AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatr*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc*.

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, and PubMed Central. The 2020 edition of Journal Citation Reports® cites the 2019 impact factor (IF) for *WJP* as 3.545; IF without journal self cites: 3.545; Ranking: 46 among 155 journals in psychiatry; and Quartile category: Q2.

Abstract

Psychiatry remains in a permanent state of crisis, which fragmented psychiatry from the field of medicine. The crisis in psychiatry is evidenced by the many different competing approaches to psychiatric illness including psychodynamic, biological, molecular, pan-omics, precision, cognitive and phenomenological psychiatry, folk psychology, mind-brain dualism, descriptive psychopathology, and postpsychiatry. The current "gold standard" Diagnostic and Statistical Manual of Mental Disorders/International Classification of Diseases taxonomies of mood disorders and schizophrenia are unreliable and preclude to employ a deductive reasoning approach. Therefore, it is not surprising that mood disorders and schizophrenia research was unable to revise the conventional classifications and did not provide more adequate therapeutic approaches. The aim of this paper is to explain the new nomothetic network psychiatry (NNP) approach, which uses machine learning methods to build data-driven causal models of mental illness by assembling risk-resilience, adverse outcome pathways (AOP), cognitome, brainome, staging, symptomatome, and phenomenome latent scores in a causal model. The latter may be trained, tested and validated with Partial Least Squares analysis. This approach not only allows to compute pathway-phenotypes or biosignatures, but also to construct reliable and replicable nomothetic networks, which are, therefore, generalizable as disease models. After integrating the validated feature vectors into a well-fitting nomothetic network, clustering analysis may be applied on the latent variable scores of the R/R, AOP, cognitome, brainome, and phenome latent vectors. This pattern recognition method may expose new (transdiagnostic) classes of patients which if cross-validated in independent samples may constitute new (transdiagnostic) nosological categories.

Core Tip: The nomothetic network psychiatry approach is a new method which aims to construct causal models of schizophrenia and mood disorders by integrating all features of those mental illnesses into a data-driven model. These features comprise data on risk-resilience, adverse outcome pathways, the cognitome, brainome, symptomatome, staging, and the phenomenome. Partial Least Squares analysis may be employed to train, test, and validate those models and to build pathway-phenotypes or biosignatures. Clustering analysis performed on all illness features, reduced into latent traits scores, may expose relevant new transdiagnostic classes.

INTRODUCTION

For the past 200 years, psychiatry remained a discipline plagued by conceptual controversies, whose roots go back to its poor ontological and epistemological foundations[1]. Psychiatry remained in a permanent state of crisis due to methodological mistrust in psychiatric case definitions, which fragmented psychiatry from the field of medicine[2]. The crisis is psychiatry is further evidenced by the many different competing approaches and ways to understand mental and psychiatric disorders including the etiological approach of psychodynamic psychiatry, biological, molecular, pan-omics, and precision psychiatry, cognitive psychiatry, folk psychology, the mind-brain dualism, descriptive psychopathology, postpsychiatry, and phenomenological psychiatry. Moreover, the gold standard taxonomies used to diagnose mood disorders and schizophrenia are not reliable[3,4].

Recently, we employed a new approach, namely the nomothetic network psychiatry (NNP) approach, which uses machine learning methods to build new data-driven models of mood disorders and schizophrenia using all features of those disorders including etiological, context centered hermeneutic, biological, molecular, cognitive, descriptive psychopathological, and phenomenological features[3-7]. The aim of this opinion paper is to review how to build nomothetic networks using Partial least Squares (PLS) analysis and how to expose new classifications of these disorders using unsupervised pattern recognition techniques.

FOLK PSYCHOLOGY

Folk or commonsense psychology tries to explain the mental state of individuals including symptoms, cognitions, or behaviors as the outcome of everyday life psychology and daily life experiences such as pleasure, sensations, pain, common beliefs, perceptions, *etc*.[8]. Folk psychology narratives are embodied in psychiatric inventories, either observational interviews or self-evaluation scales, which are supposed to deliver meaningful information intended to contribute to the diagnostic criteria of the conventional psychiatric classification systems or to rating scales that measure severity of illness. Thus, structural components of current psychiatric inventories are decomposed into items (statements and questions) some of which are formulated in a folk psychology-like language. For example, items such as "I cry easily" or "I feel down and depressed" are borrowed from folk psychology. In a futile effort to translate these symptoms into a more technical and medical jargon, such as depressive mood for instance (anhedonia and dysthymia), those items are then scored on a 4- or 7-degrees Likert scale so that the total score may resemble a statistically digestible entity. In this manner, common sense folk psychology expressions are converted into "diagnostic" statements without any reference to independent validators. The most common "state" dependent clinical measures or inventories in psychiatry remain folk psychology narratives with some window dressing for

statistical purposes. What is missing in such perspective is the biological, neuronal, and cognitive basis to better understand the existing phenomena in psychopathology, which is declared on the agenda of post-modern psychiatry.

MIND-BRAIN AND MIND-BODY DUALISM

There are two main intellectual frameworks which outline the rationale behind the scientific enterprise in psychiatry. The first is psycho-physical dualism which is supposed to drive the advances in psychotherapy and psychosocial interventions in mental illness. Mind-body dualism is the theory which proposes that mental phenomena are non-physical or that not all mental processes are physical. As such, mind and body would be, at least in part, separable entities[9,10]. The common psychiatric approach is essentially focused on what might be described as "mind" in terms of the mind-brain debate.

The second is the physicalism stance, which considers that everything is physical[11]. Physicalism and materialism are implicated as a primary assumption in influential advances in psychiatric research including biological, molecular, and pan-omics psychiatry, functional neuroimaging, and cognitive science[12].

LOCALIZATIONISM AND DYNAMIC PSYCHIATRY

Early efforts initiated by the Wilhelm Griesinger and the Wernicke-Kleist-Leonhard schools tried to consolidate psychiatric nosology using organic etiological factors[13]. These early theories, associated with the notions of localizationism, culminated in the works of Karl Wernicke and Karl Kleist and Maynert-Wernicke's connectionism. Psychodynamic theories, initiated by Sigmund Freud, and later versions of psychoanalysis, applied a conceptual organization of psychiatric syndromes based on a psychodynamic etiologic approach but remained grounded on the tacit assumptions of psychophysical dualism. However, attempts to bring together the disparate etiological explanatory models of psychodynamic paradigms and localizationism and clinical diagnoses proved to be inefficient. Neither of those views offered consolidated and sustainable pictures of psychiatric diagnoses applicable in the medical practice.

DESCRIPTIVE AND PHENOMENOLOGICAL PSYCHIATRY

Descriptive psychopathology or psychiatry focusses on readily observable behaviors and symptoms, rather than on underlying psychoanalytic or organic etiologies. Phenomenological psychopathology focuses on the patients subjective, own lived experiences of selfhood, space, time, body, and mind[14].

Current gold standard psychiatric classifications are based on descriptive and phenomenological psychopathology, including the Diagnostic and Statistical Manual of Mental Disorders (DSM) and the International Classification of Diseases (ICD) taxonomies. These case definitions are derived from cross-culturally diverse, even sometimes unique criteria[15], established *ex convention* by professional bodies like the American Psychiatric Association (APA) and the World Health Association (WHO). These *ex consensus-based* case definitions of nosological psychiatric classes use de-contextualized narratives and descriptive features of the disorder derived from folk psychology-like self-reports by the patient and observer-based interviews[16].

Due to the missing etiological and biomarker foundations, one crucial limitation of the current classifications, such as DSM-5 and ICD-10, is their top-down manner of generation[3-5,16]. The structured interviews, which are used to construct diagnostic categories, pre-define the clinical diagnosis before other tests are performed, including etiologic, state and trait-biomarkers, brain imaging, and cognitive probes. In that regard the diagnosis remains based on controversial and value laden statements, whereas the causal and biological measures are supposed to be concomitant data, either supporting the diagnosis or not. However, no falsification or dispute of the diagnostic assumption is possible based on information from outside the data source of the clinical interview, thus precluding a top-down deductive approach[3-5]. It should be added that those professional bodies are most often under the influence of para-motivation from the pharmaceutical industry or other confounds which leads to deeply controversial and in the end of the day counter-productive debates on the

existence of specific case definitions of psychiatric illness.

Moreover, the taxonomies used to make the diagnosis of psychotic disorders show inadequate reliability validity as for example indicated by significant differences in the diagnoses of DSM-III-R, DSM-IV, ICD-8, ICD-9, and ICD-10 classifications[16,17]. There is considerable inter-departmental diagnostic variability in the ICD-8 and ICD-10 diagnosis[18] explaining that schizophrenia may be often overdiagnosed or underdiagnosed[17]. In addition, the DSM suffers from a poor demarcation of the clinical heterogeneity present in schizophrenia[4,19]. For example, using machine learning techniques we discovered that schizophrenia consists of qualitatively distinct categories (including deficit *vs* non-deficit schizophrenia)[20], indicating that schizophrenia biomarker research which does not take this distinction into account is bound to fail. Also, the DSM case definitions of mood disorders including major depressive disorder (MDD) lack reliability validity[21], with MDD taxonomies showing minimal agreement between psychiatrists[22]. Furthermore, there was limited or no unification and harmonization of the DSM case definitions[18]. All in all, these taxonomies lack reliability and validity and are therefore counterproductive for research purposes[3-5,16,23-25].

BIOLOGICAL, MOLECULAR AND COGNITIVE PSYCHIATRY

A more radical physicalism theory, namely eliminative materialism, has been outlined in the past decades, especially under the influence of Churchland[26]. This theory applied to psychiatry relies on neuroscience and aims to replace the "folk" psychology vocabulary and methods on a systematic level by material concepts, namely aberrations in brain functions and neurocircuitry. Biological psychiatry aims to explain mental illness in terms of biological aberrations in neuronal functions; molecular psychiatry explains mental illness based on molecular pathways including the effects of genes and intracellular networks; and cognitive psychiatry explains mental illness though effects of cognitive impairments and their neuronal substrates. Nevertheless, the biological, molecular and cognitive approaches turned out to be insufficient to delineate biomarker or cognitive tools that externally validate the case definitions.

Biological, molecular and cognitive psychiatry research generally uses the "gold standard" DSM/ICD case definitions of mood and psychotic disorders in top-down research[3,4,16]. These methods commonly enter diagnosis as explanatory variable in GLM analysis or analysis of variance to analyze alterations in causome (*e.g.*, early lifetime trauma), biomarker levels, brainome data, and cognitive probe scores. The latter are entered as the dependent variables even when causal reasoning shows that they should be employed as the explanatory variables in logistic regression or other machine learning techniques, including neural networks. Consequently, most biological and cognitive psychiatry research projects employ unreliable diagnostic classes applied in inadequate model assumptions and tested with inappropriate statistical tests[3-5]. Also, molecular psychiatry uses a similar approach when examining pathways and networks or when conducting studies which associate genetic markers with the DSM/ICD taxonomies. A newer method, namely the Research Diagnostic criteria (RDoC), developed by the NIH, tries to integrate genetic, neurodevelopmental, environmental factors, with social, regulatory, cognitive and social domains, with negative and positive valence[25]. However, also the RDoC is largely a top-down concept driven by ex-consensus commitments by experts.

Another critical point is that the entire hypostasis of eliminative materialism of biological, molecular, and cognitive psychiatry is a fragmented or *"patchy" reductionist* approach[27] whereby psychiatric diagnoses tend to be reduced to neuronal entities, genetic markers, plasma biomarkers, intracellular signaling molecules, or functional MRI responses to emotional tasks. What is missing is an integrated model with precise mapping of genomics data, specific (causal and protective) and generalized (*e.g.*, context centered and lifestyle) environmental factors, and phenome features. All in all, the current "gold standard" DSM/ICD taxonomies are unreliable constructs and preclude using a deductive reasoning approach and, therefore, it is not surprising that biological, molecular, and cognitive psychiatry research was unable to revise the conventional classifications and did not provide valid predictions from a therapeutic perspective.

PAN-OMICS AND PRECISION PSYCHIATRY

Pan-omics psychiatry proposes to use systems biomedicine to decipher the complex non-linear interactions between pathways and intracellular networks that govern those pathways, and the multifactorial factors including genes and environmental factors that may trigger those pathways/networks[28]. Pan-omics psychiatry proposes to use a data-driven bottom-up approach to compute biosignatures consisting of molecular pathways and networks and symptoms as well as environmental features thereby developing pathway-phenotypes[28,29]. A related field is precision psychiatry, which is based on precision medicine defined as "an emerging approach for treatment and prevention that takes into account each person's variability in genes, environment, and lifestyle"[30]. Precision psychiatry aims to transform the psychiatric landscape through a bottom-up approach applied to pan-omics using system biology and computer science to compute a biosignature, which in turn may be used in a top-down approach to help to understand domains, which differ from components but allow to construct endophenotypes[31]. Both pan-omics and precision psychiatry propose to combine cognitive neuroscience, neural circuits, big data, molecular biosignatures, individual characteristics, physiology, and environment into a biosignature, which is a feature set defining an endophenotype[28,31]. These methods[31], however, do not aim to integrate all features of complex psychiatric disorders into a model characterized by causal paths linking causome (all possible causal factors), protectome (all possible protective factors), adverse output pathways (AOPs, namely biological, molecular, pan-omics, brain imaging features) and phenome (cognitome, symptomatome and phenomenome) feature sets.

BUILDING BLOCKS OF AN INTEGRATED MODEL

Figure 1 shows a causal theoretical model applicable to mood and psychotic disorders[3-7]. Causal reasoning based on state-of-the-art knowledge of these mental disorders indicates that causome features including genes and its products including enzymatic activity as well as specific environmentome factors (*e.g.*, early lifetime trauma) predict AOPs and the phenome of the illness[32]. Moreover, the generalized environmentome (including lifestyle, nutrition, toxins, context centered social, cultural, and political factors) should be added. Pan-omics may be employed to measure causome (genomics) and AOPs (*e.g.*, immunomics, epigenomics, transcriptomics, metabolomics, and proteomics). In psychiatry, another important AOP component is the brainome, which may be assessed using in vivo histology spectroscopy and magnetic resonance imaging. Also, the phenome of psychiatric disorders is very complex and consists of various feature sets including (1) staging of the disorder, as defined by recurrence of episodes and suicidal attempts, chronicity, *etc*.[32]; (2) the cognitome, namely the aggregate of cognitive features of the illness including in memory, executive functions, and attention; (3) the symptomatome, namely the aggregate of observed clinical symptoms, illness severity, subtypes, treatment responsivity; and (4) the phenomenome, namely the illness features as experienced by the patient[3,4].

One of the aims of our new nomothetic network psychiatry (NNP) approach is to reunify such data (1, 2, 3 and 4) into an illness model, which integrates different approaches including etiological, biological, molecular, pan-omics, cognitive, descriptive and phenomenological psychiatry, as well as folk psychology and postpsychiatry. In fact, machine learning conducted on these data will extract and select the most important features in a process referred to as feature re-engineering, selection, and learning to make the most accurate models of mood and psychotic disorders.

THE PRE-SPECIFIED CAUSAL FRAMEWORK

Figure 2 shows a framework or general structure which is based on scientific evidence linking a multitude of causome, protectome, AOPs, cognitome, brainome, staging, symptomatome, and phenomenome data. The selection of variables (indicators) and the concept of the framework are guided by the available theoretical knowledge, expertise, and information accumulated over the past decades and by formal causal reasoning. Nevertheless, the framework shown in Figure 2 is far for complete as for example socio-demographic data and generalized environmentome factors (*e.g.*, those

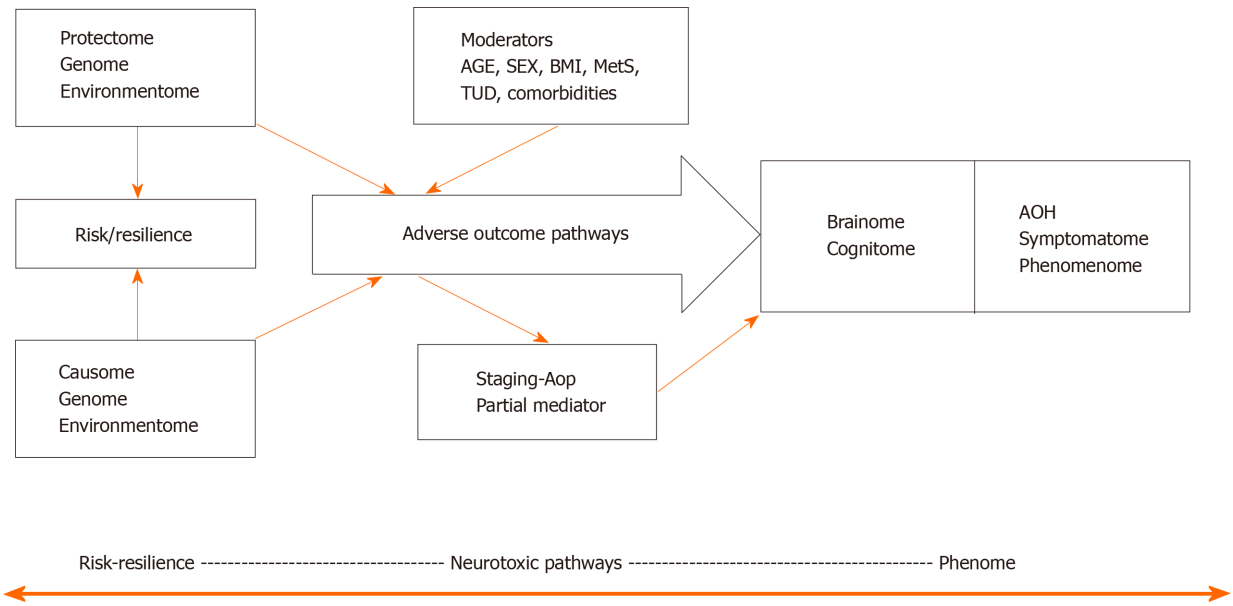

Figure 1 A causal theoretical model applicable to mood and psychotic disorders. This model links causome features (genes and gene products and environmentome factors) with adverse outcome pathways (AOP) and the phenome of the illness. The phenome consists of brainome and cognitome factors and adverse health outcomes including in the symptomatome and the phenomenome. Moreover, staging of illness may partly mediate the effects of risk/resilience and AOPs on the phenome. Age, sex, body mass index, metabolic syndrome, tobacco use disorder, and psychiatric and medical comorbidities are frequent moderators of the effects of R/R and AOPs on the phenome. AOP: Adverse outcome pathway; AOH: Adverse health outcome; MetS: Metabolic syndrome; BMI: Body mass index.

relevant to postpsychiatry) should be added to the model but are deleted from the figure for reasons of clarity. Consequently, data (facts) are accumulated to test this theoretical framework[33].

The multitude of data to be entered should first be reduced (dimensionality reduction) to a smaller number of relevant feature sets or vectors using feature construction processes[3,4]. The first step is to re-engineer the causome and protectome data into one of more new feature sets reflecting risk-resilience (R/R), namely the balance between causal and risk factors[3,4]. These R/R feature sets can consequently be used as input variables (predictors) in logistic models, regression analysis, and neural networks to expose their effects on the downstream features of the framework (AOP and phenome data). For example, in schizophrenia, we established that R/R indices re-engineered from genome data, *i.e.*, paraoxonase 1 (PON1) Q192R genotype combined with PON1 enzymatic activity, zonulin levels (a product of the haptoglobin 2-2 genotype), and lowered natural IgM (a protectome factor) predict AOPs (neuro-immune and neuro-oxidative toxicity pathways), cognitome (episodic and semantic memory and executive functions), symptomatome (psychosis, hostility, excitation, mannerism, negative symptoms) and phenomenome (self-rated quality of life) features[4]. In mood disorders, a new R/R index consisting of the PON1 Q192R genotype combined with PON1 enzymatic activity and early lifetime trauma predicts AOPs (antioxidant defenses and neuro-oxidative stress biomarkers), the symptomatome (depression severity, suicidal ideation, and mood disorders subtypes such as treatment resistance and melancholia) and the phenomenome (self-rated quality of life and disabilities)[3].

In the framework displayed in Figure 2, the newly re-engineered R/R feature sets are entered as input variables and can predict downstream feature sets as delineated through formal causal reasoning. The indicators of all downstream concepts are represented as latent vectors extracted from a set of features in reflective models because the aim is to construct a single underlying trait (*e.g.*, the symptomatome) which explains its manifestations (*e.g.*, all different symptom domains and phenotypes)[3-7]. The phenome feature sets are entered as output variables, whereas AOPs, cognitomone, and brainome feature sets predict the phenome and are predicted by the R/R features. It should be underscored that this method allows to reduce many features into a few relevant single traits. As such, the framework displayed in Figure 2 comprises one dependent variable (namely a latent vector reflecting the phenomenome) which is predicted by seven input variables, namely the RR, AOP, brainome, and symptomatome latent vectors. This parsimonious formal causal framework can then be trained, tested and validated using PLS structural equation

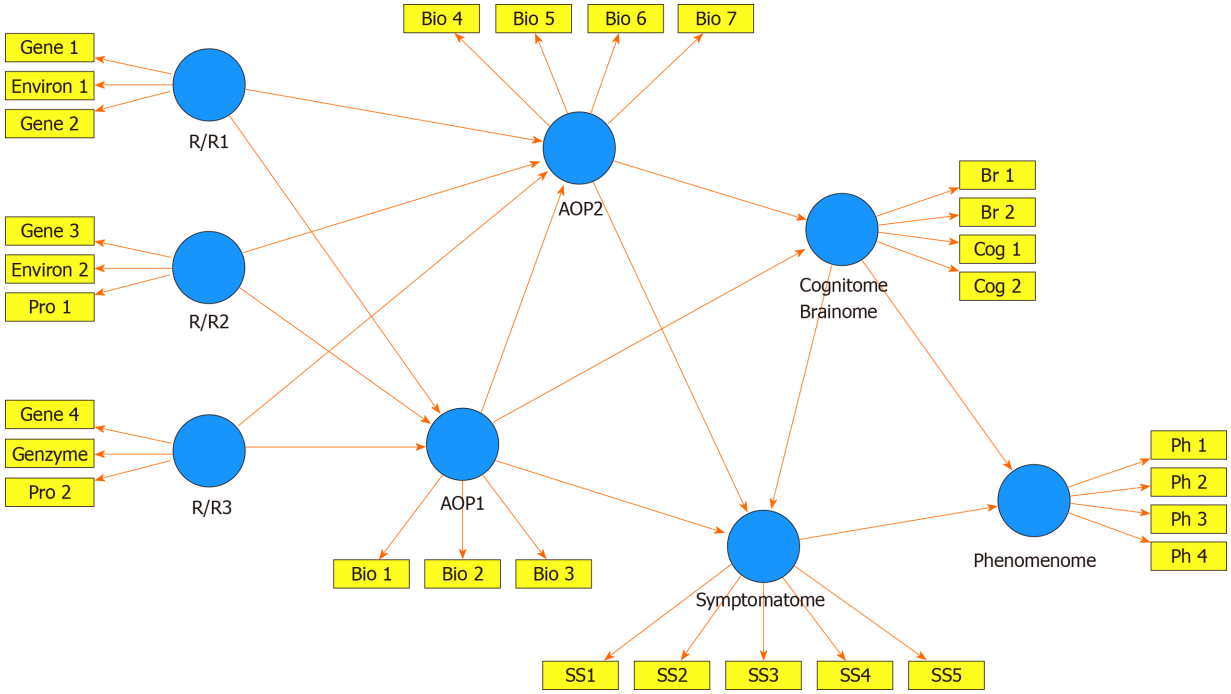

Figure 2 A causal framework of mental illness. This framework links a multitude of risk/resilience (R/R) features, with adverse outcome pathways (AOPs), the cognitome and brainome, the symptomatome, and phenomenome of mood disorders and schizophrenia. The R/R features are computed as a combination of causal and protective (Pro) genetic and environmental (Environ) features. The AOP feature sets are latent vectors (in reflective models) extracted from molecular or biological pathways/networks (Bio). The cognitome-brainome feature set is a latent vector extracted from cognitive test probe scores (Cog) and brain imaging (Br) scores. The symptomatome is entered as a latent vector extracted from symptom profiles, staging, and phenotypes (SS). The phenomenome is entered as a latent vector extracted from phenomenological data. R/R: Risk/resilience; AOP: Adverse outcome pathway; Pro: Protective; Bio: Biological; SS: Symptom profiles, staging, and phenotypes; Br: Brain imaging; Cog: Cognitive test probe scores.

modeling[3-7,34].

FROM A CAUSAL FRAMEWORK TO A CAUSALLY MODELED NOMOTHETIC NETWORK

PLS analysis allows to build pathway-phenotypes or biosignatures and train and evaluate a novel nomothetic model based on a combination of factor and regression analysis. Pathway-phenotypes may be exposed by combining for example AOPs with cognitome features into new reflective indicators of molecular paths and cognitive functions that underpin the illness[35]. Causal-pathway-phenotypes may be exposed by combining causome (*e.g.*, number of transfusions in transfusion-dependent thalassemia or TDT), AOPs (iron overload biomarkers and neuro-immune pathways as a consequence of the transfusions) with the phenome (depressive symptoms) into reflective indicators of a single latent trait, namely "depression due to immune activation as a consequence of transfusions and iron overload in TDT"[7]. Interestingly, in mood disorders, but not schizophrenia, symptomatome and phenomenome features may be combined as reflective manifestations of a single latent trait, namely the clinical – phenomenological phenome[3,4].

Figure 3 shows that the theoretical framework including new pathway-phenotypes can be trained and tested employing PLS on bootstrapped samples (*e.g.*, 5.000)[36]. Goodness of fit should be assessed using standardized root mean square residuals to avoid model misspecifications. The validity reliability of the latent vectors should be evaluated using psychometric properties such as composite reliability, rho-A, Cronbach's alpha, and average variance extracted values. All indicators of the LVs should show adequate loadings > 0.5 or by preference > 0.66[36]. Moreover, confirmatory tetrad analysis (CTA) should be used to ascertain whether the LV models are not mis-specified as reflective models, and blindfolding is used to test the construct cross-validated redundancies, which test the predictive relevance of the output LVs in the model[3,4]. Sample size determination and statistical power estimation should be performed based on (1) the psychometric properties of the vectors (factor loadings)

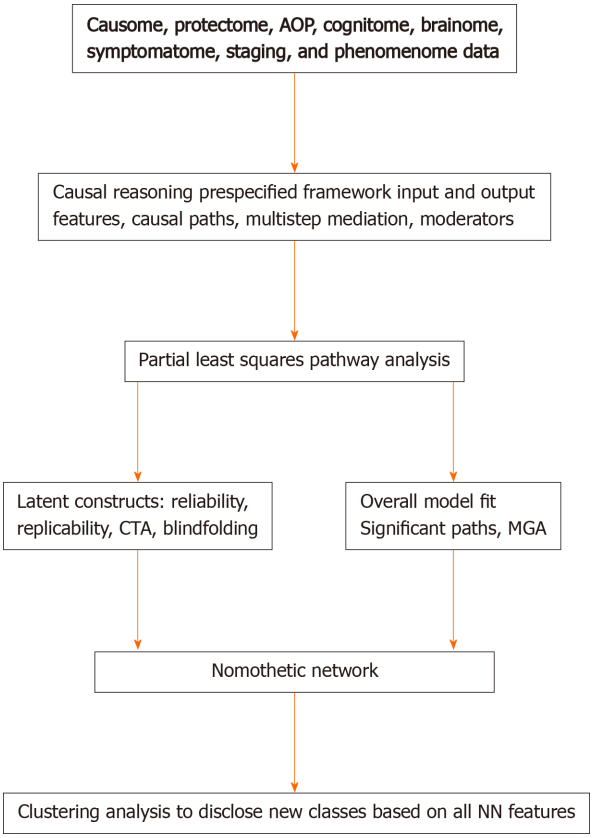

Figure 3 Nomothetic Network Psychiatry. Use of Partial Least Squares analysis to construct nomothetic networks (NN). Clustering techniques are conducted on the latent variable scores to expose new diagnostic classes. PLS: Partial Least Squares; NN: Nomothetic networks; AOP: Adverse outcome pathways; CTA: Confirmatory tetrad analysis; MGA: Multi-group analysis.

and the strength of the intercorrelations among the vectors, (2) the explained variance and the maximum number of arrows pointing to a construct, or (3) power analysis specific to multiple regression analysis[37,38]. These methods show that to achieve a power of 0.8 in the PLS model displayed in Maes *et al*[3] a relatively small sample size of n = 70-127 is sufficient. Nevertheless, larger sample sizes will yield more stable parameter estimates.

Consequently, PLS is conducted on bootstrapped samples which expose the path coefficients with exact p-values of all significant links (paths), as well as the total direct and indirect and specific indirect effects. Importantly, the indirect effects indicate the mediating effects of upstream on downstream indicators including in multistep mediating models. For example, in Figure 2, the R/R feature sets may have significant indirect effects on the phenomenome, which are mediated by the paths from AOP1 to the symptomatome or by the path from AOP2 to the cognitome to the symptomatome. In addition, also moderator (interaction) effects between 2 or more downstream indicators on upstream indicators may be added to the model which may account for possible moderating effects of age, sex, metabolic syndrome, and comorbidities. Finally, PLS allows to establish possible group differences in the model or paths using Multi-Group-Analysis (PLS-MGA) or permutations, which can be employed to examine differences in the model or paths, for example between different genotypes and between men and women. The latter is important to examine in schizophrenia and mood disorders because sexual dimorphisms were detected in those disorders[39,40]. Using PLS-MGA in schizophrenia we found significant differences between both women and men in the path from AOP to the phenomenome (quality of life) with a significant impact in women, but not in men[4]. On the other hand, no significant sex-related differences in the nomothetic network or in any of the pathways could be detected in mood disorders[3,5].

THE NOMOTHETIC MODEL AND THE REIFICATION OF DESCRIPTIVE ILLNESS NARRATIVES

In summary, a bottom-up, data-driven model of mood disorders and schizophrenia may be constructed using the knowledge-based causal framework shown in Figure 2 and by assembling R/R, AOPs, and phenome feature sets into an explicit data model, namely the PLS nomothetic network. Nomothetic indicates the tendency to generalize and to derive models ("laws") from independent variables, which explain variations in phenomena[41]. As such, the nomothetic network approach objectivates the symptomatome and phenomenome of mood disorders and schizophrenia[3-5], and, therefore, translates R/R, AOP, brainome, and cognitome feature sets into relevant descriptive narratives. The process which reifies the abstract concepts of descriptive narratives to realize a more concrete and material concept using computer science is named "reification of clinical diagnosis". It is important to note that in contrast to pan-omics and precision psychiatry, the aim of our nomothetic network approach is not only to compute pathways-phenotypes or biosignatures, but especially to make a nomothetic network, with causal links between the building blocks of the disease.

It should be added that this nomothetic network approach, in contrast to biological psychiatry models[42-44], may pass Karl Popper's critical rationalism test[33]. Indeed, our nomothetic networks are progressive (the model is based on all available knowledge), parsimonious (through feature reduction), changeable (other researchers can elaborate on the model and add more indicators or delete less robust features), provisional (the latent variable scores of the network will change when more pan-omics and brainome data are added), and falsifiable (the network can be refuted or corroborated). In this respect, our nomothetic networks deserve validation in more heterogeneous study groups consisting of individuals with comorbid psychiatric and medical disorders.

DISCOVERY OF NEW CLASSIFICATIONS BASED ON THE FEATURE SET SCORES

After integrating the validated feature vectors into a well-fitting nomothetic network, latent variable scores may be computed which reflect the severity of the various R/R, AOP, brainome, cognitome, staging, symptomatome, and phenomenome feature sets. The latter may be employed in unsupervised pattern recognition methods, including clustering analysis, to expose new categories (Figure 3). Previously, we employed different clustering techniques on such latent variable scores including K-mean, K-median, and Ward's and Forgy's methods[3-5]. Figure 4 shows a hypothetical example of cluster analysis-generated classes, with the latent variable scores (in z transformation) displayed in a clustered bar graph. This figure shows a normal cluster with healthy control subjects and two patients clusters. The second patient cluster may be discriminated from the first cluster (and from controls) by higher R/R, AOP, cognitive and brainome, symptomatome and phenomenome scores. The first patient cluster may be discriminated from controls by increased R/R3, AOP, and phenome scores. Previously, we showed that, in mood disorders, these new bottom-up cluster analysis-derived classes are more influential for classification purposes than the top-down classification into bipolar type 1 and type 2 and major depression. As such, new mechanistic, biosignature-based, and/or transdiagnostic classes may be discovered[3,5].

Nevertheless, these new classes should be cross-validated in independent samples using other machine learning methods including support vector machine with 10-fold cross-validation or soft independent modeling of class analogy (SIMCA)[7]. It is interesting to note that our nomothetic networks computed in mood disorders and schizophrenia contain self-rated phenomenological features (including self-rated quality of life and severity of disabilities), and, therefore, may comprise idiographic features[3,4]. Therefore, the latent variable scores not only delineate an objective nomothetic network and new diagnostic classes, but also shape an idiomatic feature profile, which is unique for every individual. As such, adequate treatments of mood disorders and schizophrenia should target the components of the nomothetic networks (R/R, AOP, brainome) constructed in those disorders. In addition, the individualized feature profile allows a more personalized treatment targeting aberrations in specific R/R, AOP, cognitome, brainome, and staging latent variable scores.

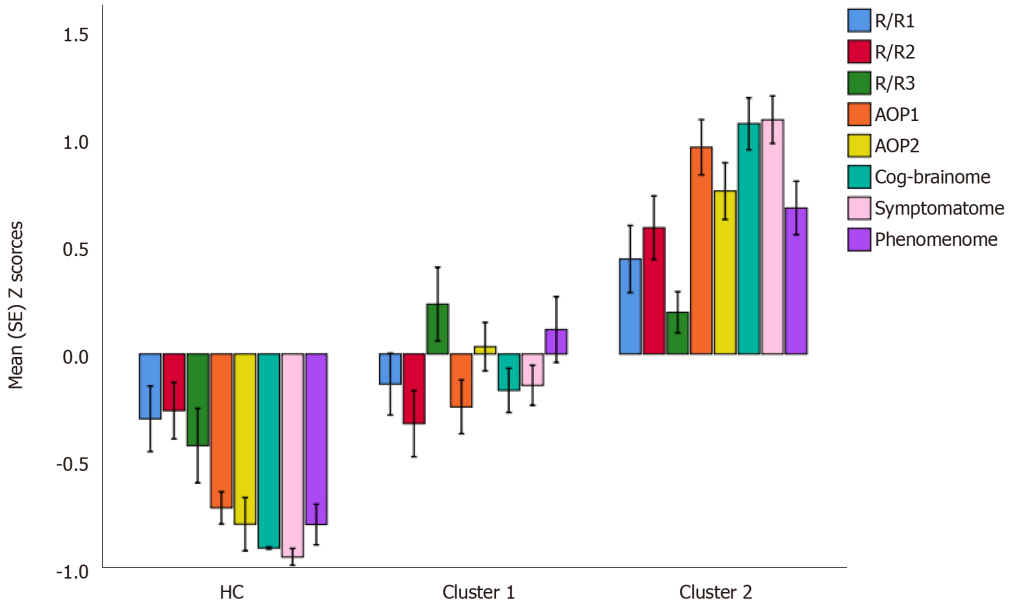

Figure 4 A hypothetical example of cluster analysis-generated classes, with the latent variable scores (in *z* transformation) displayed in a clustered bar graph. R/R: Risk/resilience; AOP: Adverse outcome pathway; HC: Healthy control.

CONCLUSION

In this paper we explained how to use the new nomothetic network psychiatry (NNP) approach to construct new causal models of mental illness by machine learning techniques, which assemble all features of mental illness, namely risk-resilience, AOPs, cognitome, brainome, symptomatome, staging, and phenomenome scores. PLS analysis may successfully be used to train, test and validate those models, to build pathway-phenotypes or biosignatures, and to construct comprehensive models of mood disorders and schizophrenia which objectivate the clinical phenome of those disorders. Clustering analysis performed on all illness features reduced into latent traits may expose relevant new (transdiagnostic) classes. The reification of the clinical diagnosis of mood disorders and schizophrenia (and by inference other psychiatric disorders) using the nomothetic network psychiatry approach is an awaited achievement which constitutes a major paradigm shift in psychiatry[16].

Abstract

BACKGROUND

Social engagement-important for health and well-being-can be difficult for people with schizophrenia. Past research indicates that despite expressing interest in social interactions, people with schizophrenia report spending less time with others and feeling lonely. Social motivations and barriers may play an important role for understanding social engagement in schizophrenia.

AIM

To investigate how people with schizophrenia describe factors that impede and promote social engagement.

METHODS

We interviewed a community sample of people with (n = 35) and without (n = 27) schizophrenia or schizoaffective disorder about their social interactions with friends and family over the past week and planned social activities for the coming week. We reviewed the interview transcripts and developed a novel coding system to capture whether interactions occurred, who had initiated the contact, and frequency of reported social barriers (*i.e.*, internal, conflict-based, logistical) and social motivations (*i.e.*, instrumental, affiliative, obligation-based). We also assessed symptoms and functioning.

RESULTS

People with schizophrenia were less likely than people without schizophrenia to have spent time with friends [t (51.04) = 2.09, P = 0.042, d = 0.51)], but not family. People with schizophrenia reported more social barriers than people without schizophrenia [F (1, 60) = 10.55, P = 0.002, ηp2 = 0.15)] but did not differ in

None declared.

reported social motivations. Specifically, people with schizophrenia reported more internal [t (45.75) = 3.40, P = 0.001, d = 0.83)] and conflict-based [t (40.11) = 3.03, P = 0.004, d = 0.73)] barriers than people without schizophrenia. Social barriers and motivations were related to real-world social functioning for people with schizophrenia, such that more barriers were associated with more difficulty in close relationships (r = -0.37, P = 0.027) and more motivations were associated with better community functioning (r = 0.38, P = 0.024).

CONCLUSION
These findings highlight the importance of assessing first person accounts of social barriers and motivations to better understand social engagement in schizophrenia.

Key Words: Social engagement; Schizophrenia; Social motivation; Social barriers

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: We examined factors that may impede and promote social engagement in schizophrenia. We coded social barriers and motivations from transcribed negative symptoms interviews. We found that barriers, such as conflicts with other people or negative beliefs about the self, were prominent in schizophrenia. Interestingly, when explicitly prompted, people with schizophrenia reported interest in and motivation for social interactions. Nevertheless, social barriers may get in the way of them following through.

INTRODUCTION

Social engagement is a central part of life and is linked to many benefits, such as wellbeing, health, and longevity[1]. Unfortunately, limited social engagement is common in schizophrenia[2] and people with schizophrenia often miss out on the benefits of such engagement. In this study, we sought to determine contributing factors to limited social engagement in schizophrenia. Specifically, we examined how people with and without schizophrenia talk about their social engagement with friends and family to better understand factors that motivate such engagement and barriers that might get in the way.

Why might people with schizophrenia engage in fewer social interactions? Limited social engagement may be indicative of social disinterest[3]. Indeed, people with schizophrenia report spending less time around others and set fewer social goals compared to people without schizophrenia[4-6]. However, other evidence indicates that people with schizophrenia describe social relationships as equally important[7,8] and express as much interest in social activity compared to people without schizophrenia[4,9]. Moreover, people with schizophrenia report a similar or even greater preference to be with others as those without schizophrenia when they find themselves alone[10,11]. People with schizophrenia also express more social interest than those with other psychiatric illnesses[12]. Even as people with schizophrenia profess an interest in social interactions, they also report feeling lonely[5,13-15], suggesting they have social needs that are not being met. Insofar as diminished interest does not fully account for limited social engagement in schizophrenia, we sought to examine other possible barriers. Understanding what might get in the way of social engagement in schizophrenia can be an important first step toward helping people with schizophrenia obtain the myriad benefits of social interactions.

Social barriers

Barriers that may interfere with social engagement in schizophrenia include internal

states, conflicts with others, or logistical factors. Prior research has identified several possible internal barriers in schizophrenia, including low self-esteem, internalized stigma, and defeatist performance beliefs[16-19]. Symptoms may also interfere with social engagement: Greater positive symptoms are associated with lower relationship satisfaction[20], and greater negative symptoms are associated with smaller social network sizes[21,22].

Conflicts with others, whether in the form of disagreements, social discrimination, or stigma-related rejection, may also interfere with social engagement. For example, families with a person with schizophrenia report more frequent arguments and heightened tension than other families[23]. People with schizophrenia are often reluctant to disclose their illness to friends, fearing that once they do, they will be rejected[24].

Logistical barriers, such as limited financial means, may also get in the way of social engagement. People with schizophrenia are more likely to be unemployed[25], which could restrict social network size and variety[26]. Social activities that require money or transportation may also be less accessible[27].

Social motivations

Considering what motivates people to form and maintain relationships is also important for understanding social engagement. Some motivations for relationships are instrumental, arising from a desire for social activity to acquire tangible benefits[28,29]. In this way, relationships are a means to an end. As caregivers of people with schizophrenia are at times responsible for meeting various needs of their loved ones[30], the desire for assistance may be a motivation for social engagement.

Alternatively, social relationships can be motivating in and of themselves[29,31]. Affiliative motivations focus on companionship, mutual care, and the exchange of emotions as drivers of engagement with others. People with schizophrenia report wanting social relationships and even consider them a primary source of meaning[32], suggesting that affiliative motivations are an important aspect of social engagement. Another type of social motivation is obligation-based, which refers to the desire to meet personally or societally determined standards of appropriate social behavior[33], or how a person "should" behave. Because it is considered normative to have relationships, people with schizophrenia report this as an important indication of health[34].

The importance of first-person accounts

How people with schizophrenia describe their social experiences can offer a window into social barriers and motivations and provide an important perspective for understanding social engagement. Of the few studies in schizophrenia that have used such an approach, most have focused on lexical characteristics of speech, linguistic abnormalities, word counts, or speech coherence and appropriateness[35-40]. A notable exception is the work of Lysaker *et al*[41], who assessed social worth, social closeness, and personal agency in spoken narratives of people with schizophrenia. The more frequently people with schizophrenia referred to these social themes in their narratives, the better their social functioning.

Present study

We sought to answer four questions about social engagement in schizophrenia. First, we asked whether people with and without schizophrenia differed in the frequency and initiation of interactions with family and friends in the past week. Second, we asked whether people with and without schizophrenia differed in reported types of social barriers and motivations. Third, we asked whether social barriers and motivations differed by relationship type (friends, family). Fourth, we asked whether social barriers and motivations were related to functioning and symptoms for people with schizophrenia.

MATERIALS AND METHODS

Participants

Thirty-five people with schizophrenia (n = 26) or schizoaffective disorder (n = 9) and 27 people without a schizophrenia spectrum disorder participated. People with schizophrenia and schizoaffective disorder did not differ from one another on any demographic, clinical, or coded variable; we collapsed across these groups for

analyses. Participants were recruited from board and care homes, nonprofit agencies, and Craigslist and were part of the multi-site study that developed the Clinical Assessment Interview for Negative Symptoms[42]. The data presented here do not overlap with that study.

Diagnoses were confirmed using the Structured Clinical Interview for DSM-IV Axis I Disorders (SCID-I/P)[43]. For controls, we administered the SCID non-patient version (SCID-I/NP)[44] to confirm absence of schizophrenia spectrum disorders. Any participant with a history of head injury or neurological disorder, a current mood episode, or substance use disorder within the past six months was not invited to participate. All participants provided written informed consent. As shown in Table 1, the groups did not differ in age, sex, race, marital status, education, or estimated intelligence quotient (measured by the Wechsler Test of Adult Reading[45]).

Measures

Clinical Assessment Interview for Negative Symptoms beta version: Trained raters administered the beta version of the Clinical Assessment Interview for Negative Symptoms (CAINS), and the interviews were videotaped. The CAINS includes several manualized open-ended probes for each item with additional questions asked as needed for clarity. The CAINS-beta differs from the final CAINS[46] in length (16 rather than 13 items) and in the inclusion of separate questions about romantic relationships.

We examined responses to the first five items of the CAINS-beta. The first three items assessed social motivation and enjoyment in (1) family; (2) romantic relationships; and (3) friendships. Participants were asked to describe their social interactions over the preceding week (*e.g.*, Have you been motivated to be around or in touch with your family/partner/friends in the past week?). The fourth item asked participants to describe pleasure experienced in past week social activities (*e.g.*, Did you have any enjoyable interactions with other people?), and the fifth item asked about expected pleasure from social activities over the next week (*e.g.*, What do you think you will enjoy doing in the next week with other people?).

Interview coding: Interviews were transcribed and coded by trained research assistants. We developed a coding manual containing definitions and examples for all variables, and four raters, blind to diagnostic status, did the coding. A different rater reviewed all data for entry accuracy and coding manual adherence.

Mirroring the final CAINS[46], marital relationships were included with family items, and dating relationships were included with friend items. For friends and family, coders rated "whether any interaction had occurred" over the past week—including phone calls, text messages, e-mails, or in-person contact—dichotomously (present, absent). When an interaction was reported, "initiation" was coded on a 3-point scale: (1) Social partner(s) initiated all interactions; (2) Participant initiated some and social partner initiated some; and (3) Participant initiated all interactions.

Coders determined which type of social barrier or motivation a statement referred to and then computed the total number of social barriers and motivations of each type. Social barriers were defined as causing an interaction to be cut short or to not occur at all. Coders counted the frequencies of three types of barriers. Internal barriers included psychological states and beliefs that prevented interaction, including negative self-perceptions or self-stigma (*e.g.*, "No one would want to be my friend"), psychiatric symptoms, negative beliefs about social interactions (*e.g.*, "People just let you down"), and having goals or priorities that took precedence over social interaction (*e.g.*, "I want to finish my degree before I look for a relationship"). Conflict-based barriers included discrimination (*e.g.*, "My parents disowned me because I'm gay"), rejection (*e.g.*, "She said she didn't want to date anymore"), and social conflict (*e.g.*, "All we ever do is fight"). Logistical barriers referred to geographic distance, lack of time, mismatched schedules, non-psychiatric illness, lack of financial resources, or perceived lack of access to an appropriate social partner.

Coders also computed the frequencies of three types of social motivations. Instrumental motivations included tangible benefits (*e.g.*, a relative paying for rent) and perceived benefits to a participant's physical or mental wellbeing or personal development (*e.g.*, "She keeps me sane"). Affiliative motivations included positive attributes of interaction partners (*e.g.*, "He's funny"), social support, acceptance of self (*e.g.*, "I feel like I can be myself around them"), physical intimacy, and avoidance of loneliness and social isolation. Obligation-based motivations included a desire to provide something to an interaction partner (*e.g.*, "I want to be a positive role model for my sister"), or expectations of normative behavior (*e.g.*, "I called my friend on her birthday because it is the polite thing to do"). Finally, we counted the total number of words participants uttered using the Linguistic Inquiry and Word Count program[47].

[a]Mean of 13 items from the final Clinical Assessment Interview for Negative Symptoms and romantic relationship motivation item from Clinical Assessment Interview for Negative Symptoms-beta. BPRS: Brief Psychiatric Rating Scale; CAINS-EXP: Clinical Assessment Interview for Negative Symptoms, Expression Subscale; CAINS-MAP: Clinical Assessment Interview for Negative Symptoms, Motivation and Pleasure Subscale; RFS: Role Functioning Scale; WTAR: Wechsler Test of Adult Reading.

Clinical ratings: We measured functioning using the Role Functioning Scale[48] with its 1 (minimal functioning) to 7 (optimal functioning) point scale. The Role Functioning Scale contains four subscales—working productivity, independent living and self-care, immediate social network relationships, and extended social network relationships. We assessed symptoms using a 24-item version of the Brief Psychiatric Rating Scale rated on a 7-point scale[49].

Data analyses

We conducted independent samples *t*-tests and chi-square tests to compare demographics, word count, contact, and initiation. For barriers and motivations, we conducted 2 Group (schizophrenia, control) X 2 Relationship Type (family, friends) X 3 Barrier (internal, logistical, conflict-based) or Motivation Type (instrumental, affiliative, obligation-based) mixed effect analyses of variance. Sphericity violations were Greenhouse-Geisser corrected; effect sizes are reported as Cohen's d and partial eta squared (ηp2). We computed Pearson correlations between barriers, motivations, functioning, and symptoms within the schizophrenia group.

RESULTS

Preliminary analyses

Two coders rated a third of interviews (equal numbers of people with and without schizophrenia) to assess inter-rater agreement. Coders achieved a high rate of agreement, with intraclass correlations[50] ranging from 0.83-1.00.

People with (M = 1652.66, SD = 958.25) and without (M = 1348.08, SD = 926.58) schizophrenia did not differ significantly in the amount of words spoken during the interview [t (59) = 1.25, P = 0.22, d = 0.32)]. Thus, any group differences in coded barriers and motivations were not a function of fewer words uttered by either group. We also found no significant differences between men and women for any variable, and thus we collapsed across sex for subsequent analyses.

Contact and initiation

Both groups were just as likely to have interacted with family over the past week, but people with schizophrenia were less likely to have interacted with friends compared to controls, [t (51.04) = 2.09, P = 0.042, d = 0.51]. People with schizophrenia were no more likely to be living with family than those without schizophrenia [t (59) = -0.96, P = 0.34, d = 0.25)], suggesting that greater ease of access did not contribute to rates of reported family interactions for the schizophrenia group. When interactions did occur, the groups were equally likely to have initiated interactions with family. However, people with schizophrenia were less likely to have initiated interactions with friends, [t (46) = 2.75, P = 0.008, d = 0.80].

Barriers

We found a significant group main effect [F (1, 60) = 10.55, P = 0.002, ηp2 = 0.15)], indicating that people with schizophrenia reported more barriers overall than people without schizophrenia (see Table 2). However, the Group X Barrier Type interaction was also significant [F (2, 120) = 3.27, P = 0.041, ηp2 = 0.05)], indicating that the group differences depended upon barrier type. As shown in Figure 1, people with schizophrenia reported more internal [t (45.75) = 3.40, P = 0.001, d = 0.83) and conflict-based barriers [t (40.11) = 3.03, P = 0.004, d = 0.73)] than people without schizophrenia; the groups did not differ in reported logistical barriers.

We also found a significant relationship type main effect [F (1, 60) = 10.35, P = 0.002, ηp2 = 0.15)], indicating that all participants reported more barriers for friends than family [t (61) = 3.36, P = 0.001, d = 0.43)]. However, this was qualified by a significant Relationship Type X Barrier Type interaction [F (2, 120) = 3.78, P = 0.026, ηp2 = 0.06)]. As shown in Table 3, whereas logistical and conflict-based barriers were similar across friends and family, all participants reported more internal barriers for friends than for family [t (61) = 4.10, P < 0.001, d = 0.52)].

Motivations

Neither the group main effect [F (1, 60) = 0.17, P = 0.68, ηp2 = 0.003)], nor the Group X Motivation Type interaction were significant [F (1, 60) = 1.92, P = 0.17, ηp2 = 0.03)]. However, the motivation type main effect was significant [F (1.10, 65.89) = 143.42, P < 0.001, ηp2 = 0.71)]; all participants reported more affiliative than instrumental [t (61) = 12.07, P < 0.001, d = 1.53)] or obligation-based [t (61) = 8.36, P < 0.001, d = 1.06)] motivations (see Table 2). In addition, participants reported more obligation-based than instrumental motivations [t (61) = 4.14, P < 0.001, d = 0.53)].

This finding was qualified by a significant Relationship Type X Motivation Type interaction [F (1.19, 71.41) = 4.14, P = 0.039, ηp2 = 0.07)]. Whereas obligation-based motivations were similar across friends and family, all participants reported more instrumental [t (61) = 2.02, P = 0.048, d = 0.26)] and affiliative motivations [t (61) = 2.14,

Values are means with standard deviations in parentheses.

$P = 0.037$, $d = 0.28$)] for friends than for family.

Correlations

As shown in Table 4, barriers and motivations were significantly associated with functioning. Internal and conflict-based barriers were moderately, negatively correlated with independent living skills, indicating that the more difficulties people with schizophrenia experienced with self-care, the greater the number of internal and conflict-based barriers they reported. More logistical barriers were associated with greater difficulties with close others. Motivations were moderately related to social functioning; in particular, more affiliative motivations were associated with significantly better social functioning within the broader community.

Interestingly, only conflict-based barriers were significantly related to total symptoms (but not negative or positive symptoms separately), suggesting that other types of barriers/motivations may be somewhat independent of symptom severity.

DISCUSSION

We investigated reported barriers to and motivations for social engagement in people with and without schizophrenia. Despite describing social engagement with the same number of words, people with schizophrenia reported more social barriers than those without schizophrenia, yet just as many social motivations. Importantly, social barriers and motivations were also related to functioning. Our findings suggest that particular

Table 4 Correlations with functioning and symptoms

types of social barriers and motivations may impede social engagement for people with schizophrenia and impact real-world social behavior, and they provide valuable information on directions for improving social engagement.

Consistent with previous research[51], we found that people with schizophrenia were less likely to have interacted with or initiated contact with friends over the past week compared to controls. However, we found no differences in contact or initiation with family. These findings are clinically important, as frequency of contact with friends is more predictive of clinical recovery than contact with family[52]. Moreover, evidence suggests that people with schizophrenia lose connections with close friends early in the course of illness[51], which may contribute to limited social engagement over the illness course[53].

Compared to controls, people with schizophrenia reported experiencing more internal barriers and conflict-based barriers. These findings are consistent with evidence that people with psychotic disorders feel less at ease and more threatened while in the company of others compared to people without psychotic disorders[11]. It is possible that people with schizophrenia are more sensitive to perceiving negativity in social encounters; however, it is also possible that negative attitudes are borne from actual social rejection.

Although speculative, conflict-based barriers may be associated with stigma-based rejection. Heightened discrimination and rejection that people with schizophrenia face may perpetuate negative beliefs about social interactions, resulting in a cycle of negative social experiences. It would be helpful for future work to explore the origins and bidirectional causality of conflicts involving people with schizophrenia. Impairments in social cognitive processes (*e.g.*, social cue perception, empathy), which we did not assess, could make resolving disagreements more challenging for people with schizophrenia[54]. Examining linkages between social barriers and stigma-based rejection is an important direction for future research.

Both groups reported more barriers to interactions with friends than with family, and this was particularly evident for internal barriers. Friendships are inherently more difficult since they are not "built in" and thus require more effort to establish and maintain. Family members may reach out frequently even if their loved one has negative beliefs about interactions. By contrast, friends may not put in this effort. Coupled with our finding that people with schizophrenia were less likely to interact with friends and also that barriers were more common for interactions with friends, it seems especially important to study friendships in future studies.

Interestingly, we found that people with schizophrenia reported being comparably motivated for friend and family interactions as people without schizophrenia. This finding may seem at odds with other studies indicating that people with schizophrenia have deficits in social motivation[55-57]. Two methodological differences may account for this discrepancy. First, similar to Gard *et al*[4], we asked people to report on their actual, "real-life" social interactions over the past week following several guided prompts. By contrast, laboratory studies of social motivation use tasks of simulated social interactions. Second, we coded actual behavior (*e.g.*, went to dinner with family) as well as articulated motives (*e.g.*, reported desire to see family). This approach differs from studies of effort expenditure[56,58] that focus on behavioral action. It will be informative in future studies to examine social motivations using a variety of approaches, such as ecological momentary assessment, passive mobile data collection, or virtual reality techniques[59]. Moreover, it will be essential to replicate this finding with a larger sample, as social motivation difficulties, like any deficit in schizophrenia, are not observed in all people with the diagnosis.

We found that both groups reported more affiliative and instrumental motivations for friendships than family relationships, which is noteworthy since people with schizophrenia were less likely to have had contact with friends. That is, people with schizophrenia reported being motivated to interact with friends for affiliative and instrumental reasons as much as controls, yet they were less likely to have done so over the past week. This finding highlights an important disconnect between reported interest and actual behavior for people with schizophrenia[59-61]. Although experiencing motivation for friendships may provide entry to important support that comes from friendships[62-65], receipt likely requires contact with friends. Understanding how internal or conflict-based social barriers can be reduced will likely help increase contact and benefits from friends.

We also found that barriers and motivations were associated with real-world functioning for people with schizophrenia. Because navigating the social world is important for autonomous living, conflict-based barriers, such as stigma and rejection, may make it more challenging for people with schizophrenia to maneuver bureaucratic systems or manage shopping or transportation. Similarly, internal barriers, like negative beliefs about the self, may be detrimental to the self-efficacy necessary to pursue independent living[66].

Encouragingly, we found no group differences in reported logistical barriers, perhaps because the groups did not differ in education or employment status. Nevertheless, for people with schizophrenia, logistical barriers were associated with functioning in close relationships. Although finances are but one type of logistical barrier, limited means can make it more difficult for people with schizophrenia to afford social activities or access transportation. Relatedly, unemployment[25] or lessened community integration[67] may make it challenging to get in touch with or visit other people.

The more that people with schizophrenia were motivated by the interpersonal aspects of relationships, the better their functioning in wider spheres of social contact such as clubs, churches, or social recreational activities. Perhaps people who value the relational aspects of social interactions seek out more opportunities for contact with members of their communities. Given the cross-sectional and correlational nature of our data, however, it is impossible to assess directionality. Nevertheless, social integration in different spheres is an important predictor of quality of life[18].

Fortunately, many of the barriers that we have identified are already the targets of

current treatments. For example, internal barriers, such as negative beliefs about relationships, have been targeted in Cognitive Behavioral Therapy for negative symptoms. Cognitive Behavioral Social Skills Training's[68,69] emphasis on communication and assertiveness skills and family therapy's focus on problem solving may assist with conflict-based barriers[70].

Although these findings provide an important step towards understanding what hinders and helps people with schizophrenia build social engagement, they should be considered in the context of limitations. First, our assessment of barriers and motivations was limited to participants' responses to the CAINS. Because specific barriers or motivations were not asked about explicitly, we may have undercounted, and we may not have captured all types of barriers (*e.g.*, social anxiety). Nevertheless, the CAINS includes more questions about social interactions than most clinical interviews, and thus the corpus of reported social engagement was richer than it might have been with a different interview.

Second, although we assessed the presence of barriers and motivations, we did not assess their relative contributions to impeding social engagement. For instance, although geographic distance (logistical barrier) and negative beliefs (internal barrier) may have been reported, it is possible that the negative beliefs were more impeding than distance. Third, the CAINS assessed the preceding and upcoming week, thus limiting the time period for reporting on social engagement. On the other hand, the strength of this approach is that it reduced difficulties and biases associated with retrospective reports. Fourth, all participants were taking antipsychotic medication so we cannot ascertain what, if any, impact medications may have had on participant responses. Finally, we did not assess related constructs, such as social network size, and thus future studies would benefit from investigating these alongside motivations and barriers to better understand the relationships between them.

CONCLUSION

In summary, we found that people with schizophrenia were less likely to interact with and initiate contact with friends compared to people without schizophrenia even as they did not differ in contact with family. Our findings suggest that certain types of social barriers get in the way of social engagement in schizophrenia, including barriers involving the self and conflicts with others. Importantly, social barriers and motivations were also related to real world functioning, suggesting that asking people to describe their social lives is linked to independent assessments of functioning. Together, our approach illustrates the benefits of simply asking people to describe their social lives and suggests that efforts to help mitigate social barriers might improve social engagement.

ARTICLE HIGHLIGHTS

Research background

Though limited social engagement is common in schizophrenia, the reasons for this remain unclear. People with schizophrenia report a desire to be with others, and yet spend more time alone.

Research motivation

Better understanding of the factors that contribute to limited social engagement can be an important first step toward helping people with schizophrenia to meet their social needs.

Research objectives

To identify and compare motivations and barriers for social engagement with friends and family among those with and without schizophrenia.

Research methods

Thirty-five people with schizophrenia or schizoaffective disorder and 27 nonclinical controls were recruited from the community to participate in this study. Participants completed measures of symptoms and functioning, as well as a negative symptoms interview, which asked participants to describe their engagement in and motivation

for social activities in the past and upcoming weeks. Using a novel coding system, we coded the frequency with which participants described six types of social motivations and barriers.

Research results

People with schizophrenia were less likely to interact with and initiate contact with friends, but not family, compared to nonclinical controls. The groups differed in reported barriers, such that people with schizophrenia reported more internal and conflict-based barriers than those without schizophrenia. People with and without schizophrenia reported similar numbers and types of motivations for social engagement. Barriers and motivations were associated with symptoms and functioning.

Research conclusions

This study suggests that barriers, such as conflicts with other people or negative beliefs about the self may interfere with social engagement in schizophrenia. People with schizophrenia report interest and motivation for social interactions, but social barriers may get in the way of them following through.

Research perspectives

Further exploration of social barriers in terms of types, frequency, and relative contribution to limiting social engagement is warranted.

ACKNOWLEDGEMENTS

The authors thank research assistants Apoorva Polisetty, Gregory Devine, Dania Smithstein, and Iliana Lopez Yanez, who helped with coding, and Gillian Chen, Renata Botello, Anna Deal, Janae Spinato, Alexandria Tu, Maryanna Winslow, and Alexandra Jensen, who helped with interview transcription. We also thank the people who chose to participate in this study.

ABOUT COVER

Thomas Sobanski, MD, Chief Doctor, Senior Research Fellow, Department of Psychiatry, Psychotherapy, and Psychosomatic Medicine, THUERINGEN-Kliniken GmbH, Saalfeld D-07318, Germany. tsobanski@thueringen-kliniken.de

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatr*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc*.

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, and PubMed Central. The 2020 edition of Journal Citation Reports® cites the 2019 impact factor (IF) for *WJP* as 3.545; IF without journal self cites: 3.545; Ranking: 46 among 155 journals in psychiatry; and Quartile category: Q2.

Abstract

Rates of childhood trauma exposure are extremely high, with approximately 70% of children and adolescents experiencing at least one traumatic event. Among the most common non-specific consequences of stress and trauma are disruptions of sleep. Sleep problems, such as shorter sleep duration, difficulty falling asleep, frequent awakenings, nightmares, sleepless nights, and early-morning wakefulness appear to have a higher prevalence among children and adolescents following traumatic events. This review will illustrate the role of sleep problems in traumatized children and adolescents, and emphasize the need to consider a wide range of etiological mechanisms for these symptoms. However, the relationship of trauma exposure to sleep problems among children and adolescents needs further investigation in future research. Moreover, in view of the adverse consequences of long-term disrupted sleep on mental health outcomes following trauma, the need to effectively address sleep disturbances in traumatized children and adolescents is crucial.

Key Words: Child abuse; Natural disasters; Nightmares; Posttraumatic stress disorder; Sleep; Trauma and stressor related disorders

INTRODUCTION

Rates of childhood trauma exposure are extremely high, with approximately 70% of children and adolescents experiencing at least one traumatic event[1,2]. Moreover, exposure to trauma during childhood leads to a number of negative physical and mental health outcomes[3-6]. Prevalence rates of posttraumatic stress disorder (PTSD) range from 0.5%-5%[1,7], while subclinical PTSD and trauma-related depression and behavioral problems are relatively frequent among trauma-exposed children[1,8-10].

Amidst the most prevalent general repercussions of stress and trauma are sleep disturbances. Sleep problems, such as shorter sleep duration, difficulty falling asleep, frequent awakenings, nightmares, sleepless nights, and early-morning wakefulness, appear to have a higher prevalence among children and adolescents following traumatic events[11-16].

Sleep occurs in every animal species and is essential for survival. It is comprised of dynamic patterns and gradual stages that take place during the night. Cohesion, timing, and ordering of these crucial stages are vital for adequate sleep[17]. Adequate sleep is linked to physical growth and psychological maturation, and is important for the optimal performance of vigilance systems[18-20]. Insufficient sleep has been associated with impaired daytime functioning, excessive tiredness, fatigue, pain, elevated blood pressure later in life, lesser regulation of affective reactions, elevated emotional dysregulation, aggression, anger, irritability, uneasiness, little frustration tolerance, high risk for developing substance use disorders, suicidal behaviors, problems sustaining attention, decreased performance on abstract reasoning tasks, and reduced academic performance in children and adolescents[21-32].

TRAUMA EXPOSURE AND SLEEP DISTURBANCES

In general population samples, approximately 16%-40% of children exhibit sleep disturbances[33-35]. Prevalence rates of sleep disturbances among trauma-exposed child samples vary considerably, from 3% to 77.1%[36-41]. Adverse effects of childhood trauma on sleep have been found immediately[42,43] as well as years after trauma[44], and can still be demonstrated in adulthood[45].

Nightmares are reported most commonly, although rates vary widely (20.3%–80.8%) depending on methodological discrepancies in sampling, measures, and informants about the child's symptoms. In fact, nightmares are a prototypic symptom of PTSD[46-52]. Nightmares have been included in the PTSD diagnostic formulation since its introduction in the Diagnostic Statistical Manual (DSM)-III[53] and have recently been expanded in DSM-5[54] to encompass sleep difficulties (as opposed to only nightmares). Recurrent distressing dreams and sleep disruptions (*e.g.*, difficulty falling or staying asleep, or restless sleep) are listed among the intrusion symptoms and the marked alterations in arousal and reactivity, respectively[54].

Sleep disturbances seem to be critically involved in PTSD development and maintenance[13,46]. Further, sleep difficulties seem to prevent recovery from traumatic events and to accelerate negative mental health outcomes[14,55,56]. Hence, trauma-related sleep problems in children and adolescents seem to be an important area of study. However, limited research has been conducted to date.

Characteristics of the traumatic event and associated risk factors may participate in understanding different types of sleep problems; still, these relationships are not well-known among children exposed to trauma.

Wamser-Nanney *et al*[57], in their study of 276 treatment-seeking children, showed that although sleep disturbances were common among trauma-exposed children, the type of traumatic event (*e.g.*, sexual abuse, physical abuse, domestic violence, emotional abuse, neglect, etc.) and the nature of trauma (*i.e.*, interpersonal *vs* non-interpersonal) or complex trauma were largely unrelated to sleep problems.

A study in 6132 adolescent survivors 3 years after a disastrous earthquake documented that older adolescents were at a significantly greater risk of sleep problems than younger children, and they had significantly higher risks of anxiety, depression, and PTSD. Other risk factors for sleep difficulties were characteristics of exposure to the earthquake, such as injury, injury of a parent, and witnessing death or feeling extremely scared in the earthquake[58]. Similarly, another cohort study[11] of 1573 adolescent survivors following a deadly earthquake found that the risk of sleep issues was significantly increased in older adolescents and in those who witnessed the tragic events directly. Depression, anxiety, poor social support, and negative life events were also associated with increased risk and persistence of sleep problems.

In a prospective study[17] of 78 females who had been sexually abused in childhood, it was found that sleep disturbances correlated significantly with both depression and PTSD 10 years after disclosure of the abuse. However, these traumatized youths showed significantly higher rates of sleep difficulties than the comparison group, in addition to depression and PTSD. Moreover, sleep difficulties were associated with revictimization rates independent of sexual abuse, depression, and PTSD.

A study on sleep quality across the developmental spectrum among avalanche survivors at 16 years after exposure showed that those who were children when the disaster occurred were more likely to report PTSD-related acting out dreams in adulthood than their non-exposed peers, while those who were adults at time of the disaster had elevated risk of trauma-related nightmares[59].

In a study of 33 children treated for injuries after road traffic accidents, it was shown that children experiencing posttraumatic stress had a prolonged subjective sleep latency[60]. Moreover, the severity of difficulties in sleep onset and maintenance was associated with female gender and the severity of child's and mothers' PTSD.

ETIOLOGICAL MECHANISMS

Caldwell and Redeker[18] have claimed that more extensive research is needed in order to improve our understanding of the elevated sleep problems among children and adolescents following trauma. Several hypotheses have been proposed to explain the mechanisms by which traumatic exposure may affect sleep (Table 1).

According to a biological perspective, traumatic stress may be related to increased levels of physiological arousal, that hinders conditions crucial for sleep onset. In fact, sleep onset problems may be more prominent compared to sleep maintenance problems among traumatized children[44,60]. It has been claimed that increased activity of the amygdala and decreased activity of the medial prefrontal cortex sustain or enhance activity in arousal-promoting brain centers and diminish activity in sleep-promoting centers[61]. The emerging pattern of enduring arousal could directly conduce to insomnia problems.

Sleep is naturally restricted to times and places that feel safe. If arousal is increased by cause of imminent threat, sleep will possibly deteriorate[25]. Safety is a notably pertinent concern for children and adolescents exposed to trauma. Moore[62], for example, concluded that interpersonal trauma hinders development of a safe attachment style, leading to the feeling that one needs to be continuously alert and on guard instead of sleeping.

Levin *et al*[63] proposed a conceptual framework for understanding disturbed dreaming following traumatic stress that accommodate data on emotional memory structures and the brain correlates of emotion. A fundamental assumption in this model is that alterations in nightmare rates, severity, and comorbidity reflect the influence of both affect load, a consequence of daily alterations in emotional pressure, and affect distress, an inclination to distressing, highly reactive emotional experiences.

The threat simulation theory of dreaming[64] states that threat simulation in the course of dreaming reenacts the cognitive mechanisms needed for adequate threat perception and threat avoidance. An assumption drawn from this theory is that real threatening events experienced throughout wakefulness may result in a heightened activation of the threat simulation system, and thus, to an elevated recurrence and severity of threatening experiences in dreams. Therefore, children living in conditions in which their physical and psychological well-being is continually jeopardized may

Table 1 Hypothetical mechanisms by which traumatic exposure may affect sleep

Hypothesis	Mechanism
Biological perspective	Physiological arousal (increased activity of the amygdala, and decreased activity of the medial prefrontal cortex) hinders sleep onset
Safety and attachment	Feeling that one needs to be continuously alert and on guard instead of sleeping
Emotional memory and affect	Alterations in nightmare rates, severity, and comorbidity reflect the influence of both affect load and distress
Threat simulation theory	Threat simulation in the course of dreaming reenacts the cognitive mechanisms needed for adequate threat perception and threat avoidance
Emotional regulation model	Individuals exposed to trauma continue to be hyper-alert to defend themselves against real or imagined hazards, such as through distressing dreaming that replays the traumatic experience during sleep
Hyperarousal-based theory	Under a hyper-arousal state, trauma survivors show an increased level of awareness and a sensitized response to the external world
Anxiety buffer disruption assumption	Fear can increase the likelihood of gathering traumatic cues in the cognitive world, resulting in intrusive thoughts
Depressive-like pathophysiology	Elevated plasma cortisol levels near sleep onset, increased sleep latency, and significant dysregulation in REM sleep patterns
Cognitive hyperactivation	Excessive worry, rumination, and negative attributions contribute to the hyperarousal interfering with sleep

REM: Rapid eyes movement.

have an extremely triggered dream production and threat simulation system. Valli *et al*[65] examined this assumption by analyzing the content of dream reports from markedly traumatized and less traumatized Kurdish children and non-traumatized Finnish children. The researchers found that the markedly traumatized children expressed a significantly higher number of dreams and their dreams involved a greater number of threatening dream experiences. Also, the nature of dream threats of traumatized children was more serious than the threats of less traumatized or non-traumatized children.

An analogous model, the emotional regulation model of trauma[66] proposes that there is a fear network that connects fear-related information in a traumatized individual's memory[67]. This information can be triggered by real or imagined trauma-related cues, and a fear response will then be evoked. Hence, individuals exposed to trauma may continue to be hyper-alert to defend themselves against real or imagined hazards, such as through distressing dreaming that replays the traumatic experience during sleep[68]. This is also supported by the finding that traumatized individuals show elevated arousal activity during sleep, which in turn leads to a lighter or more fragmented sleep[12]. Thus, fear could be a risk factor for the onset of sleep difficulties following a traumatic event.

The hyperarousal-based theory of sleep problems[69] proposes that PTSD leads to a hyper-arousal state, under which traumatized individuals will experience an increased level of awareness and a sensitized response to the external world. Hyper-arousal breaks the necessary prerequisite for optimal sleep quality and makes sleep problems more noticeable[70]. Furthermore, PTSD can also cause trauma survivors to re-experience the trauma-related cues in their cognitive world, therefore eliciting the physiological arousal and undesirable emotions that will in turn disturb their sleep[71].

Moreover, the anxiety buffer disruption assumption[72] suggests a close association between fear and PTSD. This assumption highlights that fear can increase the likelihood of gathering traumatic cues in the cognitive world, resulting in intrusive thoughts related to hyper-arousal states[67]. It is also suggested that the fear can exacerbate the severity of PTSD through hampering the constructive examination of traumatic experiences and the consolidation of traumatic memories[73,74].

In support of the emotional regulation model of trauma and the hyperarousal-based theory, Zhou *et al*[75] showed that fear and PTSD among adolescents 1 year after an earthquake mediated the relationship between trauma exposure at 1 year following the earthquake, and sleep difficulties at both 1 year and 1.5 years following the earthquake, respectively. Moreover, Zhou *et al*[76] found that intrusive, avoidance and hyperarousal symptom clusters of PTSD could be significant predictors for the emergence and persistence of sleep difficulties from 1 year to 1.5 years after the earthquake. The intrusive symptoms of PTSD may increase the frequency of cognitive

activities[77], and hyperarousal symptoms can elevate the physiological or psychological hyperarousal state[12,78]; adolescents with symptoms of avoidance may seek to avoid being dominated by traumatic cues during dreaming by avoiding falling asleep[67]. However, in the study by Zhou *et al*[76], from 1.5 years to 2 years following the earthquake, only the avoidance symptom clusters of PTSD were risk factors for sleep difficulties and the relationship between PTSD and sleep problems weakened with time change.

Last, it has been suggested that mechanisms for sleep disturbances, such as elevated plasma cortisol levels near sleep onset, increased sleep latency, and significant dysregulation in rapid eyes movement, sleep patterns, parallel aspects of underlying pathophysiology of severe adolescent depression[79]. Moreover, the depressive cognitive hyperactivation (*i.e.*, excessive worry, rumination, and negative attributions) may contribute to the hyperarousal interfering with sleep.

CONCLUSION

The present review illustrates the role of sleep difficulties in children and adolescents exposed to trauma and emphasizes the need to examine a wide range of etiological mechanisms for these symptoms. However, the relationship of trauma exposure to sleep problems among children and adolescents needs further investigation in future research. For example, work is needed to understand the mechanisms by which sleep difficulties emerge and persist in the context of childhood trauma, and if sleep problems exacerbate other trauma-related symptoms. Additionally, the long-term course of sleep problems in children exposed to trauma have not been thoroughly reported.

Moreover, in view of the negative consequences of long-term disrupted sleep on mental health outcomes following trauma, the need to effectively address sleep disturbances in traumatized children and adolescents is crucial. Thus, clinicians should be aware of sleep problems in childhood trauma victims. Trauma-focused interventions for children and adolescents may be beneficial not only for relieving child and adolescent traumatic stress but also for ameliorating adolescents' sleep problems, and could be complemented by tailored psychotherapeutic and pharmacological interventions targeting sleep disturbances.

Abstract

BACKGROUND

Major depressive disorder (MDD) is a highly disabling psychiatric syndrome associated with deficits of specific subpopulations of cortical GABAergic interneurons; however, the underlying molecular mechanism remains unknown. Type 3 adenylyl cyclase (ADCY3, AC3), which is important for neuronal excitability, has been implicated in MDD in a genome-wide association study in humans. Moreover, a study reported that ablation of AC3 in mice caused similar symptoms as MDD patients.

AIM

To determine if disruption of the AC3 gene in different subtypes of GABAergic interneurons of mice causes depression-like behaviors.

METHODS

Using immunohistochemistry, we investigated the expression of AC3 in two major subtypes GABAergic interneurons: Somatostatin-positive (SST^+) and parvalbumin-positive (PV^+) neurons. Genetic manipulations were used to selectively disrupt AC3 expression in SST^+ or PV^+ interneurons. A series of behavior tests including rotarod test, open field test (OFT), elevated plus maze test (EPM), forced swimming test (FST), and tail suspension test (TST) were used

the International Association for the Study of Pain regarding the use of laboratory animal.

to evaluate the motor ability, anxiety- and depression- like behaviors, respectively.

RESULTS

Our results indicate that approximately 90.41% of SST$^+$ and 91.22% of PV$^+$ interneurons express AC3. After ablation of AC3 in SST$^+$ interneurons, the mice spent comparable time in the center area in OFT, but significantly less time in the open arms and low frequency of entries to the open arms in EPM. Furthermore, these mice showed prolonged immobility in FST and more freezing in TST. However, there were no significant changes in these behaviors after specific disruption of AC3 in PV$^+$ interneurons.

CONCLUSION

This study indicates that ablation of AC3 in SST$^+$ interneurons of mice increases anxiety- and depression-like behaviors in mice, supporting the general hypothesis that decreased AC3 activity may play a role in human depression.

Core Tip: Dysfunction of cortical GABAergic interneurons are thought to contribute to the pathophysiology of stress-related psychiatric disorders. Little is known about the regulation of GABAergic interneurons in depression. Type 3 adenylyl cyclase (AC3) is important for the neuronal excitability and was reported as a top-ranked gene in major depressive disorder (MDD). Here, we found that majority of somatostatin-positive (SST$^+$) and parvalbumin-positive (PV$^+$) GABAergic interneurons express AC3. Selective disruption of AC3 in SST$^+$ but not PV$^+$ interneurons caused anxiety- and depression-like behaviors. Our data suggest that AC3 in specific subtype interneurons played a key role in the etiology of depression, providing new insights for therapeutic interventions for the treatment of MDD.

INTRODUCTION

Major depressive disorder (MDD) is a severe psychiatric disorder that affects up to one in six individuals worldwide[1]. Despite long-lasting efforts to explore the etiology and pathophysiology of depression, the underlying neurobiological mechanisms are not well defined. Current antidepressant pharmacological treatments are mainly focused on monoaminergic neurotransmission, which is based on the traditional catecholamine and serotonin hypotheses of mental disorders[2,3]. However, only approximately 33% of patients experience remission after pharmacological treatments, and up to one-third of these patients have a poor response to regular antidepressant treatments[4,5]. Therefore, it is important to identify new drug target sites for treatment of depression.

Recent evidence suggests that the functional interaction between the glutamatergic excitatory and GABAergic inhibitory connectivity is altered during depression and chronic stress exposure[6-8] suggesting that impairment of γ-aminobutyric acid (GABA) neurotransmission may contribute to the neurobiology of MDD[9,10]. The cortical GABAergic interneurons are divided into different subtypes according to their morphology, electrophysiological properties, and expression of calcium-binding proteins and neuropeptides[11]. Most research concerning GABAergic interneurons in depression and anxiety has focused on two major subtypes expressing somatostatin (SST) or parvalbumin (PV), which make up approximately 70% of GABAergic

P-Editor: Li JH

inhibitory neurons[12,13]. Studies focusing on SST in MDD suggest a reduction of SST in several corticolimbic brain regions in postmortem MDD patients, including the dorsolateral prefrontal cortex, subgeual anterior cingulate cortex (sgACC), and amygdala[14-16]. Mice lacking SST (SST global knockout mice) display similar behavioral and molecular features as human depression. This includes increased circulating corticosterone, elevated anxiety/depressive-like behaviors, and reduced gene expression of brain-derived neurotrophic factor (BDNF), cortistatin, and glutamate decarboxylase 67 (GAD67)[17]. However, there is less evidence for consistent alterations of PV^+ interneurons in MDD. Most studies have reported that there are no significant changes in PV expression in either MDD subjects[18-21] or rodent models[21-24]. Several studies have indicated decreased PV expression in tissues of post-mortem MDD patients[21] or in rodent models[20,25]. By contrast, increased PV expression has been reported when female mice are exposed to unpredictable chronic stress for 2 wk[26]. Since SST^+ and PV^+ interneurons differentially target specific cellular domains (distal dendritic *vs* perisomatic regions) of pyramidal neurons and other interneurons, it is reasonable to believe that they might play different roles in the pathology of MDD.

Type 3 adenylyl cyclase (AC3, ADCY3), is widely expressed in primary cilia in neurons of the central nervous system[27]. AC3 is stimulated by Gs-coupled receptors and inhibited by Gi-coupled receptors and Ca^{2+}/calmodulin-dependent protein kinase II[28]. In 2012, a genome-wide association study in humans implicated the *ADCY3* gene in MDD[29]. Moreover, a study published by Chen *et al*[30] showed that $AC3^{-/-}$ mice have similar symptoms as MDD patients. This includes increased rapid eye movement sleep time, anosphrasia, and anxiety and -depression-like behaviors.

However, there is little information on how decreases in AC3 activity contribute to the pathophysiological process of MDD. In this study, we took advantage of several transgenic mice lines. We bred $AC3^{flox/flox}$ mice with subtype-specific GABAergic interneuron Cre lines in which the Cre recombinase (Cre) is expressed under the control of SST or PV promoters to explore the roles of AC3 in SST^+ and PV^+ interneurons in the development of anxiety and depression mood disorders.

MATERIALS AND METHODS

Animals

Male C57BL/6J mice were obtained from the Shanghai Experimental Animal Center of the Chinese Academy of sciences. $AC3^{flox/flox}$ mice were generated as previously reported[30]. SST-Cre mice (JAX013044), PV-Cre mice (JAX008069), and Ai14 mice (JAX007914) were purchased from Jackson Laboratory (Bar Harbor, ME, United States). All mice were backcrossed into the C57BL/6J genetic background for at least six generations. Mice were genotyped using their tail tissue after cracking by lysis reagent (Direct PCR Lysis Reagent [mouse tail], QIAGEN, Hilden, Germany) and proteinase K (Proteinase K, QIAGEN). Seventy-eight male mice used in behavioral analysis were age 8-12 wk old with comparable body weight. Eleven male adult mice were used for immunohistochemistry. All mice were group-housed (3-6 per cage) and maintained on the a 12/12 h light/dark cycle, 50% humidity, at 23.1 °C with access to food and water *ad libitum*. All experimental procedures were designed to minimize pain or discomfort to the animals, approved by the Experimental Animal Ethics Committee of Shanghai Medical College and the Institutional Animal Care & Use Committee (IACUC) of Fudan University (Permit No. SYXK2009-0082; Shanghai, China) and followed the ethical guidelines of the International Association for the Study of Pain regarding the use of laboratory animals.

Behavioral studies

Mice were handled at least 3 d by the experimenters before the behavioral tests, and habituated to the test room for 30 min before behavioral test. All behavioral tests were performed by investigators blind to genotypes.

Accelerating rotarod test

The rotarod test was performed as previously described[31]. Briefly, the mice were placed on an accelerating rotarod (IITC Life Science, Woodland Hills, CA, United States) (4-40 rpm acceleration in 5 min) for 4 consecutive days. Training consisted of 4 trials per day at 5 min intervals. The trial ended when the mouse fell off the roller. We calculated the average latency to fall from the last two trials performed on the last day.

Open field test

The apparatus consisted of a square box (40 cm × 40 cm × 30 cm, length × width × height) with blue floor and without a celling. Both the box and floor were made of Perspex plates. During testing, the floor was separated into 16 small squares of equal area. The four squares in the center were designated the central area, and the others are called the limbic area. The light level was maintained at approximately 25 lux in the open field area. The test began when the mice were put in the center of the square. After free movement for 5 min, the mice were returned to their home cages. Video tracking software (Ethovision XT v11.5; Noldus Information Technology Inc., Leesburg, VA, United States) was used to record the distance traveled and time spent in each zone.

Elevated plus maze test

The elevated plus maze consisted of a central platform (6 cm, 6 cm), two open arms (30 cm, 6 cm) and two closed arms (30 cm, 6 cm) with protective walls 15 cm high. The apparatus was elevated 50 cm above the floor and was placed in a room with an illumination of 30 lux. Mice were put on the central platform facing an open arm, and allowed to freely explore the maze for 5 min. The traces were recorded by the video tracking system (Ethovision XT v11.5; Noldus BV). The time spent exploring time in the open arm and the frequency of entries to the open arm were calculated by Video Tracking software (Ethovision XT v11.5; Noldus BV).

Forced swimming test

Mice swam individually in a cylindrical glass container (diameter: 18 cm, height: 50 cm, depth: 12 cm) filled with water (24.1 °C). The test comprised two sessions: A training session (10 min) on the first day and a test session (5 min) on the next day, which were recorded by a video camera. Immobility in mice was defined as no active movements except for single limb paddling to keep the head and nose above the water.

Tail suspension test

The apparatus for the tail suspension test (TST) was a white plexi-glass box with a hook on the ceiling of the box. The mice were suspended 15 cm above the floor on the hook with a tape at 2 cm proximal to the tail tip. The test session lasted 6 min and was recorded with a video camera. The freezing time was scored for the last 4 min of the session.

Immunohistochemistry

Mice were deeply anesthetized with urethane (1.5 g/kg) and perfused transcardially with normal saline followed by 40 g/L paraformaldehyde in phosphate-buffered saline (PBS). The brains were collected, post-fixed in the same fixative for additional 4 h at 4 °C, and dehydrated in graded sucrose solutions (10 g/L, 20 g/L, 30 g/L). Continuous coronal sections of brains (35 μm) were prepared on a cryostat (Leica, Germany) and stored at -20 °C. Sections were washed with 0.01 mol/L PBS and blocked in 10% donkey serum in 0.01 mol/L PBS, pH 7.4, with 0.3% Triton X-100 for 2 h at room temperature (RT). For triple immunostaining of SST/AC3/NeuN, SST-Cre:Ai$^{f/f}$reporter mice were used. Sections were incubated with a mixture of rabbit anti-AC3 (1:1000, SC-588; Santa Cruz, Dallas, TX, United States) and mouse anti-NeuN (1:1000, MAB377; Millipore, Burlington, MA, United States), followed by the corresponding secondary antibodies (1:200, Alexa Fluor 647 donkey anti-rabbit, 711-605-152, Jackson Laboratory; 1:200, Alexa Fluor 488 donkey anti-mouse, A-21202, Invitrogen, Carlsbad, CA, United States) for 2 h at 4 °C. For triple immunostaining of PV/AC3/DAPI, the sections were incubated with a mixture of rabbit anti-AC3 and mouse anti-PV (1:500, P3088; Sigma, St. Louis, MO, United States) overnight at 4 °C, followed by their corresponding secondary antibodies (1:200, Alexa Fluor 546 donkey anti-rabbit, A-10040, Invitrogen; 1:200, Alexa Fluor 488 donkey anti-mouse, A-21202, Invitrogen) for 2 h at 4 °C. The nuclei were counterstained with DAPI (1:20000, 62248; Thermo Fisher Scientific, Waltham, MA, United States) for 3 min at RT. All sections were coverslipped with a mixture of 50% glycerin in PBS. Images were captured with a confocal laser-scanning microscope (FV1000; Olympus, Tokyo, Japan). The interval between two adjacent focal planes was 2 μm (*z*-stack). Image analysis was performed by Photoshop or FV10-ASW 1.7 Viewer software (Olympus).

Fluorescent in situ hybridization using RNAscope and double staining with immunohistochemistry

Brain sections (14 μm) were cut using a cryostat and mounted onto Colorfrost Plus slides (Thermo Fisher Scientific). In situ hybridization (ISH) was performed using the RNAscope system (Advanced Cell Diagnostics, Newark, CA, United States) according to the manufacturer's protocol. Sections were pretreated with hydrogen peroxide for 10 min at RT, followed by target-retrieval solution and Protease III using RNAscope 2.5 Universal Pretreatment Reagents (#322381; Advanced Cell Diagnostics). Then the commercial probe for AC3 (#478071-C1) was used. After hybridization, the RNAscope Multiplex Fluorescent Detection Kit v2 (#323110) was used to amplify signal. After ISH, sections were labeled with anti-SST antibody (goat, 1:500, sc-7819; Santa Cruz), followed by its corresponding secondary antibody (Alexa Fluor 488 donkey anti-goat, 1:200, A-11055; Invitrogen). Images were captured with a confocal laser-scanning microscope (Model FV1000; Olympus).

Statistical analysis

All data are presented as the mean ± standard error of the mean and were analyzed using Prism 7.0 (GraphPad Software, San Diego, CA, United States). Comparisons between two groups were performed using the two-sided Student's *t*-test. One way analysis of variance (ANOVA) followed by post hoc Tukey's multiple comparisons test was used for data comparison between three groups. $P < 0.05$ was considered statistically significant.

RESULTS

Expression of AC3 in SST$^+$ and PV$^+$ interneurons in mice

As a starting point, we examined the expression of AC3 in two major subtypes of cortical GABAergic interneurons. As shown in Figure 1, AC3 immunostaining was extensively distributed in the brain area examined (Figure 1A and D). Consistent with previous reports[27], the high magnification of imaging showed that AC3 was exclusively expressed in primary cilia with a rod-like shape (Figure 1B and E). To observe the expression of AC3 in SST$^+$ interneurons, we bred SST-Ai14$^{f/f}$ transgenic mice in which SST$^+$ interneurons were labeled with the tdTomato fluorescent protein carried by the *Ai14* gene. Statistical analysis showed that approximately 90.41% of SST$^+$ interneurons expressed AC3 (Figure 1C). We also examined the expression of AC3 in PV$^+$ interneurons using double immunostaining. Similar to SST$^+$, about 91.22% of PV$^+$ interneurons expressed AC3 (Figure 1F). Our results indicated that the majority of SST$^+$ and PV$^+$ GABAergic interneurons express AC3.

Deletion of AC3 from SST$^+$ neurons results in anxiety- and depression-like behaviors

To explore the functional role of AC3 in specific cell type interneurons, SST-Cre mice, PV-Cre mice, and AC3$^{flox/flox}$ mice in which exon 3 of the *ADCY3* gene was flanked by two loxP sites were used. We assessed a series of general behaviors of AC3$^{flox/flox}$ mice that served as controls. As shown in Figure 2, the behaviors of AC3$^{flox/flox}$ mice analyzed in the open field test (OFT) (Figure 2A), elevated plus maze (Figure 2B), forced swimming test (FST) (Figure 2C), TST (Figure 2D) and rotarod test (Figure 2E) were largely indistinguishable from wild-type mice, indicating that the floxed AC3 mice showed normal emotion-related behaviors and motor ability.

To characterize the functional role of AC3 in SST$^+$ neurons, we generated SST-Cre:AC3$^{f/f}$ mice by breeding SST-Cre mice and AC3$^{flox/flox}$ mice to selective delete AC3 from SST$^+$ interneurons (Figure 3A). As expected, the immunoreactivity of *ACDY3* transcript examined by RNAscope IST disappeared in SST$^+$ interneurons in SST-Cre:AC3$^{f/f}$ mice but not in AC3$^{flox/flox}$ mice (Figure 3B). Then we subjected SST-Cre:AC3$^{f/f}$ mice to test for anxiety- and depression-like behaviors. In the OFT, although the SST-Cre:AC3$^{f/f}$ mice moved less distance in the apparatus compared with the other two groups (one-way ANOVA, $F_{(2, 32)} = 3.871$, $P = 0.0312$; Figure 3C), the SST-Cre:AC3$^{f/f}$ mice did not show an obvious difference in the ratio of moving distance in central area and the center area duration (one-way ANOVA, $F_{(2, 32)} = 0.2423$, $P = 0.7863$, Figure 3D; one-way ANOVA, $F_{(2, 32)} = 0.0471$, $P = 0.9541$, Figure 3E). In the elevated plus maze test, the total entry frequency of both arms in SST-Cre:AC3$^{f/f}$ mice was significantly lower than that in the AC3$^{flox/flox}$ mice and SST-Cre mice (one-way ANOVA, $F_{(2, 32)} = 14.62$, $P < 0.0001$; Figure 3F). Further analysis revealed that SST-Cre:AC3$^{f/f}$ mice spent less time in the open arms (one-way ANOVA, $F_{(2, 32)} = 6.052$, $P = 0.0062$; Figure 3G) and a decreased

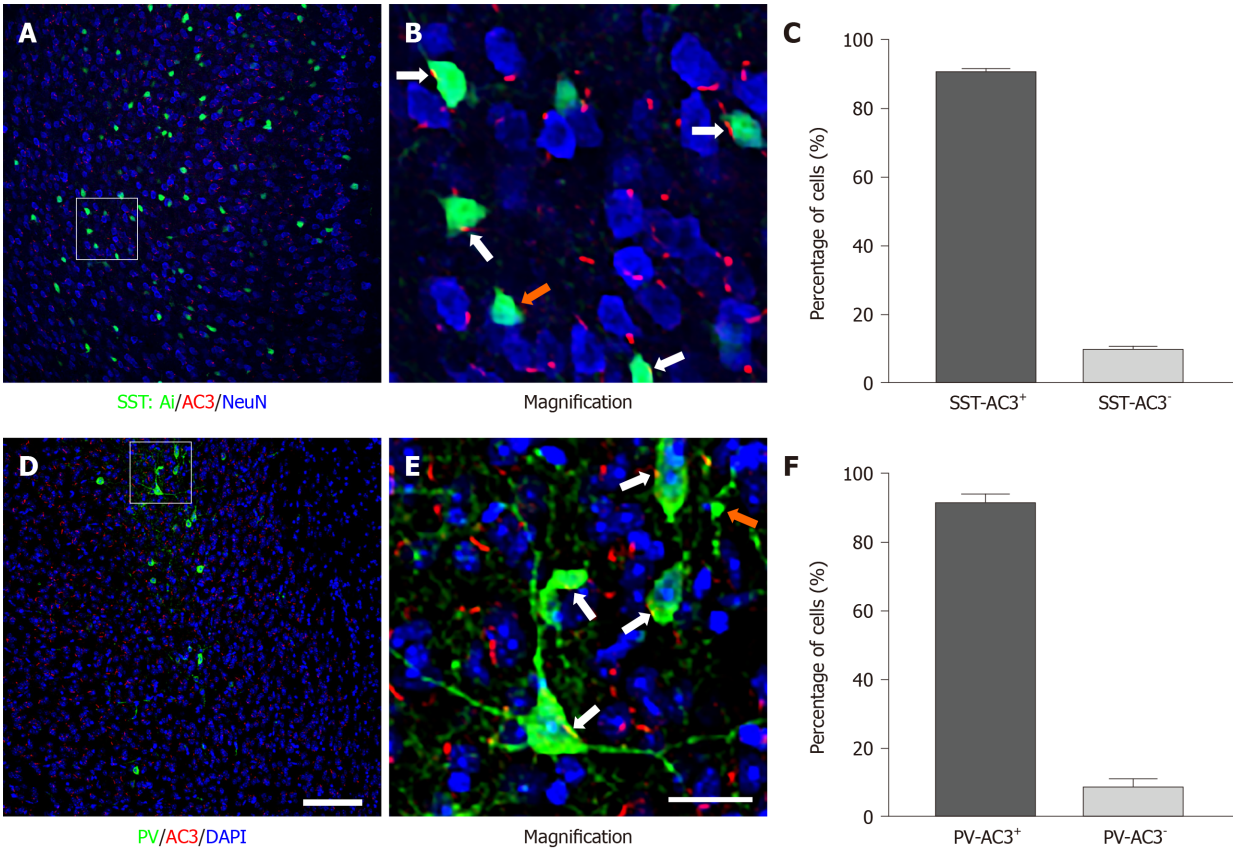

Figure 1 Expression of type 3 adenylyl cyclase in cortical somatostatin-positive and parvalbumin-positive GABAergic interneurons. A and B: Representative images showing type 3 adenylyl cyclase (AC3) expression in somatostatin-positive (SST$^+$) interneurons at low (A) and high (B) magnifications in the prefrontal cortex brain slice. Solid arrows in B indicate SST$^+$ interneurons, which are also AC3-positve (SST-AC3$^+$ cells). Empty arrow in B indicates SST$^+$ interneurons, which are AC3-negative (SST-AC3$^-$ cells); C: Proportion of AC3 expressed in cortical SST$^+$ neurons, n = 6; D and E: Representative images showing AC3 expression in parvalbumin-positive (PV$^+$) interneurons at low (D) and high (E) magnifications in the prefrontal cortex brain slice. Solid arrows indicate PV$^+$ interneurons, which are also AC3-positve (PV-AC3$^+$ cells). Empty arrow in E indicates PV$^+$ interneurons, which are AC3-negative (PV-AC3$^-$ cells); F: Proportion of AC3 expressing in cortical PV$^+$ neurons, n = 5. Scale bars represent 100 μm in D and 20 μm in E, respectively.

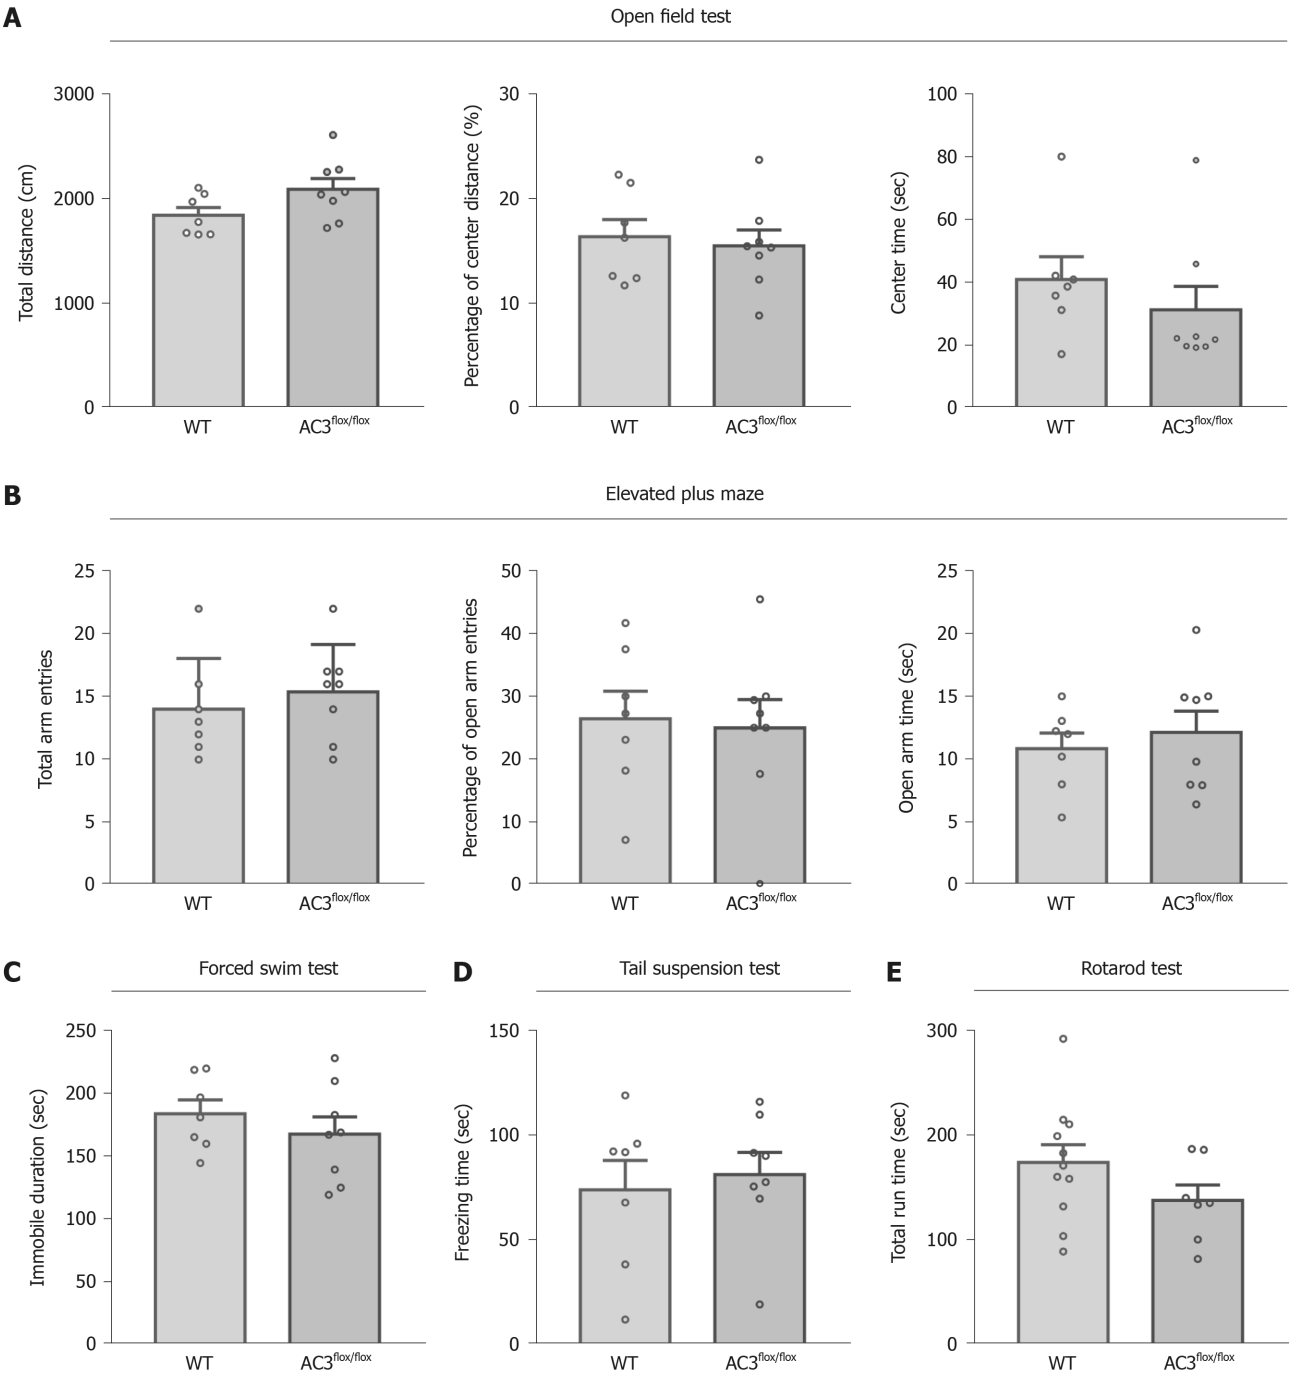
percentage of open arms entries (one-way ANOVA, $F_{(2, 32)}$ = 6.768, P = 0.0035; Figure 3H) relative to AC3$^{flox/flox}$ mice and SST-Cre mice.

We also used the FST and TST to evaluate the depression level of the mice, since anxiety and depression are common comorbid psychiatric disorders among patients. SST-Cre:AC3$^{f/f}$ mice showed increased immobility time in the FST (one-way ANOVA, $F_{(2, 32)}$ = 11.32, P = 0.0002; Figure 4A), and prolonged freezing time in TST (one-way ANOVA, $F_{(2, 32)}$ = 8.509, P = 0.0011; Figure 4B) compared with AC3$^{flox/flox}$ mice and SST-Cre mice. These data suggest that the SST-Cre:AC3$^{f/f}$ mice exhibit depression-like behaviors in two different test paradigms. There was no significant difference between the AC3$^{flox/flox}$ group and SST-Cre mice in these behavioral tests.

Deletion of AC3 from PV$^+$ neurons did not influence anxiety- and depression-like behaviors

PV$^+$ interneurons are another major group of GABAergic interneurons which are thought to play a vital role in mood disorders. Whether ablation of AC3 in PV$^+$ interneurons influences anxiety- or depression-like behaviors was unknown. Here, AC3$^{flox/flox}$ mice were crossed with the PV-Cre mice for specific disruption of AC3 expression in the PV$^+$ interneurons (Figure 5A). Ablation of AC3 expression in PV$^+$ GABAergic interneurons in PV-Cre:AC3$^{f/f}$ mice, but not in control AC3$^{flox/flox}$ mice, was confirmed by double immunostaining (Figure 5B). Then we examined PV-Cre:AC3$^{f/f}$ mice for anxiety- and depression-like behaviors. The PV-Cre:AC3$^{f/f}$ mice moved a similar total distance and percentage of central distance (one-way ANOVA, $F_{(2, 25)}$ = 0.2446, P = 0.7849, Figure 5C; one-way ANOVA, $F_{(2, 25)}$ = 0.08463, P = 0.9191, Figure 5D) and spent a similar period of time in the center arena of the open field (one-way ANOVA, $F_{(2, 25)}$ = 0.246, P = 0.7838; Figure 5E) either to control AC3$^{flox/flox}$ or PV-Cre mice. These mice also spent comparable time in the open arms (one-way ANOVA, $F_{(2, 25)}$ = 0.1231, P = 0.8847; Figure 5G) and the entries to both arms and the frequency of



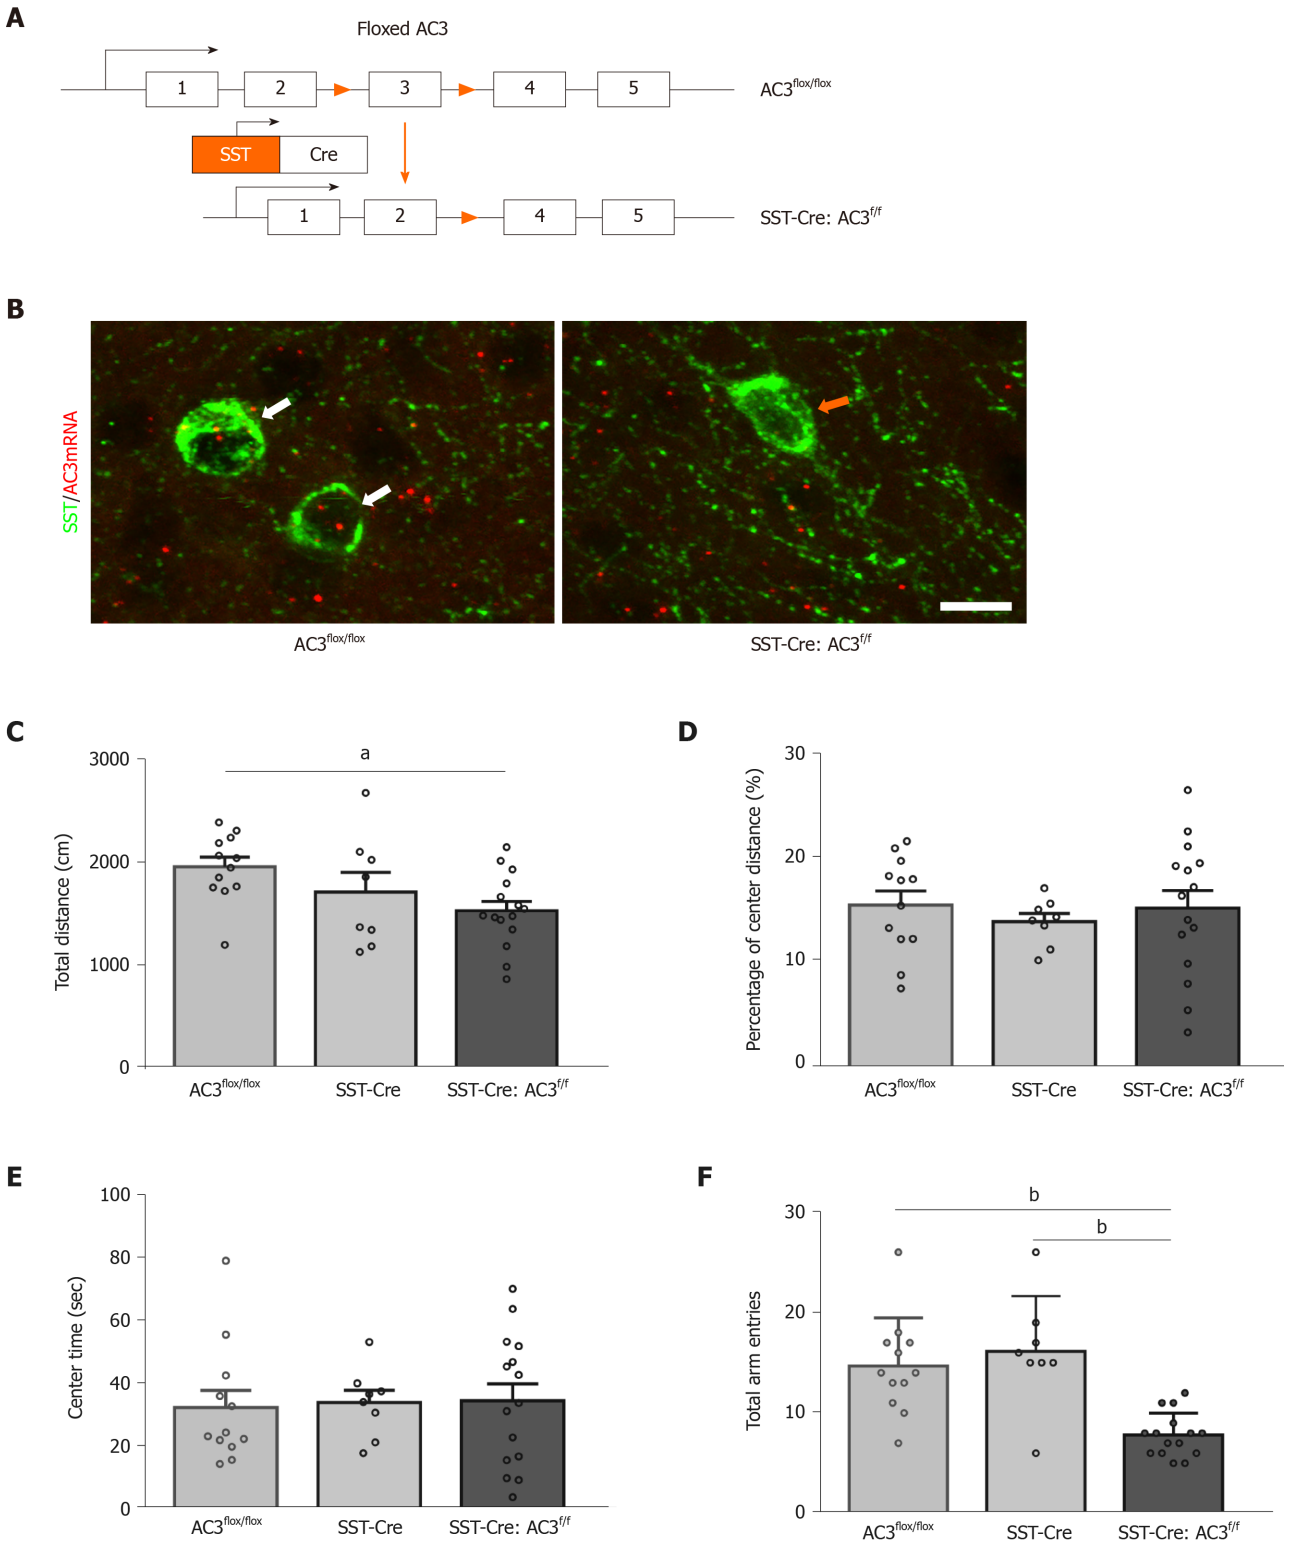


Figure 2 Type 3 adenylyl cyclase$^{flox/flox}$ mice exhibit normal emotion-related behaviors and motor ability compared with wild-type C57 mice.
A and B: Anxiety-related behavioral tests were illustrated by the open field test (A) and elevated plus maze (B); C and D: Depression-like behavioral tests were examined by the forced swimming test (C) and tail suspension test (D); E: Motor ability was examined by the rotarod test. Bars represent the mean ± standard error of the mean. Data were analyzed using the Student's *t*-test. n = 7 for the wild-type (WT) group, n = 8 for the type 3 adenylyl cyclase (AC3)$^{flox/flox}$ group.

entries to the open arms is similar compared with AC3$^{flox/flox}$ mice and PV-Cre mice (one-way ANOVA, $F_{(2, 25)}$ = 0.082, P = 0.9219, Figure 5F; one-way ANOVA, $F_{(2, 25)}$ = 0.7036, P = 0.5044, Figure 5H). Also, there was no significant differences in the immobility in the FST (one-way ANOVA, $F_{(2, 25)}$ = 0.3572, P = 0.7032, Figure 6A) or the freezing time in the tail-suspension test when selective deletion of AC3 in PV^{+} interneurons (one-way ANOVA, $F_{(2, 25)}$ = 0.136, P = 0.8735, Figure 6B). Taken together, PV-Cre:AC3$^{f/f}$ mice did not exhibit a pro-anxiety or pro-depression phenotype.

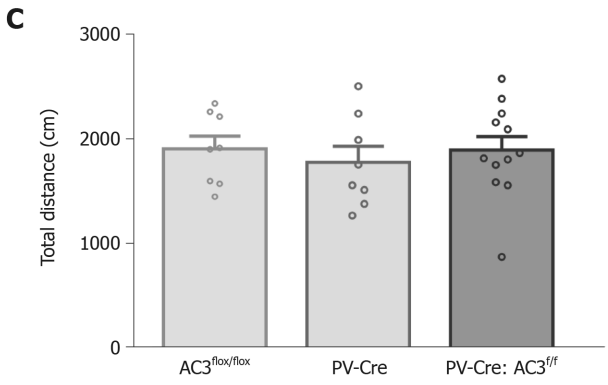
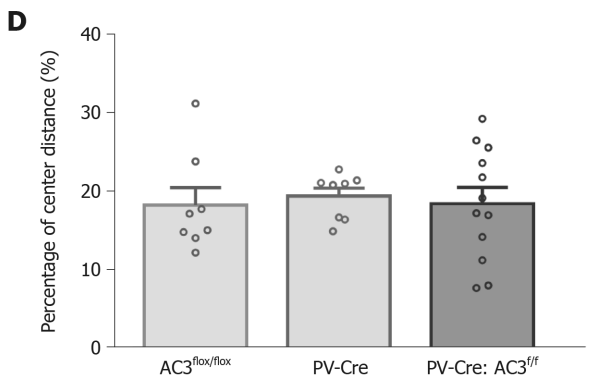
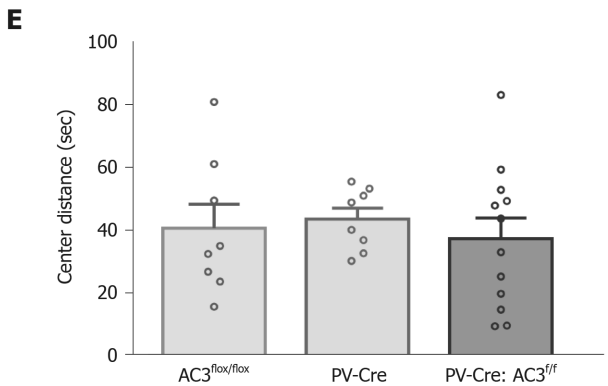
Data were analyzed using one-way analysis of variance followed by post hoc Tukey's multiple comparisons test. n = 12 for AC3$^{flox/flox}$ group, n = 8 for SST-Cre group, n = 15 for SST-Cre:AC3$^{f/f}$ group. $^fP < 0.001$ *vs* AC3$^{flox/flox}$. $^gP < 0.05$ *vs* SST-Cre. .



DISCUSSION



In this study, we determined if deletion of AC3 expression in two major GABAergic interneurons increases anxiety- and depression-related behaviors in mice. Our results indicated that the majority of SST$^+$ and PV$^+$ interneurons express AC3. Selective ablation of AC3 in SST$^+$ but not PV$^+$ interneurons induced anxiety- and depression-like behaviors, suggesting that loss of AC3 in the SST$^+$ interneurons may play an important role in the development of anxiety and depression in humans.



The balance between excitation and inhibition of neuronal circuit in the brain is interrupted in several neuropsychiatric disorders including MDD[7]. Recent evidence has shown that a deficit of inhibitory synaptic transmission contributes to the pathophysiology and development of MDD. Two major GABAergic interneurons, SST$^+$ and PV$^+$ cells, are subjects of interest in MDD. SST$^+$ interneuron synapses on the dendritic tufts of the nearby pyramidal neurons and is critical for gating the pattern of functional connectivity inputs[32]. In contrast to SST$^+$ interneurons, PV$^+$ GABAergic interneurons mainly target the soma of pyramidal neurons, thereby regulating action potential firing and promoting synchronization of electrical activity[33]. So, it is perhaps not so surprising that these two types of GABAergic interneurons play specific roles in different kinds of psychiatry disorders owing to their distinct electrical, neurochemical

and structural properties. Our study indicates that the mice with selective ablation of AC3 from SST^{+} but not PV^{+} interneurons showed an anxiety- and depression-like behaviors, supporting the notion that specific subpopulation of GABAergic interneurons are functionally different. Our data are also consistent with several previous findings. For example, studies of brain samples from MDD corpses found that SST neurons were significantly attenuated and that expression of SST mRNA was reduced in multiple brain areas[14,34]. However, less obvious changes in PV^{+} interneurons in MDD patients were reported[18-20] although a reduced SgACC PV expression has been reported[21]. Moreover, contributions of SST^{+} but not PV^{+} interneurons to the pathophysiology of MDD has been directly supported through genetic and pharmacological manipulations in rodents. SST global knockout mice showed increased anxiety- and depression-like behaviors, elevated corticosterone level and decreased expression of BDNF, GAD67 and cortistatin genes expression[17]. However, selective activation of PV^{+} interneurons in the dentate gyrus of the hippocampus did not affect depression-like behavior in the TST[35]. Furthermore, mice with reduced BDNF expression (heterozygous deletion of BDNF gene [BDNF$^{+/-}$] or targeted disruption of exon IV [BDNF^{KIV}]) exhibited depressive-like behaviors and a robust and significant decrease of SST but not changes in PV expression[21]. Taken collectively, these previous studies and ours strongly indicated that central SST^{+} interneurons, as one type of susceptible GABAergic interneurons during MDD,

participated in the pathophysiology of anxiety- and depression-related disorders.

Previous studies from mice and humans have suggested a role for deficiencies in adenylyl cyclase and cAMP in depression and antidepressant responses[36,37]. However, the relationship with adenylyl cyclase and depression is more complex because of the diversity of adenylyl cyclase isoforms. A notable finding of present study is that SST-Cre:AC3$^{f/f}$ mice produced anxiety- and depression-like behaviors after selective disruption of AC3 in SST$^+$ interneurons, suggesting that reduction of AC3 expressed in SST$^+$ interneurons may contribute to MDD. The data in this study is also confirmed with our previous studies showing that disruption of AC3 gene globally, conditionally, or targeted to forebrain caused depression-like behaviors in transgenic mice[30]. We do not know why loss of AC3, which is expressed in the primary cilia of CNS neurons, caused depression in mice. However, ablation of type III adenylyl cyclase in mice causes reduced neuronal activity and altered sleep patterns[30]. This suggests the interesting possibility that the depression-like behavior seen with AC3$^{-/-}$ mice might be caused by a chronically decreased SST$^+$ neuronal excitability, subsequently impairment of GABAergic inhibitory synaptic input from SST$^+$ interneurons to pyramid cells, which is consistent with the GABAergic deficit hypothesis of MDD.

CONCLUSION

In summary, primary cilia in SST$^+$ interneurons may sense extracellular signals through non-synaptic transmission and transduce it into the neurons. Then the cellular signals may regulate by AC3 in primary cilia and effect on the activity of SST$^+$ interneurons. The changes in SST$^+$ interneurons may further affect the downstream neurons and modulate anxiety- and depression-like behaviors in mice.

ARTICLE HIGHLIGHTS

Research background

Major depressive disorder (MDD) is a highly disabling and phenotypically heterogeneous psychiatric syndrome that is among the leading contributors to social and economic burden.

Research motivation

Studies from patients and animal models suggest a key role for functional imbalances between the excitatory and inhibitory neurotransmitters in the central nervous system. Somatostatin-positive (SST$^+$) and parvalbumin-positive (PV$^+$) neurons are two major GABAergic interneurons and play roles in excitation/inhibition balance. Type 3 adenylyl cyclase (AC3) has been reported as a top-ranked gene in MDD and our previous study indicated that AC3 globally knockout mice showed depression-like behaviors. We hope to know whether AC3 in these two subtypes of interneurons contributes to the pathophysiological process of depression.

Research objectives

To determine whether ablation of AC3 gene in different subtypes of GABAergic interneurons of mice produces depression-like behaviors.

Research methods

Immunohistochemistry, genetic manipulations, and a series of behavior tests were used in this study.

Research results

We found that selective disruption of AC3 in SST$^+$ but not PV$^+$ interneurons caused anxiety- and depression-like behaviors.

Research conclusions

AC3 in SST$^+$ interneurons play a key role in the etiology of depression.

Research perspectives

The AC3-dependent molecular mechanisms in SST$^+$ interneuron underlying MDD will

be further explored.

Abstract

BACKGROUND

Psychic euosmia (PE) has been described as a supposed psychological predisposition for which pleasant smells elicit an immediate sense of pleasure, order and calmness in obsessive-compulsive personality disorder (OCPD). In this study we tried to verify the interpretation that PE is the counterpart of disgust that has been associated to contamination and moral purity. Disgust and morality are significantly associated in people with obsessive-compulsive personality traits. We expected that OCPD patients would experience higher levels of PE.

AIM

To investigate the PE frequency in OCPD patients and healthy controls (HC) and to evaluate the relationship between PE and disgust.

METHODS

A single-center, case-control study was conducted in an outpatient service for obsessive-compulsive and related disorders. The sample consisted of 129 subjects: 45 OCPD patients and 84 HC. In both groups we submitted the Disgust Scale Revised (DS-R) and the self-report Structured Clinical Interview for DSM-5 Screening Personality Questionnaire to which we added an additional yes or no

question to investigate the presence of PE. In order to verify differences between groups, *t*-test was employed for continuous variables and ^{2} test for categorical variable; odds ratio was employed to analyze group differences in the PE survey. Correlation was explored with Pearson *r* correlations.

RESULTS

No differences were observed between groups in gender composition or education. A slight significant difference was found in mean age (t = 1.988; P = 0.049). The present study revealed significantly higher proportions of PE among OCPD patients when compared to HC (OR: 5.3, 2.28-12.46). Patients with OCPD were more likely to report PE (n = 36; 80%) whereas a much lower proportion endorsed PE in the HC group (n = 36; 42.9%). Interestingly, no differences were observed between groups in mean score for the Disgust Scale. There was also no difference between the two groups in any of the Disgust Scale Revised subscales. Moreover, no significant correlations were observed in the OCPD group between PE and Disgust Scale Revised subscales.

CONCLUSION

Results suggested that PE might be part of the clinical spectrum of OCPD, and it does not reflect the counterpart of disgust. This could also indicate that this phenomenon is a manifestation of orderliness or incompleteness. Further studies will need to be undertaken to better understand PE and its significance in OCPD.

Core Tip: Psychic euosmia (PE) is a positive aspect of obsessive-compulsive personality disorder (OCPD) recently described as a psychological predisposition for which pleasant smells elicit an immediate sense of pleasure, order and calmness. In the absence of other scientific observations, our group decided to investigate the presence of this phenomenon among OCPD patients and how PE ought to be considered. The present study revealed significantly higher rates of PE among OCPD patients compared to healthy control subjects. The absence of correlation between PE and the Disgust Scale in the OCPD group supports the hypothesis that this experience is not associated with disgust.

INTRODUCTION

Obsessive-compulsive personality disorder (OCPD), also known as anankastic personality disorder in the ICD-11[1], is one of the most represented personality disorders in the general population with a prevalence ranging from 2.1% to 7.9%[2-4]. OCPD has a high comorbidity with obsessive-compulsive disorder (OCD), with a rate ranging from 23% to 47%[5-9] as well as body dysmorphic disorder[10,11], autism spectrum disorder[12,13] and eating disorders[14,15]. The high rates of comorbidity have led researchers to speculate that OCPD bears a relationship with OCD[16]. Janet[17] described the manifestations and the core traits of OCPD, referring to particular aspects of "psychoasthenia," such as excessive controlled emotional expression, inability to achieve perfection, indecisiveness, orderliness and stubbornness. Later, Lewis[18] described two types of personalities in persons with OCPD: One characterized by negative affect, stubbornness and irritability and the other by uncertainty and submissiveness. During the years, the description of OCPD has evolved and is

currently defined by the DSM-5 as "a pervasive preoccupation for orderliness, perfectionism, mental and interpersonal control at the expense of flexibility, openness and efficiency"[2]. At the same time, the DSM-5 coded OCD in a new taxonomy called obsessive-compulsive and related disorders (OCRD). As reported by Fineberg *et al*[16], OCPD is typically associated with a restricted repertoire of rigid, stereotyped and disabling compulsive thinking patterns and behaviors with attaining completeness and intra- and interpersonal control, like doubting, checking and hoarding, are experienced as ego-syntonic or rather perceived as appropriate and correct by the person affected. Moreover, the same authors suggest the overlap of several characteristics between OCPD and OCD support the inclusion of OCPD in the OCRDs.

Thus, Riddle *et al*[19] described two specific dimensions in OCPD patients: One characterized by order and control and the other by hoarding and indecision. According to a dimensional approach, personality disorders can be considered "a quantitative" variation of personality traits, within a continuum between normality and psychopathology. In this sense, some manifestations such as orderliness and cleanliness in OCPD subjects do not necessarily represent a maladaptive variant. Few studies have focused on positive aspects of OCPD[20].

