the liver and the pancreas (lipotoxicity), triggering steatosis[8,9].



Hepatic and pancreatic steatosis compromises the physiology of these organs, collaborating with the progression to end-stage liver diseases and diabetes[10-12]. Thus, the scientific community seeks for strategies to mitigate the deleterious effects of obesity and its comorbidities, which affects the worldwide population regardless of economic income or age. The peroxisome proliferator-activated receptors (PPARs) are a family of transcription factors linked to the cellular metabolism of lipids, carbohydrates, proteins, and cell proliferation, existing in three isoforms: PPARα, PPARβ/δ, and PPARγ and emerged in recent decades as a strategy to treat obesity and its complications[13].

PPARs are binding-dependent transcription factors that regulate gene expression by specifically binding to PPAR-responsive elements (PPREs). Each receptor heterodimerizes with the retinoid X receptor (RXR, where X can be α, β/δ, or γ) and binds to its respective PPRE, forming a structure that will recognize specific DNA sequences (AGGTCA) for the transcription of their target genes. This PPAR mechanism of action is known as trans-activation. Moreover, PPARs can regulate gene expression independently of binding to PPREs, through the mechanism of trans-repression. There is a crosstalk between PPARs and other transcription factors that regulate their gene expression, and most of the anti-inflammatory effects of PPARs stem from this mechanism[14,15]. Figure 1 summarizes PPARs mechanisms of action.

PPARs regulate countless metabolic pathways after activation by endogenous ligands, such as fatty acids and their derivatives or synthetic agonists, which trigger a conformational change to interact with transcriptional coactivators[16,17]. The PPARα isoform expression is high in the liver, muscle, and heart, and its activation, according to previous studies, suggests that this receptor participates in lipid metabolism. PPARγ is mainly expressed in white and brown adipose tissue (BAT), being responsible, among other functions, for adipogenesis. Finally, PPARβ/δ has a wide body distribution with described roles in fatty acids oxidation in muscle and general energy regulation[13].

PPARs exert their physiological activities by activating the transcription of their target genes and, in this way, regulate lipid metabolism, glucose homeostasis, cell differentiation, obesity, and cancer. Furthermore, PPARs may directly participate in immune responses and inflammation mechanisms[18].

Considering that PPARs are found at the intersection of several metabolic pathways, influencing glucose homeostasis, adiposity, and mitochondrial function in the liver, this review aimed to update the potential of PPAR agonists as targets to treat metabolic diseases, focusing on adipose tissue plasticity, hepatic, and pancreatic remodeling.

Figure 1 Peroxisome proliferator-activated receptors mechanisms of action. Proliferator-activated receptors (PPARs) are ligand-activated transcription factors that regulate gene expression through two different mechanisms. A: PPAR-retinoid X receptor heterodimers bind to DNA-specific sequences called peroxisome proliferator-response elements to trigger target genes transcription (transactivation). PPARs' target genes include thermogenic [*Ucp1*, *PPAR-gamma coactivator 1 alpha* (*Pgc1α*), and *PR domain containing 16* (*Prdm16*)], mitochondrial and peroxisomal [*carnitine palmitoyltransferase I (Cpt1)*, peroxisomal acyl-coenzyme A oxidase (*Acox*), and pyruvate dehydrogenase kinase 4 (*Pdk4*)], anti-inflammatory (*Adiponectin*), insulin-sensitizing [glucose transporter 2 (*Glut2*), *Glut4*], and adipocyte metabolism [*Cd36*, adipocyte protein 2 (*Ap2*), lipoprotein lipase (*Lpl*), *Perilipin*, and acetyl CoA synthetase (*Acs*)] genes; B: PPARs regulate gene expression through transrepression, a DNA-independent mechanism. For example, PPARs inhibits the activity of nuclear factor kappa b and enzymes, yielding anti-inflammatory effects. Abbreviations: Uncoupling protein 1, *Pgc1α*, *Prdm16*, *Cpt1*, peroxisomal *Acox*, *Pdk4*, *Glut*, *Ap2*, *Lpl*, and *Acs*, inducible nitric oxide synthase, nuclear factor kappa B, and ciclooxigenase-2. PPARs: Peroxisome proliferator-activated receptors; RXR: Retinoid X receptor; PPRE: PPAR-responsive elements; NF-κB: Nuclear factor kappa B; iNOS: Inducible nitric oxide synthase; COX-2: Ciclooxigenase-2.

ADIPOSE TISSUE PHYSIOLOGY AND PLASTICITY

In mammals, the adipose organ comprises two types of tissues: WAT and BAT. Depending on the adipose tissue origin (for example, gonadal or subcutaneous), differences occur in its lipolytic or lipogenic capacity[19].

The white adipocytes are the only cells specialized in storing lipids without compromising their functional integrity. They have the necessary enzymatic machinery to synthesize triacylglycerol (TAG) when the energy supply is abundant and to mobilize them through lipolysis when there is an energy deficit[20].

The autonomic nervous system acts directly on the adipose tissue. The sympathetic nervous system promotes catabolic actions (lipolysis) *via* adrenergic stimulation, which activates the hormone-sensitive lipase (HSL) enzyme[21]. Conversely, the parasympathetic nervous system yields anabolism by stimulating insulin secretion, increasing glucose uptake, and activating lipogenesis[22].

Regarding the mature white adipocyte characteristics, it stores TAG in a single large lipid droplet that occupies the central portion of the cell, promoting displacement of the nucleus to the periphery and its consequent flattening. The single lipid droplet occupies 85%-95% of the cell volume, characterizing the white adipocyte as unilocular[23,24].

WAT, described as the chief energy reservoir in mammals, has a mesenchymal origin and is composed of adipocytes and the stromal vascular fraction (the main constituent of pre-adipocytes, immune cells, and fibroblasts); together, adipocytes and the stromal vascular fraction produce the extracellular matrix to maintain the structural and functional integrity of the tissue[25,26].

For a long time, the WAT was a secondary structure whose characteristic was the reservoir of large amounts of fat in the form of TAG. There was a lack of attention to its participation in body weight and food intake control. As a result of the discovery of the ability of WAT to secrete substances with biological effects like leptin in 1994, known collectively as adipokines, WAT emerged as a major endocrine organ[27,28].

Conversely, BAT has a smaller adipocyte than WAT, exhibiting several cytoplasmic lipid droplets of different sizes (multilocular), relatively abundant cytoplasm, spherical and slightly eccentric nucleus, and numerous mitochondria that produce energy by oxidizing acids[29]. The brownish BAT coloration stems from its high mitochondrial content, whose uncoupling protein 1 (UCP1) is one of the primary markers for brown adipocyte identification[30,31].

The brown adipocytes specialize in performing nonshivering thermogenesis (NST), by which the UCP1 acts as an alternative channel in the inner mitochondrial membrane to the proton gradient in the intermembrane space return to the mitochondrial matrix without resulting in ATP synthesis. Instead, the chemical energy is released as heat, enhancing the body temperature and EE, a promising target to treat obesity through negative energy balance[32,33].

Brown adipocytes originate from myocyte progenitor cells (myogenic lineage) and express the myogenic factor 5. *Prdm16* controls a bidirectional cell fate switching between skeletal myoblasts and brown adipose cells. Loss of the PR domain containing 16 (*Prdm16*) in brown fat precursors causes loss of brown fat characteristics and promotes muscle differentiation[34]. *Prdm16* induces a complete program of brown fat differentiation, including the expression of PPAR-gamma coactivator 1α (*Pgc-1α*) and *Ucp-1*. *Pgc-1α* is an essential transcriptional coactivator for NST and mitochondrial biogenesis[35].

Although BAT total mass in mammals is small, previous research has already shown that its adequate stimulation (cold exposure, specific drugs, some food compounds, or physical activity) could quadruple the EE of an animal, parallel to an increase in tissue perfusion[36-38]. Thus, understanding the damage obesity causes to BAT morphology and physiology can help to develop strategies to treat obesity.

Recently, experimental studies reported that diet-induced obesity (DIO) results in glucose intolerance, functional BAT hypoxia, and structural whitening. Brown adipocytes in obese animals reduce their thermogenic capacity and assume a white phenotype, becoming unilocular[39,40]. The molecular mechanisms that lead to reduced BAT activity in obesity and its physiological implications are under investigation, and altered PPAR expression may have a role in the whitening phenomenon as *Pparα* expression declines in whitened BAT[41]. Compared to WAT, BAT is more extensively vascularized, and vascular endothelial growth factor-A (VEGFA)-dependent angiogenesis is pivotal for the thermogenic response[42]. The hypoxic microenvironment in BAT, due to obesity, has been shown to lead to an accelerated loss of mitochondria, and as oxidative capacity is lost, lipid droplets accumulate, generating the white phenotype[39].

Since obesity is a public health problem in developed and developing countries, the world urges us to find new approaches to treat or prevent this metabolic disease and its comorbidities. WAT plasticity towards an intermediary adipocyte between white and brown, the beige adipocyte, may emerge as a suitable strategy to fight the obesity pandemic [43].

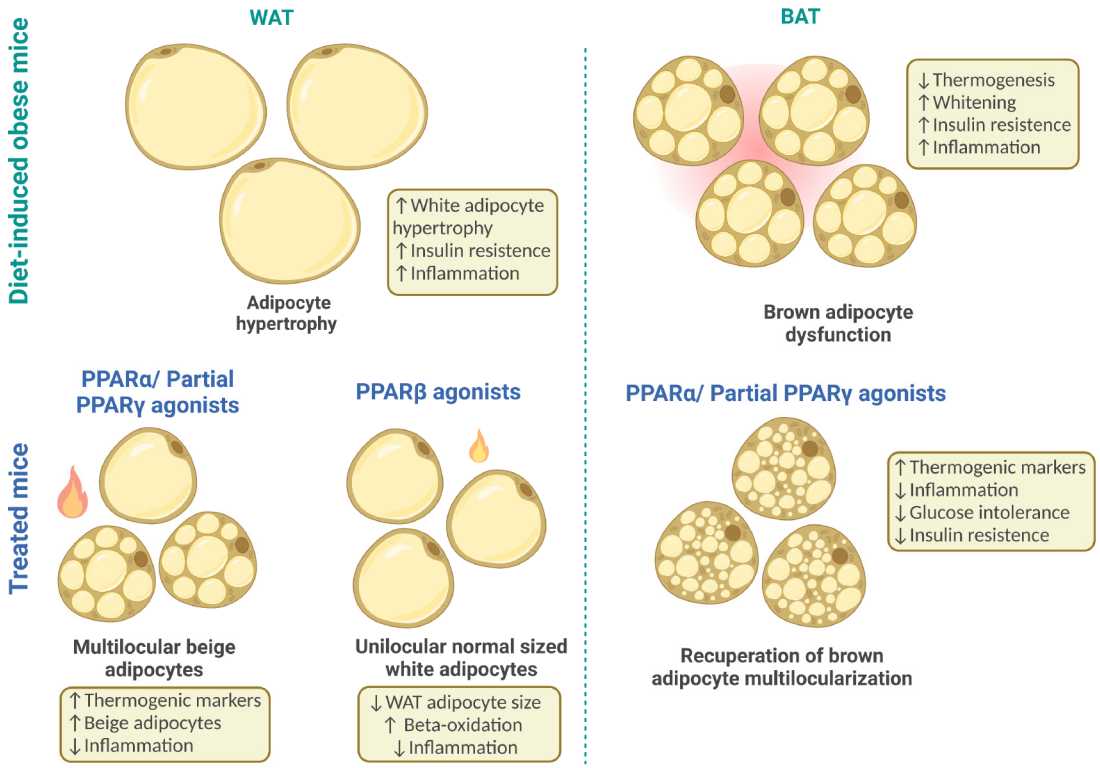
Beige adipocytes are found in the subcutaneous WAT (sWAT) and exhibit a brown-like adipocyte phenotype (multilocular). In the basal state, beige adipocytes act like white adipocytes, but under the right stimulus, they can acquire intermediate mitochondrial content and perform thermogenesis, a process called browning[44]. *Prdm16* is essential to the browning phenomenon once its down-regulation turns a beige adipocyte into a white one, showing that browning is reversible and morphophysiological changes rely on adequate PRDM16 expression and active mitochondrial biogenesis machinery to increase mitochondrial content and thermogenic capacity[45,46].

Beige adipocytes originate from mature white adipocytes [low expression of the cluster of differentiation 137 (*Cd137*)], which under specific stimulation, acquire a brown-like phenotype, or even from a beige pre-adipocyte (high *Cd137*), which differentiates into a multilocular cell capable of performing thermogenesis. The latter originates from a lineage different from the WAT[47,48]. Although the beige adipocytes have a lower thermogenic activity than the brown adipocytes, their presence is linked to a metabolically healthy phenotype in humans[49], reducing the chances of developing type 2 diabetes mellitus (T2DM), hepatic steatosis, and other metabolic constraints.

The metabolic benefits of beige/brown adipocytes presence also stem from their endocrine role in secreting the batokines. Like the adipokines from the WAT, batokines act in autocrine, paracrine, and endocrine fashions to provide increased neurovascular supply to BAT, favoring thermogenesis and inhibiting whitening besides exerting anti-inflammatory effects, favoring browning, and influencing glucose homeostasis[50]. Figure 2 depicts white and BAT plasticity under obesogenic and thermogenic stimuli.

The recent literature suggests that less than 100 g of adipose tissue in an adult human with thermogenic activity can prevent 4 kg of fat accumulation per year[51], stimulating the search for drugs that trigger browning while inhibiting whitening, relevant for metabolic disease control.

PPARS ROLE IN THE ADIPOSE TISSUE PLASTICITY



PPARα was the first receptor discovered, mapped to chromosome 22q12-13.1 in humans, found in metabolically active tissues such as the liver, kidney, heart, skeletal muscle, and brown fat[52,53]. PPARα has polyunsaturated fatty acids and leukotrienes as natural ligands, which are inflammatory mediators; as pharmacological ligands, the family of hypolipidemic drugs, fibrates, is considered an accessible PPARα agonist[54].

The participation of PPARα in the thermogenic pathway involves directing NEFAs, generated after adrenergic stimulation, to the β-oxidation instead of cellular efflux. β-adrenergic stimulus mobilizes most of NEFA in normal conditions, and this mobilization is related to the inflammatory response and the reduction of cell function in the long term. The chronic stimulation of the beta-3 adrenergic receptor upregulates PPARα expression, increasing adipocytes' oxidative capacity[55].

Natural or pharmacological ligands mainly control the expression of genes involved in lipid metabolism. If the concentration of fatty acids increases, PPARα is activated and absorbs the oxidized forms of these acids. During the influx of fatty acids, the transcription of PPARα-regulated genes increases, and the systems are activated[55,56]. Thus, PPARα functions as a lipid sensor and controls energy combustion.

A previous study showed that treatment with WY14643 (PPARα agonist) exerted lipolytic effects with reduced fat mass and increased whole-body fat oxidation. These results demonstrate a novel role for PPARα activation in beta-adrenergic regulation of adipose tissue lipolysis[57]. In addition, treatment with WY-14643 has already shown effects in reducing hepatic steatosis, serum insulin, and inflammation in adipose tissue, and these changes are generally observed in obesity onset[58,59].

In BAT, PPARα stimulates lipid oxidation and thermogenesis in synergy with PGC1α[60]. In this scenario, a study demonstrated that the activation of PPARα by a pharmacological agent (fenofibrate) activated NST (and mitochondrial biogenesis in the BAT of obese mice fed a high-fat diet[61]. Subsequently, the chronic intake of a high-fat diet caused BAT whitening, and the treatment with WY14643 mitigated this morphophysiological impairment through anti-inflammatory signals and enhanced VEGFA, resulting in increased thermogenesis. In the same experiment, the high-fructose diet did not trigger whitening, but the WY14643 also attenuated the histological changes caused by excessive dietary fructose[62].

Figure 2 Adipose tissue plasticity and peroxisome proliferator-activated receptor effects. Under an obesogenic diet, the white adipocytes undergo hypertrophy and profound change in adipokine profile release, leading to growing insulin resistance and low-grade inflammation. Conversely, under adequate stimuli [peroxisome proliferator-activated receptors α (PPARα) and dual PPARα/γ], the subcutaneous white adipose tissue can also undergo browning and form beige adipocytes, an intermediate between white and brown adipocytes with lower thermogenic capacity than brown adipocytes but whose presence points to metabolic homeostasis. Finally, the brown adipose tissue, which has the most potent thermogenic capacity, can express a whitened phenotype when exposed to a lipotoxic milieu. Whitening entails decreased vascularization and pro-inflammatory signals characterizing brown adipocyte dysfunction. In contrast, PPARα and dual PPARα/γ treatments counter whitening, increasing thermogenesis through anti-inflammatory and proangiogenic effects. Made with Biorender (www.biorender.com). PPARs: Peroxisome proliferator-activated receptors; WAT: White adipose tissue; BAT: Brown adipose tissue. Created by BioRender.

PPARα is the isoform that induces the browning of sWAT more abundantly. Fenofibrate has yielded expressive browning in DIO mice, with an irisin-*Pgc1α*-*Prdm16* interaction driven by PPARα stimulating thermogenesis and mitigating insulin resistance and inflammation, countering obesity[63]. Confirming these results, the PPARα agonist WY14643 yielded *Cd137*/*Prdm16*/*Ucp1*+ beige adipocytes, whereas the PPARβ/δ agonist GW0742 reduced sWAT adipocyte size and increased beta-oxidation without browning induction[59]. PPARβ/δ activation by GW501516 countered adipocyte hypertrophy through suppression of angiotensin-converting enzyme (ACE)/angiotensin II receptor type 1 (AT1r) axis and downstream potent anti-inflammatory effects[64].

PPARγ received much attention since the mid-1990s as the molecular target of thiazolidinediones (TZDs) or glitazones, a class of insulin-sensitizing and antidiabetic drugs[65]. PPARγ, a transcription factor from the nuclear receptor family, plays a significant role in lipid and glucose metabolism regulation[66]. WAT and BAT, large intestine, and spleen express PPARγ. However, its expression is much higher in adipocytes[67,68].

Ligand-activated PPARγ induces adipocyte differentiation, stimulates mitochondrial biogenesis, and inhibits the production of pro-inflammatory mediators[68]. In addition, PPARγ activated in adipocytes ensures a balanced and adequate secretion of adipokines (adiponectin and leptin), mediators of insulin action in peripheral tissues[69].

In WAT, PPARγ is pivotal to lipid accumulation. In contrast, PPARγ activation in BAT induces the expression of genes related to the thermogenic program, including *Pgc1α* and *Ucp1*. PPARγ is crucial for brown adipocyte differentiation, but additional transcription factors, including PRDM16, are required to activate the thermogenic program[70].

The PPARγ1 isoform is expressed in almost all cells, while PPARγ2 is mainly limited to adipose tissue. However, PPARγ2 is a more potent transcriptional activator[71]. Both PPARγ1 and PPARγ2 are essential for adipogenesis and insulin sensitivity control. However, PPARγ2 is the isoform upregulated in response to nutrient intake and obesity[72,73].

TZDs, synthetic PPARγ ligands, are antidiabetic drugs with potent insulin-sensitizing effects that confer long-term glycemic control[74]. However, its clinical use has been contested due to side effects such as weight gain, edema, and bone fractures[75]. The increase in body weight after TZDs administration is due to PPARγ-dependent WAT expansion [76] and fluid retention caused by PPARγ activation in the renal collecting ducts[77].

TZDs improve peripheral insulin sensitivity and have a spectrum of anti-inflammatory properties, including a reduction in plasma inflammatory markers and adipose tissue macrophages[72,78]. In WAT, TZDs promote adipocyte differentiation, insulin action, and the formation of beige adipocytes[66]. In BAT, TZDs activate thermogenic activity[79].

The dual PPARα/γ agonist tesaglitazar reversed iBAT whitening through gut dysbiosis and ultrastructure improvements[80]. Intestinal PPARα activation suppresses postprandial hyperlipidemia by increasing the fatty acid oxidation of intestinal epithelial cells[81]. In addition, intestinal PPARα activation reduces cholesterol esterification, suppresses chylomicron production, and increases enterocytes' HDL synthesis[82]. These observations pave a new way to treat metabolic diseases through the modulation of gut microbiota by PPARs and the consequent gut-adipose tissue stimulation of thermogenesis due to anti-inflammatory, angiogenic, and high beta-adrenergic signaling[80]. Figure 2 shows the main PPAR effects on the adipose tissue.

PANCREAS MORPHOPHYSIOLOGY AND OBESITY OUTCOMES

The human pancreas is a mixed gland made up of five anatomical divisions: Head (fitted with the duodenum), uncinate process, neck, body, and tail (nearby the spleen); measures 15-25 cm in length; and weighs 100 g to 150 g in a healthy adult[83]. The inferior pancreaticoduodenal artery, the superior pancreaticoduodenal artery, and the splenic artery are responsible for its perfusion, and the pancreatic plexus, celiac ganglia, and vagus nerve innervate this gland[84,85].

The pancreas has endocrine and exocrine functions, encompassing four structural components: The exocrine portion, constituted by acinar and ductal cells; the endocrine region formed by the islet cells; the blood vessels; and the extracellular space[84]. The exocrine portion corresponds to 85% of the pancreas volume, comprehending a ductal system like a bunch of grapes with a blinded end. Each acinus corresponds to a grape and secretes pancreatic juice enzymes that flow into bicarbonate-secreting ductal epithelial cells[83,84]. After passing through accessory ducts, these enzymes reach the main pancreatic duct that connects with the bile duct in the ampulla of Vater in the duodenum. The exocrine pancreatic secretion (amylase, lipase, and zymogens) helps to digest proteins, fats, and carbohydrates, being secreted by the autonomic nervous system stimulation in the presence of food in the duodenum and the consequent release of secretin, cholecystokinin, and other hormones by the enteroendocrine cells[83].

The endocrine portion of the pancreas comprises mini-organs called islets of Langerhans, corresponding to 1%-2% of the total pancreatic volume. Pancreatic islets have a spherical shape and secrete hormones related to glucose homeostasis. There are five islet cell types: Alpha cells (α cells, produce glucagon), beta cells (β cells, insulin), delta cells (δ cells, somatostatin), PP cells (also known as F cells, pancreatic polypeptide-containing cells), and epsilon cells (ε cells, ghrelin). Neuroendocrine, endocrine, paracrine, and endocrine mechanisms influence islet secretion. Therefore, overactivation or inactivation of their regulatory pathways can drastically impact the metabolism, causing metabolic diseases[86-88].

The most prevalent cell types in pancreatic islets are alpha and beta cells. In mice, alpha cells are restricted to the islet periphery, while the beta cells found in the core of the islet are vastly innervated and comprehend 60%-80% of the total islet mass. In humans, alpha and beta cells are interspersed all around the islets, with beta cells comprising 50%-75% of the islet mass with a sparse innervation. The remaining islet cell types do not differ significantly between men and mice. Even though there are cytoarchitectural differences regarding the islets of these species, the dynamics of islet remodeling in obesity and T2DM are similar and propitiates relevant translational studies[87].

Obesity entails an impaired glucose-stimulated insulin secretion (GSIS) triggered by the adipoinsular axis deregulation due to increased demand for insulin release. The resistance to insulin action relates to hyperleptinemia, prompted by the inflamed hypertrophied WAT[89,90]. Under an insulin-resistant state, the glucose fails to enter the pancreatic beta cell, resulting in a high demand for insulin to keep euglycemia. Islet hypertrophy and hypersecretion are commonplace features in DIO mice as the expansion of alpha and beta cell masses cope with normal glycemic levels maintenance at the beginning of glucose homeostasis impairments[91-93].

Insulin resistance (IR) precedes the T2DM diagnosis by around ten years[94]. Initially, the compensatory hyperinsulinemia prompts normal fasting glucose levels (IR). As adiposity evolves, hyperinsulinemia cannot cope with adequate glycemic control. At this point, raised plasma insulin and glucose concentrations coexist, characterizing glucose intolerance[91,95]. Glucose-intolerant mice exhibit hyperglycemia, alpha cells infiltrated to the islet core, besides a disrupted GSIS, with endoplasmic reticulum (ER) stress and loss of beta cell polarity, compromising its secretion and threatening islet survival[96,97].

Glucotoxicity (hyperglycemia) elicits ER stress, which leads to proinsulin misfolding and accumulation, a hallmark of beta cell dysfunction and T2DM onset[98]. Beta cell dysfunction originates from continuing islet hypertrophy and hypersecretion (lipotoxicity), impaired GSIS, beta cell ER stress (glucolipotoxicity), and downregulation of proliferative markers like the pancreatic duodenal homeobox-1 (PDX1)[96,99]. Compromised beta cell proliferation, increased apoptosis rate, and dedifferentiation result in beta cell failure[100]. T2DM is linked to a decreased beta cell mass (-22%-63%) and begins when beta cell mass cannot compensate for the high demand for insulin to sustain glucose homeostasis [101].

As a multi-hormonal disease, T2DM entails decreased beta cell mass coupled with the loss of incretin effect. Incretins are gut-derived hormones that enhance insulin secretion and sensitivity after meal ingestion, participating in the glycemic control at the postprandial state. Chronic high-fat diets lead to loss of the incretin glucagon-like peptide-1 (GLP-1) capacity to enhance beta cell responsiveness to glucose and proliferation, resulting in beta cell exhaustion[102,103]. Loss of incretin effect occurs even with normal GLP-1 and gastric inhibitory polypeptide levels in obese subjects, suggesting a possible resistance to their actions like described for insulin and leptin[104].

To avoid the progression of IR towards T2DM onset, therapies that could promote pancreatic alpha cell transdifferentiation into beta cells to maintain glycemic control are promising approaches to tackle beta cell exhaustion and reduced beta cell mass[105]. In this context, PPARs may be therapeutic targets for glycemic homeostasis.

PPARS EFFECTS ON PANCREATIC REMODELING AND ISLET PRESERVATION

PPARs regulate the expression of several target genes and allow the proper functioning of pathways linked to energy metabolism. An imbalance of these pathways can lead to the development of T2DM and other disorders[106,107]. Thus, PPARs are relevant therapeutic targets for the clinical management of diabetes.

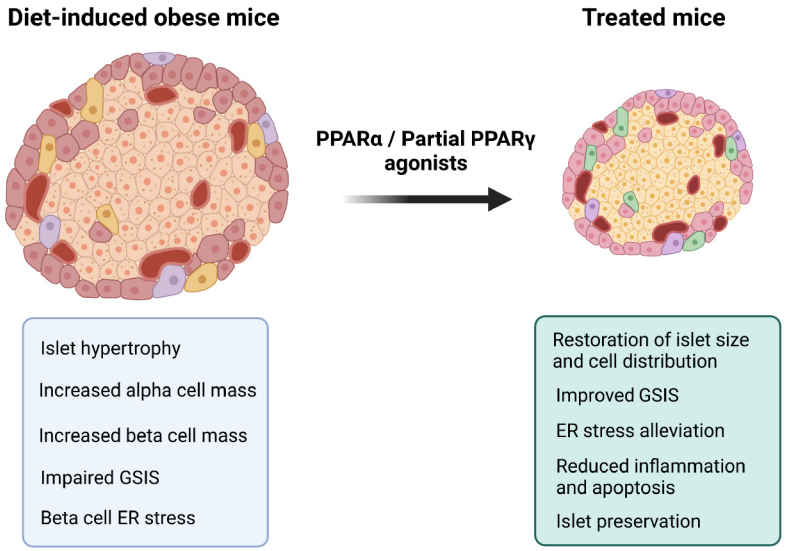
Numerous drugs have been used and developed for the treatment of hyperlipidemia and T2DM such as PPARα agonists (fibrates, *e.g.*, fenofibrate, bezafibrate and clofibrate) and PPARγ agonists (TZDs, *e.g.*, troglitazone, rosiglitazone, pioglitazone and ciglitazone). PPARβ/δ does not have a role well-established in glucose metabolism, but it is known to improve insulin sensitivity by facilitating fatty acid oxidation in some tissues and reducing glucose oxidation[108,109].

PPARα plays an essential role in glucose homeostasis and regulates enzymes and proteins involved in glucose synthesis in the fasting state[110]. In addition, it stimulates pancreatic beta cells and increases fatty acid oxidation and GSIS[111]. Fenofibrate and fish oil countered islet hypertrophy and increased adiponectin levels in diabetic KK mice [112], mitigating lipotoxicity-induced beta cell dysfunction by inhibiting the nuclear factor kappa B (NF-κB) and reducing macrophage migration[113]. In agreement, fenofibrate exerted anti-inflammatory and antiapoptotic effects besides enhancing islet innervation in young non-obese diabetic mice, providing adequate glucose handling, and preventing diabetes-associated diseases[114].

Conversely, Fenofibrate long-term use (12 wk, 100 mg/kg) disrupted beta cell function due to increased NF-κB and inducible nitric oxide synthase islet expression in monosodium glutamate-induced obese rats[115]. An *in vitro* study showed that PPARα activation by WY14643 or bezafibrate (pan-PPAR agonist) enhances GSIS. However, long-term treatments contribute to beta cell dysfunction owing to overstimulation[116]. In a clinical study, bezafibrate showed that parameters related to insulin resistance were attenuated during the follow-up period, while the placebo group showed an increase in this parameter over two years[117].

PPARγ, in turn, controls glucose homeostasis as it increases glucose transporter (GLUT4) expression and its translocation in adipocytes, causing adipose remodeling by reducing visceral fat deposits while selectively increasing sWAT, resulting in a possible insulin sensitization scenario[118,119]. Furthermore, studies have shown that PPARγ activation increases adipocytes' fatty acid uptake, reducing lipotoxic damage to insulin-sensitive tissues[120], increasing glucose uptake by skeletal muscle, and consequent peripheral reduction[120,121].

PPARγ agonists are the most developed antidiabetic and insulin-sensitizing agents to date. Studies have shown that TZDs (or glitazones) bind specifically to the ligand binding domain (LBD) of recombinant PPARγ but not to PPARα or PPARβ/δ. These agents also selectively stimulate the activity of the PPARγ gene promoter and modulate the expression of several of its target genes[122]. TZDs class increases glucose catabolism and reduces its hepatic production[123,124], sensitizes cells to insulin, improves insulin sensitivity and action[125,126], and promotes pre-adipocyte differentiation along with lipogenesis, which favors a reduction in NEFAs concentrations, attributed to increased glucose utilization and reduced gluconeogenesis.



Human and animal studies indicate that the TZDs (total PPARγ agonists) rosiglitazone and pioglitazone improve hyperglycemia by reversing insulin resistance and improving insulin sensitivity. In addition, both agents also show significant effects on plasma lipoprotein lipids in humans, although pioglitazone results in a relatively better lipid profile than rosiglitazone[127,128]. Of note, the clinical use of rosiglitazone was discouraged owing to the unwanted effects of fluid retention, arterial vasodilation, endothelial alterations[129,130], increased risk of bone fracture and congestive heart failure[131], and weight gain in both animal models and humans due to the master regulatory role of PPARγ in adipogenesis[66].

Pioglitazone (15 mg/kg per mouse) yielded healthy pancreatic islets in db/db mice, enhancing insulin and NK6 homeobox 1 expression and restoring islet function in this mice model[132]. The islet preservation due to PPARγ activation by pioglitazone encompasses anti-inflammatory effects and alleviation of ER stress[133]. Pioglitazone and vildagliptin (DPP-4 inhibitor) combination maximized pioglitazone's effects on suppressed inflammation and oxidative stress in male rats[134]. In agreement with this, pioglitazone plus sitagliptin enhanced alpha and beta cell functions at the postprandial state in T2DM subjects[135].

Telmisartan, a partial PPARγ agonist and angiotensin receptor blocker, reduces serum insulin levels and mitigates insulin resistance without affecting serum adiponectin levels[136]. The experimental background shows that telmisartan reduced islet hypertrophy, with adequate glycemic control and normalized alpha and beta cell mass in DIO mice. These effects were maximized by telmisartan combination with sitagliptin, reverting oral glucose intolerance and normalizing body mass in this DIO model[93]. Telmisartan combination with linagliptin promoted islet preservation by suppressing oxidative stress[137].

The beneficial effects of telmisartan on islet cytoarchitecture featured ultrastructural remodeling, with polarized cells and mature insulin granules reestablished after the treatment[97]. Telmisartan elicited enhanced islet vascularization, enhanced PDX1 and GLP-1 islet expression plasma concentrations, ameliorating GSIS and preserving pancreatic islets through reduced apoptosis rate and macrophage infiltration[96]. Due to improved islet proliferation capacity, telmisartan might be a candidate for beneficial islet cell transdifferentiation to slow insulin resistance to T2DM onset progression. Figure 3 summarizes the main effects of PPARα and partial PPAR γ agonists on the endocrine pancreas.

Drugs with specificity for at least two PPAR isoforms (*e.g.*, dual PPARα/γ or pan-PPAR agonists) could be more effective and have relatively fewer undesirable side effects compared with currently used agonists with specificity for a single PPAR isoform[138]. In this context, a series of dual PPARα/γ agonists, named glitazars, was designed to combine total PPARα and partial PPARγ activation, retaining the insulin-sensitizing property of PPARγ target genes with the beneficial effects of PPARα activation on energy metabolism[139,140]. However, muraglitazar showed many of the same side effects (weight gain and edema) in patients[141,142], having glitazars development halted due to safety concerns.

Figure 3 Beneficial effects of Peroxisome proliferator-activated receptor agonist on islet remodelling. Diet-induced obese mice exhibit enlarged pancreatic islets, with are prone to exhaustion in the long run due to glucolipotoxicity. Peroxisome proliferator-activated receptor α (PPARα) and partial PPARγ activation are promising targets to counter glucolipotoxicity, yielding islet preservation. Made with Biorender (www.biorender.com). PPARs: Peroxisome proliferator-activated receptors; GSIS: Glucose-stimulated insulin secretion; ER: Endoplasmic reticulum. Created by BioRender.

Research is ongoing to develop new PPAR agonists without side effects. Since PPARs orchestrate many physiological processes, agonists may play beneficial or non-beneficial effects. So, PPAR actions on pancreatic islets need elucidation to support the development of new drugs with more assertive outcomes.

LIVER MORPHOPHYSIOLOGY AND OBESITY IMPLICATIONS

The liver is a complex organ that concentrates on several physiological processes as macronutrient metabolism, immune system support, fatty acid, and cholesterol homeostasis, besides the degradation of xenobiotic compounds and many medications[143]. It is the largest solid glandular organ in the body. With versatile endocrine and exogenous functions, the liver is considered paramount for metabolic activities[144]. It has a remarkably uniform anatomical structure composed of the regular arrangement of lobules that are the functional unit of the liver. The base of the lobule is composed of hepatocytes, the most prevalent cells of the liver[145]. Hepatocytes arranged between the sinusoids along the portal-central axis demonstrate heterogeneity concerning their biochemical and physiological functions[146]. Additional cell types within the liver include cholangiocytes, Kupffer cells, stellate cells, and endothelial cells, with specialized functions[147].

The liver is enriched with cell organelles to fulfill its metabolic functions. It is one of the organs with the highest number and density of mitochondria, which interact with other organelles such as ER, lipid deposits (LDs), and lysosomes[148,149]. In the gastrointestinal tract, food digestion generates metabolic substrates (glucose, fatty acids, and amino acids) that are absorbed by the bloodstream and conducted to the liver through the portal vein circulation system. In the postprandial state, glucose forwards to glycogen storage, and the excess undergoes *de novo* lipogenesis (DNL) in the liver. DNL forms new TAG from acetyl-CoA or malonyl-CoA[150,151].

In mammals, acetyl-CoA carboxylase (ACC) and fatty acid synthase (FAS)-an enzyme intricately regulated by several nuclear receptors (NRs, *e.g.*, PPARα, PPARγ, and the bile acid receptor/farnesoid X receptor) catalyze fatty acid production. NRs are also relevant mediators of insulin signaling, whereas DNL occurs under anabolic conditions, linking glucose and lipid metabolism. Further support of this link encompasses insulin stimulation of FAS expression. In hepatocytes, NEFAs are esterified with glycerol-3-phosphate to synthesize TAG. TAG is stored in LDs within hepatocytes or secreted into the circulation as very low-density lipoprotein (VLDL) particles. In the fasted state or during exercise, fuel substrates (glucose and TAG) are delivered from the liver into the circulation and metabolized by muscle, adipose tissue, and other extrahepatic tissues[150,151]. However, the increased intake of dietary lipids, associated with upregulated DNL process, causes lipotoxicity and the abnormal accumulation of lipids, often consistent with insulin resistance in steatotic livers, which is related to disturbed ER protein folding homeostasis in hepatocytes[152,153].

The ER in hepatocytes can adapt to extracellular and intracellular changes, allowing the maintenance of essential hepatic metabolic functions. However, several alterations can disturb the ER homeostasis of hepatocytes, contributing to the dysregulation of hepatic lipid metabolism and liver diseases. Consequently, ER includes a progressively conserved pathway called unfolded protein response (UPR) to control liver protein and lipid homeostasis[154]. UPR decreases secretory protein quantity, increases ER protein folding (chaperone and foldase transcription), and enhances deletion capacity by stimulating autophagy and ER-related degradation[152]. Thus, ER stress is a cellular stress in which the demand for folding newly synthesized proteins exceeds ER capacity to fold or to correct it through UPR, generating

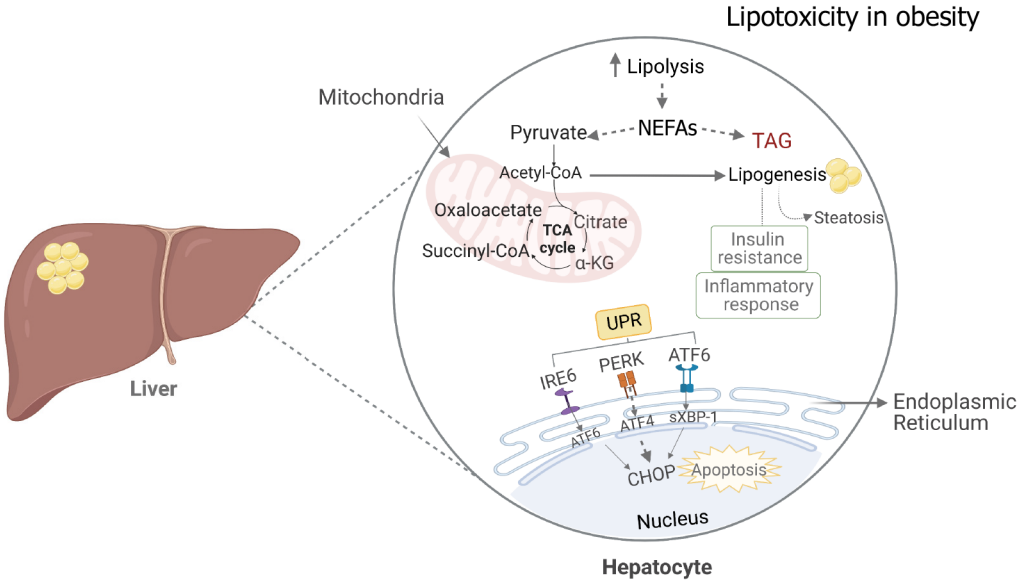
unfolded protein accumulation[155].

The existence of three transmembrane-ER proteins is understood to reveal and transduce the ER stress response: Protein kinase RNA-like ER kinase (PERK), inositol-requiring protein-1α (IRE-1α) and activating transcription factor 6 (ATF6). Activation of ATF6 and PERK elicit the expression of the C/EBP homologous protein (CHOP), whereas IRE-1α induces the activation of the N-terminal C-Jun kinase and also generates an improved form of X-box binding protein-1 (XBP1), the spliced XBP1, which attempts to the depletion of misfolded ER proteins through chaperone, folding proteins, and ERAD components encoding[156].

However, when ER stress is intense to the point that damage is irreversible, the ER cannot restore its function. Hence, inflammatory responses trigger cell death pathways[157]. There is strong communication between ER homeostasis perturbations and mitochondrial dysfunction in the onset of obesity and metabolic syndrome. The mitochondrion organelle plays an essential role in hepatic cellular redox, lipid metabolism, and cell death regulation[158], and genes related to mitochondrial fatty acid β-oxidation are mostly transcriptionally regulated by PPARα[159]. Fatty acids input into the mitochondria requires carnitine palmitoyltransferase 1a (*Cpt1a*) (a PPARα target gene), located in the outer mitochondrial membrane. PPARα activation leads to the transcription of *Cpt1a*, associated with fatty acid oxidation in mitochondria, peroxisomes (acyl-CoA oxidase, ACOX), and cytochrome P450 4A family[160].

Mitochondrial dysfunction is associated with acute and chronic liver diseases, and relevant information indicates that mitophagy, a selective form of autophagy (catabolic process, which manifests itself by selective sequestration of mitochondria by autophagosomes, phagophores, a double membrane that isolates autophagic components)[161] of dysfunctional/excessive mitochondria, plays a pivotal role in liver physiology and pathophysiology[158]. There are specificities and mechanisms mediating mitophagy, many of them mediated by the FUN14 domain containing 1 (FUNDC1), a mitochondrial outer membrane protein tightly regulated at transcriptional and post-transcriptional levels. NRF1 (nuclear respiratory factor 1) and PGC1α, the major transcription factor and related cofactor in mitochondrial biogenesis, beneficially adjust FUNDC1 expression and enhance mitophagy[162]. Therefore, mitophagy favors mitochondrial remodeling, and PPARs are implicated in this pathway[163]. Figure 4 summarizes liver alterations under lipotoxicity in obesity.

PPARS IN THE LIVER



Functional studies have demonstrated that PPARα governs hepatic expression of genes involved in nearly all aspects of lipid metabolism, including fatty acid uptake, elongation and desaturation, activation and binding of intracellular fatty acids, formation and degradation of TGs and lipid droplets, and metabolism from plasma lipoproteins[164,165]. The constitutive activity of mitochondrial β-oxidation was significantly reduced in the liver of mice lacking the *Pparα* gene (*Pparα* null mice)[166]. *Pparα* knockout mice fed a high-fat diet increased markers of oxidative stress, inflammation, and cell death[167].

Thus, PPARα has been the target of hypolipidemic drugs from the fibrate family, under investigation for treating non-alcoholic fatty liver disease (NAFLD). PPARα upregulates fatty acid β-oxidation and lipolysis, upregulating the expression of several genes involved in lipid metabolism (*Pgc1α* and *Cpt1a*), leading to less fat accumulation in NAFLD [168]. *Pgc1α* modulates the expression of key metabolic enzymes involved in gluconeogenesis, fatty acid oxidation, and oxidative phosphorylation in the liver through their functional interaction with PPARα[169]. Mitochondrial β-oxidation of long-chain fatty acids is regulated by CPT1a, an enzyme physiologically inhibited by malonyl-CoA, a glucose-derived metabolite and an intermediate in DNL synthesis[170].

Administration of Wy-14643, one of the most potent PPARα agonists, decreased serum insulin, rescued hyperglycemia, and suppressed carbohydrate response element binding protein (ChREBP), mitigating steatosis and hepatic damage. The reductions in ChREBP and FAS activity likely reflect the diminished stimulatory effects of glucose on ChREBP and as a substrate (AcylCoA) for fatty acid synthesis[171]. Moreover, WY-14643 markedly reduced hepatic steatosis in high-fat-fed C57BL/6 mice by augmenting the volume density of mitochondria per area of liver tissue and downregulating hepatic gluconeogenesis and DNL[58]. More recently, WY-14643 treated gut dysbiosis in high-fat and high-fructose-fed-mice, exerting antisteatotic effects through diminished endotoxemic inflammatory inputs to the liver, showing that PPARα mitigates liver steatosis by acting on multiple hits that trigger this outcome[172,173].

Fibrates are a less potent but clinically relevant class of PPARα agonists compared to Wy-14643, which have also been evaluated in experimental models and human studies[174]. *In vivo* experiments, treatment with pemafibrate, a selective PPARα agonist, identify PPARα as a pharmacological, sexually dimorphic target primarily related to related gene functions to lipid homeostasis, with the female liver being much more responsive to pemafibrate than the male liver[175]. The potency of synthetic PPARα agonists may differ from receptor to species as measured using the PPARα-GAL4 transactivation system, *i.e.*, fenofibrate (mouse receptor, EC50 = 18000 nM *vs* human receptor, EC50 = 30000 nM), bezafibrate (EC50 = 90000 nM *vs* 50000 nM, respectively) and Wy14643 (EC50 = 630 nM *vs* 5000 nM, respectively)[176].

In contrast, several studies have provided evidence that hepatic PPARγ expression markedly increases in many models of obesity (lipoatrophy and hyperphagic obesity), insulin resistance, and diabetes with varying degrees of steatosis[177]. PPARγ expression in the liver is low under healthy conditions but increases as steatosis develops in rodents[178]; this effect is not seen in humans[75,179]. They have tremendous potential in patients with NAFLD because they promote preadipocyte differentiation into adipocytes and may induce fat redistribution from visceral sites such as the liver and muscle to peripheral subcutaneous adipose tissue, increase circulating adiponectin levels, and improve insulin sensitivity [180].

DOI: 10.3748/wjg.v29.i26.4136 **Copyright** ©The Author(s) 2023.

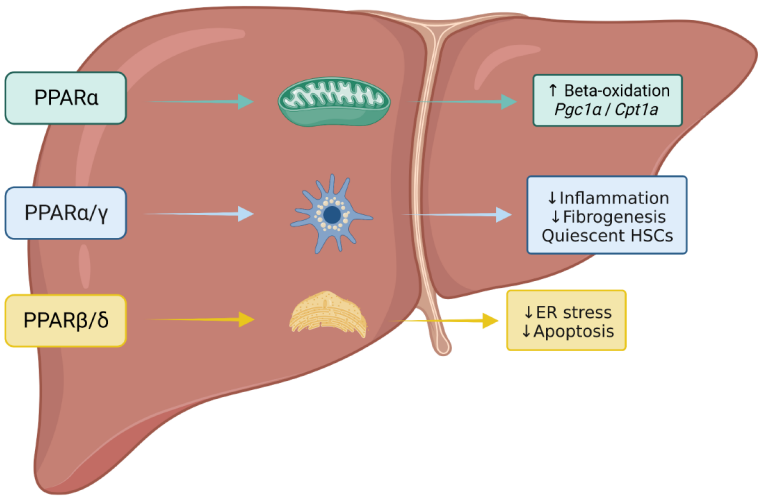


Figure 4 Schematic illustrates hepatic lipotoxicity caused by obesity. There is an increase in lipolysis, which triggers the intracellular accumulation of fatty acids (FAs) within hepatocytes, resulting in a delay in mitochondrial beta-oxidation followed by an increase in lipogenesis, favoring the deposition of lipid droplets in the hepatic parenchyma, culminating in hepatic steatosis. Concomitantly, there is a reduction in insulin signaling, potentiating inflammation, and endoplasmic reticulum (ER) stress. ER stress is detected by the unfolded protein response-IRE1, PERK, and activating transcription factor 6 (ATF6) in the ER membrane. If it is impossible to reverse the unfolded proteins, ATF4 promotes transcription of the C/element binding protein homologous protein, a transcription factor that induces apoptosis. Made with Biorender (www.biorender.com). TAG: Triacylglycerol; UPR: Unfolded protein response; UPR: Unfolded protein response; PERK: Protein kinase RNA-like ER kinase; ATF: Activating transcription factor 6; IRE6: CHOP: C/EBP homologous protein; NEFAs: Non-esterified fatty acids. Created by BioRender.

PPARγ agonists, such as the TZDs, stimulate genes that favor the storage of TAG, thus lowering circulating free fatty acid concentrations[181]. In humans, one-year treatment with pioglitazone (at low dosage) significantly improved liver steatosis, inflammation, and systemic and local adipose tissue insulin resistance in patients with T2D. A decrease in sterol regulatory element-binding transcription factor 1c (SREBP-1c) expression by pioglitazone has a primary effect in reducing hepatic steatosis[182]. Pooled results suggest that acetaldehyde produced from ethanol metabolism may increase the synthesis of the mature SREBP-1 protein, which increases hepatic lipogenesis, thus leading to the development of fatty liver[183,184].

Administration of the PPARγ agonist rosiglitazone (5 mg/kg, daily, gavage) accelerated regression of liver fibrosis as associated with increased expression of PPARγ in mice, with similar findings in human hepatic stellate cells (HSCs). Furthermore, *in vitro*, GATA binding protein 6 (GATA6)-deficient HSCs exhibit a defect in inactivation, suggesting that GATA6 and PPARγ agonists can be used to drive the inactivation of HSCs/myofibroblasts and could compose a combination strategy to halt liver fibrosis in patients[185]. On the other hand, some studies associate TZD therapy with an average weight gain of 4 kg to 5 kg[186,187]. Weight gain combines adiposity and fluid retention as the increased peripheral edema observed during the pre-marketing clinical trials of pioglitazone and rosiglitazone. Increased vascular permeability through high vascular endothelial growth factor secretion and decreased systemic vascular resistance are non-kidney factors that contribute to this edema[188,189].

Recently, dual PPAR-α/γ agonists emerged as a strategy to lessen undesirable side effects related to PPAR-γ agonism. In a randomized controlled clinical trial, Saroglitazar (PPAR-α/γ agonist, 4 mg) significantly improved alanine transaminase, liver fat content, insulin resistance, and atherogenic dyslipidemia in participants with NAFLD/nonalcoholic steatohepatitis (NASH)[190]. In an *in vitro* study on HepG2 cells, saroglitazar prevented HSC activation from quiescent cells to highly proliferative and fibrogenic cells. Pro-inflammatory cytokines, upregulated in NAFLD, can activate hepatic stellate cells, causing increased collagen deposition that initiates fibrogenesis. In turn, the use of saroglitazar reduced the expression of pro-inflammatory [tumor necrosis factor-alpha (*Tnfα*), interleukin (IL)-1β, and IL-6] and pro-fibrogenic (monocyte chemoattractant protein-1, transforming growth factor beta, collagen type I alpha 1 chain, and α-smooth muscle actin) genes in HSC[191]. Evidence is growing in favor of dual PPARα/γ agonism as a candidate for the treatment of NAFLD/NASH due to findings of improvements in all components responsible for these conditions.

In agreement with PPARα beneficial effects on the liver, PPARβ/δ possesses anti-inflammatory effects in the liver by inhibiting NF-κB activity by directly binding to its subunit p65[192-195]. The PPAR-β/δ agonist GW0742 Led to the modulation of the inflammatory response induced by NF-κB in rats, reducing the release of pro-inflammatory cytokines and neutrophils infiltration into the liver[193,196]. During the induction of inflammatory responses, the inactivated PPAR β/δ participates in the activation of NF-κB p65. Activation by ligand PPARβ/δ results in a lack of this cooperation, and consequently, activation of PPARβ/δ interferes with the function of NF-κB p65. As a result, inflammatory responses caused by a high concentration of glucose, activation of the receptor for TNF-α, IL-1β, or activation of TLR4 are reduced [197]. Along with the anti-inflammatory effects, GW0742 has recently mitigated hepatic steatosis through attenuating

Figure 5 Beneficial effects of Peroxisome proliferator-activated receptor activation on the liver. Peroxisome proliferator-activated receptor α (PPARα) activation mitigates hepatic steatosis through the activation of genes related to mitochondrial biogenesis and beta-oxidation, such as *Pgc1α* and *Cpt1a*. Dual PPARα/γ agonists emerge as promising candidates to treat nonalcoholic steatohepatitis once this approach reduces hepatic stellate cells activation, keeping their quiescent stage and impeding fibrogenesis. PPARβ/δ/δ activation entails antisteatotic effects through alleviating the hepatic endoplasmic reticulum stress, inflammation, and apoptosis. Made with Biorender (www.biorender.com). PPAR: Peroxisome proliferator-activated receptor; *Pgc1α*: Peroxisome proliferator-activated receptor gamma coactivator-1 alpha; *Cpt1a*: Carnitine palmitoyltransferase 1a; HSC: Hepatic stellate cell; ER: Endoplasmic reticulum. Created by BioRender.

hepatic ER stress (reduced p-eIF2α/ATF4/CHOP expression), yielding anti-apoptotic signals and favored beta-oxidation over lipogenesis in high-fat-fed mice[198].

Despite this, the contribution of PPARβ/δ to hepatic lipid metabolism is still controversial. PPAR-β/δ null mice on a high-fat diet showed an increased rate of hepatic VLDL production and an increase in the plasma VLDL apoB48, apoE, apoAI, and apoAII levels, as well as a reduction in hepatic lipid stores[178]. However, the other potent PPARβ/δ agonist, GW501516, increased the expression of the lipogenic enzyme ACC2 and consequently increased the hepatic TAG content in db/db mice[192,199]. The role that PPAR-β/δ has on liver metabolism is not defined as there is not a PPAR-β/δ agonist available to the population[200]. Figure 5 depicts the beneficial effects of PPAR activation on the liver. Table 1 shows the main mechanisms and endpoints of PPAR agonists on experimental, *in vitro*, and clinical backgrounds.

CONCLUSION

Overall, there is no doubt that PPARs are promising therapeutic targets for metabolic syndrome, insulin resistance, dyslipidemia, and NAFLD/NASH. However, more research, improvement, and testing are needed to apply PPAR-targeted agents to human metabolic diseases with increased safety and efficacy. Much as PPARs agonists are widely prescribed to treat dyslipidemia, hypertension, and T2DM, dual agonists are promising in the context of obesity due to the combination of anti-inflammatory, lipid oxidation, insulin-sensitizing, and thermogenesis activation, which prevails from one of the isoforms actions and might be highlighted with suitable modulation of their combined activation. Considering that the jury is still out on defined drug therapy for obesity and NAFLD (one of obesity's more prevalent comorbidity), PPARs entail a potent target to reach adequate control of the glucolipotoxicity that trigger metabolic diseases, whether as part of a combination of different PPARs isoforms or combined with agents from other drug classes.

Table 1 Summary of evidence on PPARs agonists on metabolic outcomes in clinical and experimental studies

Model	PPAR agonist	Effect/mechanism	Ref.
HF diet fed C57BL/6 mice (14 wk)	WY14643 (3.0 mg/kg BM)	Decreased body mass and increased hepatic beta-oxidation	Barbosa-da-Silva *et al* [57], 2015
HF diet fed C57BL/6 mice (14 wk)	WY14643 (2.5 mg/kg BM)	Decreased insulin, hepatic steatosis, and enhanced mitochondria per area of liver tissue	Veiga *et al*[58], 2017
HF diet fed C57BL/6 mice (14 wk)	WY14643 (2.5 mg/kg BM)	Browning of subcutaneous WAT, increased thermogenesis	Rachid *et al*[59], 2018
HF diet or high-fructose-fed C57BL/6 mice (17 wk)	WY14643 (3.5 mg/kg BM)	Reduced whitening in HF-fed mice *via* increased VEGFA and reduced inflammation	Miranda *et al*[62], 2020

HF diet fed C57BL/6 mice (15 wk)	Fenofibrate (100.0 mg/kg BM)	Increased irisin-*Pgc1α*-*Prdm16* and induced thermogenic beige adipocytes	Rachid *et al*[63], 2015
High-fructose diet-fed C57BL/6 mice (11 wk)	GW501516 (3.0 mg/kg/d)	Potent anti-inflammatory effects that reversed adipocyte hypertrophy	Magliano *et al*[64], 2015
Knockout mice for *Pparγ* in collecting duct	Rosiglitazone (320.0 mg/kg diet)	PPARγ regulates sodium transport in the collecting ducts and mediates the rosiglitazone-induced edema	Zhang *et al*[77], 2005
Human subcutaneous white adipose tissue biopsy	Pioglitazone (45 mg daily for two months)	Pioglitazone reduced CD68 and MCP-1 expression in adipose tissue, improving insulin sensitivity	Di Gregorio *et al*[78], 2005
HF diet fed C57BL/6 mice (16 wk)	Tesaglitazar (4 mg/kg BM)	PPARα/γ synergism treated dysbiosis and favored thermogenesis	Miranda *et al*[80], 2023
Human jejunal biopsies	Cells treated with GW7647 (600 nM) or GFT505 (1 μM) for 18 h	Intestinal PPARα activation induces HDL production	Colin *et al*[82], 2013
Knockout mice	25.0% fish oil in the diet	Increased adiponectin, improved glucose metabolism, and islet hypertrophy	Nakasatomi *et al*[112], 2018
Non-obese diabetic mice	0.1% fenofibrate in the diet	Anti-inflammatory, antiapoptotic effects, and enhanced islet innervation, ameliorating glucose handling	Holm *et al*[114], 2019
Monosodium glutamate induced obese rats	100 mg/kg fenofibrate for 12 wk	Long-term treatment disrupted beta cell function due to increased NF-κB and iNOS expression	Liu *et al*[115], 2011
Rat pancreatic islets *in vitro*	300 microM bezafibrate for 8 h	Bezafibrate enhanced GSIS through *Pparα* activation in short-term culture. Long-term culture caused beta cell dysfunction due to overstimulation	Yoshikawa *et al*[116], 2001
Diabetic subjects	400 mg bezafibrate for two years	Bezafibrate avoided the progressive decline of beta cell function and insulin resistance increase	Tenenbaum *et al*[117], 2007
Subjects diagnosed with type 2 diabetes and dyslipidemia	Pioglitazone 30 mg/d for 12 wk and 45 mg/d for additional 12 wk; rosiglitazone 4 mg/d for 12 wk and 8 mg/d for additional 12 wk	Pioglitazone had better effects regarding improvements in triglycerides, HDL cholesterol, LDL particle concentration, and LDL particle size	Goldberg *et al*[127], 2005
db/db mice	Pioglitazone 15 mg/kg BM for 18 d	Restoration of pancreatic islet function with increased expression of insulin and NK6 Homeobox 1 expression	Collier *et al*[132], 2021
Knockout-Ay mice	High-fat diet plus pioglitazone 0.02% for 6 wk	Islet preservation through ER stress and inflammation alleviation	Hong *et al*[133], 2018
Diabetic Wistar rats (low streptozotocin dose)	10 mg/kg pioglitazone or vildagliptin or their combination for 4 wk	Vildagliptin maximized pioglitazone effects on inflammation and oxidative stress attenuation	Refaat *et al*[134], 2016
Type 2 diabetic patients	Sitagliptin 100 mg/d or Pioglitazone 30 mg/d or their combination for 12 wk	Both drugs exerted complementary effects on blood glucose control	Alba *et al*[135], 2013
Non-diabetic hypertensive subjects	Telmisartan (80 mg/d) for 6 wk	Telmisartan enhanced insulin sensitivity in hypertensive patients independent of adiponectin induction	Benndorf *et al*[136], 2006
High-fat diet-fed mice (16 wk)	Telmisartan (5 mg/kg BM) alone or in combination with sitagliptin (1 g/kg BM) or metformin (300 mg/kg BM)	Treated animals exhibited marked mitigation of hepatic steatosis and islet hypertrophy; telmisartan combination with sitagliptin normalized alpha and beta cell mass	Souza-Mello *et al*[93], 2010; Souza-Mello *et al*[97], 2011
High-fat diet-fed mice (15 wk)	Telmisartan (10 mg/kg)	Amelioration of endocrine pancreas structure and function, with enhanced islet vascularization and reduced apoptosis rate	Graus-Nunes *et al*[96], 2017
db/db mice	Telmisartan (3 mg/kg BM), linagliptin (3 mg/kg BM) or their combination for eight weeks	Combined therapy provided better results than the monotherapies on glucose homeostasis, islet cell functions, and structure *via* reduced oxidative stress	Zhao *et al*[137], 2016
High-fat-fed foz/foz obese/diabetic mice for 16 wk	WY14643 (0.1% w/w) for 10 d or 20 d	PPARα activation mitigated steatosis, and hepatocyte ballooning, besides reducing NF-κB and JNK activation. Persistent adipose-derived MCP1 enhanced levels may limit its property to treat NASH	Larter *et al*[171], 2012
High-fructose diet-fed mice (17 wk)	WY14643 (3.5 mg/kg BM) or linagliptin (15.0 mg/kg BM) or their combination	The WY14643 monotherapy or its combination with linagliptin-treated dysbiosis, controlling endotoxemia and mitigating liver steatosis	Silva-Veiga *et al*[173], 2020
Type 2 diabetic patients	Metformin 2 g/d + Pioglitazone (15 mg/d, 30 mg/d, or 45 mg/d)	All pioglitazone doses exerted similar effects, with mitigation of liver steatosis and inflammation, with improved systemic insulin resistance	Della Pepa *et al*[182], 2021
CCl4-injured mice	Rosiglitazone (5 mg/kg BM) for two weeks	Rosiglitazone blocked liver fibrosis progression through the down-regulation of fibrogenic genes and HSCs inactivation	Liu *et al*[185], 2020
Patients with	Saroglitazar 1 mg, 2 mg, or 4 mg for 16	Saroglitazar 4 mg significantly mitigated insulin resistance	Gawrieh *et al*[190],

NAFLD/NASH	wk	and atherogenic dyslipidemia	2021
HF diet fed mice (14 wk)	GW0742 (1 mg/kg BM) for four weeks	PPARβ/δ mitigated hepatic steatosis through improved insulin resistance and ER stress alleviation	Silva-Veiga *et al* [198], 2018

HF: High-fructose; NAFLD: Non-alcoholic fatty liver disease; NASH: Nonalcoholic steatohepatitis; PPAR: Peroxisome proliferator-activated receptors; WAT: White adipose tissue; ER: Endoplasmic reticulum; NF-κB: Noncanonical nuclear factor-kappaB; HSCs: Hepatic stellate cells; iNOS: Inducible nitric oxide synthase; GSIS: Glucose-stimulated insulin secretion; HDL: High-density cholesterol; LDL: Low-density cholesterol.

Abstract

Schistosomiasis (bilharziasis) is a major neglected tropical disease. It is endemic in many tropical and subtropical communities. Schistosomal polyps (S. polyps) are not uncommon presentation of this infection. Although the colon is the most commonly affected organ, many other organs are affected. S. polyps are associated with a variable range of morbidity independent of the Schistosomal infection. S. polyps are frequently described in endemic areas and increasingly reported in non-endemic areas mainly among immigrants and visitors to the endemic areas. This review aimed to increase awareness of practitioners, especially gastroenterologists, for this peculiar type of polyps caused by this neglected infection hence improving patient outcomes. Web-based search of different databases was conducted for the literature focusing the development of S. polyps in the colon and other organs with analysis of the clinical manifestations, diagnosis and treatment. The following key words were used in the search, "Schistosomiasis" OR "Bilharziasis" AND "Polyps" OR "Polyp" AND "Colon" OR "Small intestine" OR " Duodenum" OR " Stomach" OR "Esophagus" OR " Gallbladder" OR" Pharynx" OR "Larynx" OR "Trachea" OR "Urinary bladder" OR " Ureter" OR "Renal Pelvis" OR "Urethra". All publication types including case reports, case series, original research, and review articles were retrieved and analyzed. S.

polyps are not infrequent presentation of acute or chronic Schistosomal infection. S. polyps are described in many organs including the bowel, genitourinary tract, skin, gallbladder and the larynx. Presentation of S. polyps is variable and depends on the site, number as well as the polyp size. The relationship of *S. polyps* to malignant transformation is a matter of discussion. Presence of S. polyps is sometimes the only manifestation of Schistosomiasis. Small polyps can be treated medically with praziquantel, while large accessible polyps are amendable for endoscopic excision through different polyp resection techniques. However, huge, complicated, non-accessible and suspicious polyps are indicated for surgical management or advanced endoscopic resection when appropriate. Clinicians and endoscopists should be aware about these facts when treating patients living in, immigrated from or visiting endemic areas.