Psychic euosmia (PE)[21] is a positive aspect of OCPD that was recently described as a psychological predisposition for which pleasant smells elicit an immediate sense of pleasure, order and calmness in OCPD. In the absence of other scientific observations, our group decided to investigate the presence of this phenomenon among OCPD patients and subsequently how PE ought to be considered. We delineate three possible hypotheses: PE is a manifestation of orderliness, is a just right component or is the counterpart of disgust that has been associated with contamination and moral purity. In this study we tried to verify this last interpretation. Accordingly, Ottaviani *et al*[22] supported the relationship between disgust and morality, which are significantly associated in people with obsessive-compulsive personality traits. It is possible to distinguish core disgust, elicited by different physical stimuli, and moral disgust, specifically human, induced by immoral behavior that violates justice and human dignity[23]. Disgust involves the autonomic nervous system; several studies showed neurovegetative equivalents, like nausea and changes in the normal rhythm of stomach contractions and fainting, were associated with changes in the cardiovascular system during disgust by activation of the vagus nerve[24-26]. Neuroimaging studies reported activation of brain areas implicated in the emotion of disgust, such as the insula. The insula has been strongly implicated in perceiving and experiencing different forms of disgust[27,28].

The present study aimed at evaluating the presence of PE in a group of patients with a diagnosis of OCPD without comorbidity compared with healthy controls (HC). We expected that OCPD patients would experience higher levels of PE. The second aim was to ascertain the possible relationship between PE and disgust.

MATERIALS AND METHODS

To investigate whether the frequency of PE differs in patients with OCPD and HC and whether this component is related to disgust, we conducted a case-control study in consecutive outpatients enrolled in 2019 at an outpatient service for OCRDs, Policlinico Umberto I, Rome. The study was conducted in agreement with the Declaration of Helsinki and approved by the local ethics committee. Written informed consent was obtained from all eligible participants following a complete description of study details. Participants were informed regarding their freedom to withdraw from the study at any time without any negative effect on their therapy. The sample consisted of 129 subjects: 45 patients affected by OCPD and 84 HC. HC were recruited through "word of mouth" among volunteers. All participants were assessed for the presence of a psychiatric disorder with clinical interview using the diagnostic criteria based on the DSM-5[2]. Both the HC subjects and the cases were assessed by the same trained personnel. Having comorbidity psychiatric diagnosis and/or cognitive impairment was considered an exclusion criterion. From an initial sample of 52 patients diagnosed with OCPD, 7 subjects were excluded from the analysis due to comorbidity with OCD. Demographic data were collected for all samples. To explore the presence of OCPD in both groups, we submitted self-report Structured Clinical Interview for DSM-5 Screening Personality Questionnaire[29] to which we added an additional question, derived from the most common unsolicited affirmation of patients regarding this phenomenon, to investigate the presence of PE: "Do you happen to feel an immediate sense of well-being, or be in a good mood all of a sudden, or feel

calmness as soon as you smell clean or fresh smells (like fresh laundry)? Give us some examples."

The common unsolicited affirmation of patients often refers to a prompt mood improvement upon encountering good scents in general, or fresh laundry borax on their clothes, pillows or home settings. We have asked for examples in order to verify if subjects' answers were congruent with the framework of PE.

Moreover, all participants completed the Disgust Scale Revised (DS-R) to evaluate the disgust sensitivity. We used the Italian version[30] of DS-R[31,32]. This version is a self-report questionnaire that includes 25 items describing stimuli that elicit disgust across three distinct domains: Core disgust, animal-reminder disgust and contamination-based disgust. The scale is divided into two sections, and each section presents items for each domain. There are 13 items plus 1 trick question in the first section and 12 items plus 1 trick question in the second section. All items are rated on a 5-point scale from 0 (strongly disagree/not disgusting at all) to 4 (strongly agree/extremely disgusting). The total scale score is the sum of the 25 items, after reversing the scores for items 1, 6 and 10.

Statistical analysis was performed with SPSS 24 (IBM) software. In order to verify differences between groups, *t*-test was employed for continuous variables and χ^2 test for categorical variable. In order to verify differences between groups in the presence of PE, the odds ratio and its 95% confidence level according to the Woolf's method were calculated[33]. Correlation between variables was explored with Pearson *r* correlations. Bonferroni correction for multiple comparisons was applied. Statistical review of the study was performed by a biomedical statistician. The statistical methods of this study were reviewed by Pasquini P, MD, MPH, former Head of Department of Epidemiology and Biostatistics at Istituto Superiore di Sanità, Rome, Italy.

RESULTS

Socio-demographic characteristics of the subjects are shown in Table 1. No differences were observed between groups in gender composition or education. A significant difference was found in mean age as the patient group was older than the HC (P = 0.049). Regarding the presence of PE, significant differences were found between groups in how they answered the corresponding item during the interview (OR 5.34, 2.28-12.46) (Table 2). Among our 45 study subjects with OCPD, 36 (80%) were positive, while among 84 HC only 36 (42.9%) were positive. Interestingly, no differences were observed between groups in mean score on the Disgust Scale (t = 1.298; P = 0.197). There was also no difference between the two groups in the DS-R subscales (Table 3). No significant correlations were observed in the OCPD group between PE and DS-R subscales.

DISCUSSION

The present study revealed significantly higher proportions of PE among OCPD patients when compared to HC subjects. Thereby meaning that PE might be part of the clinical spectrum of OCPD. We also found that there were no significant differences in disgust sensitivity between OCPD patients and HC. Moreover, the absence of correlation between PE and subscales of Disgust Scale in OCPD group supported the hypothesis that this experience was not associated with disgust in this population.

This finding suggests that PE does not reflect the counterpart of disgust and might also indicate that this phenomenon is a manifestation of orderliness or incompleteness. Indeed, the sense of calmness derived by an experience of a pleasant smell would seem to complete the sense of perfection in an otherwise uncomfortable person. This might suggest that PE could be a manifestation of incompleteness. According to the dimensional approach, such maladaptive variants of personality disorder traits could transition imperceptibly into a spectrum of normal[16,34]. The same could be true for adaptive traits. As an example, in a normalcy *vs* pathology continuum approach, being conscientious or a tendency to be orderly and well organized may resemble a normal condition with several advantages in certain situations. Not surprisingly few studies have focused on positive aspects of OCPD[35]. On the other hand, PE could be conceptualized as a normal reaction.

A strength of our study is that comorbidity was excluded. However, our study is limited in that the sample size was small, we did not examine a second control group composed of patients affected by other psychiatric disorders, and we only interviewed

help-seeking patients attending an outpatient clinic for OCRD. This may have biased our sample. To the best of our knowledge, this is the first case-control study on PE. There is need for additional research to better understand PE and its significance in OCPD.

CONCLUSION

Results suggest that PE might be part of the clinical spectrum of OCPD, and it does not reflect the counterpart of disgust. In our study, PE is over-represented among OCPD subjects. This supports an association, and one might speculate that PE is related to orderliness and cleanliness in this population. Using an evolutionary hypothesis, PE may reflect one's ability to differentiate between unpleasant and pleasant odors, which may have made a difference in terms of survival or death[36].

ARTICLE HIGHLIGHTS

Research background

According to a dimensional approach, personality disorders can be considered "a

quantitative" variation of personality traits within a continuum between normality and psychopathology. In this sense, some manifestations such as orderliness and cleanliness in obsessive-compulsive personality disorder (OCPD) subjects do not necessarily represent a maladaptive variant. Psychic euosmia (PE) is a positive aspect of OCPD that was recently described as a psychological predisposition for which pleasant smells elicit an immediate sense of pleasure, order and calmness in OCPD.

Research motivation

Few studies have focused on positive aspects of OCPD. In the absence of other scientific observations, our group decided to investigate the presence of this phenomenon among OCPD patients and subsequently how PE ought to be considered.

Research objectives

We delineate three possible hypotheses: PE is a manifestation of orderliness, is a just right component, or is the counterpart of disgust that has been associated to contamination and moral purity. In this study we tried to verify this last interpretation.

Research methods

The sample consisted of 129 subjects: 45 patients affected by OCPD and 84 healthy controls. To explore the presence of OCPD in both groups we submitted self-report Structured Clinical Interview for DSM-5 Screening Personality Questionnaire to which we added an additional question to investigate the presence of PE. All participants completed the Disgust Scale Revised to evaluate the disgust sensitivity. We used the Italian version of the Disgust Scale Revised.

Research results

Regarding the presence of PE, a significant difference was found between groups in how they answered the corresponding item during the interview. Among the 45 study subjects with OCPD, 36 (80%) were positive. While among 84 HC, only 36 (42.9%) were positive. Interestingly no differences were observed between groups in the mean score at the Disgust Scale.

Research conclusions

Results suggest that PE might be part of the clinical spectrum of OCPD, and it does not reflect the counterpart of disgust. In our study, PE is over-represented among OCPD subjects. This supports an association, and one might speculate that PE is related to orderliness and cleanliness in this population.

Research perspectives

To the best of our knowledge, this is the first case-control study on PE. There is need for additional research to better understand PE and its significance in OCPD.

ACKNOWLEDGEMENTS

The authors wish to thank all the patients and healthy controls participating in the study.

ABOUT COVER

Ladislav Hosak, MD, PhD, Professor, Department of Psychiatry, University Hospital, Sokolska 581, Hradec Kralove 50005, Czech Republic. hosak@lfhk.cuni.cz

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatr*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc.*

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, and PubMed Central. The 2020 edition of Journal Citation Reports® cites the 2019 impact factor (IF) for *WJP* as 3.545; IF without journal self cites: 3.545; Ranking: 46 among 155 journals in psychiatry; and Quartile category: Q2.

Abstract

Pandemics disrupt clinical trials worldwide, with lasting effects on research. It can severely impact clinical trialists ability to conduct safe and ethically uncompromised trials. Hence, the mounting pressure results in ethically and morally distressing decisions faced by clinical trial professionals during pandemic situations. Whilst clinical trialists attempt to think about preparedness and responses during a pandemic, the need to have an ethical framework that has real-world applicability is imperative. Pandemics are a challenging time for all, however, the safety and access to support for clinical trialists and patients within clinical trials should be at the forefront for their organisations and the government.

Key Words: COVID-19; Pandemic; Ethics; Clinical trials; Patients; Trialists

Core Tip: This commentary provides an important facet and argues the ethical implications surrounding clinical research practices and staff during pandemic

situations. Clinical trial professionals face ethical dilemmas whilst conducting trials safely at an unprecedented rate given the clinical urgency. This commentary highlights the detrimental impact of not having a protocol for pandemic-driven clinical research, as well the lack of an ethical framework with *real-world* applicability to support the clinical trial workforce. Unethical behaviours and practices could be introduced in the current pressurised climate in order to rapidly respond to coronavirus disease 2019 research in particular.

INTRODUCTION

A pandemic is a time to focus on containing the clinical situation, ensuring deaths are minimised, reviewing the causation and developing treatments. However, the ethical implications surrounding clinical research practices and staff may be less considered. Ethically and morally distressing decisions maybe faced by many clinical trial professionals during pandemic situations. These decisions, which could be seen as "moral injury", may impact upon an individual's ethical and moral code and may develop into feelings of shame and guilt[1]. In the current coronavirus disease 2019 (COVID-19) pandemic, the wider psychosocial and psychological impact of the pandemic amongst Clinical Trialists is yet to be explored. Whilst there is an argument that there could be personal factors that may contribute to this, Clinical Trialists have had to reprioritise their work regimes to deliver research around severe acute respiratory syndrome coronavirus 2.

A useful document that has aided Clinical Trialists in particular is the World Health Organisation's (WHO) pandemic preparedness document. Interestingly the National Institute for Health Research also provided guidance and paused non-COVID related research as of March 20, 2020. The WHO's pandemic preparedness framework was a result of a workshop conducted in 2018 amongst the Global Health Ethics Team and the African coaLition for Epidemic Research, Response and Training. The purpose of this workshop was to discuss and identify empirical processes and procedures in relation to ethics reviews and preparedness during pandemics. This included five key areas in particular; pre-review of study protocols (including multi-country reviews), coordination between national ethics committees, statistical and stakeholder considerations, data and outcome sharing, as well as transfer of samples to share knowledge and develop future proofed interventions. Another key development to come out of this workshop were standard operating procedures (SOPs) for ethical reviews, in part to protect staff and their time while conducting pandemic research. These SOPs were to provide clarity on terminology and expectations of the pre-review of protocols and to agree a specific set of standards to speed up the process. Whilst these recognised a number of complex ethical issues could be raised during pandemics, it is also imperative to consider both research and clinical staff resources. Various other aspects such as quality assurance, regulatory requirements and operational delivery of the required research, which arguably could have ethical implications due to the by-stander effect this generates, were not well discussed and reported. This should be a fundamental aspect to consider with any future pandemic preparedness documentations as well as any associated procedures. Additionally, ethical implications for specific staff groups should be considered, to ensure policy makers are able to develop relevant guidelines.

Ethical implications associated with pandemics have significantly evolved over the centuries, but developing fit for practice ethical guidelines universally applicable to policy makers, healthcare systems and clinical trial units appears to have been challenging. Furthermore, ethical implications and principles may be driven by the pandemic itself. A good example would be to consider research conducted during the H5N1 influenza endemic. A significant limitation with H5N1 research was that longitudinal data was scarce and so its wider use and applicability was constrained. In

of Health and Social Care or the Academic institutions.

order to aid future pandemic management plans or to better understand transmission of a virus on the scale of a pandemic, existing data could have been used as part of prediction model, to support research staff. Whilst, the infection was managed in various ways, clinical trial staff had a different set of ethical considerations that were needed to have been addressed. Currently, there is no evidence to suggest these ethical considerations for trial staff were explored and reported. The vulnerability in this situation, of course, is that addressing the needs of a pandemic alongside the need for clinical research to develop treatments and vaccines, has to sit alongside access to care and the ethical obligations of research and to our clinical research staff.

IMPACT OF PANDEMIC RESEARCH ON CLINICAL TRIALISTS

All clinical trials testing licensed or unlicensed drugs and vaccines are mainly led by clinicians and clinical academics and there are staff from many disciplines working as Clinical Trialists. Therefore, the research associated with a pandemic, resourcing levels and the mental and physical impact varies considerably. Whilst there is a wide acceptance resource issues in the NHS, this has been exacerbated during the current pandemic. As a result, there appears to have been a heavy reliance on clinical and non-trial staff to deliver some clinical trials, which could impact their mental wellbeing in the long term, although this hypothesis would require further investigation.

Interestingly, Alperovitch and colleagues[2] stipulated whilst there is a need for research to be conducted during a pandemic, the major implications are in respect to managing the ethical principles pertaining to the studies themselves, research participants and Clinical Trialists. A key issue to consider is the informed consent aspect. Some studies have had deferred and/or waived consent models when conducting clinical trials during previous pandemics[2]. Whilst participants, clinicians and researchers often agree emergency research consent could be waived in some urgent situations, this method isn't suitable and acceptable for all. Clinical Trialist based research requires informed consent, and recognition that an electronic method of conducting a trial could be an efficient way to gather insightful data to further evaluate this is often missed. For example, the European Medicines Agency has provided clarity that informed consent must be taken before enrolling any patients into COVID-19 clinical trials taking place in Europe. Gobat and colleagues[3] discussed this issue further in their systematic review, and highlighted that patients accept clinicians acting as surrogate arbitrators. However, research regulators were more judicious if studies had substitute consenting procedures. Also, while further recommendations around study setup and protocol design need to be fit for purpose for any pandemic-driven clinical research such research should comply with both research and practice ethics. Alternative consent models could also have major psychological impact on Clinical Trialists and research to this effect remains limited.

Balancing clinical care and research to manage pandemic preparedness

Another common ethical argument presented during pandemics is that clinical care for current patients outweighs clinical research around non-pandemic issues. This may impact both patients and ongoing clinical care in a multitude of ways. Currently there are clinical trials taking place to test the use of Lopinavir, Ritonavir or Dexamethasone for COVID-19 (*via* the RECOVERY Trial); all of which are licenced treatments for other diseases. As there is clinical and adverse effect data already available for these drugs, there are minimal risks and ethical and moral implications for staff conducting these trials, when compared with COVID-19 vaccine studies or first in human trials. However, there could be unlicensed drugs that may also be suited to combating a new infection or a modified strain of a known infection such as COVID-19.

Another facet to pandemic preparedness is whether countries have ample research capacity to ensure an efficient and effective response in terms of research. The requirement for ethical principles and merit of incorporating these into research and clinical practices using specific guidelines could be endorsed during public health emergencies and it is widely recognised this could be a cost effective way to further operational capacity for Clinical Trialists in particular. As such, policy makers, clinicians, researchers and stakeholders need to identify time and resources to provide immediate treatment and maintain other activities, inclusive of an integrated approach for research as part of a pandemic response. In situations such as the COVID-19 pandemic, developing research and clinical practice "ethics preparedness" can help provide an efficacious response.

Challenges with implementation

Whilst ethical preparedness has the potential to cover an array of factors, a key challenge is the applicability of ethical standards between the "individual" and "group". There may be conundrums around duty to act to preserve lives of patients and the general public, *vs* the personal risks of those providing clinical care. It is clear that those in frontline clinical positions put themselves at risk in order to save lives and that this is morally acceptable. However, there may be others who may feel, as a healthcare professional, their right to conduct their role in a safe manner is compromised due to the very obligations of the role they play during a pandemic.

Identifying specific risks for staff

COVID-19 has a unique aspect, that is, the infection having particular effects on the black, Asian and minority ethnic (BAME) population based on the current data reported specifically within the United Kingdom. 44% of the NHS workforce belongs to the BAME population and to date, several reports state approximately 62%-75% of the 181 healthcare worker deaths were of BAME descent[4-6]. Ethnicity has the potential to influence the disease transmission through societal, cultural and behavioural differences[7]. The Francis report[8] found the frontline doctors who are of ethnic minorities may feel more vulnerable to raising concerns at work, thus BAME staff may not have vocalised concerns around their health risks and lack of access to personal protective equipment (PPE) during the pandemic. Minimal or lack of PPE has been found to correlate with increased anxiety levels in healthcare professionals[1]. As the causation of the ethnic bias in COVID-19 is yet to be understood, this introduces ethical implications for those serving in the frontline and in COVID-19 related research and potentially needs further investigation before this impacts other frontline BAME staffing groups.

RISKS OF PREDICTION MODELS

Historically, the rate of deaths during a pandemic depends on the number of those infected, the virulence of the infection and the efficiency and effectiveness of the preventative measures[9]. In addition, accurate mortality rates can be challenging to establish. However, this may be because the use of Artificial intelligence (AI) methods, coupled with data science and its influence on healthcare, has been minimal until now. Therefore, another facet to complicate ethical implications for staff could be that prediction models for COVID-19 are AI instead of traditional statistics. Whilst, AI methods and statistics have their own strengths and weakness, the rapid reviews being conducted to develop these prediction models could lack quality and perhaps be poorly reported, which would contribute to increasing bias. This was highlighted in a recent systematic review conducted by Wynants and colleagues[10]. Therefore, there is an argument that unethical behaviours and practices could be introduced in the current pressurised climate due to the rapid response-based research conducted. Whilst conducting "rapid reviews" is very much appropriate and is a time sensitive matter, academia maybe overloading the journals with a large number of papers in a bid to put their views across and to support healthcare practitioners. This could raise more confusion within frontline services than anything else. In fact, this counter productivity itself could be deemed unethical. Furthermore, an already overstretched healthcare system may feel overwhelmed and may also have very limited time to use this evidence in a meaningful manner.

CONCLUSION

It is anticipated that national research ethics committees, research consortia, funding agencies, healthcare organisations and policy makers will work towards promoting better recommendations and for conducting effective research during a pandemic, whilst still protecting our clinical trial workforce. A key factor that must remain at the forefront as we think about preparedness and responses during a pandemic, is that, despite theoretical and conceptual debates, the real-world applicability of any ethical frameworks is imperative. This is vital to keep in mind when decisions are made with regard to research and supportive strategies for clinical research staff working during pandemics.

Abstract

Public stigma and self-stigma impact negatively on the lives of people with mental health issues. Many people in society stereotype and discriminate against people with mental ill-health, and often this negative process of marginalisation is internalised by people with lived experiences. Thus, this negative internalisation leads to the development of self-stigma. In this article, I reflect on my own experiences of shame and self-stigma as a person with mental ill-health socially bullied by peers from my community and social groups. I present a personal narrative of both public and self-stigmatisation which I hope will enable me to exorcise memories of internalised stigma, which are encountered as my demons of lived experience. Using reflexivity, a process used widely in health and social care fields, I consider how social bullying shattered my fragile confidence, self-esteem, and self-efficacy in the early days of my recovery; the impact of associative stigma on family members is also explored. Following this, the potential to empower people who experience shame and stigma is explored alongside effective anti-stigma processes which challenge discrimination. I connect the concept of recovery with the notion of empowerment, both of which emphasise the importance of agency and self-efficacy for people with mental ill-health. Finally, I consider how the concepts of empowerment and recovery can challenge both the public stigma held by peers in the community and the self-stigma of those with lived experiences.

Key Words: Stigma; User-led narrative; Reflexivity; Empowerment; Recovery; Mental health

by a person with lived experience of mental ill-health. It explores how both public stigma and self-stigma can shatter fragile confidence and impact negatively on both self-efficacy and self-esteem. Connections with the importance of empowerment and recovery in mental health are considered, and how they can overcome the sense of shame and self-pity experienced by people with mental ill-health who encounter social bullying by peers in their community.

INTRODUCTION

Stigma is at the centre of the experiences that many service users encounter when in contact with their peers and with the communities they belong to[1-3]. The word stigma originates from ancient Greek and means 'a mark of shame or discredit'[4]; this defines the exclusion and marginalisation that many people with mental ill-health experience. Two elements to stigma have been defined: Public stigma and internalised stigma[1]. Public stigma involves the construction of stereotypes about excluded groups. This process leads to prejudice which is translated into active discrimination and marginalisation against this population[1]. Self-stigma[1,5] involves the internalisation and acceptance of negative beliefs about mental illness. These elements interact[5] because people who live with conditions such as schizophrenia may also endorse stereotypes about themselves, leading to "self-discriminating behavior" such as self-imposed isolation derived from the stereotype held by others about their "risky and dangerous" behaviours. Self-stigma reduces individuals' self-efficacy and self-esteem[1,5]; moreover, internalized stigma can disrupt mental health treatment-seeking intentions and behaviours and can lead to delayed help-seeking[6]. Stigmatisation processes can also affect family members of people diagnosed with mental ill-health.

This article will explore my lived experiences of stigma as a person with a diagnosis of mental-ill health and reflect on the response by peer groups to my condition. It asks questions about the nature of both public and internalised stigma[1,5] and investigates the lack of understanding of mental health symptoms. I explore the processes that can challenge both public and internalised stigma and suggest how anti-stigma campaigns can confront discrimination. I finally propose how acts of empowerment and the concept of recovery can both challenge stigma and promote greater understanding of mental ill-health.

METHOD OF REFLECTION

I am both a social work academic and service user expert with a diagnosis of schizophrenia. Both these identities are central to the construction of this article as I reflect and analyse my experiences about the nature of stigma. At the centre of social work is the process of reflection and reflexivity, a method used to enable professionals to understand and make sense of their experiences[7]. Reflexivity enables a person to explore his/her experiences and interpret them to gain greater understanding of the context to the situation around him/her[7]. A useful method that enables reflexivity is a process that explores the art of writing and reflection in investigating practice[8]. This approach connects the narratives of lived experiences told through personal reflections to the context of practice[8], exploring the links between local encounters and the wider circumstances. I thus relate my lived experiences of stigma and illuminate their significance for understanding the wider environment through a process of reflection. This method has been used in health, social care, and education and can facilitate an investigation of the significance of personal reflection in the setting of professional practice[8].

MY REFLECTIONS

This is for me a frightening and revealing reflection. It focuses on my sense of shame and stigma as a person with mental ill-health. It is hard to write as this process reveals details of experiences I have not spoken of before or allowed to bubble to the surface. These are accounts which I have hidden deep and buried in forgotten memories. They are embarrassing and shameful-and best forgotten. But at times they can't be forgotten and come to the surface.

At the time of the experiences described in this reflection, I was very paranoid and found it difficult to manage my mental health symptoms. I heard conversations and thought that people were talking about me. I translated the words I heard into what I wanted to hear – words that had been unsaid. These are my demons of lived experience through the shame and embarrassment I encounter as I remember them.

I experienced a mental health crisis involving extreme paranoia and psychosis at the age of 18-years-old. This happened at university in the North of England in the early 1990s. At the time I was studying at university far away from home. I had no personal experience of mental ill-health and had no inkling or understanding of its manifestation. At that time, I believed that mental illness happened to "mad" people, and was not something I would experience; moreover none of my peers or tutors recognised the signs of a pending mental health crisis until the illness was quite advanced.

My parents came to visit me at my university; this visit coincided with my first episode of mental health crisis. My mother stayed in the university as my mental health was deteriorating. I eventually had an appointment to see a psychiatrist and was admitted voluntarily for a short hospital stay and prescribed medication. On leaving hospital, I continued to take medication and returned to university. I continued to experience paranoia and low levels of psychosis and was eventually diagnosed with schizophrenia two years later. I continued my university studies, with great difficulty, and finally graduated. I was awarded a lower degree classification than previously predicted; however, completion of my university degree was a real achievement.

However, alongside this success at completing my degree, I also experienced many episodes that caused (and still cause) me shame and embarrassment. I remember back to experiences of when I was unwell, and I cringe. After leaving university I returned home to live with my parents. I was very lonely and isolated and craved a relationship with somebody who would like me for who I was, support me and take care of me. I was naïve, dependent, and overweight, because of the increased appetite associated with taking the prescribed anti-psychotic medication. I had little self-confidence and felt a sense of shame at who I was. I so much wanted to be valued.

There are so many memories that cause shame and embarrassment. I remember. I really liked somebody. This person was in a social club which I joined at the age of 23-years-old. The social group was a small group of 10 people for those aged 20-30-years-old (It wasn't a mental health peer group, but a social group in the community). There were some people who became my friends in the group; they were kind and thoughtful, but some who were unkind and found a mental health issue to be amusing. The group members all had more "success" than me. I was still living at home, undertaking additional study, and trying to forge a life for myself. But I was still dependent on my parents, and I lacked self-worth. This person who I liked didn't like me. I couldn't accept it and I believed that he liked me.

I listened like a snake to the conversations of other people. I listened to their conversations for evidence that he liked me. I heard things the people didn't say, and when I would go over their words, I would hear the words that he liked me. Words that hadn't been said, but I remembered as being said. Few people without lived experience of mental ill-health, can understand how paranoid beliefs may be perceived as a true representation of the world; my peers couldn't understand that I believed these thoughts to be true. At times people in this group teased me because I was a sad and very lonely person. They would say that he liked me, but he didn't; some people teased me because I couldn't seem to accept the obvious. During this period, I was like a ship, lost at sea, hurtling from one wave to another. I always ask the question: Did those people treat me unkindly and without compassion, or did they just not understand? As I remember I cringe with embarrassment and shame. Was it my fault? I had a mental health illness. They didn't understand the impact on me.

To my lasting shame and stigma, I had a pattern of such behaviour. I would latch onto somebody and believe he liked me. I was lonely and isolated and so wished for somebody to care for me. Previously to this experience, I kept such thoughts silent and did not share them, but this situation was different as I truly believed he liked me. I

was a persistent re-offender! My behaviour wasn't obvious, and I didn't harass him, I was a bit of a "silly nuisance"! He didn't understand my pain and embarrassment, I don't think he noticed me, only I experienced the shame.

This internalised failure is linked to the messages I reinforced to myself when I wasn't well. You can't do that. You aren't good enough to do that. You are no good. These are the demons of internalised stigma that say you can't achieve; that you are no good. This is a narrative of pain. I was bullied, undermined, and shamed as they laughed at me. Did they know the impact on me?

I managed the day-to-day stigma by convincing myself that I was of no value and self-reinforced the stigma others felt towards me; this meant my confidence plummeted. This was a negative coping mechanism which was effective because it dulled all hope and optimism; I couldn't be hurt anymore and couldn't fall any further because I had failed utterly.

What saved me from being this sad and lonely person? Eventually by engaging with learning, study, and being supported by mentors throughout my social work career, I began to achieve and to succeed. I studied for a Master of Arts degree in Social Work, then a PhD. Work for me was at the centre of my recovery journey and enabled me to fight the stigma; it led to a passion to change public stigma for those experiencing mental distress. Finding a wonderful and considerate and understanding man who became my husband was at the centre of my recovery. I am not now the person who was that person at that point in time described in my reflection. I cringe at my loneliness, my embarrassment, my shame, and my isolation. Was it my fault or was it part of my recovery journey?

DISCUSSION

The meaning of stigma and its impact on my life

In the following section I discuss my reflection and contextualise the experiences in the wider literature which seeks to explore the impact of mental health stigma in society. It is important to illuminate how stereotypes and prejudice impact on people with lived experience, and lead to their sense of shame and exclusion from society. Figure 1 highlights different types of stigma encountered in my life which resulted in my low self-esteem, poor self-efficacy and which limited my recovery. It provides a framework to explore discussion in this article. The elements of stigma represented in Figure 1 include: Public stigma, structural stigma, associative stigma, personal stigma, perceived stigma, and self-stigma. Alongside the cycle of stigma, my own experiences of double discrimination as both a woman and a person with lived experience of mental ill-health are depicted; these underpin the experiences of social bullying. Whilst parallel to these feelings, but outside of my direct encounters, the associative and affiliate stigma experienced by my family are identified. Finally factors that help to challenge stigma in society, such as protest, education, and contact push out against the cycle of stigma to counteract discrimination and marginalisation. These factors, captured in Figure 1, are elucidated in the article discussion.

The social identity of a person with mental ill-health is often negatively construed because the individual does not conform to social expectations of working and living independently[9]; this thus leads to them being stigmatised and devalued and experiencing public stigma. Furthermore, as people absorb this negatively constructed social identity, this then leads to forms of internalised stigma, or self-stigma, in the individual because of negative attitudes aimed at them.

The stigma encountered by people with mental health issues has been widely explored in research[1,2,5]; perhaps the most well-known forms of stigma are public and self-stigma[1]. However, stigma exists in many forms across cultures[2]: Within the individual (self-stigma), interpersonally (personal stigma), in the shared beliefs of a social group (public stigma), and in the policies and practices that structure society (structural stigma). Figure 1 shows the elements of stigma which constrained my recovery, first exemplified in structural stigma derived from public stigma.

Structural stigma is an important concept to highlight as it expresses how stigma can exist throughout a culture and become endemic in a system[9]. From my narrative, it seems clear that my peers believed that it was acceptable for them to tease me because I was a person with mental ill-health to be pitied and undermined. The acceptance of structural stigma[9] allowed them to bully me because I was a person who was devalued and of no worth.

Furthermore, three different reactions[10] by the community to people with mental health issues have been identified. Firstly, authoritarianism is the belief that people

Figure 1 Experiencing and challenging different forms of stigma.

with mental health issues are not able to take care of themselves and need other people to take control and direct their lives. Secondly, there is a response to people with mental ill-health that is based on fear and exclusion. This reaction is founded on the belief that people with mental health problems are dangerous and should be isolated from their communities. The final reaction generated in response to people with mental ill-health is benevolence. This response is based on the belief that people with mental health issues are innocent and naïve and not able to make decisions for themselves, resulting in paternalistic help being offered. Such a reaction from peers in their community is often compounded with feelings of annoyance and anger towards people with mental health issues.

Thus, in my experiences I was a person to be excluded and isolated; my peers also felt a benevolent response towards me. I was treated with paternalism as they directed annoyance and anger towards me. I was to be pitied but simultaneously an object unable to manage her own emotions, unable to live independently, of potential risk because I failed to respond in "normal" and socially acceptable ways to my peer group. The process of structural stigma led to a sense of low self-esteem and poor self-efficacy, as illustrated in Figure 1.

Furthermore, six further forms of public stigma have been highlighted[11]; however only three are mentioned here which I particularly relate to in the context of this article. I thought I was unable to fulfil social positions (exclusionary sentiments); I believed my mental health treatment had negative effects on my social status; (treatment carryover concerns) and I believed my family experienced negative consequences from my mental health status (disclosure spillover).

Associative and courtesy stigma[11,12] were encountered by my family members This type of stigma is a process in which a person is stigmatized by virtue of his/her association with another stigmatized individual. Additionally affiliate stigma occurs when care-givers' psychological responses to caring are impacted by the public stigma that prevails in society and they internalise self-stigma[13]. My parents supported me to the best of their ability, but they didn't always understand the shame and stigma that I experienced. My family felt personally impacted by the negativity of my diagnosis; and were unable to talk to their peers in their community, encountering affiliate stigma[13]. As shown in Figure 1, their experiences were encountered in parallel to my exclusion but were different to and outside of the stigma I suffered as a person with a diagnosis of schizophrenia. They sought support from peer and mutual aid support groups at moments in their caring journey. However, I felt uncomfortable with them attending such groups because I believed they talked solely about my mental ill-health in these environments. I didn't recognise or acknowledge that they had their own needs as care-givers. However, eventually, the fears I expressed prevented them from accessing any forms of support. My parents were therefore further isolated through

the feelings of self-stigma; and, thus, stigma limited the recovery of both me and my social network.

These elements suggest that underpinning public stigma[1] are elements of fear[14], a desire to keep a social distance[10], a devaluing of the role of people with mental health issues[9]; fears that association with someone with a mental health issue can cause feelings of exclusion[10] or "courtesy stigma" and associative stigma[11,12]. These elements connect to the process of self-stigma in both myself and my parents[1,11] associated with internalising the notions of social exclusion and the inability to manage an independent life[14]. These elements of exclusion led to the belief that I was deserving of pity, that I was shameful and thus deserving of stigma.

The issue of perceived stigma may also be in play in this context[15,16]. Perceived stigma concerns how a person with mental ill-health anticipates a negative reaction from others about their diagnosis; it is particularly relevant to those people who want to be open about their diagnosis[15]. Moreover, this interacts with a sense of self-stigma as indicated in Figure 1. I anticipate a negative reaction from some people in my social circles and thus choose not to disclose my diagnosis. For example, I have not shared my diagnosis with some close family members from a fear about how they might react-I perceive that the diagnosis of schizophrenia is often linked to notions of dangerousness and anticipate a negative response. However, although I choose not to reveal my diagnosis in many social settings, I often divulge these experiences in many academic circles[17]. I have a passion to use my expertise-by-experience to change mental health services for the better and yet feel a need to protect myself from people who don't understand mental ill-health. This decision about when to reveal my diagnosis leads to an anomaly of when I choose to disclose my status and when I choose not to[17].

Returning to my experiences of exclusion, women with mental health conditions[18] often experience social devaluation through a double disadvantage based on the intersection of being both a woman and a person with a mental health condition. Such discrimination was reflected in the historical devaluing of women through the early diagnosis of hysteria, labelled as a mental health condition linked to women's health and reproductive cycles[18]. Women with mental illness, who have experienced trauma, highlighted more difficulties with low self-esteem and the stigma connected to lived experiences than women who have not experienced trauma[18]. The trauma and social bullying that I received ripped out my sense of self-esteem and self-efficacy, limiting my recovery and leaving me a pitiable and empty shell. This process of stigma is depicted in Figure 1, whilst the double discrimination of being a woman and having lived experience of mental ill-health is illustrated as existing alongside these feelings.

Furthermore, the connection between perceived stigma and experiences of victimisation for people with mental health needs has been considered in other studies[19]. Perceived stigma and victimization are significantly associated, and the stigma attached to mental illness[19], from being perceived as being dangerous, violent, or undesirable, is a statistically significant predictor of victimization experiences. However, there is little understanding of the experiences of those with mental health issues; particularly as women with mental ill-health often experience an intersection of stigma and victimisation by their peer and friendship groups[18,19], as I describe above.

More widely, the cultural heritage of people with mental ill-health can impact negatively on their experiences of acceptance in their peer and friendship groups[10,20]. Public from Eastern countries ascribed more moral attributions to people with mental illness than from Western cultures[10], thus increasing the potential to discriminate. Moreover, people from Western countries endorsed higher stigma (prejudice and discriminatory potential) and made more moral attributions when the target was a minority (as compared with majority) group member. Furthermore, concern for loss of face in Eastern cultures is part of the process preventing individuals from seeking help from mental health providers to prevent shaming one's family[20], because mental health conditions are highly stigmatized in Chinese communities. In the United Kingdom, there has been an ongoing national anti-stigma campaign, Time to change, which has sought to challenge stigmatisation and discrimination against people who experience mental ill-health[21]; it has achieved some limited success.

This section has underlined the stigma and discrimination experienced by people with mental ill-health, highlighting the potential of victimisation to this group, and particularly to women who experience double discrimination. Figure 1 captures how I have experienced different types of stigma which have limited and bounded my potential recovery journey, and that of my family. Subsequently, an acknowledgement of the importance of cultural heritage in this context has also been considered. In the next section the paper considers how society can challenge the stigma and marginalisation of those who experience mental ill-health.

HOW CAN SOCIETY CHALLENGE STIGMA?

People with mental ill health may sometimes challenge this sense of self-stigma through reactions of "righteous anger"[1] about the negative social identity ascribed to them by their community. Moreover, a sense of righteous indignation, particularly associated with collective activism and group identity, can challenge both individual and group prejudice. For example, the experiences of 800 gay and bi-sexual men were explored[22] and a sense of belonging and group activism was positively associated with improved self-esteem; indeed, extrapolating to mental health there may be "high feelings of self-esteem" from "experiencing group identity"[1]. Despite this process of empowerment, individuals who are stigmatised can resist this label by claiming their own exceptionalism to the stereotypes, thus challenging stigma as an individual[2].

A process of empowerment can help people to gain a sense of control in their lives and can foster independence and agency[5], challenging the stigma they may experience that results in dependency and low self-efficacy. Indeed, "empowerment is the flip side of stigma, involving power, control, activism, righteous indignation, and optimism"[5]. The importance of empowerment in tackling self-stigma is reinforced in the context of promoting control over treatment choices and the direction of one's life[23]. Empowering people in these choices can increase a sense of autonomy and agency, thus resulting in a positive effect on self-stigma.

Empowerment cannot happen without change in individuals and the systems around them. From their standpoint as art therapists[24], the issues of stigma and shame met by people with mental health issues were surveyed in one study. This study noted how people with mental ill-health are often devalued in society and their role is seen as inconsequential. Such ideas in the field of mental health are related to the context of learning disability, where the importance of social role valorisation is explored, a concept[25] developed to understand the need to empower people with learning difficulties and enable them to be respected and valued in their social role.

In the discussion above, it was identified that stigma against people with mental health needs derives from having a negatively construed social identity. The field of learning disabilities research offers a lot to learn in supporting the promotion of people with mental health issues as full and respected citizens with a valued social role. This leads to the question of how can society combat both public and self-stigma?

EFFECTIVE METHODS TO PROMOTE ANTI-STIGMA WORK

Three strategies to help overcome mental health stigma are explored in the literature[10] : Protest, education, and contact. Firstly, protest is the process of challenging people's negative beliefs through direct action. Secondly, education involves the provision of brief courses or facts to counteract prejudice. Finally, contact consists of directly promoting one-on-one contact between people with lived experience of mental ill-health and the public. Contact is found to be the most effective way of challenging stigma and changing attitudes. Moreover, "face-to-face contact with the person, and not a story mediated by videotape, had the greatest effect" at challenging stigma[21]. The role of each of these factors in challenging stigma is illustrated in Figure 1, as they push out of the cycle of stigma that I depict as representing my experiences.

Anti-stigma campaigns need to balance wide and broad approaches that seek to challenge discrimination in a large population of people with more local campaigns which focus on challenging the opinions of small groups[26]. This finding is reinforced by another study[27] which suggests that such strategies could be developed to also reduce self-stigma in people experiencing mental health issues. However, little is known about what elements of contact are effective in challenging stigma[10]; for example, is it equal status or promoting understanding about experiences of mental ill-health that makes contact-based strategies effective? It is essential to answer this to understand how to effectively tackle discrimination and marginalisation of people with mental ill-health.

Encouraging people with mental health needs to disclose their mental health condition may help to reduce stigmatization as individuals take control of information about their health condition and can become empowered[5]. However, on one hand, disclosing psychiatric status can have negative implications because it can cause discrimination and prejudice, on the other, people who disclose often report lower levels of self-stigma, a greater sense of personal empowerment, higher self-esteem, and enhanced quality of life[5]. Despite this, the value of disclosing a diagnosis such as schizophrenia is questioned because of the high stigma associated with this

condition[28].

It appears that the process of "contact" to reduce stigma needs to be carefully managed. There needs to be further research about what elements of contact effectively challenge stigma[10] and how people with a mental health condition can be appropriately supported through the process of disclosure[28]. Empowerment is key to challenging self-stigma and enabling the person to challenge both self-stigma and public stigma. Moreover, difference and disdain are key measures of stigma; a recent study explored how to manage these issues in the context of mental health[29]. They investigated how difference results in people with mental illness being alienated and othered making a separation of "us" from "them". Consequently, this sense of difference leads to disdain because people with mental illness are devalued and disrespected. The study concludes that anti-stigma efforts may best be focused on tackling elements of disdain, rather than difference, because disdain seems to be the main driver of self-stigma[29]. This focus on empowerment can be achieved by promoting messages such as: "I may be different, but I am not a person of lesser value."

Moreover, in the United Kingdom, the anti-stigma campaign, Time to change[21] has achieved some success in challenging stigma through publishing the personal narratives and stories of those who have lived experience of mental distress; this reflects the acceptance by service users that they may be potentially "different" from other people in society and may have different stories to tell, but that they are not of lesser value. Maybe other people without lived experience of mental distress come to acknowledge their own differences and idiosyncrasies as art of the process of learning about differences?

CONCLUSION

Empowerment through recovery

Such processes of empowerment build on the seminal work in the field of learning disability theory of social role valorisation[25] that highlights the importance of having a respected and valued role in society. Furthermore, empowerment, enhancing service user control, and self-management of a mental health condition are at the centre of the recovery approach[30] an aspirational practice in mental health that emphasises the importance of people with mental ill-health leading a good life despite the limitations of their illness[31]. Indeed, recovery is, in itself, an "effective message" to combat stigma because it reinforces that "mental illness does not keep a person from achieving a full range of positive outcomes"[30]. This process of empowerment through promoting recovery may be a key factor in challenging both the public stigma and self-stigma of people who have mental ill-health because recovery emphasises the importance of achievement, respect and value for this group[31].

As my reflection shows, occupying a valued social role and beginning to follow my dreams enabled me to begin to reconstruct my brittle self-esteem and self-efficacy. Little by little, building on confidence and true friendship, I was enabled to take on a responsible role as an academic and increase my capacity to perform[32,33]. Recovery was at the centre of my empowerment and led me to a place of increased confidence and self-esteem[32,33] where I was able to combat my own sense of self-stigma and challenge the public stigma of being a person with a diagnosis of schizophrenia. This place led me to exorcise the demons of lived experience. Thus, drawing on the research presented in this article, it is suggested that increased contact between people with lived experiences, and their peers in the community, based on respect and value[10,28], and the representation of stories of recovery[32,33], may be at the centre of promoting the social value of people with mental ill-health.

Abstract

BACKGROUND

Illness anxiety disorder (IAD) is a common, distressing, and debilitating condition with the key feature being a persistent conviction of the possibility of having one or more serious or progressive physical disorders. Because eye movements are guided by visual-spatial attention, eye-tracking technology is a comparatively direct, continuous measure of attention direction and speed when stimuli are oriented. Researchers have tried to identify selective visual attention biases by tracking eye movements within dot-probe paradigms because dot-probe paradigm can distinguish these attentional biases more clearly.

AIM

To examine the association between IAD and biased processing of illness-related information.

METHODS

A case-control study design was used to record eye movements of individuals

patients gave informed consent.

with IAD and healthy controls while participants viewed a set of pictures from four categories (illness-related, socially threatening, positive, and neutral images). Biases in initial orienting were assessed from the location of the initial shift in gaze, and biases in the maintenance of attention were assessed from the duration of gaze that was initially fixated on the picture per image category.

RESULTS

The eye movement of the participants in the IAD group was characterized by an avoidance bias in initial orienting to illness-related pictures. There was no evidence of individuals with IAD spending significantly more time viewing illness-related images compared with other images. Patients with IAD had an attention bias at the early stage and overall attentional avoidance. In addition, this study found that patients with significant anxiety symptoms showed attention bias in the late stages of attention processing.

CONCLUSION

Illness-related information processing biases appear to be a robust feature of IAD and may have an important role in explaining the etiology and maintenance of the disorder.

Key Words: Attention bias; Selective attention; Eye tracking; Dot-probe; Illness anxiety disorder; Disengagement

Core Tip: This is the first study which has examined patients with illness anxiety disorder (IAD) having an attention bias that is mainly manifested as attentional avoidance at the early stage and overall attentional maintenance when presented with illness-related stimuli. They also have demonstrated vigilance of attention at the early attention stage and overall attentional maintenance when presented with disease and positive/neutral stimuli. In addition, this study found that patients with suspected disorders with significant anxiety symptoms show attention bias in the late stage of attention processing and struggle to dismiss the stimulus, showing delayed detachment. This study suggests that patients with IAD have attention bias and this may have provided a new way of identification of IAD symptoms using an eye-tracking evaluation method.

INTRODUCTION

Illness anxiety disorder (IAD) is a common, distressing, and debilitating condition, with the key feature being a persistent conviction of the possibility of having one or more serious or progressive physical disorders[1]. IAD was formerly named hypochondriasis in DSM-4. Currently, the reported prevalence is approximately 1%[2-5]. Patients manifest persistent somatic complaints or a persistent preoccupation with their physical appearance. They repeatedly seek assurance from medical advice for physical symptoms that they think they have, and frequently have doubt or fear about negative medical test results and doctors' explanations[6]. This type of preoccupational thought persists despite appropriate medical evaluation and medical reassurance. The course of IAD is usually chronic and fluctuating, associated with costly and unnecessary medical reexaminations and the overuse of medical resources[5].

According to cognitive-behavioral models of IAD[1], IAD patients seem to hold faulty health beliefs. The dysfunctional assumptions about their bodily symptoms and

illness may be triggered by critical incidents. It has been argued that the dysfunctional beliefs about illness and misinterpretation of bodily symptoms appear to be specific and important for patients with IAD and to be a highly specific characteristic of IAD[7,8]. They tend to show a more restrictive concept of good health than do anxiety patients and healthy people[8]. They are hypervigilant to bodily symptoms or tend to amplify benign physical sensations[9-11].

It has been proposed that these psychological processes may underpin the symptoms of IAD. A cognitive-behavior therapy (CBT) for IAD that is derived from W and S's model has been effective. CBT patients had lower levels of health-related anxiety and less impairment of social roles, but IAD somatic symptoms were not improved significantly by CBT[11,12]. Other researchers have observed a positive correlation between the feature-positive effect (FPE) and illness anxiety concerns[13]. The FPE is the bias of overweighing positive and underweighing negative information. The FPE may explain the interesting fact of the IAD's sensitivity to illness cues and insensitivity to medical reassurance or negative medical results, but it cannot fully explain the initial preoccupation with bodily complaints and health.

IAD is characterized by patients focusing their attention on one or two organs or systems of their body. They attend to information that confirms their worry and conviction, but simultaneously ignore and under-weigh negative results of medical investigations and evidence of good health. Thus, they display a type of information processing bias, and cognitive processes are considered relevant to the etiology and maintenance of IAD[14].

Attention bias refers to the individuals who have different attention distribution to the corresponding threat or related stimulus, relative to the neutral stimulus[15]. Researchers studying attention bias found patients with mental illness often allocate their attention towards concern-related or mood-congruent material. A key feature of attention biases is anxiety increasing patients' attention to danger and threat-related stimuli[16]. Patients have attention bias in favor of stimuli referring to their specific disorder, and interpretational bias leads them to allocate their attention to these stimuli as more relevant. Thus, their bias is specific to the meaning of stimuli relevant to the disorder. In people with anxiety disorders, anxiety stimuli are likely to receive attention bias when they are danger or from threat-related stimuli, but in people with IAD, the content and disorder specificity of the stimuli is unclear. More recently, some non-illness-related attentional stimuli have been suggested to maintain IAD concerns; in other words, the attention bias may not be limited to illness-related stimuli but also include non-illness-related stimuli[17,18]. In sum, empirical evidence regarding measuring attention bias in IAD is scarce and equivocal.

To date, a prominent means to evaluate visual attention is the emotional stroop task. Researchers have regarded increased color-naming latencies of emotional or concern-related words as an indicator of selective attention bias, but unfortunately the emotional stroop task cannot differentiate the two possible mechanisms a facilitated engagement or a delayed disengagement[19,20]. So the precise course of such biases is obscured by the mixed nature of the test process. Alternative experimental paradigms regarding attention bias, such as the dot-probe investigation and the Posner cued-target paradigm, can distinguish these two possible biases more clearly[21,22]. Because eye movements (EMs) are guided by visual-spatial attention, eye-tracking technology is a comparatively direct, continuous measure of attention direction and speed when stimuli are oriented. 'Persistent', the dot-probe experiment, which uses EM tracking, has been undertaken primarily to examine attentional processing among anxiety disorders and in pain-related research. Researchers have tried to identify selective visual attention biases by tracking EMs within dot-probe paradigms with success[23,24]. These studies investigated individuals with high social anxiety, generalized anxiety disorder, and depressive disorder, using EMs and a modified probe detection task to pictures of faces. They found that anxiety individuals initially directed their gaze toward neutral faces more often, but were quicker to look at emotional faces and looked at emotional faces for less time. Therefore, anxiety individuals were consistent with a vigilant avoidant pattern of bias, compared with other people.

Using the dot-probe paradigm, our primary aim in the current study was to explore the specificity of attention bias in IAD. We hypothesized that patients with IAD, compared with healthy controls, show more attention bias for illness-related information when negative pictures, positive pictures, and neutral pictures are presented simultaneously. In addition, we hypothesized that patients display orienting attention biases, reflected by fixating first and more rapidly on illness stimuli than other alternatives. We analyzed differences in EM indices reflecting subsequent bias in attention maintenance, including duration of first fixation, average fixation and total gaze/first fixation, and overall gaze duration.

MATERIALS AND METHODS

Study design and participants

A case-control study design was used for the study, with the sample consisting of an IAD patient group and a healthy control (HC) group. Participants were recruited *via* e-mail and newspaper advertisement from Beijing An'Ding Hospital. The patient group fulfilled the criteria for IAD (DSM-5 and formerly named hypochondriasis in DSM-4) according to the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)[25]. Patients were screened with the Structured Clinical Interview for DSM-IV-TR Axis I Disorder (SCID-I) and Structured Clinical Interview For DSM-IV-TR Axis II Disorder (SCID-II)[26] to affirm the initial axis I disorder diagnosis and axis II personality disorders. Interviews were led by independent, professionally trained clinical psychologists. The HC group was matched to the patient group in age, sex, ethnicity, and education. People who were unable to use their hands, or those with a serious head injury or psychiatric illness, were excluded from the study. All participants had normal or correct-to-normal vision and color vision and no neurological disease, psychiatric illness, or medication use for any psychiatric disorder. Their age ranged from 18 to 60 years, and their education level was 9 years or more.

Ethical approval for this research was obtained from the Beijing An'Ding Hospital, Capital Medical University Research Ethics Committee [Ethics number: (2014) Research (No. 38), Funding number: 20131107110012]. All participants were fully informed about the study research and provided with a general overview of the dot-probe task. All participants provided written informed consent before they agreed to participate in the research in compliance with the regulations of the institution and the guidelines of the Declaration of Helsinki. They were free to terminate the experiment at any time they wished.

Materials

The stimuli used in the dot-probe task consisted of 128 pictures; we collected these pictures through Baidu image search, a search engine in China, which were grouped into four main categories: Illness-related, social threat, positive, and neutral pictures. Illness-related pictures included pictures about patients in disease/hospitals/doctors/doctors threating or checking patients and pictures about oral medicine. Social threat pictures included pictures about earthquake/quarrel/flood/wars/fires/explosion/traffic/fighting/bridge collapse/plane crash/chasing by animals. Positive pictures included mountain/flowers/children/bird/women/wedding/congratulation/dancing. Neutral pictures included pictures about furniture/meeting/beautiful scenery/shopping/roads/clothes. These pictures have clear meaning, clear content, and try to highlight the stimulus itself; at the same time, these pictures cover as wide range of meanings as possible. The color of the images was unified with Photoshop CS 6.0 about brightness, saturation and contrast. Illness-related and social threat pictures were included to determine whether IAD patients were associated with a specific threat-related attention bias or any threatening material. Positive pictures were included to examine whether a general emotional response accounted for any effects found. These images were randomly presented to participants for 2 s each. Each picture size had mean height of 4.6 cm and mean width of 6.5 cm.

Sixty healthy volunteers were recruited to classify the pictures into our four predefined categories in our pilot study. These volunteers had normal or correct-to-normal vision and color vision. They were not on any medication and had no diagnosed medical or mental health condition. Among 400 pictures, 272 (68%) pictures were excluded as they were not allocated to the correct picture category by at least 80% of the raters. The final number of selected pictures for trials was 128.

Apparatus

Stimulus pairs were presented on a DELL 19 inch TN screen, with 1980 × 1024 pixel resolution and a 60 Hz refresh rate.

EM data were recorded *via* an sr research eyelink 1000 device (sr research, Canada; https://www.sr-research.com/). The experiment was programmed and run with sr research experiment builder. The eye-tracker sampling rate was 1000 Hz, with a spatial accuracy greater than 0.5° and a resolution of 0.01° in the pupil-tracking mode. An infrared motion system tracked em/head motion. A forehead and chin rest kept viewing distance constant and minimized head movements. Participants sat 60 cm from the monitor screen, resulting in a 29 cm horizontal, 22 cm vertical visual field.

Prior to the task, a standardized 5-point calibration procedure was performed.

EM data were recorded during each trial, starting shortly before and terminating immediately after picture-pair presentation (Figure 1).

Selective attention task

Selective attention bias was assessed in a visual dot-probe paradigm. With traditional dot-probe tasks, stimulus pairs are presented in separate spatial locations (*e.g.*, left *vs* right side of computer screen) and replaced by a probe in the location previously occupied by one stimulus. For this study, the main focus was on EMs during stimulus presentation of different image types. Before the formal study, a brief training (four trials) was undertaken to increase familiarity with task requirements; training procedures were identical to those used in the formal study with the exception that different pictures were used for the present study. Participants were told that in each trial of the forthcoming spatial perception task, a triangle would appear in the right or left of the computer screen for 500 milliseconds (ms), followed by picture pairs to which they should carefully attend. Each trial of the task began with a central fixation cross (+) shown for 500 ms and then replaced by an image pair that appeared for 2000 ms. After 500 ms, the next trial began. The formal task included 224 pairs of cards presented in four blocks with 56 trials per block. The four blocks consisted of combinations of the four categories of picture meanings, including (1) Disease–neutral (*e.g.*, oral surgery *vs* rail), as shown in Figure 2; (2) Disease–positive (*e.g.*, infusion *vs* scenery), as shown in Figure 2; and (3) Disease–threat (*e.g.*, operating room *vs* traffic), as shown in Figure 2. Besides, there were four categories included as filling items in order to reduce the monotony of the test materials, including disease-disease, threat-threat, neutral-neutral, and positive-positive. Each pair of images was defined as a trial and each pair of pictures was presented randomly among the four blocks. Participants were given a 2-min break after the presentations of 56 pairs of pictures. On average, the task took 40 min to complete.

Procedure

After providing informed consent, participants were escorted to the eye-tracking experimental area. They were seated in a height-adjustable chair with their chin in a vertically adjusted chin rest. The chin rest was used to reduce participant head movements, ensuring that participants' eyes were level with the middle of the monitor on which the stimuli were presented, and to maintain participant eye distance from the monitor at 60 cm. They were instructed to free view the images at all times during each trial. Further, participants were asked to look at the fixation point before each trial to standardize the starting location of their gaze. On completion of the dot-probe task, participants were asked to fill in several questionnaires, including their self-reported measures of demographics. In addition, the Beck Anxiety Inventory (BAI)[27], Beck Depression Inventory[28], Illness Attitudes Scale[29], and Whiteley Index[30] were used to assess participants' clinical symptoms.

Statistical analyses

EM data was recorded using the Eyelink1000 tracking system (Canadian sr-research) and was processed by data retrieval. First, the trials affected by invalid calibrations and uncollected EM data were removed; as each pair had two stimulus-related trials, there are total 448 trials per participant, the average invalid trials in 30 IAD participants were 13.767 (3.07%), and the average invalid trials in HC participants were 13.500 (3.01%). Then, we used data viewer software to divide the positions of the two pictures in the same picture matrix into two interest areas and selected valid EM data, including the corresponding position of the first viewpoint, the first-fixation duration, the overall gaze durations, and the overall fixation frequencies in different interest areas. Then, they were exported to Excel (Microsoft) in text format and were collated and converted in Excel to obtain the following attention bias scores: The first-fixation direction bias score = number of views (the first view of a certain type of stimulus) / effective trials; First-fixation duration bias score: The average viewing time (the first view of a certain type of stimulus); Overall gaze duration bias score = total time gazing at a certain type of stimulus/total time gazing at all stimuli in the trial; Overall fixation frequency bias score = the total number of times (viewing a certain type of stimulus)/the total number of times of viewing all stimuli in the trial. The general demographic data and scores of each clinical scale were measured using the international business machines statistical package for the social sciences studies V21.0 software package. Metrological data were represented by mean ± SD. All four EM indicators were statistically analyzed using independent sample *t*-test. The differences

Figure 1 Experimental setup for capturing eye-movement data.

between IAD group and HC group were compared on different types of images. The mean value of the group was compared with that of independent samples test, and $P < 0.05$ indicated that the difference was statistically significant.

Our study mainly examined four types of EM indicators: (1) First-fixation direction bias (%): The percentage of the number of first percentile points that an individual directs to the area of interest in which a certain stimulus is located as a percentage of the total number of active trials. It mainly examines the individual's initial attentional alert feature; (2) First-fixation duration bias (ms): In the disease–neutral, disease–threat and disease–positive image pairing, the difference reflects the early attention to the stimulation information in the area of interest; (3) Overall gaze duration bias (ms): During the entire experimental process, the total focus time of an individual on the area of interest of a certain type of stimulus accounts for the percentage of the total time spent staring at two pictures in the trial; and (4) Overall fixation frequency bias (%): Throughout the experiment, the total number of times an individual looks at the area of interest of a certain type of stimulus as a percentage of the total number of times a person looks at two pictures in the trial.

RESULTS

Table 1 depicts demographic characteristics and clinical symptoms of the IAD patient group and HC group.

Table 2 reports attention bias-related EM data, including first-fixation direction bias (%), first-fixation duration bias (ms), overall gaze duration bias (ms), and overall fixation frequency bias (%) in the IAD group and HC group (Figure 3).

First-fixation direction difference

When the participants were presented with the disease–neutral image pairs independent sample *t*-test showed there were significant differences in the first-fixation direction when presented with disease-related and neutral images in the HC group. When presented with disease-related images, the first-fixation direction of the IAD group was lower than that of the HC group ($t = -2.467$, $P = 0.017$); while presented with neutral images, it was higher than that of HC group ($t = 2.467$, $P = 0.017$).

First-fixation duration difference

When the participants were presented with the disease–neutral image pairs, independent sample *t*-test found that the first-fixation duration of the IAD group (280.476 ± 55.154) for the disease picture was significantly greater than that of the HC group (252.807 ± 45.075) ($t = 2.128$, $P = 0.038$). There was no difference in the neutral picture (IAD group: 288.280 ± 59.083, HC group: 264.668 ± 47.270; $t = 1.709$, $P = 0.093$).

When the participants were presented with the disease–social threat image pairs, independent sample *t*-test found that the first-fixation duration of the IAD group (281.20 ± 61.472) for the disease picture was significantly greater than that of the HC group (246.40 ± 30.991) ($t = 2.769$, $P = 0.008$). There was also difference in the social threat picture (IAD group: 296.86 ± 58.129, HC group: 266.37 ± 40.172; $t = 2.363$, $P =$

0.022).

When the participants were presented with disease-positive image pairs, independent sample *t*-test showed there were no significant differences in the first-fixation duration bias when presented with disease-related and positive-related images between the IAD group and HC group.

Overall gaze duration difference

When the participants were presented with the disease–social threat, disease-positive, and disease-neutral pairs, independent sample *t*-test showed there were no significant differences between the IAD group and HC group.

Overall fixation frequency difference

When the participants were presented with the disease–positive image pairs, independent sample *t*-test results showed the overall fixation frequency of the two groups toward the illness-related and positive images were different. Independent sample *t*-test showed the overall fixation frequency bias toward the disease images in the IAD group was higher than in the HC group (t = 1.841, P = 0.071), and fixation frequency bias toward the positive images was lower than in the HC group (t = -1.841, P = 0.071).

Attention bias-related EM and clinical symptoms

Regression analysis was used to investigate the correlations between the characteristics of the clinical symptoms of the IAD group and their EMs with various image pairs. The results showed that when the participants were presented with the disease–threat image pairs, their overall gaze duration bias toward illness-related images and BAI were found to have a positive correlation with disease-related images (β = +0.156, P = 0.045) and negative correlation with threat-related images (β = -0.156, P = 0.045) (Table 3 and Figure 4).

DISCUSSION

With the changes of diagnostic criteria, discussion about IAD is increasing these years. This study discovered that in the early and late stages of attention, the IAD and HC groups were different in their information processing for illness-related images and had corresponding attention mechanisms at different stages of attention.

In the early stage of attention, when presented with different pairs of socially threatening, positive, illness-related, and neutral images, participants in the IAD group did not manifest an attention bias toward illness-related images, and no vigilance

attention bias was observed. However, the first-fixation direction of IAD participants on illness-related images was shorter than that of the HC group, indicating that patients with IAD had an early-stage attentional avoidance bias on illness-related stimuli. Once the early visual attention of these patients was captured by symptom-related or socially threatening stimuli, they were less likely to disengage their attention to such stimuli, thus exhibiting delayed engagement bias. At the late stage of attention, participants with IAD presented a noticeable avoidance of illness-related images, which was manifested as a less overall fixation frequency on such pictures and more fixation frequency on positive, neutral and threat-related images. Therefore, the attentional pattern of patients with IAD was shown as an attentional delayed disengagement bias toward illness-related and socially threatening images, and an overall attentional avoidance bias to illness-related images.

The hypervigilance–avoidance hypothesis suggests that individuals tend to show instant vigilance, followed by swift avoidance, when presented with threatening

Table 3 Regression analysis of overall gaze duration bias (ms) and beck anxiety inventory

	Adjusted *R*-square	Regression coefficient (95%CI)	*P* value
Disease image	0.055	0.156 (0.004 to 0.308)	0.045
Threat image	0.055	-0.156 (-0.308 to -0.004)	0.045

CI: Confidence interval.

stimuli to prevent further processing of threatening information. This attention mechanism allows individuals to detect more potentially threatening information during the early stage of attention. The attentional avoidance mechanism then hinders such information from being objectively evaluated, leading to a cognitive bias toward the threatening stimuli and creating a selective attention, judgment, and storage effect. For this reason, this study speculated that individuals with IAD have normal attentional processing mechanisms for stimuli related to neutral, positive and threat emotions. However, their longer attention engagement toward illness and threat-related information in the early attention stage and their overall avoidance mechanism in the late stage of attention may explain why they suffer from long-term processing failure of disease-related stimuli, and hence have psychological disorders.

Current research suggests that such an attentional maintenance bias in the early

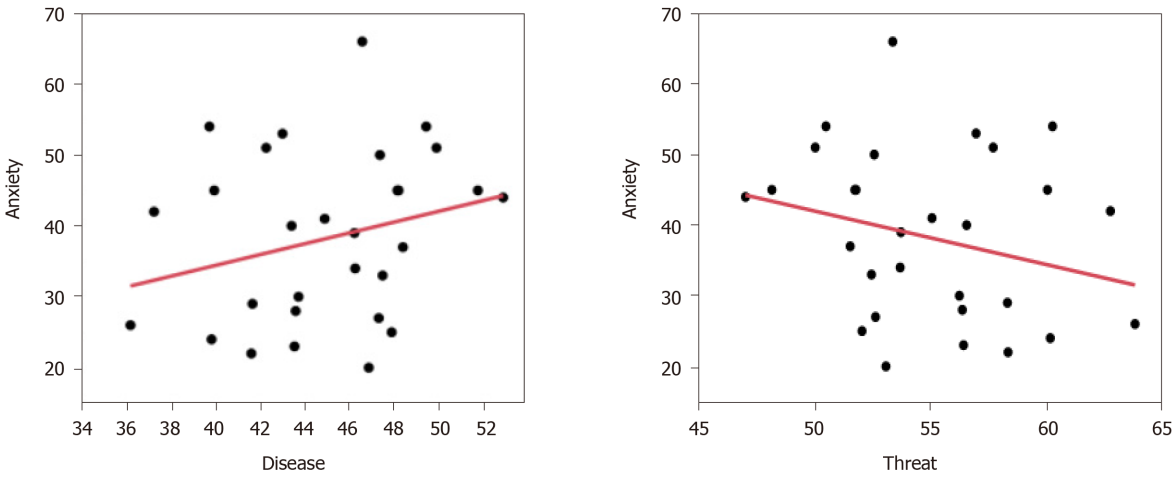

Figure 4 Total gaze duration to disease and threat in disease–threat image pairs.

attention stage may be due to the activation of disease-related schema within patients with IAD[31]. Attention schema theory suggests that if the threat stimulus is consistent with the schematic contents of an individual, then such stimulus is more likely to be processed. In addition, the activation of schemata leads to the allocation of more attentional resources to the threat stimulus at the late stage of strategic processing, manifesting as a greater frequency of selective attention. According to Salkovskis's cognitive-behavioral model of IAD, patients with IAD tend to overvalue illness-related information, giving it greater value and significance than reality, thereby inducing a cognitive bias such as selective attention. It is possible that illness-related information is more likely to activate the illness-related interpretation of the patients, leading to a longer processing period of such stimuli and the demonstration of a longer attention maintenance toward illness-related stimuli in the early maintenance stage.

At the late stage of attention, participants with IAD presented a noticeable avoidance of illness-related images, which was manifested as a shorter overall fixation duration on such pictures and a less overall fixation frequency. Therefore, the attentional pattern of patients with IAD was shown as an attentional avoidance bias toward illness-related images at the whole attention stage, but a delayed disengagement bias once attention captured by illness or threat information. The results demonstrate the attentional patterns of the participants when presented with illness-related, positive, and neutral stimuli. The findings revealed that patients with IAD showed different attentional patterns when presented with illness-related stimuli

and neutral stimuli. Specifically, patients showed an attentional maintenance bias in the early stage of attention and overall attentional avoidance toward illness symptom-related stimuli; however, they presented high levels of attention in the early attention stage and held their overall attentional maintenance when presented with normal stimuli (neutral information).

To further investigate the relationship between attention bias toward illness-related stimuli and the severity of symptoms among patients with IAD, this study utilized regression analysis. The results showed that the severity of anxiety symptoms had an impact on attention bias. In patients with mood disorder, there is a weakening of the ability to pay attention to the automatic processing of emotional information, resulting in defects and biases in the processing of emotional information[32]. Beck[33] believes that abnormal processing of emotional information in patients with mood disorders may be the main factor in the etiology of the disease and the maintenance of symptoms. Patients are sensitive to specific negative emotional information and alter their cognitive processing process, which may lead to symptom aggravation and maintenance. In many theories of clinical anxiety[19,34]. These attention biases have been regarded as initiating and maintaining clinical anxiety.

In 2009, Olatunji *et al*[35] proposed that the internal cognitive process indicates that IAD disorder may be related to anxiety disorder. The results also found that the more severe the anxiety symptoms, the more likely the disease stimulus attracts or occupies attention resources than other stimuli. Anxiety and IAD patients allocate excessive attention to disease information and struggle to dismiss the stimulus, showing delayed disengagement and attention bias; however, this feature is not obvious in their initial attentional stage.

Limitations and suggestions for future research

This study applied EM tracking technology to investigate attention biases of patients with IAD. Compared with past measurement methods based on participants' reactions, EM technology can effectively, directly, and continuously investigate the processing activities of attention of patients with IAD toward stimuli with threatening emotions, thereby differentiating the attention bias components more effectively. However, the method remains at the overt behavioral level and cannot analyze physiological parameters such as pupil changes and saccade during attentional processing. In addition, the method does not reveal the neurobiological mechanisms at play during attentional processing; hence, it is impossible to further explain the abnormality of brain function of patients with IAD. Future research is suggested to employ event-related potential technology (which has high time resolution) and functional magnetic resonance imaging technology (which has high spatial resolution) alongside eye-tracking technology to further investigate the characteristics of the attention bias and its mechanisms in patients with IAD. Furthermore, future study will use a machine learning classification method for the study to identify the IAD participants and estimate the accuracy of the eye-tracking method in identifying attention bias in patients with illness anxiety disorder.

CONCLUSION

Patients with IAD have an attention bias that is mainly manifested as an overall attentional avoidance when presented illness-related stimuli with disease, positive, and neutral stimuli, as well as avoidance of attention at the early attention stage; when presented with neutral stimuli, however, IAD performance showed higher delayed disengagement bias to illness and disease-related stimulus than in HCs. In addition, this study found that patients with suspected disorders with significant anxiety symptoms show attention bias in the late stage of attention processing, and struggle to dismiss the stimulus, showing delayed detachment. This study suggests that patients with IAD have attention bias and this may have provided a new way of identification of IAD symptoms using the eye-tracking evaluation method.

ARTICLE HIGHLIGHTS

Research background

Illness anxiety disorder (IAD) is a common, distressing, and debilitating condition with the key feature being a persistent conviction of the possibility of having one or

more serious or progressive physical disorders. Because eye movements (EMs) are guided by visual-spatial attention, eye-tracking technology is a comparatively direct, continuous measure of attention direction and speed when stimuli are oriented. Researchers have tried to identify selective visual attention biases by tracking EMs within dot-probe paradigms because the dot-probe paradigm can distinguish these attentional biases more clearly.

Research motivation

There are numerous studies that have investigated individuals with high social anxiety, generalized anxiety disorder, and depressive disorder, using EMs and a modified probe detection task to pictures of faces. However, no studies have provided an in-depth analysis of illness anxiety disorder using EMs.

Research objectives

Using the dot-probe paradigm, our primary aim in the current study was to explore the specificity of attention bias in IAD. In addition, we aimed to examine whether patients will display orienting attention biases, reflected by fixating first and more rapidly on illness stimuli than other alternatives.

Research methods

A case-control study design was used for the study, with the sample consisting of an IAD patient group and a healthy control (HC) group. Participants were recruited *via* e-mail and newspaper advertisement from Beijing An'Ding Hospital. The patient group fulfilled the criteria for IAD (DSM-5 and formerly named hypochondriasis in DSM-4) according to the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR). The stimuli used in the dot-probe task consisted of 128 pictures including 35 pictures from China internet sources, and 93 pictures selected from the International Affective Pictures System, which were grouped into four main categories: Illness-related, social threat, positive, and neutral pictures. These pictures were used to assess attentional bias in IAD patients. All four EM indicators were statistically analyzed using independent sample *t*-test. The differences between IAD group and HC group were compared on different types of images. The mean value of the group was compared with that of independent samples test, and $P < 0.05$ indicated that the difference was statistically significant.

Research results

When presented with disease-related images, the first-fixation direction of the IAD group was lower than that of the HC group ($t = -2.467$, $P = 0.017$); while presented with neutral images, it was higher than that of HC group ($t = 2.467$, $P = 0.017$). When the participants were presented with the disease–neutral image pairs, independent sample *t*-test found that the first-fixation duration of the IAD group (280.476 ± 55.154) for the disease picture was significantly greater than that of the HC group (252.807 ± 45.075) ($t = 2.128$, $P = 0.038$). When the participants were presented with the disease–social threat image pairs, independent sample *t*-test found that the first-fixation duration of the IAD group (281.20 ± 61.472) for the disease picture was significantly greater than that of the HC group (246.40 ± 30.991; $t = 2.769$, $P = 0.008$). There was also a difference in the social threat picture (IAD group: 296.86 ± 58.129, HC group: 266.37 ± 40.172; $t = 2.363$, $P = 0.022$). Independent sample *t*-test showed the overall fixation frequency bias toward the disease images in the IAD group was higher than in the HC group ($t = 1.841$, $P = 0.071$), and fixation frequency bias toward the positive images was lower than in the HC group ($t = -1.841$, $P = 0.071$).

Research conclusions

Patients with IAD have an attention bias that is mainly manifested as an overall attentional avoidance when presented illness-related stimuli with disease, positive, and neutral stimuli, as well as avoidance of attention at the early attention stage when presented with neutral stimuli; however, IAD performance showed higher delayed disengagement bias to illness and disease-related stimulus than did the HCs. In addition, this study found that patients with suspected disorders with significant anxiety symptoms show attention bias in the late stage of attention processing, and struggle to dismiss the stimulus, showing delayed detachment.

Research perspectives

This study suggests that patients with IAD have attention bias and this may have provided a new way of identifying IAD symptoms using the eye-tracking evaluation

method.

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatr*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc.*

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, and PubMed Central. The 2020 edition of Journal Citation Reports® cites the 2019 impact factor (IF) for *WJP* as 3.545; IF without journal self cites: 3.545; Ranking: 46 among 155 journals in psychiatry; and Quartile category: Q2.

Abstract

Mindfulness is a psychological technique based on Eastern meditative practices that was developed in the late 1970s by Kabat-Zinn at the University of Massachusetts. Initially, there was a debate over whether it should be considered a scientific technique or labelled as part of the "new wave" practices. Today, mindfulness is omnipresent in modern societies but has suffered from merchandising and banalization, which has been strongly criticized. Despite some limitations regarding methodological aspects of mindfulness research, it is considered effective for treating many physical and psychological disorders, and even it is recommended in clinical guidelines such the British National Institute for Health and Care Excellence. During the last 2500 years, mindfulness practices have moved from Northern India across most of Asia, but their mixing with Western science and culture at the end of the 20th century is considered a key event in recent history. For the first time in human history, due to globalization, the wisdom of all contemplative traditions can be shared with all human beings and assessed by science. Mindfulness practices, yoga included, are giving birth to a new field of knowledge, contemplative sciences, which go beyond mindfulness and is devoted to helping humanity to reach higher levels of happiness and mental peace.

INTRODUCTION

Concept and origin of mindfulness

Mindfulness practice involves developing the skill of directing one's attention to whatever is happening in the present moment[1]. According to Kabat-Zinn[2], "mindfulness is the practice of purposely bringing one's attention to experiences occurring in the present moment without judgment", a skill that can be developed through attentional meditation or other training. As noted by Brown *et al*[3], definitions of mindfulness are typically selectively interpreted based on who is studying them and how they are applied. Some have viewed mindfulness as a mental state, while others have considered it as a set of skills and techniques.

The Buddhist term translated into English as "mindfulness" originates in the Pali term *sati* and in its Sanskrit counterpart *smrti*, and it is a significant element of Buddhist traditions[4]. It is often translated as "bare attention", but in Buddhist texts, it has a broader meaning and application and can also be defined as "memory" or "recollection"[5]. *Sati* is one of the seven factors of Enlightenment, and "correct" or "right" mindfulness is the seventh element of the Noble Eightfold Path, the main teaching in this religion.

Jon Kabat-Zinn started to teach mindfulness in September 1979 at a hospital associated with the University of Massachusetts. This was the beginning of mindfulness in the West. The program was called the "Stress Reduction and Relaxation Program". He tried to bring his Buddhist practice together with his work life as one unified whole in the service of something useful[2]. Some months before, in a two-week *vipassana* retreat, he had experienced a "vision" about mindfulness that impressed him. In his own words, in the vision, he saw not only a model that could be put in place but also the long-term implications of the implementation of mindfulness across the world[1]. During the 1980s, Kabat-Zinn's main worry was to avoid mindfulness being labelled a "hippy" or "new age" practice, and for that reason, he eliminated any Buddhist terminology and focused on its medical benefits and the importance of being assessed by scientific research[2]. Today, mindfulness has become part of modern society's mainstream way of life[6], and it is considered the next revolution in public health[7].

EFFICACY OF MINDFULNESS

In the last 20 years, meta-analyses have demonstrated the utility of mindfulness for increasing psychological and physical wellbeing in healthy adults in general[8] and in specific environments such as the workplace[9] or school[10]. As a treatment, it has demonstrated efficacy in the treatment of mental disorders[11], some relevant studies are summarized in Table 1.

Mindfulness seems useful across all age ranges from, for example, adolescents[12] to middle-aged military veterans[13].

Regarding medical conditions, meta-analyses confirm the efficacy of mindfulness in treating cancer in general[14] and more specifically in treating breast cancer[15], pain[16], hypertension[17], diabetes[18], rheumatoid arthritis[19] and many other disorders.

Overall, the maximum efficacy of mindfulness as a treatment has been found in treating recurrent depression[20], and this is the reason the British Clinical Guide

Table 1 Efficacy demonstrated of mindfulness as treatment in different mental disorders

Mental disorder	Ref.
Depression and anxiety	Hofmann *et al*[39]
	Blanck *et al*[40]
	Godfrin *et al*[41]
Subtance and behavioural addictions	Sancho *et al*[42]
	Glasner *et al*[43]
Schizophrenia	Hodann-Caudevilla *et al*[44]
	Chien *et al*[45]

National Institute for Health and Care Excellence[21] recommends mindfulness, considering it the psychological treatment of choice.

However, some authors[22] have argued that published data about the efficacy of mindfulness may be oversized and that the authors of mindfulness studies may be biased and more focused on positive outcomes than on negative outcomes. In this sense, the harshest criticism of the scientific evidence regarding the benefits of mindfulness was the paper of Van Dam *et al*[23], which described the relevant methodological limitations in the research on this technique. This article was responded to by prominent researchers in the field[24], who affirmed that those limitations are commonplace for all psychological therapies and, even more important in our opinion, that mindfulness, as part of a contemplative tradition, was not developed specifically for treating human disorders but was created to improve human wellbeing and flourishing, and this is the point I would like to emphasize in this article.

LONG JOURNEY OF MINDFULNESS IN THE WEST

Mindfulness, as the core teaching of Buddhism, has travelled a long journey from its original homeland in Northeast India. Early on, it travelled to the island of Sri Lanka; centuries later, it spread to the river basins of southeast Asia, then to monasteries in the mountains of China, Korea and Japan, and on to the hidden kingdoms of the Himalayas. Across the centuries and these countries, mindfulness had to adapt to the characteristics of the people who lived there and incorporated their wisdom. However, the last stage in this journey, the growth into Western countries, has produced unparalleled consequences. According to the prestigious British historian Toynbee[25], the arrival of Buddhism in the West was the single most important fact during the 20th century, as it allowed meditation to become part of mainstream Western culture.

As a consequence, mindfulness has had to be assessed by science and demonstrated to be efficacious in different environments. At present, mindfulness has moved from its traditional settings of peaceful Buddhist monasteries and is now practiced in developed and secularized cities inhabited by people eager for pragmatic results. People who transmit these teachings are no longer venerable old meditation masters followed by groups of disciples but are instead university lecturers holding degrees in psychology or medicine. Mindfulness is used not to obtain freedom from the cycle of birth and death but to liberate people from the strains of stressful relationships, mental diseases and the worries of daily life.

This new model of understanding mindfulness has been severely criticized as the so-called "McMindfulness" movement[26]. Critics have called out the indiscriminate use of mindfulness decontextualized from the original Buddhist teachings from in which it originated and its employment in different settings. Mindfulness meditation has become so popular that many products and merchandising practices use this name. For example, the trendy fitness apparel company Lululemon is now advertising mindfulness clothing for men. There are also products called Mindful Meats and Mindful Mints, and Sherwin-Williams sells a paint colour they call Mindful Gray[27]. Mindfulness is said to be a $4B industry. More than 60000 books for sale on Amazon have a variant of "mindfulness" in their title and tout the benefits of mindful parenting, mindful eating, mindful teaching, mindful therapy, mindful leadership, mindful finance, mindful nations, and mindful dog owners, to name just a few[28].

This oversimplification also occurs in scientific research: There is a danger that the wisdom of Eastern contemplative traditions might be reduced to a matter of gaining certain skills such as attention, memory or emotion regulation. Alternatively, based on materialistic premises, the efficacy of mindful practices could be reductively explained exclusively on the basis of neurophysiology[5].

UNBELIEVABLE HISTORICAL PERIOD IN WHICH WE LIVE

The beginning of the 21st century is probably one of the most fascinating periods in human history. Many masters of contemplative traditions are teaching mindfulness as a way to reach a wider range of people. Most long-term mindfulness instructors embrace spiritual teachings, as mindfulness is not able to provide answers to the deepest questions of existence.

Today, online technologies and cheap travel around the world have facilitated a level of globalization that makes it possible to receive teachings from great masters from different countries. This was impossible centuries ago, and a disciple had to choose one only master and remain with that master for years. Now, the immediate interchanging of ideas and the dissemination of teachings considered secret for generations are accelerating human knowledge acquisition. In addition, the marriage of science and contemplative wisdom allows us to examine the impact of traditional meditative techniques and the changes they produce in the human brain and body.

CONTEMPLATIVE SCIENCES

In his 1930 book "Civilization and Its Discontents", Freud advocated for the need for a new and secular science of psychotherapy as a pragmatic alternative to the traditional healing techniques offered by religions. Since then, Western psychology/psychiatry has operated separately from religion[29]. However, in recent years, robust research has confirmed the therapeutic and wellbeing potential of qualities such as love, compassion and altruism[30-33]. For this reason, conventional psychology is moving towards contemplative science, which has always been considered non-scientific knowledge. Recent studies have confirmed, for instance, that Tibetan monks can voluntarily self-generate high-frequency gamma synchrony[34] and that mindfulness meditation increases thickness in the prefrontal and insular cortex[35]. Yoga, a group of physical, mental, and spiritual practices originated in ancient India, has also demonstrated a great efficacy in improving mental well-being[36], and is considered a relevant component of the contemplative sciences. These and other research studies have placed meditation at the axis of contemplative science and have emphasized brain neuroplasticity.

These developments in the field of psychology gave birth to the so-called contemplative sciences movement some years ago. Many experts believe that mindfulness has demonstrated to be effective and that a wider theoretical frame is necessary. Davidson *et al*[37] coined the term "contemplative neuroscience", which describes the emerging field arising at the intersection of meditation research and neuroscience. It includes any kind of meditation, yoga, mantra recitation, intensive breathing or healing movement[38]. This new science fulfils the dream of visionary pioneers in psychiatry and psychology, such as Carl Gustav Jung and Ken Wilber, and is connected to some aspects of transpersonal psychology. Several universities across the world have developed courses on or departments for on contemplative sciences or similar disciplines, some examples including Brown University (Providence, Rhode Island), the University of San Diego (San Diego, California), Naropa University (Boulder, Colorado) or the University of Mary Washington (Fredericksburg, Virginia) in the United States and Ottawa in Canada.

CONCLUSION

Future of mindfulness

I envision the future of mindfulness and related disciplines like a millennial wisdom tree with two main branches. In the first, mindfulness will develop with an instrumental aim. Its objective will be to relieve the mental and physical suffering of ill people and to increase the wellbeing of healthy persons in everyday life and in every

challenging environment they live in. However, in addition to mindfulness, there will be a second branch, contemplative sciences. This branch will be devoted to allowing humanity to experience the highest level of everlasting happiness that humankind can enjoy, regardless of external circumstances, which is linked to understanding the ultimate reality.

Abstract

The coronavirus disease 2019 pandemic affects psychiatric patients disproportionately compared to the general population. In this narrative review, we examine the impact of the pandemic on significant global health disparities affecting vulnerable populations of psychiatric patients: People of diverse ethnic background and color, children with disabilities, sexual and gender minorities, pregnant women, mature adults, and those patients living in urban and rural communities. The identified disparities cause worsened mental health outcomes placing psychiatric patients at higher risk for depression, anxiety and posttraumatic stress disorder symptoms. Those psychiatric patients who are ethnic minorities display barriers to care, including collective trauma and structural racism. Sexual and gender minorities with mental illness face discrimination and limited access to treatment. Pregnant women with psychiatric diagnoses show higher exposure to domestic violence. Children with disabilities face a higher risk of worsening behavior. Mature adults with psychiatric problems show depression due to social isolation. Psychiatric patients who live in urban communities face pollutants and overcrowding compared to those living in rural communities, which face limited access to telehealth services. We suggest that social programs that decrease discrimination, enhance communal resilience, and help overcome systemic barriers of care should be developed to decrease global health disparities in vulnerable population.

Core Tip: During the coronavirus disease 2019 (COVID-19) pandemic, many psychiatric patients encounter limited access to care due to major health disparities. In this minireview, we examine the impact of the COVID-19 pandemic on vulnerable psychiatric populations due to ethnic-racial disparities, disparities involving children with disabilities, the role of sex and gender trauma in the mental health in sexual and gender minorities, disparities among pregnant women, disparities among mature adults, and the impact in urban *vs* rural populations.

INTRODUCTION

Amid the coronavirus disease 2019 (COVID-19) pandemic, vulnerable populations are the most affected medically, resulting in limited access to care and worsened health outcomes, including death[1]. Identified vulnerable populations include children with developmental disabilities, mature adults, pregnant women, sexual and gender minorities, and Black, Indigenous and People of Color communities[2-6]. Health outcomes differ in vulnerable populations than the general public since there is a disproportionate exposure to risk factors that cause disease[7]. Among these vulnerable groups, patients with pre-existing psychiatric conditions pose an increased risk of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) infection, which causes the respiratory state known as COVID-19 illness[8]. Psychiatric patients tend to have higher comorbid medical conditions, such as diabetes mellitus and hypertension, which predispose to disease[8,9]. Isolation and small social networks limit support from friends and families during prolonged periods of quarantine[10,11]. Psychiatric patients may display inadequate social space and limited adherence to personal protection strategies such as handwashing or the use of a mask on a consistent basis[12].

Unprecedented financial stressors due to loss of jobs, limited access to adequate housing, and a higher risk of homelessness can further affect mental health care access[13]. In an ongoing study by the Center for Disease Control and Prevention in the United States, up to 12% of individuals in the general population responded that they needed counseling and medication for mental health but could not receive it during the pandemic[14]. Delays in treatment affected primarily unemployed individuals due to fears of contamination with COVID-19 when assisting appointments[15]. Most importantly, the COVID-19 pandemic disrupted mental health services globally. The World Health Organization surveyed 130 countries and over 60% reported impacts in mental health care services, including children (72%), older adults (70%), and women requiring prenatal and postnatal services (61%)[16].

Psychiatric patients in vulnerable populations are also at increased risk for mitochondrial stress, which potentially can result in an altered immune response to COVID-19 illness[17]. Mitochondria are particularly susceptible to dysfunction affected by nutrition and viral disease exposure[17]. It is posited that mitochondrial stress can eventually widen the health disparity since many vulnerable populations live in urban environments affected by toxic metal pollution[17]. Overcrowded housing, inadequate nutrition, socioeconomic stressors, age, and metabolic syndrome can further potentiate the effect of mitochondrial stress in vulnerable populations affected by COVID-19 illness[17,18].

The disparity of vulnerable populations can further be attributed to immune perturbations associated with stress that precede pro-inflammatory responses, especially in Black, Indigenous and People of Color[19]. Before the COVID-19 pandemic, these vulnerable populations lived in a heightened state of physiological stress and awareness complicated by psychological stress due to socioeconomic and environmental stressors[19]. The mechanism in which SARS-CoV-2 extends to the central nervous system is binding to peripheral nerve terminals and through retrograde transport reaching the brain[12,20,21]. The SARS-CoV-2 can also impact the central nervous system through a systemic cytokine response resulting in further

chronic inflammation and, in some cases, brain damage and even death[20,21]. Among psychiatric patients, the immune response triggered by COVID-19 may lead to depressed mood, severe anxiety, and suicidal ideations[9].

Apart from COVID-19 causing neurotropism and disarray of reactive immune responses, there is an increased risk for collective trauma in vulnerable populations[12,22]. COVID-19 is most likely to impact the mental health of psychiatric patients compared to healthy controls with a higher incidence of posttraumatic stress disorder (PTSD) (31.6% *vs* 13.8% controls)[9]. The collective trauma response is multilayered and consists of three components: Further fears of infection, prevalent economic difficulties, and disruption of established routines with isolation[22,23]. COVID-19 disproportionately affects vulnerable ethnic populations contributing to an accumulation of trauma through experiences of racism, discrimination, and social inequalities[22,24]. The COVID-19 pandemic forms a feedback loop between viral illness and disparities, leading to the accumulation of further inequities comprising a collective trauma[22].

Preceding the COVID-19 pandemic, the average untreated global rates of schizophrenia, major depressive disorder, and alcohol use disorder were 32.2%, 56.3%, and 78.1%, respectively[25]. These untreated psychiatric illnesses could potentially overburden an existing overwhelmed health care system, further increasing the inequalities in health between groups of people in countries, thus causing global health disparities[26]. Although there is a growing body of evidence of the mental health impact on the global population during the COVID-19 pandemic[27], little is known about the effects of COVID-19 in vulnerable psychiatric patients. In this minireview, we highlight the global health disparities affecting vulnerable psychiatric populations (Table 1) and examine the social barriers influencing global mental health care during the COVID-19 pandemic.

METHODS

Search engines through PubMed, Google Scholar, and PsychINFO were used with the following keywords: COVID-19, global health disparities, global mental health disparities, social barriers, social determinants of health, ethnic health disparities, sexual gender minorities, pregnant women, psychiatric patients, children, mature adults, developmental disabilities, urban and rural population. Articles in English and articles translated in English were reviewed from January 2020 to March 2021.

ETHNIC DISPARITIES

Psychiatric patients from ethnic minorities display worsened mental health outcomes during the COVID-19 pandemic. In the United Kingdom, people of color (Bangladeshi, Indian, and Pakistani men) show a more significant increase in mental health distress than White British men[28]. In the United States, ethnic minority respondents who reported prior treatment for depression, anxiety, and PTSD presented with higher prevalence of these symptoms and subsequent adverse mental health outcomes than those who did not receive treatment[29].

It is speculated that Blacks may have fewer physiological and psychiatric complications from COVID-19 based on a reduced molecular expression of angiotensin-converting enzyme-2, the binding site for SARS-CoV-2 present in the lung, kidneys, and brain[30]. However, there is a notable difference in COVID-19 outcomes since studies have shown more complications to the viral illness, including higher psychological distress and increased mortality in Blacks compared to Whites[31,32]. In the United States, a third of hospitalized COVID-19 patients are Black, although they make up only 13% of the total population[33]. In the United Kingdom, Blacks were found to have a four-fold increased risk for COVID-19 infection[31]. Black individuals diagnosed with COVID-19 (34.6%) showed psychological distress, but only a minimal (8.6%) sought out psychiatric care[31]. Poor access to services, stigma, cultural insensitivity and lack of awareness of their symptoms might prevent Blacks from obtaining mental health care during traumatic events[34].

Structural racism or the "ways in which societies foster discrimination through mutually reinforcing inequitable systems[35]" can complicate mental health disparities. A general mistrust of health systems is based on the historical mistreatment of Blacks in psychiatric care[36]. To this extent, the American Psychiatric Association issued a public apology about their role in Blacks' historical injustices acknowledging their

Table 1 Review of primary literature on coronavirus disease 2019 global health disparities

Ref.	Vulnerable population	Type of study	Country or region	Key mental health findings
El Hayek *et al*[5], 2020	Mature adults	Thirteen country case studies by thirteen early career psychiatrists	Arab Countries in the Middle East North Africa Region	General lack of mental health services for geriatric population during the COVID-19 pandemic
Proto and Quintana-Domeque[28], 2021	Ethnic minorities	Longitudinal survey	United Kingdom	Bangladeshi, Pakistani, and Indian individuals experienced significant increase in mental health distress than general population
Czeisler *et al*[29], 2020	Ethnic minorities	Cross sectional survey	United States	Significant higher suicide rates in ethnic minorities having considered suicide in the past 30 d before completing survey during COVID-19 pandemic
Lassale *et al*[31], 2020	Ethnic minorities	Cohort study	United Kingdom	Greater psychological distress experienced by Asians after hospitalization for COVID-19 than general population
Newby *et al*[39], 2020	Ethnic minorities	Longitudinal survey	Australia	Significant higher anxiety and distress in individuals with self-reported history of mental health diagnosis than those without a mental health diagnosis
Lee and Waters[45], 2020	Ethnic minorities	Longitudinal survey	United States	Over 40% of Asian Americans reported increase in anxiety, depressive symptoms and sleep difficulties during the COVID-19 pandemic
Gómez-Ramiro *et al*[54], 2020	Children with autism and developmental disorders	Retrospective study	Spain	Significant increase in acute psychiatric hospitalizations during COVID-19 lockdown
Nadler *et al*[65], 2021	Children with autism and developmental disorders	Case study	United States	Case study of child with autism and behavioral health concerns examines limited psychosocial support and availability during the COVID-19 pandemic
Bishop[69], 2020	Sexual gender minorities	Qualitative study	Global	Interviews with 59 SGM from 38 countries; majority showed increased isolation and anxiety
Suen *et al*[73], 2020	Sexual gender minorities	Community based survey	Hong Kong (China)	SGM are particularly vulnerable to poor mental health outcomes during the COVID-19 pandemic
Peterson *et al*[74], 2020	Sexual gender minorities	Cross sectional, convenience sample survey	United States	Greater psychological distress in SGM. A large number of bisexual individuals in the sample may have magnified the differences between SGM and sexual-majority groups
Durankuş and Aksu[77], 2020	Pregnant women	Cross sectional survey	Turkey	Higher depression scores on Edinburgh Postpartum Depression Scale in pregnant women than control group during COVID-19 pandemic
Liu *et al*[80], 2021	Pregnant women	Cross sectional survey	United States	Study on pregnant women and women who recently gave birth. Women with self-reported psychiatric diagnoses were 1.6-to-3.7 more likely to score at clinically significant levels of depression, generalized anxiety, and PTSD
Corbett *et al*[81], 2020	Pregnant women	Preliminary cross-sectional survey	Ireland	Pregnant women surveyed described heightened anxiety over COVID-19 affecting older adults, their children and their unborn baby
Saccone *et al*[82], 2020	Pregnant women	Cross sectional survey	Italy	More than half of pregnant respondents rated psychological impact of COVID-19 as severe
Wang *et al*[83], 2020	Female gender	Cross sectional survey	China	Increased psychological impact on female gender and having a poor self-rated health status
Liu *et al*[85], 2020	Female gender	Cross sectional survey	China	Female respondents had higher negative cognitions on posttraumatic stress symptoms than males
Berthelot *et al*[87], 2020	Pregnant women	Longitudinal cohort survey	Canada	Pregnant women assessed during the COVID-19 pandemic reported more prenatal stress and psychiatric symptoms than pre-pandemic cohort
Lebel *et al*[88], 2020	Pregnant women	Cross sectional survey	Canada	Higher symptoms of depression and anxiety in pregnant women were associated with greater concern about COVID-19 threatening the life of the mother and baby
Taquet *et al*[113], 2021	Psychiatric *vs* non psychiatric population	Retrospective medical record network study	United States	Psychiatric diagnosis might be considered an independent risk factor for COVID-19 illness.
Logue *et al*[114], 2021	Psychiatric *vs* non psychiatric population	Longitudinal prospective cohort survey	United States	2.3% of respondents reported "brain fog" at 6 mo post COVID-19 infection

COVID-19: Coronavirus disease 2019; PTSD: Posttraumatic stress disorder; SGM: Sexual and gender minorities.

influence in inequitable practices, including the misdiagnosis of schizophrenia in this population[37].

Indigenous people also face similar mental health disparities. There are presently 45 million indigenous people living in Latin America, 5.2 million in the United States, 2 million in Canada, and 798363 Aboriginal or Torres Strait Islander living in Australia[38]. In a controlled variable study, being Aboriginal or Torres Strait Islander was a strong predictor for higher anxiety, suggesting that indigenous people in Australia might be more vulnerable to poorer mental health outcomes[39]. During the COVID-19 pandemic, many indigenous people tend to handle stress independently of others by relying on spirituality to guide them, leading to a decline in seeking mental health care services[40].

Limited access to indigenous villages due to isolation in remote geographical areas can prevent obtaining mental health care for indigenous people. In Brazil, many indigenous people cannot access health services due to geographical distance and unavailability of care[41]. Restrictive bans placed by governments to prevent the pandemic's spread can further complicate travel by health care workers to these remote places[38]. In specific indigenous communities such as the First Nations, Inuit, and Métis in Canada, there have been lower rates of COVID-19 compared to non-indigenous people due to protective measures taken by their leaders[42]. Despite lower infection and mortality in Canadian indigenous cultures, 38% of indigenous people reported fair to poor mental health on a governmental online survey during the pandemic compared to 16% in prior years[43].

Public health messaging, which is essential during a pandemic, is hindered by poor access to broadband and internet service in indigenous villages. In Mexico, only 10% of indigenous villagers in Oaxaca have adequate internet service, mostly concentrated in city centers[44]. Limited access to internet service hampers the growth of telepsychiatry modalities in these communities, which could be beneficial for patient treatment.

Although the scientific literature focuses mainly on Blacks and their experience with discrimination during the COVID-19 pandemic, Asians have been significantly affected, displaying in some cases worsened mental health outcomes[45]. In the United Kingdom, 41.7% of hospitalized Asians with COVID-19 proved to have higher depression screening symptoms on Patient Health Questionnaire 4 than Blacks[31]. In the United States, many Asian Americans are targeted by their ethnicity in response to reports of the emerging virus[45]. Compared to pre-pandemic percentages, a United States cross-sectional study showed that 41% of Asians and Asian Americans reported an increase in anxiety and that 53% reported an increase in depressive symptoms[45]. A higher level of community support mitigates the impact of discrimination on depressive symptoms in Asians and Asian Americans[45]. Among other ethnic minority groups, Asians showed a lower incidence of suicide (6%) in the United States[29].

During the start of the pandemic, Hispanics displayed a higher incidence of suicidal thoughts (18.6%), higher anxiety and depressive symptoms compared to other ethnic groups in the United States[29]. In general, Hispanics have lower utilization of mental health services with a strong Spanish language social preference and higher levels of ethnic identity, which are strong predictors for mood and anxiety disorders[46]. Hispanics also have the lowest health insurance coverage rate and twice the poverty level than Whites in the United States[47]. This ethnic group is overrepresented in critical essential workers, which, during the pandemic, mainly worked in the food industry, laboring in overcrowded meatpacking factories with poor ventilation, thus increasing exposure to COVID-19 illness[29,48].

Among other ethnic minorities, cultural-religious minorities have shown worsened mental health outcomes during the COVID-19 pandemic. For instance, in India, an increased relapse of pre-existing psychiatric illness was observed during the quarantine period in Kashmir Muslims already affected by trauma and civil unrest in the area[49]. Moreover, members of the religious majority discriminated against the Muslim community in social media posts as being spreaders of viral illness[49].

DISPARITIES IN CHILDREN WITH DEVELOPMENTAL DISABILITIES

Children, adolescents, and adults with intellectual disability (ID) and neurodevelo-

pmental disorders like autism spectrum disorder (ASD) are vulnerable to significant impacts by pandemic-related changes such as social distancing standards, stay-at-home orders, and closures of nonessential services. Furthermore, many individuals with ID and ASD experience significant communication challenges in processing information[50], afflicting their ability to respond effectively and efficiently to social changes implemented secondary to the COVID-19 pandemic. Given expressive communication challenges, individuals with ID or ASD may have difficulty communicating emotional distress, pain, or illness symptoms[51]. As a result, many individuals with ID and ASD have to rely on their families or caregivers to communicate important information about the pandemic or observe for symptoms of a potential viral illness. Caregiver stress and depression increased during the COVID-19 pandemic compared to the pre-pandemic outbreak furthering the mental health disparity[52]. Furthermore, individuals with ID and neurodevelopmental disorders face various challenges secondary to the pandemic, including limited access to behavioral health services, changes in health services delivery, disruption of educational services, and vocational changes[53]. During the lockdown period in Spain, there were increased psychiatric emergency admissions in individuals with ASD, most likely due to an observed disruption of family daily routines[54].

Individuals with ASD share a physiological and genetic vulnerability for COVID-19. There are documented increased levels of pro-inflammatory cytokines present in individuals with ASD[55]. The tendency towards a pro-inflammatory state among individuals with ASD may place them at higher risk for even more severe symptoms once this virus is contracted[56], including a rare multisystemic inflammatory syndrome evident in children[57]. Focal brain inflammation in the amygdala with activation of mast cells may potentially result in a higher prevalence of ASD diagnoses due to COVID-19 infection[58]. Furthermore, individuals with ID and ASD have a greater risk for overall poor health compared to the general population[59], type 2 diabetes[60], along with sensory impairments and physical disabilities[61]; all of these have been documented as poor prognostic risk factors from COVID-19 infection[62].

Many individuals with ID and ASD share documented health disparities both in the pre-pandemic and pandemic period. This health disparity might be due in part to the higher rates of ASD among transgender and gender-diverse individuals *vs* cis-gender individuals[63]. In the pre-pandemic period, transgender and gender-diverse groups with ASD experienced increasing rates of comorbid mental illness and higher rates of being refused health services[64]. In the United States, access to existing therapeutic services, including Applied Behavioral Analysis in rural regions, has been curtailed due to job shortages[65]. In addition to disparities in medical access and services contributing to this disproportion, there is evidence about potential genetic or biological susceptibilities among various ethnic groups[66]. It could be expected that individuals with ID and ASD within these groups carry even higher risk given the vulnerabilities outlined above.

SEXUAL AND GENDER DISPARITIES

Sexual and gender minorities (SGM) include Lesbian, Gay, Bisexual, Transgender, Two-Spirit, Queer, Questioning, Intersex, and Asexual (LGBT2SQIA+) individuals[67]. SGM are a diverse group whose history of stigma, systemic discrimination, and structural violence leaves them particularly vulnerable to disproportionate impact by COVID-19 given inequitable conditions that have reduced their access to vital resources[67]. SGM share a heightened psychological vulnerability associated with minority stress, which increases their susceptibility to underlying health conditions[22,68]. Historically, SGM have been excluded from disaster research, thereby preventing identification of their unique mental health needs[69,70]. It is, therefore, no surprise that SGM experience health disparities, including higher rates of mental health diagnoses, substance use, and suicidality compared to their sexual-majority counterparts[71].

Due to discrimination, SGM are overrepresented in essential services and sex work, experience higher poverty rates than the general population, and are less likely to have adequate healthcare and are more vulnerable to poor mental health outcomes[72,73]. When SGM intersect with oppressed intersections of identity, such as race, ethnicity, socioeconomic status, or chronic illness, the compounding nature of these vulnerabilities creates even wider health disparities for communities of SGM[68,70,72]. For instance, a Hong Kong community sample found stressors beyond those of the COVID-19 pandemic, including family conflict due to sexual orientation and

disconnection to the SGM community, likely leading to a combined effect on the one-week prevalence of clinical depression (31.5%) and generalized anxiety disorder (27.9%)[73]. Given the social disadvantages and mental and physical health disparities faced by SGM, it is likely that the pandemic trauma and social isolation measures to mitigate COVID-19 transmission are exacerbating these inequalities[68].

Discrimination, oppression, and violence occur at the familial level, making isolation and quarantine dangerous for SGM who are forced to cohabitate with unsupportive and abusive family members or partners[69]. Many SGM rely upon community supports for safety and acceptance, yet due to COVID-related restrictions, SGM have been unable to connect with their supportive community safe spaces[69]. SGM experience more anxiety, depression, and peritraumatic stress responses while doubling the odds of meeting future criteria for COVID-related PTSD when compared to sexual majorities[74].

Furthermore, given the higher rates of human immunodeficiency virus (HIV), mental health diagnoses, substance use, and trauma among SGM, disruptions in mental healthcare access during COVID-19 have been particularly concerning[69,73,75]. SGM reported having difficulty obtaining HIV medications and mental health care in case studies in 59 countries[69]. Further validating this report, a convenience sample (n = 2732) of cisgender gay men and other men who have sex with men across 103 countries displayed moderate to severe psychological distress with a prevalence of 31% in depression[75]. Globally, SGM have reported that they would delay or avoid seeking care for COVID-19 symptoms due to anticipated stigma and discrimination[69].

DISPARITIES IN PREGNANT WOMEN

Pregnant women are a vulnerable group for COVID-19 due to an increased risk of physical and mental health complications, such as depression and anxiety[76,77]. Homeschooling children and taking care of elderly family members in addition to working from home has been a challenge for most women, which generally increases caregiver stress[78]. COVID-19-related health anxiety experiences may also increase the likelihood of mental health symptoms among those pregnant women without a previous psychiatric diagnosis[79]. Pregnant women in Ireland reported excessive worries regarding older relatives and their unborn baby[80], while Italian pregnant women reported high rates of anxiety regarding vertical transmission[81]. Studies from China, when COVID-19 emerged, have found that the female gender is significantly associated with higher self-reported anxiety, depression, and posttraumatic stress, causing a severe overall psychological impact[82-85]. Similarly, studies from Canada reported a higher rate of depressive and anxiety disorders, and substance use disorder[86,87].

The outcomes of psychiatric complications during the COVID-19 pandemic are complex for pregnant women since mental health problems are associated with adverse outcomes, including suicidal ideations and an unstable mother-infant bond[88]. Perinatal depression is also related to fetal complications, including fetal growth restriction and increased odds of premature delivery[89]. Maternal complications of depression are also associated with preeclampsia and gestational diabetes[77].

For many pregnant psychiatric patients, telehealth proves to be the most convenient way to obtain care. Due to governmental restrictions to halt the spread of COVID-19, many pregnant women cannot attend appointments in person. For socioeconomically disadvantaged women, telehealth can further the disparity of favoring those populations with resources to access technology *vs* those without, thus causing a gap in digital literacy[90]. This socioeconomic and educational disparity becomes apparent in developing countries where the prevalence of depression can reach around 15.6% during pregnancy and 19.8% after childbirth[91]. In Turkey, a recent online survey revealed that years of education and knowledge of COVID-19 protected against worsening of depression in pregnant women[77].

Another challenge complicating the mental health of pregnant women is dealing with the surge of domestic violence. For some pregnant women, more time at home may mean more time spent with an abusive partner[6]. According to the United Nations, domestic violence rates against women are increasing worldwide during the pandemic[92]. This increased rate is indicated by the number of calls received by emergency support lines in China, Italy, France, Brazil, and Spain during their lockdowns[85].

DISPARITIES IN MATURE ADULTS

Psychiatric patients who are mature adults are particularly vulnerable to COVID-19 because of a susceptibility to disease precipitated by a normal age-related decline in the immune system and comorbid conditions[8,93]. Comorbid conditions such as associated polypharmacy, hypertension, diabetes mellitus, chronic renal failure, and chronic obstructive pulmonary disease can contribute to an increased vulnerability to illness with poor health outcomes in this population[8,93,94]. Early identification of COVID-19 is key to mitigating illness in mature adults but can be challenging due to physical health factors.

Unique challenges are encountered specifically in mature adults with major neurocognitive disorder due to an atypical presentation of symptoms, such as low fevers, increased confusion, increased agitation, and sudden mood changes[95]. Upon the onset of the COVID-19 outbreak in China, the first psychiatric patient identified with the viral illness was a man hospitalized with a major neurocognitive disorder who supposedly ate outside food brought by family members and unknowingly infected others[8]. Masking protocols and appropriate handwashing can prove challenging to implement in the cognitively impaired within hospitals and long-term care facilities[8,96]. Mature adults with severe neurocognitive deficits may wander off, causing problems in implementing social distancing[96].

Another health inequity posited to affect mature adults more than other populations is self-isolation. Most of the daily social activities and contacts of many mature adults occur outside their homes[97]. In Canada, as the pandemic spread, leading to the cancellation of multiple community-based day programs for seniors[98]. During the early stages of the pandemic in China, self-isolation became a struggle, especially with mature adults without children or support, increasing the propensity to depressive symptoms[99]. Loneliness may also result from self-isolation. In Turkey, the pandemic has led to increased demand for home health aides to assist and accompany the elderly[94]. In the Caribbean, including Cuba, Puerto Rico, and the Dominican Republic, many mature adults with neurocognitive disorders live with extended family who can be of comfort and assistance[100]. Although social and physical distancing proves to be a difficult mitigating strategy, finding ways to connect and belong can help overcome the perceived loneliness of isolation.

Many mature patients also struggle with technology due to being unfamiliar with electronic devices, have difficulty navigating the internet or using platforms like those intended for telehealth appointments. There is a higher rate of illiteracy among the geriatric psychiatric population in the Middle East and North African countries[5]. Cognitive decline and lower education can add to the slow adaptation of technology and internet use in mature adults[94,101]. It is important to note that those mature adults who have higher education and seek social connectedness tend to adapt more rapidly to technology to overcome isolation[101]. For some mature adults who are marginalized, frequent phone calls and telephone calls from peer supports can help mitigate self-isolation[97].

DISPARITIES BETWEEN URBAN AND RURAL ENVIRONMENTS

Around 22% of Africa's population could become infected with COVID-19, a continent with a propensity to collective trauma due to the after-effects of the Ebola epidemic[101-103]. From 2014 to 2016, the Ebola virus outbreak caused psychosocial stressors such as discrimination, stigma, anxiety, and depression in Sub-Saharan communities[102]. In a cross-sectional study in Sierra Leone, knowing someone quarantined increased anxiety and depression, while PTSD was evident in 76% of Ebola virus survivors[104]. In many villages, healers and cultural treatment traditions were invalidated in preference for Westernized methods and treatment[105]. The government banned gatherings, and fear about the virus increased, causing heightened distress[105]. Due to overwhelming fears, many of the usual prevention methods of infectious spread were not practical during the Ebola epidemic[102,105]. Prevention methods to limit the spread of the Ebola virus were found to be poorly effective in those individuals with depression and trauma symptoms due to poor insight and impaired cognition[106]. Although it is unknown if the same prevention pattern with COVID-19 will result in individuals with depression, it is anticipated that such a similar pattern could occur since it has already been observed with other infectious diseases such as in the spread of HIV[106].

The inequity between urban and rural environments in mental health care becomes

evident in the villages' communal life in Africa. In these communities, there is a reliance on family members to provide for each other economically and to provide support to relatives with psychiatric symptoms[102]. The pandemic has led to income losses as many villagers can no longer sell farming goods or artisan items in urban centers[107]. Food security is an issue for many Africans during the pandemic due to economic availability[107]. Due to the governmental lockdown restrictions, the rural villagers can be further stressed, potentially increasing depression and anxiety[102]. When Africans display psychiatric symptoms, communal methods are usually exhausted first before sharing their symptoms directly to health care providers[102,105]. Plans to provide trauma-informed care by community health workers are primordial for the survivors of COVID-19 to prevent further re-traumatization due to discrimination, which was an issue with the Ebola virus[103]. Also, the ease of telehealth services is generally limited in rural environments compared to urban centers due to the availability of internet and poor signal reception[102].

The urban environment mental health disparity, which becomes apparent in densely populated cities, might be related to mitochondrial stress. Toxic metal pollutants in high dense areas can cause mitochondrial stress, increasing the vulnerability in psychiatric patients who already have mitochondrial dysfunction due to psychiatric illness, namely schizophrenia, bipolar disorder, and major depressive disorder, and who become infected and develop COVID-19 illness[17,108]. In Kuwait, a multi-ethnic country, South East Asians mostly live in highly populated dense areas where overcrowding and pollutants lead to higher exposure to COVID-19 illness[2]. This higher exposure can increase transmission of COVID-19, possibly leading to worsened mental health outcomes due to the potentiating effects of mitochondrial stress. A similar pattern occurs in Israel in which the Orthodox Jewish community populated in high dense cities contributes to an increased rate of transmission through religious rituals and gatherings[109].

LIMITATIONS

The minireview is limited mainly to observational studies due to the emergency state of the COVID-19 pandemic (Table 1). Articles in English and articles translated in English were reviewed, restricting the scope of the search. A lack of substantiated research in global health disparities, especially in ethnic minority groups, was appreciated in countries like Japan and South Korea. Although significant, other disparities involving prisoners, homeless persons, and persons with low educational attainment with psychiatric diagnoses during the COVID-19 pandemic were not addressed due to the narrow body of research.

It is essential to consider the short span since the pandemic's outbreak since the sequelae of COVID-19 are currently being studied in psychiatric and non-psychiatric patients[110,111]. The sequelae of COVID-19 may affect individuals with and without a history of psychiatric illness: A recent retrospective study showed that COVID-19 is associated with a higher incidence of a first psychiatric diagnosis following 14 to 90 days from exposure in non-psychiatric patients[110]. It is imperative to examine the impact of the COVID-19 pandemic on vulnerable populations without psychiatric illness. There is also a need to evaluate the impact on health care workers who face daily traumatic psychological stressors due to their job occupation and high exposure. Health care workers are confronted by an increased rate of mortality and increased health care demands[112].

CONCLUSION

The narrative minireview yielded evidence for worsened global mental health outcomes among vulnerable psychiatric patients during the COVID-19 pandemic. Psychiatric patients among vulnerable populations appear to be at higher risk for depression, anxiety, and posttraumatic stress symptoms. Among these vulnerable groups, collective trauma impacts marginalized individuals and communities. Expanding access to internet services and technical assistance in underserved areas can provide more effective delivery of psychiatric services through telehealth to vulnerable populations. Peer community supports for psychiatric patients can reduce social isolation. Programs promoting internet literacy for mature adults can support connectedness with family and relatives during prolonged periods of isolation. Providing programs that include psychiatric services with prenatal care can

potentially improve mental health outcomes in pregnant women. These findings suggest a need for greater implementation of programs that enhance communal resilience, decrease discrimination, and help overcome systemic barriers of care.

Abstract

As the population across the globe continues to dramatically increase, the prevalence of cognitive impairment and dementia will inevitably increase as well, placing increasing burden on families and health care systems. Technological advancements over the past decade provide potential benefit in not only relieving caregiver burden of caring for a loved one with dementia, but also enables individuals with dementia to age in place. Technological devices have served to improve functioning, tracking and mobility. Similarly, smartphones, tablets and the ubiquitous world wide web have facilitated the dissemination of health information to previously hard to reach populations largely through use of various social media platforms. In this review, we discuss the current and future uses of technology *via* devices and social media to promote healthy aging in individuals with dementia, and also limitations and challenges to consider in the future.

Key Words: Dementia; Technology; Gerotechnology; Social media; Geriatrics; Wearable technology; Health promotion; Home health; Monitoring

INTRODUCTION

With a rapidly aging population comes the rise in older adults living with chronic conditions. Of these, dementia has become one of the leading causes of disability and dependency worldwide[1]. Dementia is an umbrella term of symptoms that progress over time in which there is a gradual deterioration in cognitive and functional impairment and altered behavior. The etiology of dementia is myriad, with most common being Alzheimer's, and closely followed by vascular, Lewy body, frontotemporal, and mixed dementias. With unique pathologies and causative insults, each has its unique treatment to address the underlying cause. However, no cure currently exists for these dementias at large, nor treatment to alter its progressive course. Eventually unable to live independently, individuals with dementia require increasing levels of assistance and care. Therefore, goals for dementia care are focused on early diagnosis in order to optimize management in terms of physical health, cognition, activity and well-being.

Dementia care both in and outside of the hospital setting can prove challenging and complex. In addition to affecting individual quality of life, tremendous burden is placed on health care systems and families. One solution is to encourage and create a system for home-based dementia care. In 2015, a national consensus panel convened to address the burden of dementia and family caregiving[2]. Recommendations were made to shift the focus of future long-term care models to home based dementia care. Moreover, the majority of older adults prefer to stay in their homes for as long as possible than enter a nursing home when they require higher level care[3]. Technology, therefore, has the capacity to transform the course of dementia care, particularly at home.

Many technologies exist that have potential to support people with dementia and their caregivers through all stages[4]. Integration of existing and future technology presents an important opportunity for ameliorating the burden on individuals, families, and the health care system. A term coined "Gerotechnology" embodies this new interdisciplinary field of designing technology and an environment to promote independent living autonomy of older persons while strengthening the support of their networks[5]. Understanding and acceptance of use of technology in older adults are also key in the enduring adoption into everyday life. A recent study has established a 14-item questionnaire that can help assess older adults' acceptance of technology and effective usage[6].

In this review we address technology and social media targeted at health monitoring, proliferating dementia education and promoting psychosocial wellbeing of those with dementia. We summarize existing and in progress technologies that facilitate successful aging in place. Finally, we discuss limitations and challenges of implementing and integrating these technologies in the increasing population living with dementia.

TECHNOLOGY AS AN AID IN DIAGNOSIS

Research in Alzheimer's disease has grown exponentially over the past few decades[7]. Currently diagnosis of dementia is and remains primarily based on clinical history and presentation of the patient, with cognitive and functional testing. For Alzheimer's dementia, only post-mortem neuropathology is able to formally confirm a diagnosis. However, the advent of advanced medical imaging technologies and fluid biomarkers provide insight in the pathogenesis. As research advances, it is becoming clear that at

some point in the progression of dementia, lost neural networks cannot be regrown and excessive neurodegeneration cannot be reversed. Instead focus is shifting to slowing down early stages of progression and moreover, prevention: By reduction of overall improvement of health and wellbeing, chronic inflammation and oxidative stress[8].

Changes in how individuals use technology has been identified as an early indicator of emerging cognitive impairment. Seelye *et al*[9] designed a proof of concept study using continuous driving monitoring with unobtrusive sensors to identify and monitor subtle changes in driving patterns that may signal mild cognitive impairment (MCI). This study introduces a novel method in early detection and monitoring of functional changes in individuals with developing MCI.

Kamin and Lang[10] conducted a two-year longitudinal study looking at internet use and cognitive function in late adulthood. Looking at 29576 participants between 50 and 100 years of age, this study indicated that Internet use positively affects cognitive function in late life[11]. Similarly, Austin *et al*[12] conducted a longitudinal study in which a cohort of 113 older adult computer users were followed over a mean of 36 mo. They found that between participants with MCI and those who were intact, there was a significant decrease in the number of days with use, mean daily usage and increase in day-to-day use variability. Other studies suggest that even changes in the terms people search over the internet may be a measure of language and cognitive function in older adults[9].

Interestingly, Ihle *et al*[13] revealed in a six-year longitudinal study, the gender differences in the relationship between Internet use and cognitive decline, showing that more frequent Internet use predicted smaller subsequent cognitive decline only in men, but not in women. Together, these studies suggest the usefulness in incorporation of technology use in assessments for instrumental activities of daily living. They emphasize the potential that monitoring computer and technology use in diagnosing MCI and the progression of dementia over time, warranting further research in this area.

SMART HOMES: VOICE-ACTIVATED SMART SPEAKERS

The idea of "smart homes" is not novel. Smart homes are essentially the equipment of homes with sensors and various technology that facilitate the monitoring of inhabitants to improve quality of life and promote physical independence and reduce caregiver burden[14]. Services provided are far reaching from home automation of appliances, temperature and lighting systems, to remote monitoring capability of residents' wellbeing and safety (Table 1). With increasing prevalence and usage of smart home devices, older adults can potentially live independently and safely at home for longer, reducing or prolonging the need for caregivers both informally or formally[15].

Amazon currently has a line of Alexa-enabled home devices such as Echo, Echo Dot, and Echo Show. In addition to Amazon, there are various voice-activated smart speakers that also share similar functions[16]. Compatible smart home devices allow users to control lights and switches, set thermostats, view security cameras, thereby automating and simplifying everyday routines[17]. The Alexa mobile app includes a feature called 'Guard' that sends mobile alerts if an Echo device detects the sound of a smoke alarm or breaking glass. There is even a 'Hunches' feature that can help remind users to turn off a light or lock a door if Alexa has a 'hunch' that it was forgotten. More recently, Amazon recently launched a new feature called 'Care Hub' that allows consumers with an Alexa voice assistant to link their account to an aging relative's Alexa account[18]. This free feature includes activity feeds of smart home interactions, customized alerts for example if no activity is detected for a prolonged period of time, emergency contact notification capability, and quick access features allowing Alexa calling or 'Drop In'.

Several study protocols have been published as potential at home interventions to support caregivers of individuals with dementia[19,20]. The UP-TECH project proposed by Chiatti *et al*[19] was a 12 mo randomized controlled trial based in Italy with the purpose to reduce care burden of family caregivers and maintain Alzheimer's dementia patients at home. Technologies given included various housing adaptations such as sensors that detect falls, gas and water leak, and automatic lights. Outcomes measured were amount of caregiver burden and the number of days spent at home away from hospitalization or institutionalization. Other analyses measured were health economics, cost-effectiveness stratified by training time, social, costs of

Table 1 Summary of smart home and sensor technology

Technology	Functions	Originally developed for	Ref.
Alexa-enabled home devices, and Alexa Care Hub	Voice-activated smart speakers, connectable smart home devices, remote smart home monitoring	General use, older adults	Chung and Woo[16], and Amazon[17,18]
Tile	Locate misplaced items	General use	Tile[23]
Water-leak sensor	Smart water shutoff, mobile alerts	General use	D-Link[34], and Moen[35]
Google Nest Protect	Smoke and carbon monoxide alarm, 'pathlight' feature	General use	Google Store[38]
iGuard Stove	Smart stove shut-off valve, remote control and monitoring, emergency shut-off	Older adults	GoDaddy[39]
Automatic pill dispensers	Integrated alarms and reminders, multiple medication management, remote monitoring, adherence tracking	Older adults	Vervloet *et al*[42], Boland *et al*[43], Paterson *et al*[44], Hoffmann *et al*[45], Faisal *et al*[46], Ahmad *et al*[47], and Patel *et al*[48]

technologies and consumables for the interventions and health-related costs. In 2019, Socci *et al*[21] published the results showing high user satisfaction. Implementation and findings of this project are intended to support health care and social service professionals and policy-makers in the creation of future programs to address needs of Alzheimer's dementia patients and their care givers.

A similar study protocol based in Sweden, Malmgren Fänge *et al*[20] proposed a large randomized controlled trial called TECH@HOME. Aims were to recruit community-dwelling people with dementia and their primary informal caregivers and study the effects of technology on caregiver burden. Split into intervention and control groups, each intervention group would receive an information and communication technology kit including home-leaving sensors, smoke and water leak sensors, bed sensors, and automatic lights to monitor individual behavior. Home visits throughout the study period would measure primary outcomes of resource utilization, as well as secondary outcomes such as quality of life for both caregiver and person with dementia, caregiver anxiety and burden, and cost-effectiveness. Empirical data highlighted persons with dementia and their family members felt safe with the technology installed at home and felt that the technology was useful[22]. Ultimately sensor-based technology has the potential to be a support in ensuring a safer home environment for people living with dementia.

Results of these studies have the potential to inform policy makers and influence caregivers and families alike on the current state of technology. Implementation of similar study designs across the world are imperative in order to assess and inform of the current status of technology in alleviation of caregiver burden associated with dementia care and prolonging the independence of individuals with dementia in order to remain at home for as long as possible.

SENSORS AND SAFETY

Locator devices

Misplacing items is one of the most common symptoms of dementia, and as it can also be a common symptom of normal aging, persons living with dementia may be unable to find items again. Products such as 'Tile' are Bluetooth-enabled devices that can help locate misplaced items through activation of an audible alarm or last known position found on the mobile app[23]. From a simple tag on a keychain, card to slip into a wallet or laptop, or sticker for the remote control, products are designed to fit and locate the most common lost or misplaced items. Features include location history and also 'Tile Community' to use other individuals using running mobile Tile applications to help locate lost items when in Bluetooth range.

Falls, wandering, nighttime ambulation, security

Dementia-related wandering is present in up to sixty percent of community-dwelling people with dementia, and can be dangerous — even life-threatening — for patients and stressful for families and caregivers[24]. Modeled after the Amber Alert system for missing children, the 'Silver Alert System' was created in 2006 to provide a public alert

system about missing and vulnerable older adults[25]. Furthermore numerous technologies have been developed over the years to ease family and caregiver burden, locate missing persons and facilitate their return[26-28]. Providing a safe environment at home is important to continue to live independently and can be done by monitoring movements and alert carers or loved ones to potential breaches of safe boundaries. It is estimated that 30% of older adults fall at least once a year. Fall-related fractures can cause disability and even lead to premature death. The frequency of falls increases with age, as a result of physical, functional and cognitive impairment. Increasing technology-based interventions have been implemented for fall detection and alert[29].

There are a number of floor alarm mats by different companies. Floor pressure mats are good for fall-alarms when placed beside a bed or chair. Alternately, they can be placed at any doorway, such as an exit or the kitchen, to alert caregivers when their loved-one is on the move. Alerts can be in form of audible alarms or sent to connected smart devices. The doorway anti-wander safety beam can be placed alongside any doorway and send alarm sounds when the beam is crossed.

More innovative technologies include motion sensors embedded into socks and in floor tiles. Other floor pressure mats can be programmed to play recorded messages, for example a reminder to turn off the gas when walking out of the kitchen. There have been innovations such as the global positioning system (GPS) shoe, marketing itself as a way to locate individuals with Alzheimer's disease who have wandered away from home or their care facility. While they work with astonishing accuracy, and can be integrated with mobile application or professional call centers, there are also limitations and ethical considerations which will be discussed later[30-32].

Smart lighting technology also be placed in dark hallways and entryways to automatically turn on with motion sensor or *via* voice activation. Smart contact sensors can be multi-function. It can act as a whole home security system with alerts for open doors and windows, even refrigerator doors to indicate how often an individual has accessed comestibles. Options to self-monitor through mobile application or smart home system or professional monitoring with subscription are available. Combined, these technologies are promising to prevent or call to attention falls and wandering outside of the home and promote safer nighttime ambulation.

Water leaks

About one in fifty US homes file insurance claims annually due to water damage, which amounted to $13 billion in insurance payout for water damage[33]. These figures can easily be alleviated with technology to alert individuals of water leaks the instant they are detected. Smart water-leak sensor technology can be placed near areas of most likely leaks, such as the water heater, bathtub, sink, or toilet. Studies like the TECH@HOME study[20] have incorporated water leak sensor technology in home monitoring kits when studying technological interventions for individuals living with dementia. Currently there are many water leak detectors on the market, mostly embedded with smart technology that can be integrated into smart home systems[34,35]. Smart water shutoff can automatically turn off water supply in an emergency. Others offer wireless sensors that send alerts through mobile app in addition to triggering audible alarms or lights.

Fire safety

In 2004, the U.S. Fire Administration launched an intensive public fire education campaign for elderly Americans, and in 2006, published a report evaluating the fire situation and risks for this particular population[36]. Older adults are 2.5 times more likely to die in fires than the overall population. Common fire causes resulting in injury among the older population are cooking, open flames, smoking and heating. Decreased sensory abilities like smell, touch, vision and hearing that come with aging, and compromised cognition with progressive dementia can all contribute to impairing ability to prevent or respond to fires. Hearing impairment is the second most commonly reported in older adults in the United States[37]. The inability to hear warning sounds of fire or a smoke alarm creates significant fire risk. This decrease in reaction time and awareness places older adults at higher risk of fire, fire injury and fatality. Attention therefore needs to be placed on making the necessary home improvements to reduce fire risk. Unfortunately, many of these are overlooked or postponed because of cost or lack of knowledge or attention.

Technologies such as 'Google Nest Protect' acts as a smoke and carbon monoxide alarm that alerts by voice and siren and is capable of sending smartphone alerts to up to six contacts[38]. Also integrated into its device is a 'Pathlight' feature, a motion-activated night light.

Stove-top technologies such as the smart stove shut-off valve allows for remote

control and monitoring of stove settings and emergency shut-off system. Technologies such as the 'iGuard Stove' boast automatic shut off after 5 min of no presence in the kitchen, day and night-time activity monitor, night lock and caregiver lock modes, and alerts sent to mobile application[39].

MEDICATION AIDS

Unintentional medication nonadherence is increasingly prevalent with an aging population, particularly in older adults with compromised functional and cognitive capabilities, multiple chronic health conditions on complex medication regimens[40,41]. Current strategies to address medication management adherence include pillboxes, visual or audio reminders or alarms, and automatic pill dispensers[42-44]. Of the multiple automated pill dispensers currently on the market, these products have many features including integrated alarms and reminders and ability to manage multiple medications. Dispensers are connectable to smartphone *via* application and can notify users and allow remote monitoring. Applications can track adherence and also notify when certain medications are running low. Some devices are able to store and dispense up to 90-d supply of up to 10 different medications. Unfortunately, this creates limitations for individuals taking more than the maximum allowed medications each machine is able to manage, requiring need to decide which scheduled medications are most important to track, or allow another application to manage medications outside of the device. Other limitations are the type of medication: Some dispensers will not work with half pills, gummies, powdery, sticky or dissolvable pills.

Hoffmann *et al*[45] studied whether automated home medication dispensers could help solve unintentional medication nonadherence. Using a 6-mo prospective study in 21 patient-caregiver dyads, they found that mean adherence increased from 49.0% at baseline to 96.8% ($P < 0.001$).

Faisal *et al*[46] and Ahmad *et al*[47] examined user experience with electronic medication adherence products. Both studies have demonstrated that these products have potential to promote independent medication management in older adults. Choice of products are based on product features, facility of use, portability, and affordability. Unfortunately, many medication dispensing systems have a monthly managing free in addition to the upfront cost of the machine itself, therefore use of such technology can be limited by cost.

Patel *et al*[48] used a prospective, mixed methods study to test the usability and workload of twenty-one electronic medication adherence products. Each of 39 participants tested five products, one at a time and usability and workload were compared in the different products. This study highlights the importance of comparing products within target populations in order to guide clinicians, caregivers, and users themselves in choosing the most optimal product for their particular needs.

Alternative to automated medication dispensers, mobile applications can be a useful standalone assistive technology to ensure medication adherence. Chew *et al*[49] looked at the usability and utility of a mobile application called 'Med Assist' to improve medication adherence. To date, there are several medication adherence applications, but few studies have been conducted among their target population. Through two rounds of 'think aloud' interview and a retrospective interview at the end of using the application for a week, results showed positive feedback from participants regarding usability and reliability. Ease of navigating through the application, multiple user support capability and medication refill reminders were all positive aspects that participants found that suggest the efficacy of this and similar mobile health applications to improve medication adherence.

WEARABLE TECHNOLOGY

Wearable technology, particularly wrist-worn devices, can impact key aspects of dementia care management by providing insight into specific factors that are key determinants of health and wellbeing[50,51]. Devices are able to provide quantified information on sleep and physical activity, with more advanced technology having embedded heart rate monitor, arrhythmia and fall detection, and GPS. These objective measurements have potential to guide physicians in clinical decisions by having a tool that simplifies and facilitates data collection in a manner previously impossible. Available devices offer easily accessible and user-friendly interface. Contrary to life-

alert or medical alert buttons that have stigma of making wearers 'feel old', wrist-worn devices offer more sleek and discreet designs that can appeal to older adults. With so many available functions, these devices can aid in the care and management of older adults with dementia.

Megges *et al*[52] studied the user experience and clinical effectiveness of two similar wearable GPS watch devices. Over a period of 4 wk, measures such as usability, design features, and overall product satisfaction were taken by patients and caregivers. Feedback and findings included preference for fewer buttons, clear display and font, and ample battery life. Future comparison of GPS devices, particularly watches, are of interest in order to study how likely they are to be adopted.

A recent case study described how use of a wrist-worn device was able to aid physicians in diagnosis, treatment decision making and prognostic monitoring of treatment of an older adult's late-life depressive symptoms[53]. The patient was encouraged by the ability to track and visualize his own activity and sleep and reported positive reinforcement for remaining engaged in exercise as it noticeably improved his depression.

As many older adults already own wrist-worn devices demonstrated by the plethora of commercial wearable devices available by companies such as Apple[54], Fitbit[55], Garmin[56], and Huawei[57], it is no wonder that these devices are becoming the focus of future research that can not only support older persons with dementia, but also revolutionize the way we collect 'big data' for studying populations in aggregate[58].

Amazon most recently launched 'Halo', a wearable band and health and wellness tracker detecting body fat composition, sleep and activity tracking, and most uniquely, tone of voice analysis[59]. Voice qualities such as pitch, intensity, rhythm, tempo analyze and report emotion states of 'hopeful, elated, hesitant, bored, worried, confused, affectionate' for users to become more aware of their mood, interactions and relations throughout the day. Goals of this device are focused more on providing means for lifestyle changes including at-home workouts, guided meditations and sleep sounds.

SOCIAL MEDIA

Today more than ever, people are turning to the internet for health information. Social media are a valuable tool to deliver health education to different populations. Different platforms are available on mobile devices that facilitate information acquisition and sharing and the use of these by people globally are on the rise.

Studies have shown that YouTube is effective in delivering dementia education to older adults[60,61]. Similarly, Twitter is a novel platform for Alzheimer-related dementia awareness[62]. Other studies explore how social media platforms such as WhatsApp are becoming strong means of disseminating health information[61,63]. Further efforts in studying and optimizing how we use social media to recruit, disseminate and share health information can prove invaluable in reducing the gap in health literacy and ensure healthy aging and promotion of healthy outcomes.

It is important to consider the perceived usefulness of technology in the older adult population. Best *et al*[64] conducted a study showing a positive relationship in the perception of usefulness of computers in providing health-supporting technologies. Furthermore, Berkowsky *et al*[65] looked at different factors that predict technology adoption among older adults. With fifty-two older adults participating, they found that self-assessed abilities and computer-internet skills were predictive of individual willingness to adopt technologies. However most robust predictors were perceived value and impact on the quality of life, and confidence in ability to learn the technology. Therefore, in developing new technologies, consideration must be made in balancing functionality with complexity in order to maximize potential of technology adoption among the aging generation.

ARTIFICIAL INTELLIGENCE

The use of artificial intelligence, or robotic technology, has been explored over the years. Robots have been made to either be physically assistive (performing physical tasks), or socially assistive (providing social and psychological support).

Therapeutic robots

With progression of dementia comes increased behavioral and psychological symptoms of dementia that can be difficult for family and caretakers to manage. Non-pharmacologic interventions are sought after before turning to psychotropic medications. Therefore, therapeutic robots in form of animals may be promising forms of therapy that are also facility friendly as some do not allow animals to visit and are furthermore not limited by animal allergies.

One of the earliest examples of such social robot is PARO (comPAnion RObot), a baby harp seal robot developed in Japan as pet therapy for patients with dementia[66]. PARO is powered by artificial intelligence to respond to the user and the environment, can move its tail and fliggers, open and close its eyes, and make sounds similar to a real baby harp seal. Now an FDA approved biofeedback device, PARO's benefits, including psychosocial, have been widely studied over the past ten years all over the world. Studies have shown PARO to be a viable alternative with therapeutic benefit in managing symptoms of anxiety, depression, and chronic pain in patients with dementia, improving sleep, social interaction and overall quality of life[67-73]. Moyle *et al* [74] led one of the largest pilot studies of use of PARO at long-term care facilities in Australia. By using a cluster-randomized controlled trial, studying four-hundred participants with documented diagnosis of dementia across twenty-eight long-term care facilities across Australia, results revealed that participants with interaction with PARO (15-min sessions 3 times a week for 10 wk) were more verbally and visually engaged, and had improved mood states and agitation.

Ollie the baby otter was built by a team of undergraduate engineering students at Massachusetts Institute of Technology in 2013[75]. The prototype was created with the intention of being a therapy robot to help with anxiety and depression in patients with dementia, and more affordable than the Japanese robotic seal PARO. Similarly NeCoRo was designed as a robotic lap cat by a company called Omron in Japan and has also been the subject of research of robotherapy for older persons with dementia[76,77].

In December 2015, Hasbro released a line of companion pets called 'Joy for All' intended to provide stuffed animal therapy for individuals experiencing age-related memory loss. Now expanded into its own company: Ageless Innovation, the Joy for All line of robotic companion pets advertises therapeutic benefits such as decreasing anxiety and agitation, increased feelings of self-worth, improved mood and physical activity, and increased interaction with others[78]. Currently available are a golden retriever pup and a variety of cats all with positive testimonials from the older adult market.

The Hug by Laugh research project was development to support people with late stage dementia to amuse, comfort, engage, bring joy and improve overall wellbeing[79]. Hug is equipped with a beating heart and ability to play music that can be personalized to a favorite playlist.

Other technologies such as humanoid social robots are also being studied. One in particular called Kabochan was studied in 103 residents with dementia across seven long-term care facilities in Hong Kong. Assessed by randomized controlled trial over 32-wk, Ke *et al*[80] suggest that engaging with humanoid social robots may be promising in changing perceived ease of use of technology and that Kabochan was about to reduce short-term neuropsychiatric symptoms and caregiver distress[81].

The future of robotic product designs is promising in delivering social support, enhancing well-being and quality of life for individuals living with dementia (Table 2). As more robotic product designs are developed, socially interactive robots are being studied more and more, providing valuable insight into features and functions that these technologies can serve[82].

Assistive service robots

Service robots have the potential to assist older adults with dementia by helping to complete everyday tasks. Equipped with video chat capabilities, such robots are also able to support socially by reducing isolation. Services include reminders to complete activities of daily living such as brushing teeth, drinking water, dressing, and taking medications. Others are being developed with functional arms to reach for and bring items to the user. With the number of innovations, it becomes important firstly to study preferences and perspectives of users and whether technologies will be likely to be accepted and adopted into assisting with care of persons with dementia.

Korchut *et al*[83] worked to identify challenges for service robots in consideration of the requirements of older persons with cognitive impairments. Based on 264 surveys conducted in focus groups of medical staff, potential users and caregivers across

Table 2 Summary of therapeutic robots

Technology (company)	Form	Functions and intentions	Ref.
PARO	Baby harp seal	Managing psychosocial symptoms of anxiety, depression and social interaction	Hung *et al*[66], Petersen *et al*[67], Pu *et al*[68], Lane *et al*[69], Jøranson *et al*[70], Liang *et al*[71], Jøranson *et al*[72], Jøranson *et al*[73], and Moyle *et al*[74]
Ollie (Massachusetts Institute of Technology)	Baby otter	Relieve psychosocial symptoms of dementia	IEEE Spectrum[75]
NeCoRo (Omron)	Lap cat	Tactile and recognition sensors and feedback to engage individuals with dementia	Megadroid[76] and Libin and Libin[77]
Joy for All (Hasbro)	Golden retriever pup and cats	Providing social support for individuals experiencing age-related memory loss	Ageless Innovation[78]
Hug by Laugh	Humanoid	Amuse, comfort, engage, beating heart, personalized music playlist, bring joy to support people with late-stage dementia	Hug by Laugh[79]
Kabochan	Humanoid	Reduce neuropsychiatric symptoms and caregiver distress	Ke *et al*[80] and Chen *et al*[81]

Poland and Spain, priority function requirements of service robots were related to reacting in emergency situations and reminders about medication. Almost 60% of surveys indicated reminders about boiling water, turning off the gas and lights as priority. Similarly, Bedaf *et al*[84] surveyed the preferred characteristics of service robots across older adults, informal and professional caregivers across The Netherlands, France and the United Kingdom. Expectations involved customizability of service robots to match user needs and preferences, and also functioning and behavior with qualities similar to that of a human. Wang *et al*[85] further documented perspectives of older adults and their caregivers on using home assistive robots. They found that older adults were curious and open to the idea of using assistive robots, provided that there is clear perceived need and benefit.

In sum, service robots' ability to help older adults carry out daily activities may help to relieve caregiver strain and promote social relationships and cognitive support. However, balance needs to be maintained in order to uphold autonomy, privacy and dignity for the older adult.

DRIVERLESS VEHICLES

Driving is the predominant mode of transportation for older adults in the United States. However, driving with a compromised functional ability or lengthened reaction time, individuals with progressive dementia can eventually become a danger to themselves and others while on the road. Cessation of driving severely reduces ability to maintain previous social participation, and even disrupt a means to live including transportation to shopping and doctor appointments. Therefore, taking away a license to drive can severely prove a hindrance to living independently. Driving mobility may be composed of both either individual ability to drive or ability to obtain a ride or another means of transportation likely from a friend or caregiver. This added dependence can eventually create burden or strain on others. Automated vehicles are a rapidly developing technology with a spectrum of features from providing warnings and momentary assistance during full human operation, to transient assistance and support in steering or braking, to full automation.

In assessing awareness and openness in using automated vehicle technology, Oxley *et al*[86] found that despite low awareness of in-vehicle safety features among a sample of older adult active drivers, there was greater interest in purchasing vehicles with safety features when aware.

'Waymo' began as the Google self-driving car project in 2009 with the mission of facilitating safe transportation and access to mobility for those who may be unable to[87]. Similarly, self-driving cars by Tesla[88], General Motors[89], Toyota[90], Honda[91], and so many more reflect the rapid proliferation of this technology in the near future. 'Voyage', a start-up company based in California, is working to develop self-driving technology with the mission to provide transportation for millions of senior citizens living in retirement communities[92].

While still in early testing phases before phasing into the market, it is unclear how it

will be perceived and adopted by the public. But it is clear that there is a broad range of potential positive impacts of automated vehicle technology in the lives of older adults. Even more broadly it can help bridge disparities in social and environmental determinants associated with health[93].

CONCLUSION

With current trends towards 'aging in place', technology holds promise in helping to maintain autonomy of persons with dementia over time. When envisioning the future for older adults in the context of aging in place, technologies should be developed with goals of supporting both autonomy and independence in addition to safety[94]. While dementia is indeed a spectrum of symptoms with various etiology, and there is little to formally diagnose, for example Alzheimer's, until post-mortem, it is difficult to ascertain specific recommendations specific to each type of dementia. There is currently no neuropsychological assessment aimed at determining which technology or social media would be best suited for individuals with specific dementias. Rather, decision to adopt and implement technologies into everyday life is an individualized decision based on personal needs and goals. Creation of a formal standardized assessment to guide recommendations towards particular technology or social media is an area of future consideration and direction. Though there is indeed a limitation of specificity in utilization, with more scientific advancements in uncovering biomarkers for different dementia phenotypes, we foresee more specific recommendations to come in the future.

With the rise in use of technology, it also behooves us to consider ethical ramifications. Firstly, the existence of assistive technology has the intention of providing safety and assurance to help individuals be able to age in place. However, the mechanism of doing so introduces alternative methods of surveillance, thereby limiting privacy and restricting movement for persons who were once regarded independent. Wearable technology, home safety monitoring and location devices may be assumed as a breach of privacy even if the monitor is a close family member or friend. Be it covert or with full knowledge, or for an individual without capacity to make such decisions, the perceived loss of independence for the sake of maintaining a level of independence begs the question of how much privacy is permissible to be lost before crossing boundaries of invasion of privacy and autonomy. Such a balance of privacy *vs* utility needs to be addressed and taken into consideration when developing new technologies.

With respect to use of robotic technology, social robots' purpose is to enhance social interaction. The notion of person-to-person interaction is invaluable and can never really be replaced but critics may argue that technology, particularly use of robotic technology, undermines this entire concept. However humanoid, the use of robots in place of humans in order to partially relieve caregiver burden is a fine line to tread. A case can be made, however, for robotic pets to allay negative psychological characteristics inherent across various stages of dementia. It can be a practical alternative in environments with insufficient staffing resources, allergy limitations to real animals, safety concerns about pet behaviors or disruptive behaviors of individuals towards a real animal. Notwithstanding, the progressive loss of ability to socialize and increased behavioral symptoms are characteristic of late dementia, imploring the determination of when during the course of dementia would robotic technology, if ever, shall be deemed appropriate regardless of severity. Work needs to be done to evaluate to what extent is replacement of human interaction considered enhancement of social interaction instead of limiting and viewed as a devaluation of caring.

Practical challenges in widespread adoption of gerotechnology among older adults include financial limitations of cost of device, installation, and monitoring. Adoption of such promising technologies are thereby limited foremost by economic ability to finance, both personally and within scope of health insurance plans. This highlights a burgeoning facet that needs to be addressed in the scope of health economics. Efficient, cost-effective distribution of this increasingly valuable resource is necessary in order to most effectively alleviate healthcare burden of caring for individuals with dementia. In terms of prioritizing public health and management of health services, looking into maximizing the years of healthy life from use of these technologies can elucidate a clearer picture of the benefits to be expected. Critics may argue that the benefits are not worth the price tag that comes with equipping every older adult with technologies that enable aging in place. More quantitative evidence to measure effectiveness of these

technologies can be useful in deliberating health policy efforts, focusing on aid in funding and finance to make technologies more affordable and thereby more available to beneficiaries. Partnerships with companies to lower cost of manufacturing would help to ultimately lower cost for consumers. Currently, many if not all health insurances do not cover these technologies and individuals must pay out-of-pocket. Further work therefore needs to be done to highlight the potential of these technologies to alleviate healthcare burden in order to drive healthcare policy to aid in funding and finance to enable people with dementia and their care-givers access to these services. Work also needs to be done in educating the public, *via* ever present social media, to awareness and necessity of available technologies, and for assistance and support on how to use the technologies.

Furthermore, in developing these technologies, preferences and sustainability across all stages of aging and dementia need to be considered in order to deliver high-value, needs-based, dementia-centered care. Technology truly has the potential of creating a patient-centered care home that can ensure people living with dementia have a safe, healthy environment to live independently for as long as possible. As such an interdisciplinary field, gerotechnology presents a collective endeavor to equip older adults with the resources to successfully age in place.

Abstract

BACKGROUND

Serotonin syndrome (SS) is an underdiagnosed drug-induced clinical syndrome resulting from the excess intrasynaptic concentration of serotonin. Very limited information is available about chronic SS.

AIM

To evaluate the epidemiological, clinical, and other aspects of the insidious onset SS.

METHODS

We retrospectively evaluated 14 consecutive adult patients (> 18 years) who had complaints for more than 6 wk at the time of consultation and met the Hunter criteria for SS.

RESULTS

The mean age was 41.1 years (range: 21-61 years), with a male preponderance (64%). Although tremors were observed in all patients, this was a presenting complaint in only 43% of patients. Generalized body pain, insomnia, and restlessness were common presenting features (50% each). Other common clinical features were stiffness of the limbs (43%), diaphoresis (43%), gait disturbances (36%), bowel disturbances (36%), dizziness (29%), sexual dysfunctions (21%), incoordination (14%), and fatigue (14%) The mean duration of symptoms before the diagnosis of SS was 13.5 ± 5.8 wk (range: 6-24 wk). Amitriptyline was the most common drug (n = 6, 43%), followed by tramadol (n = 5, 36%) and sodium valproate (n = 5, 36%). All patients received cyproheptadine, a 5-hydroxytryptamine2A antagonist, as treatment and noted an excellent response

Conflict-of-interest statement: There are no conflicts of interest to report.

Data sharing statement: No additional data are available.

over the course of 4-14 d.

CONCLUSION

This study represents the largest study on chronic SS. We suggest that patients receiving serotonergic drugs should be physically examined for the presence of SS upon the development of new symptoms.

Key Words: Serotonin syndrome; Serotonin toxicity; Cyproheptadine; Serotonergic agents; Serotonin; Clonus

Core Tip: Chronic serotonin syndrome (SS) is an evolving concept. It may present with nonspecific symptoms such as generalized body pain, stiffness/rigidity, insomnia, restlessness, and tiredness. As misdiagnosis is common for typical cases of SS, a high level of clinical suspicion is required to identify patients with a chronic variant. A detailed drug history and thorough physical examinations are needed to detect a case of SS. Diagnosis of even mild SS is important as inadvertent use of another serotonergic agent may worsen the clinical symptoms, and sometimes it can be fatal.

INTRODUCTION

Serotonin syndrome (SS) is a drug-induced clinical phenomenon characterized by a triad of altered mental activity, neuromuscular hyperactivity, and autonomic disturbances. It occurs due to increased intrasynaptic concentration of 5-hydroxytryptamine (5-HT) or serotonin. Although SS is a potentially fatal condition, misdiagnosis for SS is common in clinical practice. Misdiagnosis is partly due to its protean manifestation and partly due to unfamiliarity about SS among physicians[1]. The incidence of SS is increasing worldwide due to the widespread use of various serotonergic agents. Several new concepts about SS have emerged in recent years that further complicate clinical issues associated with SS. In earlier years, SS was commonly reported in patients with psychiatric disorders, especially from toxicology centres. The identification of a variety of serotonergic agents in the past decades has expanded the clinical scenarios where SS can be noted. Cases of SS are being reported from non-toxicological departments and clinics, including surgical departments (perioperative settings), cardiac departments, headache clinics, gynaecological clinics, and paediatric clinics. Moreover, a few drugs with serotonergic properties are not marketed as serotonergic agents (such as dextromethorphan, fentanyl, linezolid, tramadol, and methylene blue). The clinical spectrum of SS has increased dramatically in recent times, and several atypical features have been noted in patients with SS[2]. The literature on SS is a bit biased for acute and severe cases, and there are only a few cases of SS that had insidious onset and prolonged course[3-5].

The onset of SS is typically described in the setting of recent administration of a proserotonergic agent. The administration of proserotonergic agent means starting a drug for the first time, increasing the dose, taking an overdose (accidental or suicidal), adding other serotonergic agents, and swapping of serotonergic agents. However, SS, including severe and fatal cases, may occur even with a stable dosage. In a review of 56 cases of fatal SS, seven patients (13%) were on a stable dosage, and there was no change in the dosage of the drugs in the recent past; and all of them had insidious onset SS[6].

The diagnosis of SS is typically made according to either the Hunter criteria or the Sternbach's criteria, and both the diagnostic criteria are primarily intended to detect acute and severe cases[7,8]. The Hunter serotonin toxicity criteria require the presence of one of the following clinical features in the presence of serotonergic agent use: (1)

Spontaneous clonus; (2) Inducible clonus/ocular clonus with diaphoresis or agitation or rigidity, with a temperature > 38.0 °C; and (3) Hyperreflexia and tremor[7]. A combination of tremor and hyperreflexia is generally noted with mild and insidious onset SS. To the best of our knowledge, no studies dedicated to insidious onset chronic SS have been conducted to date. Chronic SS is not defined in the literature. The term 'chronic' is often used when the course of the disease persists for more than 3 mo. However, in a few clinical conditions, the time limit for chronic conditions is less than 3 mo. The time limit for chronic myelitis and chronic osteomyelitis is 6 wk. Considering the seriousness of SS, we used 6 wk to define the time frame of chronic SS in this publication. Herein, to discover the different aspects of insidious onset chronic SS, we evaluated the data of the patients who met the Hunter criteria for SS and simultaneously had symptoms for more than 6 wk.

MATERIALS AND METHODS

This study was conducted as a retrospective chart review of all consecutive adult patients (≥ 18) who had 'presenting complaints' for more than 6 wk at the time of the first consultation and met the Hunter criteria for SS (Hunter criteria described above). The study included patients with a minimum of 6 wk of follow-up. The exclusion criteria included: (1) Age < 18 years; (2) A follow-up of less than 6 wk; and (3) Patients who did not give consent. Included patients were seen between February 2018 and July 2020 in the Neurology Outpatient Department of Smt. B.K. Shah Medical Institute and Research Center, Vadodara, India. Epidemiological, clinical, laboratory, management, and outcome data were collected from medical records. Our team has been working on SS for several years. Therefore, as a departmental policy, any patient fulfilling the Hunter criteria is routinely subjected to a detailed clinical history and physical examination. So, all the data were collected prospectively at the time of the first consultation. The Institutional Ethics Committee approved the study (SVIEC/ON/MEDI/RP/20116). The study was done according to the Helsinki Declaration guidelines. Written informed consent was taken from all patients to publish this observation. We used statistics with mean ± SD for continuous variables and frequencies and percentages for dichotomous variables. Anonymized data not reported here can be obtained from the corresponding author on rational demand by any qualified researcher.

RESULTS

We identified 19 patients who met the inclusion criteria. Five patients were excluded for the following reasons: Age less than 18 years (n = 1 patient), follow-up less than 6 wk (n = 2 patients), and those who did not give consent (n = 2 patients). As cases of chronic SS are not well described in the literature, we are providing details of three patients. The clinical characteristics of the other 11 cases are summarized in Table 1. Epidemiological, clinical, and other characteristics of all 14 cases are summarized in Table 2.

The median age at symptom onset was 44.1 years (range: 21-61 years), with a male preponderance (64%). All patients had tremors and hyperreflexia. A combination of tremors and hyperreflexia/inducible clonus sufficed the Hunter criteria. In addition, 11 patients (78%) also fulfilled the Sternbach's criteria of SS. Generalized body pain, insomnia, and restlessness were common presenting complaints (n = 7 patients, 50% each). Although tremor was observed in all patients, it was part of the presenting complaints in only six patients (43%). In other patients, tremors were detected only after neurological examinations. Other common symptoms included diaphoresis (n = 6 patients, 43%), gait problems (n = 5, 36%), bowel disturbances (n = 5, 36%), dizziness (n = 4, 29%), sexual dysfunctions (n = 3, 21%), incoordination (n = 2, 14%), and fatigue (n = 2 patients, 14%). Besides hyperreflexia (100%), clonus (n = 13 patients, 93%) and rigidity/spasticity (n = 11 patients, 79%) were two common physical signs. Tachycardia was reported in 9 (64%) patients. Fever was not reported in any patient. The mean duration of symptoms before getting the diagnosis of SS was 13.5 ± 5.8 wk (range: 6-24 wk). While 36% of patients were on a single serotonergic agent, about 64% of patients received two serotonergic agents. There was no history of an overdose of any serotonergic agent, and all patients were on stable doses of serotonergic agents for various periods. Amitriptyline was the most common agent causing SS (n = 6 patients, 43%), followed by tramadol and sodium valproate (n = 5 patients, 36% each). We

Table 1 Details of patients with chronic serotonin syndrome

Age/sex	Details of the clinical characteristics			Serotonergic agent and its details	Investigations	Treatment and follow up
	Presenting complaint	Other symptoms and signs	Duration of illness			
49, F	Generalized body pain, fatigue, restlessness, tremors	Dizziness, insomnia, tachycardia, rigidity, clonus	6-8 wk	Valproate for 2 yr for epilepsy, sertraline added 3 mo back for depression	CK- 566 U/L	Discontinued sertraline. Cyproheptadine (4 mg bid) was started. Marked improvement in 2 d. Complete response within 5 d. No recurrence in follow-up
57, M	Irritability, disturbed sleep, slowness in gait, disturbed bowel	Tremors, sexual dysfunctions, tachycardia, rigidity, clonus	3 mo	Tramadol and amitriptyline for paraesthesia for 1 yr	Normal	Discontinued drugs. Cyproheptadine (4 mg bid) was started. Response began within 48 h. Complete response within 7 d
32, F	Headache, generalized body pain, tremors	Intermittent diaphoresis, tachycardia, rigidity, clonus	2 mo	Valproate (500 mg bid) for 6 mo for epilepsy	CK- 1283 U/L	Marked improvement by cyproheptadine (4 mg tid). Valproate changed to levetiracetam. Follow- up was uneventful
46, F	Slowness in work and gait, bladder dysfunctions, dizziness, tremors	Dizziness, sexual dysfunctions, tachycardia, rigidity, clonus	3 mo	Amitriptyline and citalopram for 1 yr for bipolar disorder	Normal	Discontinued the offending drugs. Cyproheptadine (4 mg tid) for 3 wk. Response began in 48 h. Complete response within 10
58, M	Slowness in gait, pain and stiffness in the limbs and neck, tremors	Nystagmus, tachycardia, rigidity, clonus	10-12 wk	Tramadol, and fluoxetine for 4 mo for carpal tunnel syndrome	CK-879 U/L	Cyproheptadine (4 mg tid) for 2 wk. Response began in 2 d. Complete response within 5-7 d. No recurrence in follow-up
37, F	Tremors, irritability, fatigue, muscle pain, bowel disturbances	Tachycardia, hypertension, hypertonia, clonus	8-10 wk	Amitriptyline and valproate for chronic migraine for 6 mo	Normal	Started cyproheptadine (4 mg bid). Complete response within 4-6 d. Cyproheptadine was continued as an anti-migraine drug
31, M	Gait problems, stiff legs, bowel disturbances	Tremors, spasticity, clonus, diaphoresis	9-10 wk	Paroxetine (40 mg/d) for 6 mo for depression	CK-1279 U/L	Discontinued paroxetine. Cyproheptadine (6 mg tid) for 3 wk
47, M	Insomnia, dizziness, restlessness, bowel disturbance, episodic sweating	Tremor tachycardia, rigidity, clonus, hyperreflexia	3-4 mo	Sertraline and valproate for mood disorder for 9 mo	CK-634 U/L	Discontinued both drugs. Cyproheptadine (4 mg bid) for 4 wk
42, F	Generalized body pain, stiff body, constipation	Tremors, nystagmus, rigidity, stiff neck, hyperreflexia	8-10 wk	Tramadol and amitriptyline for 3 mo for pain after radius fracture	CK-1134 U/L	Started cyproheptadine (4 mg tid). Marked response in 7 d. Cyproheptadine was continued for 6 wk
54, M	Dystonic tremor, incoordination, stiffness in legs, episodic sweating	Tremors, nystagmus, rigidity, clonus, hyperreflexia	6-8 wk	Amitriptyline and tramadol for 3 mo for cervical spondylosis	Normal	Stopped both drugs. Started cyproheptadine (4 mg tid). Complete response in 7 d. Cyproheptadine was continued for 6 wk
61, M	Tremors, stiffness, incoordination, sexual dysfunction, insomnia	Nystagmus, rigidity, clonus, hypertension	4-5 mo	Addicted to tramadol for 2 yr for neuropathic pain	Normal	Marked improvement with cyproheptadine (4 mg tid). The patient did not stop tramadol and he continued cyproheptadine

F: Female; M: Male.

found two cases each with paroxetine and sertraline. There was 1 case each with citalopram and fluoxetine. Creatine kinase levels were raised in 6 patients (43%). Cyproheptadine, a 5HT2A antagonist, is the main drug used in cases of SS, and all patients received cyproheptadine. All patients showed a complete or almost complete response to cyproheptadine over 4–14 d.

Table 2 Epidemiological profiles and clinical features of 14 patients with chronic serotonin syndrome

Parameters	*n* (%)

Sertraline	2 (14)
Citalopram	1 (7)
Fluoxetine	1 (7)

F: Female; M: Male; SD: Standard deviation; SS: Serotonin syndrome.

Case 1

A 21-year-old male was diagnosed with a primary generalized epilepsy disorder and started taking sodium valproate (1000 mg daily) about 2 years prior. Six months ago, he developed progressively increasing tremor, irritability, bradykinesia, rigidity, and gait disturbance. When asked, the patient admitted to having irritability, disturbed sleep, and intermittent diaphoresis. Physical examinations revealed tachycardia (112 beats/min), postural tremor of both hands, rigidity in the limbs, generalized hyperreflexia, and inducible ankle clonus. Haematological and biochemical investigations (including valproate level, ceruloplasmin level, urinary copper, and

thyroid function profiles) were normal. Magnetic resonance imaging brain, electroencephalography, and cerebrospinal fluid examination revealed no abnormalities. The patient fulfilled the Hunter criteria for SS. Initially, the patient refused to discontinue valproate as he was afraid of a recurrence of seizure. Cyproheptadine was started (4 mg daily) and titrated up to 4 mg three times daily. The symptoms gradually improved, and abnormal physical examinations (tachycardia, tremor, rigidity, hyperreflexia, and clonus) returned to normal in 10-12 d. Cyproheptadine was discontinued after 3 wk. However, the symptoms gradually reappeared, which again disappeared on readministration of cyproheptadine. Later, valproate was changed to levetiracetam. There was no recurrence of the similar symptoms at 9 mo follow-up.

Case 2

A 47-year-old man had been receiving amitriptyline (25 mg daily) and tramadol (50 mg twice daily) for diabetic neuropathy for about 9 mo. About 5-6 mo ago, he developed an insidiously progressive tremor of both hands, generalized body pain associated with stiffness, and sleep disturbances. The patient also reported irritability, disturbed bowel functions, dizziness, and intermittent diaphoresis. Physical examination revealed tachycardia (104 beats/min), hand tremors, rigidity in all four limbs, hyperreflexia, and ankle clonus. Haematological and biochemical investigations were normal. Magnetic resonance imaging brain and electroencephalography revealed no abnormalities. The patient fulfilled the Hunter criteria of SS. Amitriptyline and tramadol were discontinued, and cyproheptadine was administered (4 mg thrice daily). The clinical features improved significantly over 5-6 d and disappeared in 2 wk. The symptoms did not recur in the 6-mo follow-up.

Case 3

A 36-year-old man, on paroxetine (40 mg daily) and amitriptyline (25 mg daily) for obsessive-compulsive disorder for 18 mo, developed insidiously progressive upper limbs tremor and rigidity of the lower limbs associated with gait difficulty. In parallel, he had sleep disturbances, irritability, and generalized body pain. The symptoms gradually increased in the last 4-5 mo. Physical examinations revealed tachycardia (102 beats/min), coarse postural tremor of both upper limbs, rigidity in the lower limbs, generalized hyperreflexia, and ankle and knee clonus. Biochemical parameters and neuroradiological investigations were unremarkable. The patient feared a recurrence of obsessive-compulsive disorder, so we did not attempt to discontinue paroxetine and amitriptyline. He was started on cyproheptadine (4 mg thrice daily). The patient noted an almost complete improvement in 7-8 d. Cyproheptadine was discontinued after 3 wk, but symptoms reappeared in 3-4 wk. Reintroduction of cyproheptadine provided complete cessation of the symptoms. The patient preferred to continue cyproheptadine, and paroxetine and amitriptyline as well. There was no recurrence of similar symptoms in 12 mo follow-up.

DISCUSSION

All patients met the Hunter clinical criteria of SS, and at the same time, each patient showed a positive response to cyproheptadine. Therefore, we believe that these patients had SS. There was no better alternative diagnosis for any of these 14 cases, as no biochemical or other abnormalities were found in any of the patients indicating any other pathology. The disappearance of generalized body pain, insomnia, gait problems, bowel problems, dizziness, sexual dysfunctions, incoordination, and fatigue after receiving cyproheptadine suggests that this symptom complex was the part of SS spectrum. Fever and agitation are important clinical features in both criteria of SS[7,8]; however, none of our patients had any of these two symptoms. Patients with fever and agitation often seek immediate care in the hospital. As we included only chronic cases, fever and agitation were not the part of the symptom complex in our patients.

SS typically presents within 24 h of initiation or change in the dose of serotonergic agents, and it may evolve very rapidly, leading to death within a few hours[1,6]. However, mild cases of SS (tremor with hyperreflexia and hypertonia) may be ignored by patients and doctors, and patients can continue to take serotonergic drugs for a longer period. Such patients may represent the chronic variant of SS. We reviewed the literature to find cases of SS having an indolent course or chronic SS. Alnwick[3] reported a 42-year-old female patient who had been on antidepressants for a long period. She developed generalized body pain, including headaches, and received a

diagnosis of fibromyalgia. Unfortunately, she received several additional serotonergic agents over the years. A careful observation raised the possibility of SS, and the discontinuation of the offending drugs led to complete improvement. Lamberg *et al*[4] reported a 41-year-old woman who received various serotonergic agents over the years for generalized body pain. She developed various other symptoms over the years, including aggravation of pain, hand tremors, dyskinesia, and insomnia. A detailed examination revealed the presence of clonus, hyperreflexia, and tremor, fulfilling the Hunter criteria of SS[4]. Chechani[9] reported a patient who had four episodes of SS over 3-4 years. In one episode, tremors persisted for 6 wk before the development of full-blown SS. Moreover, tremors and muscle pain persisted for about 2 mo, even after the withdrawal of the serotonergic agent (fluoxetine). This case highlights that tremors and myalgia may persist for a long period. Prakash *et al*[5] reported a patient who had been on various serotonergic agents for more than 2 years after a road traffic accident. He developed various new symptoms, which were considered to be sequelae of the road traffic accident. A detailed examination suggested a possibility of SS, and discontinuation of serotonergic agents and administration of cyproheptadine led to complete resolution of the symptoms.

In the present case series, we included those patients in whom the disease started insidiously, and the duration of illness was longer (mean duration of illness-13.5 wk, range: 6-24 wk), indicating a chronic pattern. Generalized body pain, stiffness of the limbs, insomnia, dizziness, and irritability were the common presenting features. Such nonspecific symptoms are often ignored by patients, and even physicians do not take these symptoms seriously and attribute such symptoms to underlying primary disorders or associated somatic complaints or nonspecific drug-induced side effects. Several studies have reported tremors and other nonspecific symptoms as common side-effects of serotonergic agents. However, these studies are silent regarding the presence or absence of hyperreflexia and clonus. Such side effects are frequently misdiagnosed as drug-induced tremors, drug-induced parkinsonism, or extrapyramidal syndrome. Five patients in our series received sodium valproate. Sodium valproate is known to cause SS, parkinsonism, and isolated tremor. In Armon *et al*[10] case series on valproate-induced parkinsonism, approximately 44% of patients had upper motor neuron (UMN) signs. Cognitive disturbances are also very common in valproate-induced parkinsonism. Autonomic features have also been noted in some cases of valproate-induced parkinsonism[11]. Therefore, a subset of valproate-induced parkinsonism patients may also satisfy the Hunter criteria. In addition, most of the cases of valproate-induced parkinsonism have insidious onset and chronic course. Therefore, the possibility of chronic SS exists in a subset of patients with valproate-induced parkinsonism. Various selective serotonin reuptake inhibitors and other serotonergic agents are known to cause tremors and parkinsonism-like symptoms[12,13]. Most of these observations did not mention anything about UMN signs. Since examination for clonus is not a regular phenomenon in clinical practice, it is possible that a subset of such patients may have hyperreflexia or inducible clonus, fulfilling the criteria of SS. So, the number of actual cases of chronic cases of SS may be much higher than the actual reported cases in the literature.

The clinical manifestations of SS depend on the degree of elevation of the intrasynaptic concentration of serotonin. The mild elevation of serotonin in the central nervous system leads to hyperreflexia, inducible clonus, tremors, anxiety, and restlessness[2]. The most important feature in the Hunter criteria is the presence of upper motor signs (spontaneous clonus, inducible clonus, hyperreflexia, and hypertonia). Unfortunately, the Hunter criteria are silent about the UMN related symptoms or complaints. Hypertonia and other UMN signs typically induce musculoskeletal complaints, such as pain, stiffness, slowness in the movement, tiredness, and fatigue[14]. We hypothesize that mildly elevated serotonin for a long period in the central nervous system will induce sustained UMN symptoms and signs. Persistent hypertonia or spasticity usually manifests as stiffness/rigidity, muscle pain, and functional disability. This may be a possible explanation for the presence of generalized body pain, stiffness of the limbs, gait problems, and fatigue noted in our observations and other case series. Irritability, dizziness, and insomnia may be related to mild cognitive abnormalities due to raised intrasynaptic serotonin concentration[2].

Although SS typically develops rapidly after ingestion of serotonergic drugs, our observations suggest that a subset of patients may have mild and chronic forms. A diagnosis of SS is important even in mild and indolent form, as it is not supposed to resolve spontaneously as long as serotonergic drugs are administered. Furthermore, it may progress rapidly to death by an inadvertent increase of the dose or addition of another serotonergic agent.

Limitations

This report is a retrospective study and a possibility of unrecognized selection bias exists. We reviewed the clinical features in patients with insidious onset SS. So, these are not truly representative of typical cases of SS. Although all patients fulfilled the Hunter criteria, we cannot rule out a possibility of other causes as the full evaluation was not done on each patient.

CONCLUSION

SS is not rare in clinical practice. However, various aspects of this syndrome need to be explored. Herein, we suggest that chronic SS is not rare in clinical practice, and patients may present with non-specific clinical symptoms. We suggest that patients who are on serotonergic drugs should be physically examined for the presence of clonus and other related signs upon the development of any new symptom to rule out SS.

ARTICLE HIGHLIGHTS

Research background

Serotonin syndrome (SS) is a life-threatening condition, and the clinical features largely depend on the degree of elevation of the intrasynaptic concentration of 5-hydroxytryptamine or serotonin. Mild elevation of serotonin levels causes mild serotonin toxicity and manifest as hyperreflexia, inducible clonus, tremors, anxiety, and restlessness. We hypothesize that mild SS may remain unnoticed for a longer duration and will manifest as insidious onset nonspecific symptoms.

Research motivation

Only very limited data are available about chronic SS. We believe that the diagnosis of chronic SS is important. Increasing the dose of a serotonergic agent or adding another serotonergic agent to a patient with chronic SS can be serious and fatal.

Research objectives

To describe the epidemiological, clinical, and other aspects of chronic SS.

Research methods

We retrospectively evaluated 14 consecutive adult patients (> 18 years) who had presenting complaints for more than 6 wk at the time of the first consultation and fulfilled the Hunter criteria of SS.

Research results

We identified 19 patients who met the inclusion criteria. Five patients were excluded for various reasons, and finally, the records of 14 cases were analysed. The mean age was 41.1 years (range: 21-61 years), with a male preponderance (64%). Generalized body pain, insomnia, and restlessness were common presenting features. The mean duration of symptoms before getting the diagnosis of SS was 13.5 ± 5.8 wk. Amitriptyline was the most common drug, followed by tramadol and sodium valproate. The response to cyproheptadine was satisfactory in all patients.

Research conclusions

Patients with chronic SS may have nonspecific symptoms. A detailed drug history and thorough physical examinations are essential to clinch the cases of chronic SS.

Research perspectives

The incidence of SS is increasing because of the widespread use of serotonergic drugs. There is a need to improve the awareness about SS among the physicians for early recognition and effective management.

Abstract

BACKGROUND

The perinatal period is a challenging time of substantial emotional, physiological, social, and relational changes. Depression, anxiety, and stress symptoms are common, and co-exist in the perinatal period. Digital technology continues to grow at an unprecedented pace with wide application, including psychotherapeutic intervention. A growing number of meta-analyses supported the application of digital psychotherapeutic intervention across different populations, but relatively few meta- and meta-regression analyses have concentrated on perinatal women.

AIM

To evaluate the effectiveness of digital psychotherapeutic intervention on improving psychological outcomes among perinatal women and identify its essential features.

METHODS

Randomized controlled trials (RCTs) were obtained from eight databases, including Cumulative Index to Nursing and Allied Health Literature, Cochrane Library, Embase, Scopus, PsycINFO, PubMed, Web of Science, and ProQuest Dissertation and Theses from inception up until November 24, 2020. Comprehensive Meta-analysis 3.0 software was used to conduct meta- and meta-regression analyses. The Cochrane risk-of-bias tool and the Grading of the Recommendation, Assessment, Development, and Evaluation system were adopted to assess the individual and overall qualities of the evidence, respectively.

RESULTS

A total of 25 RCTs that included 3239 women were identified. Meta-analyses revealed that intervention significantly improved depression (Hedges's g = 0.49), anxiety (g = 0.25), and stress (g = 0.47) symptoms compared to the control. Subgroup analyses demonstrated that a website platform with ≥ eight therapist-guided sessions using the theoretical principle of cognitive behavioral therapy was more effective than other treatments in improving depression symptoms in postnatal women. Meta-regression analyses observed that the age of perinatal women and the type of psychotherapy also had statistically significant effects on depression symptoms. Egger's regression asymmetry tests suggested that no publication biases occurred, but the overall quality of the evidence was very low.

CONCLUSION

This review suggests that digital psychotherapeutic intervention may be a potential solution to reduce psychological problems in perinatal women. Further high-quality RCTs with large sample sizes are needed.

Key Words: Digital psychotherapeutic intervention; Perinatal women; Meta-analysis; Meta-regression

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This systematic review identified and analyzed the findings of 25 randomized controlled trials, and the results indicated that digital psychotherapeutic intervention could significantly reduce depression, anxiety, and stress symptoms among perinatal women. The essential features of this intervention were a website platform with ≥ eight therapist-guided sessions using the cognitive behavioral therapy theoretical principle. This intervention was also effective in reducing depression symptoms when treating young postnatal women. The overall evidence grade of outcomes was very low according to the Grading of Recommendations, Assessment, Development, and Evaluation criteria. Thus, future trials need to include a high-quality design and a large sample size.

INTRODUCTION

Perinatal period is a challenging time of substantial emotional, physiological, social, familial, and role changes[1,2]. These changes may affect psychological and physical resources, resulting in increased susceptibility of psychological problems, including depression, anxiety, and stress[3]. A systematic review observed that depression, anxiety, and stress symptoms co-existed in the perinatal period[4]. The prevalence in the perinatal period was estimated to be 7.4%-12.8% for depressive disorders[5], 3%-6% for anxiety disorders[6], and 3.3%-4.0% for posttraumatic stress disorders[7]. Perinatal mental disorders during pregnancy and postpartum period are associated with considerable maternal, infant, and child morbidity and mortality[8-10]. In addition, they lead to huge economic burden on health and social care[3]. Therefore, effective intervention is imperative. Psychotherapeutic intervention is considered a highly effective intervention for depression, anxiety, and stress[11].

Psychotherapeutic interventions are based on several principles, including cognitive behavioral therapy (CBT)[12], mindfulness therapy[13], problem-solving therapy[14], stress-reduction therapy[15], psychoeducation intervention[16], or their combination. The assumption of CBT is that dysfunctional cognitive patterns result in emotional distress and subsequent maladaptive behavior[12]. CBT aims to improve psychological outcomes by helping women learn how to recognize and modify destructive thought

patterns[12]. Mindfulness therapy suggests that negative psychological outcomes are due to automatic reaction[13]. It works by training women to react to things differently, and it involves the awareness of existing thoughts, emotions, and sensations to cultivate acceptance of every moment[13].

The core assumption of problem-solving therapy is that psychological symptoms are generated when women become overwhelmed by practical problems they face in their daily lives[14]. This type of therapy aims to help perinatal women by teaching structured means to solve their problems, which in turn alleviate their psychological outcomes[14]. Stress-reduction therapy focuses on stress management that helps women develop skills to manage, cope with, and reduce stress to promote well-being[15]. Psychoeducation intervention integrates and synergizes psychotherapeutic and educational components to help women deal with problems[16]. Psychoeducational techniques are used to improve awareness of cognitive distortions, communication, and problem-solving skills by providing information in a proactive fashion[16].

Empirical evidence suggests that CBT[17], mindfulness therapy[18], problem-solving therapy[19], stress-reduction therapy[20], and psychoeducation intervention[21] using face-to-face approach is effective in improving psychological outcomes among perinatal women. However, traditional face-to-face psychotherapeutic interventions may reduce effectiveness due to structural and psychological barriers[22-24]. Structural barriers include insufficient mental health professionals, difficulties booking appointments, and transportation problems[24,25]. Psychological barriers could arise due to the lack of motivation and self-stigmatization to seek treatment or overestimated barriers to seek treatment[26,27].

Digital technology continues to grow at an unprecedented pace with wide application, including psychotherapeutic intervention[28,29]. Psychotherapeutic intervention is considered as digital when technology, such as website, mobile application, email, or text messaging services, is used in its delivery[28]. Given that 80% of the population own mobile phones and 50% have access to the Internet[30], the use of digital technology in psychotherapeutic interventions has increased rapidly over the past several years[28]. Digital psychotherapeutic interventions essentially allow for improved connectivity, accessibility, and availability of support[31]. With the interventions being delivered online, a potential exists for a larger audience to receive these interventions because they could likely be accessed regardless of geographical location[31]. The option of implementing online programs helps mitigate the problem of insufficient healthcare professionals and reduce waiting times[22]. Thus, digital psychotherapeutic interventions could be comparatively more cost effective than other interventions[32]. Another important benefit is that digital psychotherapeutic interventions may be more attractive to individuals who may not feel comfortable with being out in public places or are reluctant to seek treatment due to social stigma[33].

Digital psychotherapeutic intervention aims at alleviating psychological symptoms with different assumptions and mechanisms in accordance with the different principles of psychotherapy. Figure 1 illustrates the possible mechanisms by which digital psychotherapeutic intervention could improve depression, anxiety, and stress symptoms in perinatal women. These mechanisms were proposed by extracting the frameworks of CBT[12], mindfulness therapy[13], problem-solving therapy[14], stress-reduction therapy[15], and psychoeducation intervention[16]. Perinatal women experienced psychological problems due to dysfunctional thoughts[12], automatic reaction[13], being overwhelmed by problems[14], perceived stress[15], and knowledge deficit[16]. They may learn how to modify destructive thought patterns[12], improve awareness[13], solve problems[14], reduce stress[15], and enhance their knowledge[16]. The use of digital technology could improve the connectivity, accessibility, and flexibility of psychotherapeutic intervention in accordance with a wide array of functions of digital platform[28,29,31]. Besides, the digitalization of psychotherapy could reduce time strain, stigma, and personnel costs[22,32,33]. Consequently, perinatal women may alleviate their depression, anxiety, and stress symptoms.

A growing number of systematic reviews[28,34,35] have supported the effectiveness of digital psychotherapeutic intervention among college students[35], patients with serious mental illness[34], and young adults[28]. However, relatively little is known about its effectiveness in the perinatal population. Previous reviews[36-38] have investigated the potential effect of digital psychotherapeutic intervention among perinatal women. However, these reviews were limited to few selected trials[37,38], a mixture of different research designs[36-38], few databases[37], and only narrative synthesis[37]. None of these reviews investigated the preferred features and the overall evidence. In addition, none of them used meta-regression analysis to assess the influence of covariates on their effect size. Thus, the effectiveness and essential features of digital psychotherapeutic

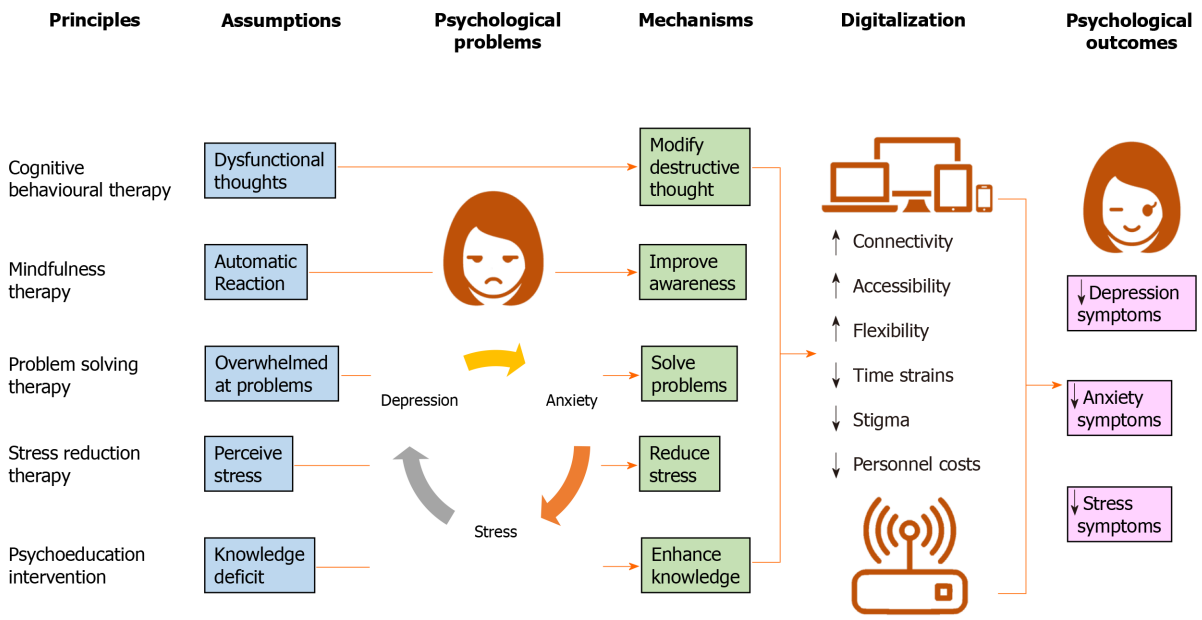

Figure 1 Potential mechanisms of digital psychotherapeutic intervention in improving psychological outcomes.

intervention among perinatal women remain unclear.

In light of the abovementioned limitations of the existing systematic reviews[36-38], the present review aims to synthesize the best evidence to (1) assess the effectiveness of digital psychotherapeutic intervention in reducing depression, anxiety, and stress symptoms; (2) evaluate the preferred design features of the intervention.

MATERIALS AND METHODS

The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines was followed[39]. This review was registered in the PROSPERO database at the Centre of Reviews and Dissemination in the United Kingdom (CRD42021226534).

Eligibility criteria

All types of randomized controlled trials (RCTs) were included because of the strongest empirical evidence of the intervention's effectiveness[40]. Published and unpublished trials in the English language without restriction to publication year were included to maximize the search scope. A description of the eligibility criteria is summarized in Supplementary Table 1. The RCTs were selected on the basis of their fulfilment of the Participants, Interventions, Comparisons, Outcomes, and Study design framework[39]. The population involved perinatal women aged 18 years and older from the start of pregnancy to first-year postpartum. The psychotherapeutic interventions were included if the content design was based on the CBT theoretical principle[12], mindfulness therapy[13], problem-solving therapy[14], stress-reduction therapy[15], psychoeducation intervention, or their combination and if they were delivered *via* website or/and mobile application[28]. The comparators or counterparts consisted of treatment as usual, waitlist control, or placebo control. Outcomes were depression, anxiety, and stress symptoms.

Searching strategies

A scoping search was conducted in the Cochrane Central Register of Controlled Trials, Joanne Briggs Institute Evidence Synthesis, and PROSPERO databases to prevent duplication of similar systematic reviews. A senior librarian was consulted regarding the search strategy. A comprehensive three-step search strategy was conducted in congruence with the recommendations of the Cochrane Handbook for Systematic Reviews of Interventions[41]. First, a search of published literature up until November 24, 2020 was conducted using keyword and index terms in eight electronic databases as follows: Cumulative Index to Nursing and Allied Health Literature, Cochrane Library, Embase, Scopus, PsycINFO, PubMed, Web of Science, and ProQuest

Dissertation and Theses, as shown in Supplementary Table 2. Next, ongoing trials from various clinical trial registries (ClinicalTrials.gov, World Health Organization International Clinical Trials Registry Platform, and ISRCTN Registry) were explored. Lastly, the bibliographies of RCTs and systematic reviews were hand-searched using snowballing. In addition, specific journals and different grey literature resources (Google Scholar and GreySource) were checked to ensure the comprehensiveness of the search[42].

Study selection

Study selection was conducted in accordance with the PRISMA flow diagram[39]. EndNote X9 (version 9.3.3) software[43] was used to import all identified citations and remove duplicates. After records from the databases were identified, two independent reviewers (JYC and KYY) screened the titles and abstracts for relevance. Full-text articles of eligible studies were retrieved and examined by the two reviewers independently on the basis of eligibility criteria. Differing responses were discussed and referred to a third reviewer (YL). Reasons for excluding trials in the full-text screening stage were recorded. A Kappa statistic (κ) larger than 0.6 was computed to determine an acceptable inter-rater agreement[44].

Data extraction

A standardized data extraction form was developed and piloted in accordance with the Cochrane Handbook for Systematic Reviews of Intervention[41]. The items extracted in relation to the characteristics of the trials included study setting, city/country, study design, sample size, participants' age (mean and standard deviation), sample size, intervention (name), comparator, outcome (measure), attrition rate, grant support, intention to treat (ITT), missing data management, published protocol, and registration. The items involving digital psychotherapeutic intervention included aim, types, component, platform, regime (length, number of sessions, frequency, duration, and follow-up), guidance (from therapist/self), and theoretical basis. Dichotomous or continuous psychological outcomes, such as depression, anxiety, and stress symptoms at post-intervention, were extracted. The authors of the selected trials were contacted to obtain unpublished data or clarify questionable information.

Quality assessment

The Cochrane Collaboration risk-of-bias tool[45] was adopted to individually evaluate the quality of the trials. Two reviewers (JYC and KYY) conducted the assessments independently to minimize errors[41]. Selection, performance, detection, attrition, and reporting biases were assessed using the following six domains: (1) Random sequence generation; (2) Allocation concealment; (3) Participant and personnel blinding; (4) Outcome assessment blinding; (5) Incomplete outcome data; and (6) Selective reporting. The risk for each author was graded as low, high, or unclear. The attrition rate, ITT, missing data management, published protocol, and registration of selected trials were investigated to further assess the quality of evidence.

The Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) checklist[46] was adopted to judge the overall quality and strength of the recommendations by using GRADEpro 3.6 software[47]. The overall evidence was graded as high, moderate, low, or very low in accordance with five aspects: Methodological limitations, inconsistency, indirectness, imprecision, and publication bias[48]. Publication bias was evaluated through visual inspection of the funnel plot asymmetry[49] and Egger's test[50] when each outcome included 10 or more trials.

Statistical analysis

Comprehensive Meta-Analysis software (version 3)[51] was used for meta-analyses. The random-effect model was also used because it accounts for the statistical assumption of variation in the estimation of mean across all trials[52]. The overall effect was computed using Z-statistics at a significance level of $P < 0.05$. The pooled mean effect sizes of psychological outcomes were estimated using Hedges' g, which provides an accurate estimation of the overall effect size when the included trials have small sample sizes[53]. The effect size was interpreted as small (0.2), medium (0.5), large (0.8), and very large (1.2)[54].

The inverse-variance statistical method was utilized to compute continuous outcomes[41]. Heterogeneity was evaluated on the basis of the Cochran Q test, in which $P < 0.10$ indicates the presence of significant statistical heterogeneity[41]. The I^2 statistic was used to quantify the degree of heterogeneity, in which I^2 indicates the variation percentage[55], such as 0%-40% (may not be important), 30%-60% (moderately

important), 50%-90% (substantially important), and 75%-100% (considerably important)[56].

Additional analysis

Sensitivity analyses were conducted to identify heterogeneous trials that were removed to maintain overall homogeneity[57]. Subgroup analyses were also performed to reduce the overall heterogeneity across studies (I^2 > 40%)[58] and compare the effects among various populations, settings, and features of intervention[59]. The predefined subgroups included population nature, theoretical principle, digital platform, aim of intervention, guidance, and number of sessions.

Meta-regression analysis was conducted to explain whether the heterogeneity between trials could be attributed to covariates[60]. A random-effect meta-regression model was used to assess if the year of publication, mean age, sample size, type of psychotherapy, number of sessions, and duration influenced the effect size of digital psychotherapeutic intervention. A significance level of P < 0.05 was used for the random-effect meta-regression analysis. Narrative synthesis of outcomes was performed when meta-analysis could not be conducted on the data.

RESULTS

Study selection

Figure 2 illustrates a PRIMSA flowchart of the selection of trials. A total of 34249 articles were identified from eight databases, and 8046 duplicates were removed using Endnote. Six additional records obtained from snowballing were included. After screening was conducted by two independent reviewers (JYC and KYY), 26167 articles were excluded in accordance with their titles and abstracts, and 42 full-test articles were selected for eligibility. Twenty-five RCTs were eventually selected. Among them, 24 were international peer-reviewed articles[61-84] and one was an unpublished doctoral dissertation[85]. Moderate agreement was reached between the dyad raters (κ = 0.78).

Characteristics of included randomized controlled trials

Table 1 summarizes the characteristics of 3239 perinatal women in the 25 included RCTs from 2009[85] to 2020[77] in Australia[73,75], Canada[81], China[84], Germany[70,71], Iran[67], Netherlands[66,76,76], Portugal[64], Scotland[72], Singapore[68], Sweden[65,74,78], Switzerland[82,83], the United States of America[62,63,69,85], the United Kingdom[79,80], and 23 countries[61]. The RCTs were two armed (k = 22) or three armed (k = 3)[67,68,74]. They were conducted in hospital (k = 2)[68,84] or in the community (k = 23). The populations studied included healthy antenatal[61,62,74,76,77] and postnatal[68,85] women and women who experienced psychological problems[64-67,73,75,77-81,84], insomnia[63,69], preterm labor[82,83], miscarriage[72], or pregnancy loss[70,71]. The sample size ranged from 25[62] to 910[80]. The mean age was between 27.7[67] and 34.6[78] years.

Risk of bias

A risk-of-bias summary is shown in Supplementary Figure 1 with moderate inter-rater agreement (κ = 0.72). Among the 25 included RCTs, 53.33% had low risk of bias across six domains. More than half (56%) had unclear allocation concealment. The participants and personnel in the majority of trials were not blinded (92%). Assessment of the outcomes was also not blinded in most trials (72%). Eleven RCTs[61,70-72,74,78-80,84,85] did not have published protocols nor were registered in any clinical trial registry. Therefore, 44% of the reported bias was unclear. The attrition rates ranged from 1.1%[69] to 66.1%[61]. The majority of trials used ITT analysis (68%) and mentioned missing data management (60%).

Digital psychotherapeutic intervention

A detailed description of digital psychotherapeutic intervention for the 25 trials is presented in Supplementary Table 3. The aims of intervention were divided into prevention and treatment using CBT principles, mindfulness therapy, problem-solving therapy, stress-reduction therapy, psychoeducation intervention, or the combined version. The interventions were mainly delivered *via* website (k = 22) or mobile application (k = 4)[63,67,77,84], and some of them were supplemented with email, phone call, short messaging service, or home visit. The elements consisted of counselling, education, advice, assignment, feedback, reminder, forum, support, self-monitoring, questions, and answers. The interventions lasted between 10[62] and 90[61] min and

Table 1 Characteristics of selected 25 randomised controlled trials

Ref.	Country/setting	Design	Population (nature)	Age (mean ± SD)	Intervention (name)	Comparator	Sample size	Outcome (Measures)	Attrition rate (%)	ITT/MDM	Protocol/registry	Grant

ranged from three sessions[73] to 12 sessions[79] for 3[74]-15[80] wk. They were either self-guided (k = 7)[61,64,65,67,73,83,85] or therapist-guided (k = 18). The majority of them reported follow-up assessment (k = 19) a using theoretical basis (k = 23).

Depression symptoms

A total of 19 RCTs[62,65-76,78-81,84,85] considered depression symptoms as the outcome among 1736 perinatal women by using various measures. Meta-analysis results observed that digital psychotherapeutic intervention had a medium effect size (g = 0.49) in alleviating depression symptoms significantly (Z = -3.75, P < 0.001) compared with the control. Figure 3 illustrates the pooled results of meta-analysis using the random-effect model. Sensitivity and subgroup analyses were conducted given the considerable heterogeneity (I^2 = 84.41). However, the heterogeneity remained unexplained.

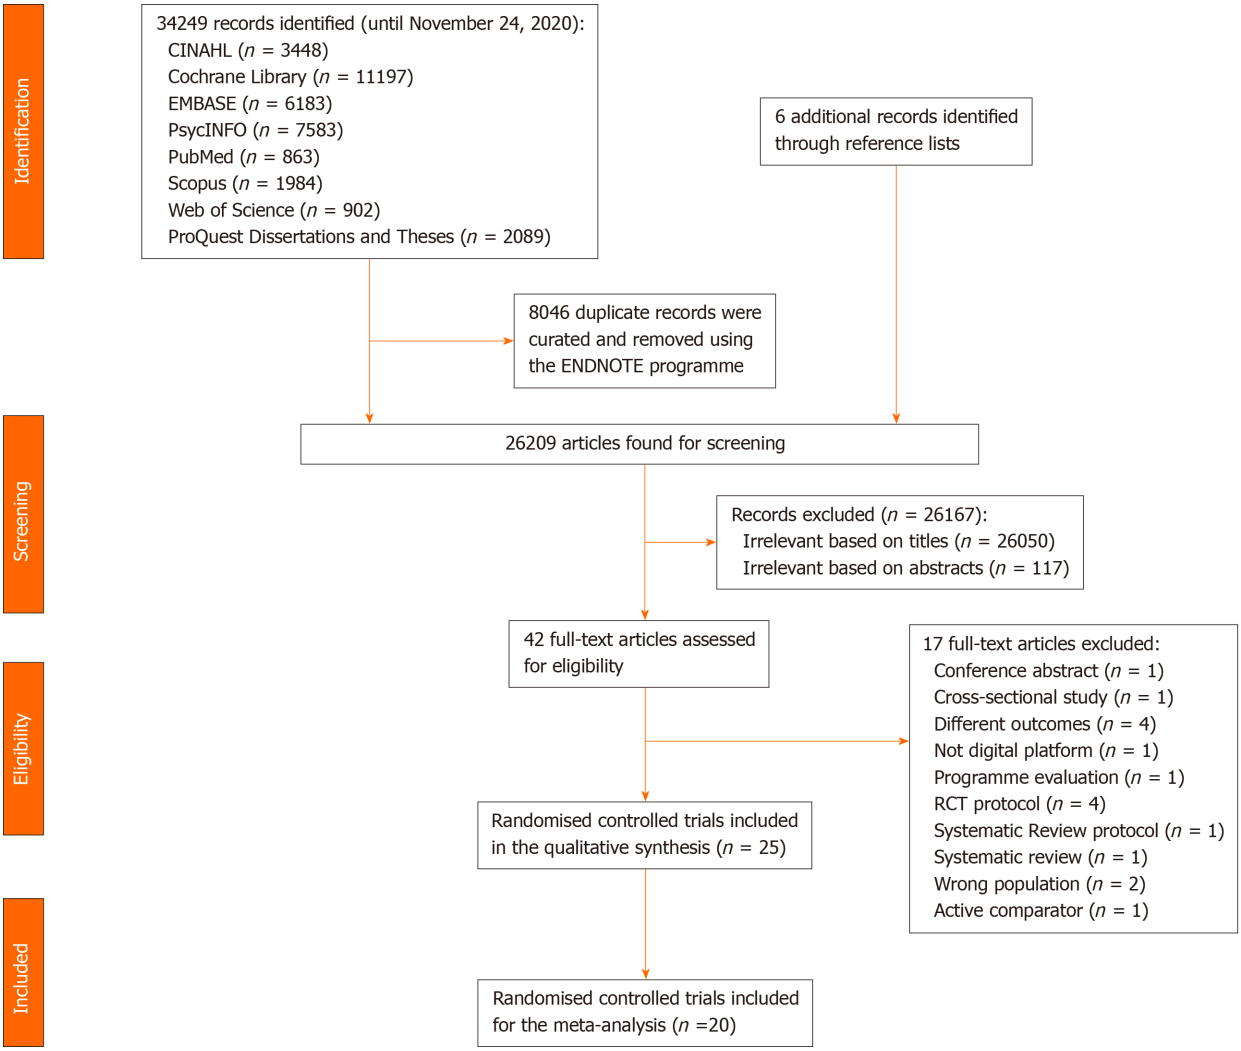

Figure 2 Study selection.

Subgroup analyses

A series of subgroup analyses was conducted (Table 2) on the basis of population nature, theoretical principle, digital platform, aim of intervention, guidance, and number of sessions. The effect sizes were greater and significant among postnatal women (g = 0.67) than antenatal women (g = 0.24). Subgroup analyses demonstrated that the essential features of the intervention, that is, the use of CBT principle only (g = 0.56) *via* a website platform (g = 0.32) for the purpose of treatment (g = 0.71) were significant. Therapist-guided intervention (g = 0.40) and ≥ eight sessions were more effective than their counterparts. However, no significant subgroup differences (P = 0.09–0.54) were found.

Meta-regression analyses

Univariate and multivariate random-effect regression was performed to examine whether the effect size magnitude was related to covariates (year of trials, age, sample size, number of sessions, type of psychotherapy, and duration of intervention), as shown in Table 3. The results of univariate and multivariate random-effect regression analyses showed that age (β = 0.18, P = 0.02; β = 0.14, P = 0.04, respectively) and the use of CBT (β = 0.07, P < 0.001; β = 0.07, P < 0.001, respectively) had significant effects on depression symptoms. The Q-value for the multivariate random-effect regression model was 68.76, with df = 16 and P < 0.001. Thus, the null hypothesis was rejected, and the effect size was related to covariates. The explained variance (R^2 = 0.364) was calculated using the regression model, and it revealed that 36.40% of the variance in true effects could be explained by these two covariates. Two bubble plots of depression symptoms on age and types of psychotherapy are presented in Supplementary Figure 2. The multivariate meta-regression model suggested that younger perinatal women who received CBT showed a larger effect size in terms of

improving depression symptoms than older perinatal women who received other psychotherapies. However, covariates such as year of trial, sample size, number of sessions, and duration of intervention had no effect on these symptoms.

Anxiety and stress symptoms

Fourteen RCTs[65,66,70-73,75,76,78,79,81,82,84,85] assessed the effectiveness of digital psychotherapeutic intervention in 1091 perinatal women by using anxiety as an outcome. Meta-analysis results indicated that digital psychotherapeutic intervention exerted a significant effect on improving anxiety symptoms (Z = -5.72, P = 0.007), with a small effect size (g = 0.25), as shown Figure 4. Moderate heterogeneity (I^2 = 50.70%) was also found. Another 10 RCTs[70,71,73-76,78,81,82,85] used stress as an outcome in 720 perinatal

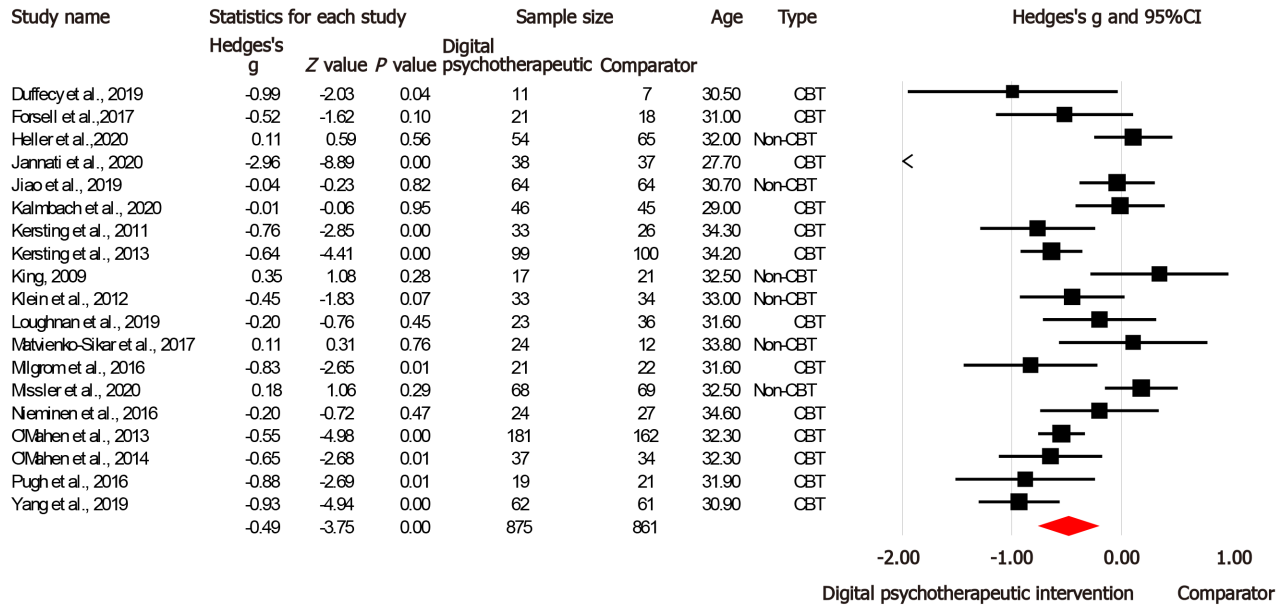

Figure 3 Forest plot of Hedges's *g* (95% confidence interval) in depression symptoms for digital psychotherapeutic intervention and comparators.

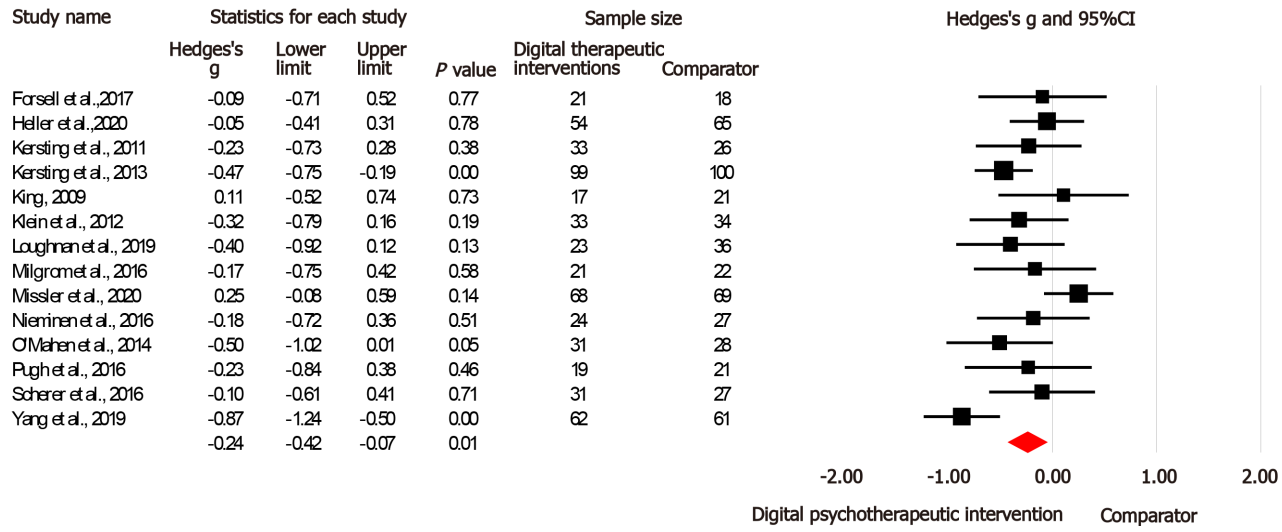

Figure 4 Forest plot of Hedges's *g* (95% confidence interval) in anxiety symptoms for digital psychotherapeutic intervention and comparators.

women. Meta-analysis results demonstrated that stress symptoms were significantly reduced (Z = -2.90, P < 0.001) in the intervention group with a medium effect size (g = 0.47) compared with the comparator (Figure 5). Considerable heterogeneity (I^2 = 75.34%) was also revealed. Sensitivity and subgroup analyses were conducted to decrease the I^2 in both outcomes, but the heterogeneity did not improve.

Narrative synthesis

Given that five trials[61,63,64,77,83] did not report inadequate data for pooling of data in the present meta-analysis, the authors were contacted three times to ask for supplementary data on the psychological outcomes. Unfortunately, the team did not receive any reply. Thus, narrative synthesis was conducted. One trial[63] showed that digital CBT considerably reduced depression and anxiety symptoms. However, one trial[62] did not clearly report psychological outcomes after intervention, and another three[61,77,83] suggested that the intervention did not significantly improve the psychological outcomes. These inconsistencies indicated the need for further investigation.

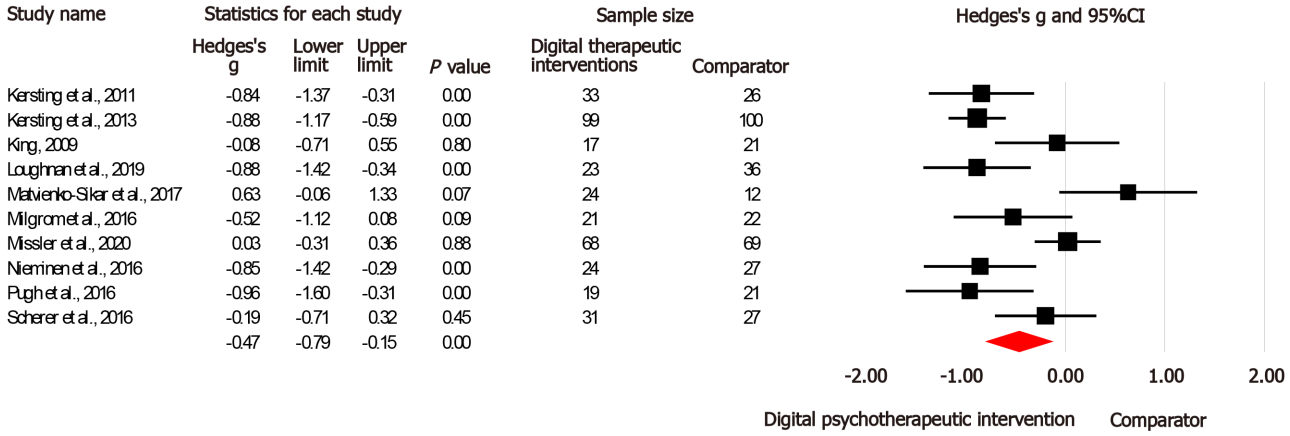

Figure 5 Forest plot of Hedges's *g* (95% confidence interval) in stress symptoms for digital psychotherapeutic intervention and comparators.

Overall evidence

In accordance with the GRADE criteria, the overall quality of evidence was graded as very low (Supplementary Figure 2). For the outcome measures of depression, anxiety, and stress symptoms, methodological limitations were downgraded because of performance, selection, and detection biases. Inconsistency was downgraded because of moderate to considerable heterogeneities (50.70%–84.41%). Indirectness was downgraded due to the variation in digital psychotherapeutic interventions. Imprecision was downgraded because of small sample size with wide confidence intervals. Publication bias was not detected for trials that reported depression, anxiety, and stress scores, as observed from the symmetrical distribution of the included trials on the funnel plots (Supplementary Table 4). The *P* value of Egger's regression asymmetry tests ranged from 0.24 to 0.33, thereby suggesting no evidence of publication bias.

DISCUSSION

This review revealed statistically significantly lower depression, anxiety, and stress symptom scores with small to medium effect in digital psychotherapeutic intervention than in the comparators. Subgroup analyses identified that the essential features of the intervention, that is a website platform with ≥ eight therapist-guided sessions using CBT principle for treatment among postnatal women appeared to be more effective in improving depression symptoms than their counterparts. Meta-regression analyses observed that the age of perinatal women and the type of psychotherapy had statistically significant effects on depression symptoms.

The findings revealed that digital psychotherapeutic interventions were effective in improving depression, anxiety, and stress symptoms among perinatal women. These results are consistent with those of previous reviews[36-38]. They could explain the proposed mechanistic pathways linking digital psychotherapeutic intervention to psychological outcomes (Figure 1). Digital psychotherapeutic interventions aid perinatal women to modify their dysfunctional thoughts[12], ameliorate their level of awareness[13], enhance their problem-solving skills[14], deal with stress[15], and acquire further knowledge[16]. Such principles of psychotherapy help build resilience, as women are able to learn and strengthen their cognitive flexibility[86]. Digital platform allows for improving connectivity, accessibility, and availability[31]. Moreover, it could reduce the time constraint, social stigma, and cost[22,32,33]. The components of digital psychotherapeutic interventions involve reminders, forums, and self-monitoring; they help enhance the ability of women to actively adapt to their circumstances and improve their abilities to cope with stressful perinatal situations[87]. As a result, perinatal women may improve their depression, anxiety and stress symptoms.

Subgroup and meta-regression analyses highlighted that the use of the CBT principle, therapist support, and ≥ eight sessions using website platform for treatment among postnatal young women could optimize the intervention effect. Efficacious intervention adopted the CBT principle, possibly because CBT is a patient-centered and personalized therapy that uses collaborative psychological approach[12]. The core

components of cognitive restructuring and behavioral activation assist perinatal women to understand their own special beliefs and behavior patterns *via* counselling, education, advice, and assignment and finding an enhanced method to modify their dysfunctional thoughts, thus bringing about emotional and behavioral changes and improving their psychological problems[12]. Therapist support involved increased levels of customized human support to provide feedback, support, questions, and answers in a flexible manner for clarifications that could intensify the effect of intervention and improve depression symptoms[88]. In addition, ≥ eight sessions was suggested to be the appropriate number for intervention. This finding seems to be a possible explanation of a dose-response effect from the cumulative intervention intensity[89].

The interventions are effective for the purpose of treatment, and they are targeted at complicated perinatal women, such as those who experienced psychological problems[65-67,73,75,78-81,84], insomnia[69], miscarriage[72], or pregnancy loss[70,71]. This finding is consistent with that of a previous review[36], which showed that preventive digital psychotherapy may not be as effective as when targeted at high-risk perinatal women. High-risk women are possibly more willing to seek help and be actively involved in psychotherapy because they felt depressed, anxious, or stressed for a long period than low-risk women[3,24].

Young women are particularly at high risk of having perinatal mental disorders because they may not access antenatal care or mental health services in a timely manner[3]. Similar to the findings of a previous review[87], interventions implemented during the postnatal period were more effective than those implemented during the antenatal period. Postnatal period is a time of adaptation to parenthood, and postnatal women need to adjust to the new role of motherhood and familial relationships[90]. Therefore, interventions were found to be more effective in postnatal women. Website was found to be the preferred platform among perinatal women. This case may be linked to perinatal women expressing interest in the use of web-based resources and their increased engagement in e-mental health[91]. One study suggested that mobile applications are an important source of support during childbearing[92]. Low statistical power in small sample size was possible because only two trials were conducted in 198 perinatal women by using mobile applications in subgroup analysis. Further investigation is necessary.

This review demonstrates that digital psychotherapeutic intervention may be a potential solution to reduce psychological problems in perinatal women. The poor quality of existing evidence reduced certainty in implementing digital psychotherapeutic intervention at this phase. However, the subgroup and meta-regression analysis results could provide a future direction in designing interventions effectively. Future designs should consider therapist-guided treatment among young postnatal women.

This systematic review has several strengths. It is the first systematic review to investigate the essential features, covariates, and quality of the overall evidence. A total of 25 RCTs were selected, and the PRISMA criteria were strictly followed, with a robust three-step search strategy throughout eight databases. RCTs were selected from over 23 countries using published and unpublished resources. Hedges's g was adopted to accurately estimate the overall effect size because of the small sample size in most of the included RCTs. However, this review also has some limitations. First, the restriction to trials in English and self-selected samples from media recruitment may have limited the generalization of the findings. Second, the high heterogeneities in the meta-analyses could have resulted from the low accuracy of pooled estimates. Third, self-report measures may have led to overestimation or underestimation of the effect size. Fourth, very low overall evidence could have diminished the internal validity of the findings. Lastly, this review only pooled post-intervention outcomes; thus, the sustainability of digital psychotherapeutic intervention remains uncertain.

This review highlighted a number of directions for future trials. Further well-designed RCTs are needed, particularly allocation concealment, participant and personnel blinding, and outcome assessment blinding. Future RCTs should stick to the consolidated standards of reporting trial statements[93]. Future trials should also consider a large sample size to provide a more precise estimate of the effect size and generalize the results. Considering that CBTs using website platform have dominated the existing literature, upcoming research should focus on different types of psychotherapy using other digital platforms for fair comparison. Future trials are warranted to assess the long-term effect and cost-effectiveness of digital psychotherapeutic intervention among perinatal women.

CONCLUSION

Meta-analyses found a small to medium and significant group difference favoring digital psychotherapeutic interventions over the comparators in regard to depression, anxiety, and stress outcomes. This systematic review provides evidence for the effectiveness of digital psychotherapeutic intervention in reducing psychological problems during the perinatal period. Future designs should consider the use of CBT principle, therapist support, and ≥ eight sessions using website platform for the treatment of postnatal young women. Further high-quality RCTs with large sample sizes are required to evaluate the sustainability of the intervention.

ARTICLE HIGHLIGHTS

Research background

Perinatal women are at increased susceptibility of psychological problems, including depression, anxiety, and stress. Perinatal psychological problems are associated with considerable adverse effects on women, offspring, family, and healthcare services.

Research motivation

Previous reviews were limited to few selected trials, a mixture of different research designs, few databases, and only narrative synthesis. None of the previous reviews investigated the preferred features of digital psychotherapeutic intervention and the influence of covariates on study effect size.

Research objectives

This review aimed to synthesize the best evidence to (1) assess the effectiveness of digital psychotherapeutic intervention in reducing depression, anxiety, and stress symptoms; and (2) evaluate the preferred design features of the intervention.

Research methods

A comprehensive three-step search strategy was conducted in congruence with the recommendations of the Cochrane Handbook for Systematic Reviews of Interventions from eight databases. Comprehensive Meta-analysis 3.0 software was used to conduct meta- and meta-regression analyses. The individual and overall quality of the evidence were evaluated using the Cochrane risk-of-bias tool and the Grading of Recommendations, Assessment, Development, and Evaluation criteria.

Research results

A total of 25 randomized controlled trials that included 3239 perinatal women were identified. Meta-analyses revealed that digital psychotherapeutic intervention significantly improved the depression (g = 0.49), anxiety (g = 0.25), and stress (g = 0.47) symptoms of perinatal women compared to the control. Subgroup analyses demonstrated that a website platform with ≥ eight therapist-guided sessions using the cognitive behavioral therapy theoretical principle was more effective than other treatments in postnatal women. Meta-regression analyses observed that the age of perinatal women and the type of psychotherapy had statistically significant effects on depression symptoms. Egger's regression asymmetry tests found no publication biases, but the overall quality of evidence was very low.

Research conclusions

This systematic review provides evidence for the effectiveness of digital psychotherapeutic intervention in reducing psychological problems during the perinatal period, particularly depression, anxiety, and stress symptoms. Future designs should consider the use of the cognitive behavioral therapy principle, therapist support, and ≥ eight sessions using a website platform for the treatment of postnatal young women.

Research perspectives

Given that the poor quality of the existing evidence reduced certainty in implementing digital psychotherapeutic intervention at this phase, further high-quality randomized controlled trials with large sample sizes are required to evaluate the sustainability of the intervention.

ACKNOWLEDGEMENTS

The authors would like to thank authors of the randomized controlled trials considered for sharing their additional data for use in our meta-analysis.

ABOUT COVER

Editorial Board Member of *World Journal of Psychiatry*, Peer Reviewer, Alexander M Ponizovsky, MD, PhD, Mental Health Research Adviser, Professor, Department of Mental Health Services, Ministry of Health, Jerusalem 9446724, Israel. alexander.ponizovsky@moh.gov.il

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatr*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc*.

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, and PubMed Central. The 2020 edition of Journal Citation Reports® cites the 2019 impact factor (IF) for *WJP* as 3.545; IF without journal self cites: 3.545; Ranking: 46 among 155 journals in psychiatry; and Quartile category: Q2.

Abstract

Relapse prevention remains a major challenge in psychiatry, thus indicating that the established treatment methods combining psychotherapy with neuropharmacological interventions are not entirely effective. In recent years, several intervention strategies have been devised that are aimed at improving psychiatric treatment by providing a complementary set of add-on tools that can be used by clinicians to improve current patient assessment. Among these, cognitive event-related potentials (ERPs) have been indexed as valuable biomarkers of the pathophysiological mechanisms of various mental illnesses. However, despite decades of research, their clinical utility is still controversial and a matter of debate. In this opinion review, I present the main arguments supporting the use of cognitive ERPs in the management of psychiatric disorders, stressing why it is currently still not the case despite the vast number of ERP studies to date. I also propose a clinically-oriented suitable way in which this technique could — in my opinion — be effectively incorporated into individual patient care by promotion of the use of individual ERP test-retest sessions and the use of a multi-component approach.

event-related potentials (ERPs) have yet to be implemented in daily psychiatric care units as an add-on tool to psychotherapy and medication. I present here the main arguments supporting the notion that ERPs represent a highly suitable tool for performing individual "neuro-cognitive" assessments in psychiatric patients. Such ERP data could help clinicians to specify individual cognitive interventions that will target each patient's specific needs, thus promoting an "individualized" or "personalized" medicine.

INTRODUCTION

The 1990s have been referred to as the "Decade of the Brain", with developments such as brain imaging tools allowing patterns of distributed neural activity associated with both normal and pathological behaviors to be identified[1]. On this basis, major mental illnesses, such as schizophrenia, autism, major depression, anxiety disorders, and addictions, were redefined as brain diseases[2], with a deep impact of the environment at both the social and physical levels[1]. Nowadays, the separation of neurology and psychiatry appears arbitrary, and in the framework of modern neuroscience, psychiatrists and neurologists could be called "clinical neuroscientists" who apply neuroscientific discoveries to the care of patients with brain disorders[3]. Clearly, the management of a mentally ill patient necessarily requires consideration (mainly through psychotherapy) of a single individual embedded in a specific social-cultural context in order to encompass the social and psychogenic aspects of individual clinical symptoms[4]. However, mapping the live brain activity of a patient, by—for instance—the use of positron emission tomography (PET), magnetic resonance imaging (MRI), or electroencephalography (EEG), has demonstrated that all normal or dysfunctional mental processes are ultimately biological[2]. It is, therefore, also important to consider these cognitive, emotional, and social processes, subtended by specific choreographed patterns of brain activity that — when dysfunctional — can mediate the onset and persistence of specific clinical symptoms[5]. For instance, an alteration of mental state attribution, the ability to infer mental states of others in order to guide social interactions, is classically observed in schizophrenic patients[6]. This deficit, mainly subtended by neural alterations in the prefrontal cortex and the superior temporal sulcus[7], is associated with a poor outcome, social functioning, and social competence in schizophrenia[8]. As antipsychotic medication has been shown to have a limited impact on recovery and social cognition[9], the challenge is to develop new therapeutic strategies to specifically improve social cognition in schizophrenia. Promising results, revealing improvement of social functioning and reduction of psychotic symptoms, have been achieved through social cognition training programs and psychosocial interventions[10] as well as by brain stimulation through transcranial direct-current stimulation (tDCS)[11] or transcranial magnetic stimulation[12]. Similarly, in major depressive disorder, deficits in cognitive inhibition, subtended by a hyperactivated amygdala insufficiently controlled by a hypoactivated prefrontal region[13] appear to be a main causal factor for ruminations[14]. Sessions of training to inhibit negative thoughts[15] as well as a combined tDCS-mindfulness program resulted in a decrease in ruminations and lower depressive scores[16], while medication only has been reported to provide modest improvements[17]. In alcohol dependence, an increased salience of alcohol-related cues grasping drinkers' attention (hyperactivated mesolimbic activity[18]) combined with a lack of inhibitory resources (anterior cingulate and frontal hypoactivity[19]) defines the main neurocognitive mechanisms triggering relapse[20]. In light of the modest effect of anti-craving medications[21], cognitive bias modification training alone[22] or combined with tDCS[23] has shown promising trend on treatment outcomes by reducing craving and by improving early abstinence. Overall, convergent empirical data illustrating alterations in brain networks that underlie cognitive impairments have provided

foundational information about transdiagnostic circuits and promising targets for intervention[24]. Indeed, numerous studies have provided consistent evidence that mental illness involves significant cognitive impairments that represent valid therapeutic targets, as enhancing cognitive functioning leads to a reduction of clinical symptoms and a better quality of life. One of the main challenges at present consists of developing new ways to use neurocognitive mechanisms as an add-on tool in the clinical and conventional management of psychiatric patients.

Due to their high anatomical resolution, PET and functional MRI (fMRI) clearly constitute the most suitable tools to assess the distributed brain networks involved in diverse cognitive functions[25]. However, their coarse temporal resolution (1-2 s) does not allow definition of the temporal activation sequence, thus preventing isolation of the series of individual sensory, cognitive, affective, and motor processes that occur between a stimulus and a response[26,27]. Electrophysiological tools, by recording spontaneous electrical brain activity from multiple electrodes placed over the scalp[28], are more suitable for this purpose due to their optimal temporal resolution on the order of milliseconds[29]. EEG is an inexpensive and non-invasive tool defining a valuable clinical first-line method to exclude a diagnosis of epilepsy, drug intoxication, or sleep disorders in psychiatric patients[30]. A derivative of the EEG technique refers to event-related potentials (ERPs), *i.e.*, averaged EEG responses that are time-locked to the cognitive processing of stimuli. The past several decades have witnessed a vast number of task-dependent ERP components being described and studied among healthy people. While studies on healthy participants have helped to define the various cognitive steps needed throughout the entire information processing stream to achieve a cognitive function, such data also have great relevance in pathology. Indeed, by accessing the various cognitive steps needed to achieve a cognitive function, cognitive ERPs may then also allow definition of where a dysfunctional behavior originates at the cognitive level. This has great clinical relevance, as a similar altered behavior may be subtended by various cognitive disorders[31]. Therefore, by indexing the specific neurocognitive functions that are dysfunctional in a patient, ERPs pinpoint cognitive functions that should be rehabilitated in each patient through specific and individualized cognitive remediation procedures[26]. However, despite a solid theoretical basis[29] and decades of research showing alterations of these components in various psychiatric diseases[32], their relevance in clinical settings is still a matter of debate[33]. The scope of this paper is not to provide an exhaustive review of the literature regarding ERPs in various psychiatric diseases. Rather, my aim is to present relevant arguments supporting the notion that it is important to incorporate the use of cognitive ERPs in the management of psychiatric disorders, by also stressing why it is still not the case nowadays despite thousands of ERP studies to date. I then propose a clinically-oriented suitable way in which this technique could—in my opinion—be effectively incorporated into individual patient care.

DECADES OF ERP STUDIES IN PSYCHIATRY: WHY SO MANY HOPES AND PROMISING RESULTS FOR SUCH A MINOR CLINICAL IMPACT TO DATE?

Depending on the cognitive task one is confronted with and the cognitive processes one is focusing on, several ERP components have been described in recent decades in the literature. The P50, the contingent negative variation (CNV), the mismatch negativity (MMN), the P300 with its P3a and P3b subcomponents, the No-go N2 and No-go P3, the error-related negativity (ERN), and the N400 are some of the most studied ERPs. When elicited through a specific task in healthy subjects, such ERPs are the neural correlates that assess the efficiency of diverse cognitive processes, such as sensory gating[34], arousal and motor preparation[35], auditory discrimination[36], novelty processing *vs* decision making[37], cognitive and motor inhibition[38], insight[39], and semantic congruency[40]. As ERP amplitudes reflect differences in the intensity of responses whereas measurements of latency inform regarding the processing time duration[40,41], several anomalies in amplitude and/or latency of these components have been reported in various psychiatric disorders[32,42]. In such a view, ERPs could characterize biological markers of pathophysiological mechanisms[43]. Such biological markers can be state (only present during the acutely ill state but stabilized after remission) or trait (always present, during and after the disease) markers[44,45]. On the one hand, by reflecting pathophysiological processes

that are active during the disease, state markers could provide clinicians important input to assist with choosing the most appropriate treatment. For instance, a decreased amplitude of the P3b component is considered to be a state marker of depression[46]: The P3b amplitude has been shown to be increased after four weeks of antidepressant treatment[47] as well as following recovery from electroconvulsive therapy[48]. Similarly, chronic schizophrenic patients exhibit reduced MMN amplitudes compared to healthy controls[49], and antipsychotics such as aripiprazole[50] or drugs acting on the NMDA (N-Methyl-D-aspartate) receptor[51] appear to induce its recovery, while the CNV is reduced in amplitude in children[52] and adults[53] with ADHD but has been shown to exhibit an amplitude recovery with even just a single dose of stimulant medication[54]. Such instances clearly highlight how ERP state markers could be particularly useful in monitoring the efficiency of a treatment. On the other hand, trait markers can also be particularly useful, mainly as indicators of vulnerability[45]. Indeed, the amplitude reduction of the P3b as well as the absence of P50 suppression in schizophrenia[55], an enhanced ERN in child and adult anxiety disorders[56], and an altered P3 component in cocaine users[57] are examples of trait markers, indexing during and after the disease, of impaired cognitive functions that play a pivotal role in the onset and persistence of these mental diseases. But importantly, such alterations can also define a risk marker for healthy people with, for instance, a positive family history to further develop it[58-60]. Therefore, such markers, if present, can improve early detection of illness, and, as such, facilitate more effective and targeted interventions[44].

Overall, state and trait ERP markers can serve to aid diagnosis (as prognostic elements[61]), assist in choosing the most appropriate treatment for psychiatric disorders[62], and help with detecting illness at an early phase[63]. However, although such empirical data, even in meta-analyses[64-68], may appear convincing and useful, the reality is quite different as, up to now, the utility of cognitive ERPs in daily clinical care settings remains (very) modest[30]. Several explanations may account for this situation. First, at a technical level, the worldwide current ERP screening procedure favours the huge number of ERP studies, despite the heterogeneity of the data. For instance, an amplitude reduction and/or a delayed latency of the P3b and the MMN is usually considered to be a state marker of depression[69] and early psychosis[70], respectively. However, contradictory data have also been reported, suggesting no P3b and MMN differences between depressive[48] and psychotic[71] patients, respectively, with controls. Such heterogeneity has understandably led to a degree of scepticism among clinicians as it raises questions regarding reliability. The main factors accounting for these discrepancies are the clinical subtypes of patients included in these studies, with comorbidities inducing particular responses[72], higher artifact contamination in clinical patients than in typical subjects[27], a potential influence of medication[27], and differences in ERP recording protocols leading to data misinterpretations[73]. In this respect, a very interesting initiative, called "ERP CORE" (Compendium of Open Resources and Experiments)[74], has recently been launched in order to provide standardized ERP paradigms for seven widely used ERP components (N170, MMN, N2pc, N400, P3, lateralized readiness potential, and ERN). By providing researchers with a useful tool and guidelines for selected tasks to record specific ERP components, this will notably promote the possibility of comparing ERP data sets from different laboratories. At a clinical level, such guidelines already exist[75]; however, their use in studies around the world is still by no means ensured, and this could notably lead to a degree of misinterpretation of the data[73]. It is, therefore, urgent to again underscore that using such guidelines accepted by the field would clearly help with clinical implementation[76] by providing access to normative data gathered on large samples in order to follow the progression of patients as a function of the treatment, but also to control for potential confounding factors, such as gender, age, medication, and comorbid symptoms. Secondly, at a conceptual level, the potential role of ERP components in the management of mental disorders has also suffered from the predominance in psychiatry of the official nosological systems, such as the Diagnostic and Statistical Manual of Mental Disorders (DSM) and the International Classification of Diseases (ICD)[77]. In such a categorical view, patients either do or do not meet the criteria to be diagnosed with a mental illness, thus suggesting that the presence of a specific cluster of symptoms will necessarily correspond to a specific mental disease (*e.g.*, borderline personality disorder). On this basis, the psychiatrist will select what they consider the best option of treatment among the range of those appropriate for that specific diagnosis (*e.g.*, selective serotonin reuptake inhibitors; SSRIs). If this treatment proves to be ineffective, they will then have to choose another option (*e.g.*, combination of SSRIs and quetiapine[78]) or reconsider the former diagnosis[79]. A main and crucial point that makes this categorical approach still

dominant in psychiatry is that it greatly facilitates clinical communication among mental health practitioners, as all textbooks and practice guidelines have been developed based on these categories[80]. In such a categorical view, mental illnesses are discontinuous entities with distinct symptoms, etiologies, and biomarkers[81]. However, inter-individual variability in the severity of symptoms among patients receiving a similar diagnosis, common symptoms across different disorders, and an extremely usual comorbidity factor are well-documented facts in clinical experience[77]. In other words, common liabilities across these "categories"[81,82] are more suggestive of a dimensional underlying cross-cutting transdiagnostic structure for mental disorders[77]. This still ongoing debate regarding the transdiagnostic *vs* the categorical frameworks to guide psychopathology assessments[83] is not the scope of this paper. However, it clearly appears that, due to the dominance of the nosological approach in psychiatry, the imprecision of categorical psychiatric diagnoses[84] has been a limiting factor in understanding the pathophysiological mechanisms of human behavioral abnormalities. Indeed, although decades of research have provided evidence of the relevance of various ERP components as biological markers of mental illnesses[32,43], their clinical sensitivity has been hampered by the fact that their parameters (*e.g.*, amplitude and latency) are diagnostically unspecific[33]. In other words, ERP deficits are a common feature of several psychiatric afflictions, but they will not assist clinicians in deciding whether a given patient is depressed, paranoid, or an alcoholic (high sensitivity but low specificity). Moreover, cognition is not considered as a primary treatment target, being still envisaged as a particular category of symptoms (among others), and not as a core phenomenon triggering the onset and/or the persistence of the disease. Many psychiatrists still then focused on finding the best suited drugs combination in order to contain symptoms et minimize side effects. Therefore, the approach using ERPs to classify patients according to DSM categories was entirely inappropriate, and, in the next section, I will specify how I think ERPs may be genuinely useful in clinical settings, mainly as predictive biomarkers, *i.e.*, as measured indices that may be used to predict clinical responses to treatment[85]. Finally, at a clinical level, a major practical issue is that the majority of ERP-based studies compare their results with matched controls using grand-averaged data. While such "group results" have ample merit at a fundamental "research" level, there is now a need for more "individualized", "personalized" medicine[86], *i.e.*, individual data that helps with devising interventions that are specifically targeted based on each patient's needs[26]. In the next section, I will try to provide some insights on how ERPs may be used effectively in clinical settings as an individual monitoring tool to reveal (or not) expected changes in brain function in response to a treatment[87].

USING ERPS IN PSYCHIATRY: WHAT PERSPECTIVES?

In an influential paper published in 1991 arguing for the use of PET in clinical care[88], Wagner[88] stated that: "…Today's medical practice is yesterday's research. The bridge linking the two is technology assessment, which makes possible the acceptance or rejection of new technologies in the practice of medicine. Experience is the key determinant of effectiveness. If the information provided is not useful to the physician caring for the patient, the procedure will eventually fall by the wayside...". The notion that ERPs are useful for managing psychiatric diseases, such as, for instance, depression[89], alcohol disorders[90], or schizophrenia[91], is not novel at all. However, despite decades of research, ERPs have yet to be implemented in the clinical management of mental illnesses[27]. It clearly appears at present that the clinical value of ERP components as a diagnostic index is low[33], merely reflecting a common measure of brain dysfunction[92]. With this in mind, it is, therefore, now urgent to precisely define what constitutes be the best use of ERPs in the management of psychiatric disorders. In order words, there is a need to find out which properties of ERPs as a tool could be the best-suited ones to help with managing a currently still unsolved clinical question.

A prominent issue in the treatment of mental illnesses relates to the relapse rate[93], which is approximately 50% at 1 year and 70% at 5 years for manic episodes in bipolar disorders[94]; approximately 35% at 18 mo and 74% at 5 years following a first episode of schizophrenia[95]; and approximately 50% at 3 mo and 85% at 1 year for recently detoxified alcoholic patients[96]. Despite the beneficial impact of psychotherapy and neuropharmacological interventions, as well as the positive effect of more recent intervention strategies such as multisystemic[97], cognitive behavioral[98], or mindful-

ness[99] therapies, the relapse rate is still extraordinarily high. Clearly, the idea is not at all to discredit the existing treatment methods, but providing a complementary set of add-on tools to be used by clinicians to improve current patient assessments is still a major challenge. Starting with the fact that mental diseases are also brain disorders, a neurocognitive approach has emerged[100]. This can be summarized as follows: (1) Mental illness involves significant cognitive impairment[101]; (2) These cognitive alterations, subtended by perturbed brain networks, may trigger the onset and/or persistence of clinical symptoms, thereby defining valid therapeutic targets[24]; and (3) Retraining these cognitive functions (through the use of cognitive retraining programs and/or neuromodulation tools) has been reported to reduce clinical symptoms and to enhance patient quality of life[11,16,22,23]. Overall, once admitted to a psychiatric care unit, there is still a huge difficulty with assessing "partial recovery", which allows patients to leave the hospital to return home, and achievement of long-term "complete clinical recovery", defined as the reduction of psychiatric symptoms and functional disabilities[102].

In my opinion, it is in this regard that ERPs may have an important clinical role in the management of psychiatric patients, as a monitoring and a predictive biomarker tool. Indeed, psychiatric evaluations are made almost entirely on the basis of clinical symptoms, and the longitudinal course is determined by a clinician speaking with the patient and informants (as well as sometimes by the use of clinical scales), but diagnostic frameworks do not usually incorporate biomarkers[103]. However, once the notion that mental illnesses are subtended by impaired neural functioning is acknowledged, a main assumption is to consider that this dysfunctional brain should undergo significant and enduring neural changes in order to be reflected in medium-to-long-term real-world behavioral modifications[104]. Indeed, test-retest ERP studies on healthy participants have, for instance, shown that subjects exhibiting improvements in inhibitory performance in a Go/No-go task had a similar residual gain in inhibition one week after post-training, albeit only when this effect was neurophysiologically indexed by faster Nogo-N2 latencies[105]. Accordingly, in neuropsychiatric conditions, several studies found that specific cognitive gains induced specific brain changes that were positively associated with decreased symptoms and better quality of life, even 6 mo later[106-108]. Taking these neural modifications into account would, therefore, be of the greatest clinical relevance, as their absence would suggest a high vulnerability to relapse. In this view, state ERP markers provide the possibility (1) to monitor the change, triggered spontaneously or by a specific treatment, in neurocognitive mechanisms that are involved in the onset and maintenance of clinical symptoms in an individual patient; and (2) to verify whether these neural changes induced by the treatment are predictive of the clinical trajectory. By fostering a longitudinal follow-up and intra-individual ERP approach, recent works have tried to verify the clinical utility of such designs, in which ERP measurements are included just as one would include measurements of symptoms. In a study by our laboratory of alcohol-dependent patients undergoing a four-week detoxification program[109], we showed that monitoring the changes in dual-processes that are well-known to trigger addictions (No-go P3 for inhibition[110] and P3 for cue reactivity[111]), at the start and at the end of the program, can provide clues about the mechanisms involved in abstinence or relapse. Indeed, specific changes in cognitive ERP markers during detoxification (a preserved oddball P3 and an enhanced No-go P3) indexed complete abstinence (over a 3-mo period) in alcoholic patients. The main clinical relevance of such test-retest ERP data is the possibility of pinpointing the change in specific neurocognitive functions (cue reactivity, inhibition) during the detoxification program that can predict further abstinence. Such a procedure necessarily implied: (1) Specification of the various cognitive mechanisms that should be considered as the primary targets subtending the clinical symptoms of interest; and (2) Selection of the appropriate cognitive tasks that will generate specific and reliable ERPs related to these specific processes at an individual level.

A crucial step, therefore, concerns the identification of the various cognitive processes of interest. As such, transdiagnostic (as opposed to disorder-specific) factors appear uniquely suited to bridge psychiatric phenomena and biological substrates of behavior[77]. Transdiagnostic impairment of cognitive control[82], self-referential processes[112], working memory[113], decision making[114], and attention[115] largely contribute to the real-world socio-occupational impairment common across disorders. Decades of research have validated reliable ERP markers for such processes (No-go P3, ERN, P300, MMN, and P50, respectively). Indeed, an altered No-go P3 response inhibition, as well as a deficit in P300 (in tasks tagging updating in working memory or decision making), are neurophysiological disorders present in psychotic[116,117], bipolar[118,119], unipolar[48,120] depressive disorders as well as

in anxiety[121,122] and substance use disorders[123,124]. Studies also commonly reported an altered ERN in anxiety disorders and in obsessive-compulsive disorders[125]; an altered MMN (indexing preattentive auditory memory processing) in major depression, schizophrenia, psychosis, and substance use disorders[36]; and a deficit in P50 sensory gating in stable schizophrenic patients and euthymic bipolar patients[58]. In such a dimensional transdiagnostic view, the lack of specificity reported for these various ERP components tagging specific cognitive functions will vanish and allow monitoring of the change in these processes during a treatment, independently of a categorical disorder. Such a proposition relies on two main "technical" recommendations for future ERP screening methods: (1) The use of individual ERP test-retest sessions; and (2) The use of a multi-component approach[126].

ERP serial recordings may be used in clinical contexts for the assessment of changes in cortical function during follow-up programs[33]. Indeed, although slight differences in the wave shape, size, and timing of ERPs between individuals are usually observed, these tend to be highly stable within an individual across recordings, as high internal consistency and high test-retest reliability have been reported[127-130]. A high degree of reliability is a key factor that makes state ERP markers highly suitable for examining changes in brain activity resulting from treatment intervention or disease progression in a single patient[12]. This could provide ERPs a novel and particularly useful role in the management of psychiatric disorders. Indeed, assessing that neural changes have been induced spontaneously and/or by a treatment is a necessary outcome to envisage medium to long-term positive behavioral changes[104]. For instance, recovering a normalized MMN amplitude or P50 suppression appears to be a good indicator of abstinence in alcohol and cocaine users, respectively[131]. In such a view, it is also particularly important to always merge ERP data obtained through "active" tasks with behavioral results. To illustrate this crucial point, we can focus on contradictory data showing that excessive alcohol users compared to controls exhibited decreased No-go P3 amplitudes[38,123], probably reflecting poor neural resources indexing a poor performance; while other studies have reported increased No-go P3 amplitudes[132], probably reflecting compensatory neuro-functional mechanisms that allow drinkers to achieve a similar performance level as controls. In other words, an increased amplitude should not necessarily be interpreted as a recovered activity, and a decreased amplitude should not necessarily be interpreted as a disrupted function. Therefore, merging test-retest ERP data with behavioral performances would allow identification of patients who need to recover more neural resources to achieve better performance (*e.g.*, an increase of inhibitory No-go P3 resources to maintain abstinence in alcoholic patients[109]), while patients exhibiting compensatory or exacerbated mechanisms may need to reduce the activity allocated to the task (*e.g.*, decreased ERN in anxiety disorders to assess better emotional regulation[56]). These types of individual assessments would help clinicians specify individual interventions that will target each patient's needs, thus providing "individualized" or "personalized" medicine[26]. For instance, a recently detoxified alcoholic patient who does not exhibit improvements on the No-go P3 component could be redirected to post-cure specific inhibitory boosting programs[109], while a patient with a severe anxiety disorder who does not exhibit a reduced ERN due to a drug treatment could be directed to therapies that address emotional regulation such as mindfulness[133]. Naturally, it is important at this point to outline that, on the basis of DSM or ICD psychiatric categories, some ERP trait markers have also been described. For instance, obsessive-compulsive disorder has been characterized by an increased ERN both before and after therapy[68] as well as for the altered P3 component in cocaine users[57]: Such trait markers, *i.e.*, neurophysiological mechanisms persisting during and after the disease, suggest that such ERP markers could be related to the risk for the disorder but not the expression of its phenotype. Even in a dimensional perspective, such trait markers, if present, can improve early detection of illness (*e.g.*, in healthy people with a positive family history), and, as such, facilitate more effective and targeted interventions[44]. Moreover, this also highlights a main challenge of future "ERP research applied to the clinic" to develop novel interventions/manipulations that could modify an ERP of interest. As such, it was found for instance that performing a secondary dual-task resulted in a reduced ERN, and this reduction was larger in patients with obsessive-compulsive disorder than in the group of healthy participants[134], as well as a single session of attention bias modification[135] or expressive writing[136], thus suggesting that increased ERNs in clinical anxiety disorders can be normalized, at least temporarily[137]. Increased sensitivity of the P3a and the P3b amplitudes to depression severity are also now observable thanks to the development of adapted new ERP protocols, such as the three-stimulus oddball design[138,139] and bimodal

oddball protocols[140,141], respectively. Research assessing the efficiency of a procedure or a treatment to impact an ERP of interest, even in healthy participants, will, therefore, remain of fundamental relevance in the ERP research area.

Many ERP studies have focused on "a single ERP component" (*i.e.*, P50, MMN, P3a, P3b, *etc.*), comparing it in a pathological population *vs* healthy matched control. However, at the clinical level, it has been suggested that although ERPs clearly exhibit high sensitivity and predictive power, they suffer from poor specificity[26,33]. The idea that a "multivariate endophenotype", based on a weighted combination of diverse electrophysiological features, may provide more information than any single endophenotype, is not novel[142]. Price and colleagues compared and contrasted four electrophysiological endophenotypes — MMN, P50, P300, and antisaccades — and showed that this combination of features decreased the impact of group heterogeneity. In the same vein, at an individual level, a prominent idea is that a psychiatric patient will exhibit various cognitive disorders, of varying severities, that will subtend their own clinical symptoms. In a dimensional view, such disturbances may evolve differentially, so that some ERP measurements that index a specific cognitive function may recover during a disorder, while others will exhibit long-lasting damage. As an example, we recently showed that a post-cure 3-mo abstinence period in alcoholic patients can be neurophysiologically indexed by an increased No-go P3 yet similar oddball P3 components between the start and the end of a detoxification program[109]. Future studies should hence adopt a multi-component approach in order to potentially increase the sensitivity of ERP recordings, as the change in the patterns of ERPs could be specific (*e.g.*, which components recover, and which remain disturbed) from one psychiatric patient to another. In my opinion, such patterns indexing the changes of various ERP components through test-retest sessions appear to be the best way for ERPs to provide clinicians with relevant information regarding change in the disease (due to a treatment) in a single patient and the residual cognitive impairments that still need to be addressed. Indeed, once cognitive disturbances have been characterized through ERP screening of individual patients, psychiatrists will be able to orient the "cognitive" treatment (individually or in groups that present homogeneous patterns of cognitive deficits). More precisely, specific cognitive retraining procedures could be used to target deficits and to increase cognitive efficiency, as both cognitive training and neuromodulation boosting methods have already been shown to reduce clinical symptoms[143,144].

CONCLUSION

The main aim of this opinion review was to present the main arguments in favour of the clinical utility of ERP components to help in the management of psychiatric disorders. ERPs may be of great value to psychiatrists for the identification and monitoring of cognitive processes that should be rehabilitated on a patient-by-patient basis[126]. Such a proposition is limited per se, as, naturally, the complexity of dealing with a mental illness encompasses a large variety of stakeholders, such as psychologists, psychiatrists, nurses, and social workers, as well as neuropsychologists and neurophysiologists. I am, therefore, fully aware that the ERP contribution would be minimal, as moreover, many other EEG tools (*e.g.*, event-related oscillations[145] or microstates[146]) could also be of interest. Also, combining ERPs data with more structural and functional information (through for instance fMRI studies[147,148]) would be of the greatest relevance in order to better capture the pathophysiological mechanisms underlying specific clinical symptoms and orient treatment. I am also fully aware that there is still a long way to go before such a proposition could be widely implemented in clinical care units: If such a procedure could be quite easy to install at a technical level for inpatients in psychiatric clinics in highly developed countries, the situation could be more problematic for lower-income countries, and even more for outpatients visiting on a punctual daily basis a psychiatric office. If such a procedure would reveal high efficiency in the future, economical discussions will have to be undertaken to furnish full access of such a material to all countries in order to (1) manage, monitor and orient treatment for inpatients; and (2) allow straight collaborations between research centers and outpatients' psychiatric office in order to deliver information to clinicians that could be of help in orienting treatment. In such a view, lack of normative data, technical artefacts linked to the recordings with patients, adoption of clear multisite guidelines, as well as a constructive dialogue between researchers and clinicians in the assessment of a suitable cognitive-ERP battery are still some of the main issues that warrant our full attention. A major issue with such a

proposal indeed relates to the fact that clinicians and researchers have to agree on a cognitive ERP-battery that could be used across centres (in terms of its content, but also, naturally, its multisite technical guidelines) and across disorders. Such a battery should be as complete as possible, but not too time-consuming in order for it to be adapted to all types of psychiatric patients (probably approximately a maximum of 45 min for a session recording?). It is nowadays well-accepted that transdiagnostic impairment of cognitive control[83], self-referential processes[112], working memory[113], decision making[114], and attention[115] largely contribute to the real-world socio-occupational impairment common across disorders. Therefore, I am inclined to suggest that such a cognitive ERP-battery should at least include two active and two passive tasks: (1) A Go/No-go task, which appears to be the best-suited task to assess cognitive control[143], and to record the No-go N2, the No-go P3, and the ERN as the main ERPs of interest; (2) A bimodal (visual-auditory) three-stimulus oddball task, in order to probe for updating memory and decision-making processes through the recording of P3a and P3b components[87,140]; (3) A passive auditory paired-stimulus paradigm, classically used to record sensory gating through the P50[149]; and (4) A passive auditory oddball design in order to access the MMN component[150]. Monitoring the changes in these components in a single patient during treatment would be of the greatest clinical interest for identifying neural changes that are positive predictors of the clinical trajectory as well as cognitive functions that still warrant being trained. Clearly, much work is still needed to achieve this aim, such as reaching an agreement regarding the battery content as well as establishing multicenter large sample recordings to obtain normative data and to test the efficiency of the procedure at a clinical level. Nevertheless, as EEG is a cheap method that can be readily implemented in any type of psychiatric care unit, and because ERPs can provide invaluable information regarding the neurocognitive status of a patient as a monitoring and a predictive biomarker tool, I very much think this method deserves attention and should be given more consideration for further development. The challenge for future studies will be to establish whether this procedure, driven by serial follow-up recordings of various ERP components in a singular patient, is efficient enough to be incorporated into novel psychiatric treatment methods.

ACKNOWLEDGEMENTS

I thank the Belgian Fund for Scientific Research (F.N.R.S., Belgium) and the Brugmann Foundation (CHU Brugmann, Brussels, Belgium). A special thanks also to all collaborators of my EEG team (Kajosch H, Hanard F, Schroder E, Dousset C and Ingels A), to Guérit JM and Debatisse D who were my mentors in using ERPs, and to Boutros N and Otte G for their support on this topic.

Abstract

Traditional therapeutic methods in psychiatry, such as psychopharmacology and psychotherapy help many people suffering from mental disorders, but in the long-term prove to be effective in a relatively small proportion of those affected. Therapeutically, resistant forms of mental disorders such as schizophrenia, major depressive disorder, and bipolar disorder lead to persistent distress and dysfunction in personal, social, and professional aspects. In an effort to address these problems, the translational approach in neuroscience has initiated the inclusion of novel or modified unconventional diagnostic and therapeutic techniques with promising results. For instance, neuroimaging data sets from multiple modalities provide insight into the nature of pathophysiological mechanisms such as disruptions of connectivity, integration, and segregation of neural networks, focusing on the treatment of mental disorders through instrumental biomedical methods such as electro-convulsive therapy (ECT), transcranial magnetic stimulation (TMS), transcranial direct current stimulation (tDCS) and deep brain stimulation (DBS). These methodologies have yielded promising results that have yet to be understood and improved to enhance the prognosis of the severe and persistent psychotic and affective disorders. The current review is focused on the translational approach in the management of schizophrenia and mood disorders, as well as the adaptation of new transdisciplinary diagnostic tools such as neuroimaging with concurrently administered psychopathological questionnaires and integration of the results into the therapeutic framework using various advanced instrumental biomedical tools such as ECT, TMS, tDCS and DBS.

INTRODUCTION

Behavioral disorders are amongst the leading causes of disability and their characteristic features including early age of onset as well as high prevalence among the working-age population are an influential determinant of their negative socio-economic impact[1,2]. The severe mental illnesses, such as schizophrenia and mood disorders demonstrate a high comorbidity rate with somatic diseases as well as with other psychiatric conditions, which in addition to the significant risk for self-inflicted death, marks a high mortality rate[3].

Unlike other branches of medicine, where the clinician can rely on objective measures (blood tests, imaging methods, *etc.*), in psychiatry, diagnosis is mediated by subjectivism, which affects the reliability of the assessment methods used. Consequently, there is a frequent change in psychotropic drugs which leads to increased risk of drug-resistant disorders and relapse[4]. The integration of neuroimaging evidence with comprehension of the role of brain networks and their abnormal interactions as a pathogenic mechanism for the development of certain behavioral deviance is an important step toward a systematic biological understanding of mental disorders.

Establishing a diagnosis and treating these disorders is challenging. Numerous molecules are assumed to have the appropriate characteristics to induce improvement; however, therapeutic outcome and adverse side effects differ significantly among patients[5]. With conventional treatments (psychopharmacology and psychotherapy), a large percentage of patients report inadequate symptom resolution, and relapse rates remain high[6,7]. A growing amount of interest has been centered on focal neuromodulation in the search for better treatments. The interest in this field is driven by the latest data considering neuroanatomical models of modulation of mood, thought, perception, and behavior, as well as more sophisticated techniques for direct and focal modification of the neural function.

In the current review we will discuss new perspectives of the translational approach in the diagnosis and treatment of severe mental disorders, namely schizophrenia and mood disorders. Although genetic risk factors and pharmacogenomics in the field of psychiatry are promising strategies to predict or mitigate the therapeutic response of medication, and thus to inform medication selection and dosing decisions, the focus in this review will be on the adaptation of new transdisciplinary diagnostic methods such as neuroimaging and concurrently administered psychopathological questionnaires and the implementation of the results into treatment using various advanced biomedical treatment methods like electro-convulsive therapy (ECT), transcranial magnetic stimulation (TMS), transcranial direct current stimulation (tDCS) and deep brain stimulation (DBS).

PSYCHIATRIC DIAGNOSTICS IN THE 21ST CENTURY

One of the most widely discussed problems in psychiatry seems to be the fact that the diagnostic process is primarily focused on patients' reports, behavioral observation and the capacity to draw conclusions about the real inner nature of patients' experiences, rather than on accurate objective biomarkers[8].

The primary diagnostic tools in contemporary psychiatry are the International Classification of Diseases[9] and the Diagnostic and Statistical Manual of Mental Disorders[10], yet their foundational criterial categorization lacks biological validity[11,12]. This phenomenon is illustrated by existing barriers, such as heterogeneity, comorbidity, and ambiguous distinctions between healthy and abnormal behavior, which impede the diagnostic process. Another significant concern is that mental illnesses are categorized purely on clinical manifestations, without consideration for their etiology. When the conventional diagnostic labels themselves are not absolutely accurate, it is difficult to recognize a biological marker for a specific disorder. For this purpose, the National Institute of Mental Health has introduced the Research Domain Criteria Project[13,14], which seeks to extend the understanding of brain-behavior correlations and eventually incorporate this knowledge into clinical practice and enhance the development of more successful treatments. Innovative brain imaging technology provides the possibility to discover disease-specific anatomical and functional neural impairments.