Key Words: Schistosomiasis; Bilharziasis; *Schistosomal polyps*; Colon; Praziquantel

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Schistosomiasis is associated with a wide range of pathological lesions including development of polyps. Colon is the commonest site for polyp development, however polyps are reported in many organs including urinary bladder, ureters, larynx, duodenum, small intestine, gallbladder, anus, uterine cervix and external genitalia. Schistosomal polyps are associated with a wide range of morbidity according to the polyp site, size and number. The malignant potential of these polyps is a hot point of discussion. Although small sized polyps can regress with medical therapy using praziquantel, large accessible polyps can be retrieved endoscopically. Complicated, huge and inaccessible polyps can be treated surgically.

INTRODUCTION

Schistosomiasis is a major neglected tropical disease. It is endemic in many geographical regions mainly in Africa, Latin America and Asia**.** Many data have been published from endemic areas and also from areas where the infection is not likely to occur with diverse clinical presentations. In non-endemic areas the infection is reported among immigrants or visitors to endemic areas[1,2].

This parasitic infestation was described in early human history, with evidence of infection reported in the ancient Egyptian papers and probably other old civilizations. The infection was characterized in the 19th century by the German pathologist Theodor Bilharz; that is why it is named after him as "Bilharziasis". There are many species of the parasite. Human infection is likely caused by five species, namely *Schistosoma Mansoni, S. Haematobium, S. Japonicum, S. Intercalatum and S. Mekongi*[1]. It is obvious that, the infection is linked to water supplies because of the snail intermediate host settles in the water canals and hence agricultural communities are the ultimate victims of the infestations, although persons who came in contact with infected water are prone also to catch the infection.

The clinical manifestation of this infection is either acute or chronic. The acute manifestations are related to the invasion of the human body by the cercarial invading stage through the skin, migration within the body and the early stage of ovi-position. Chronic manifestations are related to the establishment of adult worms and trapping of the deposited ova within the tissues and consequently granuloma formation[1]. The acute presentations include constitutional manifestations with fever, myalgia, urticarial rashes and with ovi-position the manifestations will change to hematuria (urinary Schistosomiasis), diarrhea with blood (intestinal Schistosomiasis), and chronic blood loss; manifested as anemia[1,3]. In chronic cases, development of fibrosis is the hallmark of the disease and this results in devastating sequelae including portal hypertension, hepatic peri-portal fibrosis, and splenomegaly for intestinal Schistosomiasis, while urinary Schistosomiasis is associated with obstructive lesions, increased incidence of stone formation, chronic urinary tract infections, and urinary bladder malignancy[4].

The current review aimed to increase awareness of practitioners, especially gastroenterologists, for this peculiar type of polyps caused by this neglected infection and hence improve patient outcomes.

LITERATURE SEARCH

Web-based search of different databases was conducted, including PubMed/MEDLINE, Cochrane library, Web of Science, Ovid, Science Direct, Scopus, Directory of Open Access Journals, EBSCO HOST, ProQuest, Institute for Scientific Information, EBESCO, Egyptian knowledge bank, Google scholar, *Reference Citation Analysis* (https://www.referencecitationanalysis.com/) and the Research Gate, for relevant articles focusing on the development of Schistosomal polyps (S.

polyps) in the colon and other organs with analysis of the clinical manifestations, diagnosis and treatment. The following key words were used in the search, "Schistosomiasis" OR "Bilharziasis" AND "Polyps" OR "Polyp" AND " Colon" OR "Small intestine" OR " Duodenum" OR " Stomach" OR "Esophagus" OR " Gallbladder" OR" Pharynx" OR "Larynx" OR "Trachea" OR "Urinary bladder" OR " Ureter" OR "Renal Pelvis" OR "Urethra". All publication types including case reports, case series, original research, and review articles were retrieved and analyzed.

PATHOGENESIS OF S. POLYPS

The development of polyps in general is linked to hollow organs or organs with contact to space; this enables external growth. Consequently, polyps are frequently reported in the bowel rather than other organs. The final shelters for adults Schistosomes are the intestinal and pelvic venous plexuses whatever the species are and hence the development of S. polyps in the hollow organs drained by this plexuses is not strange, *e.g.*, colon and urinary bladder, while development of polyps in other organs, *e.g.*, skin is considered ectopic. Furthermore, S. polyps may develop in atypical sites, *e.g.*, duodenum, that are not drained by the intestinal or pelvic veins.

The development of polyps in different stages

Stage of ova deposition and trapping: The eggs laid by the adult parasite had a characteristic spine that helps it to dig and find way out, *e.g.*, through the colon mucosa to be released with the stool. The initial step in polyp formation starts when Bilharzial eggs are deposited and trapped within the superficial layers of submucosa. The submucosal connective tissue is delicate and not superficially bound by firmer tissue. Consequently, accumulation of large amounts of eggs, reactive cellular debris and vascular granulation tissue do occur. In the submucosa, the trapped ova produce a TH2 cell-mediated inflammatory response with many cellular and chemical elements being recruited to the area and granuloma formation begins. The hallmark of the granuloma is infiltration by eosinophils (eosinophilic granuloma)[1], however, during this exudative stage of granuloma formation, other inflammatory cells are seen including the epithelioid macrophages and mononuclear cells[1,5].

Stage of proliferation: Within the granuloma necrosis occur[5]. Healing of the developed necrotic foci is associated with fibrous connective tissue formation. Furthermore, the adjacent muscularis mucosa becomes hypertrophied[1,5]. The fibrous tissue in the submucosa and the hypertrophied muscularis mucosa form a barrier hindering the ova transit from the veins to the lumen, hence more ova are entrapped. Sometimes, the adult worms either alone or matted are seen lodged and obstructing small venules within the polyp[5].

Stage of growth and protrusion: The granuloma formation is the basic pathology unit of chronic Schistosomiasis. Ova entrapment induces a foreign body reaction with progressive inflammation and fibrosis (chronic granuloma). As this process continues, a nodule is formed that elevates the hypertrophied muscularis mucosa and mucosa to form the polyp [6]. The polyp's mucosa harbors many goblet cells which secrete large amounts of mucus and this matches the abdominal pain and passage of mucus with stool seen among those patients. Furthermore, the delicate, and highly vascular nature of the polyp facilitates bleeding with the passage of stools[1,5-7].

This previously described mechanism of fibrosis and ova entrapment explain why the Schistosomal eggs are concentrated within the polyps more frequently than in the surrounding mucosa and submucosa[8]. Furthermore, non-inflammatory polyps associated with Schistosomiasis including adenomatous, hamartomatous, and hyperplastic polyps have been reported[1,9].

Stage of fibrosis: When the infection became chronic, the developed granulomas are infiltrated with fibroblasts, and fibrosis does occur[2,10]. Consequently, the polyps may become fibrotic. Small polyps especially when medically treated with praziquantel (PZQ) can then regress in size[11].

SCHISTOSOMAL COLONIC POLYPS

Site

The most common site for the development of S. polyps is the left colon, mainly recto-sigmoid region[3,12] because mesenteric (especially inferior mesenteric) and pelvic venous plexuses are the final habitat of the adult parasite. However, no part of the colon is immune against development of S. polyps. The polyps were described in all parts of the colon mainly in the rectosigmoid[12], but also were described in the caecum[13], ileocaecal valve[14], appendix[15], ascending colon[16], transverse colon[17] as well as the descending colon[12], some reports documented the distribution of S. polyps all through the large bowel starting from the caecum up to the anus during the course of heavy infestations in endemic areas[18].

Number

Schistosomiasis in the endemic areas, is associated with development of multiple polyps and multiplicity correlates with the density of infection[3,18]. However, there are many reports that Schistosomiasis can manifest by single colon polyp discovered either incidentally during colonoscopy or complicated[13,16,19] even without any clinical manifestations suggestive of Schistosomal infection.

Size

Schistosomiasis is usually associated with small-sized polyps[1,3,12]. However, large-sized S. polyps have been described in many case reports[12,16,18,19]. We reported earlier[20] that, no part of the colon was immune against development of large S. polyps. Many cases presented with solitary S. polyps[13,16,19,21] even in absence of any Schistosomiasis-related colon inflammation[9,13,16,19,21].

Atypical presentations and complications

Schistosomal colonic polyps had a wide range of atypical presentations. Elbatee *et al*[19], Alyhari *et al*[7], and Al-Zubaidi *et al*[22], described colo-rectal cancer (CRC) like presentation due to huge polyp size, abnormal polyp morphology or both, respectively. Furthermore, Smith *et al*[23], described diffuse colonic polypoid masses with dysensteric features, a picture endoscopically indistinguishable from familial polyposis and severe ulcerative colitis. Polyp-like lesion in the appendix manifestated as acute appendicitis was reported in a Chinese woman by Zhu *et al*[15], while pan-colonic inflammation and polyposis were described in Kenia by Bosire *et al*[18].

S. POLYPS BEYOND THE COLON

Urinary bladder polyps due to *S. Haematobium* have long been described and development of polyps correlates with heaviness of the infection in endemic areas[23]. Urinary bladder S. polyps were also reported among visitors to endemic areas[24]. Urinary S. polyps are not limited to urinary bladder, they were described within the ureters with a prevalence of 5.9% (30/511) in a large Egyptian study[25]. Due to the anatomical constraints, ureteric S. polyps tend to be small[25].

The atypical sites of S. polyps (Table 1) were described not infrequently in the literature. As early as in 1951, Gilges [26], described a skin polyp in the clitoris area of an African child. Furthermore, Schistosomal vulvual polyps have been described as vulvual swelling in 9- and 11-year-old girls from endemic areas in Senegal[27] and Nigera[28] respectively.

An ectopic cervical polyp was reported in Puerto Rico by File *et al*[29], despite the light Schistosomal infection. While Eladl *et al*[30] reported an endocervical polyp containing granulomas rich in viable eggs of *S. Hematobium* in a 43-year-old Egyptian woman who manifested with vaginal bleeding.

A slowly growing anal polyp containing Schistosomal ova as well as adult worms was described in a young Brazilian adult by Raso *et al*[5], the parasites probably migrated to the anus through the veins of hemorrhoidal plexus and it was associated with troublesome mass lesion with intense pruritus.

Duodenal polyps due to schistosomiasis have been reported in the literature although not common. In the duodenum it is discovered during endoscopic evaluation for obscure anemia and/or abdominal pain. The described duodenal S. polyps are either small, multiple and sessile[31] or solitary and large[32]. One case of dull abdominal pain was diagnosed in the United States with Schistosomiasis complicating a huge duodenal Peutz-Jeghers hamartomatous polyp[9].

The small intestine is infrequently affected with S. polyps and due to its narrow lumen, which is usually characterized by obstructive manifestations and diagnosis is established either at laparotomy or more frequently retrograde through histopathologic assessment. Small bowel obstruction due to huge polyp/polypoid mass at the ileocaecl valave[14] was described among visitors as well as residents of endemic areas[33] and small bowel obstruction is the usual presentation of such cases.

Gallbladder S. polyps are infrequently reported in the literature, the developed polyps are usually small in size and grew in the fundus, hence obstructive presentation is not likely and it is usually manifest (if any) as right upper quadrant pain. Both urinary (*S. Haematobium*) and intestinal Schistosomiasis (*S. Mansoni* and *S. Japonicum*) have been associated with gallbladder Schistosomiasis[34,35].

Larynx is less commonly affected during the course of Schistosomiasis. Toppozada described S. polyp involving the right vocal cord of a 25-year-old Egyptian male presented with 5-mo progressive hoarseness of voice, surgical microscopic excision and pathological examination showed granuloma with terminal sine ova[36].

S. POLYPS AND MALIGNANT TRANSFORMATION

The malignant potential of S. polyps is debatable. Although the relationship of urinary Schistosomiasis to malignancy is well established, the direct tumorigenic impact of intestinal S. polyps is questionable.

The bowel S. polyps have been implicated in the development of CRC and liver (HCC) cancers. The evidence supporting the malignant potential of intestinal Schistosomiasis is in favor of *S. Japonicum* rather than *S. Mansoni*. The chronic inflammatory state induced by ovi-position in the submucosa and other tissues have been proposed as the potential mechanism linking *S. Japonicum* in the Far East to the development of CRC and liver cancer[37].

So far the link between *S. Mansoni* and CRC has been viewed as no more than an epidemiological association and most published literatures deny the precancerous potential of the *S. Mansoni*-associated lesions including the polyps[38]. However, the mood of clinicians is spoiled by the emerging evidence incriminating *S. Mansoni* as a potential carcinogen. A large Egyptian study proposed an association between *S. Mansoni* infection and CRC relying on the increased levels of carcinoembryonic antigen within Bilharzial polyps' tissue[39]. In addition, one case report[40] retrieved Schistosome ova from the CRC specimens during histologic examination. Parasitism is associated with DNA repair defects with resultant genome instability, a commonly reported anomaly in CRC[38]. Furthermore, an emerging evidence through biomolecular mechanisms suggests an association between *S. Mansoni* and human carcinogenesis mainly for HCC and CRC and this is

Table 1 Summary of atypical and ectopic schistosomal polyps

Ref.	Site	Size	Presentation	Source
Raso *et al*[5], 2013	Anus	Large (2.5 cm)	Swelling with pain and intense pruritus	Endemic area
Gilges[26], 1951	External genitalia (clitoris)	Not mentioned	Mass like	Report from endemic area
Eladl *et al*[30], 2012	Cervix	Large sized (3 mc)	Vaginal bleeding	Endemic area

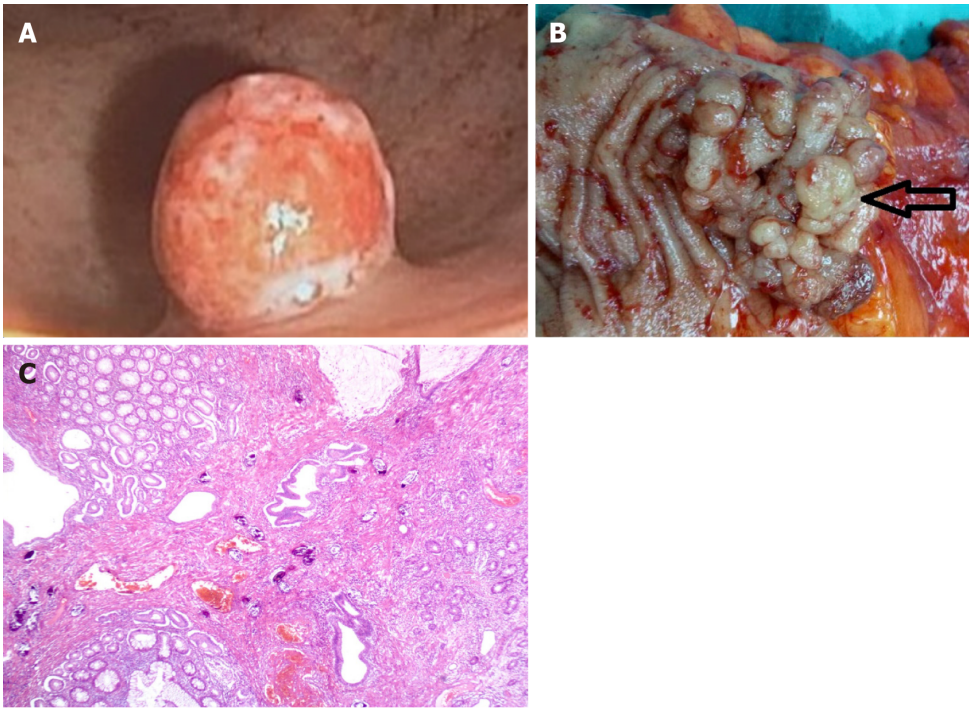
likely through many egg-related agents and Th2-immune mechanisms[41]. A single recent report described for the first time a concomitant infection with *S. Mekongi* and rectal cancer[42].

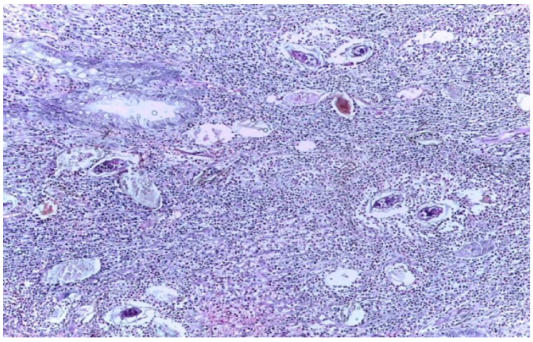
The association of *S. Haematobium* and the urinary bladder squamous cell cancer is well established[43] and that is why *S. Haematobium* is classified as group 1 definitive biological carcinogenic. This association is probable with all forms of urinary bladder- induced Schistosomal pathology including chronic bladder wall inflammation and irritation by the deposited ova, the induced ulcers, sandy patches and also to the developed S. polyps[44]. There is no clear evidence in the literature linking intestinal Schistosomiasis to bladder tumors and vice versa[9].



DIFFERENTIAL DIAGNOSIS

The severe forms of intestinal Schistosomiasis are characterized by the presence of multiple variable sized polyps against a background of diffuse mucosal affection showing mucosal erythema, and ulcerations, a picture mistaken with inflammatory bowel disease[3]. S. polyps of the colon are usually located in the recto-sigmoid region[12] and tend to be small[3, 12] (Figure 1A) and dark grey in color with surface ulceration, however other conditions with multiple colonic polyps should be considered in the differential diagnosis.

The solitary forms of S. polyps should be differentiated from other polyps according to the location. In fact, there is no characteristic morphology for S. polyps[45]. The huge polyps are commonly mistaken as malignant polyps (Figure 1B) and in such cases diagnosis is achieved through histopathology either by biopsy or after excision[19,21,22].



DIAGNOSIS

Diagnosis of polyps of the Schistosomal origin is sometimes challenging. There are no peculiar endoscopic morphologic features of S. polyps in comparison to other types of polyps and high index of suspicion is required especially in endemic areas. However, most cases are diagnosed either through endoscopic biopsy from the polyps or retrograde upon histopathology examination of removed polyps where the characteristic eosinophilic granulomas with the pathogenomic ova (Figure 2) of the parasite are seen [12-19,22] and infrequently the mature parasites may also be seen embedded within the background tissue of the excised polyps[22,29] or is seen lodged within thrombosed veins inside the polyp[5].

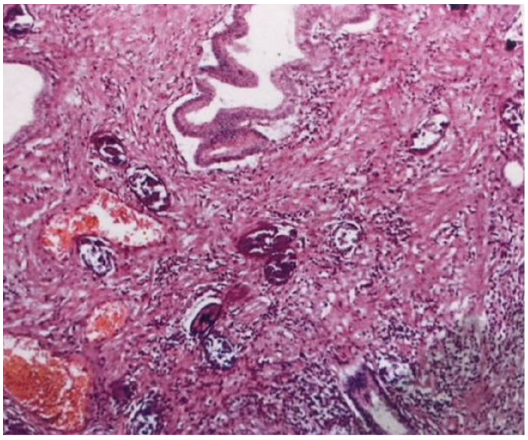

Figure 2 Active schistosomal granuloma; multiple schistosomal eggs in the submucosa surrounded by cellular infiltrate composed of eosinophils, lymphocytes, plasma cells and macrophages.

Linking the developed polyps, whatever its location, with active intestinal or urinary Schistosomiasis is not always achievable. In many cases described in the literature, identification of Bilharzial ova in fresh stool or urine samples taken from the same cases was not possible[9,16,31]. Furthermore, S. polyps may be the only clue of a Bilharzial infection[19,31].

Barium enema was used frequently to diagnose Bilharzial polyps of the bowel[46] in endemic areas before the era of endoscopy. However, currently the role of contrast study in diagnosis of intestinal or urinary Schistosomiasis is not likely to replace the standard methods for direct ova detection in stool or urine samples or detection of the ova with its characteristic granuloma on endoscopic or surgical specimens due to low sensitivity and specificity of these contrast studies[47].

Upon histologic examination, the polyp had a stalk of fibrous connective tissue that project from the submucosa into the lumen and is covered with mucosa. The overlying mucosa harbor distorted glands showing variable degrees of mucoid activity (Figure 1C), mucinous degeneration, and adenomatous hyperplasia. The covering mucosa frequently had focal areas of ulceration. Larger areas of ulceration may be replaced by granulation tissue. Mononuclear cells, eosinophils, and few polymorphonuclear leucocytes infiltrate the mucosa[48].

The peculiar granuloma had a centrally located ova (viable and/or nonviable) surrounded by cellular infiltrate characteristically with eosinophils, mononuclear cells and multinucleated histiocytes (Figure 2)[1,5], chronic granulomas are surrounded by fibroblasts (Figure 3). The supporting tissue is composed of fibrous connective tissue and muscle derived from the muscularis mucosa. Blood vessels may be present in large numbers but diminish with progression of fibrosis [48].

TREATMENT

Medical treatment

Currently, PZQ is the recommended first-line medical therapy for Schistosomiasis. The drug is active and effective in treatment of all Schistosome species with no reports of resistance[49]. Small-sized polyps can be cured with PZQ therapy alone. The dose is 40-60 mg/kg, it is given as a single dose after a meal[1] and can be divided over one day[3,9], and can be repeated[7]. The side effects associated with PZQ are usually mild and include nausea, vomiting, abdominal cramps and allergic reactions. S. polyps are exceptional types of polyps that can regress with medical treatment[11] especially when they are small and are not associated with manifestations necessitating excision. All cases associated with large or ectopic polyps after being excised either endoscopically or surgically were followed by treatment with PZQ irrespective of the patients' active intestinal or urinary Schistosomiasis state[9,13,19,34].

Endoscopic treatment

Large polyps are indicated for excision. Endoscopic excision for S. polyps have been reported thoroughly in the literature as early as the 80s of the last century[50,51] with the early time of endoscopy. S. polyps were excised with different techniques including cold snare for small polyps, standard direct hot polypectomy for larger polyps whatever the site is the duodenum[9], or the colon[3]. Hot polypectomy after application of endoloop[52], or clips[13] has been associated with good outcomes. While advanced endoscopic resection techniques including endoscopic mucosal resection[21,22] and endoscopic submucosal dissection[53] were also used for endoscopic removal of large S. polyps. All endoscopic resection techniques were used with accepted safety profile. The adverse events reported were not different from those reported with other types of polyps[3,9,13,16,22]. Resection of S. polyps combined with medical treatment using PZQ was successful [3,9,13,16,22,48]. Endoscopic resection of urinary S. polyps is less frequently performed in comparison to bowel and was associated with acceptable success rates[24].

Surgical treatment

Surgical excision is not the standard of care in treatment of S. polyps. However, surgery is usually the ultimate solution for challenging situations including cases presented with bowel obstruction[14,33], or when the lesion is morphologically or radiologically suspected to be malignant[7,12,19] and also for lesions in ectopic areas including the anus[5], cervix[30] and the external genitalia[27,28]. Atypical sites of S. polyps may require special surgical approaches, *e.g.*, in the larynx, the surgical microscope is essential to excise the polyp[36], while in other situations, *e.g.*, gallbladder, the organ is excised with the polyp en bloc[34]. All cases managed by surgery, similar to endoscopic management, should be followed by PZQ therapy.

Outcomes of treatment

The outcome of S. polyps achieved by the above mentioned treatments depend on many factors. First, the number of lesions detected. For single lesions excision (either endoscopic or surgical) is usually curative, while multiple lesions may require more rounds of excision[3]. Second, patients' residency; patients residing in endemic areas are susceptible to re-infection and hence should follow the general preventive measures together with PZQ therapy that sometimes given as chemoprophylaxis or as mass treatment campaigns even without testing for the presence of the parasite[54], while patients out of the endemic areas a single course of PZQ is usually sufficient for treatment. Third, the location of the polyps, some polyps are accessible for endoscopic treatment, such as polyps in the colon, and urinary bladder, while other lesions, *e.g.*, gallbladder are not. Last, presentation of the lesions, such as lesions presented with acute manifestations including bowel obstruction, surgery usually the corner stone of treatment and in such cases diagnosis is often achieved retrograde[14,33].

CONCLUSION

Schistosomiasis is a neglected tropical disease and its prevalence is no more limited to endemic areas. S. polyps are not infrequent presentation of acute or chronic Schistosomal infection. S. polyps are described in many organs including the bowel, genitourinary tract, skin, gallbladder and the larynx. Presentation of S. polyps is variable and depends on the site, number as well as the polyp size. The relationship of S. polyps to malignant transformation is a matter of discussion. Small polyps can be treated medically with PZQ, while large accessible polyps are amendable for endoscopic excision through different polyp resection techniques. However, huge, complicated and suspicious polyps are indicated for surgical management or advanced endoscopic resection if appropriate. Clinicians and endoscopists should be aware about these facts when treating patients living in, immigrated from or visiting endemic areas.

Abstract

Prepandemic time trends in mortality from chronic liver disease (CLD) differed according to specific cause of death (decreasing for liver cirrhosis, stable or increasing for liver cancer), etiology (increasing for nonalcoholic fatty liver disease, generally decreasing for other etiologies), and world region (decreasing in areas with the highest burden of hepatitis B virus, increasing in Eastern Europe and other countries). The coronavirus disease 2019 (COVID-19) pandemic affected mortality of patients with CLD both directly, with a higher risk for severe illness and death depending on age, stage and etiology of the disease, and indirectly, through social isolation and loss of support, harmful drinking, and difficulties in access to care. Nevertheless, only sparse data are available on variations in CLD as a cause of death during the pandemic. In the USA, in 2020-2021 a growth in mortality was registered for all liver diseases, more marked for alcoholic liver disease, especially among young people aged 25-44 years and in selected ethnic groups. COVID-19 related deaths accounted only for a minor part of the excess. Further data from mortality registers of other countries are warranted, preferably adopting the so-called multiple cause-of-death approach, and extended to deaths attributed to viral hepatitis and liver cancer.

Core tip: Preliminary data on causes of death during the coronavirus disease 2019 pandemic suggest that mortality from chronic liver disease (CLD) increased especially in countries where the alcoholic etiology was predominant, or with a prepandemic growing trend in mortality from alcoholic liver disease. Population-based studies on the direct and indirect effects of the pandemic on CLD mortality are strongly warranted. Analyses adopting the multiple cause-of-death approach might be better suited to fully investigate the impact of the pandemic on complex long-term pre-existing trends.

INTRODUCTION

According to a systematic analysis of the Global Burden of Disease (GBD) Study 2017, deaths from cirrhosis and other chronic liver diseases (CLDs) were estimated at 1.32 million in 2017, compared to 889 000 in 1990. However, the corresponding age-standardized rate decreased from 21.0 to 16.5 per 100000 population. Rates decreased or remained constant in all regions except for Eastern Europe and Central Asia. Globally, age-standardized death rates associated to all main etiologies (alcohol, hepatitis B, and hepatitis C) declined, except for nonalcoholic steatohepatitis[1].

However, interpretation of mortality data on CLD poses several challenges. Cirrhosis mortality captures only a limited fraction of deaths due to CLD. In the USA, by adopting the standard definition for CLD mortality, a 38% decrease in rates was observed from 1979 to 2008; if other liver-related causes of death including viral hepatitis and liver cancer were examined, rates remained essentially unchanged[2]. Liver cirrhosis mortality dropped, whereas death rates for primary liver cancer were stable in Northeastern Italy in 1995-2010[3], and increased in China in 1987-2016[4]. A more comprehensive assessment on mortality from CLD can also be achieved by analyses not limited to the underlying cause of death, but extended to all conditions mentioned in death certificates. The so-called multiple cause-of-death approach can unveil rapidly changing trends limited to specific etiologies within selected birth cohorts. As an example, a rise in mortality related to hepatitis C virus (HCV) was registered in the USA in 2003-2013; most deaths were confined to the 1945-1965 birth cohort, affected by the highest prevalence of HCV infection[5]. A similar growth in HCV-related mortality within a specific birth cohort was observed in Northern Italy[6]. After 2014, time trends in the USA changed and mortality related to HCV started to decline, whereas death rates related to alcoholic liver disease and nonalcoholic fatty liver disease (NAFLD) were on the rise[7].

In the most recent years, patients with CLD represented a vulnerable population during the coronavirus disease 2019 (COVID-19) pandemic due to immune dysregulation and coagulopathy among those with advanced disease, and coexisting comorbidity, including obesity, diabetes and cardiovascular diseases. Notably, baseline liver disease stage and alcoholic liver disease were demonstrated to be independent risk factors for death from COVID-19[8]. Nevertheless, to date, population-based data on trends in CLD as a cause of death during the pandemic are lacking, except for an increase in mortality from liver cirrhosis reported from the USA already in its early phases[9]. We review here the available evidence on the impact of the pandemic on pre-existing time trends in mortality from CLD.

MORTALITY TRENDS BEFORE THE PANDEMIC

In 2017, there were 2.14 million estimated liver-related deaths; liver cirrhosis and liver cancer accounted for 61.7% and 38.3%, respectively. Between 2012 and 2017 the global age-standardized death rate increased (annual percent change, APC = 0.51%, 0.05%-0.98%) for liver cancer and decreased (APC = 0.70%, 1.01% to 0.40%) for liver cirrhosis. In Asia, the most common cause was hepatitis B virus (HBV) infection (highest in East Asia), whereas HCV was the most common cause in high-income Asia Pacific and Middle East and North Africa (MENA), and alcohol-related liver disease in Central Asia. Incidence and mortality associated with NAFLD increased globally, and this increase was recorded in almost every region worldwide[10].

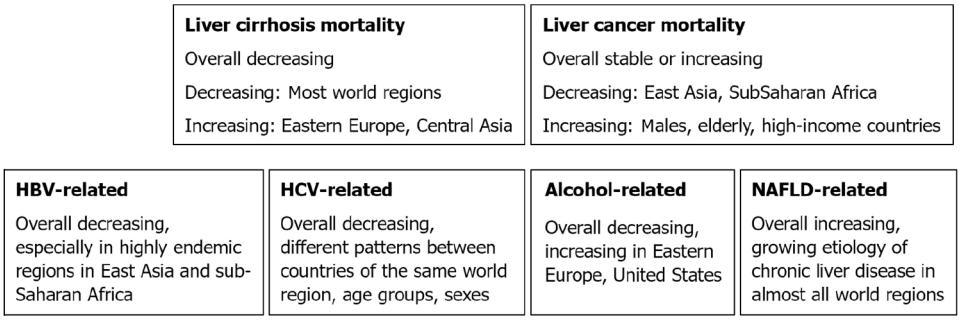
Hepatitis B is the leading etiology for liver cancer mortality and the third largest contributor to deaths from cirrhosis. HBV-related diseases resulted in 555 000 global deaths in 2019; the number of HBV-related deaths increased between 1990 and 2019. By contrast, age-standardized death rates declined globally and in all world regions. Meanwhile, there was a 31.3% decrease in the prevalence of HBV at all ages[11]. Mortality trends related to hepatitis C are less pronounced; in 2010-2019 the decline in mortality was larger for acute hepatitis C than for HCV-related cirrhosis, with no significant change for HCV-related liver cancer[12].

A number of studies addressed global trends in liver cancer incidence and mortality. According to the GBD 2015 study, globally, HBV accounted for 33% of a total of 810 000 liver cancer deaths, alcohol for 30%, and HCV for 21%. The highest share for HBV was observed in Western sub-Saharan Africa, East Asia, and Andean Latin America; that for HCV in high-income Asia Pacific, MENA, Central and Southern Latin America, and Western Europe; and that for alcohol in Central and Eastern Europe. From 1999 to 2015, age-standardized mortality rates declined substantially in regions with high liver cancer burden such as East Asia and sub-Saharan Africa, probably due to the effect of primary liver cancer prevention through HBV vaccination[13]. These trends parallel those in liver cancer incidence. The burden in highly endemic regions has been partially alleviated due to improved control of viral hepatitis, especially among young and middle-aged people. By contrast, an unfavorable trend was observed in most developed countries and in older populations[14]. In fact, the most significant increases in incidence were generally observed in countries with a high sociodemographic index, including the UK and the USA[15]. Nevertheless, chronic HBV and HCV remain important risk factors for liver cancer. Based on the GLOBOCAN database, the overall increasing trend in incidence and mortality from liver cancer was confirmed among older male subjects, and in countries with a higher prevalence of HCV-related liver cancer. The increasing prevalence of alcohol consumption and obesity may have contributed to this epidemiological scenario in high-income countries[16].

As regards mortality from liver cirrhosis, analyses of the GBD 2017 study showed that deaths due to cirrhosis constituted 2.4% of total deaths globally. Central Asia had the highest age-standardized death rate, followed by Sub-Saharan Africa. Central Asia and Eastern Europe were the only two regions in which mortality rates significantly increased during 1990-2017; in both, prevalent cases were predominantly caused by alcohol-related liver disease. At the national level, the highest mortality rate was registered in Egypt, whereas the steepest growth was observed in Lithuania. Deaths from cirrhosis in males were mostly attributed to hepatitis B (31.5%), alcohol (27.3%), and hepatitis C (25.5%); the corresponding percentages in females were 24.0%, 20.6%, and 26.7%[1].

In view of the above, prepandemic global patterns in CLD mortality differed according to cause of death (liver cirrhosis or liver cancer), etiology, and world region (Figure 1). Furthermore, even within a single country, different patterns of mortality could be registered according to complex interactions between demographic characteristics (sex, age group, ethnicity, and socioeconomic status) and etiology of liver disease. Mortality from CLD overall, and especially that from alcoholic liver disease, is in fact strongly associated with socioeconomic status[17]. Different trends in CLD mortality by etiology have been investigated in the USA by means of the multiple cause-of-death approach. Overall, an increase in mortality from cirrhosis and hepatocellular carcinoma has been registered in the prepandemic period[18]. However, drastically different trends were observed according to etiology. HCV-related mortality increased from 2007 to 2014 and sharply declined in 2014-2016, after the introduction of direct-acting antiviral therapies; meanwhile, a decrease in HBV-related mortality, and an increase in alcoholic liver disease and NAFLD mortality was observed in 2007-2016. Minorities were disproportionately affected, especially non-Hispanic blacks by HCV-related mortality and Asians by HBV-related mortality[7]. An increase in mortality related to NAFLD was confirmed by other authors in the same period, especially among older subjects, females, non-Hispanic whites, and American Indian/Alaskan Natives[19].

CLD AND COVID-19



Although COVID-19 primarily affects the respiratory system, causing pneumonia and acute respiratory distress syndrome in severe cases, it can also result in multiple extrapulmonary complications. The pathogenesis of extrapulmonary damage in patients with COVID-19 is probably multifactorial, involving both the direct effects of SARS-CoV-2 and the indirect mechanisms associated with the host inflammatory response[20]. Research has shown that COVID-19 can cause liver injury due to inflammation, which can lead to liver damage or failure, particularly in people with pre-existing liver conditions such as cirrhosis. People with COVID-19 who have pre-existing liver conditions may be at a higher risk for severe illness and death[21]. For these reasons, they should always continue to follow their treatment plan and keep in close contact with their healthcare provider.

Etiology of liver disease and COVID-19 impact

It is reported that liver diseases of viral etiology are not associated *per se* with the severity or outcome of COVID-19, and this finding has been consistent across Asia, Europe and the USA. According to recent data from the European Reference Network for Rare Liver Diseases, autoimmune liver diseases and the related immunosuppressive therapy do not represent a specific risk factor for COVID-19, and the risk, as with other etiologies, is determined by the stage of cirrhosis [22]. Several studies highlighted the presence of severe complications in patients with SARS-CoV-2 infection and metabolic-syndrome-associated comorbidities, including NAFLD. The shared genetic influence between COVID-19 susceptibility and NAFLD, the sex-linked and the liver single-cell differential expression level of diverse transcripts and biological pathways might uncover shared disease mechanisms that explain the severe complications and increased in-hospital mortality risk associated with comorbidities, including NAFLD[23]. Lockdown, economic hardship, and the psychological impact of the pandemic all had a detrimental effect on people with liver disease, including poorer metabolic control in people with metabolic syndrome and fatty liver disease. This likely had deleterious consequences on the liver and cardiovascular outcomes of people with NAFLD, particularly those with advanced liver disease. Mortality has been shown to increase in people with alcohol-associated liver disease[24].

The role of cirrhosis

Prospective data from multicenter studies confirmed that patients with cirrhosis, particularly those who are

Figure 1 Trends in mortality from liver diseases before the pandemic, by cause of death and etiology. HBV: Hepatitis B virus; HCV: Hepatitis C virus; NAFLD: Nonalcoholic fatty liver disease.

decompensated, are at a higher risk of hospitalization, ventilation and death than those without CLD. Older age and cirrhosis severity, as assessed by Child-Pugh class, are the most important predictors of mortality[25]. Overall mortality in patients with cirrhosis following SARS-CoV-2 infection was 32% in a large registry cohort of 729 predominantly hospitalized patients with CLD across 29 countries, with case-fatality rates incrementally increasing with each Child-Pugh class (CLD without cirrhosis 8%; class A 19%; class B 35%; class C 51%). The multivariable analysis of factors associated with death demonstrated persisting positive associations with age [odds ratio (OR) 1.02; 95% confidence interval (CI) 1.01-1.04; $P = 0.011$], the different stages of cirrhosis compared with CLD without cirrhosis (Child-Pugh class A, OR 1.90; 95%CI: 1.03-3.52; $P = 0.040$; class B, OR 4.14; 95%CI: 2.4-7.65; $P < 0.001$; and class C, OR 9.32; 95%CI: 4.80-18.08; $P < 0.001$), and alcoholic liver disease (OR 1.79; 95%CI: 1.03-3.13; $P = 0.040$)[8].

Patients with CLD and especially cirrhosis, have multiple mechanisms of immune dysfunction that can lead to increased susceptibility to infection and an aberrant inflammatory response during infection, collectively known as cirrhosis-associated immune dysfunction[26]. This immune dysfunction includes reduced components of the complement system, macrophage activation, impaired lymphocyte and neutrophil function, Toll-like receptor upregulation, and intestinal dysbiosis[27].

The role of vaccination

By April 2022, more than half of the world's population had received at least one vaccine dose, with real-world data showing that vaccination is generally safe and significantly reduces mortality. However, the initial high efficacy against infection has decreased following the emergence of new SARS-CoV-2 variants. Vaccine efficacy is particularly low against the Omicron variant, although fortunately it still confers considerable protection against severe COVID-19[28,29]. Although vaccines and previous infections largely protect against severe clinical courses of COVID-19, particularly in the current phase of the pandemic, which is dominated by sublineages of the SARS-CoV-2 Omicron variant, there is still a significant unmet medical need for therapeutics to treat severe disease in unvaccinated or older patients and patients with chronic disease conditions[30]. The impact of liver disease severity on vaccine efficacy should be convened to patients, so that they are aware of their increased risk and continue to take personal protective measures[31].

CLD AS A CAUSE OF DEATH DURING THE COVID-19 PANDEMIC

Between 2012 and 2019, rates of alcohol-specific deaths in the UK remained stable, whereas during the pandemic years, they rose from 11.8 per 100000 in 2019 to 14.8 in 2021. Alcoholic liver disease accounted for 78% of alcohol-specific mortality: the number of registered deaths grew from 5840 in 2019 to 7518 in 2021. This rise was attributed to increased alcohol consumption during the pandemic. Although alcoholic liver disease takes many years to develop, a further increase in alcohol intake among high-risk consumers can lead to rises in mortality in a short period of time, from what is known as acute-on-chronic liver failure[32].

In Minnesota, USA, an increase in both alcoholic liver disease and cirrhosis/other CLD as the underlying cause of death was registered in 2020 with respect to 2018-2019[33]. The growth in deaths from alcoholic liver disease as the underlying cause was confirmed at the national level[34]. According to analyses of national US multiple cause-of-death data, during the first year of the COVID-19 pandemic, the pre-existing growing trend in alcoholic liver disease mortality further accelerated, with the quarterly increase rising from 1.1% to 11.2%. Similarly, the quarterly increase in NAFLD grew from 1.9% to 6.6%. Mortality related to HBV and HCV, previously declining in the prepandemic period, remained stable[35]. Similar analyses were extended to 2021 data from the USA, confirming the increase through the second year of the pandemic for all liver diseases. This was more marked for alcoholic liver disease, especially among the young population aged 25-44 years and in selected ethnic groups such as American Indian/Alaskan Natives. The decline in HCV-related mortality observed since 2014 slowed down[36]. Years of potential life lost from premature deaths (< 65 years) attributable to cirrhosis listed as one of the causes of death in US certificates grew by 20.7% in 2020 and by 29.5% in 2021. COVID-19-related deaths accounted only for a minor part of such excess. Again, the increase was more pronounced for the alcoholic etiology, consistent with growing alcohol sales in the USA during the pandemic[37]. Patients with

alcoholic liver disease might have disproportionally suffered from a surge in harmful drinking, social isolation, and loss of familial and social support, along with barriers to access to outpatient clinics and rehabilitation services. Another study of US national multiple cause-of-death data reported a marked increase in mortality from CLD and/or cirrhosis among decedents with mention of diabetes, specifically associated with increased mortality from NAFLD and alcohol-related liver diseases[38].

By contrast in Spain, no major change in the number of deaths from CLD in 2020 compared to the 2018-2019 average was observed, based both on the underlying cause of death (0.9%) and on multiple cause-of-death data (+3.1%)[39].

In view of the paucity of published evidence outside the USA, we retrieved mortality rates for liver cirrhosis (International Classification of Diseases-10th Revision codes K70 and K74) from the World Health Organization (WHO) mortality database (https://platform.who.int/mortality). Table 1 shows countries with data updated at least until 2020; few had data available for the year 2021. In 2020 a large increase was registered in the USA (+18% with respect to 2019) and the UK (+16%). Among the other most populous countries, rates in the Americas were almost unchanged (Mexico, Brazil and Argentina) or declined (Peru and Colombia). European countries showed no increase (Spain) or only a limited mortality increase (Germany and Poland). Rates decreased in Malaysia and showed only minor growth in other Asian countries (Kazakhstan, Japan and Korea) and in Australia. Among less populous countries, a marked increase was registered in some Eastern European countries: Estonia, Lithuania, and in 2021 Latvia, Czechia and North Macedonia. A more comprehensive evaluation will however be possible when complete 2021 data become available, in consideration of how the pandemic involved different world regions in subsequent phases (*e.g.*, Central and Eastern Europe were more severely affected in 2021 compared to 2020). Additional nationwide data not included in the WHO database can be retrieved from institutional websites. As an example, in Italy age-adjusted mortality rates from liver cirrhosis, fibrosis and chronic hepatitis in 2020 showed a 3% reduction with respect to 2019, which is consistent with the decreasing trend observed in recent years (http://dati.istat.it/). Mortality from liver cirrhosis more closely parallels mortality from alcoholic liver disease with respect to that associated with other etiologies, and analyses including codes for viral hepatitis and liver cancer are warranted[3]. Lastly, also due to coding rules set by WHO[40], COVID-19 itself may have acted as a competing condition for the selection as the underlying cause of death in patients affected by pre-existing chronic diseases[35].

CONCLUSION

A large variation in trends of mortality from CLD was observed at the global level before 2020. Based on the few available published reports, the COVID-19 pandemic had a different impact depending on the local epidemiological context. Probably, mortality from CLD increased, especially in areas where the alcoholic etiology was predominant, or where a growing trend in mortality from alcoholic liver disease was already in place. Therefore, population-based studies on the direct and the indirect effects of the COVID-19 pandemic on CLD mortality are strongly warranted. Analyses adopting the multiple cause-of-death approach, and extended to deaths attributed to viral hepatitis and liver cancer, might be better suited to fully investigate the impact of the pandemic on complex long-term pre-existing trends.

Abstract

Neuroendocrine neoplasms (NENs) are rare heterogeneous tumors that can develop in almost any organ, with the digestive organs, including the gastrointestinal tract and pancreas being the most commonly affected sites. Despite the fact that advances in initial therapies have progressed, there is presently no recognized effective treatment for advanced NEN. Immune checkpoint inhibitors (ICIs) have shown superior efficacy in treating several types of solid tumors. Despite their successful role in the treatment of partial NENs, such as small cell lung cancer, and Merkel cell carcinoma, the role of ICIs in most of the NENs remains limited. Nevertheless, due to their specific anti-tumor mechanisms and acceptable safety profile, ICIs are a promising avenue for further study in NENs therapy. Recent clinical trials have illustrated that combination therapy with ICI is more efficient than monotherapy, and multiple clinical trials are constantly ongoing to evaluate the efficacy and safety of these combination therapies. Therefore, the purpose of this review is to provide a comprehensive summary of the clinical progress of immunotherapy in NENs affecting the digestive system, with a specific emphasis on the application of programmed cell death protein 1/programmed death receptor ligand 1 inhibitor. Furthermore, this review has an exploration of the potential beneficiary population and the inherent value of utilizing immunotherapy in the management of NENs.

Key Words: Immunotherapy; PD-1 inhibitor; Neuroendocrine neoplasm; Neuroendocrine tumor; Neuroendocrine carcinoma; Gastrointestinal; Pancreatic

Core Tip: The application of immune checkpoint inhibitor (ICI) in neuroendocrine neoplasm (NEN) is regulated by the latest clinical practice guidelines. However, immunotherapy has achieved some breakthroughs for high-grade or advanced NENs of the digestive system, for which there is currently no effective drug therapy. In this regard, we investigated the causes of the heterogeneous efficacy of ICI in NEN with different grades, differentiation, and primary organs. This review summarizes the state-of-the-art progress and trend of clinical trials for different ICI-containing regimens in NENs of the digestive system, which will aid in the conduct of subsequent clinical trials and research of related mechanisms.

INTRODUCTION

Neuroendocrine Neoplasms (NENs) are a group of rare and heterogeneous neoplasms that may originate from cells throughout the endocrine system[1]. These tumors express neuroendocrine markers and can occur in any part of the body, with a particular prevalence in the digestive system, such as the gastrointestinal (GI) tract and hepatopancreato-biliary organs. The majority of NENs are sporadic, and the exact etiology is still unknown[2]. However, less than 5% of gastroenteropancreatic (GEP) NENs occur as hereditary neoplastic syndromes, associated with gene deletions or alterations, including multiple endocrine neoplasia type 1 associated with duodenopancreatic NENs[3,4], and the von Hippel-Lindau syndrome associated with pancreatic NENs[5].

NENs of the digestive system consist of a range of tumor types, including well-differentiated neuroendocrine tumors (NETs), poorly differentiated neuroendocrine carcinomas (NECs), and mixed neuroendocrine-non-neuroendocrine neoplasms (MiNENs), which based on the degree of NEN malignancy according to the World Health Organization (WHO) classification of tumors of the digestive system (5th edition, 2019)[6]. NETs can be further classified and graded into three categories: Neuroendocrine tumors grade 1 (NET G1; low grade), NET G2 (intermediate grade), and NET G3 (high grade). This classification is determined based on the Ki-67 proliferation index and the number of mitotic figures per 2 mm^2. NECs include large cell-type NEC (LCNEC) and small cell-type NEC (SCNEC), both of which are considered as high grades. MiNENs exhibit varying degrees of differentiation and grades because they possess both neuroendocrine and non-neuroendocrine components in a single patch of neoplastic tissue, with each component accounting for ≥ 30%.

In recent years, with widespread improvements in clinical diagnosis and treatment, including endoscopy and imaging, there has been a noticeable worldwide upward trend in the detection of early-stage and non-functioning NENs from the digestive system. NEN incidence increased 6.4 times between 1973 (1.09/100000) and 2012 (6.98/100000), according to an analysis published in 2017 and based on 64971 NEN cases from the Surveillance Epidemiology and End Results database of the National Cancer Institute[7]. According to statistics from England, the incidence of NENs was about 9/100000 in 2018, and the incidences of pancreatic and rectal NENs have increased significantly[8]. Similarly, based on Taiwanese data, the incidence of NENs in digestive organs increased from 0.15 per 100000 people in 1996 to 2.36 per 100000 people in 2015[9].

The most prevalent primary sites have also been shown to vary across different regions. In the United Kingdom, the order of frequency among all primary sites of GEP-NETs, was as follows: Small intestine (25.6%), appendix (23.6%), pancreas (17.7%), colon (9.8%), stomach (9.8%), and rectum (7.8%)[10]. In China, however, the order was different, with the pancreas (31.5%), rectum (29.6%), and stomach (27.0%) being the common sites. The small intestine (5.6%) and colon (3.0%) accounted for relatively small proportions of NENs in this region[11]. Compared with others, gallbladder NENs are more scarce and account for only 0.5% of all NENs[12]. NETs are prone to metastasis to the liver; however, the liver itself is rarely the primary site of NENs, accounting for only 0.46% of primary liver tumors[13]. Owing to the rarity of the diagnosis and a lack of valid statistics for relevant cases, the quality of published data is limited, and the epidemiology of patients with digestive MiNENs remains unknown[14].

Immune checkpoint inhibitors (ICIs) have potent, strong anti-tumor activity in the management of various cancer types. These inhibitors, which target programmed cell death protein 1 (PD-1) or programmed death receptor ligand 1 (PD-L1), are profoundly researched and widely used in tumor immunotherapy. Both PD-1 and PD-L1 targeted antibodies relieve the functional inhibition of T cells and reactivate the immune response against cancer cells. Several α-PD-1 (*e.g.*, palivizumab, nivolumab, and toripalimab) and α-PD-L1 antibodies (*e.g.*, atezolizumab and durvalumab) have been licensed by the Food and Drug Administration (FDA) for the treatment of multiple forms of tumor owing to their efficacy in clinical trials. More than 10 different cancer types have been authorized for therapy with single-agent PD-1 or PD-L1 monoclonal antibodies, with objective response rates (ORR) ranging from 15%-20%[15]. However, the PD-1 or PD-L1 axis is not the only signaling access that contributes to tumor immunosuppression, and the inhibition of this pathway alone is insufficient to effectively elicit anti-tumor immunity. Consequently, several combination immunotherapies, such as PD-1/PD-L1 antibodies combined with chemotherapy, radiotherapy, angiogenesis inhibitors, other ICIs, gut microbiota transplantation, and metabolic modulators, may improve the overall anti-tumor activity and raise the response rates (RRs) of NENs of the digestive system[16].

Herein, we comprehensively summarize the clinical application status and research progress of immunotherapy drugs, mainly PD-1 and PD-L1 inhibitors, for the treatment regimen of NENs of the digestive system, which might provide more potent and widely applicable regimens as well as direction for subsequent studies.

IMMUNOTHERAPY AND NENS OF THE DIGESTIVE SYSTEM

The use of immunotherapy to treat NENs of the digestive system is still in the clinical exploration phase and is not yet recommended as the preferred regimen. This is because available clinical trials have demonstrated low ORRs to immunotherapy using PD-1 or PD-L1 inhibitors. Currently, several immunotherapeutic strategies for NENs are undergoing clinical trials, including ICI monotherapy, dual ICI therapy, anti-angiogenesis with ICIs, and chemotherapy with ICI. Table 1 provides a summary of relevant data from the clinical trials mentioned below.

Application status of ICIs in NENs of the digestive system

According to the National Comprehensive Cancer Network Clinical Practice Guidelines of Neuroendocrine and Adrenal Tumors (version 2.2022), ICIs are not currently available as a preferred regimen for the systemic treatment of patients with unresectable locally advanced or distant metastases from NEN. In the preferred regimen, the molecularly targeted drug everolimus is more effective in advanced G1 or G2 NET. In phase III clinical research, mPFS in the everolimus group was longer than in the placebo group (11 *vs* 3.9 mo; $P < 0.00001$) and decreased recurrence rate as well as mortality by 52%[17]. Somatostatin analogs, such as octreotide and lanreotide, are mainly used in the treatment of NENs that are somatostatin receptor-positive, slow-growth as well as Ki-67 ≤ 10% and are usually combined with molecularly targeted drugs to control the symptom of functional NETs. Chemotherapy is typically the preferred treatment option for G3 NET and NEC. The ORR of cisplatin or carboplatin combined with etoposide in the treatment of advanced NECs ranged from 30.8%-63.2%, and the median overall survival (mOS) was between 8.9-12.5 mo[18,19]. Temozolomide combined with capecitabine has more efficacy in pancreatic NET (pNET) than in GI NET, and the mPFS and mOS in high-grade NET were longer than those in NEC (15.3 mo *vs* 3.3 mo; 22 mo *vs* 4.6 mo)[20].

Although most NENs have not demonstrated the greatest effectiveness, ICIs can still be used as the primary treatment for well-differentiated grade 3 NETs, extrapulmonary poorly differentiated NECs, and MiNENs. Patients with advanced tumor mutational burden-high [tumor mutational burden (TMB)-H], microsatellite instability-high (MSI-H), or mismatch repair deficiency (dMMR) tumors, as identified by an FDA-approved test performed after prior therapy, may be candidates for the PD-1 inhibitor pembrolizumab if no other appropriate options for therapy are available. For biologically favorable or unfavorable locally advanced or metastatic G3 NETs (unresectable with clinically considerable tumor burden or indication of disease progression), pembrolizumab is the primary treatment[21,22]. In the event of extrapulmonary, locoregional, unresectable, or metastatic NECs/MiNENs, pembrolizumab can also be considered for systemic therapy[21,22,23]. Nivolumab combined with ipilimumab (category 2B), which is known as a type of dual ICI therapy, is a recommended option for locally progressed or metastatic G3 NETs with unfavorable biologies[24]. Similarly, if the illness advances after chemotherapy, ipilimumab paired with nivolumab (category 2B) might also be taken into consideration for extrapulmonary poorly differentiated (LCNEC/SCNEC) or unknown primary tumors.

However, the Guidelines of the Chinese Society of Clinical Oncology for Neuroendocrine Neoplasms (version 2022) only suggest the use of ICIs as a treatment option for metastatic NECs. Specifically, pembrolizumab is recommended as a first-line treatment (category 3) or as a level-2 recommendation for the second-line treatment of metastatic NEC in patients with performance status (PS) scores of 0-2 and the presence of dMMR, MSI-H, or TMB-H (category 1A)[25]. In addition, ICIs such as ipilimumab, combined with nivolumab[24] or other ICIs[26-28], may be considered for patients with metastatic NECs who have previously received systemic therapy and continue to experience disease progression and who lack standard treatment options. For these patients, ICIs are recommended as a level-3 recommendation for second-line treatment (category 3A).

ICI monotherapy

ICI monotherapy has shown remarkably low RRs in NENs, especially in poorly differentiated ones. The Keynote-028 trial demonstrated the actual clinical outcomes of pembrolizumab monotherapy in patients who had carcinoid tumors and pNET with PD-L1 expression[29]. In the pNET cohort, 16 PD-L1-positive patients out of 106 pNET patients received pembrolizumab monotherapy with ORRs of 6.3% [95% confidence interval (CI): 0.2%-30.2%], only one patient confirmed partial response (PR), 31% developed stable disease (SD) lasting more than 6 mo, and 12-mo progression-free survival (PFS) and overall survival (OS) rates of 27% and 87%, respectively. However, studies comparing the efficiency of pembrolizumab in patients with or without PD-L1 expression reported no significant differences in the disease control rate (DCR), PFS, or OS between the two groups[30]. Among 29 patients who had experienced prior treatments, 48% and 34% had GI and pancreatic NENs, respectively. Only one patient (95%CI: 0.1-17.8%) with an esophageal LCNEC had an objective PR that persisted for 13 mo before he discontinued his participation in the study. Six patients (95%CI: 7.9-39.7%) had SDs, and DCR was 24.1%[30]. In an open-label phase II trial, pembrolizumab single-agent therapy in 107 well-differentiated NETs of the lung, appendix, small intestine, colon, rectum, or pancreas with previously failed standard treatments resulted in an ORR of only 3.7% (95%CI: 1.0-9.3). The median PFS (mPFS) was 4.1 mo (95%CI: 3.5-5.4), the estimated PFS rate at 6 mo was 39.3%, and the mOS was 24.2 mo. Among 40 patients with pancreatic NETs, 25 patients with small intestine NETs, and 18 patients with other GI NETs, only 4 patients had a PR as assessed by Response Evaluation Criteria in Advanced Solid Tumors version 1.1, including cases in the pancreas (3) and rectum (1); all of them were PD-L1 negative. It is noteworthy that the response rate in the pancreatic NETs subgroup was 7.5%[31]. In another

Table 1 Clinical trials mentioned in the review

Intervention	Study phase	Actual enrollment	NEN type of the digestive system	ORR (%)	mPFS (mo)	mOS (mo)	Ref.
Pembrolizumab	I	16	pNET	6.3	4.5	21.0	[29]
	II	29 (14 GI, 10 pancreas)	GI-NEN, pNEN	3.4	2.0	4.7	[30]
	II	107 (83 GEP)	WD NETs	3.7	4.1	24.2	[31]
Toripalimab	Ib	40 (23 GI, 9 pancreas)	GI-NEN	13.0	2.5	7.8	[32]
			pNEN	22.0			
Nivolumab	II	185 (93 GEP)	GEP-NEC	7.0	1.8	7.2	[33]
Spartalizumab	II	95 NETs (32 GI, 33 pancreas); 21 GEP-NECs	GI NET	3.1	3.8	Not estimable	[34]
			pNET	3.0			
			GEP-NEC	4.8	1.8	6.8	
Avelumab	II	27 (21 GEP)	GEP-NET	--	3.3	14.2	[35]
Nivolumab + Ipilimumab	--	34 (21 from digestive organs)	NENs	14.7	1.0	5.0 (from treatment initial); 14.0 (from diagnosis)	[36]
	II	32 (15 GI)	Non-pNETs	25.0	4.0	11.0	[37]
	II	19 (9 from digestive organs)	High-grade NENs	26.0	2.0	8.7	[38]
	II	185 (93 GEP)	GEP-NEC	14.9	1.9	5.8	[33]
	--	11	Metastatic EP-NEC (mainly of GEP origin)	--	8.5	Not reached	[39]
Durvalumab + Tremelimumab	II	123 (31 GI, 32 pancreas, 33 GEP)	G1/G2 GI-NETs	0	5.8	29.5	[40,41]
			G1/G2 pNETs	6.3	5.5	23.8	
			G3 GEP-NENs	9.1	2.4	5.9	
Atezolizumab + Bevacizumab	II	40 (20 pNET, 20 non-pNET)	pNET	20.0	19.6	30.1	[44,45]
			Non-pNET	15.0	14.9	Not reached	
Pembrolizumab + Lenvatinib	II	20 (10 GI)	GI-NEN	10.0	10.0	--	[46]
Pembrolizumab + Irinoteca/Paclitaxel	II	22 (16 GI)	GI-NEC	9.0	2.0	4.0	[47]
Nivolumab + Tezolomide	II	15 (12 evaluable and 7 GEP)	GEP-NET	25.0	--	--	[48]
Nivolumab + Cisplatin/Carboplatin	II	38 (31 GEP)	G3 NENs	54.1	5.7	13.9	[49,50]

WD: Well-differentiated; NET: Neuroendocrine tumor; NEN: Neuroendocrine neoplasm; NEC: Neuroendocrine carcinoma; GEP: Gastroenteropancreatic; SCLC: Small cell lung cancer; MCC: Merkel cell carcinoma; pNET: Pancreas NET; ORR: Objective response rate; mOS: Median overall survival; mPFS: Median progression-free survival; EP-NEC: Extrapulmonary neuroendocrine carcinoma.

multicenter phase Ib clinical trial investigating toripalimab for metastatic or recrudescent NENs where standard therapies had failed, 40 patients were enrolled. Of these, for ex-pancreatic GI-derived, pancreatic, and nondigestive NENs, the ORRs were 13.0% (3/23), 22.2% (2/9), and 37.5% (3/8), respectively[32].

The effectiveness of ICI monotherapy in treating NECs has also been proven in a number of clinical trials. In a phase II trial involving 185 patients with NECs (93 were GEP) and randomly assigned (1:1) to receive nivolumab monotherapy or nivolumab combined with ipilimumab. In the monotherapy group, the ORR at 8 wk, mPFS, and mOS were 7.2% (95%CI: 2.7-15.1), 1.8 mo (95%CI: 1.7-2.0), and 7.2 mo (95%CI: 3.7-14.1), respectively. However, these results indicated that the therapeutic effect was not ideal[33]. Spartalizumab, another anti-PD-1 agent, was evaluated in a clinical trial involving 21 patients with poorly differentiated GEP-NECs and 95 patients with metastatic G1 or G2 NETs (32 GI and 33 pancreatic), all of whom had received prior treatments for their advanced diseases. The ORR in the GI NET, pNET, and GEP-NEC groups was 3.1% (95%CI: 0.1-16.2), 3.0% (95%CI: 0.1-15.8), and 4.8% (95%CI: 0.1-23.8), respectively. In the NET cohort, the mPFS, 12-mo PFS, and OS rates were 3.8 mo, 19.5% (95%CI: 11.6-28.9), and 73.5% (95%CI: 63.0-81.4) respectively. For the GEP-NEC cohort, the respective values were 1.8 mo, 0%, and 19.1% (95%CI: 4.8-40.6)[34]. Although the efficacy of spartal-

izumab for digestive NEN treatment is limited and not worthy of further investigation, its AEs are mild and manageable. Fatigue (29.5%) and nausea (10.5%) were the most frequently reported spartalizumab-related AEs that emerged during the trial of the NET cohort; they were mainly distributed in the grade 1/2, while elevated aspartate/alanine aminotransferase levels (14.3% each) were common in the GEP NEC group[34]. Other trials, however, reported contrary conclusions regarding the use of ICI monotherapy. Two trials of avelumab monotherapy, which enrolled 27 patients in total, had 21 GEP-NET, with none achieving OR but only 33% obtaining SD. AEs related to avelumab were observed in 58% of patients, including grade 3-4 AEs in 3 cases, leading directly to trial termination[35].

The aforementioned ICI monotherapy regimens have indicated mild anti-tumor activity with neither NET nor NEN of the digestive system. Nonetheless, the AEs were manageable, which made them relatively safe and applicable under most conditions. It is speculated that the severity of adverse reactions may be correlated with the efficacy. In pembrolizumab treatment, for instance, only 21.5% of treatment-related adverse reactions occurred at grade ≥ 3, while the frequent adverse reactions were malaise (22.4%) and diarrhea (13.1%)[31]. Therefore, combination therapies to improve the efficacy of ICIs against NENs in the digestive system have emerged as a major research direction.