Neuroimaging techniques such as magnetic resonance imaging (MRI), positron emission tomography, single-photon emission computed tomography, magnetoencephalography and electroencephalography provide resources for a non-invasive analysis of the brain structure and function associated with mental diseases with excellent precision[15]. Understanding the complex mechanisms of communication between different brain regions at rest and in the conditional performance of tasks is a promising field for studying the etiological mechanisms of severe mental illnesses that lead to personal and social decline. For example, functional MRI (fMRI) used in schizophrenia research was able to detect anatomical and functional aberrations of brain plasticity and connectivity, which clinically manifest as cognitive disturbances[16]. Another example of an accessible translational method is pharmacological fMRI[17], which facilitates the study of the effects of different pharmacological agents on the central nervous system (CNS) and the search for accurate neuroimaging biomarkers[18].

TRANSLATIONAL APPROACH

The concept of translation can be defined as a mechanism for improving health status, thus reducing mortality and morbidity rates among patients by incorporating scientific findings from research into clinical applications[19]. The translational approach in psychiatry encompasses a wide range of scientific disciplines and innovative techniques. MRI techniques such as quantitative structural imaging, voxel-based neuromorphometry, functional neuroimaging and spectroscopy are widely used in psychiatric research. These imaging tools, together with the knowledge gained regarding the underlying neurochemical dysfunctions have the potential to change the current state of "crisis" in psychiatry[20,21] through the use of evidence-based biomarkers and insight into the etiology of mental disorders.

Disruptions in communication within and between brain networks and the pathological processes involving their nodes are a promising discovery of translational neuroscience towards gaining a biological understanding of mental disorders and defining them as impaired connectivity disorders. Low-frequency variations in random brain functions can be localized by resting state fMRI (rs-fMRI), representing a common instrument for macro-scale functional connectomics to characterize inter-individual discrepancies in brain activity and mind-brain interactions observed in various mental disorders[22]. These metrics have a tremendous potential for accelerating the discovery of biomarkers for different mental disorders, which need first and foremost reliability and reproducibility to be addressed.

In this sense, critical questions are whether the progress in this field has succeeded in contributing to the development of more effective therapeutic methods, and whether biomarkers could be incorporated into everyday practice. However, despite years of efforts in this area, the results remain inconsistent[23]. Over the past decades, substantial advancement has been made in recognizing and understanding the fundamental neurobiological correlations of psychiatric disorders, such as schizo-

phrenia spectrum disorders and mood disorders, but the effects of these advancements have not yet been established in clinical practice[24-26]. This may be partly due to the specificity of the design of the methods used. A common practice in fMRI studies is to conduct a clinical assessment before and after the scanning. Yet, in cases such as examining patients with bipolar disorder with rapid cycling, which presents with mood shifts from depression to mania within hours for example, this could affect the accuracy of the findings. To address this issue, fMRI gathered neuroimaging data, together with the parallel implementation of a self-assessment scale[27], could construct a scientifically valid instrument that can be used by clinicians in daily practice with trust in the reliability of the method. This initiative might positively affect the diagnostics, prevention, treatment, as well as facilitate the decision regarding the choice of the appropriate therapeutic method.

With the aim of implementing the translational model in psychiatry, our research group is concentrating on developing a new paradigm that combines a clinical self-assessment scale (von Zerssen and Koeller[28]'s paranoid-depressive scale) applied simultaneously with the acquisition of fMRI in two groups of patients—with a paranoid syndrome in the context of schizophrenia and with a depressive syndrome in the context of recurrent depressive disorder or bipolar disorder[29-33]. The goal is to compare the differences in brain activation during the task-related fMRI (tr-fMRI) with structural and functional changes in connectivity at rest with the hypothesis that the zones which demonstrate differential activation may have aberrant effective connectivity patterns and structural abnormalities. The results of the study can be summarized as follows: (1) In terms of grey matter (GM) volume alterations, the comparison at a whole brain level, voxel by voxel, yielded no significant structural differences between the two groups; (2) The paranoid group was associated with significantly more robust activations in the default mode network (DMN) structures—left precuneus (PreCu), left posterior cingulate cortex (PCC), and angular gyrus (AngG) during the processing of paranoid items from the scale (Figure 1); and (3) There was an aberrant connectivity pattern in the paranoid group—abnormal inhibitory connection from the prefrontal cortex (PFC) to the anterior insula (aI) (Figure 2).

We suggest that the observed activations of the PreCu, PCC, and AngG (DMN components) may be indirect evidence of the inhibitory influence from PFC⇒aI, which interferes with the balancing function of the insula as a dynamic switch in the DMN and fronto-parietal network (FPN)[32]. Impaired aI⇒DMN and aI⇒FPN connections lead to hyperactivity of DMN[34], which could explain social withdrawal and autistic behavior observed in patients with schizophrenia. In addition, the identified inhibitory effective connectivity from PFC⇒aI offers new insights into how the PFC dysfunction may contribute to cognitive impairment[35-37], behavioral disorganization[38], and functional decline observed in patients with schizophrenia. We propose a pathophysiological model in which cognitive deficits are due to the inability of the CNS to initiate and maintain an organized fronto-insular network[36].

On the other hand, we raise the question of whether and to what extent the prediction of clinical diagnostic classes can be improved by superimposing different dimensions of MRI (structural, tr-fMRI and rs-fMRI) compared to a single modality by application of a multivariate linear model (MLM)[36]. Using MLM and principal component analysis, we have made progress towards distinguishing the two psychiatric populations. The dopamine-ergic and noradrenaline-ergic pathways with DMN nodes were reported to be significant. The regions involved [planum polare (PP), inferior frontal gyrus (IFG), insula, nucleus accumbens, *etc.*] have both structural and functional characteristics that can distinguish the two groups. When focusing on the discriminatory power of the functional modalities, the predominant regions are a part of the effort mode network, DMN, and subcortical areas with mainly glutamate-ergic and GABA-ergic neurotransmission. The most significant structure in our MLM study is PP, which is a part of the superior temporal gyrus (STG) and is not only involved in auditory and linguistic processing but is also a critical construct for cognitive processes. Neuroimaging studies show that subjects with schizophrenia have structural abnormalities in the STG[39], suggesting that it plays a key role in the etiology of auditory perceptual disturbances and disorganization of thoughts[40]. There is evidence that auditory hallucinations are associated with a functional network of brain areas, namely the auditory and linguistic areas of the STG and IPG, as well as speech motor areas in the IFG[41-43], which are also significant regions in our study. Those findings support the abovementioned aim to develop a translationally valid instrument in the diagnostic process of schizophrenia and depression.

TREATMENT IMPLICATION OF THE TRANSLATIONAL APPROACH

Considering the controversial efficacy of the conventional treatments (psychopharmacology and psychotherapy), a large percentage of patients do not achieve complete remission (*i.e.*, become asymptomatic) or retain symptomatic improvement. This lack of efficacy has led to the quest for alternative solutions, which involve the utilization of more invasive interventions for treatment-resistant patients with psychiatric illnesses[44]. Therefore, the focus has been on neuromodulation, *i.e.*, modulation of the connections between various pathways and neurotransmitter systems in the brain. This emphasis has been driven by enhanced neuroanatomical concepts of mood, thought, and behavioral control, as well as more techniques to modify neural activity directly and focally.

ECT

ECT was first performed by a team of physicians led by Ugo Cerletti and Lucio Bini in 1938[45,46], along with Accornero[47] who contributed to the development of what they called electroshock[48] leading to the replacement of less effective biological interventions such as deep sleep therapy[49] and insulin shock therapy[50]. ECT has come a long way in refining the method and is still used today in cases of severe major depressive disorder (MDD), mania, and catatonia as a safe and effective treatment, despite the numerous critiques. ECT is an ideal example of translational neuroscience, involving the application of an instrumental method that generates electricity acting at a neurobiological level and modulating neuronal plasticity and brain connectivity. In the macro- and micro-environment of the brain, ECT induces numerous

neurophysiological as well as neurochemical changes. It has been suggested that changes in gene expression, functional connectivity, neurotransmission, membrane permeability, and immune system function are responsible for the therapeutic effects of ECT[51]. Neuroimaging studies show that the GM volume of key regions like the amygdala, hippocampus, and anterior cingulate cortex (ACC) is decreased in patients with depression and increases following administration of ECT[52]. It remains an unresolved issue as to whether ECT efficacy in various psychiatric conditions (depression, mania, catatonia, delirium, and psychosis) is due to common neurobiological features shared by those disorders or to a single mechanism of action[53]. A mechanism that has recently been suggested is that the seizures triggered by ECT may induce a significant alteration in the sleep structure[54].

We suggest that this and other hypotheses concerning neuroplasticity can be tested by our paradigm as it can be used as a tool to monitor the therapeutic effect of ECT by comparing the results before and after the procedure, considering the fact that the von Zerssen and Koeller[28]'s self-assessment scale was primarily designed for monitoring the treatment response.

TMS

TMS was developed in 1985 as a non-invasive method to stimulate the cerebral cortex[55]. A strong magnetic field is produced by a TMS device, which induces an electrical current in a specific area. This is a method based on the principle of electromagnetic induction, which can have a different effect on the targeted areas depending on the stimulation parameters and the physiological activity of the areas. Low frequencies around and below 1 Hz (low frequency TMS) have been found to suppress the excitability of the stimulated cortical zone and functionally related structures, while those above 1-3 Hz (high frequency TMS) lead to its activation[56].

Unlike ECT, the administration of TMS requires no anesthesia and therefore patients are awake and alert during the procedure and it is often performed in an outpatient setting[57]. The short-term effect of the procedure is prolonged by applying a series of stimuli with a certain frequency, the so-called repetitive TMS (rTMS). TMS affects the underlying brain structures by altering the regional activity in the underlying cortical structures. Such changes have also been found in brain areas distant from the site of stimulation, proving that the effect of rTMS propagates in other remote parts of the brain, and these changes are functionally significant and take place on existing neural networks[58].

Depressive disorders are the most studied area of therapeutic use of TMS. Recently there has been an increasing interest in the management of schizophrenia as research results indicate that the negative symptoms of schizophrenia appear to be attributed to PFC hypoactivity, whereas positive symptoms appear to be correlated with left temporo-parietal cortex hyperactivity[59]. It has also been hypothesized that auditory hallucinations may be attributed to aberrant activation of language perception zones (*i.e.*, Wernicke's area) in the left temporo-parietal cortex[60]. It is therefore proposed that the use of high frequency TMS in the left PFC may reduce negative symptoms of schizophrenia, whereas the application of low-frequency TMS to the left temporo-parietal cortex may reduce the positive symptoms[60,61].

Considering the fact that all of those structures appear to be significant in our MLM study, we support the abovementioned model for applying rTMS in individuals suffering from schizophrenia. Moreover, our finding of the effective connectivity aberration between the PFC and the insula provides further insight on the etiopathophysiology of schizophrenia and the role of the disruption of the salience and executive systems processing due to the insular dysfunction because of its failure as a dynamic switch between the DMN, FPN and salience network (SN). Due to its deep location, the insula is considered to be beyond the reach of rTMS. However, we suggest that the insula may still be indirectly modulated by the identified abnormal connectivity from PFC to aI by focusing on PFC, the localization of which makes it accessible for stimulation.

Despite the promising applications of TMS, in about 30% of cases the standard procedure misses the target area, as it only allows stimulation of focal areas just below the skull[62,63]. Deep TMS (dTMS) has been implemented to overcome these drawbacks. dTMS offers all the advantages of conventional TMS with the benefit of stimulating deeper brain zones with lower focal distribution of the electric field[64]. Some studies have been conducted on the use of conventional TMS for the treatment of auditory hallucinations in drug-resistant patients with schizophrenia, which have shown that the method is moderately effective[65,66]. In this sense, we propose inhibitory dTMS as a therapeutic intervention targeting temporal, frontal, and parietal areas, taking into account data from functional neuroimaging which established that hallucinations are accompanied by transient hyperactivity in specific zones—STG, PFC, ACC, inferior parietal cortex, *etc.*[67] and dTMS may be even more effective than conventional TMS due to greater stimulus depth. In addition, dTMS can even be used as a method to modulate the function of the insula directly, unlike standard TMS, in which this area is inaccessible and can only be reached indirectly. Restoring the function of the insula and the networks in which it participates will further improve the function of the SN as a dynamic switch between DMN and FPN. Finally, our paradigm in tr-fMRI can also be applied as a tool for monitoring TMS, with good enough accuracy and reliability of the method.

tDCS

TDCS is a neuromodulatory procedure that facilitates or inhibits spontaneous neuronal activity by delivering low-intensity direct current to cortical areas *via* scalp electrodes. Over the past decade, the physiological mechanisms of action of tDCS have been studied to support the investigation of its clinical neuropsychiatry applications. TDCS was developed as a treatment method for brain injuries and neuropsychiatric disorders, especially MDD. Given the absence of a triggered seizure, it is hypothesized that this technique operates by plastic effects exerted by endogenous firing potentiation[68].

A variety of studies have found that in healthy individuals, anodal tDCS to dorsolateral PFC (DLPFC) leads to increased cognitive performance[69]. In the treatment of MDD, the anode is located over the left DLPFC, which is hypoactive, helping to improve local activation and regain regular functioning[70]. The cathode is located either over the right DLPFC or the right supraorbital or frontotemporal area, leading to distinct current distributions. In addition, after anodal DLPFC tDCS in patients with schizophrenia, enhanced results on working memory tasks[71], probabilistic learning tasks[72], adaptive control tasks[73], and attention-vigilance tasks[74] have been demonstrated. A consistent feature of these diverse tasks is that they all depend, in part, on cognitive control mechanisms such as goal maintenance mediated by DLPFC.

We suggest a model in which the tDCS, instead of focusing on a single cortical area, could simultaneously target several zones that are part of a common network. Considering the results of our imaging studies, they point to the hypothesis that in schizophrenic patients the DMN is incorrectly activated in conditions that are not typical for such activation (tr-fMRI), while based on the study of connectivity we note

that the DMN is deactivated in rest conditions, which is the normal condition of its activation.

Our views are that tDCS can be useful for restoring the normal connectivity of the different components of the DMN if the electrodes are placed simultaneously in several areas of the parietal cortex, namely the PreCu, PCC and AngG, which can potentially regulate the disrupted connection between the individual components of DMN and thus lead to improved symptoms such as cognitive impairment in schizophrenia.

DBS

DBS is the most invasive focal neuromodulation tool for mental disorders available. This technique allows us to deliver electrical stimulation of GM or white matter in a therapeutic attempt to improve the dysfunctional activity of the brain. DBS is probably the most elegant and complex perfect example of the translational approach – integration of instrumental, neurobiological, neurosurgical, and psychopathological knowledge in performing this precise and innovative psychosurgical procedure. It involves a high-frequency deep-brain stimulation by stereotactic inserted electrodes. It is known to act primarily by functional inhibition around the electrode, but it may also have excitatory effects on local axons and far-reaching excitatory effects[75].

DBS has proven to be beneficial in the treatment of severe mental illnesses like major depression[76], obsessive-compulsive disorder (OCD)[77], Tourette's syndrome[78] and addiction[79]. The use of DBS in patients suffering from schizophrenia is still in its early stages and at present has not been officially approved. There seems to be no consensus regarding the particular brain structures, networks, and circuits which could be clinically beneficial for DBS treatment of schizophrenia. Studies have reported DBS of the habenula[80], nucleus accumbens and ACC[81]. These early experiments indicate the capacity of DBS to have beneficial effects in schizophrenic patients who do not respond to any other treatment. In order to assess the magnitude of the advantages and whether they can be accomplished without psychiatric side-effects, further studies would be needed with thoughtful consideration.

We suggest that the future research on the therapeutic effect of DBS in schizophrenia should focus extensively on two important areas, namely the insula and the PreCu, as they are the key nodes of the SN and DMN — the two brain networks that appear to be disconnected in the paranoid group in our study. We speculate that the enhancement of the altered function of the DMN and SN could ultimately restore the cognitive deficits and the disorganized thought and behavior observed in schizophrenic patients.

CONCLUSION

Psychotic and mood disorders affect a large number of people all over the world and have significant effects for individuals, their loved ones and society. To improve the prognosis and outcome of these disorders, it is crucial to make changes in their management. Unconventional instrumental biomedical methods have proven effectiveness for different psychiatric conditions (*e.g.*, ECT for depression, mania, and catatonia; TMS for drug-resistant depression; tDCS for cognitive enhancement in schizophrenia; DBS for OCD, addiction and severe MDD). However, their usage is still limited, and these tools remain in the shadow of psychopharmacology and psychotherapy.

Results from our studies on cross-validation of tr-fMRI, effective connectivity at rest and the MLM point to some interesting and new therapeutic applications that can modulate the SN and thereby the DMN and FPN function that are impaired in people suffering from schizophrenia. Moreover, these findings could be translated in the protocols of methods like ECT, TMS, tDCS and DBS that have the potential to modulate the network plasticity of the brain. The comprehensive approach towards modifying dysfunctional SN and DMN found in patients with schizophrenia is likely to require a combination of pharmacogenomic testing to inform pharmacotherapy selection and dosing decisions in order to restore the aberrant plasticity of brain networks, together with targeted neurostimulation to trigger network reorganization. However, this approach and the specific mechanisms that influence the complex abnormal interactions between the SN and the DMN are not fully understood and need further investigation.

Abstract

BACKGROUND

Measures for effective control of the coronavirus disease 2019 (COVID-19) pandemic include identifying the causal organisms, applying appropriate therapies, and developing vaccines, as well as improving understanding among the general public.

AIM

To evaluate the knowledge, awareness, perception, and response of the general public to COVID-19 in China.

METHODS

A detailed questionnaire comprising 47 questions designed in both English and Chinese was developed. The survey was conducted *via* WeChat, a multipurpose messaging, social media, and mobile payment app that is widely used by the Chinese population. In total, 1006 participants responded, and most of them were from different provinces of mainland China.

RESULTS

Overall, this comprehensive survey revealed that the general public in China is highly aware of the basic information concerning COVID-19 and its precautions. Interestingly, more respondents (99.3%) were aware of the term severe acute respiratory syndrome (SARS) than COVID-19 (97.2%) and Middle East respiratory syndrome (MERS) (73.4%). Among them, 2.4%, 1.6%, and 0.9% said that they or their family members or friends were affected by COVID-19, SARS, and MERS,

respectively. The majority of the respondents (91.2%) indicated that knowledge about COVID-19 was received mainly from WeChat, followed by TV (89%), friends (76.1%), and QQ (a Chinese instant messaging software service) (57.7%).

CONCLUSION

The general public in China is highly aware of COVID-19 and the necessary precautions. Unexpectedly, 2.8% of the participants were unaware of the current epidemic. The remaining information gaps highlight the necessity of further enhancing awareness and preparedness.

Core Tip: This study comprehensively evaluated the knowledge, awareness, and perceptions about coronavirus disease 2019 (COVID-19) among the general Chinese population. Overall, the general public is well aware of the COVID-19 epidemic, knows what COVID-19 is, and is familiar with the precautionary measures. Strikingly, this survey indicated that 2.8% of the participants in China were unaware of the current COVID-19 epidemic.

INTRODUCTION

Coronavirus disease 2019 (COVID-19) is caused by infection with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and is now affecting the global population[1]. In addition to significant losses in terms of morbidity and mortality, COVID-19 has imposed major negative impacts on society and the economy in various aspects. COVID-19 was initially sparked in Wuhan, the capital of Hubei Province, and subsequently spread to the entire province and other parts of China, and eventually to the rest of the world[2]. Measures for effective control of outbreaks include identifying the causal organisms, applying appropriate therapies, and developing vaccines, as well as promoting understanding among the general public.

Syndemics is a group of interlinked health issues associated with two or more conditions that interact synergistically and cause an increased disease burden in the population. At this moment, COVID-19 and an array of noncommunicable diseases interact on a social and economic background, which exacerbates its adverse effects[3]. Strict guidelines with specific emphasis on protective measures such as city lockdowns, travel bans, and within-population quarantines were developed by the authorities for controlling the pandemic. As these measures lead to physical inactivity, they also had an adverse impact on health, such as promoting obesity, premature ageing, cardiovascular vulnerability, bone loss, muscle atrophy, decreased aerobic capacity[4], and psychological issues[5-8]. Physical activity is vital for public health[6], as it acts on the cardiovascular and respiratory systems[7].

Furthermore, the effectiveness of epidemic control implementations relies substantially on the support and cooperation of the public. Thus, awareness and knowledge about the epidemic are essential[9-11]. Despite the experience of the SARS outbreak in 2003 in China, the early response to the COVID-19 outbreak was inadequate from both the Chinese authorities and the general public[12]. Subsequent implementation of strict control measures by the authorities with strong support and cooperation from the public finally resulted in the control of COVID-19 in China. However, COVID-19 has grown into a pandemic and may become endemic[13]. Knowledge gaps always exist about disease epidemics, their potential risks, and the clinical spectrum[13]. Thus, we designed and conducted this survey to evaluate the knowledge, awareness, perception, and response of the general public to COVID-19 in China.

MATERIALS AND METHODS

Study design and participants

A detailed questionnaire comprising 47 questions related to COVID-19 with some questions about SARS and Middle East respiratory syndrome (MERS)[14-16] was designed in both English and Chinese. The survey was conducted *via* WeChat, a Chinese multipurpose messaging, social media, and mobile payment app. It is widely used in China, with monthly active users estimated at one billion.

Knowledge about COVID-19, MERS, and SARS was assessed with questions about whether they had heard about these infections, whether they or their family members or friends had been infected, whether they knew what COVID-19 is and knew its causes, whether they knew the zoonotic origin of the infection, whether they ever ate civet or other wild animals, and whether they knew about the death rate from COVID-19. The participants were assessed regarding COVID-19 risks and associated factors along with their knowledge of possible control measures to avoid the infection. The participants were also asked about general signs and symptoms of the disease and from where they obtained information regarding this infection.

Statistical analysis

Descriptive and inferential statistics were calculated using SPSS version 20.0 for Windows (SPSS Inc., Chicago IL, United States). Awareness and knowledge about COVID-19, SARS, MERS, and related factors are shown as percentage values. All independent variables were divided into two or more categories. Variables that were statistically significant in the univariate analyses were included in the final multivariate logistic regression analysis using SPSS. All statistical tests were two-sided, with a P value < 0.05 considered statistically significant.

RESULTS

The questionnaire was completed from March 11 to 14, 2020. In total, 1006 individuals (aged 18-71 years) from all over China participated in the survey by filling out the questionnaires. The majority of our participants (99.3%) were distributed across 29 provinces of China, with 8.7% from Hubei Province and 0.7% residing outside of China (Supplementary Table 1). Among the respondents, 99.1% were Chinese and 0.9% were foreigners residing in China. Based on ethnicity, 65.4% were Hans and 34.6% were from other Chinese ethnic groups or foreigners. Approximately 63% of participants were female. The detailed sociodemographic characteristics of the participants are presented in Table 1.

Interestingly, more respondents (99.3%) were aware of the term SARS than COVID-19 (97.2%) and MERS (73.4%). Among them, 2.4%, 1.6%, and 0.9% said that they or their family members or friends were affected by COVID-19, SARS, and MERS, respectively. Most of the participants (87.4%) believed that COVID-19 is more dangerous than SARS and MERS, while 47.9% of participants answered that the death rate for COVID-19 patients is less than that of SARS and MERS (Table 2). Approximately 81% of respondents answered that SARS-CoV-2 infection could be transmitted through oral, nasal, and eye routes. Up to 69.7% of people believed that the virus has been transferred from animals to humans and that bats (82.4%) are the reservoir for SARS-CoV-2. The proportion of respondents who had recently consumed wildlife meat was found to be 1.4%. A total of 62.4% of individuals thought that a treatment is available for COVID-19 (Table 2).

This study further revealed that the majority of respondents (46.4%) were experiencing psychological pressure along with economic (19.1%) losses due to the current COVID-19 epidemic in China. A total of 69.4% indicated that they still had not resumed their normal life due to the ongoing epidemic. Unfortunately, 1.5% of people replied that they had lost a loved one due to COVID-19. Furthermore, most of the participants (78%) preferred going in private cars for treatment to hospitals in cases of infection, while 2.2% refused to go to hospitals (Table 2).

Knowledge about the signs and symptoms of COVID-19, such as fever, chills, cough, shortness of breath, and flu, was known by 86.3%, 36.9%, 83.4, 79.0%, and 53.3% of the participants, respectively. However, knowledge about other questions related to the disease incubation period was poor (Table 2). Pearson correlation analysis indicated that the risk of acquiring COVID-19 was negatively associated with general information/knowledge and knowledge about precautionary measures (Supplementary Table 2).

Table 1 Demographic characteristics of participants

Variable	Respondents	Percentage (%)
Sex		
Male	373	37.1
Female	633	62.9
Age, yr		
< 30	524	52.1
31-39	170	16.9
40-49	150	14.9
50-59	98	9.7
> 60	64	6.4
Ethnicity		
Han	658	65.4
Others	348	34.6
Residence		
Rural	372	37.0
Urban	634	63.0

COVID-19: Coronavirus disease 2019; SARS: Severe acute respiratory syndrome; MERS: Middle East respiratory syndrome; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2.

other hand, information about the protective effects of wearing masks and washing hands with soap for at least 30 s was significantly higher among women (P = 0.007) and rural residents (P = 0.007) (Supplementary Table 3). Chinese people, compared to foreigners (P = 0.024), and farmers, compared to other professions (P = 0.001), were

significantly more satisfied with their community health centre facilities (Supplementary Table 4).

The majority of respondents (91.2%) indicated that information about COVID-19 was received mainly from WeChat, followed by TV (89%), friends (76.1%), and QQ (a Chinese instant messaging software service) (57.7%). Some participants said that they received information related to COVID-19 from newspapers (35.5%), magazines (29.2%), WhatsApp (24.9), and Facebook (24.0%), as shown in Figure 1.

DISCUSSION

Preparing the general population for epidemics or pandemics of infectious diseases is not a static or binary exercise but a dynamic state that is continuously changing[16,17]. Therefore, different states prepare their populations with different methods built on their interpretation of disease outbreak threats and global contracts, such as the International Health Regulations[18].

This study represents a comprehensive survey report about the knowledge, awareness, perception, and response of the general public in China regarding COVID-19. Our results indicate that knowledge and awareness of COVID-19 are high among the general Chinese population. Interestingly, the majority of participants said that WeChat was their main source of information, indicating that valuable information about diseases can be effectively communicated among the general public *via* WeChat in mainland China[19]. Moreover, information dissemination through health departments was surprisingly low (48.1%). As 37% of the participants live in rural areas, these people do not regularly engage with doctors, practitioners, or healthcare officials. This might be the possible cause of their low level of knowledge and awareness about different aspects of COVID-19. Interestingly, WhatsApp and Facebook were not the main sources of information for respondents in mainland China; therefore, information and recommendations regarding COVID-19 and other diseases from international stakeholders such as the World Health Organization should use all possible resources to increase knowledge and awareness among the public.

This study was based on an online questionnaire method; hence, limitations such as recall and social desirability biases cannot be excluded. However, the impact of these biases in this study is difficult to assess, as other similar studies have not been conducted so far. The inclusion of innovative interventional methods with informative evaluation plans to monitor the level of knowledge among the community, respond to their needs, and fill the gaps with better preventive methods would be helpful in prospective research.

CONCLUSION

In summary, this study comprehensively evaluated knowledge, awareness, and perceptions about COVID-19 among the general Chinese population. The overall knowledge, awareness, and attitudes about the disease are at a high level, but strikingly, 2.8% of the participants in China were unaware of the current COVID-19 pandemic, which is unexpected. Therefore, we emphasize the importance of initiating health promotion programs to educate the public and healthcare workers about infectious diseases in general for better preparedness for future epidemics and pandemics.

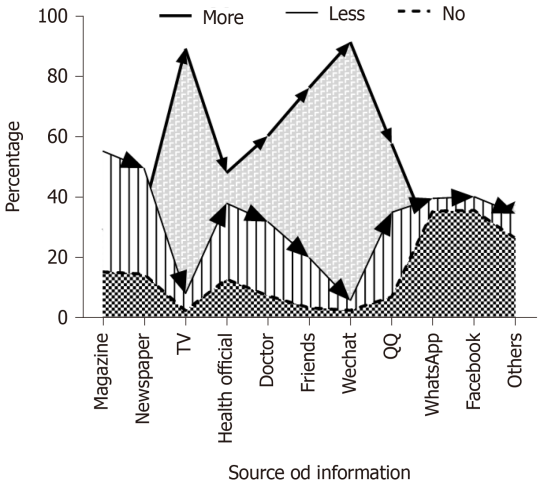

Figure 1 Source of information (little, much, and no) about coronavirus disease 2019. WeChat is a Chinese multi-purpose messaging, social media and mobile payment app. QQ is a Chinese instant messaging software service and web portal. WhatsApp is an American freeware, cross-platform messaging and voice service. Users can send text and voice messages, make voice and video calls, and share images, documents and other media. Facebook is an American online social media and social networking service.

ARTICLE HIGHLIGHTS

Research background

Coronavirus disease 2019 (COVID-19) was initially sparked in Wuhan, the capital of Hubei Province, and subsequently spread to the entire province and other parts of China, and then around the globe. Measures for effective control of outbreaks include identifying the causal organisms, applying appropriate therapies, and developing vaccines, as well as improving understanding among the general public.

Research motivation

COVID-19 has grown into a pandemic and may become endemic. Knowledge gaps always exist about disease epidemics, their potential risks, and the clinical spectrum.

Research objectives

We designed and conducted this survey to evaluate the knowledge, awareness, perception, and response of the general public to COVID-19 in China.

Research methods

A detailed questionnaire comprising 47 questions designed in both English and Chinese was developed. The survey was conducted *via* WeChat, a multipurpose messaging, social media, and mobile payment app that is widely used by the Chinese population. In total, 1006 participants responded from different provinces in mainland China.

Research results

Overall, this comprehensive survey revealed that the general public in China is highly aware of the basic information concerning COVID-19 and the necessary precautions. Interestingly, more respondents were aware of the term severe acute respiratory syndrome than COVID-19 and Middle East respiratory syndrome. The majority of the respondents indicated that knowledge about COVID-19 was received mainly from WeChat, followed by TV, friends, and QQ (a Chinese instant messaging software service).

Research conclusions

We comprehensively evaluated the knowledge, awareness, and perceptions about COVID-19 among the general Chinese population. The overall knowledge, awareness, and attitudes about the disease are at a high level, but strikingly, 2.8% of the participants in China were unaware of the current COVID-19 pandemic, which is unexpected.

Research perspectives

We emphasize the importance of initiating health promotion programs to educate the public and healthcare workers about infectious diseases in general for better preparedness for future epidemics and pandemics.

Abstract

BACKGROUND

An inconclusive result from BRCA1/2 genetic testing indicates that a genetic variant of uncertain significance is detected. This case constitutes the majority of genetic test results, but studies specifically addressing the psychological adjustment of people with inconclusive results are scarce.

AIM

To examine psychological outcomes of receiving an uninformative BRCA1/2 test result.

METHODS

PubMed, PsychInfo, and Cochrane Central Register of Controlled Trials were screened for studies focusing on distress, anxiety, and depression levels in individuals with inconclusive genetic test results. This review is based on the Preferred Reporting Items for Systematic Reviews and Meta-Analyses method.

RESULTS

Studies on psychological outcomes of inconclusive BRCA1/2 focused on general and specific distress, anxiety, and depression. Overall, they produced mixed results. These inconsistent findings are probably due to the uncertainty caused by this type of result, that may also influence the decisions of individuals about surveillance and prophylactic options, reducing their compliance. In addition, this review highlights specific risk and protective factors that affect psychological adjustment in individuals with an inconclusive genetic testing result.

CONCLUSION

Individuals with inconclusive genetic test results need specific educational programs and support to better understand the meaning of their results in order

Core Tip: Undergoing BRCA1/2 genetic testing can produce a significant psycho-social impact. The possible test results are positive (increased risk of developing cancer), negative (the same probability of developing cancer as the general population), or inconclusive. This last outcome produces a more complex situation, as it means that a deleterious mutation is neither identified nor definitively excluded. Though the inconclusive case constitutes most genetic test results, studies specifically addressing psychological adjustment of people with such a result are scarce. The current review aims to address this gap, highlighting psychological outcomes following this kind of result and highlighting specific risk and protective factors.

INTRODUCTION

In the context of breast and ovarian cancer surveillance, genetic screening for the detection of mutations in *BRCA1* (chromosome 13) and *BRCA2* (chromosome 17) genes is a significant advance in cancer care. Each individual carries these two genes, which are responsible for the control and repair of DNA alterations; however, in their mutated form, they are linked to an increased risk of tumor development[1]. These genes are characterized by autosomal dominant inheritance, so one parent has a 50% chance of transmitting them to their children[1,2]. The lifetime risk of developing breast cancer in the general population ranges from 10%-14%, and this risk rises to 85% in women who carry a mutation in the *BRCA1* and *BRCA2* genes[2,3].

For individuals with high cancer history, genetic counselling is proposed. Medical and family histories are collected, and if there is at least 10% likelihood, a buccal smear or a blood sample is taken. The possible test results are positive, negative, or inconclusive[4]. The first one implies that the individual is a carrier of a mutation with an increased risk of developing cancer during his life. A negative result means that the individual is not a carrier of mutation, so he has the same probability of developing cancer as the general population. An inconclusive result produces a more complex situation, as it means that a deleterious mutation is neither identified nor definitively excluded. This may be due to two main reasons: (1) No known BRCA1/2 mutations were found, but a genetic variant of uncertain significance is detected; and (2) Not detecting a mutation in a cancer-affected person who is the first member tested (proband) in a high-risk family[5,6]. In the current review we indistinctly use the terms "inconclusive" and "uninformative" to refer to both the aforementioned situations. Though the inconclusive case constitutes the majority of genetic test results[1,7], research and clinical attention is lacking in this topic, as stated by several authors[5,8].

Undergoing genetic testing and its results can produce a significant psycho-social impact[2,9]. Generally, individual who receives a positive test result reports higher levels of distress, anxiety, and depression[10] while who receives a negative test result reports a decrease in distress levels following the discovery of test results[11]. A recent review of existing literature[12] highlighted that a positive genetic testing results can be traumatic, although not all individuals with such a result experience increased distress. The high distress levels experienced by individuals who receive a positive test results may depend by an increased risk of future diseases and the implications for their whole family[12]. A study highlighted that a possible factor that influences affective states is the perceived risk of developing cancer, regardless of test result[13].

Overall, higher levels of distress, anxiety and depression could depend by some risk factors as having a cancer diagnosis, having a greater history of breast/ovarian cancer, being younger than 40 years old, being unmarried and having high pre-test levels of anxiety and depression[12].

As for those who receive an inconclusive result, the literature is conflictual; some studies identify higher levels of distress in those with an inconclusive result[14] while other studies found that individuals who receive an inconclusive result seem reassured[15]. However, as stated by several authors[12,16], studies specifically addressing psychological adjustment of people with inconclusive genetic test results are scarce. According to Vadaparampil *et al*[8], this gap should be filled, as the topic of inconclusive test results is a key topic deserving clinical and research attention.

Starting from these premises, the main purpose of the current review was to investigate short-, intermediate-, and long-term consequences of receiving uninformative BRCA1/2 test results. To pursue this aim, we analyzed cross-sectional and longitudinal studies which examined anxiety, depression and distress in individuals who receive inconclusive results compared to positive and negative results. In addition, we aimed to highlight risk and protective factors that affect psychological adjustment in individuals with an inconclusive genetic testing result, also considering differences associated with being or not affected by a cancer diagnosis.

MATERIALS AND METHODS

Identification and selection of studies

This systematic review followed the guidelines of Preferred Reporting Items for Systematic Review and Meta-Analyses[17].

We conducted a comprehensive literature search in PubMed, PsychInfo, and Cochrane Central Register of Controlled Trials. All search results were limited to the last 21 years (1999-2020).

We combined search terms related to genetic counselling and its result [(Genetic*, Familial*, OR Mutation*) and (Inconclusive OR Uncertain) and (Breast* OR BRCA*)] with terms relating to psychological outcomes (Psycho*, Distress, Emot*, Anxiety, OR Depression). The reference sections of previous reviews were also checked to ensure that all relevant studies for this review were included.

Selection of eligible articles

Studies were included if they: Analyzed psychological outcomes of receiving an uncertain result; included adult, human subjects; and were written in the English language.

Exclusion criteria were: Articles not specific to BRCA mutation; articles not reporting psychological outcomes; articles that assessed the impacts of genetic counselling before subjects received genetic test results; and literature reviews, qualitative studies, commentaries, letters to the editor, unpublished articles and doctoral theses, abstracts of conferences, congresses, books, and case-reports.

Following the review by Hamilton *et al*[18], we defined short-term as within 1 mo of genetic testing results, intermediate term between 1 and 6 mo, and long-term over 6 mo.

The eligibility criteria were evaluated according to the following aspects: Participants, intervention, comparison, outcome, and study design. (1) Participants: Human adult participants receiving an uncertain result from genetic testing about the presence of BRCA mutation; (2) Intervention: The focus was not limited on a specific intervention; (3) Comparison: Studies comparing people with inconclusive genetic test results to positive and negative results; (4) Outcomes: We analyzed studies that considered short- (1 mo), intermediate- (1-6 mo), and long- (6+ mo) term psychological outcomes (*i.e.*, general and specific distress, anxiety, and depression); and (5) Study design: We included observational and/or quantitative studies.

Anxiety, depression, and distress (both general and specific) have been the focus of the review as they were the outcome measures most frequently evaluated.

RESULTS

A total of 341 studies were identified; of those, 174 were removed as duplicates. The

titles of the selected studies were double screened by two authors independently, 66 studies were excluded because they were not consistent with the eligibility criteria. The abstract of 101 selected studies and the full text of all potentially relevant articles were double screened and evaluated by two authors independently; discrepancies were resolved by discussion; the following were excluded: 11 were reviews, 46 did not focus on psychological variables, 23 studies involved a sample with a different genetic mutation from BRCA or did not focus on inconclusive results, and 11 had an inadequate study design (qualitative studies, unpublished articles, case-reports, books or abstracts of congresses). A total of 10 articles met our inclusion criteria and were, therefore, considered in this systematic review (Figure 1). Included studies were published between 2002-2017 and were most commonly conducted in the United States, followed by Canada and the United Kingdom. Eight studies were longitudinal (80%) and two were cross-sectional (20%). All the included studies were classified on the basis of the timing of questionnaire administration; most studies (n = 7) assessed also baseline levels of psychological measures before the blood test or buccal smear test.

Only one study considered exclusively short-term psychological outcomes, four studies only intermediate-term, and three studies long-term (Table 1). Sample sizes from the reviewed studies ranged from 48 to 465 (mean = 193.30, standard deviation = 135.14), resulting in a total of 1933 participants. Of these, 38% (n = 730) received inconclusive test results, 32% (n = 620) received negative results, 21% (n = 408) received positive results, 7% (n = 126) decided not to undergo genetic testing, and 2% (n = 49) were still waiting for their test results. Only two studies included male participants; the sample was predominantly female (98%).

Of the reviewed articles, six studies compared people with and without a cancer history. The majority of the sample (73%) had a cancer diagnosis. Only four studies reported the type of cancer diagnosis; of these, 94% had breast cancer, 4% had ovarian cancer, and 2% had both.

Outcome measures of the included studies

The findings were divided into four categories: (1) General distress; (2) Anxiety; (3) Depression; and (4) Genetic testing-specific distress. The tools used for the evaluation of each construct are synthesised in Table 2.

The Brief Symptoms Inventory (BSI)[19-22], the Symptom Checklist 90 Revised (SCL-90)[23-25], the Impact of Event Scale[26,27], the General Health Questionnaire[28,29], and the Hopkins Symptom Checklist[30,31] were used to assess general distress symptoms. Depressive symptoms were assessed using the BSI[6,19,20], the SCL-90[23,24], the Hospital Anxiety and Depression Scale (HADS)[29,32], and the Center for Epidemiologic Studies Depression Scale[25,33].

The BSI[6,19,20], the SCL-90[23,24], the HADS[29,32], and the State Trait Anxiety Invento-ry[25,34] evaluated anxiety symptoms.

Finally, genetic testing-specific distress was evaluated by means of the Multidimensional Impact of Cancer Risk Assessment[6,20,27,35,36].

General distress

The majority of the reviewed studies did not find significant differences in psychological adjustment among individuals who received inconclusive, positive and negative results[22,24,25,29,31]. One study observed higher levels of distress, especially on the somatization scale, in those who received inconclusive results compared with positive and negative results, and people deciding not to undergo genetic testing[21]. Instead, a recent study of Lumish *et al*[27] highlighted that individuals receiving an inconclusive result reported intermediate levels of general distress, higher than negative but lower than positive result.

Schwartz *et al*[31] did not find increased levels of distress in people with inconclusive results compared to positive and negative results, but they did not identify a decrease in distress levels in the intermediate-term (*i.e.*, 1-6 mo) in individuals with inconclusive results, which occurs in those who receive negative results. Two studies found that general distress decreased slightly over time, from pre-test to 6 mo post-test[20,25]. Other studies reported that there were no differences in distress levels from pre-test levels up to 6 mo after genetic test disclosure[22,29].

Regarding differences between cancer affected patients and unaffected patients, overall, unaffected patients with positive or inconclusive results reported higher levels of distress compared to both affected patients and unaffected patients with negative results[27]. Other studies highlighted that having had a cancer diagnosis did not influence distress levels; in fact, they did not detect differences between affected and unaffected patients[21,22,25].

Schwartz *et al*[31], 2002[1]		Y	
Smith *et al*[25], 2008[1]	Y	Y	

[1]Studies that assessed also baseline levels of general distress, anxiety, depression and genetic test specific distress (*i.e.*, before genetic test disclosure).
Y: Yes.

In addition to genetic test results, other factors which could increase distress levels in those who receive an inconclusive result may be a cancer diagnosis[27], higher distress levels before genetic testing[25], the intolerance of uncertainty[20], and cancer-related distress[20].

However, there are also some protective factors that could mitigate or decrease distress levels such as marital status[20], partner support, and protective buffering[21].

Anxiety

None of the reviewed studies found differences in anxiety levels among individuals with inconclusive, positive and negative results[24,25,29] except for one study that found that patients with inconclusive results reported higher levels of anxious symptoms after test result disclosure than negative ones[6].

Some studies observed anxious symptoms in the intermediate-term[25] and long-term[6,29]. Two studies of these did not find changes in anxiety levels in the intermediate-term[25,29], while O'Neill *et al*[6] detected a decrease in anxiety over time for individuals who received negative test result and stable levels of anxiety in those who received inconclusive results from the discovery of the test result up to 6 mo later, with a subsequent decrease.

Only one of the reviewed articles that focused on anxiety investigated whether there were differences among affected and unaffected patients and found that there were no differences between them[25].

Overall, some factors that could influence anxiety levels in individuals who receive an inconclusive test results, might be: Higher distress levels before genetic testing[25], higher pre-testing anxiety[6], correctly interpreting the meaning of the genetic test result[24,29], primary appraisal, namely the way people evaluate the importance of a stressful situation[6], and ethnicity[6].

Depression

Four of the included studies focused on depression[6,24,25,29]. The majority of the reviewed studies did not identify differences between those receiving inconclusive, positive and negative results[24,25,29].

Two studies did not identify effects of time on depression in the intermediate-term[25,29]. Only one study analyzed long-term outcomes (6 mo), highlighting that depressive levels were significantly higher in individuals receiving inconclusive results compared to negative[6].

Having received a cancer diagnosis did not influence depressive levels, regardless of the test results[25]. Other factors could influence depressive levels among individuals who receive an inconclusive test result: Misinterpretation of test results[24,29], pre-test depressive levels[6,25], primary appraisal[6], and ethnicity[6].

Table 2 Characteristics of included studies

Ref.	C country	AAim	Study design	Psychological measurements	Sample size and gene mutation status	Personal cancer history
Bish *et al* [29], 2002	United Kingdom	Examine the effects of an uncertain test results affects mood and behavior	Longitudinal	HADS; IES; GHQ-28; Cancer Worry Scale	Total sample = 48. Positive = 0. Negative = 0. Inconclusive = 48	History = 48. No history = 0

Genetic testing-specific distress

Four of the included studies focused on genetic testing-specific distress[6,20,27,36], which was assessed only after genetic test disclosure. All the reviewed studies measured specific distress in the long-term[6,27,36] except for one study that assessed it in the intermediate-term[20].

Two studies found that inconclusive results were associated with lower levels of genetic testing-specific distress than positive test results[27,36] but higher than negative results[27,36].

Higher levels of genetic testing-specific distress were observed from 1-6 mo and 1 year after genetic test disclosure[6,20,36]; specifically, individuals with inconclusive

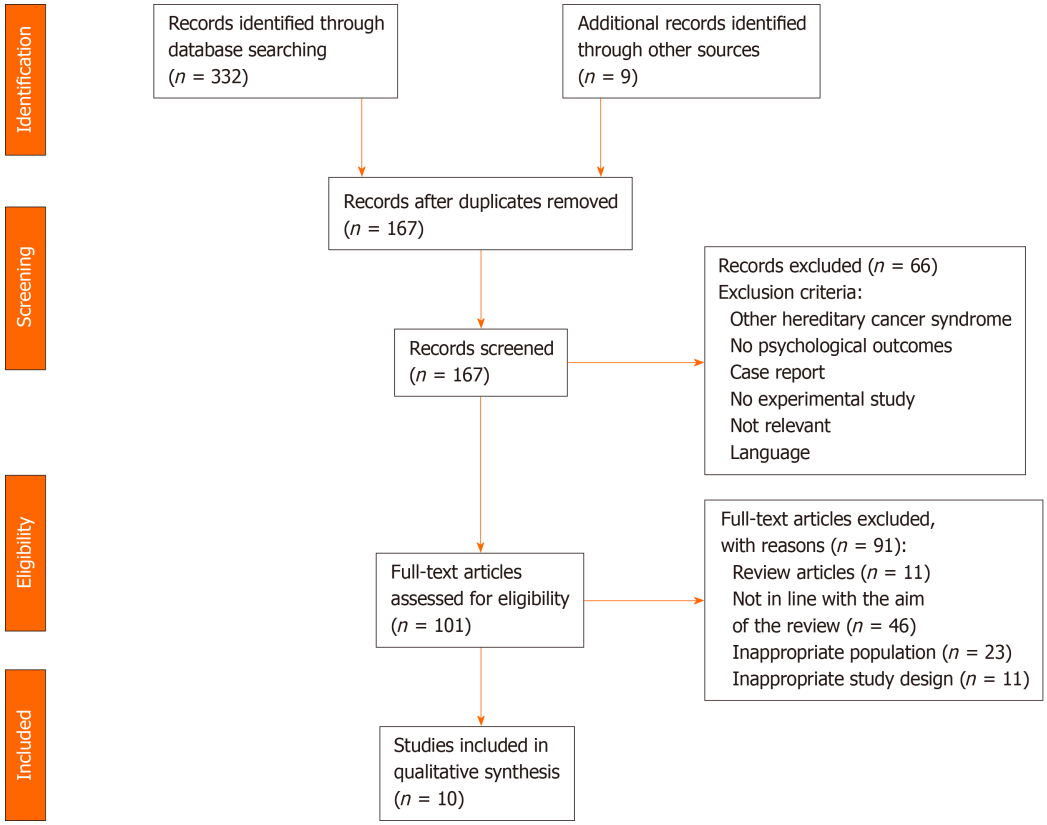

Figure 1 Flow chart of selection and inclusion process, following the Preferred Reporting Items for Systematic Reviews and Meta-Analysis statement.

results reported higher levels of specific distress persisting even 1 year after test disclosure[6]. O'Neill *et al*[6] detected that distress levels among inconclusive results stayed stable over time and decreased among negative results.

Individuals affected by cancer who receive inconclusive results showed higher levels of distress related to genetic testing than unaffected individuals with inconclusive results, affected carriers, and both affected and unaffected non-carriers[27]. On the contrary, Graves *et al*[36] identified that mutation carriers with a cancer diagnosis had higher levels of distress than affected individuals with uncertain results.

In general, some potential risk factors that could influence genetic testing-specific distress in individuals who receive an inconclusive result are higher pre-test perceived risk[6,20], lower education level[27,36], younger age[27,36], ethnicity[6,36], lower genetic knowledge[27], coping with uncertainty[20], confusion regarding the interpretation of test results[27], pre-test distress[6,36], pre-test anxiety[36], and stronger levels of primary appraisal[6]. Some protective factors, such as being married[36] and stronger secondary appraisal[6], can reduce distress related to genetic testing.

DISCUSSION

The main purpose of the current review was to investigate the consequences of receiving inconclusive results from BRCA1/2 genetic testing on psychological outcomes such as general distress, anxiety, depression, and genetic testing-specific distress. To our knowledge, our review is the first to explore the short-, intermediate-, and long-term psychological effects of receiving inconclusive results in both affected and unaffected patients, as previous reviews were mainly based on individuals who receive a positive or a negative result[12,13,37]. From the analysis of the selected articles, overall different results were found.

Most studies (five of the ten considered) did not report differences in levels of general distress, anxiety, and depression among individuals with inconclusive results, as compared with both positive and negative results[22,24,25,29,31]. Other studies

have found that those who receive inconclusive results experience higher levels of general and specific distress, anxiety, and depression than who have a negative result[6,27,36], but lower than positive ones[27,36]; and finally, a study identified that the inconclusive results caused greater levels of general distress when compared with both positive and negative results[21].

The differences detected from the reviewed studies might depend on the different tools used to assess distress, anxiety, and depression, which might not be sufficiently sensitive in this field[12]. As evidenced by a study by Power *et al*[21], individuals with an uninformative BRCA1/2 test result reported higher levels of distress, specifically in the somatization scale, so it could be that this subgroup of patients experienced distress through the body. Hence, it could be useful to develop more sensible tools, specifically addressing this field.

Although no differences were found between negative and inconclusive results, there was no decrease over time in the levels of distress, anxiety, or depression, which instead occurred in individuals with a negative result[6,31]. A possible explanation for these results might be the lack of relief from this type of test result[16] and having to copy with the uncertainty[21,24,29,38,39]. Indeed, individuals who have difficulty in coping with uncertainty have higher levels of ongoing distress[20]. The uncertainty related to this type of result also influences the decisions of individuals about surveillance and prophylactic options; only a fraction of patients who receive this type of result decides to increase cancer screening[27]. Moreover, some patients determine not to carry out preventive surgery, as they need a more certain result before deciding on this irreversible option[24], from which psychological benefits might be derived due to the cancer risk decrease[40], or it can also lead to adverse psychological impacts and dissatisfaction[41-43]. Graves *et al*[36] identified that having prophylactic surgery does not reduce distress levels but only the perceived risk of developing cancer.

Two studies showed that individuals with a cancer diagnosis have greater levels of distress, anxiety, and depression than those without a previous cancer diagnosis[27,36]; in the group of affected people, being mutation carriers[36] or having received an inconclusive result[27] were associated with a worse psychological adjustment. Patients with a recent cancer diagnosis could represent a population more vulnerable to higher levels of distress, anxiety, and depression due to the impact of the diagnosis and its treatment[44,45]. Other studies did not find differences between affected and unaffected patients[20,25,31]. A possible explanation for these inconsistent results could be the psychological benefit that affected patients derived from genetic testing[12,37], because medical surveillance protocols make the process predictable and understandable[37]. Due to this, affected patients and individuals who receive a positive test result might be better able to cope with this situation than individuals who have to cope with the uncertainty[20,46,47].

Apart from having had a cancer diagnosis[27,36], other factors that influence the psychological outcomes related to genetic test disclosure also emerged from the current review. Among the major risk factors are: Higher pre-test levels of distress and anxiety[6,24,25,31], younger age[6,22,27,36], correctly interpreting the meaning of the test result[24,29], intolerance of uncertainty[20], use of the primary appraisal[6], higher perceived risk before genetic testing[6,20], having a family history of cancer[25,36], lower education level[27,36], lower genetic knowledge[27], having children[36], lower income[36], and belonging to a minority ethnicity[6]. Regarding appraisal, it consists in the evaluation of the relevance of a stressful event such as genetic testing and/or cancer diagnosis[48,49]. Some studies have shown that different coping and evaluation strategies influence distress and stress levels; using a higher primary appraisal and emotional suppression are associated with higher levels[50,51], while increased use of secondary appraisal and cognitive reappraisal are associated with better psychological outcomes[50,52].

In addition to secondary appraisal and cognitive reappraisal, other factors could decrease distress levels such as being married[20,36], having partner support[22], having a bilateral salpingo-oophorectomy[36], and protective buffering[22].

This review revealed that those who receive inconclusive results are a subgroup of patients who need educational programs and more pre-test information to better understand the meaning of their test so they can make decisions about surveillance and prophylactic options.

This literature review has some limitations. First, only a few studies were included in this review because the majority of studies focus on the psychological outcomes of those who receive positive or negative results, although inconclusive results are the most common[1,7]. Another limitation is that the studies we analyzed included different standardized measures concerning distress, anxiety, and depression. It could be that these standardized tools are not sufficiently sensitive in this field and that those

who receive positive, negative, and inconclusive results experience emotional distress differently. Moreover, the sample is unbalanced, as some studies exclusively include patients affected by a cancer diagnosis, a factor that contributes to experiencing higher levels of distress, anxiety, and depression. Finally, there was high variability between the time elapsed from the genetic test to the administration of the psychological questionnaires among the reviewed articles, and not all the reviewed studies administered the questionnaires at the same time to all patients. These limitations lead us not to generalize our results.

CONCLUSION

The results of this systematic review give a fuller picture of the psychological impact of receiving inconclusive results and can help genetic counsellors, health professionals, and researchers to provide more support to this subgroup of patients, by providing adequate information about the meaning of inconclusive genetic test result and its implications in terms of risk to develop cancer. The present review could also be able to improve the knowledge of experiences related to coping with uncertainty, suggesting which are the psychological aspects to consider when working with this type of patients. There is still much to understand in this difficult context, and it is necessary to take into greater consideration those who receive inconclusive results in the research and pre-test and post-test educational program to fully explain to people that inconclusive results do not exclude the possibility that they still might face a higher risk of developing ovarian or breast cancer. These considerations are required in health care contexts to provide adequate psychosocial support for people undergoing genetic testing.

ARTICLE HIGHLIGHTS

Research background

The majority of BRCA1/2 genetic test consists of an inconclusive result, which produces a complex situation, as it means that a deleterious mutation is neither identified nor definitively excluded.

Research motivation

Studies specifically focusing on the psychological adjustment of people with inconclusive results are scarce and a systematic review on this topic is missing.

Research objectives

The principal purpose of this review was to examine short-, intermediate-, and long-term psychological outcomes of receiving an uninformative BRCA1/2 test result, with regard to distress (both general and genetic testing-specific), anxiety, and depressive levels. A further purpose was to highlight risk and protective factors affecting psychological adjustment in individuals with an inconclusive genetic testing result, also considering differences associated with being or not affected by a cancer diagnosis.

Research methods

The guidelines of Preferred Reporting Items for Systematic Review and Meta-Analyses were followed in the current review. A comprehensive literature search in PubMed, PsychInfo, and Cochrane Central Register of Controlled Trials was carried out. Search results referred to the last 21 years (1999-2020).

Research results

Studies on psychological outcomes of inconclusive BRCA1/2 focused on general and specific distress, anxiety, and depression. Overall, they produced mixed results. These inconsistent findings are probably due to the uncertainty caused by this type of result, that may also influence the decisions of individuals about surveillance and prophylactic options, reducing their compliance. In addition, this review highlights specific risk and protective factors that affect psychological adjustment in individuals with an inconclusive genetic testing result.

Research conclusions

This review highlights that individuals who receive an inconclusive result are a subgroup of patients who need educational programs and more pre-test information to better understand the meaning of their test in order to make adequate decisions about surveillance and prophylactic options.

Research perspectives

Overall, the current review highlights the importance to address two main issues in this field: From a research perspective, it is recommended the development of tools more sensible to detect the psychological outcomes of inconclusive BRCA1/2 genetic test results; from a clinical perspective, health professionals and genetic counsellors should provide more psychoeducational support to this subgroup of patients about the meaning and the management of the uncertainty associated with their condition.

ABOUT COVER

Editorial Board Member of *World Journal of Psychiatry*, Peer Reviewer, Vijaya Anand Arumugam, PhD, Professor, Department of Human Genetics and Molecular Biology, Bharathiar University, Coimbatore 641046, Tamil Nadu, India. avahgmb@buc.edu.in

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatr*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc*.

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, and PubMed Central. The 2020 edition of Journal Citation Reports® cites the 2019 impact factor (IF) for *WJP* as 3.545; IF without journal self cites: 3.545; Ranking: 46 among 155 journals in psychiatry; and Quartile category: Q2.

Abstract

Depression is a common mental disorder and one of the leading causes of disability around the world. Monoaminergic antidepressants often take weeks to months to work and are not effective for all patients. This has led to a search for a better understanding of the pathogenesis of depression as well as to the development of novel antidepressants. One such novel antidepressant is ketamine, which has demonstrated both clinically promising results and contributed to new explanatory models of depression, including the potential role of neuroplasticity in depression. Early clinical trials are now showing promising results of serotonergic psychedelics for depression; however, their mechanism of action remains poorly understood. This paper seeks to review the effect of depression, classic antidepressants, ketamine, and serotonergic psychedelics on markers of neuroplasticity at a cellular, molecular, electrophysiological, functional, structural, and psychological level to explore the potential role that neuroplasticity plays in the treatment response of serotonergic psychedelics.

Key Words: Serotonergic psychedelics; Psychedelics; Depression; Antidepressants; Neuroplasticity; Ketamine; Hallucinogens

INTRODUCTION

Depression is a common mental disorder, and considered to be a major contributor to the overall global burden of disease, affecting an estimated 300 million people worldwide[1]. We have known for more than 60 years that medications with antidepressant action increase monoaminergic transmission[2]. Since imipramine was first introduced in 1957, numerous antidepressants have been developed with increasing specificity for the monoamine systems, including agents selective for serotonin, dopamine and norepinephrine. Surprisingly, while these agents lead to an immediate change in monoaminergic neurotransmission, they typically require at least 4 wk of treatment before leading to beneficial effects, and they are only effective around 30%-40% of the time. These observations have led to the conclusion that, rather than treating a "serotonin deficit" (or some other monoamine deficit) antidepressants may work by promoting some form of neuroplasticity in brain circuits that are relevant to depression[3].

Neuroplasticity is a general term that encompasses molecular, cellular, electrophysiological, structural, functional and psychological changes in the brain. Neuroplasticity underlies our ability to learn and is important for recovery after injury [4]. However, the neuroplasticity model of depression suggests that maladaptive plasticity can also lead to problems, such as those that occur in major depressive disorder (MDD). Antidepressants may work in part by harnessing the power of neuroplasticity to change brain circuits driving maladaptive cognitions and behaviors and thereby improve symptoms[5]. This neuroplasticity-based theory of depression and antidepressant action may also provide an explanatory model for how the novel antidepressant, ketamine, exerts its antidepressant effects.

Ketamine modulates glutamate receptors: It is a non-competitive antagonist at the glutamate N-methyl-D-aspartate (NMDA) receptors (and its metabolite, hydroxynorketamine acts on AMPA receptors). It has been utilized for decades as a dissociative anesthetic. In the early 2000s, the intravenous formulation was discovered to have rapid antidepressant effects at sub-anesthetic doses[6]. Since then, numerous randomized controlled trials have replicated ketamine's antidepressant effects[7-9]. In the last few years the S+ enantiomer of ketamine, esketamine, has received an FDA indication for treatment resistant depression and acute MDD with suicidal ideation or behavior. Due to its non-traditional mechanism of action as well as its rapid effects, ketamine has broadened our understanding of the possible mechanisms behind depression and antidepressant action; and has contributed to the shift in focus from monoamine functioning to neuroplasticity as a target for antidepressant action.

Since the emergence of glutamatergic agents as new approaches to the treatment of MDD, we have also witnessed renewed enthusiasm for the potential therapeutic role of serotonergic psychedelics. Serotonergic psychedelics encompass a broad category of compounds including lysergic acid diethylamide (LSD), psilocybin, mescaline, dimethyltryptamine (DMT, an active ingredient of ayahuasca), and other derivates that induce non-ordinary states of consciousness, and act as agonists or partial-agonists at the serotonin 2A (5-HT_{2A}) receptor[10-12]. Serotonergic psychedelics have been used for thousands of years in traditional medicine and religious ceremonial settings[11]. In the 1940s, LSD played an increasingly important role in the field of psychiatry in clinical and research settings until the end of the 1960s when psychedelics were made illegal and clinical research abruptly ceased[13]. More recently, clinical research with serotonergic psychedelics has slowly started to reappear. Recent clinical research in the context of psychedelic-assisted psychotherapy, has demonstrated the efficacy of psilocybin in treatment resistant depression[14], in MDD [15], and in cancer-related anxiety and depression, with positive effects lasting up to several months after treatment[16]. Similarly recent trials with ayahuasca in recurrent

MDD and in treatment resistant MDD suggest its potential efficacy for MDD[17]. Although clinical trials with LSD are limited, a randomized control double-blind crossover study of LSD in healthy subjects demonstrated lasting changes in positive attitudes about life, positive mood changes, positive social effect and positive changes in well-being[18]. It is important to note that psychedelics may also be associated with transient anxiety, negative affect, and psychosis, which appears to be more common in unprepared users or users with vulnerability to psychosis, however there is no evidence of prolonged psychotic reactions in modern clinical trials when individuals are properly screened[19]. While these early findings suggest that psychedelics may have a potential therapeutic benefit in certain patient populations, the antidepressant mechanism of serotonergic psychedelics remains poorly understood.

One hypothesis is that all antidepressants share, in common, efficacy in driving neuroplasticity relevant to depression circuits. This paper seeks to briefly review the changes in neuroplasticity associated with MDD, and the larger established literature demonstrating the role that neuroplasticity plays in the therapeutic effect of classic antidepressants and ketamine. We will use this as a basis for exploring what is known about serotonergic psychedelics on markers of neuroplasticity (Figure 1).

MOLECULAR CORRELATES OF PLASTICITY ASSOCIATED WITH MDD, CLASSIC ANTIDEPRESSANTS AND PSYCHEDELIC AGENTS

Neurotrophic factors play an important role in neuroplasticity. Neurotrophic factors are a family of molecules that, by binding to specific neurotrophic receptors, support growth, survival, differentiation and synaptic plasticity of neurons. Brain derived neurotrophic factor (BDNF) is a key neurotrophic factor involved in most forms of synaptic plasticity. By binding to its corresponding receptor tropomyosin receptor kinase B (TrkB), BDNF activates intracellular pathways that play an important role in the survival and differentiation of neurons and during synaptogenesis[20-22].

Alterations in BDNF-TrkB signaling have been associated with depression in both humans and animals models[23]. In multiple rodent models of chronic, intermittent, or social defeat stress, BDNF-TrkB signaling has been found to be decreased in the prefrontal cortex (PFC) and hippocampus[24,25]. Chronic stress also may increase BDNF/synaptic plasticity in the amygdala and nucleus accumbens[25], suggestive of maladaptive plasticity. In humans, decreased blood levels of BDNF, and cortical expression of BDNF (measured in postmortem studies) have been noted in subjects with MDD[26,27]. Lower levels of BDNF and TrkB expression have also been found in the hippocampus and PFC of subjects who had died by suicide[28].

Typical antidepressants seem to work in part by activating BDNF/TrkB pathways. Chronic antidepressant treatment has been shown to increase BDNF and TrkB receptor mRNA expression in the hippocampus[29] and heterozygous BDNF knockout mice show an impaired antidepressant response[24]. The antidepressant effect of ketamine has also been associated with an increase in BDNF levels in several studies[30,31] and as with typical antidepressants, heterozygous BDNF knockout mice do not show the typical anti-depressant effects of ketamine[32]. Moreover, NMDA antagonists (*e.g.*, memantine) that do not increase BDNF also do not show antidepressant effects, providing further evidence that it is the mechanism of plasticity, rather than NMDA antagonism, that mediates the antidepressant effects of ketamine[33]. This is further bolstered by recent evidence that direct activation of AMPA receptors by a metabolite of ketamine, hydroxy-nor-ketamine, may be sufficient to increase BDNF and induce an antidepressant response[30]. Down-stream from BDNF, there is much evidence that antidepressants like ketamine work *via* TrkB-induced activation of mTOR[34,35]. In animal models, this mTOR pathway seems critical for the rapid effects of ketamine[36].

In vitro research suggests serotonergic psychedelics can also rapidly increase BDNF levels[37]. Cortical neurons were treated with DOI (a psychedelic amphetamine), DMT or LSD for 24 h before measuring *BDNF* gene and protein expression using droplet digital polymerase chain reaction and enzyme-linked immunosorbent assay, respectively. Although serotonergic psychedelics did not increase the presence of the BDNF transcript they did result in a 2-fold increase in BDNF protein levels[37]. In human trials, a study in Brazil demonstrated that a single dose of ayahuasca in healthy controls (HCs) and patients with treatment resistant depression led to higher levels of serum BDNF which has been previously negatively correlated with depressive symptoms[38]. Similarly, a recent study of low doses of LSD demonstrated increased serum BDNF levels in HCs at 4 h and 6 h after administration, compared to placebo [39].

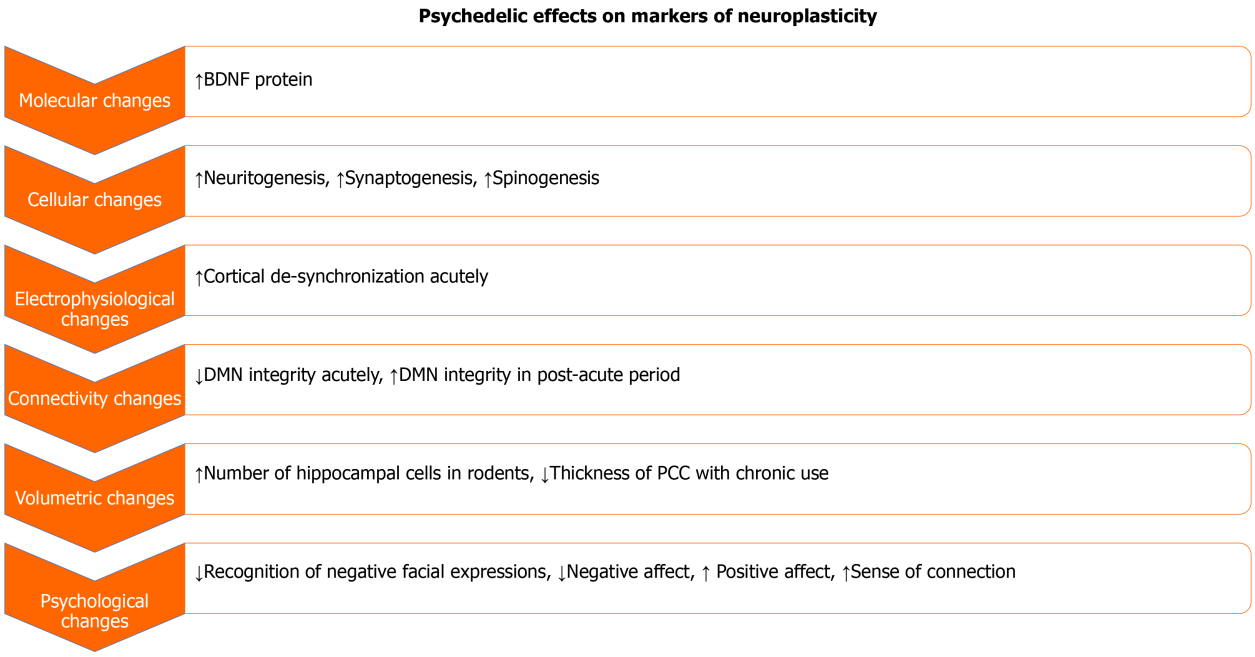

Figure 1 Psychedelic effects on markers of neuroplasticity. At the molecular level serotonergic psychedelics have been associated with increases in brain derived neurotrophic factor protein; at the cellular level serotonergic psychedelics have been associated with increases in neuritogenesis, spinogenesis, and synaptogenesis; at the electrophysiological level serotonergic psychedelics have been shown to lead to cortical desynchronization acutely, less is known about the long term electrophysiological changes although; at the level of functional connectivity serotonergic psychedelics lead to a decrease in default mode network (DMN) integrity acutely but longer-term they may lead to a normalization of DMN integrity; less data exists about volumetric changes with serotonergic psychedelics although in rodents hippocampal neurogenesis has been observed and in long term ayahuasca users decreased thickness of the posterior cingulate cortex has been observed; at a psychological level serotonergic psychedelics have been associated with changes in emotional processing specifically: decreased negative affect, increased positive affect, and an increased sense of connection to the self, others, and the world. BDNF: Brain derived neurotrophic factor; DMN: Default mode network; PCC: Posterior cingulate cortex.

CELLULAR CORRELATES OF PLASTICITY ASSOCIATED WITH CHRONIC STRESS, CLASSIC ANTIDEPRESSANTS AND PSYCHEDELIC AGENTS

There is a large body of literature demonstrating that chronic stress, of various forms, leads to atrophy of prefrontal and hippocampal dendrites[40-43] and synapse loss in those brain regions[44-46]. By contrast, chronic stress models show increased spine density in the basolateral amygdala and nucleus accumbens[47,48]. Postmortem studies in humans are limited but have demonstrated similar findings. For example, there is reduced dendritic branching in the hippocampus and PFC[49] with reduced synapse number in the PFC of depressed subjects[50]. In rodent models of depression, there is evidence that chronic antidepressant treatment can block or reverse some of the above noted changes, including dendritic atrophy and spine loss in the hippocampus and the PFC[51]. Ketamine has also been observed to rapidly increase the number of spine synapses in layer V neurons of the mPFC of rodents in association with its antidepressant behavioral response, and with a similar time course in which the antidepressant effects occur[36,52,53].

Recent research on serotonergic psychedelics suggests that they, likewise, promote rapid dendritic and axonal remodeling. A detailed *in vitro* report observed increased dendritic arbor complexity when cortical neurons were treated with the serotonergic psychedelics (DMT, DOI, LSD, and psilocin) as well as the entactogen (MDMA) which appeared to arise from an increase in number of dendritic branches and the total length of branches[37]. The effects were even greater to those seen when cortical neurons were treated with ketamine at similar doses. These effects were not observed after treatment with serotonin or D-amphetamine. The *in vivo* effects of serotonergic psychedelics on neuritogenesis were measured in this study and drosophila larvae treated with LSD and DOI were observed to have increased dendritic branching of class 1 sensory neurons. Serotonergic psychedelics also had an effect on spinogenesis in rat cortical cultures treated with DOI, DMT, and LSD showed an increase of dendritic spines, with LSD doubling the number of spines observed. Adult rats treated with an intraperitoneal dose of DMT also showed a significant increase in synaptic spine density in the PFC 24 h after dosing, coupled with an increase in excitatory post

synaptic currents (EPSCs). Interestingly, the effect on neuritogenesis and spinogenesis in cortical neurons was blocked by a TrkB antagonist, ANA-12 and by treatment with rapamycin, an mTOR inhibitor. Thus, this study demonstrated rapid effects of serotonergic psychedelics on neuritogenesis and synaptogenesis are likely mediated by TrkB and mTOR pathways. The effects of serotonergic psychedelics on neuritogenesis and spinogenesis in cultured rat cortical neurons was also reduced by inhibition of the 5-HT_{2A} receptor with ketanserin, a 5-HT_{2A} receptor antagonist, suggesting that activation of 5-HT_{2A} receptor by serotonergic psychedelics may play a role in their neuritogenesis and synpatogenic properties[37].

ELECTROPHYSIOLOGICAL MECHANISMS UNDERLYING RAPID PLASTICITY ASSOCIATED WITH KETAMINE AND SEROTONERGIC PSYCHEDELIC AGENTS

We have described above how ketamine and serotonergic psychedelics have been shown to promote rapid synaptic plasticity, with this plasticity possibly mediated *via* BDNF/TrkB and mTOR pathways. However, one question is why ketamine and serotonergic psychedelics have such rapid effects on plasticity. One hypothesis is that they do so because they induce molecular/cellular correlates of plasticity while simultaneously activating brain circuits in ways that amplifies or drives activity-dependent plasticity[22].

To understand how serotonergic psychedelics might result in rapid plasticity, we reviewed the evidence around whether such agents modify brain activity in a way that, like ketamine, might drive activity-dependent plasticity. Ketamine has long been shown to increase cortical excitability[54]. These changes may occur by suppressing activity of inhibitory neurons preferentially[55-57], resulting in an overall state of disinhibition. More recent work has shown that that ketamine-induced antidepressant effects are specifically linked with inhibition of somatostatin neurons[58] resulting in increases in excitability of parvalbumin in addition to glutamatergic neurons and thus protection of spines that would otherwise have been pruned[59]. Evidence from humans corroborates that there is a net increase in both glutamate and GABA (gamma-aminobutyric acid) concentrations in PFC measured using proton spectroscopy after ketamine suggesting that, in humans too, there is a relative disinhibition of prefrontal cortical activity[60]. This data is verified using *in vivo* electrophysiology as well. Multiple studies, across both humans and animals, suggest that ketamine (and its metabolite, hydroxy-norketamine) results in a clear increase in gamma activity (30-80 Hz activity, a useful index of an increase in cortical excitability [61,62].

Some research suggests that serotonergic psychedelic drugs may directly modulate prefrontal cortical activity, leading to activity-dependent plasticity, *via* 5-HT_{2A} receptor activation in the cortex, though it appears to do so in a way very different then ketamine[63]. The 5-HT_{2A} receptor is expressed in deep layer V pyramidal neurons and GABAergic (particularly parvalbumin, PV+) neurons[63,64]. Activation of the 5-HT_{2A} receptor depolarizes and directly excites a subpopulation of deep Layer V pyramidal neurons[65,66], leading to an increase in glutamatergic EPSCs[67-70]. There are reports that pyramidal neurons show both increases and decreases in spiking in response to 5-HT_{2A} agonists, though typically a higher proportion of pyramidal neurons are increased[71-73]. However, unlike ketamine, serotonergic psychedelics like DOI and 5-MeO-DMT actually reduce low-frequency oscillations[71,72] and gamma oscillations [73]. Data from humans also shows that serotonergic psychedelics are all associated with a broadband reduction of power less than 100 Hz[74-77].

In summary, while there is some preliminary evidence that both ketamine and serotonergic psychedelics increase molecular and cellular aspects of synaptic plasticity (activation of BDNF/TrkB pathways; increased synapse/dendritic structure), the mechanisms by which ketamine and serotonergic do this seem to be quite different. With ketamine, there is evidence of an increase in gamma activity/excitability in the cortex, which could serve to activate activity-dependent mechanisms of plasticity and may explain some of the rapid effects observed. With serotonergic psychedelic agents, changes in activity have been shown for certain deep pyramidal cells, but overall evidence from *in vivo* studies suggests that there is not a global level of disinhibition or increase in neural synchrony as a general or wide-spread phenomenon during psychedelics exposure.

PLASTICITY WITHIN DEFAULT-MODE-NETWORK STRUCTURES

Neuroplasticity may also be observed on the level of changes in brain networks[78]. The literature suggests that symptoms of depression are associated with network alterations in "default-mode" brain networks, as well as in salience, affective and cognitive control/executive function brain networks[79]. The default mode network (DMN) defined by the anterior medial PFC, posterior cingulate cortex (PCC) and angular gyrus has consistently demonstrated altered connectivity in depression[80]. The normal functioning of the DMN has been associated with self-referential processes, which may be maladaptively heightened in patients with depression[81]. Processes such as maladaptive rumination that are associated with depression, and involve a repetitive reflection of negative thoughts and emotions[82], are associated with hyper connectivity of the DMN both in depressed patients and healthy subjects [83].

It is likely that a simple linear relationship between increased or decreased connectivity in the DMN being correlated to depression and antidepressant response is over-simplified, and instead antidepressant therapies may work to reconfigure the default mode towards healthier patterns. In that vein, antidepressants have been found to affect and normalize altered DMN connectivity. In a study of healthy volunteers a two week administration of the serotonin-norepinephrine reuptake inhibitor (SNRI) duloxetine was found to reduce default mode connectivity in healthy individuals during rest[84]. In a study of 41 patients with dysthymic disorder, a depressive disorder similar to MDD, who were found to have alteration of DMN activity compared to normal controls, 10 wk of treatment with duloxetine was found to normalize function in the DMN, compared to placebo which had no such effect[85]. Ketamine has also been associated with circuit level changes in the DMN. In a randomized, placebo-controlled, double-blind, crossover study in healthy subjects, ketamine was found to decrease functional connectivity of the DMN to the dmPFC [86]. A different study comparing HCs with patients with MDD measured functional connectivity at baseline and at 2 and 10 d after ketamine infusion. In subjects with MDD, connectivity between the insula and the DMN was normalized compared with HCs 2 d post ketamine infusion. This change was reversed after 10 d, a typical time course when the effects of ketamine begin to diminish and did not appear in either of the placebo scans, indicating this effect was an important aspect of the antidepressant function of ketamine[87].

Serotonergic psychedelics clearly alter DMN function and connectivity. A number of studies using LSD[88,89], psilocybin[90-92] and ayahuasca[93-95] have observed changes in functional connectivity of the DMN, and a common finding is an acute decrease in the integrity of the DMN. There are few studies that have looked at longer-term changes in DMN activity or connectivity. However, one study showed that in patients with depression treated with psilocybin, DMN integrity has been observed to increase or normalize in the post-acute period (1-d post-dose) accompanied by improvements in mood, and DMN normalization was predictive of treatment response at five weeks[96]. It is striking that in the early studies serotonergic psychedelics seem to have longer lasting treatment response than typically seen in ketamine studies, although clearly more evidence is required.

CHANGES IN BRAIN VOLUME ASSOCIATED WITH ANTIDEPRESSANTS AND PSYCHEDELIC AGENTS

Depression and antidepressant treatment have also been associated with neuroplastic changes at the volumetric level. One area that has been heavily implicated in being involved in depression is the hippocampus. Reductions of hippocampal volume have been seen in cynomolgus monkeys and in mice[46], and in humans reduction of hippocampal volume is one of the most common brain changes associated with depression and chronic stress[97,98]. The hippocampus (and medial temporal lobe) is a key part of the human default-mode-network, and stress-induced alterations in this structure may contribute to some of the network-changes observed above. Other consistently reported grey matter abnormalities associated with depression in humans include decreased volumes of the cingulate cortex, the PFC, the orbitofrontal cortex, amygdala, and the basal ganglia[99]. White matter lesions have also been demonstrated in depression and have been demonstrated as being especially prominent in late-life depression[100].

Amazingly, antidepressants have been shown to normalize hippocampal volume. One study found increased right hippocampal volumes in female responders compared to non-responders after eight weeks of treatment with the selective serotonin reuptake inhibitor (SSRI) fluoxetine[101]. Other studies have demonstrated that patients treated with antidepressants who do not remit have lower bilateral hippocampal volumes at baseline and follow-up compared to remitted patients[102], though not all studies have found this relationship[103]. Studies investigating the effect of ketamine on structural brain changes are limited, although one study investigating the use of repeated ketamine treatment in patients with MDD observed increases in the volumes of the amygdala and hippocampus after just 6 ketamine infusions[104]. Studies on structural changes associated with serotonergic psychedelics are even more limited particularly with regards to humans with depression. However, in rodent models of trace fear conditioning, mice injected with low doses of psilocybin exhibited faster extinguishing of fear conditioning and an increased number of cells in the hippocampus compared to mice injected with saline or high dose psilocybin[105]. In non-depressed patients, one study found that 22 regular users of ayahuasca had thinning in the PCC and noted that cortical thickness values in the PCC were inversely correlated with personality traits measuring religiousness, transpersonal feelings and spirituality[106].

PSYCHOLOGICAL CHANGES ASSOCIATED WITH DEPRESSION, ANTIDEPRESSANTS AND PSYCHEDELIC FUNCTION

Plasticity can also relate to psychological changes in emotional, self, and social processing, which all play an important role in depression and antidepressant responses. Several studies have demonstrated that individuals with MDD demonstrate a bias towards negative emotional information compared to HCs[107,108]. Depression is also associated with perseverative negative ruminations[109]. Depression can also affect social processing, and has been associated with diminished desire for socialization, increased sensitivity to rejection, reduced cooperativeness, and impairment in understanding how others are feeling[110].

Antidepressants have been associated with changes in emotional processing[111], including changes in positive emotional recall with SSRIs and SNRIs in healthy volunteers, and changes in recognition of emotional facial expression, with the SSRI citalopram and the SNRI reboxetine reducing the identification of the negative facial expressions of harm and fear[112]. Ketamine may also lead to changes in these psychological processes. In a double-blind, placebo-controlled crossover study of 33 individuals with treatment-resistant MDD and 24 HCs, participants received ketamine and placebo infusions 2 wk apart, and functional magnetic resonance imaging scans were conducted at baseline and 2 days after each infusion during an attentional bias dot probe task with emotional face stimuli using "happy", "angry" or "neutral" faces across multiple time points. Ketamine infusion was found to have opposite effects on brain activation in regions associated with emotional processing in MDD *vs* HC participants, and in participants with MDD led to similar brain activity as HCs after placebo suggesting a possible "normalizing" effect on emotional processing in patients with MDD[113].

Serotonergic psychedelics also result in sustained and profound changes in emotional processing and sociability. LSD and psilocybin have been observed to decrease the recognition of negative facial expressions in healthy participants[114, 115]. Another study of healthy participants looking at changes in affect one week and one month after administration of psilocybin observed that negative affect decreased 1 wk after administration of psilocybin and positive affect increased, and while the changes in negative affect normalized after 1 mo, changes in positive affect persisted [116]. Beyond this, other unique psychological changes have been associated with serotonergic psychedelics, including a shift from a sense of disconnection from oneself, others, and the world to a sense of connection, and from avoidance of emotion to acceptance[117]. Both LSD and psilocybin have also been shown to acutely increase emotional empathy, and LSD was found to increase prosocial behavior on a social value orientation test. One unique property of serotonergic psychedelics is the experience of ego-dissolution which may occur during peak psychedelic experiences or "mystical experiences" where one experiences a loosening sense of boundaries between themselves and the world and a sense of unity and interconnectedness. It is possible that this subjective experience may in part account for shifting the relationship to one's sense of self and towards one's sense of connection with others. It

is interesting that the quality of the subjective "peak experience" has been associated with therapeutic efficacy[118]. Indeed, one plausible explanation for why serotonergic psychedelic agents are effective is that they evoke psychological experiences acutely while (at a molecular/cellular level) activating mechanisms of plasticity that help to engrain these experiences in long-term memory.

CONCLUSION

There is increasing evidence that psychedelic agents may induce rapid synaptic plasticity, and that this plasticity may be a key mechanism by which they can exert long-term antidepressant effects. However, it is important to note that plasticity is not, by itself, an inherently "anti-depressant" action. Indeed, as reviewed above, depression, anxiety and PTSD can, themselves, be caused or exacerbated by maladaptive forms of plasticity. Thus, the particular locus of this plasticity (neuronal sub-type, brain region, large-scale brain network) is important in understanding how such drugs cure depression. Psychedelic agents affect the brain in very different ways than ketamine (both when measured at the level of single units and local field potentials, or fMRI). However, longer-term changes in default-mode-network function may be a common endpoint linking both ketamine and psychedelic drugs in explaining antidepressant function of both agents. It is also vitally important to consider the psychedelic experience itself. The psychedelic experience has been described by some participants as being among the most meaningful or spiritually significant experiences of their lives[119]. If psychedelic agents produce these altered brain states, while simultaneously activating molecular/cellular cascades linked with plasticity, it could, indeed, provide a completely unique way of rapidly consolidating the effects of the experience for long-term retention. Trauma provides an example of how a single event, linked to mechanisms of plasticity, can cause long-term detrimental effects on brain and behavior[120]. Serotonergic psychedelics may well be the opposite — a pharmacologically-induced state of altered consciousness in which experiences are consolidated due to heightened mechanisms of synaptic plasticity.

Many questions remain. First, the question of to what extent neuroplasticity plays a role in depression. MDD is a complex disorder, and numerous factors play a role in its development including genetic, epigenetic, developmental, inflammatory, endocrine and psychological changes. A complete model of depression would account for how these various factors interlink to lead to the ultimate outcome of depression. Similarly, the question exists of to what extent neuroplasticity plays a role in the therapeutic effect of serotonergic psychedelics. The question also remains as to whether the therapeutic effect of serotonergic psychedelics is dissociable from the drugs subjective effects. While it is likely that neuroplasticity plays a role in the antidepressant treatment response of serotonergic psychedelics, further research is warranted to better characterize the other factors that play a role.

Abstract

Intimate partner violence has been recognized as a serious public health issue. Exposure to violence contributes to the genesis of, and exacerbates, mental health conditions, and existing mental health problems increase vulnerability to partner violence, a loop that imprisons victims and perpetuates the abuse. A recently described phenomenon is when male violence against females occurs within intimate relationships during youth, and it is termed adolescent or teen dating violence. In this narrative review, factors associated with intimate partner violence and consequences of exposure of children to parental domestic violence are discussed, along with possible intensification of violence against women with the spread of coronavirus disease 2019 pandemic and subsequent lockdown. Intervention programs with a multicomponent approach involving many health care settings and research have a pivotal role in developing additional strategies for addressing violence and to provide tailored interventions to victims. Prevention policy with a particular attention on healthy child and adolescent development is mandatory in the struggle against all forms of violence.

Core Tip: Intimate partner violence represents a serious public health issue. Exposure to violence contributes to the genesis of, and exacerbates, mental health conditions, and existing mental health problems increase vulnerability to partner violence. A recently described phenomenon is when male violence against females occurs within intimate relationships during youth, and it is termed adolescent or teen dating violence. Coronavirus disease 2019 pandemic is causing a tremendous impact on women's possible exposure to violence. Possible interventions against violence are discussed.

INTRODUCTION

Intimate partner violence is described as physical violence, sexual violence, stalking, or psychological aggression by a current or former intimate partner. It represents a serious public health issue. It has been estimated that more than 30% of women in the United States have experienced intimate partner violence, and it represents the leading cause of homicide death for women. Prevalence is higher among young women (18 to 24 years of age), among racial and ethnic minority groups, and among people with mental and physical disabilities[1]. Psychological violence is estimated to be the most common subtype of intimate partner violence (compared to physical and sexual violence) in the United States and Europe[2].

In women of reproductive age, intimate partner violence has been linked with poor reproductive health and poor sexual health (unintended pregnancy and sexually transmitted infections) and heightened risks of obstetrical and gynecologic complications (pregnancy-associated death, preterm birth, low birth weight) and represents a risk factor for peripartum depression and substance abuse[1]. There are specific physical injuries in women that can be considered as indicators of intimate partner violence: Contusions, lacerations, and fractures (especially in the head, neck and face) and are frequently reported by patients as domestic accidents. Partner violence has been associated with many mental health consequences: Depression, anxiety, post-traumatic stress disorder, eating disorders, suicidal behavior, alcohol or drug abuse, sexual problems, problems with concentration, somatization, social, educational, or occupational difficulties, as well as feelings of blame and guilt or reproach. It is also linked to several and often disabling physical health problems (chronic pain, gastrointestinal problems, sexually transmitted infections, traumatic brain injury, cardiovascular diseases).

Exposure to violence can contribute on one side to the genesis of psychopathological conditions or can exacerbate mental health conditions, but on the other side existing mental health problems can increase vulnerability and predisposition to partner violence.

It has been estimated that emotional violence is the most common form of intimate partner violence across all continents worldwide[3]. Factors associated with intimate partner violence originate from multiple levels: Individual, relationship, community, and societal level[4]. Subjects who are at greater risk of experiencing intimate partner violence more likely come from a lower education background and poorer socio-economic status (with difficulty of access to resources and greater acceptance towards violence), have a history or a current substance abuse, and have been exposed to prior abuse or violence (with a history of abuse reinforcing the normative nature of violence and developing violence-condoning attitude). For example, many immigrant women have to cope with issues regarding their cultural integration into another society while at the same time concurrently feeling related and profoundly bounded by cultures and traditions from their countries of origin. Dependence on one's partner, difficulties in language proficiency, financial problems, lack of social support, and uncertain legal status can leave these subjects feeling fragile and socially isolated and can prevent them from seeking assistance; besides, women linked to particular cultural backgrounds may refuse to acknowledge certain acts and behaviors as abusive due to

beliefs and traditions regarding familial obligations and culturally prescribed gender roles[5].

People with mental illness may have a heightened risk of becoming victims of domestic violence and can be reluctant to disclose abuse. On the other hand, mental ill-health can also be a consequence of victimization and can involve post-traumatic stress disorder, depression, suicidality, and alcohol or substance misuse: Physical sequalae of abuse are added to psychological morbidity[6].

EXPOSURE OF CHILDREN TO PARENTAL DOMESTIC VIOLENCE

It has been outlined by recent research that the presence of intimate partner violence often compromises a child's attachment to primary caregivers, which results in an additional risk factor for social, emotional, and psychological impairment[7]. A child can be exposed to domestic violence also through the awareness that violence occurs between parents, regardless of whether the child directly witnesses it. Infancy is a critical period of developing a secure attachment, and infants spend most of the time with caregivers, in a relationship of close proximity to them and high and obliged dependence from them; in addition, younger children have not completely strengthened the cognitive ability to discern between intimate partner violence as a threat to caregiver or to the self. As a consequence, the situation of violence in the household can indirectly impact on the child because it compromises the caregiving system in the parent. The presence of intimate partner violence increases a child's risk of developing a wide variety of negative outcomes (internalizing symptoms, externalizing behaviors, problems with perceptual and cognitive functioning, academic difficulties, interpersonal difficulties). Possible consequences can be affected by the child's age, relationships with other caregivers, and period of exposure to violence.

Violence against young girls causes physical and psychological effects, which can manifest as mild anxiety symptoms, apprehension, flashbacks, or feeling ashamed or worried to more severe anxiety signs, including a variety of sleep or eating disorders, post-traumatic symptoms, and even thoughts of self-harm and suicide. The inaction of a valid support system may further worsen this complex situation[8].

Children exposed to parental domestic violence are predisposed to physical and mental health disorders and are subjected to an increased risk of become a victim or a perpetrator of intimate partner violence in adolescence and adulthood[9]. Besides, adverse childhood experiences, such as child abuse, maltreatment, substance abuse in the household, incarceration of household members, and emotional or physical neglect, have long-term consequences with poorer physical, mental, individual behavioral, and social/interactional outcomes: The larger the number of adverse childhood experiences, the higher the odds of worst physical and mental health outcomes, including heart disease, stroke, asthma, diabetes, and mental distress[10]. Adolescence is a critical developmental period characterized by puberty, progressive autonomy from parents and family, changes in social relationships, and often the beginning of romantic relationships. Child sexual abuse, child physical abuse, witnessing parental intimate partner violence, exposure to school-related violence (*e.g.*, bullying), and community violence (*e.g.*, racism or discrimination) during childhood are potentially related to future intimate partner violence. Recently, it has been demonstrated that adverse childhood experiences in adolescence are predictive of interpersonal violence 15 years later[10].

Teen dating violence

When male violence against females occurs within intimate relationships during youth, it is termed adolescent or teen dating violence, occurring in individuals aged 10-24 years, including early, middle, and late adolescence, and described as physical, sexual, or psychological/emotional abuse, comprising threats, towards a dating partner. Six forms of teen dating violence have been assessed: Threatening behaviors, verbal/emotional abuse, relational abuse, physical abuse, sexual abuse, and stalking.

The cultivation of emotional relationships during adolescence are pivotal to the progressive growth of interpersonal communication skills, autonomy, and self-perceived competence, but together with affective and behavioral vulnerability experienced during adolescence, a variety of individual, social, and community risk factors may favor the emergence of adolescent dating violence[11]. Victims of teen dating violence may develop adverse health outcomes such as increased sexual risk behaviors, suicidality, unhealthy behaviors (*e.g.*, lack of physical activity and negative weight-controlling behaviors), inauspicious mental health outcomes, substance use,

injuries, victimization, and death. Additionally, it is common for adolescents who experience dating violence to struggle with their academics, drop out of school, or skip school to avoid seeing their partner.

Risk factors for perpetration of adolescent dating violence seem to be a history of experiencing, witnessing, and/or initiating abuse within the home, school, and community; childhood trauma in the form of physical and emotional abuse or neglect (due to personality anxiety traits formed during childhood, so that the individual feels a lack of security in the relationship and worries about being left by the partner); sexism and gender roles present in society; bullying; developing and formulating ineffective interpersonal communication and conflict resolutions skills during adolescence; alcohol or substance use during adolescence; attachment insecurities (anxiety and avoidance) expressed as anger, hostility, aggression, and emotional dysregulation[12]. Recent research suggests that there are multiple form of adolescent dating violence and that males may be victimized at similar rates as females[13]. Increasingly high rates of technology usage, as well as diffusion of apps and social media platforms, has created more opportunities for cyber teen violence dating (typically people who are no longer with their dating partner perpetrate this form of violence against an ex-partner).

Abusive behavior in adolescent dating relationships is associated with a risk of intimate partner violence later in adulthood[14].

Violence during coronavirus disease 2019 pandemic

Coronavirus disease 2019 (COVID-19) has had a dreadful impact on the world's economy, and women are forced to take on additional risks as they are already disadvantaged and vulnerable, especially in rural and remote settings[8]. Sexuality suffers because it has to deal with the arrogance of a death drive rekindled by the current pandemic condition. A life in which less libido is exchanged stably than one would like can become unbearable. But the libido, in the forms of stasis and engorgement, can turn, in the unconscious, into anguish and give rise to internal conflicts that inevitably end up resulting in the relationship with the other[15]. As the COVID-19 pandemic has intensified, its effects diversified by gender have begun to gain attention[16]. During the institutional lockdown, victims of domestic violence were required to remain closed with partners and without help or support: In such scenario there is a great chance that abusive situations can further aggravate, with a possible increase of domestic homicides or murder-suicides or deviant behaviors towards children. Increased concerns about domestic violence have been expressed in many countries. The reasons for this include social isolation, exposure to economic and psychological stressors, increase in negative coping mechanisms (such as alcohol or drugs misuse), and inability to access usual health and social services[6]. School closure due to lockdown can potentiate the risk for children to witness violence, exploitation, and abuse at home and away from help[8].

As the outbreak of COVID-19 has developed, referral rates to mental health and psychology services have declined, despite a likely increase in psychological distress, victimization, and mental illness. It is well-known that intimate partner violence has short-term and long-term effects on physical and mental-health of affected subjects and in particular might increase the risk of cardiovascular disease in women, by indirect (chronic inflammation or dysregulation of the hypothalamic pituitary axis as a consequence of chronic stress) and indirect pathways (coping strategies used by victims of abuse to deal with stress, such as smoking and overeating, and higher incidence of depressive disorders correlated to chronically elevated levels of cortisol, catecholamines, and inflammatory markers, all of which promote the development and progression of cardiovascular disease)[17].

Psychological distress linked with the pandemic itself, arising in response to fears about personal and familial infection as well as the sequelae of social distancing and quarantine measures, add worry about possible consequences of intimate partner violence during this global pandemic.

Particularly during the COVID-19 pandemic, programs are necessary to provide funding sources to guarantee telephone or remote counseling services or psychological assistance hotlines to manage and attempt to prevent crisis situations[18,19]. The use of mobile health and telemedicine to support safely subjects experiencing violence must be urgently improved, together with other strategies to reach women at risk in settings where access to mobile phones or the internet is limited or completely lacking. We must learn lessons from the past epidemics and also from the present about errors and defeats to recognize and address gender related effects of outbreaks[16].

Prevention and management of the violence against women of all ages should be expected and potentiated as a pivotal service in the COVID-19 response plan.

CONCLUSION

Possible interventions against violence

Lifetime and current intimate partner violence is common and unacceptably high. It has been outlined that approximately 1 in 4 women becomes a victim of violence at some point in their life regardless of their age, economic status, or ethnicity. Domestic violence against women is a well-recognized health concern and has serious negative impact on women's lives. It is important to stress the fact that most of the factors associated with violence against women are preventable. Studies assessing screening and interventions practice in primary care services for women who experience intimate partner violence have demonstrated that clinical programs can mitigate the risk of subsequent violence[20]. In addition, interventional studies have stressed that gender-norms transformation through behavioral change and communication focused program can promote gender equality norm and avert domestic violence against women[21].

Intimate partner violence is often not obvious, and patients may present with nonspecific signs and symptoms. Clinicians must be aware of the red flags of domestic violence and incorporate the principles of trauma-informed care into their practice. This means asking about violence or risk of violence when it is safe and appropriate, in a private discussion and in a compassionate and nonjudgmental way, discussing needs, preferences, and immediate options. It is necessary to support the subject's autonomy, provide emotional and practical support, and personalize responses and possible solutions to the individual patient[22].

For pregnant women suspected or known to be exposed to partner violence, it is mandatory to consider a pregnancy high-risk and to provide prenatal assessment and counseling for the mother and home-visitation programs in the child's first years. Screening in primary care for mental health disorders such as depression or anxiety should reasonably include an inquiry about current and previous intimate partner violence. In parallel, current or past intimate partner violence should be appropriately included in the differential diagnosis of many medical and behavioral health conditions, particularly in women[1]. It should be taken into account the fact that violence victims may not disclose their experience immediately but in the context of multiple queries and a trusting relationship. It results important that a multicomponent approach involving many health care settings, training of staff, clinical specific tools of assessment (including multiple violence domains: Physical, sexual, emotional/psychological), established workflows, connection to follow-up social services, and legal services can be dedicated and promoted to improve the prevention and response and care to the problem of intimate partner violence and its serious consequences. It has been observed that women have the tendency to remain with violent partners due to a variety of reasons, including social norms, worry for children, and economic issues. Immigrant women require a specific culturally-tailored approach and may need specific advocacy and interventions that also focus on financial abuse and are finalized to economic empowerment, including individual mental health counseling (when the shame and stigma associated to intimate partner violence in many ethnic communities increase the reluctance to discuss in groups) and services provided in community member's native language or in intervention delivery settings (shared community environments including churches, mosques, temples)[5].

Interventions integrating legal framework and programs that focus on transformation of traditional gender-norms are of great importance in order to prevent violence against women of all ages. There is an increasing need of intervention programs and techniques to reduce violence among offenders (group therapy or counseling aimed to work on impulsive and angry behavior or inability to control emotions) with a particular focus on trauma and substance abuse[23]. Since it has been observed that men with mental health problems (in particular depression, anxiety, alcohol or drug use disorder, attention deficit hyperactivity disorder, personality disorders) carry a higher probability to perpetrate domestic violence against women, treatment for any co-existing mental illness and in particular substance abuse or misuse should be prioritized to reduce risk[24].

Also, research has a pivotal role in developing additional strategies for addressing violence and to provide personalized interventions to victims. For example, qualitative studies exploring the emotional impacts of intimate partner sexual violence on women

Table 1 Proposed interventions against intimate partner violence

No.	
1	Clinical routine screening for indicators of intimate partner violence
2	Prenatal assessment and counseling for pregnant women suspected or known to be exposed to violence and home-visitation programs
3	Culturally tailored specific approach for immigrant women victims of violence
4	Intervention tecniques to reduce violence among offenders
5	Implementation of research aimed to develop additional strategies for addressing interpersonal violence
6	During COVID-19 pandemic, enhancement of telephone or remote counseling services or psychological assistance hotlines to manage crisis situations
7	Specific programs for prevention of domestic violence with a particular attention on healthy child and adolescent development

COVID-19: Coronavirus disease 2019.

are scarce. Understanding should be deepened of the so-called invisible impacts of violence, described as the emotional repercussions (sense of powerlessness, helplessness, shame, ongoing fear of men) that are difficult to quantify and measure but may be a trigger for mental health outcomes, such as post-traumatic stress disorder, anxiety, and depression[25]. Research can guide attachment- and family-based interventions for families impacted by interpersonal violence. Besides, there is an urgent need for rigorous research to understand better which interventions are most effective and tailored for ethnic minority populations.

Last but not least, prevention is mandatory: Interventions focusing on community and domestic health and violence prevention and, focusing on high-risk and disadvantaged socio-economic groups (such as institutionalized children or adolescents), with a particular attention on healthy child and adolescent development, may greatly contribute to lower intimate partner violence victimization in adulthood by correcting attitudes on violence and improving help-seeking behavior (Table 1).

Abstract

Mental health symptoms secondary to trauma exposure and substance use disorders (SUDs) co-occur frequently in both clinical and community samples. The possibility of a shared aetiology remains an important question in translational neuroscience. Advancements in genetics, basic science, and neuroimaging have led to an improved understanding of the neural basis of these disorders, their frequent comorbidity and high rates of relapse remain a clinical challenge. This project aimed to conduct a review of the field's current understanding regarding the neural circuitry underlying posttraumatic stress disorder and SUD. A comprehensive review was conducted of available published literature regarding the shared neurobiology of these disorders, and is summarized in detail, including evidence from both animal and clinical studies. Upon summarizing the relevant literature, this review puts forth a hypothesis related to their shared neurobiology within the context of fear processing and reward cues. It provides an overview of brain reward circuitry and its relation to the neurobiology, symptomology, and phenomenology of trauma and substance use. This review provides clinical insights and implications of the proposed theory, including the potential development of novel pharmacological and therapeutic treatments to address this shared neurobiology. Limitations and extensions of this theory are discussed to provide future directions and insights for this shared phenomena.

Core Tip: Traumatic stress disorders and substance use disorders are highly co-morbid in community and clinical samples. Recent findings from basic and clinical neuroscience support a shared neural basis of these disorders, specifically related to the processing of fear and reward cues. Understanding the overlapping neurobiology of these disorders will improve our understanding of disease aetiology and improve prevention and treatment efforts.

INTRODUCTION

Research focused on trauma and posttraumatic stress disorder (PTSD) dates back to 1889, when Pierre Janet, a prominent French psychiatrist, published *L'Automatisme Psychologique*, an early attempt to describe how the mind processes traumatic events [1]. Janet argued that patients suffering from dissociation and hysteria had unresolved traumatic memories and that this subconscious experience was routed in the physical effects of past negative experiences. When an individual experiences a traumatic event, they are overwhelmed with intensely negative emotions and are unable to accurately process and remember details surrounding the event[2]. The traumatic experience dissociates from conscious awareness. Janet believed that the individual would relive the memory of the trauma in fragmented pieces, such as emotional states, somatic conditions, visual images, or behavioral re-enactments. Janet was the first to identify dissociation as the crucial psychological technique involved in a variety of post-traumatic symptoms[1].

Decades of research on understanding the psychological and biological effects of trauma have provided support for many of Janet's early observation[1]. Psychological distress following a traumatic event can manifest through a variety of symptoms including anxiety and exaggerated fear as well as anhedonia, dysphoria, anger, aggression, or dissociation[3]. The 5th edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) provides a description of seven different diagnoses which all relate to exposure to a prominent or stressful event, the most prevalent of these diagnoses are Acute Stress Disorder and PTSD. Criteria for PTSD include direct exposure to or indirect witnessing of a traumatic or stressful event, as well as the presence of intrusive symptoms, negative mood, dissociation, avoidance and/or arousal. These symptoms must cause clinically significant distress or impairment and must not be attributable to the effects of a substance, a medical condition, or a brief psychotic disorder[3]. Patients with PTSD must also display at least one or more symptom across each category (intrusive, avoidance, negative alterations in cognition and mood, alterations in arousal and reactivity). Interpersonal trauma is one of the most common criteria A events and is more likely to lead to poorer functional outcomes[3].

Given the diversity and complexity of individual responses to trauma, it has been difficult to fully understand the neurobiological substrates involved in PTSD. The majority of basic neuroscience and neuroimaging research on PTSD has focused primarily on two areas; the effect of stress on sympathetic nervous system functioning and the impact of trauma on frontal striatal brain circuitry[4]. Although such research has begun to shed light on the adverse neurobiological effects of repeated stress, many patients continue to suffer from the effects of trauma and are resistant to empirically validated treatments for PTSD[5]. An emerging area of research that may help to further elucidate the neurobiological mechanism of trauma relates to the important role of reward circuitry in translational models of PTSD. After providing an overview

of animal and clinical research on the biological effects of PTSD, this article will review recent research that suggests an important role for the brain's reward pathway in understanding the neurobiological effects of complex trauma.

THE PHYSIOLOGY AND NEUROBIOLOGY OF PTSD

The human stress response and PTSD

During stress, the sympathetic nervous system prepares an individual for action while the pituitary-adrenocortical system dampens initial physiological aspects of arousal [6]. The hypothalamic (HPA) axis releases corticotrophin releasing factor (CRF) which stimulates the release of cortisol from the adrenal cortex, and increases the release of catecholamine neurotransmitters within several regions of the brain[7]. Catecholamines have an integral role in the adaptive response to stress through the breakdown of glycogen, the suppression of the insulin release, and increased functioning of the cardiovascular system[6]. Increased levels of norepinephrine (NE) and epinephrine (EPI) during stress result in increased neuronal activity in limbic areas such as the amygdala, and hypothalamus, and decreased activation of cortical areas involved in higher-order cognitive functioning[8].

For individuals at risk for developing PTSD, traumatic experiences can alter the normal functioning of the sympathetic nervous system. Many of the core symptoms of PTSD reflect a state of hyperarousal including exaggerated startle response, initiating and maintaining sleep and poor concentration[9]. Patients with PTSD demonstrate exaggerated sympathetic nervous system responses including tachycardia and skin conductance during acute stress and increased sensitivity of the HPA axis[10]. Compared to healthy controls, patients with PTSD have reduced baseline cortisol levels, and increased levels of CRF[11]. Several studies have demonstrated that patients with PTSD have higher urinary secretion levels of NE, and EPI, compared to controls and that neurotransmitters levels correlate with the severity of self-reported PTSD symptoms[10,12]. Previous PTSD studies have reported related abnormalities in sensory processing including deficits in the P50 and P300 evoked potential component [13].

Abnormalities in HPA axis and neurotransmitter function can alter neural circuitry both structural and functional changes of, especially in brain circuits integral to affective and cognitive processing. While high levels of cortisol enhance the formation of emotional memories (mediated by the increased amygdala function) and facilitates fear conditioning, high levels of cortisol upon trauma exposure decreases hippocampus function, resulting in memory and learning deficits[14]. Structural changes occur as well; high levels of stress can result in dendritic hypertrophy of the prefrontal cortex (PFC), and dendritic remodeling of the amygdala[15].

Between stimulus and response

How does the brain process sensory information that may be perceived as a threat? LeDoux was among the first to demonstrate the underlying neural circuitry of fear (Figure 1) For example, imagine that a door slams shut in the middle of the night, waking you up from sleep. The initial sensory information about the threat is relayed to the thalamus and then quickly sent to the amygdala, activating the stress response and generates an immediate reaction. The body begins to sweat, a diaphoretic response that precipitates a rapid response. The hippocampus and PFC process contextual information about the stimulus by providing reasoning (perhaps it was a windy day) and episodic memory (a slamming door has never caused you any harm) that dampens the stress response and allow an individual to relax, returning to baseline. The signal from the thalamus to the amygdala is rapid, while signals from the hippocampus and PFC are transmitted with less velocity[16]. Recent translational research has demonstrated how structural, chemical and functional differences in each of these brain areas evolve in the neurobiology of PTSD.

Given the role of intrusive memories in PTSD, many have speculated that hippocampal dysfunction is a critical component of the underlying neurobiology. The hippocampus has a high concentration of corticosteroid receptors that are involved in the termination of the stress response through the negative feedback of the HPA axis [17]. Both animal and human studies have demonstrated that high levels of stress can damage the hippocampus, resulting in memory impairments[18]. During an acute stress response, high levels of cortisol can diminish dendritic branching in the hippocampus while augmenting neurogenesis in the amygdala, enhancing the emotional salience of the event, but impairing memory functioning[15,19]. When

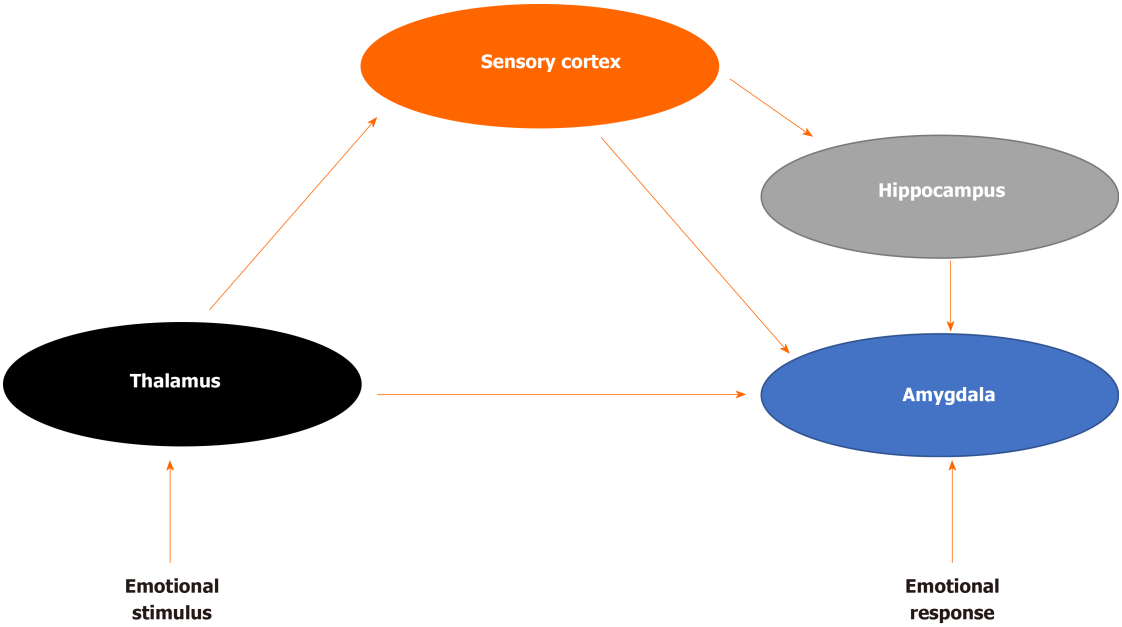

Figure 1 Fear brain circuitry.

compared with healthy controls, patients with PTSD demonstrate impairments in short-term memory and some studies (but not all) have demonstrated reduced hippocampal volumes in patients with PTSD[20]. Patients with PTSD often have difficulty describing details related to traumatic events and some studies have correlated hippocampal regional cerebral blood flow with PTSD symptom seve-rity [21,22].

The amygdala receives input from the thalamus as well as sensory processing regions of the neocortex, and transmits signals to autonomic brain structures, thereby playing a critical role in both the sympathetic and parasympathetic stress respo-nse[23, 24]. In human studies, the amygdala has been demonstrated to have a critical role in processing emotional stimuli, and in the formation of emotionally salient memories [25]. It also has a role in fear conditioning, whereby a neutral conditioned stimulus is associated with an unconditioned stressful stimulus. Exposure to the conditioned stimulus initiates the stress response, activates the amygdala, and engages the autonomic nervous system[26]. Lesion of the amygdala interrupts fear learning and the conditioned response in animals[27,28]. Human neuroimaging studies have confirmed the involvement of this region in fear learning, conditioning and extinction [29,30]. Compared to healthy controls, patients with PTSD demonstrate increased activation of the amygdala when presented with trauma-related cues, as well as when presented with unrelated affective stimuli[31,32]. Amygdala response in patients with PTSD has been found to correlate with self-reported symptom severity[33,34].

Alterations in prefrontal cortical (PFC) activity may help to link the role of memory impairment in PTSD as well as increased amygdala activation during the stress response[20]. In patients with PTSD, repeated exposure to trauma damages these neural structures. The ability to extinguish emotional memories involves the ventro-medial PFC as well as the amygdala while extinguishing conditioned fear involves the anterior cingulate cortex and the amygdala[24,35]. Activation of the medial PFC also occurs when inhibiting fearful responses or altering one's perception of a negative emotional event and therefore decreased functioning of the PFC may explain why patients with PTSD exhibit difficulties in extinguishing fearful memories[36,37].

COMORBIDITY OF PTSD AND SUBSTANCE USE DISORDERS

Clinical observations, case reports and epidemiological studies first suggested high rates of comorbidity between PTSD and substance use disorders (SUD), prompting translational research examining the possibility of overlapping neural mechanisms. Many studies have demonstrated a high comorbidity of PTSD with drug addiction in both clinical and community samples[38,39]. Approximately 36% to 50% of those that

meet criteria for SUD also meet criteria for lifetime PTSD, and those with PTSD predictably have a history of drug abuse or dependence[40]. Comorbidity of these disorders is associated with negative treatment outcomes, increased risk for chronic diseases, and poorer functionality[41]. Co-twin studies have also demonstrated a link between childhood trauma and the later development of SUD[42].

Robinson and Berridge[43] proposed a model of addiction that demonstrates how repeat drug use disrupts normal reward processing. The Incentive-Sensitization Theory postulates that although increased pleasure is initially an important part of addiction behavior, regular substance use increases an individual's sensitivity to drug cues, causing them to become hyper-responsive to drug cravings, even in the absence of pleasure[43]. This hyper-sensitization produces goal-directed behavior ("wanting") not only in the absence of subjective pleasure, but also in the absence of consciously being aware of "wanting". Recent research has supported this theory, demonstrated that substance use can alter brain reward circuitry[43].

BRAIN REWARD CIRCUITRY AND SUD

Data from several studies suggest that the reward circuit of the brain (the mesocortical dopamine pathway) provides a common molecular pathway with which to understand SUD. The mesolimbic pathway involves connections between the ventral tegmental area (VTA), the nucleus accumbens (NAc) in the ventral striatum, and the PFC. The mesolimbic dopamine reward circuit controls the reinforcing and rewarding effects related to food, sex, and social interaction[44]. Drug-induced adaptations in mesolimbic dopamine system (includes common adaptations to many different drugs) mediate changes in reward mechanisms that in part underlie addiction — including tolerance, dependence-withdrawal, sensitization, and relapse. Drug-induced adaptations include regulation of dopamine and opioid systems (mechanisms of tolerance and sensitization), regulation of glutamate systems (influences drug-related memories), upregulation of the cyclic adenosine monophosphate (cAMP) pathway, and transcription factor cAMP Response Element-Binding (CREB) protein, (mechanisms of drug tolerance, dependence, and withdrawal), structural changes in VTA neurons (influences drug tolerance), and structural changes in NAc neurons (influences drug sensitization)[45].

Many studies show that dopamine and accumbens neurons often become most active in anticipation of rewards, not during the reward phase, and also activated by the anticipation of aversive stimuli and events[46,47]. The role of the mesolimbic DA system is to increase the salience of stimuli and events associated with activation of the system. Stimuli are imbued with salience, making them "wanted" incentive stimuli. Alcaro *et al*[46] have theorized the role of the mesolimbic pathway as driving an organism toward "seeking" behaviors, searching to boost the salience of activities that are life-promoting while avoiding those that are harmful to survival. This proposed role is not only congruent with evidence of the importance of SUD, but also a mechanism that explains the connection of the VTA to the hippocampus, amygdala, and PFC, all of which have been implicated in the neurobiology of PTSD.

OVERLAPPING NEUROBIOLOGY OF PTSD AND SUD

Both animal models and clinical studies of PTSD have noted deficits in reward processing consistent with hypofunctionality of the mesolimbic pathway. Upon exposure to chronic stress, animal models demonstrate reduced striatal dopaminergic activity and decreased reward-seeking behavior that mimic symptoms of anhedonia experienced by PTSD patients[48]. Corral-Frias *et al*[49] utilized a novel animal model of PTSD to demonstrated that inactivation of the VTA can lead to long-term behavioral changes that mimic the clinical symptoms of PTSD. Inactivation of the VTA through either a dopamine antagonist or bilateral dissection can also lead to chronic changes in baseline VTA dopaminergic cell firing, demonstrating that trauma can lead to long-term alterations of the reward pathway. Evidence of deficits in the brain reward and reinforcement circuits in patients with PTSD also supports the involvement of the mesolimbic dopamine reward circuit[50,51]. In clinical studies, PTSD patients spend less time engaging in reward-seeking behavior compared to controls, report lower levels of reward expectation and are less satisfied with monetized rewards[52,53]. When compared to healthy controls, patients with PTSD demonstrate reduced bilateral striatal activation when responding to positive to reward gains and reported

significantly higher levels of motivational and social deficits[50]. Collectively, these findings suggest a strong overlap in the brain regions involved in both fear processing and addiction. In particular, the VTA, through its connections to the amygdala, hippocampus and PFC, may serve as the common substrate of this overlapping circuitry, explaining the high co-morbidity in PTSD and SUD.

Several rodent models provide converging evidence for the overlapping circuitry of these two disorders, including the dorsal and ventral subdivisions of medial PFC and their respectively outputs to the amygdala and NAc (Figure 2). The prelimbic (PL) cortex projects to the basal (BA) nucleus of the amygdala, which excites the central (CE) nucleus of the amygdala, thereby promoting the expression of conditioned fear [54]. The BA also receives excitatory input from lateral amygdala, which also drives the expression of conditioned fear. The infralimbic (IL) cortex, in contrast, excites a class of GABAergic inhibitory neurons (the intercalated cell masses) which inhibit the CE, thereby promoting extinction of the conditioned fear[55]. PL and IL control drug seeking *via* their differential projections to the core and shell subdivisions of the NAc. The PL projects to the core, which promotes the expression of drug-seeking behavior. The IL projects to the shell, which also promotes the expression of extinction[56].

Functional magnetic resonance imaging studies provide consistent support for similar networks in human studies of fear and addiction (Figure 3). The dorsal portion of the anterior cingulate cortex is associated with fear expression during conditioning behavioral tasks, and overlaps with proximal regions that are activated when SUD patients respond regarding their craving levels after exposure to cocaine-related cues [57-59]. These findings are congruent with results from positron emission tomography mapping of cerebral blood flow using 15O-labeled water[60]. The ventral medial PFC (vmPFC) is activated during fear extinction recall and during recall of addiction cues in individuals with SUD disorders[57,61]. During states of cocaine craving, the vmPFC is deactivated, suggesting a failure to engage extinction[54]. Collectively, these studies suggest that the vmPFC is homologous to rodent IL, whereas the dorsal regions of anterior cingulate cortex are homologous to rodent PL.

CONCLUSION

This review examined evidence in support of a shared neurological origin between PTSD and SUD, in an effort to explain the high rates of comorbidity. It is clear that abnormalities in the PFC and VTA are central to the pathology of both disorders. The VTA is negatively affected during trauma and stress, and results in a decrease of dopaminergic activity and a subsequent alteration in the reward pathway. The PFC is involved in drug seeking behavior as well as the extinction of fear conditioning, playing a role in both addiction and PTSD. This review did not examine the genetic vulnerabilities nor neurodevelopmental pathways that may confer increased risk for either or both disorders, and it remains an important question whether the shared biology reviewed here is due to more distal risk factors, or are a result of one disorder conferring increased risk for the other.

It is important to gain a better understanding of the connection between PTSD and SUD in order to develop improved treatments that target both disorders. Despite shared neurobiology, there are few treatment options that target both, although notably some do exist (*e.g.*, Seeking Safety). Yet many patients are not able to benefit from combined treatment interventions during the earlier stages of substance use recovery, and clinicians often struggle to determine the priority of treatment[62]. Many individuals diagnosed with comorbid PTSD-SUD believe that the outcomes of their disorders are interconnected, yet are not offered treatment for PTSD alongside SUD interventions[63].

Understanding comorbidity may also further prevention efforts, consistent with the "self-medication" hypothesis, as individuals with untreated trauma utilize substance as unhealthy coping mechanisms[64]. Earlier identification, access to care, and treatment of trauma across the lifespan is critical for intervening before the development of SUD or other maladaptive behaviours. Further research must leverage mechanisms between these two disorders, to ensure a more effective and efficient treatment option.

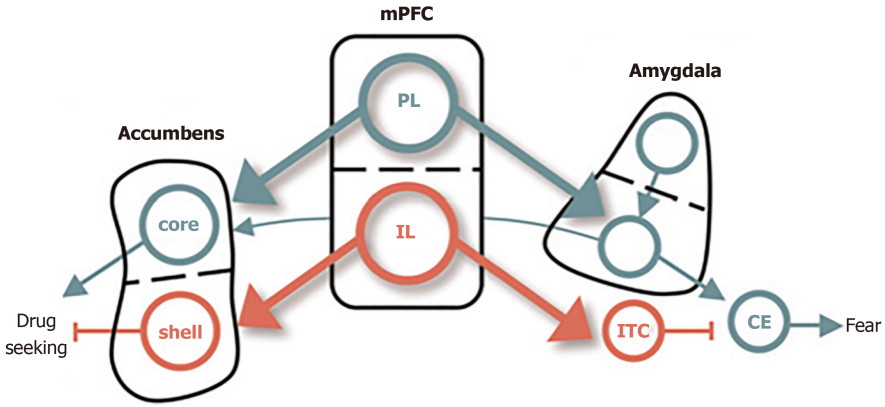

Figure 2 Conditioned fear in cocaine use. The dorsal and ventral subdivisions of medial prefrontal cortex are shown at the center, with their respective outputs to the amygdala controlling fear shown at right, and those to the nucleus accumbens, controlling cocaine, seeking shown at left. Abstract

BACKGROUND

The ongoing coronavirus disease 2019 (COVID-19) pandemic and the universal implementation of control measures are fundamentally affecting every aspect of our society and daily lives.

AIM

To evaluate the prevalence of post-traumatic stress disorder symptoms and their associated factors as well as the effects and attitudes towards online education in Chinese high school students.

METHODS

A total of 883 students were included. The first, second and third-year students of a high school in Lanzhou, Gansu province of China were invited to participate in this study. They were requested to involve their parents to complete the survey together. A detailed questionnaire of 65 questions was designed and divided into five sections. The survey was anonymously conducted *via* WeChat, a Chinese multipurpose messaging, social media and mobile payment app.

RESULTS

Overall, 32.94% of students experienced post-traumatic stress disorder due to the COVID-19 epidemic. The majority of students (60.82%) felt that online education was not (10.76%) or less effective (50.06%) in terms of gaining knowledge and improving practical and communications skills. Correlation analysis revealed that the class level, residential background and whether living with parents were

significantly linked with the effectiveness and satisfaction of the online education system. Of the final year students, 74.2% said that the COVID-19 outbreak has negatively affected their preparation for the college entrance exam, and 68% of students felt that this outbreak increased psychological pressure for their college entrance examination preparation. In case of having COVID-19 symptoms during the exam, 50.7%, 13.3%, and 10.2% would notify the proctor, teacher and parents, respectively.

CONCLUSION

We found a high prevalence rate of post-traumatic stress disorder symptoms in high school students. Thus, our results call for urgent attention from both government and schools to implement effective interventions to cope with the psychological effects and the disturbance of education by COVID-19 on children.

Key Words: COVID-19; Post-traumatic stress disorder; Students; College entrance examination; China; Education

INTRODUCTION

The ongoing coronavirus disease 2019 (COVID-19) pandemic and the universal implementation of control measures are fundamentally affecting every aspect of our society and daily lives. School closure is one of the most important measures widely implemented worldwide. According to UNESCO's estimates, more than 190 countries have adopted nationwide school closures, resulting in roughly 90% of the global student population out of school and confined at home[1]. The classroom syllabus has been swiftly changed into an online education system. However, the education sector was not well-prepared to launch such large-scale online education programs. Thus, the effectiveness of this new education format and the effects on students remain largely uncertain.

According to epidemiological research after a traumatic event, about 5%-12% of individuals may develop post-traumatic stress disorder (PTSD) [2]. School closure, living in confinement and risk of the infection are creating anxiety and are affecting education, psychological health and well-being of students [1]. According to Chinese government estimates approximately 220 million teenagers were not allowed to go out during the COVID-19 epidemic in China. However, the consequences and the degrees of impact could vary among different levels of students.

In China, the schooling system includes primary school (6 years), junior middle school/secondary school (3 years) and senior middle school/ high school (3 years). Afterwards, students have the opportunity to continue to higher education by passing the college entrance examination, a nine-hour national higher education entrance exam. It is offered once a year and taken by around 10 million students annually. It is the sole determinant for admission to virtually all Chinese colleges and universities. Because of a limited amount of university spots available, it is an ultra-competitive

exam and imposes tremendous pressure on the third-year high school students.

The COVID-19 epidemic was first reported in China. The teenagers were restricted at home for a long time and were the first to switch to online education. Although the rises of psychosomatic issues caused by COVID-19, especially in teenagers, have been widely reported [3-5], innovative investigation into this issue remains scarce. In this study, we conducted a large cohort survey in a high school at the end of the COVID-19 epidemic in China. We evaluated the prevalence of PTSD symptoms and their associated factors as well as the effects and attitudes towards online education. We further investigated the impact on the final year high school students relating to the college entrance examination.

MATERIALS AND METHODS

Study population

The first, second and third-year students of a high school in Lanzhou, Gansu province of China were invited to participate in this study. They were requested to complete the survey with their parents. The study was conducted from April 20 to April 30, 2020.

Survey instrument

A detailed questionnaire comprising of 65 questions was designed and divided into five sections. The first four sections were designed for all the students, comprising of 11 demographic, 11 COVID-19, 9 online educations and 22 PTSD related questions. The final section consisted of 11 college entrance examination related questions specific for the final year students. The survey was anonymously conducted *via* WeChat, a Chinese multipurpose messaging, social media and mobile payment app.

The 9 online education related questions were designed to assess effectiveness (3 questions), efficiency (3 questions) and satisfaction (3 questions). Each question was comprised of five options including no, low, average, good and excellent.

In this study, we used Impact of Events Scale-Revised (IES-R) self-questioner to examine the psychological impact[6,7]. Further detail has been documented previously [5]. IES-R questioner was translated into Chinese language. IES-R questioner validity and reliability has been extensively reported[8-10].

Statistical analysis

Descriptive statistical analysis was done to demonstrate the demographic characteristics of the participants. First, a univariate analysis was done to screen statistically significant variables, which were subsequently subjected to multivariate logistic regression analyses. The estimations of the strengths of associations were revealed by the odds ratio with a 95% confidence interval. Descriptive and inferential statistics were calculated using SPSS version 20.0 for Windows (SPSS Inc., Chicago, IL, United States). All statistical tests were two-sided, and a P value < 0.05 was considered statistically significant.

RESULTS

In total, 893 students participated in the survey. Ten students declined to continue. Therefore, 883 students were included. Participant demographic characteristics were given in Table 1. There were 33.4% first-year, 23.6% second-year and 43.0% final year students. Most students were from the Han ethnic background (98.1%), and 53.2% were girls and 46.8% were boys. The majority of the students were living with parents (96.3%) in urban areas (85.4%) (Table 1).

The majority of students (683 of 866) reported that their families are fully aware of COVID-19. Overall, students reported that they were affected economically (41.6%), psychologically (22.1%), emotionally (6.8%), socially (6.8%) and physically (6.8%) by the COVID-19 epidemic. In contrast, 14.9% of students reported that they were unaffected. A large percentage (93.0%) reported that they have gone back to their normal routine (Table 2). The outbreak negatively affected 68.3% of student's studies. Although 96.5% of the respondents were willing to returning back to schools, 63.0% of students have concerns regarding the risk of getting COVID-19 once back to school. Knowledge about the signs and symptoms of COVID-19 such as fever, difficulty/shortness of breath, cough, flu-like symptoms, diarrhea, fatigue, sore throat and chills were found to be known by 65.2%, 12.9%, 7.6%, 4.4%, 1.6%, 1.0%, 0.9% and

0.1% of participants, respectively. When students suspect infection, 51.0% of the participants prefer to inform their teachers, whereas 29.7% would go into self-isolation (Table 2).

In this study, a total of 33.0% students had an IES-R score above 20 (Table 3). PTSD symptoms were significantly higher in rural (P = 0.001) compared to urban students. PTSD symptoms were also significantly more prevalent in students whose parents have lower education and profession levels (Table 3).

Students felt that online education was not (10.8%) or less effective (50.1%) for acquisition of knowledge, enlightening practical as well as communication skills. Students reported that it was not (17.9%) or less (43.9%) effective that students were not able to complete their homework, communicate with teachers and take advantages of the multimedia setup. Over half (64.8%) of the students reported that they were not or less satisfied and had difficulties adapting to the online education system (Supplementary Table 1). Correlation analysis revealed that the class level, residential background and whether they lived with parents were significantly associated with satisfaction and effectiveness of the virtual tutoring system (Supplementary Table 2).

This study showed that IES-R scores were substantially associated with residential background, the education level and profession of parents and family monthly income (Supplementary Table 2). According to univariate analysis, residential background, family monthly income and the professions of mother and father were significantly linked with PTSD symptoms. For multiple logistic regression analysis, only residential background remained as a significant factor relating to PTSD symptoms in children (Supplementary Table 3).

In this study, 380 participants were final year students and thus were eligible to fill in the college entrance examination section of the questionnaire. Twenty-seven participants did not complete all questions and were excluded, resulting in 353 students for final analysis. Among them, 74.2% said that the COVID-19 outbreak negatively affected their preparation for the college entrance exam. The outbreak increased psychological pressure for the college entrance examination preparation in 68.0% of students. Although 54.7% students regarded the online learning system as helpful to their preparation, 97.7% said that school opening would be beneficial for preparing for the college entrance examination. The postponement of the college entrance examination was favored by 90.4% of students. There were concerns regarding the risk of getting COVID-19 during the exam from 61.8% of students. To minimize the risk, 41.6% participants said that they would follow strict personal hygiene during the college entrance examination. A face mask would be worn during the exam by 19.5%, and 17.8% would use the mask on the way to the exam and to home. If a student had COVID-19 symptoms during the exam, then 50.7%, 13.3% and 10.2% would notify the proctor, teacher and parents, respectively (Supplementary Table 4).

DISCUSSION

To minimize the spread of COVID-19, China has implemented strict quarantine measures including school closures, travel bans, lockdowns and within-population quarantine. These measures have majorly impacted the mental health of young

children and adolescents[3,4]. Here, we first measured the COVID-19 epidemic effects on the mental health of high school students. Further, we identified the potential risk factors linked with PTSD symptom development in this youth cohort. Our results showed that 33.0% of students experienced PTSD signs and symptoms due to the COVID-19 epidemic. The high PTSD symptom incidence rate is likely attributed to several factors, including confinement at home, worrying about their academic progress and future plans as well as fearing the risk of infection [3,4,11-15]. We found that PTSD symptoms were significantly higher in rural students and students whose parents have lower levels of education and professions. This is in line with the fact that COVID-19 has had a substantial effect on the global economy, including an increase in

COVID-19: Coronavirus disease 2019.

the unemployment rate[16]. Families with low social economic status having such economic loss will likely experience immediate effects on their daily livelihood. This will subsequently increase psychological and economic pressure on their children[17].

To minimize education losses, the authorities have swiftly launched online portals and web-based applications and switched the education system to a virtual education system. However, virtual education systems need an efficient and well-organized learning environment and implementation. However, the sudden outbreak of COVID-19 in China caused a substantial variance in virtual systems among schools of different provinces. In this study, the majority of students were not satisfied with online education. The class level of the students, residential background and living with parents were significantly linked with the online education system effectiveness. There are two possible reasons. First, students from higher classes are skilled enough to adapt the virtual education system. Provinces or families with an advanced socioeconomic background are more equipped with the latest technologies. Second, the majority of the participants were not happy with the virtual teaching system. The education department officials should take this issue seriously to improve the virtual education system effectiveness and ensure all students have access to the digital devices and its use.

The final year high school students are facing with mounting pressure of the national college entrance exam. The results of this exam often have a lifelong effect on most Chinese citizens[18]. The college entrance examination usually takes place from June 7 to June 8 every year. The Chinese Ministry of Education postponed the exam by 1 mo due to the COVID-19 epidemic. In our survey, over half of the final year students felt that the COVID-19 outbreak negatively affected their preparation for the exam and increased their psychological pressure. Although half of the students thought the online learning system helped their preparation, almost all the students preferred school opening for better preparation of the college entrance examination. Over 90.0% of students favored the postponement of the college entrance examination. Over half have concerns of the potential risk of getting COVID-19 during the exam, but they are prepared to take precaution measures.

A limitation in this study is that this survey was conducted in a single school in China in a region with a low number of confirmed COVID-19 cases. Therefore, the findings in this study may not represent other schools and regions in China. Finally, we did not study the content of online education in detail in our cohort as it cannot represent the format of other regions because it varies markedly among different schools and regions in China.

CONCLUSION

In this study, we found that 33.0% of high school students have experienced PTSD symptoms due to the COVID-19 epidemic. These symptoms are significantly more common in students living in rural areas and whose parents have a low education level and low grade jobs. The epidemic has affected the preparation of the national college entrance exam for the final year students, but they appreciate the postponement of the exam by 1 mo. Notably, a large proportion of respondents were not satisfied with online education. Therefore, it is suggested that the authorities optimize the online education program and ensure equal opportunities for the students to get access to the digital learning. Our results call for urgent attention from both government and schools to implement effective interventions to manage the psychological effects and the disturbance of education by COVID-19 on children.

ARTICLE HIGHLIGHTS

Research background

Coronavirus disease 2019 (COVID-19) pandemic control measures are disturbing every aspect of our daily lives. School closures have been widely implemented according to COVID-19 cases in the world. Therefore, approximately 90% of the global student population is confined at home.

Research motivation

School education was suddenly replaced with a virtual education system but the education sector was not ready to adopt it. Therefore, the effects of this new education system on student learning remain ambiguous. Additionally, the risks of infection and confinement at home are affecting student education and psychological health.

Research objectives

The current study was designed to explore the prevalence of post-traumatic stress disorder (PTSD) symptoms and their associated factors in high school students and their assessment of the online education system.

Research methods

The first, second and third-year students of a high school at Lanzhou were invited to participate *via* WeChat, a local social media app in this study. Descriptive and inferential statistics were calculated using SPSS version 20.0 for Windows (SPSS Inc., Chicago, IL, United States). All statistical tests were two-sided, and a P value < 0.05 was considered statistically significant.

Research results

In total, 883 students were included in this study. Among them, 33.4% were first year, 23.6% were second year, and 43.0% were third year students. The majority (98.1%) of students' families were well-aware of COVID-19. Overall, 41.6% of students were affected economically, and 22.1% were affected psychologically due to the COVID-19 epidemic. Interestingly, 14.9% of students said that they were not affected by the COVID-19 epidemic. In this study, the prevalence of PTSD symptoms was 33.0%, and its prevalence was significantly higher in rural students (P = 0.001) than in urban students. The high prevalence of PTSD symptoms significantly correlated with the education level, residential background, parent's profession and family monthly income.

Research conclusions

In summary, our results showed that the prevalence of PTSD symptoms was 33.0% among high school students due to the COVID-19 epidemic, and a significantly high prevalence occurred in students who live in rural areas and whose parents had low-grade jobs and education level. Our results further highlighted that the COVID-19 epidemic has also affected the final year student's national college entrance exam preparation. Most notably, the majority of respondents were not pleased with the virtual education system.

Research perspectives

Education department officials should take measures to optimize the online education system and guarantee equal access to the digital learning devices. Further, we suggest that effective measures should also be implemented to minimize the risk of psychological issues caused by COVID-19 on students.

ACKNOWLEDGEMENTS

We sincerely thank all the participants who took part in this study.

Abstract

BACKGROUND

Panic disorders frequently occur with affective disorders, particularly bipolar disorder. Patients with panic disorder and bipolar disorder are more likely to present with severe symptoms, such as high rates of suicidal behavior, poor symptomatic and functional recovery, and poor drug responses.

AIM

To investigate the psychological characteristics of panic disorder patients related to bipolarity.

METHODS

A total of 254 patients (136 men and 118 women, mean age = 33.48 ± 3.2 years) who were diagnosed with panic disorder were included in the study. Panic disorder with bipolarity (BP+) was defined as a score of ≥ 7 on the Korean version of the Mood Disorder Questionnaire (K-MDQ), and a score lower than 7 was considered as a panic disorder without bipolarity (BP-). Self-report questionnaires were analyzed to examine their association with bipolarity. Psychological tests used in the study were the Mood Disorder Questionnaire (MDQ), Panic Disorder Severity Scale, Beck Depression Inventory, State-Trait Anxiety Inventory (STAI), Temperament and Character Inventory (TCI), and Minnesota Multiphasic Personality Inventory (MMPI). Statistical analyses were performed to evaluate the correlation between bipolarity of panic disorder patients and various psychological test results indicative of psychological characteristics.

RESULTS

Patients with a K-MDQ score of 7 or more were considered to have a history of manic or hypomanic episodes (BP+ group, n = 128), while patients with K-MDQ scores below 7 were defined as those without bipolarity (BP- group, n = 126). The BP+ group were more likely to be unmarried (single 56.2% *vs* 44.4%, P = 0.008)

and younger (30.78 ± 0.59 *vs* 37.11 ± 3.21, $P < 0.001$). Additionally, the BP+ group had significantly higher scores on psychological assessment scales, such as the hypochondriasis, psychopathic deviate, masculinity-femininity, psychasthenia, schizophrenia, and hypomania (Ma) in MMPI, and novelty seeking, harm avoidance and self-transcendence in TCI, and STAI (state and trait) compared to the BP- group. In logistic regression analysis, depression in MMPI, self-directedness in TCI, and age were negatively associated with MDQ score, meanwhile, Ma in MMPI and STAI (trait) were positively associated with MDQ score.

CONCLUSION
The result of this study suggests that almost 50% of patients with panic disorder are likely to have hypomanic or manic symptoms, and certain psychological factors are associated bipolarity in panic disorder.

Key Words: Panic disorder; Bipolar disorder; Bipolarity; Anxiety; Minnesota Multiphasic Personality Inventory; Temperament and Character Inventory

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The close relationship between panic disorder and bipolar disorder has been suggested in the literature. In this study, we showed that panic disorder patients with high anxiety trait were more likely to have bipolar symptoms. Moreover, low self-directedness scores on the Temperament and Character Inventory and high scores on the hypomanic clinical scale in Minnesota Multiphasic Personality Inventory were also associated with bipolarity in patients with panic disorder. We suggest that certain psychological characteristics may help clinician to make a tailored treatment strategy for panic disorder.

INTRODUCTION

Previous studies have shown that patients with bipolar disorder have a high risk of comorbid panic disorder[1]. In addition, patients with bipolar disorder have a higher risk of intra-episode panic disorder during mania[2]. A family study of bipolar disorder showed that there is a possible complex genetic etiology in bipolar disorder and panic disorder comorbidity[1]. MacKinnon *et al*[3] studied 528 members of 57 families for a genetic linkage study of bipolar disorder. They found that 10 families had a higher rate of comorbid panic disorder, suggesting that comorbid panic disorder can be a specific marker for a familial subtype of bipolar disorder. Contreras *et al*[4] found that the anxiety trait is a heritable phenotype in subjects with bipolar I disorder in a study of 619 individuals. In another study, relatives of patients with bipolar disorder and panic disorder comorbidity showed a higher risk of both bipolar disorder and panic disorder[5]. Many studies have found that panic symptoms are prodromal symptoms of bipolar disorder or atypical presentation of bipolar disorder[6,7]. In addition, Wu *et al*[8] compared neuropsychological test scores among a group of bipolar patients with comorbid anxiety disorder, a group of bipolar patients without comorbidity, and a healthy control group. They concluded that patients with bipolar II disorder and comorbid anxiety disorder had the greatest cognitive impairment among the three groups[8]. Moreover, the presence of anxiety disorder in youth increases the risk of bipolar disorder in the future[9].

The lifetime prevalence of panic disorder is approximately 21% of bipolar disorder, which is much higher than approximately 10% of major depressive disorder. Birmaher *et al*[10] found that panic disorder or bipolar disorder are likely to co-occur with other psychological disorders in youths. Moreover, patients with concomitant panic disorder

and bipolar disorder have a higher risk of psychotic symptoms and suicidal ideation. In other studies, patients with panic disorder and comorbid bipolar disorder had higher rates of suicidal behaviors, severe and longer depressive episodes, higher severity of illness scores, poorer treatment outcomes, and lower quality of life[11-14]. In addition, they tend to have a higher risk of rapid switching and a shorter euthymic period[15,16]. Patients with bipolar disorder with high global anxiety levels developed a greater proportion of weeks in major depressive episodes[17]. Therefore, an early diagnosis of bipolarity in panic disorder patients is important to establish an appropriate treatment plan to improve the prognosis of patients.

Antidepressants are often used in the treatment of panic disorder, and it is well known that antidepressant-induced manic symptoms are quite common in such patients[11]. The lack of information regarding bipolar disorder comorbidity in patients with panic disorder can negatively impact the choice of treatment and management, which is the reason why an early diagnosis of bipolar disorder in patients with panic disorder is important in the treatment outcome of patients[7,11]. Previous studies have discussed the prognosis of bipolar disorder according to the presence of panic disorder[8,10-17], however, few studies have investigated bipolarity in patients with panic disorder[18,19]. The aim of this study was to compare clinical characteristics of panic disorder according to the bipolarity, and to investigate factors that predict the potential risk of bipolar disorder in patients with panic disorder.

MATERIALS AND METHODS

Study design and participants

This cross-sectional study was conducted in Konkuk University Hospital, Korea. A total of 254 consecutive patients, who were newly diagnosed with panic disorder according to the DSM-V (Diagnostic and Statistical Manual of Mental Disorders), were included in the study. The exclusion criteria include history of (1) Schizophrenia like psychosis; (2) Cognitive impairment due to dementia; (3) Intellectual disability; (4) A history of major neurological disorder; (5) Organic mental disorder; and (6) Substance use problem. This study was approved by the Institutional Review Board of Konkuk University Hospital (IRB number: KUMC 2021-01-028), and written informed consent was waived due to the retrospective nature of the study.

Instruments

Demographic data and psychological test results were also collected. Psychological tests included the Mood Disorder Questionnaire (MDQ), Panic Disorder Severity Scale (PDSS), Beck Depression Inventory (BDI), State-Trait Anxiety Inventory (STAI), Temperament and Character Inventory (TCI), and Minnesota Multiphasic Personality Inventory (MMPI).

MDQ, which was used as a screening tool for bipolar disorder, is a self-report instrument that takes approximately five minutes to complete. Patients with scores above the threshold score of 7 were considered as patients with bipolarity (BP+ group) and the remaining were considered as patients without bipolarity (BP- group). The Korean version of the MDQ (K-MDQ) was used in this study, and the validity and reliability of the questionnaire have been proven to be useful for screening bipolar disorder[20].

PDSS is a standard measurement scale for panic disorders. The instrument included seven items associated with symptoms accompanied by panic disorder[21,22]. This study used the Korean version of the PDSS, which has good test-retest reliability and inter-rater reliability[21].

The BDI-II is a self-report checklist for assessing the severity of depressive symptoms. The 21 items included emotional, physiological, and cognitive symptoms of depression. This study used the Korean version of the BDI-II, which is considered a valid and reliable tool[23].

The STAI is a 40-item self-report instrument used to evaluate anxiety symptoms. The State Anxiety Scale measures an individual's current state of anxiety, and the Trait Anxiety Scale evaluates an individual's stable tendency toward anxiety[24]. This study adopted the Korean version of the scale translated by Lee *et al*[21], which has demonstrated fine psychometric properties[24].

The TCI is a self-report questionnaire based on a biosocial personality model. Cloninger's biosocial model of personality was used to develop the TCI questionnaire. The temperament, which is related to the biosocial model of personality, is composed of novelty seeking, harm avoidance, reward dependence, and persistence. The

character is evaluated in three different aspects of a person's characteristics: self-directedness, cooperativeness, and self-transcendence[25]. The Korean version of the TCI was used in the study. The Korean version of the TCI has been reported to be reliable for assessing personality[26].

The MMPI is commonly used in personality and psychopathology assessments of patients[27]. It contains 10 clinical subscale to evaluate personality and psychopathology of patients: hypochondriasis (Hs), depression (D), hysteria (Hy), psychopathic deviate (Pd), masculinity-femininity (Mf), paranoia (Pa), psychasthenia (Pt), schizophrenia (Sc), hypomania (Ma), and social introversion (Si). The Korean version of the MMPI-II was used in this study and has been reported to be reliable in assessing personality and psychological symptoms in Korean adults[28].

Statistical analysis

Kolmogorov-Smirnov test determined whether the data were normally distributed. The Mann-Whitney and chi-square test was conducted to compare demographic and clinical variables between the group with an MDQ score of less than 7 and the group with an MDQ score of 7 or more (BP+ group). The relationships between the MDQ scores and other psychological variables were analyzed using the Spearman's rank correlation analysis and the logistic regression analysis. The statistical significance level was set at $P < 0.05$. All statistical analyses were performed using the Statistical Package for the Social Sciences (SPSS 17.0) software (SPSS Inc., Chicago, IL, United States).

RESULTS

Table 1 presents the characteristics of the participants. The average age at diagnosis was 33.5 years (range, 18-68 years). There were more female (54.7%) than male participants, and most had at least a high school education. The mean score of K-MDQ was 6.4 ± 3.6 (range, 0-13). Half of the patients (n = 128) had high K-MDQ scores (≥ 7). The mean score of K-MDQ was 9.4 ± 1.7 in the BP+ group *vs* 3.4 ± 2.2 in the BP- group.

Patients in the BP+ group were younger (30.78 ± 0.59 *vs* 37.11 ± 3.21) at the time of the diagnosis and were either unmarried or divorced (single 56.2% *vs* 44.4%, $P = 0.008$) compared to patients in the BP-group. (Table 1) However, a gender, a past psychiatric history, and a family history of psychiatric disorders did not significantly differ between the two groups (Table 1). The BP+ group had significantly higher scores on the MMPI clinical scales. These clinical scales include hypochondriasis, psychopathic deviate, masculinity-femininity, psychasthenia, schizophrenia, and hypomania. In addition, BP+ group had significantly different scores in some TCI dimensions than BP- group. Compared to BP- group, BP + group had higher novelty seeking, harm avoidance, and self-transcendence scores, and lower self-directedness and cooperativeness scores. Moreover, the BP+ group also showed higher levels of depressive symptoms as measured by the BDI (31.5 *vs* 21, $P < 0.001$), and anxiety symptoms measured by STAI (state) and STAI (trait) (state: 63 *vs* 57, $P < 0.001$/trait: 61.5 *vs* 51.5, $P < 0.001$) (Table 2).

In correlation analyses (Table 3 and Supplementary Table 1), K-MDQ scores were associated with increasing Hs, D, Pd, Mf, Pa, Pt, Sc, Ma and Si in MMPI clinical scales, TCI novelty seeking, harm avoidance and self-transcendence dimensions, and higher BDI, STAI (state), and STAI (trait) scores. K-MDQ scores were negatively associated with TCI self-directedness dimension scores ($P < 0.05$).

This study used logistic regression analysis to assess the association of K-MDQ and clinical variables, and the age at onset, MMPI (depression), MMPI (hypomanic), TCI (self-directedness), and STAI (trait) were found to be significantly associated with bipolarity in patients with panic disorder (Table 4). Younger age was significantly associated with an increased K-MDQ score (BP+ group). Moreover, in the MMPI and TCI questionnaire, as the MMPI (depression) and TCI (self-directedness) clinical scales decreased, K-MDQ scores increased. In addition, the increase in MMPI (hypomanic) clinical scale scores was significantly associated with the BP+ group (bipolarity of patients). The patients who showed an innate trait of anxiety tested by STAI (trait) tended to be more related to high K-MDQ scores (BP+ group).

Table 1 Comparison of demographic and clinical features between panic disorder with bipolarity and panic disorder without bipolarity groups

	BP+	BP-	*P* value
Demographic features			
Patients: *n* (%)	128 (50.4)	126 (49.6)	
Marital status			0.008
Married: *n* (%)	32 (25.0)	53 (42.0)	
Single: *n* (%)	72 (56.2)	56 (44.4)	
Not answered: *n* (%)	24 (18.7)	17 (13.4)	
Age (yr)	30.78 ± 0.59	37.11 ± 3.21	< 0.001
Gender (M/F, %)	73/55 (57)	63/63 (50)	0.261
Illness history			
Psychiatric history: *n* (%)	41 (32)	32 (25.4)	0.172
Family history: *n* (%)	18 (23.1)	22 (17.5)	0.960

Sex and employment status is expressed as *n* (number of patients, %). Other variables are expressed as mean ± SD. M: Meal; F: Female; BP+: Panic disorder with bipolarity; BP-: Panic disorder without bipolarity.

DISCUSSION

Among the 254 subjects who were diagnosed with panic disorder, approximately 50% of the patients scored 7 or more on the K-MDQ, suggesting a history of manic/hypomanic symptoms in the past. Younger age and the Ma subscale of the MMPI were associated with the higher risk of bipolarity. In addition, the STAI (trait) score, which indicates the innate anxiety level, is positively related to the bipolarity of panic patients, while the self-directedness score in the TCI was negatively associated.

In line with our data, in a previous study, an early age at onset of panic disorder was associated with an increased morbidity risk for bipolar comorbidity[29]. In addition, an early onset of bipolar spectrum disorders is characterized as a severe form of bipolar disorder and tends to have a higher risk of having first-degree relatives with affective disorders[29]. In this study, the patients with bipolarity showed a younger age at onset, which has been found in previous studies[18,30]. Moreover, a previous study has already shown that the risk of anxiety disorder increases as the onset age of bipolar disorder decreases[31]. So, it would be important to evaluate bipolarity thoroughly in younger panic disorder patients in clinics. In our study, patients with a bipolar tendency were more likely to be unmarried at the time of assessment. In previous investigations, bipolar patients had a higher risk of experiencing difficulties in marriages, which is also shown in this study[18,32].

Several psychometric tests have been developed to help diagnose psychiatric patients and the MMPI is one of the most commonly used standardized psychometric tests of adult personality and psychopathology[33]. It is well known that the MMPI Ma subscale is used to identify manic symptoms of individuals at the time of evaluation [34]. In our study, it was found that MMPI hypomanic subscale scores were positively correlated with bipolarity in patients with panic disorder. The result of this study was consistent with previous studies, stating that the high score of hypomanic subscale is indicative of diagnosis of bipolar disorder[35,36]. Higher Ma score in MMPI indicates that patients with panic disorder and bipolarity experience more physical and psychological vitality; however, they also experience dissatisfaction, tension, and anxiety in life[36]. In addition, patients with panic disorder and bipolarity felt less depressed compared to patients without bipolarity, which results from the nature of bipolar disorder manic symptoms.

Engström *et al*[37] conducted a study with 100 euthymic bipolar patients and 100 controls from the normal population to determine the differences in temperament and character of each group. They showed that bipolar patients scored higher in harm avoidance and lower in reward dependence, self-directedness, and cooperativeness in TCI than controls[37]. In addition, in a previous study focusing on the relationship between temperament and panic disorder, high scores of harm avoidance, and reward dependence were related to panic symptoms[38]. The results of our study were

consistent with those of a previous study indicating that patients with bipolarity showed a negative relationship with self-directedness scores in the TCI test. This result suggests that panic disorder patients with bipolarity are more likely to be aimless and inept than panic disorder patients without bipolarity. The TCI harm avoidance, reward dependence, and cooperativeness scores did show some correlation with bipolarity based on our correlation analyses, but not in our regression analysis. This suggests that a lower self-directedness score can be used as a marker to predict bipolarity in patients with panic.

In this study, the STAI (trait) score was positively related to the bipolarity of patients with panic disorder. High levels of anxiety were positively correlated with bipolarity, particularly when having anxious characteristics in patients with panic disorder. Bipolarity was more related to the anxious characteristics of patients than to the current anxiety levels. In other words, patients with higher anxiety levels and anxiety sensitivity were more likely to be diagnosed with bipolar disorder in the future. Anxiety sensitivity is known to be a contributing factor to the high prevalence and severity of panic disorder comorbid with bipolar disorder, particularly during the manic state of bipolar disorder, as our study has suggested[19]. Contreras *et al*[39] found a significant positive correlation between trait anxiety score and mania episodes in lifetime. However, there was no correlation between trait anxiety scores and lifetime depressive episodes. Azorin *et al*[40] also stated that an irritable temperament is a

source of mood instability and stress, which interacts with other temperamental characteristics to induce both anxiety and bipolar symptoms. In addition, studies have shown that when the level of anxiety sensitivity is high, the prognosis of patients with bipolar disorder is worse and panic disorder symptoms are more severe[7,19,41,42]. Therefore, it is important to make an evaluation about panic disorder patients' anxiety sensitivity to diagnose bipolar disorder for a better prognosis.

This study has several limitations. First, this study was a cross-sectional, retrospective study with relatively small number of participants. We included consecutive patient who were clinically diagnosed with panic disorder based on the strict diagnostic criteria. However, the study design may be related to the selection bias and hinder the generalizability of the results. Second, even though we have consulted a biomedical statistician to confirm the proper statistical method to use in the study, there is a possibility of type I error because the *P* value was not corrected in the multiple comparison. Finally, a self-report questionnaire was used to evaluate the bipolarity. The MDQ is a validated questionnaire for evaluating manic/hypomanic symptoms in patients with various psychiatric conditions, however, clinicians did not confirm the history of manic/hypomanic symptoms of the participants in this study.

CONCLUSION

In this study, we were able to predict bipolarity in panic disorder patients through simple self-report questionnaires, which have been widely used. Early diagnosis of bipolarity in patients with panic disorder will have a positive effect on the patient's treatment outcome. It should be noted that among patients with panic disorder, patients with an anxious personality have a high comorbidity rate for bipolar disorder. Based on the results of this study, it is possible to detect bipolarity in advance through a simple questionnaire in actual clinical practice.

ARTICLE HIGHLIGHTS

Research background

Panic disorders frequently occur with affective disorders, particularly bipolar disorder. The lifetime prevalence of panic disorder is about 21% of bipolar disorder, much higher than about 10% of major depressive disorder. Patients with panic disorder and bipolar disorder are more likely to present with a severe course of disorder, such as high rates of suicidal behavior, poor symptomatic and functional recovery, and poor drug responses.

Research motivation

Patients who suffer from both panic disorder and bipolar disorder have a poorer prognosis than patients who suffer from only one disorder. So, it is crucial to predict a bipolarity of a patient who is diagnosed with panic disorder at early phase of disease course to select a proper treatment for the patients. However, there is no standard evaluation tool to predict a bipolarity of panic disorder patients.

Research objectives

In this study, we tried to identify the specific symptoms of patients with panic disorder that indicate bipolarity to establish a proper treatment plan.

Research methods

A total of 254 patients (136 men and 118 women, mean age = 33.48 ± 3.2 years) were diagnosed with panic disorder. Panic disorder with bipolarity (BP+) was defined as a score of ≥ 7 on the Korean version of the Mood Disorder Questionnaire (K-MDQ), and a score lower than 7 was considered a panic disorder without bipolarity (BP-). Self-report questionnaires were analyzed to examine their association with bipolarity. Psychological tests included the Mood Disorder Questionnaire (MDQ), Panic Disorder Severity Scale, Beck Depression Inventory, State-Trait Anxiety Inventory (STAI), Temperament and Character Inventory (TCI), and Minnesota Multiphasic Personality Inventory (MMPI). Statistical analyses were performed to evaluate the correlation between panic disorder and bipolarity. Our collected data was not normally distributed. So, for statistical analysis, we used Mann-Whitney test to compare continuous variables between two groups, and Spearman's rank correlation to find the relationship between the MDQ scores and other variables.

Research results

Patients with a K-MDQ score of 7 or more were considered to have a history of manic or hypomanic episodes (BP+ group, n = 128), while patients with K-MDQ scores below 7 were defined as those without bipolarity (BP- group, n = 126). The BP+ group were more likely to be unmarried (single 56.2% *vs* 44.4%, P = 0.008) and younger (30.78 ± 0.59 *vs* 37.11 ± 3.21, P < 0.001). Moreover, the BP+ group had significantly higher scores on some psychological assessment scales, such as the hypochondriasis, psychopathic deviate, masculinity-femininity, psychasthenia, schizophrenia, and hypomania (Ma) in MMPI, and novelty seeking, harm avoidance and self-transcendence in TCI, and STAI (state and trait) compared to the BP- group. In logistic regression analysis, MMPI (depression), MMPI (paranoia), and age were negatively associated; however, MMPI (Ma) and STAI (trait) were positively associated with the BP+ group (K-MDQ score ≥ 7). In addition, BP+ was positively associated with current manic symptoms (1.080, P = 0.000) and trait anxiety (1.062, P = 0.006), and negatively associated with current depressive symptoms.

Research conclusions

The result of this study suggests that MMPI, TCI and STAI can be used to predict the bipolarity of panic disorder patients. These psychological assessments can be considered to performed in clinics to establish proper treatment plans for a better prognosis.

Research perspectives

Further investigations should aim to assess the validity of specific psychological factors to be used to detect bipolarity in panic patients prospectively.

Abstract

BACKGROUND

Coronavirus disease 2019 (COVID-19) has affected daily life globally dramatically over the last year. The impact of the COVID-19 epidemic on mental health is expected to be immense and likely to be long-lasting, raising a range of global problems that need to be addressed accordingly.

AIM

To analyze the Scopus-based depression research and COVID-19, explain the advancement of research nowadays, and comment on the possible hotspots of depression research and COVID-19 to obtain a more global perspective.

METHODS

In this report, bibliometric analysis and visualization are used to explain COVID-19's global research status on depression and provide researchers with a guide to identify future research directions. Relevant studies on depression and COVID-19 were retrieved from the Scopus database. Visualization maps were produced using the VOSviewer software, including research collaboration.

RESULTS

At the time of data collection (November 18, 2020), 77217 documents were released by Scopus to COVID-19 in all areas of research. By limiting the search to depression and COVID-19 (January 2020 up until November 18, 2020), there are 1274 published articles on depression and COVID-19 in the Scopus. The great majority of which are original articles (n = 1049, 82.34%), followed by 118 review articles (9.26%), 66 letters (5.18%). The United States had the highest number of publications at 282 (22.14%), followed by China (19.07%) at 243 and Italy at 121 (9.5%). The major two clusters are signified by mental health outcomes among the general population and mental health outcomes among health care workers.

CONCLUSION

The evidence from this study found that many articles focused on mental health

outcomes among the general population and health care workers. With adequate psychological support offered by the government or community agencies, mental health in various communities should be put within the local and global public health agenda. This changing situation involves the scientific community's collaborative efforts to contribute to population monitoring during quarantine and COVID-19 outbreaks and to examine the short- and long-term adverse effects on psychological well-being.

Core Tip: This is the first study to describe and visualize scientific research on coronavirus disease 2019 (COVID-19) and its effect on depression. Therefore, the current study would enable professionals, psychiatrists, and experts from other fields of medicine, in addition to local authorities and community health staff, to obtain an empirical view of the evolution of this topic because current knowledge on the main psychological distress effects of COVID-19 is scarce and little is known in the development of research on this topic.

INTRODUCTION

In December 2019, new cases of pneumonia of unknown causes were detected in Wuhan city. In Jan 2020, Chinese authors identified a novel coronavirus, which was later known as severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) or coronavirus disease 2019 (COVID-19). After that incidence, COVID-19 was spared in several places in the world, then the World Health Organization considered the SARS-CoV-2 virus as a pandemic disease on March 11, 2020[1]. Like other coronaviruses, COVID-19 is transmitted by respiratory droplets or contact routes. Most people affected by this novel virus experienced mild to moderate symptoms such as dry cough, fever, sputum production, shortness of breathing, headache, chills, sore throat, joint and muscle itches, *etc.* Symptoms become serious and severe in elderly patients and in people who have chronic diseases[2]. As of November 21, 2020, more than 56.9 million COVID-19 cases and more than 1.3 million death cases from the disease have been reported worldwide[3].

A condition of socio-economic crisis and deep psychological trauma rapidly emerged worldwide as a result of the advent of the COVID-19 epidemic[4]. The current COVID-19 pandemic may have psychological implications for many reasons [5]. Some of these reasons, including physical distance, fear of infection, inadequate information, stigma, quarantine measures, contribute to the pandemic, and government response[6]. As a result of such experiences, such as social isolation, widespread anxiety; unemployment, and financial difficulties; and stress in health-care workers, both the infected and noninfected population may be susceptible[5]. These major stressors have anticipated that lead to an elevated risk of psychopathology, such as depression or anxiety[7,8]. A recent meta-analysis study was designed to review community-based depression studies performed during the COVID-19 epidemic and found that depression rates may be seven times higher in the general population in the COVID-19 outbreak[9]. Another United States study found that the prevalence of depressive symptoms among adults during the COVID-19 pandemic was more than three times higher than the most recent population-based mental health estimates in the United States[10]. In China, 50.4% of health care workers who were exposed to COVID-19 patients reported symptoms of depression[11].

Several systematic reviews or meta-analysis studies show the increasing number of publications addressing the effect of COVID-19 on mental health published from

numerous countries during the outbreak[5,8,12-16]. To date, there is not a bibliometric study assessing depression research and COVID-19 at the global level. In several studies in virology[17-22], more specifically on the COVID-19 outbreak[23-29], bibliometric analysis means evaluating the research output of authors, countries, journals, and institutions[30,31]. Capturing the relevant literature is essential and promotes the comprehension of a particular focus area's characteristics and patterns. It can also rapidly and reliably present the most relevant study, which provides the theoretical foundation for further research. Therefore, we performed the bibliometric analysis to analyze the Scopus-based depression research and COVID-19, explain the advancement of research nowadays, and comment on the possible hotspots of depression research and COVID-19 to obtain a more global perspective. Because current knowledge on the key psychological distress impacts of COVID-19 is scarce and little is known in the production of reports on this subject, a descriptive and visual quantification of scientific research on COVID-19 and its impact on depression will allow information professionals, psychiatrists, and experts from other fields of medicine, in addition to local authorities and community health staff, to obtain an empirical view of evolution, current scope, and depression.

MATERIALS AND METHODS

Data source

Scopus is known for bibliometric research as one of the most appropriate online databases. In the Scopus online database, we pick the 'Advanced search" feature and insert keywords to obtain all publications related to COVID-19 and depression literature between January 1, 2020, and November 18, 2020.

Search strategies

To avoid possible bias produced by continuous database update, the retrieval and export of publications should be created within one day (November 18, 2020). The retrieval and export of documents should be done within one day to prevent any bias in data collection that might be caused by constant updating of the database. This research's retrieval method was as follows: Step 1: The terms related to COVID-19 entered into the Scopus engine were chosen from the related studies on COVID-19 to achieve the goals of this study. All following ''terms'' were entered as ''Article Title/Abstract/Keywords'': "COVID 19" OR "coronavirus 2019" OR "2019 novel coronavirus" OR "2019-novel CoV" OR "coronavirus disease 2019" OR "2019 ncov" OR COVID19 OR "COVID 2019" OR "corona virus 2019" nCoV2019 OR "nCoV-2019" OR "nCoV 2019" OR COVID-19 OR 2019-ncov OR "SARS-CoV-2" OR "Severe acute respiratory syndrome coronavirus 2". Step 2: We then restricted our collected publications in step 1 to all those included in their title or/And Abstract depression and related terms. The terms related to depression entered into the Scopus engine were chosen from previous related studies on depression[32,33]. All the following ''terms'' were entered as ''Article Title/Abstract'': depression OR depressive OR "seasonal affective" OR "dysthymia" OR "affective disorder" OR "mood disorder" OR "bipolar disorder". Step 3: We omitted publications that had been indexed as an erratum. No language restriction was imposed on the literature search.

Bibliometric analysis

The following bibliometric parameters were assessed: Publication count, authorship, citation count, institution, country/region, journal, document type, and *h*-index.

Visualise analysis

To evaluate the collaborative relationships between countries/regions, VOSviewer 1.6.15 software was used to construct network visualization maps[34]. In addition, VOSviewer will identify terms with high frequencies of co-occurrence into many clusters and color them simultaneously. The co-occurrence analysis of terms is a significant method to determine the hotspots related to COVID-19 and depression research. By counting the number of times that terms frequently appear in both titles and abstracts of the selected publications, the principle is to determine the value of terms. The minimum number of recurring terms is 20 by setting the counting method to binary counting.

RESULTS

At the time of data collection, 77217 documents were released by Scopus to COVID-19 in all areas of research. By limiting the search to depression and COVID-19 (January 2020 up until November 18, 2020), there are 1274 published articles on depression and COVID-19 in the Scopus. The great majority of which are original articles (n = 1049, 82.34%), followed by 118 review articles (9.26%), 66 letters (5.18%), and 41 (3.22%) were others.

Publications analyzed in this study were authored by researchers from 95 countries. Of the overall publications, the top 10 countries accounted for 88.93% (1133 documents) (Table 1). The United States had the highest number of research outputs at 282 (22.14%), followed by China (19.07%) at 243 and Italy at 121 (9.5%). International research collaboration among active countries was assessed in countries with a minimum contribution of 10 publications (Figure 1). The United States, followed by China and Italy are at the heart of collaboration and have the strongest alliance partnerships in research with other countries.

Table 2 shows the ten institutions that have contributed the most in the field of depression and COVID-19. Among them, the Huazhong University of Science and Technology in China published the most documents (29 publications). This was followed by Tongji Medical College from China (28 publications), the University of Toronto from Canada (23 publications), and Università Degli Studi di Roma La Sapienza from Italy (23 publications).

Table 3 illustrates the top 10 most popular journals for publishing articles linking COVID-19 and depression. The International Journal of Environmental Research and Public Health had the largest number of published articles (61 publications, 4.79% of all documents), followed by Psychiatry Research (48, 3.77%), Journal of Affective Disorders (46, 3.61%), and Frontiers in Psychiatry (33, 2.59%).

The ten most cited publications have been listed in Table 4 along with the total number of citations per document. There were 8206 citations for 569 documents, with 16 documents having a minimum of 100 citations. The h-index was 35, and, on average, each paper earned 6.44 citations. The citation counts for the top 10 most cited articles in the range of 151 to 887[11,15,35-42].

We analyzed all included 1274 publications using the VOSviewer. In Figure 2, among the 22839 terms, only 399 terms (defined as terms that occurred more than 20 times appeared in titles and abstracts in all publications) were divided into 3 clusters. The major two clusters are represented by two colored clusters. Cluster number 1 (red color) contained terms such as “economy”, “isolation”, “home order”, “home”, “physical activity”, “daily life”, “lockdown”, “citizens’ wellbeing”, “child”, or “social distancing” linked to mental health outcomes in the general population. While Cluster number 2 (green color) contained terms such as “health care worker”, “medical staff”, “depression scale”, “insomnia severity index”, “severe depression”, or “depression symptoms” linked to mental health outcomes amongst health care workers.

DISCUSSION

This research is the first bibliometric analysis of depression-related publications following the pandemic of COVID-19. The appropriate bibliometric indicators for analyzing 1274 relevant research works have been followed in this study. Our rapid review of available studies demonstrated that the COVID-19 pandemic had produced a global emergency in less than a couple of months. This infectious virus does not only pose concerns about public health in general but also causes several psychological and behavioral diseases.

High-income countries, including the United States, China, Italy, United Kingdom, and Canada, are the leaders in the world in depression-related publications following the COVID-19 pandemic, which contribute to more than 65% of the total publications. The high prevalence of COVID-19 in those experiencing the first outbreak is a possible explanation for these results[43-49]. Most studies were carried out within populations from highly educated, high-income, and Western nations in particular. These settings can make successful mental health treatment much more imperative and give more attention to non-Western environments, which characterize by the higher population density[50]. There is still limited information available on the COVID-19 pandemic's mental health impact in low- and middle-income countries[51]. The prevalence of depression symptoms in low- and middle-income countries is close to that recorded during the pandemic in most high-income countries[51]. People with low socioeco-

nomic status are also at a higher risk of contracting COVID-19 and its complications, which include death as well as mental health concerns[52,53]. Notably, clinically relevant post-traumatic stress disorder symptoms were identified in about 30% of COVID-19-infected patients who required hospitalization at the early stage of infection or months later[5,54]. Immunological mechanisms and inflammatory biomarkers, fear of disease, anxiety about the future, stigma, traumatic memories of serious illness, and social alienation encountered by patients during the COVID-19 are all important psychological stressors that may interact in determining psychopathological outcome [55,56].

Our study showed that the United States was the most prolific country in research output in the depression-related COVID-19 pandemic, leading to more than 20 percent of the topic's publications. Perhaps this United States research production is because of the large size of the economic power or population. In addition, most of the social networking sites in the United States were developed and built. These results are close to earlier bibliometric studies in various fields[57-61], primarily because the United States has the highest activity in the worldwide development of scientific research and international cooperation networks[62,63].

This study has found that, generally, many articles focused on mental health outcomes among the general population and health care workers. A clear theme to arise from the findings is that the most widely cited depression-related publications following the COVID-19 pandemic illustrated a variety of subtopics as well as hot research topics. The most cited article was by Wang *et al*[41] and published in the

International Journal of Environmental Research and Public Health, which was cited 887 times. This China study demonstrated that over fifty percent of the respondents rated their psychological effects as mild to extreme during the initial phase of the COVID-19 outbreak. A greater psychological effect of the outbreak and higher levels of depression were correlated with female gender, student, and particular physical symptoms. The higher negative psychological impact was associated with longer quarantine periods, fear of infection, insufficient knowledge, stigma, or financial loss. It is expected that these significant stressors will contribute to an increased risk of depression[9].

The second most cited article was by Lai *et al*[11] and published in *JAMA network open*, was cited 719 times. This is also a Chinese study that found that in hospitals with COVID-19 patients, health care staff reacting to the spread of COVID-19 recorded high rates of depression symptoms and distress. Faced with this critical situation; health care staff who are at the front-line and are actively involved in the diagnosis, recovery, and care of COVID-19 patients are at risk of experiencing psychiatric depression and other signs of mental health. The ever-increasing number of COVID-19 cases, disproportionate workload, few personal security services, extensive media attention, lack of specific medications, and feelings of insufficient help can all add to these stressors, which leads to the mental burden of health professionals[11,64-66]. Therefore, mental health issues must also be incorporated into COVID-19 management, including psychiatric symptoms (*e.g.*, depression or anxiety) monitoring, and social requirements

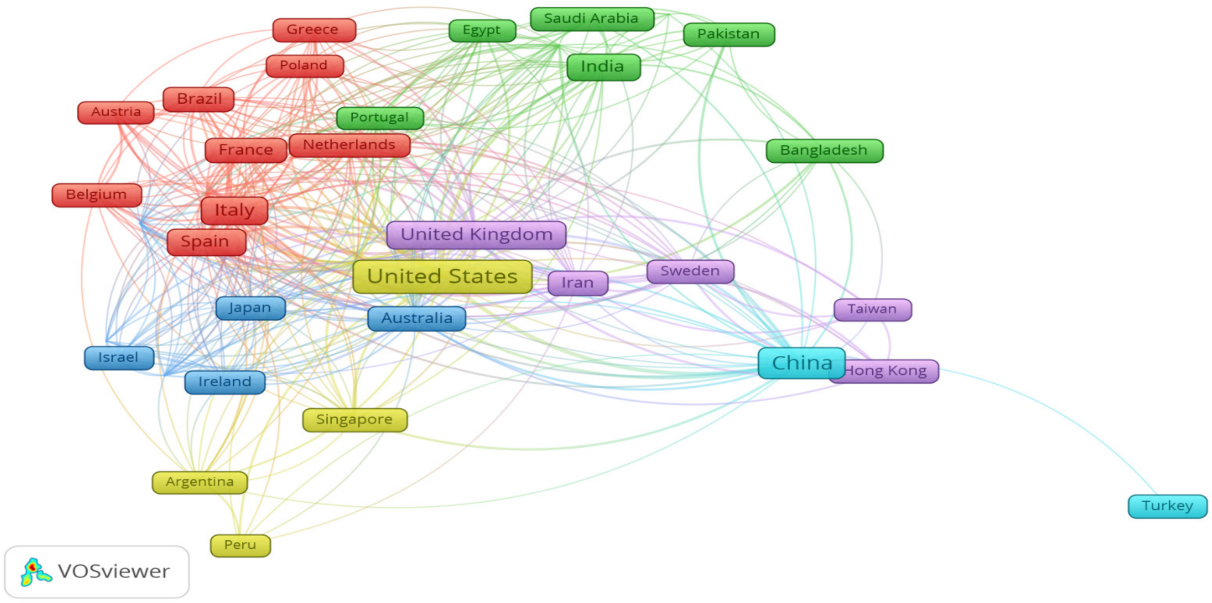

Figure 1 Network visualization map for international collaboration on for publishing articles linking coronavirus disease 2019 and depression.

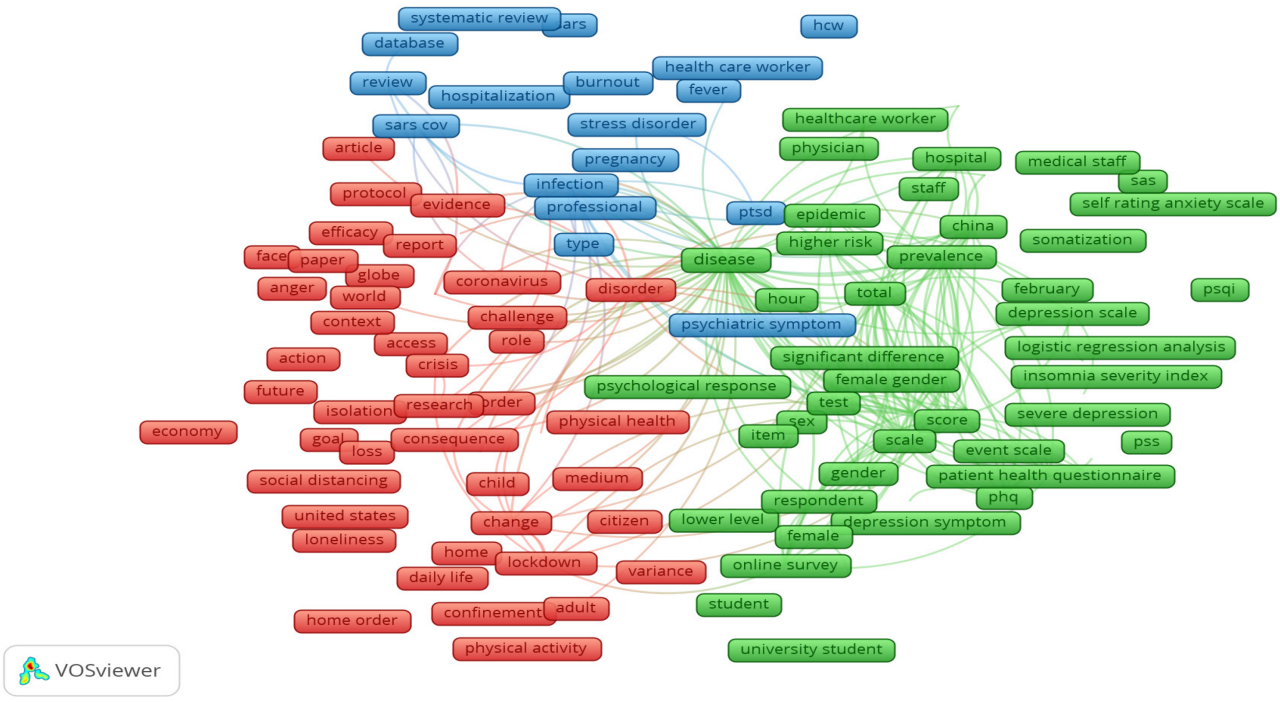

Figure 2 Network visualization map of the most common terms in the retrieved literature's titles/abstracts that refer to coronavirus disease 2019 and depression. The three clusters represent the major research themes in the retrieved literature.

within the general population[8,67].

This bibliometric review represents the first concise overview of global depression-related publications following the COVID-19 pandemic. It illustrates the advantages of bibliometric analysis in a structured manner for assessing research productivity. There were some limitations that we should explain. First, the publications are only derived from Scopus. Second, due to the online database's continuous updating, there is a certain deviation between our bibliometric research outcomes and the actual findings. Regarding this issue, new studies are still being published, and the number of new studies is expected to appear during the upcoming months.

CONCLUSION

During the initial stage of the COVID-19 epidemic, this bibliometric analysis can enable researchers to discover the current status and emerging trends in depression-related publications. High-income countries which include the United States, China, Italy, United Kingdom, and Canada, are the leaders in the world in depression-related publications following the pandemic of COVID-19, contributing to the majority of the total published literature. The United States had the most collaboration with other countries worldwide. The research has also shown that a large number of articles focused on mental health outcomes among the general population and health care workers. With adequate psychological support offered by the government or community agencies, mental health in various communities should be put within the local and global public health agenda. This changing situation involves the scientific community's collaborative efforts to pay attention to population monitoring during quarantine and COVID-19 outbreaks and examine the short- and long-term adverse effects on psychological well-being.

ARTICLE HIGHLIGHTS

Research background

Over the last year, coronavirus disease 2019 (COVID-19) has had a major impact on daily life around the world. The COVID-19 epidemic is predicted to have a massive and long-lasting effect on mental health, resulting in a range of global issues that must be tackled.

Research motivation

To date, there is not a bibliometric study assessing depression research and COVID-19 at the global level. Capturing relevant literature is important for understanding the characteristics and trends of a specific focus area. It can also rapidly and reliably present the most relevant studies regarding depression research and COVID-19, which provides the theoretical foundation for further research.

Research objectives

This bibliometric analysis was conducted to examine Scopus-based depression research and COVID-19, clarify current research progress, and illustrate the potential hotspots in depression research and COVID-19 in order to gain a more global perspective.

Research methods

The Scopus database was used to find relevant research on depression and COVID-19. The VOSviewer program was used to build visualization maps, which included research collaboration.

Research results

During the initial stage of the COVID-19 epidemic, this bibliometric analysis can enable researchers to discover the current status and emerging trends in depression-related publications. High-income countries which include the United States, China, Italy, United Kingdom, and Canada, are the leaders in the world in depression-related publications following the pandemic of COVID-19, contributing to the majority of the total published literature. The United States had the most collaboration with other countries worldwide. The research has also shown that a large number of articles focused on mental health outcomes among the general population and health care workers.

Research conclusions

According to the findings of this report, several articles focused on mental health outcomes in the general population and among health-care staff. Mental health in diverse populations should be included in the local and global public health agenda with sufficient psychological support provided by the government or community organizations.

Research perspectives

Because current knowledge on the key psychological distress impacts of COVID-19 is scarce and little is known in the production of reports on this subject, a descriptive and visual quantification of scientific research on COVID-19 and its impact on depression will allow information professionals, psychiatrists, and experts from other fields of medicine, in addition to local authorities and community health staff, to obtain an empirical view of evolution, current scope, and depression.

ACKNOWLEDGEMENTS

I would like to thank the Clinical Research Centre of An-Najah National University Hospital for the constant support and wise advice.

ABOUT COVER

Peer Reviewer of *World Journal of Psychiatry*, Ravi N Shah, MD, MBA, Assistant Professor, Chief, Department of Psychiatry, Columbia University Irving Medical Center, New York, NY 10032, United States.
rns2142@cumc.columbia.edu

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatr*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc*.

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, and PubMed Central. The 2021 edition of Journal Citation Reports® cites the 2020 impact factor (IF) for *WJP* as 4.571; IF without journal self cites: 4.429; 5-year IF: 7.697; Journal Citation Indicator: 0.73; Ranking: 46 among 156 journals in psychiatry; and Quartile category: Q2.

RESPONSIBLE EDITORS FOR THIS ISSUE

Abstract

In this editorial we comment on the article by Cahn-Hidalgo D published in a recent issue of the *World Journal of Psychiatry* 2020; 10(1); 1-11. We focus on the importance of utilizing psychometrically valid cognitive screening tools when assessing for cognitive decline in older adults in a psychiatric outpatient setting. We compared the use of Cognivue® to use of the montreal cognitive assessment (MoCA) as a cognitive screening tool. A total of 58 patients aged 55 and over participated in this comparison study. Patients completed cognitive screening on Cognivue®, a new Food and Drug Administration-cleared computer screening device, and the MoCA. The results of patient performance using these two instruments were analyzed. Sixteen (28%) patients screened negative for cognitive impairment on both assessments. Forty-two (72%) patients screened positive on one or both of the assessments. There was 43% agreement between Cognivue® and the MoCA in identifying patients with cognitive impairment, and individual subtests were weakly correlated. The MoCA was determined to be the preferred instrument due to its high sensitivity and specificity (100% and 87%, respectively) when screening for cognitive impairment. We propose that the use of Cognivue® cognitive screening tool be closely reviewed until more research proves that the test meets the standards for reliability and validity. It is important for clinicians to remember that screeners should not be used to diagnosis patients with neurocognitive disorders; instead, they should be used to determine whether further evaluation is warranted. Additionally, misdiagnosing of neurocognitive disorders can pose unnecessary psychological and emotional harm to patients and their families and also lead to incorrect treatment and undue healthcare costs.

INTRODUCTION

Cognitive decline is the leading cause of functional impairment among older adults [1]. As the population of older adults in the United States continues to rise, recognition and prevention of neurocognitive disorders becomes increasingly important. Screening for cognitive deficits facilitates early identification of these disorders, which, in turn, helps providers determine when to refer patients to neurology, psychology, or geriatric specialists for more extensive evaluation. Further, recognition of cognitive impairments allows clinicians to more effectively monitor safety and adherence to treatment, determine when to include family in treatment/decision making, and make accommodations during visits (such as providing materials and instructions the patient can understand and remember). Early and accurate diagnosis enables clinicians to educate patients and their families on symptoms and prognoses and to advise on treatment and support options.

There are different types of neurocognitive disorders (*i.e.*, mild and major) that vary in symptom presentation, degree of impairment, prognosis, and treatment. Screening for and differentiating among these conditions can be a challenge. When testing for cognitive impairments, an ideal screening tool should sample the various cognitive domains that are most often compromised. These domains include executive functioning, visuospatial skills, language, processing speed, attention, memory, abstraction, and psychomotor skills[2]. In addition to using the cognitive screening tool, direct observation of the patient and collection of collateral information from a close family member, friend, or caregiver can provide important details regarding symptoms and level of functioning. This information will assist clinicians in making informed decisions on how to proceed with further evaluation and treatment. Clinicians should not rely solely on cognitive screening tools to diagnose patients with neurocognitive disorders, as gathering additional information is imperative in confirming a diagnosis and providing the most appropriate treatment for patients. Incorrectly diagnosing any type of neurocognitive disorder can lead to mismanagement of symptoms, improper use of medications, anxiety and distress for patients and their families, and unnecessary health care costs.

CRITICAL EVALUATION OF SCREENING INSTRUMENTS

It is important to critically evaluate screening tools to ensure they are psychometrically valid. Currently, there are a number of readily available screening instruments from which to choose[3]. Among the more widely researched and utilized screeners are the montreal cognitive assessment (MoCA), saint louis missouri mental status (SLUMS), and mini-mental state examination (MMSE). The MoCA detects symptoms of dementia with 100% sensitivity and 87% specificity[4]. It has been shown to evaluate many cognitive domains that are impacted in the various types of neurocognitive disorders. The pen-and-paper tool is administered by a clinician and takes about 10 min to complete. Scores range from 0-30 (+1 for 12 or fewer years of education); a score of 26 or higher indicates "normal" cognitive functioning, while a score of 25 or lower indicates "impaired" functioning.

Cognivue® is a recently introduced screening tool that is administered using a standalone computer and onscreen instructions. The instrument has been "cleared" by the Food and Drug Administration (FDA), signifying that the administration does not perceive it to pose any danger to patients when used as directed[5]. Notably, clearance of a "de novo medical device" implies there is no comparable instrument and, thus, imposes few, if any, requirements for comparative analyses. Cognivue® provides scores ranging from 0-100, with a score of 75 or higher signifying "normal" cognitive functioning, a score of 51-74 signifying low-moderate cognitive impairment, and a score of 50 or lower signifying severe cognitive impairment. There are a few research studies on this device which have been company-funded and focused on comparing Cognivue® results with that of the SLUMS and several other neuropsychological assessment tools. This research by Cahn-Hidalgo *et al*[6] was published in a recent issue of the *World Journal of Psychiatry* [2020; 10(1); 1-11].

In the Cahn-Hidalgo *et al*[6] article they noted correlations between various neuropsychological tests and the "components" of the Cognivue®; however, it is unclear which subtests of the Cognivue® fell under each of the five "components". It did label the components as verbal processing, manual dexterity and speed, visual acuity, visuospatial and executive function, and speed and sequencing, which doesn't align with the domains on the clinician report generated by the Cognivue® (*i.e.*, Visuospatial, Executive Function/Attention, Naming/Language, Memory, Delayed Recall, and Abstraction). The results from Table of their article highlight strong correlations (0.529 to 0.902) between verbal processing and the SLUMS naming task and Rey Auditory Verbal Learning Test; manual dexterity and speed with Groove Peg Board Task; visuospatial and executive function with Trails B and Judgment of Line Orientation; and speed and sequencing with Trails A (Cahn-Hidalgo *et al*[6], 2020). Correlations with other Cognivue® components and neuropsychological tests administered had low to moderate correlations (0.003 to 0.408) also outlined in Table. There was no good indication in this research that the Cognivue® tapped into the domains of attention, immediate memory, delayed recall, or abstraction, which are important areas to consider when screening for neurocognitive disorders. For example Cognivue® presentation of stimuli is all visual, which is a limitation. After initial exposure a few seconds pass before the participant is given a multiple choice paradigm to recognize and respond. This brief delay can be categorized as a short-term memory process, but not a long-term memory one. Additionally when considering models of memory, recognition of stimuli in a multiple choice format is easier than free recall of information or encoding the stimuli to long-term memory[2]. Since recognition can be intact in some individuals with neurocognitive disorders, such as with vascular dementia or mild cognitive impairment, presentation of information in this way could lead to false-negatives. Additionally it is unclear how the Cognivue® subtests measure executive functioning skills even though Cahn-Hidalgo *et al*[6] research suggests correlations with Trails B, an executive function test.

It is also important to highlight that correlations between subtests do not necessarily mean that they are valid or even that they measure the intended variables. For example, the naming task on the SLUMS had a strong correlation (0.529) with the "language" measures on Cognivue®[6]. The SLUMS naming task requires the subject to verbally generate as many animals as they can in one minute and is intended to screen for aphasia and other language/speech disturbances. In comparison, the language section on Cognivue® does not have a verbal component. The tasks consist of single letters or simple three-letter words being visually displayed on a screen and then presents the subject with a visual multiple-choice paradigm, which requires them to select what was previously presented from items that were not. While this task involves some elements of language, it does not assess the same area of the brain as a naming task that requires verbal fluency and word finding skills, which are commonly observed deficits in neurocognitive disorders like Alzheimer's disease[2]. The cognitive domains measured by the Cognivue® are not well defined or researched in comparison to other screeners and neuropsychological measures.

Importantly, there are potential conflicts of interest with the aforementioned article. The research was funded by the makers of Cognivue® and the authors were employees or consultants for the company. Therefore it is important that studies with larger sample sizes are completed by unaffiliated researchers for validation of the Cognivue®. Additionally the company did not use trained psychologists or clinicians to administer the neuropsychological assessments in their research, calling the validity of the results into question. These authors concluded that the Cognivue® is either the equivalent or superior to the SLUMS when screening for cognitive impairment and "superior" for test-retest reliability[6,7]. They do admit more comparison studies are warranted; however they go on to infer that the Cognivue® will be equivalent in terms

Table 1 Demographics and montreal cognitive assessment and Cognivue® Scores

	Positive MoCA score, *n* = 12	Positive Cognivue® score, *n* = 12
Gender, *n* (%); Male; Female	5, (41.7); 7 (58.3)	0, (0.0); 12 (100.0)
Age, yr	63.1 (5.0)	68.0 (7.2)
Length of education, yr	15.5 (2.2)	15.4 (2.4)
MoCA score	24.3 (0.8)	27.1 (1.3)
Cognivue® score	81.3 (4.7)	62.7 (11.6)

Presented as mean (SD), unless otherwise indicated. MoCA: Montreal cognitive assessment.

of its sensitivity, specificity, and psychometric validity to commonly used screeners like the MoCA and MMSE[6]. Without more research, with larger sample sizes, it is not appropriate to suggest the Cognivue® is more useful or accurate than other screening instruments. Furthermore the researchers claim the Cognivue® reduces "costs" associated with screening for cognitive impairments; however the cost saving advantage of this device *vs* other tools has not been established.

Unfortunately there are limited validation studies of the Cognivue®, especially ones that are not associated with or funded by the company. There has been research examining the use of the Cognivue® with a small sample of MS patients, which was coauthored by the founder and chief executive officer of Cerebral Assessment Systems and inventor of Cognivue®. This study compared Cognivue® total scores to the paced auditory serial addition test (PASAT) (which assesses auditory information processing speed, attention, and flexibility) and symbol digit modalities test (SDMT) (which assesses visual processing speed and attention)[8]. The PASAT and SDMT are commonly used cognitive screeners and research tools when working with Multiple Sclerosis (MS) patients[9]. Smith *et al*[8] found strong correlation between the Cognivue® Total Score and SDMT (0.79) and the PASAT (0.61)[8]. In 2020 Bomprezzi expanded this research and found moderate correlations (0.67) between the Cognivue® Total Score and SDMT results in a small sample of MS patients[10]. The finding of these studies suggests the Total Cognivue® score correlates with tests that are measuring elements of attention and processing speed.

Digital and computer based screeners and tests show promise for detecting cognitive impairments[11]. In addition to the Cognivue® there has been development of different computerized cognitive screeners. For example the historical Clock Drawing Test has been transformed into a digital version. The five minute Digital Clock Drawing Test is registered as a FDA Class II medical device for cognitive screening[12]. The tablet uses a digitizing pen that captures and analyzes the drawing. One Harvard research study concluded the DCT clock showed "excellent discrimination" between individuals with cognitive impairment and controls[12]. Unfortunately much of the technology and test adaptations for these devices are new, with few studies, small sample sizes, and lack of evidence, making it risky to suggest that computerized testing should be used clinically for the detection, diagnosis, and monitoring of neurocognitive disorders without complete and validated research[11].

We compared the Cognivue® to the MoCA to assess its ability to screen for cognitive deficits among older adults in a mental health outpatient clinic. Both instruments were administered to 58 adult clinic outpatients aged 55-89 years by trained personnel. The results showed 28% agreement between tests for patients who did not screen positive for cognitive impairment according to their scores. In contrast, 42 (72%) patients screened positive on one or both measures. Of all patients who screened positive, the tests showed only 43% agreement in terms of identifying patients who may benefit from further assessment. Both Cognivue® and the MoCA independently identified 12 different patients as being positive for cognitive impairment. Demographics as well as MoCA and Cognivue® scores are described in Table 1. As can be seen here, there may be particular risks for false positive results among older women using Cognivue® and among patients who score close to the cutoff (24 or 25) using the MoCA.

Given the lack of agreement between these measures, we then determined whether correlations exist between domains of the MoCA and Cognivue® and whether Cognivue® measures the same or similar domains as the well-established MoCA. The results, presented in Table 2, suggest there are a few low to moderate correlations between subtests of the two instruments, in terms of ability to assess visuospatial abilities, naming ability, and attention. The results also indicated that most subtests,

Table 2 Correlations between Subtests of the montreal cognitive assessment and Cognivue®

MoCA: Montreal cognitive assessment.

which purportedly measure the same domains, do not demonstrate commensurate correlations.

CONCLUSION

The findings of this limited study raise questions regarding the utility of Cognivue® for its intended purposes. We compared instruments and based on our findings and previous research which determined that the MoCA is the preferable screening tool. While both instruments seemed comparable with regard to their acceptability to patients, the MoCA does require more time from trained personnel to administer. In addition, the use of MoCA is now restricted to trained users as there were significant variations observed in the quality of the tests that were administered and the potential liability that this issue causes to its users[13]. The training to administer and score the MoCA has been deemed necessary starting September 1, 2019. The users will have 1 year to complete their training and will continue during that time to access the test without any restriction. After September 1, 2020, the access to the test has been restricted to certified users. We believe the requirement of additional time is offset by the extensive body of research supporting its psychometric properties and the significant risks to patients when screeners result in misdiagnosis.

Our findings call into question claims pertaining to the domains that Cognivue® measures, which are crucial for correctly identifying potential neurocognitive deficits. Most Cognivue® subtests appear to place cognitive demands in the domains of visual

ability, motor control, attention, processing speed, visual discrimination, and short-term memory/recognition. These areas are important; however, if patients have deficits in one or more of these domains, it may impact their performance on some, if not all, subtests of the Cognivue® given the way tasks are presented. Therefore, results may be skewed, potentially creating false positive outcomes. Additionally the subtests do not appear to assess long-term memory, executive functioning, language, or abstraction. Clearly defining the subtests of the Cognivue® is crucial in determining its efficacy as a screening tool. More research by unaffiliated researchers, on large samples of participants, is needed to determine what specifically the Cognivue® subtests are measuring and what modifications can be made to improve its screening capabilities.

Practicing clinicians should be aware of the importance of identifying cognitive impairments among older adults. Screening tools may play an important role in the identification of cognitive impairments and should not be seen as an inconvenience, but as an essential part of optimizing patient care. A cognitive screening tool should not be chosen because it is new and easily administered, but because it is the most efficacious way to accomplish the task. We recommend that clinicians primarily use the MoCA for this purpose. Further, we propose that use of Cognivue® be evaluated carefully, until its subtests are modified or more research proves that the test meets standards for reliability and validity. Inadequate evaluation and misdiagnosis of neurocognitive disorders can be distressing for patients and their families and lead to inappropriate treatment and unnecessary healthcare costs. It is important to remember that a cognitive screening tool should not be used in isolation to establish a diagnosis of neurocognitive disorder, rather, it should be used to assist clinicians in determining when further evaluation is indicated.

Abstract

Primary care has been dubbed the "de facto" mental health system of the United States since the 1970s. Since then, various forms of mental health delivery models for primary care have proven effective in improving patient outcomes and satisfaction and reducing costs. Despite increases in collaborative care implementation and reimbursement, prevalence rates of major depression in the United States remain unchanged while anxiety and suicide rates continue to climb. Meanwhile, primary care task forces in countries like the United Kingdom and Canada are recommending against depression screening in primary care altogether, citing lack of trials demonstrating improved outcomes in screened *vs* unscreened patients when the same treatment is available, high false-positive results, and small treatment effects. In this perspective, a primary care physician and two psychiatrists address the question of why we are not making headway in treating common mental health conditions in primary care. In addition, we propose systemic changes to improve the dissemination of mental health treatment in primary care.

Core Tip: Primary care has been dubbed the "de facto" mental health system of the United States since the 1970s. Two psychiatrists and an internist at a major academic medical center review difficulties with implementation of collaborative care in academic primary care settings along with novel recommendations to improve dissemination of this evidence based practice.

INTRODUCTION

Much of the evidence for integrating mental health treatment into primary care settings comes from collaborative care (CC) interventions for depression. While the effect of CC on clinical outcomes like glycemic control has been inconsistent[1], CC has proven effective in improving depressive symptoms, satisfaction, quality of life and costs[2,3], especially among racial and ethnic minorities[4]. Policymakers and researchers designed CC to optimize the care of psychiatric patients, the majority of whom receive mental health treatment in primary care. The last decade saw remarkable improvements in CC implementation and reimbursement[5]. However, the recent coronavirus disease 2019 (COVID-19) pandemic contributed to physical morbidity and mortality but also social isolation, loneliness, economic insecurity, and alarming rates of acute stress, anxiety, and depression among patients[6] and providers alike[7]. Depression for example increased 3-fold in the United States[8], and up to 7-fold according to recent meta-analysis of multiple countries[9]. Few if any recent articles have addressed how best to overcome barriers to CC implementation in the post-COVID era, however. In this perspective, we address emerging barriers and challenges to treating common mental health conditions. In addition, we propose systemic changes to improve the dissemination of mental health treatment in the telemedicine era.

CHALLENGES PRIMARY CARE PHYSICIANS FACE IN TREATING MENTAL HEALTH

Policymakers, providers and researchers developed CC models, in part, to address gaps in the access to quality mental health treatment in primary care and to offload busy primary care providers (PCPs). The lynchpin of these models are care managers, typically nurses or licensed social workers, who provide monitoring (using standardized screening tools) and problem-solving therapy under the supervision of a psychiatrist who assists with case review and complex cases. It remains unknown whether the programs can handle or even effectively treat the new deluge of patients with mental health issues. In fact, studies from multiple countries conducted in 2020 (53 studies; n = 158000) report high point prevalence estimates of stress (29%-31%), depression (25%-47%), anxiety (32%-47%), sleep disturbances (34%-36%), and posttraumatic stress disorder (16%-18%)[9-17].

At the systems level, even prior to COVID-19, settings with CC programs reported insufficient resources (*e.g.*, care manager fulltime equivalents) to address the volume and complexity of common mental health disorders seen in real-world primary care settings[18]. This remains an issue despite inroads in payment models and an expanded non-physician workforce. There are a variety factors contributing factors to the insufficient number of care managers to meet patient demand, including low reimbursement rates, limited time due to competing demands (*i.e.*, coordination *vs* therapy), low job satisfaction, and suboptimal relationships with PCPs, particularly in large primary care settings with numerous PCPs per care manager[18]. Relatedly, CC outcomes also hinge on having a strong, integrated primary health care system[5], which has also historically been difficult to widely implement[19]. Furthermore, the rapid uptake of telemedicine during the COVID-19 pandemic affected clinical roles,

particularly for medical assistants who traditionally administered depression screening but lack pre-visit telemedicine workflows. Meanwhile, communication infrastructures among staff, patients, and providers have become fragmented. Due to the economic effects of COVID-19, many medical settings now have a greater percentage of uninsured, Medicare and Medicaid patients and higher costs on a case-mix adjusted basis. Few studies, however, examine the unique barriers to CC implementation in settings that operate in fee-for-service models that devalue mental health care[18].

Provider engagement is also crucial to CC implementation[18,20], but PCPs increasingly face shortened, now remote, visits, administrative/teaching/telemedicine onboarding tasks, high turnover (*i.e.*, of trainees) as well competing quality improvement priorities (*e.g.*, diabetes targets, domestic violence screening), all resulting in fatigue and burnout[18]. Many providers in academic settings are not always physically present in clinics (*e.g.*, have half day sessions) and lack formal mental health/CC training in residency, producing physicians ill-equipped to successfully manage their patients' mental health conditions and provide population health-based 'shared-care' with a psychiatrist[21]. Increasing rates of provider psychological distress may also make it difficult to detect and address mental health issues in patients[7]. Finally, direct communication between PCPs and psychiatrists remains rare in these models despite the fact that physician-to-physician engagement often fosters a medical learning environment that enhances the psychiatric treatment skills of PCPs. This may explain why even successfully implemented CC programs see remission in less than half of patients[22].

Meanwhile, patient level barriers include stigma, fear of side-effects, low treatment availability and preferences for focusing on physical concerns resulting in patient nonadherence[23], which is compounded by chronic, resistant, psychosomatic symptoms often seen in primary care settings. It's unclear whether the mental but also long-term physical sequelae of COVID-19 can be effectively managed by the short-term treatment provided by CC.

ROLE DISCORDANCE: CHALLENGES FOR PSYCHIATRISTS

Integrated care models require psychiatrists to step back from direct patient care and collaborate with a care manager who provides therapy and communicates with the PCP for medication management. Although in an idealized CC setting, psychiatrist time would be focused on educating the team and supervising the care manager, often the psychiatrist's limited time quickly becomes filled with direct patient consults. This is the result of several factors. Psychiatry residency, like all the other medical residency training programs, offers little if any training in supervising other clinicians (*e.g.*, care managers) or liaising with PCPs during psychiatry residency. Concrete data does not exist to dictate whether a patient would be better suited for independent care by the PCP as opposed to direct or indirect (*via* care manager) psychiatric consultation, resulting in a patchwork of unnecessary psychiatric consultations or patients remaining in primary care who need referral to more specialized treatment. In addition, like in most other specialty residency training programs, many physicians enter psychiatry specifically to spend time delivering individual care to patients, creating a tendency to veer towards direct *vs* indirect consultation. Combined with the general psychiatrist workforce shortage, these factors make locating psychiatrists for these roles challenging. Finally, while the advent of telepsychiatry comes with improvements in access and convenience for patients and providers, corresponding decreases in direct face-to-face interaction with PCPs and care managers can create unique challenges, such as reduction in non-verbal cues and informal interactions that are often necessary for clarifying clinical and process details and building team-based trust and rapport[24].

LEVERAGING ADVANCES IN MENTAL HEALTH AWARENESS AND TREATMENT TO ADDRESS PRIMARY CARE NEED IN THE POST-COVID ERA

In the post-COVID era, telehealth both for primary care and mental health is increasingly the norm and will at least partially remain in place, offering a rare opportunity to address the above barriers and expand and improve the delivery of CC

for mental disorders in primary care. Prior research suggests that off-site telemedicine-based CC may yield better outcomes than local practice-based CC albeit through better fidelity[25], but widespread implementation will require innovative, multi-disciplinary solutions and adaptations. In Table 1, we recommend several interventions to improve mental healthcare in the primary care setting, starting with requiring dedicated time during outpatient internal medicine residency rotations to learn psychopharmacological and CC principles but also self-care strategies for reducing provider burnout. The Advancing Integrated Mental Health Solutions Center is a valuable resource for CC training. In addition, groups like the Association of American Medical Colleges have begun to create online curricula and modules for residents, and topics include cognitive behavioral therapy for insomnia and trauma informed care. Second, telemedicine era primary care settings may benefit from leveraging technology to make psychoeducation, cognitive behavior therapy (CBT) apps, and symptom self-monitoring, all proven effective in prevention and/or managing mild symptoms, part of routine care[26] (perhaps as part of new pre-visit telehealth roles of medical assistants or patient portals). This may be particularly important given the deluge of patients with mental health concerns in the post-COVID-19 era[6]. The American Psychiatric Association developed toolkits of telepsychiatry and CBT apps, which will be important resources.

Regardless, medication and therapy remain first-line in moderate-severe cases[26]. Patient-preference driven or precise, individualized algorithms (*e.g.*, machine learning) for targeting screening and treatment according to patient depression phenotypes or risk[27] is now possible with integrated electronic health records and may further help address resource limitations, patient engagement and treatment efficiency. In CC settings, improved designations for referrals to care management *vs* direct psychiatry, ideally both remotely delivered, will also be essential and improve efficiency and engagement. Care will need to be taken to avoid technology-driven disparities among the socioeconomically disadvantaged populations often seen in community and academic medical centers (*e.g.*, addressing concerns with stigma and confidentiality; offering phone *vs* video visits). True inroads in mental health treatment in primary care will require flexibility and acknowledging that not every setting is suitable for CC and may instead benefit from improving psychiatry-PCP communication, particularly in non-integrated medical settings where collaboration remains siloed[28]. Advances in telemedicine and technology have the potential to improve communication and make "colocation" even more possible, particularly in settings where a higher density of PCPs and psychiatrists practice.

DISSEMINATING SKILLS FOR PSYCHIATRISTS WORKING IN PRIMARY CARE

While the Accreditation Council for Graduate Medical Education-required experience in consultation-liaison psychiatry provides some inpatient training in collaboration, the outpatient environment is meaningfully different. Trainees need practice and supervision to know the limits of what can and cannot be done with a patient they have not directly interviewed, and how to teach colleagues clinical pearls in a digestible and helpful manner. These skills can and should be part and parcel to psychiatric training. In the interim, the American Psychiatric Association has developed trainings for psychiatrists already in practice to learn the skills needed to successfully operate in a CC setting. Systems should compensate psychiatrists not only for direct patient time but also indirect consultations and teaching primary care colleagues the nuances antidepressant titration strategies. These are the tools that will help scale an expertise-driven treatment of depression and anxiety much faster than having these patients wait to see a psychiatrist. Relatedly, financial models now compensate for telepsychiatry and tele-CC models but should also align with the long-term need for indirect e-consultations as well as with new roles of PCPs and psychiatrists within integrated care settings particularly in the post-COVID-19 financial milieu.

CONCLUSION

In conclusion, long-standing barriers to addressing mental health in primary care settings are underscored in today's environment. COVID-19 propelled the use of

Table 1 Recommendations to improve treatment of common mental health conditions in primary care settings

Recommendations
(1) ACGME requirements should be amended to require dedicated time for primary care physicians to learn self-care/burnout prevention as well as basic problem-solving therapy and psychopharmacological care on outpatient psychiatry rotations or through internal medicine resident-run mental health clinics and for psychiatrists to learn how to supervise other clinicians, including but not limited to: social workers, psychologists, and primary care doctors who function as the primary prescribers; (2) Health systems should streamline communications systems (pagers, cellphones, telehealth) to create access to e-consultations for primary care doctors needing psychiatric expertise; (3) Financial models should align with the long-term need for indirect consultations as well as with new roles of primary care providers and psychiatrists within integrated care settings particularly in the post-COVID-19 financial milieu; (4) Integrated care models should leverage technology to fill administrative functions (such as tracking patient health questionnaire (PHQ-9 forms), develop guidelines for determining when and how to use smartphone treatment applications and self-care resources in primary care settings, and rapidly expand telemedicine to address workforce gaps particularly in socioeconomically disadvantaged groups who face technology-driven disparities; (5) Primary care practices must partner with psychiatry specialty services to create a robust process for referring appropriate patients to specialty mental health care; and (6) Real world effectiveness research should be conducted to elucidate the effectiveness of precisely and efficiently targeting screening and treatment recommendations according to patient phenotype, risk and preference

ACGME: Accreditation Council for Graduate Medical Education; COVID-19: Coronavirus disease 2019.

telehealth and telepsychiatry, offering multiple opportunities for improving the uptake of CC. Future success in these settings will require that primary care and mental health providers apply lessons learned during this period and consider innovations in training, technology, workforce, and treatment selection.

Abstract

Schizophrenia is a severe psychiatric disorder characterized by emotional, behavioral and cognitive disturbances, and the treatment of schizophrenia is often complicated by noncompliance and pharmacoresistance. The search for the pathophysiological mechanisms underlying schizophrenia has resulted in the proposal of several hypotheses to explain the impacts of environmental, genetic, neurodevelopmental, immune and inflammatory factors on disease onset and progression. This review discusses the newest insights into the pathophysiology of and risk factors for schizophrenia and notes novel approaches in antipsychotic treatment and potential diagnostic and theranostic biomarkers. The current hypotheses focusing on neuromediators (dopamine, glutamate, and serotonin), neuroinflammation, the cannabinoid hypothesis, the gut-brain axis model, and oxidative stress are summarized. Key genetic features, including small nucleotide polymorphisms, copy number variations, microdeletions, mutations and epigenetic changes, are highlighted. Current pharmacotherapy of schizophrenia relies mostly on dopaminergic and serotonergic antagonists/partial agonists, but new findings in the pathophysiology of schizophrenia have allowed the expansion of novel approaches in pharmacotherapy and the establishment of more reliable biomarkers. Substances with promising results in preclinical and clinical studies include lumateperone, pimavanserin, xanomeline, roluperidone, agonists of trace amine-associated receptor 1, inhibitors of glycine transporters, AMPA allosteric modulators, $mGLUR_{2-3}$ agonists, D-amino acid oxidase inhibitors and cannabidiol. The use of anti-inflammatory agents as an add-on therapy is mentioned.

INTRODUCTION

Schizophrenia is a serious mental disorder with a lifelong prevalence of approximately 1% and a peak age of onset of 23-34 years in women and the early twenties in men. It is a very complex syndrome that involves widespread brain multi-dysconnectivity. It is characterized by cognitive, behavioral and emotional dysfunctions. To fulfil the diagnostic criteria for schizophrenia, patients must exhibit two or more negative, disorganized or positive symptoms that persist for a minimum of six months, and at least one symptom must be disorganized speech or a positive symptom[1]. Positive symptoms include hallucinations and delusions; negative symptoms are characterized by deficits in normal behavior, including asociality, alogia, anhedonia, blunted affect, and avolition[2]. There is a wide range of treatment possibilities; however, the effectiveness and/or adverse effects of antipsychotics with different pharmacological profiles vary. Successful treatment of schizophrenia is complicated by noncompliance and pharmacoresistance. The prevalence of pharmacoresistant schizophrenia is estimated to range from 12.9% to 48%[3]. It has been estimated that approximately 20% of patients with schizophrenia receive combination treatment and/or antipsychotic polypharmacy[4]. Augmentation strategies used in clinical practice include the addition of another antipsychotic, concurrent administration of benzo-diazepines or mood stabilizers, repetitive transcranial magnetic stimulation or electroconvulsive therapy.

The pathophysiological mechanism of the onset and progression of schizophrenia, the diagnostic neuropathology, and sensitive and specific biomarkers have not yet been identified. Several different hypotheses have been proposed to explain the neuropathology of schizophrenia that focus on environmental, genetic, neurodevelopmental, and neurochemical effects. Research and development in imaging methods and in preclinical studies have led to the improvement of these theories. Positron emission tomography (PET) and single photon emission computer tomography enable *in vivo* quantification of dopaminergic functions in the brain and dopamine synthesis, release, and availability in postsynaptic dopaminergic neurons and transporters.

The targeting of existing and new drugs is based primarily on the dopamine and glutamate hypotheses of schizophrenia. All current antipsychotics modulate the function of the dopamine D_2 receptor. A nonlinear relationship between D_2 receptor occupancy, clinical response, and adverse effects of current antipsychotics was found. A small response to antipsychotic treatment appears at 50% dopamine receptor occupancy; as receptor occupancy increases, the response increases as well as the risk of extrapyramidal adverse effects[5]. These findings were proven in a double-blind study in patients with first episode schizophrenia; 65% occupancy of D_2 receptors was the borderline between responders and nonresponders[6]. Recently, research has focused on the prodromal phase of schizophrenia. Dopamine synthesis increases

during the acute phase of the disease. Stress and other risk factors affect the dopamine systems, leading to their dysregulation and consequently to the development of psychotic disorder[7].

Excitatory glutamate neurotransmission occurs though ionotropic and metabotropic glutamate receptors. The glutamate hypothesis of schizophrenia is based on the dysfunction of the N-methyl-D-aspartate (NMDA) receptor. Currently, the effects of ketamine on brain function in healthy volunteers are being examined; studies are focused on glutamate concentrations in the brains of patients with prodromal symptoms during the first episode and other episodes of schizophrenia. Dysfunction of both NMDA receptors and presynaptic synthesis of dopamine has been implicated in the clinical symptoms of schizophrenia. Relationships between presynaptic dopamine dysfunction and positive symptoms and between glutamate dysfunction and negative and cognitive symptoms are expected[7].

To improve the diagnosis of schizophrenia, predict the therapeutic response to antipsychotics, develop new drugs, and personalize treatment, it is necessary to identify new specific and sensitive biomarkers of the disease[8]. Blood-based biomarkers are regarded as a feasible option because the dysregulation of gene expression, epigenetic patterns, protein quantities, and metabolic and inflammatory molecules in peripheral blood have been shown to have distinct patterns in patients with schizophrenia[8]. The aim of this review is to provide the newest insights into the pathophysiology and risk factors of schizophrenia and novel approaches to antipsychotic treatment.

GENETICS AND SCHIZOPHRENIA

Schizophrenia is closely linked to genetic factors, including small nucleotide polymorphisms (SNPs), copy number variations and changes in gene expression. Combinations of different pathogenic mechanisms, including aberrant DNA methylation, altered histone code, dysregulated long noncoding RNA (lncRNA)-dependent tethering of epigenetic complexes to DNA, aberrant polyadenylation of pre-mRNAs, and mis-splicing, have been reported to play a role in schizophrenia development[9]. The hereditary burden of schizophrenia is estimated to be approximately 80%. Genome-wide association studies (GWAS) have identified more than 100 loci, many of which contain multiple genes that are significantly associated with schizophrenia. The assessment of polygenic scores allows us to determine the risk of schizophrenia based on the number of risk alleles weighted by the odds ratio of each allele.

DNA methylation, an epigenetic process that produces 5-methylcytosine, is mediated by DNA methyltransferases and has a key role in several processes, such as imprinting, inactivation of the X-chromosome, silencing of transposons or regulation of genomic stability and chromatin structure. Schizophrenia is linked to pathophysiological DNA methylation of several genes, including those encoding reelin, catechol-O-methyltransferase (COMT), monoamine oxidase A, serotonin receptor 2A, the transcription factor SOX-10, and others. Unfortunately, no schizophrenia-specific "methylation panel" has been proposed, and it has not yet been clarified whether these changes represent causes or consequences of schizophrenia development[9].

Approximately 70%-80% of the genome is transcribed into noncoding transcripts, and the majority of schizophrenia-associated risk variants have been found in noncoding regions. LncRNAs can interact with DNA, RNA, and proteins, influencing transcription and posttranscriptional processes such as splicing, polyadenylation and/or regulation of transcript stability. MicroRNAs (miRNAs) are small noncoding RNAs that regulate more than 50% of protein-coding genes by acting as promoter or enhancer elements; miRNAs might participate in histone, DNA, or chromatin methylation and modification. Both lncRNAs and miRNAs can be affected by different genetic variants, especially SNPs, which could increase the risk of schizophrenia onset [9,10].

Microdeletions in chromosomal region 22q11.2 are one of the well-established genetic risk factors for schizophrenia and increase the risk of schizophrenia development to 30%-40%[11,12]. COMT is a major dopamine catabolic enzyme, and its gene is located in this microdeletion region. In addition, a functional COMT polymorphism [valine/methionine (VAL/MET) substitution at codon 108] causes differences in its catabolic activity, dopamine baselines and stress-induced cortical dopamine release[13]. The MET version of the allele is not as stable as the VAL version, causing decreased COMT activity and an increase in dopamine levels,

especially in the prefrontal cortex[14].

The major histocompatibility complex (MHC) locus located on chromosome 6, which contains genes encoding proteins essential for adaptive immunity, has one of the strongest links to schizophrenia. Specifically, there was increased expression of complement component 4A (C4A). Sex differences in the *C4* gene could explain the higher male susceptibility to schizophrenia. Schizophrenia patients with higher C4 Levels were characterized as low responders or nonresponders to antipsychotic medication. The expression of the genes encoding CSMD1 and CSMD2, which are important regulators of C4, has been found to be decreased in schizophrenia and connected with reduced cognition and executive function[15,16]. Other immune receptors, including toll-like receptors (TLRs), which take part in microbe-derived molecular signaling, early brain development, synaptic plasticity, and neurogenesis, have been identified as schizophrenia susceptibility genes by GWAS. Both TLR2 and TLR4 were altered in the blood and brain tissue of schizophrenic patients[15].

The genes encoding for neuregulin 1 and neuregulin 3 are candidate schizophrenia genes and produce several possible proteins that influence neuronal differentiation and migration. The role of neuregulin 1 in schizophrenia is not well known, but increased neuregulin 1 signaling led to NMDA receptor hypofunction (in accordance with the glutamate hypofunction hypothesis of schizophrenia). There is no evidence of hyperexpression of neuregulin 1 itself; however, the possibility of mutations causing the production of proteins with enhanced function is still present[14]. Neuregulin 3 is a ligand for receptor tyrosine-protein kinase erbB-4 (ErbB4), and different genetic variants of the neuregulin 3 gene, especially the rs10748842 allele, are connected with higher schizophrenia risk and cognitive impairment[17]. Mutant mice with ErbB4 deletion from fast-spiking interneurons exhibited increased cortical excitability and oscillatory activity and desynchronized neurons in the cortical region, probably caused by the disruption of the proper function of inhibitory GABA circuits in interneurons. These functional changes manifested in increased locomotion, impaired social and emotional behavior and cognitive dysfunction, which are common symptoms of schizophrenia[18,19].

The gene encoding dystrobrevin-binding protein 1 (also referred to as dysbindin or DTNBP1) has been identified as a gene associated with schizophrenia; however, no specific protein coding mutations increasing the risk of schizophrenia have been identified. Decreased dysbindin expression has been found in the brains of schizophrenia patients, and dysbindin risk haplotypes have been associated with increased negative symptomatology in schizophrenia[14].

The gene most closely linked to schizophrenia is probably the gene encoding the protein disrupted in schizophrenia 1 (DISC1), which has been associated with schizophrenia mainly due to a mutation causing a translocation between exons 8 and 9. The molecular mechanism of this mutation is not known, but the shortened mutant DISC1 protein is incapable of dimerization, and it may interact with other proteins. DISC1 expression is especially high during neurodevelopment in the late fetal and early postnatal phases, during which it participates in hippocampal development; however, DISC1 expression continues into adulthood. In schizophrenia pathophysiology, not only DISC1 itself but also its binding and interaction partners, such as microtubule-associated protein 1A, glycogen synthase kinase 3β, phosphodiesterase 4 and fasciculation and elongation protein zeta-1, might play a crucial role[14,20-22].

The synaptosomal-associated protein SNAP25 is involved in synaptic vesicle docking and fusion during neurotransmitter release. The promoter variant rs6039769 with the C risk allele caused an increase in SNAP25 expression, probably causing a larger amygdala and greater functional connectivity between the amygdala and ventromedial prefrontal cortex in male schizophrenic patients. This modulation in the plasticity of the prefrontal cortex-limbic connection caused higher schizophrenia risk [23].

The gene encoding transcription factor 4 (TCF4) is another GWAS-confirmed gene associated with schizophrenia. It encodes class I basic helix-loop-helix transcription factors and plays a role in neurodevelopment. Altered expression of TCF4 in the forebrain of a transgenic mouse caused altered cognition and long-term depression increased the density of immature spines[24]. Many other genes have been associated with schizophrenia diagnosis and have been reported in the literature[25-27]; description of all schizophrenia-linked genes is beyond the scope of this review.

TRIGGERS AND RISK FACTORS

Environmental model of schizophrenia

The onset and severity of schizophrenia are always modulated by an interplay between genetic and environmental risk factors[28]. Many epidemiological studies have investigated putative environmental risk factors for schizophrenia and peripheral biomarkers of the disease[29,30]. According to an umbrella review of meta-analyses on risk factors and peripheral biomarkers for schizophrenia[31], history of obstetric complications, exposure to stressful events in adulthood or to childhood adversity, cannabis use, and serum folate level showed robust evidence of association with schizophrenia.

The prenatal and perinatal periods are characterized by great neural vulnerability to environmental insults. A recent systematic review and meta-analysis of 152 studies revealed numerous prenatal and perinatal risk factors, calculated with odds ratios (ORs), that were statistically linked to schizophrenia onset[32]. The biggest risk factors for schizophrenia onset are any familial psychopathology, especially maternal psychosis (OR: 7.61). Maternal infections (herpes simplex 2, OR: 1.35; unspecified infections, OR: 1.27), a suboptimal number of antenatal care visits (OR: 1.83), or maternal stress (OR: 2.4) can lead to a higher prevalence of obstetric events (OR: 1.52), which are the longest-studied and best replicated environmental risk factors for schizophrenia. Significantly relevant obstetric events include maternal hypertension (OR: 1.4), hypoxia (OR: 1.63), premature rupture of membranes (OR: 2.29) and polyhydramniosis (OR: 3.05). There is experimental and clinical evidence showing significant risks of prenatal infection and inflammation for the later development of schizophrenia. According to the viral model of schizophrenia, prenatal viral and bacterial infections and inflammation play an important role in the development of schizophrenia[33].

Nutritional deficits or famine in pregnancy (OR: 1.4) or more than two pregnancies (OR: 1.3) can be associated with reduced allocation or lower socioeconomic status. Another risk factor is congenital malformations (OR: 2.35)[32]. The most relevant postnatal environmental risk factors are childhood trauma (OR: 2.87), urban living (OR: 2.19), migration (2.10) and cannabis use (OR: 5.17), and these stress factors lead to the sensitization of the subcortical dopamine system[11].

Many genes relevant to schizophrenia, especially immune genes, can be altered by air pollution. Children with greater exposure to traffic-related air pollution had increased levels of proinflammatory cytokines. It is not yet clear whether air pollution itself causes brain changes or inflammatory changes caused by air pollution contribute to the pathology of schizophrenia[15].

A study of the roles of both genetic and environmental influences on the development of schizophrenia is necessary to explain the fact that in approximately 40%-55% of cases, monozygotic twins do not share a diagnosis of schizophrenia[34]. How genetic and environmental factors interact and the related neurobiological mechanisms that induce schizophrenia are not yet known.

Stress and schizophrenia

The vulnerability-stress model of schizophrenia proposes that when stress exceeds the vulnerability threshold, an individual is likely to develop a psychotic episode[35]. Stressful life events or psychological stress, especially in key periods of neurodevelopment, increase the risk of schizophrenia. These events include physical or mental abuse, lower socioeconomic status, urban environment, and neglect. The molecular mechanisms connecting these stressful situations with schizophrenia remain unclear. It was proven that patients with schizophrenia have altered cortisol function, and its release is linked to the inflammatory response rather than the anti-inflammatory response. Observation of HPA axis activation and cortisol release as a result of stress events in individuals with schizophrenia has produced inconsistent results; however, HPA axis dysfunction has been observed[15].

Neurons are extremely sensitive to redox imbalance during neurodevelopment and differentiation, mostly because of their high lipid content and metabolic rate. Increased reactive oxygen species (ROS) production and/or lowered antioxidant system capacity are considered risk factors for schizophrenia development. Increased protein and lipid oxidation and lowered levels of vitamin C and E, catalase, glutathione peroxidase and superoxide dismutase have been detected in schizophrenia patients. A study revealed that participants with low vitamin D3 Levels in the first year of life were at two times higher risk of schizophrenia. Glutamate-cysteine ligase is the rate-limiting biosynthetic enzyme of glutathione. One allelic variant of the GCLC gene is linked to the decreased

activity of glutamate-cysteine ligase and schizophrenia. NMDA receptors are regulated by the redox state, and glutathione deficiency induces NMDA receptor hypofunction, which leads to cortical oxidative stress and glutathione decrease[36,37].

Neurodevelopmental model

The neurodevelopmental model postulates that an increased risk of schizophrenia development is the result of abnormal brain neurodevelopment caused by genetic and environmental factors years before the onset of the disease[38]. The hypothesis is based on clinical, epidemiological, brain imaging, and genetic studies[39,40]. Schizophrenia is supposed to be a developmental disorder of the brain, and changes in brain neuroplasticity are involved. The disconnection hypothesis[41] presumes the involvement of abnormal synaptic connections in the pathophysiology of schizophrenia. Impaired synaptic plasticity and synaptic efficacy, mainly in areas of the brain responsible for learning, memory, and emotion, participate in schizophrenia pathophysiology. Modulation of ascending neurotransmitter systems and consolidation of synaptic connections during learning are implicated in schizophrenia neuropsychology, especially in impaired adaptive behavior and disintegrative aspects [42].

The unitary hypothesis of schizophrenia includes different types of pathophysiological models[43]; according to the hypothesis, early brain insults can lead to dysplasia of selective neural circuits, which is responsible for premorbid cognitive and psychosocial dysfunction in patients with schizophrenia. The onset of psychosis in adolescence may be associated with the excessive elimination of synapses with subsequent dopaminergic over activity. Decreased glutamatergic neurotransmission can predispose the brain to these processes. After the onset of the disease, these neurochemical changes can lead to further neurodegenerative processes. Brain plasticity includes both synaptic and nonsynaptic plasticity. The dysplastic model of schizophrenia suggests that impaired neuroplasticity during brain development may underlie cognitive and deficit symptoms and may lead to reorganization in other neuronal circuits, which may lead to affective and psychotic symptoms[44].

The multiple hit theory of schizophrenia[45] presumes that schizophrenia can be conceptualized as a process involving multiple vulnerability factors across numerous neurodevelopmental windows in which some hits are applied prenatally, in childhood, in adolescence, and in adulthood. Thus, the development of schizophrenia is driven by the interactions between genetic vulnerability and environmental influences (including prenatal vitamin D, nutrition, childhood trauma, viral infections, IQ, smoking, cannabis use, and social defeat), which are cumulative and interact with each other. The neurodevelopmental phase involves changes in synaptogenesis, synaptic enhancement, and myelination, leading to excessive elimination of synapses and loss of neuroplasticity.

An extension of the neurodevelopmental model[46] proposes that the abnormal formation and maturation of connectomes (an extensive network of interconnected neurons) is central to the etiology of the disease. That is, abnormal anatomical architecture and functional organization of the connectome may be a final common pathway leading to the manifestation of schizophrenia symptoms. To further refine the developmental hypothesis of schizophrenia, progress in our understanding of brain connectivity during development and dysconnectivity resulting from genetic and environmental factors is necessary.

Oxidative stress and apoptosis

Disconnection of the prefrontal cortex in schizophrenic patients is associated with abnormalities in white matter, oligodendrocytes, and myelin. Myelin is produced by mature oligodendrocytes, and oligodendrocyte precursor cells are extremely sensitive to oxidative stress. A redox-induced prefrontal oligodendrocyte precursor cell-dysfunctioning hypothesis of cognitive symptomatology in schizophrenia has been proposed[47]. According to this hypothesis, the combination of environmental factors and genetic predisposition causes oxidative stress due to the excessive generation of ROS and reactive nitrogen species in oligodendrocyte precursor cells. Oxidative stress can lead to the downregulation of myelin-related genes in oligodendrocytes, decreased expression of myelin basic protein, and a reduced number of oligodendrocytes in the rat brain. During adolescence, a high concentration of ROS impairs the proliferation and differentiation of oligodendrocytes and their precursors. This leads to their dysfunction and hypomyelination and consequently to the disruption of connectivity in the prefrontal cortex. The resulting cognitive symptoms coincide with the onset of schizophrenia.

Additionally, oxidative stress induces dysregulation of the immune system and favors a proinflammatory response. Inflammation and disruption of immunity are other factors contributing to the pathogenesis of schizophrenia, as described in the following sections.

Mitochondria play a major role in cellular bioenergetics, oxidative stress, and apoptosis. According to the mitochondrial hypothesis of schizophrenia, mitochondrial dysfunction leads to distorted neuronal activity and plasticity, causing imbalanced brain circuitry and finally abnormal behavior[48]. Massive loss of white matter oligodendrocytes is a hallmark of schizophrenia. Therefore, it has been hypothesized that mitophagy is increased in oligodendrocytes in schizophrenia, which contributes to disease-related white matter neuropathology.

The intrinsic pathway of apoptosis is activated by intracellular signals generated during cellular stress and is triggered by the release of proapoptotic factors from mitochondria. Thus, consistent with the mitochondrial hypothesis, the apoptotic hypothesis postulates that apoptosis contributes to the pathophysiology of schizophrenia. The data indicate a dysregulation of apoptosis in several cortical areas in schizophrenia. The potential involvement of nonlethal localized apoptosis in the early stages of the disease is presumed[49].

NEUROCHEMICAL HYPOTHESES

Dopamine hypotheses

According to the classic (receptor) dopamine hypothesis of schizophrenia, psychotic symptoms are related to dopaminergic hyperactivity in the brain. Hyperactivity of dopaminergic systems during schizophrenia is the result of increased sensitivity and density of dopamine 2 (D_2) receptors. This increased activity can be localized in specific brain regions[50,51]. The dopamine hypothesis does not assume that dopamine hyperactivity fully explains schizophrenia. Over activation of D_2 receptors appears to be only one effect of the overall dysregulation of chemical synapses in this disease.

The modified dopamine hypothesis assumes that schizophrenia is characterized by abnormally low prefrontal dopamine activity (causing negative symptoms) that leads to excessive dopamine activity in mesolimbic dopamine neurons (causing positive symptoms). Thus, this hypothesis presumes the co-occurrence of high and low dopamine activity in different neuronal circuits, which could explain the concurrent presence of positive and negative symptoms[52].

The unifying dopamine hypothesis of schizophrenia, called "the final common pathway", proposes that multiple environmental, genetic, and other risk factors (such as stress, drugs, or frontotemporal dysfunction) interact and result in striatal dopamine dysregulation, which alters signal transmission and leads to psychosis[53]. This hypothesis combines dopamine dysfunction with other risk factors, including pregnancy and obstetric complications, stress and trauma, drug abuse, genetic predisposition and environment–gene interactions, with both increased presynaptic striatal dopaminergic function and other brain functions that underlie negative and cognitive symptoms.

A model has been presented of how genes and environmental factors may sensitize the dopamine system so that it is vulnerable to acute stress, leading to progressive dysregulation and the onset of psychosis[13]. The main steps of this model are as follows: genetic risk factors lead to impaired glutamatergic regulation, followed by increased striatal dopamine release, aberrant salience, and psychotic symptoms. Acute psychosocial stress can activate increased striatal dopamine release both directly and indirectly *via* blunted cortical dopamine release and impaired glutamatergic regulation. The dopaminergic system interacts also with muscarinic cholinergic system and closely related muscarinic hypothesis of schizophrenia.

Glutamate hypotheses

The glutamate hypothesis assumes that schizophrenia is caused by developmental abnormalities in glutamate synapse formation at specific sites, particularly at GABA interneurons in the cerebral cortex. These abnormalities may lead to subsequent excessive glutamate signaling to the ventral tegmental area (VTA), and excessive activation of this pathway may result in an excess of dopamine in the ventral striatum *via* the mesolimbic pathway[54]. The role of dysregulation of glutamatergic neurotrans-mission in the pathophysiology of schizophrenia is supported by evidence from genetics, pharmacological, postmortem, and brain imaging studies[55]. The conver-

gence of GABA impairment and glutamate neurotransmission in the dorsolateral prefrontal cortex could explain the impairment of certain cognitive functions in schizophrenia[56].

The NMDA receptor hypofunction hypothesis[57] assumes that genetic and other risk factors induce epigenetic alterations leading to NMDA receptor hypofunction in schizophrenia. NMDA receptor hypofunction induces a cascade of downstream disturbances in neuronal activity, calcium entry, and epigenetic machinery, leading to abnormal synaptic development and dopaminergic and GABAergic dysfunction. These changes in neurotransmission result in the cognitive and social deficits found in schizophrenia. According to this hypothesis, changes in the dopamine system are secondary to NMDA receptor hypofunction.

Antagonists of NMDA receptors (*e.g.*, phencyclidine) have been shown to cause symptoms similar to the positive and negative symptoms and cognitive defects in schizophrenia[58]. According to increasing evidence, deficits in NMDA transmission are linked to cognitive defects and negative symptomatology[59].

Serotonin hypothesis

There are 3 interconnected pathways hypothetically associated with hallucinations and delusions: (1) Dopamine hyperactivity at D_2 dopamine receptors in the mesolimbic pathway, which extends from the VTA to the ventral striatum; (2) NMDA receptor hypoactivity on GABAergic interneurons in the prefrontal cortex; and (3) Serotonin (5-HT) hyperactivity of 5-HT_{2A} receptors on glutamate neurons in the cerebral cortex. All 3 pathways can lead to hyperactivity of the mesolimbic dopamine pathway[54].

According to the serotonin hypothesis[60], the basic cause of schizophrenia is stress-induced serotonergic hyperfunction in the cerebral cortex, especially in the anterior cingulate cortex and the dorsolateral frontal lobe. The serotonin hypothesis assumes hyperfunction of 5-HT_{2A} receptors on glutamate neurons in the cerebral cortex. This overactivation of 5-HT_{2A} receptors may be due to an excess of serotonin, upregulation of 5-HT_{2A} receptors, or the effects of 5-HT_{2A} receptor agonists. Subsequent release of glutamate in the VTA may activate the mesolimbic pathway, resulting in excess dopamine in the ventral striatum[54].

Cannabinoid hypothesis

According to the cannabinoid hypothesis[61-63], changes in the endocannabinoid system may contribute to the pathogenesis of schizophrenia. This hypothesis proposes that increased activation of the endocannabinoid system through CB_1 receptors on GABAergic interneurons in the ventral tegmental area, basolateral amygdala, and medial prefrontal cortex may lead to a hyperdopaminergic and hypoglutamatergic status, which may cause schizophrenia. The hypothesis was supported by evidence that cannabis use in adolescence is an independent risk factor for schizophrenia development (OR: 3.90)[31] and by the confirmation of interactions between the cannabinoid and dopamine systems that may be related to the processes associated with drug addiction or schizophrenia[64].

BLOOD BRAIN BARRIER

The pathophysiology of many central nervous system (CNS) disorders, including schizophrenia, includes altered function of the blood brain barrier (BBB), as shown by evidence from neuroimaging studies, research of both cerebrospinal fluid (CSF) and blood-based biomarkers, and postmortem studies[65]. It remains to be elucidated whether BBB dysfunction is the cause or consequence of schizophrenia pathology[65]. P-glycoprotein is highly expressed in capillary endothelial cells. P-glycoprotein limits the accumulation of psychotropic drugs in the brain and is responsible for the efflux of drugs from the CNS by using the energy from ATP hydrolysis to return the compound to the bloodstream.

According to increasing evidence, malfunction of the BBB and microvascular abnormalities contribute to the pathophysiology of schizophrenia[66]. In a postmortem study, the cellular expression of ABCB1 [the gene encoding P-glycoprotein 1 (P-gp); multidrug resistance protein 1] was examined in patients with schizophrenia. A reduced density of P-gp-expressing neurons was found in the medial habenula of patients with schizophrenia compared to that of controls[66]. Furthermore, polymorphisms of *ABCB1* have been associated with changes in drug disposition and pharmacotherapy response[67].

P-gp is not the only efflux protein; multiple drug resistance (MRP) and breast cancer resistance protein (BCRP) also facilitate the efflux of ATP-dependent substrates. In addition to P-gp, BCRP (ABCG2) and the multidrug resistance proteins MRP1 (ABCC1) and MRP2 (ABCC2) are ATP-dependent efflux transporters present in the BBB[68].

Claudin-5 is a component of tight junctions and is specifically expressed in endothelial cells in the CNS. Polymorphism of claudin-5 has been associated with schizophrenia risk[65], and serum claudin-5 Levels were decreased in patients with schizophrenia[69]. The expression of claudin-5 in the hippocampus was reduced in patients with schizophrenia; the levels of claudin-5 correlated with the duration and age of onset of the disease[70]. The BBB impedes the transfer of many drugs, including antipsychotics, as well as some inflammatory molecules, such as cytokines, which play an important role in the pathophysiology of schizophrenia (see below).

Other explanations of pharmacoresistance in schizophrenia involve abnormal structure of the BBB, downregulation of genes encoding ion transport proteins, impaired immune system, dysfunctional glutamatergic transmission, *etc.*

NEUROINFLAMMATION

Based on the observation that schizophrenia is often associated with chronic neuroinflammation in the CNS[71], the vulnerability-stress model has been expanded into the vulnerability-stress-inflammation model[72], which suggests that the symptoms of schizophrenia are associated with specific changes in dopaminergic, serotonergic, noradrenergic, and glutamatergic neurotransmission following neuroinflammation and microglial activation. The hypothesis is based on the following findings: (1) Stress can increase proinflammatory cytokines and may even contribute to a chronic proinflammatory condition; (2) The typical changes in neurotransmission observed in schizophrenia have also been found in low-level neuroinflammation; (3) Risk factors for schizophrenia include genes whose expression promotes inflammation, environmental stressors, alterations of the immune system, severe infections, and autoimmune disorders; and (4) Antipsychotics also provide anti-inflammatory and immunomodulatory effects.

The vulnerability-stress-inflammation model of schizophrenia suggests that genetic vulnerability and infection during pregnancy may induce a proinflammatory response in the mother, causing deleterious effects on the neurodevelopment of the fetus and increasing the risk of developing schizophrenia. The development of the glutamate system may be disrupted. Re-exposure to stress at a later age may be followed by increased cytokine release, astrocyte activation or loss, dopaminergic hyperactivity, and NMDA antagonism, leading to the positive, negative, and cognitive symptoms of schizophrenia. Immune conditioning and immune sensitization can elicit a repeated response to stress leading to the symptoms of the disease.

Immunologic processes in schizophrenia

Currently, the immune system, immunological processes and inflammation are believed to have a significant role in the neurobiology of schizophrenia[73]. Evidence of immune etiology in schizophrenia comes from GWAS, where a significant association between schizophrenia and the expression of MHC, located on chromosome 6, was observed[16,74].

The relationship between neurotransmitters and mediators of the inflammatory response can be reciprocal; an immunoregulatory function of dopamine has been described. Increased expression of dopamine D_3 receptors and increased synthesis of interferon gamma (IFNγ) in lymphocytes were observed in nonmedicated patients suffering from schizophrenia[75]. An important finding from PET studies of inflammation with elevation of proinflammatory cytokines produced by microglia was an elevated microglial activity in subjects with subclinical symptoms and patients with schizophrenia[64].

Numerous studies have found immune dysregulation in patients with schizophrenia compared to healthy controls, and several meta-analyses have concluded that patients with schizophrenia exhibit signs of low-grade peripheral inflammation characterized by upregulated proinflammatory cytokines and acute phase proteins[76-78]. A recent meta-analysis of postmortem brain studies evaluating histological alterations of cellular composition and those assessing molecular parameters strengthened the immunologic hypothesis of schizophrenia[79]. The authors found significant increases in the density of microglia (especially in the temporal cortex) and

the overall expression of pro-inflammatory genes but no difference in the expression of anti-inflammatory genes in patients with schizophrenia compared to those in controls. However, it is important to note that these immunological alterations have been found only in a subgroup of patients with schizophrenia: approximately 40% of studied patients have exhibited some level of inflammation[80,81]. As schizophrenia is seen as a syndrome consisting of several disease phenotypes with different underlying pathologies, it is crucial to define robust immune biomarkers that would help in the identification of patient groups that might benefit from anti-inflammatory therapy[76, 82]. Cytokines represent a broad category of signaling molecules produced by a wide range of cells, including immune cells such as B and T lymphocytes, macrophages, and mastocytes, as well as endothelial cells and fibroblasts. A meta-analysis of 18 studies found alterations in both proinflammatory and anti-inflammatory cytokines, and these disturbances were stage dependent[83]. In patients with first-episode psychosis, elevated levels of proinflammatory cytokines were found, whereas the level of interleukin (IL)-4 was significantly reduced. In acutely ill patients, increased pro-inflammatory cytokines were observed, and lower levels of IL-4 and IL-10 Levels were found than in controls. In chronically ill patients, augmented levels of IL-1β, sIL-2R, IL-6, and tumor necrosis factor alpha (TNF-α) and reduced IFNγ levels were observed compared to those in controls. Details are summarized in Table 1.

Moreover, a study evaluating the gene expression of cytokines in peripheral blood mononuclear cells reported increased mRNA levels of IL-6, IL-8 and TNF-α and decreased anti-inflammatory IL-2 mRNA[81]. Alterations in these cytokines were also found in CFS[84], and a meta-analysis of 16 studies found significantly higher CSF levels of IL-1β, IL-6 and IL-8 in patients with schizophrenia compared to healthy controls. Interleukins (*e.g.*, IL-1β and IL-6) play important roles in neurotransmitter systems in schizophrenia. A relationship exists between increased concentrations of IL-6 in childhood and a higher risk of subclinical psychotic symptoms in young adulthood. Increased concentrations of IL-6 and other proinflammatory cytokines, such as TNF-α, IL-1β, and IFNγ, are normalized in episodes of remission after antipsychotic treatment. Some studies have suggested an association among increased serum concentrations of cytokines, including IL-6, severity of the disease, and duration and antipsychotic therapy[74].

Alterations in the immune system influence the neurotransmission of dopamine, 5-HT, norepinephrine, and glutamate. The immune system can activate indoleamine 2,3-dioxygenase, an enzyme involved in tryptophan/kynurenine metabolism[73]. Kynurenic acid acts as a naturally occurring NMDA antagonist in the human brain. Increased levels of kynurenic acid were found in the CSF of patients with schizophrenia[85,86]; however, no changes in kynurenic acid levels were observed in the peripheral blood of patients with schizophrenia[73]. Proinflammatory cytokines increase the concentration of kynurenic acid. Approximately 10% of nonmedicated patients in acute episodes of schizophrenia produce NMDA receptor antibodies, and this finding supports the hypothesis of NMDA receptor antagonism in schizophrenia [72,73].

C-reactive protein (CRP) appears to be the most promising theranostic marker for inflammation, and patients with increased CRP might benefit from anti-inflammatory therapy[76,87]. CRP is synthesized in the liver in response to IL-1β, IL-6 and TNF-α and is released from macrophages and adipocytes[76]. CRP has been reported to correlate both with positive and negative symptoms of schizophrenia[88] and with cognitive dysfunction[89]. Recently, "ultraresistance" to treatment in schizophrenia (defined as current clozapine treatment and a mean positive and negative syndrome scale (PANSS) score ≥ 70) was found to be associated with abnormal CRP levels (> 3 g/L), providing further justification for treating ultra-resistant patients with anti-inflammatory agents[90]. Additionally, other acute phase proteins, including haptoglobin, alpha-1 antitrypsin, and alpha-2-macroglobulin, were also found to be elevated in a subgroup of individuals with schizophrenia and other psychoses[91,92].

Additional biomolecules and metabolites essential for inflammation and endothelial cell function (*e.g.*, creatine kinase m/B, angiotensin-converting enzyme, matrix metalloproteinase, thyroid-stimulating hormone, thyroxine-binding globulin, intercellular adhesion molecule 1, cortisol, α-2-macroglobulin, and thrombopoietin) have been found in lower concentrations in drug-naïve patients than in controls[93]. The authors commented that most of these proteins are involved. Additionally, upregulation of leucocyte adhesion molecules was described in psychotic disorders, increased levels of soluble L-selectin were detected in the serum of drug-naïve patients with schizophrenia, and the serum levels of L-selectin and P-selectin in patients with schizophrenia did not differ from those in healthy controls[94]. In another study, P-selectin plasma levels were found to be increased in patients with acute psychosis[95].

Table 1 Possible diagnostic/theranostic immunologic biomarkers in schizophrenia

Parameter	Serum/plasma/peripheral blood	CSF
Pro-inflammatory cytokines	↑ IL-6, IFN-γ, IL-1RA, IL-1β, IL-6, IL-8, IL-12, sIL-2R, TGF-β, and TNF-α	↑ IL-1β, IL-6 and IL-8
Anti-inflammatory cytokines	↓ IL-10 and IL-4	
Acute phase proteins	↑ CRP, haptoglobin, α-1 antitrypsin, and α-2 macroglobulin	
Antibodies	↑ Anti-cardiolipin IgG and anti-NMDA receptor titers	
Immune cells	↑ CD4+, CD3+ and CD56+	
Other biomolecules/metabolites	↓ Creatine kinase m/B, MMP3, ACE, cortisol, TBG, α-2 macroblobulin, thrombopoietin, TSH, and ICAM-1, P-selectin	

ACE: Angiotensin-converting enzyme; CRP: C-reactive protein; CSF: Cerebro-spinal fluid; ICAM: Intercellular adhesion molecule; IFNγ: Interferon gamma; IL: Interleukin; MMP3: Matrix metalloproteinase 3; NMDA: N-methyl-D-aspartate; TBG: Thyroxine-binding globulin; TGF-β: Transforming growth factor-beta; TNF-α: Tumor necrosis factor-alpha; TSH: Thyroid-stimulating hormone.

Certain studies have also found changes in the number of immune cells in patients with schizophrenia compared to healthy controls. A meta-analysis of 16 studies evaluating blood lymphocyte counts found a significant increase in the percentages of CD4+ (T-helper lymphocytes) and CD56+ (natural killer cells) lymphocytes in acutely relapsed inpatients and a significant increase in the absolute numbers of total lymphocytes and CD3+ (T-lymphocytes) and CD4+ cells[96]. However, a significant decrease in the percentage of CD3+ cells was found in drug-naïve patients in the first episode of schizophrenia. Additionally, some autoimmune responses were also found in schizophrenic patients, but their clinical relevance remains elusive. Regarding the pathogenesis of schizophrenia, different autoantibodies, as well as antibodies against diet antigens, *e.g.*, gliadin and casein, were investigated in different parts of the brain, serum, and CSF. A systematic quantitative review of 81 studies found significantly increased anti-cardiolipin IgG and anti-NMDA receptor autoantibody titers in patients in the first episode of schizophrenia[97]. The authors also reported increased titers of anti-cardiolipin IgG and IgM and nerve growth factor in patients with schizophrenia compared with controls.

As mentioned, there is a strong link between oxidative stress and the immune system; therefore, by counteracting oxidative stress, antioxidants reduce inflammation and the overactive immune response. Glutathione is an antioxidant that is essential in the myelinization and maturation of white matter and can be supplemented as the amino acid precursor N-acetyl cysteine. N-acetyl cysteine possesses antioxidant properties and mild anti-inflammatory effects and regulates synaptic NMDA receptors. NAC supplementation for 6 mo ameliorated positive symptoms and improved neurocognition (processing speed) in patients with schizophrenia with high peripheral oxidative stress[98]. Omega-3-type polyunsaturated fatty acids have also exerted antioxidative capacity and anti-inflammatory effects[99].

Non-steroidal anti-inflammatory drugs in pharmacotherapy

Anti-inflammatory agents have shown some benefits as adds-ons to antipsychotic treatment in schizophrenia, as reported by two recent meta-analyses[100,101]. A meta-analysis of 62 double-blind randomized clinical trials studying aspirin, celecoxib, omega-3 fatty acids, estrogens, pregnenolone, minocycline, N-acetyl cysteine, and erythropoietin in 2914 patients found an overall significant effect of a decrease in the PANSS score[100]. Additionally, cognitive improvement was significantly associated with minocycline and pregnenolone therapy. Another meta-analysis of 70 randomized clinical trials including 4104 subjects investigated either primarily non-steroidal anti-inflammatory drugs (NSAIDs), minocycline and monoclonal antibodies, or drugs with potential anti-inflammatory properties (N-acetyl cysteine, melatonin, neurosteroids, estrogens, fatty acids, statins, and glitazones) as adjunctive therapies to antipsychotics. The analysis also found a decrease in the PANSS score[101]. Small but significant effect sizes were observed on both negative and positive symptoms, general psychopathology and working memory. Interestingly, primarily anti-inflammatory drugs were not found to be superior to potential anti-inflammatory drugs. However, the authors highlighted that the reported effects might be overestimated due to the many small study samples included in the analysis.

In conclusion, changes in the frequencies of immune cells, the levels and expression of cytokines, and the levels of acute phase proteins in the blood and CSF were observed in patients with schizophrenia compared to healthy controls, and CRP seems to be a promising theranostic biomarker for schizophrenia. Moreover, larger studies with longer treatment durations and the inclusion of only schizophrenic patients with proven inflammation (CRP levels > 3 g/L) are warranted to elucidate the efficacy of anti-inflammatory treatment in schizophrenia.

The challenges of drug development include the development of novel molecules affecting the immune system and of immunotherapy using autoantibodies as well as the stratification of patients with schizophrenia according to their immune phenotypes to enable the selection of effective pharmacotherapeutic agents[74].

MICROBIOME-BRAIN AXIS MODEL

The microbiome-gut-brain axis model postulates that bidirectional communication between the central and enteric nervous systems ensures the connection of the brain with peripheral intestinal functions[102,103]. It is presumed that the gut microbiome can program brain function during early development; in other words, active signals from the microbiome play a critical role in brain development. It is thought that the microbiome may affect brain development through epigenetic mechanisms[104]. Signal pathways from the gut microbiome to the brain include: (1) The direct activation of the vagus nerve; (2) The production or induction of various metabolites that may cross the BBB to regulate neurological functions; and (3) An immune system whose cytokines affect neurophysiology[105].

Probiotics modulate the immune responses of the host and could be beneficial for schizophrenia patients[106]. The immunomodulatory effects of probiotic supplementation were examined after 14 wk in chronic patients with schizophrenia, and *Lactobacillus* and *Bifidobacterium* were administered as adjuvant treatments. Increased levels of brain-derived neurotrophic factor, chemokine ligand 5 (RANTES), monocyte chemotactic protein and macrophage inflammatory protein-1 beta were found[106]. Gut-brain communication suggests the direct secretion of some neuroactive substances, and some intestinal bacteria can produce mediators, *e.g.*, GABA, acetylcholine.

INNOVATIVE DRUG APPROACHES AND TARGETS

All antipsychotics for schizophrenia treatment are based on dopamine agonism/antagonism, and no nondopaminergic antipsychotics have yet been developed or approved (Figure 1). Lumateperone is characterized as a partial D_2 receptor agonist/antagonist and a 5-HT_{2A} antagonist, and it is a serotonin reuptake inhibitor that indirectly modulates glutamatergic transmission (effect on NMDA receptor subtype 2B, NR2B)[107,108]. It has no metabolic or extrapyramidal adverse effects and positively affects cognition[109]. Another study found that lumateperone was well tolerated with minimal extrapyramidal and cardiometabolic adverse effects and maintained or reduced the symptoms of schizophrenia after a switch from a previous antipsychotic[110].