COMBINED IMMUNOTHERAPY FOR NENS OF THE DIGESTIVE SYSTEM

Dual ICI therapy

Cytotoxic T lymphocyte-associated antigen-4 (CTLA-4) antibody, another type of ICI, have mechanisms of action complementary to those of PD-1 and PD-L1 antibodies. The binding of CTLA-4 and CTLA-4 antibodies to the surface of activated T cells indirectly promotes the activation and proliferation of T cell development by relieving the inhibitory effect of antigen-presenting cells on T cells. One preliminary retrospective evaluation for the treatment with ipilimumab plus nivolumab reported ORR, DCR, and mPFS of 15%, 41.2%, and one month (95%CI: 0.54-1.46 mo), respectively, in 34 patients with G3 NENs (79% NEC and 21 from digestive organs) who had previously undergone at least one cytotoxic chemotherapy regimen and, on average, two prior lines of treatment[36]. These findings suggest that dual ICI therapy has therapeutic effects on aggressive NECs that progress after chemotherapy, as well as in heavily pre-treated NENs. The S1609DART trial established the combination of ipilimumab and nivolumab as an option for extrapulmonary poorly differentiated (LCNEC/SCNEC) or unknown primary tumors. Results of the trial revealed that the ORR of 32 cases was 25% (95%CI: 13%-64%), and the median overall survival (mOS) was 11 mo. The ORR was 44% for non-pancreatic (non-p) high-grade NECs (8/18, CR = 1, PR = 7), including lung primaries[37]. Furthermore, in the following research on high-grade NENs, 19 patients were involved, of which 11% (each) were from the pancreas, gastroesophageal junction, and rectum. The ORR of this cohort was 26% (95%CI: 11-45%), the DCR was 32% (95%CI: 13%-57%), and the 6-month PFS was 32% (95%CI: 16%-61%); however, durable control was observed in patients with long-term diseases[38]. Based on the existing outcomes, Mohamed *et al*[39] conducted a retrospective study of 70 metastatic EP-NEC cases, mostly derived from GEP, of which 11 received Nivolumab in combination with Ipilimumab. The PFS (56.5 d, 47 d, and 258 d) and OS (not reached, 18.7 mo and 10.5 mo) were compared among patients treated with ICI monotherapy (8 patients), cytotoxic agents (23 patients) and dual ICI therapy. Thus, dual ICI therapy did show some improvement in high-grade NENs, in line with previous findings.

However, not all dual ICI therapies elicit a significant response or treatment effect. The final results from a prospective Phase II study of durvalumab plus tremelimumab in 123 patients with NENs who experienced disease progression and failure to respond to standard therapy administration were presented at the ENETS Annual Conference 2022. The cases were divided into four cohorts based on grading and primary sites: 27 patients with typical/atypical lung carcinoids for Cohort 1 (C1), 31 patients with G1/G2 GI-NETs for C2, 32 patients with G1/G2 pNETs for C3, and 33 patients with G3 GEP-NENs (91% NECs) for C4. The ORRs for the last three cohorts were 0%, 6.3%, and 9.1%, respectively, and the mPFSs were 5.8, 5.5, and 2.4 mo, in the same order. The median OSs were 29.5 mo, 23.8 mo, and 5.9 mo, respectively[40]. The 9-month DCRs for these cases were 22.8% (95%CI: 16.0-30.8), and 35.5% (95%CI: 20.5-53.0), 25% (95%CI: 12.6-41.7), and 6.1% (95%CI: 1.3-18.1) for C2 to C4, respectively[41]. Therefore, this study showed that the therapeutic effectiveness of dual ICI therapy in well-differentiated NENs was limited after the failure of standard treatment and had a relatively lower ORR. Only G3 GEP-NEN or NEC cases showed a modest survival benefit. In the NIPI-NEC phase II trial, 185 patients with platinum-refractory disease, including 93 patients with GEP-NEC, were enrolled. They were randomly assigned to receive nivolumab monotherapy or nivolumab plus ipilimumab, with ORR at eight weeks as the primary outcome measure. The cohort of nivolumab combined with ipilimumab in the trial demonstrated a prominent ORR of 14.9% (95%CI: 8.2-24.2) when compared to the nivolumab single-agent cohort of 7.2% (95%CI: 2.7-15.1); however, PFS was 1.9 mo (95%CI: 1.6-2.1) *vs* 1.8 mo (95%CI: 1.7-2.0), OS was 5.8 (95%CI: 3.3-7.6) *vs* 7.2 mo (95%CI: 3.7-14.1)[33]. Thus, most patients with NECs are not eligible for ICIs monotherapy, and the anti-tumor activity of dual ICIs therapy for both NETs and NECs needs further validation.

ICI combined with targeted anti-angiogenesis

Patients with refractory tumors or those who are chemo-intolerant have a high-quality option to de-chemotherapy in the form of ICIs combined with anti-angiogenic medications. Basic research has demonstrated a synergistic impact between ICIs and anti-angiogenic medications, encouraging angiogenesis in healthy tissues and boosting anti-tumor immunity [42]. Besides, anti-angiogenic targeted medications not only prevent angiogenesis in tumor tissue but also support the efficacy of ICIs by relieving the negative regulatory process of vascular endothelial growth factor (VEGF) in the immune microenvironment. They also influence lymphocyte and macrophage infiltration into tumor tissue, thereby alleviating the suppression of the tumor immune system[43].

Daniel and colleagues examined atezolizumab with bevacizumab combination therapy in G1/G2 pNET and non-pNET patients who had progressed under any previous therapy. Preliminary results showed that ORR, mPFS, and 1-year PFS of the two cohorts with 20 patients each were 20% (95%CI: 6%-44%) and 15% (95%CI: 3%-38%), and 19.6 mo (95%CI: 10.6-NR), and 14.9 mo (95%CI: 6.1-NR), 75% and 52%, respectively. These findings manifested that pNET patients might benefit more from this drug application regimen than non-pNET patients[44]. More recently, the MD Anderson Cancer Center released the final trial results showing that the ORR of the two groups remained consistent with the previous data; however, the PFS of the pNET and the non-pNET group descended to 14.9 mo (95%CI: 4.4-32.0) and 14.2 mo (95%CI: 10.2-19.6), respectively[45].

Al-Toubah *et al*[46] tested an alternative regimen, involving pembrolizumab plus lenvatinib, with efficacy in 20 patients with well-differentiated GI or thoracic NETs (including 9 of the small intestine, and 1 of cecal), and the response rate of the treatment was unsatisfactory. Among them, only one NET presented with PR, and the mPFS was 10 mo (95%CI: 5.9-14.1) in the small intestine, and the adverse effect rate was also high. Potentially related or related grade 3 AEs, were experienced by 12 patients, 14 patients required dose reduction or discontinuation of one of the drugs. Consequently, further research into this regimen was not deserved since it did not demonstrate substantial effectiveness for GI-NET. Therefore, it may be more worthwhile to delve into the safety and beneficial effects of ICIs paired with anti-angiogenesis in NECs from the digestive organs.

ICI combined with chemotherapy

Immunotherapy paired with chemotherapy has been successfully applied in the treatment of non-small cell lung cancer, gastric cancer, and esophageal cancer due to their synergistic mechanisms. Moreover, to expand the scope of application, some clinical study outcomes on the application of this sort of regimen in the NEN of the digestive system have been published.

The result of a phase II trial reported by Chan *et al*[47] revealed an unsatisfactory treatment response rate. The trial included twenty-two patients with extrapulmonary poorly differentiated NECs who had experienced disease progression after prior first-line therapy. These patients participated in a clinical trial investigating the combination of pembrolizumab and chemotherapy combination (16 of these patients had a primary GI site), 17 (77%) were treated with irinotecan, and 5 (23%) were treated with paclitaxel. The ORR was 9% among the patients, PR was achieved only in 2 cases, SD in 14% of cases, and PD in 60%. As inferred from the results, after biomarker selection, combination therapy with pembrolizumab and chemotherapy may improve treatment efficacy in cases of poorly differentiated GI-NEC.

In another phaseIIclinical study, twelve of the fifteen patients with advanced NET who were enrolled in and treated with nivolumab and temozolomide could be assessed for their response to this treatment, with the major locations being six small bowels, one pancreas, and five bronchial tubes[48]. According to the interim efficacy results, 25% of patients (3/12) had the best response of PR, 67% of patients (8/12) had SD, and one patient (8%) had PD.

The NICE-NEC study, which included 38 patients with advanced or irresectable gastroenteritis or G3 NENs of unknown origin, was the first to assess the efficacy of first-line chemotherapy plus ICIs in G3 NENs. Of these patients, 81.6% were GEP-NENs, and 68% were NECs, that received nivolumab combined with cisplatin or carboplatin[49]. The latest results, presented at the ESMO Congress 2022, confirmed the combinations had relatively promising therapeutic action, with an ORR and mPFS of survivors of 54.1% and 5.7 mo (95%CI: 5.1-9 mo), respectively[50]. Preliminary findings suggest that adding nivolumab to chemotherapy for G3 NENs has conceivable effectiveness without noticeably raising the toxicity profile of preferred standard chemotherapy.

Naturally, in certain rare circumstances, the combined effects of immunotherapy and chemotherapy may be therapeutically productive for some patients with terminal NECs, or those who have failed to respond to initial therapies. Chorath *et al*[51] reported a female case with metastatic high-grade NEC of the gallbladder who received immunochemotherapy treatment. A substantial decrease in liver metastases was observed following six cycles of comprehensive treatment with etoposide, carboplatin, nivolumab, and ipilimumab with a sustained response. However, further investigation is needed to comprehend the specific mechanisms and biomarkers that predict treatment efficacy. This survival benefit occurred in the absence of known predictive biomarkers to immunotherapy (PD-L1 status, mismatch repair status, and TMB).

Contrary to conventional perception, chemotherapy drugs can induce immunogenic tumor cells to undergo apoptosis, which mobilizes antigen-presenting cells and primes tumor-specific immune responses[52]. This fundamental principle underlies the previously described synergistic impact and the advantages of chemotherapy paired with ICIs in the application of NEN from the digestive system.

Table 2 provides an overview of ongoing clinical trials, which can be tracked to obtain the latest research progress of immunotherapies in NENs of the digestive systems.

BIOMARKERS FOR PREDICTING IMMUNOTHERAPY RESPONSE

MSI/dMMR, TMB, and PD-L1 expression are key biomarkers used to judge the potential benefit of ICIs for patients. Among these, MSI-H/dMMR, and TMB-H are independent adverse prognostic indicators[53]. However, the incidence of MSI-H/dMMR in NENs is relatively low, reported to be present in only 8 out of 152 GEP-NECs (5.3%) and only 1 in 29 G3 NETs (3.4%)[54]. TMB is the ratio of non-synonymous mutations in somatic cells per megabase pair of a certain genomic region. Although TMB is linked to the prognostic status of patients after ICIs therapy for the majority of malignancies, the selection of detecting genes will directly impact the TMB calculation's outcomes[55]. It is unlikely that there is an exact universal value that defines TMB-H in a way that can predict the benefit of ICI in all types of cancer[56]. In a number of published trials, PD-L1 positive patients treated with ICIs had a higher ORR than PD-L1 negative patients,

Table 2 Ongoing clinical trials related to immune checkpoint inhibitors in neuroendocrine neoplasms of the digestive system

Indentifier of Clinical Trails	Intervention	Study phase	Primary outcome measures	Estimated or actual enrollment	Trial status	Estimated study completion date	Condition related to NENs of the digestive system
NCT04079712	Nivolumab + Ipilimumab + Cabozantinib	II	overall response rate	30	Active, not recruiting	October 2023	NECs: Excluding SCLC and MCC
NCT03980925	Nivolumab + Platinum-doublet chemotherapy	II	OS at 12 mo	38	Active, not recruiting	December 2023	G3 NENs: GEP or unknown primary site
NCT04197310	Cabozantinib + Nivolumab	II	ORR	35	Active, not recruiting	December 2023	WD-NET: Non-pancreatic (*i.e.*, carcinoid) origin
NCT03290079	Pembrolizumab + Lenvatinib	II	ORR	28	Active, not recruiting	January 2024	NETs: WD small bowel or colon origin, including unknown primary, excluding pNENs
NCT04400474	Cabozantinib + Atezolizumab	II	ORR	93	Active, not recruiting	March 2024	WD G1/2 NET: Digestive system; G3 NEN: Excluding SCLC
NCT04579757	Surufatinib + Tislelizumab	Ib/II	DLT, ORR	135	Active, not recruiting	June 2024	G1/2 NETs: Thoracic or GEP origins
NCT04525638	Nivolumab + 177Lu-DOTATATE	II	overall response rate	30	Recruiting	September 2024	G3 NET or NEC of GEP, lung, and unknown primary site
NCT05058651	Atezolizumab + Platinum drug (cisplatin or carboplatin) + Etoposide	II/III	OS	189	Recruiting	October 2024	NEC: Extrapulmonary
NCT05113355	Chidamide + Sintilimab	II	ORR	23	Recruiting	November 2024	High-grade NEN, advanced and metastatic
NCT04969887	Nivolumab + Ipilimumab	II	CBR, 6 mo PFS	240	Recruiting	December 2024	NECs and G3 NETs: Independent of primary site, excluding SCLC
NCT04701307	Dostarlimab + Niraparib	II	6 mo PFS, 3 mo ORR	48	Active, not recruiting	May 2025	NECs: Excluding prostate origin
NCT03475953	Avelumab + Regorafenib	I/II	Phase I: Recommended dose of regorafenib; Phase II (cohort G): CR or PR	747 (only cohort G consists of GEP-NETs)	Recruiting	December 2025	G2/3 GEP-NETs
NCT05746208	Lenvatinib + Pembrolizumab	II	ORR	29	Not yet recruiting	July 2027	WD G3 NET: GIsite and pancreas primary
NCT05289856	Avelumab + Cabozantinib	II	DCR, CR, PR, SD	30	Recruiting	December 2025	G3 NET: Excluding MCC and SCLC
NCT05627427	Surufatinib + Sintilimab	II	PFS	60	Recruiting	December 2024	G3 NET and NEC: Metastatic and advanced
NCT05262556	NP-101 (TQ Formula) + Nivolumab + Ipilimumab	I	CR, PR, SD	10	Recruiting	December 2024	GEP-NET, GEP-NEC: Poorly differentiated

CR: Complete response; CBR: Clinical benefit rate; DCR: Disease control rate; DLT: Dose-limiting toxicity; ORR: Objective response rate; OS: Overall survival; PFS: Progression-free survival; PR: Partial response; WD: Well differentiated; NET: Neuroendocrine tumor; NEN: Neuroendocrine neoplasm; NEC: Neuroendocrine carcinoma; GEP: Gastroenteropancreatic; SCLC: Small cell lung cancer; MCC: Merkel cell carcinoma; pNET: Pancreas NET; GI: gastrointestinal; G1, 2, 3: Grade 1, 2, 3.

which indicated that PD-L1 expression may be relevant to the efficacy of immunotherapy[45]. However, PD-L1 expression appears quite heterogeneous across different studies[57], even though some studies revealed no relevance between the effectiveness of ICIs and PD-L1 expression[30,31,40]. Reasons for these results may be subject to limitations due to factors such as different methods of analysis, defined cutoffs, and the freshness of biopsy tissue obtained[58]. Therefore, based on identifying the expression of PD-L1, investigate the content of other predictive biomarkers to provide patients with the best immunotherapy prediction possible.

In recent years, somatic mutation analysis of NETs has emerged as a novel approach for identification and prediction. Unlike conventional monoanalytic biomarker testing, mRNA-based liquid biopsy is a non-invasive genetic testing method. The NET transcriptome signature (NETest), a pre-spotted PCR plate that targets 51 genes, measures the amount of tumor-derived mRNA extracted from a patient's blood using PCR[59]. Compared to CGA, the diagnostic accuracy of GEP-NENs with NETest is significantly better (99% *vs* 21%-36%), and it also has good sensitivity and specificity for evaluating the course and prognosis of NENs[60]. However, despite these advancements, the gold standard for NETest has not been established in clinical practice preventing its use as a routine test for NEN and limiting its ability to completely replace biopsy procedures.

Future research should prioritize the integration of data on the circulating tumor DNA, T-cell regulatory factors, and other characteristics of NEN patients who will receive immunotherapy. By employing multidimensional and dynamic combinations of biomarkers, researchers can enhance the predictive effect and fully elucidate the potential causes of patients' poor responses to ICIs.

DISCUSSION

It is necessary for the body to trigger an appropriate anti-tumor immune response through the infiltration of immune cells into the tumor immune microenvironment (TIME). The strength of individual anti-tumor immunity depends significantly on the quantity and variety of T cells[61]. As a result, there is now broad acceptance that effector T cell plays an irreplaceable role in the anti-tumor response[62].

Malignancies that exhibit significant tumor-infiltrating lymphocyte (TIL) infiltration, high PD-L1 expression, potential genetic susceptibility, and the existence of an active anti-tumor immune response, often known as the hallmarks of "hot tumors," are more receptive to immunotherapy[63]. Although recent outcomes of clinical trials suggest that the efficacy of ICIs for NEN of the digestive system fell short of expectations, considerable TIL infiltration has been observed in various NECs, including pNECs[64]. Moreover, the likelihood that NEN will match the TIME of hot tumors increases with NEN grade. In a study of 244 patients with GEP-NEN, the G3 NEN cohort contained considerably more patients with high TILs infiltration than the G1/G2 NEN group (50% *vs* 17.1%)[65]. PD-L1-expressing GEP-NEC more frequently exhibited T cell exhaustion and an abundance of regulatory T cells than did G3-NET[66], indicating that poorly differentiated NECs are more prone to benefit from immunotherapies, particularly ICIs. Additionally, there was heterogeneity in the TIME of the primary sites of NENs. For instance, in comparison to NETs from the jejunum and ileum, the duodenum NETs had a more positive detection rate of PD-1 and immune infiltration[67]; and compared to NETs of extra-pancreatic origin, pNETs had higher expression levels of PD-1 and PD-L1, as well as more TILs[65]. At the same primary site, PD-L1 expression varies across multiple NET subtypes as well, with prior research demonstrating that the metastasis-like primary (MLP)-1 subtype expresses PD-L1 at the highest levels in pNET[68]. This illustrates the need for further research into the variations in the immune microenvironments of distinct differentiated primary sites and subtypes of NEN, which may guide the therapeutic application of ICIs and assist in selecting the best immunotherapy regimens for patients during clinical trials.In addition, probing into the processes which transform NEN with modest levels of TIL infiltration and PD-L1 expression into immunologically "hot" tumors could potentially serve as a research avenue to enhance the therapeutic effectiveness of ICIs. So far, several mechanisms have been implicated in altering the low immune state of "cold" tumors, for example, stimulating T cell priming (*e.g.*, injection of Neoepitope Cancer Vaccine), accelerating T cell expansion (*e.g.*, application of interleukin (IL)-15), and inducing T cell recruitment (*e.g.*, through the use of epigenetic modulators and chemokines), *etc*[69]. Further research is needed to evaluate the feasibility of the above treatments for NEN of the digestive system.

CONCLUSION

Due to the complexity of NENs in the digestive system, the prognosis following the failure of first-line treatment is frequently poor, and the options for subsequent treatment are constrained. ICI monotherapy for the NEN is less effective, has a shorter duration of disease control, and may only be effective in selected patients. Combination therapy may improve the efficacy of ICI treatment in certain cases. Dual immunotherapy has some effect on highly malignant NECs and may be considered after the failure of standard treatment; however, more relevant clinical studies are needed in this field. The combination of ICI and anti-angiogenic drugs has exhibited certain advantages and promising applications for advanced NETs. The combination of ICI and chemotherapy has shown some efficacy for advanced NENs and NECs; however, further studies are required to determine whether it ultimately improves patient outcomes, and how to select the best combination regimen. Additionally, several preclinical studies and clinical trials have investigated the combination of ICIs with other clinical oncology treatment modalities, including pericyte therapy (CAR-T cell therapy), cytokine therapy, oncolytic virus therapy, and cancer vaccines, but experimental data in NEN are lacking. Other strategies to modify the TME of NEN, such as enhancing T-cell homing, preventing T-cell depletion, and preserving

CD8+ T-cell immune response, are also worth investigating in conjunction with ICIs for targeted therapy[70]. TMB-H, PD-L1, and MSI-H/dMMR have been identified as biomarkers for screening patients who may benefit from immunotherapy; however, their overall predictive efficiency is limited. Further research on the immune microenvironment and the search for more predictive immunotherapy markers with higher sensitivity and specificity to guide clinical treatment are urgently needed.

Owing to the rarity of NENs of the digestive organs, most previous and ongoing clinical trials have predominantly used small samples and on small scales approaches, resulting in limited trial results on the subject. Currently, the evidence supporting the use of ICI for NENs of the digestive systems is primarily based on a small number of phase I or II studies and a few case reports. To address this limitation, it is crucial to conduct multi-center, prospective, large-sample clinical trials. Such trials can further validate the conclusions drawn from studies like those discussed here. Additionally, these trials can guide the application of ICI for the treatment of NENs from the digestive system, and provide promising ideas for future research in the field of immunotherapy.

Abstract

BACKGROUND

Radical resection remains an effective strategy for patients with hepatocellular carcinoma (HCC). Unfortunately, the postoperative early recurrence (recurrence within 2 years) rate is still high.

AIM

To develop a radiomics model based on preoperative contrast-enhanced computed tomography (CECT) to evaluate early recurrence in HCC patients with a single tumour.

METHODS

We enrolled a total of 402 HCC patients from two centres who were diagnosed with a single tumour and underwent radical resection. First, the features from the portal venous and arterial phases of CECT were extracted based on the region of interest, and the early recurrence-related radiomics features were selected *via* the least absolute shrinkage and selection operator proportional hazards model (LASSO Cox) to determine radiomics scores for each patient. Then, the clinico-pathologic data were combined to develop a model to predict early recurrence by

Cox regression. Finally, we evaluated the prediction performance of this model by multiple methods.

RESULTS

A total of 1915 radiomics features were extracted from CECT images, and 31 of them were used to determine the radiomics scores, which showed a significant difference between the early recurrence and nonearly recurrence groups. Univariate and multivariate Cox regression analyses showed that radiomics scores and serum alpha-fetoprotein were independent indicators, and they were used to develop a combined model to predict early recurrence. The area under the receiver operating characteristic curve values for the training and validation cohorts were 0.77 and 0.74, respectively, while the C-indices were 0.712 and 0.674, respectively. The calibration curves and decision curve analysis showed satisfactory accuracy and clinical utilities. Kaplan-Meier curves based on recurrence-free survival and overall survival showed significant differences.

CONCLUSION

The preoperative radiomics model was shown to be effective for predicting early recurrence among HCC patients with a single tumour.

Key Words: Hepatocellular carcinoma; Contrast-enhanced computed tomography; Radiomics; Early recurrence

INTRODUCTION

Hepatocellular carcinoma (HCC) is a growing health issue worldwide, ranking sixth in incidence and third in mortality among all cancers[1]. For early-stage HCC patients, liver resection and liver transplantation are considered the main strategies to prolong overall survival (OS)[2,3]. However, the majority of HCC patients are diagnosed at later disease stages, and thus, surgical care is no longer a treatment option for these individuals[4]. Moreover, due to the high malignancy and suppressive immune microenvironment of HCC[5], there remain high recurrence and metastasis rates even for patients who undergo resection. Therefore, it is of vital importance to conduct systematic surveillance of HCC recurrence, and there is an urgent need to precisely predict recurrence in patients with HCC.

Currently, the recurrence rate for postoperative HCC patients is over 50% within 5 years[6], and studies have shown that patients with early recurrence – *i.e.*, recurrence occurring within 2 years – have worse outcomes and poorer prognosis than those with recurrence over 2 years[7]. Typically, the identification of primary and recurrent tumour depends on the detection of genotype, in other words, on the molecular scale[8,9]. However, its complexities have limited the widespread adoption of this method. To evaluate the prognosis of HCC patients, many staging systems have been introduced to clinical use, such as the Barcelona Clinic Liver Cancer (BCLC) staging system and albumin-bilirubin (ALBI) grading[4, 10]. Given that the staging systems above are more suitable for use in evaluating liver function or guiding treatment, there is a lack of an efficient and accurate approach to evaluate recurrence.

Radiomics is an emerging discipline based on medical imaging. Medical imaging, which includes ultrasound (US), computed tomography (CT), and magnetic resonance imaging (MRI), has played a crucial role in the screening and diagnosis of HCC[11]. However, the conventional imaging process relies on the experience and judgement of radiologists and might miss or be hard to quantify some crucial details. Many studies have shown that radiomics features may contain pathophysiological characteristics, which reflect tumour heterogeneity and are associated with patient prognosis [10]. Based on artificial intelligence technology, radiomics has shown certain potential in HCC related gene analysis, microvascular invasion, postoperative survival and recurrence prediction, *etc*[12-16]. However, there are few externally validated reports that studied on the use of radiomics to assess the risk of early recurrence in HCC patients after surgery.

In this study, we aimed to establish a radiomics model to predict early recurrence for patients who underwent radical resection based on contrast-enhanced CT (CECT) and clinical variables, evaluate this model's performance, and verify its feasibility in clinical application.

MATERIALS AND METHODS

Patients

We retrospectively enrolled 537 HCC patients from two institutions (Affiliated Hospital of Guilin Medical University; Peking University People's Hospital) who underwent radical resection. According to the exclusion criteria in Figure 1, 277 patients enrolled from October 2009 to May 2017 at the Affiliated Hospital of Guilin Medical University were set as the training cohort, while 125 patients enrolled from June 2010 to December 2017 at Peking University People's Hospital were set as the validation cohort. Along with the CECT images, information regarding demographic characteristics, clinicopathological data, and laboratory data were also retrospectively collected. Patient demographic characteristics included sex and age, while clinicopathological data were collected from electronic case records, containing tumour size and vascular invasion. Furthermore, laboratory data were collected before surgery, including routine blood test, liver function, and alpha-fetoprotein (AFP) level.

Diagnostic criteria and exclusion criteria

All enrolled patients were diagnosed with HCC by postoperative pathological examination; solitary HCC was confirmed by preoperative CECT and intraoperative palpation or US. In addition to CECT, at least US and MRI supported an HCC diagnosis. Radical resection was defined as complete removal of the tumour with no residual tumour or new lesion observed in two observations at an interval of no less than 4 wk. Two independent pathologists histopathologically examined resected tumour specimens. The main exclusion criteria were as follows: (1) CECT image unavailable; (2) CECT scan over 1 mo before operation; (3) previous treatment including hepatectomy, ablation, or transarterial chemoembolization; and (4) incomplete clinical or follow-up data.

Follow-up surveillance

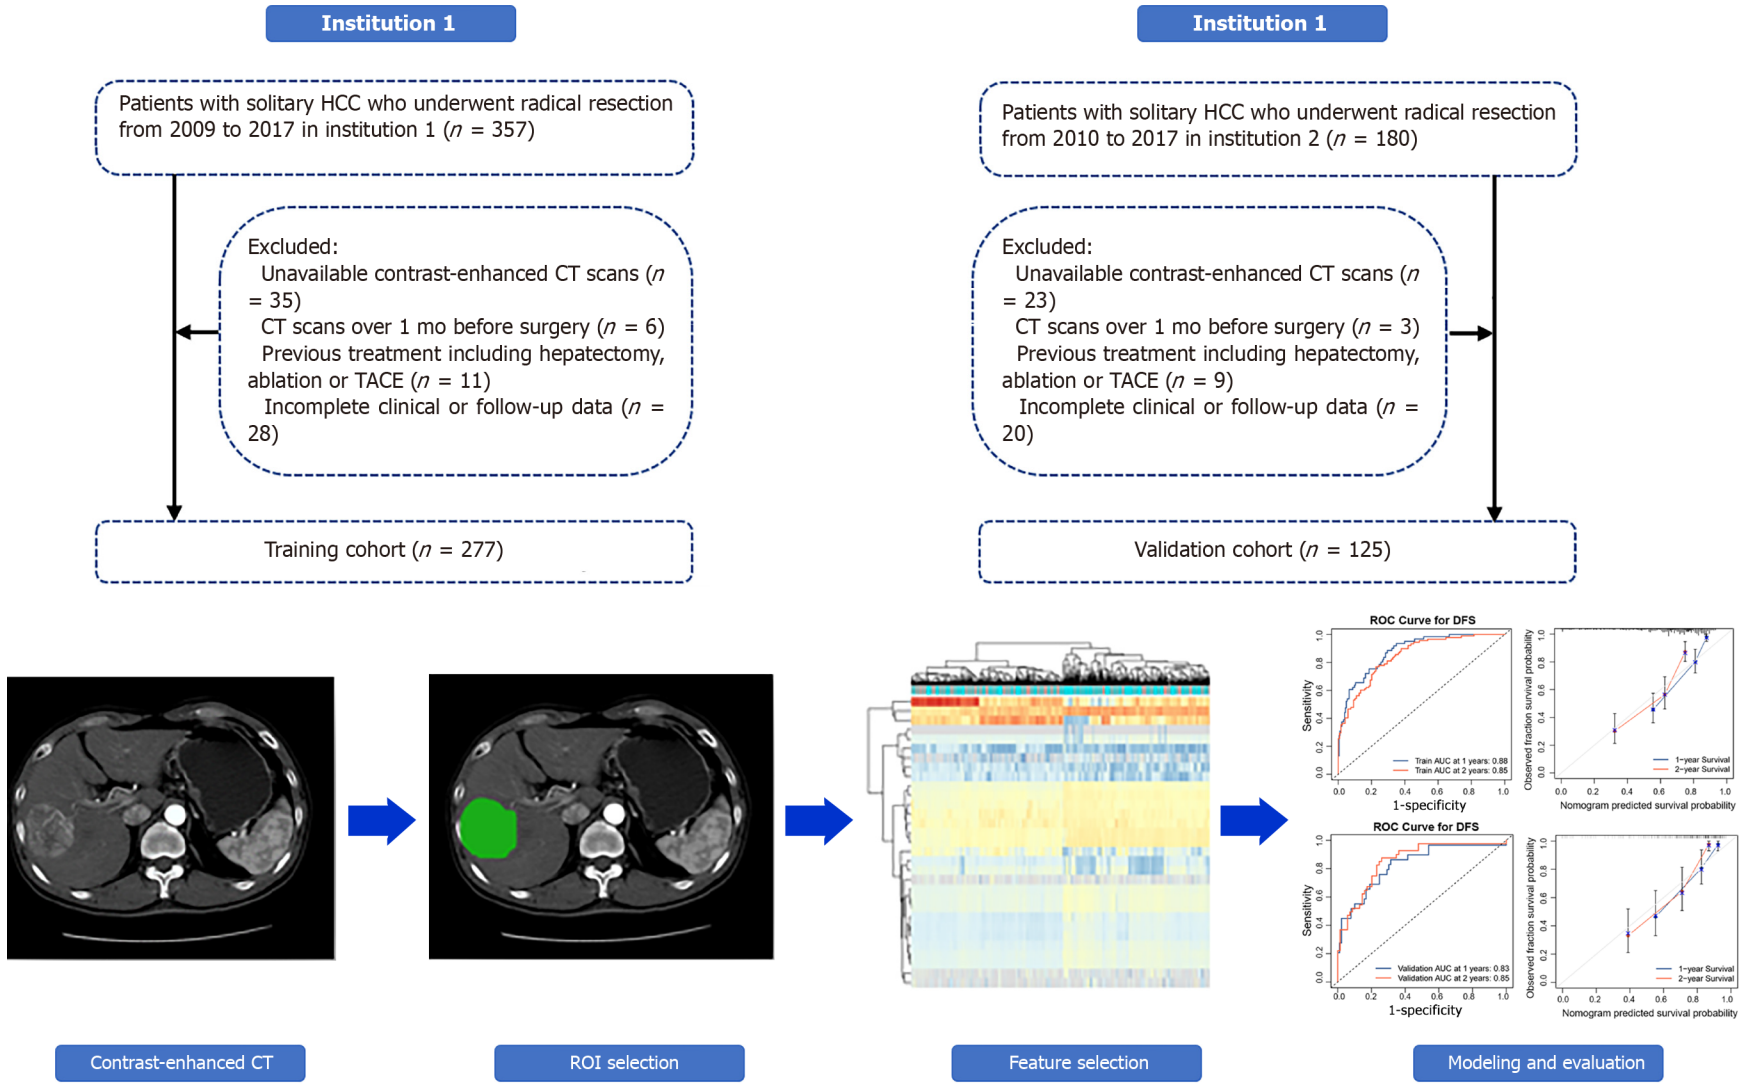
Postoperative surveillance at each institution was conducted according to the protocol. Patients were followed every 2 mo within the first 2 years and every 3-6 mo after 2 years postoperatively (abdominal ultrasonography, serum AFP, and other serological tests were performed). CECT or MRI examination was performed if recurrence was suspected. OS was determined as the interval between the operation date and the date of death or last follow-up. Recurrence-free survival (RFS) was determined from the operation date of radical surgery to the date of the first recurrence at any site, death, or the last follow-up. Recurrence within 2 years after operation was considered as early recurrence.

CT image acquisition

The CECT images were obtained from each institution according to routine procedures, and the usage of contrast medium is described in the Supplementary material.

Region of interest segmentation and radiomics feature extraction

Regions of interest (ROIs) were defined as the tumour areas in both arterial and portal venous phases, which were delineated *via* 3D Slicer (v4.11, https://www.slicer.org) by two experienced radiologists (Reader 1: H.Y. with 10 years of working experience; reader 2: Z.Z. with 20 years of working experience). If they could not reach a consensus, the third radiologist intervened in the evaluation.



To minimize the variability and normalize the CT images, all the images were resampled to a voxel size of 1 mm × 1 mm × 1 mm. Then, the radiomics features were extracted from the ROI segments based on the Pyradiomics package (version 3.0.1). The categories of radiomics features were as follows: First-order statistics, shape-based features (2D and 3D), grey level cooccurrence matrix (GLCM), grey level run length matrix (GLRLM), grey level size zone matrix (GLZM), neighbouring grey tone difference matrix (NGTDM), and grey level dependence matrix (GLDM). LASSO Cox regression was performed to filter and obtain the early recurrence-related radiomics features according to the minimum criteria with 10-fold cross-validation. The radiomics score was determined according to the coefficients.

Modelling and validation

A radiomics and clinical combined model was developed *via* univariate and multivariate analyses, in which the optimal cut-off value of the radiomics score was determined *via* X-tile (Version 3.6.1). The candidate clinical indicators were hepatitis B surface antigen (HBsAg) (positive *vs* negative), cirrhosis (present *vs* absent), microvascular invasion (MVI) (present *vs* absent), serum AFP (> 200 *vs* ≤ 200 ng/mL), tumour size (cm), platelets (× 10^9/L), gamma-glutamyl transpeptidase (GGT) (U/L), and ALBI. The combined model was presented as a nomogram and validated in an independent cohort.

Statistical analysis

Continuous variables that follow a normal distribution are shown as the mean ± SD and were compared by using the Student's *t* test. Otherwise, the Mann-Whitney *U* test was performed. Categorical variables were compared by chi-squared tests. RFS and OS analyses were conducted by using the Kaplan-Meier method and compared by log-rank test among different groups. Time-dependent receiver operating characteristic (ROC) curves were plotted based on the timeROC package. The concordance index (C-index) was determined to evaluate the predictive ability of the combined model. The calibration curves were plotted with the rms package, while decision curve analysis (DCA) was based on the rmda package. SPSS18.0 (SPSS Inc., Chicago, IL, United States) and R (version 4.0.3, https://www.rproject.org/) were used for statistical analyses. $P < 0.05$ was considered statistically significant.

Figure 1 Flowchart of the study cohorts. HCC: Hepatocellular carcinoma; CT: Computed tomography; TACE: Transarterial chemoembolization; ROI: Region of interest.

RESULTS

Patient characteristics

A total of 402 patients who underwent preoperative CECT were enrolled according to the exclusion criteria from two institutions, and the baseline characteristics are illustrated in Table 1. There were no significant differences in the variables evaluated between the two cohorts except aspartate aminotransferase (AST); most patients were male (both 85.60%), with liver cirrhosis (92.06% and 93.60%) and HBV-related HCC (83.75% and 82.40%, respectively). In institution 1, the median follow-up time was 54.2 mo, the median OS time was 40.0 mo, and the early recurrence rate was 36.82% (102 recurred among 277). In institution 2, the median follow-up time was 50.7 mo, the OS time was 37.0 mo, and the early recurrence rate was 32.80% (41 recurred among 125).

Determination of the radiomics score for early recurrence

A total of 1915 CECT-based radiomics features were extracted from images acquired at both the arterial and portal venous phases among 277 patients in institution 1 as the training cohort. To filter early recurrence-related features, LASSO Cox regression was performed, and 31 features were obtained (Supplementary Figure 1). Figure 2 displays the distribution and correlations among these features. Then, a radiomics score was determined according to the coefficients in Supplementary Table 1 for each patient, and the optimal cut-off value was identified as 15.93, based on which the low and high radiomics risk groups were divided accordingly. As shown in Figure 3A, the radiomics scores were significantly different between the early and nonearly recurrence groups, while the area under curve (AUC) value was 0.73 for both institutions (Figure 3B), thus demonstrating the predictive value of the radiomics score for early recurrence HCC.

Development and assessment of the radiomics and clinical combined model

To further improve the predictive performance of the model, univariate and multivariate Cox regression analyses were conducted among the radiomics model and clinicopathologic indicators. The results from univariate analysis (Table 2) illustrated that the radiomics score, MVI, serum AFP, tumour size, and GGT were statistically significant and were included in the multivariate analysis. Multivariate analysis showed that radiomics score [hazard ratio (HR), 3.86; 95%CI: 2.41-6.16; $P < 0.001$] and serum AFP (HR, 1.52; 95%CI: 1.00-2.30; $P = 0.048$) were identified as independent predictive indicators for early HCC recurrence.

Next, a predictive and visible nomogram was developed based on the radiomics and clinical combined model (Figure 4), and the AUC values of the combined model were 0.79 (95%CI: 0.73-0.84) and 0.77 (95%CI: 0.70-0.83) for 1-year and 2-year recurrence prediction in the training cohort (Figure 5A), respectively. The AUC values of the validation cohort were 0.65 (95%CI: 0.58-0.73) and 0.74 (95%CI: 0.63-0.77) for 1-year and 2-year recurrence, respectively (Figure 5B). The C-index was 0.712 and 0.674 in the training and validation cohorts, respectively. Moreover, the calibration curves illustrated good agreement between predictive and observed outcomes (Figure 5C and D), while the DCA showed that the combined model had a relative high net benefit (Figure 5E and F).

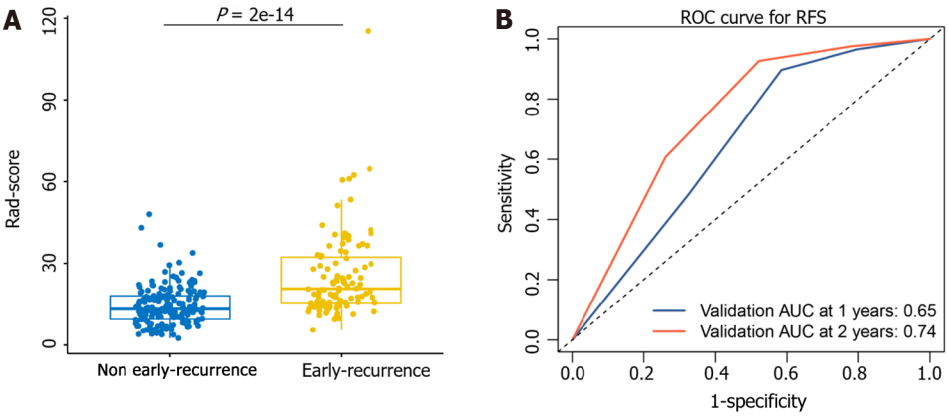
Predictive significance and subgroup analysis of the combined model

To verify the discrimination ability of the combined model, survival curves for RFS and OS were plotted based on the median risk points in the training and validation cohorts. For early recurrence, the high-risk group was more likely to present recurrence than the low-risk group in both the training and validation cohorts (log-rank, $P < 0.0001$ for both) (Figure 6A and C). Furthermore, OS was significantly different (log-rank, $P < 0.0001$ for the training cohort and $P = 0.0446$ for the validation cohort) (Figure 6B and D).

Next, we performed subgroup analysis in AFP-negative (< 20 ng/mL) and AFP-positive (≥ 20 ng/mL) groups. Regardless of the AFP level (Figure 6E-H), the model calculated points were closely related to early recurrence and OS (log-rank, $P < 0.0001$ for all). The results above illustrated the discrimination ability of the combined model.

Representative case reports

Two representative case reports were displayed to demonstrate the distinguishing ability for similar cases (Figure 7). Both of them were male with BCLC A stage HCC and similar ages, and the ROI, also known as the tumour area, was similar in tumour size and position. MVI was present in AFP-negative case 1, while MVI was absent in AFP-positive case 2. However, their outcomes were different. Case 1 was both low risk at the radiomics score and model prediction point and without recurrence until the last follow-up. Case 2 was high risk with worse outcomes, and recurrence was present at 14 mo after the operation. Thus, we concluded that the radiomics combined model could support to distinguish similar cases using CECT in clinical practice.



DISCUSSION

Due to the lack of indicators to predict early recurrence for patients who underwent radical resection, we determined a radiomics score based on preoperative CECT for patients from two independent centres, which was shown to be closely related to the occurrence of early recurrence. Next, serum AFP was included to establish a radiomics and clinical combined model, which elevated the accuracy of the model. The AUC values for the two cohorts were 0.77 and 0.74, respectively, and our findings supported that radiomics is able to be adopted to evaluate the RFS of HCC patients and might support preoperative risk stratification and postoperative surveillance management. Previous studies have

illustrated the usage of radiomics in predicting recurrence of HCC[15,16], but few studies focused on early recurrence and conducted external validation, in which early recurrence was defined as recurrence occurring within 2 years. Furthermore, the model divided the HCC patients into two risk subgroups with a favourable distinction of recurrence and a significant difference in OS. AFP-negative subgroup analysis was also performed to evaluate the reliability of the model.

The heterogeneity in primary and recurrent HCC is quite different. Typically, the gene profile and microenvironments are supposed to be able to distinguish them[8,9]. Villanueva *et al*[17] developed a composite prognostic model for HCC recurrence based on gene expression in tumour tissues. However, the majority of recurrent HCC cases occur within 2 years after surgery, which is regarded as real recurrence. Many studies have indicated that patients with early recurrence have worse outcomes than those with late recurrence[18]. Hence, it is of vital significance to monitor early recurrence in

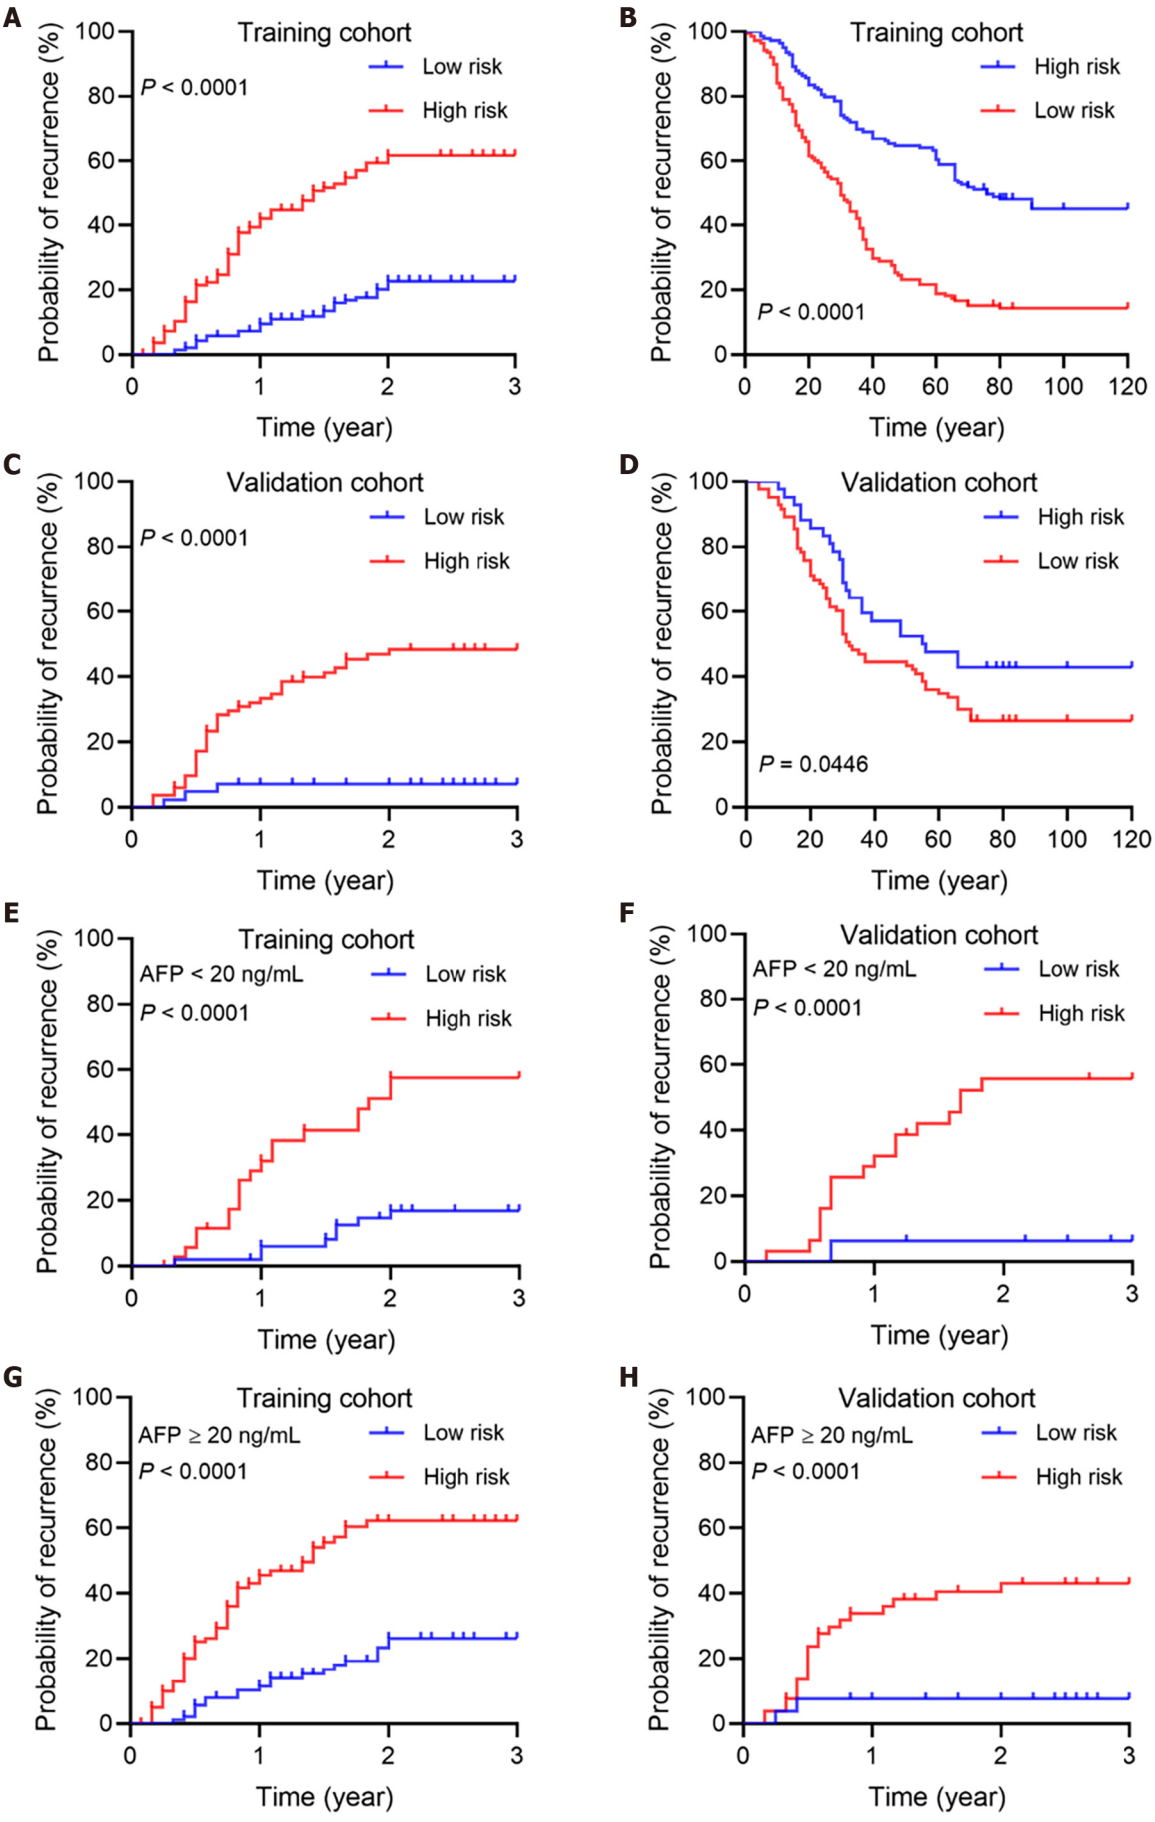
Figure 4 A radiomics and clinical combined model is built based on the radiomics score and preoperative alpha-fetoprotein. According to the total score of each indicator, the recurrence rate corresponding to the total score is the nomogram-predicted rate. AFP: Alpha-fetoprotein; RFS: Recurrence-free survival.

clinical practice. Increasing evidence has illustrated that the immune microenvironment plays a crucial role in the early recurrence of HCC. Sun *et al*[19] revealed the unique characteristics of early relapse HCC at single-cell resolution. Additionally, metabolic microenvironments, such as lipogenesis and glycolysis, might promote oncogenic transformation [20-23]. The mechanism above reveals the complexity of recurrent HCC. Many staging systems have been applied in the diagnosis and treatment of HCC, including the AJCC TNM staging system and the BCLC and Child-Pugh staging systems. Nevertheless, none of them are capable of predicting recurrence. Serum AFP level has long been used as an indicator to predict recurrence in both hepatectomy and liver transplantation[24,25], which showed effect in our model, as well.



Preoperative imaging plays a very important role in the effective diagnosis and treatment of HCC, and CECT is part of this process. For BCLC stages A and B patients, liver resection is considered the main treatment strategy. However, the postoperative recurrence rate is extremely high. Hence, we employed radiomics to explore more details from CECT images. In this study, radiomics scores were determined based on the 31 features. There were 16 features extracted from images in the arterial phase and 15 features from images in the portal venous phase, which was consistent with the

diagnosis of HCC depending on the dynamic changes in vascular findings from the arterial phase to portal venous phase [26-29]. Consistently, among these features, most of them were based on wavelet filtered features that accounted for the greatest weight, which coincided with the previous studies[15], and might represent tumour heterogeneity of HCC and peritumoral tissues that were hard to explain and easy to be ignored by the radiologist. The potential use of radiomics has been widely reported. Hence, we combined radiomics and serum indicators to evaluate the risk of early recurrence, which was validated in an independent cohort. Our findings showed favourable value in predicting early recurrence for patients with HCC *via* non-invasive indicators and might guide clinical decisions.

Figure 7 Representative case reports. AFP: Alpha-fetoprotein; BCLC: Barcelona Clinic Liver Cancer; CECT: Contrast-enhanced computed tomography; MVI: Microvascular invasion; ROI: Regions of interest.

There were several limitations in our study. First, because this was a retrospective analysis, inherent biases were inevitable. Second, even though the radiomics features were extracted *via* a standard process, the features might differ and be critically dependent across CT machines and centres. Third, with the development of multimodality radiomics, Gd-EOB-DTPA-enhanced MR or 18F-FDG PET/CT has been widely used and have more favourable discrimination in adipose tissue and tumour capsules[30,31]. Therefore, we should conduct prospective trials with multimodality radiomics to confirm our results.

CONCLUSION

In summary, the radiomics scores calculated herein revealed significant differences between early and nonearly recurrence HCC patients. Then, we integrated the scores with serum AFP to develop a radiomics and clinical combined model that showed advantages and might serve as a powerful tool to predict early recurrence of HCC. We will perform further validation and translate the results into clinical application.

ARTICLE HIGHLIGHTS

Research background

Hepatocellular carcinoma (HCC) seriously endangers human life and health, but there is still a lack of satisfactory treatment options. Even if it is diagnosed at early stage, the recurrence rate is still very high. The clinical monitoring strategy for HCC recurrence is limited, so there is a need to find a new and effective recurrence prediction model for HCC. And we developed a radiomics model based on preoperative contrast-enhanced computed tomography (CECT) to evaluate early recurrence in patients with a single tumour.

Research motivation

Due to the high malignancy and suppressive immune microenvironment of HCC, there are still high recurrence and metastasis rates even in HCC patients who have undergone radical resection. Therefore, it is of vital importance to conduct systematic surveillance of HCC recurrence, and there is an urgent need to precisely predict recurrence in patients with HCC. If tumour recurrence can be detected earlier, the survival and quality of life of HCC patients might be greatly improved.

Research objectives

Despite the rapid development in the treatment of HCC in recent decades, patients' outcomes remain unsatisfactory. One of the reasons is that the early diagnosis system of HCC recurrence is not yet well developed, so our research team established a recurrence prediction model for HCC based on medical imaging such as computed tomography (CT) to predict HCC recurrence earlier, so that timely treatment measures can be taken.

Research methods

We collected CT images from 537 clinical patients in two institutions and extracted valuable CT image features with 3D Slicer (v4.11, https://www.slicer.org). SPSS18.0 (SPSS Inc., Chicago, IL, United States) and R (version 4.0.3, https://www.rproject.org/) were used for statistical analyses and the prediction model of HCC recurrence was established jointly with AFP.

Research results

The radiomics scores calculated herein revealed significant differences between early and nonearly recurrence HCC patients. We combined radiomics and serum indicators to evaluate the risk of early recurrence, which was validated in an independent cohort. Our findings showed the value of predicting early recurrence in HCC patients by noninvasive indicators and might guide clinical decisions making. However, this is a retrospective analysis, and inherent biases are inevitable. We would conduct prospective trials with multimodality radiomics to confirm our results in future.

Research conclusions

The preoperative radiomics model was shown to be effective for predicting early recurrence among patients with single HCC. Compared with pathological biopsy or other tests, this model is noninvasive and more convenient for HCC patients.

Research perspectives

For HCC diagnosis, treatment, or prognosis assessment, more non-invasive methods are of great significance and needed.

Abstract

BACKGROUND

Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors of the gastrointestinal tract. Tyrosine kinase inhibitors, such as imatinib, have been used as first-line therapy for the treatment of GISTs. Although these drugs have achieved considerable efficacy in some patients, reports of resistance and recurrence have emerged. Extracellular signal-regulated kinase 1/2 (ERK1/2) protein, as a member of the mitogen-activated protein kinase (MAPK) family, is a core molecule of this signaling pathway. Nowadays, research reports on the important clinical and prognostic value of phosphorylated-ERK (P-ERK) and phosphorylated-MAPK/ERK kinase (P-MEK) proteins closely related to raf kinase inhibitor protein (RKIP) have gradually emerged in digestive tract tumors such as gastric cancer, colon cancer, and pancreatic cancer. However, literature on the expression of these downstream proteins combined with RKIP in GIST is scarce. This study will focus on this aspect and search for answers to the problem.

AIM

To detect the expression of RKIP, P-ERK, and P-MEK protein in GIST and to analyze their relationship with clinicopathological characteristics and prognosis of this disease. Try to establish a new prognosis evaluation model using RKIP and P-ERK in combination with analysis and its prognosis evaluation efficacy.

METHODS

The research object of our experiment was 66 pathologically diagnosed GIST patients with complete clinical and follow-up information. These patients received surgical treatment at China Medical University Affiliated Hospital from January 2015 to January 2020. Immunohistochemical method was used to detect the expression of RKIP, P-ERK, and P-MEK proteins in GIST tissue samples from these patients. Kaplan-Meier method was used to calculate the survival rate of 63 patients with complete follow-up data. A Nomogram was used to represent the new prognostic evaluation model. The Cox multivariate regression analysis was conducted separately for each set of risk evaluation factors, based on two risk classification systems [the new risk grade model *vs* the modified National Institutes of Health (NIH) 2008 risk classification system]. Receiver operating characteristic (ROC) curves were used for evaluating the accuracy and efficiency of the two prognostic evaluation systems.

RESULTS

In GIST tissues, RKIP protein showed positive expression in the cytoplasm and cell membrane, appearing as brownish-yellow or brown granules. The expression of RKIP was related to GIST tumor size, NIH grade, and mucosal invasion. P-ERK protein exhibited heterogeneous distribution in GIST cells, mainly in the cytoplasm, with occasional presence in the nucleus, and appeared as brownish-yellow granules, and the expression of P-ERK protein was associated with GIST tumor size, mitotic count, mucosal invasion, and NIH grade. Meanwhile, RKIP protein expression was negatively correlated with P-ERK expression. The results in COX multivariate regression analysis showed that RKIP protein expression was not an independent risk factor for tumor prognosis. However, RKIP combined with P-ERK protein expression were identified as independent risk factors for prognosis with statistical significance. Furthermore, we establish a new prognosis evaluation model using RKIP and P-ERK in combination and obtained the nomogram of the new prognosis evaluation model. ROC curve analysis also showed that the new evaluation model had better prognostic performance than the modified NIH 2008 risk classification system.

CONCLUSION

Our experimental results showed that the expression of RKIP and P-ERK proteins in GIST was associated with tumor size, NIH 2008 staging, and tumor invasion, and P-ERK expression was also related to mitotic count. The expression of the two proteins had a certain negative correlation. The combined expression of RKIP and P-ERK proteins can serve as an independent risk factor for predicting the prognosis of GIST patients. The new risk assessment model incorporating RKIP and P-ERK has superior evaluation efficacy and is worth further practical application to validate.

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors of the gastrointestinal tract. It is believed that GISTs originate from Cajal cells, and mutations in the kit and platelet-derived growth factor receptor-alpha (PDGFR-α) genes are considered to be the cause of most cases of GISTs. Based on this discovery, specific tyrosine kinase inhibitors, such as imatinib, have been used as first-line therapy for the treatment of GISTs. Although these drugs have achieved considerable efficacy in some patients, reports of resistance and recurrence have emerged[1]. Even second-line target therapy drugs such as sunitinib, protein kinase C (PKC) 412, or BMS-354825 are not effective for all patients[2].

To overcome tumor resistance, research on GISTs has focused on the search and validation of new targeted therapy sites and regulatory genes. The Raf-MEK-ERK pathway, which is closely related to GIST, is one of the well-studied pathways. Extracellular signal-regulated kinase 1/2 (ERK1/2) protein, as a member of the mitogen-activated protein kinase (MAPK) family, is a core molecule of this signaling pathway. It works with upstream activating molecules and downstream effector molecules to form an efficient and accurate signal transduction system. The MAPK/ERK Kinase 1/2 (MEK 1/2) protein is a MAPKK (MAPK kinase) that can activate the Thr and Tyr sites on the ERK1/2 protein, thereby phosphorylating and activating it to produce the activated form of P-ERK1/2. Raf-1 protein is an upstream MAPKKK (MAPKK Kinase) that can activate the entire pathway by phosphorylating MEK1/2 to obtain P-MEK1/2. The pathway is regulated by the cell cycle and extracellular stimuli, thus regulating downstream protein kinases, phospholipases, and transcription factors to play important biological functions[3-5].

The RKIP protein is a structurally complex protein with a "multidirectional switch" regulatory role in multiple signaling pathways. First, it can regulate multiple signaling pathways and has an inhibitory effect on the Raf-MEK-ERK pathway, affecting cell invasion and proliferation[6]. Additionally, the RKIP protein is also a phosphorylation target, such as its binding to G protein-coupled receptor kinase 2 (GRK2) in the G protein-coupled pathway[7]. Recently, the study of RKIP protein's tumor regulatory function has gradually become a hot spot, and previous studies have reported that RKIP protein is related to the size of GIST tumors, National Institutes of Health (NIH) staging, and whether the tumor invades the mucosa, but RKIP cannot be used as an independent factor for GIST prognosis evaluation[8].

Nowadays, research reports on the important clinical and prognostic value of phosphorylated (P)-ERK and P-MEK proteins closely related to RKIP have gradually emerged in digestive tract tumors such as gastric cancer, colon cancer, and pancreatic cancer. However, literature on the expression of downstream proteins of the ERK/MAPK pathway combined with RKIP in GIST is scarce. This study will focus on this aspect and use immunohistochemistry methods, large sample survival analysis data, and the latest bioinformatics analysis techniques to search for answers to the problem. We aim to find new tumor treatment targets for GIST and develop more reliable and efficient diagnostic and prognostic evaluation methods.

MATERIALS AND METHODS

Patients

The research object of the immunohistochemical experiment was 66 paraffin-embedded specimens that were surgically resected and pathologically diagnosed at China Medical University Affiliated Hospital from January 2015 to January 2020, with complete clinical and follow-up information. There were 36 male cases and 30 female cases, with an age range of 21-83 years and a mean age of 56.2 years. The tumor occurrence sites were: Stomach in 37 cases (56.1%), duodenum in 12 cases (18.2%), jejunum in 15 cases (22.7%), and colon in 2 cases (3.0%) (Table 1).

The diagnostic criteria for GISTs were histopathological features consistent with GISTs and immunohistochemical positivity for CD117, immunohistochemical negativity for CD117 but positivity for CD34, or immunohistochemical negativity for CD117 and CD34 as well as smooth muscle actin, desmin, and S-100 (to exclude smooth muscle tumors and neurogenic tumors). Among them, 59 cases (90.8%) were CD117-positive, and 50 cases (76.9%) were CD34-positive.

The risk grade criteria for GIST used the modified NIH 2008 risk classification system, which combines three assessment factors: Tumor location (gastric *vs* non-gastric: Small intestine and colon, *etc*.), tumor diameter (< 2 cm, 2-5 cm, 5-10 cm, > 10 cm), and mitotic count [< 5/50 high-power fields (HPFs), 5-10/50 HPFs, > 10/50 HPFs]. GISTs were classified as very low risk (I), low risk (II), moderate risk (III), and high risk (IV).

Among the 66 cases of GIST in this study, except for 2 cases who died due to other reasons and 1 case who was lost to follow-up, the follow-up information of the remaining 63 cases was complete. The follow-up time ranged from 5 to 61 mo, with a mean of 48 mo.