A promising therapeutic drug strategy for schizophrenia is the use of antipsychotics without D_2 receptor binding[111]. Agonists of trace amine-associated receptor 1 (TAAR1) seem to selectively affect dopamine and may represent a new class of psychotropic drugs[112,113]. A novel compound, SEP-363856, was described as a TAAR1 and 5-TH_{1A} agonist and was tested in a pilot trial with 120 patients with an acute exacerbation of schizophrenia. The reduction in the PANSS score of the treatment group was significant compared with that of the placebo group; longer and larger trials are necessary to prove the efficacy and safety of this TAAR1 agonist[113]. Other TAAR1 agonists, *e.g.*, RO5263397, have been developed and are being tested for use in schizophrenia. RO5263397 was found to be safe, but a great variety in metabolism and plasma levels was found that depended on ethnicity and genotype [112,114].

Novel drugs indirectly targeting glutamate neurotransmission are among the strategies being pursued for antipsychotic development. Inhibitors of glycine transporters (*e.g.*, sarcosine and bitopertin), coadministration of NMDA agonists, allosteric modulators of AMPA receptors (ampakines), and allosteric modulators of $mGluR_5$ are being tested; novel drugs affecting the glutamate ionotropic and meta-

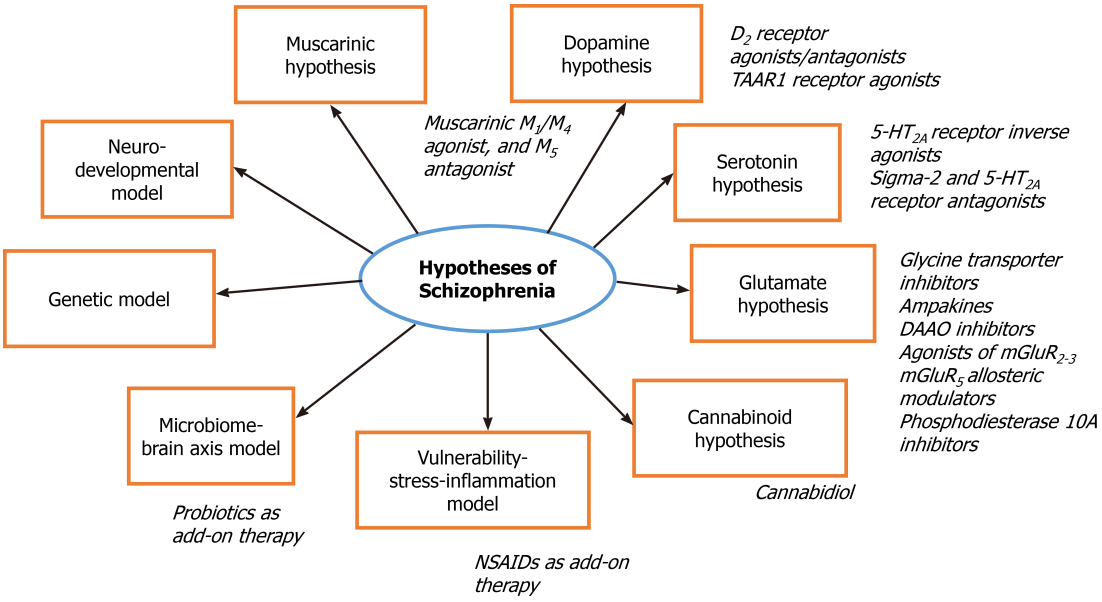

Figure 1 Illustration of current hypotheses and novel approaches in treatment of schizophrenia. DAAO: D-Amino acid oxidase; TAAR1: Trace amine-associated receptor 1; NSAIDs: Non-steroidal anti-inflammatory drugs.

botropic receptors $mGluR_{2-3}$ have been developed[115].

Agonists of $mGluR_{2-3}$ have anxiolytic properties and reverse the effects of stress; agonists of the $mGluR_3$ receptor antagonize the effect of phencyclidine and amphetamine. Novel drugs directly affecting receptors were found to be ineffective and/or to have adverse effects. Pomaglumetad methionil is an $mGluR_{2-3}$ agonist[58]. It was tested as an adjunctive therapy for patients with negative symptoms of schizophrenia, and the study did not find a difference between the pomaglumetad group and the placebo group[116]. Post hoc analyses suggested the efficacy of pomaglumetad in patients suffering from schizophrenia for less than or equal to 3 years or in patients previously treated with antipsychotics predominantly acting as D_2 antagonists [117,118]. Thus, the potential of novel $mGluR_{2-3}$ agonists is suggested for treating psychosis and aggression/agitation associated with neurodegenerative diseases (Parkinson's disease, Alzheimer's disease, dementia with Lewy bodies, *etc.*)[117].

D-Amino acid oxidase (DAAO) inhibitors were found to modulate NMDA transmission. Sodium benzoate, a DAAO inhibitor, has been tested as an add-on therapy and improved symptoms in clozapine-resistant patients[119]. In another study, sodium benzoate was administered to patients with schizophrenia as an add-on therapy compared to placebo. The adjunctive therapy was well tolerated, and chronic schizophrenia patients showed improved function, especially neurocognition[120].

Cannabidiol seems to be a promising candidate for the treatment of schizophrenia. Increased function of the endocannabinoid system was observed in schizophrenic patients; cannabidiol was found to decrease mesolimbic dopaminergic activity. There is evidence that chronic and acute administration of cannabidiol led to improvement of schizophrenia symptomatology[121].

Based on the serotonin hypothesis, pimavanserin was developed and characterized as an inverse agonist at 5-HT_{2A} receptors, and it has binding affinity for sigma-1 receptors. This antipsychotic has been FDA-approved for the treatment of psychosis associated with Parkinson's disease. Further randomized controlled trials are needed to consider pimavanserin as a drug for schizophrenia treatment[122].

Antagonism at sigma-2 receptors was described for roluperidone, which was developed as a novel antipsychotic affecting 5-HT_{2A} receptors and sigma-2 receptors [58]. Roluperidone has been found to be effective in the treatment of negative symptoms[123].

Xanomeline is a muscarinic M_1/M_4 agonist and M_5 antagonist that was originally developed for Alzheimer´s disease. Currently, it is being tested in combination with trospium, which reduces peripheral adverse effects (nausea and vomiting), as a new antipsychotic with a novel mechanism of action.

Phosphodiesterase inhibitors have been investigated as drugs to enhance cognition in schizophrenia[124]. Phosphodiesterase 10A inhibitors likely modulate D_1 (directly) and D_2 (indirectly) striatal pathways and regulate glutamate receptors[112]. TAK-063, a

phosphodiesterase 10A inhibitor, was tested, but the clinical trial did not meet the primary endpoint, and extrapyramidal syndromes occurred more often in the TAK-063 group than in the placebo group[125].

CONCLUSION

Genetic predisposition and neurodevelopmental and environmental risk factors for schizophrenia were summarized. Nevertheless, the understanding of schizophrenia pathophysiology is limited, and current pharmacotherapy is complicated by adverse effects, pharmacoresistance, and low compliance of patients. Novel targets and approaches of antipsychotic treatment are being developed with the aim of covering the wide range of schizophrenia symptoms, especially negative symptomatology, cognitive impairment, and residual and treatment-resistant symptoms. Novel drug targets based on current schizophrenia hypotheses include molecules indirectly targeting glutamate neurotransmission, DAAO inhibitors, 5-HT_{2A} receptor inverse agonists, sigma-2 receptor antagonists, phosphodiesterase inhibitors, *etc*. In pharmacoresistant patients, possible comorbidities may be related to inflammation or a disrupted microbiome-gut-brain axis, and augmentation of antipsychotic treatment *via* NSAID or probiotic administration can be considered. Further research on schizophrenia pathophysiology, genetic predisposition (based on GWAS), regulatory mechanisms in impaired mediator transmission and other factors is needed to improve the clinical outcomes of pharmacotherapy.

Abstract

The versatility of glutamate as the brain's foremost excitatory neurotransmitter and modulator of neurotransmission and function is considered common knowledge. Years of research have continued to uncover glutamate's effects and roles in several neurological and neuropsychiatric disorders, including depression. It had been considered that a deeper understanding of the roles of glutamate in depression might open a new door to understanding the pathological basis of the disorder, improve the approach to patient management, and lead to the development of newer drugs that may benefit more patients. This review examines our current understanding of the roles of endogenous and exogenous sources of glutamate and the glutamatergic system in the aetiology, progression and management of depression. It also examines the relationships that link the gut-brain axis, glutamate and depression; as it emphasizes how the gut-brain axis could impact depression pathogenesis and management *via* changes in glutamate homeostasis. Finally, we consider what the likely future of glutamate-based therapies and glutamate-based therapeutic manipulations in depression are, and if with them, we are now on the final chapter of understanding the neurochemical milieu of depressive disorders.

Core Tip: The versatility of glutamate as the brain's foremost excitatory neurotransmitter, and modulator of intermediary metabolism in the gastrointestinal tract is considered common knowledge. Years of research suggest glutamate has a role to play in depression. Also, there is increasing evidence of a possible relationship between glutamate and the pathophysiology and/or treatment of depression. The complexity of depression suggests dysregulation of glutamate in sites such as the gastrointestinal tract and brain. The communication link involving dietary glutamate, the gut, endogenous glutamate, and the brain is a multidirectional pathway; the understanding of which is necessary to fully account for glutamate's role in depression.

INTRODUCTION

Clinical depression or major depressive disorder (MDD) is a chronic, debilitating, and disabling mental health disorder that affects over 300 million people (across all age groups) globally[1-4]. It contributes significantly to the global burden of disease and escalating incidence of suicides amongst teenagers and young adults worldwide. Globally, the prevalence of depression continues to increase[4,5]; with factors such as worsening poverty, increasing unemployment, adverse life events and genetics[4] being recognized as important risk factors for its development.

The discovery of monoamine oxidase inhibitors and tricyclic antidepressants opened opportunities for the treatment of depression and provided insights into the role of neurotransmitters such as dopamine, serotonin and norepinephrine in the pathophysiology of depression[6,7]. However, the shortcomings of the currently-approved pharmacotherapies such as the lag time between the effect of drugs on monoamine availability and their therapeutic effect, inadequate response, and the increasing incidence of treatment-resistant depression[7-9] means that there is still a critical need to better understand the pathophysiology of depression; and develop more-effective and efficient therapeutic interventions for depressive disorders.

The monoamine hypothesis supports the notion that the pathology in depression is primarily depletion in the levels of brain monoamine neurotransmitters including serotonin, norepinephrine, and dopamine[10-12]. In the almost seven decades since its formulation, it has largely explained the symptoms and response to currently available antidepressant therapy. However, inconsistencies in the hypothesis have resulted in further research to better understand depression pathophysiology and management. In the last three decades, there has been compelling clinical[13,14] and preclinical[15,16] evidence demonstrating the involvement of the glutamatergic system in the pathophysiology of depression.

Since the first mention of the glutamate hypothesis of depression in the 1990s[15], our understanding of the versatility of glutamate as the brain's foremost excitatory neurotransmitter, and modulator of neurotransmission and function has increased considerably. Years of research have continued to uncover glutamate's effects and roles in several neurological and neuropsychiatric disorders, including depression. More recently, the antidepressant actions of ketamine, an N-methyl-D-aspartate (NMDA) glutamate receptor antagonist especially in treatment-resistant depression [17,18] was reported; suggesting a deeper understanding of the roles of glutamate in depression could open new doors to understanding the pathological basis of the disorder, improve the approach to patient management, and lead to the development of newer drugs that may benefit more patients. Also, the roles of the gut-brain axis in glutamate signalling have been investigated, with reports that these could also impact the pathophysiology and treatment options in depression[19,20]. This review examines current understanding of the roles of endogenous and exogenous sources of glutamate and the glutamatergic system in the aetiology, progression and management of depression. It also examines the relationships that link the gut-brain axis, depression and glutamate (Figure 1); as it emphasizes how the gut-brain axis could impact

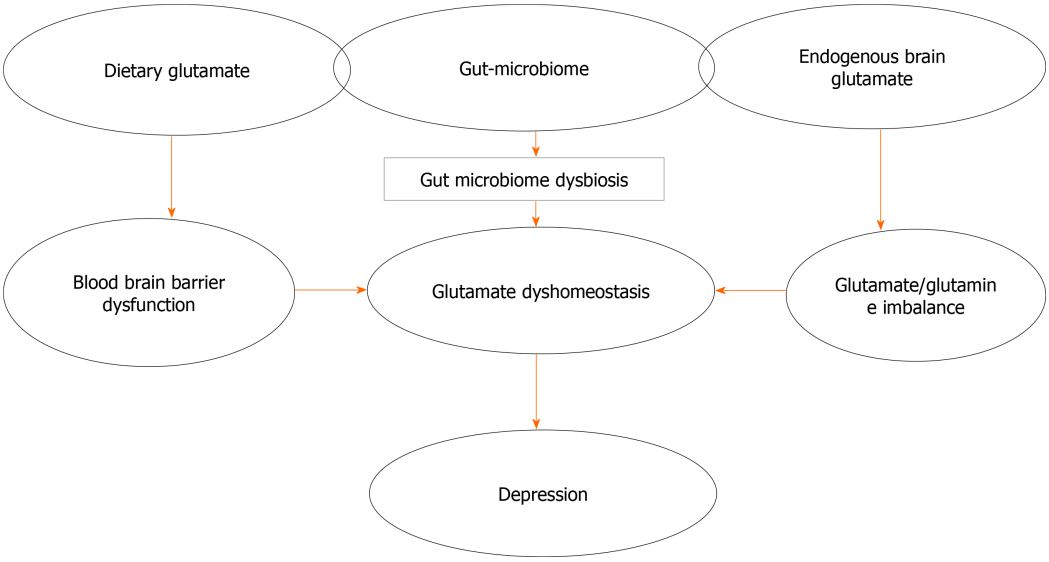

Figure 1 Possible relationships that link dietary glutamate, the gut-brain axis, endogenous glutamate and depression.

depression pathogenesis and management *via* changes in glutamate homeostasis. Finally, we consider what the likely future of glutamate-based therapies and glutamate-based therapeutic manipulations in depression are, and if with them, we are now on the final chapter of understanding the neurochemical milieu of depressive disorder.

GLUTAMATE AND DEPRESSION

Glutamate is an amino acid and the major excitatory neurotransmitter in the brain[21]. In the last few decades, there has been increasing insights into the roles played by the glutamatergic system (Figure 1) in the pathophysiology and treatment of mood disorders generally, and depressive disorders specifically[12,22,23]. Although glutamate is ubiquitous in the brain, excessive release of glutamate has been associated with excitotoxicity-induced brain injury[24]. The possible involvement of the glutamatergic system in mood disorders is supported by preclinical evidence of the antidepressant effects of NMDA antagonists[15,25]. Also, the results of early studies showing alterations in the levels of glutamate (peripherally and centrally) in persons with mood disorders confirmed this involvement[13,26]. Alterations in excitatory and/or inhibitory neurotransmitters resulting in the alteration of functional connectivity patterns within large brain networks have also been reported[27]. More recently, there is overwhelming evidence of the anxiolytic and antidepressant response to subanaesthetic-doses of ketamine in clinical[27-30] and preclinical studies[31,32].

The ability of diet to cause depression and depression-like phenotypes has been reported[33,34]. Research has continued to show that the consumption of diets rich in fat, deficient in magnesium, or high in monosodium glutamate can cause depression-like behaviours such as decreased social interaction, anhedonia and behavioural despair in rodents[35-37]. While there have been suggestions that these effects are linked to the ability of dietary factors to alter the composition of the gut microbiota[36,37], emerging evidence of the interactions between the gut microbiota and brain neurotransmitters such as dopamine, serotonin, gamma amino-butyric acid and glutamate[9,38] are opening new vistas into possible novel treatment modalities for depression.

Dietary glutamate and depression

Glutamate is an α-amino acid that is useful in the biosynthesis of proteins and important in intermediary metabolism, through its ability to link carbohydrate and amino acid metabolism *via* the tricarboxylic acid cycle[39,40]. Glutamate (in addition to being synthesized in the body in humans) is also derived from dietary sources such as cheese, meat, and several food-seasonings including monosodium glutamate[21,41].

While endogenous brain glutamate has been linked to the pathophysiology of psychiatric conditions such as schizophrenia and mood disorders, the possible role of dietary glutamate (Table 1) in the development of neuropsychiatric conditions is still being evaluated[42]. There have been suggestions that the consumption of diets containing high concentrations of monosodium glutamate could increase body levels of glutamic acid, resulting in hyperglutamatergic neurotransmission, which could possibly contribute to the development of depression[43]. Also, a few studies have reported that factors such as chronic stress that reduce brain levels of glutamate and glutamine causing hypoactive glutamatergic signaling in the mouse prefrontal cortex are also associated with the development of depression[44], suggesting that regarding brain glutamatergic transmission a delicate balance always needs to be maintained.

In the last few years, reports from preclinical studies have associated the use of monosodium glutamate with the development of behavioural phenotypes such as anxiety and depression; and the ability to influence brain endogenous glutamate and glutamatergic neurotransmission[35,42,44-46]. There have also been reports from studies that monosodium glutamate could directly influence the concentrations of brain neurotransmitters such as serotonin and glutamate[21,35,45,47], although there have also been reports to the contrary[48].

The relationship between dietary monosodium glutamate and depression has been examined by a few studies[35,43,47]. The results of a clinical analysis that examined the relationship between the consumption of a diet high in glutamic acid and the development of depressive symptoms in a group of persons with schizophrenia revealed that in non-obese patients the consumption of high dietary glutamic acid was associated with an increase in depressive symptoms, although this was linked to the susceptibility of persons with one psychiatric condition to develop other co-morbidities[42]. A preclinical study by Quines *et al*[35] that examined the effects of monosodium glutamate administered parenterally in the neonatal period with exposure to behavioural paradigms on postnatal days 60-64 reported the presence of anxiety and behavioural despair. However, studies from our laboratory revealed that while orally administered monosodium glutamate was associated with the development of anxiety behaviour, especially in male mice[21,45,49], an antidepressant effect was observed in the behavioural-despair paradigms irrespective of sex [47]. The results of these studies from our laboratory suggest that the antidepressant response observed when monosodium glutamate was administered by gavage (compared to the response following parenteral administration) could have been influenced by the gut microbiota or the gut-brain axis, or by the ability of monosodium glutamate (at these doses) to minimally increase brain levels of glutamate which could have antidepressant benefits as previously reported[44].

Endogenous brain glutamate and depression

Glutamate plays an important role in the modulation of synaptic plasticity and transmission. It is also the precursor of the inhibitory neurotransmitter gamma amino-butyric acid (GABA). Studies have shown that dysregulation of glutamatergic transmission or alterations in brain concentrations of glutamate is associated with derangement of brain function, development of excitotoxic brain injury, and cell death [24,47]. There have also been reports showing that alterations in glutamatergic neurotransmission contribute significantly to the development of peripheral and central nervous system disorders[50]. In the last few years, the possible relationships that exist between glutamate/glutamatergic system and the development of neuropsychiatric disorders such as depression have continued to be examined[22,24,51].

Several studies have linked dysregulation of glutamate neurotransmission with the development and progression of neurodevelopmental, neurodegenerative and psychiatric disorders such as autism, epilepsy and schizophrenia[52,53]. There is also emerging evidence (Table 2) linking the pathogenesis of depression to alterations in glutamate and glutamate signalling[12,52]. Levine *et al*[54], using a proton magnetic resonance spectroscopy (MRS) technique examined the relationship between cerebrospinal fluid (CSF) metabolites, such as glutamate and glutamine on depressive symptoms in hospitalized persons with severe unmedicated depression, and reported that compared to control subjects, glutamine level in the CSF of depressed patients was elevated. Also, using high performance liquid chromatography with fluorometric detection, Mitani *et al*[55] examined the relationship between plasma levels of glutamate on severity of depression and concluded that plasma levels of glutamate as well as alanine and L-serine were reflective of the severity of depression. The impact of brain glutamate levels on depression and depression phenotypes have been studied extensively[56-60]. Auer *et al*[56] and Hasler *et al*[57] using MRS reported region-specific changes in the levels of brain glutamate in patients with depression. The result

Table 1 Dietary glutamate and depression

Subject	Outcome	Ref.
Human	In non-obese participants, diets high in levels of glutamic acid were associated with greater depression symptomatology	Kumar *et al* [43]
Adult mice	While chronic immobilization stress decreased sodium-coupled neutral amino acid transporter (SNAT)-1 and 2 in neurons and glutamate transporter (GLT)1, SNAT3, and SNAT5 in astrocytes in the medial prefrontal cortex, glutamine—supplemented diet ameliorated these decrements	Baek *et al*[44]
Neonatal rats	Subcutaneous injection of monosodium glutamate (MSG) increased the immobility time in the forced swim test and the freezing reaction in the contextual fear conditioning. MSG also increased serotonin uptake in the cerebral cortices and caused deregulation of the hypothalamic-pituitary-adrenal axis	Quines *et al* [35]
Mice	Anxiolytic and memory-enhancing effects at low doses of MSG; however, at higher doses, anxiety and memory retardation were observed	Onaolapo *et al* [45]
Mice	Higher doses of dietary glutamate resulted in an increase in plasma glutamate and glutamine but no difference in total brain glutamate or glutamine levels	Onaolapo *et al* [21,45,46]
Mice	Anxiolytic response in females, and anxiogenic response in males following dietary MSG. A decrease in behavioural despair was observed in both sexes (females more than males)	Onaolapo *et al* [46,47]
Mice	Anxiogenic effect was observed following subchronic oral administration of MSG	Onaolapo *et al* [49]

Table 2 Endogenous glutamate and depression

Subject	Method	Outcome	Ref.
Human	Using a proton magnetic resonance spectroscopy technique	Compared to control subjects, glutamine levels in the cerebrospinal fluid of the depressed patients were elevated	Levine *et al* [54]
Human	High performance liquid chromatography with fluorometric detection	Plasma levels of glutamate as well as alanine and L-serine were reflective of the severity of depression	Mitani *et al* [55]
Human	Single voxel (1)H-Magnetic resonance spectroscopy in 19 patients with major depressive episodes	A significant decrease was observed in the levels of glutamate and glutamine in the anterior cingulate	Auer *et al*[56]
Human	Magnetic resonance spectroscopy	Depressed patients had reduced glutamine and glutamate levels in the dorsomedial/dorsal anterolateral prefrontal cortex	Hasler *et al* [57]
Human	Magnetic resonance spectroscopy	Compared with controls, depressed patients showed an increase in glutamine levels	Godlewska *et al*[59]
Human	Meta-analysis	Decreased levels of glutamatergic metabolites were observed in the medial frontal cortex of depressed subjects	Moriguchi *et al*[60]
Human	Meta-analysis	Glutamate and glutamine concentrations were found to be lower in the anterior cingulate cortex in patients compared to controls	Luykx *et al* [58]
Human	Functional magnetic resonance imaging and magnetic resonance spectroscopy	Patients with anhedonic major depression showed decreased glutamine but normal glutamate and gamma-aminobutyric acid concentrations	Walter *et al* [61]
Human	Resting state functional magnetic resonance imaging	Decreased amplitude of low frequency fluctuation level in right putamen and right middle temporal cortex correlated positively with glutamate concentration in female patients with depression	Zhang *et al* [66]
Mice	Preclinical study	Blockade of glutamate transporter-1 in the central amygdala and prefrontal cortex induced both anhedonia and anxiety	John *et al*[62,63]

of a recent meta-analysis of MRS studies also supported the hypothesis that glutamatergic neurotransmission was involved in the pathophysiology of depression[60]. In another meta-analysis, Luykx *et al*[58] also reported region and state specific alterations in glutamate and glutamine concentrations in depression. The importance of glutamatergic neurotransmission in depression has been further supported by studies that showed altered glutamine concentrations despite normal glutamate levels [59,61].

Abnormalities of the glutamatergic system such as those associated with glutamate clearance at the synaptic cleft and glutamate-related alterations in astrocytic energy modulation have also been observed in depression[61,62]. The results of preclinical studies have also demonstrated that blockade of astrocytic glutamate uptake in the prefrontal cortex and central nucleus of the amygdala was associated with the development of anhedonia and anxiety[62,63]. Furthermore, results from post-mortem

and magnetic resonance imaging studies have also revealed the presence of altered expression of glutamate-related genes, elevated levels of glutamate, reduced glutamine/glutamate ratio, and/or reduced levels of glutathione (a reservoir of neuronal glutamate) in brain regions such as the medial prefrontal cortex (which have been linked to depression symptomatology) in persons with depression[64-67].

Finally, the rapid antidepressant effects of drugs such as tianeptine and NMDA receptor antagonist ketamine further validate the importance of glutamate and the glutamatergic transmission in depression[22,68,69]. While reports provide some evidence for the involvement of endogenous glutamate in the pathogenesis and treatment of depression[22,50,69,70], the complexity of the disorder would suggest that the dysregulation of glutamate needs to occur in multiple sites (Figure 1) such as the gastrointestinal tract and brain, as can be seen if there is a communication link involving exogenous glutamate, the gut, endogenous glutamate, and then the brain in a multidirectional pathway which we would call the "GLUTAMATE-GUT-GLUTAMATE-BRAIN AXIS".

The gut-brain axis and glutamate

The impact of the gut (microbiota and gut peptides) in times past was not considered significant in brain development and functioning. Previously, it was believed that the commensal bacteria and their genes which constitute the gut microbiome enjoy a symbiotic relationship with man. In this relationship, they reside in a nutritionally enriched and protected habitat of the human gastrointestinal tract, while they in turn protect humans against colonization of the gut by pathogenic bacteria and provide the body with a rich source of indigestible nutrients. In the light of new evidence, it is now clear that they also play a key role in the brain, either in health or disease.

The gut-brain axis or microbiome-gut-brain axis describes the bidirectional, at times multidimensional system of communication that links the gastrointestinal tract with the central nervous system. It ensures that not only does the central nervous system modulate gastrointestinal function; the gut can also regulate or modulate brain signalling and impact brain structure and function[19]. There is now ample evidence supporting the view that the microbiome-gut-brain axis can influence the development or progression of central nervous system disorders. Some of these include observations of psychiatric co-morbidities occurring in several enteric neuropathies such as chronic inflammatory intestinal disorders[38,71,72]. The presence of altered gut microbial flora and concentration in neurodevelopmental disorders such as autism[73,74] as well as the results of microbial challenge using pathogenic bacteria or pharmacological manipulations with pre or probiotics, are also pointers to the possible roles played by the gut microbiota in the development of brain disorders[72,75]. Further reports have also shown that the gut microbiota influences brain function *via* its ability to modulate endocrine, immunologic and neurocrine signalling pathways; and brain neurotransmitters[38,76].

Also, several possible mechanisms through which microbiome-gut-brain communication could impact the genesis or progression of central nervous system disorders have been proposed. There have been suggestions that communications occur through the activation of neurotransmitters such as serotonin, dopamine, GABA and noradrenaline in the enteric nervous system; these neurotransmitters are secreted by gut microbiota and are akin to the neurotransmitters in the central nervous system [76]. The possible role of gut peptides and metabolites as mediators of the gut-brain crosstalk have also been suggested[77].

Gut-brain axis and depression

Studies have continued to demonstrate the deleterious effects that alterations in gut microbiome composition and microbiome-related metabolites could exert on the development of obesity, autoimmune disorders, inflammatory bowel disease, irritable bowel syndrome, and neuropsychiatric disorders[77-80]. Also, scientific information showing how gut microbes and gut stimuli (such as intragastric infusion of glucose or fatty acid) can directly influence emotional and cognitive functions[81,82] are pointers to the possible involvement of the gut-brain axis in psychiatric disorders. Several preclinical studies have also shown that the gut microbiota modulates brain behaviours such as behavioural despair, anhedonia and anxiety-like behaviours that have construct validity with clinical depression and anxiety[83-86]. Arentsen *et al*[84] and Kamimura *et al*[86] showed that compared to specific pathogen-free (SPF) mice, germ-free (GF) mice showed impaired social interactions choosing to spend more time with an object than conventionally raised mice. Huo *et al*[85] also observed that the exposure of GF mice and SPF mice to chronic restraint stress paradigm was associated with an increase in open field exploration time in GF compared to the SPF mice; with

SPF mice exhibiting more anxiety-like behaviours compared to GF mice. Chronic prebiotic administration has also been shown to exhibit anxiolytic and antidepressant behaviours in mice. The ability of the prebiotic to modulate behaviour correlated positively with its effects on hippocampal and hypothalamic gene expression and its ability to ensure a balance in the concentrations of short-chain fatty acids[87].

Although the mechanisms by which the gut microbiota influences mood and mood-related behaviours are still being studied; there have been suggestions that because the gut and brain share peptide and receptor similarities the gut microbiome is able to modulate brain function through the activity of gut peptides[77]. Also, studies evaluating the impact of gut microbiome modulation (using prebiotics and probiotics) on brain function have demonstrated that chronic treatment with prebiotic had both antidepressant and anxiolytic effects, which could be linked to reduction in stress-induced corticosterone and proinflammatory cytokine release, and modification of the expression of specific genes in the hippocampus[86,87]. Also, probiotics such as GABA-producing *Lactococcus lactis* strain have been shown to possess the capacity to modulate behaviours. In one study, in which *Lactococcus lactis* was grown in both glutamate and non-glutamate supplemented media, a significant increase in GABA production was observed in the glutamate supplemented medium[87], reinforcing the importance of glutamate in the modulation of mood and mood disorders.

There is now ample evidence suggesting that microbes play the role of signalling components in the gut-brain axis. This emerging concept of a microbiota-gut-brain axis suggests that our ability to modulate the gut microbiota may be a potential tool towards the development of novel therapies for complex brain disorders such as psychiatric disorders[19,71,72] (Table 3).

Is there a dietary glutamate-gut-endogenous glutamate-brain axis and how can it impact depression pathogenesis?

Glutamate is a multifunctional amino acid that is involved in intermediary metabolism in the gastrointestinal tract and is also crucial for the normal functioning and development of the brain. In the gut, it is derived from exogenous sources including dietary proteins and from free glutamate present in food additives; also, a fraction of the free glutamate in the lumen is from bacterial synthesis[88]. In the central and enteric nervous systems, respectively, glutamate is the major excitatory neurotransmitter[50,89].

Glutamate and the glutamatergic pathways are also crucial to microbiota-gut-brain communication. There is increasing evidence that glutamate is both a neurotransmitter and neuromodulator of several functions[77,89]. Glutamate receptors and their transduction molecules have been demonstrated on the epithelial cells of the gut, splanchnic, vagal, and/or pelvic afferents[89-91]. The stimulation of gut glutamate receptors by dietary or luminal glutamate has been associated with the activation of vagal afferents which directly or indirectly influence brain areas such as the cerebral cortex, limbic system, hypothalamus and basal ganglia[90,92]. Also, the activation of glutamate receptors present on splanchnic, vagal, and/or pelvic afferents, allows the communication of sensory inputs to regions of the brain involved in the gut-brain axis, while, also influencing efferent pathways that convey excitatory or inhibitory inputs to the gastrointestinal tract[89,91].

While in health, the enteric ganglia and the brain are impermeable to dietary or luminal glutamate; there have been reports suggesting that glutamate permeability in these systems increases in diseased states such as enteric neuropathies, or conditions that alter the integrity of the blood-brain-barrier. The gut microbiome also influences brain glutamate, with the results of metabolomic studies revealing that alterations in the composition of the gut saprophytic microflora also affected brain concentrations of glutamate[93,94]. Although there is enough scientific evidence in support of the impact of central glutamate and the glutamatergic system in depression, there is however a dearth of information regarding the possible ways luminal glutamate (either from dietary sources or microbial activities) may influence depression pathophysiology.

However, from the foregoing, it is evident that while exogenous glutamate (from dietary sources or secreted by gut microbiota) can influence brain function through activation of the gut glutamatergic pathways, endogenous glutamate can be influenced by gut microbial composition or metabolites to impact brain function. This shows that glutamate may be more important in the bidirectional communication system of the microbiome-gut-brain axis than previously considered.

Table 3 Gut brain axis and depression

Subject	Outcome	Ref.
Germ-free mice	Germ-free (GF) mice showed impaired social interactions, anxiety and derangement of brain-derived neurotrophic factor levels	Crumeyrolle-Arias *et al*[83], Huo *et al*[85], and Kamimura *et al*[86]
GF and SPF mice	Exposure of GF mice and specific pathogen-free (SPF) mice to chronic restraint stress paradigm revealed an increase in open field exploration time in GF compared to SPF mice. Also, SPF mice exhibited more anxiety-like behavior than GF mice under the same external stress	Arentsen *et al*[84]
C57BL/6J male mice	Chronic administration of prebiotic (fructo-oligosaccharides and galacto-oligosaccharides) have been associated with antidepressant and anxiolytic effects	Kamimura *et al*[86]
Glutamate and non-glutamate supplemented media	Gamma amino-butyric acid (GABA)-producing *Lactococcus lactis* strain increased GABA production in the glutamate supplemented medium	Burokas *et al*[87]

GLUTAMATE AND DEPRESSION MANAGEMENT

In the preceding sections, the possible crucial roles that glutamate and glutamatergic neurotransmission play in the pathogenesis of mood disorders were discussed. The results of studies demonstrating the impact of glutamate dyshomeostasis and an imbalance between glutamatergic neurotransmission and synaptic plasticity on mood disorders have been pivotal in the search for novel pharmacotherapeutic strategies [51]. Also, evidence from studies demonstrating the possible antidepressant-like effects of agents acting at the glutamate receptors including NMDA receptors, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and metabotropic glutamate (mGlu) receptors are all pointers to the possible roles of glutamate and glutamate receptors in depression management.

GLUTAMATE-BASED THERAPIES IN DEPRESSION

For more than six decades, drugs that modulate biogenic amines, increasing their availability at the synaptic cleft by selectively blocking the uptake of serotonin and/or norepinephrine have been used in the management of depression. While the safety profile of the newer biogenic amine drugs has improved considerably (compared to the older monoamine oxidase inhibitors and tricyclic antidepressants), they do not address the major drawbacks that have been associated with this mechanism[95-97].

Delayed therapeutic onset, low remission rates, and increased treatment refractoriness are among the major limitations or drawbacks of the standard pharmacological agents for depression treatment[95,96]. Again, up to a third of patients are diagnosed with the treatment-resistant phenotype, adding significantly to the global burden of depression[98]. These limitations are evidence of therapeutics that were still based on an incomplete understanding of disease pathogenesis.

Evidence of ketamine's quick and relatively sustained antidepressant, anti-suicidal, and anti-anhedonic effects in treatment-resistant depression has been documented; and it represents a turning point in our understanding of the possibly crucial role that the glutamatergic system plays in depression. Such findings also prompted further research into developing novel glutamate-based therapeutic targets with better antidepressant effects and without dissociative side-effects, meaning an improvement over ketamine. The results of animal studies evaluating immobility in the forced swim test and tail suspension tests highlighted that both competitive and non-competitive NMDA receptor antagonists had antidepressant-like effects[15]. Decades later, these findings eventually culminated in the approval of esketamine (Spravato®) by the US Food and Drug Administration[99] and the European Medicines Agency[100]; esketamine was selectively approved for use (in addition to a known antidepressant) in adults with treatment-resistant MDD. Apart from this, clinical investigations also continue to affirm that a single intravenous bolus administration of ketamine can evoke a rapid (within 2 h) and lasting (up to 7 d) antidepressant action[101-103].

NMDA antagonists

Ketamine: In humans, ketamine's ability to alleviate depressive symptoms (Table 4) was first highlighted by a small, randomized, double-blind study demonstrating that a single subanaesthetic (0.5 mg/kg) dose of ketamine administered intravenously

Table 4 Glutamate-based therapies in depression

Study	Receptor type	Outcome	Ref.
Randomized, double-blind study	NMDAR antagonist	A single subanaesthetic (0.5 mg/kg) dose of ketamine administered intravenously improved depressive symptoms within 72 h in seven persons with treatment resistant major depressive disorder (MDD)	Berman *et al*[68]
Double-blind, placebo-controlled, crossover study	NMDAR antagonist	A single ketamine infusion (0.5 mg/kg over 40 min) had a rapid, robust and mildly sustained antidepressant effect (1 wk) in treatment resistant MDD	Zarate *et al*[104]
Open label study	NMDAR antagonist	Rapid anti-depressant effects of a single ketamine infusion in persons with treatment-resistant bipolar depression	DiazGranados *et al*[105]
Preclinical	NMDAR antagonist	Memantine exhibited a dose-dependent antidepressant-like response in the tail-suspension test, with the response observed at a dose of 15 mg/kg persisting with sub-chronic administration	Kitanaka *et al*[112]
Double-blind placebo controlled	NMDAR antagonist	Memantine administered at doses of between 5-20 mg/d, showed no significant effects on depression phenotypes	Parsons *et al*[110], Kos and Popik[111], and Muhonen *et al*[114]
Preclinical	NMDAR antagonist	The antidepressant effects of amantadine have been observed in situations where it is administered in combination with standard antidepressants such as fluoxetine and imipramine	Czarnecka *et al*[115] and Maj and Rogóz[116]
Preclinical	NMDA (NR2B) receptor blockers	Ro 25-6981 exhibited behavioural antidepressant-like effects in the forced swim test	Mathews *et al*[118] and Refsgaard *et al*[119]
Preclinical	NR2B-selective NMDA antagonist	CP-101,606 that was well-tolerated and devoid of psychotropic side effects was also used in a clinical trial involving subjects with traumatic brain injury	Refsgaard *et al*[119]
Randomized, placebo-controlled, double-blind study	NR2B-selective NMDA antagonist	CP-101,606 demonstrated efficacy in treatment-refractory MDD subjects	Merchant *et al*[120]
Cross-over pilot study	NR2B-selective NMDA antagonist	Oral formulation of MK-0657 in persons with treatment-resistant MDD showed a significant antidepressant effect compared with placebo while no improvement in symptoms was noted using the primary efficacy measure	Preskorn *et al*[121]
Preclinical	AMPA-antagonist	LY392098 and LY451616 exhibited antidepressant effects in a number of animal models of depression; including the inescapable stressors, learned-helplessness models, and exposure to chronic mild stress models	Li *et al*[122] and Lauterborn *et al*[123]
Preclinical	mGLu	LY341495, MSG0039, and MPEP exhibited significant antidepressant effects in rodent models of behavioural despair	Jaso *et al*[7] and Chaki *et al*[130]

NMDA: N-methyl-D-aspartate; NMDAR: N-methyl-D-aspartate receptor; AMPA: α-Amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; mGLu: Metabotropic glutamate.

improved depressive symptoms within 72 h in seven persons with treatment resistant MDD[68]. A larger, double-blind, placebo-controlled, crossover study also found that a single ketamine infusion (0.5 mg/kg over 40 min) had a rapid, robust and mildly sustained antidepressant effect (1 wk) in treatment-resistant MDD[104]. Adverse effects that included confusion, euphoria, dizziness, perceptual disturbances, blood pressure elevation and increased libido were self-limiting[104].

Since the first clinical study that demonstrated the antidepressant effects of ketamine, several other studies have continued to examine its efficacy across other depression phenotypes[104,105]. Diazgranados *et al*[105] demonstrated the rapid anti-depressant effects of a single ketamine infusion in persons with treatment-resistant bipolar depression, which was replicated in a double-blind, randomized, crossover, placebo-controlled study[104]. The impact of ketamine on reducing suicides has also been examined. Ketamine was reported to have a rapid and significant anti-suicidal effect in persons with MDD[101]. While the discovery of ketamine's antidepressant effect was met with enthusiasm, its associated sedative and psychotomimetic effects remain limitations to its use. Therefore, efforts continue to be directed towards blunting these effects. Studies have tried to research the effects of augmenting ketamine with other drugs that are probably better-tolerated; these drugs such as riluzole and lamotrigine have been examined for their ability to either improve ketamine antidepressant effects and/or reduce its psychotomimetic effects[106-108]. However, a number of these studies reported that these add-ons showed no significant ability to improve the course of the antidepressant response (compared to ketamine alone) or reduce the side effects of ketamine[107,108]. Anand *et al*[106] on the other

hand reported lamotrigine's ability to decrease the perceptual abnormalities induced by ketamine.

Memantine and amantadine: The dampening of the enthusiasm that arose from the rapid and robust antidepressant effects of ketamine due its psychotomimetic side-effects prompted research into the possible antidepressant activities of other non-competitive NMDA receptor antagonists such as memantine, which has been reported to be devoid of these effects, at least at therapeutic doses[109-111]. The anti-depressant effects of memantine, a low-affinity, non-competitive, open-channel NMDA receptor antagonist which is approved for use in the management of Alzheimer's disease has been extensively studied [104,112]. The results of a preclinical study by Kos and Popik [111] revealed a dose-dependent antidepressant-like response in the tail-suspension test, with the response observed at a dose of 15 mg/kg persisting with sub-chronic administration. However, the results of clinical studies have shown mixed results[110, 111]. In one double-blind, placebo-controlled trial in which memantine was administered at doses of between 5-20 mg/d, no significant effects were observed [113]. This result was also supported by another double-blind placebo-controlled study that examined the effect of memantine administered at 10 mg/kg on late-onset depression[113]. However, the result of a large double-blind randomized Finnish study reported a significant antidepressant effect with memantine in persons with co-morbid alcohol dependence[114].

Amantadine is another NMDA receptor antagonist with possible influence on the serotonergic, dopaminergic and monamine-oxidase systems. The antidepressant effects of amantadine have been observed in situations where it is administered in combination with standard antidepressants such as fluoxetine and imipramine[115, 116]. However, clinical trials are limited, mostly using amantadine as an augmentation agent (up to 300 mg/daily) in treatment resistant MDD, where it had shown some modest effects[117].

Subtype-selective NMDA (NR2B) receptor blockers: Investigations into subtype-selective blockers of the NMDA receptor (Table 4) have also been undertaken to by-pass the psychotomimetic effects of ketamine. Along this line, agents such as Ro 25-6981 that can block NR2B receptors have been studied. In preclinical experiments, the NR2B antagonist Ro 25-6981 exhibited behavioural antidepressant-like effects in the forced swim test[118]. The NR2B-selective NMDA antagonist (CP-101,606) that was well-tolerated and devoid of psychotropic side effects was also used in a clinical trial involving subjects with traumatic brain injury[119].

Other selective NMDA NR2B antagonists such as MK-0657 have also been examined. Again, in a randomized, placebo-controlled, double-blind study, the anti-depressant efficacy of CP-101,606 was demonstrated in treatment-refractory MDD subjects[120], while the result of a crossover pilot study that evaluated the potential antidepressant efficacy and tolerability of an oral formulation of MK-0657 in persons with treatment-resistant MDD observed a significant antidepressant effect compared with placebo using recognized secondary efficacy scales; with no improvement noted when symptoms were assessed using the primary efficacy measure[121].

Other glutamate receptors

The AMPA glutamate receptors are main contributors in excitatory neurotransmission, as they mediate the fast, rapidly desensitizing excitation of many synapses. The potential beneficial role of AMPA receptor modulators (Table 4) in the treatment of mood disorders has been highlighted by studies that have shown that AMPA receptor potentiators such as LY392098 and LY451616 possess antidepressant effects in a number of animal models of depression; including the inescapable stressors, learned-helplessness models, and exposure to chronic mild stress models[122]. Also, they do not seem to affect the extracellular concentration of monoamines[122]; yet they enhance the neurotrophic actions of BDNF mRNA and protein in primary neuronal cultures[122,123]. However, of the AMPA receptor positive allosteric modulators being investigated for MDD treatment, ORG-26576 was amongst the most-promising until it failed Phase II trial. Currently, while the potential roles of AMPA receptor modulators in experimental models of depression are still being researched, the world is still waiting for drugs whose actions are primarily linked to this. Stimulation of the AMPA receptor has also been associated with mediating the antidepressant-like effects of ketamine and group II mGlu receptor antagonist MGS0039[124], with suggestions that increased transmission *via* glutamatergic AMPA receptors possibly provide a common mechanism of antidepressant response[51].

Kainate receptors are now recognized as important mediators of the pre- and postsynaptic actions of glutamate and GABA, through mechanisms that are still being evaluated[125]. The results of some studies have associated genetic variations in certain kainate receptor subtypes with the therapeutic outcome of antidepressant medications like citalopram and venaflaxine[125-127]. While it is generally accepted that kainate receptors have modulatory effects on synaptic transmission, the paucity of selective kainate receptor subtype agonists or antagonists has hampered research into the possible mechanisms through which kainite receptors modulate brain function and/or impact the pathogenesis and treatment of depressive disorders[125].

mGlu receptors have been shown to regulate glutamate's neuronal transmission through the ability to alter neurotransmitter release or modulate the post-synaptic responses to glutamate release. There is enough evidence from studies to support the notion that regulation of glutamatergic neurotransmission through mGlu receptors is associated with the development of mood, leading to suggestions that they could serve as novel targets in depression management[128,129]. Modulation of the mGlu receptor has also been reported to increase neurogenesis and neurotransmitter release that has now been associated with therapeutic response in humans[128]. Several mGlu2, mGlu3 and mGlu5 receptors' (Table 4) negative allosteric modulators (LY341495, MSG0039, MPEP) have been reported to have significant antidepressant effects in rodent models of behavioural despair[7,130]. Also type III mGluRs (4-8) are mostly expressed presynaptically, modulating glutamate release and response; but while a number of preclinical studies have identified possible type III mGluR novel drug targets such as the mGluR7[131,132], there is a dearth of clinical studies evaluating the possible therapeutic benefits of these type III mGluRs in depression. There have however been reports that a positive allosteric modulator of mGluR7 (AMN082) has antidepressant-like properties in rodent models of behavioural despair[7], that can be linked to its ability to modulate glutamate transmission in the hippocampus[133].

CAN THE RELATIONSHIP BETWEEN GLUTAMATE AND THE GUT-BRAIN AXIS BE OF THERAPEUTIC BENEFIT IN DEPRESSION?

There is ample evidence that dietary and endogenous glutamate (directly or indirectly) influences glutamatergic neurotransmission in the gastrointestinal tract and the brain, respectively. The gut microbiome has been shown to be involved in the synthesis and release of neuroactive molecules, including those involved in the pathogenesis of depression. Alterations in glutamate concentration and glutamatergic neurotransmission have also been linked to the pathophysiology of depressive disorders. Scientific evidence has shown that diet influences the gut microbiota composition and density, and that both diet and gut microbiota influence emotional behaviour and neurological processes[134,135]. By direct evidence and inference, we now know there is a complex interplay involving diet, the gut microbiome and depression. Hence, specific dietary patterns that can help prevent or mitigate mood disorders, possibly *via* shifts in gut microbiota equilibrium can be identified and offered as components of clinical management.

Also, the use of dietary intervention may prove to be attractive and cost-effective as an alternative or adjuvant therapy in the clinical management of depression. However, despite the tantalizing prospect, the directionality and mechanism of the relationship involving diet, the gut microbiome, and depression are still subjects of research. That being said, diets rich in vegetables, fruits, cereals, nuts, seeds, pulses and moderate amounts of dairy, eggs, fish and unsaturated fats have been associated with a lower incidence of depression[136-139], a view not supported by some studies[140,141]. Research has shown that different microbiota profiles may be associated with positive or negative mental health, emphasizing the behavioural impact of the gut microbiome. Also, if we know that behaviour is determined by the brain's neurotransmitter milieu, then the link involving diet, the gut microbiome, neurotransmitters and depression will be easier to appreciate.

Humans with depression have been shown to harbor variations in gut microbiota which tend towards a general pattern of increases in potentially harmful and inflammation promoting bacteria such as *Proteobacteria*, and a decrease in commensal bacteria, which are normally more abundant[77,141-144]. However, the lack of a specific depression-associated gut microbiota profile is a major challenge[9]. Despite this, the presence of bacteria that produce neuroactive molecules strengthens the link between gut microbiota and behavioural disorders such as depression. *In vitro* and *in vivo* studies have demonstrated the ability of intestinally cultured strains of *Lactoba-*

cillus brevis and *Bifidobacterium dentium* to efficiently produce GABA from monosodium glutamate enriched medium or monosodium glutamate supplemented food, respectively[145,146]; leading to suggestions that this could represent a promising therapeutic approach for depression management. Also, *Lactobacillus rhamnosus* (JB-1) has been shown to reduce stress-induced corticosterone levels in mice and ameliorate depression-like behaviour in the forced swim test; while also increasing brain glutamate and glutamatergic activity[9]. Other specific relationships involving glutamate are still being investigated, and their direct implications for therapy are being considered.

CONCLUSION

The limitations of the amine theory redirected the research focus to what was supposedly missing in the scientific understanding of the aetiology, course and management of depression. The discovery of the antidepressant effect of ketamine brought attention to the impact that manipulation of the glutamatergic system can have on the management of depression. Also, the role of diet and the gut microbiome in glutamate homeostasis is being continuously examined. As it becomes evident that gut microbes are involved in the synthesis and secretion of molecules that directly impact the brain, including glutamate, we now know that their manipulation through diet can become a cornerstone for the prevention and management of behavioural disorders. However, while glutamate-based therapies for depression are still in their infancy (and much more is dietary manipulation of glutamate balance *via* the gut microbes), it appears that understanding the diet, gut microbiome, gut-brain axis and glutamate link may be the next frontier in advancing our understanding of depression.

Abstract

Patients with schizophrenia (SCZ) are at high risk of cardiovascular disease (CVD) due to an inherited predisposition, a sedentary life style and the use of antipsychotic medications. Several approaches have been taken to minimize this risk but results continue to be unsatisfactory. A potential alternative is prescribing selective serotonin reuptake inhibitors (SSRIs). SSRIs decrease platelet aggregation and reduce the risk of coronary heart disease in patients with depression. We therefore aim to investigate whether there is evidence that supports the use of SSRIs to reduce the risk for CVD in SCZ. A review of the literature revealed five published reports relating to the impact of SSRIs on CV risk in SCZ. Three trials assessed the influence on metabolic parameters of fluvoxamine when combined with clozapine. Two of those studies found improvements with fluvoxamine. Of the other two reports, one indicates SSRIs as a group caused minimal but statistically significant increments in total cholesterol, low-density lipoprotein and triglyceride. The second report suggests that when SSRIs are combined with antipsychotics, the metabolic impact depends on the antipsychotic prescribed. While there are promising results, no conclusions can be made currently on whether SSRIs increase or decrease CV risk in SCZ. Further studies are needed to resolve this matter.

Core Tip: We searched MEDLINE and Google Scholar to find articles related to the cardiovascular effects of selective serotonin reuptake inhibitors (SSRIs) in patients with schizophrenia (SCZ) who are taking antipsychotics. We found evidence showing that fluvoxamine reduces metabolic factors in patients taking clozapine, but we also found that SSRIs as a group cause significant yet small increments in metabolic factors. There is also evidence that the effect of SSRIs on metabolic factors depends on which antipsychotics the patient is concurrently taking. Further research in this area is needed before any firm conclusion can be reached on whether SSRIs are beneficial or harmful for cardiovascular risk in SCZ.

INTRODUCTION

Life expectancy of patients with schizophrenia (SCZ) is significantly lower than for the rest of the population[1]. While multiple factors are at play, a common culprit is cardiovascular disease (CVD)[2-5]. The risk for CV illness is compounded by several characteristics surrounding SCZ, such as an inherited predisposition to develop metabolic abnormalities[6] and the fact that patients often experience apathy and anhedonia, symptoms that lead to a sedentary lifestyle. In addition, high rates of smoking and diets rich in calories and fat are also common among patients with SCZ [7]. But perhaps even more significant is the impact of antipsychotics, particularly second-generation antipsychotics. These medications induce weight gain, hyperlipidemia and diabetes[8] all risk factors for CVD.

Mitigation of CV risk in patients with SCZ already includes a polydimensional approach that considers promoting changes in life style such as increased exercise and improved diet, switching or reducing the dose of antipsychotic medications[8], as well as the potential use of statins[9] and metformin[10]. But according to a recent meta-analysis, all these efforts continue to fall short of a desirable outcome[1]. In the general population, patients at risk for CVD are often placed on aspirin or an anticoagulant like clopidogrel, but these medications are associated with increased risk of bleeding [11] and thus guidelines for their use are becoming more restrictive[11]. A potential alternative is the use of selective serotonin reuptake inhibitors (SSRIs). SSRIs decrease platelet aggregation and appear to have a lower risk of bleeding than other anticoagulants[12,13]. Moreover, there is evidence indicating that SSRIs can reduce the risk of coronary disease[14] and lower the severity of ischemic strokes[15]. Therefore, our hypothesis is that SSRIs could be a safe alternative to reduce the risk of CVD in patients with SCZ taking antipsychotics.

In order to challenge our hypothesis, we first present evidence indicating patients with SCZ are at an increased risk of CVD. Second, we review emerging data on the impact of SSRIs for CV risk and third, we describe and discuss currently available published literature on the role SSRIs have on CVD in patients with SCZ.

A review of the literature was conducted *via* MEDLINE and Google Scholar using search terms such as SCZ, SSRIs, CV risk, metabolic abnormalities, metabolic syndrome and morbidity. The search was limited to studies published in English. For each of the scientific manuscripts identified relating to the impact of SSRIs on metabolic or CV risk in patients with SCZ, its references were thoroughly inspected for secondary publications.

Schizophrenia and Cardiovascular risk

Patients with SCZ appear to have an inherited predisposition to develop risk factors for CVD. For instance, drug-naïve patients have greater than three times as much intra-abdominal fat as age-and body mass index (BMI)-matched individuals[16]. They also have impaired fasting glucose tolerance and are more insulin resistant than healthy subjects[6]. In addition, apathy and anhedonia are symptoms commonly experienced by patients with SCZ. These symptoms lead to limited physical activity

which in combination with high intake of fat and sugar often seen in SCZ, ultimately result in the development of metabolic syndrome[7]. Metabolic syndrome understood as dyslipidemias, insulin resistance and elevated blood glucose, frequently results in diabetes mellitus type 2 and CVD[17]. Not surprisingly, the prevalence of both diabetes and obesity is two to four times higher in patients with SCZ than in the general population[18]. Another contributing factor for the high prevalence of diabetes and the increased risk for CVD is antipsychotic intake.

All antipsychotics, including older typical neuroleptics, can elicit metabolic abnormalities[8,19]. The rate at which these side effects occur however, differs among medications. In the typical antipsychotic class, lower potency antipsychotics such as chlorpromazine and thioridazine induce greater weight gain compared to higher potency antipsychotics such as fluphenazine and haloperidol[20]. Likewise, chlorpromazine and thioridazine are more strongly associated with diabetes compared to other typical antipsychotics[21]. But comparisons between typical *vs* atypical antipsychotics, also known as second generation antipsychotics (SGA), have clearly shown that SGA are more commonly associated with metabolic side effects[22]. Among SGA, clozapine and olanzapine appear to have the strongest association with weight gain and diabetes [23,24]. Quetiapine is not far behind in its ability to elicit metabolic dysregulations. According to the clinical antipsychotic trials of intervention effectiveness study[25], olanzapine and quetiapine are associated with increases in total cholesterol and triglyceride (TG) levels. When ranked for its potential to cause weight gain and other metabolic abnormalities, clozapine and olanzapine are at the top of the list followed by quetiapine and risperidone, while aripiprazole and ziprasidone are found at the bottom of the ranking[23,26,27]. For those medications with higher risk, data indicates there is a dose-dependent relationship between dose and metabolic complications[28]. For aripiprazole and ziprasidone no such relationship has been found[28]. Newer antipsychotics such as lurasidone, cariprazine and paliperidone are poorly studied to date.

SSRIs and Cardiovascular disease

Serotonin is needed for platelets to elicit platelet aggregation and vasoconstriction[29]. Platelets rely on reuptake of serotonin as they lack the capacity to synthetize this amine[29]. By inhibiting serotonin reuptake in platelets, SSRIs alter hemostasis[12,13] and therefore, are associated with increased risk for bleeding[30]. This potentially serious side effect however, is most commonly observed in individuals with medical conditions that already carry an increased risk of bleeding[13] or those taking other anticoagulant medications[30]. Overall, SSRIs are safe medications that rarely cause any serious side effects[31].

In the context of CVD, disrupting platelet aggregation could become an advantage. Not surprisingly, several studies have tried to establish whether SSRIs can minimize the risk of CV events. The majority of these publications indicate that SSRIs are cardioprotective in patients with depression (For a review refer to Andrade *et al*[9] and a recent meta-analysis by Guo *et al*[32]) but inconsistencies remain[9,33]. Variations in the cardioprotective effects of SSRIs could be related to differences in its mechanism of action. While all SSRIs diminish vasoconstriction and platelet aggregation by lowering serotonin release in platelets, other signaling cascades are also at play. For instance, sertraline impairs platelet aggregation by inhibiting CD9, GPIb, GPIIb/IIIa surface receptors while its inactive metabolite, N-desmethylsertraline, targets P-selectin and platelet endothelial cell adhesion molecule-1[12]. Sertraline also diminishes E-selectin and β-thromboglobulin concentrations[34]. In contrast, citalopram, fluvoxamine and fluoxetine inhibit tumor necrosis factor (TNF)-α-induced expression of vascular cell adhesion molecule and intracellular adhesion molecule in human aorta endothelial cells and TNF-α-stimulated adhesiveness to monocytes, resulting in less inflammation and more cardioprotective effects in patients with heart disease[35].

Recent clinical data also indicates there are differences in the potential CV benefits offered by SSRIs. Escitalopram appears to be the most advantageous for CV safety in older individuals at risk of coronary heart disease, whereas fluoxetine provided little benefit if at all[32]. In this same study, sertraline, citalopram and paroxetine delivered better caridoprotection than fluoxetine but less than escitalopram[32].

In addition to its effects on platelet aggregation and vasoconstriction, SSRIs could also impact metabolic markers. Diagnosis appears to be an important factor determining the role of SSRIs on metabolic markers. For instance, several studies have shown that SSRIs increase cholesterol levels in patients with panic disorder[36-38] with paroxetine being the main offender[37,38]. For women with generalized anxiety disorder (GAD) the impact varies according to the SSRI taken. Paroxetine increased BMI, waist circumference, fasting glucose, total cholesterol, low-density lipoprotein

(LDL), and TG after 16 wk, while citalopram and escitalopram only resulted in higher TG levels[39]. This study involving women with GAD also found that sertraline elevated total cholesterol, in contrast, fluoxetine lowered total cholesterol, weight and TG[39]. Similarly, adding fluoxetine to olanzapine for patients with bipolar depression did not affect cholesterol levels or body weight (BW) when compared to treatment with olanzapine alone[40].

SSRIs and Cardiovascular risk in Schizophrenia

The first study to assess the metabolic impact of SSRIs in SCZ is a randomized, prospective trail published in the year 2000 (Table 1)[41]. The authors tested whether clozapine alone or in combination with fluvoxamine differentially impacted BW, BMI or leptin levels among other parameters during a 6-wk follow-up period. They found no changes in weight or BMI between groups. Leptin levels however, were higher in patients receiving the combined therapy. Levels of clozapine, norclozapine or the ratio norclozapine-clozapine were similar between cohorts. Eleven patients received the dual therapy while 12 patients were prescribed only the antipsychotic. Fluvoxamine was prescribed at either 50 or 75 mg/d while clozapine was given at doses of 100 to 150 mg/d in the combined group and around 300 mg/d for patients receiving clozapine alone.

The second study on SSRIs, CV risk and SCZ is a prospective, randomized, open-label study that also compared clozapine monotherapy *vs* clozapine with fluvoxamine (Table 1)[42]. The medications were prescribed at slightly different doses than on the previous trail. The monotherapy group received up to 600 mg/d of clozapine, whereas the combined group could only take up to 250 mg/d together with fluvoxamine 50 mg/d. The rationale was that fluvoxamine increases the serum clozapine level 2.3 times[43]. Sixty-eight patients were recruited, thirty-four for each group. The authors assessed BW weekly during the 12-wk follow-up period. Fasting glucose, cholesterol and TG were measured at baseline and then at the end of the study. Their results showed that clozapine significantly increased weight, BMI, blood sugar and TG when baseline numbers were compared to values obtained after 12 wk. Comparisons between groups, revealed that individuals receiving clozapine alone had higher levels of blood sugar and TG by the end of the follow-up period. The authors also found that levels of norclozapine correlated with elevated blood sugar and TG while levels of clozapine did not. It is important to note that this study was conducted entirely with inpatients and therefore, their food intake was restricted to a hospital diet.

Lu *et al*[44] followed their open-label study on the metabolic effects of fluvoxamine in patients taking clozapine with a double-blind, randomized, clinically controlled trial (Table 1). Eighty-five patients were recruited and followed for 12 wk, with 43 receiving clozapine monotherapy at a target dose of 300 mg/d and 42 given fluvoxamine at 50 mg/d and clozapine at 100 mg/d. The authors found that the clozapine-fluvoxamine combination limited increments in BW and waist circumference and reduced levels of insulin resistance, blood glucose, cholesterol and TG when compared with clozapine monotherapy. The Positive and Negative Symptoms Scores also improved on the dual therapy cohort. Liquid chromatography revealed no differences in blood levels of clozapine but, levels of norclozapine and clozapine N-oxide were higher on the monotherapy group. The norclozapine-clozapine ratio was higher in the combination group.

Through a naturalistic, cross-sectional study, Fjukstad *et al*[45] aimed to determine the effects of SSRIs on total cholesterol, LDL, high-density lipoprotein (HDL), TG, glucose, BMI, waist circumference and blood pressure. Their database included 868 patients with SCZ of whom 169 were taking SSRIs and 433 individuals with bipolar disorder of whom 111 were taking SSRIs (Table 1). Linear regression analyses, indicated that SSRIs caused minimal but statistically significant increments in total cholesterol, LDL and TG. The authors also found that patients taking SSRIs had a slightly higher risk for developing metabolic syndrome. Blood glucose, BMI, waist circumference and blood pressure were not affected by the use of SSRIs. Unfortunately, the authors did not parcel patients by diagnosis. Potential differences among the different SSRIs included in the analysis namely, escitalopram, citalopram, sertraline, fluoxetine and paroxetine were not investigated.

This research group published a second study mining the same cohort of patients (Table 1)[46]. Their new objective was to determine whether adding SSRIs to antipsychotic medications would increase metabolic risk factors[46]. Three antipsychotics were included in their analysis, olanzapine, quetiapine and risperidone. SSRIs added to olanzapine or quetiapine led to small but statistically significant elevations in total cholesterol and LDL. Blood glucose increased when olanzapine was given together with SSRIs, in contrast, combining risperidone with SSRIs led to lower blood

Table 1 Selective serotonin reuptake inhibitors and cardiovascular risk in patients with schizophrenia

Ref.	SSRI studied	Number of patients	Sex	Average age	Duration	Metabolic parameters
Hinze-Selch *et al* [41], 2000	Fluvoxamine[1]	23	M: 11 F: 12	32 ± 15[1]	6 wk	BW, BMI, Leptin

[1]In combination with clozapine.
[2]the authors also included 433 individuals with bipolar disorder.
[3]The authors studied SSRIs combined with olanzapine, quetiapine and risperidone.
SSRI: Selective serotonin reuptake inhibitors; BW: Body weight; BMI: Body mass index; LDL-C: Low-density lipoprotein cholesterol; HDL-C: High-density lipoprotein cholesterol; TG: Triglyceride; SBP: Systolic Blood Pressure; DBP: Diastolic blood pressure; FPG: Fasting plasma glucose; HOMA-IR: Homeostasis model assessment of insulin resistance.

glucose. The authors reported that none of the other parameters studied were affected by coadministration of risperidone and SSRIs. Dual therapy with SSRIs and either olanzapine or quetiapine also did not alter HDL, TG, BMI or blood pressure. What the authors did not mention but appears to be evident from their figures, is that risperidone alone led to statistically higher levels of LDL but when prescribed in conjunction with SSRIs, LDL did not increase. Likewise, quetiapine monotherapy caused a modest but statistically significant elevation in TG, while in combination with SSRIs TG did not change. Quetiapine without SSRIs significantly increased BMI but with these antidepressants, BMI was unaffected. The authors emphasized that their results have to be pondered with caution as their methodology did not allow excluding the potential impact of diet and even more importantly, they did not have access to non-psychotropic medications being taken by their patients such as statins or insulin.

CONCLUSION

Several factors place individuals with SCZ at risk of CVD including an inherited predisposition to metabolic anomalies[6,16], a sedentary life style prompted at least in part by core symptoms of this psychotic disorder and the use of antipsychotic medications which elicit metabolic syndrome[8]. So far, attempts to reduce all these risk factors have rendered unsatisfactory results[1]. Therefore, the search for new approaches continues.

Because of their capacity to decrease platelet aggregation and vasoconstriction[12,13], SSRIs have been investigated as a potential alternative. Specially, considering that SSRIs have delivered promising cardioprotective results when prescribed for other mental illnesses such as major depressive disorder[9,14]. In addition to its effects on hemostasis, SSRIs can also influence CV risk by altering metabolic markers such as total cholesterol, LDL, BMI, blood glucose and others. But in contrast with its effects on platelet aggregation and vasoconstriction which are directly linked to SSRIs ability to block serotonin[12,13], how these medications elicit changes in metabolic parameters is yet undetermined. What the evidence currently indicates is that SSRIs impact on CV risks varies according to diagnosis and the specific SSRI prescribed. For instance, the risk for CVD is likely to increase if patients with panic disorder take paroxetine[36-38]. Gender also has to be considered. If women with GAD receive paroxetine, their likelihood of developing CVD also augments[39]. Conversely, fluoxetine has a cardioprotective effect on women with GAD[39]. Age also appears to be a factor. Older individuals at risk of coronary heart disease obtain no benefit from

receiving fluoxetine, whereas, escitalopram can be advantageous[32].

Not surprisingly, how SSRIs affect CV risk in patients with SCZ also depends on which specific one is being prescribed. Two trials developed by the same research team have shown that fluvoxamine diminishes at least some of the metabolic side effects elicited by clozapine[42,44]. These two studies took important steps to limit potential confounding factors such as excluding individuals taking medications known to affect metabolic parameters and at least one of those trails controlled their cohort's food intake. There is also one publication that encountered different results. An independent team that also assessed the effects of fluvoxamine coadministered with clozapine did not find any metabolic benefits[41]. It is possible that the short duration of this study of only 6 wk could have prevented the authors from finding any significant differences. The two studies that found fluvoxamine to be effective, lasted for 12 wk. All three studies measured blood levels of clozapine and its metabolites and two of them found norclozapine levels to be associated with metabolic abnormalities. The three trials recruited a relatively small number of patients (Table 1).

The first cross-sectional study that Fjukstad *et al*[45] published found that SSRIs increased total cholesterol, LDL and TG in patients with SCZ and bipolar disorder. Nonetheless, there are several confounding factors that have to be pondered when assessing these results. Their study design did not allow discrimination of metabolic parameters between patients with SCZ and bipolar disorder as they were considered a single cohort. Likewise, escitalopram, citalopram, sertraline, fluoxetine and paroxetine were all clustered together in the analysis and consequently its potential individual impact could not be determined. Diet was not controlled for either this or their second study discussed below. Also applicable for both studies is that the authors did not have access to other medications their patients may have been taken such as statins or insulin which could ultimately impact their results.

Fjukstad *et al*[46] second cross-sectional study presents intriguing results consistent with previous publications suggesting that SSRIs influence the metabolic impact of antipsychotics in patients with SCZ. The authors found that when olanzapine is combined with an SSRI, several metabolic parameters worsened. Similarly, the combination of quetiapine and SSRIs leads to increases in total cholesterol and LDL. But this dual therapy prevents increments in TG and BMI caused by quetiapine alone. SSRIs appear to be beneficial when taken with risperidone. This combination lowers blood glucose and prevents rises in LDL elicited by risperidone monotherapy. Unfortunately, whether each of the SSRIs studied affects metabolic markers differently, was not determined, as all SSRIs included in the analysis were clustered as one group (Table 1).

SSRIs could improve CV risk by another mechanism of action. One of the factors that place patients with SCZ at increased CV risk is a sedentary life style. Negative symptom of SCZ can significantly contribute to lower levels of psychical activity. Thus, successfully treating negative symptoms would lead to benefits in CV health. Antidepressants have been successfully used in treating negative symptoms of SCZ, though not always[47].

The information currently available does not allow us to draw any firm conclusions. However, it suggests that for patients with SCZ, adding fluvoxamine to clozapine brings metabolic benefits[42,44], though clinicians have to be cautious with this combination as fluvoxamine can drastically increase clozapine levels[43]. Similarly, dual therapy with risperidone and SSRIs also appears to improve some metabolic parameters[46] but whether a specific SSRI is more advantageous than others is yet to be established. What appears to be clear is that SSRIs impact CV risk by affecting metabolic markers and that each SSRI has its own unique metabolic advantages and disadvantages depending on gender, age, diagnosis and the presence or absence of antipsychotics. Therefore, when metabolic parameters are being studied, SSRIs should be considered a confounder. Also evident is that no conclusions can be made currently on whether SSRIs increase or decrease CV risk in patients with SCZ. Further studies are needed to resolve this matter.

ACKNOWLEDGEMENTS

The authors would like to thank the Ling and Esther Tan Early Career Professorship endowment given to AB. We are also grateful for the thorough editorial comments from Professor Andrew Francis.

Abstract

Depression is the most prevalent mental disorder in pregnancy, and yet it is less studied than postpartum depression despite the consequences it may have on both the pregnant woman and her offspring. Therefore, it would be important to know which risk factors may favour the appearance of antenatal depression in order to carry out appropriate prevention interventions. The aim of the present review was to identify the main risk factors of antenatal depression. We searched in databases PubMed and PsycINFO for articles published about the factors associated with antenatal depression from January 2010 through December 2020. The literature review identified three main groups of antenatal depression risk factors: sociodemographic, obstetric, and psychological. First, among the sociodemographic variables, the low level of studies and the economic income clearly stood out from the rest. Then, not having planned the pregnancy was the main obstetric variable, and finally, the main psychological risk factors were having a history of psychological disorders and/or depression as well as presenting anxiety, stress, and/or low social support during pregnancy. This review shows that the antenatal depression is affected by multiple factors. Most can be identified at the beginning of the pregnancy, and some are risk factors potentially modifiable through appropriate interventions, such as psychological factors. For this reason, it is important to carry out a good screening for depression during pregnancy and consequently, be able to prevent its appearance or treat it if necessary.

psychological factors are associated with the presence of antenatal depression. Most of them can be identified in early pregnancy. Therefore, a complete medical history along with the routine use of screening instruments to detect the risk profile of these women would allow the prevention and early detection of antenatal depression.

INTRODUCTION

Traditionally, it was thought that pregnancy protected women against the onset or relapse of a depressive disorder. However, it has been shown that pregnancy does not protect them, and together with postpartum are two periods of great vulnerability for women[1]. Some studies have found that antenatal depression is as frequent, or even more frequent than postpartum depression[2-4]. Still, it is often underdiagnosed and, as a consequence, undertreated[5]. Furthermore, antenatal depression constitutes a major public health problem[6] due to the reasons discussed below.

Despite the fact that many women remain undiagnosed[7], the prevalence of depression during pregnancy is high[8,9] and varies in the different trimesters across studies[8,10,11].Therefore, diagnosing antenatal depression can be difficult if women are only screened once throughout pregnancy.

Depression during pregnancy has received much less attention than postpartum depression, although in the last decade the study of antenatal depression is becoming more and more prominent. This may be due to either an increase in diagnosed cases of depression in pregnant women or to the acquisition of greater awareness of the consequences of antenatal depression[12] among professionals.

During pregnancy, depression has a negative impact on both the course of pregnancy and on the foetal and neonatal outcome[13-15], with growing research in the field of "foetal programming," triggering interest in the study of depression during pregnancy. According to this theory, the perinatal period is a critical stage where mental health protection efforts should be focused, and prevention models be developed[16]. It is now known that the psychological state of a mother during pregnancy has an important impact on the subsequent development and health of her child[15]. In this regard, the association between maternal stress, depression, or anxiety in pregnancy and an adverse neurodevelopmental outcome of the child is evident[17]. In addition, studies focusing on the perinatal period found that depression during pregnancy is the most important risk factor for postpartum depression[18,19].

Reviews identifying risk factors associated with prenatal depression are scarce and focus on a few risk factors, analyze them separately[20-22], or in a particular country/culture[23]. In light of the foregoing, it would be important to identify the risk factors associated with the presence of antenatal depression from the beginning of pregnancy, as this would allow us to offer more efficient help in accordance with the needs of future mothers, improving their self-perception of well-being. This would also prevent this depressive state from extending to the postpartum period, with the consequences that this would entail for both mothers and their children.

Therefore, the objective of this review is to describe and group the main risk factors found in the studies published in the last 10 years that simultaneously may be associated with the presence of antenatal depression.

LITERATURE REVIEW

A literature search was performed in PsycINFO and PubMed databases, using the search string: "antenatal depression" OR "depression during pregnancy" AND "risk factors" OR "variables associated." The literature search was restricted to studies written in the English language and published from January 2010 to December 2020. Reference lists from retrieved articles were also examined.

INCLUSION AND EXCLUSION CRITERIA

The variables/risk factors associated with antenatal depression were the epidemiological parameters of interest. Studies were included as long as they made use of population-based surveys representative of communities, regions, or countries under study. Non-representative samples (*e.g.*, inpatient groups, minority populations, victims of gender-based violence, immigrants, with presence of concomitant medical conditions, at risk of social exclusion) were excluded as they would probably provide biased estimates of risk factors associated with antenatal depression in the general population. Finally, studies using screening instruments (*e.g.*, Edinburgh Postnatal Depression Scale, Patient Health Questionnaire, Beck Depression Inventory) and structured interviews (*e.g.*, Structured Clinical Interview for Diagnostic and Statistical Manual of Mental Disorders) for diagnosis were included.

RESULTS AND DISCUSSION

Details of results are presented in Table 1. Out of the 466 titles identified on risk factors of antenatal depression, 29 studies met inclusion criteria. The analysis of the literature showed that the factors associated with antenatal depression can be classified into three domains of risk factors: sociodemographic, obstetric, and psychological risk factors. Although some variables are related to lifestyle, such as weight and substance use, they are also mentioned in several studies. In the studies, when information was available, the level of significance of the association (*P* value) and the odds ratio of the predictor variables are shown with the objective of showing the strength of the association between variables.

The variability of risk factors associated with antenatal depression found across studies can be attributed to several reasons. First, different instruments are used for assessing antenatal depression. More specifically, 27 studies assessed antenatal depression with self-reported questionnaires, with the Edinburgh Postnatal Depression Scale being the most commonly used (n = 16). However, with different cut-off points across countries, even in studies carried out in the same country[24-26]. Only 2 studies used clinical interviews for diagnosis. In this regard, women may overestimate or underestimate their responses to a self-report questionnaire based on their beliefs, perceptions, culture, and stigmatisation of mental health in their communities[27]. It is also important to consider cultural differences, as they may explain part of the variability of some of the risk factors [for example, the type of public and/or private health care, prenatal health care and the ease of access, the professionals who monitor the pregnancy (*e.g.*, gynaecologists, midwives, nurses), the quality of care available, religious customs, attitudes towards pregnancy and motherhood, gender roles, and/or the role of women in making decisions about her pregnancy][27].

Of the 29 studies included in this review, Arab countries contributed with the largest number of articles (n = 8), followed by Europe (n = 6), Asia (n = 5), Brazil (n = 4), Africa (n = 3), Australia (n = 3), and India (n = 1). The samples of these studies were obtained from women who attended their follow-up pregnancy check-ups at their health centres of reference.

Particularly, there are 15 cross-sectional/cohort studies and, hence, evaluated women at any time regardless of their gestational age; 10 studies included women in their third trimester of pregnancy, and 4 studies evaluated women in their first trimester. No studies were found that analyzed risk factors associated with antenatal depression by trimester. The absence of studies that separately identify the risk factors associated with antenatal depression by trimester may offer a biased information on these variables. This is because each trimester of pregnancy has specific characteristics because both the physical changes, the medical tests, and the concerns that pregnant women face vary throughout the gestation. Therefore, variables that in a given trimester could be significantly related to antenatal depression (*e.g.*, being in the first trimester and having had previous abortions) are perhaps not if women are evaluated in another trimester.

Sociodemographic variables

Different sociodemographic variables have been evaluated in the scientific literature (*e.g.*, age, marital and employment status, educational level, *etc.*). In this section, we will present those most studied in relation to the presence of depression during pregnancy.

Table 1 Risk factors for antenatal depression

[1]Odds ratio of predictor variables; (*P* value). Low Educational L.: Low Educational Level; Low Socioeconomic S.: Low Socioeconomic Status; U. pregnancy: Unplanned pregnancy.

Although the age of a woman is a variable considered in all the studies, it is not always analyzed in relation to the presence of depression in pregnancy. In this regard, the results provided by the studies are inconsistent. Several studies have indicated that younger maternal age increases the likelihood of depression during pregnancy[28-32]. Thus, age younger than 25[12], younger than 20[23], or between 15-20-years-old[33]

have been associated with increased risk of antenatal depression. This may be because younger women tend to have a more unfavorable and unstable economic position. Likewise, younger age may be associated with lower educational attainment and income level, lower paying jobs, or unemployment[33]. On the contrary, other studies have found that older maternal age has been associated with higher risk of antenatal depression. Specifically, it was found that age older than 35[24] and older than 30-years-old[34] were associated with increased risk of depression. Accordingly, rather than age *per se*, the explanation behind these inconsistencies may be more related to cultural issues, such as the fact that in some societies being a young mother is the norm and expected, while in others the opposite is true. Also, the personal baggage that older women bring to motherhood with regard to potential difficulties in conceiving along with anxiety about obstetric and pregnancy complications associated with advanced maternal age[35,36] could be a possible explanation for their higher prevalence of depression.

Regarding educational level, there seems to be a consensus among researchers as when an association has been found, it has always been between lower educational level and antenatal depression[24,33,37-39]. It should be noted, though, that a low level of education is often related to other socioeconomic disadvantages, such as low income[24]. Thus, it can also be explained by the fact that these women present low self-esteem and self-efficacy[40,41], as they may feel inferior both socially and because of their inability to access better paid jobs.

Another factor that has been studied in relation to depression during pregnancy is socioeconomic status. In this case, different studies also agree that being in an unfavorable socioeconomic situation is associated with the presence of antenatal depression[11,34,42-44]. It has been proposed that during the perinatal period women with low socioeconomic status may fear being unable to care for their children[45]. Similarly, low socioeconomic status is often followed by increased stress related to economic hardship, which in turn is a risk factor for antenatal depression[46].

One factor related to socioeconomic status is the employment status of both the woman and her partner. In this regard of not having a paid job, the woman[12,23,47] and/or the partner[38], has been associated with the presence of antenatal depression. In the same vein, being a homemaker has also been associated with antenatal depression[12]. A possible explanation could be the fact that not working and/or being a homemaker implies having a smaller social support network and a certain isolation[47]. Likewise, being a homemaker may be an indicator of low educational level and lower economic resources[12]. It is worth noting that studies such as that of Husain *et al*[38] in Iran did not find such a relationship, but they did find a connection with the fact that it is the partner who is unemployed. Cultural issues related to the role of women in the world of work may be the background of this association. Another aspect that could explain this association could be women's frustrations at the fact that pregnancy did not allow them equal access to the labor market.

Another factor associated with depression in pregnancy is related to marital status. Being single, not cohabiting with a partner, not having a stable partner or with a certain level of commitment[11,25,33,34,42], and/or cohabiting as a domestic partner [23] has been associated with increased risk of antenatal depression. The absence of a partner may mean less social support[15,24] or lead to a worse economic situation, and it is sometimes associated with unintended pregnancy[33].

On the other hand, maintaining an unsatisfactory relationship with a partner has been associated with increased risk of depression during pregnancy[46-50]. One possible explanation for this relationship is based on the fact that physiological and psychological changes that occur during pregnancy often influence women's moods, and they seek support from their partner. Consequently, the lack of such support may increase the likelihood of prenatal depression. Indeed, difficult or strained couple relationships marked by disharmony increase rates of prenatal depression[21,51]. Similarly, partners of women who have a depressive episode report greater marital distress. Likewise, these couples tend to resort to less constructive tactics to resolve their conflicts[51]. In the same way, being a victim of gender-based violence has also been associated with increased risk of antenatal depression[26,33,43].

The context of belonging of the pregnant woman as well as the social environment in which she lives and socializes are also factors that may be related to the risk of suffering depression. Thus, not being of the same race as the country in which one lives and/or being a foreigner[15,25,47] along with social isolation[23] have been described as variables associated with depression in pregnancy. The explanation behind all these situations is the lack of social support.

Obstetric variables

It is increasingly common for researchers to consider obstetric and/or pregnancy-related factors when looking for variables associated with antenatal depression. Pregnancy planning is one of the most studied variables, having been found by several studies that the situation of unplanned pregnancy is a risk factor for antenatal depression[11,34,46-48,52]. An unplanned or unwanted pregnancy carries an enormous emotional burden. Moreover, these women may not be financially, psychologically, or socially prepared to cope with the demands of pregnancy[53]. That is, they may have difficulty reconciling maternal needs and other responsibilities at home or at work. Another explanation may be the fact that these women tend to have more unstable psychosocial environments and feel a lack of security and attachment with their partner[54]. In addition, couples with unplanned pregnancies tend to have more marital conflicts[55], which in turn increases the risk of antenatal depression.

Regarding parity, there are contradictory results. While one study has found nulliparity was associated with increased risk of antenatal depression[50], most studies have found that being multiparous has been associated with increased risk of antenatal depression[6,10,12,24-26,52]. One possible explanation is that the caregiving and parenting-related stress experienced by these women (*e.g.*, expectations of coping with the new child) may make them more vulnerable to depression[24].

Variables related to the woman's previous and current obstetric history have also been studied in relation to antenatal depression. Thus, the existence of previous abortions[6,34,37,52], complications in previous delivery and/or pregnancy as well as those that may exist in the course of the current gestation[6,33,38], and a history of caesarean section[33,56] have been associated with increased risk of depression during pregnancy. These events are very stressful during pregnancy[21]. As a matter of fact, women who have had a previous surgical delivery are more likely to experience feelings of loss, personal failure, and low self-esteem[33].

Additionally, the presence of physical symptoms, such as nausea, vomiting, and fatigue, have been associated with increased risk of antenatal depression because they can have negative effects on women's daily lives[39]. With respect to caesarean section, this sort of delivery is highly influenced by cultural issues too. In some countries, having a caesarean birth would be an adverse event, while in others the adverse event is having a normal delivery. In fact, in recent decades, caesarean deliveries have become normalized in many countries, up to the point that organizations such as the World Health Organization have warned of the risks that these entail. It is worth highlighting the aspect of "perception" here because in many cases what the woman considers a complication is not so from the clinical point of view. For instance, some women perceive that having low back pain or nausea are complications, while for a health professional both entities would be considered physiological or within normality. Therefore, what it is relevant at a psychological level is not what is reflected in the medical history or what the professional thinks, but the perception that the woman has of her own process.

Psychological variables

The psychological variables that have been most closely related to antenatal depression will be discussed below. Notable among these variables are a history of depression, anxiety, stress, and low perception of social support.

History of depression: Family and personal history of psychological disorder, specifically, personal history of depression[10-12,24,26,44], or psychological disorders in general[47] as well as family history of depression[48] have been associated with an increased risk of antenatal depression. Specifically, it was found that women with a previous history of depression had a tenfold increased risk of antenatal depression [26]. Patton *et al*[57] followed a sample of women for more than 30 years and found that 85.0% of those who had depressive symptoms during pregnancy also had mental health problems during adolescence or adulthood. This association may be due to the existence of a vulnerability to depression that may be intensified by lifestyle changes (sleep and eating patterns) as well as physical changes (symptoms and limitations) that take place in pregnancy[24]. Another possible reason that could explain this fact is the interruption of depression pharmacological treatment by the mother at the beginning of pregnancy for fear of possible teratogenic effects for the foetus[5].

Anxiety and stress: Regarding anxiety, its presence before and/or during pregnancy has been found to be associated with antenatal depression[10,15,46,50,56]. This may be due to the frequent comorbidity of both disorders[56]. In addition, both anxiety and antenatal depression share risk factors[58]. Ross *et al*[59] concluded that more than

50.0% of pregnant women with depression had also been diagnosed with anxiety. Therefore, depressive and anxiety disorders during pregnancy are probably not independent clinical entities[60]. It is worth noting that the Edinburgh Postnatal Depression Scale, designed specifically to detect depressive symptomatology, includes three items that assess anxiety, so it is not surprising that women who score high on this scale score high on depression and on anxiety.

Likewise, different studies have found that high levels of perceived stress during pregnancy and adverse life events play an important role in the onset of antenatal depression[15,42,46,50,61-63]. This may be because the time of pregnancy is especially considered as stressful for many women because of the changes this period causes in their lives[64]. They may experience fear for the baby's health and well-being, fear of impending childbirth, hospitals, postpartum, and maternal role coping[65]. In fact, maternal stress, also called pregnancy-specific distress or pregnancy-related stress[66], is considered a negative emotional state different from depression and anxiety[67].

Social support: Regarding social support, research agrees that the absence or low perception of social support[39,46,49] and specifically the lack of partner support[43, 52] increases the risk of antenatal depression. Social support has been found to be crucial for psychological well-being during pregnancy[39]. In this regard, family contexts are important, although they differ substantially across cultures[52]. On the one hand, nuclear family settings are common in Western countries, whereas extended family structures are more frequent elsewhere such as Asia and/or Arab countries [18]. Some authors[38,68] found that women living in a nuclear family environment were at higher risk of developing antenatal depression *vs* those in the context of a multigenerational household. This may be due to women feeling isolated and less socially supported than they would in a larger family setting. In contrast, living in an extended family has been identified as a protective factor for antenatal depression[69]. However, González-Mesa *et al*[52] found the opposite scenery, as women living in larger families, with a larger number of children and more relatives living in the same household, were at higher risk for antenatal depression. Despite beliefs about the strength of traditional family relationships, 40.0% of these women claimed to have had insufficient family support. Perhaps in the case of social support it is not so much the number of people you live with, but rather the support they give you.

In this respect, the possible explanations provided in the studies, for the connection between lower perception of social support and depression, are more based on the protective effect of social support on depression than on low social support as a risk factor for depression. Moreover, social support during times of stress can be a protective factor against the onset of depression, as it moderates the stress of pregnancy and childbirth and increases maternal self-efficacy[70], that is, the belief in one's own capacity as a mother. Therefore, continuous social support can facilitate the process of adaptation to motherhood[71]. However, it should be noted that the important thing is that the woman perceives that she is indeed receiving this support.

Limitations

This review has met some limitations that ought to be mentioned. First, the review is confined to studies published in English, and thus generalizability of the findings is limited. Second, we did not conduct a meta-analysis of the findings, which may have added additional information about the differential impact of each risk factor. Nevertheless, most of the risk factors described in this review have been independently replicated by a number of studies. This review has excluded research prior to 2010 and based on high-risk populations (*e.g.*, studies conducted in women with pre-existing diseases, residents of war zones, poverty conditions, victims of gender-based violence). Therefore, the generalizability of the findings to these populations may be limited.

CONCLUSION

In view of the results found in this review, there seems to be evidence that sociodemographic, obstetric, and psychological factors can influence the mental health of pregnant women. Many of these factors cannot be modified, such as age and obstetric and psychological history, but others, such as anxiety, stress, or lack of social support, can be influenced through appropriate interventions. Therefore, it is important to identify these risk factors from the first pregnancy follow-up visits in order to be able to carry out preventive and/or therapeutic interventions if necessary. For this purpose,

we consider it necessary to implement routine and protocolized screening tools to identify women at risk of depression in regular pregnancy check-ups. Likewise, better use could be made of health resources already available as is the case of maternal education classes. The mere fact of attending, of being in contact with other women in the same situation and with the same needs, and of having a professional of reference who listens empathetically and resolves doubts can minimize the impact of the possible fears and worries that most women have during pregnancy. Both strategies would prevent and/or reduce the psychological distress of pregnant women, limit its continuation in the postpartum period, and, therefore, reduce the costs of care for the depression. By intervening at the right time, future problems can be prevented.

Abstract

The coronavirus disease-19 (COVID-19) pandemic has put healthcare workers in an unprecedented situation, increasing their psychological and mental health distress. Much research has focused on the issues surrounding anxiety, depression, and stress among healthcare workers. The consequences of mental health problems on healthcare workers' physical health, health-compromising behaviours, suicide ideation, family relationships, and job satisfaction during the COVID-19 pandemic are not well studied. Enhanced psychological stress has known effects on an individual's physical health. In healthcare workers with pre-existing comorbidities, psychological stressors may exacerbate their current health problems. Healthcare professionals are known to have a high risk of substance use, hence they may be at risk of development of substance use addiction or vulnerable to addiction relapse. Frontline COVID-19 healthcare workers are being pushed above and beyond their limits, possibly resulting in suicidal tendencies. Furthermore, the burden of high workload and burnout may also have serious manifestations in relationships with family and an intention to quit their jobs. Future studies should explore the above-mentioned deleterious consequences to provide insight into the development of mental healthcare strategies to combat the psychological impact of COVID-19 on healthcare workers during the COVID-19 emergency. It is imperative to employ strategies to care for and policies to protect the psychological well-being of healthcare workers.

Core Tip: Much has been investigated surrounding the issue of anxiety, depression, and stress during the coronavirus disease-19 (COVID-19) pandemic among the healthcare workers in China. Nonetheless, the consequences of psychological and mental distress on healthcare workers' physical health, general well-being, family relationships, job satisfaction, and anticipated turnover are not well studied. We herein discuss the multi-faceted consequences of psychological and mental health on healthcare workers in China during the COVID-19 pandemic. This review also highlights the important areas overlooked in research and mental health policies.

INTRODUCTION

Coronavirus disease-19 (COVID-19) infection was first reported in Wuhan, China in December 2019, and spread rapidly throughout China. Just 3 mo later, the World Health Organization (WHO) declared the spread of the COVID-19 as a pandemic. In a short one year, the COVID-19 pandemic has become a major global health crisis. While the pandemic is still a crisis in many countries worldwide, China has managed to control the pandemic rapidly and effectively in just over 3 mo after its onset[1]. As of the end of December 2020, China had confirmed 96324 cases of COVID-19 and 4777 deaths, while there have been over 79.2 million cases and over 1.7 million deaths globally since the start of the pandemic[2].

The COVID-19 pandemic is not only a threat to human life. Beyond the direct impacts of the virus, the mental health of the entire population is profoundly impacted. More importantly, the psychological and mental health of healthcare workers has been greatly challenged during this pandemic owing to their often extensive and close contact with COVID-19 patients in healthcare settings. High rates of infections and deaths among the healthcare workers involved in the fight against COVID-19 are causing them to experience high levels of distress and fear[3,4]. Worldwide, COVID-19 has affected large numbers of frontline healthcare workers. As of April 8, 2020, the WHO estimated that over 20000 health workers in 52 countries had contracted COVID-19[5]. In China, the outbreak has forced health professionals to work under extreme pressure and uncertainty, battling the novel coronavirus that is not fully understood and has claimed many lives. In a short intense 3 mo of battle against the coronavirus, the outbreak has exerted significant negative psychological impacts on healthcare professionals, particularly frontline health workers. A study of over 72000 patients with COVID-19 by the Chinese Centre for Disease Control and Prevention showed that around 3000 healthcare workers had become infected by February, accounting for 3.8% of all cases of COVID-19[6]. In addition to the fear of contagion during the early phase of the outbreak, healthcare workers in Wuhan also faced enormous pressure, including inadequate protection from contamination, work burden, isolation, witnessing patients suffering and dying, a lack of contact with their families, fear of transmitting the disease to families and loved ones, and exhaustion, which collectively contributed to serious mental health problems such as stress, anxiety, depressive symptoms, and insomnia[4,7].

Since the onset of the pandemic, there have been many published studies on the mental health of healthcare workers in the COVID-19 pandemic in China and other countries impacted by the COVID-19 pandemic. There were also several systematic reviews and meta-analyses that synthesised the findings of all published studies. A systematic review and meta-analysis of 13 studies of mental health during the COVID-19 pandemic published up to April 17, 2020, of which 12 were from China and one from Singapore, reported a pooled prevalence of 23.2% for anxiety, 22.8% for depression, and 38.9% for insomnia[8]. An integrative review of the mental health of healthcare professionals in China during the new coronavirus pandemic found intense psychological experiences, traumatization, and various mental health disorders among healthcare workers, while also describing the importance of self-coping and psycho-

logical needs[9]. A recently published meta-analysis of eight studies of frontline healthcare workers in China reported that the pooled prevalence of depression and anxiety was 31.5% and 23.7%, respectively[10], which was relatively higher than the former.

Although much has been investigated surrounding the issue of psychological and mental health impacts of the COVID-19 pandemic, most of the current published literature and reviews have investigated the level of anxiety, depression, and stress. The negative consequences of psychological and mental impacts during the era of the COVID-19 pandemic remain a relatively neglected area of inquiry. Among these are physical health, health-compromising behaviours, such as substance use disorders, suicide attempts or suicidal ideation, the disruption of family relationships, and the intention to leave jobs. To date, it has been over a year since COVID-19 first emerged in China. Many countries in the world are facing a resurgence of COVID-19 cases as the pandemic progresses. Healthcare workers in China may once again resume the COVID-19 battlefield and continue facing psychological distress. In light of the preceding discussion, this article discusses the multi-faceted consequences of psychological and mental health on healthcare workers in China during the COVID-19 pandemic.

PHYSICAL HEALTH

Recent research continues to demonstrate that poor mental health is related to adverse physical health[11]. Mounting evidence is showing associations between psychological distress and physical health such as hypertension and cardiovascular diseases[12]. Emerging evidence indicates that the COVID-19 pandemic has posed significant psychological stress on the community with emerging cardiovascular implications [13]. Recent reports show the link between emotional pressure caused by COVID-19 and takotsubo cardiomyopathy presenting as acute heart failure[14]. Despite this, increasing trends in the prevalence of chronic diseases are not prominent. This could be due to a large delay in treatment-seeking during the pandemic[13]. Henceforth, public as well as healthcare workers with pre-existing cardiovascular comorbidities and psychological stressors may exacerbate their current health conditions. More importantly, a study in China showed that patients with hypertension were associated with severe outcomes from COVID-19[15]. Furthermore, there is also a significant association between the fatality rate in COVID-19 patients and cardiovascular metabolic diseases[16]. As in many developing countries, in China, hypertension remains a pervasive problem among Chinese adults. Results from the China Hypertension Survey 2012–2015 stated that 23.2% (approximately 244.5 million) of the Chinese adult population ≥ 18 years of age had hypertension[17]. The high prevalence of cardiovascular risk factors was also reported among healthcare workers in China and is of growing concern. The prevalence of hypertension among nurses in China was reported to be close to 30%[18]. Although it is well established that stressful life events are a factor mediating the progression of chronic diseases such as cancer growth and development of metastases[19], as well as metabolic syndrome and type II diabetes mellitus[20], direct evidence linking to COVID-19 pandemic related stress has yet been reported. Considering that untreated psychological and mental health problems may cause severe physical health problems, it is of utmost importance not to downplay the psychological and mental health of healthcare workers with cardiovascular risk factors or chronic illnesses during their fight against COVID-19.

Thus, it is essential to build a work environment where there is some recognition of mental health as a dangerous risk factor to physical health, particularly during the current pandemic situation. Raising awareness of mental health as a dangerous risk factor to physical health is also important because mental health literacy may help an individual to cope, seek help, or self-advocate for health improvement[21]. Having a workplace mental health policy that looks into the well-being of healthcare staff with health issues or comorbidities is of paramount importance. Local evidence on the interlink of physical and mental health problems remains a crucial area of investigation in China.

SUBSTANCE USE DISORDERS

The COVID-19 pandemic has serious implications for people with substance use disorders. Fear of contagion, uncertainty and anxiety, social distancing and isolation, loneliness, and economic repercussions were among the factors that promote substance use during the pandemic[22]. Deaths from alcohol, drugs, and suicide, collectively known as "deaths of despair", are receiving growing international attention[23,34]. According to the findings of a study from the Well Being Trust released in May 2020, an estimate of 75000 "deaths of despair" associated with drug, alcohol, and suicide has been directly related to the COVID-19 pandemic[25]. Recently, it is estimated that the number of "deaths of despair" could double up to 150000 due to the pandemic's slow recovery[26]. Stressful events have long been known to also cause increased substance use risk in healthcare workers[27-29]. An issue that is overlooked in the COVID-19 pandemic crisis among healthcare workers is the reactive behaviour to negative impacts of disasters such as the development of addiction and addiction relapse vulnerability. There has been a report of an increase in substance use among people who have existing substance problems in China in the era of the COVID-19 pandemic[30]. Nevertheless, to date, relatively little has been reported in substance use among healthcare workers in China during the COVID-19 pandemic. Healthcare workers may similarly be vulnerable to substance use disorders during the COVID-19 pandemic. In a previous report, post-traumatic stress disorder (PTSD) and alcohol abuse or dependence symptoms 3 years post Beijing's 2003 SARS outbreak were prevalent among hospital employees who lived through the outbreak[31]. Substance use prevention and cessation support should be provided in healthcare settings. Increased substance abuse during the COVID-19 pandemic among people without a substance abuse history has not been reported and warrants further observation. Despite this, psychological intervention and advice for preventing substance use during the COVID-19 pandemic should be disseminated to the public at large and specifically targeted at people with a history of substance abuse. Given the amount of intensified psychological and mental issues facing medical care workers during the pandemic, understanding the extent and nature of healthcare workers' substance use disorders is essential for appropriate psychosocial management and successful treatment. However, the stigma associated with substance use disorders covers the entire trajectory of diagnosis, prevention, treatment, and recovery; hence, this is a major obstacle for healthcare-providers seeking diagnosis and treatment. There is a need to sensitise the public and healthcare organisations about addiction-related issues among healthcare workers during this pandemic. Family members' awareness and involvement in the treatment of substance use disorders are imperative[32]. Health systems should also facilitate access to substance use disorder treatment for healthcare workers, particularly those with pre-existing psychiatric conditions.

SUICIDE ATTEMPTS AND SUICIDAL IDEATION

Suicide is a worldwide phenomenon and studies have shown that suicide deaths are related to mental health disorders. There is growing concern that multiple lines of evidence point towards the increase in the rates of suicide attempts and completed suicides during the COVID-19 pandemic[22,32-35]. The profound pandemic related psychological impacts associated with prolonged social isolation, loneliness, fear of COVID-19 infection, uncertainty, occupational deprivation, and economic difficulties lead to the development or exacerbation of depression and anxiety, and ultimately aggravate vulnerability to suicidal thoughts and behaviours[22]. Vulnerable populations to the exacerbation of psychological or mental-related disorders and suicidal thoughts include individuals with pre-existing psychiatric disorders, less resilient people, those living in high COVID-19 prevalence areas, and people who have lost loved ones to COVID-19[36,37]. People in the medical-related profession have also been known to have a high prevalence of suicide attempts and suicidal ideation[38]. It was noted that the COVID-19 pandemic has increased the risk of suicide among healthcare workers due to the increased psychological distress, including witnessing COVID-19 patients' deaths, a lack of feelings of control, personal blame for the inability to do more for patients, and increased working hours[39]. Suicide cases among healthcare workers have been reported across many countries including the United States, England, Italy, Mexico, and India[40-42].

In China, relatively little has been reported on suicidal ideation or suicide attempts among the healthcare workers in Wuhan, the epicentre of the coronavirus outbreak,

despite a high level of psychological and mental disorders during the early phase of the outbreak. China has promptly launched a psychological intervention and mental health support system to cope with the widespread psychological stress during the COVID-19 pandemic[43,44]. Psychological assistance hotlines providing online psychological counselling services have been established by mental health professionals in medical institutions, universities, and academic societies throughout all provinces and regions in mainland China, which provide free 24-h services that were widely made available to the public and healthcare workers. The online psychological self-help intervention systems include online cognitive behavioural therapy for depression, anxiety, and insomnia[45]. Of note, the current literature is lacking on suicide attempts or suicidal ideation in healthcare workers in China. It is unclear whether the lack of evidence is due to under-reporting or under-diagnosis. It is well known that despite the high rates of depressive and anxiety disorders among physicians, dealing with suicide is challenging as stigma and embarrassment prevent a large number of them from seeking care for mental health diagnosis and treatment[46].

Although the COVID-19 pandemic is largely under control in China now, PSTD in the aftermath of the COVID-19 pandemic is an issue that should not be overlooked. The impact on mental health can be long-lasting for large-scale crisis events like the COVID-19 pandemic[47]. The distressing events of the past 3 mo, particularly among the frontline healthcare workers providing care to patients with COVID-19, witnessing the pandemic's massive death and trauma, could lead to long-term mental health problems. A study reported that a total of 3.8% of 377 healthcare workers in China reported PTSD a month after the outbreak and those with PTSD had a significantly higher probability of experiencing poor sleep quality[48]. Another study of 863 medical care workers from seven provinces in China reported that 40.2% were positive for PTSD[49]. PTSD is known to be a risk factor for suicide and was found to account for 0.6% of suicides in men and 3.5% in women[50]. The psychological sequelae of the pandemic will probably persist for months and years to come and suicide is probably going to become an even more significant concern as the pandemic unfolds[35]. Suicide prevention research emphasises that building meaningful social connections and interventions to decrease burdensomeness among healthcare workers are urgently needed.

FAMILY RELATIONSHIP AND WELL-BEING

The coronavirus pandemic has profound negative emotional impacts affecting personal and family harmony worldwide. The fear and uncertainty associated with pandemics provide an enabling environment that may aggravate family conflicts or violence in a family or relationship[51-53]. Prolonged lockdown and long-term home isolation measures and the stress of the COVID-19 pandemic have aggravated family conflicts and strained relationships, leading to a variety of family problems, including family violence and divorce. In China, after the 2-mo lockdown, the number of cases of family violence and divorces surged in March[51]. It is unclear if the strain of life under lockdown has contributed to the increase in divorce rate as the unprecedented number of divorces could also be due to backlog in cases as the pandemic has forced offices to close for months. Little is known about whether the adverse psychological or mental health of healthcare workers during the COVID-19 pandemic has negative effects on their families or personal lives. It is well established that the high workload of healthcare workers has restricted their family life, leading to burnout and distress, which consequently have serious manifestations on family relationships and marital complications[54,55].

More research is needed to assess the experience of family turbulence due to the COVID-19 pandemic among healthcare workers in China. Sudden changes in daily work lives during the pandemic and high exposure to psychological distress are situations that put healthcare providers at an increased risk of negative effects on family relationships. Policies should take into consideration the implications of the pandemic on the family members of healthcare providers. Current mental health services and interventions for healthcare providers should adopt a more holistic approach, including supportive care for their family members and loved ones.

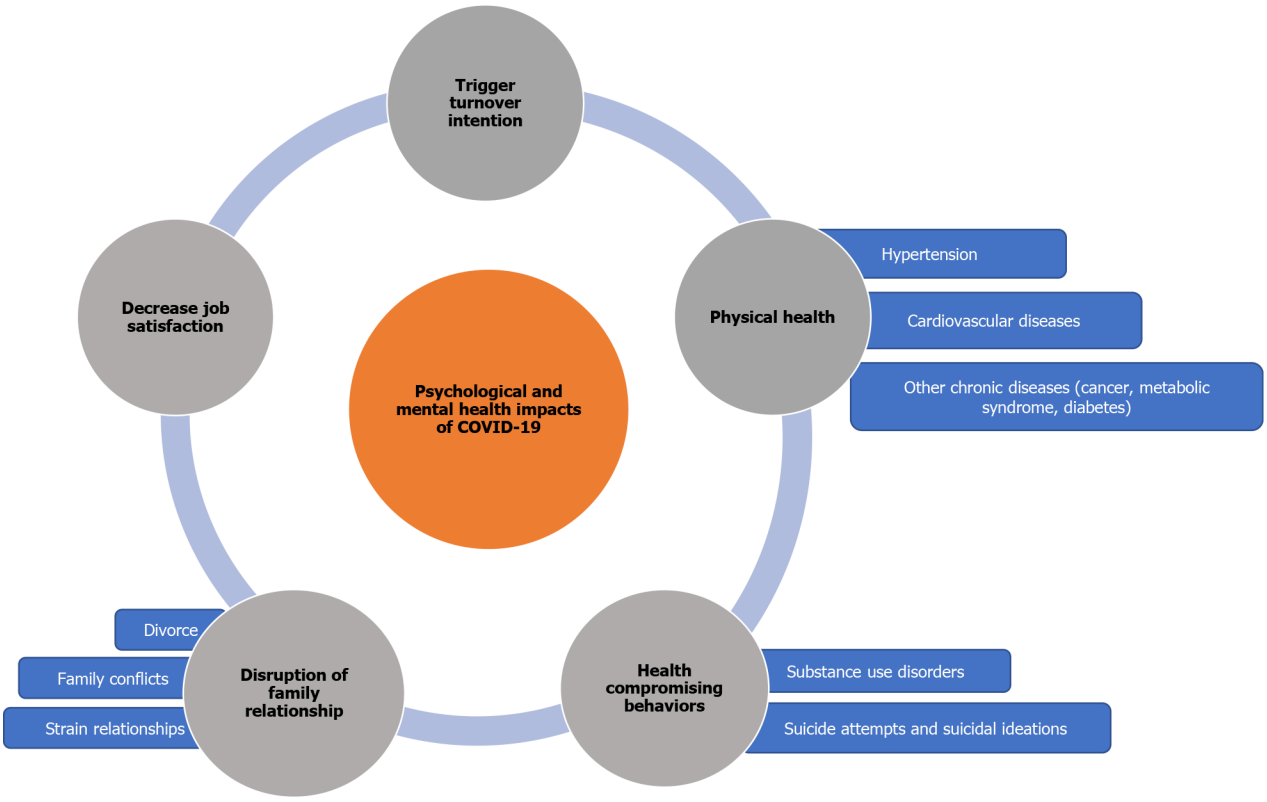

Figure 1 Summary of the psychological and mental health impact of coronavirus disease-19 pandemic. COVID-19: Coronavirus disease-19.

JOB SATISFACTION AND TURNOVER INTENTION

As the pandemic progressed, evidence began to show a deterioration in the psychological and mental well-being of healthcare workers, resulting in decreased job satisfaction and triggering turnover intention[56,57]. In China, although the statistics of healthcare workers quitting their jobs during the COVID-19 pandemic are unknown, poor psychological well-being and heightened turnover intention were evident in healthcare workers fighting COVID-19 during the peak of the outbreak[58,59]. It is crucial for healthcare workers to feel satisfied with their jobs during the COVID-19 pandemic. Poor level job satisfaction among healthcare workers during the COVID-19 pandemic has been reported in several studies worldwide. Mean occupational satisfaction of 3.6 (score range, 1-5) was reported during the COVID-19 pandemic among Israeli nurses[60]. Job satisfaction score of 2.8 (out of a possible score of 4) was reported in a large-scale study among healthcare workers in Italy[61]. Large-scale empirical study assessing the level of job satisfaction of healthcare workers in China is lacking. To date, two small-scale studies reported a job satisfaction score of 32 (out of possible 48)[59] and 82 (out of possible 100)[62] in healthcare workers in China during the COVID-19 pandemic. Further large-scale studies are warranted to accurately determine the level of job satisfaction of healthcare workers in China in the era of the COVID-19 pandemic. The shortage of healthcare professionals in China is an issue that has long been at the forefront of the healthcare industry before the COVID-19 pandemic, and the COVID-19 pandemic has simply increased the demand for healthcare professionals in China, resulting in the heightened importance of preventing the loss of the medical workforce in the healthcare service[63]. It is important to identify specific psychological or work problems surrounding poor job satisfaction and turnover intention among healthcare workers to enable more accurate targeted interventions. The catastrophic toll on mental health, inadequate protection, and fear of safety, along with that of their families, may cause many healthcare workers to choose to step away from their jobs[58]. As the need for medical doctors continues to increase with the world facing the unprecedented global health threat of coronavirus infection, the government must do everything in its power to retain employees in the healthcare setting.

The summary of psychological and mental health impacts of COVID-19 pandemic discussed is illustrated in Figure 1.

CONCLUSION

There is a need to recognise the adverse consequences of psychological and mental health problems on the well-being of healthcare workers. Poor psychological and mental health among healthcare workers is harmful not only to themselves, but also to their patients, families, organisations, and healthcare services. The public, healthcare organisations, and government authorities should be made aware of the manifestations of mental health among healthcare workers, their correlations, and the fact that any strategies to manage them must encompass all levels of society. The lacunae in the existing literature on the consequences of psychological and mental problems on healthcare workers may need to be completed over time through further research. Psychiatry and psychological first aid should be considered broadly during a crisis such as the COVID-19 pandemic. Efforts to destigmatise help-seeking behaviour for psychological and mental health problems are warranted. A workplace mental health strategy and policy are essential for a healthy workplace environment during a pandemic crisis.

Abstract

Evolving data show a variable expression of clinical neurological manifestations in patients suffering with coronavirus disease 2019 (COVID-19) from early disease onset. The most frequent symptoms and signs are fatigue, dizziness, impaired consciousness, ageusia, anosmia, radicular pain, and headache, as well as others. Based on the high number of series of cases reported, there is evidence for the implication of the immune system in the pathological mechanism of COVID-19. Although the exact role of the immunological mechanism is not elucidated, two main mechanisms are suggested which implicate the direct effect of severe acute respiratory syndrome coronavirus 2 infection in the central nervous system and neuroinflammation. In the context of neurological manifestations associated with COVID-19, neuropsychiatric disorders show an exacerbation and are described by symptoms and signs such as depression, anxiety, mood alterations, psychosis,

post-traumatic stress disorder, delirium, and cognitive impairment, which appear to be common in COVID-19 survivors. A worsened score on psychopathological measures is seen in those with a history of psychiatric comorbidities. We review the neuropsychiatric manifestations associated with COVID-19 and some critical aspects of the innate and adaptive immune system involved in mental health disorders occurring in COVID-19.

Key Words: COVID-19; Immunological mechanism; Neuropsychiatric manifestation; Cytokine storm; Adaptive immune response; Innate immune response

INTRODUCTION

The Coronavirus Disease 2019 (COVID-19) pandemic, at the time of this publication, has shown a tendency to a reduction in contagiousness globally; however, the fire has not gone out. Reports of the World Health Organization and Johns Hopkins University confirm as of March 18, 2021 that there have been 121 214 686 cases diagnosed around the world and 2 680 740 deaths as consequence of the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). It is accepted that this infection affects the nervous system in various ways as the virus is deeply neurotropic and neuroinvasive [1]. It will be necessary to understand the post-infectious manifestations of COVID-19 to guide long-term management of neurodevelopmental and neuropsychiatric diseases.

Data derived from published clinical papers and case reports indicate that the main clinical manifestations of COVID-19 include anosmia, ageusia, central respiratory failure, stroke, acute inflammatory demyelinating polyneuropathy, toxic metabolic encephalopathy, headache, myalgia, myelitis, ataxia, and others[2,3]. As suggested earlier, in the acute phase, COVID-19 is a potential causal factor of neuropsychiatric manifestations, such as encephalopathy, psychosis, insomnia, and mood changes[4].

The neuropsychiatric manifestations of both viral infection *per se* and secondary to the host neuroinflammatory reaction are attributed to: (1) Microglial activation[5,6]; (2) An imbalance of central neurotransmitters, such as noradrenaline, epinephrine, and serotonin (with potential implication in neuropsychiatric disorders); and (3) A disruption of the blood–brain barrier (BBB) leading to peripheral immune cell transmigration into the central nervous system (CNS)[7]. This manuscript reviews core critical aspects of neuropsychiatric disorders and COVID-19 while focusing on the immunopathology and related clinical symptoms.

POTENTIAL IMMUNE MECHANISM AND NEUROPSYCHIATRIC SYMPTOMS IN COVID-19

The neuroinvasive potential of coronavirus has been reported in SARS-CoV-1 patients

and experimental animals[6], and it was also speculated to include SARS-CoV-2 in relation to the routes and mechanisms of CoV neurotropism[8,9]. Potential mechanisms of neuropsychiatric manifestations in COVID-19 are discussed from different viewpoints[10-13]; however, we will focus this short review on two main core mechanisms in support of CNS involvement in mental health associated with COVID-19: Direct viral infiltration into the CNS and neuroinflammation with related neuropsychiatric manifestations (Figure 1).

DIRECT VIRAL INFILTRATION INTO THE CNS

It is well-known that viral infection takes place by recognition and binding of SARS-CoV-2 virus-host receptor, specifically angiotensin-converting enzyme 2 (ACE-2), which is expressed in multiple tissues within the human body, including the CNS[1]. In the CNS, infection has been identified in glial cells and endothelial cells of blood vessels in the brain. In brain blood vessels, it has been demonstrated that it can induce disruption of the BBB and increase permeability[14-16].

One pathway for CoV invading the CNS is through synaptic routes of nerve cells, which seems to infect CNS retrograde *via* peripheral sensory nerves[17]. On the other hand, the olfactory nerve cells seem to be a feasible route for direct CNS infection, facilitated by the ACE-2 receptor expressed in olfactory epithelial cells[1]. Although this mechanism does not have a full consensus from various research groups, several pieces of evidence confirm that after cell infection by CoVs, death can be caused by autophagy, apoptosis, pyroptosis, or by elimination *via* innate immune cells[17,18] (Figure 1).

NEUROINFLAMMATION

It has been found that following SARS-CoV-2 infection, activation of both the innate and adaptive arms of the immune system are induced toward an uncontrolled systemic response with the intervention of a non-specific immune mechanism involving activated macrophages, neutrophils, and natural killer cells, as well as an adaptive immune mechanism with a relevant effector function mediated by dendritic cells and lymphocytes. The adaptive mechanism includes T helper cells (CD4), T cytotoxic cells (CD8) and B cells, which is followed by exaggerated pro-inflammatory cytokine release from these effector cells, such as interleukin (IL)-1b, IL-6, IL-10, IL-12, interferons (IFN)-alpha, IFN-gamma, tumor necrosis factor (TNF)-alpha, transforming growth factor-beta, and chemokines (CCL2, CCL3, CCL5, CXCL8, y/o CXCL10). This begins the so-called "cytokine storm", which is critical for the multi-organ failure leading to high lethality observed in affected patients[12,19-22].

The neuroinflammation caused by SARS-CoV-2, secondary to the cytokine storm and immune cells reactivation, also becomes an additional effect of CoV infection[21]. In this context, several pathways have been discussed regarding the strong immune response in humans secondary to SARS-CoV-2 infection[22]. A marked reduction in absolute count of T cells, monocytes, eosinophils, and basophils has been found during this infection, with a main impact on the absolute decrease of T cells, memory T helper and regulatory cells[23,24].

Besides the explosive cytokine release syndrome and the macrophage activation syndrome co-existing in SARS-CoV-2 infection and affecting the CNS, there is also a strong increase in pro-inflammatory cytokines, such as IL-6, IL-2, IL-17, granulocyte-colony stimulating factor and TNF[24]. Inflammatory conditions can also induce the increase of IL-1, IL-6 and TNF soluble mediators that might facilitate major BBB permeability[25], as they have been responsible for neurological manifestations such as encephalitis, CNS demyelination and neuropsychiatric disorders[26].

Even in the absence of SARS-CoV-2 CNS infiltration, a transmigration of peripheral cytokines derived from the systemic host antiviral response may also take place to induce neuropsychiatric symptoms by the neuro-inflammatory response and BBB disruption. This may be caused by the peripheral effector immune cells migrating into the CNS, as well as local impairment of the neurotransmission system[27,28]. High levels of neurotransmitters, mainly noradrenaline, epinephrine, and serotonin, have been associated with psychological manifestations, such as depression, anxiety, and post-traumatic stress disorder[20].

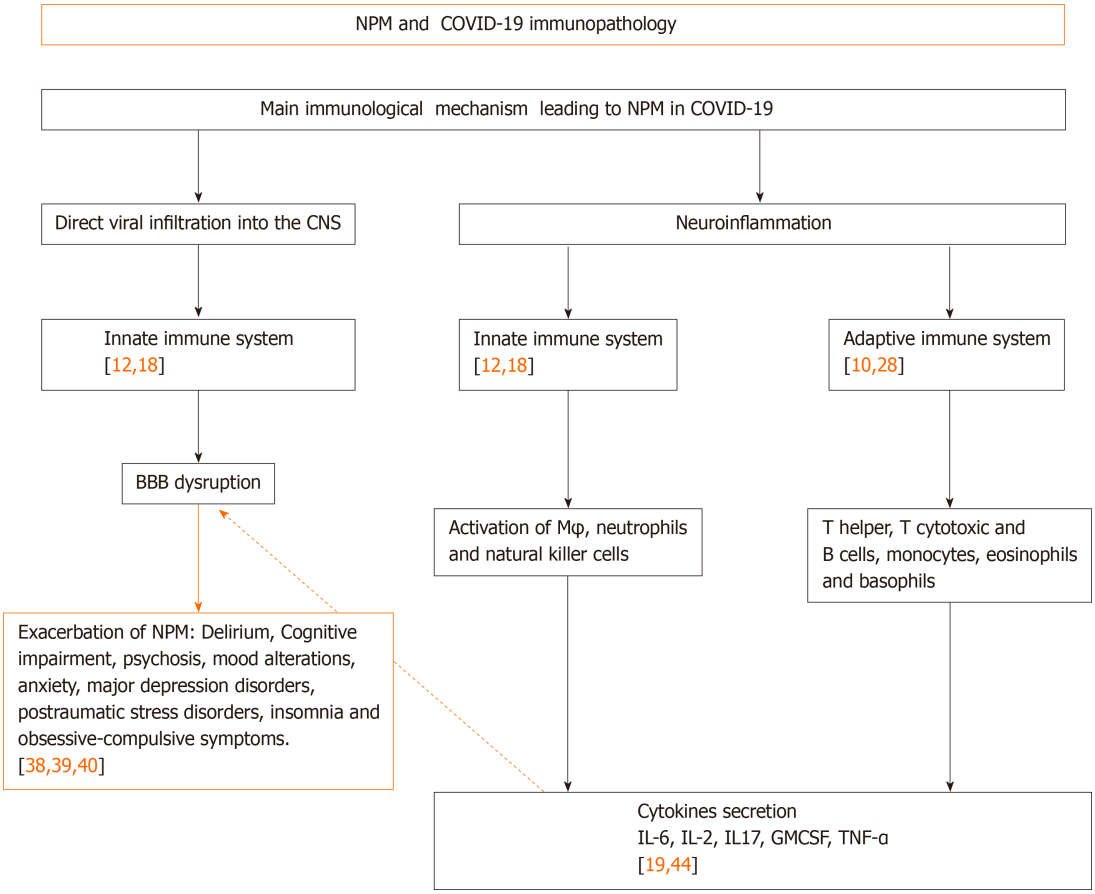

Figure 1 Immunological mechanisms of neuropsychiatric manifestations derived from severe acute respiratory syndrome coronavirus 2 infection. COVID-19: Coronavirus disease 2019; CNS: Central nervous system; NPM: Neuropsychiatric manifestation; M: Macrophages; BBB: Blood-brain barrier; GMCSF: Granulocyte-colony stimulating factor; IL: Interleukin; TNF: Tumor necrosis factor.

It seems possible that the hypothesis of cytokine storm being associated with psychiatric manifestation induction is an indirect consequence of the hyperinflammation. Previous studies regarding pandemics caused by respiratory viruses suggest that diverse occurrence of neuropsychiatric symptoms can take place during or after the acute infection, which may be underlined by the presence of persistent cognitive deficits.

In the COVID-19 acute phase, besides the psychosocial stressor factors, it has been argued that the infection underlying the pathophysiology of neuropsychiatric manifestations, such as encephalopathy, psychosis, insomnia, and mood changes, post-traumatic stress disorder, panic attacks, and anxiety, mostly seen in health care workers and survivors of SARS-CoV infection, have been mainly attributed to viral infection *per se* and secondary to the host immune response. In this way, direct viral infiltration of the CNS can trigger an inflammatory reaction at the brain level leading to local microglial activation, which in turn induces demyelinating processes that are one of the primary causes of encephalopathy. In the absence of direct viral infiltration, a peripheral cytokine storm causing an imbalance of neurotransmitters within the CNS has been implicated in neuropsychiatric manifestations. This cytokine storm induces a neuroinflammatory response causing disruption of the BBB, leading to peripheral immune cell transmigration into the brain and, in turn, causes imbalances in neurotran -smission.

It continues to be a challenge for researchers to elucidate the real core mechanisms of COVID-19 associated neuropsychiatric complications due to general findings caused by SARS-CoV-2 infection. This may be difficult to distinguish from the encephalopathy arising from systemic infection without affecting brain tissue[29]. Evidence such as the increase in IL-6 has been linked to high mortality in patients with COVID-19[19], similar to the increase in this cytokine observed in other neuropsychiatric disorders such as schizophrenia and depression[19].

Other arguments underlining the immunological mechanism identify that peripheral myeloid cells are also infected by CoV[5], which can be recruited to

transmigrate to the CNS under an increased BBB permeability. Virus-infected monocytes in the CNS can promote microglial activation as well as induce neuropsychiatric symptoms[5,27,28]. The role of microglial activation in schizophrenia and autism is well known[30,31,32]. Other mechanisms implicating mental disease in COVID-19 are the close inter-relation between the systemic compartment and the brain[7] (Figure 1).

NEUROPSYCHIATRIC FINDINGS IN THE COVID-19 PANDEMIC

Since the initial phase of the COVID-19 pandemic, a large number of studies have shown the clinical symptoms and signs of the infection. These principally include fever, cough, sore throat, dyspnea, nausea, diarrhea, and fatigue[27,33]. However, numerous reports also reveal an accumulation of frequent neurological symptoms in COVID-19 positive patients, such as dizziness, ageusia, fatigue, headache, impaired consciousness, and anosmia[34-36].

Parallel to the neurological events, evidence is growing for neuropsychiatric disorders that are also reported as secondary complications of SARS-CoV-2 infection [37], which will be made clear in the few years. In this context, an exacerbation of mental health disorders has been described in COVID-19 that include delirium, cognitive impairment, mood alterations, and psychosis[38-40]. Delirium occurs in 90% of COVID-19 cases, while cognitive disorder is also considered a direct consequence of CNS infection by SARS-CoV-2[39]. Anxiety, depression, post-traumatic stress disorder, insomnia, and obsessive-compulsive symptomatology, mainly in females, appear to be quite common in COVID-19 survivors and coworkers with worsened scores on psychopathological measures in those with a history of psychiatric comorbidities. In addition, hypoxemia, a frequent clinical finding in COVID-19, can also produce mental health impairment[38]. Thus, a consequence of acute respiratory syndrome and associated relative hypoxia also shows worsening of attention, executive function, and verbal memory[41].

An exaggerated immune response, under a dysregulated cytokine network, occurring during the COVID-19 pandemic would also drive symptoms of visceral stress with an impact on mental health[38,42]. In this line of thinking, authors have defined a relationship between COVID-19 disease severity, somatic and psychiatric symptoms, and cytokine levels in patients positive for SARS-CoV-2 infection. There is also some evidence that patients with comorbidities and immunosuppression are more susceptible to developing psychiatric disorders, such as cognitive impairment, anxiety, and depression[43,44].

Considering the trajectory of the occurrence of COVID-19 around the world, from its beginnings in China in December 2019, it is clear that not only patients but also their family and the normal population are victims of the psychosocial impacts derived from this pandemic[42,45]. From this viewpoint, it is clearly necessary to investigate the behavioral aspects of this disease, either in the short- or long-term, to identify a more valuable strategy to control the transmission by carriers and assess the impact of COVID-19, not only in affected patients, but also in the general population. We are proposing a diagram regarding the impact of the immunological mechanism involved in SARS-CoV-2 infection by the occurrence of neuropsychiatric manifestation as a tool of acknowledgment of the way the disease progresses which could allow better management of the disease and prevention of the consequences in the short- or long-term.

The long-term neuropsychiatric consequences of SARS-CoV-2 infection have been demonstrated in a fraction of cases; however, they appear to be significant for the future due to the global burden of COVID-19. In this context, to understand the evolution and specificity of neuropsychiatric outcomes stemming from SARS-CoV-2 infection and to elucidate the pathogenic mechanisms involved in these events should be useful in targeting critical interventions for the prevention of mental disorders derived from COVID-19. Nevertheless, the work of psychologists and psychiatrists concentrated on handling the psyche at clinics and paraclinics looking for more effective evidence of recovery from the potential neurological consequences will not be enough. It will be necessary to develop programs and strategies to achieve a more humanist medical approach to promote the resilience of the individuals affected as well as their parents to avoid the long-term occurrence of mental disorders due to the lost connection between the body and the soul. This is the neurobiological substrate in the development of neuropsychiatric disorders as a consequence of COVID-19. Finally, an earlier understanding of the characteristics of neuropsychiatric outcomes stemming

from SARS-CoV-2 infection and their pathogenic mechanisms will be necessary as an intervention target to avoid the sub-acute or chronic neuropsychiatric consequences of SARS-CoV-2 infection.