Immunohistochemical staining

The GIST specimens were fixed with formalin, embedded in paraffin, and sectioned into 4 μm-thick slices. The sections underwent routine dewaxing in water, followed by H_2O_2 treatment at room temperature to inactivate endogenous enzymes. Subsequently, they were washed three times with distilled water. Antigen retrieval was performed, followed by incubation with a blocking solution containing 5% BSA at room temperature for 20 min. Primary antibodies (RKIP/P-ERK/P-MEK antibodies, rabbit IgG) were then added at an appropriate dilution and incubated at room temperature for 12 h. Next, the sections were treated with a secondary antibody (goat anti-rabbit IgG) and incubated at 25 °C for 20 min. SABC-AP reagent was applied to the sections, followed by incubation at 25 °C for 20 min. For color development, the BCIP/NBT substrate was prepared by diluting it in TBS, thoroughly mixed, and added to the slides. The sections were incubated at 25 °C for 20 min, with the reaction time monitored under a microscope. After washing with distilled water, the sections were lightly counterstained with nuclear red, rinsed, dried, and mounted with a water-soluble mounting medium for microscopic observation.

Evaluation of immunohistochemical staining

The positive staining of RKIP, P-ERK, and P-MEK proteins was mainly located in the cytoplasm and cell membrane, while P-ERK and P-MEK were occasionally observed in the nucleus. The semi-quantitative dual scoring method was used to evaluate the protein expression of proteins. Under high-power microscopy, scoring was performed based on the staining intensity and the proportion of positive cells. Ten random high-power fields were selected on each slide, and the number of positive cells was counted among 100 cells in each field. The average value was calculated and expressed as a

[a]Raf kinase inhibitory protein (RKIP)-positive percentage were compared using the χ^2 test, $P < 0.05$ were considered statistically significant.
HPFs: High-power fields; NIH: National Institutes of Health; P-ERK: Phosphorylated extracellular-signal regulated kinase; P-MEK: Phosphorylated mitogen-activated protein kinase\ERK kinase.

percentage, representing the positivity index of proteins. The detailed scoring criteria were as follows:

(1) Staining intensity scoring criteria: no staining, 0 points; yellow, 1 point; light brown, 2 points; dark brown, 3 points;

(2) Scoring criteria for the proportion of positive cells: < 25% positive cells, 0 points; 25%-50%, 1 point; 51%-75%, 2 points; > 75%, 3 points;

And (3) The overall score was the product of the staining intensity and the proportion of positive cells, and graded as negative (0-2), mildly positive (+, 3), moderately positive (++, 4-6), or strongly positive (+++, 9). RKIP/P-ERK/P-MEK expression was judged to be either negative (0-2) or positive (3-9).

Follow-up

Telephone follow-up was the primary method, with outpatient review and correspondence as secondary measures.

Survival time was calculated as the time from the date of surgery to the date of the last follow-up for surviving patients, the date of death for deceased patients, and the date of the last follow-up for lost patients. Among them, 63 cases had complete follow-up data, 2 cases were excluded due to death from other diseases or accidents, and 1 case was excluded due to loss to follow-up. The follow-up period was from January 2020 to December 2022.

Statistical analysis

SPSS 22.0 software (IBM Corp., Armonk, NY, United States) was used for statistical analysis. Chi-square test was used for comparing percentages. Spearman analysis was used for correlation analysis of two groups of ordinal data. Kaplan-Meier method was used to calculate survival rate, and log-rank test was used. Cox univariate analysis was used for single-factor prognosis analysis, and Cox multivariate regression was used for multi-factor prognosis analysis. A Nomogram was used to represent the new prognostic evaluation model. The Cox multivariate regression analysis was conducted separately for each set of risk evaluation factors, based on two risk classification systems (the new risk grade model *vs* the modified NIH 2008 risk classification system). Receiver operating characteristic (ROC) curves were used for evaluating the accuracy and efficiency of the two prognostic evaluation systems, and statistical significance was set at $P < 0.05$.

RESULTS

Immunohistochemical results of RKIP, P-ERK, and P-MEK proteins and their correlation with clinical pathology

In GIST tissues, RKIP protein showed positive expression in the cytoplasm and cell membrane, appearing as brownish-yellow or brown granules. The immunohistochemical staining result is shown in Figure 1A and B under light microscopy. Among the 66 specimens tested, RKIP protein was expressed positively in 35 cases (53%) and negatively in 31 cases (47%). Statistical analysis revealed that the expression of RKIP was related to GIST tumor size, NIH grade, and mucosal invasion ($P < 0.05$) (Table 1).

P-ERK protein exhibited heterogeneous distribution in GIST cells, mainly in the cytoplasm, with occasional presence in the nucleus, and appeared as brownish-yellow granules, as shown in Figure 1C and D. Positive expression of P-ERK protein was detected in 38 cases (57.6%), while negative expression was detected in 28 cases (42.4%). Clinical pathology analysis indicated that the expression of P-ERK protein was associated with GIST tumor size, mitotic count, mucosal invasion, and NIH grade ($P < 0.05$) (Table 1).

P-MEK protein expression in GIST cells was observed as brownish-yellow granules, mainly distributed in the cytoplasm, with some in the nucleus, and showed a relatively uniform distribution, as shown in Figure 1E and F. Among the 66 cases, positive expression of P-MEK protein was found in 29 cases (43.9%), while negative expression was detected in 37 cases (56.1%). However, no significant correlation was observed between P-MEK protein expression and any independent clinical-pathological factors of GIST (Table 1).

RKIP, P-ERK, and P-MEK protein co-expression analysis

Spearman's correlation test was used to analyze the correlation between RKIP protein expression and P-ERK/P-MEK expression. The results showed that in GIST cases, RKIP protein expression was negatively correlated with P-ERK expression (correlation coefficient = -0.575, $P < 0.001$); RKIP protein expression also had a certain negative correlation with P-MEK protein expression (correlation coefficient = -0.323, $P < 0.001$) (Table 2).

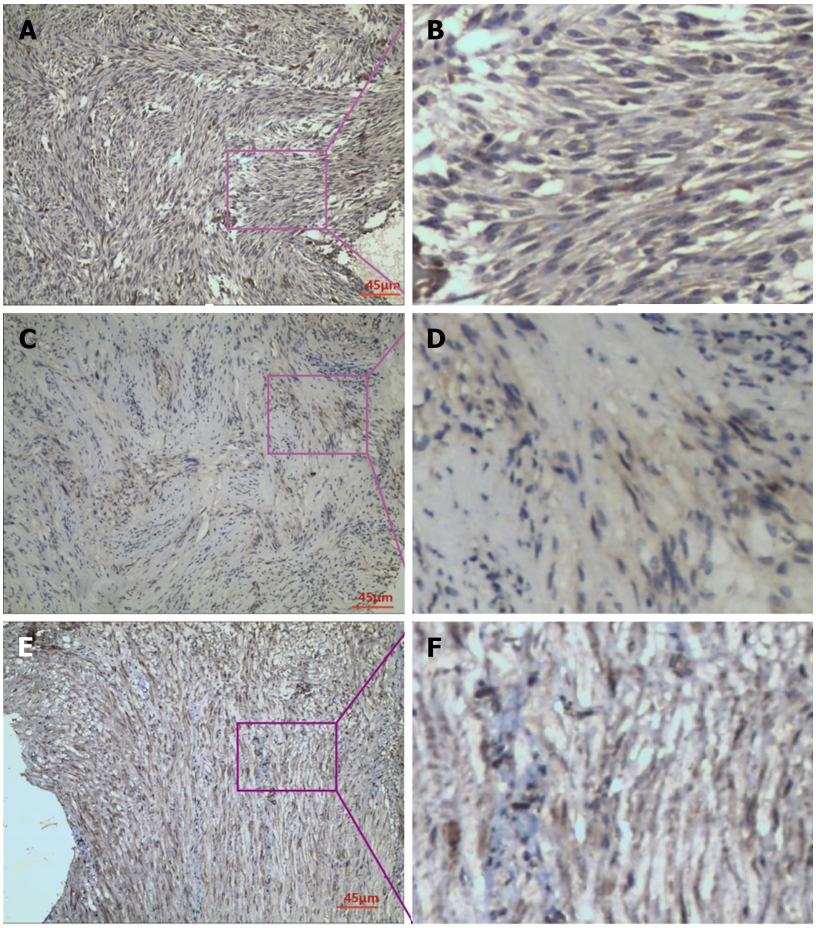
Univariate and multivariate regression analysis

Univariate regression analysis was performed on complete follow-up data from 63 cases, which indicated that tumor location, tumor size, mitotic count, RKIP protein expression, P-ERK protein expression, RKIP combined with P-ERK protein co-expression, and NIH grading were all correlated with patient prognosis ($P < 0.05$).

These univariate factors were further included in COX multivariate regression analysis. The results showed that RKIP protein expression was not an independent risk factor for tumor prognosis ($P = 0.061$). However, tumor size ($P = 0.037$), NIH grading ($P = 0.014$), P-ERK protein expression ($P = 0.041$), and RKIP combined with P-ERK protein expression ($P = 0.044$) were identified as independent risk factors for prognosis with statistical significance. Among them, the impact of RKIP combined with P-ERK protein expression on survival time was the highest with a weight factor of Exp (B) at 11.320, followed by NIH grading, P-ERK expression, and tumor size (Table 3).

Survival analysis curve of RKIP combined with P-ERK in GIST

Based on the expression of RKIP and P-ERK proteins in GIST specimens, we divided the cases into two groups: 1. RKIP (-) and P-ERK (+) group, and 2. The control group with RKIP (+) or P-ERK (-). We drew survival curves for both groups to better represent the significance of the combination of these two proteins in predicting GIST prognosis. The results showed that the survival rate and survival time of Group 1 were significantly lower than those of Group 2 ($P = 0.0312$) (Figure 2).



Establishment of a new prognosis evaluation model using RKIP and P-ERK in combination and its prognosis evaluation efficacy analysis

We included "RKIP expression, P-ERK protein expression, tumor size, tumor location, and mitotic count" as five risk assessment factors (Table 4: Multivariate 2) and used multivariate Cox regression analysis to draw a new nomogram for this new evaluation model. We also conducted ROC analysis to evaluate its prognostic performance. As a control, we

A, C and E were taken under 200 × magnification.

used the three conventional risk factors (tumor location, tumor size, and mitotic count) in the modified NIH 2008 risk classification system as evaluation factors (Table 4: Multivariate 1) and performed the same statistical analysis.

After analyzing the results of the above analysis (Table 4), we obtained the nomogram of the new prognosis evaluation model (Figure 3). ROC curve analysis also showed that the new evaluation model (red curve, AUC = 0.860) had better prognostic performance than the modified NIH 2008 risk classification system (blue curve, AUC = 0.796) ($P = 0.0312$) (Figure 4).

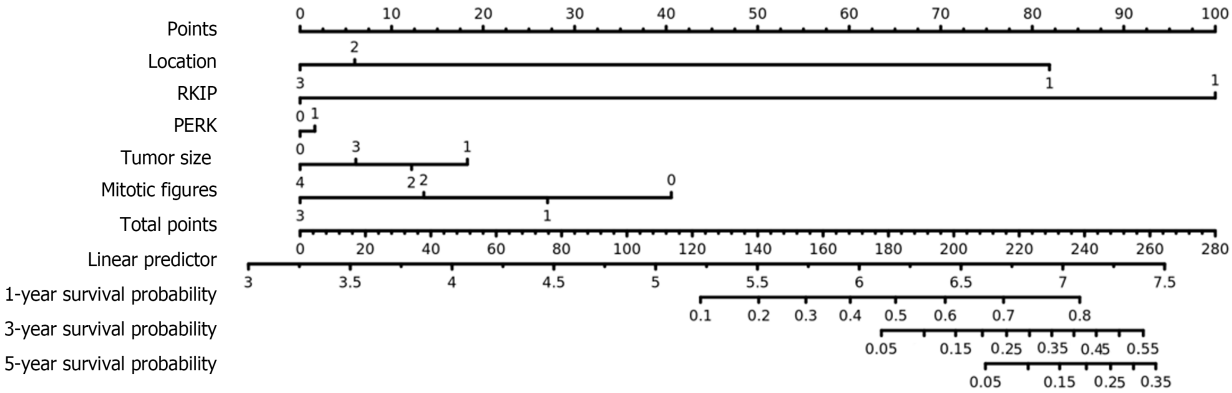
DISCUSSION

GIST is the most common mesenchymal tumor in the gastrointestinal tract, accounting for approximately 60%-70% of all cases. Currently, effective treatment for GIST involves surgery combined with appropriate targeted therapy[9]. However, resistance to targeted therapy often occurs, and prognosis assessment is still being explored and modified. Therefore, there is an urgent need to find better therapeutic targets and a more efficient risk grading system.



ERK and MEK proteins are two core proteins in the Raf1-MEK-ERK pathway, which are downstream targets activated by abnormal C-kit and PDGFR-α *genes* closely related to GIST. ERK protein is associated with various diseases[10] such as tumors, heart failure, developmental disorders, and autoimmune diseases[11-13]. RKIP protein is a natural inhibitor of Raf-1 protein and is widely present in living organisms. It has an inhibitory effect on the metastasis and proliferation of various tumors.

In our preliminary experiments, we found that high expression of RKIP protein was related to GIST tumor size, invasion of the mucosa, and NIH grading. However, the single expression of RKIP protein alone is not sufficient as a single risk factor for evaluating GIST prognosis. Recent reports have suggested that RKIP protein regulates the expression

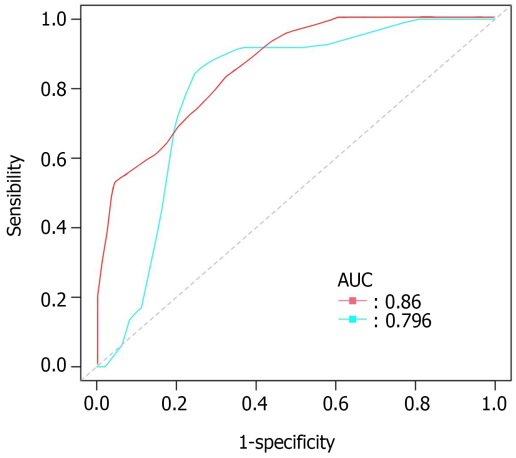
Figure 3 Nomogram for the new risk grade model with consideration of raf kinase inhibitory protein and phosphorylated-extracellular-signal regulated kinase to predict the probabilities of 5-yr survival with gastrointestinal stromal tumors. Raf kinase inhibitory protein (RKIP) expression, phosphorylated-extracellular-signal regulated kinase (P-ERK) expression, tumor size, tumor location and mitotic count are involved as assessment factors.



of the MEK/ERK pathway in pancreatic cancer[14,15], thereby affecting tumor resistance and invasion. Additionally, it has been found that the combination of RKIP and P-ERK proteins in gastric cancer has a predictive significance for tumor prognosis[16]. These findings inspired us to focus on the combined detection of RKIP, P-ERK, and P-MEK proteins in GIST, in hopes of gaining further insights.

Clinical and pathological correlations

In this experiment, we analyzed the expression of RKIP, P-ERK, and P-MEK proteins in GIST and found that RKIP expression is related to GIST tumor size and NIH staging. This result is consistent with the research findings of Yuan *et al* [17], who found that knocking down the RKIP gene promotes cell growth in nasopharyngeal carcinoma cell lines[17].

In addition to its correlation with tumor size and NIH staging, P-ERK protein is also related to the mitotic count in GIST cells. Zhang *et al*[18] found that high expression of RKIP protein leads to low expression of P-ERK protein in the human choriocarcinoma cell line JEG-3. Furthermore, transfection with low P-ERK level tumor cells significantly reduced their growth activity compared to the control group, indicating that P-ERK protein is related to tumor cell proliferation [18].

The mechanism may be that low RKIP expression in GIST tumor cells leads to more phosphorylation of downstream ERK1/2 protein, forming P-ERK protein, which can control important structures in cell division such as centrosomes, spindle fibers, and centromeres[19,20], accelerating the tumor cell cycle and mitosis[21]. In addition, low RKIP expression causes dysregulation of its ligand Raf-1 protein, which upregulates the cell mitotic cycle[22,23], accelerating tumor growth. Moreover, ERK protein can be rapidly transported into the nucleus, further phosphorylating and activating proliferation-related transcription factors such as AP-1, ELK-1, and Serum Response Factor Accessory Protein (SAP), promoting cell proliferation and causing abnormal nuclear division[24]. Thus, low RKIP expression in GIST upregulates P-ERK, leading to tumor enlargement and increased nuclear division.

Figure 4 Receiver operating characteristic curves for two risk grade system in predicting overall survival of gastrointestinal stromal tumors. The red curve represents for the new risk grade model and the blue one represents for National Institutes of Health (NIH) 2008 Risk Grade System. The area under the curve was 0.860 for the new risk grade model, while 0.796 for NIH 2008 Risk Grade System. Compared with the traditional NIH 2008 system, the new model which is with consideration of raf kinase inhibitory protein and phosphorylated-extracellular-signal regulated kinase is correlated with a better prediction efficiency for overall survival of gastrointestinal stromal tumors, the difference was significant. Log-rank analysis, $P = 0.0312$. AUC: Area under curve.

The NIH 2008 risk classification system is a recognized postoperative prognostic assessment system for GIST, which is based on three independent risk factors: Tumor location, tumor size, and mitotic index. RKIP and P-ERK proteins are associated with two of these factors, and it is easy to understand that protein expression is also related to NIH 2008 risk classification results. Schoppmann *et al*'s report suggests that loss of RKIP expression tends to increase the risk level of GIST cases in Fletcher's risk classification and a similar conclusion is drawn in Miettinen's risk classification[25]. Wang *et al*[26] also found that RKIP protein expression is related to TNM staging in non-small cell lung cancer[26].

We also found that both RKIP protein and P-ERK protein are related to the mucosal invasion status of GIST tumors. Martinho *et al*[27] found in experiments that low expression of RKIP protein often indicates a tendency of GIST tumors to invade and metastasize[27]. A similar correlation is found in gastric cancer between RKIP protein expression and tumor invasion depth, lymph node metastasis, and distant metastasis. The mechanism may be related to the interaction between RKIP protein and Snail protein, which regulates tumor Epithelial-Mesenchymal Transition (EMT)[28]: Snail protein can bind and downregulate E-cadherin protein, thereby regulating EMT; at the same time, it binds to the RKIP protein promoter E-box region to downregulate RKIP protein transcription. Thus, when Snail upregulates EMT, RKIP is often reduced[29].

In the analysis of clinical and pathological factors, no statistically significant results were found for P-MEK protein expression. However, there is a certain negative correlation between RKIP and P-MEK expression, which is statistically significant. This may indicate that RKIP has a certain regulatory effect on P-MEK. Schoppmann *et al*[25] found in their immunohistochemical study of GIST specimens that P-MEK1/2 expression is related to whether the tumor can be completely resected, but has no significant relationship with other factors. The conclusions of this study are mutually corroborated.

Analysis of co-expression of RKIP and P-ERK proteins

In this experiment, it was found that the expression of RKIP and P-ERK in GIST was negatively correlated ($P < 0.05$). Yang *et al*[14] found that inhibiting ERK phosphorylation would upregulate RKIP expression in pancreatic cancer cell lines; while Yuan *et al*[17] reported that high expression of RKIP in nasopharyngeal carcinoma cells can also inhibit ERK protein activation. Therefore, RKIP protein and P-ERK protein have mutual regulatory functions. Recently, the novel and revolutionary "Phospho-Theft" hypothesis about RKIP provides a perfect explanation for its possible mechanism[30]. RKIP protein has two completely different functions: When not phosphorylated, RKIP protein inhibits the activation and signal transmission of Raf-1 protein, which can reduce the activation of downstream MEK/ERK; after RKIP is phosphorylated by PKC protein at S153, P-RKIP substrate transfers to GRK2[31], which can enhance the activation of the β-AR pathway and activate downstream substrate ERK[32]. In addition, RKIP is regulated by feedback of KRAS-ERK pathway. At the same time, P-ERK can undergo self-phosphorylation, thereby activating downstream substrates such as Elk1, mitogen-and stress-activated protein Kinase, c-myc, *etc*[33].

Univariate and multivariate survival analysis and survival curve

Combining univariate and multivariate COX regression analysis, it was found that RKIP protein expression could not serve as an independent risk factor for predicting tumor prognosis ($P = 0.061$). Tumor size ($P = 0.037$), NIH grading ($P = 0.014$), P-ERK protein expression ($P = 0.041$), and RKIP combined with P-ERK protein expression ($P = 0.044$) could serve as independent prognostic factors with statistical significance. Among them, the combined expression of RKIP and P-ERK had the highest impact on survival, with a weight factor of Exp (B) at 11.320, followed by NIH grading, P-ERK expression, and tumor size. Furthermore, we plotted survival curves for GIST cases based on their combined RKIP and P-

ERK expression, revealing a significant difference in survival rates between groups. Therefore, the combined expression of RKIP and P-ERK has significant prognostic value for evaluating the prognosis of GIST patients and carries greater weight. This is consistent with findings in a study on nasopharyngeal carcinoma where RKIP was found to be an independent risk factor for predicting prognosis. In gastric cancer, the combined expression of P-ERK and RKIP was found to be associated with a 5-year relapse-free survival after surgery.

Establishment of a GIST prognostic model based on RKIP and P-ERK protein expression

Standardized treatment for GIST includes timely surgery and rational targeted therapy. The indication for targeted therapy is currently based on the NIH 2008 risk classification system applied to postoperative pathology results, with Imatinib (a representative TKI drug) for the intermediate and high-risk population[34]. Meanwhile, the Armed Forces Institute of Pathology and World Health Organization 2013 risk classifications are also used[35]. However, there are differences in the results among various risk classification systems, and there are difficulties in using and interpreting them for the public. As mentioned in this article, we found that the combination of RKIP and P-ERK protein expression is of great significance for the prognostic evaluation of GIST patients. Therefore, we incorporated RKIP and P-ERK protein expression, as well as tumor size, tumor location, and mitotic count, into a new GIST risk assessment model and plotted a survival curve. We analyzed its evaluation efficiency using the ROC curve, and the results showed that it is superior to the NIH 2008 risk classification system (Area Under Curve 0.860 *vs* 0.796).

Perspectives and limitations

In recent years, GIST-related research has been devoted to identifying new biomarkers and finding new therapeutic targets[36]. As one of the hotspots, our study found that the combination of RKIP and P-ERK proteins can effectively indicate the prognosis of GIST and can be used to guide GIST targeted therapy. More researchers have focused on the application and exploration of RKIP and P-ERK proteins in tumor diagnosis and treatment, such as the recent successful case of using urine RKIP monitoring to evaluate the prognosis of clear cell renal cell carcinoma (ccRCC)[37]. Serum RKIP levels have also been used to monitor the efficacy of treatment for multiple sclerosis[38]. In terms of treatment, ERK inhibitors combined with chloroquine can improve the adjuvant therapy for pancreatic cancer with K-Ras mutations[39], and imatinib combined with chloroquine (to inhibit autophagy) has also been attempted in GIST drug-resistant experimental studies[40].

Our experiment fills the gap in the research on the relevance of RKIP and P-ERK in GIST, further confirming the significance of these proteins in tumor physiology and clinical treatment. However, the experiment still has some limitations. Firstly, due to the lower incidence of GIST comparing to other gastrointestinal tumors, the sample size was limited. We will continue to recruit more samples and track their follow-up, using more abundant data for further validation and research. Secondly, this experiment used immunohistochemical methods for protein level research. In the future, we will supplement molecular level experiments to further elucidate the mechanism of action of relevant sites on the RKIP and ERK/MAPK pathways, and better guide targeted therapy. The above is also the focus of our project and ongoing work. We are confident in making improvements and will strive to promote a new chapter in the RKIP-related diagnosis and treatment of GIST.

CONCLUSION

Our experimental results showed that the expression of RKIP and p-ERK proteins in GIST was associated with tumor size, NIH 2008 staging, tumor invasion, and p-ERK expression was also related to mitotic count. The expression of the two proteins had a certain negative correlation. The combined expression of RKIP and p-ERK proteins can serve as an independent risk factor for predicting the prognosis of GIST patients. The new risk assessment model incorporating RKIP and p-ERK has superior evaluation efficacy and is worth further practical application to help validate results.

ARTICLE HIGHLIGHTS

Research background

Nowadays, research reports on the important clinical and prognostic value of phosphorylated-extracellular signal-regulated kinase (P-ERK) and phosphorylated-mitogen-activated protein kinase (MAPK/ERK) kinase (P-MEK) proteins closely related to raf kinase inhibitor protein (RKIP) have gradually emerged in digestive tract tumors.

Research motivation

The expression of downstream proteins of the ERK/MAPK pathway combined with RKIP in gastrointestinal stromal tumor (GIST) is scarce.

Research objectives

To detect the expression of RKIP, P-ERK, and P-MEK proteins in GIST and to analyze their relationship with clinicopathological characteristics and prognosis of this disease. Try to establish a new prognosis evaluation model using RKIP and P-ERK in combination and analyze its prognosis evaluation efficacy.

Research methods

This study will focus on this aspect and use immunohistochemistry methods, large sample survival analysis data, and the latest bioinformatics analysis techniques to search for answers to the problem.

Research results

Our experimental results showed that the expression of RKIP and P-ERK proteins in GIST was associated with tumor size, NIH 2008 staging, tumor invasion, and P-ERK expression was also related to mitotic count. The expression of the two proteins had a certain negative correlation.

Research conclusions

The combined expression of RKIP and P-ERK proteins can serve as an independent risk factor for predicting the prognosis of GIST patients. The new risk assessment model incorporating RKIP and P-ERK has superior evaluation efficacy and is worth further practical application to validate.

Research perspectives

As one of the hotspots, our study found that the combination of RKIP and P-ERK proteins can effectively indicate the prognosis of GIST and can be used to guide GIST targeted therapy. More researches are needed to focus on the application and exploration of RKIP and P-ERK proteins in tumor diagnosis and treatment.

Abstract

BACKGROUND

Deep angiomyxoma (DAM) is a very rare tumor type. Magnetic resonance imaging (MRI) is considered the best imaging modality for diagnosing DAM. Computed tomography (CT) is used mainly to assess the invasion range of DAM. The value of ultrasonography in the diagnosis of DAM is still controversial. Through a literature review, we summarized the current state of ultrasonic examination for DAM and reported for the first time the contrast-enhanced ultrasound (CEUS) features of DAM seen using a biplane transrectal probe.

CASE SUMMARY

A 37-year-old woman presented with a sacrococcygeal mass that had gradually increased in size over the previous 6 mo. MRI and CT examinations failed to allow a definite diagnosis to be made. Transperineal core needle biopsy (CNB) guided by transrectal ultrasound and CEUS was suggested after a multidisciplinary discussion. Grayscale ultrasound of the lesion showed a layered appearance with alternating hyperechoic and hypoechoic patterns. Transrectal CEUS showed a laminated distribution of the contrast agent that was consistent with the layered appearance of the tumor on grayscale ultrasound. We performed transperineal CNB of the enhanced area inside the tumor under transrectal CEUS guidance and finally made a definitive diagnosis of DAM through histopathology. The patient underwent laparoscopic-assisted transabdominal surgery combined with transperineal surgery for large pelvic tumor resection and pelvic floor peritoneal reconstruction. No recurrence or metastasis was found at the nine-month follow-up.

CONCLUSION

Transrectal CEUS can show the layered perfusion characteristics of the contrast agent, guiding subsequent transperineal CNB of the enhanced area within the DAM.

INTRODUCTION

Deep angiomyxoma (DAM) is a very rare tumor that mainly occurs in the pelvis and perineum of women of reproductive age[1]. DAM is classified as a "tumor of uncertain differentiation" in the World Health Organization classification. Since it was first described in 1983, DAM has been described in multiple single case reports and some case series reports[1-3]. Imaging examinations play an important role in the diagnosis of DAM and in evaluating the scope of lesion invasion. Magnetic resonance imaging (MRI) is considered the best imaging modality for the diagnosis of DAM; computed tomography (CT) is mainly used to evaluate the invasion range of DAM, and the value of ultrasound in the diagnosis of DAM is still controversial. This article reports for the first time the contrast-enhanced ultrasound (CEUS) features of DAM seen using a biplane transrectal probe and reviews the imaging features of DAM in the literature.

CASE PRESENTATION

Chief complaints

A 37-year-old woman presented with a sacrococcygeal mass that had been increasing in size over the previous 6 mo.

History of present illness

The patient inadvertently found a sacrococcygeal mass 6 mo prior, which was approximately the size of a pigeon egg at first, without pain or other discomfort. The mass gradually increased in size, accompanied by lumbosacral distension. No definite diagnosis was made after an examination at the local hospital; thus, the patient was transferred to our hospital for further diagnosis and treatment.

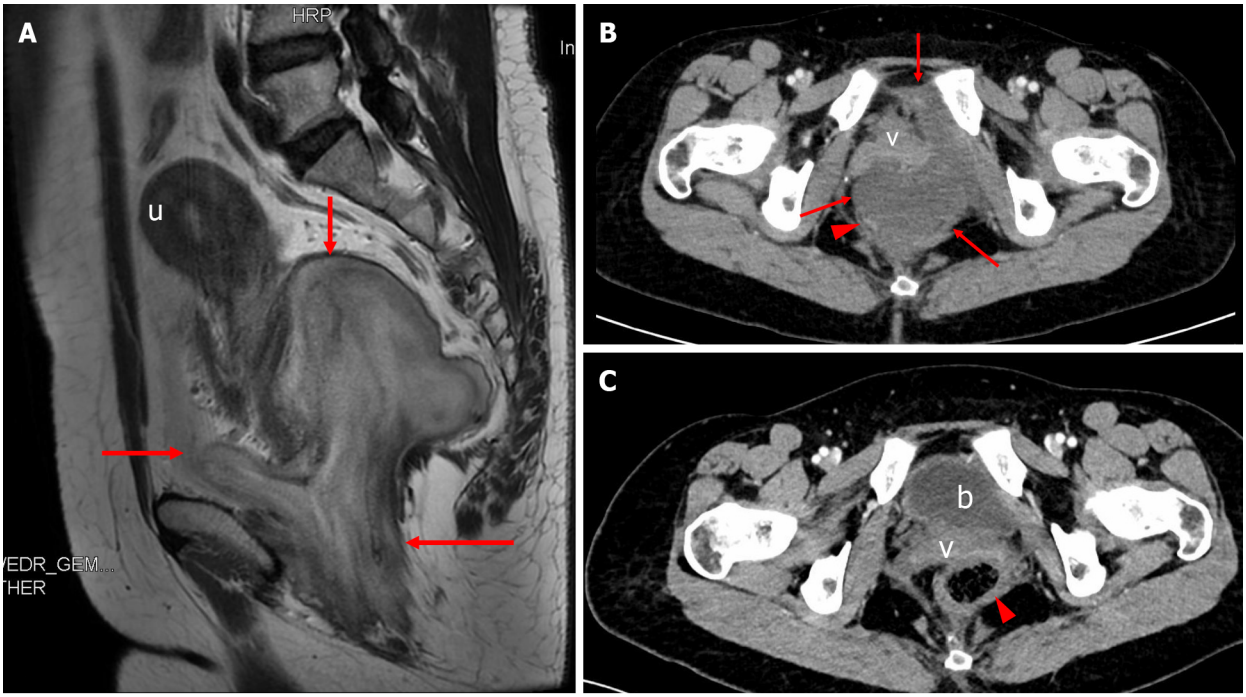
History of past illness

The patient had no previous medical history.

Personal and family history

The patient and family histories were negative.

Physical examination



A digital rectal examination revealed a large solid mass in the anterior rectal wall, with a hard texture and fixed position. The mass boundary could not be palpated.

Laboratory examinations

The results of laboratory examinations were normal, including routine blood analysis, carcinoembryonic antigen (CEA), alpha-fetoprotein (AFP), carbohydrate antigen (CA) 19-9, and CA125 results.

Imaging examinations

Preoperative MRI showed a paracervical mass in the pelvis, measuring approximately 9.5 cm × 8.1 cm in size (Figure 1A). T2-weighted imaging (T2WI) presented stratification changes with alternating high and low signals that were clearly demarcated from the surrounding tissue, and the uterus was pushed and displaced cephalad. Preoperative contrast-

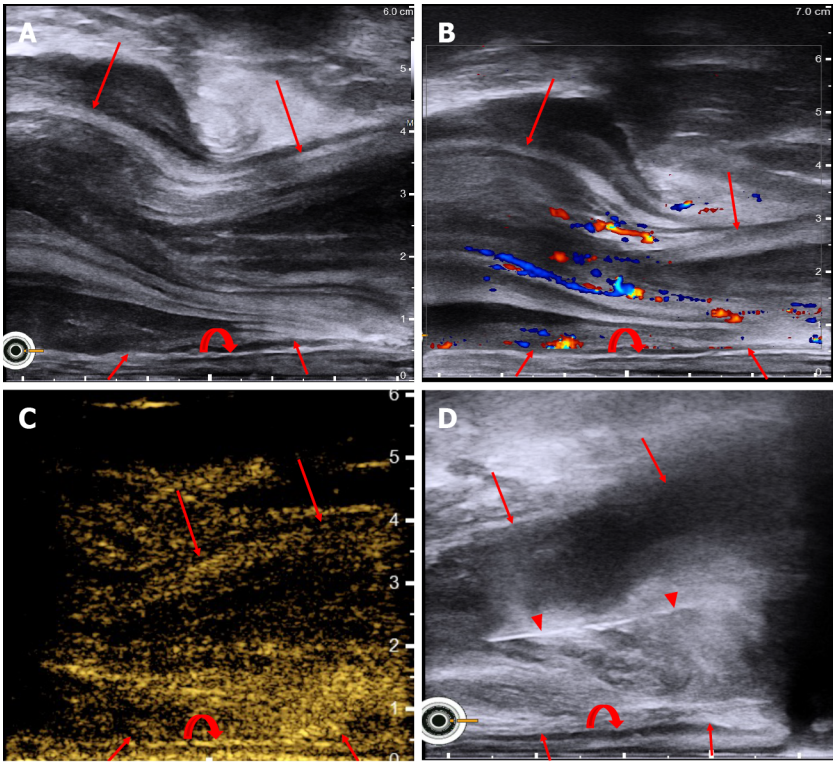
Figure 1 Magnetic resonance imaging and contrast-enhanced computed tomography images in our case. A: Preoperative sagittal T2-weighted imaging. The mass (arrows) was 9.5 cm × 8.1 cm in size, showing a layered appearance with alternating high and low signals and a clearly demarcated boundary with respect to surrounding tissue, and the uterus was pushed and displaced cephalad; B: Preoperative transverse contrast-enhanced computed tomography (CECT) showed that the anterior vagina and the right posterior rectum (arrowhead) were pushed by the mass (arrows); C: Six months after surgery, transverse CECT showed that the filled bladder, vagina, and rectum (arrowhead) were in normal positions, with no evidence of tumor recurrence. u: Uterus; v: Vagina; b: Bladder.

enhanced CT (CECT) demonstrated a pelvic mass between the cervix and rectum with nonenhanced areas (Figure 1B). The mass pushed against and displaced the anterior vagina and the right posterior rectum.

Preoperative transrectal ultrasound (TRUS) was performed with the MyLab Twice ultrasound system (Esaote, Genoa, Italy) equipped with a biplane endoscopic probe (TRT33, linear frequency of 4-13 MHz, convex frequency of 3-9 MHz). Grayscale ultrasound showed that the left pelvic mass had an irregular shape (Figure 2A). The internal echo of the mass presented a layered appearance with alternating hyperechoic and hypoechoic patterns, and the boundary between the mass and rectum wall was clear. Color Doppler flow imaging (CDFI) showed some blood vessels scattered in the tumor (Figure 2B), and the dispersed intratumoral blood vessels were consistent with the layered appearance of the tumor on grayscale ultrasound. Then, transrectal CEUS was performed with a bolus injection of 2.4 mL of SonoVue (Bracco, Milan, Italy) through the elbow vein (Figure 2C). A laminated distribution of the contrast agent was observed within the mass, which was also consistent with the layered appearance of the tumor on grayscale ultrasound.

Further diagnostic work-up



Transperineal core needle (16G) biopsy (CNB) was performed under the guidance of TRUS (Figure 2D). The probe was switched to linear mode, and puncture sampling was performed under real-time monitoring by TRUS, avoiding the nonenhanced areas of the tumor. No complications occurred during the biopsy.

FINAL DIAGNOSIS

Postoperative immunohistochemical staining showed the following results: CD34 (vascular +), CK (pan) (-), ER (+), PR (+), Desmin (+), S-100 (-), SMA (+), CDK4 (-), and MDM2 (±). FISH revealed an unbalanced translocation of the HMGA2 gene. The final diagnosis was a DAM in the deep pelvis (Figure 3).

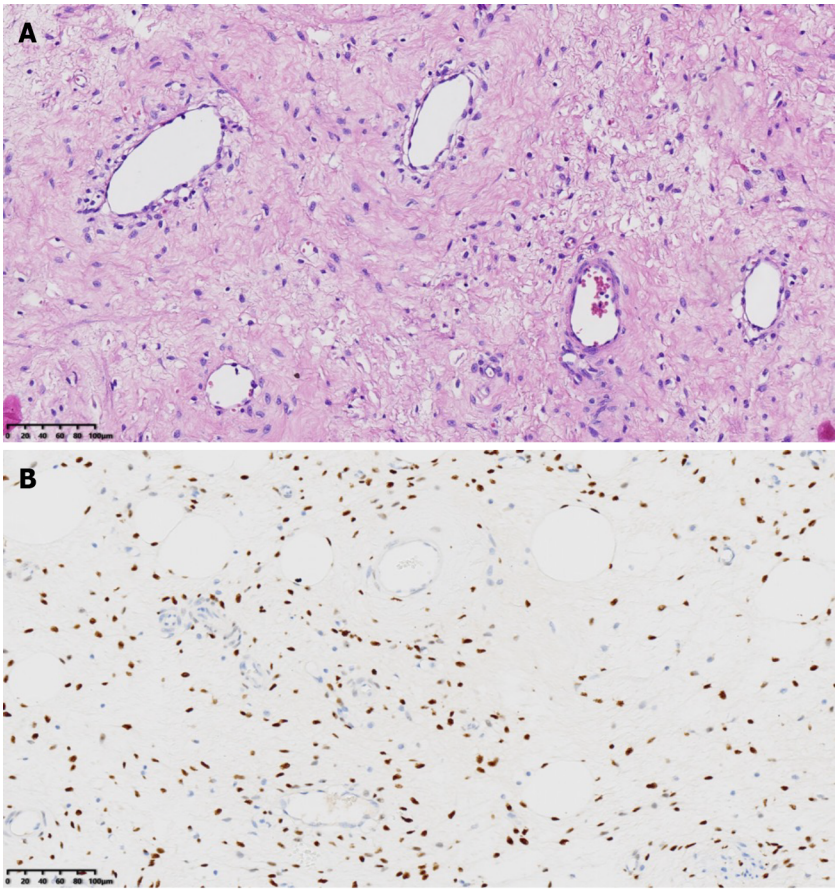
TREATMENT

A preoperative examination was completed. The patient underwent laparoscopic-assisted transabdominal surgery combined with transperineal surgery for large pelvic tumor resection and pelvic floor peritoneal reconstruction on February 10, 2022.

DOI: 10.3748/wjg.v29.i26.4214 **Copyright** ©The Author(s) 2023.

Figure 2 Scanning with a TRT33 biplane transrectal probe linear array. A: Grayscale ultrasound showed that the mass (arrows) was irregular in shape, with a layered appearance of alternating hyperechoic and hypoechoic areas inside and a clearly demarcated boundary with respect to the rectal wall (curved arrow); B: Color Doppler flow imaging showed that the dispersed intratumoral blood vessels were consistent with the layered appearance of the mass (arrows) on grayscale ultrasound; C: Transrectal contrast-enhanced ultrasound showed a laminated distribution of the contrast agent in the mass (arrows), also consistent with the layered appearance of the tumor on grayscale ultrasound; D: Transperineal core needle (arrowheads) biopsy was performed under the guidance of transrectal ultrasound.

During surgery, the tumor was found to be located below the pelvic peritoneal reflex plane, behind the cervix, and in front of the left side of the rectum. It was irregular in shape, with a smooth capsule, and contained both cystic and solid components. The postoperative pathological report was consistent with DAM.



OUTCOME AND FOLLOW-UP

The patient recovered well after surgery and underwent regular outpatient follow-up examinations. CECT of the pelvic cavity was performed on August 12, 2022 (Figure 1C), six months after resection, and indicated no obvious signs of tumor recurrence. No recurrence or metastasis was found by the last follow-up on November 9, 2022.

DISCUSSION

DAM is a very rare type of tumor that most commonly occurs in the pelvis and perineum of women of reproductive age [1]. Histologically, the typical morphology of DAM is an infiltrating, uniformly hypocellular tumor, consisting of small-sized spindled or stellate cells scattered randomly in the myxoid stroma and containing many small to medium/Large blood vessels, without nuclear atypia[1] (Figure 3). Clinically, DAM presents as a slowly growing painless mass. DAM is characterized by locally aggressive growth, with recurrence and metastasis occurring in some cases[2,3]. Accurate preoperative diagnosis and complete resection of the lesion are key to the treatment and prevention of recurrence[4]. Imaging examinations play an important role in the diagnosis of DAM and in assessing the extent of lesion invasion[5]. Commonly used imaging examinations include MRI, CT, and ultrasound[6].

CT is mainly used to evaluate the invasion range of DAM and perform follow-up observations, but its value in displaying typical signs such as a laminated or swirled appearance of the DAM tissue is limited[5-7]. MRI is considered the best imaging modality for the diagnosis of DAM[6,8-10]. T2WI can reveal the swirled or layered appearance of the mass, which has been reported in at least 83% of cases[6]. MRI is also critical to determining the range of tumor extension into the surrounding space and the mode of tumor invasion into surrounding organs[6,9]. Retrospective analysis of the T2WI MRI data in our case showed a typical laminated and swirled appearance consistent with the reports in the literature[8-10] (Figure 1A). However, we failed to make a definitive diagnosis, mainly because DAM is rare; we had insufficient experience in diagnosing this tumor. Some experts believe that it is difficult to accurately diagnose DAM

DOI: 10.3748/wjg.v29.i26.4214 **Copyright** ©The Author(s) 2023.

Figure 3 Pathological results of the deep angiomyxoma puncture sample. A: Small-sized spindled or stellate cells scattered in the myxoid stroma containing many blood vessels of varying caliber, without cellular atypia or mitotic activity (HE × 200); B: Immunohistochemistry showed positive expression of estrogen receptors in the tumor cells (× 200).

before surgery, and these tumors are often misdiagnosed as other soft tissue tumors[11-13], such as Bartholin cyst, lipoma, and cellular angiofibroma. The misdiagnosis rate is as high as 82%[11].

Although MRI has many advantages in the diagnosis of DAM, the cost of MRI is relatively high, and patients with metal in the body cannot be examined by MRI. Similar to MRI, ultrasound can also be applied to avoid radiation exposure. Because of its low cost, convenient operation, and noninvasiveness, ultrasound can be used for multiple examinations in cases of DAM and follow-up examinations after surgery. In addition, ultrasound is not limited by the presence of metal objects such as heart stents and is also the preferred choice for patients with claustrophobia.

However, the literature related to ultrasound for DAM is scarce[14], and the value and role of ultrasound have not been systematically summarized. Through a literature review, we found that the previous ultrasonography methods related to DAM mainly consisted of examinations with transabdominal convex array probes[10,15], intracavity convex array probes[9,14,16,17], and transperineal linear array probes[18,19]. Among the 53 reports related to DAM, only 2[9,15] reported a typical laminated or swirled appearance on grayscale ultrasound. In all reports, CDFI did not show swirled or layered blood vessel distribution characteristics corresponding to the grayscale ultrasound findings, and CEUS examination was not performed in any of the previous reports, as shown in Table 1.

We report for the first time the CEUS features of DAM in the pelvic cavity seen using a biplane transrectal probe. In this case, transrectal grayscale ultrasound showed a laminated appearance with alternating hyperechoic and hypoechoic patterns inside the mass (Figure 2A), demonstrating the same details as MRI and excellent resolution, which confirms the high sensitivity of transrectal high-frequency ultrasound in detecting the characteristic histological structure of DAM. We also observed that the distribution of scattered blood vessels within the tumor on CDFI was consistent with the layered appearance of the tumor on grayscale ultrasound (Figure 2B). This layered distribution of vascular features has not been previously reported in the literature[9-11,15,18,19], which may be related to the fact that more anatomical details of the tumor can be displayed by high-frequency ultrasound with a biplane transrectal probe[9,20,21]; however, this is yet to be verified by subsequent cases. Reportedly, CEUS may be of great value in the diagnosis of DAM[15], as this modality can better show the characteristics of DAM and help to determine the role of ultrasound in tumor treatment. However, to our knowledge, the diagnosis of DAM by CEUS has not been reported. In our case, the mass was examined by transrectal CEUS (Figure 2C). The characteristic laminated perfusion of the contrast agent was observed within the mass, which was also consistent with the layered appearance of the tumor on grayscale ultrasound.

Table 1 Summary of sonographic features of deep angiomyxoma from the literature

No.	Ultrasonographic approach and probe	No. of tumors	Sex	Age (yr)	Location	Maximal diameter (cm)	Internal echogenicity	No. of cystic component	Laminated/swirled pattern in 2D
1	Transabdominal convex array probe	4	F	18-50	Pelvis	3-38.8 (mean: 16.2 ± 9.4)	Hypoechoic or isoechoic internal components	3	No
2	Transabdominal convex array probe	8	7F; 1M	35-64 (median 39)	Vulva, pelvis, perineal region, spermatic cord, and scrotum	7-21	Heterogeneous, isoechoic internal components	2	Yes
3	Transvaginal end-fire probe	1	F	40	Pelvis extending to the perineum	11.8	Mixed echogenicity	0	Yes
4	Transvaginal end-fire probe	1	F	54	Behind the uterus	18	Heterogeneous hypoechoic internal components	1	No
5	Transvaginal end-fire probe	1	F	44	Left pelvis	12	Hypoechoic to isoechoic internal components	0	No
6	Transrectal radial probe	1	F	61	Left perirectal mass	10.7	Hypoechoic to isoechoic internal components	NA	No
7	Transperineal linear probe	36	M	1-81 (mean 48.3 ± 20.6)	Epididymis, testes, spermatic cord, scrotum	1.6-25 (mean: 8.36)	Heterogeneous hypoechoic internal components	NA	No
8	Transperineal linear probe	1	F	28	Vulva	4.8	Heterogeneous hypoechoic internal components	0	No

F: Female; M: Male; NA: Not available.

We believe that the advantages of ultrasound with a biplane transrectal probe and CEUS in the diagnosis of DAM in the deep pelvic cavity are as follows:

First, the biplane transrectal high-frequency probe can enter the pelvic cavity along the anal canal and rectum and clearly display the laminated or swirled appearance of DAM, as well as the boundary of the mass and its relationships with adjacent structures, allowing this modality to be comparable to MRI. Typically, transperineal ultrasound and transabdominal ultrasound cannot simultaneously meet the requirements of satisfactory detection depth and high resolution of images when examining deep pelvic lesions. Additionally, the biplane transrectal probe effectively overcomes the obvious limitation of the observation angle of the convex end-fire probe.

Second, the laminated perfusion characteristics inside the mass can be displayed in real time by CEUS, which is helpful for the diagnosis and differential diagnosis of DAM.

Third, the gold standard for the diagnosis of DAM depends on histopathology and immunohistochemistry[18]. However, the proportion of cystic components in DAM is as high as 75%[10], and these components appeared as unenhanced areas on transrectal CEUS, which were easy to distinguish from enhanced areas of the mass, guiding subsequent precise and effective puncture of the enhanced area (Figure 2D). After transrectal CEUS, our patient immediately underwent transperineal CNB[22,23] guided by TRUS at the examination bed, and a clear pathological diagnosis was obtained, which provided a basis for formulating the surgical plan and reducing the patient's waiting time before surgery.

Fourth, compared with MRI and CT, TRUS is convenient, rapid, radiation-free, and economical. TRUS can dynamically display the internal and adjacent structures of the lesion in real time and can be used for repeated monitoring of the lesion before surgery.

Fifth, for patients with cardiac pacemakers, internal metal stents, or claustrophobia, ultrasound with a biplane transrectal probe and CEUS can be used instead of MRI.

Sixth, long-term follow-up is necessary due to the high recurrence rate of DAM[24]. Due to the above advantages, ultrasound with a biplane transrectal probe and CEUS are ideal tools for the postoperative follow-up of pelvic DAM patients. In summary, ultrasound with a biplane transrectal probe and CEUS can be one of the first choices for the diagnosis and follow-up of DAM patients.

CONCLUSION

In conclusion, pelvic DAM is a rare tumor. In our case, the typical laminated appearance of DAM could be observed by ultrasound with a biplane transrectal probe and CEUS. Moreover, CNB of the enhanced area inside the tumor could be accurately guided by transrectal CEUS, enabling the pathological gold standard for the diagnosis of DAM; thus, this modality is expected to be one of the preferred methods for the diagnosis of DAM in the pelvic cavity.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Mark C Mattar, AGAF, FACG, MD, Professor of Medicine, Department of Gastroenterology, MedStar Georgetown University Hospital, Washington, DC 20007, United States. mark.c.mattar@medstar.net

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now abstracted and indexed in Science Citation Index Expanded (SCIE), MEDLINE, PubMed, PubMed Central, Scopus, Reference Citation Analysis, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJG* as 4.3; Quartile category: Q2. The *WJG*'s CiteScore for 2021 is 8.3.

Abstract

Non-variceal upper gastrointestinal bleeding (NVUGIB) is a common gastroenterological emergency associated with significant morbidity and mortality. Gastroenterologists and other involved clinicians are generally assisted by international guidelines in its management. However, NVUGIB due to peptic ulcer disease only is mainly addressed by current guidelines, with upper gastrointestinal endoscopy being recommended as the gold standard modality for both diagnosis and treatment. Conversely, the management of rare and extraordinary rare causes of NVUGIB is not covered by current guidelines. Given they are frequently life-threatening conditions, all the involved clinicians, that is emergency physicians, diagnostic and interventional radiologists, surgeons, in addition obviously to gastroenterologists, should be aware of and familiar with their management. Indeed, they typically require a prompt diagnosis and treatment, engaging a dedicated, patient-tailored, multidisciplinary team approach. The aim of our review was to extensively summarize the current evidence with regard to the management of rare and extraordinary rare causes of NVUGIB.

Key Words: Gastrointestinal bleeding; Upper gastrointestinal bleeding; Non-variceal upper gastrointestinal bleeding; Rare causes; Vascular causes; Upper endoscopy

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Rare and extraordinary rare causes of non-variceal upper gastrointestinal bleeding (NVUGIB) are commonly life-threatening conditions. Thus, a prompt diagnosis and a subsequent equally early treatment are required, typically involving a patient-tailored, multidisciplinary team approach. However, given the rare occurrence, their management is not covered by NVUGIB current guidelines. Our study aimed to review the current evidence with regard to the management of rare and extraordinary rare causes of NVUGIB.

INTRODUCTION

Acute upper gastrointestinal bleeding (UGIB) is a common medical emergency with an annual incidence of approximately 50/100000-150/100000 adults[1-3]. It is defined as hemorrhage originating above the ligament of Treitz, in the esophagus, stomach, or duodenum. According to its etiology and reflecting differences in its management, UGIB tends to be subclassified to variceal and non-variceal UGIB (NVUGIB). Peptic ulcer disease (PUD) is the most common cause for UGIB and accounts for approximately 35%-50% of cases, followed by erosive disease, esophagitis and Mallory-Weiss tear. Varices are another common source of UGIB, representing approximately 10% of all UGIB hospitalizations. Less common causes of UGIB include neoplasm, angiodysplasia, gastric antral vascular ectasia and portal hypertensive gastropathy. Finally, up to 5% of all UGIB cases are caused by rare and extraordinary rare sources[1-5].

Despite marked advances in its diagnosis and treatment, UGIB is still associated with high morbidity and mortality. Indeed, the overall mortality rate is approximately 8%-10% in *de novo* UGIB hospitalizations[5,6], increasing up to 40% in high-risk patients[7]. In accordance to current international guidelines, esophagogastroduodenoscopy (EGD) is recommended as the procedure of choice for both diagnosis and treatment of NVUGIB, with transcatheter angiographic embolization (TAE) or surgery only in case of refractory bleeding[8-12]. However, merely NVUGIB due to PUD is largely addressed by current guidelines. Conversely, rare and extraordinary rare NVUGIB causes very often require a dedicated, multidisciplinary approach, in order to provide prompt diagnosis and effective treatment[13-16]. The aim of our review was to summarize and discuss the current evidence with regard to most relevant rare and extraordinary rare causes of NVUGIB, in order to enrich the gastroenterologists and all involved physicians' knowledge of the etiology of NVUGB and to broaden their judgment in its management.

RARE CAUSES OF NVUGIB

Aorto-enteric fistula

First described by Cooper[17], aorto-enteric fistulas (AEF) are rare though life-threatening pathological communications between the aorta and the wall of an adjacent segment of the gastrointestinal (GI) tract. Pathogenesis is still not fully understood, most likely encompassing a combination of infection, aortic and GI wall degeneration, and chronic mechanical pulsatile trauma, finally resulting in erosion and fistula creation[18]. AEF are traditionally classified as either primary (PAEF) or secondary (SAEF). PAEF arise from the native aorta, in the setting most commonly of aortic aneurysm or less frequently of infection, malignancy, foreign bodies, radiation, trauma or inflammation[19]. Conversely, SAEF generally develop as late complication of either surgical or endovascular aortic reconstruction[20]. SAEF are much more common than PAEF, with a reported incidence of 0.3%-1.6% in patients after aortic reconstruction[21] and 0.02%-0.07% among general population[22], respectively. Reported mortality is still extremely high, even with prompt diagnosis and treatment[20].

The most frequent involved site is the duodenum (62%), followed by the jejunum and ileum (12%), and the colon (5%). Aorto-esophageal and aorto-gastric fistula are only rarely encountered[18,20]. The classic triad of NVUGIB, abdominal pain, and pulsatile abdominal mass was initially described by Cooper[17]. However, it is currently believed that the combination of all 3 facets of the triad tends to occur infrequently[19]. The most common clinical presentation of AEF is NVUGIB, with or without sepsis[18]. AEF patients often present with a ''sentinel or herald bleed'', in which self-limited episodes of bleeding are followed by the recurrence of massive exsanguinous hemorrhage hours or even to days later[23].

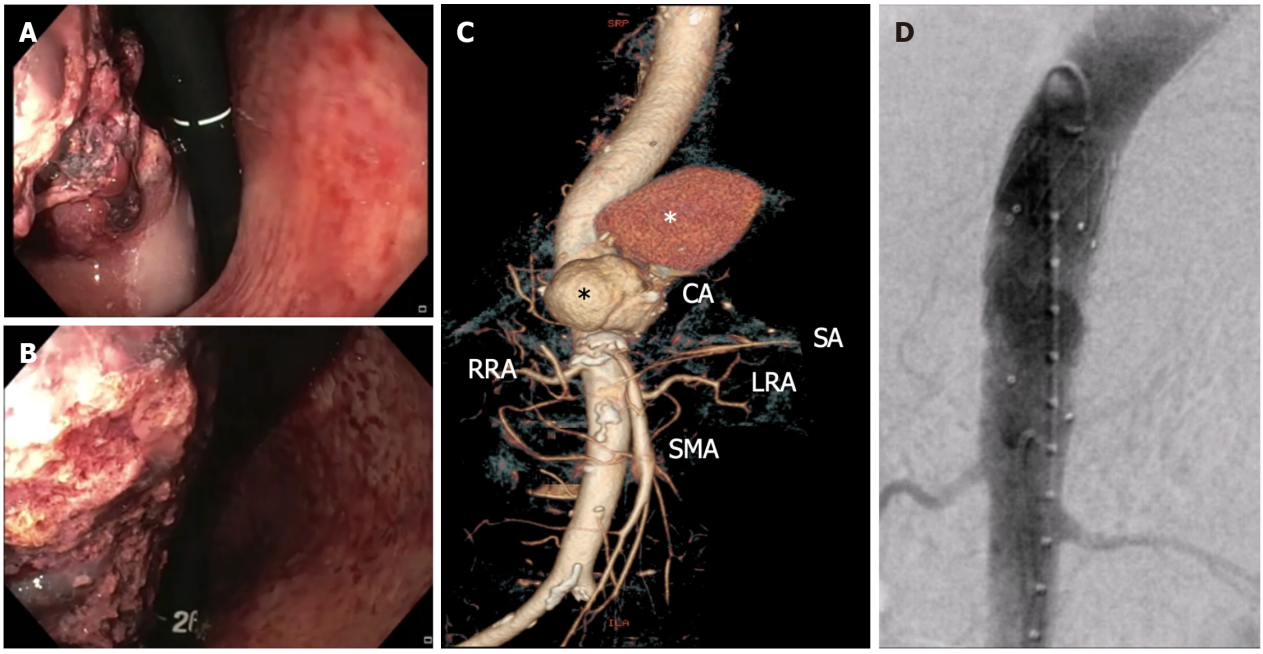
Multidetector computed tomography angiography (MDCTA) is the diagnostic modality of choice for AEF[18,24,25]. It has a relatively high sensitivity and specificity for the diagnosis of AEF, approximately of 94% and 85% respectively[25]. Although pathognomonic of AEF, active contrast medium extravasation from the aorta into the GI lumen is an exceptional MDCTA feature usually seen with ongoing exsanguination. MDCTA findings of AEF include para-aortic or intra-aortic foci of gas, loss of the fat plane between the aorta and the GI wall, and disruption of aortic wall or pseudoaneurysm. Moreover, MDCTA signs of SAEF encounter perigraft gas persisting more than 4 wk following repair of ruptured abdominal aortic aneurysm (AAA) and perigraft fluid and edema persisting more than 3 mo after elective AAA repair[24-26]. Although EGD is the first line diagnostic modality in acute NVUGIB, its usefulness in the setting of AEF is limited. AEF may occasionally be suspected by means of EGD, with endoscopic findings suggestive of AEF including visible graft, bleeding, adherent clot, GI wall defect, ulcer/erosion or pulsatile mass[27-29]. However, the experience of the GI endoscopist, a high index of suspicion and the careful exploration of the distal duodenum, are key factors to properly endoscopically identify AEF. Furthermore, given EGD may disturb the clot which had been preventing exsanguinous bleeding from the AEF, it should be performed in the operating theater and its adoption limited to hemodynamically stable patients, with other imaging suggestive of an occult AEF[18]. Among patients admitted with massive NVUGIB and with an history and a clinical presentation suggestive for AEF, emergent MDCTA should be performed as the first-line diagnostic modality.

Treatment of AEF includes either an open surgical or an endovascular approach[30]. Surgery aims to maintain perfusion while extirpating the infection and restoring GI patency. Strategies to maintain perfusion are grouped into *in situ* aortic reconstruction and extra-anatomic bypass with aortic ligation[18]. Conversely, the most commonly used endovascular technique is stent-graft repair[18,25]. Being associated with lower perioperative mortality rate as compared with open surgery, it is frequently adopted as the first-line treatment modality for AEF[20]. Moreover, endovascular balloon occlusion may be used to gain rapid control of the aortic bleeding source in hemodynamically unstable patients. Similarly, coil and plug embolization might be used as a temporizing measure to stop bleeding[18,25]. Of note, surgical and endovascular management of AEF could be integrated in a complementary approach, by the adoption of endovascular treatment as a bridge to open repair[31].

Finally, endoscopic treatment mainly as a part of multidisciplinary approach or as a bridge to definitive therapy has been anecdotally reported. The adopted endoscopic techniques mostly included clips, fully covered self-expanding metal stents, plastic stents and injection therapy[32-35]. However, evidence regarding the role of endoscopic treatment is scarce and it may not be currently recommended. Worth pointing out, especially in the absence of active bleeding (*i.e.*, adherent blood clot), the authors discourage any attempt of endoscopic hemostasis for AEF. Given the recent advent of endoscopic devices capable to realize full-thickness GI defect closure, such as endoscopic suturing systems and over-the-scope clips (OTSC), in the next future endoscopy might probably play a crucial role for the mini-invasive closure of the GI defect after endovascular aortic repair[36]. A case of AEF is shown in Figure 1.

Ruptured visceral artery aneurysms

First reported in 1809 by Wilson[37], ruptured visceral artery aneurysms (VAA) are a rare but potentially lethal cause of acute NVUGIB. Histopathologically, VAA are broadly divided into true aneurysms (TVAA) and pseudoaneurysms (VAPA). TVAA are defined as focal arterial dilatations greater than 1.5 times the diameter of the original vessel involving all 3 layers of the arterial wall, whereas VAPA, also termed false aneurysms, result from a tear in the vessel wall with extravasated blood contained by only 1 or 2 arterial wall layers[38,39]. The main cause of TVAA is atherosclerosis, followed by fibromuscular dysplasia, connective tissue diseases, inflammatory conditions, and other rare inherited illnesses. Conversely, VAPA may be secondary to trauma, inflammatory conditions such as pancreatitis, cholecystitis, and ulcer, infection, or iatrogenic injury, including surgical, endoscopic and interventional radiological procedures. To be noted, the leading cause of VAPA is chronic pancreatitis (CP). Indeed, more than half of VAPA are secondary to pancreatitis and pseudocyst formation, with up to 17% of CP patients developing VAPA[38,39].



Their reported incidence is approximately 0.1%-2%[38-40]. However, because of the widespread use of advanced imaging techniques and increased aging population, VAA are being incidentally diagnosed with increased frequency [41]. Depending on size, location, and associated clinical conditions (*i.e.*, pregnancy), VAA rupture may be associated with a 20%-80% mortality rate[42].

The splenic artery (SA) is the most common site of VAA, followed by the hepatic artery (HA), accounting for nearly 60% and 20% of cases, respectively. Less common sites include in decreasing order of frequency superior mesenteric (SMA) and coeliac arteries (CA). The gastric or gastroepiploic, jejunal-ileal-colic, pancreaticoduodenal (PDA), gastroduodenal (GDA), and inferior mesenteric arteries are rarely involved[39,43].

The natural history of VAA and their potential for rupture or other complications are relatively poorly defined because of their overall scarcity. However, depending on location, size, etiology, subtype, and associated clinical conditions (*i.e.*, pregnancy), the reported risk of rupture ranges widely from 2% up to 80%[42]. Furthermore, pseudoaneurysms, CA, SMA, gastric and gastroepiploic, GDA, PDA and colic aneurysms are associated with a significantly higher risk of rupture regardless of size, requiring prompt treatment upon diagnosis[41,44].