CONCLUSION

According to the numerous articles published since the beginning of the COVID-19 pandemic, it could be surmised that the accumulated knowledge would be enough to understand many of the events occurring in this illness. However, there is not enough data to understand the long-term consequences of this disease. The neuropsychiatric dysfunctions as part of the group of disorders unknown in the evolutionary context of COVID-19 could also be the result of an exaggerated host response against SARS-CoV-2 infection. The impact on the permeability of the BBB which facilitates the migration of immune cells to the CNS and their deleterious effect on neural function, followed by deregulation of the cytokine network that affects mental health, are manifested more frequently by anxiety, cognitive impairment and major depressive disorder. More studies will continue to be necessary to address this topic.

Abstract

The dopamine hypothesis of how antipsychotic drugs exert their beneficial effect in psychotic illness has an interesting history that dates back to 1950. This hypothesis is not to be confused with the dopamine hypothesis of schizophrenia; the aim of the latter is to explain the etiology of schizophrenia. The present review does not deal with schizophrenia but, rather, with the historical development of our current understanding of the dopamine-associated actions of the drugs that reduce the symptoms of psychosis. This historical review begins with the serendipitous discovery of chlorpromazine, a drug synthesized around a chemical core that initially served to produce man-made dyes. This molecular core subsequently contributed to the chemistry of antihistamines. It was with the aim of producing a superior antihistamine that chlorpromazine was synthesized; instead, it revolutionized the treatment of psychosis. The first hypothesis of how this drug worked was that it induced hypothermia, a cooling of the body that led to a tranquilization of the mind. The new, at the time, discoveries of the presence of chemical transmitters in the brain soon steered investigations away from a temperature-related hypothesis toward questioning how this drug, and other drugs with similar properties and effects, modulated endogenous neurotransmission. As a result, over the years, researchers from around the world have begun to progressively learn what antipsychotic drugs do in the brain.

Key Words: Chlorpromazine; Haloperidol; G-Protein coupled receptors; Binding assays; Receptor imaging; High affinity states

Core Tip: This history starts with the synthesis of chlorpromazine in 1950 and traces the steps taken to discover how this drug, and related drugs, work to reduce, sometimes to reverse, the delusions and hallucinations associated with psychosis. The task to understand how these drugs work in the brain continues, as many unknowns remain.

INTRODUCTION

The synthesis of chlorpromazine in 1950 marks the beginning of modern psychopharmacology. While the clinical usefulness of this drug was almost immediately recognized, it took another 20 years to begin to uncover its mode of action. This review covers the history of these years and the steps that were taken to arrive at the dopamine hypothesis of antipsychotic drug action. It more briefly also outlines how this hypothesis has fared over the ensuing years (Table 1).

HISTORY

Prior to the availability of chlorpromazine, many drugs had been used in psychiatry to tranquilize agitated patients, but this was the first psychoactive agent to not only calm patients, but also to decrease the intensity of their psychotic symptoms. Synthesized by Paul Charpentier of the French pharmaceutical company Rhône-Poulenc, chlorpromazine was the product of a long process that began in the mid-1800s, starting out as a search for a method to synthesize dyes. This search led, in 1883, to the identification by August Bernthsen of a molecular structure, which he called a phenothiazine nucleus, around which later generations of chemists began to make antihistamine drugs for the treatment of allergies. In 1947, the pharmaceutical company, Rhône-Poulenc, produced promethazine, a first generation antihistamine[1] (Figure 1).

Promethazine induced hypothermia in laboratory animals so, in 1949, French military surgeon, Laborit[2] tried giving it to soldiers in order to lower their body temperature and prevent shock before, during, and after surgical operations. He noted that promethazine induced a "euphoric quietude" in his soldiers[2].

Hoping to increase the potency of promethazine, on December 11, 1950, Charpentier *et al*[3] introduced a chlorine atom into one of the rings of promethazine (Figure 2).

The new drug was called RP (for Rhône-Poulenc) 4560. It was tested on rats and produced "detachment, slow reaction to stimuli, and a decrease in initiative." The compound was again sent for human trials to Laborit, now at the Val de-Grâce Hospital in Paris, and, because of its psychological effects in animals, to a variety of French psychiatrists as well.

The first published report of its effect in humans was by Laborit and his team in February 1952. They reported that the drug calmed anxious patients without producing oversedation[4]. Three psychiatrists reported on the effect of the drug one month later[5]. This team concluded that 50-100 mg of RP4560, diluted in a glucose solution and given intravenously to patients with mania, kept them calm for 3 to 18 h, as long as an analgesic or a barbiturate was administered concurrently.

In May 1952, psychiatrists Delay and Deniker[6] published their observation on the soothing effect of the drug in patients with psychosis[6]. In June, this team once again reported positive results[7]. Going on the theory that the drug worked by cooling the body, a therapeutic intervention commonly used by psychiatrists at the time[8-10], in July, Delay *et al*[11] published more detailed results of 8 cases treated with RP4560 [11]. They diagnosed six of these patients as suffering from acute mania, one was said to show "excited delirium." One patient showed "recurrent excitement" and was described as having "trouble thinking" and using "over rationalization." In today's classification systems, this patient might be diagnosed with schizophrenia. In this clinical group's hands, RP4560 was administered without adjuncts, by injection, with oral tablets substituted for injections usually by the 10th treatment day. The results were remarkable–calm was induced in all patients, with minimum sedation. This created such a sensation in psychiatric circles that, by November 1952, the drug had become available by prescription in France[12].

The pharmaceutical firm Smith Klein and French bought the American rights to the drug and, in 1954, received Food and Drug Administration approval to market it in the United States under the name, Thorazine. The advertisement in the May 1954 issue of the American Journal of Psychiatry read: "Thorazine is useful in controlling anxiety,

Table 1 Major steps in the dopamine hypothesis of antipsychotic drug action

Year	Major Advances
1950	Synthesis of chlorpromazine[3]
1952	Preliminary evidence of antipsychotic effect of chlorpromazine[6,7,11]
1958	Synthesis of haloperidol[16]
1960	Parkinson basal ganglia are deficient in dopamine[19]
1963	Neuroleptics raise level of monoamine metabolites[18]
1966	Neuroleptics may antagonize dopamine receptors[26]
1971	2 nmol haloperidol in plasma effective in psychosis[34]
1974	Synthesis of (+-) butaclamol[36]
1975	Tritiated haloperidol binds DA receptors[38]
1975	Effective neuroleptic dose correlates with D2 block[39]
1979	Multiple dopamine receptors[54]
1984	Bimodal D2 distribution in schizophrenia[45]
1984	High and low affinity states for D2[58]
1988	Cloning of the D2 receptor[63]
1988	*In vivo* imaging of D2 occupancy[47]
1990	Cloning of D3[67]
1999	Fast-off theory[71]
2000	Multiple genetic variants of D2 receptor[73-75]
2000	Impact of the D3 receptor[81]
2005	Impact of other neurotransmitter receptors[83]
2010	Impact of receptor heterodimers[85]
2017	Impact of D2 high affinity state[77]
2021	Structure and specificities of D1, D2 signaling complexes[79]

tension, agitation, confusion, delirium, or hostility, whether occurring in schizophrenic, manic-depressive, toxic, or functional states." [1]. In France and also in Canada[13-15], the drug was called Largactil. Since it was mainly used in hospitalized patients who, for the most part, suffered from psychotic disorders, it swiftly gained a worldwide reputation for being able to reverse the symptoms of psychosis.

The phenothiazine core molecule was malleable and comparably easy to copy so that compounds with very similar efficacy were readily produced. By 1964, a variety of pharmaceutical companies had synthesized and marketed their own phenothiazines: promazine, trifluprom azine, methoxypromazine, trifluoperazine, fluphenazine, thioridazine, and prochlorperazine. In 1958, haloperidol, a non-phenothiazine drug [a butyrophenone synthesized on the base of an opioid analgesic, meperidine (Demerol)] was created by pharmaceutical genius, Paul Janssen. This compound proved to be more potent against delusions and hallucinations than the phenothiazines[16].

Both phenothiazines and butyrophenones were initially called 'major tranquilizers' to distinguish them from the 'minor tranquilizer,' meprobamate[17], which was being widely marketed at the time for anxiety.

Searching for the mode of action of major tranquilizers, in 1963, Carlsson and Londqvist[18] reported that this category of drugs increased the level of metabolites of catecholamines. They suggested ''. . . that chlorpromazine and haloperidol block monoaminergic receptors in brain . . . .'' It was not possible at the time to selectively distinguish among alpha-adrenoceptors, beta-adrenoceptors, and dopamine receptors.

There were, nevertheless, several reasons to believe that it was the dopamine pathway that was involved. Firstly, the clinical side effects of chlorpromazine and haloperidol were tremor, rigidity, and akinesia -*e.g.* Parkinsonian signs and, by then, Parkinson's disease had been linked to a deficiency of dopamine[19]. Secondly, it had already been suggested that dopamine-mimetic drugs such as amphetamine acted *via*

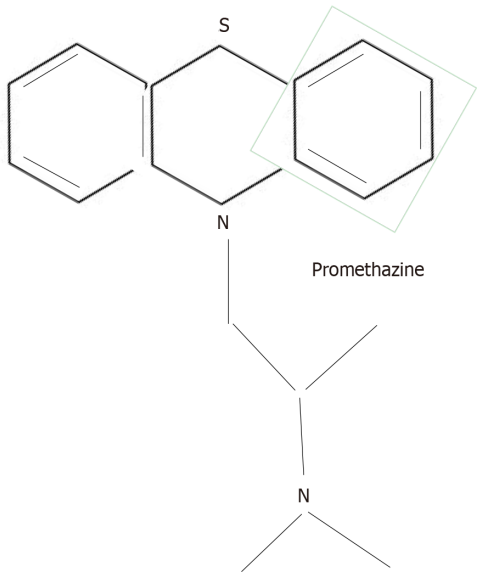

Figure 1 Promethazine.

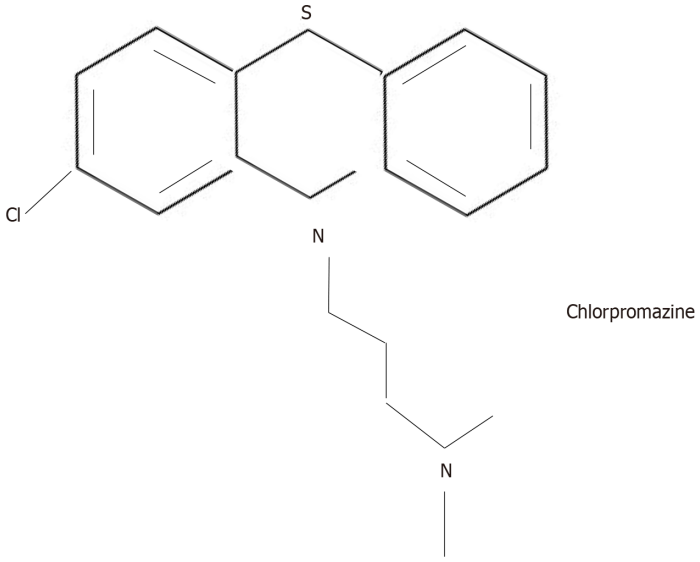

Figure 2 Chlorpromazine.

dopamine receptors[20] and that amphetamines could induce schizophrenia-like psychotic symptoms in patients[21,22]. Disulfiram (Antabuse), in clinical use to prevent alcohol addiction, was known to inhibits dopamine beta-hydroxylase, the enzyme that converts dopamine to noradrenaline, and this drug, too, was capable of inducing psychosis[23].

There were also reports of chlorpromazine accelerating the turnover of dopamine [24]. Van Rossum[25] had noticed in 1965 that major tranquilizers (or neuroleptics as they were called by this time), though not, as was first thought, particularly antiadrenergic, were, instead, potent amphetamine antagonists[25].

The significance of dopamine for the action of antipsychotic drugs, a breakthrough often attributed to Arvid Carlsson (who did not seriously consider dopamine in the context of the action of these drugs until much later) was first formulated by Jacques van Rossum. In 1966, van Rossum[26] hypothesized that dopamine receptor blockade was a likely explanation for the mechanism of action of this group of drugs. He referred to neuroleptics as the first available dopamine antagonists. In 1967, van Rossum[27] wrote: "When the hypothesis of dopamine blockade by neuroleptic agents can be further substantiated, it may have far going consequences for the pathophysiology of schizophrenia. Overstimulation of dopamine receptors could then

be part of the aetiology. Obviously such an overstimulation might be caused by overproduction of dopamine, production of substances with dopamine actions (methoxy derivatives), abnormal susceptibility of the receptors, *etc.*"[27].

Van Rossum, thus, formulated *two* dopamine hypotheses (1) The hypothesis that dopamine receptor blockade was responsible for the antipsychotic effects of drugs like chlorpromazine, haloperidol, and similar drugs; and (2) The hypothesis that an excess of dopamine might be part of the etiology of schizophrenia. These two distinct hypotheses are often conflated[28].

They are conflated because, in the 1970s, it was hoped that the discovery of how neuroleptics work could lead to understanding the nature of schizophrenia itself. Based on the fact that amphetamine releases dopamine and amphetamine-induced psychosis is clinically very similar to an acute episode of schizophrenia[29], van Rossum[27] thought that schizophrenia might be due to an overproduction of dopamine[27].

From today's standpoint, overactivity of dopamine, while possibly explaining the hallucinations and delusions of schizophrenia, does not shed light on the more fundamental negative and cognitive symptoms of schizophrenia. Over the years, many attempts have been made to elaborate and expand on van Rossum's dopamine hypothesis of schizophrenia to account for symptoms other than delusions and hallucinations[30,31]. It remains the case, however, that schizophrenia is too multifaceted and heterogeneous a disorder to be fully explained by dopamine overactivity alone. That being said, it is still possible that the secretion and transmission of dopamine serves as a final common pathway to the expression of specific schizophrenia symptoms[32].

Van Rossum's first hypothesis-that neuroleptics (today referred to as antipsychotics) exert their effect through dopamine receptors–has enjoyed a longer life than his second. In 2020, Kaar *et al*[33], in their review of mechanisms underlying clinical response to antipsychotics, conclude that "all currently licensed antipsychotic drugs show appreciable binding to dopamine D2 receptors at therapeutic doses, and this action is core to their therapeutic action."

Van Rossum[25-27] had pointed out that overstimulation by dopamine could result from a number of potential causes, from overproduction by the secreting cell to oversensitivity of receptors on the post-synaptic cell. By extension, antipsychotic drugs could theoretically act by blocking dopamine synthesis or secretion or by interfering with its transport across the synapse or by blocking membrane receptors.

In 1971, Zingales[34] reported that the concentration of haloperidol in the plasma of treated patients was approximately 3 nanograms *per* millilitre of plasma (3 nmol)[34]. Because over 90% of haloperidol in plasma is bound to plasma proteins, the actual free concentration that enters the brain would then have to be approximately 1 nmol. This was a problem for the radioactive tagging needed in the search for specific targets of haloperidol action. The classical way to find a drug target was to tag the drug with a radioactive marker. In this case, however, because the drug needed to be diluted down to 1 nmol and still have enough radioactivity left for the experiment to succeed, the radioactive label had to be extra powerful. No such label existed at the time.

In November 1971, Philip Seeman, a Toronto physician/pharmacologist, asked Paul Janssen to persuade the company, I.R.E. Belgique, to prepare radioactive haloperidol at a high specificity of 10.5 Curies *per* millimole, which the company succeeded in doing in 1974.

True drug receptor targets have to take up the radioactively labelled ligand; a second important criterion in identifying a specific site of action is stereoselectivity–the configuration of the relevant molecule must fit the configuration of the target[35]. Seeman obtained mirror image antipsychotic molecules (+butaclamol and -butaclamol), the first one active, the second inactive[36,37]. A specific antipsychotic target was confirmed when the site was blocked by +butaclamol to a significantly greater degree than it was by -butaclamol. This more or less settled the identity of the antipsychotic receptor. A further step was to see which of the endogenous neurotransmitters had the most affinity for this location. When tested against noradrenaline, acetylcholine, serotonin, and dopamine, dopamine proved to be the most potent. This meant that the antipsychotic receptor was a dopamine receptor[38].

Soon after discovering the receptor, Seeman *et al*[39,40] showed that the published clinical doses of all antipsychotic drugs available at the time, regardless of their molecular structure, directly correlated with their ability to displace radioactive haloperidol[39,40]. This graph has recently been called "the most famous graph in schizophrenia therapeutics."[41]. The findings from the Seeman laboratory were soon confirmed by binding studies from other labs[42-44]. A further confirmatory finding was that treatment with antipsychotic drugs increased the density of dopamine

receptors in post mortem brain tissue of individuals with schizophrenia[45].

In vivo molecular imaging studies were not initially available but, when they were, they were eventually able to confirm striatal dopamine D2 receptor blockade at clinically effective doses of all antipsychotic drugs, including first and second-generation agents and dopamine partial agonists[46-52]. The initial molecular imaging studies in patients with treated schizophrenia suggested a therapeutic window (relatively good response without unacceptable extrapyramidal adverse effects) of between 60% and 80% D2 receptor occupancy. The definition of 'response,' of course, varies and non-response did not necessarily correlate with low occupancy rates[53].

Since then, the field of dopamine receptors has considerably expanded[54]. The receptor labeled by [3H] haloperidol was called D2[55,56], because, by the mid 1980s, five dopamine receptors, all belonging to a G-protein coupled set of receptors, had been isolated. Today, D1 and D5 are known to stimulate the cyclic adenosine monophosphate signaling pathway through G_s G-proteins, whereas D2R, D3, and D4 inhibit this signal *via* G_i/o G-proteins[57]. Moreover, each of these receptors can exist, as can all G-protein linked receptors, in a state of high or low affinity for their ligand [58,59]. Of the 5 known dopamine receptors, D1, D4, and D5 were cloned in the Seeman laboratory[60-62].

The dopamine D2 receptor was cloned in 1988 in the Civelli lab[63,64]. In 1989, Grandy *et al*[65] used in situ hybridization to map the gene to the 11q22–q23 junction.

Because of the excellent correlation between the affinity for striatal D2 receptors and the average clinical dose of antipsychotic drugs given to patients with schizophrenia, there was at first general agreement that all effective antipsychotic drugs must act by not only blocking dopamine D2 receptors in the striatum, but also blocking them in the mesolimbic system, where symptoms of psychosis are thought to originate[66].

In 1990, the D3 receptor (closely related to D2) was cloned in the laboratory of Jean-Claude Schwartz[67].

Soon after, the 2nd generation antipsychotic drugs were brought to market, and they appeared to have much lower affinity for the D2/D3 receptors (they induced far fewer extrapyramidal symptoms) but to be just as potent against psychotic symptoms (delusions and hallucinations) as the older drugs. Clozapine, in particular, the best antipsychotic in that patients resistant to all other drugs often respond when prescribed clozapine, attached to many neurotransmitter receptors besides D2/D3 [68]. Many of the new drugs[69], including clozapine[70] had affinity for serotonin 2AR, which was thought explain their much lower relative rate of extrapyramidal effects.

Another explanation was that the antipsychotics drugs that do not elicit extrapyramidal symptoms, such as clozapine and quetiapine, bind to the D2 receptor more loosely than dopamine itself so that endogenous dopamine displaces them very quickly from the target receptor. Drugs that bind most tightly to the D2 receptor (chlorpromazine, trifluoperazine, fluphenazine, haloperidol, risperidone) stay on the receptor for 20-30 min and it is this long continuous occupation that may be responsible for parkinsonism[71,72]. This explanation suggests that, though a certain threshold percentage of D2 receptors still need to be bound in order to obtain an antipsychotic effect, the binding need not be of long duration. 'Hit and run' or 'fast-off' binding is able to prevent some of the adverse effects while still maintaining efficacy against psychosis.

An unresolved continuing problem with respect to antipsychotic drug action is that at least one third of patients with schizophrenia do not respond to drugs that block D2, whether transiently or for long periods, whether with or without serotonin 2A binding. One possible explanation is that individuals inherit different genetic variants of the D2 receptor[73-76], and that these variants determine response. Since the functional state of the dopamine receptor in the anterior pituitary[58], and perhaps everywhere in the brain[77], is its high affinity form, it is perhaps the relative duration of time that these receptors spend in their various affinity states that determines the extent of clinical response. It has been hypothesized that an interaction between D1 and D2 receptors influences the time spent in the high affinity functional state[78]. Every year, more knowledge accumulates about the signaling complexes of D1 and D2 receptors[79] and new radioactive ligands are available that bind specifically to high affinity sites[80].

Although binding to the D2 receptor continues to be considered as the cornerstone of antipsychotic action, the original hypothesis has undergone several refinements, such as the acknowledgement that other dopamine receptors as well as other neurotransmitter receptors play a part[81-84]. There now exist effective antipsychotic drugs that defy the earlier established D2 receptor occupancy threshold, which makes it difficult to attribute antipsychotic effect to any single neurotransmitter receptor[85-

87].

CONCLUSION

Dopamine D2 receptor blockade remains necessary in order to obtain antipsychotic response in most patients. Individuals differ, however, and it remains possible, even probable, that specific subgroups of patients showing psychotic symptoms may respond most robustly to pharmaceutical agents that mainly affect brain chemical transmitters other than dopamine. Pimavanserin, for instance, a serotonin 2A receptor antagonist, has had some success in treating the psychosis associated with Parkinson's disease, a condition of dopamine deficiency[88], but the Food and Drug Administration in the United States has recently found it insufficiently effective for the psychosis associated with Alzheimer's dementia. Differently caused psychoses may respond to differently configured drugs. Looking for the mechanism of action of drugs for psychosis continues, and, as new mechanisms are found, the secrets of the multiple causes of psychotic disorders may be decoded.

Abstract

BACKGROUND

The coronavirus disease 2019 (COVID-19) pandemic has caused major public panic in China. Pregnant women may be more vulnerable to stress, which may cause them to have psychological problems.

AIM

To explore the effects of perceived family support on psychological distress in pregnant women during the COVID-19 pandemic.

METHODS

A total of 2232 subjects were recruited from three cities in China. Through the online surveys, information on demographic data and health status during

pregnancy were collected. Insomnia severity index, generalized anxiety disorder 7-item scale, patient health questionnaire-9, somatization subscale of the symptom check list 90 scale, and posttraumatic stress disorder checklist were used to assess the psychological distress.

RESULTS

A total of 1015 (45.4%) women reported having at least one psychological distress. The women who reported having inadequate family support were more likely to suffer from multiple psychological distress (≥ 2 psychological distress) than women who received adequate family support. Among the women who reported less family support, 41.8% reported depression, 31.1% reported anxiety, 8.2% reported insomnia, 13.3% reported somatization and 8.9% reported posttraumatic stress disorder (PTSD), which were significantly higher than those who received strong family support. Perceived family support level was negatively correlated with depressive symptoms (r = -0.118, P < 0.001), anxiety symptoms (r = -0.111, P < 0.001), and PTSD symptoms (r = -0.155, P < 0.001).

CONCLUSION

Family support plays an important part on pregnant women's mental health during the COVID-19 pandemic. Better family support can help improve the mental health of pregnant women.

Key Words: Pregnant women; Perceived family support; Coronavirus; Psychological distress

Core Tip: The coronavirus disease 2019 (COVID-19) pandemic has caused major public panic in China. Pregnant women may be more vulnerable to stress, which may cause them to have psychological problems. The purpose of this study was to explore the effects of perceived family support on psychological distress in pregnant women during the COVID-19 pandemic. We found that family support plays an important part on pregnant women's mental health during the COVID-19 pandemic. Better family support can help improve the mental health of pregnant women.

INTRODUCTION

The outbreak of the coronavirus disease 2019 (COVID-19) is a global health threat[1] and is listed by World Health Organization (WHO) as a Public Health Emergency of International Concern (PHEIC). According to WHO data, there were 72546247 confirmed cases and 1614014 deaths worldwide[2]. In China, there are more than 90000 confirmed cases, with deaths exceeding 4758[2]. Corona viruses mainly cause respiratory diseases, ranging from the common cold to severe respiratory diseases, with a fatality rate of around 1%[3].

The COVID-19 pandemic seriously threatens people's physical health and can trigger various psychological crises. COVID-19 was associated with increased psychological distress not only in the general population[4], but also in clinical samples[5]. Importantly, women are more vulnerable to psychological distress, when experiencing disasters or traumatic events, compared to men[6]. During the outbreak of COVID-19, approximate 35% of the 52730 people in China experienced psychological distress[7]. Another online survey showed that during the COVID-19 outbreak, among the general Chinese population, 31.3% of participants had depressive symptoms and 36.4% of participants experienced anxiety[8]. In both studies, women showed higher

study.

levels of stress, anxiety and depression[7,8]. The impact of the epidemic on women's mental health is significantly higher compared to men[7,8].

As the changes in the level and function of the endocrine system during pregnancy, pregnant women often experience great mood swings and even mental disorders, such as anxiety[9], depression[10]. During the COVID-19 pandemic, pregnant women may suffer extra psychological stress for worrying about the adverse effects on their offspring caused by 2019-nCoV. A recent study reported that after the announcement of the COVID-19 epidemic, the prevalence of depressive symptoms among pregnant women was spiked as to before the announcement[11].

In Wuhan city, a total of 50340 have been confirmed of COVID-19, making it the worst-hit area in China. Wuhan was cordoned off 3 wk after the outbreak. To prevent infection, most all of Wuhan residents had to stay at home and isolated from society. Loss of income was the following stress for them. As a result, most Wuhan residents may not only suffer from the epidemic, but also suffer from isolation, stress and the loss of income[12].

Women who have supportive networks of friends and family may experience less stress and have better mental health conditions. Conversely, poor family relationships and social support might be associated with depressive symptoms[13]. A longitudinal study in pregnancy has found that partnership tension was the only predictor of women's transient and chronic anxiety during pregnancy or postpartum period[14]. The active support of the partner is a critical factor affecting the mental health of pregnant and postpartum women, and the support of the extended family is also important for the mental health conditions of pregnant women[14].

For family-centered Chinese culture, family support is probably the most important sources of social support[15]. Chinese women pay more attention to the family and are more susceptible to family relationships, compared with western women[16]. However, in the context of COVID-19 pandemic, it is unknown whether good family support can still benefit the psychological status of women. Therefore, after the announcement of the coronavirus epidemic in China, we conducted a mental health survey for pregnant women in different provinces of China, including Wuhan (Confirmed COVID-19 case > 60000), Beijing (Confirmed COVID-19 case: 581) and Lanzhou (Confirmed COVID-19 case: 24) in China. In addition, economic loss caused by COVID-19, characteristics related to pregnancy was investigated. The hypothesis of the study is that perceived family support is more important for the mental health of women during pregnancy than the economic loss caused by COVID-19 and the severity of the COVID-19.

MATERIALS AND METHODS

Participants

A cross-sectional survey was performed in this study after the Chinese government announced the coronavirus epidemic (from February 1 to April 28, 2020). The women during pregnancy were invited electronically to complete an anonymous online questionnaire in Wuhan, Beijing and Lanzhou by social media app WeChat (WeChat, Tencent Inc, China), since the Chinese government demanded the public staying at home. The questionnaire was disseminated through notifications from the maternal and child health hospitals. As a result, a total of 2232 valid responses were received from Wuhan (34.8%), Beijing (40.2%) and Lanzhou (25.0%).

The protocol of the study was approved by the ethics committee of the Institutional Review Board of the Institute of Psychology, Chinese Academy of Sciences. All participants provided the informed consent before participating in the study.

Questionnaire survey

A structured questionnaire was used to collect personal data, including socio-demographic variables, information of pregnancy, information of psychological distress, information about COVID-19 and the perceived family support in pregnancy. The socio-demographic variables included age, nationality, marital status, occupation, and education. The information of pregnancy included gestational age, parity, period and pregnancy complications. The information of psychological distress of the participants was assessed by the Chinese version of 5 international validity scales, include insomnia severity index (ISI), generalized anxiety disorder 7-item scale (GAD-7), patient health questionnaire-9 (PHQ-9), somatization subscale of the symptom check list 90 scale (SCL-90) and posttraumatic stress disorder checklist (PCL-5). Information about COVID-19 included income loss caused by COVID-19 and whether

or not their relatives or friends were infected with COVID-19.

ISI is a 7-item self-report questionnaire that assesses the severity and impact of insomnia[17]. Each item is rated on a 5-point scale (0 = no problem; 4 = very severe problem), with a total score ranging from 0 to 28. The total score is interpreted as follows: No insomnia (0-7); sub-threshold insomnia (8-14); moderate insomnia (15-21); and severe insomnia (22-28)[18]. Participants with a total score ≥ 15 were rated as having insomnia in this study. GAD-7 is a tool for assessing the severity of generalized anxiety. The 7 items are rated on a 3-point Likert scale, with a total score ranging from 0 to 21 (0–4: Normal; 5–9: Mild anxiety; 10–14: Moderate anxiety and 15–21: Severe anxiety). Clinically significant anxiety can be detected when the total score reaches 5 or above[19,20]. PHQ-9 is a 9-item instrument for assessing the presence and severity of depressive symptoms. The PHQ-9 specially includes 9-item diagnostic criteria of the Diagnostic and Statistical Manual of Mental Disorders, fourth edition (DSM-IV), on which the clinical diagnosis of depressive disorder is based[21]. Each item is rated on a 3-point scale (0 = no symptom; 3 = presence of symptom almost every day), with a total score ranging from 0 to 27(0–4: Normal; 5–9: Mild depression; 10–14: Moderate depression, 15–19: Moderately severe depression, and 20-27 severe depression)[21]. In this study, participants with a total score ≥ 5 were rated as suffering from depression. SCL-90[22] somatization subscale was used to assess the severity of somatization symptoms. The responses to these 12 items can be scored from 0 (none) to 4 (too much) on a Likert scale, with a total score ranging from 12 to 60. Participants with a total score ≥ 24 were rated as having somatic symptoms in this study. PCL-5[23] was used to assess the presence and severity of posttraumatic stress disorder (PTSD) symptoms. This is a 20-item self-report scale. Respondents were rated on a 5-point scale ranging from 0 (not at all) to 4 (extremely) to indicate how much troubled they have been in the past month according to PCL-5. The recommended PCL-5 cut-off score for the diagnosis of PTSD is 33[24]. In this study, participants with a total score ≥ 33 were rated as suffering from PTSD.

The perceived family support level was measured with the items of objective support from family numbers (husband, parents, parents-in-law, sisters / brothers, children and other family members) of Social Support Rating Scale (Chinese version) [25]. Participants rated on a 4-point scales (1 = none, 2 = rarely, 3 = some support/care, 4 = strong support/care)[15].

Statistical analysis

Analysis of variance was used to compare continuous variables, and χ^2 test were used for categorical variables. Spearman correlation analysis was performed to examine the relationship between perceived family support level and the five types of maternal psychological distress. Multiple linear regression was performed to examine the linear relationship between the scores of ISI, GAD-7, PHQ-9, SCL-90, PCL-5 and family support levels. In addition, a binary logistic regression analysis was conducted to estimate the association between perceived family support and psychological distresses by calculating odds ratio (OR) and 95% confidence interval (CI).

All analyses were performed using SPSS version 22.0 software (SPSS Inc., Chicago, IL, United States). All tests were two-tailed, and the statistical significance was defined at $P < 0.05$.

RESULTS

Sample characteristics

The socio-demographic characteristics of the participants are shown in Table 1. Women with a history of mental illness were not excluded from this study due to the small proportion (13 women).Significant differences were found between the women with and without psychological distress in terms of age ($\chi^2 = 2.16$, $P = 0.031$), region ($\chi^2 = 89.7$, $P < 0.001$), educational level ($\chi^2 = 13.61$, $P = 0.001$), annual household income ($\chi^2 = 10.23$, $P = 0.017$), income loss caused by COVID-19 ($\chi^2 = 13.83$, $P = 0.003$) and perceived family support ($\chi^2 = 13.57$, $P = 0.001$).

Psychological distress in different perceived family support levels

A total of 1015 (45.4%) women reported at least one instance of psychological distress. As shown in Figure 1, more women with less or some family support reported suffering multiple instances of psychological distress (≥ 2 type of psychological distress) than those with strong family support. A total of 5.2% of women with less family support reported having four types of psychological distress and 5.9% of them

[1]Confirmed COVID-19 cases in participating city: Wuhan: > 50000 cases; Beijing: 581 cases; Lanzhou: 24 cases.
[2]Participants rated on "none" and "rarely" scale.

had five types of psychological distress, which was significantly higher than those with some family support (3.2%,1.3%) or those with strong family support (2.6%, 0.7%).

Women with less or some family support reported significantly higher rates of psychological distress than women with strong family support (all $P < 0.05$). Among women with less family support, 41.8% reported depression, 31.1% reported anxiety, 8.2% reported insomnia, 13.3% reported somatization and 8.9% reported PTSD (Table 2).

Association between family support and psychological distress

The perceived family support levels negatively correlated with depressive symptoms (PHQ-9 score, $r = -0.118$, $P < 0.001$), anxiety symptoms (GAD-7 scores, $r = -0.111$, $P < 0.001$), and PTSD symptoms (PCL-5 score $r = -0.155$, $P < 0.001$). Logistic regression results showed there was a significant association between perceived family support and psychological distress of pregnant women (Table 3). After adjusting for age, marital status, region, educational level, annual household income, and income loss caused by COVID-19, less perceived family support displayed a significant association with anxiety (GAD-7 score ≥ 5, OR = 1.98, 95%CI: 1.32-2.96, $P < 0.01$), insomnia (ISI score ≥ 15, OR = 3.47, 95%CI: 1.68-7.16, $P < 0.01$), and PTSD (PCL-5 score ≥ 33, OR = 6.69, 95%CI: 3.07-14.55, $P < 0.01$) (Table 3).

DISCUSSION

To our best knowledge, this is the first study to explore the relationship between perceived family support and psychological distress in pregnant women during major life-threatening public health events. In this study, we had 3 main findings: (1) A significant proportion (45.4%) of pregnant women reported at least one psychological distress during COVID-19 pandemic; (2) The risk of insomnia, anxiety and PTSD in women with less family support was 3.46 times, 1.97 times and 6.69 times higher than that in women with strong perceived family support, respectively; and (3) Depression symptoms (PHQ-9 score), anxiety symptoms (GAD-7 score) and PTSD symptoms (PCL-5 score) were significantly negatively associated with perceived family support.

It is speculated that residents living in Wuhan suffered from higher levels of psychological distress, because this place was most affected by the epidemic[7] in mainland China. This may also increase the risk of psychological distress in pregnant women[11]. Interestingly, our study did not find an increase in the rate of maternal psychological distress amongst women in Wuhan. On the contrary, more women living in Lanzhou reported suffering from psychological distress, though it was only 24 confirmed COVID-19 cases in Lanzhou. That may be due to the fact that more women living in Lanzhou reported insufficient support from family numbers than women living in Beijing and Wuhan. The results showed that depression (35.6%) and anxiety (22.0%) were the most common disorders reported by pregnant women. In addition, at the peak of the COVID-19 epidemic, the pregnant women also suffered from somatization (8.1%), insomnia (3.4%) and PTSD (2.3%). The findings were similar to those of previous studies, indicating that pregnant women may be more vulnerable to depression in the context of the COVID-19 epidemic. A recent study reported that during the COVID-19 epidemic, the depression rate amongst Chinese pregnant women rose to 29.6%[11]. Another study showed that 28.8% of Danish women had anxiety/depressive symptoms during the COVID-19 pandemic[26].

There is extensive evidence that psychological distress during pregnancy are thought to increase the risk of developing psychological dysfunction in the offspring [27]. Pregnancy are very special periods for women. Affected by changes in the level and function of the endocrine system during pregnancy, mothers often experience huge mood swings and even mental disorders, such as anxiety[9], depression[10], and sleep disturbance[28]. The prevalence of depression in pregnant and postpartum women was estimated to be between 7% and 25%[10,26,27], and the prevalence of anxiety disorders is estimated to be between 4% and 39%[29]. However, our results showed that with different levels of family support, there were significant differences in the proportion of women with mental disorders during pregnancy. Women with inadequate family support were more likely to suffer from multiple psychological distresses. The strengthening of family support, the reporting rate of maternal psychological distress reduced. These findings highlight the essential role of adequate family support in mental health of pregnant women through major life-threatening public health events.

Social support, including supports from family members, colleagues, friends, neighbors, professionals, and organizations, is important for maternal mental health [15]. Due to the sudden outbreak, features and clinic symptoms of the COVID-19 are still unclear during the peak of the epidemic. The Chinese government intensified its management of the pandemic through public health interventions, such as strengthening some blockades, demand of staying at home. Hospitals had to terminate health care services for pregnant women to prevent infection, and most of them were trapped at home and isolated themselves from society. The confinement conditions have made the support of family members the only source of social support. In the general population, social support is widely regarded as a key factor in relieving perinatal depression[30]. A large number of studies have confirmed that family support has a positive effect on the level of perceived psychological stress[6,31-33]. According to Cohen[34], the relationship between perceived family support and life satisfaction was very strong.

Perceived family support makes a person feel cared for, loved, and dependent on family numbers when needed[33]. The levels of perceived family support can affect the way people deal with and adapt to stressful events, thereby reducing the negative effects on mental and physical health[6]. Therefore, adequate family support can alleviate the pressure caused by the COVID-19 outbreak. However, although physical care for pregnant women has been greatly improved in China in the past few decades, little attention has been paid to emotional care[15]. The findings of this study emphasized the importance of emotional care for pregnant women. The role and mechanism of family support in alleviating the negative psychological effects of

adverse events have not been clearly or fully explained. Further research is needed to understand the role and mechanism of this factor in order to utilize family support to help pregnant women in major life-threatening public health events.

However, several limitations have to be considered when interpreting these findings. Firstly, the data obtained from online surveys and maternal psychological distress relied on self-reported measurements. Women may inaccurately report the presence or absence of psychological distress. Secondly, although internationally valid and reliable questionnaires were utilized in this study, these questionnaires did not provide a diagnosis of mental disorders. Thirdly, the evaluation of family support used the subjective feelings of women rather than the social support rating scale. This may make our results less precise. Fourthly, other influencing factors such as family relationship, family conflict, and family resources are also important variables that affect the psychological well-being of pregnant and postpartum women, which were not taken into account in this study. Finally, a cross-sectional analysis of this study suggests that there is an association between maternal psychological distress and family support, rather than a causal relationship. Future research may focus on a longitudinal study to confirm causality.

CONCLUSION

The results of this study indicate that the COVID-19 pandemic has a negative impact on the mental health of Chinese pregnant women. Family support was significantly negatively correlated with psychological distress. Compared with women with strong family support, women with insufficient family support were more associated with the risk of anxiety, insomnia, depression and PTSD. This study shows that in major life-threatening public health events, family support has a positive impact on the

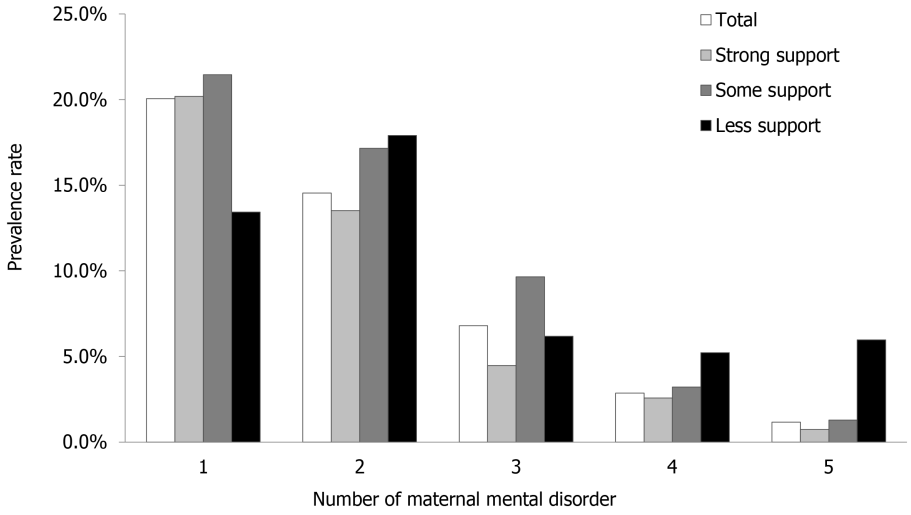

Figure 1 Frequency for self-reported multiple psychological distresses in different perceived family support level. 1: Report one type of psychological distress; 2: Report two type of psychological distress; 3: Report three type of psychological distress; 4: Report four type of psychological distress; 5: Report five type of psychological distress.

mental health of pregnant women. However, cross-sectional nature limits the interpretation of the causal relationship between family support and mental health. Further longitudinal studies about the causal relationship between family support and mental health will be an essential area of future research, which may help to identify appropriate and effective interventions for pregnant and postpartum women to prevent from the mental health problems.

ARTICLE HIGHLIGHTS

Research background

Pregnant women may be more vulnerable to psychological distress during major life-threatening public health events. The spread of the corona virus disease 2019 (COVID-19) is likely to cause greater psychological stress, which may cause extra psychological problems for pregnant women.

Research motivation

The spread of the COVID-19 may cause extra psychological problems for pregnant women. Women who have better supportive networks of family may experience less psychological stress. However, the literatures on the role of family support in maternal psychological distress during the COVID-19 pandemic was limited.

Research objectives

This study aimed to clarify the potential role of family support on psychological distress for women during pregnancy stages at the peak of the COVID-19 epidemic.

Research methods

The authors retrospectively collected socio-demographic variables, information of pregnancy, and information of psychological distress and the perceived family support of pregnant women in China.

Research results

Among 2232 pregnant women, 45.4% women reported having at least one psychological distress during the COVID-19 pandemic. The women who reported having inadequate family support were more likely to suffer from multiple psychological distress than women received adequate family support. Perceived family support was negatively correlated with depressive symptoms, anxiety symptoms, and PTSD symptoms.

Research conclusions

Family support was significantly negatively correlated with psychological distress. Adequate family support has a positive impact on the mental health of pregnant women during the COVID-19 pandemic.

Research perspectives

Adequate family support is important for maternal mental health. Further research is needed to understand the role and mechanism of this factor in order to utilize family support to help pregnant women in major life-threatening public health events.

Abstract

BACKGROUND

Grouping eating disorders (ED) patients into subtypes could help improve the establishment of more effective diagnostic and treatment strategies.

AIM

To identify clinically meaningful subgroups among subjects with ED using multiple correspondence analysis (MCA).

METHODS

A prospective cohort study was conducted of all outpatients diagnosed for an ED at an Eating Disorders Outpatient Clinic to characterize groups of patients with ED into subtypes according to sociodemographic and psychosocial impairment data, and to validate the results using several illustrative variables. In all, 176 (72.13%) patients completed five questionnaires (clinical impairment assessment, eating attitudes test-12, ED-short form health-related quality of life, metacognitions questionnaire, Penn State Worry Questionnaire) and sociodemographic data. ED patient groups were defined using MCA and cluster analysis. Results were validated using key outcomes of subtypes of ED.

RESULTS

Four ED subgroups were identified based on the sociodemographic and psychosocial impairment data.

CONCLUSION

Informed consent statement: All study participants provided informed written consent prior to study enrollment.

Conflict-of-interest statement: The authors of this manuscript having no conflicts of interest to disclose.

Data sharing statement: There is no additional data available.

CONSORT 2010 statement: The authors have read the CONSORT 2010 statement, and the manuscript was prepared and revised according to the CONSORT 2010 statement.

ED patients were differentiated into well-defined outcome groups according to specific clusters of compensating behaviours.

Key Words: Multiple correspondence analysis; Eating disorders; Compensating behaviour; Observational descriptive study

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This is the first study to apply multiple correspondence analysis to eating disorders (ED) diagnostic data and to use cluster analysis (CA) in such detail to search for ED patient groups in this area. Multiple correspondence analysis and CA made it possible to identify different typologies of patients with specific features. Grouping ED patients into subtypes could help improve the establishment of more effective strategies of diagnosis and treatment, and improve patient care and prognosis in clinical practice.

INTRODUCTION

Eating disorders (ED) are serious psychiatric conditions; clinical presentations of persons with ED[1,2] vary substantially and they may be associated with many factors, *e.g.*, sociodemographic as gender[3] or clinical as personality profiles[4]. The Diagnostic and Statistical Manual of Mental Disorders (DSM)-5[5] aims to better capture the presentations of ED symptoms observed by modifying previous ED diagnostic criteria. However, as Turner *et al*[6] have, noted some researchers remain concerned, that these adjustments will fail adequately to address the substantial heterogeneity in clinical presentations amongst patients with ED[1]. It is important to research subtypes of ED, since otherwise the field might merely end up 'studying what it defines' (or failing to study anything it does not define)[7]. Thus, removing any reference to non-purging compensatory behaviors would reinforce the impression-(created by subtyping) that bulimic-type ED characterized by purging behaviors is more severe than that involving non-purging behaviors when there is actually little empirical evidence to support this view[7,8]. Insofar as distinct subgroups of ED patients can be reliably identified, it is possible that these groupings might be used to inform assessment, treatment and future diagnostic nosologies[9]. Multiple correspondence analysis (MCA) is an exploratory technique that offers descriptive patterns based on the categories of the original active variables[10,11]. It transforms the information on the categorical active variables into continuous factors. The relative positions of the categories given by the MCA factors are used to perform the cluster analysis (CA) which classifies information into relatively homogenous groups. By combining MCA and CA it might be possible to arrive at a classification of the subjects suggested by the data, rather than defined *a priori*, where subjects in each group are similar to one another but dissimilar to those of other groups[10,12].

Grouping ED patients into subtypes could help improve the establishment of more effective strategies of diagnosis and treatment, and improve patient care and prognosis in clinical practice. The aim of this study was to identify ED patient subtypes. To this end, MCA and CA statistical techniques were combined to analyze clinical data obtained in a prospective cohort study of ED patients treated in an ED Outpatient Clinic. The subtypes were then validated by estimating their relationships to key outcomes such as health-related quality of life (HRQoL), psychosocial impairment due to ED, worry and metacognitions, eating problems, and sociodemographic variables.

MATERIALS AND METHODS

Participants

A prospective cohort study was conducted of all patients diagnosed with and treated for an ED at the Eating Disorders Outpatient Clinic The clinic forms part of the psychiatric services at the hospital, which serves a population of 300000. It is part of the Basque Health Care Service, which provides unlimited free care to nearly 100% of the population. Outpatients recruited between January 2010 and January 2011 were considered eligible for the study if they had received a diagnosis of anorexia nervosa (AN), bulimia nervosa (BN), or an ED not otherwise specified (EDNOS) by a psychiatrist, on the basis of the criteria listed in the Diagnostic and Statistical Manual of Mental Disorders, 4th edition text revision[5]. Patients were required to provide written informed consent before participating. They were excluded if they had a malignant, severe organic disease were unable to complete the questionnaires because of languagedifficulties, or had not given their written informed consent to participate in the study.

The study received approval from the institutional review board of the Hospital.

Measures

ED patients gave their sociodemographic data, including age, gender, marital status, education, employment status, and living situation.

The clinical impairment assessment (CIA v.3.0)[13,14] is a 16-item self-report instrument specifically designed to assess psychosocial impairment secondary to features of an ED. A higher score indicates greater impairment. The CIA report of psychometric properties indicated that the measure was both adequate and valid[13,15].

Eating pathologies were measured using the eating attitudes test-12 (EAT-12)[16]. This is a 12-item instrument, which uses a 4-point scale, with scores from 0 (never) to 3 (always). Higher scores indicate more disordered eating. Its validity as a measure of disordered eating has been backed by previous studies[17,18].

The quality of life of ED patients was evaluated using the health-related quality of life in ED-short form)[19] ,a 20-item questionnaire divided into two domains: social maladjustment and mental health and functionality. The lower the quality of life, the higher the score[15,20].

The metacognitions questionnaire (MCQ-30)[21] is a brief multidimensional measure of a range of metacognitive processes and metacognitive beliefs related to worry and cognition relevant to vulnerability to and maintenance of emotional disorders. Higher scores reflect a more dysfunctional metacognitive belief. The subscales have good psychometric properties[21,22].

The Penn State Worry Questionnaire (PSWQ-R) is a 16-item self-report measure of trait worry that is widely used to measure pathological worry[23]. A Spanish version reduced to 11 items was used[24]. Higher scores indicate greater levels of pathological worry. The PSWQ-R has been shown to have good psychometric properties[25,26].

Procedure

Data gathering began in 2010. Psychiatrists who collaborated in the study informed their patients of the aims of the study and recorded sociodemographic information. Patients agreeing participate were mailed questionnaires and an informed consent form ,which they were asked to mail back using an enclosed, pre- franked envelope. Two reminders were mailed out at 15-d intervals to patients who failed to reply to the first mailing.

Statistical analysis

Various multivariate techniques are used in order to synthesize the information contained in a large set of explanatory variables into a few components, also called factors. One of them is the technique selected for this analysis, MCA, which is designed for categorical explanatory variables, while others, as principal component analysis, are designed for continuous variables. Based on the categories of the original variables, MCA provides descriptive patterns by factors. In the continuous factors, therefore, each category of variables is represented by a numerical value and a positive/negative sign, used for interpretation. Graphical displays of these factors are very useful in interpretation, as the association between the categories is indicated by their relative position on the graph. The closer the categories are to one another, the stronger the association. Variables included in the analysis are known as active variables, whilst those not included in the analysis but used to verify the relationship

with active variables are termed illustrative variables or outcomes[10]. A descriptive analysis was made of sociodemographic and psychosocial impairment data, using frequencies and percentages. Means and standard deviations were also used as additional information for questionnaires of psychosocial impairment. The active variables in the MCA were gender, age (13-25, 26-35, 35-63), marital status [single, spouse/partner, divorced/widow(er)], education completed (primary, secondary, higher), employment status (employed, unemployed, student, disabled, unpaid work/housewife), living situation (living alone, with partner/children, friends, parents/siblings), MCQ-30 questionnaire (≤ 57, 58-75, > 75), CIA questionnaire (< 16, ≥ 16), EAT-12 questionnaire (< 8, ≥ 8), HeRQoLED-SocM (≤ 50, > 50), HeRQoLED-MHF (≤ 50, > 50) and PSWQ-R (≤ 28, > 28). Type (AN, BN and EDNOS) and subtype (restrictive, purgative and binge) of ED patients were used as illustrative variables.

For classification purposes, CA organizes information into relatively homogeneous groups based on their values in a range of variables — in this case, based on the factors derived from the MCA. In other words, the objective of the CA is to assign individuals into different groups, in the way that individuals from the same group are similar to each other, but dissimilar from individuals of other groups. The number of groups derived from the CA is selected using the minimum inertia lost method[27].

The association between the active variables and the groups derived from the CA was evaluated using the chi-square test (or Fisher's exact test when expected frequencies were less than 5). The non-parametric Kruskal-Wallis test was used for the scores of the psychosocial impairment questionnaires. In addition, the relationship of outcomes or illustrative variables was evaluated according to the groups obtained from the CA. In order to see the stability of the groups obtained and since we had all the active variables measured at 12 mo of follow up too, the same analysis was replicated with the variables at 12 mo of follow up. Statistical analyses were carried out with R v3.0.2 and SAS 9.4 software (copyright, SAS Institute Inc.). "SAS" and the names of all other SAS Institute Inc. products and services are registered trademarks or trademarks of SAS Institute Inc., Cary, NC, United States.

The study was approved by the Ethics Committee of the Galdakao-Usansolo Hospital. Written consent for participation was obtained. ClinicalTrials.gov Identifier: NCT02483117. All methods were used in accordance with the relevant guidelines and regulations.

RESULTS

A total of 244 patients with ED were invited to take part in the study. Of these, 176 filled out the questionnaires. Early dropouts were largely due to patients failing to consent to participation. The mean of the CIA questionnaire was 19.5 (SD 13.6), which indicates a high level of impairment due to ED.

Results from the MCA showed that 74% of data variability could be explained by two factors, the first primarily associated with the HRQoL and the second with socio-demographic data. Figure 1 shows the map created by the first and second factors. The first factor is represented on the horizontal axis and the second on the vertical axis. Variables that were well-represented in the first factor were: the questionnaires related to psychosocial impairment; eating problems; HRQoL; worry; and metacognitions. Categories located in the positive part (right) of the map included lower values at CIA, EAT-12, HeRQoLED-s, MCQ-30, PSWQ. In contrast, higher values of the questionnaires were in the negative part (left). This axis was defined as "Psychosocial impairment: from high to low".Moreover, the relative position of the illustrative variables on the graph indicates that some subtypes of diagnosis according to compensatory behaviour as well as some subtypes of diagnosis related to DSM-IV-TR classification were well represented by this factor. Indeed, restrictive behaviour (AN, EDNOS) was located in the right side of the axis, whereas purgative behaviour (BN, EDNOS) stood on the left of the axis. The variables that were well-represented in the second factor were socio-demographic variables. Categories such as being male, having a spouse, having secondary studies, being a housewife and living with a partner/children were related to the positive part (top). In contrast, the categories of being single, having higher studies, being a student and living with friends or parents or/and a sibling, were related to the negative part of the axis (bottom). This axis was therefore interpreted as "socio-demographic data". As in the other axis, some categories of the illustrative variables were well-represented by this axis. Purgative AN was located in the negative part, while binge behaviour (only in patients with EDNOS diagnosis) was located in the positive part.

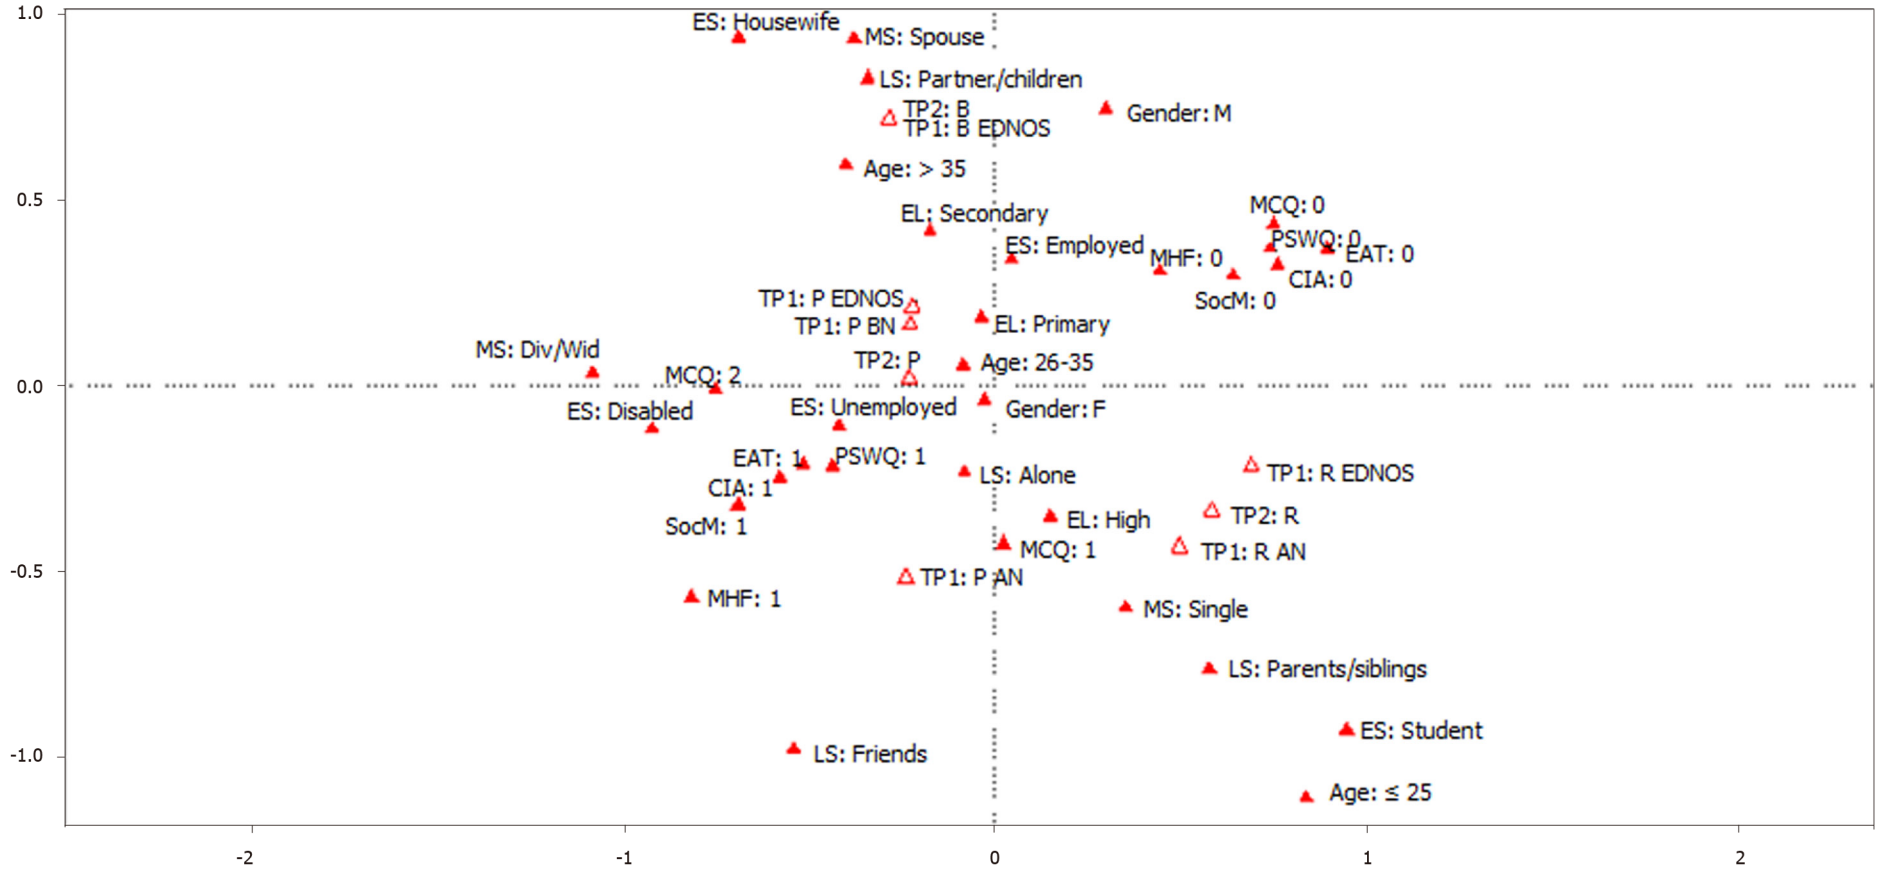

Figure 1 Graphical displays of the two factors/components derived from the multiple correspondence analysis. Active variables (sociodemographic variables). Age (≤ 25, 26-35, > 35); Marital status (single, spouse/partner, divorced/widow(er); Educational level (primary education, secondary education, higher education); Employment status (employed, unemployed, student, disabled, non-paid work/housewife); Living situation (alone, partner/children, friends, parents/siblings). Active variables (questionnaires). Metacognitions questionnaire, (0: ≤ 57, 1: 58-75, 2: > 75). Clinical impairment assessment, (0: ≤ 16, 1: ≥ 16); Eating attitudes test, (0: ≤ 8, 1: ≥ 8). Health-related quality of life in eating disorder-short form, [social maladjustment domain, (0: ≤ 50, 1: > 50); Mental health and functionality domain, (0: ≤ 50, 1: > 50); Penn state worry questionnaire (0: ≤ 28, 1: > 28). Red triangles represent the categories of the active variables. White triangles represent the categories of the illustrative or outcome variables. TP1: B EDNOS: Type of patient 1: Binge-eating disorder not-otherwise specified; TP1: P EDNOS: Type of patient 1: Purgative- eating disorder not-otherwise specified; TP1: R EDNOS: Type of patient 1: Restrictive- eating disorder not-otherwise specified; TP1: P BN: Type of patient 1: Purging-bulimia nervosa; TP1: P AN: Type of patient 1: Purging-anorexia nervosa, TP1: R AN: Type of patient 1: restrictive-anorexia nervosa; TP2: R: Type of patient 2: restrictive; TP2: P: Type of patient 2: Purgative; TP2: B: Type of patient 2: binge; G: Gender; F: Female; M: Male; MS: Marital status; EL: Educational level; ES: Employment status; LS: Living situation; MCQ: Metacognitions questionnaire; CIA: Clinical impairment assessment; EAT: Eating attitudes test; HeRQoLED-s: Health-related quality of life in eating disorder-short form; SocM: Social maladjustment domain; MHF: Mental health and functionality domain; PSWQ: Penn State Worry Questionnaire.

Following application of CA to the factors derived from the MCA, four ED patient types were identified (Figure 2) and labelled from A to D. Types A and C were patients with high psychosocial impairment, while types B and D were patients with

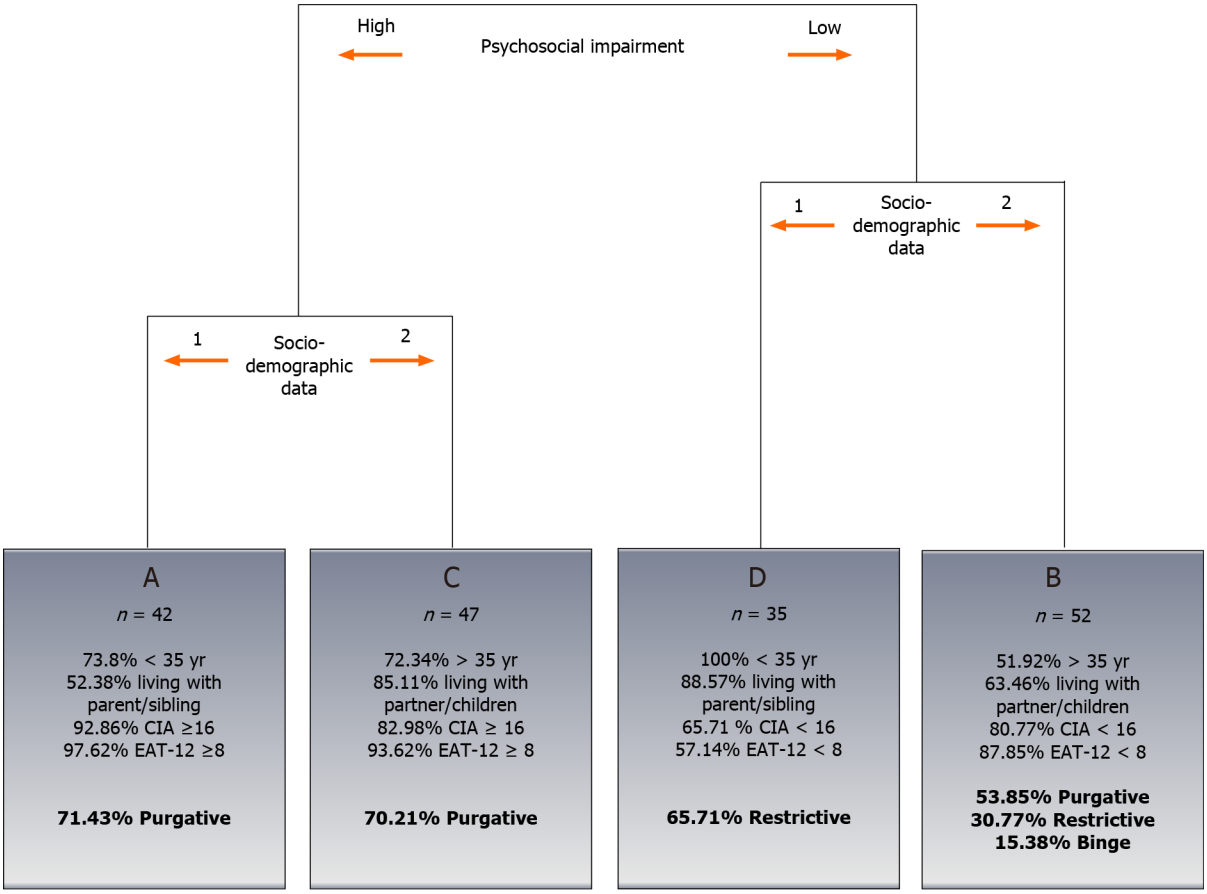

Figure 2 Dendogram obtained from the cluster analysis. The dendogram represents the results from the cluster analysis performed with the two components obtained from the multiple correspondence analyses. The graphical display includes an easy interpretation of the clustering and a brief description of the identified groups. [1]Having < 35 years, being single, having higher studies, being a student and living with friends or parents or/and a sibling; [2]Having > 35 years, being male, having a spouse, having secondary studies, being a housewife and living with partner/children.CIA: Clinical impairment assessment; EAT: Eating attitudes test.

low psychosocial impairment. However, types A and C, and B and D, differed in their socio-demographic characteristics. Figure 3 shows the two-dimensional distribution resulting from graphing the first and second factors. Types were represented by colours and the relative positions of the two illustrative variables were projected on the graph.

Tables 1 and 2 summarize the variables collected for all ED patients across the four ED subtypes. Statistically significant differences between subtypes were observed in all socio-demographic and psychosocial impairment variables, except for gender. Table 2 shows the associations between the subtypes and the illustrative variables and subtypes. Among patients in subtypes A (n = 42) and C (n = 47), 71.43% and 70.21% respectively had purgative behaviours. Subtype D included 35 patients, of whom 65.71% had restrictive behaviours. Among the 52 patients in subtype B, 58.85% had purgative behaviours, 30.77% had restrictive behaviours, and 15.38% had binge behaviours. The distribution of patients across the subtypes was significantly associated with the illustrative variable (P < 0.0001). In order to see the stability of the groups obtained in another way, results at 12 mo of follow-up showed that factors created by the MCA with the 12 mo follow-up data were the same as in the baseline (see material online, Supplementary Tables 1 and 2, Supplementary Figure 1). So, the characteristics that define the groups derived from the CA (A, B, C, D) are stable. Table 3 shows the differences in quality of life among the three groups defined in the literature (AN, BN and EDNOS).

DISCUSSION

The purpose of this study was to identify clinically meaningful subgroups among subjects with ED using multiple correspondence analyses. MCA is a well-established statistical technique that is suitable for suggesting possible diagnostic categories, as

Table 1 Distribution of the active variables related to the patients with eating disorders: Sociodemographic and health-related quality of life variables

	n (%)	Type of patient				*P* value
		A	B	C	D

Types of patients have been labeled in alphabetical order. The four subtypes (A, B, C and D) identified for the MCA factors "Psychosocial impairment" (first factor), and "Socio-demographic data" (second factor) provide a typology of eating disorders patients. ED: Eating disorder; AN: Anorexia nervosa; BN: Bulimia nervosa; EDNOS: Eating disorder not otherwise specified. Type and subtype of eating disorder are based on DMS-IV-TR.

seeks to identify clusters of individuals with similar features. In this study, ED outpatients can be categorized by two main components: one related to sociodemographic data (in graphical terms, shown by the second factor, in which negative values were associated with being old and living with partner/children and positive values were associated with being young and living with parents/siblings), and the other related to psychosocial impairment data (shown by the first factor, in which positive values were associated with better HRQoL and negative values were associated with worse HRQoL). In the hierarchy used, patients were first classified based on HRQoL variables, followed by the sociodemographic variables. The four subtypes (A, B, C, and D) provide a typology of ED patients.

Moreover MCA and CA made it possible to identify different typologies of patients with specific features. Types D and A were similar with regard to sociodemographic data, while Types A and C (D and C) were similar with regard to psychosocial impairment variables. In relation to the sociodemographic variables, Types D and A were characterized by being younger, having a higher education level, being single, and living with their parents or siblings. Types B and C, in contrast, were characterized by being older (> 35 years), having secondary education and living with their partner/children. According to psychosocial impairment variables, Types A and C had the most severe ED and were characterized by higher psychosocial impairment, ED severity, lower HRQoL, higher dysfunctional metacognitive belief and level of pathological worry, while Types D and B had a lower psychosocial impairment and less severe ED. As regards the diagnostic, as in this study, other research[28,29] have also failed to identify specific differences between the HRQoL effect of distinct ED diagnostic groups. With regard to the type of compensating behaviour, 65.71% of patients in Group D, and 53.85% of patients in Group B belong to the group of restrictive patients; while 71.43% of patients in Group A and 70.21% of those in Group C belong to the group of purgative patients.

Table 3 Differences in quality of life among the three groups defined in the literature

	Total	Type of ED			*P* value

[1]Results showed as mean (standard deviation). MCQ: Metacognitions questionnaire; CIA: Clinical impairment assessment; EAT: Eating attitudes test; HeRQoLED-s: Health-related quality of life in eating disorder-short form; SocM: Social maladjustment domain; MHF: Mental health and functionality domain; PSWQ: Penn state worry questionnaire; ED: Eating disorders; AN: Anorexia nervosa; BN: Bulimia nervosa; EDNOS: Eating disorder not otherwise specified.

These findings are consistent with those of DeJong *et al*[30], who explored whether purge spectrum groups have a higher degree of clinical severity than restrictive groups. Indeed, a major meta-analysis concluded that vomiting and purgative abuse suggested an unfavourable prognosis[31].

Patients with restrictive subtypes of ED are known to tend to underestimate the impact of their illness on their everyday activities and often continue to work and to maintain an active lifestyle, even at extreme levels of starvation[32]. There is some evidence that individuals with bingeing and/or purging forms of AN are more impaired than those with restrictive AN[30,33]. Several authors have suggested that restrictive EDs are often experienced as ego-syntonic as a result of the highly valued weight loss associated with these disorders[30,34,35]. In the study by DeJong *et al*[30], there were no differences in the CIA scores of different diagnostic groups (AN, BN, EDNOS). However when the groups were divided into restrictive and binge-purge subtypes, significant differences were found, as in this study. This suggests a greater degree of functional impairment amongst binge-purge spectrum diagnoses. This is consistent with an apparently higher degree of clinical severity amongst binge-purge spectrum groups than restrictive groups[30]. As Fairburn *et al*[2] have suggested, is that EDs are not stable. As Fairburn *et al*[36] one possible explanation note, the current arrangement used for classifying EDs is a historical accident that poorly reflects the clinical reality. They propose a (transdiagnostic) model highlighting similarities amongst diagnoses rather than focusing on differences between EDs[36]. Such similarities include extreme dietary restraint and restriction, binge eating, self-induced vomiting and misuse of laxatives, driven exercising, body checking and avoidance, and an over-evaluation of control over eating, shape and weight[37,38].

In DSM-5 the subtypes of BN disappear, since in clinical practice, the non-purging subtype was uncommon and tended to be confused with the diagnosis of binge ED [39]. Although it is important to clarify that fasting and/or excessive exercise are still considered as control behavior in order not to gain weight in BN, so that this type of

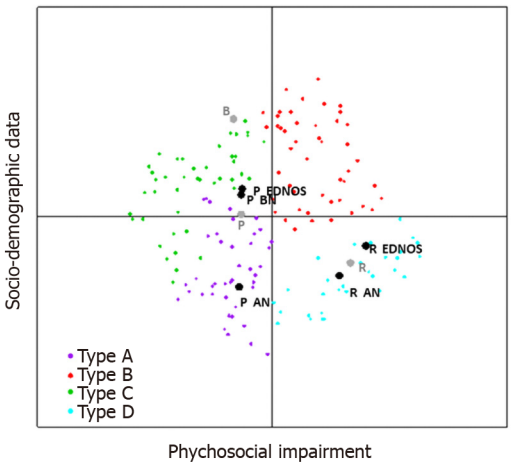

Figure 3 Map created by the first and second factors derived from the multiple correspondence analysis. Black dots in the plane represent the categories of the illustrative variable "subtypes of diagnosis according to compensatory behaviour and Diagnostic and Statistical Manual of Mental Disorders-IV classification". Grey dots represent the categories of the illustrative variable "subtype of diagnosis according to compensatory behaviour". The relative positions of the patients in this plane are represented by different colours, depending on the type derived from the cluster. B EDNOS: Eating disorder not otherwise specified, subtype binge; P EDNOS: Eating disorder not otherwise specified, subtype purgative; P BN: Bulimia nervosa, subtype purgative; P: Purgative; P AN: Anorexia nervosa, subtype purgative; R EDNOS: Eating disorder not otherwise specified, subtype restrictive; R: Restrictive; R AN: Anorexia nervosa, subtype restrictive.

patients could continue to be diagnosed. The main purpose of the DSM is to be clinically useful, *i.e.,* to improve the assessment and care of individuals with mental disorders[39]. The current focus of the DSM on "clinical utility" may incentivize the use of MCA and CA methods; the groups of ED patients formed after applying this methodology, do so based on common characteristics (sociodemographic, clinical and HRQoL), which may or may not coincide with the clinical diagnosis of each patient (DSM criteria). The data of this study may have important implications for ED patient care. The development of compensating behaviour-oriented treatments may prove useful for management of ED patients. But before these findings can be used to justify adjustments in therapeutic interventions, they will have to be replicated using the DSM-5 criteria to examine whether similar, or different clusters are present in different populations. Furthermore, future studies are needed to evaluate our ability to use this CA prospectively to classify disease severity and improve ED control by personalizing ED management. It would be interesting to determine whether the cluster groups have a differential response to one or more specific ED treatments. The potential interest in clinical practice is the usefulness that this method can have for clinicians, detecting typologies that may be useful for decision-making in these types of patients.

Strenghts and limitations

This study has several strengths. The MCA sought to identify groups of patients with homogeneous characteristics. For quality of life, the MCA methodology shows groups that are more discriminating, *i.e.*, patients of each group (A, B, C, D) are more similar/homogeneous among themselves and dissimilar/heterogeneous among the different groups. This methodology has proven useful for eliminating superfluous variables and retaining significant ones[10]. Traditional statistical methods, such as regression models, are designed to test the relationship between explanatory or independent variables and one outcome or dependent variable. In contrast, the aim in this study was to create ED patient typologies that were not strictly related to a specific outcome. The utility of this approach lies in the fact that the classification does not depend on a specific outcome, but is instead related to several[10]. Appropriate validation of the subtypes identified was provided by statistically significant relationships between the subtypes and several key outcomes.

To the authors' knowledge, this is the first study to apply MCA to ED diagnostic data and to use CA in such detail to search for ED patient groups in this area. Based on a review of the existing literature, only one study[40] used MCA in ED patients, but only in AN patients, and for another purpose (the aim was to differentiate patients with AN into well-defined outcome groups according to specific clusters of prognostic factors).

This study has a number of limitations. The first of these is that it only included patients who were attending a dedicated ED outpatient care program. It may therefore not necessarily be possible to extrapolate the results to other settings, such as

inpatients or patients treated as part of primary care. Another limitation is the large number of non-completors, and that there were no analyses of those patients who did and did not participate to determine if they differ based on certain characteristics. The third limitation is that this research was conducted prior to the publication of the DSM-5, and thus used DSM-IV-TR criteria for ED. An examination of patient subtypes across a range of ED patients using the new DSM-5 criteria, will be helpful.

CONCLUSION

In conclusion, four subtypes of ED patients were identified, which were associated with different illustrative variables. The classification was primarily driven by two components: (1) The HRQoL status; and (2) The sociodemographic data. As Fairburn *et al*[37] have noted, a classificatory scheme that reflects the clinical reality would greatly facilitate research and clinical practice.

ARTICLE HIGHLIGHTS

Research background

Eating disorders (ED) pose special problems for patients and have serious implications, including impaired health, psychiatric comorbidity and poor quality of life. Some authors assert that there is heterogeneity in clinical presentations that characterize patients with ED. It is relevant to research subtypes of ED, and these groupings might possibly be used to inform assessment, treatment and future diagnostic nosologies.

Research motivation

This is the first study to apply multiple correspondence analysis to EDs diagnostic data and to use cluster analysis (CA) in such detail to search for EDs patient groups in this area.

Research objectives

The aim of our study was to characterize groups of patients with ED into subtypes according to sociodemographic and psychosocial impairment data using multiple correspondence analysis (MCA), and to validate the results using several illustrative variables and arrive at a classification of the subjects that is suggested by the data, rather being defined *a priori*, where subjects in each group are similar to one another but dissimilar to those from other groups.

Research methods

This study involved ED patients, who were receiving psychiatric care at the Hospital Galdakao-Usansolo in Biscay, Spain, all of whom were informed of the nature of this research by their psychiatrist before agreeing to participate. MCA provides descriptive patterns based on categories of the original variables, and CA organizes information from apparently heterogeneous individuals into relatively homogeneous groups based on their values in different variables.

Research results

Of 176 ED patients were differentiated into well-defined outcome groups according to specific clusters of compensating behaviours. Types D and A were similar with respect to sociodemographic data, while types D and B were similar with respect to psychosocial impairment variables. Types B and D had the least severe ED (according to psychosocial impairment variables); Types A and C had the most severe.

Research conclusions

In our study, the MCA methodology shows groups that are more discriminating, *i.e.*, patients of each group (A, B, C, D) are more similar or homogeneous among themselves and dissimilar or heterogeneous among the different groups. A technique such as MCA synthesizes information on the original variables into a small number of components, making data interpretation easier and more viable.

Research perspectives

Grouping ED patients into subtypes could help improve the establishment of more effective diagnostic and treatment strategies, and improve patient care and prognosis in clinical practice.

ACKNOWLEDGEMENTS

We thank the Research Committee of Galdakao-Usansolo Hospital for help in editing this article. We are most grateful to the individuals with an eating disorder who collaborated with us in our research.

Abstract

BACKGROUND

Children diagnosed with autism spectrum disorder (ASD) may have great difficulties when their routines change, and this may affect the psychological well-being of their parents. For this reason, it is important to examine studies that address the mental health of parents in order to adapt to the coronavirus disease 2019 (COVID-19) pandemic.

AIM

To determine the mental health status of parents with children diagnosed with ASD in the COVID-19 pandemic.

METHODS

The study, which is a systematic review, was conducted between December 15, 2020 and December 30, 2020 by scanning articles in English. The Scopus, Science Direct, PubMed, Cochrane, Web of Science, and Google Scholar databases were used for scanning. The keywords COVID-19 AND ("autism" OR "autistic" OR "autism spectrum disorder") AND parent AND ("mental health" OR "anxiety" OR "stress") were used in the search process. The inclusion criteria in the study were findings regarding the mental health of parents with children diagnosed with ASD in the COVID-19 pandemic, addressing their anxiety and stress situations, being a research article, and accessing the full text of the article.

RESULTS

In the study, a total of 6389 articles were reached, and the full texts of 173 articles were evaluated for eligibility. After the articles excluded by the full-text search were eliminated, 12 studies involving 7105 parents were included in the analysis. The findings obtained from the articles containing data on mental health in the COVID-19 pandemic of parents with children with autism spectrum disorder

original work is properly cited and the use is non-commercial. See: http://creativecommons.org/Licenses/by-nc/4.0/

were discussed in three groups. These were findings on the experiences of parents with children with ASD in the COVID-19 pandemic regarding the areas where parents with children with ASD need support in the COVID-19 pandemic and methods of coping with the COVID-19 pandemic for parents with children with ASD. In the systematic review, it was determined that the anxiety and stress of the parents increased, they needed more support compared to the pre-pandemic period, and they had difficulty coping.

CONCLUSION
In this systematic review, it was concluded that the COVID-19 pandemic negatively affected the mental health of the parents of children with ASD.

Key Words: Autism spectrum disorder; COVID-19; Mental health; Pandemic; Parents

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Parents with a child diagnosed with autism spectrum disorder (ASD) in the coronavirus disease 2019 (COVID-19) pandemic may have a hard time explaining the COVID-19 pandemic, changes in routines and safety measures to their children in a comprehensible way. Parents may feel stressed and anxious as they have difficulty managing the process and need support in using effective coping methods. It is important to analyze the results of studies on the mental health of parents with children with ASD in the COVID-19 pandemic period. This is the first study to systematically examine the mental health status of the parents of children with ASD in the COVID-19 pandemic period.

INTRODUCTION

The coronavirus disease 2019 (COVID-19) pandemic and disaster processes significantly adversely affect individuals with severe and chronic mental illness. Data on individuals diagnosed with autism spectrum disorder (ASD), which is one of the most common neurodevelopmental disorders in the world, and their parents' experiences in extraordinary conditions are still limited[1]. The Diagnostic and Statistical Manual of Mental Disorders Fifth Edition defines autism as a pervasive developmental disorder characterized by disturbances in social interaction and communication (difficulty in social-emotional response, inability to use and understand non-verbal communication behaviors, inability to initiate and maintain communication appropriate to the level of development), limited and repetitive behaviors. The prevalence of autism, which causes limitations in performing the daily life functions of the individual with its early symptoms, continues to increase[2]. Autism begins in childhood and affects one in every 160 children in the world[3]. In a study conducted throughout the United States, it was reported that ASD was observed in one of every 54 children[4,5].

The World Health Organization (WHO) declared the COVID-19 epidemic as a global pandemic on March 11, 2020[6]. With the announcement of the pandemic, some restrictions started to be applied in countries. Initiatives to reduce the rate of transmission include behavioral recommendations such as comprehensive and frequent hand washing, maintaining social distance, avoiding in-person contact and wearing a facemask[7]. Groups with special needs have faced bigger problems during the pandemic. Children with ASDs and their parents are among the groups adversely affected by the COVID-19 pandemic[8-10]. The pandemic that caused mental problems even in healthy individuals has caused much more distress in children with ASD, who are extremely sensitive to changes in their routine[11,12]. Children with ASD may

present the psychosocial distress they experience due to the pandemic in the form of aggression, tantrums or refusing to participate in daily activities[8]. Furthermore, children with ASD may have difficulties without training in hand washing, avoiding eye contact, and especially wearing a facemask. The necessity to wear a mask is particularly disturbing for any child who has sensory sensitivity and does not understand the rationale for wearing a mask[13,14].

Parenting a child with ASD may be stressful[15]. Meeting the needs of these children may be more difficult for parents due to the seriousness of their condition and the chronic spectrum, mental health comorbidities, intense interventions that children need and the difficulty of getting services[16]. During the pandemic, disruption in daily routines, difficulty in accessing health services, inability to access private care and the increased anxiety of parents worsen the psychological wellbeing of children and increase their behavioral problems[17]. Parents have a difficult period in management of children with special needs during the pandemic where people are confined to homes. Normally, the burden of parents was shared with care centers, schools and special education centers. Social distancing is placed between caregivers who can support parents in the care process, and individuals who support these parents in care such as grandparents and parents are left alone due to the risk of COVID-19 transmission[18,19]. As the burden of parents increases, their coping capacity may decrease[20]. The parents of children with ASD, who had felt isolated before the COVID-19 pandemic, may feel more lonely and stressed during the pandemic with compulsory social distancing[21].

Parental health and well-being are directly related to the quality of care parents can provide to their children[21]. In the COVID-19 pandemic, international organizations such as WHO, the United Nations International Children's Emergency Fund and the American Academy of Pediatrics have created guidelines to support parents in management of the pandemic and stress management[22-24]. Similarly, Narzisi[12] recommended the parents of children with ASD to explain what COVID-19 is to the child, structure their daily routines according to this process and maintain their connections with educational institutions so that they can have a healthy pandemic process. It is important for parents to be able to explain the pandemic process to their children so that they and their children feel safer. For this reason, parents should be supported in teaching their children social distancing rules[21]. It is very important that the parents of children with ASD receive social support and have access to professional health services in reducing their stress and improving their emotional wellbeing [16,25]. In the COVID-19 pandemic, anxiety and stress situations, needs and coping methods should be determined, as well as mental health conditions in parents with children with ASD.

This systematic review determined the mental health status of the parents of children with ASD in the COVID-19 pandemic.

MATERIALS AND METHODS

This study is a systematic review. The Preferred Reporting Items for Systematic Reviews and Meta-Analyses protocol was followed in preparation of the study and the report. In this systematic review, to reduce the risk of possible bias, the processes of literature review, article selection, data extraction and evaluation of article quality were carried out independently by two researchers, each stage was checked in a session with the third researcher, and a consensus was established. In a session where the three researchers were together for carrying out the process in appropriate form and quality, a pilot study was conducted including searching through the PubMed search engine with a keyword (COVID-19, autism, parent) within the scope of the study, selecting an article, extracting data with five research articles and evaluating the quality of the articles. The differences of opinion and information that emerged after the pilot study were resolved through discussion.

Search strategy

The search processes for this systematic review were conducted between December 15, 2020 and December 30, 2020 and updated on 17 March 2021 to include the latest publications in the publication process. The search procedure was achieved by browsing the Web of Science, PubMed (including MEDLINE), Cochrane, Scopus, Science direct and Google Scholar databases using the keywords COVID-19 AND ("autism" OR "autistic" OR "autism spectrum disorder") AND parent AND ("mental health" OR "anxiety" OR "stress"). The list of references of the included studies was

reviewed to access additional studies.

Selection criteria and selection of studies

Inclusion and exclusion criteria: The articles in English, which could be accessed in full text without any limitation of publication year and country, were included in the study. The systematic review was created according to the PICOS strategy. Participants: the parents of children with ASD; Interventions: effects of the COVID-19 pandemic on mental health; Comparators: the parents of children without ASD; Main outcomes: anxiety, stress, difficulty in coping, loneliness, inadequacy of support systems, social isolation, change in routines and financial difficulties; Additional outcomes: exercise at home, practicing yoga and meditation, reading newspapers, getting support from a therapist, cooking meals, talking to their loved ones on online platforms during the pandemic. These results have been reported in studies and included and presented in this systematic review.

Studies suitable for this systematic review were included based on the following inclusion criteria. In the COVID-19 pandemic, the findings related to the mental health of parents with children with ASD and the anxiety and stress situations they experienced were handled, being a research article, the publication language was English, and the full text of the article was available. Studies with an unknown method and those dealing with the experiences of children with ASD in the COVID-19 pandemic were excluded.

Identification and selection of the studies were achieved independently by two researchers (Yılmaz B, Azak M) in accordance with the inclusion criteria. After repetitive studies were removed from the search results, selection was made according to the title, abstract and full text, respectively. The selection process followed in the systematic review is given in Figure 1.

Data extraction

A data extraction tool developed by the researchers was used to obtain data in the study. With this data extraction tool, data about the authors of the studies and the publication year, research type, method, sample size, number of cases, the country in which the data were collected, the year the data were collected, the data collection instrument and the main results were obtained.

Evaluation of methodological quality

The methodological quality of the articles included in this systematic review was evaluated by one of the researchers and checked by the other two researchers. The Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) Statement[26] was used to evaluate the quality of the observational (descriptive, cross-sectional and case-control) studies, and the "Critical Appraisal Skills Program: Quality Appraisal Criteria for a Qualitative research" (CASP) was used for qualitative research (https://casp-uk.net/wp-content/uploads/2018/01/CASP-Qualitative-Checklist-2018.pdf). The STROBE Statement is a checklist of 22 items that indicate the sections that should be written in the article during the preparation of observational research articles. CASP is a form consisting of 10 items that may be used to evaluate the quality of qualitative research.

Data analysis

The narrative synthesis method was used in the analysis of the data. Narrative synthesis is a method that may be used to synthesize both quantitative and qualitative studies, and it can be used when the findings of studies included in the systematic review are not similar enough for meta-analysis[27]. The pattern, data collection methods and data collection instruments of the studies examined in this systematic review were different. Therefore, the findings are presented with the narrative synthesis method.

Ethical aspect of research

In the study, the research articles included in the sample did not require ethics committee approval because they were obtained from accessible electronic databases and search engines. All stages of the study were carried out in accordance with the principles in the Declaration of Helsinki.

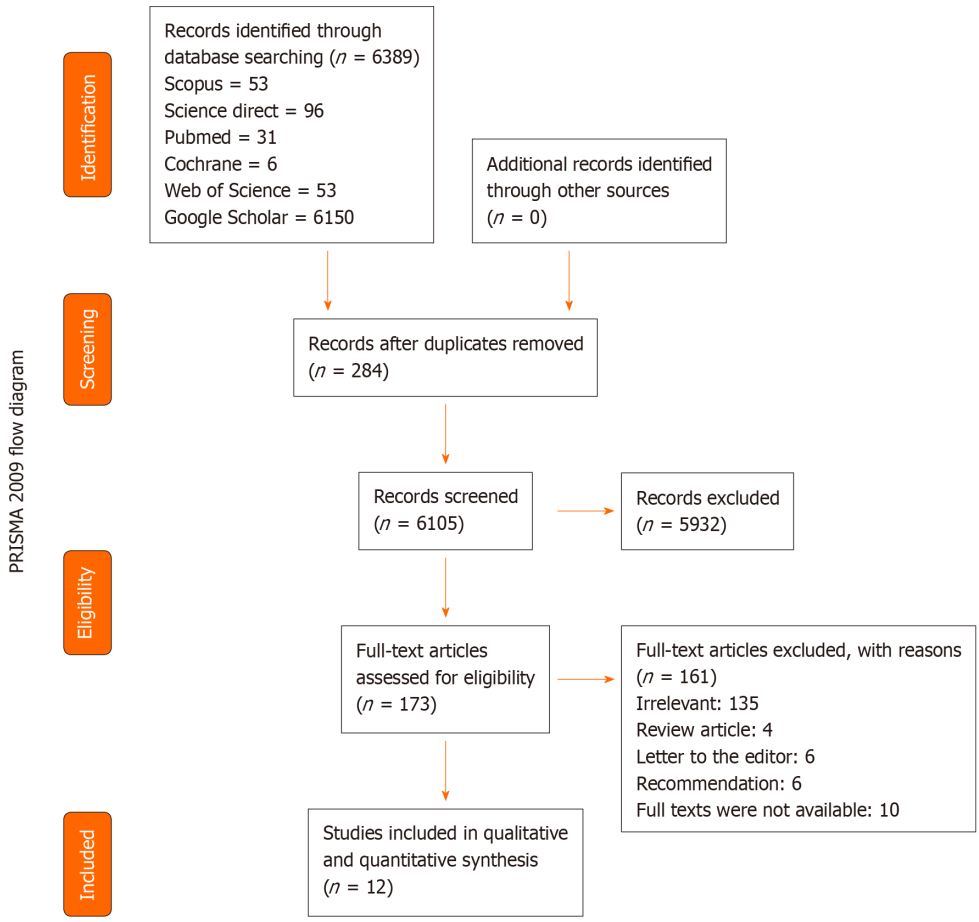

Figure 1 PRISMA flow diagram.

RESULTS

Scanning results

As a result of the search, 6389 records were initially reached. As a result of the examination made according to the title, abstract and full text, respectively, 173 articles were reached. Repetitive records were removed, and data extraction was performed with twelve studies after the examination according to the inclusion criteria. Explanations about the selection process of the articles are shown in Figure 1. In this review, twelve studies that met the inclusion criteria were analyzed, and Table 1 shows the country, type, sample characteristics, data collection instruments and main results of these studies. A total of 12 studies were included in a quantitative and qualitative design (cross-sectional descriptive: 8; comparative cross-sectional descriptive: 1; cohort study: 1; quasi-experimental design: 1; qualitative design: 1). A total of 7105 parents who have children with a diagnosis of ASD were enrolled in the studies that were included in this study. The included studies were carried out in United States, China, Spain, Italy, Saudi Arabia, Portugal and Turkey. While the quantitative research data included in the study were collected through online questionnaires, the qualitative research data were obtained by phone call *via* semi-structured forms.

Methodological quality assessment results

When the reporting quality of the observational studies was evaluated over 22 points with the 22-item STROBE, the mean score was found to be 19.54 (range: 17-22). In the evaluation of qualitative research using CASP, it was found that the quality score was 9.0 (Table 1). While disasters and epidemics affect the whole society negatively, they affect individuals with ASD in the disadvantaged group and their parents mentally. In the systematic review, the results obtained from the articles containing data on the mental health of parents with children with ASD in the COVID-19 pandemic were discussed in three groups. These were results regarding the experiences of parents with children with ASD in the COVID-19 pandemic, results regarding the areas where parents with children with ASD need support in the COVID-19 pandemic and

Table 1 Summary of the studies included in this systematic review

Ref.	Country	Research type	Data collection instrument	Sample	Main results	Critical appraisal toll
Alhuzimi [28], 2021	Saudi Arabia	Cross-sectional descriptive	Demographic Form The Parent Stress Index-Short Form The General Health Questionnaire	150 parents of children with ASD	While 94% of the parents reported that their stress levels increased in the COVID-19 pandemic, 78.7% of them reported that the pandemic negatively affected their emotional well-being. The parents stated that the support they received from their relatives during this process reduced their stress levels, fatigue and improved emotional their wellbeing	19/22 STROBE
Althiabi [34], 2021	Saudi Arabia	Cross-sectional descriptive	Demographic Form The General Health Questionnaire The Hospital Anxiety and DepressionScale The Family Impact Questionnaire	211 parents of children with ASD	The parents reported that, in the COVID-19 pandemic, they had difficulty calming their children due to changes in routine and experienced fear and anxiety. They reported that they had difficulties in finding activities and games to keep their children entertained at home. During this process, the parents reported that they sought help from their friends, teachers, doctors and psychologists	21/22 STROBE
Amorim *et al* [29], 2020	Portugal	Comparative, cross-sectional descriptive	Questionnaire form created by researchers	43 parents of children with ASD and 56 control group participants (parents of children without neurodevelopmental problems)	In the study, it was determined that the parents of children with ASD had higher anxiety levels than those with healthy children. The parents reported that they felt tired during the pandemic as they had to spend extra time on their children with ASD. In the study, 55.8% of the parents of children with ASD and 29.6% of the control group reported that the pandemic had a negative effect on emotion management. Social isolation, inability to spend time outside, sudden changes in routines, boredom and distance education practices were reported as the most difficult areas for parents. The parents stated that they frequently talked to their families, close friends, colleagues, and some parents received support from a therapist	17/22 STROBE
Bent *et al* [31], 2020	China	Qualitative	Interview formcreated byresearchers	15 parentsofchildren withASD	The parents had trouble explaining COVID-19 and safety measures to their children. Sudden changes in routines increased children's crying spells and aggression. The parents had difficulty coping with these behavioral problems and adapting to e-learning. The participants reported that they exercised, practiced yoga, meditation, prayed, read newspapers and talked with their close friends online during this period.	9/10 CASP
Colizzi *et al* [30], 2020	Italy	Cross-sectional descriptive	40-question questionnaire created by researchers	527 parents of children with ASD	The parents reported that having a single child, the inability of the child with ASD to speak, the male gender of the child and a single parent having the child's responsibility were among the factors increasing their stress during the pandemic. 19.1% of the parents reported that they received support from a neuropsychiatrist due to the onset of new behavioral problems in their children and due to feeling helpless. The sudden curfew restrictions caused stress for the parents and their children. 47.4% of the participants stated that they needed more health services during the pandemic, 30% needed to strengthen their home support systems, and 16.8% needed more state support in quarantine	18/22 STROBE
Liu *et al*[36], 2021	China	Quasi-experimental	The Self-rating Anxiety Scale The Self-rating Depression Scale The Parenting Stress Index-Short Form	125 mothers having children with ASD	With web-based support, it was found that the mothers' stress and anxiety levels decreased in the COVID-19 pandemic period. The parents reported feeling relaxed as the program facilitated parent-child interaction	20/22 STROBE

			The Herth Hope Index			
Lugo-Marín *et al*[33], 2021	Spain	Cross-sectional descriptive	The Child Behavior Checklist The Symptom Checklist 90 Revised	104 children with ASD, their parents and caregivers	In the data collected 8 wk after the lockdown onset, it was observed that there was an increase in somatization, obsessive-compulsive, interpersonal sensitivity, depression, anxiety, hostility, phobic anxiety, paranoid ideation and psychoticism in the parents	21/22 STROBE
Manning *et al*[32], 2020	The United States of America	Cross-sectional descriptive	Questionnaire form created by researchers	474 parents of children with ASD	It was determined that the children with ASD and their parents experienced high levels of stress and fear during the pandemic. The children who had to spend a long time at home exhibited aggressive and problematic behaviors, causing more stress in their parents and making it difficult to cope. 54.5% of the participants stated that they were worried about their children being at home all the time, 52.1% were afraid that they or their children could be infected with COVID-19, and 30.7% stated that they experienced stress due to economic problems. The parents reported that they received the most support from family, friends, school guidance, therapy center and parent support group, respectively, during the pandemic.	18/22 STROBE
Mumbardo-Adam *et al* [35], 2021	Spain	Cross-sectional descriptive	A semi-structured online survey	47 individuals with ASD and parents	The parents reported that they developed new strategies to better manage quarantine with their children with ASD. During this period, 36.2% of the parents reported that they communicated with their relatives online, and 23.4% received online psychological support	20/22 STROBE
Mutluer *et al* [17], 2020	Turkey	Cross-sectional descriptive	Sociodemographic FormThe Beck Anxiety Inventory (for parents) The Aberrant Behavior Checklist (for children) The Pittsburgh Sleep Quality Index (for children)	87 individuals with ASD and parents	The parents reported that children with ASD felt under house arrest because they had difficulty obeying social distancing rules and did not want to wear masks. The participants stated that their children's sleep patterns were disturbed during the pandemic, and they also had sleep problems. The majority of the parents said they could not continue distance education and needed support in this regard. It was determined that 25% of the parents had minimal anxiety, 29% had mild anxiety, 21% had moderate anxiety, and 25% had severe anxiety. The parents reported that they provided each other rest breaks when there was more than one adult at home who could take care of the child with ASD	17/22 STROBE
Wang *et al* [37], 2021	China	Cross-sectional descriptive	Sociodemographic Form The COVID-19 Questionnaire The Connor-Davidson Resilience ScaleThe Simplified Coping Style Questionnaire The Self-Rating Anxiety Scale	1764 parents of children with ASD and 4962 parents of typically developing children	It was found that the parents of children with ASD had more deterioration in their diet, less physical exercise, less social support, higher levels of psychological stress, anxiety and depression, and worse coping strategies than the parents of children with normal development	22/22 STROBE
White *et al* [38], 2021	The United States of America	Cohort study	Brief Family Distress Scale	3502 parents of children with ASD	80% of the parents reported disruptions in their children's special education. 64% of them stated that these disruptions had severely or moderately impacted their children's ASD symptoms, behaviors or challenges. Increasing distress and stress negatively affected their lives	22/22 STROBE

ASD: Autism spectrum disorder; COVID-19: Coronavirus disease 2019.

methods of coping with the COVID-19 pandemic for parents with children with ASD.

Results on the experiences of parents of children with* ASD *in the COVID-19 pandemic

The COVID-19 pandemic affected the parents of children with ASD mentally. In the study conducted in Saudi Arabia, 94% of the parents reported that their stress levels increased, while 78.7% stated that the pandemic affected their emotional wellbeing negatively[28]. Amorim *et al*[29] found that parents with children with ASD had higher anxiety levels than those with healthy children. Colizzi *et al*[30] reported that having a single child, the child with ASD not being able to speak, the child with ASD being male and a single parent having the child's responsibility were among factors that increased stress in the parents. Curfew restrictions that emerged suddenly during the pandemic caused stress in parents and children. Bent *et al*[31] stated that parents had difficulty explaining the restrictions and security measures to their children. The parents reported that their children had difficulty in obeying the social distancing rules, they could not take their children to the market, *etc.* because they did not want to wear a mask and felt under house arrest[17,31]. In the study by Manning *et al*[32], 54.5% of the participants stated that they were worried about their children being at home all the time, 52.1% were afraid that they or their children could be infected with COVID-19, and 30.7% reported that they had stress due to economic difficulties. In Spain, it was observed that there was an increase in somatization, obsessive behavior, depression, anxiety, hostile behavior, paranoid ideas, phobic anxiety and aggression in the parents according to the data collected 8 wk after the start of the lockdown[33].

For individuals with ASDs, changes in their routine may be very disturbing and challenging. It was reported that this situation led to serious behavioral disorders such as crying episodes, increase in aggression and rejection of transition[31]. In the study by Amorim *et al*[29] the mean anxiety score (8.75 ± 0.96) of parents with a child with ASD in the COVID-19 pandemic was found to be significantly higher than the mean score of parents with healthy children (5.36 ± 2.71). Althiabi[34] also reported that the stress levels of parents increased, and they had difficulty in maintaining their mental wellbeing. Children's adaptation levels affect the parents' anxiety. It was determined that children who could continue their routines (7.72 ± 1.84) had significantly higher levels of adaptation than those who could not (5.25 ± 2.75). In the same study, the parents reported that they felt helpless because there was not enough time to change routines. In the study, some parents reported that their children adapted to the situation without any major problems and thought of this process as a school holiday. The majority of parents, on the other hand, stated that other children had to continue their education in the home environment due to the pandemic, and they were tired of housework. One of the changing routines during the pandemic is that e-learning has been placed at the center of life. Parents reported that they felt tired as they had to spend extra time on their children with ASD during the pandemic. Parents revealed that they felt lonely and bored as they had to assume the role of educators during the pandemic. Some participants stated that their children who spent more time at home during the pandemic felt better as they took more responsibility in housework. In another study, 40.4% of the parents reported that they could spend more time with their ASD-diagnosed children, and 31.9% calmed their children by creating school-related activities[35]. In the study by Mutluer *et al*[17] parents stated that their children's sleep patterns were disturbed during the pandemic, and they also had sleep problems. In the study by Amorim *et al*[29], 55.8% of the parents of children with ASD and 29.6% of the control group reported that the COVID-19 pandemic had a negative effect on emotion management. The most difficult areas for parents were expressed as social isolation (41.4%), not being able to spend time outside (13.1%), sudden changes in routines (11.1%), boredom (9.1%) and distance education practices (7.1%). In the quasi-experimental study by Liu *et al*[36] in two sessions per week for 12 wk, relaxation-muscle exercises, home activities with the child, protection strategies, emotional management, parental stress coping strategies and psychological counseling strategies to cope with the pandemic situation were used. With web-based support, it was found that mothers' stress and anxiety levels decreased in the COVID-19 pandemic period. The parents reported feeling relaxed as the program facilitated the parent-child interaction. In a study conducted in China, it was found that the parents of children with ASD had more deterioration in their diet, less physical exercise, less social support, higher levels of psychological stress, anxiety and depression, and worse coping strategies than the parents of children with normal development[37].

Results regarding the areas where parents of children with ASD need support in the COVID-19 pandemic

Parents stated that they had difficulties during the COVID-19 pandemic due to deficiencies in support systems[30]. In the study conducted in Italy, it was reported

that parents with children with ASD needed local health service support, supportive training for e-learning and decrease in quarantine restrictions during the COVID-19 [30]. In the study conducted in Saudi Arabia, it was found that the support that parents received from their relatives reduced parental stress, fatigue and contributed to improving emotional wellbeing[28]. In the study conducted in Turkey, the majority of parents reported that they could not continue distance education and needed support. In the same study, it was determined that 25% of the parents had minimal anxiety, 29% had mild anxiety, 21% had moderate anxiety, and 25% had severe anxiety according to the Beck Anxiety Inventory[17].

In the study conducted in Portugal, 13% of the parents stated that they took their children to a specialist psychologist, and 1.5% of them visited emergency health services at the moment of their children's tantrums[29]. In the study conducted in Saudi Arabia, parents reported that their children with ASD mostly experienced problems in maintaining their care skills, coping with tantrums, controlling their negative behaviors and maintaining communication with their children. Additionally, the parents stated that they needed psychological and financial support the most, respectively[34]. In the study conducted in the United States, it was observed that tele-health services were insufficient in meeting the education and treatment needs of the children of parents. In the study, most of the parents of children with ASD stated that they had difficulty coping with the increasing negative behaviors of their children, and distress and stress negatively affected their lives[37].

In the study conducted in Italy, it was found that 19.1% of parents visited a neuropsychiatrist due to the onset of new behavioral problems in their children and feeling helpless[30]. It was stated by 47.4% of the participants that they needed more health services during the pandemic, 30% needed to strengthen their home support systems, and 16.8% needed more state support in quarantine. It was stated by 25% of the parents that one of the parents had to quit their job (26.1% of mothers, 27.5% of fathers) to take care of their children with ASD. The majority of the participants (94%) stated that this situation was financially difficult for them. During the pandemic, only 27.7% of the parents reported that they could get support from local health services. It was specified by 23% of the parents that they had difficulties in regulating the eating behaviors of their children, 31% had difficulties in providing authority to their children, 78.1% had difficulties in making use of spare time, and 75.7% had difficulties in having their children do homework[30].

The coping methods of parents with children with ASD with the COVID-19 pandemic

The parents of children with ASD resorted to various coping methods in the COVID-19 pandemic process. In the study by Bent *et al*[31], it was found that parents exercised at home, practiced yoga and meditation, read newspapers, cooked meals, talked to their loved ones on online platforms and spent time (bathing, nail care and online shopping) during the pandemic. In the study of Mutluer *et al*[17], it was reported that parents provided each other with rest breaks when there was more than one adult at home who could take care of the child with ASD. In the study by Amorim *et al*[29], it was determined that parents frequently talked to their family, friends and colleagues by video, and some of them received support from a therapist. In another study, it was observed that parents received the most support from their families, friends, school guidance services, therapy centers and parent support groups, respectively, during the pandemic process[32]. In the study conducted in Saudi Arabia, most parents reported that they received online counseling and guidance services to deal with the child's behavior at home and tantrums[34]. In another study, 36.2% of parents stated that they communicated with their relatives online, 23.4% received online psychological support, and 6.4% occasionally walked with their children[37].

DISCUSSION

This study is the first systematic review aimed at determining the mental health status of the parents of children with ASD in the COVID-19 pandemic. The systematic review showed that the difficulties associated with the COVID-19 pandemic negatively affect the mental health of the parents of children with ASD. Restriction of face-to-face education, social activities, and child monitoring during the pandemic process threaten the physical and mental health of children. Parents worldwide are concerned about how to support their children best under these difficult conditions[8-10]. The distinctive features of the diagnosis of ASD put children with ASD and their parents at risk of more adverse effects from the COVID-19 pandemic. Since these children may

have difficulties in social communication, they can develop when they are in environments that support their social interactions[38]. Although regular physical activity may provide a calming and regulating effect on children, they lack this opportunity due to the pandemic[8]. Considering all of these effects on children diagnosed with ASD, the inability of parents, who are deprived of support during the pandemic process, to maintain their mental health becomes prominent. Parents often experience mental distress as they postpone their own needs for their children with ASD and their families[21]. Disruption in healthcare support or services is an additional stressor on families with a child or dependent with ASD during an already stressful time because of the COVID-19 pandemic[39]. Restrictive social and economic regulations, discomfort caused by COVID-19, fear of transmission, isolated family life, closure of schools, lack of support programs for parents, loss of loved ones, work from home and the resulting increase in full-time childcare and home responsibility, as well as financial difficulties, are the main problems that parents experience in this process [8,17,28-32,39,40]. There has been a consensus on this issue in the studies included in this systematic review[17,28-37,39].

Sleep problems significantly affect children with ASD[41]. Studies on children with ASD reported that sleep problems lead to symptoms such as social withdrawal, anxiety and depression and behavioral problems such as self-aggression, hyperactivity, aggression and high levels of irritability during the day[42,43]. Another study noted that disruption in the circadian sleep rhythm increased the symptoms of ASD[44]. All of these effects of sleep problems negatively influence parents, causing an increase in the burden of these parents and an increase in their stress levels. In a study, it was determined that the situation of being home during the pandemic process caused sleep problems in children with ASD, and this situation increased the severity of ASD symptoms[45]. In the study conducted in Italy, it was reported that more behavioral problems were observed during the COVID-19 pandemic process, and these problems were associated with sleep[17]. The occurrence of these problems creates a sense of loss of control in parents and increases their stress[45]. All of these changes in the lives of parents and children also hinder the physical and cognitive development of the child. Therefore, it is clear that there is also an increase in parental stress levels during a pandemic that directly affects children's quality of life[46]. In a study, it was reported that, during the COVID-19 pandemic process, the parents of children with ASD experienced higher levels of anxiety about themselves and their children in comparison to the parents of children without neurobehavioral disorders [29,37]. Similarly, in the study by Alhuzimi[28] it was emphasized that the parents of children with ASD have higher stress levels and lower welfare levels. Manning *et al* [32] stated that children with ASD and their parents experienced high levels of stress during the pandemic process and reported that there were disruptions in their daily life routines. In this process, the issues regarding which they experienced the most stress were related to illness, isolation and materiality[32]. The fear of getting infected in the event of a pandemic is significant in the parents of children with ASD, and this fear increases stress significantly[47]. This was supported by the findings of the study by Manning *et al*[32] on the COVID-19 pandemic. Although staying at home during the isolation process and the obligation to quarantine are measures taken to reduce the transmission of COVID-19, harmful effects of social isolation on the mental health of children and parents may be observed[48]. This may further increase stress in children diagnosed with ASD and their parents[29,30,32]. Lugo-Marín *et al*[33] reported that there was an increase in somatization, obsessive behavior, depression, anxiety, hostile behavior, paranoid ideas, phobic anxiety and aggression in parents in 2 mo after the lockdown onset. Interruptions in the care process are an important need in the parents of children with ASD[49] and have an important role in reducing stress for the parents of children with ASD[50]. However, the decrease in the support received from caregivers during the isolation process and the fact that parents have taken on the entirety of the care burden have made it difficult for these parents to cope. Parents had difficulties in regulating their children's eating behaviors, providing authority to their children, making use of spare time and finding activities, and having their children do homework, and they felt lonely[30,34,35]. In the studies included in the systematic review, it was reported that, in order to cope with this situation, parents had rest breaks when there was another adult at home who could take care of their children with ASD[17,31].

An increase in the severity of ASD symptoms in children has an important role in affecting the stress and wellbeing levels of parents[51-54]. The COVID-19 pandemic process have caused more intense and more frequent behavioral problems in children with ASD[30]. In the study by Manning *et al*[32] one of the studies included in the systematic review, it was reported that the increasing severity in the symptoms of

children with ASD along with the pandemic caused an increase in the stress reported by parents. Children who are confined at home exhibit aggressive and problematic behaviors, causing more stress for their parents and making it difficult to cope. In other studies supporting these results, the pandemic and the increasing behavioral changes in children with ASD were found to play a significant role in the increase of stress in parents[17,30]. Parental stress also reportedly had an effect on emotional well-being[28]. In this sense, there has been a consensus that there is a lack of support for children and parents.

The positive attitude of parents during the COVID-19 pandemic is necessary for them to manage their stress and also control their children's behavior at home[34]. Pottie and Ingram[55] pointed out the importance of social support in helping a parent with a child with ASD cope with stress and raise their mood. All kinds of support from the community and from parents who experience similar situations facilitate the home care processes of children with ASD and their parents[56]. For this reason, during the pandemic, it is necessary to maintain contact in online environments with all individuals and institutions that parents can receive support from such as other parents, teachers, therapists and health professionals who experience similar situations [12]. In a qualitative study, parents stated that, although they could not get together with other parents who were in the same situation during the pandemic, they supported each other in home care through groups established *via* online messaging applications and mentioned how this helped them[57]. Similarly, in the studies included in the systematic review, parents reported that they frequently made video calls with their families and friends[29,31]. Althiabi[34] found that parents sought support from teachers, family members and therapists to take care of their children with ASD during the pandemic outbreak. Bent *et al*[31] stated in their study that it is important to seek help from friends, family, co-workers, therapists and healthcare professionals, as parents must remain strong for their families and children. With the closure of schools, parents are struggling to find different activities at home to support the development of their children with ASD and prevent their symptoms from appearing[57]. In the studies included in the systematic review[30,31,34,35], in accordance with the literature, parents stated that they sought daily activities and events that their children enjoyed. All family members including parents who leave their jobs or work from home due to the pandemic and children whose schools are closed are at home all together. In this process, the support of all family members for each other in the care of the child with ASD also provides a significant reduction in their burden of care[57].

Children diagnosed with ASD can only survive the pandemic with healthy parents. Therefore, parents should take care of their health, both for themselves and their children. Firstly, parents should not disrupt their physical care with adequate nutrition and rest and accept the emotional burden they experience. They should practice spiritual self-care by planning an activity they enjoy. Parents should be encouraged to plan activities they can do with their children in the home environment. Moreover, they should be encouraged to seek help from healthcare professionals when they feel they have mental problems that they cannot cope with[21]. Consistent with the literature, Bent *et al*[31] reported that parents spend time with activities such as bathing, nail care and online shopping as a method of coping with stress. In the qualitative study, the parents stated that they used methods such as walking, cycling, yoga, meditation, reading a newspaper and praying to cope with stress during the COVID-19 pandemic[31]. With the web-based support program prepared by Liu *et al* [36] relaxation-muscle exercises, home activities with the child, protection strategies, emotional management, parental stress coping strategies and psychological counseling strategies to cope with the pandemic situation were implemented. Their study stated that mothers' stress and anxiety levels decreased, and parents reported feeling relaxed as the program facilitated parent-child interaction.

Limitations

The limitations of this study were that studies whose full texts were not available and those published in languages other than the English language were not included in the systematic review, 12 databases were searched, and the gray literature was not screened. Since the pandemic has only the last year, studies in the field are limited. Therefore, the results should be interpreted with caution, as the systematic review was performed with a limited number of descriptive studies (twelve articles) with lower levels of evidence.

CONCLUSION

The COVID-19 pandemic has negatively affected the mental health of children with ASD and their parents. While many factors play a role in increasing the stress levels of parents, stress may also lead to different problems. In this case, it is possible for children with ASD to continue their lives in a healthy way with mentally healthy parents. In the systematic review, it was concluded that parents with children with ASD had difficulty with their children being at home all day long and financial difficulties as they had to quit their jobs. The parents were also able to devote less time to themselves during this process, and their stress and anxiety levels increased. During the pandemic where face-to-face services are interrupted, governments and relevant institutions should provide support for parents with children with ASD, and institutions that provide support should also work to improve the quality of the support they provide. In this process, it may be recommended to research new ways such as online health monitoring, online diagnosis systems, support groups for children and parents, increased tele-health services, tele-therapies and e-health support. Additionally, after the restrictions imposed by the pandemic are removed, it is important to support children with ASD and their parents while they are getting used to their social lives. Support services, such as counseling and helplines, may be created to help parents share their concerns and receive assistance in dealing with specific situations. Parents should be evaluated in terms of mental health, and professional help should be provided for individuals who need support.

ARTICLE HIGHLIGHTS

Research background

Although staying at home prevents the spread of coronavirus disease 2019 (COVID-19), this poses a number of challenges, especially for children with special needs such as autism spectrum disorders (ASD) and their parents. The parents of children with ASD participate in special education practices that involve physical activity in order to cope with the behavioral, cognitive and mental problems of their children. However, during COVID-19 pandemic, this process was disrupted, and the mental health of the parents was affected.

Research motivation

Although there were many studies on the effects of the COVID-19 pandemic in the literature search, it was observed that there was very limited information on mental health effects on the parents of children with ASD, and there was no systematic review on this topic.

Research objectives

In this systematic review, it is aimed to determine the mental health status of the parents of children with ASD in the COVID-19 pandemic.

Research methods

Articles in English, which could be accessed in full text without any limitation of publication year and country, were included in the study. The systematic review was conducted according to the PICOS strategy (Participants: The parents of children with ASD; Interventions: Effects of COVID-19 pandemic on mental health; Comparators: The parents of children without ASD; Main outcomes: Anxiety, stress, difficulty in coping, loneliness, inadequacy of support systems, social isolation, change in routines and financial difficulties; Additional outcomes: Exercise at home, practicing yoga and meditation, reading newspapers, receiving support from a therapist, cooking meals, talking to their loved ones on online platforms during the pandemic. These results have been reported in studies and included and presented in this systematic review. Study design: Quantitative/qualitative studies). The search results were reached by browsing the Web of Science, PubMed (including MEDLINE), Cochrane, Scopus, Science direct and Google Scholar databases using the keywords COVID-19 AND ("autism" OR "autistic" OR "autism spectrum disorder") AND parent AND ("mental health" OR "anxiety" OR "stress"). The list of the references of the included studies was reviewed to access additional studies.

Research results

The systematic review was conducted according to the PICOS strategy, and a total of 12 studies were included in a quantitative and qualitative design. The studies have revealed that parents are negatively affected by the COVID-19 pandemic. It was reported that the parents of children with ASD had increased anxiety and stress during the pandemic, children became aggressive as their routines changed, and the parents had difficulty coping with this process. During the pandemic, the parents met with their friends *via* online platforms, practiced yoga and meditation, the spouses provided rest breaks to each other and received support from therapists.

Research conclusions

The COVID-19 pandemic negatively affected the mental health of children with ASD and their parents. It may be recommended to plan more interventions that will positively affect the mental health of parents and support them.

Research perspectives

Given the uncertainty of how long the COVID-19 pandemic will last, it is important to conduct a large number of descriptive and interventional studies on the mental health of parents with children who have ASD. In this systematic review, it was revealed that the number of studies on this topic is quite limited. It is thought that this systematic review will form the basis for future studies.

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatr*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc*.

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, and PubMed Central. The 2021 edition of Journal Citation Reports® cites the 2020 impact factor (IF) for *WJP* as 4.571; IF without journal self cites: 4.429; 5-year IF: 7.697; Journal Citation Indicator: 0.73; Ranking: 46 among 156 journals in psychiatry; and Quartile category: Q2.

Abstract

Suicidal behaviors in adolescence are a major public health concern. The dramatic rise in self-injurious behaviors among adolescents has led to an overwhelming increase in the number of those presenting to the emergency rooms. The intervention described below was constructed on the basis of brief and focused interventions that were found to be effective among suicidal adults using an adaptation of interpersonal psychotherapy for adolescents. The intervention has four main objectives: first, a focused treatment for reducing suicide risk; second, a short and immediate response; third, building a treatment plan based on understanding the emotional distress and interpersonal aspects underlying suicidal behavior; and lastly, to generate hope among adolescents and their parents. The intervention includes intensive five weekly sessions, followed by 3 mo of email follow-up.

Key Words: Suicide; Depression; Adolescents; Crisis intervention; Interpersonal psychotherapy

Core Tip: Waiting time for treatment for adolescents who are at risk for suicide in Israel is unreasonably long. The purpose of the interpersonal psychotherapy based intervention for suicidal children and adolescents is to allow more children to receive an acute preventive intervention within a reasonable period of time. INTRODUCTION

Suicidal behaviors in adolescence are a major public health concern; recent elevation in adolescents suicidality highlight an increasing need for its prevention and treatment. The prevalence of non-fatal suicidal acts among children and adolescents is considerably high. In fact, suicide risk is the most frequent reason for presentation to psychiatric emergency rooms among this population[1]. Risk factors for suicide are numerous and utterly complex. Particularly, non-fatal self-injurious behaviors, which are generally recurring, constitute an especially elevated risk for suicide[2]. Unrecognized and/or untreated depression is the psychiatric disorder that is the most commonly associated with suicide[3]. Inappropriate management of depression may produce a range of adverse outcomes for children and adolescents, such as school failure and dropout, avoidance of friends, eating disorders, substance and alcohol abuse and of course the propensity to self-harm[3].

The dramatic rise in self-injurious behaviors among children and adolescents has led to an overwhelming increase in the number of those presenting to the emergency rooms worldwide[1]. In Israel each year, about 400 such incidents are accepted to our emergency room at Schneider Children's Medical Center, with about a hundred of these cases necessitating subsequent treatment[4]. As a result, the average waiting time for treatment before the current study was about 12-18 mo; such a lengthy delay often culminated in deterioration of the child's condition and led to an increased probability of adverse consequences. Evidently, the need to develop a brief and targeted intervention for this population is unequivocal. The need for emergency intervention has become even more important due to the coronavirus disease 2019 pandemic. Many countries reported an increase in suicide rates among children and adolescents during this period[5]. Studies among suicidal adults have demonstrated the efficacy of brief and focused treatments in reducing suicide risk[6]. For example, receiving postcards from a clinic was found to reduce suicidal behaviors over time[7].

Interpersonal psychotherapy for adolescents (IPT-A), a manualized, short-term (12 sessions) therapeutic intervention for adolescents with depression[8] is among the most common forms of therapy provided at our clinic. We decided to attempt to lessen the number of sessions even further in the hope of reducing our waiting list and enable a larger number of adolescents to receive therapeutic care. The rationale for selecting IPT-A specifically is based on present research linking interpersonal problems to suicide risk[9]. Previous studies found that individuals at risk for suicide suffer from significant challenges in their relationships[10]. Insecure attachment, in particular, has been identified as a major risk factor for adolescent suicidality[11]. In addition, difficulty expressing and sharing feelings with others has been found to significantly increase the risk of severe suicide attempts, above and beyond the contribution of depression and hopelessness[12].

IPT BACKGROUND

IPT is a commonly used, evidence-based, time-limited treatment for depression in adults[13] and adolescents (IPT-A)[8,14] as well as other psychiatric disorders (*e.g.*, anxiety disorders)[15]. IPT has demonstrated efficacy in reducing depressive symptoms and improving overall performance and social functioning[16]. IPT-A is an

adaptation of IPT tailored specifically for adolescents with depression[8]. Similar to the original adult version, IPT-A is time-limited and evidence-based[8]. IPT-A focuses on addressing the link between depressed mood and current interpersonal problems. The goal of IPT-A is to reduce depressive symptoms and improve interpersonal functioning by identifying an interpersonal problem area of focus and developing communication/interpersonal, emotional skills and problem-solving strategies[8].

Recently, a number of studies documented the potential for effectiveness of IPT in treating suicidal patients. Mufson *et al*[17] presented preliminary outcomes of a small sample of suicidal adolescents treated with IPT-A (IPT-A-Suicide Prevention). Tang *et al*[18] examined the effects of intensive interpersonal psychotherapy for adolescents with depression who were at risk for suicidal behavior and compared these adolescents with patients who received treatment as usual at schools. Results illus-trated lower post-intervention severity of depression, anxiety, suicidal ideation and hopelessness among those treated with intensive IPT-A compared to treatment as usual.

To the best of our knowledge, despite the tremendous service gap and devastating consequences of the global suicide epidemic among children and adolescents, no protocol exists that offers a very short, practical and feasible crisis intervention for children and adolescents who are at risk of suicide. The intervention described below was constructed on the basis of brief and focused interventions that were found to be effective among suicidal adults using an adaptation of IPT-A.

INTERPERSONAL PSYCHOTHERAPY BASED INTERVENTION FOR SUICIDAL CHILDREN AND ADOLESCENTS

The efficacy of IPT based intervention for suicidal children and adolescents has been recently published elsewhere[4]. The following is a thorough description of the intervention itself. The intervention has four main objectives: first, a focused treatment for reducing suicide risk; second, a short and immediate response to be able to deliver the intervention within a month from the date of referral; third, building a treatment plan based on understanding the emotional distress and interpersonal aspects underlying suicidal behavior and the associated, distinct difficulties of the patient (such as interpersonal skills deficits and emotion dysregulation); and lastly, to generate hope among patients and their parents. Our assumption is that achieving these four goals allows the patient and parents to feel that things can get better, which in turn helps to decrease the patient's suicide risk.

Structure of the intervention

The intervention is comprised of an intensive phase of five weekly sessions and a follow-up phase consisting of four emails across a 3 mo period. The emails are sent to both the adolescent and his/her parents. In the first month post-intervention, two emails are sent (one email every 2 wk). In the following 2 mo, two additional emails are sent (an email every month) for a total of four follow-up emails (Figure 1).

Parental involvement: The intervention is intended for children and adolescents ages 6-18-years-old. We require parental attendance at the first and final sessions and invite parents to attend additional sessions as needed. For children under 10 years of age we recommend that the parents be present during all five sessions.

The intensive phase: The intensive phase is based on IPT-A with the addition of some elements adapted from Cognitive Behavioral Therapy for Suicide Prevention[19] and Dialectical Behavioral Therapy[20].

The first and second sessions constitute the initial phase of the acute intervention and involve assessment and diagnosis of depression and suicide risk (risk assessment), interpersonal assessment and problem area formulation. The third and fourth sessions comprise the middle phase of the acute IPT-A intervention, which focuses on fostering emotional and interpersonal skills within the specific problem area. The termination phase includes the final fifth session in which the patient and therapist summarize the therapeutic process, and the therapist provides recommendations for further treatment. Below is a detailed description of each session.