Rupture of VAA occurs more frequently within the GI tract, manifesting with life-threatening NVUGIB, or into the peritoneal cavity. Rupture may less commonly occur into the retroperitoneal space. Finally, rupture within the hepatobiliary tract or the pancreatic duct may be rarely observed, causing hemobilia or hemosuccus pacreaticus (HP), respectively[39,43].

MDCTA is currently regarded as the diagnostic tool of choice, providing accurate vascular anatomy characterization and interventional planning. Indeed, it is frequently regarded as the "new" gold-standard, alongside with angiography [39]. Rupture is seen as an extravasation of contrast medium which is not contained within a round structure and often flows away from the point of injury. On delayed images, there will be washout of the aneurysm, whereas extravasation

will persist[39]. Given the common presentation with NVUGIB, patients with ruptured VAA may undergo EGD if hemodynamically stable. However, the role of EGD in this setting is limited, mainly directed to exclude more common sources of NVUGIB. GI rupture of VAA may occasionally be suspected by means of EGD, with unspecific reported endoscopic findings mainly encountering gastric or duodenal ulcer/erosion with or without adherent clot, submucosal bulging mass and visible vessel[45,46]. However, a highly experienced GI endoscopist along with a high index of suspicion are necessary to suspect GI rupture of VAA. Furthermore, a detailed medical history focusing on well known risk factors for VAA development and rupture, including pancreatitis and its local complications, atherosclerosis, and recent traumatic or iatrogenic injury, such as percutaneous or endoscopic ultrasound (EUS)-guided procedures, is crucial in the diagnostic process of ruptured VAA within the GI tract.

Being associated with lower perioperative morbidity and mortality than open surgery, emergent endovascular treatment, most commonly by means of coil embolization, is currently recommended as the first-line interventional modality for ruptured VAA. Conversely, open surgery is nowadays generally reserved in case of anatomically unfeasible or failed EVT[41,44]. To date, endoscopy plays no role in the treatment of ruptured VAA. Endoscopic cyanoacrilate or epinephrine injection has been anecdotally reported[45,46]. However, we do not recommend endoscopic hemostasis attempt when GI VAA rupture is suspected or diagnosed, especially in the absence of active bleeding during endoscopic examination. Finally, EUS-guided embolization by the use of thrombin or glue injection, alone or in combination with coil deployment, has been successfully reported for the treatment of VAPA[47-49]. Although evidence is currently lacking, with growing experience, EUS-guided obliteration could represent a minimally-invasive and fashionable alternative to an endovascular approach for the treatment of selected ruptured VAPA among referral centers[50]. A case of rupture of VAA into the GI tract is shown in Figure 2.

Gastric submucosal arterial collaterals

First reported by Spriggs[51] in 1984, bleeding gastric submucosal arterial collaterals (GSAC) are an extraordinary rare cause of severe NVUGIB, with only few cases reported up to date, including a fatal one[52]. They result from either occlusion or congenital absence of the SA, being not related to portal hypertension. SA occlusion may be congenital, idiopathic, or secondary to various conditions, including surgery, endovascular intervention, trauma and extrinsic compression. In the case of SA occlusion, in order to provide splenic blood supply, extensive collaterals may arise from adjacent proximal patent arteries, such as the pancreatic, left gastric, gastroepiploic, and short gastric arteries, and pass through the gastric wall[53]. GSAC may be clinically asymptomatic or may less frequently present with severe NVUGIB from erosion of GSAC.

Since GSAC appear endoscopically as varicose shaped and tortuous submucosal vessels located at the gastric fundus [52], the differential diagnosis mainly includes type 1 isolated gastric varices (IGV)[54]. Indeed, GSAC have a very similar endoscopic appearance to IGV, being frequently misinterpreted on EGD[52]. However, they are, as opposed to GSAC, secondary to cirrhotic portal hypertension or left-sided portal hypertension[54]. Therefore, given their different management, an accurate differential diagnosis between these two entities is crucial. Indeed, endoscopic cyanoacrylate

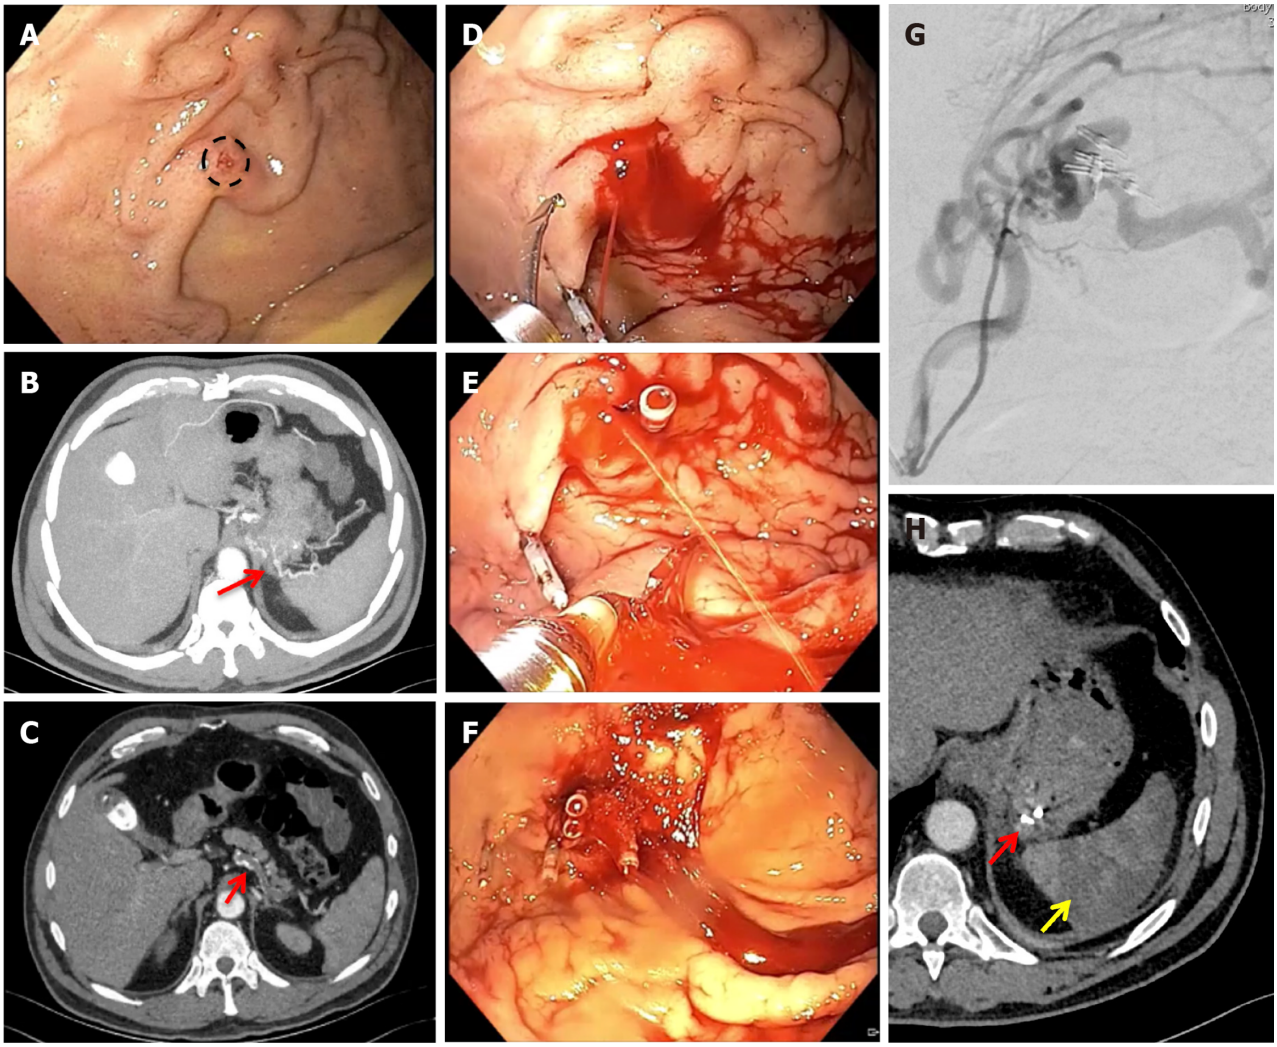
Figure 2 Non-variceal upper gastrointestinal bleeding due rupture of a superior mesenteric artery pseudoaneurysm into the duodenum. A and B: Upper endoscopy showing a bulging, focally ulcerated, lesion in the second-third part of the duodenum, with a suspected small fistulous orifice on its surface (arrow); C and D: Contrast-enhanced computed tomography axial scan in the arterial phase (C) and its maximum intensity projection oblique-coronal reconstruction (D) showing a large lesion (dotted area, C and D) arising from the second-third part of the duodenum, with peripheral vascularity and a pseudoaneurysm (long arrow, C and D) arising from branches of the superior mesenteric artery (short arrow, B); E: Superselective superior mesenteric artery angiography showing a pseudoaneurysm (red dotted circle) fed by the inferior pancreaticoduodenal artery; F: Successful endovascular embolization by the use of cohesive glue (Onyx-18®, Medtronic, Dublin, Ireland) with disappearance of the pseudoaneurysm and visibility of the Onyx-18® cast (red dotted circle).

glue injection (ECGI), currently recommended as the first-line therapeutic option for bleeding IGV[55], may be complicated by systemic embolization and life-threatening adverse events when applicated to an arterial source[56,57]. Conversely, being potentially associated with severe adverse events, endoscopic mechanical hemostasis is currently not recommended for the treatment of IGV[55].



Proper diagnosis is only made by MDCTA and/or digital subtraction angiography (DSA)[52]. Thus, in case of endoscopic evidence of fundal varicose shaped submucosal vessels among UGIB patients without portal hypertension history or clinico-laboratory signs, emergent MDCTA should be performed prior to any endoscopic treatment attempt, if feasible (*i.e.*, absence of active bleeding at the time of EGD).

Definitive treatment is mainly represented by surgical splenectomy and arterial ligation with or without gastrectomy. However, effective treatment by means of endovascular embolization has also been reported. As mentioned before, endoscopic mechanical hemostasis rather than ECGI may be used for the bleeding control among experienced centers, if needed, mainly in a step-up approach[52]. A case of bleeding GSAC is shown in Figure 3.

Dieulafoy's lesions

Dieulafoy's lesion (DL) is a rare cause of acute NVUGIB, accounting for approximately 1.5% of cases, with a tendency to cause severe, life-threatening, recurrent GI bleeding[58,59]. It was originally reported by Gallard[60] in 1884 and subsequently referred to as "exulceratio simplex" in 1898 by the French surgeon Dieulafoy[61], who believed it was the first stage of a gastric ulcer. DL is a vascular abnormality, consisting of a pathologically dilated submucosal caliber-persistent artery, that typically protrudes through a small 2-5 mm mucosal defect and erodes into the GI lumen, in the absence of any abnormality such as ulcers, erosions or aneurysms[58,59]. Similarly to primary AEF, DL bleeding is thought to occur as a result of the mucosal surface disruption due to the persistent mechanical pressure perpetrated by the underlying submucosal ectatic artery[58,59].

The mortality has markedly declined from up to 80% during the pre-endoscopy era to 9%-13% currently with advances in endoscopic hemostasis[58,59]. The most common DL site is by far the stomach, typically the proximal lesser curvature within 6 cm from the gastroesophageal junction[58]. This predilection may be related to the local blood supply. Indeed, the gastric lesser curve is not irrorated by a submucosal plexus, receiving its arterial blood supply directly from the branches of the left and right gastric arteries[62]. Other less common locations include in decreasing order of frequency

DOI: 10.3748/wjg.v29.i27.4222 **Copyright** ©The Author(s) 2023.

Figure 3 Non-variceal upper gastrointestinal bleeding due to gastric submucosal arterial collaterals secondary to splenic artery thrombosis. A: Retroflexed endoscopic view of the gastric fundus showing varicose-shaped submucosal vessels with a small erosion (circle), in the absence of active bleeding; B and C: Pre-operative axial computed tomography arterial phase showing an arterial cluster at the gastric fundus (B: arrow) arising from splenic artery collateral vessels due to splenic artery complete thrombosis (C: arrow); D-F: Successful endoscopic mechanical hemostasis attempt, with intraprocedural spurting active bleeding following first endoclip application (D and E); G: Operative angiography with selective arterial embolization using microspheres; H: Post-operative axial computed tomography arterial phase showing gastric vascular lesion exclusion (red arrow) and splenic infarction (yellow arrow).

the duodenum, the colon, surgical anastomoses, the small bowel, and the esophagus[58].

Given the arterial nature of the bleeding, typical clinical presentation of DL include severe painless NVUGIB, most commonly manifesting with both hematemesis and melena and frequently associated with signs of hemodynamic instability[59]. In the absence of prompt treatment, recurrent bleeding within 72 h after the initial bleed is frequently observed, being commonly more severe. If unidentified and left untreated, DL mortality is extremely high[63].

Endoscopy is the first-line diagnostic modality and is regarded as the gold standard method for the diagnosis of DL[58, 59]. The reported endoscopic criteria for the diagnosis of DL include: (1) Active arterial spurting bleeding from a small (< 3 mm) mucosal defect or through normal mucosa; (2) Protruding vessel, with or without active bleeding, within a small mucosal defect or normal mucosa; or (3) Fresh adherent clot to a minute mucosal defect or to normal-appearing mucosa [64]. However, the reported diagnostic yield of initial EGD is only 70%, and repeat endoscopic examinations may thus be required. Main reasons for diagnostic failure of EGD encounter small lesion size, intermittently active bleeding, DL site between folds or underneath an adherent clot, or presence of a large amount of fresh blood within the gastric cavity[65]. Thus, especially in the setting of non-actively bleeding DL, endoscopic diagnosis may be challenging and a high index of clinical suspicion is required. A meticulous examination especially of the gastric cardia should be performed during EGD. In addition to adequate insufflation, in case of negative EGD, the execution of a provocative endoscopy by the use of water-jet irrigation to target wash as much of the gastric cardia as possible, particularly along the lesser curvature, has been suggested in order to disrupt a fibrin plug and provoke active bleeding from an underlying DL[15]. Of interest, in the setting of non-active bleeding, EUS may be useful to confirm the diagnosis of DL, being capable to clearly depict the pathological submucosal vessel penetrating the muscularis propria[66].

Further diagnostic modalities include MDCTA and DSA. MDCTA findings encounter abnormally enlarged submucosal vessel, which may appear tortuous, linear or as a non-specific "blush" of contrast medium at the mucosal/submucosal level[14]. However, diagnosis of DL by the use of MDCTA is usually challenging, and requires highly experienced radiologists. Conversely, angiographically, DL appears as a non-tapering, tortuous vessels in the arterial phase with no early venous return, with or without contrast medium extravasation within the GI tract[67].

Treatment is recommended for virtually all identified DL, even in the absence of recent bleeding stigmata. Dual combination endoscopic therapy with epinephrine injection followed by mechanical or thermal contact hemostasis is recommended as the first-line treatment modality for DL, being effective in more than 90% of cases. Although requiring higher endoscopic skill and experience, especially if performed in a gastric retroflexion position as frequently needed, mechanical therapy by means of band ligation or endoclip placement is currently favored over thermal hemostasis[59]. Moreover, given the risk of perforation, especially in GI tracts with thin walls such as the gastric fundus, and the risk of bands drop off with rebleeding, endoscopic band ligation may be less desirable than endoscopic clipping, especially in inexperienced hands[59,68]. Finally, mechanical hemostasis by means of OTSC has been successfully reported with good outcomes, not only for refractory cases[69,70].

If feasible (*i.e.*, absence of active bleeding), the so called acoustic Doppler mapping technique, by the use of a through-the-scope endoscopic Doppler ultrasound (DopUS) probe to delineate the subsurface route and path of the pathologically large-caliber artery, may be performed prior to endoscopic treatment, in order to treat the entire length of the superficially located artery, thus maximizing its efficacy. Furthermore, following endoscopic hemostasis achievement, the DopUS may be used to show the blood flow cessation, thus proving the successful eradication of the lesion[71].

Worth mentioning, endoscopic tattooing of the DL site should also be performed, in order to facilitate endoscopic or surgical localization in case of rebleeding occurrence[58,59]. Intriguingly, various EUS-guided treatments have been reported with good outcomes among case reports and small case series, mainly in the setting of DL refractory to standard endoscopic hemostasis. As previously mentioned, despite standard endoscopic treatment, complete ablation of a DL may be accurately evaluated at the end of treatment by Doppler EUS showing the absence of blood flow in the targeted vessel. However, up to date, evidence is still anecdotal and their adoption should be limited to referral centers in a research context[72]. TAE represents a useful second-line treatment modality, whereas surgical wedge resection has currently become the last resort for uncontrolled or unidentified DL bleeding[58,59]. A case of DL is shown in Figure 4.

Cameron lesions

Initially reported by Truesdale[73] in 1924 and subsequently extensively illustrated by Cameron[74] in 1976, Cameron lesions (CL) refer to linear gastric erosions or ulcerations located on the mucosal folds at the distal neck of a hiatal hernia (HH), in close proximity to the diaphragmatic impression. CL are thought to occur as a result of mechanical trauma and local ischemia, secondary to repetitive movement of the hernia sac against the diaphragm during respiratory excursions, and acid injury[75]. Their estimated prevalence is between 3% and 5% in the presence of a HH, reaching up to 10%-20% among patients with large HH (> 5 cm)[76-78]. Moreover, they have been reported to be the source of overt UGIB in 0.2% of cases[79].

Although commonly incidentally diagnosed during EGD, CL may clinically present with either acute or chronic NVUGIB[75,80]. EGD is considered the gold standard for the diagnosis of CL. However, they may often be missed at the index EGD[81,82]. Meticulous endoscopic evaluation of the HH neck and sac, especially in a retroflexed view, is thus required.

Although technically demanding, due to CL anatomical location requiring a retroflexed position and the movement of the HH sac with respiration, endoscopic hemostasis is indicated in case of active bleeding, visible vessel or adherent clot, similarly to peptic ulcers. Injection of epinephrine, thermal contact therapy, clipping and band ligation may be adopted [14,83,13]. However, because of the thin wall and the lack of fibrous support tissue in the gastroesophageal junction, caution is needed when attempting endoscopic therapy, given the potential risk of deep ulcer or perforation[15,75]. Finally, a surgical approach with laparoscopic or open fundoplication should be considered in patients with refractory or recurrent CL bleeding[75,80]. A case of CL is shown in Figure 5.

HP

First described in 1931 by Lower and Farrell[84], HP is an exceptionally rare cause of potentially fatal NVUGIB, with a reported incidence of about one in 1500 cases[85]. Also referred to as pseudohemobilia or wirsungorrhagia, the term HP was coined in 1970 by Sandblom[86]. It is defined as bleeding within the pancreatic duct exteriorizing through the major duodenal papilla. Of note, hemorrhage can also occur *via* the minor duodenal papilla, also known as santorinirrhage, in case of pancreas divisum. The reported mortality rate of HP is high, reaching up to approximately 10%[85]. If untreated, the mortality rate may increase up to 90%[87].

HP is commonly observed among patients with an history of pancreatic diseases, mainly including acute or CP and less frequently pancreatic neoplasms[87]. The most common cause of HP is ruptured VAPA[87]. Indeed, VAPA formation and rupture in the setting of pancreatitis, are thought to be secondary to local leakage of proteolytic enzymes with destruction of the arterial wall. Alternatively, they may also result from erosion of nearby pseudocysts or walled-off necrosis into adjacent arteries[88]. Given its close anatomical relationship with the pancreas, SA is the most common involved site of pseudoaneurysm, followed by the GDA, the PDA, and the HA[87]. Less common causes of HP include pancreatic neoplasms, pseudocysts, pancreas divisum, vascular malformations, TVAA, and traumatic or iatrogenic injuries, including endoscopic retrograde cholangiopancreatography (ERCP) and EUS interventional procedures[87,88].

The classical Sandblom's triad of clinical presentation associated with HP consists of abdominal pain radiating to the back, intermittent UGIB manifesting as melena, hematemesis, and rarely, hematochezia, and hyperamylasemia[86]. Pain is secondary to transient increase in intraductal pancreatic pressure due pancreatic duct obstruction from blood clot. It is

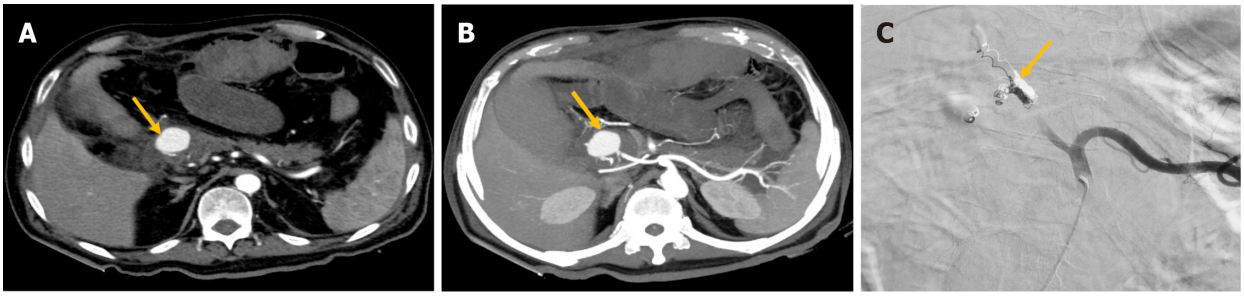
alleviated following bleeding episodes, due to clots clearance. Icterus from retrograde biliary obstruction may also occur [88].

Diagnosis of HP is challenging, requiring a multidisciplinary and integrative approach. Given the hidden and intermittent nature of the bleeding and its anatomical location, EGD was reported to be able to direct visualize active bleeding *via* the major duodenal papilla in only about 30%-75% of cases[87,88]. Suspicion for HP should be increased by indirect signs of bleeding, including clots within the duodenum in the absence of an alternative explanation. Furthermore, when HP is suspected, repeated endoscopy and the adjunct of a duodenoscope to properly visualize the major papilla are often necessary to establish the diagnosis[87,88].

ERCP may highlight filling defects within the pancreatic ducts, favoring the diagnosis. However, being associated with potential bleeding worsening and pancreatic duct disruption, and having a limited therapeutic role especially in the setting of ruptured VAPA, ERCP is generally not recommended for the diagnosis and treatment of HP[15,89].



Intriguingly, EUS has been shown to be a promising tool in the diagnosis of HP, being capable to clearly depict bleeding within the pancreatic duct and its underlying cause[90,91]. Among experienced centers, EUS could be performed immediately after EGD in suspected cases, in order to provide prompt diagnosis and treatment.

MDCTA represents a very useful diagnostic tool for HP, providing characterization of the local anatomy, detection of bleeding within the pancreatic duct and its underlying etiology, thus effectively guiding further management in most of cases[15,87,88]. On pre-contrast MDCTA, the characteristic feature of clotted blood within the pancreatic duct, known as the sentinel clot sign, may also be observed. However, the diagnostic gold standard for HP is currently represented by DSA[87,88].

Percutaneous endovascular treatment, mainly by means of TAE, is currently recommended as the first choice of treatment for HP, with surgery being reserved for patients with persistent hemodynamic instability and unsuccessful embolization[89]. Although therapeutic ECRP with pancreatic multistenting has been successfully reported for the tamponade of a iatrogenic post-ERCP case of HP, its adoption may not be recommended, especially in the setting of ruptured VAPA[92]. Finally, the promising role of EUS-guided embolization in the treatment of VAPA has been previously discussed. A case of HP is shown in Figure 6.

Hemobilia

First described in 1654 by Glisson[93] on autopsy, hemobilia is defined as bleeding into the intra- or extra-hepatic biliary system exteriorizing *via* the major duodenal papilla. It occurs as a result of a fistula formation between a splanchnic blood

DOI: 10.3748/wjg.v29.i27.4222 **Copyright** ©The Author(s) 2023.

Figure 6 Non-variceal upper gastrointestinal bleeding due to hemosuccus pancreaticus. vessel and the biliary system. Arterial vessels are more commonly involved, due to their higher intravascular pressure. However, biliary venous fistulas have also been reported, especially in the setting of portal hypertension[94].

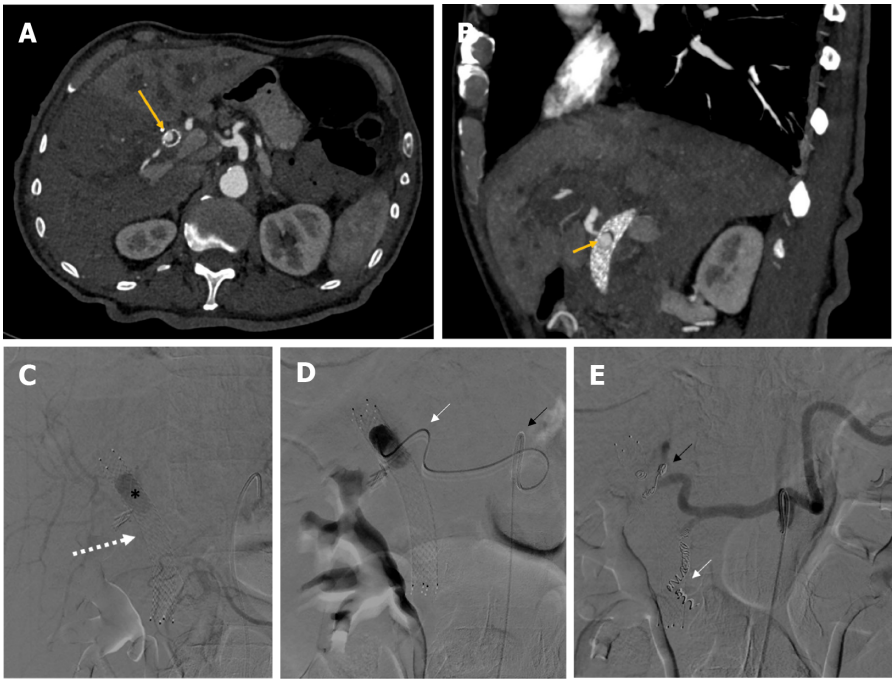
Due to their increased adoption, the most common reported etiology of hemobilia is currently represented by iatrogenic causes involving hepatopancreatobiliary (HPB) manipulation, including percutaneous radiological interventions, ERCP, interventional EUS, and HPB surgery. In these situations, hemobilia may be secondary to traumatic arteriobiliary fistula formation or less frequently to rupture of a HA, or rarely cistyc artery, pseudoaneurysm. Less common etiologies include traumatogenic causes, HPB malignancies, portal biliopathy, chronic ductal obstruction, inflammatory conditions, such as cholecystitis, gallstone disease, ruptured HA true aneurysms, and intraductal infection[94].

The classic clinical presentation of hemobilia is Quincke's triad, consisting of right upper quadrant pain, jaundice and UGIB[95], but all three findings are simultaneously observed in only 22%-35% of cases[94,96]. The diagnosis of hemobilia may be challenging and a high index of suspicion, mainly based on a patient's clinical presentation and suggestive medical history, is crucial. Furthermore, as with HP, bleeding can be intermittent and difficult to visualize endoscopically, even with the use of a side-viewing endoscope or a forward-viewing endoscope with distal attachment cap[94,96]. ERCP can improve diagnosis by detecting findings suggestive of hemobilia, such as amorphous, tubular, or cast-like filling defects with unexplained dilation of the common or perihilar bile duct[97]. However, it is rarely performed with a solely diagnostic intent. Of note, the use of per oral cholangioscopy has been suggested in the management of unexplained hemobilia[98]. Finally, a promising role of EUS in the diagnosis of hemobilia has been reported. Indeed, EUS was shown to be able to detect aneurysm or pseudoaneurysm in the hepatic vasculature, presence of blood within the gallbladder and common bile duct, presenting as mobile hyperechoic material, and bleeding from intra- and para-choledochal varices in portal biliopathy[99-102].

In hemodynamically stable patients with suspected major hemobilia, MDCTA should be performed in order to rule out vascular complications, such as HA aneurysms, pseudoaneurysms and cholangiovenous or arterio-ductal fistulas, and thus guiding further management[94,96].



The aim of treatment consists of both hemorrhage control and maintenance of biliary patency. In the absence of vascular complications detected by MDCTA, ERCP is commonly the initial therapeutic procedure of choice, being able to provide simultaneous management of both bleeding and biliary obstruction[94,96]. Several endoscopic hemostatic techniques have been reported, varying according to etiology, location, and source of hemobilia. In case of post-sphincterotomy hemobilia, which typically is a result of injury to the posterior branch of the superior PDA, or distal hemobilia, hemostasis may be achieved by epinephrine spraying or injection, monopolar or bipolar coagulation, fibrin sealant injection, clipping, balloon tamponade, and stenting. Conversely, biliary stenting is the preferred option for proximal hemobilia[94,96]. In selected cases, biliary stents are capable to achieve immediate hemostasis, by creating a tamponade effect on the biliary wall, while maintaining luminal patency and thus bile flow. Of note, as compared with plastic stents, fully covered self-expanding metallic stents appear to have superior tamponade effect and greater patency, and should be favored in this setting[103-105]. Finally, ERCP may provide bile flow restoration, by directly extracting intraductal blood clots and/or by biliary stenting, thus preventing complications related to biliary obstruction[94,96].

In case of vascular complications, refractory hemodynamic instability, or endoscopic treatment failure, interventional radiology is recommended[94,96]. TAE is the most widely adopted technique. However, it is contraindicated in liver transplant recipients, portal vein thrombosis, and cirrhosis with concomitant shock, due to compromised collateral blood flow from the portal vein and the consequent risk of severe hepatic ischemia. In this setting, arterial stenting should be preferred[106].

Intriguingly, EUS-guided obliteration has been recently successfully reported also in the setting of hemobilia due to cystic artery pseudoaneurysm[107]. Surgery is typically reserved as a last resort, due to its high morbidity and mortality rate[94,96]. A case of hemobilia is shown in Figure 7.

CONCLUSION

Upper GI endoscopy is currently recommended as the gold standard modality for both diagnosis and treatment of

DOI: 10.3748/wjg.v29.i27.4222 **Copyright** ©The Author(s) 2023.

Figure 7 Non-variceal upper gastrointestinal bleeding due to hemobilia. NVUGIB. However, NVUGIB due to PUD only is mainly addressed by current international guidelines, whereas rare causes of NVUGIB are not covered due to their scarcity. In these instances, EGD may often not represent the gold standard for the diagnosis and may not have any role in their treatment. Conversely, a multidisciplinary approach involving not only the GI endoscopists, but also the diagnostic and the interventional radiologists, and the general and the vascular surgeons, is in most cases needed for both diagnosis and treatment. Nevertheless, EGD is inevitably the most frequently first diagnostic modality performed or requested even in NVUGIB due to rare causes. Thus, the GI endoscopists are commonly the main actors in driving further diagnostic and therapeutic process, rising the suspect of rare NVUGIB causes when appropriated. In this setting, the diagnostic role of EGD is commonly limited, mainly directed to exclude common causes of NVUGIB, whereas the diagnostic gold standard is frequently represented by MDCTA and/or DSA.

Worth mentioning, NVUGIB due to rare causes are generally associated with morbidity and mortality significantly higher as compared with those secondary to common sources. Moreover, given any delay in proper diagnosis and/or treatment is inevitably associated with increased mortality, a prompt and effective management is crucial. Thus, not only the gastroenterologists, frequently the first actors involved in the management of NVUGIB due to both common and uncommon causes, should be aware and very confident with rare NVUGIB causes, but also the diagnostic and the interventional radiologists, and the general and the vascular surgeons.

Finally, a multidisciplinary, patient-tailored, and minimally-invasive, when feasible, approach should be pursued for the management of most of the rare NVUGIB causes. Given their complexity, often requiring a strict cooperation between different specialists, rare and extraordinary rare causes of NVUGIB should be desirably managed among highly-experienced referral centers.

Abstract

Decreased muscle mass and function, also known as sarcopenia, is common in patients with cirrhosis and is associated with a poor prognosis. Although the pathogenesis of this disorder has not been fully elucidated, a disordered gut-muscle axis probably plays an important role. Decreased barrier function of the gut and liver, gut dysbiosis, and small intestinal bacterial overgrowth (SIBO) can lead to increased blood levels of ammonia, lipopolysaccharides, pro-inflammatory mediators, and myostatin. These factors have complex negative effects on muscle mass and function. Drug interventions that target the gut microbiota (long-term use of rifaximin, lactulose, lactitol, or probiotics) positively affect most links of the compromised gut-muscle axis in patients with cirrhosis by decreasing the levels of hyperammonemia, bacterial translocation, and systemic inflammation and correcting gut dysbiosis and SIBO. However, although these drugs are promising, they have not yet been investigated in randomized controlled trials specifically for the treatment and prevention of sarcopenia in patients with cirrhosis. No data exist on the effects of fecal transplantation on most links of gut-muscle axis in cirrhosis; however, the results of animal experimental studies are promising.

INTRODUCTION

Sarcopenia is defined as the loss of muscle mass, strength, and physical function[1]. Sarcopenia has been detected in 14%-55% of patients with cirrhosis[2-6] and attracts the attention of researchers increasingly[7-10]. Sarcopenia was found in 68.5% of patients with cirrhosis who were admitted to the intensive care unit[11]. Recent studies have shown that sarcopenia in patients with cirrhosis is associated with poor short- and long-term prognoses[3,6,11,12]. The decrease in muscle mass in patients with cirrhosis over a year also has an unfavorable prognostic value[13]. A recent meta-analysis of 22 studies confirmed that sarcopenia is an independent predictor of increased mortality in patients with cirrhosis[14].

Sarcopenia in patients with cirrhosis is associated with a decrease in the quality of life[15], increased hepatic venous pressure gradient[12], portal hypertension-related complications (ascites and upper gastrointestinal varices), infections (urinary tract infection and spontaneous peritonitis), hepatic encephalopathy, increased risk of hepatocellular carcinoma, longer hospital stay, higher 30-d readmission rate, lower body mass index and serum albumin levels, longer prothrombin time, higher total bilirubin concentrations, and higher Child-Pugh score[16-20]. In addition, patients with cirrhosis have an increased amount of fat in the muscles (myosteatosis), which is also an unfavorable prognostic factor[21].

The exact mechanisms underlying the development of sarcopenia in patients with cirrhosis have not yet been established. Among the factors contributing to the development of sarcopenia in cirrhosis, are disorders of the metabolic function of the liver, decreased appetite[22], increased muscle autophagy[2], increased serum myostatin (a protein that blocks muscle growth)[6], catabolic effects of systemic inflammation induced by bacterial translocation from the gut[23-24], and low testosterone levels[25] were found.

GUT-MUSCLE AXIS IN CIRRHOSIS

Gut dysbiosis in patients with cirrhosis

Cirrhosis is associated with a disturbed composition of the gut microbiota, or dysbiosis[26-29]. Despite some inconsistencies, most studies have shown that in patients with cirrhosis, there was an abundance of harmful bacteria of taxa Bacilli, Streptococcaceae, Enterococcaceae, Proteobacteria, and Enterobacteriaceae, and there was a decrease in beneficial gram-positive bacteria of families Ruminococcaceae and Lachnospiraceae[30-42]. The harmful bacteria are facultative anaerobes; therefore, they can survive in oxygenated tissues, penetrate them, and spread throughout the body. This process was termed bacterial translocation and is believed to be an important contributor to the progression of cirrhosis, including the development of a systemic inflammatory response[26-29]. In addition, harmful Enterobacteriaceae of the phylum Proteobacteria, which are abundant in the gut microbiota of patients with cirrhosis, have an active endotoxin [lipopolysaccharide (LPS)]. Since cirrhosis increases the permeability of the intestinal barrier[43-46], LPS can penetrate the body (molecular bacterial translocation), leading to a systemic inflammatory response. The production of short-chain fatty acids (SCFA) by beneficial bacteria also decreases in patients with cirrhosis[30]. These SCFAs are used as a source of energy by intestinal epithelial cells, strengthen the intestinal barrier, and act on specific receptors to regulate human body functions[47]. The metabolism of bile acids, which also affect many human metabolic pathways through their special receptors[48], depends on the gut bacteria and disturbs in cirrhosis[42].

The values of the MELD scale that used to assess the risk of death in patients with cirrhosis are directly correlated with the abundance of harmful gut bacteria from the families Staphylococcaceae, Enterococcaceae, and Enterobacteriaceae, and inversely correlated with the abundance of beneficial bacteria from the families Lachnospiraceae and Ruminococcaceae [36]. Patients with acute-on-chronic liver failure have a lower abundance of beneficial gram-positive bacteria[36]. The Child–Turcotte–Pugh score, used to assess cirrhosis severity, correlates positively with the abundance of Streptococcaceae and negatively with the abundance of Lachnospiraceae[41]. Severe dysbiosis is associated with higher C-reactive protein (CRP) levels, lower serum albumin and cholinesterase levels, and poorer long-term prognosis[40]. The abundance of Lachnospiraceae is negatively correlated with the risk of hospitalization of cirrhosis patients in the intensive care unit

[49]. Abundant Enterobacteriaceae, Enterococcaceae, and Streptococcaceae are associated with hepatic encephalopathy, circulatory failure, and respiratory failure within 30 d of hospitalization of these patients, respectively[49].

Serum LPS levels are positively correlated with the abundance of Enterobacteriaceae and negatively correlated with the abundance of Lachnospiraceae and Ruminococcaceae[36]. Most of the bacterial genetic material found in the blood and ascitic fluid of patients with cirrhosis is from harmful Proteobacteria and Bacilli instead of the beneficial Lachnospiraceae and Ruminococcaceae that are dominant in the gut[50,51]. The serum level of pro-inflammatory cytokine tumor necrosis factor-alpha (TNF-α) is positively correlated with the serum LPS level and the risk of cirrhosis decompensation, spontaneous bacterial peritonitis, and acute-on-chronic liver failure[52].

Therefore, gut dysbiosis in patients with cirrhosis is associated with bacterial translocation, systemic inflammation, decompensation of liver function, and poor short- and long-term prognoses.

Small intestinal bacterial overgrowth in cirrhosis

Small intestinal bacterial overgrowth (SIBO) is an increase in the content of bacteria in the small intestine[53] and has been detected in almost half of patients with cirrhosis[54]. The prevalence of SIBO increases with increasing severity of cirrhosis[54]. Patients with cirrhosis and SIBO have ascites, minimal and overt hepatic encephalopathy, and spontaneous bacterial peritonitis more often than those without SIBO[54-55]. No relationship has been found between SIBO on the one hand and hypocoagulation, alanine aminotransferase, glutamyl transpeptidase activity, white blood cell, platelet counts, hemoglobin, ascitic fluid albumin levels, and esophageal varices on the other hand in cirrhosis[54]. In patients with cirrhosis, SIBO is associated with the presence of bacterial DNA in peripheral blood[56], higher serum LPS[57] and CRP [58] levels, splanchnic vasodilation, and hyperdynamic circulation[58]. Gut microbiota changes in patients with both cirrhosis and SIBO do not correspond to cirrhosis-associated gut dysbiosis. Therefore, gut dysbiosis and SIBO are most likely separate disorders[59] and SIBO is an independent factor associated with bacterial translocation, systemic inflammation, and the development of several complications in cirrhosis.

Gut-muscle axis in cirrhosis

The pathology of the gut microbiota (gut dysbiosis and SIBO) influences the development of sarcopenia (gut-muscle axis) in patients with cirrhosis.

Bacterial translocation-induced systemic inflammation causes protein catabolism and decreases muscle mass. This is evidenced by the association of sarcopenia with biomarkers of bacterial translocation (LPS) and systemic inflammation (TNF-α) in cirrhosis[23-24]. TNF-α reduced the formation of proteins in muscles[60]. The injection of LPS into the bodies of experimental animals had a similar effect[61].

The second mechanism of harmful effect of the gut microbiota disorders on the muscle tissue in cirrhosis is based on the fact that an excess amount of bacteria in SIBO competes with the human body for nutrients that enter the intestine with food. In support of this mechanism, an association was found between SIBO and malnutrition in cirrhosis[62].

A third mechanism linking the pathology of the gut microbiota with sarcopenia in cirrhosis is associated with an increase in the formation of myostatin, a protein that enhances protein catabolism in muscles, and inhibits their growth [63-65]. Serum myostatin levels are elevated in patients with cirrhosis and are correlated with the severity of sarcopenia [6]. Increased myostatin formation in patients with cirrhosis is likely associated with hyperammonemia that led to an increase in the myostatin level as well as a decrease in muscle mass and strength by an NF-κB-mediated mechanism in experimental animals[66]. However, such effects were not observed in mice with knockout of the myostatin gene[66]. The muscles are normally one of the main sources of ammonia in the body. Therefore, through negative feedback, hyperammonemia may reduce muscle mass to reduce the formation of ammonia by muscles. However, in patients with cirrhosis, the main source of ammonia for systemic circulation is the gut microbiota, which catabolize dietary and mucous proteins. Normally, gut microbiota-derived ammonia is neutralized by the liver; however, in patients with cirrhosis, the detoxifying function of the liver is reduced and portocaval shunts work around it, which leads to a dysfunction of this mechanism for regulating the volume of muscle mass[67-70]. In addition, hyperammonemia may lead to the development of sarcopenia in other ways[69], including increased autophagy[71] and inhibition of muscle protein anabolism[72].

The increased serum TNF-α levels are associated with the increased myostatin gene expression and the decreased muscle mass in experimental cirrhosis, suggesting that systemic inflammation can lead to sarcopenia increasing myostatin production among other mechanisms[24].

Several recent studies have reported changes in the composition of the gut microbiota associated with sarcopenia[73-76]. The abundances of Bacteroidaceae, *Eggerthella*, *Escherichia coli*, *Fusobacterium*, Micrococcaceae, *Rothia*, *Veillonella*, *Weissella*, and other bacteria are associated with a decrease in muscle mass, while the abundances of *Acidaminococcus*, *Akkermansia*, *Anaerotruncus*, *Anaerostipes*, *Barnesiellaceae*, *Bifidobacterium catenulatum*, *Catenibacterium*, *Collinsella*, *Coprococcus*, *Coriobacteriaceae*, *Desulfovibrio*, *Dialister*, *Dorea*, *Erysipelatoclostridiaceae*, *Granulicella*, *Intestinimonas*, *Lachnospiraceae*, *Megasphaera*, *Methanobrevibacter*, *Oscillospira*, *Prevotella*, *Ruminococcus flavefaciens*, *Senegalimassilia,* and other bacteria showed an association with normal muscle mass in patients with cirrhosis. The pronounced heterogeneity of these results were obtained that may be caused by different methods used to assess the muscle mass of patients. Patients with sarcopenia had higher serum levels of CRP, TNF-α, interleukin 1-beta, 2 and 6, granulocyte-macrophage-colony-stimulating factor, fibroblast growth factor, and C-X-C motif chemokine ligand 10 than patients without it[73]. Although serum LPS and myostatin levels in this study were higher in patients with sarcopenia than in those without, this increase did not reach the limit of significance[73]. There was no significant difference in zonilin and other cytokines levels and reported manifestations of cirrhosis between patients with and without sarcopenia[73]. Patients with sarcopenia were more likely to have ascites, higher Child-Pugh scores[76], and lower albumin levels[75] than patients with normal muscle mass. No other significant associations were reported in these studies on associations between gut microbiota and muscle mass in cirrhosis.

Disorders of the gut-muscle axis in cirrhosis are shown simplified in Figure 1.

Therefore, it is assumed that the condition of the gut microbiota plays an important role in the development of sarcopenia in patients with cirrhosis and therapy aimed at the gut microbiota (antibiotics, prebiotics, probiotics, and fecal transplantation) may be useful in the treatment and prevention of sarcopenia.

PROSPECTS FOR GUT-MUSCLE AXIS THERAPY IN CIRRHOSIS

Treating gut microbiota in patients with cirrhosis: rifaximin

Rifaximin is a poorly-absorbed antibiotic used against harmful intestinal bacteria. Recent meta-analyses have shown that rifaximin effectively eliminates SIBO[77,78] in patients with irritable bowel syndrome[79-82], cystic fibrosis[83], Crohn's disease[84], diabetes[85], celiac disease[86], acromegaly[87], uncomplicated diverticular disease[88,89], systemic sclerosis [90], rosacea[91], and ulcerative colitis[92]. However, rifaximin was ineffective against SIBO in patients after gastrectomy [93]. The meta-analyses also noted that rifaximin is generally well-tolerated and has a low incidence of side effects[77,78]. Other antibiotics, such as chlortetracycline[94], neomycin, doxycycline, amoxicillin/clavulanate, ciprofloxacin[95], and metronidazole[96] were less effective than rifaximin in eradicating SIBO.

Rifaximin also improved intestinal barrier function (reduced blood levels of diamine oxidase and D-lactic acid), mitigated systemic inflammation (decreased serum CRP level and erythrocyte sedimentation rate)[92], and accelerated orocecal transit[85].

Rifaximin increases the abundance of beneficial bacteria (*Akkermansia*, *Bifidobacterium*, *Faecalibacterium prausnitzii*, and Ruminococcaceae) and decreases the number of harmful ones (Alphaproteobacteria, *Eggerthella, Enterococcus*, and Streptococcaceae) in several studies (Table 1)[79,97-106].

Meta-analyses have shown that rifaximin is effective in the primary and secondary prevention of spontaneous bacterial peritonitis, a clinical manifestation of bacterial translocation in patients with cirrhosis; rifaximin was superior to norfloxacin and other antibiotics in this respect[107-110]. Rifaximin also reduces the risk of mortality and need for liver transplantation in patients with cirrhosis[111]. In addition, it is effective in the management of hepatic encephalopathy, which is associated with hyperammonemic conditions such as sarcopenia, and significantly reduces blood ammonium levels in patients with cirrhosis[111-113]. One study reported that rifaximin eradicated SIBO in 76% of patients with cirrhosis-associated minimal hepatic encephalopathy, and this was associated with a more prominent decrease in blood ammonium levels than in patients with cirrhosis without SIBO that were also treated with rifaximin[114].

Rifaximin decreased the blood LPS levels in cirrhosis[115-121], and this was associated with a decrease in serum ammonia levels[118]. Rifaximin also reduces circulating neutrophil expression of TLR-4, which is the main endotoxin receptor[122]. However, the effects of rifaximin on various biomarkers of systemic inflammation in cirrhosis have been inconsistent across studies.

Importantly, rifaximin does not alter the overall resistome[123]; *i.e.,* their intake does not lead to the development of antibacterial resistance. Rifaximin also reduces the rate of all bacterial infections[124] and variceal bleeding in patients with cirrhosis[125-126], prevents the development of hepatorenal syndrome[127-128] and refractory ascites[129-130]. The use of rifaximin in patients with cirrhosis led to a decrease in the abundance of harmful *Streptococcus*, *Eggerthella*, and *Veillonella* (Table 2)[42,117-120,122,130,131].

Overall, the literature suggests that rifaximin does positive affect the main pathogenetic links of the disordered gut-muscle axis in cirrhosis, in particular SIBO, hyperammonemia, and bacterial translocation. Rifaximin also modulates the composition of the gut microbiota reducing the number of bacterial taxa has been associated with muscle loss in patients with cirrhosis. This drug has shown excellent safety and tolerability for long-term use in patients with cirrhosis[127,132, 133]. It is very important, since the prevention and treatment of sarcopenia require long-term therapy. This suggests that rifaximin may be effective and safe for these purposes in cirrhosis.

Although other antibiotics have also had positive effects on the prevention of spontaneous bacterial peritonitis, hepatic encephalopathy, and the reduction of bacterial translocation and hyperammonemia in patients with cirrhosis[111,134-136], most of them have poorer safety profiles and fewer number of studies. Thereby, recommendations to investigate their long-term effects on the prevention and treatment of sarcopenia in patients with cirrhosis seem premature. However, this does not exclude their potential use when new data on the efficacy and safety of their long-term use become available.

Rifaximin prevents skeletal muscle atrophy and weakness by decreasing intramuscular myostatin and pro-inflammatory cytokine levels in experimental cirrhosis[24,137]. An uncontrolled study showed that the long-term use of rifaximin in patients with cirrhosis improved nutritional status and allowed patients to maintain a constant amount of muscle mass[138]. Randomized placebo-controlled studies on the effects of long-term rifaximin use on muscle mass, serum myostatin, and other biomarkers of gut-muscle axis disorders in cirrhosis are required to verify this data.

Treating gut microbiota in patients with cirrhosis: prebiotic disaccharides lactulose and lactitol

Lactulose and lactitol are artificial disaccharides that are not broken down by human digestive enzymes and are utilized by the intestinal microbiota. These drugs are primarily used as osmotic laxatives for conditions that involve constipation (including irritable bowel syndrome)[139-141]. They also used for the prevention and treatment of hepatic encephalopathy[142,143], because the abundance of these carbohydrates switches the metabolism of gut bacteria from proteolytic to saccharolytic. This leads to a decrease in the formation of ammonium and other neurotropic metabolites of amino acids[144], and their laxative effects accelerate the removal of these harmful products from the intestine.

Table 1 The effect of rifaximin on the composition of the gut microbiota in various diseases

Disease	Taxa that increase in the abundance after rifaximin	Taxa that decrease in the abundance after rifaximin
Alzheimer's disease [97]	Anaerostipes, Blautia, Erysipelotrichaceae, Erysipelatoclostridium, Faecalitalea, Lactobacillus, and *Ruminiclostridum*	
Irritable bowel syndrome[79,98-100]	Acidimicrobiales, *Acidobacteria, Alteromonas, Arthrobacter, Bacillus*, Bacteroidaceae, *Butyricimonas, Chloroflexi, Cytophagia, Coprobacillus, Bifidobacterium, Deinococcales, Devosia, Dyella, Faecalibacterium prausnitzii, Frankiales, Gordonibacter, Holdemania, Kocuria*, Methylophilales, Micrococcales, Micromonosporales, Nitriliruptorales, Parabacteroides, Prevotellaceae, Propionibacteriales, Rhizobiales, Rhodobacterales, Sphingomonadales, and Streptomycetales	Alphaproteobacteria, *Anaerotruncus, Blautia luti, Butyricimonas, Cronobacter, Escherichia, Eubacterium ventriosum, Rhodospirillales, Romboutsia, Roseburia inulinivorans*, Streptococcaceae, and *Tyzzerella*
Symptomatic uncomplicated diverticular disease [101-102]	Akkermansia, Bacteroidaceae, *Citrobacter, Coprococcus, Dialister* Ruminococcaceae, and Veillonellaceae	Anaerotruncus, Anaerostipes, Blautia, Christensenellaceae, Dehalobacteriaceae, *Eggerthella lenta, Haemophilus parainfluenzae*, Mogibacteriaceae, and Pasteurellaceae
Chronic Kidney Disease[103]	-	Anaerotruncus, *Clostridium*, and *Turicibacter*
Gut diseases[104]	Faecalibacterium	Ruminococcus and *Roseburia*
Ulcerative colitis [105]	Bacteroides and *Bifidobacterium*	Enterococcus and *Lactobacillus*
Crohn's disease[106]	Bifidobacterium, Atopobium, and *Faecalibacterium prausnitzii*	

Table 2 The effect of rifaximin on the composition of the gut microbiota in patients with cirrhosis

Ref.	Taxa that increase in the abundance after rifaximin	Taxa that decrease in the abundance after rifaximin
Bajaj *et al*[120]	Eubacteriaceae	Veillonellaceae
Kaji *et al*[117]		Streptococcus, Veillonella
Kaji *et al*[118]		Streptococcus, Veillonella
Kakiyama *et al*[42]		Veillonellaceae
Kawaguchi *et al* [131]		Lactobacillus, Streptococcus, Veillonella
Lv *et al*[130]	Bacteroidetes vulgatus	Bacteroides uniformis, Eggerthella lenta, Haemophilus, Prevotella, Roseburia
Patel *et al*[122]		Akkermansia, Hungatella, Streptococcus, Veillonella
Zeng *et al*[119]	Bacteroidaceae	Veillonellaceae

Meta-analyses have shown that lactulose and lactitol are effective against hepatic encephalopathy and that they reduce blood ammonia levels. They also decrease the risk of other serious liver-related adverse events, such as liver failure, variceal bleeding, hepatorenal syndrome, spontaneous bacterial peritonitis and other serious infections. These drugs also have excellent safety profiles and have been shown to reduce mortality[111,145-148].

Lactulose and lactitol can be safely taken for six months or more[149-151]. However, they may cause steatorrhea, which can worsen the nutritional status of patients[152].

We were unable to find any data on the effects of these disaccharides on SIBO. Two factors should be considered in this case. First, since these drugs are growth factors for bacteria, they can provoke the development of SIBO. However, SIBO can be eliminated by accelerating intestinal motility caused by these drugs. Further research is required to determine which effect outweighs the other.

The intake of lactitol was accompanied by an increase in the abundance of *Bifidobacterium, Lactobacillus, Veillonella, Enterobacter, Sutterella, Haemophilus*, and *Aggregatibacter*, and a decrease in the abundance of *Bacteroides, Clostridium, Eubacterium*, *Klebsiella*, *Pseudoflavonifractor*, and coliform bacteria (Table 3)[153-157]. In addition, there was a decrease in the LPS concentration in the blood of patients with chronic viral hepatitis[158].

The use of lactulose is associated with an increase in the levels of *Bifidobacterium* and *Lactobacillus* and a decrease in the abundance of *Clostridium*, *Eubacterium*, *Enterococcus*, and Enterobacteriaceae in patients with cirrhosis (Table 3)[153,154,159,160]. However, other studies have not shown an effect of lactulose on the composition of gut microbiota[161,162]. Several studies demonstrated that the use of lactulose in patients with minimal hepatic encephalopathy led to a decrease in the blood levels of LPS, bacterial DNA, and pro-inflammatory cytokines (TNF-α, IL-6 and IL-18)[160,163,164].

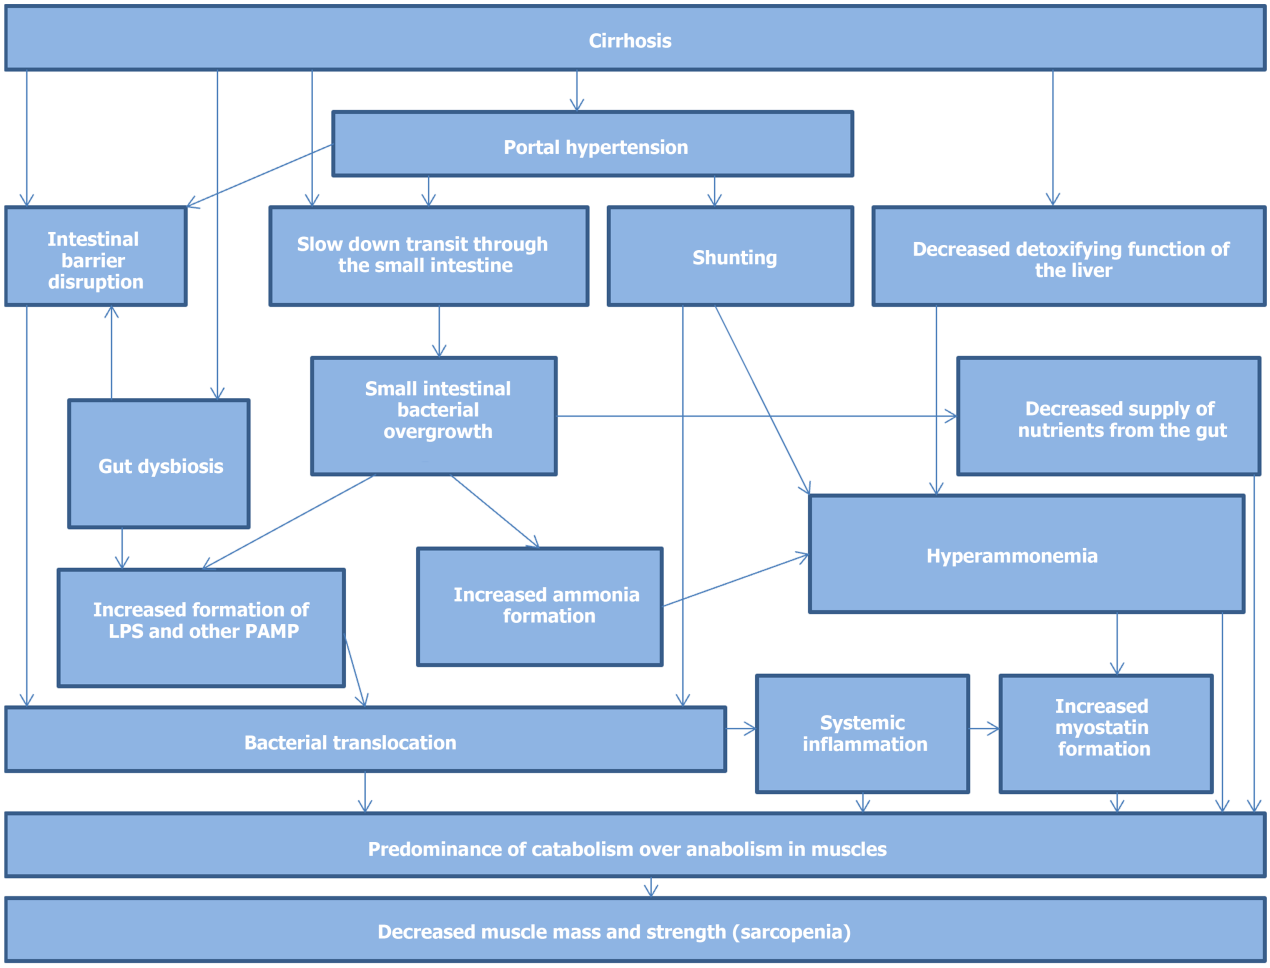
Table 3 The effect of lactitol and lactulose on the composition of the gut microbiota

Ref.	Disease	Taxa that increase in the abundance after disaccharide	Taxa that decrease in the abundance after disaccharide
Lactitol			
Riggio *et al* [153]	Cirrhosis	Lactobacilli	Enterobacteria and Enterocicci
Ballongue *et al*[154]	Healthy persons	Bifidobacterium, *Lactobacillus* and *Streptococcus*	Bacteroides, Clostridium, coliforms, and *Eubacterium*
Li *et al*[155]	Chronic constipation	Actinobacteria, Bifidobacteriales, Bifidobacteriaceae, *Anaerostipes*, and *Bifidobacterium*	-
Tarao *et al* [156]	Cirrhosis	Bifidobacterium and *Lactobacillus*	Bacteroides and *Clostridium*
Lu *et al*[157]	Cirrhosis	Bifidobacterium, Veillonella, Enterobacter, Sutterella, Haemophilus, *Aggregatibacter,* Lactobacillus salivarius, L. fermentium, and L. oris	Klebsiella *Pseudoflavonifractor*, and others
Chen *et al* [158]	Chronic viral hepatitis	Bifidobacterium and *Lactobacillus*	Clostridium perfringens
Lactulose			
Riggio *et al* [153]	Cirrhosis	Lactobacilli	-
Ballongue *et al*[154]	Healthy persons	Bifidobacterium, *Lactobacillus* and *Streptococcus*	Bacteroides, *Clostridium*, coliforms and *Eubacterium*
Ziada *et al* [159]	Minimal hepatic encephalopathy	Bifidobacterium, Lactobacillus, and Bacteroidaceae	Enterobacteriaceae and *Enterococcus*

The use of lactulose and lactitol has also been associated with a decrease in the amount of bacterial proteolysis products such as cresol, skatol, phenol, and indole in the feces, as well as an increase in the amount of lactate in the feces. Lactate can acidify the feces[154] and convert neutral ammonia to ammonium ions which, unlike ammonia, do not pass through the intestinal barrier because of the presence of an electric charge. Thus, these drugs not only decrease the bacterial catabolism of amino acids with the formation of ammonia, but also decrease ammonia absorption from the intestine. These drugs significantly reduce hyperammonemia after an amino acid load[143].

Thereby, these prebiotic disaccharides reduce the severity of the following adverse factors of the disordered gut-muscle axis in cirrhosis: hyperammonemia, bacterial translocation, and systemic inflammation. Most studies have shown positive effects of these drugs on the composition of the gut microbiota. However, their impact on SIBO is yet to be explored. These drugs are considered safe for long-term use. However, their effects on myostatin levels and muscle mass in patients with cirrhosis and other diseases have not been studied.

Treating gut microbiota in patients with cirrhosis: probiotics



Probiotics are live microorganisms that confer health benefits to the host when administered in adequate amounts[165]. They can be used to treat liver diseases[165-166].

Meta-analyses have shown that probiotics are effective in the prevention and treatment of hepatic encephalopathy and that they decrease the blood levels of LPS and ammonia. However, they do not have a significant effect on mortality or the incidence of spontaneous bacterial peritonitis in patients with cirrhosis[111,167-170]. A meta-analysis did not show that probiotics have a significant effect on the serum level of pro-inflammatory cytokines (TNA-alpha and IL-6)[169]. Another meta-analysis revealed that prebiotics do not significantly affect CRP levels, but they lead to a decrease in TNF-α levels[171]. Among the studies not included in these meta-analyses, the following described the effect of probiotics on inflammatory biomarkers in cirrhosis. The probiotic fungus *Saccharomyces boulardii* decreases serum CRP levels and ameliorates hyperdynamic circulation in patients with decompensated cirrhosis[172]. *Escherichia coli* Nissle 1917 reduced the serum levels of IL-6, IL-8, and interferon-γ in patients with hepatic encephalopathy[160]. The probiotics that included *Clostridium butyricum* and *Bifidobacterium infantis* strengthen the intestinal barrier[173].

Probiotics have been shown to be safe when used for six months in patients with cirrhosis[174].

The use of probiotics in cirrhosis leads to an increase in the numbers of *Bifidobacterium*, *Lactobacillus*, Lachnospiraceae, Bacteroidaceae, Clostridiales incertae sedis XIV, *Faecalibacterium prausnitzii*, *Syntrophococcus sucromutans*, *Bacteroidetes vulgatus*, *Prevotella*, *Alistipes shahii*, *Clostridium* cluster I, *Clostridium coccoides*, and *Eubacterium cylindroides* and a decrease in the numbers of Enterobacteriaceae, *Enterococcus*, *Proteus hauseri*, *Citrobacter* sp., and *Morganella* (Table 4)[159,160,175-178].

Meta-analyses have also shown that probiotics effectively eliminate SIBO[179-180]. This has been observed in patients with cirrhosis[181], chronic liver disease[182], secondary lactase deficiency[183], diarrhea-predominant irritable bowel syndrome[184-186], gastric and colorectal cancer[187], systemic sclerosis[188], and bariatric surgery[189].

Figure 1 Simplified diagram of gut-muscle axis disorders in patients with cirrhosis. LPS: Lipopolysaccharide; PAMP: Pathogen-associated molecular patterns.

The meta-analysis showed that probiotics enhance both muscle mass and muscle strength in patients with sarcopenia that was not associated with cirrhosis[190]. The probiotic that included *Akkermansia muciniphila* and *Faecalibacterium prausnitzii* decreased myostatin levels in a mouse model of muscular atrophy[191].

Although probiotics have been shown to be effective against several pathological links of the disturbed gut-muscle axis in patients with cirrhosis (SIBO, gut dysbiosis, hyperammonemia, and bacterial translocation), improve muscle function, and increase muscle mass in sarcopenia of another origin, no study has evaluated the effect of probiotics on muscle mass and function in cirrhosis.

Treating gut microbiota in cirrhosis: fecal transplantation

Fecal transplantation involves the transfer of intestinal microbiota from the donor to the intestine of a recipient. This procedure is effective in hepatic encephalopathy[192-194] and leads to an increase in the abundance of Ruminococcaceae and Bifidobacteriaceae and a decrease in the abundance of Streptococcaceae and Veillonellaceae in patients with cirrhosis [193].

No data exist on the effects of this procedure on the severity of hyperammonemia, bacterial transplantation, systemic inflammation, myostatin levels, muscle mass and strength, or SIBO in patients with cirrhosis. No human studies have been conducted on the effect of fecal transplantation on muscle mass and strength in patients with sarcopenia of any origin; however, the results of animal experimental studies are promising[195].

CONCLUSION

Drug interventions targeting the gut microbiota positively affect most links of the compromised gut-muscle axis in cirrhosis (Table 5, Figure 2). Therefore, they are promising for the treatment and prevention of sarcopenia in cirrhosis, but have not yet been investigated in randomized controlled trials for these purposes. There are no data on the effect of fecal transplantation on most links of the gut-muscle axis and sarcopenia in cirrhosis, but the results of animal experimental studies are promising.

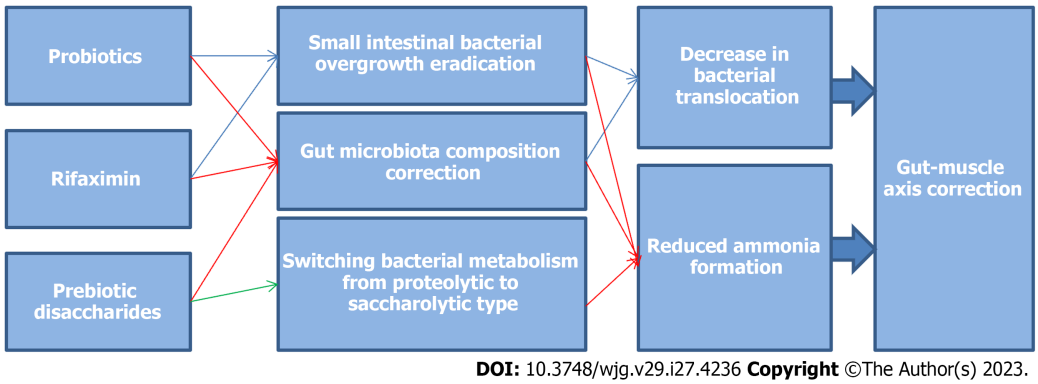

Table 4 The effect of probiotics on the composition of the gut microbiota in cirrhosis

Probiotic	Taxa that increase in the abundance after the probiotic	Taxa that decrease in the abundance after the probiotic
Lactobacillus acidophilus[159]	Bifidobacterium, Lactobacillus, and Bacteroidaceae	Enterobacteriaceae and *Enterococcus*
Escherichia coli Nissle 1917[160]	Bifidobacterium and *Lactobacillus*	Pathogenic enterobacteria
Escherichia coli Nissle 1917[175]	Bifidobacterium and *Lactobacillus*	Proteus hauseri, Citrobacter, and *Morganella*
Yakult 400[176]	Clostridium coccoides and *Eubacterium cylindroides*	Enterobacteriaceae
Lactobacillus GG[177]	Clostridiales Incertae Sedis XIV and Lachnospiracea	Enterobacteriaceae
Bifidobacterium bifidum W23, Bifidobacterium lactis W51, Bifidobacterium lactis W52, Lactobacillus acidophilus W37, Lactobacillus brevis W63, Lactobacillus casei W56, Lactobacillus salivarius W24, Lactococcus lactis W19 and Lactococcus lactis W58[178]	Faecalibacterium prausnitzii, Syntrophococcus sucromutans, Bacteroides vulgatus, Alistipes shahii, and *Prevotella*	

Table 5 Effects of interventions targeting the gut microbiota on pathogenic factors in the gut-muscle axis in cirrhosis

Intervention	SIBO	Gut dysbiosis	Hyperammonemia	Bacterial translocation	Systemic inflammation
Rifaximin	+	+	+	+	CR
Prebiotic disaccharides	ND	+	+	+	+
Probiotics	+	+	+	+	CR
Fecal transplantation	ND	+	ND	ND	ND

+: A positive effect of this drug on this disorder has been reported; SIBO: Small intestinal bacterial overgrowth; CR: Conflicting results, ND: No data.

Abstract

Chronic and recurrent inflammatory disorders of the gastrointestinal tract caused by a complex interplay between genetics and intestinal dysbiosis are called inflammatory bowel disease. As a result of the interaction between the liver and the gut microbiota, bile acids are an atypical class of steroids produced in mammals and traditionally known for their function in food absorption. With the development of genomics and metabolomics, more and more data suggest that the pathophysiological mechanisms of inflammatory bowel disease are regulated by bile acids and their receptors. Bile acids operate as signalling molecules by activating a variety of bile acid receptors that impact intestinal flora, epithelial barrier function, and intestinal immunology. Inflammatory bowel disease can be treated in new ways by using these potential molecules. This paper mainly discusses the increasing function of bile acids and their receptors in inflammatory bowel disease and their prospective therapeutic applications. In addition, we explore bile acid metabolism and the interaction of bile acids and the gut microbiota.

Key Words: Bile acids; Inflammatory bowel disease; Intestinal immunology; Bile acid receptors; Bile acid metabolism; Gut microbiota

INTRODUCTION

Inflammatory bowel disease (IBD) is a group of chronic and recurrent inflammatory diseases of the gastrointestinal tract, including two main subtypes: Ulcerative colitis (UC) and Crohn's disease (CD). Globally, the prevalence of IBD is increasing, especially in newly industrialized countries, with a prevalence of 0.5% in 2010, 0.75% in 2020, and a projected 1% in 2030, increasing the burden on health care systems around the world[1,2]. The etiology and pathogenesis of IBD are not well understood. However, it is generally accepted that IBD is a persistent and excessive immune inflammatory response in people with genetic susceptibility when exposed to environmental factors[3]. Immune homeostasis in the intestine involves the coordinated action of epithelial cells and innate and adaptive immune cells. As a result of impaired intestinal epithelial barrier function in IBD, commensal microorganisms translocate into the intestinal wall. The innate immune cells then take up the microbes and their mediators and respond, which activates immune cells and produces cytokines and chemokines. This process, in turn, upsets the homeostasis of the intestine, recruiting more immune cells to the intestinal wall and activating adaptive immunity[4,5]. IBD usually presents with chronic recurrent abdominal pain, diarrhea, mucus, and bloody stools and can also present with serious complications such as anal fistula, intestinal obstruction, and intestinal perforation[6]. Additionally, IBD patients frequently experience symptoms outside of the digestive system, such as joint, eye, or skin inflammation[7]. With the introduction of new biological and small molecule therapies, such as anti-TNF-α biologic agents, anti-interleukin (IL)-12/23 biologic agents, and anti-integrin biologic agents, significant progress has been made in the pharmacological treatment of IBD, but at a high financial and physical cost to patients. Moreover, these therapies can potentially produce life-threatening side effects and cannot cure IBD, and a significant proportion of patients still require surgical treatment. This underscores the need for new treatment strategies for IBD[8,9].

As a result of the interaction between the liver and gut bacteria, bile acids are a class of atypical steroids produced in mammals. Bile acid receptors are a type of cell membrane and nuclear receptor that is found in several digestive and immune system cells. Bile acids exert the majority of their biological effects by serving as ligands for specific bile acid receptors. In the past, bile acids were widely assumed to aid in intestinal nutrition absorption and biliary transport of lipids, toxic metabolites, and foreign substances. However, it is now well established that bile acids can act as multidirectional signaling metabolites, modulating physiopathological processes associated with a variety of digestive diseases *via* dynamic interactions with germline-encoded host receptors and microbiota[10-12]. In particular, in IBD, bile acids can modulate IBD pathophysiological pathways by acting on several bile acid receptors, including farnesol X receptor (FXR), retinoid-related orphan receptor γt (RORγt), G protein-coupled bile acid receptor 1 (GPABR1), vitamin D receptor (VDR), pregnane X receptor (PXR), constitutive androstane receptor (CAR), and sphingosine-1-phosphate receptor 2 (S1PR2)[13] (Table 1). This review primarily outlines the growing function of bile acids and their receptors in IBD, as well as their prospective therapeutic applications. Furthermore, we explore bile acid metabolism and the interaction of bile acids and microbiota to present fresh perspectives and molecular targets for diagnosing and treating IBD.

BILE ACID METABOLISM

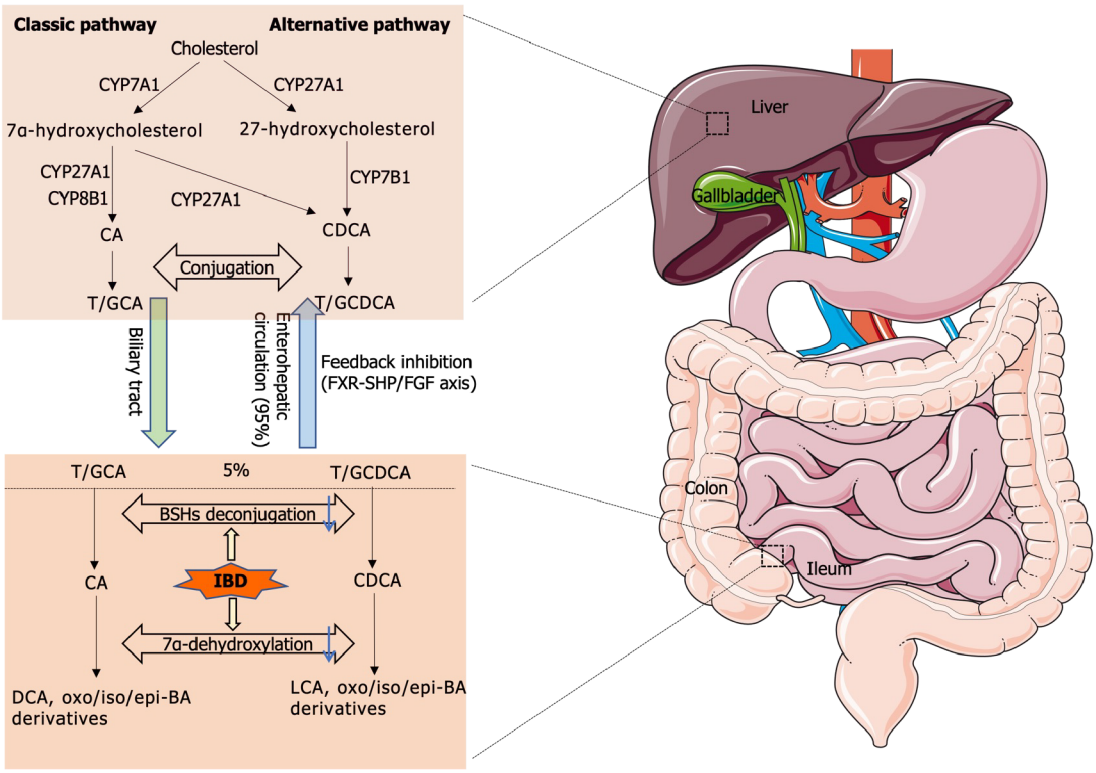
Bile acids are the end product of cholesterol metabolism. Bile acids are composed mainly of cholesterol, and unlike other steroid hormones, bile acids are amphiphilic molecules with a hydrophobic (beta side) and a hydrophilic (alpha side) surface. They have detergent properties due to their amphiphilic nature, which helps to solubilize lipids in micelles, facilitating emulsification and absorption of dietary fatty acids and cholesterol[14,15]. Mammals have two main types of bile acids: Primary bile acids (PBAs) and secondary bile acids (SBAs). PBAs are formed by cholesterol catabolism in hepatocytes, whereas SBAs are derivatives of PBAs and are generated by the gut microbiome. The bile acid pool is maintained in balance by their hepatic synthesis, enterohepatic circulation, and microbial metabolism[16] (Figure 1).

Bile acid metabolism in the liver

In the liver, cholesterol is generated in the central hepatocyte in several steps to produce PBAs of 24 carbons. In humans, cholic acid (CA) and chenodeoxycholic acid (CDCA) are the most prevalent PBAs, while rats create the 6-hydroxylated

Table 1 Nuclear and membrane receptors of bile acids

Bile acid receptor	Abbreviation	Type	Bile acid agonists	Main tissue distribution
Farnesol X receptor	FXR	Nuclear hormone receptor	CDCA > DCA > LCA > CA	Intestinal epithelial cells, hepatocytes
Retinoid-related orphan receptor γt	RORγt	Nuclear hormone receptor	3oxo-LCA, isoLCA	Th17 cells, ILC3 and γδT cells
G protein-coupled bile acid receptor 1	GPBAR1 or TGR5	Membrane-bound receptor	LCA > DCA > CDCA > UDCA > CA	Epithelial cells, immune cells, and intestinal nerves in the gut and biliary tract
Vitamin D receptor	VDR	Nuclear hormone receptor	LCA, 3-oxoLCA, and isoalloLCA	Intestinal epithelial cells
Pregnane X receptor	PXR	Nuclear hormone receptor	CDCA, LCA	Intestinal epithelial cells, hepatocytes
Costitutive androstane receptor	CAR	Nuclear hormone receptor	CDCA, LCA	Hepatocytes
Sphingosine-1-phosphate receptor 2	S1PR2	Membrane-bound receptor	GCA, TCA, GCDCA and TCDCA	Intestinal epithelial cells, hepatocytes



DCA: Deoxycholic acid; LCA: Lithocholic acid; CA: Cholic acid; CDCA: Chenodeoxycholic acid; isoLCA: Isolithocholic acid; isoalloLCA: Isoallolithocholic acid; 3-oxoLCA: 3-oxolithocholic acid; FXR: Farnesoid X receptor; GPABR1: G protein-coupled bile acid receptor 1; PXR: Pregnane X receptor; VDR: Vitamin D receptor; RORγt: Retinoid-related orphan receptor γt; CAR: Costitutive androstane receptor; S1PR2: Sphingosine-1-phosphate receptor 2; GCA: Glycocholic acid; TCA: Taurocholic acid; GCDCA: Glycochenodeoxycholic acid; TCDCA: Taurochenodeoxycholic acid.

versions of CA and CDCA, named muricholic acid (MCA)[17]. The conventional or alternative/acidic pathways are both possible for this process to take place in the human liver. The first limiting step in the conventional route is the 7-hydroxylation of cholesterol catalysed by cholesterol-7-hydroxylase (CYP7A1), which irreversibly transforms cholesterol to 7-hydroxycholesterol. This intermediate is then converted to 7α-hydroxy-4-cholesten-3-one by 3β-hydroxy-Δ5-C27-steroid oxidoreductase, which can be used for generating both CA and CDCA in the classic pathway. In contrast, the alternative/acidic pathway begins with the conversion of cholesterol by sterol 27-hydroxylase (CYP27A1) to 27-hydroxy-cholesterol, followed by B-ring hydroxylation and metabolic side chain modification by oxysterol 7-hydroxylase (CYP7B) to create CDCA. The alternate pathway generates solely CDCA, which accounts for 10% of the liver's total bile acids[18-20]. Subsequently, PBAs are converted to tauro-CA (TCA) and tauro-CDCA (TCDCA) and glyco-CA (GCA) and glyco-CDCA (GCDCA), respectively, by the actions of BA-CoA synthase and BA-CoA amino acid N-acetyltransferase. Conjugation turns bile acids into stronger acids and increases their aqueous solubility at acidic pH and the retention of their amphiphilic structure. This limits their passive reabsorption and is essential for their lipid emulsification activity in the acidic environment of the duodenum[21,22]. Notably, conjugation with glycine is common in the human liver, accounting for 90% of the bile acid pool. However, approximately 95% of PBAs in mice are taurine-conjugated[23]. Conjugated bile acids will be stored in the gallbladder, forming bile with phospholipids, cholesterol, and other components. Finally, the gallbladder releases bile acids into the duodenum after each meal[24].

Bile acid metabolism in the intestine

Upon release into the small intestine, bile acids form micelles with cholesterol and dietary fats to facilitate their dissolution and absorption[25,26]. However, conjugated bile acids are not absorbed and are instead retained in the small intestine. At the end of the ileum, approximately 95% of the conjugated bile acids are reabsorbed *via* the apical sodium-dependent bile acid transporter (ASBT) and enter the liver *via* the portal vein[27]. It is estimated that humans complete the enterohepatic circulation of bile acids between six and eight times a day, depending on their dietary habits. The bile acid pool in healthy persons remains between 4 and 6 g. In contrast, changes in the intestinal epithelium of individuals with IBD decrease the reabsorption of bile acids by ASBT and increase the number of bile acids discharged in the feces [28]. It is important to note that the bile acid pool that is returned from the ileum to the liver directly suppresses the production of new bile acids in hepatocytes through FXR, FXR-dependent transactivation of the small isomeric partner (SHP), and SHP-mediated suppression of CYP7A1 and CYP8B1 expression[17,29,30]. In addition, bile acid-activated FXR drives fibroblast growth factor (FGF-15/19; FGF-15 in mice and FGF-19 in humans) expression in intestinal epithelial cells (IECs). Subsequently, FGF-15/19 is secreted into the portal circulation, translocated to the liver, binds to heterodimeric receptors on hepatocytes, and reduces hepatic bile acid synthesis by inhibiting CYP7A1 expression[26,31].

The intestinal microbiota can be directly involved in the biotransformation of bile acids through microbial enzymes. The five known mechanisms of bile acid metabolism by the intestinal microbiota are dehydroxylation, dehydration, exo-embedding of the cholesterol backbone, depolymerization of amino acids (glycine or taurine), and amide conjugation of the bile acid backbone with the amino acids phenylalanine, tyrosine, and leucine. Many potential mechanisms still exist to be discovered and explored[32]. Approximately 5% of bile acids are retained in the intestinal lumen for further metabolism by the intestinal microbiota to generate SBAs *via* the aforementioned processes[33]. In particular, the depolymerization reaction of bile acid metabolism is first carried out by the gut bacteria (enzymatic hydrolysis of the C-24N-

Figure 1 Synthesis, recirculation, and microbial modification of bile acids in the gut. Bile acids are synthesized from cholesterol in the liver. In the classical pathway, cholesterol-7α-hydroxylase converts cholesterol to 7α-hydroxycholesterol, which is then metabolized to cholic acid *via* mitochondrial sterol-27-hydroxylase (CYP27A1) or CYP8A1, or to chenodeoxycholic acid (CDCA) *via* CYP27A1. In the alternative pathway, CYP27A1 begins the conversion of cholesterol to 27-hydroxycholesterol, which is then metabolized to CDCA by oxysterol 7α-hydroxylase. These primary bile acids are then conjugated with taurine or glycine and then released into the bile for secretion into the duodenum. At the end of the ileum, 95% of the conjugated bile acids (BAs) are reabsorbed through the enterohepatic circulation, while the remaining 5% depolymerizes and enters the colon, where BAs undergo a series of chemical modifications by intestinal bacteria, including catabolism, desulfurization, dehydrogenation, dehydroxylation, and exo-embedding reactions to form secondary bile acids (mainly lithocholic acid and deoxycholic acid) and their oxidative, isomeric, and exo-derivatives. IBD: Inflammatory bowel disease; CA: Cholic acid; CDCA: Chenodeoxycholic acid; GCA: Glycocholic acid; TCA: Taurocholic acid; GCDCA: Glycochenodeoxycholic acid; TCDCA: Taurochenodeoxycholic acid; DCA: Deoxycholic acid; LCA: Lithocholic acid; BA: Bile acid; CYP7A1: Cholesterol-7α-hydroxylase; CYP27A1: Mitochondrial sterol-27-hydroxylase; CYP8B1: Sterol-12α-hydroxylase; CYP7B1: Oxysterol 7α-hydroxylase; BSHs: Bile salt hydrolases; FXR: Farnesol X receptor; FGF: Fibroblast growth factor; SHP: Small isomeric partner.

acylamide bond). Bile salt hydrolases (BSHs), which are extensively found in both Gram-positive and Gram-negative bacteria in the gut, including *Clostridium*, *Bifidobacterium*, *Lactobacillus*, *Bacteroides*, and *Enterococcus*, mediate this process [34]. It eliminates the glycine or taurine conjugates and stops the small intestine's active reabsorption. The depolymerized PBAs are then converted to SBAs in the colon by dehydroxylation at the carbon-7 position. Bacteria that express 7-dehydroxylases, such as *Clostridiu*m and *Eubacterium*, play a major role in mediating this process. The two SBAs that are most frequently produced by these reactions are lithocholic acid (LCA from CDCA) and deoxycholic acid (DCA from CA). Additionally, a variety of oxo-, iso-, and epi-derivatives of bile acids can also arise in the colon as a result of different intestinal microbiota dehydrogenation and exo-embedding processes[35]. For example, in *Escherichia*, *Clostridium*, *Bacteroides*, and *Eubacerium*, C7β exochimerization of CDCA can occur to produce the 7β exochimer, 3α-,7β-dihydroxy-5β-cholic acid, also known as ursodeoxycholic acid (UDCA)[36]. The complete metabolic pathway for the conversion of PBAs (CA and CDCA) to the two major SBAs (DCA and LCA) has been identified[37]. It is still unclear how the gut microbiota converts PBAs into other bile acid derivatives. Moreover, it is not clear which exact bacterial species or strains are required for these processes. Furthermore, it is noteworthy that the gut microbiota can also regulate the hepatic enzymes CYP7A1 and CYP27A1, thus affecting the synthesis of bile acids in the liver[38].

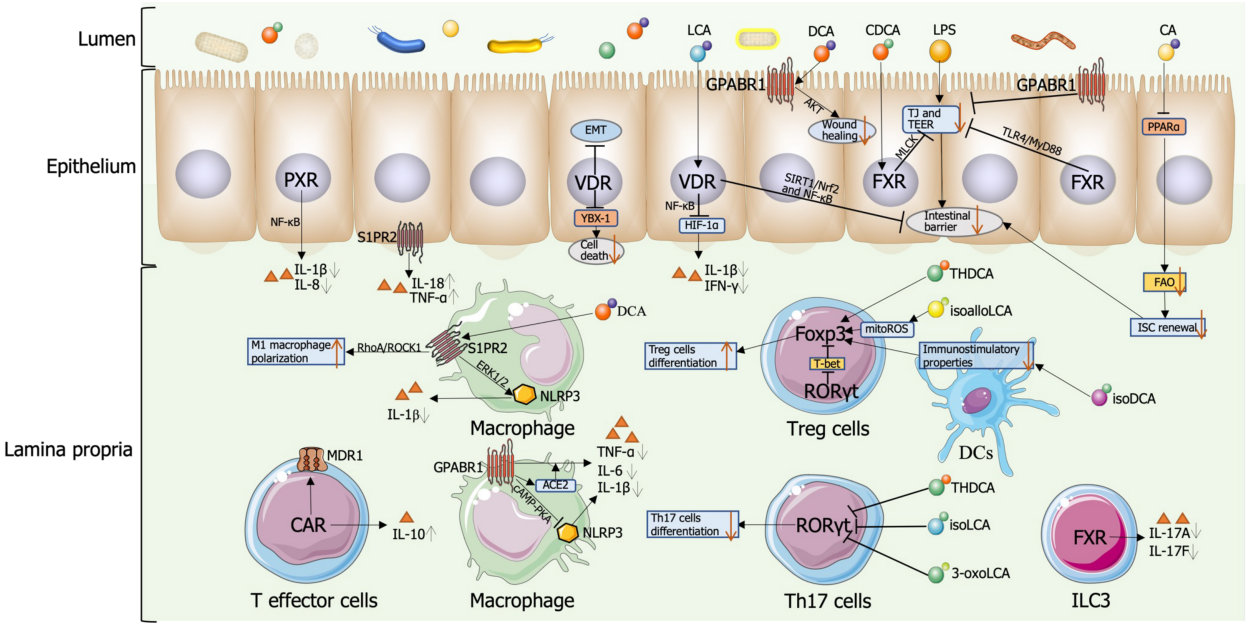
The intestines of IBD patients have been found to have dysbiosis of the intestinal bacterial flora and a considerable loss in microbial diversity. Most importantly, the abundance of bacteria containing BSH and bile acid-inducible enzymes (BAIs), such as *Firmicutes, Ruminococcaceae, Lachnospiraceae*, and *Eubacterium*, was decreased. This alteration reduces depolymerization and 7α-dehydroxylation, strongly decreasing the conversion capacity of the microbiota, resulting in a decrease in SBAs (DCA and LCA) and an elevation in primary and conjugated bile acids (CA, CDCA, TCA, and GCA)[39-41]. Multiple risk factors (genetics, psychological factors, Western food, and antibiotics) may lead to intestinal flora dysbiosis and bile acid abnormalities, which are linked to the pathophysiology of IBD[42]. Notably, it has been reported that disturbances in bile acid metabolism will, in turn, exacerbate IBD damage, affect intestinal stem cell differentiation and renewal, and impair intestinal mucosal barrier function[30].

Notably, the composition of the microbiota is directly or indirectly affected by bile acids in several studies. It has been shown that bile acids inhibit bacteria by increasing cell membrane permeability and causing cell damage, as well as causing oxidative DNA damage in bacteria. Alternatively, bile acids can indirectly influence bacterial growth through FXR and VDR[40]. The overall number of bacteria in rats' feces decreased with increased CA concentration in their meal, as determined by DAPI staining, sequencing of 16S rRNA gene clone libraries, and FISH analysis. The proportion of *Bacteroidetes* and *Actinobacteria* decreased dramatically in the CA-fed group, whereas the proportion of Firmicutes increased significantly[43]. Considered together, bile acids and the gut microbiota have a bidirectional effect on each other, and this balance is critical for human health and disease.

IMPACT OF BILE ACIDS AND THEIR RECEPTORS IN IBD

FXR

FXR is a nuclear receptor belonging to a subclass of metabolic receptors, first described by Forman *et al*[44] in 1995. FXR is predominantly found in intestinal epithelial cells, hepatocytes, and some immune cells (such as macrophages and dendritic cells) of the colon and liver[45]. Its main endogenous ligand is bile acids, in the order of FXR activation potency: CDCA > DCA > LCA > CA. Numerous studies demonstrate that through modulating bile acid metabolism, FXR can improve the pathogenesis of IBD. The enzyme CYP8B1, which synthesises CA, was increased in the liver of mice with colitis. Chen *et al*[30] found that mucosal barrier repair was impaired in CYP8B1 overexpressing mice, which resulted in more severe colitis. The specific mechanism was shown that CA leads to impaired fatty acid oxidation (FAO) and LGR5+ intestinal stem cell (ISC) renewal through inhibition of peroxisome proliferator-activated receptor alpha (PPARα). Surprisingly, they found that activation of FXR inhibited hepatic CYP8B1 expression and ameliorated colitis in mice. FGF19-M52, an analog of FGF19, has been reported to inhibit bile acid synthesis, modulate bile acid pool composition, and inhibit intestinal inflammation in mice. The particular mechanisms underlying these processes are associated with maintaining intestinal epithelial barrier integrity, suppressing inflammatory immune responses, and controlling microbial composition. However, the FGF19-M52-induced anti-inflammatory effect was completely abolished in FXR-deficient animals[46]. In addition, in UC mouse models, dextran sodium sulfate (DSS)-induced colitis activates the intestinal PPARα-UDP-glucuronosyltransferases (UGTs) axis, which inhibits downstream FXR-FGF15 signaling, resulting in up-regulation of hepatic CYP7A1 and promotion of hepatic bile acids synthesis. Both inhibition of PPARα and stimulation of the FXR-FGF15 axis greatly decreased colitis induced by DSS[47]. As a result, intestinal FXR-FGF15 signaling may play a key role in controlling bile acid homeostasis and colitis development.



Mammalian innate lymphocyte type 3 (ILC3) is important in IBD, especially in innate intestinal immunity and mucosal barrier function[48]. Activation of FXR has been reported to block the production of IL-17A and IL-17F in ILC3, thereby eliminating ILC3-dependent intestinal inflammation and attenuating IBD injury. Interestingly, they also found that activation of FXR reduced characteristic transcription factors (including Batf3 and Tcf7)[49]. Transforming growth factor-beta (TGF-β) belongs to a family of multifunctional polypeptides produced by non-lymphoid cells and various lymphocytes. Previous studies have shown that TGF-β is essential for regulating immune cells and that TGF-β production is also associated with the pathogenesis of colitis. This implies that the pathological changes in UC may be caused by disorders of the TGF-β pathway[50]. A recent study revealed that a high-fat diet accelerated the course of DSS-induced UC and led to the down-regulation of FXR target genes (*FXR*, *Shp*, and *Ibabp*). The addition of the FXR agonist FexD repaired the high-fat diet-induced phenotype, whereas the TGF-β inhibitor SB431542 prevented FexD's restorative activity in DSS-induced UC mice[51]. This study showed that FXR alleviates inflammation in UC through a TGF-β-dependent pathway. In conclusion, these findings suggest that FXR can improve IBD by modulating intestinal immunity.

Western diets have high levels of fecal DCA, a substance that can cause inflammation in the intestines. The researchers discovered that mice fed a DCA-supplemented diet showed localised ileal and colonic inflammation, as well as changes in gut microbiota composition and faecal bile acid buildup. Dysregulation of gut microbiota homeostasis induced by DCA reduced bile acid depolymerization. This regulation was associated with the repressed expression of target genes in the FXR-FGF15 axis, leading to increased hepatic *de novo* bile acid synthesis. These results suggest that DCA-induced intestinal dysbiosis may be a key etiology of intestinal inflammation associated with disturbed bile acid metabolism and down-regulation of the FXR-FGF15 axis[52]. Subsequently, Xu *et al*[53] used the FXR agonist fexaramine to restore intestinal FXR activity. Activating FXR increased the abundance of bacteria producing short-chain fatty acids and normalized bile acid metabolism. DCA-induced intestinal inflammation can be reduced by targeting the FXR-gut microbiota signaling pathway.

In addition, FXR may ameliorate IBD through modifying the function of the intestinal mucosal barrier. By blocking lipopolysaccharide (LPS)-induced activation of the myosin light chain kinase (MLCK) pathway in an FXR-dependent manner, Song *et al*[54] showed that CDCA reversed LPS-induced decreases in intestinal permeability and tight junction protein expression and mitigated LPS-induced intestinal barrier breakdown. In another study, using the FXR agonist GW4064 to restore FXR activity, Liu *et al*[55] discovered that activation of FXR attenuates intestinal tight junction damage by inhibiting the LPS-induced TLR4/MyD88 signaling pathway. In summary, these recent findings suggest that FXR can influence the pathophysiological processes of IBD by regulating bile acid metabolism, intestinal immunity, intestinal flora, and intestinal mucosal barrier function (Figure 2). Activation of FXR may be considered a new therapeutic strategy for IBD.

RORγt

RORγ is one of three retinoid-related orphan nuclear receptors with two main isoforms: RORγ1 and RORγt (or RORγ2),

encoded by the *RORC* gene. RORγ1 is normally involved in the regulation of transcription of metabolic genes and some circadian rhythms in the liver and adipose tissue. However, the expression of RORγt is restricted to specific subpopulations of lymphoid spectrum immune cells, namely T helper 17 (Th17) cells, ILC3, and γδ T cells[19,56]. Recently, increasing attention has turned to RORγt, as it acts as a key transcription factor for Th17 cell and regulatory T(Treg) cell differentiation in IBD (Figure 2). Moreover, ROR-γt can depend on ILC3 to provide protective immunity[23,48]. Hang *et al* [57] discovered that 3-oxolithocholic acid (3-oxoLCA) decreased Th17 cell differentiation by directly interacting with the important transcription factor RORγt by giving mice 3-oxoLCA and isoallolithocholic acid (isoalloLCA). In contrast, isoalloLCA decreases intestinal inflammation by increasing Treg cell differentiation by generating mitochondrial reactive oxygen species (mitoROS), which enhances the expression of Forkhead box P3 (Foxp3). Interestingly, similar to 3-oxoLCA, isolithocholic acid (isoLCA) can also de-suppress Th17 cell differentiation by inhibiting RORγt[58]. In *in vivo* models, another study demonstrated that the secondary bile acid 3β-hydroxydeoxycholic acid (isoDCA) promotes Treg cell differentiation by increasing the induction of Foxp3 through its action on dendritic cells (DCs). Surprisingly, the researchers found that disruption of FXR in DCs enhanced Treg cell generation[59]. In addition, taurohyodeoxycholic acid (THDCA) was reported to not only inhibit RORγt-mediated Th17 cell differentiation, but also trigger Foxp3 expression and promote Treg cell differentiation[60]. These recent findings demonstrate the potential of bile acid derivatives to improve IBD prognosis by acting on RORγt. Kathania *et al*[61] identified a serine/threonine kinase, Pak2, directly associated with RORγt. Pak2 recognizes the conserved KRLS motif within RORγt and phosphorylates S-316 within this motif. Genetic deletion of Pak2 in Th17 cells decreases RORγt phosphorylation, increases IL-17 expression, and induces severe colitis after adoptive transfer to Rag1-/- mice. This suggests that other biological molecules *in vivo* can also regulate the developmental process of IBD by acting on RORγt and are potential targets for the treatment of IBD to be explored further.

RORγt+ immune cells are generally thought to coordinate immunity, inflammation, or tolerance in the gut. In IBD, the function of RORγt+ immune cells can be significantly altered[62-64]. According to a recent study, ILC3 in intestinal draining lymph nodes expressed numerous significant class II histocompatibility complexes (MHCIIs). To increase microbiota-specific RORγt+ Treg cells and prevent them from proliferating into inflammatory Th17 cells, ILC3 is both essential and sufficient. AlphaV integrin, competing IL-2, and ILC3-mediated antigen presentation all contributes to this impact. Single cell analysis indicated that in IBD, the interaction between ILC3 and RORγt+ Treg cells was impaired[65]. It is interesting to note that Akagbosu *et al*[66] described a class of RORγt+ antigen-presenting cells dubbed Thetis cells. These cells had dendritic cell and medullary thymic epithelial cell (mTEC) transcriptional signatures. Colitis results from the loss of MHCII or ITGB8 by Thetis cells, which severely impairs peripheral Treg (pTreg) cell differentiation in the intestine. MHCII expression by RORγt+ ILC3 and classic dendritic cells, in contrast, is neither sufficient nor essential for pTreg cell formation. In a colitis model, Liu *et al*[67] demonstrated that *Akkermansia muciniphila* improves colitis by up-

regulating the RORγt+ Treg cell-mediated immune response, and this process is regulated by Toll-like receptor 4 (TLR4). RORγt is a main transcription factor for Th17 cells. However, in the intestine, RORγt is co-expressed in peripherally induced pTreg cells together with Foxp3. Surprisingly, Bhaumik *et al*[68] observed that RORγt-mediated T-bet inhibition is essential for regulating the immunosuppressive function of pTreg cells in inflammatory states, restoring Foxp3 expression, and preventing the onset of severe colitis. Despite these advancements, the full-spectrum cellular heterogeneity of RORγt+ immune cells, the potential for functional interactions between subpopulations, and the specific mechanisms influencing the pathophysiological processes of IBD in the context of complex microbiota remain unknown and require further investigation.

GPABR1

Kawamata *et al*[69] first described GPABR1 (TGR5 or M-BAR) in 2003 as a receptor for bile acids in the membrane. GPABR1 is mainly found in epithelial cells, immune cells, and intestinal nerves in the gut and biliary tract and belongs to the superfamily of G protein-coupled receptors. Bile acids agonistically affect GPABR1 in different ways: LCA > DCA > CDCA > UDCA > CA[20]. The adaptor apoptosis-associated speck-like protein containing a caspase recruitment domain, sensor NLRP3, and procaspase-1 form the cytosolic polyprotein complex NLRP3 inflammasome. The pathogenesis of IBD is closely linked to the NLRP3 inflammasome[70,71]. An *in vivo* experimental study showed that bile acids could inhibit NLRP3 inflammasome-dependent inflammation *via* the GPABR1-cAMP-PKA axis, suggesting GPABR1 as a potential target for alleviating intestinal inflammation in IBD[72]. Biagioli *et al*[73] found that activation of GPBAR1 can lower macrophage inflammatory gene expression (mRNA for TNF-α, IL-1, IL-6, and CCL2), hence reducing inflammation in animal models of IBD. Deletion of the anti-inflammatory gene angiotensin-converting enzyme 2 (*ACE2*) from mice with colitis resulted in worse inflammation[74]. Biagioli *et al*[75] further discovered that activation of GPBAR1 could regulate ACE2 colonic expression through a glucagon-promoting factor glucagon-like peptide (GLP)-1-dependent mechanism. Furthermore, the regulation of *ACE2* mRNA in the colitis setting may contribute to the anti-inflammatory effects of GPBAR1. A recent study showed that supplementation with LCA and DCA reduced intestinal inflammation in three mouse models of colitis. This anti-inflammatory effect partially depends on GPABR1[76].

AKT, a serine/threonine kinase, is crucial for the differentiation, proliferation, survival, and metabolism of cells. In a mouse model of DSS-induced colitis and the colonic epithelium of UC patients, Azuma *et al*[77] showed that DCA could slow wound healing in the colonic epithelial cell environment by acting as a ligand for GPABR1 to activate the AKT signaling pathway. Interestingly, another recent study showed that in a Caco-2 cell model, GPABR1 activation ameliorated LPS-induced reduction in trans-epithelial electrical resistance (TEER) and up-regulated tight junction protein expression, thereby enhancing mucosal barrier function to alleviate the progression of IBD[78]. However, inhibition of GPABR1 expression in the porcine jejunal epithelial cell line IPEC-J2 did not affect the function of the intestinal barrier [54]. This may be due to the different expression levels of GPABR1 in different intestinal slices. In conclusion, these findings suggest that GPABR1 plays different roles in the gastrointestinal tract of IBD (Figure 2). Moreover, the functions of GPABR1 may also differ due to differences in species and cell types. Therefore, the role of GPABR1 on the pathophysiological mechanisms of IBD deserves further investigation.

VDR

A nuclear receptor activated by 1,25-dihydroxyvitamin D is the VDR. The human metabolism, immunity, and cancer are all regulated by this receptor, which is widely expressed in a range of tissues. Additionally, the secondary bile acid LCA and its metabolites (3-oxoLCA and isoalloLCA) can activate VDR[79,80]. LCA was reported to ameliorate the TNF-α-induced decrease in the expression and distribution of tight junction proteins (ZO-1, occludin, and claudin-1) through activation of VDR. Furthermore, it significantly blocked TNF-α-mediated down-regulation of the oxidative stress-related genes silent information regulator 1 (*SIRT1*), nuclear factor erythroid 2-related factor 2 (*Nrf2*), and heme oxygenase-1. In addition, the TNF-α-induced increase in NF-κB p-p65 and p-IκB-α was significantly suppressed by LCA[81]. This study reveals that LCA strongly protects against TNF-α-induced intestinal barrier degradation *via* VDR. Activation of hypoxia-inducible factor 1α (HIF-1α) as a heterodimeric transcription factor has been shown in previous research to accelerate the course of DSS-induced colitis in mice[82,83]. However, the association of VDR signaling and HIF-1α in the development of IBD has been enigmatic. A recent study showed that in an animal model of colitis, VDR signaling suppressed the overexpression of HIF-1α in colonic epithelial cells by regulating the NF-κB pathway, thereby inhibiting the overproduction of interferon-gamma (IFN-γ) and IL-1β in these cells and attenuating the development of colitis in the animal model[84]. Another study showed that VDR could physically bind to Y box binding protein 1 (YBX-1), blocking its nuclear translocation, thus ameliorating the death of colonic epithelial cells in the presence of inflammation[85]. Furthermore, Fernández-Barral *et al*[86] demonstrated for the first time that activation of VDR can regulate stemness-related genes, including *LGR5, SMOC2, LRIG1, MSI1, PTK7*, and *MEXA*, and decrease cell proliferation in LGR5+ human colonic stem cells. This function is essential for maintaining colonic epithelial homeostasis in IBD.

Paneth cells, which are positioned at the base of small intestinal crypts, release α-defensins and play a crucial role in regulating intestinal flora and preserving intestinal homeostasis[87]. Paneth cells showed a significant decrease in lysozyme activity, a diminished inhibition of pathogenic bacterial growth, and a reduced autophagic response in a Paneth cell-specific VDR knockout mouse model, resulting in an increased inflammatory response. These findings suggest the importance of VDR on Paneth cells in IBD in preventing intestinal inflammation[88]. Claudin-2 is a linker protein that mediates water transport between epithelial cells, and elevated claudin-2 has been reported to be associated with active human IBD[89]. Another study showed that in a Salmonella colitis model and a DSS-induced colitis model, VDR deficiency may lead to claudin-2 hyperfunction and increased permeability in an inflammatory state, resulting in more severe intestinal leakage and intestinal inflammation in mice[90]. This study highlights the importance of VDR in intestinal mucosal barrier function. In addition, intestinal fibrosis is a common complication of CD. The epithelial-

mesenchymal transition (EMT) describes the process by which epithelial cells change from epithelial to mesenchymal cells, a crucial component of fibrogenesis. In addition to inhibiting fibroblast activation and epithelial mitochondria-mediated EMT, Yu *et al*[91] revealed that VDR activation attenuates intestinal fibrosis.

Several recent studies have shown that colonic mucosal VDR expression is reduced in patients with IBD and that VDR transcript expression negatively correlates with IBD inflammation[92,93]. Yang *et al*[94] found that dysbiosis of the gut microbiota and altered fecal bile acids could regulate the immune response in UC patients. VDR may alleviate intestinal inflammation by down-regulating NF-κB signaling and activating autophagy. These findings suggest that restoring intestinal VDR expression in IBD may be a viable therapeutic strategy. In conclusion, these findings contribute to a better understanding of the role of VDR in the etiology of IBD and serve as a significant reference for future research aimed at developing more effective therapeutic options (Figure 2).

PXR and CAR

PXR and CAR are members 2 and 3 of nuclear receptor subfamily 1, group I, NR1I2, and NR1I3, respectively. PXR was first described as a major regulator of CYP family 3 subfamily A (CYP3A) transcription by Kliewer *et al*[95] and Lehmann *et al*[96] in 1998. In contrast, CAR was first reported by Baes *et al*[97] in 1994 and was later found to be a transcriptional regulator of CYP2B6. PXR and CAR have the typical modular nuclear receptor structure, which consists of a hinge, a DNA-binding domain, a ligand-binding domain, activation function 1, and activation function 2. In addition to many endogenous and exogenous complex ligands, several subsequent studies have shown that PXR and CAR are hybrid receptors that can also accommodate LCA and CDCA and function as sensors for LCA and CDCA[98]. PXR and CAR are key transcription factors that regulate intestinal homeostasis. Uehara *et al*[99] demonstrated that PXR might reduce apoptosis in a mouse model of DSS-induced colitis by lowering the mRNA expression of pro-inflammatory cytokines (TNF-α and IL-1β). CAR inhibits apoptosis by inducing Gadd45b. Both of them protected mice from DSS-induced colitis. Interestingly, they also observed that the protective effect of FXR activation on CAR knockout mice and the protective effect of CAR activation on PXR knockout mice were reduced. CAR and PXR can synergistically ameliorate DSS-induced colitis. Another study showed that PXR and CAR deficiency synergistically increased the pro-inflammatory bacteria *Helicobacteraceae* and *Helicobacter* and the relative abundance of *Lactobacillus*. *Lactobacillus* has BSHs activity, corresponding to a decrease in primary taurine-bound bile acids in feces. This may lead to an increased internal burden of taurine and unbound bile acids, which are associated with inflammation, oxidative stress, and cytotoxicity[100].

The metabolism of tryptophan produces indole-3-propionic acid (IPA) in the intestine *via Clostridium perfringens*. Previous studies have shown that it can affect mucosal barrier function and inflammation through interaction with PXR [101]. Flannigan *et al*[102] found that PXR-deficient myofibroblasts overreact to stimuli and produce higher inflammatory mediators. In addition, biopsies from CD and UC patients revealed a correlation between decreased PXR expression and increased expression of fibrosis and innate immune genes. Intriguingly, they discovered that IPA decreased intestinal inflammation and fibrosis in mice with DSS-induced colitis *via* activating PXR, whereas microbiota removal increased intestinal inflammation and fibrosis[102]. These findings suggest that the interaction of the microbiota metabolite IPA with PXR may be an important determinant of the progression of fibrotic complications in IBD. In addition, Deuring *et al* [103] found a strict negative association between colonic epithelial PXR levels and NF-B target gene expression in CD patient colon biopsy tissue. During IBD, their findings show that PXR is a substantial and clinically relevant antagonist of NF-B activity in the intestinal epithelium[103].

MDR1 is a membrane-associated, ATP-dependent efflux pump preferentially expressed in intestinal and circulating human CD4+ effector T cells[104]. Chen *et al*[105] discovered CAR as a regulator of MDR1 expression in T cells that prevents bile acid toxicity and inflammation in the mouse small intestine. Activation of CAR induces not only the expression of detoxifying enzymes and transporters in CD4+ T effector cells in the lamina propria of the small intestine, but also the expression of the key anti-inflammatory cytokine IL-10. The activation of these programs provides an unexpected strategy for treating IBD and defines the subspecialization of lymphocytes in the small intestine.

S1PR2

S1PR2 is highly expressed in the ileum and colon, and it can be activated by the conjugated main bile acids GCA and TCA as well as GCDCA and TCA[23]. Vascular and immune dysfunction is thought to be involved in the pathogenesis of IBD, but the exact mechanisms of mucosal vascular endothelial barrier dysfunction and macrophage phenotypic transformation are not fully clarified. Wang *et al*[106] discovered that S1PR2 expression was considerably enhanced in intestinal mucosal vascular endothelial cells and macrophages from IBD patients and animals with DSS-induced colitis, as well as in vascular endothelial cells and macrophages treated with LPS *in vitro*. Knockdown or inhibition of S1PR2 expression significantly reduced the expression of RhoA and ROCK1 in vascular endothelial cells and macrophages. Furthermore, they discovered that inhibiting S1PR2 and ROCK1 reversed impaired vascular barrier function and M1 macrophage polarisation *in vivo* and *in vitro*, while decreasing endoplasmic reticulum stress and macrophage glycolysis in vascular endothelial cells, and reversing LPS-induced impairment of M1 macrophage polarisation and vascular endothelial cell barrier dysfunction. The results imply that the S1PR2/RhoA/ROCK1 signalling pathway, which regulates vascular endothelial cell barrier function and M1 macrophage polarisation, may have a role in the aetiology of IBD[106]. Chen *et al*[107] previously demonstrated that S1PR2 is abundantly expressed in intestinal epithelial cells and stimulates IEC proliferation and migration. However, the precise role of S1PR2 in UC is unknown. They recently discovered that S1PR2 may play a significant role in intestinal epithelial cell proliferation and barrier maintenance by influencing the expression levels of SphK2, HDAC1, HDAC2, and ERK1/2 signaling pathways. Surprisingly, they discovered that inhibiting S1PR2 in the UC mouse model might also reduce the severity of colonic pathological injury in mice, which was followed by a drop in TNF-α and IL-18 Levels in their serum[107]. These findings reveal that S1PR2, despite its beneficial effects on intestinal epithelial cell proliferation and barrier maintenance, may be a key pathogenic

factor in UC. In addition, researchers discovered that DCA dose-dependently increased S1PR2 expression in a mouse model of colitis. Meanwhile, at least in part, DCA-induced NLRP3 inflammasome activation was achieved by stimulating the ERK1/2 signaling pathway downstream of S1PR2 to promote cathepsin B release. S1PR2/ERK1/2/cathepsin B signaling is key in triggering DCA activation of inflammatory vesicles[108]. The results of this study suggest that S1PR2 should be investigated further as a possible treatment for IBD.

POTENTIAL THERAPEUTIC TARGETS OF BILE ACIDS AND THEIR RECEPTORS IN IBD

Bile acid receptor agonists or inhibitors

Based on growing knowledge and understanding of the mechanism of action of bile acid receptors, the development of medications targeting the bile acid receptor activity that changes considerably during the progression of IBD may give a more specific therapeutic effect. The development of bile acid receptor agonists or antagonists is widely recognized as a promising therapeutic avenue for treating IBD and is a hot area of research (Table 2). Recently, Miyazaki *et al*[109] showed that administration of the novel FXR agonist nelumal A induced the expression of FXR target genes and tight junction proteins in the intestine while decreasing the expression of hepatic bile acid synthesis genes, effectively reducing colitis and inhibiting colitis-related carcinogenesis. Another study found that the FXR agonist nigakinone alleviated DSS-induced experimental colitis *via* regulating bile acid profile and the FXR/NLRP3 signaling pathway. It inhibited inflammatory cytokine production by activating the FXR/NLRP3 signaling pathway and regulated bile acid metabolism by controlling cholesterol hydroxylase and FXR-mediated transporter proteins, reducing bile acid accumulation in the colon and thereby reducing colitis[110]. Although FXR agonists exhibit very positive effects, they are also commonly associated with many side effects. Its most common side effects are dose-dependent pruritus and an increased LDL:HDL ratio, which may increase the risk of atherosclerosis. Its long-term efficacy remains to be determined[111]. Qi *et al*[112] used structure-based virtual screening to identify 2',4'-dihydroxy-2,3-dimethoxychalcone (DDC). This is a chalcone derivative enriched in plants and food, located in the binding pocket of RORγt, which can target and inhibit RORγt activity, thereby indirectly stabilizing Foxp 3 expression, achieving regulation of Th17/Treg homeostasis, and improving Th17-mediated inflammation. In another study, Chen *et al*[113] proposed a dual-targeting approach for treating IBD using RORγt and dihydroorotic dehydrogenase (DHODH). Dual RORγt/DHODH inhibitors are expected to reduce RORγt-driven Th17 cell differentiation and attenuate T cell expansion and activation, which may enhance anti-inflammatory effects. They found that the 2-aminotetrahydrobenzothiazole compound 14d could act as a potent dual RORγt/DHODH inhibitor, exhibiting significant *in vivo* anti-inflammatory activity and dose-dependently reducing the severity of DSS-induced acute colitis in mice. Furthermore, by screening a large combinatorial library of 1,5-disubstituted acylated 2-amino-4,5-dihydroimidazoles and using a positional scanning library strategy to rapidly identify a novel class of RORγ inhibitors, Ortiz *et al*[113] found that compound 1295-273 had the highest activity against RORγ in this series, with almost twofold selectivity for this receptor isoenzyme. However, they did not further validate it *via in vivo* or *in vitro* experiments.

Genistein, a key isoflavone, stimulates GPABR1 receptors in a DSS-induced mouse colitis model, dramatically lowering inflammatory cell infiltration and generation of pro-inflammatory mediators in the blood and colon and reducing weight loss and increasing colon length in mice[114,115]. In another study, Nakhi *et al*[116] observed that the acid group of CDCA can be replaced by a wide range of chemical groups that can simultaneously maintain or significantly increase its agonistic potency against GPABR1. In particular, pyrrolidinamide 9 and 1,3,4-oxadiazole analog 23 were 10- and 70-fold more potent than CDCA. There is a slight loss of potency when the hydroxyl group at position 3 of the bile acid scaffold is methylated. Surprisingly, however, a more than 100-fold increase in potency was observed upon methylation of the 7-hydroxyl group of pyrrolidinamide 9. Based on these observations, they synthesized the 7-methylated oxadiazole analogue 17, which proved to be a highly potent agonist at the GPABR1 receptor. However, the specific efficacy has to be further de-validated in IBD models[116]. However, most of the GPABR1 agonists studied are unrestricted GPABR1 agonists, and the pharmacological application would be limited by the systemic targeting effect, with associated side effects such as gallbladder overfilling and gallbladder emptying block. Recently, researchers are exploring a series of intestinal-restricted GPABR1 agonists in an attempt to avoid these side effects. Dipeptidyl peptidase IV (DPP4) is a serine exopeptidase, and DPP4 inhibitors have been reported to reduce colitis *via* the GLP pathway after colonic administration in mice[117]. Recently, Han *et al*[118] identified a series of highly potent intestine-restricted GPABR1-DPP4 bifunctional molecules for the first time by integrating GPABR1 agonistic and DPP4 inhibitory efficacy into a single molecule. The effects of GPABR1 and DPP4 on UC were exploited and made to act locally in the gut to avoid unwanted systemic effects. In particular, racemic compound 15, a highly potent GPABR1-DPP4 bifunctional molecule, showed good intestinal distribution, efficacy, and gallbladder safety in a mouse model of colitis[118]. Chen *et al*[119] also described the discovery and optimization of a series of intestinal-restricted selective thiazolidine-type GPABR1 agonists that elicit a potent response with minimal effects on the gallbladder. In this series of drugs, they mainly explored compound No. 12, with minimal systemic availability, which stimulates prolonged and potent GLP-1 (7-36) amide (tGLP-1) secretion and may have significant therapeutic value in IBD[119].

Dvořák *et al*[120] proposed microbial metabolite mimicry as a new strategy for drug discovery based on the effect of microbial metabolites on PXR and reported the functionalized indole derivative lead compound Felix Kopp Kortagere 6 (FKK6) as the first class of non-cytotoxic PXR agonists as a proof of concept for microbial metabolite mimicry. In cells, human organs, and animals, FKK6 can directly bind PXR and stimulate PXR-specific target gene expression. In mice expressing human *PXR* genes, FKK6 dramatically suppressed the production of pro-inflammatory cytokines and prevented inflammation[120]. The development of FKK6 provided the first evidence that microbial metabolite mimicry is a viable drug discovery strategy and opened the door to an underutilized chemical space for IBD drug development.

Table 2 Potential applications of bile acids and their receptors in inflammatory bowel disease

Types	Ref.	Subjects	Treatment	Major findings
Bile acid receptor agonists or inhibitors	Miyazaki *et al*[109], 2021	Mice with AOM/DSS-induced colitis	Fed nelumal A for 15 wk	Nelumal A induced the expression of FXR target genes and tight junction proteins in the intestine; Nelumal A decreased the expression of hepatic bile acid synthesis genes
	Liu *et al* [110], 2023	Mice with DSS-induced colitis	Fed nigakinone for 9 d	Nigakinone inhibited inflammatory cytokine production by activating the FXR/NLRP3 signaling pathway; Nigakinone regulated bile acid metabolism by controlling cholesterol hydroxylase and FXR-mediated transporter proteins
	Qi *et al* [112], 2022	Mice with DSS-induced colitis	DDC gavage treatment for a week	DDC targeted and inhibited RORγt activity, thereby indirectly stabilizing Foxp 3 expression and achieving regulation of Th17/Treg homeostasis
	Chen *et al* [113], 2022	Mice with DSS-induced colitis	Fed compound 14d for 9 d	Compound 14d reduced RORγt-driven Th17 cell differentiation; Compound 14d attenuated T cell expansion and activation
	Chen *et al* [115], 2019	Mice with DSS-induced colitis	Fed genistein 14d for 9 d	Genistein lowered inflammatory cell infiltration and generation of pro-inflammatory mediators in the blood and colon; Genistein reduced weight loss and increased colon length in mice
	Han *et al* [118], 2022	Mice with DSS-induced colitis	Fed racemic compound 15 for 9 d	Racemic compound 15 showed good intestinal distribution and efficacy; Racemic compound 15 avoided unwanted systemic effects and showed better gallbladder safety
	Chen *et al* [119], 2018	Diet-induced obese mice	Fed compound 12 for 4, 8, 12, or 16 h	Compound 12 elicited a potent response with minimal effects on the gallbladder; Compound 12 stimulated prolonged and potent tGLP-1 secretion
	Dvořák *et al* [120], 2020	Mice with DSS-induced colitis	FKK6 oral gavage plus FKK6 intrarectal bolus for 10 d	FKK6 dramatically suppressed the production of pro-inflammatory cytokines and prevented inflammation; FKK6 provided the first evidence that microbial metabolite mimicry is a viable drug discovery strategy
Traditional Chinese medicine	Hua *et al* [122], 2021	Mice with DSS-induced colitis	Administrated with BTWT for 7 d	BTWT normalized the levels of some bile acids, especially CA and MCA; BTWT increased the expression of FXR and TGR5 in the liver; Relative species abundance and gut microbiota diversity were significantly higher in the BTWT-exposed group; BTWT significantly ameliorated colonic inflammation and clinical signs
	Su *et al* [123], 2022	Caco-2 cells treated with bile acids	Pre-incubated with GXD at subtoxic concentration for 24 h before treatment with BAs	GXD improved intestinal barrier dysfunction caused by abnormal bile acid metabolism in IBD by regulating tight junction protein expression levels, inhibiting oxidative stress, and reducing apoptosis
	Li *et al* [125], 2022	Mice with DSS-induced colitis	Fed SFE for 11 d	SFE regulated the transcriptional levels of RORγt and Foxp 3 in the colon and down-regulating the expression of the pro-inflammatory factor IL-17 A in colon tissue
	Shi *et al* [126], 2022	Mice with DSS-induced colitis	Fed LWE for a week	LWE inhibited the transcriptional activation of RORγT and IL-17A, thereby suppressing the differentiation of Th17 lymphocytes; LWE reduced inflammation and increased the protective action of the intestinal mucosal barrier *via* the TLR4/MyD88/NF-κB signal transduction pathway
	Xia *et al* [127], 2022	Mice with DSS-induced colitis	QCWZD gavage for a week	QCWZD inhibited the phosphorylation of JAK2-STAT3 pathway, reducing the transcriptional activation of RORγT and IL-17A
	Xiong *et al* [128], 2022	Mice with DSS-induced colitis	Fed HGT for 10 d	HGT inhibited DSS-induced necrotizing lesions in the colon through up-regulation VDR levels
	Zhang *et al* [129], 2020	Mice with DSS-induced colitis	PA administered intragastrically for 10 d	PA activated PXR signaling and inhibited NF-κB signaling, thereby ameliorating inflammation
	Yu *et al* [130], 2020	Mice with DSS-induced colitis	Fed Alpinetin for 9 d	Alpinetin activated PXR/NF-kB, thereby ameliorating inflammation

IBD: Inflammatory bowel disease; FXR: Farnesoid X receptor; PXR: Pregnane X receptor; VDR: Vitamin D receptor; RORγt: Retinoid-related orphan receptor γt; DSS: Dextran sodium sulfate; HGT: Huanglian Ganjiang Tang; QCWZD: Chingchang Wenzhong Decoction; LWE: Licorice water extraction; SFE: *Sophora flavescens* Aiton total flavonoids extracts; BTWT: Baitouweng Tang; GXD: Gualou Xiebai Decoctio; MCA: Muricholic acid.

In conclusion, the research and development of bile acid receptors and their agonist or inhibitor medicines is a viable treatment method for IBD. However, there are still numerous issues, such as the increased adverse effects of non-selective agonists and activators. Increasing the intestinal restriction of agonists by identifying modifications that block the active transport of ASBT while reducing passive absorption by increasing the compounds' size and polar surface area is a feasible solution to their side effects. However, the synthesis of existing intestinal restricted activators or inhibitors is very complex and expensive, and further research is needed to explore this.

Traditional Chinese medicine

Chinese medicine is garnering more attention as the global pharmaceutical industry develops, and herbal medicine has distinct advantages in treating IBD due to allopathic treatment[121]. Many academics have recently conducted basic research on traditional Chinese medicine for the treatment of IBD from various angles, and they discovered that traditional Chinese medicine may benefit the treatment of IBD by affecting bile acids and their receptors, which support intestinal mucosal barrier function, regulate intestinal immunity, and influence bile acid metabolism (Table 2). In China, Baitouweng Tang (BTWT) is a commonly prescribed drug for the treatment of UC. In a DSS-induced mouse model of UC, mice were given BTWT for 7 d. Surprisingly, the researchers found that BTWT treatment reduced the increased UDCA, HDCA, MCA, CA, and GLCA in UC and normalized the levels of some bile acids, especially CA and MCA. Moreover, BTWT increased the expression of FXR and GPBAR1 in the liver. In addition, they found that the relative species abundance and diversity of the gut microbiota were significantly higher in the BTWT-exposed group. BTWT significantly ameliorated colonic inflammation and clinical signs, such as histological damage and colonic shortening, in mice. This result may be achieved by affecting the intestinal microbiota and bile acid metabolism[122]. Gualou Xiebai Decoction (GXD) is a classic formula used in China for thousands of years to treat inflammatory diseases. A recent study showed that GXD significantly improved intestinal barrier dysfunction caused by abnormal bile acid metabolism in IBD by regulating tight junction protein expression levels, inhibiting oxidative stress, and reducing apoptosis[123].

"Kushen", the dried root of the *Sophora flavescens* Aiton, is a classical drug widely used in China to treat UC in ancient and modern times, with alkaloids and flavonoids as the main components. Previous studies have shown that *Sophora flavescens* Aiton total flavonoids extract (SFE) exhibits anti-UC effects by restoring the balance of the "host-microbe" co-metabolic network and modulating the intestinal microbial structure in UC mice[124]. A recent study further found that SFE, especially the flavonoid component represented by kurarinone, had a significant protective effect against UC by regulating the transcriptional levels of RORγt and Foxp 3 in the colon and down-regulating the expression of the pro-inflammatory factor IL-17A in colon tissue[125]. In addition, Chingchang Wenzhong Decoction (QCWZD) and licorice water extraction (LWE) also inhibited the transcriptional activation of RORγT and IL-17A, thereby suppressing the differentiation of Th17 Lymphocytes and reducing colonic inflammation[126,127]. Huanglian Ganjiang Tang (HGT) is the classic formula in Danxi Xinfa, used to relieve diarrhea, abdominal pain, and blood in the stool; it is currently used clinically for the treatment of UC with remarkable efficacy, but its mechanism of action needs to be further elucidated. Xiong *et al*[128] recently showed that HGT could reduce DSS-induced colitis in mice by inhibiting DSS-induced necrotizing lesions in the colon through up-regulation of VDR levels. Furthermore, in animal models of IBD, researchers found that patchouli alcohol (PA) and alpinetin from ginger plants could activate PXR signaling and inhibit NF-κB signaling, thereby ameliorating inflammation[129,130]. In conclusion, the results of these herbal studies provide new options for treating IBD and provide a theoretical basis for pharmacological studies of herbal medicines, which are beneficial for their application.