First session

The first session should ideally include both patient and parents to establish initial rapport and commitment as well as focus on depression and suicidal risk. It is an

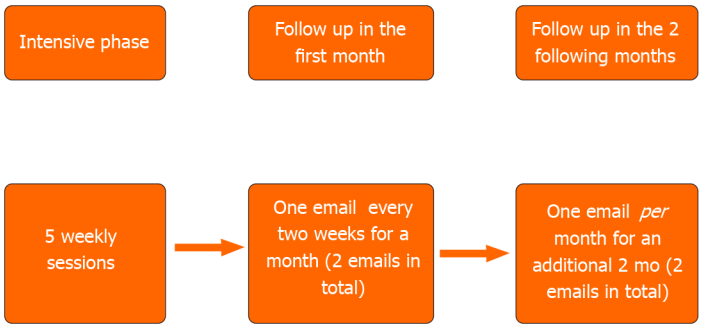

Figure 1 The intervention is comprised of an intensive phase of five weekly sessions and a follow-up phase consisting of four emails across a 3 mo period.

especially intensive meeting requiring an active therapeutic approach and should include:

(1) Risk assessment: A short risk assessment is conducted in addition to the initial risk assessment generally conducted at the intake. This portion of the first session includes an evaluation of depressive symptoms using scales like the Mood and Feelings Questionnaire[21] as well as an assessment of suicidality based on the Columbia Suicide Rating Scale[22] and/or Suicide Ideation Questionnaire[23].

(2) Safety plan[24]: In the event of suicidal risk, an interpersonal safety plan is constructed in collaboration with the patient and the parents. The safety plan includes a list of coping strategies arranged in a hierarchical order, available for the patient, should a suicidal crisis occur. The main purpose of the plan is to provide a predetermined course of action for potential coping strategies as well as a list of specific and relevant support resources. The plan includes internal strategies that a patient employs on his own (*e.g.*, self-talk) in addition to a list of contacts of individuals in the patient's life (*e.g.*, family members, healthcare providers) who can be contacted in real time to help reduce the risk of suicidal behavior. A collaborative approach is recommended between the therapist, the patient and the parents. The plan is a dynamic therapeutic program reviewed periodically by the patient and therapist to evaluate the need for any particular changes or additions.

(3) Chain analysis: A chain analysis is performed in order to outline and discern the events that occurred in the hours prior to the attempt. The chain analysis allows for better understanding of the context of the suicidal act and the emotional and interpersonal/social triggers preceding the attempt.

(4) Presenting the intervention to adolescents and their parents: A thorough explanation of the nature, structure and goals of the intervention is presented to the adolescent and parents. The need for parental cooperation is addressed directly, and the topic of confidentiality is discussed. Further, the obligation to share details of the patient's risk and needs with the school is discussed. The goal of collaboration with the school is to increase the support the patient receives from the school in the areas he struggles the most (*e.g.*, academic, social or emotional realms). Although the communication with the school is addressed in the first session, in practice the school is contacted only after the end of the second session, once we have gotten to know the patient better and have jointly delineated with the patient the main problem area that underlies his/her suicidality. Finally, the limitations of the intervention and the need for long-term psychological treatment and/or consultation about psychotropic medication are addressed. The family is accompanied throughout the intervention in the challenge of finding appropriate follow-up care after the acute IPT-A for suicidal children and adolescents intervention.

and (5) Psychoeducation: Extensive psychoeducation about depression, suicidality, adolescence, parenting and other patient-specific topics is provided. The patient is presented with an explanation of the concept that suicidal crises come in waves and that the purpose of the intervention is to prepare for the next wave. The underlying assumption is that it is likely there will be more crises in the future even if, at the moment, the patient is feeling better. We also use the IPT-A concept of a "Limited Sick Role," which is an aspect of the medical model of IPT. This role refers to the need to match expectations between functional requirements and the patient's mood. The patient is encouraged to function to the best of his ability, while adjusting the pace and progress to his mental state. The concept of the limited sick role is also explained to the patient's parents and teachers.

Second session

Each session begins with an evaluation of the patient's mood and suicidal risk on a scale of 0-10 and discussion about the changes needed in the safety plan. While the first session focuses on the depression and suicidal risk, the second session concentrates on interpersonal functioning. The purpose of the second session is to define the problem area that will be the main focus of the intervention. In order to achieve this, the therapist uses the Closeness Circle and the Interpersonal Inventory[25]. The Closeness Circle is a series of circles, one inside the other (Supplementary material 1). The therapist explains that the circles around the patient's name represents circles of closeness, and the goal is to place the patient's significant relationships within the appropriate circles according to the relevant degree of intimacy; the result is a visual representation of the patient's significant relationships. Then, the therapist and the patient discuss the patient's meaningful relationships using the Interpersonal Inventory. The Interpersonal Inventory includes questions related to facts, opinions, particular events and feelings about the relationships with the people outlined in the patient's circles. The goal of this session is to reach as deep of an understanding as possible of the patient's emotional and interpersonal world and to identify the most relevant emotional and interpersonal struggles that may be the underlying issues contributing to the patient's suicidal risk.

The first two sessions lead to the formulation of the main problem area that the patient is currently dealing with[25]. The problem area is a framework in which the patient and therapist learn and practice skills in the middle phase of the intervention. The line of questioning taken by the therapist in exploration of the various potential problem areas (*e.g.*, grief, conflicts, role transitions and interpersonal deficits) should be directed towards obtaining relevant information in order to ascertain which is currently most significant. There are four main problem areas: (1) grief: relates to actual death and refers to situations in which depression developed due to complicated grieving following the loss of a significant other; (2) interpersonal disputes: conflicts or problems managing expectations in significant relationships. With adolescents this is usually between the patient and his/her parents but may also occur with a teacher, sibling or friend; (3) role transitions: significant life events that may be positive or negative and can be identified as the point at which the patient became depressed such as entry to middle/high school, parental divorce or a diagnosis of an illness; and (4) interpersonal deficits: difficulties with interpersonal skills, leading to loneliness or social detachment. The problem can be in social/group settings or intimate/dyadic situations. It is important to establish an understanding of the specific hardships involved, such as asking for help, learning to forgive, dealing with disagreements in groups, *etc.*

During or after the second session, the therapist contacts and communicates with the school staff.

Sessions three and four

These sessions are focused on fostering and practicing interpersonal, emotional and behavioral skills. Each session begins with an examination of the patient's mood during the past week as well as his suicidal risk. The safety plan is reviewed and readjusted. These two sessions focus on skills learning and practicing within the formulated problem area.

As there is very little time within this brief intervention for skill learning, the therapist should choose one or two IPT-A skills that the patient exhibits the greatest deficits in and that are most relevant to his suicidal risk. These skills are typically related to mood and/or interpersonal relationships. There are three skill sets to choose from including emotional, behavioral and interpersonal. Emotional skills include an emphasis on emotional regulation techniques. The work on emotions with these at-risk children and adolescents include raising their awareness to the various emotions, cultivating their ability to label their emotions, monitoring their intensity and learning ways to regulate them in order to control behaviors associated with these feelings. This promotes the patient's realization and understanding that it is normal to feel lonely, sad or hopeless at times. Yet, when these emotions are intensive and overwhelming, the adolescent should act to control their behavior. Behavioral skills include decision analysis (interpersonal problem-solving), which are crucial in every type of interpersonal interaction. Lastly, enhancement of interpersonal skills incorporates communication analysis, in which the patient learns to identify maladaptive communication skills and learns flexible and adaptive alternatives. All skills are taught through role-play and entail interpersonal experiments intended to be conducted between sessions (*i.e.* in real life) and processed with the therapist during the sessions

themselves. Many of the parents benefit from these skills training as well and are therefore encouraged to attend these sessions as needed.

Session five

The concluding session of the intensive phase includes a summary of the interpersonal and emotional work that has taken place and recommendations for further treatment. In this session we re-emphasize that suicidal risk and behaviors occur in waves and address the possibility that the adolescent may feel suicidal again by discussing relapse prevention. We return to the safety plan devised together in the beginning of treatment in order to ensure its relevance and verify that the patient is familiar with it and willing to use it when needed.

Follow-up phase

Following the intensive phase, periodic emails are sent to the patient and his parents over a 3 mo timespan. During the first month following termination, an email is sent every 2 wk. Then, during the following 2 mo, one email is sent each month. The emails are sent to the patient's personal e-mail and/or his parent's email depending on the patient's age and preferences.

The email is written in a fixed format and is sent directly from the clinic. The email includes patient-specific information in order for it to be personalized (Supplementary material 2).

CASE STUDY

Background

Rona (pseudonym) is a 16-and-a-half-year-old, 11th grade student. She lives with her parents and two brothers in a city in the center of Israel. Her father is a software engineer, and her mother works as a teacher. Both parents were born in the Soviet Union and immigrated to Israel in their early 20s.

Rona presented with a significant suicide attempt in which she swallowed 50 pills with an intention to die. The psychiatric evaluation concluded that she was diagnosed with depression. She began anti-depressant medication and was simultaneously referred for IPT-A for suicidal children and adolescents.

First session

Assessment and psychoeducation: The first session took place with Rona and her parents. After taking Rona's history, psychoeducation was provided, focusing primarily on symptoms of depression and suicide prevention. Further, the intervention itself was explained in terms of its structure, content and goals and the need to find continued, psychological care post-treatment even though we just started.

The next step was performed with Rona alone. A clinical evaluation of depressive symptoms and suicidal risk was repeated, and Rona completed a few self-report questionnaires. In the clinical assessment, Rona denied current suicidality. She stated she understood she had made a mistake attempting suicide and declared she would avoid future attempts. She denied suicidal ideation and intent to die. She also reported significant improvement in her depressive symptoms. Her questionnaires indicated significant depression (Mood and Feelings Questionnaire = 29), moderate severity of suicidal ideation (Suicide Ideation Questionnaire = 33) and high suicide risk (Columbia Suicide Rating Scale = 5).

Safety plan: The next step included a collaborative drafting of a safety plan with Rona. Although Rona insisted it was unnecessary, the need to build a plan for handling potential suicidal waves was explained to her. Rona was cooperative, and the program seemed to be a good fit for her (Supplementary material 3). Despite the proper plan and the fact that Rona denied suicidal risk, we kept in mind the immense gap between the current circumstances and the serious suicide attempt she had made just a month prior to her referral. A substantial portion of the present therapeutic intervention focused precisely on this gap.

Chain analysis: From the chain analysis it became evident that the night before the suicide attempt, Rona was very stressed because of an exam she was supposed to take the next day at school. She knew that she had not studied properly and was extremely afraid that she would fail. She felt that she could not afford to fail this exam especially because she knew how much her failure would disappoint her father.

She tried not to think about it and watched TV, but she could not concentrate. She only imagined the reaction of her father when he finds out that she failed the exam. She was not able to sleep all night. When the day started the pressure increased, and there seemed to be no other solution. She felt stressed and helpless. She got ready for school as if she were planning on going, her parents wished her luck on the exam and left for work. She was left alone at home and finally decided she was not going to go to school. She felt desperate. She went to her shower and saw a packet of pills. She felt that she would rather die than face whatever would happen if she went on with her day as planned. She took all the pills in the container. Her mother found her half an hour later, in the bath with the pills next to her. When Rona recovered in the hospital and saw her parents, she was very disappointed to find that she was still alive and felt awfully guilty and ashamed.

After we conducted the chain analysis, we came back to the safety plan and addressed the need to use it whenever stressful events occur. Towards the end of the session, we invited the parents to rejoin and shared with them the safety plan; we clarified what was required from them when Rona approaches them in times of crisis.

Second session

The second session focused on the interpersonal assessment; to enhance this process we used the Closeness Circles and the Interpersonal Inventory. Rona had many people in the circles (Supplementary material 1), and it seemed she had many significant individuals in her life. She described close and meaningful relationships with her friends, juxtaposed to the fact that she recently moved away from them. Her father was in the closest circle to her. She described a special and close relationship with him that was different from her father's relationship with her brothers. She explained that her academic success was always important to her father and that when she was younger, he tutored her for many hours. However, Rona explained she was not invested in her studies and preferred to spend time with her friends; she described ongoing conflicts between her and her father about it. Rona felt that her dad did not understand her needs. In the last year she was less invested in her studies, and this negatively impacted her relationship with her father. Rona felt he was dissatisfied with her and believed he was distancing himself from her. She felt that the two were no longer as close as they used to be. Rona shared that she missed the closeness they had, and she felt she failed to be the daughter her father wanted her to be. Further, Rona shared her parents' relationship was deteriorating and that they quarreled often. In the past, Rona's father had shared with her some of his feelings about her mother, and Rona felt that she understood her father better than her mother did. She missed being the one her father trusted and confided with.

Rona's mother was in the second circle. Rona describes she was never very close to her mother and felt that her mother was unable to truly understand her. Rona described she did her best to help around the house whenever her mother asked her to, which she felt helped avoid arguments with her mother and assisted in maintaining a somewhat normal relationship between the two of them. There was no real closeness between Rona and her mother, but Rona insisted it did not bother her and that their relationship was this way as long as she could remember. The more we talked about their relationship, the more likely it seemed that Rona actually wished to be closer to her mother but that she was too afraid to expect intimacy with her and be disappointed.

In the third circle Rona wrote her ex-boyfriend. Rona shared she decided to break up with him 2 mo ago because she felt she was no longer fun to be around and that she would probably disappoint him soon as she disheartened others in her life. She felt she was changing; she was no longer in the mood to hang out with friends and found she mostly preferred to be alone. After the interpersonal inventory, we introduced Rona to the concept of problem areas and collaboratively chose the problem area of interpersonal disputes (surrounding her conflicting relationship with her father).

Session three and four

Learning skills: The third and fourth sessions focused on skill acquisition and rehearsal. The goal was to teach Rona skills that would help her communicate better with her father (communication skills) as well as skills that would help her respond differently if she felt similarly to how she felt prior to her suicide attempt (emotional regulation skills). We used communication analysis and identified the need to work on Rona's ability to speak more openly with her father and express her feelings to him without fearing she would be disappointing him. Through communication analysis we were able to uncover that Rona predominantly avoided discussing her school difficulties with her father or share with him that she wished to be more engaged in

other activities such as spending time with her friends.

Together, we brainstormed some goals Rona wished to achieve in a potential conversation with her father. Rona wanted to relieve stress from her studies and accomplishments without feeling she would be disheartening her father too much. We planned numerous possible scripts for the conversation and used the teen tips to promote effective communication. Between sessions, Rona practiced her communication skills with her father, eventually introducing a possibility for a different kind of dialogue between them.

Further, sessions centered on fostering Rona's emotional regulation skills. At first, Rona found it difficult to recognize the feelings she experienced before attempting suicide (*e.g.*, the fear of disappointing her father, hopelessness and loneliness, in particular). She was only able to describe she felt she was "under pressure." Through processing Rona's feelings prior to the attempt, we were able to elucidate Rona's explicit fear of disappointing her father, which led her to distance herself from him initially and avoid others subsequently, the latter behavior culminating in a detrimental increase in her feelings of loneliness and sadness. Between sessions Rona was requested to monitor the intensity of her negative emotions in various situations, and together we practiced numerous self-calming methods such as self-talk and relaxation techniques. Further, Rona was asked to practice additional soothing techniques at home, and these skills were added to her safety plan. Our intention was to teach Rona to recognize situations in which she would be likely to have a decreased ability to regulate her emotional state, so that once becoming aware of them she would have adaptive means of calming herself.

Fifth meeting

As described above, the objectives of the fifth session are to summarize the therapeutic process, focus on relapse prevention, provide recommendations for further treatment and review the safety plan. The meeting was divided into two parts; in the first half of the meeting we met Rona alone, and her parents joined us in the second part of the session. We addressed the focus of Rona's difficulties, her experiences and her needs in the relationships with her parents. Her parents were invited to express their desire for closeness in addition to their concern for her well-being. We repeated and reevaluated the safety plan with Rona and later with the parents to ensure each of them was knowledgeable of what to do should Rona feel suicidal again.

Although the need for continuous treatment for Rona had been discussed earlier in treatment, present difficulties of finding available individual psychotherapy in the community disabled her immediate transition into follow-up care. Rona was waitlisted for long-term treatment at our clinic, and in the meantime, the family began family therapy.

CONCLUSION

At the end of the intervention, there was a significant reduction in Rona's depressive symptoms, and she continued to deny current suicidal ideation. The family remained in family therapy for 8 mo, and treatment was found to be helpful and led to tremendous therapeutic gains. A year later, Rona began long-term treatment at our clinic. Of note, throughout this period, Rona refrained from further engagement in suicidal behaviors.

Abstract

A severe impairment of cognitive function characterizes dementia. Mild cognitive impairment represents a transition between normal cognition and dementia. The frequency of cognitive changes is higher in women than in men. Based on this fact, hormonal factors likely contribute to cognitive decline. In this sense, cognitive complaints are more common near menopause, a phase marked by a decrease in hormone levels, especially estrogen. Additionally, a tendency toward worsened cognitive performance has been reported in women during menopause. Vasomotor symptoms (hot flashes, sweating, and dizziness), vaginal dryness, irritability and forgetfulness are common and associated with a progressive decrease in ovarian function and a subsequent reduction in the serum estrogen concentration. Hormone therapy (HT), based on estrogen with or without progestogen, is the treatment of choice to relieve menopausal symptoms. The studies conducted to date have reported conflicting results regarding the effects of HT on cognition. This article reviews the main aspects of menopause and cognition, including the neuroprotective role of estrogen and the relationship between menopausal symptoms and cognitive function. We present and discuss the findings of the central observational and interventional studies on HT and cognition.

Core Tip: Cognitive complaints are more common in postmenopausal women than in premenopausal women. Due to the reduction in ovarian function, a progressive decrease in serum estrogen levels occurs, leading to menopausal symptoms with an emphasis on vasomotor symptoms. In addition to these symptoms, cognitive impairment can affect postmenopausal women to varying degrees. Several aspects of the relationship between menopause and cognitive function were reviewed. We report the latest evidence on the topic. In this sense, considering current knowledge, we do not recommend the prescription of hormone therapy to prevent cognitive decline or dementia in postmenopausal women.

INTRODUCTION

Approximately 50 million people worldwide live with dementia, with Alzheimer's disease (AD) being the most frequent cause[1]. Dementia is characterized by severe cognitive decline and subsequent functional disability[2]. It is the fifth leading cause of death and is responsible for 28.8 disability-adjusted life-years[3]. A few decades before the onset of Alzheimer's dementia, AD-related neuropathological changes are observed in the brain, which may be accompanied by subtle cognitive decline[4]. Accordingly, patients with early cognitive symptoms are at increased risk of dementia [5,6].

Mild cognitive impairment (MCI) is defined as individuals with objective cognitive deficits in neuropsychological tests (usually defined as a performance of 1.5 standard deviations below the mean established for age and education) and preserved functional independence for activities of daily life[2]. MCI is related to a nine-fold increase in the risk of dementia compared to the general population[5]. Subjective cognitive complaints with normal performance on neuropsychological tests are related to a two-fold increase in the risk of dementia compared to the general population[6]. Identifying and understanding the predisposing and triggering factors of the neurobiological mechanisms underlying early cognitive decline may contribute to the development of preventive interventions to mitigate the risk of dementia.

Female sex is a consistent risk factor for dementia, and the greater longevity of women does not fully explain this relation. In addition, estrogen plays an essential role in the neurobiology of cognitive processing and neuronal function, and the menopausal transition is associated with subtle cognitive decline. However, the relationships among decreased estrogen levels in menopause, the effects of hormone therapy (HT) on cognition, and the risk of dementia are still conflicting and puzzling.

Considering the relevance of the issue and seeking to contribute to the existing literature, several aspects of the relationship between menopause and cognitive function were reviewed in this paper. We describe the most recent evidence, presenting what we know and the gaps in knowledge on the subject.

SEARCH METHODS

A search was conducted in Medline and Embase for the period from 1980 to 2020. The search terms cognition, climacteric, cognitive decline, estrogen effects, menopause, menopausal symptoms, hot flashes, middle-aged women, perimenopause, neuropsychology, HT, progestogen, MCI, subjective cognitive decline, risk of dementia, neuroimaging, and vasomotor symptoms were used.

Original articles, systematic reviews, meta-analyses, narrative reviews, and consensus reports were evaluated. Both human and animal studies published in

English were considered. The bibliographies of the articles were searched to identify related studies. All articles were critically evaluated by the authors, including those more specifically related to the theme of this narrative review and those that resulted in agreement between the authors for their inclusion.

EVIDENCE OF THE RELATIONSHIP BETWEEN MENOPAUSE AND COGNITIVE DECLINE

Subjective cognitive decline is one of the most frequent complaints of women undergoing the menopausal transition, with a 44%-62% prevalence estimated in population-based studies[7,8]. Reports of memory problems are associated with the perimenopausal period compared to pre- or postmenopausal periods[9]. The incidence of MCI was 4.5% in 6376 postmenopausal women evaluated for 5.4 years in the Women's Health Initiative Memory Study (WHIMS)[10], but the relationship between MCI and menopausal factors has still been poorly studied. In contrast, changes in women's cognitive test performance, regardless of cognitive complaints or cognitive impairment, are consistently related to the reproductive period and menopausal transition.

After adjusting for age, cognitive performance during postmenopause tended to be lower than that during pre- and perimenopausal periods, particularly verbal delayed memory and executive function[11], which involve cognitive domains that are assumed to be more sensitive to changing estrogen levels[12]. The Study of Women's Health Across the Nation evaluated 2362 American women by repeated administration of neuropsychological tests for four years. Women's scores on delayed and immediate memory tests in the early and late perimenopausal periods did not improve over time with test repetition. However, the incremental changes in scores normalized in the postmenopausal period, returning to the pattern observed during premenopause[13]. Similarly, Kilpi *et al*[14] studied 2411 middle-aged United Kingdom women, verifying that processing speed and immediate and delayed verbal episodic memory decreased in the perimenopausal period; additionally, changes in verbal episodic memory tests correlated with follicle-stimulating hormone and luteinizing hormone levels.

Several studies have also reported that prolonged lifetime estrogen exposure results in better cognitive outcomes[15]. A younger age at first menses, older age at menopause, age at birth of a first child more than 20 years, and an extended reproductive period were related to a more remarkable performance on neuropsychological tests at postmenopause[16,17]. However, the data are conflicting regarding reproductive period factors and the risk of progressive cognitive decline or dementia. Although the meta-analysis by Georgakis *et al*[15] found that age at menopause and the reproductive period were not associated with the risk of dementia, two more recent population-based studies documented an increased risk of dementia by up to 23% with late menarche, early menopause and a short reproductive period[18,19]. Interestingly, patients who underwent bilateral oophorectomy before menopause had a higher risk of cognitive impairment over time than age-matched natural menopausal women; additionally, oophorectomy at ≤ 45 years of age was associated with an increased risk of dementia[20,21]. In women with Down syndrome, a condition with a higher incidence of AD than the general population, age at menopause was directly correlated with the age of dementia onset[22].

Evidence on AD biomarkers in middle-aged women strengthened the hypothesis that decreased estrogen levels in the menopausal transition explain cognitive decline during perimenopause and the greater risk of dementia related to the female sex. Rahman *et al*[23] compared 40- to 65-year-old women with age-matched men in terms of cerebral volumetry using structural magnetic resonance imaging, cerebral metabolism using 18F-fluorodeoxyglucose positron emission tomography, and the β-amyloid load using 11C-Pittsburgh compound B positron emission tomography. Women presented lower gray and white matter volumes, lower glucose metabolism, and higher deposition of β-amyloid; this neuroimaging pattern was consistent with an AD endophenotype. Menopause was the strongest predictor of these findings. Other studies reported a gradient of AD biomarkers, with the most remarkable abnormalities in menopausal women, an intermediate number of abnormalities in perimenopausal women, and the lowest number of abnormalities in premenopausal women[24,25]. In addition, cerebral glucose hypometabolism in AD-vulnerable regions of peri- and postmenopausal women correlated with reduced platelet mitochondrial cytochrome oxidase activity; mitochondrial cytochrome oxidase is an enzyme involved in

adenosine triphosphate (ATP) synthesis that is regulated by estrogen[24]. Based on these findings, the decrease in estrogen levels during the menopausal transition disrupts brain bioenergetics due to mitochondrial cytochrome oxidase dysfunction that is accompanied by reduced cerebral metabolism, β-amyloid deposition, synaptic loss, and cognitive decline.

PATHOPHYSIOLOGY

Estrogen and the brain

Accumulating evidence shows a significant neurotrophic and neuroprotective effect of estrogen on the central nervous system. Cognitive deficits have been described in women during the menopausal transition, particularly in cognitive domains such as working memory, attention, reduced processing speed, and reduced verbal memory. This review briefly describes the plausible biological functions of estrogens in aspects of cognitive function and the mechanisms involved[26].

The effects of estrogen on the brain include complex cellular mechanisms ranging from classical nuclear to nonclassical membrane-mediated actions. In classical mechanisms, estrogen modulates gene transcription by interacting with nuclear receptors. The estrogen receptors (ER) α and ERβ have distinct differences in their binding affinities for different ligands and selective ER modulators[27].

Through genomic mechanisms, steroids exert long-term effects on neurons, modulating the synthesis, release, and metabolism of many neuropeptides and neuroactive transmitters and the expression of their receptors. The nongenomic (nonclassical) estrogen action is probably mediated by receptors integrated or associated with the cell membrane and by the activation of distinct intracellular signaling cascades through the high-affinity membrane-associated G protein-coupled estrogen receptor GPR30/GPER1[28,29].

These effects of estrogens include rapid actions on the excitability of neuronal and pituitary cells, activation of cyclic adenosine monophosphate and mitogen-activated protein kinase pathways that affect the activity of targets such as kainite and insulin-like growth factor-1 receptors, modulation of G-protein coupling, modulation of calcium currents, modulation of calcium channels and calcium ion entry and protection of neurons from damage by excitotoxins and free radicals[30-33].

Decreases in estradiol levels may impact three systems. Researchers must determine how therapeutic modulation of estradiol levels may augment normal or disease-related cognitive decline. The three predominant systems postulated to be involved in cognitive aging concerning hypoestrogenism include the basal forebrain cholinergic system, the dopaminergic system, and the mitochondrial bioenergetic system[34].

Reduced nicotinic cholinergic binding sites in the cortex and reduced cholinergic acetyltransferase activity (a marker of cholinergic neurons) have been shown to correlate with reduced cognitive performance[35]. Choline acetyltransferase-expressing neurons are a marker for cholinergic neurons, and thus the expression of GPR30/GPER1 on cholinergic neurons provides increasing evidence for an interaction between estrogens and the cholinergic system. Clinical magnetic resonance imaging studies have shown that estradiol treatment also modulates anti-muscarinic and anti-nicotinic induced brain activity. Estradiol treatment alters anticholinergic-related brain activation during working memory in postmenopausal women[36].

The effects of estradiol on dopaminergic signaling have been less well characterized than its effects on the cholinergic system. *In vitro*, estradiol protects against 6-hydroxydopamine toxicity in dopamine neurons[37]. Magnetic resonance imaging evidence has shown that dopaminergic agonists increase working memory activity, suggesting that the dopaminergic system is responsive to pharmacological manipulation after the menopausal transition[38]. The potential mechanism by which estradiol exerts its neuroprotective effects on dopaminergic neurons is to modulate the neurotoxic effects of the renin-angiotensin system[39].

The mitochondrial aging hypothesis is related to increased mitochondrial DNA damage, leading to increased reactive oxygen species-mediated damage and a reduction in mitochondrial activity[40]. Clinical studies support the postulated role for estradiol in maintaining appropriate mitochondrial bioenergetics; clinical studies also support the hypothesis that decreasing estradiol levels are correlated with reduced synaptic plasticity, an indicator of cognitive performance, suggesting that a failure of glucose metabolism might influence cognitive deficits. As glucose uptake decreases, ATP production also decreases, consistent with aerobic cellular respiration[41].

Finally, low-grade inflammation has also been identified as a potential cause of cognitive decline. Postmenopausal women present an increase in the levels of inflammatory markers such as interleukin (IL)-1, IL-6, and tumor necrosis factor-alpha. These increases in inflammatory markers appear to be normalized following treatment with sex HT, exerting a relevant anti-inflammatory effect[42,43].

Neuroprotective effect of estrogen

A reasonable hypothesis is that estrogen might exert an important protective effect on the deterioration of cognitive functions that occurs with normal aging. The potential mechanisms involved in the neuroprotective effects of estrogens include modulation of neuropeptides, neurotransmitters, and neurosteroid synthesis and activity[44,45]; reduced cell apoptosis[46]; modulation of neuronal growth and synaptic plasticity[47] and mitochondrial activity[48]; antioxidant properties[49]; modulation of the brain immune system[50]; and reduced formation of β-amyloid[51].

Importantly, the effects of treatment with sex hormones on cognitive symptoms appear to be more evident during the menopausal transition or in the first years of menopause when the levels of estradiol and estrogen receptors are initially decreasing [52].

Moreover, some selective estrogen receptor modulators, such as tamoxifen and raloxifene, have shown promising effects by interacting with ERα, ERβ, and GPR30[53] and exert neuroprotective effects[54]. Selective estrogen receptor modulators have shown efficacy in reducing anticholinergic effects on cognitive performance in some cognitive domains by reducing proinflammatory cytokine levels[55].

Findings from primary studies have shown that testosterone also exerts neuroprotective and anti-inflammatory effects on the brain. Testosterone protects against oxidative stress, serum deprivation-induced apoptosis, and soluble amyloid β (Aβ) toxicity; this effect is mediated by estrogen. Aβ toxicity induced by testosterone appears to involve an androgen receptor-dependent mechanism that leads to the upregulation of the Aβ-catabolizing enzyme neprilysin[56,57].

Notably, testosterone studies in women have yielded differing findings according to the women's ages, the testosterone dose administered, and the study duration. Observational and interventional studies have shown an association between verbal learning and memory and physiological concentrations of testosterone administered to postmenopausal women exogenously. The effects of testosterone on verbal learning and memory in postmenopausal women do not seem to rely on the aromatization of estradiol. The statistically significant improvements in verbal memory following testosterone therapy in postmenopausal women suggest that further investigations of the ability of testosterone to enhance cognitive performance or delay cognitive decline are warranted, but the results currently do not justify using testosterone for this purpose[58].

In conclusion, increasing evidence linking menopausal hormone changes and cognition has revealed a complex biological mechanism. A better understanding of this mechanism is fundamental to enable earlier and personalized pharmacological treatment with the potential to delay the onset of cognitive decline during the menopausal transition.

CLIMACTERIC FACTORS AND COGNITIVE DECLINE

The climacteric period often involves problematic symptoms, including vasomotor symptoms, vaginal dryness, decreased libido, insomnia, and fatigue[59]. In clinical practice, cognitive changes are also frequently observed during this period, with subjective reports of "cerebral fog" affecting daily cognitive performance. Some of the most common symptoms are deficits in attention, processing speed, and memory, which subsequently manifest as lack of focus, slow thinking, and forgetfulness[60].

In the Study of Women's Health Across the Nation with 16065 women between the ages of 40 and 55, 31% of premenopausal women reported complaints of forgetfulness, compared to 44% of women in early perimenopause, 41% of women in late perimenopause, and 41% of postmenopausal women[61]. This study later reported a compromise in cognitive performance, mainly in learning skills during the menopausal transition, with a subsequent improvement in the postmenopausal period. Cognitive changes that occur late after menopause are associated with aging and not with the last menstrual period[8].

In the Kinman women's health investigation, a longitudinal study, the cognitive performance of 694 premenopausal Chinese women was evaluated. Verbal memory,

mental flexibility, verbal fluency, and processing speed were measured at baseline and after 18 mo. An improvement in cognitive test scores was observed, which was expected due to the learning effect of repetition of neuropsychological tests. However, perimenopausal women recorded worse results than those who remained in the premenopause group[62].

Studies indicate that this decreased cognitive performance during perimenopause appears to normalize in postmenopause[8,62]. If this pattern of change in memory during the menopausal transition is valid, the decreases in estradiol levels alone are not likely solely responsible for cognitive changes, as memory appears to recover while decreases in estradiol levels persist[13,63].

Although self-reported vasomotor symptoms (VMSs) are generally not related to memory performance[64], when this relationship was observed using 24-h monitoring to measure physiological VMSs, verbal memory differences were found. Among middle-aged women, moderate to severe VMSs related to worse verbal memory were recorded with ambulatory skin conductance monitors and not self-reported VMSs[65,66].

Another cross-sectional study was performed with women with moderate to severe VMSs. Researchers recorded physiological VMSs using ambulatory monitors associated with or without a diary to record subjective VMSs and performed a battery of neuropsychological tests. A higher frequency of physiological VMSs, but not subjective VMSs, particularly during sleep, was associated with poor verbal memory testing performance[67]. Recently, a study evaluating the association between VMSs and worse memory was replicated in breast cancer survivors, confirming evident associations only with physiological VMSs[68].

Thus, in addition to being passive predictors of depressed mood, sleep problems, and worse quality of life during menopausal transition, VMSs also appear to be linked to the leading indices of physical and neurocognitive health[65,68].

HT AND COGNITION

Although many questions remain about the effects of HT on cognitive function, two factors seem to be consistently involved: Age and time of exposure concerning menopause. Researchers have postulated that a critical window exists that explains the more evident effects of HT when administered early when symptoms manifest and when administered to young women. However, published studies have reported conflicting results in this regard and are presented and discussed below.

Contradictory evidence presented to date

Although a considerable number of studies have examined the effects of HT on cognitive function in postmenopausal women, the results are still conflicting. Some studies showed benefits[69-71], others showed a lack of effect[72-74], and worsening of cognitive function was observed in some, including a more significant risk of MCI and various types of dementia[75,76]. Importantly, observational studies are prone to biases, such as selection bias, type, time of HT use, and age at HT initiation, which are often not controlled. These biases may at least partially explain the divergence between the findings of observational and interventional studies.

Many investigators presented their results for different aspects of HT and cognition at the same time. Because the same study published data on global cognitive function, MCI, and dementia, we chose to discuss the best evidence available, presenting the data jointly, as in the original articles of the critical observational and interventional studies on this topic.

Observational studies

Evidence from older women: The Cache County Study (CCS), a longitudinal, population-based study, investigated the association between HT and global cognitive function. The modified Mini-Mental State Examination (MMSE) was administered to 2073 women over 65 years old with no prior diagnosis of dementia. After three years of follow-up, HT was associated with an apparent benefit in global cognitive function and reduced cognitive decline, especially in older women (75 years or older) and even more so in women older than 85 years[77]. In another CCS publication, the relation between HT and AD was evaluated in 1889 women with an average age of 74.5 years. Compared to nonusers, women who received HT for more than ten years presented a 2.5-fold lower risk of AD incidence[78]. With seven more years of follow-up, the CCS cohort verified that starting HT (any type) within five years of menopause was

associated with a 30% reduction in the risk of developing AD. However, if HT was initiated after five years of menopause, no associations were observed.

Furthermore, if HT was initiated within five years of menopause and used for ten years or more, the reduction observed in AD risk was 37%. Additionally, the use of estrogen alone within five years of menopause reduced the risk of AD by 35%[79], which supports the critical window hypothesis. The main information obtained from the observational studies is shown in Table 1.

In a recent 12-year update of the follow-up of the CCS cohort, which included 2,114 women, a longer HT duration was associated with better cognitive function. Additionally, women who initiated HT within five years of menopause presented better cognitive performance than those who initiated it six or more years after menopause, once again supporting the critical window hypothesis. However, another interesting finding in the CCS was that even women who initiated HT after six years of menopause still presented cognitive benefits compared to women who never used HT [71].

In a French longitudinal study, the Three-City Study, 3310 postmenopausal women aged 65 years and over were followed every two years and were subjected to a series of cognitive tests to examine the association of HT with dementia and some specific cognitive domains. After a 4-year follow-up period, no associations were observed between HT and dementia or AD. Additionally, active HT users had significantly better performance on verbal fluency, working memory, and psychomotor speed tasks than those who never used HT. These associations varied according to the type and duration of HT. The findings of this study suggest that transdermal estrogen combined with progestogen and a lengthier HT duration are better at improving cognitive function. Notably, current HT users exhibited a reduction in the detrimental effect of apolipoprotein E (ApoE) E4, a known risk factor for dementia, on the incidence of dementia and AD. Moreover, starting HT near menopause had no relation to improved cognition[69], potentially refuting the critical window hypothesis.

In another longitudinal study with 5504 postmenopausal women conducted at the Kaiser Permanente Medical Care Program of Northern California, women who used HT only during their midlife period presented a 26% reduced risk of dementia than women who never used HT. Those who used HT in late life experienced detrimental effects, with a 48% higher risk of dementia in the 8-year follow-up[80]. These findings support the critical window hypothesis.

The largest longitudinal study was the Nurses' Health Study, a prospective cohort study that included a subgroup of 13087 participants aged 70 or older to evaluate global cognitive function, attention, verbal memory, and category fluency. Generally, few differences were observed between average cognitive decline when comparing current users or former users of HT and those who had never used it. On the other hand, the data suggest an increased risk of cognitive decline in long-term users (*i.e.*, 5 to 10 years) of estrogen alone or estrogen combined with progestogen, with a greater risk identified in women who initiated HT at an older age than in those who never received HT [relative risk: 1.74; 95% confidence interval (CI): 1.08-2.81]. The authors also did not identify a relation between HT and the ApoE E4 allele. The authors concluded that postmenopausal HT provides no relevant cognitive benefit in older women[76].

In a population-based nested case-control study that included 59 women with AD and 221 controls, no relationship was observed between the use of HT (estrogen with or without progestogen) and AD risk[72], corroborating the findings from a previous case-control study[81]. The Multi-Institutional Research in Alzheimer's Genetic Epidemiology case-control study included 971 postmenopausal women from different countries (426 patients with AD and 545 nondemented patients). HT was associated with a 30% reduction in the AD risk. The ApoE genotype did not influence the relationship between HT and AD. The protective effect of HT was modified by age, as it was observed only in younger women aged between 50 and 63 years, who presented a 65% reduction in the AD risk[82].

These findings suggest that HT use during the first years after the last menstrual period, named the critical window, may protect cognitive function. In another case-control study conducted in Finland, 84739 women diagnosed with AD and 84739 women without an AD diagnosis were included. Systemic HT was associated with a 9% to 17% increased risk of AD, with no significant difference between those who used estrogen alone and those who used estrogen and progestogen in combination. The exclusive use of vaginal estradiol did not increase the risk of AD. Moreover, the age at which HT was initiated (younger than 60 years or older than 60 years) had no effect on the AD risk. Notably, in women who initiated HT before 60 years of age, the increase in the AD risk was associated with the use of HT for ten years or more. The

Table 1 Observational studies on hormone therapy and cognition in women

Ref.	Study	Country	Design	*n* (%)	Age (yr)	Hormone therapy	Main findings
Carlson *et al* [77], 2001	Cache County Study	United States	Longitudinal	2073	≥ 65	ET or EPT	HT reduced cognitive decline
Seshadri *et al* [72], 2001		United Kingdom	Case-control	AD: 59. Controls: 221	Mean: 66.7	ET or EPT	HT was not associated with AD
Kang *et al*[76], 2004	Nurses' Health Study	United States	Longitudinal	13807	≥ 70	ET or EPT	HT was not associated with relevant cognitive benefits
Henderson *et al* [82], 2005	Mirage Study	United States, Canada, Germany	Case-control	AD: 426. Controls: 545	Mean: 71.1	ET or EPT	HT reduced the AD risk by 30%
Ryan *et al*[69], 2009	Three City Study	France	Longitudinal	3130	≥ 65	ET or EPT	HT was not associated with dementia or AD, but current users had better cognitive performance in specific domains
Shao *et al*[79], 2012	Cache County Study extended	United States	Longitudinal	1768	≥ 65	ET or EPT	HT initiated within five years of menopause decreased the AD risk by 30%
Whitmer *et al* [80], 2011	Kaiser Permanente Medical Care Program of Northern California	United States	Longitudinal	5504	Mean in midlife: 48.7	ET or EPT	The use of HT only in midlife reduced the dementia risk. On the other hand, the use of HT in late-life increased this risk
Imtiaz *et al*[70], 2017	Kuopio Osteoporosis Risk Factor and Prevention study	Finland	Longitudinal	8195	46 a 56	ET or EPT	Long-term HT users (> 10 yr) exhibited a 47% reduction in the AD risk
Savolainen-Peltonen *et al* [83], 2019		Finland	Case-control	AD: 84739. Controls: 84739	Mean age at onset of systemic HT: 52	ET or EPT	HT increased the AD risk by 9%-17%, regardless of the age of onset of use and the type of HT

ET: Estrogen-only therapy; EPT: Estrogen-progestogen therapy; HT: Hormone therapy; AD: Alzheimer's disease.

authors concluded that prolonged use of systemic HT might be accompanied by an increased risk of AD, which is not related to the type of progestogen or the age of HT initiation[83].

Few observational studies have evaluated the effects of HT exclusively in younger women. A recent prospective study conducted in Finland with 8195 women between 47 and 56 years of age with a 20-year follow-up showed little evidence of the protective effect of HT on dementia or AD, as only women who reported long-term (*i.e.*, more than ten years) use of HT presented a significant reduction in the AD risk of 47% compared to nonusers[70].

Interventional studies and the critical window hypothesis

As previously stated, the critical window hypothesis postulates that the effects of HT vary according to the moment of exposure, as related to menopause. According to this theory, estrogen administered closer to menopause would exert neuroprotective effects, whereas no benefit or harm would be observed when HT was administered years later[80]. Similarly, an ideal moment would exist to start HT and obtain cognitive benefits. Table 2 shows the main findings from the pertinent randomized clinical trials.

Evidence from older women

Due to possible biases regarding HT in observational studies, clinical trials were conducted to clarify these doubts. The WHIMS is an ancillary study of the Women's Health Initiative (WHI). The WHIMS included women aged 65 years or older. The effect of HT on the incidence of MCI and all-cause dementia (Alzheimer's, vascular and other types) was evaluated in hysterectomized women treated with conjugated equine estrogen (CEE), nonhysterectomized women treated with CEE plus medroxyprogesterone acetate (MPA), and the placebo group.

Table 2 Randomized clinical trials on hormone therapy and cognition in women

Ref.	Study	Country	*n* (%)	Age (yr)	Hormone therapy	Main findings
Shumaker *et al*[75], 2003	Women's Health Initiative Memory Study-WHIMS	United States	HT users: 2229. Placebo: 2303	≥ 65	CEE + MPA	HT increased the dementia risk
Shumaker *et al*[84], 2004	Women's Health Initiative Memory Study-WHIMS	United States	HT users: 1464. Placebo: 1483	65 to 79	CEE alone	Estrogen alone did not decrease the incidence of mild cognitive impairment or dementia
Greenspan *et al*[85], 2005		United States	HT users: 187. Placebo: 186	≥ 65	CEE with or without MPA	HT did not affect cognitive function
Yaffe *et al* [86], 2006		United States	HT users: 208. Placebo: 209	60 to 80	Ultra–low dose unopposed transdermal estradiol	Transdermal estradiol did not affect cognitive function
Espeland *et al*[87], 2010	Women's Health Initiative Study of Cognitive Aging-WHISCA	United States	HT users: 1125. Placebo: 1179	65 to 80	CEE with or without MPA	HT was associated with worsening global cognitive function and some specific cognitive domains. This worsening persisted after the interruption of HT
Espeland *et al*[73], 2013	Women's Health Initiative Memory Study of Younger Women-WHIMSY	United States	HT users: 696. Placebo: 630	50 to 55	CEE with or without MPA	HT did not alter global cognitive function or specific cognitive domains
Gleason *et al* [74], 2015	Cognitive and Affective Study-KEEPS-Cog	United States	HT users: 431. Placebo: 262	Mean: 52.6	CEE + micronized progesterone ortransdermal estradiol + micronized progesterone	HT did not affect cognition
Henderson *et al*[92], 2016	Early *vs* Late Intervention Trial with Estradiol Cognitive endpoints-ELITE-Cog	United States	HT users: 284. Placebo: 283	Early postmenopause: 55.6. Late postmenopause: 64.9	Estradiol with or without micronized progesterone	HT did not affect verbal memory, executive function and global cognition, regardless of whether it was started < 6 yr or ≥ 10 yr after menopause
Espeland *et al*[91], 2017	WHIMSY extended + Women's Health Initiative Memory Study of the Epidemiology of Cognitive Health Outcomes (WHIMS-ECHO	United States	WHIMSY-HT users: 701. Placebo: 635. WHIMS-ECHO-HT users: 1402. Placebo: 1478	Two groups: 50 to 54; 65 to 79	CEE with or without MPA	HT prescribed to younger women had no significant effect on cognitive function in the long term. HT administered to older women produced decreased global cognitive function, executive function, and working memory

CEE: Conjugated equine estrogen; MPA: Medroxyprogesterone acetate; HT: Hormone therapy.

In the CCE/MPA arm of the study, in which 4532 women participated (CEE/MPA group: 2.229; placebo group: 2.303), the hazard ratio (HR) for dementia was 2.05 (95%CI: 1.21-3.48; 45 *vs* 22 *per* 10000 person-years; $P = 0.01$), resulting in 23 additional cases of dementia *per* 10000 women *per* year. AD was the most common dementia type in both groups. The effects of treatment on the risk of MCI did not differ between groups (HR: 1.07; 95%CI: 0.74-1.55; 63 *vs* 59 cases *per* 10000 person-years; $P = 0.72$). The authors concluded that HT with the combination of estrogen and progestogen increased the risk of probable dementia in postmenopausal women aged 65 years older. These data indicate a lack of protection from MCI in these women receiving HT [75].

In the WHIMS arm with CEE alone, 2947 participants were included (CEE group: 1464; placebo group: 1483), with ages ranging from 65 to 79 years. No significant differences in the dementia risk (HR: 1.49; 95%CI: 0.83-2.66) and MCI risk (HR: 1.34; 95%CI: 0.95-1.89) were observed between groups. However, the joint analysis of the MCI or dementia risk showed a greater risk for women who received CEE alone than the placebo group (HR: 1.38; 95%CI: 1.01-1.89; $P = 0.04$)[84]. Isolated estrogen therapy did not reduce the incidence of MCI or dementia. Based on the combination of WHIMS data, HT with estrogen alone and CEE/MPA resulted in an increased risk of dementia or MCI in women aged 65 or older, and HT was not recommended to prevent cognitive decline[84].

In two randomized clinical trials with a smaller population of older postmenopausal women, including a study with 373 women and a 3-year follow-up period[85] and another with 417 women and a 2-year follow-up period[86], HT had no significant effect on cognitive function. The WH Study of Cognitive Aging, another ancillary study of the WHI, had two arms, CEE alone and CEE/MPA with matching placebos, and included 2304 women. HT initiated after 65 years of age was associated with worsening global cognitive function and changes in a few cognitive domains; notably, this reduction persisted after the interruption of HT. The authors highlighted that this difference in cognitive function was small and might have no clinical meaning[87].

A meta-analysis that included 16 clinical trials with 10114 women reported no beneficial effect of HT (estrogen with or without progestogen) administered in the short or long term (up to five years) on the cognitive function of older postmenopausal women. Moreover, the authors were unable to establish definitive conclusions on the effects of different administration routes and HT dosages on women's cognitive function[88]. Another meta-analysis concluded that HT is not indicated to prevent cognitive decline or dementia in postmenopausal women[89].

Evidence from younger women

Since younger women more frequently receive HT, its effects on cognitive function when used precociously must be clarified. Clinical trials on this topic are rare.

A systematic review included data from nine randomized, double-blind, placebo-controlled clinical trials of HT with estrogen alone and two with estrogen combined with progestogen, in which cognitive tests were administered to women aged less than 65 years, although the sample size was small. Seven of nine studies reported a small advantage for estrogen treatment in at least one cognitive test, particularly in verbal memory and attention. Only two studies assessed the effect of combined HT (estradiol valerate and dienogest), showing some benefit only on verbal memory[90]. Thus, although scarce, evidence from HT in younger women suggests potentially beneficial effects on specific cognitive domains, particularly in symptomatic women and women who recently underwent menopause, as well as inadequate evidence of damage. Studies examining the cognitive effects of estrogen combined with progestogen on younger women are scarce[90].

In the WHIMS of Younger Women (WHIMSY), an ancillary study of the WHI study, the effect of HT (CEE/MPA, CEE-alone, and placebo) on cognition was evaluated in 1326 postmenopausal women aged 50 to 55 years. Cognitive testing was performed, on average, 7.2 years after the end of the WHI study, when participants had an average age of 67.2 years at their first evaluation. HT did not alter global cognitive function or the specific domains of cognition (verbal memory, working memory, verbal fluency, attention, and executive functions). WHIMSY data indicated that CEE-based HT administered to younger women in the initial postmenopausal period had no long-term beneficial or harmful effects[73]. Afterward, the authors published data from the extended follow-up accomplished through WHIMSY and WHIMS-Epidemiology of Cognitive Health Outcomes, in which HT was prescribed to women aged 65 to 79 years. The use of HT by younger women for up to 6 years had no significant effect on cognitive function in the long term. On the other hand, the use of HT for five years by older women was related to a decline in global cognitive function, executive functions, and working memory, which persisted for more than ten years after administration [91].

Another investigation that included younger women was the Cognitive Affective Study (KEEPS-Cog)[74], an ancillary study of the Kronos Early Estrogen Prevention Study (KEEPS). The KEEPS-Cog studied the effects of HT administered for up to four years on cognition (global cognitive function, mental flexibility, verbal learning/memory, auditory attention, and executive functions) and humor in recently postmenopausal healthy women. In this randomized, double-blinded, placebo-controlled clinical trial, 0.45 mg of CCE was administered orally, plus 200 mg of micronized progesterone or 50 mcg of transdermal estradiol, plus 200 mg of micronized progesterone, as well as a placebo. Participants had a mean age of 52.5 years and were tested at an average of 1.4 years after menopause. HT did not affect cognition, and the use of oral CEE combined with micronized progesterone reduced anxiety and depressive symptoms, changes that were not observed in the group receiving transdermal therapy[74]. The KEEPS-Cog results regarding the lack of effect of HT on cognition are consistent with the WHIMSY findings.

The Early *vs* Late Intervention Trial with Estradiol (ELITE) was a randomized clinical trial in which participants received oral estradiol, micronized progesterone, or a matched placebo. The ELITE-Cog evaluated the effects of HT on cognition in postmenopausal women who were divided into two groups according to time since

menopause: early (less than six years, mean age of 55.6 years) or late (ten years or more, the mean age of 64.9 years). After an average of 57 mo of treatment, no significant differences in verbal memory, executive function, or global cognition were observed among women who initiated estradiol use within six years or ten years or more after menopause. These data suggest that estradiol has no beneficial or harmful effect on the evaluated cognitive domains, regardless of time elapsed since menopause; hence, the authors did not confirm the critical window hypothesis for cognitive function[92].

CONSIDERATIONS FOR CLINICAL PRACTICE

Clinical management of cognitive symptoms in perimenopausal women should consider that cognitive impairment does not appear to be frequent in this population [10], and an increased risk of dementia due to menopause is not well established[15,16, 18,19]. Nevertheless, patients with cognitive complaints and no objective impairment exhibited worse performance on cognitive tests than women without complaints[93]. Hence, some perimenopausal women might perceive the decline in verbal memory and learning performance compared to their ability during their premenopausal period, although they performed within normal parameters on neuropsychological tests[13]. Therefore, clinicians must validate the concerns about the cognitive decline of perimenopausal patients and evaluate their cognitive performance. Cognitive screening tests such as the MMSE[94] and the Montreal Cognitive Assessment (MoCA) [95], functional tests such as the Functional Assessment Questionnaire (FAQ)[96], and neurological examinations should comprise routine clinical evaluations. Due to the menopausal transition, cognitive symptoms are not expected to coincide with alterations on the MMSE, MoCA, FAQ, or neurological examination[97]. In these cases, patients should be advised that cognitive complaints are probably due to the menopausal transition associated with a subtle and transient cognitive decline[13]. Women with early menopause or those undergoing surgical or chemotherapy-induced menopause should be evaluated more carefully with repeated cognitive assessments during follow-up since these characteristics are more strongly associated with worse cognitive outcomes at older ages[15,20,21]. Scores less than 28 on the MMSE and less than 26 on the MoCA, indicating functional decline in daily activities (FAQ > 0), or altered neurological examinations are associated with cognitive impairment[98-100]. Notably, lower educational levels may bias cognitive tests, impairing their accuracy [101].

Suppose that screening tests indicate cognitive impairment in perimenopausal women. In that case, a comprehensive neuropsychiatric and neuropsychological assessment would be required to confirm the diagnosis of MCI or dementia in addition to a laboratory workup, neuroimaging examination, and, eventually, other tests to investigate underlying causes of cognitive decline. Thyroid hormones disturbances, vitamin B12 or folic acid deficiency, anemia, decompensated diabetes or hypoglycemia, electrolyte disturbances, renal or hepatic impairment, neurosyphilis or other infection of the central nervous system, and the use of benzodiazepines or medications with anticholinergic effects are potentially modifiable causes of cognitive impairment that should be excluded. Depression and other affective symptoms, such as anxiety, sleep disturbances, and attention deficit hyperactivity disorder, may exacerbate cognitive decline due to the menopausal transition, causing MCI in middle-aged women. In addition, presenile dementias such as familial AD, frontotemporal lobar degeneration, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy are uncommon neurocognitive disorders that may affect perimenopausal women.

Concerning the relationship between HT and cognition in postmenopausal women, the literature reports conflicting data. Notably, research differs in terms of the study design, age of the studied population, starting moment of HT, type, route of administration, and HT duration, among other aspects. An analysis of these studies allows us to verify dissonant findings, even among observational studies. Generally, observational studies have suggested some beneficial effects of HT on cognition, although some researchers, as previously described, have identified cognitive decline or an increased risk of dementia associated with HT. Regarding interventional studies, the findings are also not uniform concerning whether HT exerts detrimental or no effects on cognition. Overall, the results of interventional studies indicated detrimental effects of HT on older women, leading to cognitive decline and a greater risk of dementia, including AD.

Data on HT and cognition in younger postmenopausal women are scarce. Although observational studies suggest that HT may protect against future cognitive impairment in the early years of postmenopause, data from the WHIMSY trial[73,91], KEEPS-Cog trial[74], and ELITE-Cog trial[92] showed no benefits of HT in terms of the cognitive function of postmenopausal women compared to that of younger women. In younger symptomatic women, for whom benefits of using HT for symptom improvement have been reported, limited evidence suggests that these women do not appear to have a more significant risk of developing future cognitive problems.

Building big data and using data-driven approaches such as machine learning would help resolve conflicting data regarding the role of the menopausal transition in the risk of dementia and the effect of HT. In this context, big data may contribute to the prevention and early diagnosis of cognitive impairment in women undergoing the menopausal transition and facilitate evidence-based decision-making.

Based on the best available evidence, no robust data have been published that indicate that the use of HT with estrogen alone or combined with progestogen prevents cognitive decline or dementia in postmenopausal women. Thus, the prescription of HT is not recommended for this purpose.

CONCLUSION

The increasing number of people living with dementia will significantly impact life in years to come. Its effects will be felt individually, as it decreases the quality of life, both in patients and caregivers and at a population level, as it overburdens the health system and influences policies worldwide.

Being at greater risk of developing dementia, women are a target group of great interest for future studies. The link between sex and the risk of dementia still must be better understood. Along these lines, the menopausal transition is important, as it is a period of intense hormonal changes and symptomatic stress, which may be related to cognitive decline. Estrogen may play an essential role as a neuroprotective agent, although numerous other aspects are also relevant. A better understanding of the physiology involved in the cognitive impairment in this population, as well as the aspects of this decrease in cognition–which functions are affected and to what extent–may contribute to the elaboration of preventive measures and eventually may contribute to better treatment strategies, focusing on this possibly reversible cause of the cognitive decline.

Abstract

About 40%-70% of the patients with treatment-resistant schizophrenia have a poor response to adequate treatment with clozapine. The impact of clozapine-resistant schizophrenia (CRS) is even greater than that of treatment resistance in terms of severe and persistent symptoms, relapses and hospitalizations, poorer quality of life, and healthcare costs. Such serious consequences often compel clinicians to try different augmentation strategies to enhance the inadequate clozapine response in CRS. Unfortunately, a large body of evidence has shown that antipsychotics, antidepressants, mood stabilizers, electroconvulsive therapy, and cognitive-behavioural therapy are mostly ineffective in augmenting clozapine response. When beneficial effects of augmentation have been found, they are usually small and of doubtful clinical significance or based on low-quality evidence. Therefore, newer treatment approaches that go beyond the evidence are needed. The options proposed include developing a clinical consensus about the augmentation strategies that are most likely to be effective and using them sequentially in patients with CRS. Secondly, newer approaches such as augmentation with long-acting antipsychotic injections or multi-component psychosocial interventions could be considered. Lastly, perhaps the most effective way to deal with CRS would be to optimize clozapine treatment, which might prevent clozapine resistance from developing. Personalized dosing, adequate treatment durations, management of side effects and non-adherence, collaboration with patients and caregivers, and addressing clinician barriers to clozapine use are the principal ways of ensuring optimal clozapine treatment. At present, these three options could the best way to manage CRS until research provides more firm directions about the effective options for augmenting clozapine response.

Core Tip: About 40%-70% of patients develop clozapine-resistant schizophrenia, which has serious health, economic, and social consequences. Research on clozapine-resistant schizophrenia has provided little support for the efficacy of psychotropics, electroconvulsive therapy, and cognitive-behavioural therapy in augmenting clozapine non-response. Therefore, newer approaches are needed including a clinical consensus about using the most effective of the currently available augmentation strategies. Augmentation with long-acting antipsychotic injections or multi-component psychosocial interventions could also be tried. Finally, the best option at present may be to prevent clozapine resistance from developing by optimizing clozapine treatment and collaborating with patients and caregivers to ensure its continuation.

INTRODUCTION

Although antipsychotic treatment is one of the principal options for the management of schizophrenia, about a third of the patients with schizophrenia do not respond well to first- or second-generation antipsychotics[1,2]. People with treatment-resistant schizophrenia (TRS) continue to have psychotic symptoms and functional impairment despite adequate antipsychotic use. TRS is associated with greater severity of symptoms, more frequent relapses, repeated hospitalizations, poorer socio-occupational functioning, and poorer quality of life(QOL). Consequently, it imposes a substantial economic and social burden on patients, families, and healthcare services[1,3]. Despite some contrary opinions, there is a widespread consensus that clozapine is the treatment of choice for patients with TRS[4,5]. However, even with optimal clozapine treatment, 40%-70% of the patients with TRS do not benefit from monotherapy with clozapine[6-9]. Patients with clozapine-resistant schizophrenia (CRS) are probably among the most severely ill of all patients with this disorder. A study comparing TRS and CRS found that the overall severity of the illness and positive and negative symptoms were significantly higher, while the QOL score was significantly lower among patients with CRS[10] Moreover, symptom severity among patients with CRS did not improve much over 6 mo of follow-up. Other estimates have suggested that apart from the greater symptom severity, patients with CRS are likely to be more frequent users of healthcare services and more likely to have multiple and prolonged hospitalizations[11].

Consequently, the cost of their care and the adverse impact of CRS on patients and their caregivers is also likely to be substantially greater than TRS[7,12]. Such serious consequences of CRS often compel clinicians to try new and different strategies to treat these patients. The option most commonly adopted is to add another psychotropic agent to clozapine to enhance its effects[9,11]. However, the evidence to date indicates that augmentation with medications or other treatments yields little or no additional benefits for these patients[13]. The treatment of CRS thus continues to pose a formidable challenge for clinicians. Moreover, the size of this group of patients will increase as the use of clozapine for TRS increases. Therefore, newer ways of managing CRS have to be explored. Accordingly, this review attempts to briefly summarize the research in this area, followed by a discussion of certain treatment options and strategies that appear promising.

DEFINING AND CONCEPTUALIZING CRS

The key elements of the current definitions of CRS are depicted in Table 1. These include a diagnosis of schizophrenia, moderate baseline severity, and non-response and persistence of symptoms, and functional impairment despite adequate treatment with clozapine[12,14-16]. Though these operationalized definitions of CRS represent an improvement, it is also apparent that the majority of clinical trials of patients with

Table 1 Key components of the current definitions of clozapine-resistant schizophrenia[12,14-16]

Diagnosis	Diagnosis of schizophrenia using standardized criteria and after ruling out psychosis due to substance use or medical conditions
Adequate clozapine treatment	
Dose	200-500 mg/d
Blood levels	≥ 350 ng/mL
Treatment duration	2-3 mo[1]
Treatment adherence	≥ 80% of prescribed doses for the duration of treatment
Response to clozapine	
Baseline symptom severity and functional impairment	Moderately severe illness either globally or in positive and negative symptom domains assessed using standardized scales (CGI, BPRS, PANSS, SAPS, SANS). Moderate levels of functional impairment assessed using standardized scales (GAF, SOFAS)
Non-response	< 20% reduction in symptoms and minimal response in levels of functional impairment during an adequate trial of clozapine treatment
Persistence	Moderately severe illness and functional impairment should persist following an adequate trial of clozapine treatment

[1]It has been proposed that duration of clozapine trials should be 2 mo for patients with aggression or self-harm, 3 mo for those with positive symptoms, and 4 mo for those with negative and cognitive symptoms[13].

BPRS: Brief Psychiatric Rating Scale; CGI: Clinical Global Impression scale; GAF: Global Assessment of Functioning scale; PANSS: Positive and Negative Syndrome Scale; SANS: Scale for the Assessment of Negative Symptoms; SAPS: Scale for the Assessment of Positive Symptoms; SOFAS: Social and Occupational Functioning Scale.

CRS have not utilized such definitions. Moreover, a major criticism of the current constructs of CRS is that they rely excessively on positive symptoms of schizophrenia [11,17,18]. Other domains such as negative, cognitive, or depressive symptoms, or QOL have not received sufficient attention. This gives rise to substantial heterogeneity in the CRS groups selected using such definitions, which further hinders research. Although measures such as more precise delineation of target symptoms and differentiating between "minimum and optimal criteria" required for CRS have been proposed [15,16], the current definitions are still far from perfect[11,15,18,19]. Finally, from a clinical perspective there are many practical difficulties in determining adequate doses, estimating blood levels, judging adherence, and conducting prospective observation of patients during treatment with clozapine[15,16].

AUGMENTATION STRATEGIES FOR CRS: A BRIEF REVIEW

Medication augmentation

In routine clinical practice, the commonest strategy to deal with CRS is augmentation with another antipsychotic[9,11,20,21]. Mood stabilizer or antidepressant augmentation is used less frequently. Some treatment guidelines also endorse augmentation with antipsychotics[13]. Over the past 25 years, many trials of clozapine augmentation with medications and other treatments have been conducted. Additionally, more than 50 reviews on the subject including narrative and systematic reviews, individual meta-analyses, and reviews of different meta-analyses have been published.

Antipsychotic augmentation: Some of the recent reviews of augmentation of clozapine with a second antipsychotic in CRS are included in Table 2[22-44].

Among all augmentation trials, the largest number has involved antipsychotic augmentation of clozapine non-response. Risperidone, aripiprazole, and amisulpride are the most commonly evaluated augmenting agents. Despite the size of the evidence, the majority of reviews have concluded that adding a second antipsychotic to clozapine does not have any significant impact on clinical response, overall symptom severity, or severity of positive symptoms[7,8,20,45,46]. Though some benefit has been noted when all trials are included, there appear to be no significant effects when only high-quality trials are considered[2,18]. Even when benefits are evident in well-designed randomized controlled trials (RCTs), the combined effect sizes are small to moderate casting doubts on the clinical significance of these findings. The effect of antipsychotic combinations with clozapine on negative and depressive symptoms has

Table 2 Reviews of antipsychotic augmentation strategies in clozapine-resistant schizophrenia[1]

Ref.	Type of review	Details	Effect on positive or psychotic symptoms	Effect on negative or depressive symptoms
Wagner *et al* [2], 2019	Systematic review	14 meta-analyses of FGA and SGA augmentation of clozapine.	Some evidence of benefits based on low-quality studies (SIGN grade B).	
Roerig *et al* [8], 2019	Systematic review	4 meta-analyses and 1 naturalistic study of FGA and SGA augmentation of clozapine.	No benefits of antipsychotics when high-quality RCTs were considered.	
Bartoli *et al* [22], 2019	Meta-analysis	12 RCTs of SGA augmentation of clozapine-risperidone (n = 5) and aripiprazole (n = 3).	No difference between SGA augmentation and placebo in improving positive symptoms.	A small benefit of SGA augmentation for negative and depressive symptoms.
Siskind *et al* [23], 2018	Meta-analysis	19 RCTs of FGA and SGA augmentation of clozapine-aripiprazole (n = 7), risperidone (n = 3), and amisulpiride (n = 2).	Evidence for benefit with aripiprazole, but effects were lost when low-quality studies were excluded.	
Correll *et al* [24], 2017	Meta-analysis	Meta-analysis of 29 previous meta-analyses of antipsychotic combinations-5 clozapine combinations examined.	Clozapine combinations no different from clozapine monotherapy for positive symptoms.	Clozapine combinations no different from clozapine monotherapy for negative symptoms.
Galling *et al* [25], 2017	Meta-analysis	20 RCTs of FGA and SGA augmentation of clozapine-risperidone (n = 6) and aripiprazole (n = 6).	No evidence for additional benefits of augmentation in double-blind, high-quality RCTs.	Improvement in negative symptoms with aripiprazole augmentation. No effect of augmentation on depressive symptoms.
Ortiz-Orendain *et al*[26], 2017	Meta-analysis	31 RCTs and quasi-RCTs of augmentation with SGAs (n = 26) and FGAs (n = 5) including clozapine augmentation.	Low-quality evidence that augmentation improves global clinical response. No specific effects on positive symptoms.	No effect of augmentation on negative symptoms.
Barber *et al* [27], 2017	Meta-analysis	5 RCTs of clozapine augmentation with SGAs or haloperidol.	Low-quality evidence that augmentation may improve global clinical response. Effects on positive symptoms not clear.	Effects on negative symptoms not clear.
Jiménez-Cornejo *et al* [28], 2016	Meta-analysis	17 prior meta-analyses and reviews of FGA and SGA augmentation (62 studies) of clozapine.	Little evidence that augmentation improves clinical response (> 20% reduction in PANSS/BPRS scores).	
Taylor *et al* [29], 2012	Meta-analysis	14 RCTs of FGA and SGA augmentation of clozapine.	A small benefit in overall symptom reduction with augmentation.	
Sommer *et al* [30], 2012	Meta-analysis	10 RCTs of FGA and SGA augmentation of clozapine.	One RCT showed that sulpiride augmentation led to overall symptom reduction. No specific effects on positive symptoms.	No specific effects on negative symptoms.
Porcelli *et al* [31], 2012	Systematic review and meta-analysis	Systematic review of 25 studies of SGA augmentation of clozapine - risperidone (11 trials) and aripiprazole (6 trials). Meta-analysis of 5 RCTs of risperidone augmentation of clozapine.	Low quality evidence indicated benefits for aripiprazole and amisulpiride augmentation. No benefit of risperidone augmentation.	Some benefit of aripiprazole in reducing negative symptoms from 1 RCT.

[1]Several other systematic reviews[9,12,14,32,33] and meta-analyses[17,34-37] have been unable to find significant benefits, while others have reported modest benefits for antipsychotic augmentation of clozapine[38-44].

BPRS: Brief Psychiatric Rating Scale; FGA: First-generation antipsychotic; RCT: Randomized controlled trial; PANSS: Positive and Negative Syndrome Scale; SGA: Second-generation antipsychotic; SIGN: Scottish Intercollegiate Guidelines Network.

been examined less frequently. A similar inconsistency is apparent with some meta-analyses showing modest benefits, while others report no effects on these symptoms.

Antidepressant and mood stabilizer augmentation: As depicted in Table 3, the number of RCTs examining the augmentation of clozapine with antidepressants and mood stabilizers is comparatively less. Moreover, the trials are more often of poorer quality. Consequently, there is little evidence of the benefits of antidepressant augmentation on the severity of symptoms[23,24,30,37]. When some evidence of a positive effect has been found, it is usually based on single, high-quality RCTs[23,24,30,37]. Similarly, though mood stabilizer augmentation is reported to be beneficial in some meta-analyses[47,48], others have either found no benefit[7,24,46,49] or evidence of significant symptom reduction only in low-quality trials[2,8,23,30,50].

Table 3 Meta-analyses of antidepressant and mood stabilizer augmentation in clozapine-resistant schizophrenia

Ref.	Type of review	Details	Results
Antidepressants			
Siskind *et al* [23], 2018	Meta-analysis	10 RCTs of fluoxetine, paroxetine, duloxetine, and mirtazapine augmentation	Some evidence for fluoxetine augmentation in reducing in overall symptom severity based on 1 high-quality RCT.
Correll *et al* [24], 2017	Meta-analysis	Analysis based on the earlier meta-analysis of Veerman *et al*[37]	No benefit of antidepressant augmentation on reduction in overall, positive, and negative symptom severity.
Veerman *et al* [37], 2014	Meta-analysis	4 RCTs of mirtazapine, duloxetine, and fluoxetine augmentation	No benefit of antidepressant augmentation on reduction in overall, positive, and negative symptom severity.
Sommer *et al* [30], 2012	Meta-analysis	4 RCTs of mirtazapine, citalopram, and fluoxetine augmentation	Some evidence for citalopram augmentation in reducing overall and negative symptom severity based on 1 RCT.
Mood stabilizers			
Siskind *et al* [23], 2018	Meta-analysis	5 RCTs of valproate (n = 2), lamotrigine (n = 2), lithium (n = 1), and topiramate(n = 1) augmentation	Low-quality evidence for valproate and lithium augmentation in reducing total symptom severity. Reduction of positive and negative symptom severity by topiramate augmentation based on1 RCT.
Correll *et al* [24], 2017	Meta-analysis	Analysis based on the earlier meta-analysis of Veerman *et al*[37]	No benefit of lamotrigine and topiramate augmentation on reduction in overall, positive, and negative symptom severity.
Zheng *et al* [50], 2017	Meta-analysis	22 RCTs of valproate (n = 9), lamotrigine (n = 8), and topiramate (n = 4) augmentation	Significant benefits for valproate and topiramate in reducing total and positive symptom severity but based on low-quality studies. No effects on clinical response.
Zheng *et al* [48], 2016	Meta-analysis	4 RCTs of topiramate augmentation	Significant benefits of topiramate augmentation in reducing overall, positive, and negative symptom severity.
Veerman *et al* [49], 2014	Meta-analysis	6 RCTs of lamotrigine and 4 RCTs of topiramate augmentation	No benefit of lamotrigine and topiramate augmentation on reduction in overall, positive, and negative symptom severity.
Sommer *et al* [30], 2012	Meta-analysis	7 RCTs of lamotrigine (n = 4) and topiramate (n = 3) augmentation	Benefits of lamotrigine and topiramate augmentation for total and positive symptoms based on single RCTs that did not persist on further analysis.
Tiihonen *et al* [47], 2009	Meta-analysis	5 RCTs of lamotrigine augmentation	Evidence for benefit of lamotrigine augmentation in reducing overall, positive, and negative symptom severity.

RCT: Randomized controlled trial.

Methodological lacunae: One of the principal reasons for the inability to find effective medication augmentation options for CRS is the methodological shortcomings of current research. Even in the better quality RCTs, there is considerable heterogeneity in terms of the definitions used, the types and numbers of patients included, the duration of trials, and the outcomes examined. The methodological lacunae of the RCTs have in turn affected the methodological quality of meta-analytic examinations of the evidence. For example, in a systematic review of 21 meta-analyses only one was judged to have "very little risk of bias;" 7 had "low risk of bias," and the rest had "high risk of bias"[2]. Therefore, there is considerable uncertainty even about the findings of meta-analytic studies.

Augmentation with electroconvulsive therapy and recurrent transcranial magnetic stimulation

Some of the more recent reviews have concluded that electroconvulsive therapy (ECT) is an effective augmentation strategy, especially when medications fail to decrease persistent positive symptoms[2,8,20,46,51]. However, this conclusion appears to be based on a single meta-analysis of 18 RCTs[52], which showed that the ECT-clozapine combination was better than clozapine alone in reducing positive symptoms. Then again, 17 of these RCTs were conducted in China and are not easily accessible[53]. As shown in Table 4, there are only two small RCTs of ECT augmentation of clozapine response. The first showed that the clozapine-ECT combination was more effective than clozapine alone in TRS[54], whereas the second did not find the combination to be more effective in CRS[55]. The rest of the evidence consists of non-randomized trials[56] and case studies. Thus, the higher response rates of the clozapine-ECT combination reported in systematic reviews[57-61] and other meta-analyses[62-64] are largely based on low-quality evidence, obtained mainly among patients with TRS, and

Table 4 Electroconvulsive therapy and recurrent transcranial magnetic stimulation augmentation in clozapine-resistant schizophrenia

ECT			
Ref.	**Study/review**	**Details**	**Results**
Masoudzadeh *et al*[56], 2007	Controlled trial, (non-randomized, non-blinded)	18 patients with TRS; 3 groups of clozapine-ECT treatment, only clozapine and only ECT treatment (n = 6 each)	Significant differences between the clozapine- ECT combination and monotherapy groups in reduction of PANSS scores.
Petrides *et al*[54], 2015	Single-blind cross-over RCT	39 patients with TRS randomized to clozapine-ECT (n = 20) and clozapine only treatment (n = 19)	Significantly greater response on BPRS psychosis & CGI scores in the clozapine-ECT combination group.
Melzer-Ribeiro *et al*[55], 2017	Single-blind sham-controlled RCT	23 patients with CRS randomized to treatment with clozapine-ECT (n = 13) and clozapine-sham ECT (n = 10)	No significant differences between the groups on PANSS total and positive symptom scores and CGI scores.
Kupchik *et al*[57], 2000	Systematic review	Case reports of 36 patients with TRS and clozapine non-responders	67% of the patients on the clozapine-ECT combination showed good response.
Braga *et al*[58], 2005	Systematic review	12 case reports or chart reviews of patients with TRS and clozapine non-responders	The clozapine-ECT combination was efficacious.
Havaki-Kontaxaki *et al*[59], 2006	Systematic review	One open trial and 6 case studies of patients with CRS	73% patients on the clozapine-ECT combination showed marked improvement.
Pompili *et al*[60], 2013	Systematic review	31 studies examining indications for ECT in schizophrenia	The clozapine-ECT combination was efficacious in patients resistant to medications.
Grover *et al*[61], 2015	Systematic review	40 studies, mainly case reports of patients with CRS	Short-term response rates of the clozapine-ECT combination varied from 37%-100%.
Lally *et al*[62], 2016	Systematic review and meta-analysis	Pooled analysis of patients with TRS treated with clozapine and ECT based on 4 open trials, 2 controlled trials (1 RCT)[1], 2 chart reviews, 6 case series, and 15 case reports	Pooled response rate with the clozapine-ECT combination was 54% on meta-analysis. Systematic review showed 76% overall response rate with clozapine-ECT treatment and a relapse rate of 32%.
Manubens *et al*[63], 2016	Systematic review and meta-analysis	6 systematic reviews of ECT in TRS including 6 controlled trials of the clozapine-ECT combination in clozapine non-responders (1 RCT)[1]	Modest effect of ECT in augmenting clozapine response with low certainty of evidence.
Ahmed *et al*[64], 2017	Systematic review and meta-analysis	9 studies of the clozapine-ECT combination in TRS including 2 controlled trials (1 RCT)[1], 3 open trials, and 4 case series/chart-reviews *vs* 9 studies of ECT-non-clozapine antipsychotic combination	The ECT-clozapine combination was significantly better than the ECT-non-clozapine antipsychotic combinations in reducing positive symptoms on the PANSS and the BPRS.
Wang *et al*[52], 2018	Meta-analysis	18 RCTs of clozapine augmentation in CRS (17 from China and 1 from the United States[1])	Adjunctive ECT was superior to clozapine monotherapy in reducing positive symptoms after 1–2 wk but with moderate effect size.
rTMS			
Wagner *et al*[66], 2020	Meta-analysis	Pooled data from 10 RCTs for 131 patients with persistent positive and negative symptoms being treated with clozapine	No differences between active and sham rTMS in improving clinical response and reducing PANSS scores. No benefit of rTMS augmentation for patients with persistent symptoms on clozapine.

[1]The RCT from United States is by Petrides *et al*[54].

BPRS: Brief Psychiatric Rating Scale; CGI: Clinical Global Impression scale; CRS: Clozapine-resistant schizophrenia; ECT: Electroconvulsive therapy; PANSS: Positive and Negative Syndrome Scale; RCT: Randomized controlled trial; rTMS: Recurrent transcranial magnetic stimulation; TRS: Treatment resistant schizophrenia.

limited to the short-term efficacy of ECT augmentation. Though the combination appears to be relatively safe, about 20% of the patients develop adverse effects, and there is some evidence of greater cognitive impairment[52,57,59,62,63]. Nevertheless, augmentation with ECT may result in a faster response, which is particularly useful among patients with high risks of aggression or self-harm[9,11,60,65]. Therefore, though the evidence is still inconclusive, the effects of ECT augmentation certainly merit further examination. On the other hand, augmentation with recurrent transcranial magnetic stimulation appears to be largely ineffective in CRS despite promising results from recent trials[66,67].

Psychosocial augmentation strategies

Two systematic reviews of psychosocial interventions have concluded that CBT can be effective among patients with poor response to clozapine[33,68]. As shown in Table 5, the evidence-base for CBT until recently had consisted of a few trials with small

Table 5 Psychosocial augmentation strategies in clozapine-resistant schizophrenia

Ref.	Study/participants	Interventions	Results
Studies			
Pinto *et al*[69], 1999	Single-blind RCT of 41 patients with TRS started on clozapine	CBT and social skills training *vs* supportive therapy for 6 mo.	Significant reductions in positive and negative symptom severity in the CBT group.
Buchain *et al*[70], 2003	Single-blind RCT of 41 patients with TRS started on clozapine	Occupational therapy and clozapine *vs* clozapine alone for 6 mo.	Significant improvements in the occupational performance and interpersonal relationships with OT.
Barretto *et al*[71], 2009	Single-blind RCT of 21 patients with CRS	CBT *vs* supportive treatment ("befriending") for 21 wk.	Significant reductions in overall symptom severity and improvement in quality of life with CBT.
Morrison *et al*[75], 2018	Double-blind RCT of 425 patients with CRS	CBT *vs* usual treatment for 9 mo. Follow-up for 21 mo.	Significant reductions in PANSS scores with CBT at 9 mo but no differences at 21 mo.
Sensky *et al*[72], 2000; Valmaggia *et al*[73], 2005; Edwards *et al*[74], 2011	RCTs of patients with TRS (n = 48-90) including patients on clozapine or clozapine non-responders	CBT *vs* supportive treatment or clozapine alone or comparisons with combinations of CBT with other antipsychotics.	Significant reductions in positive, negative, and depressive symptom severity, improvement in clinical response and functioning with CBT; benefits at end of treatment usually maintained during follow-up.
Reviews			
Ranasinghe *et al*[33], 2014	Systematic review	Review of the 2 CBT and 1 OT trial mentioned above.	Benefits of psychosocial interventions noted for overall symptom severity, quality of life, and social functioning.
Polese *et al*[68], 2019	Systematic review & meta-analysis	Review of all the above trials and meta-analysis of 4 RCTs including Morrison *et al*[75].	Benefits of psychosocial interventions noted for overall and positive symptom severity.

numbers and inadequate study designs[69-71] or RCTs that included some patients with CRS[72-74]. However, interest in the effects of CBT augmentation has been re-awakened with a large, well-designed RCT among patients with CRS[75]. This was the largest trial among all RCTs of clozapine augmentation. It employed standardized definitions of CRS and trained therapists who administered manual-based CBT to patients from routine clinical settings. After 9 mo of active treatment, the total Positive and Negative Symptom Scale scores, positive symptoms, emotional distress, and excitement had reduced significantly in the CBT group compared to the usual treatment group. However, at the end of 21 mo, there were no significant differences in the Positive and Negative Symptom Scale scores between the two groups, leading to the conclusion that CBT augmentation was not effective in CRS. Nevertheless, other indices suggested that CBT might be useful for a proportion of patients, and patients' ratings of recovery were greater in the CBT group at 21 mo. Other noteworthy advantages of CBT were the high adherence rates, negligible adverse effects, high acceptability, and effect sizes comparable to medication augmentation. Therefore, others have interpreted these results differently to emphasize the positive effects of CBT augmentation[2,66,76]. Moreover, it has been pointed out that the persistence of positive effects beyond the active treatment period is not the best indicator of the efficacy of CBT[76]. Thus, if the standards for medication trials were to be applied to this RCT, the conclusion would be that CBT was an effective augmentation strategy for CRS after 9 mo of treatment.

AUGMENTATION STRATEGIES FOR CRS: FROM EVIDENCE TO PRACTICE

Relying on clinical consensus

This brief update of the existing literature shows that augmentation of clozapine response in CRS with medications, ECT, or CBT is largely ineffective. Any favourable outcome for augmentation is usually based on low-quality or limited evidence, and the clinical significance of the small effects obtained in some meta-analyses is unclear. Moreover, because of the inconsistent results and methodological uncertainties, the

evidence offers no definite conclusions about the most effective augmentation strategies. Nevertheless, it has been suggested that the lack of evidence should not discourage clinicians from trying out these strategies in individual patients. This advice appears to be based on two assumptions. First, the lack of significant benefits applies only to entire groups of patients being evaluated in RCTs, whereas there may be considerable variability in individual responses of the patients comprising these groups[18,25,29,40]. Thus, there is a possibility that some patients may benefit from augmentation, though at present there is no way to identify these potential responders. Moreover, given the widespread adverse impact of CRS, even modest benefits are considered acceptable in clinical settings[7,22,46]. Therefore, the sequential use of different augmentation strategies is considered to be a realistic option in clinical practice.

To reduce the disparity between the evidence-based findings and clinical practice, researchers have been increasingly relying on clinical consensus to guide the management of complex and burdensome conditions such as CRS. A recent effort on these lines arrived at the following recommendations for augmentation of clozapine non-response: personalizing doses to reach plasma levels ≥ 350 ng/mL; a 3 mo trial for patients with positive symptoms; shorter treatment trials for those with violence or self-harm (2 mo) and longer periods (4 mo) for patients with negative or cognitive symptoms[13]. For persistent positive symptoms, adding aripiprazole, amisulpride, or ECT was suggested. Augmentation with antidepressants was recommended for negative symptoms while adding antidepressants, antipsychotics, mood stabilizers, or ECT to clozapine was proposed for CRS with increased risks of aggression or self-harm. Lastly, CBT or other psychosocial interventions were also felt to be useful. It was apparent that these clinicians were going beyond the current evidence while making some of these recommendations.

For example, though there is little support in the literature for augmentation of clozapine with a second antipsychotic, low-quality evidence or single RCTs have suggested that risperidone, aripiprazole, and amisulpride may be beneficial (Table 2). The group also relied on naturalistic studies showing that the clozapine-aripiprazole combination may have positive effects[77]. Similarly, for recommendations about antidepressants, positive evidence for antidepressant augmentation in schizophrenia was cited[78,79], though the evidence for similar effects of antidepressant augmentation in CRS is limited (Table 3).

Augmentation with mood stabilizers and ECT was recommended despite the acknowledgement that the evidence for these strategies is insufficient (Tables 3 and 4). The recommendation for using CBT if other treatments failed was based on the recent CBT trial[75], which concluded that certain individuals with CRS may benefit from a practical trial of CBT augmentation. Clozapine augmentation was preferred over a switch to a different antipsychotic because of the consistent evidence of adverse outcomes following cessation of clozapine[8,11,80-82]. Switching to high-dose olanzapine has been suggested as an alternative, but this option is not supported by evidence[81,83]. Finally, though most of the evidence indicates that these augmentation strategies are safe and well-tolerated[22,25,26,29], the possibility of new side effects arising during combined treatment could not be discounted[9,12,18,28,32]. Therefore, cautious monitoring of all patients for the duration of the augmentation trial was also recommended.

Trying newer options for augmentation

Augmentation with long-acting antipsychotic injections: Apart from problems of resistance, non-adherence is a major hindrance to effective treatment with clozapine. Although non-adherence with clozapine may be lower than other antipsychotics, rates of intentional non-adherence vary from 23%-55% during treatment[84-88]. In such situations initiating a long-acting antipsychotic injection (LAI) remains the only option [89]. Intramuscular clozapine appears to have some benefits in enhancing adherence, but it has not been used frequently[90,91]. Recent studies suggest that apart from reducing non-adherence, LAI augmentation of clozapine may also have a role in enhancing clozapine response in CRS. As shown in Table 6, this evidence is still preliminary and consists mostly of series of patients and observational studies[92-102]. However, mirror-image studies that are considered the current standard for evaluating LAI efficacy[103,104] have also been conducted. Taken together, this body of evidence suggests that the combination of clozapine with LAIs leads to a reduction in all types of symptoms and behavioural problems such as aggression and suicidality as well as improvements in social functioning. The lowered risk of relapses and reduction in the number and length of hospitalizations has also been replicated consistently. Lastly, it appears that lower doses of both medications are required,

Table 6 Augmentation of clozapine with long-acting antipsychotic injections in clozapine-resistant schizophrenia

Ref.	Study details	Results
Kim *et al*[92], 2010	4 patients treated with clozapine and risperidone LAI for 1 yr	Reduction in number and length of hospitalizations and improvement in social skills after LAI addition. Fewer side effects with the combination.
Malla *et al*[93], 2013	One patient with poor response to clozapine treated with clozapine and an LAI	Improvement in symptoms and social functioning without any increase in side effects with combination treatment.
Baruch *et al* [94], 2014	8 patients, 6 with TRS. Treated with olanzapine LAI and clozapine or other antipsychotics up to 2 yr	Reduction in aggression in all 8 patients and in symptom severity in 6 patients.
Maia-de-Oliveira *et al* [95], 2015	2 patients with CRS treated with clozapine and paliperidone LAI for 9-10 mo	Remission of positive symptoms after LAI augmentation.
Kasinathan *et al* [96], 2016	9 patients with TRS and comorbid personality disorders/substance use and violence; 1 on clozapine but non-adherent treated with olanzapine LAI combination	1 yr of retrospective pre- and post-LAI comparisons showed significant improvements in psychotic symptoms, violence, and reduction in number and length of hospitalizations and emergency visits.
Sepede *et al* [97], 2016	One patient with poor response to clozapine treated with clozapine and aripiprazole LAI for 1 yr	Symptoms reduced by 50% with the combination without any increase in side effects.
Oriolo *et al*[98], 2016	Retrospective observational of 23 patients with TRS in whom paliperidone LAI was added toclozapine	Significant reductions in severity of global, positive, negative, depressive, and cognitive symptoms with the combination. Significantly lower doses of clozapine and paliperidone LAI required with combination treatment *vs* monotherapy.
Souaiby *et al* [99], 2017	Retrospective observational study with a mirror-image design of 20 patients with TRS treated with clozapine and LAIs for 32 mo	Significant reductions in number and length of hospitalizations during 32 mo of combination treatment *vs* 1 yr of monotherapy. No increase in side effects with the combination.
Grimminck *et al* [100], 2020	Retrospective observational study with a mirror- image design of 20 patients with poor response to clozapine or LAIs treated with clozapine and LAI combinations for 2 yr	Significant reductions in hospital admissions and emergency visits during 2 yr of combination treatment *vs* 2 yr of monotherapy. Overall improvement in behaviour and social functioning but no change in symptoms.
Bioque *et al* [101], 2020	Retrospective observational study with a mirror- image design of 50 patients with TRS treated with clozapine and paliperidone LAI for 6 mo	Significant reductions in BPRS scores, emergency visits, number and length of hospitalizations, and number and severity of adverse effects as well as significant improvements in social functioning during 6 mo of combination treatment *vs* 6 mo of monotherapy.
Caliskan *et al* [102], 2021	Retrospective observational study with a mirror- image design in 29 patients with TRS treated with clozapine and LAI combinations for 1 yr	Significant reductions in number of relapses and number and length of hospitalizations during 1 yr of combination treatment *vs* 1 yr of monotherapy. No differences in side effects with the combinations.

BPRS: Brief Psychiatric Rating Scale; CRS: Clozapine resistant schizophrenia; LAI: Long-acting antipsychotic injection; TRS: Treatment resistant schizophrenia.

while side effects are either less, or no more common with the combination than with clozapine monotherapy.

Indirect evidence for the effectiveness of clozapine-LAI combinations also comes from several Scandinavian nationwide cohort studies of antipsychotic treatment summarized in Table 7[77,82,105-109]. These provide the strongest support for the notion that clozapine and LAIs are the two most effective treatments for patients with both first episode and chronic schizophrenia. Incidentally, some of these studies have also shown that the combination of clozapine and aripiprazole is more effective than clozapine monotherapy[77]. Therefore, the combination of clozapine and LAIs appears to be a promising option that needs to be examined further for its usefulness in the management of CRS.

A re-evaluation of psychosocial augmentation strategies: Although the evidence reviewed in Table 5 suggests that augmentation with CBT does not yield consistent benefits in CRS, there are several reasons to re-examine the usefulness of psychosocial augmentation strategies. To begin with, CBT augmentation appears to be effective for persistent positive symptoms in TRS[20,68,75,76]. Moreover, the largest and most meticulously conducted CBT trial has shown a small but significant benefit for patients with CRS following the active intervention phase[66,75,76]. The same trial has suggested that CBT is one of the safest and acceptable augmentation options for patients with CRS. The evidence from this study and other trials shows that CBT augmentation has added benefits such as improvements in socio-occupational functioning and QOL. Moreover, symptomatic remission appears to be faster with CBT augmentation, and the benefits obtained may persist longer[71,72,74]. CBT augmentation early in the course of clozapine treatment may further enhance its benefits[68-70,74].

Table 7 Scandinavian nationwide cohort studies of antipsychotic treatment

Ref.	Study details	Results
Tiihonen *et al* [105], 2006, Finland	2230 inpatients followed up for 3.6 yr	Significantly lower risks of rehospitalization or treatment discontinuation in patients on perphenazine LAI, clozapine, or olanzapine *vs* those on oral haloperidol.
Tiihonen *et al* [106], 2009, Finland	66881 outpatients followed up for 11 yr	Clozapine was associated with a substantially lower mortality than any other antipsychotics singly or in combination, with perphenazine as a comparator.
Tiihonen *et al* [107], 2011, Finland	2588 inpatients followed up for 2 mo after discharge	Significantly lower risks of rehospitalization with LAIs than oral medications. Clozapine and olanzapine were associated with significantly lower risk of rehospitalization than risperidone.
Tiihonen *et al* [108], 2017, Sweden	29823 patients followed up for 5.7 yr	Significantly lower risks of rehospitalization and of treatment failure[1] with LAIs and clozapine *vs* no antipsychotic treatment.
Taipale *et al* [109], 2018, Finland	62250 inpatients followed up for 20 yr	Significantly lower risks of rehospitalization with LAIs and clozapine *vs* no antipsychotic treatment in first episode and chronic schizophrenia.
Tiihonen *et al* [77], 2019, Finland	62250 inpatients on antipsychotic monotherapy or antipsychotic combinations followed up for 14 yr	Combination of clozapine and aripiprazole was associated with significantly lower risk of rehospitalization and mortality than clozapine alone in first episode and chronic schizophrenia. Clozapine monotherapy was associated with the most favourable outcomes compared to other antipsychotics.
Luykx *et al*[82], 2020, Finland	2250 patients on clozapine treatment followed up for more than 1 yr before discontinuation	Compared to no antipsychotic treatment, significantly lower risks of rehospitalization with re-institution of clozapine alone, oral olanzapine, and antipsychotic combinations. Significantly lower risks of treatment failure**1**with aripiprazole LAI, re-institution of clozapine alone, and oral olanzapine.

[1]Treatment failure included re-hospitalization, suicide attempt, treatment discontinuation, medication switch, or death.
LAI: Long-acting antipsychotic injection.

Further, it has been proposed that rather than using only CBT, multi-component psychosocial interventions using different techniques might be more effective in enhancing clozapine response[33,110,111]. Though CBT is the most common psychosocial treatment used in patients with TRS, there is evidence to suggest that other types of interventions might be equally effective[68,112]. Psychoeducation and family interventions are also effective for schizophrenia[113], but they have not been tried out as augmenting strategies in TRS or CRS[20,68]. Lastly, psychosocial aug-mentation might be useful in other ways, for example in improving adherence to clozapine. An RCT that compared CBT with psychoeducation among patients with TRS on clozapine showed that both treatments led to improvements in patient empowerment, treatment alliance, and medication persistence[114]. Thus, while there may be no compelling evidence in favour of psychosocial augmentation strategies in CRS, there is scope for further evaluation of these potentially useful treatments.

PREVENTING RESISTANCE TO CLOZAPINE TREATMENT

The relative ineffectiveness of the different augmentation strategies suggests that a more fruitful option could be to try and prevent resistance to clozapine treatment from developing.

Predicting clozapine resistance

Predicting who among patients with TRS will not respond adequately to clozapine may be helpful because augmentation strategies could be instituted early in such patients to mitigate the adverse effects of clozapine resistance. However, despite over 300 studies of prediction of clozapine response, consistent predictors of response have not been found. Some reviews have concluded that there are no reliable predictors of clozapine response because of the inconsistent results and methodological uncertainties of existing research[115,116]. On the other hand, an older systematic review and a more recent meta-analysis have found that older age, greater severity of symptoms, especially negative symptom severity, poorer functioning, and non-paranoid subtypes could predict clozapine non-response[117,118]. Low cerebrospinal homovanillicacid to 5-hydroxyindoleacetic acid ratios and normal structure and

function of the prefrontal cortex have also emerged as reliable predictors of good response in some studies[117,119]. Consequently, because of the inconclusive nature of this evidence, currently the only way to predict clozapine resistance is to carry out an adequate trial of clozapine treatment under optimal conditions[20,115].

Optimizing clozapine treatment

Ensuring adequate treatment with clozapine may thus be the best option to prevent clozapine resistance. The necessary steps for optimizing clozapine treatment are listed in Table 8. Personalized dosing is a key component because of the wide variations in dose-blood level ratios between individuals and because many patients respond at lower doses[120,121].

Data on gender differences in clozapine treatment are scarce, and results are often inconsistent[122]. This is particularly true for response to clozapine treatment. Though the response is usually poorer in women[116,117,122], research on clozapine's effectiveness has also found better outcomes among women, although these differences in their favour are often of doubtful clinical significance[115,117,123]. Others have found no differences in outcome between the two genders[118].

In contrast, differences in pharmacokinetics are reported more consistently[122,124,125]. Women have lower renal clearance of clozapine than men because of differences in the activity of cytochrome P450 enzymes such as CYP1A2. Most studies have found higher plasma levels of clozapine in women, and some have also found higher levels of its metabolite norclozapine. Higher dose-blood level ratios have also been found in women. Therefore, women usually require lower doses of clozapine[124]. These pharmacokinetic differences also increase the risk of dose-dependent side effects in women, particularly metabolic side effects[122,126]. Accordingly, most of the evidence on gender differences in side effects of clozapine relates to metabolic disturbances [122]. However, findings are not consistent, and both genders appear to have increased risk of metabolic syndrome in different reports[122,126-128]. Hypertension, elevated triglycerides, lower high-density lipoprotein levels, and cardiac abnormalities appear to be more common in men[122]. Women are more likely to develop hyperglycaemia and diabetes and increases in weight and body mass index[122,126]. There is very little evidence of gender differences in other side effects, though certain studies have found haematological abnormalities and constipation to be commoner among women[122,125,128,129].

Unlike the influence of gender, ethnicity does not appear to have any impact on treatment response obtained with clozapine[115,130]. On the other hand, there are ethnic differences in pharmacokinetic profiles of clozapine[122]. More specifically, several studies among Asian patients have consistently indicated that they require about half the standard dose of clozapine due to their lowered clozapine metabolism [131-135]. The dose of clozapine required for adequate response among Asians varies from 150mg/d among women to 300 mg/d for men who smoke. Therefore, Asian patients need lower doses at the start of treatment and slower upward titration to reach their optimum dose. Despite these pharmacokinetic dissimilarities, ethnic differences seem to have minimal impact on the prevalence of adverse effects of clozapine[129]. Nevertheless, non-White ethnicity is a risk factor for metabolic syndrome, and certain studies have found a higher prevalence of hypertension and weight gain in Asians[127,136]. Others have found a higher risk of agranulocytosis in Asian patients[137]. This again emphasizes the fact that the best way to individualize clozapine doses is to base them on blood levels. Doing so has the added advantages of lessening side effects and allowing adherence to be monitored. However, facilities for blood levels are not always available. Standardized dosing schedules could be used in such instances[132].

Many of the side effects encountered with clozapine are dose-dependent including sedation, tachycardia, hypersalivation, enuresis, constipation, delirium, obsessive-compulsive symptoms, seizures, and orthostatic hypotension[81,120,138] Among all antipsychotics, the prevalence of metabolic dysfunction or metabolic syndrome is the highest for clozapine and olanzapine[81,126,127,132,139]. Whether metabolic side effects are also dose-dependent is not clear[81,138]. However, systematic reviews and meta-analyses have indicated a dose-outcome association between clozapine and metabolic side effects, particularly with lipid levels and weight gain[140,141]. Risk factors for metabolic syndrome include higher baseline weight or body mass index, gender, non-White, possibly Asian ethnicity, and several genetic and peptide markers [126,127,136,139,142]. Somewhat paradoxically, metabolic disturbances are also associated with a reduction in symptoms[126,127].

Table 8 Steps for ensuring optimal clozapine treatment[65,81,110,111,120,123,132]

Steps for ensuring optimal clozapine treatment	
Adequate assessment	Diagnosis should be established properly. Comorbid conditions should be looked for. Adherence should be determined. Symptoms and other outcome domains should be preferably rated using validated instruments. Caregiver burden and coping should be assessed. Stressors and adverse circumstances should be evaluated.
Proper dosing	Inter-individual and ethnic variability in optimal doses should be considered. If facilities for serum levels are available, doses should be titrated to ensure plasma levels > 350 ng/mL. Doses should be increased slowly with careful monitoring of side effects to reduce the burden of dose-dependent side effects.
Adequate duration	A minimum of 2-3 mo is considered necessary. Durations could be shorter in those with high risk of aggression or self-harm. Durations could be longer in those with negative or cognitive symptoms and in partial responders.
Managing side effects	Many of the common side effects of clozapine can be managed by slow titration, using the least effective dose, reducing doses when side effects develop, adding medications, or adopting lifestyle changes to counter side effects. Additionally, careful monitoring should be carried out for the more serious and idiosyncratic adverse reactions such as agranulocytosis and cardiopulmonary complications.
Managing non-adherence	Careful monitoring of adherence based on multiple sources is necessary. Managing side effects, educating patients to deal with negative attitudes to clozapine, developing a trusting alliance to improve motivation, caregiver education and support to increase their involvement in the patient's care may help. These measures should ideally be initiated right at the beginning of treatment. Use of long-acting antipsychotic injections may be considered.
Collaboration with patients and caregivers	Both patients and caregivers should be the focus of treatment. Measures should be tailored according to their needs. Goals of treatment should be reduction of symptoms and distress, improving support, forging effective alliances, and promoting patient and caregiver engagement. Simple psychosocial measures including cognitive or behavioural strategies, psychoeducation, and emotional and practical support should be implemented at the start of treatment or as early as possible. More structured interventions can be tried depending on availability of resources and expertise.
Addressing clinician related barriers	Clinicians' lack of awareness and experience of clozapine treatment and negative attitudes towards clozapine use should be addressed by proper education, dissemination of information, and dedicated facilities.

Optimizing clozapine doses is the principal way of managing most dose-dependent side effects. Using the lowest effective dose, slow increase in doses, and dose adjustments to minimize side effects is always recommended[81,120,123]. Discontinuation of concomitant medications that might not be essential also reduces the side effect burden[120]. Only serious and life-threatening adverse reactions such as agranulocytosis and some cardiopulmonary complications require abrupt discontinuation of clozapine[81,120]. Some side effects such as neuroleptic malignant syndrome, thromboembolism, or diabetic ketoacidosis may require temporary discontinuation followed by re-initiation of clozapine[81]. In most other situations, the dose of clozapine should be reduced very gradually to avoid worsening of clinical state or emergence of withdrawal symptoms[120]. When side effects persist despite optimizing the dose of clozapine, the options include adding other medications, instituting non-pharmacological measures to manage side effects, or combining clozapine with another antipsychotic[120,138]. In the case of metabolic syndrome, adequate treatment of risk factors and metabolic derangements is essential[143].

Meta-analyses of interventions for metabolic side effects have shown that adjunctive metformin is the most effective strategy[144,145]. Behavioural weight management strategies are also recommended though the evidence for their efficacy is uncertain [120,138,144]. Adding aripiprazole to clozapine to reduce both the clozapine dose and metabolic disturbances has also been suggested, but the evidence for this option is limited[120,144].

Minimizing the side effect burden is necessary because about 40% of the patients (range 21%-67%) stop taking clozapine in the first few years of treatment[82,84,86,87,146]. In 20%-30% of them, discontinuation is because of intolerable side effects, though intentional non-adherence appears to be somewhat more common[84,85,87,88,147]. Managing non-adherence requires open and non-judgmental discussions about medication-taking with patients, monitoring of adherence based on all available methods including caregiver reports, education to deal with misconceptions about treatment, and building trusting alliances with patients and families to ensure continued treatment. A collaboration with the patient and the family is an essential part of optimizing clozapine treatment that is often overlooked[65,110,111,120]. Shared decision-making about treatment, education, stress-management, support, and involvement of caregivers are ways of ensuring truly collaborative alliances.

Lastly, increasing evidence indicates substantial underutilization and delayed use of clozapine[148,149]. Clinician's lack of awareness and experience with clozapine, their misplaced concerns about its use, and the discrepancy between clinicians' and patients' attitudes regarding clozapine are among the main causes of inappropriate use

of clozapine[150,151]. Therefore, dealing with these clinician-related barriers is also necessary to ensure the proper use of clozapine.

CONCLUSION

Clozapine resistance is probably one of the most difficult conditions that clinicians treating patients with schizophrenia are likely to encounter. Unfortunately, the existing research evidence does not provide any firm guidelines about treatment options once clozapine fails. However, because of the seriousness of the condition and the widespread negative impact of CRS, clinicians need to look beyond the evidence and rely on consensus-based recommendations. At present, effective ways to deal with CRS are to optimize clozapine treatment, choose among the best available options judiciously, explore newer ways of augmentation, and adopt a holistic approach to treatment that includes simple psychosocial measures in addition to pharmacological ones. Finally, cautious optimism, commitment to treatment, patience, and persistence from clinicians, patients, and caregivers are almost always required for the effective use of clozapine.

Abstract

BACKGROUND

Cancer is a growing threat to human health. Due to the double torment of cancer and cancer treatment, patients with advanced cancer generally have a low quality of life. At present, there is a lack of systematic spiritual care plans for patients with advanced cancer as well as systematic guidance plans on the specific clinical application of spiritual care for advanced cancer patients. We hypothesized that our care plan would be effective in improving the spiritual and mental health and quality of life of patients with advanced cancer.

AIM

To construct a spiritual care plan suitable for Chinese patients with advanced cancer through literature analysis.

METHODS

From February to December 2018, through purpose sampling, we selected 100 advanced cancer patients from the Oncology Department and Hospice Ward of a tertiary hospital in Liaoning Province who met the study standards. Patients were randomly divided into experimental and control groups, with 50 cases in each

group. The control group received the current routine care, while the experimental group received the advanced cancer spiritual care intervention in addition to routine care.

RESULTS

After the intervention, the overall spiritual health score for the experimental group was higher than that of the control group (4.68 ± 1.36 *vs* 3.63 ± 1.71). The difference between the groups was statistically significant ($P < 0.05$). The proportion of anxiety-free patients in the experimental group was 95.45%, which was significantly higher than the 60.98% in the control group. Moreover, the proportion of non-depressed patients in the experimental group was 97.73%, which was significantly higher than the 85.37% in the control group ($P < 0.05$). The overall quality of life score for the experimental group was significantly higher than that of the control group (5.36 ± 1.16 *vs* 4.39 ± 1.36, $P < 0.05$).

CONCLUSION

Our spiritual care plan for patients with advanced cancer could improve their spiritual health and quality of life and reduce negative mental health symptoms.

Key Words: Cancer; Spiritual care; Depression; Anxiety; Spiritual health; Quality of life

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: We constructed a spiritual care program for advanced cancer patients suitable for Chinese culture and national conditions, and carried it out for advanced cancer patients. Results showed that the spiritual health status and quality of life of advanced cancer patients were improved, and their anxiety and depression reduced.

INTRODUCTION

As the environment is deteriorating, human health is facing a growing number of threats. One such threat that has grown increasingly significant is cancer. It has been estimated that the number of cancer patients worldwide had risen to 3 million in 2020, two-thirds of which are advanced cancers with low chances of cure[1]. Patients with advanced cancer generally have a low quality of life. Due to the double torment of cancer and cancer treatment, their psychological, physical, social, familial, and other aspects of their lives are all negatively affected in varying degrees[2]. Spiritual care is a complex and multidimensional concept with different definitions[3] and refers to patients seeking the meaning of life, gaining peace and comfort, obtaining emotional support from family members, and alleviating the fear of death during illness with the help of professional medical service teams, social groups, families, volunteers, and religious personnel, thereby improving the quality of life of patients with advanced cancer[4]. Global research on the spiritual care of patients with advanced cancer is relatively novel. A relatively mature care model that includes a professional care team and complete tools for evaluating the spiritual needs of patients with advanced cancer has been created. At present, the spiritual care model in China is based on the four-in-one holistic care model of body-mind-community-spirit. Intervention measures are embodied in several aspects, such as peaceful, holistic, special, hospice, overall nursing care, palliative treatment, death education, *etc*. However, there is a lack of systematic spiritual care plans for patients with advanced cancer as well as a lack of systematic guidance plans on the specific clinical application of spiritual care for them, which greatly reduces the effectiveness of care. The purpose of spiritual care is to pay attention to the patient's attitude towards the disease. This means that the patient's

to declare.

spiritual care is more important than their physical care[5]. We used advanced global spiritual care guidelines as references and combined them with information around the Chinese setting to construct a spiritual care plan that was suitable for Chinese culture. Our care plan achieved good results when applied to advanced cancer patients.

MATERIALS AND METHODS

Construction of a spiritual care plan for patients with advanced cancer

We searched the Chinese Biological Medicine Database, China National Knowledge Infrastructure, Wanfang Database, and VIP Information Resource System using Chinese search terms such as cancer, tumor, advanced stage, spirituality, spiritual care, spiritual intervention, *etc.* We also searched the PubMed, Science Citation Index Expanded, and Web of Science databases. To collect data as comprehensively as possible, we combined the aforementioned keywords in Chinese and English and included references from the retrieved literature. We invited nine experts in oncology and its related fields to revise the constructed spiritual care plan for advanced cancer patients through meetings with experts[6]. The selection criteria for the experts were as follows: (1) working in the fields of advanced cancer clinical nursing, nursing management, nursing education, advanced cancer clinical medicine, psychology, and other related disciplines; (2) having an under graduate degree or higher; (3) having a medium-grade professional title or higher; (4) having 10 or more years of work experience in their professional fields and being familiar with the content of our study; and (5) participating in our study voluntarily.

Evaluative research on the spiritual care plan for patients with advanced cancer

From February to December 2018, cancer patients from the Oncology Department and Hospice Ward of a tertiary hospital in Liaoning Province who qualified for our study were selected through objective sampling. Patients were stratified according to the different departments to which they were admitted. In each ward, 20% of the actual number of hospitalizations were sampled. We sampled a total of 100 patients and used randomized grouping to separate them into our study groups. The inclusion criteria were as follows: (1) a histological or cytological diagnosis of a tumor node metastasis stage III or IV malignant tumor; (2) age >18 years; (3) being able to communicate and understand; (4) being able to provide informed consent and participate voluntarily; and (5) being aware of their condition. The exclusion criteria were as follows: (1) impaired consciousness; and (2) being unable to understand or fill in the scale correctly.

Research tools

General information survey form: This included details of the patient's age, gender, education, family income, medical expense payments, *etc.*

Clinical data questionnaire: This questionnaire was self-designed and based on the literature review. It included information such as the patient's cancer diagnosis and stage, as well as whether there was metastasis.

The Chinese version of the European Organization for Cancer Research and Treatment Quality of Life Questionnaire-Spiritual Well-Being 32 (EORTC QLQ-SWB32)[7] scale: The original English scale was developed and validated by the EORTC QOL Group in 2017 for the assessment of the spiritual health status of patients with advanced cancer. EORTC QLQ-SWB32 consists of 32 items, with 22 items forming four multiitem scales: Existential; Relationship with Self; Relationships with Others; and Relationship with Someone or Something Greater. The first 31 items were scored using a four-point Likert Scale with answers ranging from "not at all" to "very". Item 32 was mainly used to reflect the patient's overall spiritual health status: 0 point, did not know or was unable to answer; 1 point, very poor; 7 points, very good. As the score increased, the patient's overall spiritual health improved[8]. In 2017, the author translated the scale into Chinese version[9] (it is not an official EORTC translation), and the total Cronbach α coefficient of the scale was 0.808.

The General Hospital Anxiety and Depression Scale: This scale was created by Zigmond *et al*[10] in 1983 and translated into Chinese by Ye *et al*[11] in 1993 to form its Chinese version. It is used in general hospitals to assess patients' anxiety and depression. Cronbach's α for the Chinese version of the scale was 0.870.

The Chinese version of the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Core 15 Palliative (EORTC QLQ-C15-PAL): The EORTC QLQ-C15-PAL was based on the EORTC QLQ-C30 and created by Groenvold *et al*[12] in 2005. It was translated into Chinese by Luo *et al*[13] in 2014 and was used to assess the quality of life of cancer patients in palliative care. Excluding the emotional function dimension, Cronbach's α values for the other dimensions were all > 0.7.

Research content

Intervention plan for the control group: The control group received routine care plans, including general and symptomatic care; tumor chemotherapy, radiotherapy, biotherapy, intracavitary therapy care, and psychological care.

Intervention plan for the experimental group: Based on routine care implementation and guided by the "Spiritual Care Plan for Patients with Advanced Cancer", we provided spiritual care for patients with advanced cancer. This included the following services: (1) Admission evaluation: For the patients who met the inclusion criteria, after informed consent was obtained from the patient and their caregivers, the research participant's basic information was collected and their spiritual care needs and spiritual health status were evaluated; (2) Spiritual care intervention: From 2–3 d after admission, based on the "Spiritual Care Plan for Advanced Cancer Patients" that we created, the researchers and oncology specialist nurses from each department worked together to carry out the intervention. Interventions included participating in activities and watching face-to-face guidance videos or targeted explanations and were implemented in a small conference room or ward in the Oncology Department. Patients' examination, treatment, nursing, and meal times were avoided, and their free and rest times were designated as the times when the interventions could take place; this was usually between 3:00 pm and 5:00 pm. A total of five interventions were carried out, each 30–60 min long. The patients' psychological and emotional states were closely monitored during each intervention. If the patient felt unwell, they could choose to take a break or have their session at another time; and (3) Post-intervention evaluation: After the intervention, patients' self-expression was asked in time. They were also asked to fill in the spiritual health assessment scale and other questionnaires to analyze quantitatively the effects of the spiritual care plan on patients with advanced cancer.

Data collection and analysis

The researchers collected data before and after the intervention. Before collection, our study's purpose, requirements, and precautions were explained, and patients were reassured of the confidentiality of the questionnaire and their data. After the patients' consent was obtained, they were asked to fill in a questionnaire to ensure objectivity. EpiData 3.1 was used for data entry, and the database was established using the Chinese version of SPSS version 21 (SPSS Inc., IBM Corp., Armonk, NY, United States). General data were depicted using statistics: Count data were expressed using the rate and composition ratio; and measurement data were expressed using the mean ± SD and comparison using a *t*-test and non-parametric test. Frequency, percentage, and the χ^2 square test was used for count data. A P value < 0.05 was considered statistically significant.

RESULTS

Construction of a spiritual health care intervention plan for patients with advanced cancer

A total of 10 articles that met the requirements were included and analyzed in our study. Nine experts in oncology and its related fields were invited to revise the constructed spiritual care plan for patients with advanced cancer. Finally, a final version of the spiritual health care intervention plan was developed.

Evaluation of the effect of application of the spiritual health care intervention plan for patients with advanced cancer

The effective sample sizes for the experimental and control groups were 41 and 44 cases, respectively, and the final effective sample size was 85 cases. The age range for

the experimental group was 28–83-years-old (50.05 ± 12.44-years-old), and for the control group it was 27–79-years-old (54.88 ± 13.78-years-old). The independent sample *t*-test results showed that there was no significant difference in age when the two groups were compared (t = 0.059, P = 0.953). The general demographic characteristics of the two groups were count data, such as gender, ethnicity, living conditions, religious beliefs/cultural beliefs, highest education, *etc.* Pearson's χ^2 test was used for the comparison, and the differences were not statistically significant (P > 0.05). The general data of the two groups were comparable (Table 1).

Clinical data

The differences in the research participants' clinical data were not statistically significant (P > 0.05), indicating two groups were comparable (Table 2).

Spiritual health

Before the spiritual care intervention, there was no significant difference in the spiritual health scores between the two groups (P > 0.05). The spiritual health scores of the two groups were comparable (Table 3).

After the spiritual care intervention, there were no significant differences in the existence (EX) and relationship with self (RS) scores when the two groups were compared (P > 0.05); thus, spiritual care was not yet considered meaningful to the patients' EXs and RSs. However, the differences in the relationship with others (RO), relationship with something greater (RSG), and overall spiritual health scores were statistically significant (P < 0.05 for all; Table 4).

Anxiety and depression

When the anxiety levels from the two groups before and after the spiritual care intervention were compared, the difference in anxiety levels before the intervention was not statistically significant (P > 0.05), indicating the anxiety levels of the two groups were comparable. After the intervention, the difference in anxiety levels when the groups were compared was statistically significant (P < 0.05; Table 5).

The comparison of the two groups' depression before and after the spiritual care intervention showed that there was no statistically significant difference in depression between the groups before the intervention (P > 0.05), indicating the depression levels of the two groups were comparable. The difference in the levels of depression after the intervention when the groups were compared was statistically significant (P < 0.05; Table 6).

Quality of life

The Chinese version of the EORTC QLQ-C15-PAL was used to evaluate the quality of life of the two groups before the intervention. The differences in the results were not statistically significant (P > 0.05), and the data from the two groups were comparable (Table 7).

After the spiritual care intervention, there was no statistically significant difference in the quality of life when the patient groups were compared in terms of physical function, pain, dyspnea, insomnia, and constipation (P > 0.05). Thus, spiritual care was not yet considered meaningful with regard to these parameters. The differences between the groups in terms of symptoms such as emotional function, fatigue, nausea and vomiting, loss of appetite, and overall quality of life were statistically significant (P < 0.05; Table 8).

DISCUSSION

Construction of an intervention plan for the spiritual healthcare of patients with advanced cancer

In this study, the first draft of the spiritual care plan for patients with advanced cancer was formulated through literature analysis. Some items of the plan were deleted, revised, or adjusted through expert meetings. When the experts were selected, their representativeness was fully considered. The literature analysis combined with the expert meeting made the spiritual care plan practical and scientific.

General characteristics and the baseline level of the participants

Studies have demonstrated that the general demographic characteristics and clinical data of patients with advanced cancer (such as age, gender, race, tumor type, cancer

Table 1 General information characteristics, *n* (%)

location, employment status, religious beliefs, *etc.*) have an impact on their spiritual health[14-16]. The older the patient, the better their spiritual health. This holds particularly true for those older than 60 years, who have been shown to have significantly better spiritual health[9,17]. Women demonstrate better spiritual health than men; however, the aspects of spiritual health (belief, peace, meaning, overall spiritual health) are not balanced. The level of spiritual health also differs among patients with advanced cancer belonging to different races. However, some studies have demonstrated that spiritual health has nothing to do with general characteristics such as age, gender, race, cancer grade, metastasis, medical insurance, marital status, religious beliefs, *etc.*[18]. The inconsistency of conclusions may be related to different sample size or data collection methods. The general demographic data of the two groups in our study were consistent, except for their living conditions. Consistency was also demonstrated between the two groups in all aspects of the clinical data. Thus, the baseline levels of the two groups were guaranteed before the intervention.

Spiritual care improving spiritual health of patients with advanced cancer

In our study, we found that the provision of spiritual care to patients with advanced cancer could significantly improve their overall spiritual health. The overall spiritual score of the experimental group was higher than that of the control group (4.68 ± 1.36 *vs* 3.63 ± 1.71), and the difference between the two groups was statistically significant ($P = 0.002$). This finding was consistent with the results from other studies that found that spiritual care could promote the spiritual health of patients with advanced cancer [19-22]. In our study, after spiritual intervention, there were inconsistencies in the findings regarding the four dimensions of spiritual health when the two groups were compared. The RO and RSG scores for the experimental group were higher than those for the control group (3.07 ± 0.57 *vs* 2.81 ± 0.58 and 2.65 ± 0.40 *vs* 2.18 ± 0.42, respectively). The differences between the RO and RSG scores before and after the intervention were statistically significant ($P < 0.05$). However, the findings regarding

the EX and RS scores were not statistically significant. This may have been related to the characteristics of the different dimensions of spiritual health. The purpose of spiritual care is to help patients seek the meaning of life, self-realization, hope and creation, faith and trust, peace and comfort, prayer, love and forgiveness, *etc.*, while suffering from illness and pain[23]. Therefore, as core components of quality oncology, spiritual health and spiritual care both promote and influence each other[24].

Spiritual care reducing the levels of anxiety and depression in advanced cancer patients

In our study, after the spiritual care intervention, the number of advanced cancer patients that did not feel anxious and depressed increased significantly, and the differences in these values were statistically significant ($P < 0.001$). This was consistent with the results from a study by Chida *et al*[25], as well as those from other studies, which demonstrated that in advanced cancer patients, effective spiritual care can

reduce negative emotions such as anxiety and depression, reduce suicide risk, and improve their mental health[25,26]. The higher the level of spiritual health, the higher the quality of life; thus, the happier the patient is, the less depressed, anxious, and fatigued they feel, and the less pain they experience[18]. Spiritual health is a valuable coping mechanism. It has unique advantages in its ability to protect cancer survivors from depressive symptoms[27]. As a part of overall health, spiritual health plays an important role in coping with disease-related psychological symptoms and influencing medical decisions before death[28]. Spiritual care interventions can quickly, accurately, and reliably identify the spiritual health of patients with advanced cancer and help them understand their own life, feelings, hope, peace, and other mental states. In our study, following the spiritual care intervention, we found that the emotional function score of the experimental group was lower than that of the control group (2.98 ± 1.34 *vs* 3.73 ± 1.72). This was consistent with the results from the patients' anxiety and depression investigations that were performed after the spiritual intervention.

Spiritual care improving the quality of life of patients with advanced cancer

In our study, after the spiritual intervention, we found that the overall quality of life score of the experimental group was higher than that of the control group (5.36 ± 1.16 *vs* 4.39 ± 1.36), and that the difference between the two groups was statistically significant ($P = 0.002$). This was consistent with the results from several studies[29-31]. Spiritual health, as a potential or direct influencing factor, can effectively improve the quality of life of patients with advanced cancer. It can also improve the efficacy of palliative care and is an important indicator for evaluating the quality of life of patients with advanced cancer[32]. In terms of fatigue, the fatigue score of the experimental group was lower than that of the control group (3.41 ± 1.26 *vs* 4.39 ± 1.64), and this difference was statistically significant ($P = 0.005$). We found that spiritual care can alleviate the fatigue experienced by cancer patients, which was consistent with the results from studies by Rabow *et al*[18] and Heidari *et al*[33]. All cancer patients experience fatigue, and higher fatigue scores are observed in patients with stage IV tumors. There is a significant negative correlation between fatigue scores and spiritual health. The more obvious the symptoms of fatigue and the more severe the fatigue that the cancer patient is experiencing, the worse their spiritual health is. Therefore, we propose that fatigue can be used as the primary negative predictor of the spiritual health in patients with advanced cancer[13].

Table 8 Quality of life after spiritual care intervention

Dimension	Control group (*n* = 41)	Experimental group (*n* = 44)	*Z* score	*P* value
Function				
Physical function	5.68 ± 2.61	4.70 ± 1.65	–1.590	0.112
Emotional function	3.73 ± 1.72	2.98 ± 1.34	–2.103	0.035[a]
Symptom				
Fatigue	4.39 ± 1.64	3.41 ± 1.26	–2.829	0.005[a]
Nausea and vomiting	2.05 ± 1.00	1.52 ± 0.73	–2.521	0.012[a]
Pain	3.56 ± 1.45	2.95 ± 1.06	–1.857	0.063
Dyspnea	1.51 ± 0.67	1.36 ± 0.65	–1.198	0.231
Insomnia	1.83 ± 1.05	1.66 ± 0.68	–0.196	0.844
Poor appetite	2.07 ± 0.93	1.66 ± 0.78	–2.179	0.029[a]
Constipation	1.83 ± 0.89	1.50 ± 0.73	–1.823	0.068
Overall quality of life	4.39 ± 1.36	5.36 ± 1.16	-3.077	0.002[a]

[a]$P < 0.05$.

In our study, the effect of spiritual care on pain was not obvious, and the difference between the findings from the two groups was not statistically significant ($P = 0.063$). However, this finding was inconsistent with the results from other studies[34]. This may have been related to the short duration of the intervention or the different grades of pain. Many studies have confirmed that patients with advanced cancer experience significant problems with pain, and the severity of the pain has a negative correlation with their spiritual health[35]. The more severe the patient's pain, the worse their spiritual health is. Our study also found that after the spiritual care intervention, the nausea and vomiting and loss of appetite scores for the experimental group were lower than those for the control group (1.52 ± 0.73 *vs* 2.05 ± 1.00 and 1.66 ± 0.78 *vs* 2.07 ± 0.93, respectively) and these differences were statistically significant. This may have been due to the patients' calmness after undergoing spiritual care. Their psychological disposition had an impact on their physiological function, thus reducing their gastrointestinal reaction and increasing their appetite.

CONCLUSION

Although spiritual care in China began relatively late, many studies have verified that when it was applied to the clinical care of patients with advanced cancer, it could effectively guide clinical nurses or palliative care teams towards providing nursing services to patients with advanced cancer in a systematic, scientific, and targeted manner. We included specific spiritual care content for cancer patients based on psychological cancer care, providing specific help and guidance strategies for the spiritual care of patients with advanced cancer, and complementing psychological care to promote the quality of life of this patient population. We made the palliative care team and its supporters more aware of the spiritual confusion that patients with advanced cancer experience, guided the team to conduct comprehensive patient assessments, implemented spiritual care for the spiritual problems that patients with advanced cancer encountered, and evaluated the effects of this intervention both before and after its implementation. In addition, this intervention can draw the attention of medical staff to the spiritual health of patients with advanced cancer and strengthen their attention to spiritual care. Although it cannot extend the length of the patient's lifespan, it can allow the patient to complete their last journey of life quietly, peacefully, and without regrets.

ARTICLE HIGHLIGHTS

Research background

The quality of life of patients with advanced cancer is generally low, including psychological, physical, social, family, and other aspects. Spiritual care is thought to improve the quality of life for people with advanced cancer. While developed countries have developed mature care models, there is currently a lack of systematic spiritual care programs for patients with advanced cancer in developing countries. This study referred to the mature spiritual care programs in developed countries, and combined the national conditions of China to construct spiritual care programs suitable for Chinese culture and evaluated its effects.

Research motivation

This study constructed a spiritual care plan suitable for Chinese culture and provided a basis for clinicians to take intervention measures to improve the spiritual health of patients with advanced cancer.

Research objectives

This study aimed to build a spiritual care program for advanced cancer patients suitable for China's national conditions and evaluated its application effect in the Chinese population. Future research could explore the extensibility of this program in different cancer populations.

Research methods

This research adopted the Delphi method to construct the spiritual care plan and the method to study the randomly assigned experimental group and control group. The experimental group used the spiritual care plan, while the control group used conventional care plan. The two groups of patients' were evaluated for spiritual health score, anxiety score, depression score and quality of life score to evaluate the effect of spiritual care plan.

Research results

The results showed that the spiritual-care group had higher overall spiritual health scores, lower prevalence of anxiety and depression, and higher overall quality of life scores than the control group, indicating that the spiritual care plan was an effective solution for Chinese patients with advanced cancer.

Research conclusions

The spiritual care program for patients with advanced cancer developed in this study could improve the spiritual health and quality of life of patients with advanced cancer and reduce negative emotions such as anxiety and depression. Spiritual care for patients with advanced cancer is recommended in oncology and hospice units.

Research perspectives

Future studies may evaluate the generalizability of the plan in a broader population of cancer patients.