UDCA

UDCA is a secondary bile acid generated from CDCA, which is found in low concentrations in humans and was initially licensed by the FDA to treat cholestatic liver disease. However, several studies have shown that UDCA may play an important role in IBD by acting on bile acid receptors. For example, a previous study showed that DCA could inhibit the expression of CFTR Cl^- channels by activating FXR, thereby delaying the repair of the intestinal mucosal barrier. Interestingly, UDCA inhibits this process and promotes epithelial cell migration and recovery[131]. In a recent study, UDCA was shown to reduce inflammatory cytokine production by activating FXR while inhibiting NF-κB activation in macrophages in a piglet model of intestinal inflammation[132]. These findings suggest a protective role for UDCA in IBD and support its use as a novel approach to treat IBD. In addition, UDCA can improve IBD injury through a few other potential mechanisms. MAdCAM-1 binds to integrin α4β7 on circulating T cells and recruits intestinal homing lymphocytes to intestinal damage sites during inflammation[133]. A recent study showed that by inhibiting NF-κB signaling, UDCA could directly attenuate the endothelial expression of MAdCAM-1 and other adhesion molecules, leading to a decrease in the accumulation of α4β7+ lymphocytes in the colon, thereby reducing the severity of colitis[134]. Another study showed that in a DSS-induced mouse model, UDCA and LCA prevented intestinal inflammation *in vivo*, at least in part by inhibiting epithelial cell apoptosis and promoting barrier function. Interestingly, LCA was more effective than UDCA in inhibiting epithelial cytokine release and preventing DSS-induced mucosal inflammation[135,136]. Mesalazine is the main drug used clinically for the treatment of UC and has been shown to induce remission of IBD and prevent IBD recurrence[137]. UDCA + mesalazine has been reported to have a better therapeutic effect than mesalazine alone, which may be related to the significant reduction of IL-23 and IL-17 and the altered distribution ratio of intestinal flora[138]. Tauroursodeoxycholic acid, a taurine conjugated UDCA, has been shown to reduce the accumulation of MPO activity, decrease colonic tissue levels of IL-1β, IFN-γ, and TNF-α, and also down-regulate nuclear receptor and bile acid transporter protein levels[139,140]. Hyodeoxycholic acid, glycine ursodeoxycholic acid, and taurocholate have similarly reduced colitis severity in in a mouse model of IBD[141-143]. However, it has also been shown that long-term use of high-dose UDCA increases the risk of colorectal neoplasia in patients with IBD, suggesting that we need to control the course and dose of the drug rationally[144]. In conclusion, secondary bile acids such as UDCA may be promising therapeutic agents for reducing ecological dysregulation and improving inflammation in human IBD and are attractive candidates for treating IBD.

Probiotics and fecal microbiota transplantation

Probiotic therapy introduces specific bacteria that have a recognized advantage in competitively suppressing pathogens and normalizing intestinal microbiota composition. Probiotics are classified by the World Health Organization as live

microorganisms that, when consumed in sufficient quantities, can help the host's health. The probiotics *Bifidobacterium, Lactobacillus*, and *Lactococcus* are the most frequently utilized. As an adjuvant therapy for addressing the functional symptoms of IBD, probiotics have shown promise in numerous human and animal studies[145-147]. Wong *et al*[148] recently demonstrated that *Lactobacillus casei* strain Shirota (LcS) not only increased beneficial bacterial species but also modified the circulating bile acid profile in a mouse model of DSS-induced acute colitis. Furthermore, LcS treatment increased mucin-2 and occludin expression in the colon while improving intestinal integrity. It was also shown that LcS therapy decreased the expression of pro-inflammatory mediators IFN-γ and NO and raised the expression of anti-inflammatory mediators in colonic tissue, possibly due to an altered bile acid profile[148]. Another study showed that probiotic mixtures containing *Lactobacillus rhamnosus* and *Lactococcus lactis* reduced the expression levels of IFN-γ, IL-17F, IL-1α, and IL-25, as well as the levels of the main NLRP3 inflammasome components (NLRP3, ASC, caspase-1, and IL-1β) and NOD2 in IBD mice. Probiotics have also increased FXR, GPABR1, vitamin D, and CAR expression in IBD mice[149]. Furthermore, the probiotic *Lactobacillus* has anti-inflammatory activity and induces cellular autophagy, and these effects are achieved by increasing VDR expression[150]. Recently, Zhou *et al*[151] designed a bile acid consortium (BAC) composed of three species of *Bacteroides ovatus*, *Clostridium* AP sp000509125, and *Eubacterium limosum*. They observed that BAC restored secondary bile acid metabolism in DSS-treated mice, thereby increasing the levels of UDCA and LCA, which induced activation of GPABR1 to improve the integrity of the intestinal barrier and reduce inflammation[151]. In addition, the probiotic strain *Bifidobacterium longum* CECT 7894 could improve the efficacy of infliximab against DSS-induced colitis by modulating intestinal flora composition and bile acid metabolism[152]. Probiotics may increase the risk of bacteremia, adverse effects, and the spread of antibiotic resistance in IBD patients because of their bioactivity and other characteristics. In addition, probiotics used for adjuvant therapy may be unsuccessful in some patients due to strain specificity or individual differences, in which case they should be discontinued. Therefore, the duration of probiotics should be dependent on various therapeutic benefits, objectives, and practical circumstances. Future clinical and animal investigations are required to study the direct effects and specific mechanisms of probiotics on bile acids and their receptors in IBD patients.

Fecal microbiota transplantation (FMT) is a novel and appropriate route to modify the microbial ecosystem in the host gastrointestinal tract. In recent decades, FMT has improved diseases such as *Clostridioides difficile* infections, IBD, and irritable bowel syndrome. However, the exact mechanisms still need to be better understood[153,154]. Several recent studies have found that FMT may improve IBD by acting on bile acids and their receptors. Lima *et al*[155] showed that FMT induced the production of RORγt+ regulatory T cells, IL-10, and short-chain fatty acids by macrogenomic analysis and strain tracing in 60 donor and recipient samples of active UC treated by FMT, thus protecting patients from colitis [155]. Another study showed that the long-term *Faecalibaterium* colonization following FMT could reduce intestinal inflammation by regulating the expression of RORγt and Foxp3 in UC, thereby ameliorating the imbalance in Th 17/Treg levels[156]. In addition, a mouse model of colitis was shown to be significantly inhibited by the intestinal fungus *C. metapsilosis* M2006 B, which was isolated from human feces. Moreover, the researchers identified two acyclic sesquiterpenoids (F4 and F5) as the main active metabolites of M2006 B. Surprisingly, in an animal model, these metabolites were able to effectively ameliorate colitis by selectively activating FXR. These findings suggest that M2006 B in human feces may be a beneficial intestinal fungus for treating and preventing IBD[157]. Interestingly, another recent study found that administering antibiotic pretreatment to IBD patients contributed to microbial implantation and possible clinical effectiveness[158]. In conclusion, these findings support the use of FMT in treating IBD, but the safety and efficacy of FMT remain to be investigated.

Bile acid sequestrants

A bile acid sequestrant is a positively charged indigestible resin that binds to bile acids in the intestine and forms insoluble compounds in the feces. They are mainly used in treating primary hypercholesterolemia and hypercholesterolemia with mild hypertriglyceridemia[159,160]. Currently, there are three major medications available for purchase: Cholestyramine, colestipol, and, more recently, colesevelam. Bile acid malabsorption (BAM), also known as bile acid diarrhea (BAD), is a prevalent, underappreciated, and frequently missed indicator of IBD. Clinically relevant BAM is most commonly seen in patients with IBD, especially in ileal resected CD patients.

In most cases, BAM in IBD is caused by impaired reabsorption of conjugated bile acids[161]. CD patients with BAM treated with bile acid sequestrants achieved a good response in 72.2% of cases. Researchers also analyzed the relationship between the degree of BAM (moderate or severe), intestinal surgery, and response to bile acid chelation therapy, but unfortunately, this was not statistically significant[162]. Another study showed a significant improvement in the quality of life of CD patients after terminal ileal resection when molecular treatment was given to them[163]. Although some research progress has been made, the specific mechanisms of bile acid chelators in treating BAM caused by IBD need to be further explained.

CONCLUSION

The data suggest that bile acid metabolism and receptor signaling play a key role in regulating dysregulated gut homeostasis in IBD. Changing bile acid metabolism and bile acid receptor signalling has been found to influence the pathogenesis of IBD *via* modulation of immunology, intestinal epithelial barrier function, and the gut microbiome. It is an attractive and highly promising therapeutic target for IBD. Many therapeutic strategies have shown positive effects, such as bile acid receptor agonists or inhibitors, traditional Chinese medicine, UDCA, probiotics, FMT, and bile acid sequestrants. However, due to the differences between species and cell types (IBD is exclusively a human disease),

valuable preclinical mechanistic studies must be performed to elucidate the function of bile acids and their receptors in human intestinal models. In this regard, human organoid technologies and bioinformatics approaches may be good tools to address this issue. In addition, the current therapeutic strategies described above have yet to be widely validated in clinical trials in patients with IBD, despite the promising results documented in cellular and animal studies. Future research efforts should focus on clinical trial data collection in IBD patients.

Abstract

Hepatocellular carcinoma (HCC), the predominant type of liver cancer, is a major contributor to cancer-related fatalities across the globe. Diabetes has been identified as a significant risk factor for HCC, with recent research indicating that the hormone resistin could be involved in the onset and advancement of HCC in diabetic individuals. Resistin is a hormone that is known to be involved in inflammation and insulin resistance. Patients with HCC have been observed to exhibit increased resistin levels, which could be correlated with more severe disease stages and unfavourable prognoses. Nevertheless, the exact processes through which resistin influences the development and progression of HCC in diabetic patients remain unclear. This article aims to examine the existing literature on the possible use of resistin levels as a biomarker for HCC development and monitoring. Furthermore, it reviews the possible pathways of HCC initiation due to elevated resistin and offers new perspectives on comprehending the fundamen-tal mechanisms of HCC in diabetic patients. Gaining a better understanding of these processes may yield valuable insights into HCC's development and progression, as well as identify possible avenues for prevention and therapy.

Key Words: Hepatocellular carcinoma; Resistin; Insulin resistance; Obesity; Diabetes; Liver cancer

INTRODUCTION

Liver cancer, particularly hepatocellular carcinoma (HCC), poses a significant global health challenge. As the sixth most prevalent cancer and the third leading cause of cancer-related deaths worldwide, it accounts for roughly one million fatalities each year[1-3]. HCC also ranks as the second primary factor contributing to premature cancer-related deaths[4], with projections indicating that annual liver cancer diagnoses will exceed one million by 2025[5]. Moreover, between 2020 and 2040, the number of liver cancer diagnoses is predicted to rise by 55.0%[6]. Although liver cancer prevalence and mortality have decreased in some East Asian countries, they have escalated in other parts of the world[7]. HCC represents the most frequent liver cancer variety, comprising 90% of cases[8]. It is commonly associated with chronic liver diseases (CLD), including viral hepatitis[9-12], alcoholic liver disease, liver cirrhosis[13-15] and "non-alcoholic fatty liver disease (NAFLD)"[16-18]. Because of the increased prevalence of obesity and type 2 diabetes mellitus (T2DM), the incidence of NAFLD and associated consequences, such as "non-alcoholic steatohepatitis (NASH)", is rapidly increasing. NAFLD is currently the major cause of liver cirrhosis, which in turn, raises the probability of developing HCC[19]. The development of HCC is influenced by various factors, including oxidative stress[20], inflammation[21,22], and insulin resistance (IR)[22-25].

Diabetes is a chronic metabolic condition characterized by high blood sugar and IR, which is associated with an increased risk of several health complications, including cardiovascular disease, kidney disease, and fatty liver[26]. The most common form of diabetes, T2DM, is caused primarily by IR. The relationship between diabetes and HCC is complex and multifaceted. On the one hand, diabetes is a risk factor for the development of liver diseases, including liver fibrosis and HCC[27]. On the other hand, HCC can lead to diabetes due to IR, impaired glucose tolerance, and liver dysfunction[28,29].

Resistin, a hormone secreted by both adipocytes and macrophages, and linked to obesity and T2DM, has been connected to HCC development and progression[30-33]. High levels of resistin have been associated with IR, inflammation, and oxidative stress. All these factors are known risk factors for the development of HCC[32-34]. Studies have found that high resistin levels are correlated with a greater risk of getting HCC[30,32,35]. Nevertheless, the mechanisms by which resistin contributes to the initiation and progression of HCC in diabetic patients are not fully understood. Therefore, the purpose of this review is to assess the current literature on the potential use of resistin levels as a biomarker for the development and monitoring of HCC in diabetic patients. Additionally, this review aims to explore resistin's role in HCC pathogenesis among this patient group and provide novel insights into the involved underlying mechanisms. These findings could help identify new targets for preventing and treating HCC in diabetic patients.

PREVALENCE OF HCC IN DIABETIC PATIENTS

HCC is more prevalent in diabetic individuals than in those without diabetes. A thorough meta-analysis of 42 studies, including 17 case-control and 32 cohort studies, demonstrated that diabetic patients have a 2.31 times higher chance of developing HCC compared to non-diabetics. Furthermore, diabetic individuals experience a 2.43 times higher HCC mortality risk than their non-diabetic counterparts[36,37]. HCC patients also exhibit a higher prevalence of diabetes, with reported rates between 20% and 70%[38]. Additionally, a systematic review and meta-analysis of ten studies reported a 70% prevalence of liver cancer among those with elevated fasting blood glucose levels[39].

Numerous investigations have corroborated the heightened incidence of HCC in diabetic individuals. For instance, a population-based study in Taiwan discovered that diabetic patients had a 2-3 times greater risk of developing HCC than those without diabetes[40]. Similarly, a prospective cohort study of Chinese men and women in Singapore found a heightened HCC risk in diabetics[41]. Furthermore, an Italian hospital-based case-control study involving 224 HCC patients and 389 control subjects determined that the risk of HCC was significantly higher among patients with T2DM, especially those with longer disease durations[42]. Additionally, a Korean prospective cohort study using the "National Health Insurance Service-Health Screening Cohort" found a hazard ratio of 1.82, indicating an elevated HCC risk in diabetic patients[43].

Recent research has established that metabolic factors, such as diabetes mellitus, obesity, dyslipidemia, and metabolic syndromes, are substantial risk factors for HCC development[44,45]. In populations with low viral hepatitis prevalence, the overall influence of metabolic factors on HCC may be more substantial than that of viral hepatitis. A recent multicenter study in China found that 9.3% of hepatitis B virus (HBV)-infected patients undergoing curative resection for HCC had concomitant metabolic syndrome. During a median follow-up of 50.4 months, patients with metabolic syndrome had worse 5-year overall survival and recurrence-free survival rates, with increased overall recurrence rates, particularly after two years of surgery. Multivariate analyses revealed that metabolic syndrome was an independent risk factor for reduced overall survival and recurrence-free survival following curative resection for HCC. As a result, proper management of metabolic syndrome is essential for preventing post-hepatectomy recurrence. This information further emphasizes the importance of implementing a more rigorous surveillance program for recurrence in HBV-infected patients with concurrent metabolic syndrome, in addition to routine antiviral therapy[46].

POTENTIAL MECHANISMS AND RISK FACTORS FOR HCC IN DIABETIC PATIENTS

The elevated incidence of HCC in diabetic patients is attributable to a multitude of factors, such as IR, chronic inflammation, the administration of antidiabetic medications, and the progression of NAFLD and NASH[47-50]. IR and diminished glucose tolerance in diabetic individuals can result in hepatic fat accumulation, thereby promoting the onset of NAFLD[51,52]. NAFLD has been linked to a heightened risk of liver fibrosis and HCC[18,53,54]. Furthermore, the prevalence of diabetes has been recognized as a risk factor for the emergence of NASH and its subsequent progression to cirrhosis and HCC[50].

NAFLD is a multifaceted condition that can advance to severe fibrosis, cirrhosis, liver failure, and HCC[55]. In the United States, NAFLD contributes to roughly 20% of HCC cases and is associated with an increased risk of HCC development, especially in patients with metabolic syndrome, specific ethnic groups, and hepatic siderosis. The incidence of HCC in NASH-related cirrhosis varies considerably, ranging from 2.4% over seven years to 12.8% over three years, with some patients developing HCC *de novo* as a result of NASH[55]. Patients with T2DM have a higher risk of developing severe manifestations of NAFLD, such as cirrhosis and HCC[56-58].

The coexistence of diabetes and NASH may contribute to the elevated prevalence of HCC in diabetic individuals. A recent study found that the global burden of NASH-related liver cancer, attributable to increased fasting plasma glucose levels, has significantly risen over the past three decades, particularly in "low- and middle-income countries". Consequently, effective prevention and management of high fasting plasma glucose levels are vital for reducing the worldwide burden of NASH-related liver cancer[59].

Besides NAFLD and NASH, other diabetes-associated complications may also contribute to the heightened HCC risk in diabetic patients. Such patients are more prone to chronic kidney disease, leading to the accumulation of uremic toxins and oxidative stress-both implicated in HCC development[60,61]. Diabetic patients are also more prone to hypertension [62], which has been linked to a higher HCC risk in some studies[44,63,64].

The consumption of antidiabetic medications, for instance, insulin and metformin, may also influence the HCC risk in diabetic patients[49]. Some studies suggest that IR and hyperinsulinemia could promote HCC development, potentially increasing the risk of HCC with insulin therapy[64-67]. Conversely, metformin has shown protective effects against HCC development in some studies, possibly due to its antineoplastic, anti-inflammatory, and antifibrotic properties[42,64,68-70].

Hyperglycemia and hyperinsulinemia are believed to promote HCC development and progression[71,72]. These conditions can activate various signaling pathways, such as the insulin-like growth factor-1 (IGF-1) pathway, phosphatidylinositol 3-kinase (PI3K)/protein kinase B (AKT), mitogen-activated protein kinase (MAPK), and mTOR pathway, all involved in HCC development and progression[73-77].

Hyperinsulinemia can increase hepatic growth hormone receptor expression, leading to IGF-1 release and the activation of growth factor-like activity on hepatocytes. Insulin and IGF-1 inhibit cell proliferation and apoptosis, increasing the risk of HCC[78]. High glucose levels can also contribute to HCC development by generating advanced glycosylation end products, which activate inflammatory signaling pathways and produce reactive oxygen species that promote HCC development. IR might directly hasten the development of HCC by promoting the formation of new blood vessels in the liver[79,80].

Moreover, dyslipidemia, which is common in diabetic patients, may have a role in HCC initiation and progression[81,82]. Dyslipidemia can cause lipid accumulation in the liver, leading to liver damage and inflammation that promote HCC development[83]. Research has demonstrated a strong correlation between reduced total cholesterol levels and a heightened likelihood of HCC development[84-87]. Additionally, diabetic patients who exhibit high triglyceride levels and low high-density lipoprotein cholesterol levels, a pattern often seen in dyslipidemia, have been identified as being at a greater risk for HCC. However, the correlation between the levels of high-density lipoprotein cholesterol with HCC remains uncertain[85,88].

Furthermore, diabetic patients may experience weakened immune systems[89,90], which could increase the risk of developing chronic HBV or hepatitis C virus (HCV) infections, both of which are significant risk factors for HCC[91-95]. Although the connection between DM and HCC risk appears to be stronger in HCV than HBV, a United States study involving 52671 HCV-liver cirrhosis patients (including 7605 HCC cases) did not find a significant association between DM and HCC risk[96]. Moreover, immunosuppressive medications prescribed to manage diabetes-related complications, such as kidney and pancreas transplants, might also contribute to an elevated risk of HCC development[97-99].

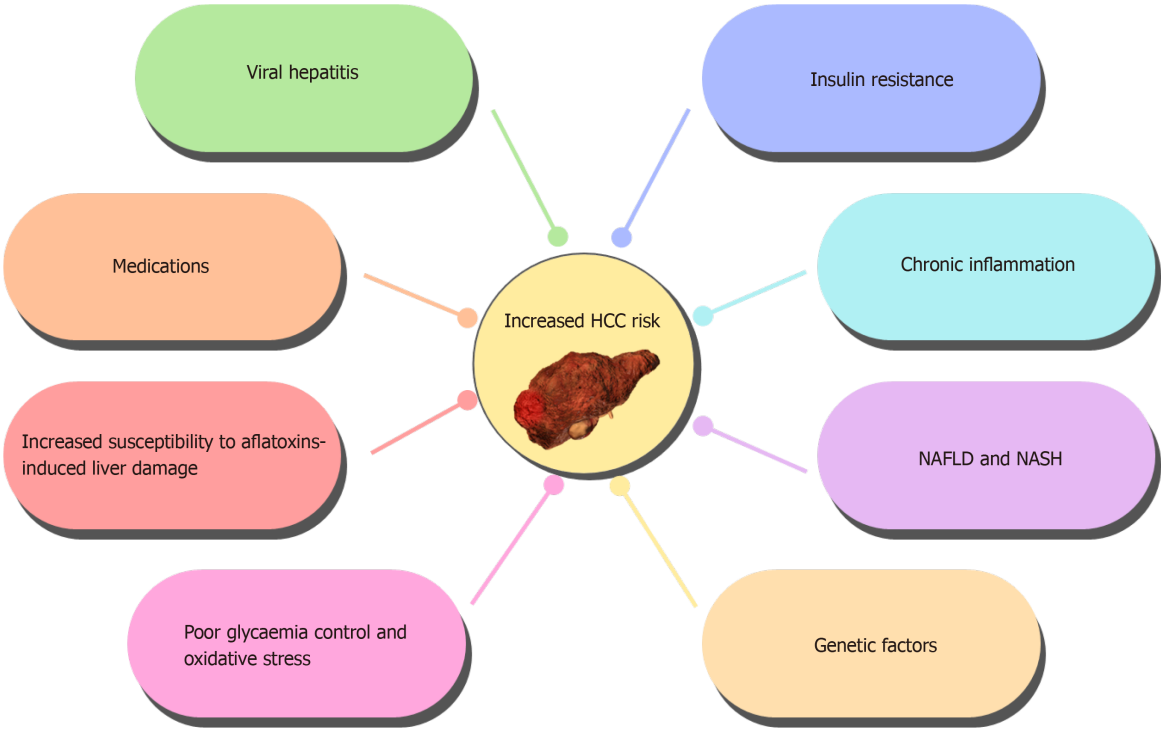
Overall, the increased prevalence of HCC in diabetic patients is due to a combination of factors outlined in Figure 1. Further research is necessary to comprehensively understand the mechanisms linking diabetes and HCC and to devise effective strategies for preventing and treating HCC in diabetic patients.

DIAGNOSIS AND MANAGEMENT OF HCC IN DIABETIC PATIENTS

Early detection of HCC is crucial for successful treatment. Although HCC can be diagnosed early in 30%-60% of cases, recurrences can still affect up to 80% of patients within five years, even after receiving curative treatments[100].

Screening for HCC in diabetic patients is challenging due to the high prevalence of coexisting liver illnesses such as NAFLD and NASH, and there is currently a lack of effective methods to monitor NAFLD-related HCC[101]. Although guidelines recommend regular HCC surveillance for high-risk individuals, which involves at least once every six months of liver ultrasonography and serum alpha-fetoprotein monitoring[102-106], the insidious onset of HCC often leads to late detection. Consequently, it is crucial to establish effective monitoring strategies and ensure early diagnosis and treatment to enhance patient outcomes.

The lack of official guidelines for NAFLD-related HCC diagnosis criteria results in clinical symptoms being the primary diagnostic tool, which can lead to late detection of the disease. Patients with NAFLD-related cirrhosis are considered high-risk subgroups for HCC, and ultrasonography is the primary surveillance test[107-109]. Imaging modalities such as ultrasound, computed tomography, and magnetic resonance imaging are commonly used for HCC screening in diabetic patients, and diagnostic accuracy can be improved by combining different imaging techniques[108-110].



The management of HCC in diabetic patients requires a multidisciplinary approach that considers the potential interactions between diabetes medications and cancer treatments, as well as their impact on glycaemic control[49,111-113]. Although surgical removal of the tumour and liver transplant are curative treatments for HCC, they may not be suitable for all diabetic patients due to the higher risk of surgical complications in this population. Furthermore, diabetic individuals with HCC are more likely to have advanced illnesses at the time of diagnosis, which may limit the effectiveness of these treatments[107-109].

Until recently, Sorafenib was the only medication approved by the United States Food and Drug Administration (FDA) for advanced HCC. Multi-kinase inhibitors like cabozantinib and ramucirumab have been approved as second-line treatments since 2017[114-116]. Nivolumab[117] and pembrolizumab[118], the checkpoint inhibitors have either received FDA approval or are currently being investigated. However, systemic therapies may pose significant challenges in managing side effects in patients with cirrhosis[119]. Moreover, the high cost of approved medications makes their usage difficult in low-income countries[120]. Thus, HCC prevention in high-risk individuals could be a viable alternative to HCC treatment since identifying high-risk individuals is possible, and the survival rates after diagnosis are low. Local therapies such as radiofrequency ablation, percutaneous ethanol injections, and transarterial chemoembolization (TACE) are available options for early-stage HCC[121-125]. Among these options, TACE is commonly used as a treatment approach. TACE involves the direct delivery of chemotherapy drugs into the blood vessels that supply the tumour, followed by the injection of embolic agents to obstruct the tumour's blood flow. This targeted approach allows for the direct impact on the tumour while minimizing the systemic effects of chemotherapy. TACE is often recommended for patients with early-stage HCC who are not suitable candidates for surgery or liver transplantation. Additionally, it can serve as a bridge therapy prior to other definitive treatments or as a palliative measure to reduce tumor size and alleviate symptoms[124,125]. Systemic therapy with chemotherapy, targeted therapy, or immunotherapy may be used for advanced-stage HCC, but the choice of treatment should consider the potential interactions with diabetes medications and their impact on glycaemic control[126-128].

PREVENTION STRATEGIES FOR HCC IN DIABETIC PATIENTS

Preventing HCC development in diabetic patients is a crucial objective of diabetes management. Lifestyle adjustments, such as weight loss, exercise, and dietary changes, can enhance glycaemic control, diminish the risk of developing NAFLD and NASH, which are vital risk factors for HCC[101,109,111], and also minimize the risk of HCC[102,109,129]. Regular HCC screening for diabetic patients can facilitate early detection of the disease when curative therapies are more likely to succeed. The American Association for the Study of Liver Diseases recommends that diabetic patients with cirrhosis and advanced fibrosis undergo ultrasound screening every six months for HCC[107].

In addition, antidiabetic drugs may also aid in preventing HCC development in diabetic patients. Metformin, in particular, has demonstrated a protective effect against HCC development in some studies, potentially because of its anti-neoplastic, anti-inflammatory, and anti-fibrotic effects[49,64,68-70]. However, the use of other antidiabetic medications like insulin may raise the risk of HCC, though further investigation is necessary to completely comprehend the association between diabetes medications and HCC risk[67].

RESISTIN AS A POTENTIAL BIOMARKER FOR HCC: INSIGHTS INTO ITS ROLE IN HCC DEVELOPMENT AND DIAGNOSIS

The timely diagnosis and detection of HCC is crucial for improving patient outcomes, which has led to an increased interest in identifying biomarkers for early detection. Resistin has emerged as a promising candidate in this regard. First identified in 2001, resistin is a hormone that is implicated in IR and is characterized by its pro-inflammatory properties. Resistin is predominantly synthesized by adipocytes in rodents. In contrast, in humans, while adipocytes have the capacity to synthesize resistin, the hormone is primarily produced by immune cells called macrophages, which are integral to immune responses and inflammation. The presence of resistin in human serum typically ranges within a physiological concentration of 7-22 ng/mL[130]. The *RETN* gene encodes resistin protein, which is also known as "adipocyte-specific secretory factor, Fizz3, RSTN, or cysteine-rich protein 1"[131-134].

Resistin contributes to IR by inducing persistent low-grade inflammation associated with obesity-induced macrophage infiltration in adipose tissues. Furthermore, resistin promotes p38 MAPK signaling, altering insulin signaling, modulating the cellular oxidative stress response, and enhancing cells proliferation by increasing the production of various inflammatory molecules such as interleukin (IL)-1β, IL-6, IL-8, IL-12, and tumor necrosis factor-alpha (TNF-α)[34,135-137]. Elevated resistin expression has been associated with inflammation, autoimmune illnesses, metabolic diseases, and malignant conditions, suggesting that it could be a reliable biomarker for HCC diagnosis, early detection, and prognosis [131,132,138,139].

Several clinical studies have investigated the potential of resistin as a diagnostic and prognostic biomarker for HCC[33,140-142]. Studies have shown that resistin is expressed in HCC tissue and is involved in the progression of HCC through its effects on cell proliferation, apoptosis, invasion, and angiogenesis[138,143-145]. Serum resistin levels have been found to be positively correlated with tumour size, TNM stage, and vascular invasion, highlighting that resistin might be a helpful HCC predictive biomarker[32]. Moreover, resistin has been assessed as a diagnostic biomarker for HCC in combination with other biomarkers, such as alpha-fetoprotein and des-gamma-carboxy prothrombin. The combination has been reported to exhibit higher diagnostic accuracy compared to any of the biomarkers alone[32,146,147].

Yagmur *et al*[139] investigated the clinical significance of resistin in CLD by measuring serum resistin levels in 82 CLD patients and 76 age and gender-matched healthy controls, and monitoring the patients for six years. The study found that resistin levels were significantly higher in liver cirrhosis patients compared to the healthy controls, with levels increasing as cirrhosis advanced. Resistin levels also showed a positive correlation with insulin secretion, a negative correlation with insulin sensitivity, and associations with inflammatory markers and clinical complications. The study concluded that patients with higher resistin levels had increased mortality within six years, suggesting that resistin could be a useful clinical biomarker for evaluating liver cirrhosis and its potential link to IR in patients with severe liver disease[140].

Da Silva *et al*[141] conducted a prospective cohort study to investigate potential factors associated with adiponectin and resistin levels in cirrhosis patients and their clinical significance. The study involved 122 cirrhosis patients from an

outpatient clinic and a control group of 30 healthy subjects. The study found that patients with cirrhosis had higher adiponectin and resistin levels compared to the control group. Adiponectin levels, but not resistin well established levels, were significantly associated with the severity of liver dysfunction and a worse prognosis in patients with alcoholic liver disease, suggesting a potential role as a prognostic biomarker[142].

A recently published systematic review and meta-analysis investigated the correlation between serum resistin levels and NAFLD in adults. The review comprised 28 studies that included 4088 participants, which were analyzed using meta-analysis techniques. The study findings indicated that patients with NAFLD had considerably higher serum resistin levels when compared to healthy individuals. In contrast, patients with NASH had lower serum resistin levels than healthy controls. No significant difference was observed in serum resistin levels between patients with NAFLD and healthy controls or between patients with NAFLD and NASH. The study also suggested that serum resistin may be a potential biomarker for predicting the risk of developing NAFLD, a known risk factor for HCC, and could also differentiate between NAFLD and NASH. However, further research is necessary to support these findings and to comprehend the underlying mechanisms of this association[148].

EVALUATION OF RESISTIN AS A DIAGNOSTIC AND PROGNOSTIC BIOMARKER FOR HCC: INSIGHTS FROM CLINICAL STUDIES

A thorough search was executed on PubMed and Google Scholar databases, employing a set of keywords including "resistin and HCC", "resistin and hepatocellular carcinoma", "resistin and liver cancer", "resistin as a biomarker for hepatocellular carcinoma", and "resistin and hepatic cancer" with the objective of identifying research that investigates the role of resistin as a biomarker specifically for HCC. The search yielded four studies that delved into the clinical utility of resistin in the diagnosis and prognosis of HCC. The ensuing compilation of studies is presented in a chronological fashion, commencing with the pioneering study conducted in 2014 and culminating with the latest research from 2022.

Elbedewy *et al*[30] conducted a study to investigate whether serum resistin and IR could be considered as risk factors for HCC in HCV-cirrhotic patients with T2DM. The study involved 50 adult patients with HCV infection who were categorized into three groups based on their HCC status, and were subjected to routine tests for DM, HCV, liver cirrhosis, and HCC. The results revealed that patients with HCC and diabetes (group I) had significantly higher levels of homeostasis model assessment-IR (HOMA-IR) and resistin than diabetic patients with cirrhosis (group II) and control subjects (group III). The study concluded that HOMA-IR and serum resistin could potentially serve as novel biomarkers to identify HCV-cirrhotic patients with T2DM who are at a greater risk of developing HCC[30].

Furthermore, a prospective case-control study was conducted by Elsayed *et al*[33] to investigate the implications of IR and serum resistin as possible risk factors for HCC among individuals with HCV-related liver cirrhosis. The study involved 200 patients with HCV-related liver cirrhosis (100 with HCC and 100 without HCC) as well as 50 healthy controls. The study found that patients with HCC had significantly higher levels of resistin and HOMA-IR than cirrhotic patients and healthy controls. Patients with resistin levels more than or equal to 12 ng/mL and HOMA-IR values higher than or equal to 4 were 1.6 times more likely to experience HCC. These data imply that HOMA as well as serum resistin, may be useful in identifying HCV-cirrhotic individuals at high risk of developing HCC[33].

Mohamed *et al*[32] conducted a study to evaluate the potential of serum resistin levels as a biomarker for assessing response to therapy in individuals with hepatic cirrhosis and HCC. The study included 50 patients with HCV-related cirrhosis, 30 of whom had HCC and the remaining 20 did not. Patients with HCC had higher levels of serum resistin, which showed strong positive correlations with hepatic focal lesions, portal vein invasion, total bilirubin, international normalized ratio, and model of end-stage liver disease score. After one month of HCC intervention, serum resistin levels were significantly lower than before the intervention. These findings suggest that serum resistin could be used as a reliable biomarker for evaluating treatment response in HCC patients[32].

More recently, Ashour *et al*[31] conducted a case-control study to investigate the relationship between serum resistin levels and HCC in patients with liver cirrhosis. The study included 80 cirrhotic patients (40 with HCC and 40 without HCC). The results showed that serum resistin levels were significantly higher in the HCC group compared to the control group, with a strong positive correlation between resistin and total cholesterol and low-density lipoprotein. Additionally, the study found that resistin levels could be used as a diagnostic marker for HCC, with a sensitivity of 90% and specificity of 95% at a cutoff value of > 13.7 ng/mL. These findings support the use of serum resistin levels as a diagnostic biomarker for HCC in patients with liver cirrhosis[31]. Table 1 provides a summary of the above-mentioned studies.

POTENTIAL MECHANISMS OF HCC INDUCTION BY ELEVATED RESISTIN LEVELS

Resistin has been implicated in cancer development through various signaling pathways. Among these, the toll-like receptor 4 (TLR4), PI3K, and nuclear factor kappa-light-chain-enhancer of activated B cells (NFκβ) pathways are particularly noteworthy. These signaling cascades are instrumental in modulating various cellular processes that are crucial for cancer development and progression. In the context of different cancer types, these signaling pathways have been demonstrated to play an imperative role in fostering cellular proliferation. Notably, specific pathways are often selectively associated with distinct types of cancer. For instance, the AKT pathway, a downstream effector of PI3K, has been predominantly associated with prostate cancer, serving as a key regulator in promoting cell survival and growth [149]. Conversely, lung cancer demonstrates a more complex network of signaling pathways. Among these, PI3K, NFκβ,

Table 1 Summary of the clinical studies assessing serum resistin as a potential biomarker for hepatocellular carcinoma

Study ID	Ref.	Study design	Number of participants (HCC/cirrhosis/control)	Age range or mean ± SD	Sex distribution	Resistin levels (ng/mL) (HCC)	Resistin levels (ng/mL) (cirrhosis)	Resistin levels (ng/mL) (control)	Main findings	Resistin as HCC biomarker
1	Elbedewy *et al*[30], 2014, Egypt	Prospective case-control study	25 (HCC), 25 (cirrhosis), 25 (control)	HCC: Mean 53.92 ± 5.9 yr; range 43-65 yr. Cirrhosis: Mean 52.92 ± 7.371 yr; range 40-66 yr. Control: Mean 51.4 ± 6.028 yr; range 38-63 yr	HCC: 19 males/6 females. Cirrhosis: 17 males/8 females. Control: 20 males/5 females	6.11 ± 1.654[1]	3.11 ± 1.533[1]	1.31 ± 0.3198[1]	Patients with HCC have significantly higher mean value of resistin than cirrhotic patients and control subjects	Promising biomarker for HCC
2	Elsayed *et al* [33], 2015, Egypt	Prospective case-control	100 (HCC)/ 100 (cirrhosis)/ 50 (control)	52.3 (HCC), 52.2 (cirrhosis), 51 (control)	85% male (HCC), 66% male (cirrhosis)	23.8 ± 7.8[1]	9.9 ± 2.7[1]	7.1 ± 1.8[1]	HCC patients had higher HOMA-IR and resistin levels; resistin and HOMA considered independent risk factors for HCC	Yes
3	Mohamed *et al*[32], 2018, Egypt	Prospective case-control	50 (HCC)/-/25 (control)	59.8 ± 9.6 (HCC), 57.6 ± 10.1 (control)	37 males/13 females (HCC), 18 males/7 females (control)	5.5 ± 1.7[1] (pre-treatment)	-	3.3 ± 1.1[1]	Higher resistin levels in HCC patients compared to controls, and significant reduction in resistin levels after treatment	Yes
4	Ashour *et al* [31], 2022, Egypt	Case-control study	80 (40 HCC/40 cirrhosis/0 control)	HCC: Median 62 yr (range 18-75). Cirrhosis: Median 59 yr (range 48-72)	HCC: 23 males/17 females. Cirrhosis: 25 males/15 females	19.4[2]	3.4[2]	N/A	Higher serum resistin levels in HCC patients compared to cirrhotic patients; resistin > 13.7 ng/mL able to diagnose HCC with 90% sensitivity and 95% specificity	Promising biomarker for HCC

[1]Data presented as mean ± SD.

[2]Data presented as median. Resistin was measured using ELISA in all studies listed in the table.

HCC: Hepatocellular carcinoma; HOMA-IR: Homeostasis model assessment-insulin resistance; N/A: Not applicable.

epidermal growth factor receptor, and TLR4 have been implicated[150]. These pathways collaboratively contribute to the progression of lung cancer through mechanisms such as cell proliferation, angiogenesis, and resistance to apoptosis.

Additionally, melanoma, a malignancy of melanocytes, has been found to be under the influence of distinct signaling axes, such as the phosphorylated AKT and Caveolin-1, which are critical in dictating the course of the disease[151].

Resistin's influence extends beyond these pathways; it has been implicated in the activation of the IL-6 dependent signal transducer and activator of transcription 3 (STAT3) signaling pathway[152,153]. This pathway is especially noteworthy in breast cancer progression. Moreover, resistin has been linked to the progression of ovarian cancer through the modulation of microRNAs, such as "miR let-7a, miR-200c, and miR-186"[154].

Diving deeper into the IL-6/STAT3 axis, this signaling pathway has been linked with various aspects of cancer biology, including tumor progression, metastasis, and therapy resistance in diverse cancer types such as breast, colorectal, and HCC. The crux of this axis lies in the overexpression of IL-6 and the consequent hyperactivation of STAT3, a combination frequently associated with a grim prognosis. Resistin further exacerbates this by promoting the secretion of pro-inflammatory cytokines like IL-6, which activates STAT3. This sets into motion an autocrine loop intensifying STAT3 signaling, leading to aggressive tumor behavior[153,155,156].

Intriguingly, Resistin dons yet another hat - that of a potential tumor suppressor. It has been shown to induce cell cycle arrest in colon cancer cells through the upregulation of suppressor of cytokine signaling 3 (SOCS3)[157]. SOCS3, part of the SOCS protein family, is integral in curbing cytokine signaling. This implies that resistin may play a role in keeping the proliferation of colon cancer cells in check, revealing its context-dependent pleiotropic nature. In summary, resistin orchestrates a plethora of pathways, including the activation of pro-inflammatory cytokines, fostering angiogenesis, modulating insulin signaling, and influencing cell proliferation and survival[155,156,158]. Its context-dependent roles in both promoting and potentially suppressing tumors accentuate the complexity of resistin's function in cancer. This warrants a nuanced understanding and approach in considering resistin as a potential target for therapeutic interventions.

Resistin's role in proinflammatory cytokine activation

The role of resistin in activating proinflammatory cytokines has been well-established in various studies. These cytokines, including TNF-α, IL-6, and monocyte chemoattractant protein-1 are crucial in inflammation, cell proliferation, and apoptosis, all of which contribute to HCC development and progression[159-163].

Resistin has been demonstrated to directly stimulate TNF-α and IL-6 production in macrophages by binding to TLR4 and initiating downstream signaling pathways, such NFκβ[164,165]. The activation of the NFκB pathway results in the transcription of proinflammatory cytokines, perpetuating chronic inflammation associated with an increased risk of HCC [166].

In addition to direct stimulation, resistin activates other inflammatory pathways, notably the c-Jun N-terminal kinase and STAT3 pathways[167-170]. These pathways contribute to the production of proinflammatory cytokines and are implicated in the pathogenesis of HCC[168,169,171]. Moreover, resistin-induced cytokines have been linked to hepatic stellate cell activation, subsequently leading to liver fibrosis and cirrhosis, both of which are significant precursors to HCC[172-174]. In this regard, resistin's activation of proinflammatory cytokines serves as a vital connection between resistin and the development of HCC in diabetic patients.

Resistin and the modulation of immune responses

In addition to resistin's proinflammatory effect, resistin has been implicated in macrophage activation and polarization of tumor-associated macrophages towards the M2 phenotype[175]. M2 macrophages are characterized by their pro-tumorigenic properties, such as promoting angiogenesis, immunosuppression, and tissue remodeling, which further advance HCC progression[176].

Additionally, resistin has been implicated in the modulation of the immune response through increased expression of the macrophage inflammatory protein-alpha (MIP-α), a chemokine also known as CC chemokine ligand 3[177]. It is a small signaling protein secreted by various immune cells, including macrophages, T cells, and dendritic cells. MIP-α plays a crucial role in immune response modulation by attracting and activating leukocytes, particularly monocytes and neutrophils, to the site of inflammation or infection. This chemokine is involved in various biological processes, including inflammation, immune cell activation, and the regulation of cell migration during an immune response. MIP-α has also been implicated in the progression of certain diseases, such as autoimmune disorders, chronic inflammatory conditions, and even cancer, due to its ability to modulate immune responses[178]. Furthermore, resistin has been reported to modulate the function of other immune cell populations, including natural killer cells and T lymphocytes, impairing their antitumor activities and allowing HCC tumor evasion[179,180]. Taken together, these findings highlight the multifaceted role of resistin in HCC pathogenesis through the modulation of the immune responses and tumour microenvironment.

Resistin and promotion of angiogenesis

Angiogenesis, the formation of new blood vessels from existing ones, is a pivotal process in tumor growth, invasion, and metastasis. Resistin promotes angiogenesis through various mechanisms, including the upregulation of vascular endothelial growth factor (VEGF), activation of the hypoxia-inducible factor-1α (HIF-1α) pathway, and modulation of other signaling pathways[181-184].

VEGF, which spurs endothelial cell proliferation, migration, and survival, is crucial for angiogenesis[185]. Studies have demonstrated that resistin boosts VEGF expression in different cell types, including cancer cells[186,187]. In a study by Tsai *et al*[178], resistin was found to upregulate VEGF expression in osteosarcoma *via* the activation of NFκβ signaling [181]. Furthermore, Chen *et al*[179] demonstrated that resistin enhanced VEGF formation in human chondrosarcoma cells through a PI3K/AKT-dependent mechanism[182]. Elevated VEGF expression in HCC tissue has been associated with a worse prognosis[188,189].

Resistin can also contribute to angiogenesis by stimulating the HIF-1α pathway[190]. Under hypoxic conditions, HIF-1α is stabilized and translocated to the nucleus, where it binds to hypoxia-response elements and promotes the transcription of various genes, including VEGF[191]. It has been demonstrated that resistin increased HIF-1α expression in human adipocytes under hypoxia, leading to enhanced VEGF expression[182].

Resistin's impact on insulin signaling

Insulin signaling is critical for maintaining glucose homeostasis and is often disrupted in diabetes, obesity, and cancer. Resistin has been implicated in modulating insulin signaling, contributing to IR and affecting HCC development in diabetic patients[158].

Resistin has been demonstrated to disrupt insulin-driven glucose uptake in peripheral tissues like adipose tissue and skeletal muscle by interfering with insulin signaling[192,193]. Fu *et al*[191] found that resistin inhibited insulin-induced glucose uptake in 3T3-L1 adipocytes by reducing the activity of glucose transporters[194]. Similar results were observed

in skeletal muscle cells, where resistin impaired insulin-stimulated glucose uptake by decreasing IRS-1-associated PI3K activity[195].

Resistin has been shown to affect liver glucose metabolism by enhancing hepatic gluconeogenesis[196]. In a study by Rajala *et al*[193], resistin administration in mice led to elevated liver glucose production and hyperglycemia. The researchers suggested that this effect occurs *via* activating the cAMP-protein kinase A pathway.

In L6 rat myotubes, resistin overexpression was shown to hinder insulin-mediated glucose uptake without altering glucose transporter type 4 (GLUT4) translocation, GLUT1 expression, or IRS signaling[197]. Moreover, resistin or RELMβ infusion in adult male Sprague Dawley rats led to hepatic IR, characterized by increased hepatic glucose production *via* AMP-activated protein kinase[198]. Lastly, resistin treatment in rat hepatocytes and mice with liver-specific resistin expression resulted in impaired hepatic insulin action by reducing phosphorylation of GSK3β at serine 9. This observation was made in a study conducted on C57BL/6 J mice[199].

The modulation of insulin signaling by resistin may indirectly contribute to HCC development by exacerbating hyperinsulinemia and IR in diabetic patients. Hyperinsulinemia has been associated with an increased risk of HCC, as insulin can promote cell proliferation and survival through the activation of mitogenic signaling pathways, such as the PI3K/Akt and Ras/MAPK pathways[200,201]. Furthermore, IR may lead to chronic inflammation and liver damage, which can promote HCC development[202,203]. Hence, resistin modulates insulin signaling by impairing insulin-stimulated glucose uptake and promoting hepatic gluconeogenesis. These effects may indirectly contribute to HCC development in diabetic patients by exacerbating hyperinsulinemia, IR, and inflammation.

Resistin's induction of matrix metalloproteinases

Matrix metalloproteinases (MMPs) are enzymes responsible for the breakdown of extracellular matrix components, thereby aiding tumour invasion and metastasis[204]. Resistin has been found to increase MMP expression in various cell types, including endothelial cells and cancer cells[136,205]. In a study by Di Simone *et al*[203], resistin was shown to stimulate MMP-2 production in human endothelial cells, potentially contributing to angiogenesis and tumour invasion [206]. Similarly, Huang *et al*[207] demonstrated that resistin increased MMP-2 and MMP-9 expression in human colorectal cancer cells. Furthermore, a study by Tsai *et al*[178] revealed that resistin enhanced MMP-2 expression *via* the activation of the AMPK/p38 signaling pathway and downregulation of miR-519d, contributing to chondrosarcoma metastasis[208].

Moreover, resistin has been implicated in the promotion of HCC metastasis through the upregulation of vascular cell adhesion molecule-1 and intercellular adhesion molecule-1, both of which are critical mediators of cancer cell adhesion and migration. Evidence suggests that resistin stimulates the expression of these adhesion molecules in endothelial cells [206], thereby facilitating the adhesion and transendothelial migration of HCC cells. Taken together, the available evidence suggests that resistin contributes to HCC progression and metastasis through multiple mechanisms, including the promotion of angiogenesis, upregulation of VEGF, activation of the HIF-1α pathway, induction of MMP expression, and increased expression of cell adhesion molecules.

Promotion of cell proliferation and survival by resistin

Resistin has been associated with the enhancement of cell proliferation as well as survival in various cell types, including cancer cells, which can contribute to HCC development and progression in diabetic patients. This is achieved through the activation of mitogenic signaling pathways like PI3K/AKT and MAPK/ERK[135,140,183,207,208]. These pathways have been found to mediate cell proliferation and HCC progression[207,208]. Additionally, resistin promotes cell survival by upregulating anti-apoptotic proteins like Bcl-2 and Bcl-xL[145]. For instance, a study by Pang *et al*[144] demonstrated that resistin increased Bcl-2 expression in human myeloma cell lines, contributing to improved cell survival and resistance to chemotherapy, potentially through the activation of the NFκβ signaling pathway.

Moreover, resistin impacts cell cycle regulation. Research revealed that resistin increased the expression of cyclin D1 in colon cancer patients[157]. Cyclin D1 is integral for cell cycle progression, particularly for the transition from the G1 to S phase. This upregulation of cyclin D1 was suggested to be a result of SOCS 3 upregulation, mediated by the activation of the ERK signaling pathway[157].

Overall, resistin contributes to cell proliferation and survival through various mechanisms, including the activation of mitogenic signaling pathways, induction of anti-apoptotic proteins, and modulation of cell cycle regulation. Figure 2 provides a schematic representation of the mechanisms through which resistin influences the development and metastasis of HCC.

CONCLUSION

Resistin, an adipokine implicated in obesity and IR, plays a crucial role in promoting HCC development and progression in diabetic patients. There is evidence supporting the potential use of resistin as a biomarker for HCC in diabetic patients. The potential mechanisms through which resistin promotes HCC include the activation of proinflammatory cytokines, promotion of angiogenesis, modulation of insulin signaling, and enhancement of cell proliferation and survival. These diverse effects highlight the need for further research to better understand the complex interplay between resistin and HCC development in diabetic patients.

Limitations

This review, while offering a comprehensive overview of resistin's role in HCC development among diabetic patients, possesses several limitations. First, the scope is bound to the literature available at the time, which may not encompass

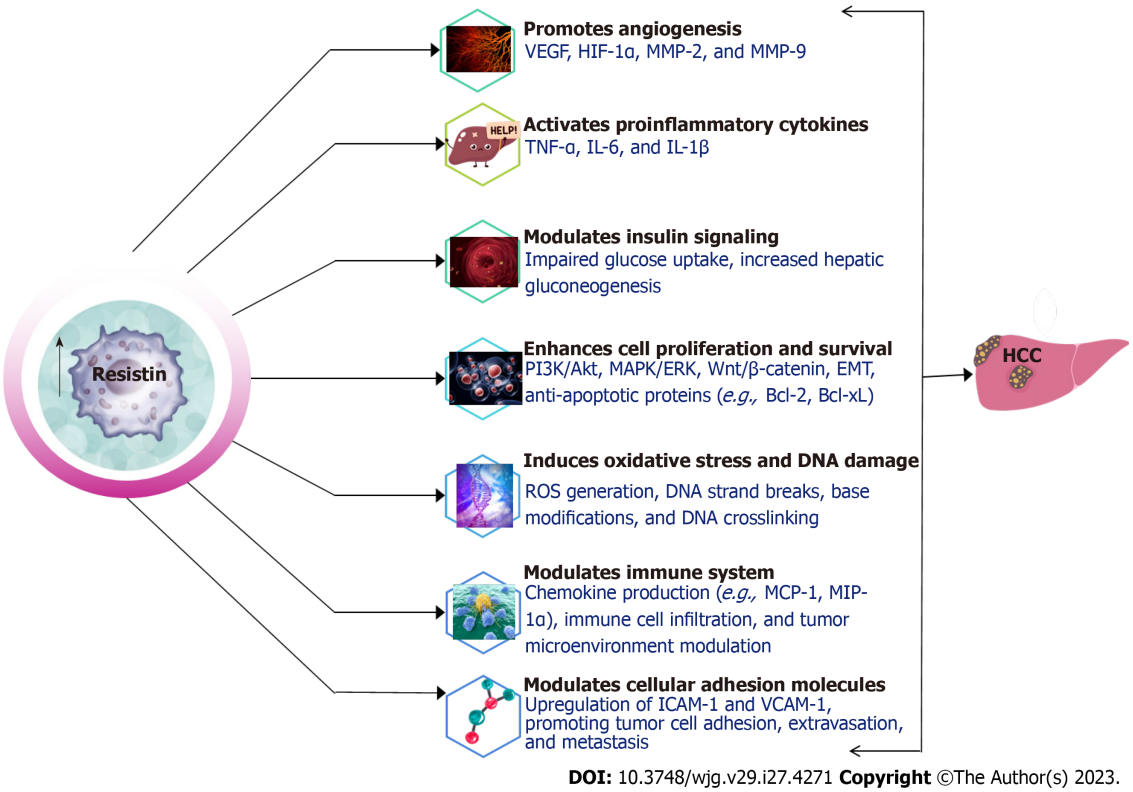

Figure 2 Mechanisms of resistin-induced hepatocellular carcinoma. VEGF: Vascular endothelial growth factor; HIF-1α: Hypoxia-inducible factor-1α; MMP-2: Matrix metalloproteinases-2; MMP-9: Matrix metalloproteinases -9; TNF-α: Tumour necrosis factor-α; IL-6: Interleukin -6; IL-1β: Interleukin--1β; ROS: Reactive-oxygen species; MCP-1: Monocyte chemoattractant protein-1; MIP-α: Macrophage inflammatory protein-alpha; ICAM-1: Intercellular adhesion molecule-1; VCAM-1: Vascular cell adhesion molecule-1; HCC: Hepatocellular carcinoma.

recent developments. Additionally, the multifaceted molecular mechanisms discussed are highly complex, and there may be aspects not extensively covered here. It is also imperative to differentiate between correlation and causation, as the review addresses associations but does not confirm causal relationships. Furthermore, the generalizability of the conclusion is uncertain, as genetic diversity, lifestyle factors, and additional health conditions could affect the interplay between resistin and HCC in different populations. Lastly, the reliance on studies that might contain biases or have their own limitations could inadvertently influence the conclusion drawn in this review. Recognizing these limitations is vital for a well-rounded understanding and highlights the importance of further studies.

Future studies

Future studies should focus on identifying novel molecular targets for therapeutic intervention and developing strategies to counteract the deleterious effects of resistin on HCC development and progression. Understanding the molecular mechanisms underlying resistin's role in HCC could lead to the development of novel diagnostic and therapeutic strategies for the management of HCC in diabetic patients. Additionally, the development of effective therapies targeting resistin and its associated signaling pathways may help mitigate the risk of HCC in diabetic patients, especially those with obesity and IR. Further research is required to assess the effectiveness and safety of such therapeutic strategies in preclinical and clinical settings.

Moreover, given the complexity of the molecular mechanisms underlying resistin's role in HCC, a multidisciplinary approach involving collaboration between experts in endocrinology, oncology, and molecular biology is essential for advancing our understanding of this complex relationship. This collaborative effort may help identify potential biomarkers for early detection and prognosis of HCC in diabetic patients and facilitate the development of personalized medicine approaches.

Abstract

BACKGROUND

Using rat stomach perforation as a prototypic direct lesion applied in cytoprotection research, we focused on the first demonstration of the severe occlusion/occlusion-like syndrome induced by stomach perforation. The revealed stomach-induced occlusion/occlusion-like syndrome corresponds to the previously described occlusion/occlusion-like syndromes in rats suffering multicausal pathology and shared severe vascular and multiorgan failure. This general point was particularly reviewed. As in all the described occlusion/occlusion-like syndromes with permanent occlusion of major vessels, peripheral and central, and other similar noxious procedures that severely affect endothelium function, the stable gastric pentadecapeptide BPC 157 was resolving therapy.

AIM

To reveal the stomach perforation-induced general occlusion/occlusion-like syndrome and BPC 157 therapy effect.

METHODS

The procedure included deeply anesthetized rats, complete calvariectomy,

laparotomy at 15 min thereafter, and stomach perforation to rapidly induce vascular and multiorgan failure occlusion/occlusion-like syndrome. At 5 min post-perforation time, rats received therapy [BPC 157 (10 μg or 10 ng/kg) or saline (5 mL/kg, 1 mL/rat) (controls)] into the perforated defect in the stomach). Sacrifice was at 15 min or 60 min post-perforation time. Assessment (gross and microscopy; volume) included: Brain swelling, peripheral vessels (azygos vein, superior mesenteric vein, portal vein, inferior caval vein) and heart, other organs lesions (*i.e.*, stomach, defect closing or widening); superior sagittal sinus, and peripherally the portal vein, inferior caval vein, and abdominal aorta blood pressures and clots; electrocardiograms; and bleeding time from the perforation(s).

RESULTS

BPC 157 beneficial effects accord with those noted before in the healing of the perforated defect (raised vessel presentation; less bleeding, defect contraction) and occlusion/occlusion-like syndromes counteraction. BPC 157 therapy (into the perforated defect), induced immediate shrinking and contraction of the whole stomach (unlike considerable enlargement by saline application). Accordingly, BPC 157 therapy induced direct blood delivery *via* the azygos vein, and attenuated/eliminated the intracranial (superior sagittal sinus), portal and caval hypertension, and aortal hypotension. Thrombosis, peripherally (inferior caval vein, portal vein, abdominal aorta) and centrally (superior sagittal sinus) BPC 157 therapy markedly reduced/annihilated. Severe lesions in the brain (swelling, hemorrhage), heart (congestion and arrhythmias), lung (hemorrhage and congestion), and marked congestion in the liver, kidney, and gastrointestinal tract were markedly reduced.

CONCLUSION

We revealed stomach perforation as a severe occlusion/occlusion-like syndrome, peripherally and centrally, and rapid counteraction by BPC 157 therapy. Thereby, further BPC 157 therapy may be warranted.

Key Words: Stomach perforation; General occlusion/occlusion-like syndrome; Stable gastric pentadecapeptide BPC 157; Cytoprotection; Therapy; Rats

Core Tip: Rats with perforated stomachs exhibited the rapidly emerging severe occlusion/occlusion-like syndrome, an innate general vascular and multiorgan failure, peripherally and centrally. The pentadecapeptide BPC 157 application into stomach defects was efficacious therapy. With an activated azygos vein-rescuing pathway, there was cause-consequence counteraction of lesions in the brain (swelling, hemorrhage), heart (congestion), lung (hemorrhage), and congestion in the liver, kidney, and gastrointestinal tract. Whole occlusion/occlusion-like syndrome, arrhythmias, blood pressure disturbances (intracranial (superior sagittal sinus), portal and caval hypertension, and aortal hypotension), major vessel failure, and widespread thrombosis, Virchow triad circumstances peripherally and centrally were all attenuated/eliminated by BPC 157 therapy.

INTRODUCTION

As a novel approach with the beneficial effect of the stable gastric pentadecapeptide BPC 157[1-6] to the stomach perforation therapy, we intend to better implement in practice Robert's and Szabo's cytoprotection concept[7-9]. Conceptually, this might improve the original acceptance of basic cytoprotection maxim, the direct epithelium (Robert)[7,8], endothelium (Szabo)[9] protection/maintenance in the stomach *vs* direct agent's noxious effect (*i.e.*, intragastric alcohol [7]; stomach perforation[10]). To resolve this issue, along with the recently reported stomach perforation in the rats[10], this report describes the rats with a perforated stomach rapidly emerging severe general syndrome occlusion/occlusion-like syndrome recently reviewed[1-4,11-24] as an innate general vascular and multiorgan failure and its therapy with the stable pentadecapeptide BPC 157 application (activation of the collateral pathways)[1,2,11-24].

In the rats with perforated stomachs, noxious course progression, and general detrimental syndrome peripherally and centrally, the BPC 157 therapy outcome might be similar to the beneficial effect that occurs peripherally and centrally during major vessel occlusion[11-19] and other similar noxious procedure application[20-24]. To specifically link the occlusion/occlusion-like syndrome and cytoprotection issue we should mention BPC 157 as a novel cytoprotection mediator maintaining gastrointestinal mucosa integrity, used in ulcerative colitis trials, lethal dose (LD1) not achieved in

toxicology studies, native to and stable in human gastric juice, and thereby, easy applicable cytoprotective capabilities and also permitting per-oral application[1-6]. Further, this occlusion/occlusion-like syndrome[11-24] includes, in particular, the absolute alcohol intragastric instillation as a challenge, the prototype commonly used in cytoprotection studies[7,8,24]. Given the previous therapy effects in the occlusion/occlusion-like syndrome[11-24] and in the cytoprotective studies (for review see[25-31]), including perforated defects[10,32], the stable gastric pentadecapeptide BPC 157, might be the resolving therapy (for additional review see[1-6]) equally acting peripherally and centrally. These might be the novel particular shared pathology and shared therapy indication. This might be due to the BPC 157 therapy advantages, its particular capabilities, cytoprotection[1] as a particular vascular effect[2], wound healing[5], and neuroprotection[6,33]. These implemented its particular additional cytoprotective capabilities[1], and thereby, in the severe vessel and multiorgan failure occlusion/occlusion-like syndrome[2], the prompt particular activation of the collateral pathways (*i.e.,* azygos vein direct blood flow delivery) rapidly occurred as resolving key, and recovery of the muscle disturbances, striated, smooth, and heart failure recovery as whole[3,4].

As mentioned, very recently, in the surgically perforated stomach, the stable gastric pentadecapeptide BPC 157 therapy, which locally immediately restored vessels, counteracted bleeding and contracted perforated defect, and eventually, leads to complete healing (day 7), and fewer adhesions, unlike the failed effect of the standard anti-ulcer agents[10]. Now, given the complexity of the stomach perforation lesions, given the general syndrome simultaneously progressing peripherally and centrally, some additional particular parallel effects of its therapy might be further demonstrated[1-6]. Considering the stomach perforation as the part or cause of the occlusion/occlusion-like syndrome of the vascular and multiorgan failure[11-24] might better define the whole emergency made by perforation injury. Previously, in the occlusion/occlusion-like syndrome studies[11-24], with consistently evidenced BPC 157 therapy resolving effect[11-24] due to particular activation of collateral pathways, reported were the counteractions of the severe lesions in the brain and intracerebral and intraventricular hemorrhage, heart (congestion, infarction, and arrhythmias), hemorrhage and congestion in the lung, liver, kidney and gastrointestinal tract. BPC 157 therapy effect included the attenuation/elimination of the blood pressure disturbances, (intracranial superior sagittal sinus), portal and caval hypertension, and aortal hypotension). Arterial and venous thrombosis peripherally and centrally were almost annihilated; congested inferior caval and superior mesenteric vein, collapsed azygos vein as failed major vessels were recovered to rescuing pathways organization[11-24]. Together, on the one hand, these were summarized as rapidly acting Virchow triad circumstances, and on the other hand, as rapidly acting, "key bypassing" therapy with BPC 157 application [11-24], and likely, they might occur rapidly also in the rats after stomach perforation[10]. As particular damaging points appeared the variety of the major vessel occlusion (inferior caval vein, infrarenal and suprahepatic[11,12], portal vein and hepatic artery[13], superior mesenteric vein[14,15] and artery[15,16], superior sagittal sinus[17], both carotid arteries[18], and cauterized episcleral veins[19]). A variety of other similar severe procedures appeared as additional particular points, *i.e.,* myocardial infarction and re-infarction induced by isoprenaline[21], bile duct occlusion acute pancreatitis[23], severe intra-abdominal hypertension mechanically maintained[20], and the intoxication with endothelium damaging agents, alcohol[24] or lithium[22] prototype agent in bipolar disorders, in particular, all as occlusion/occlusion-like syndrome[20-24].

As an important conceptual point to combine all these lesions and to resolve the shared therapy, the prototype ulcerogenic procedure in cytoprotection studies, the absolute alcohol intragastric instillation[24], was one of the innate injury models readily combined with full occlusion/occlusion-like syndrome[11-24]. Thereby, the resolution of the prime lesion and the resolution of the whole syndrome might be evidence of the full cytoprotective effect of the BPC 157 therapy. As the perforated defect is direct damage analogous to the intragastric alcohol-induced direct damage[10,24] (Robert's lesion by direct contact[7]), it represents an analogous prototype lesion and an essential hallmark in cytoprotection studies[10]. Thereby, the therapy for the perforated stomach defect mandated the resolution of the full occlusion/occlusion-like syndrome to be achieved as in the previous studies[11-24]. Thus, in cytoprotection terms, in the perforated stomach defect[10], the advantageous effect of the BPC 157 therapy, to the same wide extent, might likely occur. Nevertheless, the resolving intragastric alcohol stomach lesions and full occlusion/occlusion-like syndrome might be the successful therapy effects[10] (*i.e.,* activated azygos vein to provide direct blood delivery and inferior caval vein-superior caval vein rescuing pathway[2]) suited for generalization[11-24] of the activated collateral pathways occurring as resolving key.

Conceptually, within the standard view and standard cytoprotection agents, the recovery of the perforated stomach defect[10] may be still outside of the cytoprotection concept although born in the stomach[2]. Cytoprotection has essential theoretical and practical points (*i.e.,* holding direct epithelial cell protection[7,8], beneficial effect on other organs[7] (cytoprotection→organoprotection)[34]; direct endothelium cell protection[9], and endothelial maintenance→epithelial maintenance[7-9]). However, these could be hardly assumed to recover a perforated stomach[10] within the standard cytoprotective agents[1,2] as limited more to the prophylaxis, not therapy effect[7-9]. On the other hand, BPC 157 therapy, based on the noted effects[1-6], thereby, may be proof of the corresponding significance (*i.e.,* the counteraction of the leaky gut syndrome[35], and free radical scavenging activity in the various tissues[35-37]). It may be that the rapid upgrading of the minor vessel to take over and compensate for the function of the failed major vessels, and the specific activation of the collateral pathways, are highlights of the innate cytoprotection function[1-6] as an effective cytoprotection mediator. As native and stable in human gastric juice, it may take the continuous maintenance of the stomach and gastrointestinal mucosa integrity, thereby, the pleiotropic beneficial effect occurred[1-6] (including the recovery of the muscle disturbances, striated, smooth, and heart failure recovery as a whole[3,4]). As such, it might be easily applicable as therapy and might override limitations known for the standard cytoprotective agents[1-9] and contribute to the recovery of stomach perforation as both local and general (occlusion/occlusion-like syndrome) disturbance. These might be particular effects in the vascular studies[11,13-16,21,22,26,35-37], given its special interaction with nitric oxide (NO)-system[29,38-40], thrombocytes[40-42] and many molecular pathways[43-52] (*i.e.,* the counteraction of tumor-induced

muscle cachexia and the signaling process implicated in cancer cachexia)[49].

On the other hand, whatever the cause, there were all organ lesions, progressing venous/arterial thrombosis/stasis, peripherally and centrally, all counteracted by BPC 157 therapy application. As additional proof of the concept, the ECG disturbances, intracranial (superior sagittal sinus) hypertension, portal and caval hypertension, and aortal hypotension were eliminated/attenuated[11-24]. Accordingly, given the considerable blood volume that might be trapped with(in) failed vessels[11-24], there might be also a comparable syndrome that might be also induced rapidly with the stomach perforation as the initial injury[10]. Likewise, in the rats with stomach perforation, along with the therapy effect realized locally in the perforated stomach[10], BPC 157 therapy's particular beneficial effect might be realized with the rapid upgrading of the minor vessel to take over and compensate the function of the failed major vessels, making possible the specific activation of the collateral pathways, as before[11-24]. Thus, the activated azygos vein (and thereby, direct blood flow delivery from the inferior to the superior caval vein) might serve as a "bypassing vascular key" taking general significance (for review see[11-24]) to recover otherwise imminent occlusion/occlusion-like syndrome also in rats with the perforated stomachs.

For this purpose, given its cytoprotective stomach capability to counteract the whole imminent occlusion/occlusion-like syndrome, and brain lesions, in particular[11-24], we used the calvariectomized rats, for direct monitoring, and the BPC 157 therapy was given directly into the perforated stomach defect. We focused on the subsequent presentation of the stomach and the presentation of the brain swelling and all organ lesions. Then, progressing venous/arterial thrombosis/stasis, peripherally and centrally, were all counteracted by BPC 157 therapy application. These were along with attenuation/elimination of the arrhythmias, intracranial (superior sagittal sinus) hypertension, portal and caval hypertension, and aortal hypotension. Thus, full therapy effects were determined during the essential early period.

MATERIALS AND METHODS

Animals

Male Albino Wistar rats, 200 g bw, kept under standard laboratory conditions, were randomly assigned at 6 rats/group/interval for all experiments, approved by the Local Ethic Committee, carried out under a blind protocol, and the effects evaluated by the examiners who were unaware of the applied protocol.

Drugs

Stable gastric pentadecapeptide BPC 157 (GEPPPGKPADDAGLV, molecular weight 1419; Diagen, Slovenia), was used in dose and application regimens described previously (*i.e.,* without the use of a carrier or peptidase inhibitor) (for review see[1-6]).

Experimental protocol

In deep anesthesia [40 mg/kg thiopental (Rotexmedica, Germany) and 10 mg/kg diazepam (Apaurin; Krka, Slovenia) intraperitoneally] rats underwent complete calvariectomy[17], and laparotomy at 15 min thereafter, and to induce rapid vascular failure and concomitant general and peripheral occlusion/occlusion-like syndrome, stomach perforation was performed as described before[10,17]. Sacrifice was at 15 min or 60 min post-perforation time.

At 5 min post-perforation time, rats received therapy [BPC 157 (10 μg or 10 ng/kg) or saline (5 mL/kg, 1 mL/rat) (controls)] into the perforated defect in the stomach.

Before the procedure, after perforation, after therapy application, and before sacrifice, recordings [camera attached to a VMS-004 Discovery Deluxe USB microscope (Veho, United States)] of brain swelling, corresponding presentation of the peripheral vessels (azygos vein, superior mesenteric vein, portal vein, and inferior caval vein), and organ lesions, were as in our vascular studies[11-24], and assessed as before[11-24]. At all the indicated time points until the end of the 15-min period stomach defect closing or widening (both as % of the presentation immediately before therapy) was assessed as described[10].

In a separate group of animals, the stomach perforation-induced bleeding as bleeding time from the perforation(s) was assessed throughout the 15 min, given the quite short time after perforation available as described[10]. Immediately after perforation induction, rats received BPC 157 (10 μg or 10 ng/kg) or saline (5 mL/kg, 1 mL/rat) (controls) as therapy applied to the perforated defect in the stomach.

Superior sagittal sinus, portal, caval vein, and abdominal aorta pressure recording

The recording procedure in rats was described in detail in our previous vascular studies[11-24]. At 15 min and 60 min post-perforation time, under deep anesthesia, a cannula (BD Neoflon™ Cannula) connected to a pressure transducer (78534C MONITOR/ TERMINAL; Hewlett Packard, United States), inserted into the portal vein, inferior caval vein and superior sagittal sinus, as well as the abdominal aorta at the level of the bifurcation.

Accordingly[11-24], -24 mmHg to -27 mmHg values of superior sagittal sinus pressure were in healthy rats. The 3-5 mmHg values were considered normal in portal pressure in healthy rats. Similar to that were in the inferior vena cava, though with values at least 1 mmHg higher in the portal vein. Abdominal aorta blood pressure values of 100-120 mmHg at the bifurcation level were considered normal in healthy rats.

ECG recording

In rats under deep anesthesia, before the procedure, and in post-perforation time (*i.e.,* after stomach perforation, after

therapy application, and before sacrifice), precise recordings, measurements, and analysis of ECG parameters (PQ intervals, QTc, heart frequency) as specifically described[11-24] were with ECGs recorded continuously for all three main leads, by positioning stainless steel electrodes on all four limbs using an ECG monitor with a 2090 programmer (Medtronic, United States) connected to a Waverunner LT342 digital oscilloscope (LeCroy, United States)[11-24].

Thrombus assessment

After rats' sacrifice, the clots were weighed when the superior sagittal sinus, and peripherally the portal vein, inferior caval vein, and abdominal aorta were removed[11-24].

Brain volume, heart, and vessel volume presentation

We applied the procedure used in our previous vascular studies[11-24]. Brain volume and vessel volume and heart volume or stomach volume were proportional to the change in the brain or vessel or heart or stomach surface area. The presentation of the brain and peripheral vessels (superior mesenteric vein, inferior caval vein, and azygos vein) was recorded in deeply anesthetized rats, with a camera attached to a VMS-004 Discovery Deluxe USB microscope (Veho, United States). The border of the brain (or vessels, or heart or stomach) in the image was marked using ImageJ software and then the surface area of the brain (or veins, or heart or stomach) was measured. This was done with brain (or veins or stomach) images for healthy rats, and then/or for both the control (saline) group and treated (BPC 157) group of rats at the same intervals after the application and at the time of sacrifice. The arithmetic mean of the surface areas was calculated for both groups. Then, the ratio of these two areas was calculated as (A_{con}/A_{bpc}), where A_{con} is the arithmetic mean brain (or veins) area of the control group and A_{bpc} is the arithmetic mean brain (or veins or heart or stomach) area of the treated group. Starting from the square-cube law equations[1,2], an equation for the change in brain (or veins, or heart, or stomach) volume proportional to the change in brain surface area (or veins, or heart, or stomach)[6] was derived. In expressions[1-5], "*l*" is defined as any arbitrary one-dimensional length of the brain (for example rostro-caudal length of the brain) (or veins or heart or stomach), used only for defining the one-dimensional proportion (l_2/l_1) between two observed brains (or veins or heart or stomach) and as an inter-factor (and because of that not measured[6]) for deriving final expression[6].

The procedure was as follows: (1) $A_2 = A_1 \times (l_2/l_1)^2$ (square-cube law); (2) $V_2 = V_1 \times (l_2/l_1)^3$ (square-cube law); (3) $A_2/A_1 = (l_2/l_1)^2$ [from (1), after dividing both sides by A_1]; (4) $l_2/l_1 = (A_2/A_1)^{1/2}$ [from (3), after taking the square root of both sides]; (5) $V_2/V_1 = (l_2/l_1)^3$ [from (2), after dividing both sides by V_1]; and (6) $V_2/V_1 = [(A_2/A_1)^{1/2}]^3$ [after incorporating expression (4) into equation (5)].

Gross assessment of gastrointestinal lesions

In rats laparatomized under anesthesia, gross lesions in the gastrointestinal tract and in the stomach (sum of the longest diameters, mm) assessment was with the camera attached to a VMS-004 Discovery Deluxe USB microscope (Veho, United States) before sacrifice as described before[11-24].

Microscopy

As described in the previous studies[11-24], evaluation was done by light microscopy using an Olympus 71 digital camera and an Olympus BX51 microscope (OLYMPUS Europa SE & CO. KG). Digital images were saved as uncompressed 24-bit RGB TIFF files using the software program AnalySIS (Olympus Soft Imaging System GmbH, Munster, Germany). The field size was measured and marked with a manufacturer's default scale bar in the software program AnalySIS (Olympus Soft Imaging System GmbH, Munster, Germany). Representative tissue specimens (*i.e.*, the brain, liver, kidney, stomach, small and large intestine, lungs, and heart taken at the end of the experiment, fixed in 10% neutral buffered formalin (pH 7.4) at room temperature for 24 h) were embedded in paraffin, sectioned at 4 μm, stained with hemalaun and eosin.

Brain histology: As described in the previous studies[11-24], the brain was dissected according to NTP-7, at levels 3 and 6 with neuroanatomic subsites presented in certain brain sections using coronal sections with three mandatory sections. We used a semiquantitative neuropathological scoring system, and the sum of analyzed affected areas (0-4) (i) and karyopyknotic cells in the brain areas (0-4) (ii) making (i)+(ii) a combined score (0-8), as follows: (1) Specifically affected brain areas [cerebral (NTP-7, level 3), cerebellar cortex (NTP-7, level 6), hippocampus, thalamus, and hypothalamus (NTP-7, level 3)] were scored (0-4), (score 0 indicates no histopathologic change), as follows. Small, patchy, complete, or incomplete infarcts (≤ 10% of the area affected) represented score 1. Partly confluent or incomplete infarcts (20%-30% of the area affected) represented score 2. Large confluent complete infarcts (40%-60% of the area affected) represented score 3. In the cortex total disintegration of the tissue, in the hypothalamus, thalamus, and hippocampus large complete infarcts (> 75% of the area affected) represented score 4; and (2) Analyzed were karyopyknotic cells in the affected brain areas (0-4) (score 0 indicates no change), cerebral (NTP-7, level 3), cerebellar cortex (NTP-7, level 6), hippocampus, thalamus, and hypothalamus (NTP-7, level 3) as follows: A few karyopyknotic of neuronal cells (≤ 20%, score 1); patchy areas of karyopyknotic cells (50%, score 2); more extensive karyopyknotic areas (75%, score 3); complete infarction (100%, score 4). Brain tissue hemorrhage was obtained estimating a percentage of affected areas. Intraventricular hemorrhage was noted as present or absent.

We also assessed the neuronal pathological changes in acquired digital images saved as uncompressed 24-bit RGB TIFF files in the software program AnalySIS (Olympus Soft Imaging System GmbH, Munster, Germany) performing quantitative analysis of neuronal damage in the karyopyknotic areas. The neurons of the cortical cerebral, cerebellar region, hippocampus, and hypothalamus were counted in 10 different high-powered fields (HPF, 400 ×) and 3 to 5 serial

sections of each sample were used to do the count as described[53]. The field size was 0.24 μm².

We used four criteria for the estimation of the edema: Pale myelin, the sieve-like appearance of myelinated areas, dilation of perivascular and pericellular spaces, and vacuolar appearance of the neuropil of gray matter. Edema was graded as heavy, moderate, slight, or no edema (score 0-3)[54].

Lung histology: The same scoring system as in the previous studies[11-24] was used to grade the degree of lung injury in lung tissue analysis. Each of the features (*i.e.*, focal thickening of the alveolar membranes, congestion, pulmonary edema, intra-alveolar hemorrhage, interstitial neutrophil infiltration, and intra-alveolar neutrophil infiltration) was scored (0-3) as absent (0) or present a mild (1), moderate (2), or severe (3) degree and a final histology score were determined.

Renal, liver, and heart histology: The same scoring system as in the previous studies[11-24] was used to grade renal (*i.e.*, the degeneration of Bowman's space and glomeruli, degeneration of the proximal and distal tubules, vascular congestion, and interstitial edema), liver (*i.e.*, vacuolization of hepatocytes and pyknotic hepatocyte nuclei, activation of Kupffer cells, and enlargement of sinusoids) and heart (*i.e.*, dilatation and congestion of blood vessels within the myocardium and coronary arteries) histology. Each specimen was scored using a scale ranging from 0-3 (0: none, 1: mild, 2: moderate, and 3: severe) for each criterion, and a final histology score was determined (0: none, 1: mild, 2: moderate, and 3: severe).

Gastrointestinal histology: As in previous studies[11-24], we used a histologic scoring scale adapted from Chui and coworkers[55] for the stomach tissue damage scoring 0-5 (normal to severe) in three categories (mucosal injury, inflammation, hyperemia/hemorrhage) for a total score of 0 to 15, as described by Lane and coworkers[56]. Illustratively, the assessment included morphologic features of mucosal injury (*i.e.*, different grades of epithelial lifting, villi denudation, and necrosis), inflammation (*i.e.*, focal to diffuse according to lamina propria infiltration or subendothelial infiltration), and hyperemia/hemorrhage (*i.e.*, focal to diffuse according to lamina propria or subendothelial localization).

Statistical analysis

Statistical analysis was performed by parametric one-way analysis of variance (ANOVA), with the Newman-Keuls post-hoc test or the non-parametric Kruskal-Wallis test and subsequently the Mann-Whitney *U* test to compare groups. Values are presented as the mean ± SD and as the minimum/median/maximum. To compare the frequency difference between groups, the chi-squared test or Fischer's exact test was used. $P < 0.05$ was considered statistically significant.

RESULTS

Along with the recently described stomach perforation course notated in the injured stomach, particular vascular failure (vessels "disappear"/empty), prolonged bleeding, debilitated defect large widening[10], stomach perforation consistently induced the vascular and multiorgan failure, progressing thrombosis, intracranial (superior sagittal sinus), portal and caval hypertension, and aortal hypotension. These were fully compatible with the general occlusion/ occlusion-like syndrome occurring peripherally and centrally. There were also cause-consequence lesions in the brain (swelling, hemorrhage), heart (congestion), lung (hemorrhage), congestion in the liver, kidney, and gastrointestinal tract, arrhythmias, and vessel failure, peripherally and centrally. Noteworthy, the vascular failure studies confirmed similar occlusion/occlusion-like syndromes induced by major vessel occlusion or other similar noxious procedures such as alcohol or lithium intoxication, myocardial infarction, acute pancreatitis, intra-abdominal hypertension that all severely affect endothelium function[11-24].

With counteraction by BPC 157 therapy, beneficial effects were along with those noted before in the healing of the perforated defect (raised vessel presentation; less bleeding, defect contraction) comparable to the previous BPC 157 therapy of the mentioned occlusion/occlusion-like syndromes. A common key finding to recovering rats with perforated stomachs that might break instantly the injurious circle might be the prompt and sustained activation of the azygos vein direct blood flow delivery as the particular effect of the stable gastric pentadecapeptide BPC 157 therapy application. Consistently attenuated/counteracted intracranial (superior sagittal sinus) hypertension and aortal hypotension, major arrhythmias, progressing arterial and vein thrombosis, lesions in the brain, heart, lungs, liver, kidneys, and gastrointestinal tract)[11-24] all prove counteraction of whole occlusion/occlusion-like syndrome.

A perilous syndrome occurred peripherally and centrally

Blood pressure disturbances: In the rats with perforated stomachs, the rapidly presented, portal and caval hypertension, and even more the intracranial (superior sagittal sinus) hypertension (gross brain swelling) as well as the aortal hypotension were markedly attenuated by BPC 157 application. This might be a cause-consequence relation relevant to the effectiveness of the therapy application as BPC 157 reduced consistently blood pressure disturbances that were otherwise induced rapidly by similar occlusion/occlusion-like syndromes. This includes a peripheral presentation (portal and caval hypertension, aortal hypotension) as well an even more central presentation (superior sagittal sinus hypertension, Table 1).

Thrombosis

After perforation of the stomach, as a shared effect with other occlusion/occlusion-like syndromes, in the rats with perforated stomachs, thrombosis was rapidly presented, progressing peripherally in veins (*i.e.*, portal and inferior caval vein) as well as in arteries (*i.e.*, abdominal aorta) and centrally (*i.e.*, superior sagittal sinus). Contrary, with BPC 157 therapy thrombosis was promptly reduced both peripherally and centrally (Table 1) as the effective cause-consequence

Table 1 Blood pressures and thrombosis in rats at 15 min and 60 min following stomach perforation

Application of the 1 mL/rat through the perforated defect in the injured stomach at 5 min following perforation	Blood pressures and thrombosis in rats at 15 min and 60 min following stomach perforation

Blood pressures (intracranial (superior sagittal sinus), portal and caval hypertension and aortal hypotension, mmHg), and thrombosis (thrombus mass, g) in rats at 15 min and 60 min following perforation of the stomach. Saline (5 mL/kg) (control) or BPC 157 (10 μg/kg and 10 ng/kg) were given at 5 min thereafter.

course of the therapy both peripherally and centrally.

Stomach presentation

As before with the application of the BPC 157 as a bath in the abdominal cavity, which might beneath the damaged stomach[10], the application of the BPC 157 directly into the injured stomach through the perforated defect, might rapidly

Table 2 Relative volume of the stomach of the heart, azygos vein, in rats at 5 min and 15 min following stomach perforation

101 ± 2	BPC 157 10 ng/kg	81 ± 7[a,b,c]	79 ± 9[a,b,c]

[a]$P < 0.05$, at least *vs* healthy.
[b]$P < 0.05$, at least *vs* immediately after perforation.
[c]$P < 0.05$, at least *vs* corresponding control at the time of the assessment.
Relative volume (healthy/perforation, healthy/perforation + therapy, %) of the stomach of the heart, azygos vein, in rats at 5 min and 15 min following stomach perforation. Saline (5 mL/kg, control) or BPC 157 (10 μg/kg and 10 ng/kg) were given at 5 min after perforation.

reduce the defect size. Illustratively, given the perforation defect size ratio (%) after therapy/before therapy, considerable widening of the perforated defect occurred in the controls (235 ± 56 and 255 ± 66, at 15 min and 60 min after perforation, respectively). Contrarily, there was a marked shrinking of the defect after BPC 157 therapy (75 ± 8, 65 ± 8, BPC 157 10 μg at 15 min and 60 min perforation-time; 80 ± 8, 75 ± 8, BPC 157 10 ng at 15 min and 60 min perforation-time, $P < 0.05$, at least *vs* control). Likewise, accordingly with previous findings[10], the bleeding time (sec) was also reduced in BPC 157 treated rats (*i.e.*, 100 ± 8 in controls *vs* 50 ± 8 BPC 157 10 μg and 55 ± 7 BPC 157 10 ng, $P < 0.05$, at least *vs* control). In addition, with BPC 157 therapy into the perforated defect, upon volume application instead of volume-induced dilatation as regular finding in the rats with the perforated stomach, the whole stomach reacted with marked shrinking (Table 2, Figure 1).

Collateral pathways, blood vessels, and brain gross presentation: All rats with perforated stomachs without therapy converge to the similar failed effects consistently noted with other occlusion/occlusion-like syndromes. Indicatively for a not functioning common clue (lack of activation of collateral pathways) might be the failed azygos vein, superior mesenteric vein, inferior caval vein, and abdominal aorta. We used their disturbed presentation as indicative illustrations (Figure 2) to envisage the failed collateral pathways presentation.

On the other hand, the attenuation of blood pressure disturbances, peripherally and centrally, we perceived as an effect of BPC 157 along with progressing thrombosis fully counteracted in all vessels investigated, veins and arteries, peripherally and centrally (Table 1). Thus, the major vessel failure and blood stasis, the particular vessels recruitment might compensate. Peripherally, note the rescued presentation of the superior mesenteric vein and inferior caval vein as well as the activated azygos vein, and thereby the heart as well (Figure 2), and centrally, note brain swelling rapidly disappeared (Figure 3). Thus, with BPC 157 therapy, advanced collateral pathways presentation occurred as a key therapy effect.

The relative volume of the brain, heart, azygos vein, superior mesenteric vein, and inferior caval vein might summarize the harmful event of the stomach perforation and subsequent deleterious worsening (swollen brain, congested superior mesenteric vein and inferior caval vein for the congested lung, liver, kidney and gastrointestinal tract and heart failure) (Table 3, Figures 2 and 3). On the other hand, vice versa, relative volume change might clearly indicate the strong therapy effect of the BPC 157 application, and reversal toward the normal vessels (presentation close to normal of the superior mesenteric vein and inferior caval vein that had been over-congested), likely due to the activation of the azygos vein (direct blood delivery) that had been failed. Heart dilatation was reversed. Likewise, the brain swelling was rapidly reversed. Note, upon sacrifice, ex vivo, the control/treated brain volume ratio (%) reached for BPC 157 10 μg or 10 ng/kg ($P < 0.05$, at least *vs* control) 120 ± 4 and 122 ± 4 at 15 min and 123 ± 4 and 121 ± 4 at 60 min after perforation.

Heart and ECG disturbances: Commonly, in the procedure with the stomach perforation, BPC 157 therapy counteracted the whole noxious chain of events (*i.e.*, continuous tachycardia along with prolonged PQ prolonged and QTc intervals) (Table 4). Tachycardia, QTc intervals or PQ intervals disturbances were regularly attenuated or absent in all BPC 157-treated rats.

A perilous syndrome occurred peripherally

Gastrointestinal, lung, liver, kidney, and heart lesions: In the untreated rats, all of the post-perforation intervals consistently expressed the particular lesion severity evidenced in the affected organs (Figures 4-7, Table 5). Also, the evidenced intracranial (superior sagittal sinus), portal, and caval hypertension, aortal hypotension, progressed thrombosis, peripherally and centrally, failed collateral recruitment, and ECG disturbances may together indicate a common clue that might be failed. Thereby, there is the immediate impact of the activated collateral pathway that the reduced severity of lesions by BPC 157 therapy evidently occurred along with the reduced intracranial (superior sagittal sinus), portal, and caval hypertension, and reduced aortal hypotension, counteracted ECG disturbances. Thus, BPC 157

[c]$P < 0.05$, at least *vs* corresponding control at the time of the assessment.
Relative volume (healthy/perforation, healthy/perforation + therapy, %) of the brain, inferior caval vein, and superior mesenteric vein, and relative volume (control/treated, %) of the heart, azygos vein, in rats at 15 min and 60 min following stomach perforation. Saline (5 mL/kg) (control) or BPC 157 (10 µg/kg and 10 ng/kg) were given at 5 min after perforation.

therapy appeared as part of the cause-consequence therapeutic course.

Gastrointestinal lesion: Transmural hyperemia of the stomach wall in the control group with marked mucosal congestion at perforation's margins (Figure 4, Table 5). No congestion of the stomach wall in the BPC 157 group, and only mild mucosal congestion was at the stomach perforation's margins (Figure 5, Table 5).

Heart: Severe myocardial congestion was commonly noted in all the control rats. Contrarily, in rats treated with BPC 157, these lesions were completely annihilated (Figures 6 and 7, Table 5). These findings were along with counteracted heart dilatation and counteracted ECG disturbances (Tables 3 and 4, Figure 2).

Lung: Without therapy, focal thickening of the alveolar membranes occurred, lung congestion, pulmonary edema, and severe intra-alveolar hemorrhage. Contrarily, BPC 157 rats exhibited only mild congestion in lung parenchyma (Figures 6 and 7, Table 5).

Liver: Severe enlargement of sinusoids with liver congestion occurred in all control rats, while BPC 157 exhibited no changes in liver parenchyma (Figures 6 and 7, Table 5).

Kidney: Severe vascular congestion and mild interstitial edema occurred in all control rats. Contrarily, no changes were found in renal parenchyma in BPC 157 treated rats (Figures 6 and 7, Table 5).

Table 4 ECG changes, PQ interval, QTc interval, msec, heart frequency, beats/min, in rats at 15 min and 60 min following stomach perforation

Application of the 1 mL/rat through the perforated defect in the injured stomach at 5 min following perforation	ECG changes in rats at 15 min and 60 min following stomach perforation

[a]$P < 0.05$, at least *vs* control.

Lesions scored microscopically (heart, lung, liver, kidney, and stomach), or macroscopically (stomach, in rats at 15 min and 60 min following stomach perforation. Saline (5 mL/kg, control) or BPC 157 (10 μg/kg and 10 ng/kg) were given at 5 min thereafter.

A perilous syndrome occurred centrally

Brain lesions, cerebral and cerebellar cortex, hypothalamus/thalamus, and hippocampus: All of the control rats with perforated stomachs converge to a similar brain lesion (Figures 7 and 8, Table 6) indicating a common clue that might be failed. Namely, these occurred along with intracranial (superior sagittal sinus), portal, and caval hypertension, aortal hypotension, progressed thrombosis, peripherally and centrally, failed collateral recruitment, disturbed ECG presentation, and peripheral organs lesion. The brain swell (Figure 3) occurred with the increased intracranial (superior sagittal sinus) hypertension in the immediate and prolonged post-application-period. These rats with perforated stomachs exhibited marked edema and congestion in neocortical brain tissue with an increased number of karyopycnotic nuclei of cortical neurons, marked edema, and an increased number of karyopycnotic nuclei of cerebellar Purkinje cells. Marked edema and congestion in the hypothalamic area appeared with an increased number of karyopycnotic cells. Marked edema and an increased number of karyopycnotic nuclei occurred also in the hippocampal area.

Contrarily, with BPC 157 therapy, there was a marked reduction of intracranial (superior sagittal sinus) hypertension (and elimination of portal and caval hypertension). These went along with the counteracted brain swelling (Figure 3). BPC 157-treated rats had only mild edema in the neocortex, no change in cerebellar Purkinje cells, only a few karyopycnotic cells in the hypothalamic area, and no change in the hippocampal area (Figures 8 and 9, Table 6).

In summary, in rats with stomach perforation after BPC 157 therapy, in either of the regimens (μg, ng, and intragastrically), there was an immediate effect on the perforated stomach (*i.e.*, decreased bleeding, shrinking of the defect and whole stomach). At the same time, rats rapidly exhibited markedly attenuated portal and caval hypertension, and superior sagittal sinus hypertension, ameliorated aortal hypotension, and had no ECG disturbance, almost annihilated venous and arterial thrombosis, both peripherally and centrally. They had reduced or eliminated central and peripheral organ lesions, in the brain, heart, lung, liver, kidney, and gastrointestinal tract. Gross assessment (*i.e.*, rapid counteraction of the brain swelling, counteraction of the heart dilatation), and microscopic assessment (*i.e.*, myocardial congestion completely annihilated) support each other. Thus, BPC 157 therapy suggests that the consistent antagonization exerted probably takes place as a network of interrelated beneficial effects. The reversal of the failed vessel presentation (*i.e.*, inferior caval and superior mesenteric vein severely congested; azygos vein collapsed) might be the key finding of an activated particular collateral pathway responsible for the noted beneficial effects. The rescued and activated azygos vein may combine in rats the inferior caval vein and the left superior caval vein, and may effectively reorganize blood flow.

DISCUSSION

In the rats with surgically perforated stomachs, Robert's direct injury[10] and occlusion/occlusion-like syndrome[11-24] occur as a particular model for cytoprotection studies[1,2]. Thus, the success of the BPC 157 therapy given directly into the perforated defect might likely resolve several cytoprotection issues.

As expected, we evidenced complete correspondence between the perforated stomach-induced occlusion/occlusion-like syndrome and the intragastric alcohol-induced stomach injuries and whole occlusion/occlusion-like syndrome equally presented in rats[24]. Thereby, the correspondence between the BPC 157 therapy resolving the immediate course after alcohol intragastric application and BPC 157 therapy resolving the immediate course after stomach perforation in the rats, might support each other effect. These findings (*i.e.*, effectively applied directly into the perforated defect) are consistent with BPC 157 as a novel cytoprotection mediator native to and stable in human gastric juice rapidly acting to maintain gastrointestinal mucosa integrity, capable to induce a general beneficial effect as well[1-6]. In the rats with perforated stomachs, there was the counteraction of the immediate triad, particular vascular failure (vessels "disappear"/empty), prolonged bleeding, and a large widening of the debilitated defect[10]. Without therapy, these might fairly extend an unresolved local cytoprotection stomach issue to the rapidly emerging severe widespread syndrome occlusion/occlusion-like syndrome as the general cytoprotection failure[10-24]. As a follow-up, the therapy essentially represents the resolution of the perforated stomach defect as the innate vascular and multiorgan failure like that which might occur during the major vessel occlusion and other alike noxious procedure application, occlusion/occlusion like-syndrome[11-24]. Consequently, this implies a wide range of the therapy effect as with the other occlusion/occlusion-like syndromes[11-24], as the perforation of the stomach in the occlusion/occlusion-like syndrome course might be rapidly complicated with the severe lesions. These lesions could be widespread in the brain with intracerebral and intraventricular hemorrhage, heart (congestion, arrhythmias), hemorrhage and congestion in the lung, liver, kidney and gastrointestinal tract. As proof of the therapy concept might be the attenuated/eliminated blood pressure disturbances [10-24]. Otherwise, the blood pressure disturbances occurred instantly (intracranial (superior sagittal sinus) hypertension

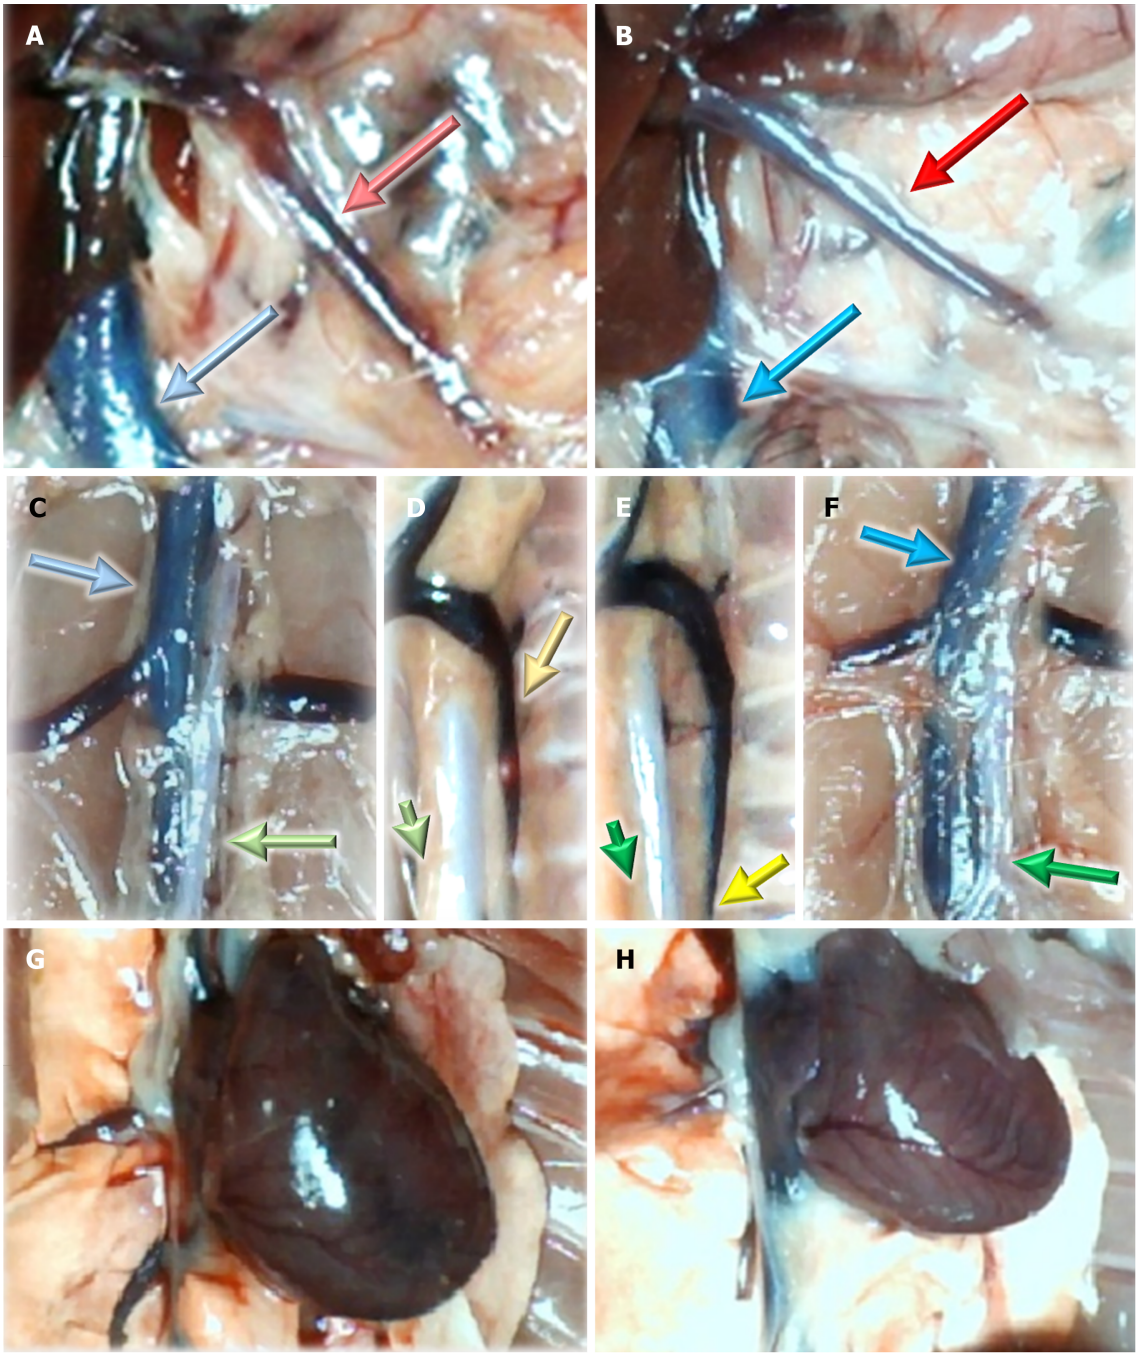
[a]$P < 0.05$, at least *vs* control.

Lesions were assessed microscopically (cerebrum, cerebellum, hypothalamus, and hippocampus), in rats at 15 min and 60 min following stomach perforation. Saline (5 mL/kg, control) or BPC 157 (10 μg/kg and 10 ng/kg) were given at 5 min thereafter.

(grossly, immediate brain swelling), portal and caval hypertension, and aortal hypotension). These might mean the perpetuating noxious circle, initiated peripherally/centrally hampered healing, but successfully reversed by the therapy effects. This might be illustrative, as the stomach perforation combines the arterial and venous thrombosis, peripherally and centrally, failed major vessels (*i.e.*, congested inferior caval and superior mesenteric vein, collapsed azygos vein). Consequently, as in other occlusion/occlusion-like studies[11-24], the almost annihilated thrombosis, vessels presentation close to normal (inferior caval vein, superior mesenteric vein), and activated azygos vein (direct blood flow delivery) (thus stasis eliminated) might verify that Virchow triad circumstances are resolved (and thereby, attenuated/eliminated bleeding/attenuated/eliminated thrombosis). Thus, such therapy might provide an adequate resolution at both local and general levels as the perforation regularly goes with the failed spontaneous cytoprotection maxim endothelial maintenance→epithelial maintenance[7-9], failed upgrading of the minor vessels as a whole, and the widespread rapidly acting Virchow triad circumstances[10-24].



Previously, in the surgically perforated stomach, BPC 157 therapy might have particular effects[10]. Illustrating these particular effects, BPC 157 reversed to the normal healthy values in the stomach tissue surrounding the defect the otherwise increased malondialdehyde- and decreased NO-values. Likewise, already in very early post-perforation-time, BPC 157 may act beneficially in the perforated stomach lesion throughout NO- and prostaglandinds-system[10], two of

the essential cytoprotection systems[1-6], as shown in the findings of the mRNA expression studies (*Cox2*, *VEGFa*, *Nos1*, *Nos 2*, *Nos3*, *Nkap* (NF-kappa-B activating protein gene)), done at that very early post-perforation-time. These might be the maintenance of the proper function of the entirety of the NO-system. There was the release of the NO by its own[29,38-40,47,48], counteraction of the adverse effects of L-NAME (*i.e.*, L-NAME-hypertension[38] and pro-thrombotic[40] effect), counteraction of the adverse effects of L-arginine (*i.e.*, L-arginine-hypotension[39] and anti-thrombotic[40] effect). These suggested a modulatory effect (thereby, counteraction of NOS-blockade and counteraction of NOS-over-stimulation)[29,38-40,47,48] controlling vasomotor tone and the activation of the Src-Caveolin-1-eNOS pathway[47,48]. Thrombocyte function was maintained (*i.e.*, without interfering with coagulation pathways)[40-42]. Counteraction of all adverse effects of NSAIDs[30] includes acting as membrane stabilizers and counteracted leaky gut [26] and acting as free radical scavengers, particularly in vascular studies[11,13-16,21,22,26,35-37]. The therapy effect on NSAIDs is widespread,

Figure 3 Brain illustrative presentation in the rats with perforated stomach. A, C, E, G: Control rats before perforation (A); after perforation (C, E, G), before saline medication (C), specifically after saline application (5 mL/kg, 1 mL/rat into the perforated defect in the stomach; E and G), immediately thereafter (E), and later after sacrifice (G); B, D, F, H: BPC 157 rats before perforation (B); after perforation (D, F, H), before BPC 157 medication (D), specifically after BPC 157 application (10 μg or 10 ng/kg, 1 mL/rat into the perforated defect in the stomach, capitals; F, H), immediately thereafter (F), and later after sacrifice (H).

including both nonspecific NSAIDs[26,41,42,57-61] and specific NSAID[62]. In particular, there BPC 157 may cure stomach lesions that regularly were perforated or about to perforate[58-60]. Furthermore, the healing of the fistula may be an important analogy for the perforated lesions healing, as "two sides" wounds[63], and BPC 157 may cure both external [64-66], and internal[67-69] fistulas in rats.

Summarizing, the findings presented in the rats with perforated stomachs and occlusion/occlusion-like syndrome might demonstrate how the initial cytoprotective effect (stomach epithelium maintenance) is translated to the systemic or generalized cytoprotection to many other organs (organoprotection) where the vascular endothelium might be the possible target, as it had been long-ago envisaged[34]. The local effect of the BPC 157 therapy in the stomach (*i.e.*, immediately restored stomach vessels (vessels filled/reappeared, "run" toward the defect), counteracted bleeding and contracted perforated defect, and later, complete healing (day 7), and fewer adhesions[10]), might be, at the same time, consistently translated into the rapid beneficial effect on the whole syndrome. There, BPC 157 therapy application counteracted all organs lesions, progressive venous/arterial thrombosis/stasis, peripherally and centrally, along with the ECG disturbances, intracranial (superior sagittal sinus) hypertension, portal and caval hypertension, and aortal hypotension eliminated/attenuated[10-24]. Thus, the particularly activated azygos vein (direct blood flow delivery), and minor vessel upgrading might provide a consistent basis for the demonstrated pleiotropic beneficial effect as cytoprotection endothelial maintenance→epithelial maintenance maxim as general cytoprotective (organoprotective) effect. This may implement and reorganize blood flow and instantly attenuate the consequences of maintained perforation occlusion/occlusion-like syndrome-induced vascular and multiorgan failure[10-24]. Along with the activated azygos vein, the congested inferior caval vein and superior mesenteric vein were quickly reversed to the normal vessel presentation. These highlight the inferior caval vein-superior caval vein *via* azygos vein as rescuing pathway, portal and caval hypertension eliminated, aortal hypotension attenuated, thrombosis almost annihilated, as congestion in the lung, liver, kidney, and gastrointestinal tract markedly attenuated or even eliminated[10-24]. Note, BPC 157 might specifically maintain the function of thrombocytes[42], without affecting coagulation pathways, as shown by aggregometry and thromboelastometry studies. There, BPC 157, given with aspirin, clopidogrel, or cilostazol in rats, counteracted their inhibitory effects on aggregation activated by arachidonic acid, ADP, collagen, and arachidonic acid/PGE1[42]. These findings might be responsible for the attenuation of the bleeding from the perforated defect, and lack of hemorrhage in other organs (*i.e.*, brain and lung) and thrombosis, peripherally and centrally, attenuated/eliminated[10-24]. These particular points might be along with the beforementioned particular modulatory effect on NO-system function (either NO-reduction or NO-overload can be harmful), opposing mentioned both NO-reduction (L-NAME-adverse effects) and NO-overload (L-arginine-adverse effects)[29,38-40]. Besides, BPC 157 therapy has particular wound healing capabilities (thereby, a distinctive effect on all four major events in clot formation and dissolution) as a cytoprotective agent's essential effect that realized the healing process for ruptured blood vessels as a whole[5]. Thus, BPC 157 therapy might

Figure 4 Stomach histology and control. A-F: Margins of the stomach perforation showed mucosal congestion. Transmural hyperemia of the stomach wall at the margins of the stomach perforation and in the rest of the stomach wall (A, E). HE staining: Magnification 20 × (A, B), magnification 100 × (C-E), magnification 200 × (F).

have this innate distinctive effect on all four major events in clot formation and dissolution and the therapy effects might be used in distinctive ways depending on the given injury and time of agent application[5,41]. As mentioned, these combined effects (attenuated/eliminated bleeding/attenuated/eliminated thrombosis) occurred as consistent findings commonly seen in the BPC 157 therapy of the counteraction of the occlusion/occlusion-like syndromes (intracerebral and intraventricular, and internal organs hemorrhage/progressive thrombosis, peripherally and centrally)[10-24]. This might accord with the evidence that BPC 157 therapy might reverse heart failure as a whole, including arrhythmias and thrombosis[3,4] which was also noted in the rats with stomach perforation.

Thereby, the BPC 157 therapy given into the perforated defect initiates a consistent chain of events verified by immediate counteraction of the gross brain swelling, and attenuated intracranial (superior sagittal sinus) hypertension as the upgraded venous system, adequately resolving the anatomical imbalance in venous drainage, which would thereby not occur[10-24]. Centrally, evidencing rapid counteraction of such venous and intracranial hypertension[14-17,20-24] reveals successful resolution, ability to drain venous blood adequately for a given cerebral blood inflow without rising venous pressures, and harmful inability resolved. As specifically shown in the maintained intra-abdominal hypertension studies[20], the three interconnected body cavities[14-17,20-24] require the venous system upgraded so that these might act peripherally (*i.e.*, perforated defect), centrally (*i.e.*, huge intraventricular hemorrhage), and then peripherally and centrally, and centrally and peripherally. Otherwise, if the venous system is not adequately upgraded, the disturbances may be rapidly transmitted through the venous system from the periphery to centrally, and from centrally to the periphery. Consequently, given the upgraded venous system, rats with BPC 157 therapy may smoothly sustain without major harm even the conditions of severe grade III and grade IV intra-abdominal hypertension[20]. Likely, the BPC 157

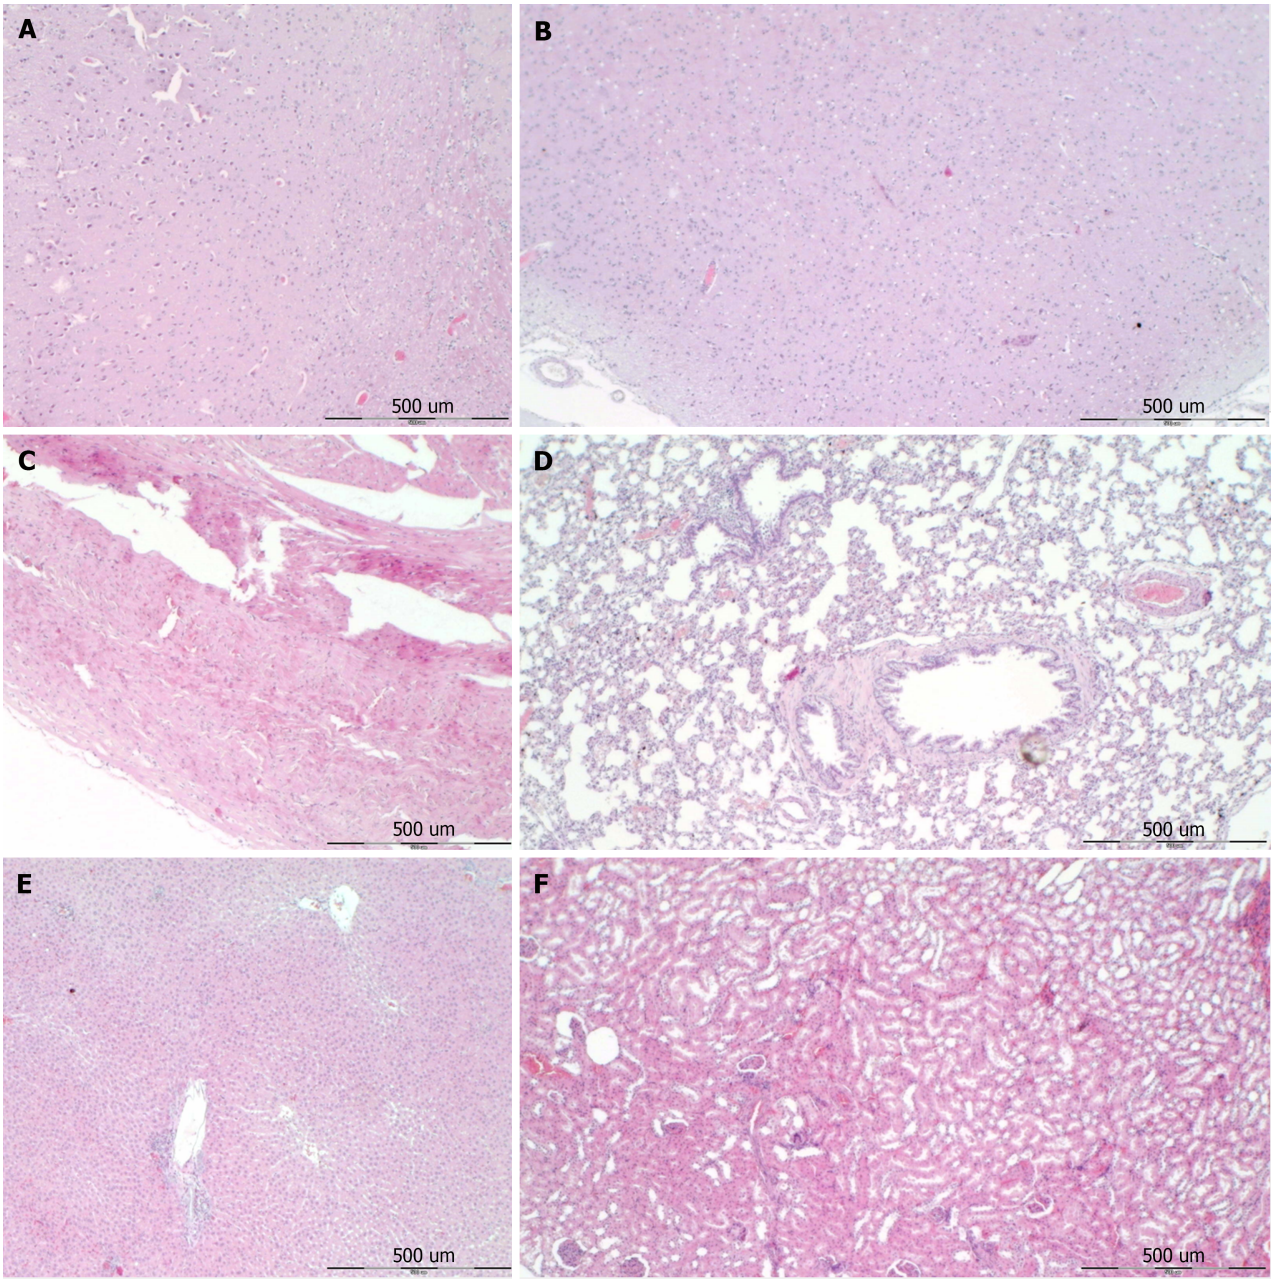
Figure 5 Stomach histology, BPC 157. A-F: Margins of the stomach perforation showed only mild mucosal congestion. No congestion was found in the rest of the stomach wall (A and E). HE staining: Magnification 20 × (A and B), magnification 40 × (C-E), and magnification 100 × (F).

therapy's effect in the rats with perforated stomachs might also effectively operate and might accommodate the particular central/peripheral and peripheral/central equation[10-24] to counteract perforated defect[10]. Note, with BPC 157 therapy into the perforated defect, upon volume application instead of volume-induced dilatation as regular finding in the rats with the perforated stomach, the whole stomach reacted with marked shrinking. This finding might be a sign of the rapid smooth muscle stomach function recovery and might occur along with noted smooth muscle function recovery (*i.e.*, various sphincters to counteract esophagitis development[36,57,70-74], urinary incontinence[35,67,75], pupil dysfunction, miosis[76] and mydriasis[76] (in particular in glaucoma therapy[19]). Likewise, the rapid smooth muscle stomach function might be along with the recovery as rapid adaptation following injury (*i.e.*, short bowel rats)[77]. Thus, as proof of the concept, peripherally and centrally, BPC 157 therapy might rapidly overwhelm Virchow triad circumstances, which are otherwise commonly presented in the rats with perforated stomach occlusion/occlusion-like syndrome as in the rats with occlusion/occlusion like syndromes induced with major vessel(s) occlusion or application of other similar noxious procedures[10-24].

By doing so, the pleiotropic lesions counteraction in the studies of the perforated stomach and other vascular occlusion/occlusion-like syndromes[10-24], was particular cytoprotection/organoprotection background of the cytoprotective agents' innate activity. This cytoprotection/organoprotection background of the cytoprotective agent might be also in the previous non-vascular studies since there was a particular counteraction of the lesions in the brain[57-62,78,79], lung[80-83], liver[57-62,79,84-86], kidney[87-89] and gastrointestinal tract[26,57-62,73], and in particular, the counteraction of the heart arrhythmias and infarction[83,90-95]. Together, these findings might suggest a particular regulatory role.



Finally, we envisaged the perforated defect as direct damage, and prototype lesion that as such should be the core hallmark in cytoprotection studies[10]. This might be further indicative for additional implementation of the cytopro-

tection concept into the whole occlusion/occlusion-like syndrome[10-24], and demonstration of the therapeutic potential of the stable gastric pentadecapeptide BPC 157, in particular, and cytoprotective agents in general. In conclusion, it might be the cytoprotection phenomenon with application in distinctive injuries, analogous to, if not identical with, that which might occur during major vessel occlusion and application of other alike noxious procedures[10-24]. Furthermore, it might be that in both cases, the same agent - pentadecapeptide BPC 157, also suggested being the novel cytoprotection mediator as native and stable in human gastric juice, easily applicable[1-6]-might be responsible for the effect. The investigated and counteracted lesions all attenuated/eliminated might provide full support[10-24]. The attenuated/eliminated lesions, brain swelling, and lesions, heart dysfunction, lung lesions, liver and kidney failure, gastrointestinal lesions, widespread arterial and venous thrombosis, and vessel failure, each as the ultimate outcome of the tightly interconnected network, suggests that stomach perforation-induced occlusion/occlusion syndrome was resolved in all cause-consequence terms. The additional support might provide the counteraction of the severe intracranial (superior sagittal sinus), portal and caval hypertension, and aortal hypotension, and ECG disturbances fully counteracted as well. Finally, BPC 157 was found in human fetuses and adult in various tissues (*i.e.*, gastrointestinal mucosa, lung bronchial epithelium, the epidermal layer of the skin, and kidney glomeruli) (*in situ* hybridization and immunostaining)[5,96]. Consequently, as evidenced by the resolution of the complex occlusion/occlusion-like syndrome[10-24], BPC 157 may have a regulatory physiologic role in bodily functions. Similar importance was suggested also for other species (*i.e.*, birds [72] and insects[97,98])based on the alike beneficial effects. A very safe BPC 157 profile supports a LD1 not achieved in toxicological studies and clinical trials (ulcerative colitis, phase II) without adverse effects (for review see[1-6,29,30,96]). This favorable point was recently confirmed in a large study conducted by Xu and collaborators[99]. Finally, very recently, the essential point, rapid functional improvement of minor vessels to take over the function of disabled major vessels, reorganize blood flow, and compensate failed vessel function when confronted with major vessel occlusion and

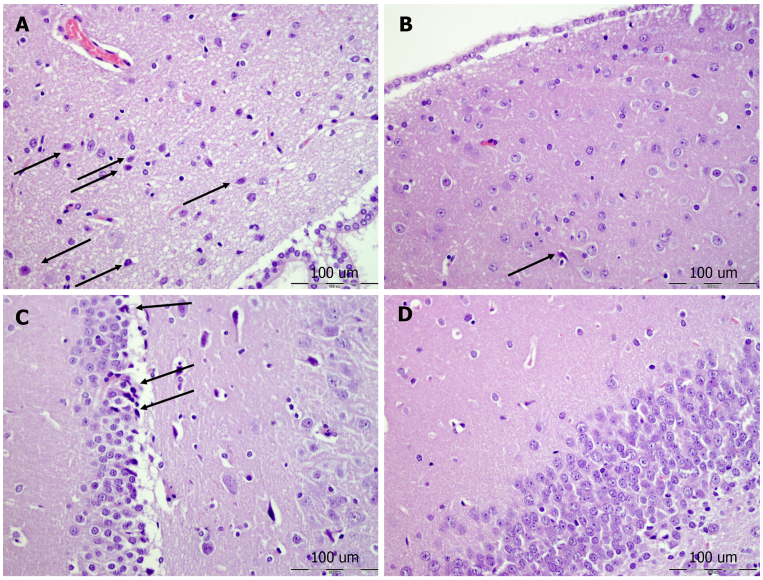
vascular failure was supplemented with Fourier transform infrared spectroscopy evidence[100]. Illustratively, there was an increased capability of the rat thoracic aorta to function even in the worst circumstances due to the rapid change in the lipid contents and protein secondary structure conformation produced instantly by BPC 157 therapy[100].



CONCLUSION

Together, these findings, providing firm evidence of the suited models (*i.e.*, perforated stomach-occlusion/occlusion-like syndrome)[1-6,29,30,96] may be suggestive for further BPC 157 therapy application. Besides, such an experimental design strongly emphasizes the need for patients to receive timely treatment, providing that in general with full medical care life-threatening situations rarely occur.

ARTICLE HIGHLIGHTS

Research background

Taking stomach perforation as a prime direct injury regularly used in cytoprotection studies, as a new insight in resolving the full extent of the cytoprotection issue, there is the rapid progression of severe occlusion/occlusion-like syndrome considerably complicating the course following stomach perforation in rats. Otherwise, such occlusion/occlusion-like syndrome may suffer rats with permanent occlusion of the major vessel(s), veins and/or arteries, peripherally and centrally, and rats who underwent similar noxious procedures that all severely affect endothelium function. There were cause-consequence lesions in the brain (intracerebral and intraventricular hemorrhage), heart (congestion), lung (hemorrhage), congestion in the liver, kidney, and gastrointestinal tract, arrhythmias, vessel failure (congested inferior

caval and superior mesenteric vein, collapsed azygos vein), and blood pressure disturbances (intracranial (superior sagittal sinus), portal and caval hypertension, and aortal hypotension), and widespread thrombosis, peripherally and centrally.

Research motivation

In occlusion/occlusion-like syndromes, stable gastric pentadecapeptide BPC 157 was recognized as counteracting therapy, and has already presented in recent reviews (*Curr Med Chem* 2023; 30: 1568-1573; *World J Gastroenterol* 2022; 28: 23-46). In the rats with perforated stomachs, and subsequent occlusion/occlusion-like syndrome, we emphasized the cytoprotection potential of the stable gastric BPC 157 as native and stable in gastric juice, thought to play the role of cytoprotection mediator maintaining stomach mucosa integrity. As a particular clue recognized also in the counteraction of stomach perforation-induced occlusion/occlusion-like syndromes, there was activation of collateral pathways depending on the injury, locally (raised vessel presentation; less bleeding, defect contraction) and systemically. Accordingly, BPC 157 therapy induced direct blood delivery from the inferior caval vein to the superior caval vein *via* the azygos vein. Application of the BPC 157 therapy (10 μg/kg and 10 ng/kg) into the perforated defect, induced immediate shrinking and contraction of the whole stomach. Simultaneously, there were attenuated/eliminated intracranial (superior sagittal sinus), portal and caval hypertension, and aortal hypotension. Thrombosis, peripherally (inferior caval vein, portal vein, abdominal aorta) and centrally (superior sagittal sinus) BPC 157 therapy markedly reduced/annihilated, and the severe lesions in the brain, heart (congestion and arrhythmias), lung (hemorrhage and congestion) and marked congestion in the liver, kidney and gastrointestinal tract markedly reduced. In conclusion, with stomach perforation severe occlusion/occlusion-like syndrome, and rapid progression peripherally and centrally, the rapid counteraction should be by BPC 157 therapy.

Research objectives

The first objective was stomach perforation presentation in rats as severe occlusion/occlusion-like syndrome, peripherally and centrally. The second objective was rapid counteraction by BPC 157 therapy.

Research methods

In deeply anesthetized rats underwent calvariectomy, stomach perforation was performed and rats received BPC 157 therapy or saline into the defect in the stomach. Then, in addition to assessing shrinking and contraction/enlargement of the whole stomach, the assessment (gross and microscopy, volume) was as in the occlusion/occlusion-like studies and included all points regularly analyzed. Assessed were swollen brain, failed peripheral vessels (azygos vein, superior mesenteric vein, portal vein, inferior caval vein) and heart, other organs lesions (*i.e.*, stomach, defect closing or widening); intracranial (superior sagittal sinus), portal and caval hypertension, aortal hypotension; clots peripherally and centrally; ECGs; and bleeding time from the perforation(s).

Research results

BPC 157 effects accord with the beneficial effect noted before in the healing of the perforated defect (raised vessel presentation; less bleeding, defect contraction) and in the occlusion/occlusion-like syndromes. In rats with perforated stomachs, BPC 157 therapy (10 μg/kg and 10 ng/kg) given into the perforated defect, induced immediate shrinking and contraction of the whole stomach (unlike saline-induced immediate stomach considerable enlargement). There were cause-consequence lesions all eliminated/attenuated by BPC 157 therapy (*i.e.*, direct blood flow delivery *via* azygos vein). There were eliminated/attenuated lesions in the brain (*i.e.*, swelling, hemorrhage), heart (congestion), lung (hemorrhage), congestion in the liver, kidney, and gastrointestinal tract, arrhythmias, and blood pressure disturbances (intracranial (superior sagittal sinus), portal and caval hypertension, and aortal hypotension). Counteracted was major vessel failure (*i.e.*, reversal of congested inferior caval vein and superior mesenteric vein, collapsed azygos vein), and eliminated widespread thrombosis, peripherally and centrally.

Research conclusions

Stomach perforation occurred as severe occlusion/occlusion-like syndrome, peripherally and centrally. Rapid counteraction was by BPC 157 therapy. Thereby, further BPC 157 therapy may be warranted.

Research perspectives

Stomach perforation as severe occlusion/occlusion-like syndrome needs immediate additional medical attention. There, BPC 157, as a prototype cytoprotective agent, should be also considered as further therapy.

Abstract

BACKGROUND

Gastric cancer (GC) is one of the most common cancer types worldwide, and its prevention and treatment methods have garnered much attention. As the active ingredient of licorice, 18β-glycyrrhetinic acid (18β-GRA) has a variety of pharmacological effects. The aim of this study was to explore the effective target of 18β-GRA in the treatment of GC, in order to provide effective ideas for the clinical prevention and treatment of GC.

AIM

To investigate the mechanism of 18β-GRA in inhibiting cell proliferation and promoting autophagy flux in GC cells.

METHODS
